[272] Both the dioxolane derivative used here and its enantiomer are accessible in two steps from (*R,R*)- or (*S,S*)-tartaric acid. It was first used as a ligand in the enantioselective addition to aldehydes via alkyl titanium compounds [273,274] and later also for the TiX_4-mediated Diels–Alder reaction [275] (see also Scheme 22, enantioselective catalysis, and Sec. 7). Preparation of the compound has been described in detail [274,275].

Engman, *Acc. Chem. Res. 18* (1985) 274–279; c) First α-Te–C–Li compounds: D. Seebach, A. K. Beck, *Chem. Ber. 108* (1975) 314.

[329] a) W. Korytnyk, S. Valentekovic-Horvath, C. R. Petrie III, *Tetrahedron 38* (1982) 2547; b) an interesting contribution to the history of noble-gas compounds: "One or Several Pioneers? The Discovery of Noble-Gas Compounds": P. Laszlo, G. J. Schrobilgen, *Angew. Chem. 100* (1988) 495–506; *Angew. Chem. Int. Ed. Engl. 27* (1988) 479–489.

[330] a) For this reason it pleases me as a former *Criegee* student on the one hand to see recent papers in which the strain in *small rings* is exploited for synthetic purposes [339]: "Strained Polycyclic Systems Consisting of Three- and Four-Membered Rings": D. Seebach, *Angew. Chem. 77* (1965) 119–129; *Angew. Chem. Int. Ed. Engl. 4* (1965) 121–131; "Methoden zur Herstellung und Umwandlung isocyclischer Vierring-Verbindungen": D. Seebach in E. Müller (Ed.): *Methoden der Organischen Chemie (Houben–Weyl), Vol. IV/4*, Thieme, Stuttgart 1971, pp. 1–444; b) on the other hand, the former *Corey*-coworker *D. S.* [18,31] is fascinated by the host of developments since 1976 [330c] in the area of applications of sulfur and selenium compounds in organic synthesis stemming directly from the laboratories of former *Corey*-group members. A few examples are cited under [330d]; c) "Verwendung von Schwefel- und Selenderivaten in der Organischen Synthese": D. Seebach, K.-H. Geiss, M. Kolb, A. K. Beck, *Mod. Synth. Methods 1* (1976) 173–299; d) "Zwiebelanes": T. Bayer, H. Wagner, E. Block, S. Grisoni, S. H. Zhao, A. Neszmelyi, *J. Am. Chem. Soc. 111* (1989) 3085; "The Chemistry of Mixed Organosulfur–Silicon Compounds": E. Block, M. Aslam, *Tetrahedron 44* (1988) 281–324; T. P. Burkholder, P. L. Fuchs, *J. Am. Chem. Soc. 110* (1988) 2341; see also the review article by *P. Fuchs* et al. in [376]; A. Krief, L. Hevesi: *Organoselenium Chemistry I, Functional Group Transformations*, Springer, Berlin 1988; K. C. Nicolaou, C.-K. Hwang, M. E. Duggan, *J. Am. Chem. Soc. 111* (1989) 6682 and [342a]; "Asymmetric synthesis using α-sulfinyl carbanions and β-unsaturated sulfoxides": G. H. Posner in S. Patai, Z. Rappoport, C. J. M. Stirling (Eds.): *The Chemistry of Sulphones and Sulphoxides*, Wiley, New York 1988, pp. 823–849; "Total Synthesis Mediated by Cyclic Sulfides": E. Vedejs, article for the book by E. Block (Ed.): *Organic Synthesis—Theory and Application*, JAI Press, Greenwich, in press; I wish to thank Professor *Edwin Vedejs* for providing me with a manuscript copy.

[331] a) The following book is an excellent source of information and discussion of the fundamental contributions by *Mukaiyama*: T. Mukaiyama: *Organic Synthetic Reactions*, Tokyo Kagakudojin 1987; English version: *Challenges in Synthetic Organic Chemistry*, Int. Ser. Monographs on Chemistry No. 20, Oxford University Press, Oxford 1990; b) "The Directed Aldol Reaction": T. Mukaiyama, *Org. React. (N. Y.) 28* (1982) 203–331; c) "The Aldol Addition Reaction": C. H. Heathcock in J. D. Morrison (Ed.): *Asymmetric Synthesis, Vol. 3*, Academic Press, Orlando, FL 1984, pp. 111–212. The contributions by *Masamune* are covered in [437]; d) most recent, comprehensive review: "Recent Developments in Stereoselective Aldol Reactions": M. Braun in V. Snieckus (Ed.): *Advances in Carbanion Chemistry*, JAI Press, Greenwich, CT 1990, in press; cf. also "Stereoselective Aldol Reactions with α-Unsubstituted Chiral Enolates": M. Braun, *Angew. Chem. 99* (1987) 24–37; *Angew. Chem. Int. Ed. Engl. 26* (1987) 24–37; M. Braun, D. Waldmüller, H. Sacha, *Chemiedozententagung 1990*, Ulm, 26–28 March 1990, Wissenschaftliches Programm und Vortragsreferate, Universitätsverlag Ulm, A 33; e) for diastereoselective nitroaldol additions see [308].

[332] a) "Selective Reactions Using Organoaluminum Reagents": K. Maruoka, H. Yamamoto, *Angew. Chem. 97* (1985) 670–683; *Angew. Chem. Int. Ed. Engl. 24* (1985) 668–682; b) "The Beckmann Reactions: Rearrangements, Elimination–Additions, Fragmentations, and Rearrangement–Cyclizations": R. E. Gawley, *Org. React. (N. Y.) 35* (1988) 1–420.

[349] The most complete up-to-date review of the current state of organic synthesis will be provided by the eight-volume work *Comprehensive Organic Synthesis* (B. M. Trost, Ed.), Pergamon Press, London, which is to be released this year.

[350] Diastereoselectivity is at the heart of a series of seven essays by *E. Winterfeldt* published between 1985 and 1987 in the Merck magazine *Kontakte (Darmstadt)*, which have in the meantime appeared in book form: E. Winterfeldt: *Prinzipien und Methoden der Stereoselektiven Synthese*, Vieweg, Braunschweig 1988. The Diels–Alder reaction, the Claisen–Cope rearrangement, the aldol and Michael additions, stereoselective additions to carbonyl groups, and the utilization of small rings are all subjects of extensive discussion (altogether over 800 references).

[351] ... often referred to as "tandem reactions", "multiple-component coupling", or "multiply convergent reactions".

[352] "Syntheses of Enantiomerically Pure Compounds (EPC Syntheses)—Tartaric Acid, an Ideal Source of Chiral Building Blocks for Synthesis": D. Seebach, E. Hungerbühler, *Mod. Synth. Methods 2* (1980), 91–173.

[353] "EPC Syntheses with C–C Bond Formation *via* Acetals and Enamines": D. Seebach, R. Imwinkelried, T. Weber, *Mod. Synth. Methods 4* (1986) 125–259.

[434] I wish to thank Professor *Ryoji Noyori* most sincerely for providing me with manuscript copies prior to their publication [432,433], as well as for the chromatogram in Fig. 13 and permission to include these findings here.
[435] "Asymmetric catalysis in organic synthesis with industrial perspectives": H. B. Kagan, *Bull. Soc. Chim. Fr. 1988*, 846–853.
[436] We suggested [352] in 1980 use of the abbreviation "EPC synthesis" as a generic term for the preparation of enantiomerically pure compounds. While there might be disagreement over the definition of "purity" (which is dependent above all on the sensitivity of the analytical methods employed), the terminology is otherwise unambiguous. Expressions like "homochiral compounds" [437] or "isochiral compounds" [438] are unfortunate in several respects. Thus, "homochiral" has long been used in comparing the chirality of *two* similar compounds, or a pair of chiral molecules in the unit cell of a crystal, but it is now considered appropriate for describing a flask full of (+)-tartaric acid (10^{23} molecules per mole)! Expressions like "chiral synthesis" and "racemic synthesis" have also become common; while these may be permissible in English (which also tolerates combinations like "married name" and "fishing pond"), they certainly cannot be translated directly into German. The equally correct expression "chiral, not racemic" is more awkward than "enantiomerically pure". Finally, let me urge that the matter not be carried too far; in most cases all that is required is judicious use of *R* or *S*!
[437] *Homochiral:* "Double Asymmetric Synthesis and a New Strategy for Stereochemical Control in Organic Synthesis": S. Masamune, W. Choy, J. S. Petersen, L. R. Sita, *Angew. Chem. 97* (1985) 1–31; *Angew. Chem. Int. Ed. Engl. 24* (1985) 1–30.

[476] D. Seebach, U. Mißlitz, P. Uhlmann, *Angew. Chem. 101* (1989) 484; *Angew. Chem. Int. Ed. Engl. 28* (1989) 472.

[477] D. Seebach, R. Naef, *Helv. Chim. Acta 64* (1981) 2704.

[478] "Synthesis of Chiral Non-Racemic Compounds", Tetrahedron Symposia-in-Print Number 15: D. Seebach, R. Naef, G. Calderari, *Tetrahedron 40* (1984) 1313.

[479] "Methodology for the construction of quaternary carbon centers": S. F. Martin, *Tetrahedron 36* (1980) 419–460.

[480] Numerous pheromones have been prepared by *Mori* and coworkers starting with 3-hydroxybutyric acid, as well as with 3-hydroxyvaleric acid, which is also accessible from biopolymers: "Chiral Synthesis: Examples in the Pheromone Field": K. Mori, *Spec. Publ. R. Soc. Chem. 53* (1985) 293–306; "Chiral synthesis of bioactive natural products employing the building blocks of microbial origin": K. Mori, *Stud. Nat. Prod. Chem. 1* (1988) 677–712; "Recent Progress in Pheromone Chemistry": K. Mori, S. Kuwahara, *Yuki Gosei Kagaku Kyokaishi (J. Synth. Org. Chem. Jpn.) 46* (1988) 467–477; "Synthesis of optically active pheromones": K. Mori, *Tetrahedron 45* (1989) 3233–3298.

[481] There continues to be a role for such old standbys as derivatives of glycerol and glyceraldehyde, which remain convenient and versatile sources of a *single* center of chirality: "Der 2,3-Isopropyliden-glycerinaldehyd—eine Modeverbindung" (Synthese im Blickpunkt): *Nachr. Chem. Tech. Lab. 32* (1984) 146–149; "Optisch aktive Glycerinderivate" (Synthese im Blickpunkt): H.-J. Altenbach, *ibid. 36* (1988) 33–38.

[482] Finally, sugars are still "in" as sources for the "pool" of chiral synthetic building blocks: "Chirale Bausteine aus Kohlenhydraten" (Synthese im Blickpunkt): K. Krohn, *Nachr. Chem. Tech. Lab. 35* (1987) 1155–1160; "New Chiral Synthons Derived from D-Glucose": H. Hashimoto, N. Kawaguchi, *Yuki Gosei Kagaku Kyokaishi (J. Synth. Org. Chem. Jpn.) 45* (1987) 408–420; "Synthesis of Versatile Chiral Building Blocks Starting from D-Mannitol": S. Takano, K. Ogasawara, *ibid. 45* (1987) 1157–1170.

[483] "The Microbiological Production of Industrial Chemicals": D. E. Eveleigh, *Sci. Am. 245* (1981) No. 3, p. 120; *Spektrum Wiss. 1981*, No. 11, p. 88.

[484] T. H. Maugh II, *Science (Washington, D. C.) 221* (1983) 351.

[485] Even a general-circulation newspaper like DIE ZEIT (R. Schwerthöffer, *Die Zeit* No. 10, 2 March 1990, p. 96) recently devoted a half page in its science section to the subject *The Art of Catalysis* ("Die Chemie nutzt natürliche Vorbilder"), mentioning among other things *Corey*'s "Chemzymes".

[486] Previously cited books and reviews covering biological-chemical synthetic methods [79, 114, 125, 126, 241, 354]. A few additional, more recent articles: a) "Enzymes in Organic Syntheses": J. B. Jones in *F. E. C. S. Int. Conf. Chem. Biotechnol. Biol. Act. Nat. Prod. (3.)*, VCH Verlagsgesellschaft, Weinheim 1987, pp. 18–39; b) "Microbial and Enzymatic Processes for the Production of Biologically and Chemically Useful Compounds": H. Yamada, S. Shimizu, *Angew. Chem. 100* (1988) 640–661; *Angew. Chem. Int. Ed. Engl. 27* (1988) 622–642; c) "General Aspects and Optimization of Enantioselective Biocatalysis in Organic Solvents: The Use of Lipases": C.-S. Chen, C. J. Sih, *ibid. 101* (1989) 711–724 and *28* (1989) 695–707; d) "Resolution of Enantiomers *via* Biocatalysis": C. J. Sih, S.-H. Wu, *Top. Stereochem. 19* (1989) 63–126; e) "Baker's Yeast as a Reagent in Organic Synthesis": S. Servi, *Synthesis 1990*, 1–25.

[487] The following biological-chemical procedures have so far been incorporated into *Organic Syntheses*: a) yeast reduction of hydroxyacetone to (*S*)-propan-1,2-diol [P. A. Levene, A. Walti, *Coll. Vol. 2* (1943) 545]; b) emulsin-catalyzed dimerization of glucose to gentobiose [B. Helferich, J. F. Leete, *Coll. Vol. 3* (1955) 428]; c) yeast reduction of acetoacetic ester to ethyl (*S*)-3-hydroxybutyrate [D. Seebach, M. A. Sutter, R. H. Weber, M. F. Züger, *Vol. 63* (1985) 1]; d) the lactone from (1*S*,2*R*)-2-hydroxymethylcyclohexane carboxylic acid using horse liver alcohol dehydrogenase/NAD/FMN [J. B. Jones, I. J. Jakovac, *Vol. 63* (1985) 10]; e) yeast reduction of 2,2-dimethylcyclohexan-1,2-dione to (*S*)-3-hydroxy-2,2-dimethylcyclohexanone [K. Mori, H. Mori, *Vol. 68* (1989) 56]; f) (1*S*,2*S*,3*R*)-3-hydroxy-2-nitrocyclohexyl acetate by hydrolysis of the corresponding *meso*-nitrodiacetate with pig liver esterase [M. Eberle, M. Missbach, D. Seebach, *Vol. 69* (1990), 19].

[488] Numerous procedures for carrying out biological-chemical reactions can be found in the articles by *Fischli* as well as *Crout* and *Christen* (*Vol. 2* and *5* in the series *Modern Synthetic Methods*). A comparison reveals the progress in this field between 1980 and 1989: a) "Chiral Building Blocks in Enantiomer Synthesis Using Enzymatic Transformations": A. Fischli, *Mod. Synth. Methods 2* (1980) 269–350; b) "Biotransformations in Organic Synthesis": D. H. G. Crout, M. Christen, *ibid. 5* (1989) 1–114.

[489] A truly outstanding new book treating all the biological-chemical methods of preparative interest: H. G. Davies, R. H. Green, D. R. Kelly, S. M. Roberts: *Biotransformations in Preparative Organic Chemistry (The Use of Isolated Enzymes and Whole Cell Systems in Synthesis)* from the series *Best Synthetic Methods* [A. R. Katritzky, O. Meth-Cohn, C. W. Rees (Eds.)], Academic Press, London 1989.

[490] Previously cited books and reviews on the topic of organometallic catalysis [263b, 388, 390, 394, 400, 402, 405–407, 433, 435], above all the articles by *J. K. Stille, L. S. Hegedus* and *R. Scheffold* in [389] and citations in Scheme 17. A few additional more recent articles: a) "Enantioselective Synthesis with Optically Active Transition-Metal Catalysts": H. Brunner, *Synthesis 1988*, 645–654; b) "Enantioselective Synthesis of Organic Compounds with Optically Active Transition Metal Catalysts in Substoichiometric Quantities": H. Brunner, *Top. Stereochem. 18* (1988) 129–247; c) "Asymmetric homogeneous catalysis": J. M. Brown, *Chem. Br. 25* (1989) 276–280; d) "Recent Advances in Catalytic Asymmetric Reactions Promoted by Transition Metal Complexes": I. Ojima, N. Clos, C. Bastos, *Tetrahedron 45* (1989) 6901–6939; e) A particularly useful review because of the inclusion of representative procedures and numerous citations: "Enantioselective Catalysis with Chiral Cobalt and Copper Complexes": A. Pfaltz, *Mod. Synth. Methods 5* (1989) 199–248.

[491] D. W. Blackburn (Ed.): *Catalysis of Organic Reactions*, Marcel Dekker, New York 1990.

[492] See also the *Journal of Molecular Catalysis*, published since 1975, and a recent review article: "Catalysis from the perspective of an organic chemist: common problems and possible solutions": C. A. Maryanoff, J. E. Mills, R. C. Stanzione, J. T. Hortenstine, Jr., *Chem. Ind. (Dekker) 33* (1988) 359–379.

[493] In other words, biotechnology really *is* just an "old hat with new feathers" (H. Metz in *Merck-Spektrum*, Switzerland, No. 2, 1987).

[494] For example, shikonin from the firm Mitsui Petrochemical Industries, Ltd., Iwakuni, Yamaguchi-ken 740 (Japan).

[495] Recent brief review: "Cultured Plant Cells—the Factory Within": F. DiCosmo, P. J. Facchini, M. M. Kraml, *Chem. Br. 25* (1989) 1001–1004.

[496] See also the preparation of polyphenylene [231] and enantiomerically pure diols of this type from substituted arenes by ICI in England. Recent example: D. W. Ribbons, A. E. G. Cass, J. T. Rossiter, S. J. C. Taylor, M. P. Woodland, D. A. Widdowson, S. R. Williams, P. B. Baker, R. E. Martin, *J. Fluorine Chem. 37* (1987) 299; examples in Scheme 28.

[497] W. Charney, H. L. Herzog: *Microbial Transformations of Steroids*, Academic Press, New York 1967; see also non-steroidal cyclic compounds: K. Kieslich: *Microbial transformations on non-steroid cyclic compounds*, Thieme, Stuttgart 1976.

[498] Only papers of interest to the synthetic chemist have been considered [488b].

[499] B. Wipf, E. Kupfer, R. Bertazzi, H. G. W. Leuenberger, *Helv. Chim. Acta 66* (1983) 485.

[500] The yeast reduction of acetoacetic ester in a "chemostat": M. Rohner, T. Münch, B. Sonnleitner, A. Fiechter, *Biocatalysis 3* (1990) 37.

[501] "Bioreaktoren—Einführung in die Technik": W. F. Hess, M. B. Gatzemeier, *Chem. Ing. Tech. 60* (1988) A554–A559.

[502] One need only consider the many possible conditions for an aldol addition (see [331] and Scheme 26), or for reduction with a complex hydride $M^1(M^2H_{4-n}X_n)_b$, in which M^1 = Li, Na, K, Zn, Bu_4N, M^2 = B, Al, X = RO, RCOO, R_2N with $n = 1-3$ (there are entire books on the subject!).

[503] B. Zhou, A. S. Gopalan, F. VanMiddelsworth, W.-R. Shieh, C. J. Sih, *J. Am. Chem. Soc. 105* (1983) 5925; W.-R. Shieh, A. S. Gopalan, C. J. Sih, *ibid. 107* (1985) 2993.

[504] a) J. Ehrler, F. Giovannini, B. Lamatsch, D. Seebach, *Chimia 40* (1986) 172; b) T. Haag, T. Arslan, D. Seebach, *ibid. 43* (1989) 351, and references cited therein.

[505] For extensive, competent discussions of the subject containing numerous literature citations see [486b,e; 488b].

[506] a) D. Seebach, M. F. Züger, F. Giovannini, B. Sonnleitner, A. Fiechter, *Angew. Chem. 96* (1984) 155; *Angew. Chem. Int. Ed. Engl. 23* (1984) 151; b) D. Seebach, F. Giovannini, B. Lamatsch, *Helv. Chim. Acta 68* (1985) 958; c) C. H. Wong, D. G. Drueckhammer, H. M. Sweers, *J. Am. Chem. Soc. 107* (1985) 4028; d) "Synthetic Applications of Alcohol-Dehydrogenase from *Thermoanaerobium brockii*": E. Keinan, K. K. Seth, R. Lamed, *Ann. N. Y. Acad. Sci. 501* (1987) 130–149.

[507] Cubes of concentrated cell masses of the anaerobic microorganism *Thermoanaerobium brockii* can be kept wrapped in aluminum foil in a freezer—like baker's yeast in a refrigerator—for long periods of time without loss of reductase activity [506b].

[508] Proteinogenic amino acids are produced in Japan either by fermentative techniques or by the enantioselective cleavage of amino acid derivatives with immobilized microorganisms or peptidase enzymes: "Production of

Optically Active Amino Acids Using Immobilized Biocatalysts": T. Tosa, *Int. Chem. Congr. Pacific Basin Societies,* 17–22 Dec. 1989, Honolulu, HI, Abstr. ORGN 615.

[509] Degussa utilizes membrane techniques [233], cf. also [511]. Nevertheless, much of the Degussa amino acid output is derived from protein hydrolyzates (animal skin, hair, horn, hoof, or feathers, or protein-containing material from plants) [233].

[510] α-Branched amino acids are manufactured [for example, by DMS Research, Bio-organic Chemistry Section, Geleen (Netherlands)] through the enantioselective cleavage of amino acids with *Mycobacterium neoaurum*: W. H. Kruizinga, J. Bolster, R. M. Kellogg, J. Kamphuis, W. H. Boesten, E. M. Meijer, H. E. Schoemaker, *J. Org. Chem. 53* (1988) 1826; J. Kamphuis, H. F. M. Hermes, J. A. M. van Balken, H. E. Schoemaker, W. H. J. Boesten, E. M. Meijer in G. Lubec, G. A. Rosenthal (Eds.): *Amino Acids,* Escom, Leiden 1990, pp. 119–125.

[511] Application of membrane techniques (cf. [509]) on a laboratory scale ("*M*embrane-enclosed *e*nzymatic *c*atalysis = MEEC): M. D. Bednarski, H. K. Chenault, E. S. Simon, G. M. Whitesides, *J. Am. Chem. Soc. 109* (1987) 1283.

[512] C. Laane, J. Tramper, M. D. Lilly (Eds.): *Biocatalysis in Organic Media,* Elsevier, Amsterdam 1987.

[513] An entirely different case in which the change to an organic solvent proved crucial is the enantioselective cyanohydrin reaction catalyzed by mandelonitrile benzaldehyde lyase (MBL) and discovered by *Pfeil* [W. Becker, H. Freund, E. Pfeil, *Angew. Chem. 77* (1965) 1139; *Angew. Chem. Int. Ed. Engl. 4* (1965) 1079], a process that was long thought impractical due to its reversibility. Three years ago it was demonstrated that the problem can be circumvented with immobilized enzyme in ethyl acetate, permitting the large-scale preparation of cyanohydrins in > 98% *ee* and high yield: F. Effenberger, T. Ziegler, S. Förster, *ibid. 99* (1987) 491 and *26* (1987) 458; J. Brussee, E. C. Roos, A. Van Der Gen, *Tetrahedron Lett. 29* (1988) 4485; see Scheme 28, B.

[514] J. J. De Frank, D. W. Ribbons, *Biochem. Biophys. Res. Commun. 70* (1976) 1129; *J. Bacteriology 129* (1977) 1356; S. J. C. Taylor, D. W. Ribbons, A. M. Z. Slawin, D. A. Widdowson, D. J. Williams, *Tetrahedron Lett. 28* (1987) 6391; T. Hudlicky, H. Luna, G. Barbieri, L. D. Kwart, *J. Am. Chem. Soc. 110* (1988) 4735.

[515] T. Kitazume, N. Ishikawa, *Chem. Lett. 1984,* 1815.

[516] "Baker's Yeast Mediated Preparation of Carbohydrate-like Chiral Synthons": C. Fuganti in M. P. Scheider (Ed.): *Enzymes as Catalysts in Organic Synthesis,* D. Reidel, Dordrecht 1986, pp. 3–17.

[517] Another case I would prefer to regard as a "youthful sin" (cf. Scheme 24b) is my suggestion [352]–taken up by many others as well–that this process be designated the "*meso* trick". Such expressions really should be confined to the–important!–realm of laboratory jargon.

[518] I now deliberately refrain from using the terms *prochiral* (let alone "pro-prochiral") and *prostereogenic.* They have contributed too much to a state of confusion (e.g., "prochiral hydrogen", "prochiral ketones"), and they are unnecessary. See also the remarks in the caption to Scheme 24B, the comments in [353], and CIP nomenclature [444, 445]. The thoughts expressed on the subject by *Mislow* ["Stereoisomerism and Local Chirality": K. Mislow, J. Siegel, *J. Am. Chem. Soc. 106* (1984) 3319] derive more from fundamental and theoretical considerations than from practical concerns.

Corey, *J. Org. Chem. 55* (1990) 1693.

[538] This has been designated as "reagent control" [437]–in contrast to "substrate control". In German it would have to be expressed as "durch das Reagens gesteuert". I well remember the sermons on a similar theme by my thesis advisor *Rudolf Criegee,* who was at that time editor of *Chemische Berichte*: "es muß heißen kinetisch oder thermodynamisch *gesteuerte,* nicht kontrollierte Reaktion; Kontrolle hat im Deutschen eine vom Englischen 'control' verschiedene Bedeutung!" From the fact that the term "stereocontrol" is about to replace "stereoselectivity", we must conclude that now everything is "under control".

[555] With few exceptions, lithium also does not exceed the limit of four tetrahedrally oriented ligands; see [172] and references cited therein. Higher coordination numbers with this element appear to result largely from ionic interactions.

[556] Mean lengths for the bonds [Å] between N, C, and O and a number of the metals that are important in synthetic applications.

Li-N	2.11(8)	Li-C	2.214	Li-O	2.0(1)
B-N	1.404	B-C	1.597	B-O	1.367
C-N	1.469	C-C	1.530	C-O	1.426
Mg-N	2.21(7)	Mg-C	2.15	Mg-O	2.11(6)
Al-N	1.94(5)	Al-C	1.97(3)	Al-O	2.04(9)
Ti-N	2.296	Ti-C	see below	Ti-O	2.205
Zn-N	2.159	Zn-C	1.964	Zn-O	2.093
Sn-N	2.24(6)	Sn-C	2.12(2)	Sn-O	2.7(1)

Commentary: The average bond lengths for pure B/C/N/O-compounds are taken from [102a]. Average bond lengths for Ti and Zn compounds are derived from [102b] and apply to compounds containing a metal bonded to a methyl group, or complexes with aliphatic amines or aliphatic ethers. In the case of the Ti-CH_3 group only two widely divergent values have been reported (1.969 and 2.206 Å). The rest of the data resulted from a search in the CSD [189] for comparable bonds (only trimethyl compounds in the case of Al-C and Sn-C). If more than twenty values were found, the average has been supplemented (in parentheses) with the standard deviation applicable to the last reported digit. Since the reported values were obtained on the basis of differing criteria they should be regarded only as points of reference.

[567] The amino alcohols used for preparing the catalysts **c**–**f** were derived from *N*-protected proline esters and phenyl or naphthyl Grignard reagents. The diphenylmethanol group has proven effective as part of a chiral auxiliary in other cases as well (*M. Braun* in [331d], Schemes 14, 22 [275]). For the use of other 2-hydroxymethylpyrrolidine or "prolinol" derivatives in enantioselective synthesis see also Scheme 26, chapters 11 and 14 of [331a], and D. Seebach, H.-O. Kalinowski, B. Bastani, G. Crass, H. Daum, H. Dörr, N. P. du Preez, V. Ehrig, W. Langer, C. Nüssler, H.-A. Oei, M. Schmidt, *Helv. Chim. Acta 60* (1977) 301.

[568] The prophetic observations of *Woodward* in his famous 1956 essay on the subject of "Synthesis" [39] remain just as valid today. On the other hand, it was left to a magician like Stork to propose a time scale: "So it is not surprising that organic synthesis is far from the level that many people assume. Progress is continuing, but there will not be any dramatic developments. It is more like a glacier that gradually moves forward until it has finally covered an entire region, but it will still be *centuries* before synthesis has acquired the status that many people already ascribe to it today" [44].

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Inorganic Crystal Structures. By *B. G. Hyde* and *S. Andersson*. Wiley, Chichester 1988. xv, 430 pp., hard cover, £ 41.55.—ISBN 0-471-62897-2

In the last few decades the determination of chemical structures—especially of crystal structures—has become more important, is carried out more often, and is more useful as regards the information obtained. A knowledge of the structure of a compound not only gives very important insights into the spatial arrangement of atoms, clusters, and molecules, but also provides the starting point for various, more advanced theoretical studies (e.g. MO or band structure calculations) and experiments (e.g. on structure-property relationships, phase transformations or diffusion processes).

As a result of far-reaching developments in methods for structure determination, such as the work of *J. Karle* and *H. Hauptmann* (as described in their Nobel Prize address: *Angew. Chem. 98* (1986) 600, 611; *Angew. Chem. Int. Ed. Engl. 25* (1986) 603, 614), the majority of crystal structure determinations can now be carried out rapidly and easily. Every year many new structures or new variations of older structural types are described. Consequently it is becoming increasingly difficult to keep track of the whole field of structural chemistry.

To maintain an overview of the field, it is very important to classify crystal structures and to recognize cross-correlations between them. Where can one find information about whether a "new structure" is in fact completely new, or whether and in what way it is related to known structural types? Again and again cases occur where this question is relevant, but is disregarded or simply overlooked. For example, who would guess that $LiGaO_2$, Li_2SiO_3 and Li_3PO_4 are practically isostructural, or that the Fe_2P structure is closely related to that of Li_2ZrF_6?

Despite the existence of some important more or less up-to-date resources for systematizing and standardizing structures (e.g. standardization according to *Parthé*, categorization according to *Pearson*, and data banks), this is still a difficult task, and sometimes only specialists can hope to succeed. An exhaustive treatment of the topic, including new structures, could in fact only be undertaken by a large team of experienced scientists. That such a work is needed, and would remain in demand for a long time if it were available, is shown by the fact that monographs which are partly already quite old, such as those by *Wells, Pearson*, and *Schubert*, to name only a few, are still frequently used. Where else could one find cross-correlations between structures?

The monograph by *B. G. Hyde* and *S. Andersson* is dedicated to this task; the title "Inorganic Crystal Structures" is at the same time both ambitious and modest. In fact the book only treats a selection of inorganic structures, and the authors do not make any claim of completeness. Both authors are old hands at the business of investigating complex crystal structures and analyzing structural relationships. There are many places in the book where it becomes clear that many years of experience are being brought to bear and very interesting aspects are illuminated. Both, especially *S. Andersson*, are known for their extraordinary insights into apparently familiar topics, something which they have often proved in their publications (e.g. *Angew. Chem. 95* (1983) 67; *Angew. Chem. Int. Ed. Engl. 22* (1983) 69). The concepts of "chemical twinning" and of block and shear structures are especially thoroughly explained, and are used widely for elucidating structural correlations. The authors have concentrated throughout on a method of describing structures which uses the coordination polyhedra as basic units. Each of the 15 chapters constructs relationships between simple basic types and structures of increasing complexity, using diagrams which are mostly of excellent quality. Unfortunately though, a few of the diagrams suffer a loss of clarity due to too much scale reduction.

In the first six chapters structures are put into directly comparable forms by the use of suitably chosen projection directions. At the beginning of each chapter the different types of polyhedra are described in the appropriate projections. The variants of these with cubic and hexagonal symmetry having the highest spherical packing densities are then studied in detail in different viewing directions. Combinations of the most densely packed cubic and hexagonal structures are also treated. In these sections the basis structures are discussed in a variety of representations and in different relationships; this procedure is very useful both for beginners and for advanced readers, and it makes the book a valuable learning aid.

Two chapters are also devoted to the derivatives of the cubic and hexagonal primitive arrangements; these include discussions of the large families of structures that have the fluorite and AlB_2 structures as their basis.

Another chapter deals, in a very interesting way throughout, with the steric effects of electron lone pairs and their influence on crystal structures. The authors have themselves developed some interesting models to help in understanding these effects, as well as topological transformations, which are first described for polyhedra and networks, and are then carried over to various structural types. A longer section deals with some selected deformed variants of the perovskite structure.

The next chapter is devoted to crystal forms containing noncommensurate partial structures. The so-called chimney-ladder, layer misfit, and vernier structures are discussed, illustrated by excellent diagrams. A treatment of derivatives of body-centered cubic and cubic primitive structures with tetrahedral stars (Schubert stars) as structural elements leads into the structures of intermetallic phases. Here again the size of the monograph allows only a few structures to be discussed; however, some of the aspects considered are not found in the older treatments by *Schubert* or *Pearson*.

The final chapter is concerned with a selection of silicate structures, but regrettably the discussion is very brief. The diagrams given here compete with those seen in the earlier treatments by *Wells* or *Liebau*. Here, however, the interpre-

tations of complex structures in terms of chemical twinning by translational or rotational operations—one of *Andersson*'s specialities—again provide new insights.

As a whole, the book discusses a selection of compounds which spans the whole of inorganic chemistry, from fluorides to intermetallic phases. At the end one is left with the feeling that the book could have been much more detailed, especially in the last two chapters. This is not so much a criticism of the book's content as of its length, and is an expression of the desire for a modern treatment of inorganic structures which would be, as far as possible, complete.

It is also noticeable that the book appears to have been started several years ago, and in some places the literature coverage is out of date. This shortcoming, together with a few errors, should be corrected in a subsequent edition.

On the other hand there are other parts of the book where one finds "brand-new" information, e.g. on the new high-temperature superconductors. One must also single out for special praise the fact that for most of the structures discussed the complete structural parameters are given. This gives the reader direct access to more advanced studies, and avoids the often tedious searching out of data.

For beginners the "polyhedral" view of structures may at first seem strange and difficult. However, after a little practice the consistent projections used (Chapters 2–6) allow one to recognize correlations quickly. For experienced structural chemists too, polyhedral models are very important; they can even be used as a sort of "analog computer" (*H. G. von Schnering*) for "calculating" ideal structures and structural parameters, as is done frequently in this book.

The book undoubtedly enriches the literature in this field, and it also motivates the reader to look at structures from different points of view, to understand them, and to look for cross-correlations. It is useful both for teaching purposes and for those engaged in structural chemistry research.

Reinhard Nesper [NB 1029 IE]
Max-Planck-Institut für Festkörperforschung,
Stuttgart (FRG)

Houben-Weyl. Methoden der Organischen Chemie. 4th Edition, supplementary volumes. **Carbene(oide), Carbine, Teil 1 und 2.** (Volumes E 19b). Edited by *M. Regitz*. Thieme, Stuttgart 1989. Part 1: xxxvi, pp. 1–1021; Part 2: xxi, pp. 1022–2214; hardcover, DM 2680.00 (subscription price: DM 2412.00).—ISBN 3-13-219704-1

Whereas previously the main emphasis in Houben-Weyl was on functional groups and compound classes, the editors have now also turned their attention to reactive intermediates. A two-volume work on free radicals (E 19a) was followed at the end of 1989 by the present work on carbene(oid)s, which is also in two volumes. As the most recent monograph on carbenes was published in 1975 (reviews since then have treated only parts of the topic), a serious information gap had appeared. This shortcoming was especially felt by the synthetic organic chemist wishing to use carbene(oid)s as building blocks for synthesizing target molecules. A welcome resource in this respect is now available in the amazingly comprehensive, reliable and up-to-date Houben-Weyl volumes.

The introduction (*W. W. Schoeller*, 56 pages) unfortunately does not succeed in clearly presenting the basic principles of carbene chemistry. Instead it describes what the theory of carbenes and their reactions has to offer. The contributions of the theory are treated thoroughly and competently, but the relationship to experiment is often not adequately covered. For example, the four pages of theory on the 1,4-cycloaddition of carbenes are not accompanied by a single practical example. Strangely, the authoritative studies by *Bickelhaupt* and *Mayr* are presented as *unsuccessful* attempts at 1,4-cycloaddition (p. 34). *Schoeller* explains the negative activation energies of some carbene addition reactions as being due to the formation of π-complexes (p. 16), and in support of this cites *Houk*, despite the fact that he is responsible for the much more plausible explanation in terms of entropy control. Other factual errors are on page 49, where the protonation of **I** occurs after the carbene rearrangement of **II**, not before it as stated, and on page 55, where neither the educts (cycloalkylcarbenes) nor their reaction path b are given correctly. Although it contains useful information on the capabilities and limitations of the theory, this article is not a good "calling card" for the work as a whole.

A chapter on carbynes (*H. Heydt*, 36 pages) includes everything that is worth knowing about the R-Ĉ: bonding arrangement, which combines the properties of carbenes and free radicals. The subject matter ranges from the gas phase reactions of methylidyne and halocarbynes to the formation of carbynes from their (transition) metal complexes and by chemisorption.

The entire field of carbene(oid) chemistry is then treated in about 1800 pages. The subject matter is arranged according to the substitution patterns of the intermediates. These main chapters and their authors are as follows: alkylidenecarbenes, alkenylidenecarbenes, etc. (*P. Stang*, 80 pp.); methylene and alkyl- and dialkylcarbenes (*K. P. Zeller, H. Gugel*, 171 pp.); cycloalkylcarbenes and cycloalkylidenes (*U.-H. Brinker* with *J. Arct, J. Backes, W. Erdle, M. Fermann, L. K. Sydnes*, 328 pp.); alkenyl- and alkynylcarbenes (*U. Misslitz, A. de Meijere*, 110 pp.); cycloalkenylcarbenes and cycloalkenylidenes (*H. Dürr*, 48 pp.); aryl-, diaryl- and heteroarylcarbenes (*C. Wentrup*, 198 pp.); acylcarbenes (*G. Maas*, 388 pp.); silylcarbenes, etc. (*H. Tomioka*, 49 pp.); halocarbenes (*E. V. Dehmlov*, 166 pp.); oxycarbenes (*H. Heydt, M. Regitz*, 55 pp.); sulfocarbenes (*K. Schank*, 63 pp.); nitrogen-substituted carbenes (*H. Heydt, M. Regitz*, 77 pp.); phosphocarbenes (*H. Heydt, M. Regitz, G. Bertrand*, 78 pp.). The way in which these chapters are subdivided according to second substituent, complexity, etc. largely prevents overlapping and makes it easy to find a particular carbene without referring to the subject index. An exception: dihalo- and trihaloalkylcarbenes appear in the chapter on acylcarbenes, where they belong according to their oxidation state but not their reaction properties.

All the chapters show a high level of expert knowledge, orientated according to the authors' own fields of research. A few carbene(oid) types that are of preparative importance (e.g. dihalocarbenes) are not given as much space as one would expect, as their reactions are already covered in earlier volumes of the Houben-Weyl series (e.g. 4/3 on cyclopropanes). However, the cross-references are always supplemented by new knowledge and further developments. As the preparation of reactive intermediates is necessarily linked to their further reaction, it is not possible in discussing the various types of carbenes to stick to the traditional Houben-Weyl scheme of presentation (A. Preparation, B. Reactions). Where some of the authors have nevertheless tried to do so, it seems artificial and leads to repetition. The most sensible arrangement, and also the one most often used, is according to the co-reactants, thus: "preparation of ... in the presence of ...". The value of the numerous tables with their detailed information cannot be too highly praised. Sometimes the

tations of complex structures in terms of chemical twinning by translational or rotational operations—one of *Andersson*'s specialities—again provide new insights.

As a whole, the book discusses a selection of compounds which spans the whole of inorganic chemistry, from fluorides to intermetallic phases. At the end one is left with the feeling that the book could have been much more detailed, especially in the last two chapters. This is not so much a criticism of the book's content as of its length, and is an expression of the desire for a modern treatment of inorganic structures which would be, as far as possible, complete.

It is also noticeable that the book appears to have been started several years ago, and in some places the literature coverage is out of date. This shortcoming, together with a few errors, should be corrected in a subsequent edition.

For example, the four pages of theory on the 1,4-cycloaddition of carbenes are not accompanied by a single practical example. Strangely, the authoritative studies by *Bickelhaupt* and *Mayr* are presented as *unsuccessful* attempts at 1,4-cycloaddition (p. 34). *Schoeller* explains the negative activation energies of some carbene addition reactions as being due to the formation of π-complexes (p. 16), and in support of this cites *Houk*, despite the fact that he is responsible for the much more plausible explanation in terms of entropy control. Other factual errors are on page 49, where the protonation of **I** occurs after the carbene rearrangement of **II**, not before it as stated, and on page 55, where neither the educts (cycloalkylcarbenes) nor their reaction path b are given correctly. Although it contains useful information on the capabilities and limitations of the theory, this article is not a good "calling card" for the work as a whole.

A chapter on carbynes (*H. Heydt*, 36 pages) includes everything that is worth knowing about the R-Ĉ: bonding arrangement, which combines the properties of carbenes and free radicals. The subject matter ranges from the gas phase reactions of methylidyne and halocarbynes to the formation of carbynes from their (transition) metal complexes and by chemisorption.

The entire field of carbene(oid) chemistry is then treated in about 1800 pages. The subject matter is arranged according to the substitution patterns of the intermediates. These main chapters and their authors are as follows: alkylidenecarbenes, alkenylidenecarbenes, etc. (*P. Stang*, 80 pp.); methylene and alkyl- and dialkylcarbenes (*K. P. Zeller, H. Gugel*, 171 pp.); cycloalkylcarbenes and cycloalkylidenes (*U.-H. Brinker* with *J. Arct, J. Backes, W. Erdle, M. Fermann, L. K. Sydnes*, 328 pp.); alkenyl- and alkynylcarbenes (*U. Misslitz, A. de Meijere*, 110 pp.); cycloalkenylcarbenes and cycloalkenylidenes (*H. Dürr*, 48 pp.); aryl-, diaryl- and heteroarylcarbenes (*C. Wentrup*, 198 pp.); acylcarbenes (*G. Maas*, 388 pp.); silylcarbenes, etc. (*H. Tomioka*, 49 pp.); halocarbenes (*E. V. Dehmlov*, 166 pp.); oxycarbenes (*H. Heydt, M. Regitz*, 55 pp.); sulfocarbenes (*K. Schank*, 63 pp.); nitrogen-substituted carbenes (*H. Heydt, M. Regitz*, 77 pp.); phosphocarbenes (*H. Heydt, M. Regitz, G. Bertrand*, 78 pp.). The way in which these chapters are subdivided according to second substituent, complexity, etc. largely prevents overlapping and makes it easy to find a particular carbene without referring to the subject index. An exception: dihalo- and trihaloalkylcarbenes appear in the chapter on acylcarbenes, where they belong according to their oxidation state but not their reaction properties.

All the chapters show a high level of expert knowledge, orientated according to the authors' own fields of research. A few carbene(oid) types that are of preparative importance (e.g. dihalocarbenes) are not given as much space as one would expect, as their reactions are already covered in earlier volumes of the Houben-Weyl series (e.g. 4/3 on cyclopropanes). However, the cross-references are always supplemented by new knowledge and further developments. As the preparation of reactive intermediates is necessarily linked to their further reaction, it is not possible in discussing the various types of carbenes to stick to the traditional Houben-Weyl scheme of presentation (A. Preparation, B. Reactions). Where some of the authors have nevertheless tried to do so, it seems artificial and leads to repetition. The most sensible arrangement, and also the one most often used, is according to the co-reactants, thus: "preparation of ... in the presence of ...". The value of the numerous tables with their detailed information cannot be too highly praised. Sometimes the

tables contain even more than their titles claim; for example, Table 155 (p. 1253) on Wolff rearrangements lists not only heterocyclic but also polycyclic diazoketones. The retro-rearrangement of alkynes to alkylidenecarbenes (*R. F. C. Brown*) and their preparative applications (*A. S. Dreiding*) are to be found in Table 29 (pp. 131–134) but not in the associated text.

The arrangement according to carbene types is useful from the standpoint of the synthetic chemist who comes across a carbene during a retrosynthetic analysis of the molecule in which he is interested, and needs further information on it. However, it is rather inadequate when one is interested in the carbene aspects of particular reactions. "How can one selectively functionalize adamantane by C-H insertion of a carbene at the 1-position?" or "Which carbene(oid)s add preferentially at the lower (or higher) substituted double bond of a diene?"—questions such as these can only be approached in a laborious way by using the 200-page subject index, which is arranged in order of increasing complexity (acyclic, cyclic, bicyclic...). Some carbene(oid)s have their own separate entries, while others appear *after* the corresponding hydrocarbons. The substitutive nomenclature that is used exclusively (e.g. "Carboxycyclopropan" rather than "Cyclopropancarbonsäure") serves the purpose well, although it corresponds to neither the IUPAC nor the Chemical Abstracts rules. Also the bibliography (13 pages) and the author index (100 pages) often give further help; in the latter the aristocracy stay together, and even *Doering* and *Schleyer* appear under V!

How do these volumes measure up to the traditional virtues of Houben-Weyl? *Reliability:* It seems to me that printing errors are more frequent than in earlier volumes, though many of them are not serious (e.g. wrong column titles on pages 59–69 and 103–133), some are comical (e.g. optically acute allenes on p. 51; "Cyclopentanten", p. 1073; yields quoted in °C, p. 1469) and only a few are misleading (p. 848: the rate constant for the S → T interconversion of diphenylcarbene is $3 \times 10^9\ s^{-1}$, not $3 \times 10^{-9}\ s^{-1}$; on p. 878 even a laboratory recipe is given for the wrong product **IV**). Without making a detailed search I found twenty errors in structural formulas (with about ten formulas per page this gives a rate of only 0.1%!). Of about 350 literature references chosen at random, only six contained minor errors. This is an excellent result when compared with the quality of the citations in many original papers. *Completeness of coverage*: For the period 1977–83 my own (selective) literature collection contains 227 papers of preparative importance on carbenes; of these, 178 (78%) are cited in the work. The only gap that I noticed in the systematic coverage was that benzocycloalkenylidenes are not dealt with under either the cycloalk(en)ylidenes or the arylcarbenes. *Up-to-date-ness*: Expressing the cited publications for each year as a percentage of those in my own literature collection, a maximum of 92% is reached for 1987, and the figure for 1988 is still as high as 48%. There are even some references to 1989 papers.

As a penalty for the rapid publication the editors have occasionally had to resort to "reaction paths of lowest energy" (pp. 22, 23). "Aus dieser Sicht müssen auch die Berichte über die [1.4]-Addition eines Triplett-Carbens an einem intermediären Ylid oder über ein Vinylcyclopropan/Cyclopenten-Umlagerung ablaufen" (p. 37)—such grammatical liberties are below the standard of Houben-Weyl (and of most other works).

However, minor defects can have an endearing effect in a book which is otherwise perfect. These volumes will be enthusiastically received by readers with interests in reactive intermediates, and will become their primary information resource. However, it is preparative chemists who will benefit most, as the work will give them a much better overview of the synthetic potential of the carbene(oid)s and enable them to use it more effectively.

CC Bond Formation by Addition of Carbenium Ions to Alkenes: Kinetics and Mechanism

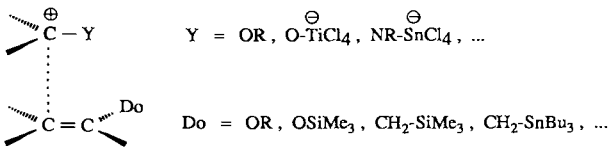
By Herbert Mayr*

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

The addition of carbenium ions to CC double bonds, a key step in many syntheses in organic and macromolecular chemistry, is analyzed using the Lewis acid promoted reactions of alkyl chlorides with alkenes as an example. Stereochemical and kinetic experiments suggest that the transition state is slightly bridged and product-like. Rearrangements of the carbenium ions that result from the electrophilic attack can be minimized by adding salts with nucleophilic counter ions. The thermodynamics of the addition reactions are analyzed, and the conditions necessary in order to observe the back reaction (i.e. the Grob fragmentation) are discussed. Multiparameter equations that predict rate constants are derived from kinetic studies on the reactivities of carbenium ions and alkenes. Reactivity-selectivity relationships over a reactivity range that covers eight orders of magnitude show that the structure of the transition state is only changed by variation of substituents in the immediate vicinity of the reaction center.

1. Introduction

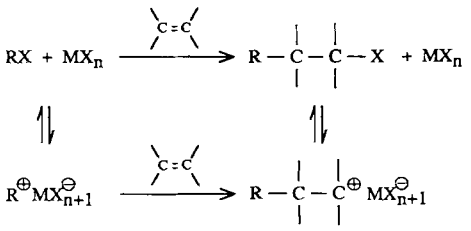
Lewis acid promoted carbon–carbon bond formation reactions have found considerable interest in organic synthesis in recent years.[1] Generally, the function of the Lewis acid is to activate an electrophile so strongly (e.g. by complexation to a carbonyl group or imine or by ionization of acetals and related compounds) that it can attack an electron-rich doubly bonded system such as a silyl enol ether or an allylmetal compound (Scheme 1).



Scheme 1.

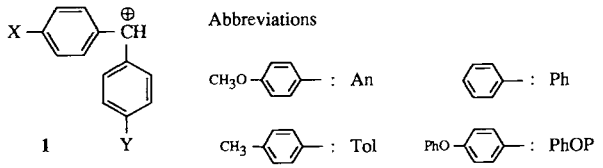
[*] Prof. H. Mayr
Institut für Chemie
Medizinische Universität zu Lübeck
Ratzeburger Allee 160, W-2400 Lübeck 1 (FRG)

The prototype for this type of reaction is the addition of a carbenium ion to a normal CC double bond, as exemplified by the Lewis acid induced reaction of alkyl halides with alkenes and dienes (Scheme 2). Now that the conditions necessary to perform such reactions selectively (i.e. to avoid polymerization) are known,[2] it has become possible to investigate their mechanisms.



Scheme 2.

para-Substituted diarylcarbenium ions **1** proved to be particularly suitable model compounds, because their reactivity can be varied over a wide range by changing the substituents

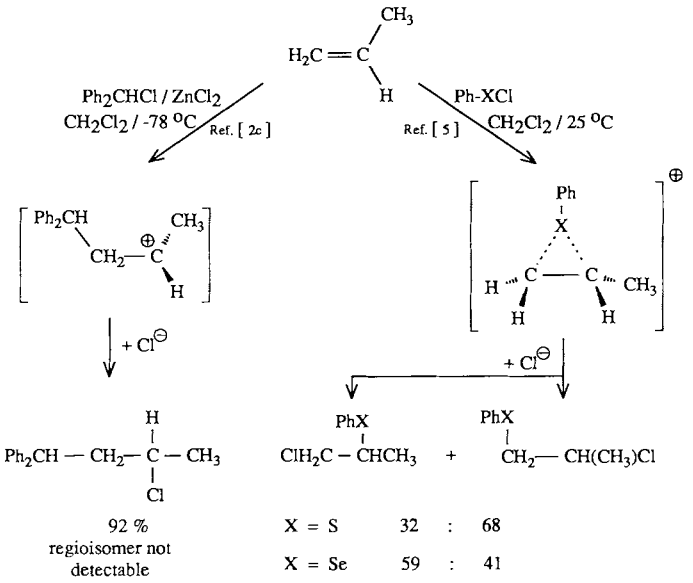


X and Y without affecting the steric environment of the reactive center.

For such studies the carbenium ions **1** can either be used as stable salts or they can be generated as short-lived intermediates in the presence of alkenes.

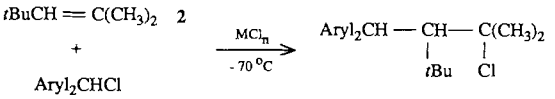
2. Regio- and Stereoselectivity

Like proton-induced HX additions,[3] additions of carbenium ions to alkenes proceed strictly regioselectively, the orientation being determined by the stability of the intermediate carbenium ions[2,4] according to the Markownikow rule. They differ in this respect from other electrophilic additions, such as sulfenylation or selenylation, in which the orientation is determined by the direction of nucleophilic attack on the bridged intermediate (Scheme 3).

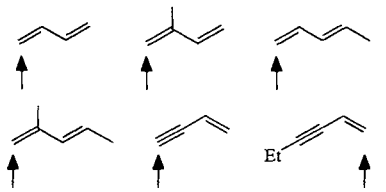


Scheme 3.

Even the sterically crowded olefin **2** is attacked by diarylcarbenium ions **1** exclusively at the *tert*-butyl-substituted vinyl carbon atom,[6] emphasizing the control of the direction of addition by electronic factors in the intermediate carbenium ion.

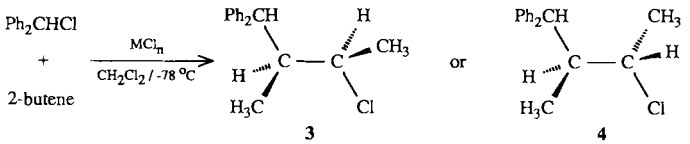


Similarly, the Lewis acid catalyzed addition of alkyl halides to alkyl- and aryl-substituted acetylenes strictly follows the Markownikow rule.[7,8] Alkyl-substituted 1,3-dienes react so that the allyl cation with the highest possible number of terminal alkyl groups is formed, leading to the regioselectivity indicated in Scheme 4.[4,6,9] 1-Butene-3-yne is attacked by C-electrophiles at the 4-position, and the reversal of the direction of addition in 1-hexene-3-yne (Scheme 4) can be explained by the electronic effect of the extra ethyl group on the cationic intermediate.[2d,9]



Scheme 4. Sites for attack by carbenium ions on conjugated dienes and enynes.

According to MINDO/3 calculations,[10] the addition of carbenium ions to alkenes should occur via π-complexes. This would explain the high *anti*-stereoselectivity in carbocationic cyclizations.[1b,11] Stereochemical studies on Lewis acid catalyzed intermolecular reactions of diphenylmethyl chlorides with (*Z*)- and (*E*)-2-butene showed that the ratio of the *syn*- and *anti*-addition products depends on the nature of



Herbert Mayr was born in Weilheim, Bavaria in 1947 and obtained his doctorate under R. Huisgen at the Universität München in 1974. After one year as postdoc at the Case-Western-Reserve-University in Cleveland/Ohio under G. A. Olah, he returned to Germany in 1976 and joined P. von R. Schleyer in Erlangen, where he completed his "Habilitation" in 1980. In 1984 he took over the direction of the Institute of Chemistry at the "Medizinische Universität zu Lübeck", and in 1990 he was offered a professorship at the "Technische Hochschule Darmstadt". His areas of interest are syntheses via carbocationic intermediates, kinetics of ion-molecule reactions, linear free energy relationships, carbocationic telomerisations and unusual cycloadditions.

the Lewis acid, but that in all cases the formation of the *anti*-products **3** or **4**, respectively, is strongly favored (Table 1).[12]

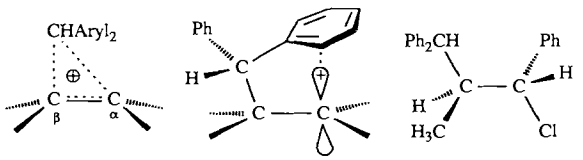
The data shown in Table 1 have been explained by the occurrence of partially bridged intermediates **5**.[12] Alternatively, it has been suggested that free rotation is hindered by an interaction between the carbenium center and the neighboring aryl ring (see **6**).[13] We consider such a stabilizing interaction to be unlikely, however, because the solvolysis of tertiary alkyl chlorides is not accelerated, but rather slowed down slightly, by a β-diphenylmethyl group.[14]

Table 1. Diastereomeric ratios of the products of Lewis acid catalyzed reactions of diphenylmethyl chloride with (*Z*)- and (*E*)-2-butene (CH_2Cl_2, −78 °C)[a].

Alkene	MCl_n	3:4
(*Z*)-2-Butene	$ZnCl_2$	86:14
	BCl_3	83:17
	$SnCl_4$	91:9
	$TiCl_4$	96:4
(*E*)-2-Butene	$ZnCl_2$	4:96
	BCl_3	12:88
	$SnCl_4$	8:92
	$TiCl_4$	<1:>99

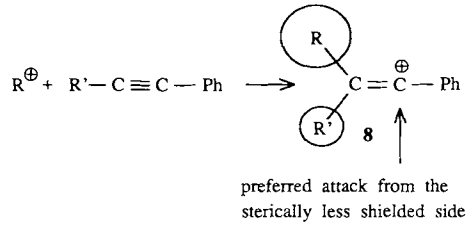
[a] The reaction also produces rearrangement products via H-shifts (see Section 3).

As the electron-donor strength of the substituents on C_α increases, the bridging in **5** becomes less significant. Thus, diastereomer **7** is formed as the major product with both isomers of β-methylstyrene, indicating an almost free rotation in the intermediate. Corresponding changes in stereoselectivity have been observed for brominations of butenes and styrenes.[15]



5 **6** **7**

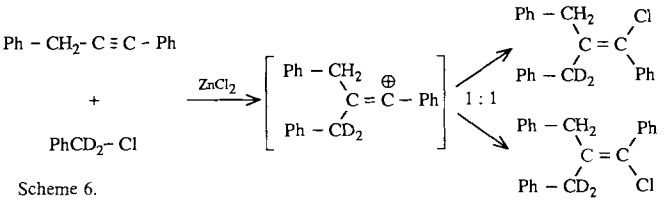
On the other hand, the stereochemical results of Lewis acid induced additions of alkyl chlorides to alkynes can be explained by the intermediacy of non-bridged species.[8] The direction of attack of a nucleophile on the intermediate vinyl cation **8** is determined by the relative sizes of the substituents R and R′ (Scheme 5).



preferred attack from the sterically less shielded side

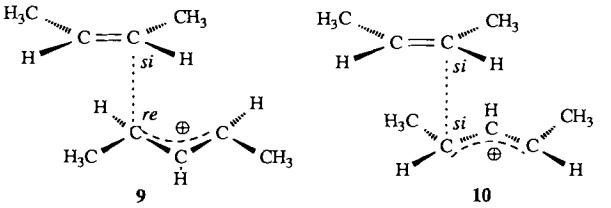
Scheme 5.

This interpretation is supported by the fact that a 50:50 mixture is isolated from the benzylation of 1,3-diphenylpropyne with labeled benzyl chloride (Scheme 6).[8]



Scheme 6.

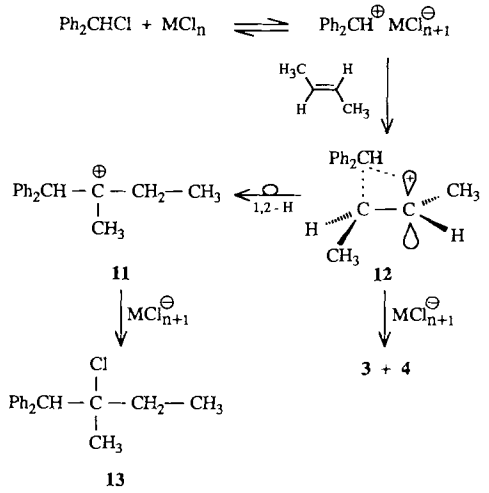
There have been very few investigations of the diastereoselectivity of the CC bond-forming step in electrophilic attack of carbenium ions on alkenes. Generally, we found only low stereoselectivity, as shown by the Lewis acid catalyzed addition of 4-chloro-2-pentene ("1,3-dimethylallyl chloride") to (*Z*)-2-butene. The *si,re*-transition state **9** is only slightly favored over the *si,si*- (and *re,re*-) transition state **10** (75:25), and for the corresponding addition to (*E*)-2-butene, the advantage of *si,re* over *si,si* (or *re,re*) sinks to 57:43.[16]



9 **10**

3. Rearrangements

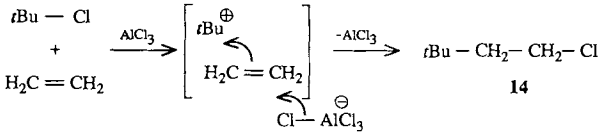
1,2-Alkyl and hydrogen shifts are among the fastest reactions known in organic chemistry.[17] Degenerate 1,2-migrations in persistent carbocations can often not be frozen out on the NMR time scale, even at −120 °C, so that special techniques have been developed to determine the structure of such cations.[17a, b] The barrier for degenerate 1,2-hydrogen and methyl shifts in tertiary carbenium ions is usually about 12–15 kJ mol^{-1}. The barrier decreases if the rearrangement leads to a stabilization of the carbenium ion. Despite these very low barriers, rearrangements of the intermediate cations shown in Scheme 2 often play an astonishingly minor role. Although 1,2-H shifts forming tertiary from secondary carbenium ions occur without activation barriers,[17] the reaction of diphenylmethyl chloride with (*E*)- and (*Z*)-2-butene yields a mixture of the normal addition products **3** and **4** and the product **13** that is derived from the rearranged cation **11** (Scheme 7).[12] Because **12** is partially bridged, the rotation about the original double bond that must precede the 1,2-shift is slow, so that the reaction of **12** with $MCl^{\ominus}_{n+1}$ (yielding **3** and **4**) can compete with the rearrangement to **11**. Thus, the normal addition products **3** and **4** are formed predominantly in the reaction of diphenylmethyl chloride with (*E*)-2-butene (Table 1) and only 20% of the products are derived from the rearranged cation **11** if $ZnCl_2 \cdot OEt_2$,



Scheme 7.

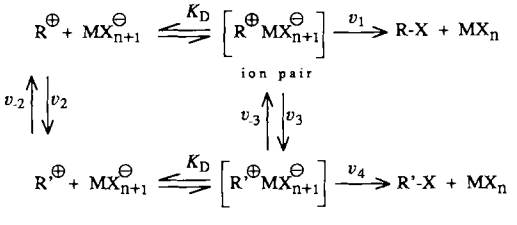
BCl_3, or $SnCl_4$ are used as catalysts (CH_2Cl_2, $-78\,^{\circ}C$). The rearrangement can be reduced to 4% with $TiCl_4$. The corresponding reaction with (*Z*)-2-butene yields a higher proportion (up to 65%) of rearranged product. This is, once again, lowest (21%) when $TiCl_4$ is used.[12]

Because electrophilic additions to 1,2-dialkylethylenes always yield secondary carbenium ions that can rearrange to tertiary carbenium ions via 1,2-H shifts, significant amounts of rearrangement products are always formed in reactions with cyclopentene and cyclohexene.[18] In view of these results, it is surprising that no rearrangement occurs when the reaction of *tert*-butyl chloride with ethylene is catalyzed by aluminum chloride.[19] The intermediacy of a primary carbocation can therefore be ruled out and the formation of **14** can be rationalized by assuming the intermediacy of a bridged cation (*tert*-butyl bridged ethylene). Alternatively, the attack of the *tert*-butyl cation at ethylene may be nucleophilically assisted by the $AlCl_4^{\ominus}$ ion because of the low stability of the 3,3-dimethyl-1-butyl cation (Scheme 8).[20]



Scheme 8.

Rearrangements that result in little or no stabilization of the carbenium ion (e.g. tertiary → tertiary or secondary → secondary) are observed occasionally, but can be partly or totally suppressed by increasing the rate of ionic recombination (v_1, Scheme 9).



Scheme 9.

Because rearrangements ($R^{\oplus} \rightarrow R'^{\oplus}$) can occur in paired or unpaired ions, their rate ($v_2 + v_3$) depends little ($v_2 \approx v_3$) or not at all ($v_2 = v_3$) on the degree of ion-pairing. The rate of ionic recombination (v_1, v_4), on the other hand, is almost proportional to the concentration of ion pairs and can, for instance, be increased by addition of a quaternary ammonium salt ($R_4N^{\oplus}MX_n^{\ominus}$). Table 2 shows how the yield of **17** relative to that of the cyclization product **18** increases with increasing $BCl_4^{\ominus}$ concentration. The **17**:**18** ratio remains essentially constant, however, once the majority of the ions are paired.[14, 21]

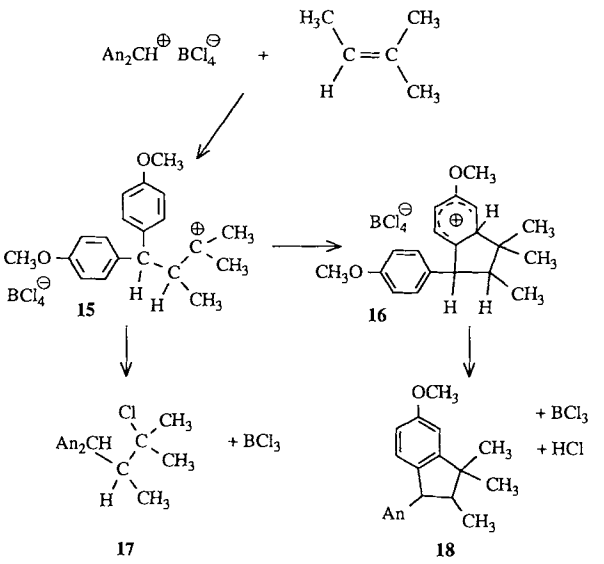


Table 2. The influence of benzyltriethylammonium tetrachloroborate on the product ratio observed in the reaction of bis(*p*-anisyl)carbenium tetrachloroborate with 2-methyl-2-butene in CH_2Cl_2 at $-70\,^{\circ}C$.[14, 21]

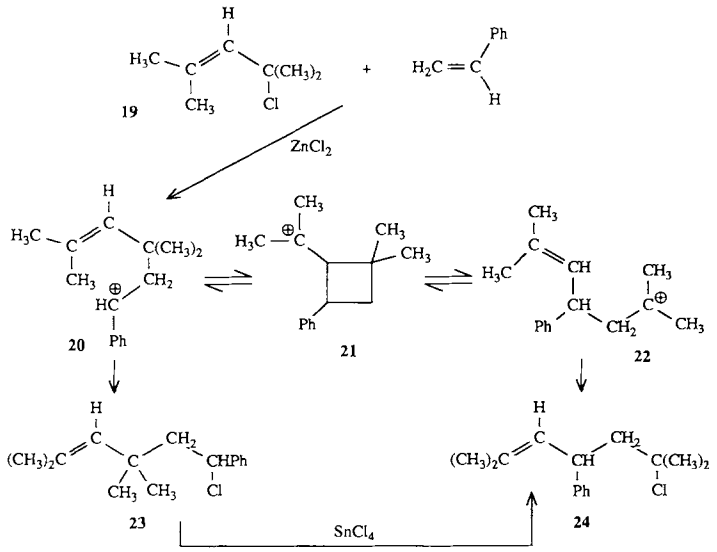
$c(An_2CH^{\oplus})$ [mol L^{-1}] [a]	$c\,(BCl_4^{\ominus})$ [mol L^{-1}] [a, b]	Ions paired:unpaired	Product ratio **17**:**18**
5.5×10^{-5}	5.5×10^{-5}	17:83	41:59
5.5×10^{-5}	5.6×10^{-4}	54:46	68:32
5.5×10^{-5}	3.4×10^{-3}	78:22	82:18
5.5×10^{-5}	1.5×10^{-2}	89:11	86:14
5.5×10^{-5}	4.9×10^{-2}	94:6	84:16

[a] Initial concentration [b] Sum of $c\,(An_2CH^{\oplus}BCl_4^{\ominus})$ and $c\,(BzNEt_3^{\oplus}BCl_4^{\ominus})$.

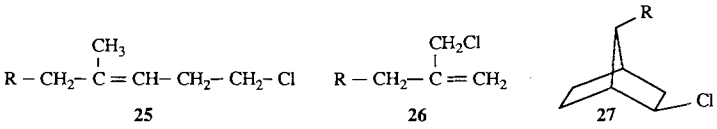
The fact that the $ZnCl_2$-catalyzed reaction of the allyl chloride **19** with styrene yields a 65:35 mixture of **23** and **24**, whereas pure **23** is obtained under the same conditions on addition of benzyltriethylammonium trichlorozincate, can be explained in the same way.[4b, 22] Thus the 1,3-vinyl shift **20** → **21** → **22** can be suppressed by increasing the $ZnCl_3^{\ominus}$ concentration and thereby accelerating the transfer of a chloride ion to **20** (Scheme 10).

As a rule-of-thumb one may assume that reducing the strength of the Lewis acid will also suppress a rearrangement, because a decrease in the stability of $MX_{n+1}^{\ominus}$ will facilitate the transfer of the halide ion $X^{\ominus}$ to a carbenium ion. There is, however, no strict relationship between the tendency to rearrange and the thermodynamic stability of $MX_{n+1}^{\ominus}$,



Scheme 10.

as shown by the reaction of benzhydryl chloride with the 2-butenes discussed above. Although $TiCl_4$ is a stronger chloride acceptor than $ZnCl_2 \cdot OEt_2$, less rearrangement product was formed in the presence of $TiCl_4$. We were unable to suppress rearrangement when cations of the cyclopropylcarbinyl, cyclopropyl or norbornyl types are formed by the electrophilic attack. Alkylation of 1-methylethenylcyclopropane,[23] methylenecyclopropane,[24] and norbornene[25] yielded exclusively the rearranged products **25**–**27**, respectively.



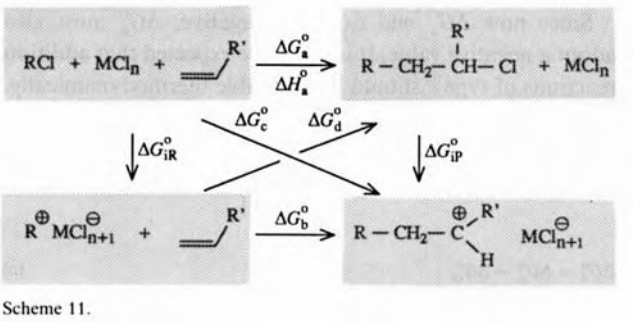
4. Thermodynamics of Addition Reactions: Addition versus Grob-Fragmentation

In order to treat the thermodynamics of addition reactions, we consider four extreme cases that differ in the degree of ionization of reactants and products:

a) Reactants and products are covalent.
b) Reactants and products are ionic.
c) Reactants are covalent, products ionic.
d) Reactants are ionic, products covalent.

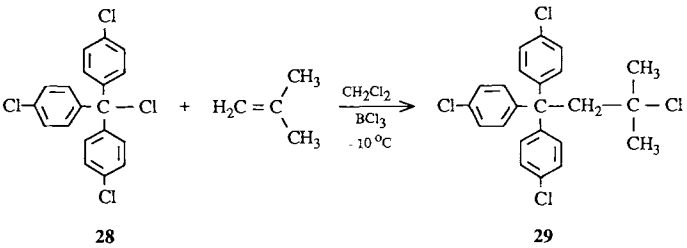
The classifications (a–d) are also used in the subscripts ($\Delta G_a^0 \ldots \Delta G_d^0$) in Scheme 11.

Case a: If carbenium ions are only present in small equilibrium concentrations (i.e., the reactants and products are predominantly covalent), ΔH_a^0 is given by the energy gain for the conversion of a π_{cc} into a σ_{cc} bond. This energy is estimated from mean bond energies[26] to be $\Delta H_a^0 = -84$ kJ mol^{-1}, in fair agreement with the calorimetrically determined heats of reaction[27] for the addition of benzhydryl chloride to 2-methyl-1-pentene (−84.5), styrene (−83.4),



Scheme 11.

2-methyl-2-butene (−78.9), and isoprene (−74.2). Changes in the ground state energy of the π-systems and different degrees of steric strain in the addition products have little effect on the magnitude of the enthalpy of addition. Using reaction entropies of −150 to −175 J mol^{-1} K^{-1} determined from increments,[28] we obtain ΔG_a^0 (−70 °C) ≈ −50 kJ mol^{-1}. ΔG_a^0, which is independent of the Lewis acid, only varies significantly if considerable steric strain is present in the addition products. However, as even the strongly hindered *tris*(*p*-chlorophenyl)methyl chloride **28** reacts with isobutene at −10 °C to give the adduct **29**,[29] we can conclude that ΔG_a^0 only becomes positive in extreme cases.



Case b: If the reactants and products are ionic, the standard free energy of reaction according to Scheme 11 is given by Equation (a).

$$\Delta G_b^0 = \Delta G_a^0 - (\Delta G_{iR}^0 - \Delta G_{iP}^0) \quad \text{(a)}$$

Equation (a) shows that ΔG_a^0 must be corrected by the difference in the free energies of ionization of reactants and products in this case. Previously we discussed the fact that for case b the selective formation of 1:1 products is only possible if $\Delta G_{iR}^0 > \Delta G_{ip}^0$, i.e., when $R^{\oplus}$ is less stabilized than the product carbenium ion R–CH_2–$^{\oplus}$CHR′ (addition rate control). If this is not the case, polymers are formed.[2a, 30] Because ΔG_a^0 is usually negative, as discussed above, ΔG_b^0 must also be negative if $\Delta G_{iR}^0 > \Delta G_{iP}^0$. In other words, the addition of a poorly stabilized carbenium ion to a CC double bond leading to a better stabilized carbenium ion is always exergonic at the usual reaction temperatures.

Case c: If ionic products (i.e. $\Delta G_{iP}^0 < 0$) are to be formed from covalent reactants (i.e. $\Delta G_{iR}^0 > 0$), the standard free energy of reaction is given by Equation (b).

$$\Delta G_c^0 = \Delta G_a^0 + \Delta G_{iP}^0 \quad \text{(b)}$$

Since now ΔG_a^0 *and* ΔG_{iP}^0 are negative, ΔG_c^0 must also adopt a negative value. It is therefore expected that addition reactions of type *c* should be favorable thermodynamically.

Case d: If covalent products (i.e. $\Delta G_{iP}^0 > 0$) are to be formed from ionic reactants ($\Delta G_{iR}^0 < 0$), the standard free energy of reaction is given by Equation (c).

$$\Delta G_d^0 = \Delta G_a^0 - \Delta G_{iR}^0 \qquad (c)$$

According to Equation (c), ΔG_d^0 is negative if $\Delta G_a^0 < \Delta G_{iR}^0$. A value of -50 kJ mol^{-1} was estimated for ΔG_a^0 (-70 °C) above, so that carbenium salts can only add to olefins to form covalent products if $\Delta G_{iR}^0 \gtrsim -50$ kJ mol^{-1}. As ΔG_{iR}^0 depends both on the structure of $R^{\oplus}$ and on the Lewis acidity of MCl_n, we can conclude that the thermodynamic driving force for Case *d* increases when the stabilization of $R^{\oplus}$ or the chloride-ion affinity of MCl_n decreases. Correlation (d) can be derived for the ionization of diarylmethyl chlorides with BCl_3.[31]

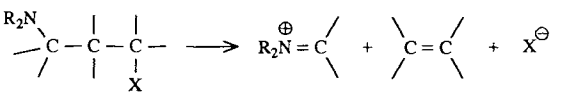
$$\Delta G_{iR}^0/\text{kJ mol}^{-1} = -6.1\ pK_{R^{\oplus}} - 67.1 \qquad (d)$$

Substituting expression (d) and $\Delta G_a^0 \approx -50$ kJ mol^{-1} in Equation (c) gives:

$$\Delta G_d^0/\text{kJ mol}^{-1} \approx 6.1\ pK_{R^{\oplus}} + 17.1 \qquad (e)$$

Therefore, a positive value for ΔG_d^0 is calculated for the addition of carbenium tetrachloroborates to alkenes to give covalent products (CH_2Cl_2, -70 °C) if carbenium ions with $pK_{R^{\oplus}} \gtrsim -2.8$ are used.[33] If such highly stabilized carbenium ions ($pK_{R^{\oplus}} \gtrsim -2.8$) are to be made to react with olefins, $BCl_4^{\ominus}$ must be replaced by an anion with higher Lewis basicity.

The reverse of the addition reactions discussed here is the Grob fragmentation.[32] In qualitative agreement with Equation (e), fragmentation is observed if the CC bond cleavage yields a well stabilized carbenium ion (large $pK_{R^{\oplus}}$ value), as for instance in the ionization of β-amino-substituted alkyl derivatives (Scheme 12).



Scheme 12.

Fragmentation to form the aromatic tropylium ion ($pK_{R^{\oplus}} = +4.76$) is observed when **30** (R = H) is treated with sulfuric acid.[34] In order to demonstrate the counter ion effect discussed above, we combined tropylium tetrafluoroborate (**31**·$BF_4^{\ominus}$) with isobutene in *methanol* and isolated **30** (R = CH_3) in 45% yield.[35]

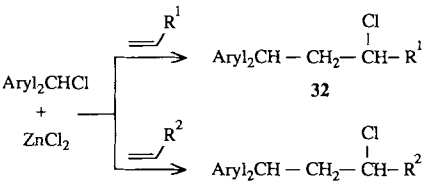
5. Kinetic Studies

5.1. Methods

The relationship between structure and reaction rates has been determined by competition experiments and by measuring absolute rate constants. Because the reaction rates do not depend on the nature of the counter ion (see Section 5.1.2), the results of the two types of experiment can be directly combined.

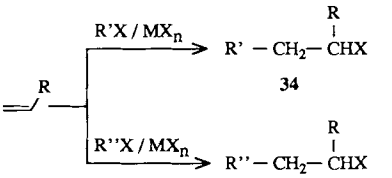
5.1.1. The Determination of Relative Rate Constants by Competition Experiments

The relative reactivities of alkenes are determined by generating diarylcarbenium ions in situ from diarylmethyl chlorides and Lewis acids in the presence of an excess of two competing olefins.[23, 36] If conditions are chosen under which subsequent reaction of the 1:1 products with excess olefin cannot occur, the reactivity ratio of the two alkenes can be determined from the ratio of the addition products **32** and **33** (Scheme 13).



Scheme 13.

Similarly, the relative reactivities of electrophiles are determined from the ratio of the 1:1 adducts **34** and **35** that results when an alkene is added to a mixture of electrophiles (Scheme 14).[30, 37] As will be shown in Section 5.2, the relative electrophilicity is strongly dependent on the type and amount of Lewis acid MX_n.



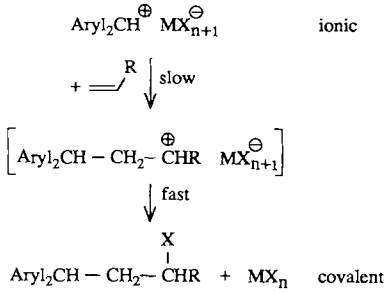
Scheme 14.

5.1.2. Determination of Absolute Rate Constants

Absolute rate constants for the reaction of carbenium ions with alkenes were first determined by observing the decrease

in absorption due to benzhydryl and benzyl cations produced pulse-radiolytically[38] in the presence of alkenes and dienes.[39] This technique is, however, only suitable for very fast reactions ($k_2 > 10^5 - 10^6$ L mol^{-1} s^{-1}).

A considerably broader set of data is based on the fact that many diarylmethyl chlorides can be ionized fully by Lewis acids in dichloromethane to give colored, electrically conducting solutions.[40] If alkenes are added to these solutions, covalent products are often formed (Scheme 15) and the



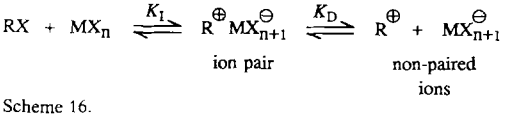
Scheme 15.

reaction can be followed both photometrically and conductimetrically.[41, 14] These are second order reactions according to Eq. (f) in which [Aryl$_2$CH$^\oplus$] represents the sum of the concentrations of paired and unpaired diarylcarbenium ions.

$$d[Aryl_2CH^\oplus]/dt = k_2[Aryl_2CH^\oplus][Alkene] \quad (f)$$

As the ion concentration sinks during the reaction, and the ratio of unpaired to paired ions therefore rises, the validity of Equation (f) implies that unpaired ions and those paired with complex counterions have the same reactivity towards alkenes. In agreement with this conclusion, the reation rate is not changed by the addition of quaternary ammonium salts with the same counter ion.

The fact that, in contrast to the ionization constant K_I (Scheme 16), the dissociation constant K_D is essentially inde-



Scheme 16.

pendent of the nature of the ions provides an explanation for this observation. K_D values of about 10^{-4} mol L^{-1} were found in dichloromethane for all combinations of the cations Aryl$_2$ CH$^\oplus$, Aryl$_3$ C$^\oplus$, tropylium, pyrylium, and tetraethyl ammonium with the anions $BCl_4^\ominus$, $SbCl_6^\ominus$, $SbF_6^\ominus$ and $AsF_6^\ominus$ known to us.[40] We can therefore assume that K_D also adopts a similar value for reactants, products and activated complexes of the reaction shown in Figure 1. This leads to a constant population ratio between paired and unpaired ions in ground and transition states. The fact that the reaction

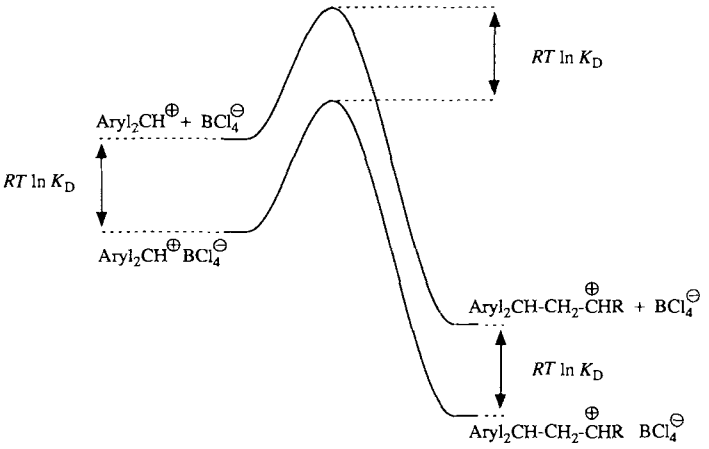


Fig. 1. Energy profiles for the rate-determining steps of the additions of paired and unpaired carbenium ions to alkenes.

rate is independent of the degree of ion-pairing can thus be explained.

It is well known that the dissociation constant K_D for organometallic compounds depends on the nature of the cation and the structure of the anion.[42] In agreement with this observation, large differences in reactivity are found for free and paired carbanions.[43, 44]

In a few cases, the energy profiles for the entire reaction sequence shown in Scheme 15, including the initial ionization step, have been determined.[14] These studies showed that a fast ionic recombination usually follows the slow attack of the carbenium ion on the alkene.

Because one carbenium ion is produced from another in the rate-determining step, it is not surprising that changes in solvent have only a minor effect on the reaction rate. We found a linear correlation of the rate of reaction of An$_2$CH$^\oplus$ with 2-methyl-1-pentene with the solvent parameter E_T (30).[45] The addition occurs 4.8 times faster in nitromethane ($E_T = 46.3$) than in chloroform ($E_T = 39.1$).[14]

Secondary kinetic isotope effects have been measured for the reaction of AnPhCD$^\oplus$ with some olefins. Their magnitude ($k_D/k_H \approx 1.2$) indicates that the rehybridization ($sp^2 \rightarrow sp^3$) of the benzhydryl carbon is very advanced in the transition state.[14]

5.2. Variation of the Carbenium Ion

As expected, decreasing the electron donating power of the *para*-substituent leads to an increase in the reactivity of diarylcarbenium ions. As shown in Table 3, this is due to a decrease in the enthalpy of activation, ΔH^+. The entropy of activation ΔS^+ remains essentially constant within a series of reactions. We have attempted to interpret the negative enthalpy of activation observed in a few cases.[46]

$$Aryl_2CHCl + BCl_3 \xrightarrow[-70\,^\circ C]{\Delta G_1^0} Aryl_2CH^\oplus BCl_4^\ominus \quad (g)$$

$$Aryl_2CH^\oplus BCl_4^\ominus + R^1CH{=}C(CH_3)R^2 \xrightarrow[-70\,^\circ C]{k_2,\ \Delta H^*,\ \Delta S^*} Aryl_2CH{-}CHR^1{-}CR^2Cl{-}CH_3 \quad (h)$$

Table 3. Free ionization enthalpies ΔG_i^0 of diarylmethyl chlorides [Eq. (g)] and kinetics of the additions of diarylcarbenium ions to 2-methyl-1-pentene and 2-methyl-2-butene [Eq. (h)] in dichloromethane [14, 46].

Carbenium ion	ΔG_i^0 (−70 °C) [kJ mol^{-1}]	2-Methyl-1-pentene k_2(−70 °C) [L mol^{-1} s^{-1}]	2-Methyl-1-pentene $\Delta H^{\neq}$ [kJ mol^{-1}]	2-Methyl-1-pentene $\Delta S^{\neq}$ [J mol^{-1} K^{-1}]	2-Methyl-2-butene k_2(−70 °C) [L mol^{-1} s^{-1}]	2-Methyl-2-butene $\Delta H^{\neq}$ [kJ mol^{-1}]	2-Methyl-2-butene $\Delta S^{\neq}$ [J mol^{-1} K^{-1}]
$An_2CH^{\oplus}$	−35.1	2.92×10^{-2}	29.7	−125	8.38×10^{-2}	21.9	−155
An(PhOP)$CH^{\oplus}$	−27.9	1.69×10^{-1}			7.5×10^{-1}		
An(Tol)$CH^{\oplus}$	−22.8	3.38	22.7	−120	1.83×10^{1}	13.6	−151
An(Ph)$CH^{\oplus}$	−16.6	2.58×10^{1}	18.6	−123	2.47×10^{2}	7.5	−159
PhOP(Tol)$CH^{\oplus}$	−15.4	3.30×10^{1}					
PhOP(Ph)$CH^{\oplus}$	−9.2	2.86×10^{2}	15.3	−119	3.92×10^{3}	5.3	−147
$Tol_2CH^{\oplus}$	−7.0	3.40×10^{3}	11.6	−117	6.79×10^{4}	−1.4	−156

The reactivities shown in Table 3 correlate only moderately well with $\Sigma\sigma^+$, because different aryl rings in the diarylcarbenium ions are twisted by different amounts out of the plane, and substituent effects are therefore not additive.[14, 47] Plots of the free energy of activation for the addition ($\Delta G^{\neq}$) against the free energy of ionization of the benzhydryl chlorides (Fig. 2) give linear relationships with gradients between 0.64 and 0.94. This indicates that more than 2/3 of the carbenium ion character of the diarylmethyl fragment has been lost in the addition transition state; i.e. the transition states are product-like.

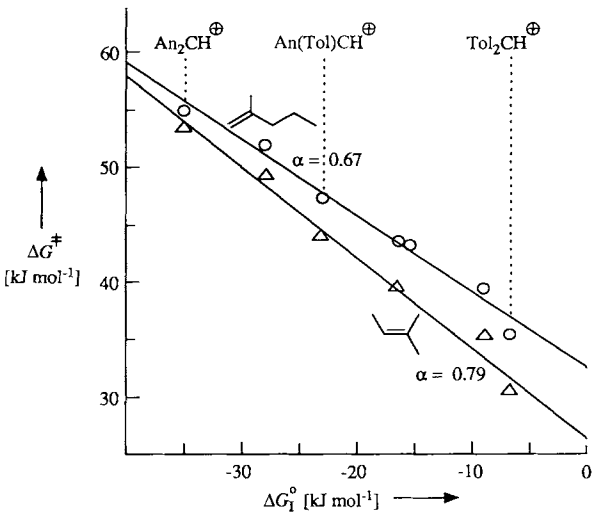

Fig. 2. Correlation between $\Delta G^{\neq}$ for the reactions of diarylcarbenium ions with alkenes [Eq. (h)] and ΔG_i^0 for the ionization of the corresponding diarylmethyl chlorides [Eq. (g)].

Figure 3, in which the energies of the non-ionized benzhydryl chlorides are set at the same level, shows clearly that the order of stability of the benzhydryl cations is retained in the transition states for the additions, but that the separations of the energy levels are much smaller than in the ground states.

The reverse of the reactivity order for the electrophiles discussed above is observed in competition experiments according to Scheme 14, if only catalytic amounts of Lewis acid are used.[2a, 30] Under these conditions, the benzhydryl chloride that forms the better stabilized carbenium ion is more reactive, because according to the Curtin–Hammett principle[48] the relative reactivity is determined solely by the height of the transition state for the CC-coupling step in Figure 3, as long as the equilibrium in the preceding ionization step is established fast compared to the rate of addition. The fact that electrophilicity orders can be inverted by variation of the Lewis acid has been used in synthesis planning.[2a] Although the existing kinetic work has been concerned primarily with diarylcarbenium ions, the conclusions reached can be extended to other systems, as shown in Figure 4. The relative reactivities of benzhydryl, phenethyl, cumyl and propargyl chlorides toward allyltrimethylsilane (which can be regarded as a substituted ethylene, see Fig. 5–7) in the presence of catalytic quantities of zinc chloride are proportional to the rates of ethanolysis of these compounds. As the rates of ethanolysis provide a measure of the "stability" of the intermediate carbenium ions,[50] Figure 4 provides experimental support for the fact that, in the presence of *catalytic amounts* of Lewis acid, the relative electrophilicity of alkyl chlorides increases with the "stability" of the intermediate carbenium ions.

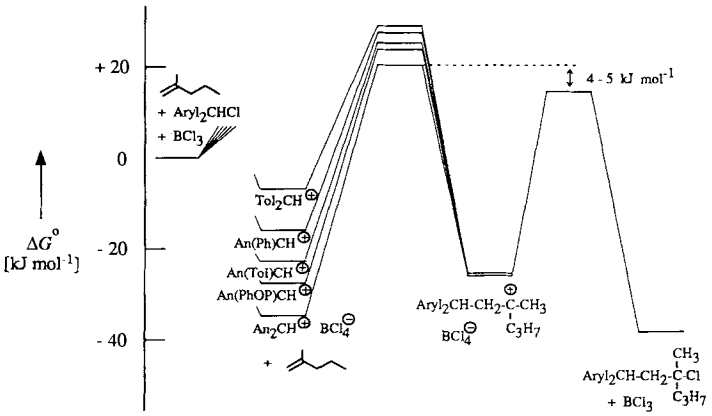

Fig. 3. Free-energy profiles for the boron trichloride induced additions of diarylmethyl chlorides to 2-methyl-1-pentene [14].

The reactivity correlation shown in Figure 4 covers six orders of magnitude and indicates that steric effects are insignificant compared to electronic effects in these systems. The limitations of this approximation become apparent, however, from the fact that triarylcarbenium ions react many times slower than would be expected from their "sta-

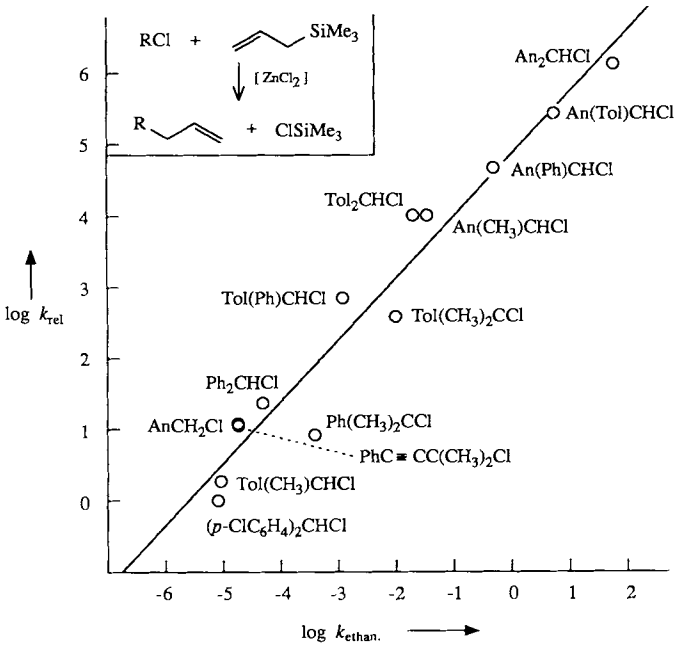

Fig. 4. Plot of the relative reactivities of alkyl chlorides towards allyltrimethylsilane (from competition reactions with $ZnCl_2$ in CH_2Cl_2 at $-70\,^{\circ}C$) [49] vs the logarithms of the ethanolysis rate constants log k_{ethan} (100% EtOH, 25 °C) [50].

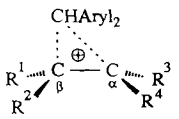
bility" ($pK_{R\oplus}$ or solvolysis rates) because of their large steric requirements.[29,49]

5.3. Variation of the Alkene

Stereochemical studies (Section 2) suggest that the attack of carbenium ions on alkenes proceeds via partially bridged transition states, so that different effects can be expected from substituents on the α-carbon atom (the developing carbenium center) and β-carbon atom (the point of attack of the electrophile) (see **36**).



36

5.3.1. α-Effects

The Hammett constant ϱ is often used to characterize the charge distribution in the activated complex.[51] Competition experiments with ditolylcarbenium ions generated in situ (Scheme 17) gave a moderate Hammett correlation with $\varrho^+ = -5.0$ (r = 0.993) and $\varrho = -5.2$ (r = 0.984).[23]

$Tol_2CH^{\oplus}$ +  $(ZnCl_2 \cdot OEt_2, CH_2Cl_2, -70\,^{\circ}C)$

X	H	p-F	p-Br	p-Cl	m-NO_2
k_{rel}	1.00	1.14	0.26	0.26	0.00031

Scheme 17. See [23].

The reaction constants are thus in the region of those for the protonation ($\varrho^+ = -3.6$ to -5.4, $\varrho = -4.8$ to -7.0)[52] and bromination ($\varrho^+ = -4.2$)[53] of styrenes and are significantly more negative than those found for NOCl addition ($\varrho = -3.84$, $\varrho^+ = -2.08$)[54] or addition of 2,4-dinitrophenylsulphenyl chloride ($\varrho = -2.33$, $\varrho^+ = -2.03$).[54] These values suggest a high positive charge density on the α-carbon atom in the transition state, which is compatible with the strong dependence of the reaction rate on R shown in Table 4.[6]

Table 4. Rate constants for the reaction of 2-substituted propenes with the *p*-methoxy-substituted diphenylmethyl cation (CH_2Cl_2, $-70\,^{\circ}C$): $An(Ph)CH^{\oplus} + H_2C{=}C(CH_3)R$.

R	k_2[L mol^{-1} s^{-1}]	k_{rel}
$-C{\equiv}CH$	no reaction	< 0.1
H	9.39×10^{-4}	1.0
CH_3	23.3	2.5×10^4
$CH{=}CH_2$	15.6	1.7×10^4
C_6H_5	1.45×10^3	1.5×10^6
Cyclopropyl	5.65×10^3	6.0×10^6

Table 4 shows that the reaction rate increases by a factor of 25 000 when the hydrogen atom in position 2 of propene is replaced by a methyl group (→ isobutene). The $\Delta\Delta G^{\neq}$ value obtained from these data ($\Delta\Delta G^{\neq} = 17$ kJ mol^{-1}) corresponds to about half the difference between the proton affinities of propene and isobutene in the non-nucleophilic solvent SO_2ClF.[36b] Whereas a vinyl group has about the same accelerating effect as methyl (isobutene ≈ isoprene), phenyl and cyclopropyl cause millionfold rate increases. Surprisingly, the ethynyl group is deactivating relative to hydrogen, so that 2-methyl-1-butene-3-yne is inert under conditions in which propene reacts smoothly with electrophiles.

Somewhat different substituent effects are found, however, if variations of R on a secondary carbon are considered (Table 5).[6] Butadiene is 21 times more reactive than propene, showing that in this case a vinyl group exerts a much stronger activating effect than a methyl group. The additional methyl group in *trans*-piperylene causes a 2400 times rate increase relative to butadiene. The activating effect of a phenyl group is also significantly larger than in the example shown in Table 4: whereas α-methylstyrene only reacts 62 times faster than isobutene, styrene is 12 000 times more reactive than propene. Styrene is thus about as nucleophilic towards carbenium ions as isobutene, in agreement with the rule-of-thumb that carbenium ions are stabilized about as

Table 5. Rate constants for the reaction of monosubstituted ethylenes with the *p*-methoxy-substituted diphenylmethyl cation (CH_2Cl_2, $-70\,^{\circ}C$): $An(Ph)CH^{\oplus} + H_2C{=}CHR$.

R	k_2 [L mol^{-1} s^{-1}]	k_{rel}
CH_3	9.39×10^{-4}	1.0
$CH{=}CH_2$	1.93×10^{-2}	21
C_6H_5	10.9	1.2×10^4
$CH{=}CH(CH_3)$	46.2	4.9×10^4

well by two methyl groups as by one phenyl.[55] On the other hand, isobutene may be up to 1000 times more reactive than styrene towards other classes of electrophiles.[56]

Branching of the the α-substituent in the allylic position leads to a moderate decrease in reactivity. The *tert*-butyl-substituted compound in Scheme 18 reacts 19 times slower than isobutene.

$An(Ph)CH^{\oplus} + H_2C = C(CH_3)R$ (CH_2Cl_2, −70 °C)

k_2 [L mol^{-1} s^{-1}]	23.3	18.4	6.08	1.21

Scheme 18. Effect of methyl groups in an allylic site [6].

In contrast, branching in a homoallylic position actually leads to a small increase in reactivity. In this case, the hyperconjugative effect outweighs the steric effect (Scheme 19).

$An(Ph)CH^{\oplus} + H_2C = C(CH_3)CH_2R$ (CH_2Cl_2, −70 °C)

R	Me	Et	*t*Bu
k_2 [L mol^{-1} s^{-1}]	18.4	25.8	28.6

Scheme 19. Effect of methyl groups in a homoallylic site [6].

5.3.2. β-Effects

Whereas α-effects are predominantly enthalpic in nature, β-effects result from a complex interplay of enthalpic and entropic influences. Furthermore, α-effects are found to be independent of the nature of the reference cation, whereas β-effects vary with different benzhydryl cations (cf. Section 5.4). In general, however, the introduction of a methyl group into the β-position results in a more negative $\Delta S^{\neq}$ and a simultaneous decrease in the enthalpy of activation, $\Delta H^{\neq}$ (*cis*-1-phenylpropene is an exception). A methyl group in the β-position may thus either facilitate or hinder electrophilic attack (Table 6). The discussion of the influence of a second β-methyl group is more difficult, because the CC bond formation step is no longer rate-determining for the reaction of diarylcarbenium ions with tetramethylethylene.[21]

Table 6. The influence of β-methyl groups in alkenes on their reactivities toward the methoxy-substituted benzhydryl cation $An(Ph)CH^{\oplus}$ (CH_2Cl_2, −70 °C).

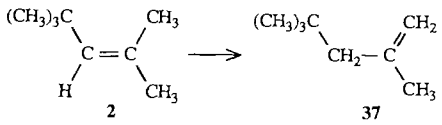
	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J mol^{-1} K^{-1}]	k_2 [L mol^{-1} s^{-1}]	k_{rel}	$\Delta\Delta S^{\neq}$(rel.)
	32.6	−139	9.39×10^{-4}	1.0	0
	31.4	−145	1.01×10^{-3}	1.1	−6
	29.9	−150	1.26×10^{-3}	1.3	−11
	21.1	−112	23.3	1.0	0
	7.5	−159	247	10.6	−47
	(8.0)	(−188)	>5.62	>0.24	−76
	19.3	−127	10.9	1.0	0
	15.5	−154	3.87	0.36	−27
	26.1	−134	0.083	0.0076	−7
	22.4	−99	46.2	1.0	0
	15.1	−124	182	3.9	−25

$An(Ph)CH^{\oplus}$ + RHC = $C(CH_3)_2$ (−70 °C, CH_2Cl_2)

R	CH_3	*t*Bu
k_2 [L mol^{-1} s^{-1}]	247	< 0.247

Scheme 20. See [6].

Very large steric effects are observed when a *tert*-butyl group is introduced into the β-position. Thus, **2** reacts at least 1000 times slower than 2-methyl-2-butene (Scheme 20). As **2** undergoes acid-catalyzed rearrangement to the far more reactive **37**, this value must be considered a lower limit.



2 **37**

5.3.3. Cyclic Alkenes and Dienes

Cycloalkenes and methylenecycloalkanes sometimes show very different nucleophilicity to their acyclic analogues.[6, 36b] As the reasons for this behavior are still largely unclear, they will not be discussed here. For cycloalkadienes, increasing non-planarity of the π system causes a decrease in the nucleophilicity (Scheme 21).

$An(Ph)CH^{\oplus}$ + (CH_2Cl_2, −70 °C)

n	1	2	3	4
k_2 [L mol^{-1} s^{-1}]	1740	27.5	3.04	0.326

Scheme 21.

5.3.4. Comparison with Other Nucleophilicity Series

Both the kinetic and the stereochemical results indicate that the transition state for the attack of carbenium ions on alkenes is only slightly bridged, so that it is not surprising that the order of reactivity towards carbenium ions does not correlate with those found for bridging electrophiles. Table 7 shows, for instance, the similarity of α- and β-methyl effects in brominations.[57] (*E*)-2-Butene and isobutene are brominated with comparable rates, whereas styrene is significantly less reactive. As in the case of carbenium ion addition, very

different α- and β-effects are observed for protonation (isobutene/(*E*)-2-butene = 10^4; Table 7). However, π-conjugation has a much weaker activating effect in proton addition than in carbenium ion addition. Thus the protonation of isoprene is one and that of styrene three orders of magnitude slower than that of isobutene, although these three compounds are almost equally reactive towards carbenium ions.

Table 7. Relative reactivities of π-nucleophiles toward some electrophiles.

					Ph
$An(Ph)CH^{\oplus}$ (−70 °C) [a]	1.00	1.34	2.48×10^4	1.66×10^4	1.16×10^4
Br_2 (CH_3OH, 25 °C) [b]	1.00	32.3	92.3		3.80
$H_3O^{\oplus}$ (H_2SO_4, 25 °C) [c]	1.00	14.8	1.56×10^5	1.34×10^4	1.01×10^2

[a] Ref. [6]. [b] Ref. [57]. [c] Ref. [58].

A comparison of the reactivity of 20 alkenes and dienes towards $H_3O^{\oplus}$ and $AnPhCH^{\oplus}$ shows that the two data sets are only weakly correlated (r = 0.71),[6] so that there is little chance at present to predict reactivity towards carbenium ions from data for other electrophilic additions. In agreement with the postulated product-like nature of the transition state for carbenium ion addition, however, a reasonable correlation (r = 0.91) was found between addition rates to alkenes and solvolysis rates of the addition products.[6]

5.4. Linear Free Energy Relationships

Better correlations than those shown in Figure 2 result when the reactivities of alkenes towards diarylcarbenium ions are compared with each other (i.e. when the reactivity of these carbenium ions towards a standard nucleophile is used as a reference scale). Figure 5 shows that the reactivity-reactivity correlations thus obtained for terminal alkenes give essentially parallel straight lines, i.e. the relative reactivity of these vinyl compounds is independent of the electrophile.[46]

An alternative representation of this relationship (Fig. 6) shows that the selectivity of the carbenium ions remains constant towards a given pair of nucleophiles, even if the reactivity of the carbenium ion is varied by eight orders of magnitude. This is an example of "constant selectivity correlations", as described by *Ritchie*,[59] even though the usual explanation of these relationships using solvent effects[60] is not applicable here.

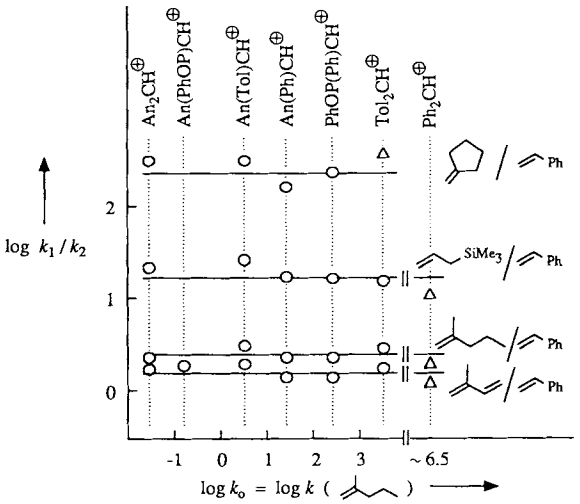


Fig. 6. Constant selectivities of diarylcarbenium ions towards pairs of terminal alkenes (−70 °C, CH_2Cl_2). The selectivities that are plotted as triangles are derived from competition experiments [23, 36b], the others from directly measured rate constants.

We can therefore conclude that structural variations in the reactants remote from the reaction center do not influence the structure of the transition state. This interpretation is all the more attractive, because if alkenes with non-terminal double bonds are included they also give linear reactivity-reactivity relationships, but with corrrelation lines that are no longer parallel (Fig. 7). Changes in the transition state

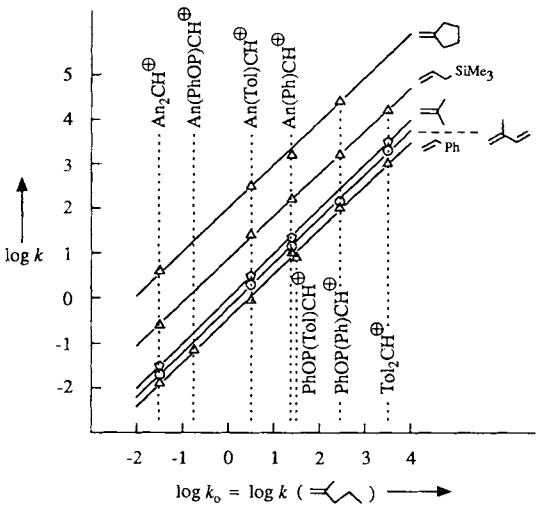

Fig. 5. Reactivities of terminal alkenes towards diarylcarbenium ions (−70 °C, CH_2Cl_2, reference reaction: $Aryl_2CH^{\oplus}$ + 2-methyl-1-pentene) [46].

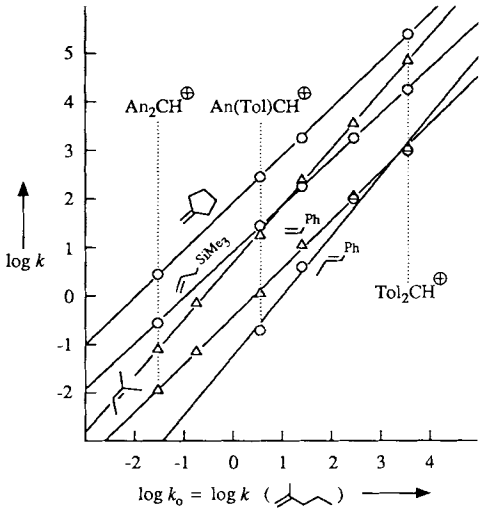

Fig. 7. Reactivities of olefins toward diarylcarbenium ions (−70 °C, CH_2Cl_2, reference reaction: $Aryl_2CH^{\oplus}$ + 2-methyl-1-pentene) [46].

structure caused by variation of substituents at the reaction center are thus indicated. In contrast to Figure 5, the lines now cross, and the nucleophilicity order found for a given carbenium ion is not the same for other electrophiles.

As there is a linear correlation (Fig. 2) between the reactivities of the diarylcarbenium ions and their ground state energies (ΔG_i^0) which in turn are related to the $pK_{R\oplus}$ values by Equation (d), Equation (i) can be derived for the reactivity of diarylcarbenium ions with alkenes. Correspondingly, Equation (j) follows from the correlation between ΔG_i^0 and the ethanolysis rate constants for the benzhydryl chlorides.[46]

$$\log k(CH_2Cl_2,\ -70\,^\circ C) = -7.42 \cdot s - 1.07 \cdot s \cdot pK_{R\oplus} + c \qquad \text{(i)}$$

$$\log k(CH_2Cl_2,\ -70\,^\circ C) = 0.90 \cdot s - 1.26 \cdot s \cdot \log k_{ethan} + c \qquad \text{(j)}$$

Values for c, a nucleophilicity parameter for the alkenes, and for s, a parameter which describes the sensitivity of the rate constant on variation of the carbenium ion, are given in Table 8. $pK_{R\oplus}$ values are listed in reference [61] and ethanolysis rates for the benzhydryl chlorides at 25 °C ($\log k_{ethan}$) in reference [31]. Because the gradients (s) of the reactivity-reactivity correlations (Fig. 7) depend chiefly on the substituents attached to the electrophilically attacked carbon atom, Equations (i) and (j) can also be used to calculate the reactivity of further alkenes that are not included in Table 8. Details for this procedure are given in reference [46]. Because of the correlation shown in Figure 4, it is likely that correlations (i) and (j) can also give approximate values for other classes of carbenium ions, provided that systems with large steric requirements, e.g. triphenylmethyl systems, are excluded.

Table 8. Alkene parameters for the calculation of reactivities toward diarylcarbenium ions according to Equation (i) and (j) [46].

	1.106	−0.633
	1.248	−1.26
	1.394	−1.25

5.5. Are SET Processes Important?

An alternative to the mechanisms discussed above is the single electron transfer (SET) shown in Equation (k) to give a diarylmethyl radical and an alkene radical cation followed by combination of these two radicals.[62]

$$Ar_2CH^\oplus + H_2C{=}CH\text{-}R \xrightarrow{\Delta E \approx 2eV} Ar_2\dot{C}H + [H_2C \dot{-} CH\text{-}R]^{\cdot\oplus} \qquad \text{(k)}$$

(Ar = Aryl)

Dorfman et al.[39] ruled out such an electron-transfer step, because of the unfavorable thermodynamics of the process (ionization potentials, $Ph_2CH^\cdot$ 7.32 eV; isobutene 9.23 eV). Although the ionization potentials refer to the gas phase, it is unlikely that solvation will significantly change the energetics because the polarity is little changed by the single electron transfer.

Nevertheless, if we assume that the electron-transfer step shown in Equation (k) is rate-determining in the addition of carbenium ions to alkenes, the reaction rates should be related to the ionization potentials of the alkenes. Table 6 shows, however, that isobutene is 20 000 times more reactive than the 2-butenes, despite its slightly higher ionization potential (9.23 eV vs 9.13 eV).[63] This result speaks against a rate-determining SET step, but steric effects cannot be rigorously ruled out as reason for the discrepancy in reactivity.

In Figure 8 the reactivities of terminal alkenes are plotted against their ionization potentials. It can be seen, for instance, that butadiene and methylenecyclopentane differ by five orders of magnitude in their reactivity despite having similar ionization potentials. On the other hand, isobutene is as reactive as styrene despite a difference of 0.8 eV in their ionization potentials. As we have concluded from Figure 5 that all the transition states for the attack of diarylcarbenium ions on terminal alkenes are structurally very similar, we interpret the lack of correlation between reactivity and ionization potential in Figure 8 as evidence against a rate-determining SET process.

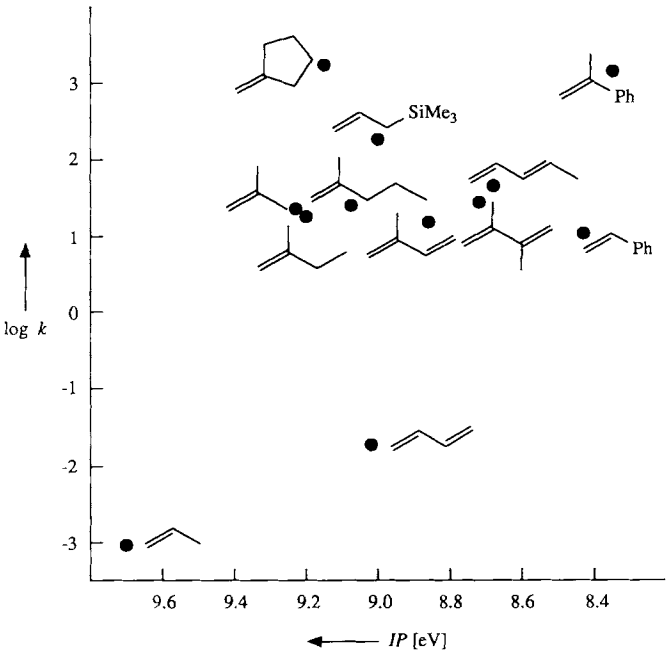

Fig. 8. The reactivities of terminal alkenes toward An(Ph)CH$^\oplus$ plotted against their ionization potentials IP [64].

6. Outlook

As described in the introduction, diarylcarbenium ions **1** were chosen as mechanistic probes, beause their reactivity can be modified by *para*-substituents without changing the steric environment at the reaction center. The principles and relationships thus obtained are, however, transferrable to other electrophiles. Kinetic studies with cyclopentenylium ions have shown, for instance, that the *relative* reactivities of alkenes shown in Tables 4 and 5 change only slightly if allyl cations are used as reference electrophiles instead of benzhydryl cations.[65] It can therefore be expected that the nucleophilicity orders given in Section 5.3 can be used as an approximation for alkylations of alkenes with any carbenium ion. As shown in Figure 4, there is a correlation between the relative electrophilicity and the rate of ethanolysis (S_N1-reactivity). This is not only true for diarylmethyl chlorides, but also for other S_N1-active compounds, including the primary *p*-methoxybenzyl chloride and the tertiary cumyl chloride. The synthetic chemist may therefore predict relative and absolute rates of alkylations on the basis of Figure 4 or Equation (j) if the solvolysis rates of the carbenium ion precursors are known.

Diarylcarbenium ions have therefore shown themselves to be suitable probes for obtaining information about the mechanism of carbenium ion attack on alkenes and about some basic interrelationships between reactivity and selectivity. As these ions can also be produced by laser pulse photolysis in the presence of more reactive olefins (enol ethers etc.),[66] it is possible to extend the reactivity series described here into the region of diffusion-controlled reactions. Kinetic studies on the reactions of diarylcarbenium ions with allyl–element compounds of the fourth main group[67, 68] and with arenes[68] have shown that these nucleophiles obey the same linear free energy relationships as alkenes. It is therefore now possible to describe a wide variety of polar CC bond forming reactions using a consistent mechanistic scheme. Some of the consequences of this work for synthesis planning have been presented in a short summary.[2a]

The majority of the work described here was carried out by Drs. R. Pock, R. Schneider, and C. Schade with the able support of M. Deters (Rubow) and U. Grabis. Only their dedicated and enthusiastic work enabled such a complex reaction sequence to be clarified within a mere few years. This work would not have been possible without a generous initial grant from the Universität Lübeck and the constant unbureaucratic support of the Deutsche Forschungsgemeinschaft. Thanks are also due to the Fonds der Chemischen Industrie and to the Volkswagen-Stiftung for the grant of a Kekulé fellowship to C. Schade.

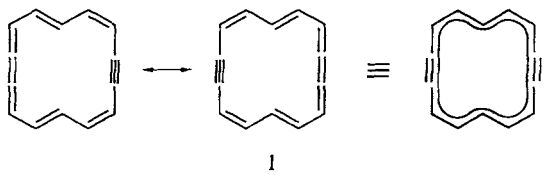
Acetylene-Cumulene Porphyrinoids**

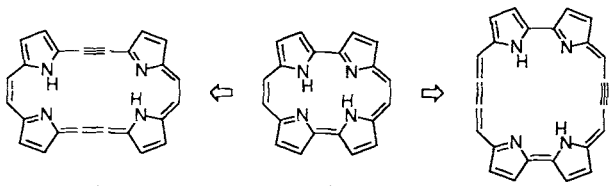
By *Norbert Jux, Peter Koch, Hans Schmickler, Johann Lex*, and *Emanuel Vogel**

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

The aromatic 1,2,8,9-tetradehydro[14]annulene (**1**), discovered accidentally by *Sondheimer* et al. in the course of the synthesis of [14]annulene, is the prototype of the theoretically interesting acetylene-cumulene dehydroannulenes.[1] These annulenes, characterized by the pairwise occurrence of linear $C_{sp^2}C_{sp}C_{sp}C_{sp^2}$ structural units,[2] can be represented by Kekulé resonance structures containing acetylene and cumulene bonds, as exemplified by **1**. Although acetylene-cumulene dehydroannulenes have received much attention owing to the work of *Nakagawa* et al.,[2b,3] the potential usefulness of acetylene-cumulene structural units in the design of "advanced materials" has hitherto not been considered.

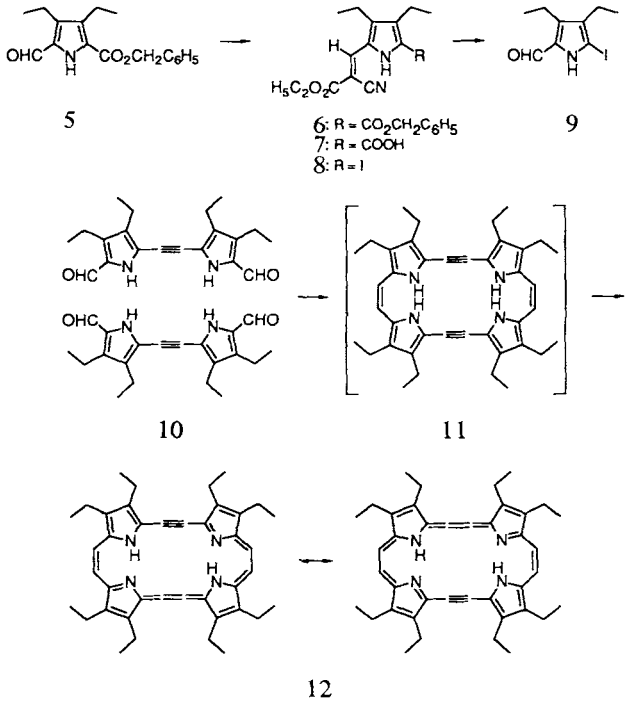


1



3 2 4

Since porphyrins[4] and porphycenes[5] can be regarded as annulenes in disguise, employment of acetylene-cumulene structural units as building blocks in the development of novel porphyrinoids suggests itself. Assuming that acetylene-cumulene porphycenes should be more readily accessible than the corresponding porphyrins, we turned our initial attention to the former type of compounds. Two structurally isomeric acetylene-cumulene porphycenes, **3** and **4**, may be derived conceptually from porphycene (**2**). Both compounds fulfill the electronic and steric prerequisites for aromaticity, since they possess a main conjugation pathway that involves 22π electrons and is embedded into a planar ring skeleton. The successful synthesis of the octaethyl acetylene-cumulene prophycene **12** (Scheme 1), a porphyrinoid exhibiting high crystallinity and good solubility in organic solvents owing to the presence of the ethyl groups, confirmed this prognosis for the compound of type **3**.



5 6: R = $CO_2CH_2C_6H_5$, 7: R = COOH, 8: R = I 9

10 11

12

Scheme 1. **5** → **6**: $NCCH_2CO_2Et$, EtOH, $MeNH_2$, 5 min, 78 °C, 81%. **6** → **7**: Pd/C, H_2, 1 atm, 4 h, 25 °C, 94%. **7** → **8**: ICl, AcOH, NaOAc, 20 min, 70 °C, 85%. **8** → **9**: NaOH, $MeOH/H_2O$, reflux, 3 h, 70%. **9** → **10**: acetylene, $Pd(PPh_3)_2Cl_2$, CuI, $HNEt_2$, 7 h, 45 °C, 22%. **10** → **12**: $TiCl_4$, Zn, CuCl, THF, reflux, 10 min, 18%.

The synthetic concept for **12** was based on the expectation that the acetylenic dipyrroledialdehyde **10** would undergo reductive coupling in the presence of low-valent titanium[6] to give the true tetrapyrrolic macrocycle **11**, which should show behavior analogous to that of *N,N'*-dihydroporphycene[7] and thus be oxidized spontaneously by air with formation of the acetylene-cumulene porphycene **12**. The actual task would therefore be reduced to synthesis of **10**. To obtain **10**, we first used established methods of pyrrole chemistry[9] to convert the known pyrrolealdehyde **5**,[8] via **6** [yellow needles (ethanol), m.p. 108 °C; yield 81%], 7 [yellow platelets (ethanol), m.p. 184–185 °C (dec.); yield 94%; crude product sufficiently pure for further reaction], and **8** [yellow-orange platelets (ethanol), *E/Z*-isomeric mixture; yield 85%], into iodoaldehyde **9** [bright pink platelets (ethanol/water 1:1), m.p. 105–106 °C; yield 70%]. When acetylene is admitted into a solution of **9** in diethylamine in the presence of bis(triphenylphosphane)palladium(II) chloride and copper(I) iodide,[10] the desired dialdehyde **10** is formed as the nonpolymeric main product. Chromatography on silica gel with ethyl acetate/pentane (1:1) as eluent followed by recrys-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Stiftung Volkswagenwerk.

tallization from ethanol afforded **10** as yellow-orange cubes [m.p. 255 °C (dec.); yield 22%]. The reductive coupling of **10** to give **12** (via **11**), regarded as the critical step of the synthesis, was carried out as described in the *Experimental Procedure* by a modification of the method used to synthesize **2** and several of its alkyl derivatives.[11]

Table 1. Selected physical data for **6**–**10** and **12**.

6: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 10.26 (br. s, 1H), 8.00 (s, 1H), 7.43, 7.36, 7.31 (m, 5H), 5.35 (s, 2H), 4.33 (q, 2H), 2.73 (q, 2H), 2.59 (q, 2H), 1.36 (t, 3H), 1.13 (t, 3H), 1.12 (t, 3H). MS (EI, 70 eV): *m/z* 380 ($M^{\oplus}$, < 1%), 91 (100). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3426, 2207, 1714, 1595. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 239 (17000), 381 (35200).

7: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 11.39 (br. s, 1H), 10.24 (br. s, 1H), 8.03 (s, 1H), 4.34 (q, 2H), 2.76 (q, 2H), 2.62 (q, 2H), 1.37 (t, 3H), 1.16 (t, 3H), 1.15 (t, 3H). MS (EI, 70 eV): *m/z* 290 ($M^{\oplus}$, 64%), 200 (100). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3419, 2615, 2210, 1724, 1666. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 239 (15300), 378 (32300).

8: (E/Z-isomeric mixture 58:42): ^{1}H NMR (300 MHz, $CDCl_3$): δ = 12.49 (*Z*, br. s, 1H), 9.62 (*E*, br. s, 1H), 7.81 (*E*, s, 1H), 7.12 (*Z*, s, 1H), 4.32 (*Z*, q, 2H), 4.30 (*E*, q, 2H), 2.61 (*E*, q, 2H), 2.60 (*Z*, q, 2H), 2.40 (*E* and *Z*, q, each 2H), 1.36 (*Z*, t, 3H), 1.33 (*E*, t, 3H), 1.13 (*E*, t, 3H), 1.12 (*Z*, t, 3H), 1.07 (*E* and *Z*, t, each 3H). MS (EI, 70 eV): *m/z* 372 ($M^{\oplus}$, 8%), 157 (100). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3264, 2205, 1707, 1685. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 227 (10200), 260 (1000), 306 (3300), 402 (41200).

9: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.54 (br. s, 1H), 9.38 (s, 1H), 2.73 (q, 2H), 2.38 (q, 2H), 1.21 (t, 3H), 1.07 (t, 3H). MS (EI, 70 eV): *m/z* 277 ($M^{\oplus}$, 100%), 262 (84). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3246, 1620, 1367. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 226 (4100), 313 (19700).

10: ^{1}H NMR (300 MHz, [D_6] dimethyl sulfoxide): δ = 12.30 (br. s, 1H), 9.60 (s, 1H), 2.70 (q, 2H), 2.52 (q, 2H), 1.13 (t, 3H), 1.12 (t, 3H). MS (EI, 70 eV): *m/z* 324 ($M^{\oplus}$, 100%). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3233, 1614, 1442, 1277. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 246 (17700), 257 (18700), 283 (20700), 381 (36000), 400 (37200).

12: ^{1}H NMR (300 MHz, CS_2/CD_2Cl_2): δ = 9.99 (s, 4H, H-11,12,23,24), 4.50 (q, 8H, H-3a,8a,15a,20a), 4.16 (q, 8H, H-2a,9a,14a,21a), 2.34 (t, 12H, H-3b,8b,15b,20b), 2.28 (br. s, 2H, NH), 2.03 (t, 12H, H-2b,9b,14b,21b). ^{13}C NMR (75.5 MHz, CS_2/CD_2Cl_2):δ = 143.28, 142.76, 140.82, 126.72, 111.85, 105.75, 22.02, 21.02, 19.43, 18.41. MS (EI, 70 eV): *m/z* 582 ($M^{\oplus}$, 100%), 291 ($M^{2\oplus}$, 6). IR (CsI): $\tilde{\nu}$[cm^{-1}] = 2962, 2067, 1479, 1267, 1216, 1200, 1116, 994, 941, 932. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 297 (12800), 381 (45600) sh, 405 (188700), 439 (76500), 492 (6200) sh, 619 (4900) sh, 651 (15300) sh, 677 (38900), 724 (73300), 766 (79400).

The structure and aromaticity of **12** are already evident from the spectra of the new tetrapyrrolic macrocycle. The ^{1}H NMR spectrum (300 MHz, CS_2/CD_2Cl_2), for which no temperature dependence has been so far observed (− 100 °C to + 25 °C), consists of a singlet at δ = 9.99 (H-11), two quartets at δ = 4.50 (H-3a) and 4.16 (H-2a), two triplets at δ = 2.34 (H-3b) and 2.03 (H-2b), and a broadened signal at δ = 2.28 (NH). In its general features, this spectrum, which is indicative of a porphyrinoid compound with strong N-H · · · N hydrogen bonds,[12] resembles that of 2,3,6,7,12,13,16,17-octaethylporphycene (**16**),[13] but agrees even better with that of unsubstituted porphycene ($\delta_{H\text{-}9}$ = 9.83; δ_{NH} = 3.15) with respect to the position of the resonances of the vinylic and NH protons.[5] That the NH signal of **16** appears at relatively high field (δ = 0.6) is explained by the increase in the N1N2′ and N1′N2 distances owing to the steric interaction between the inner ethyl groups (weaker N-H · · · N hydrogen bonds). The presence of the $C_{sp} \equiv C_{sp}$ bonds in **12** is revealed by the ^{13}C NMR spectrum, which shows, in addition to the resonances corresponding to those in the spectrum of **16**, a signal at δ = 105.75, typical for C atoms of this kind of compound.[14] The NMR spectroscopic results provide compelling evidence that **12**, like **2**, is a planar molecule exhibiting effective D_{2h} symmetry.

In the UV/VIS spectrum of **12**, the close electronic relationship of **12** with **2** and its alkyl derivatives is very impressively manifested. The spectra of **12** and 2,7,12,17-tetrapropylporphycene (**13**)[11a] (Fig. 1) have almost the same appearance, although in the spectrum of **12** the Soret double band and Q bands exhibit pronounced bathochromic shifts, consistent with the increased length of the main conjugation pathway (22π- instead of 18π-electron system). The mass spectrum (EI, 70 eV) shows the molecular ion (*m/z* 582, 100%) as the base peak and, as additional peak, the doubly charged molecular ion (*m/z* 291, 6%). The presence of strong N-H · · · N hydrogen bonds, as revealed by the position of the NH signal at relatively low field in the ^{1}H NMR spectrum, is further supported in the IR spectrum (CsI) by the absence of a band in the region of 3360–3300 cm^{-1} typical for the NH stretching vibration. An intense absorption at 2067 cm^{-1} corresponds to the asymmetric $C_{sp}C_{sp}$ stretching vibration.

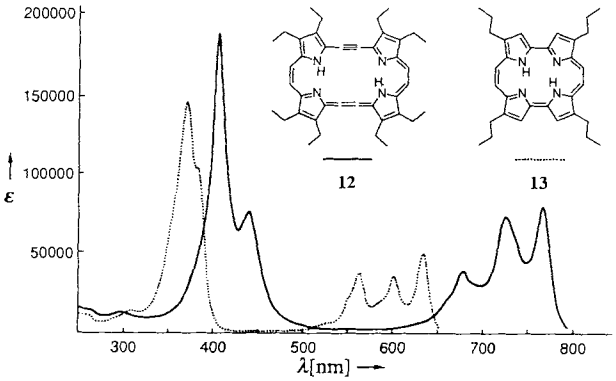

Fig. 1. UV/VIS spectrum of **12** and 2,7,12,17-tetrapropylporphycene (**13**) in dichloromethane.

In the crystal[15] (Fig. 2), the acetylene-cumulene porphycene **12** exists as a centrosymmetric molecule with a prac-

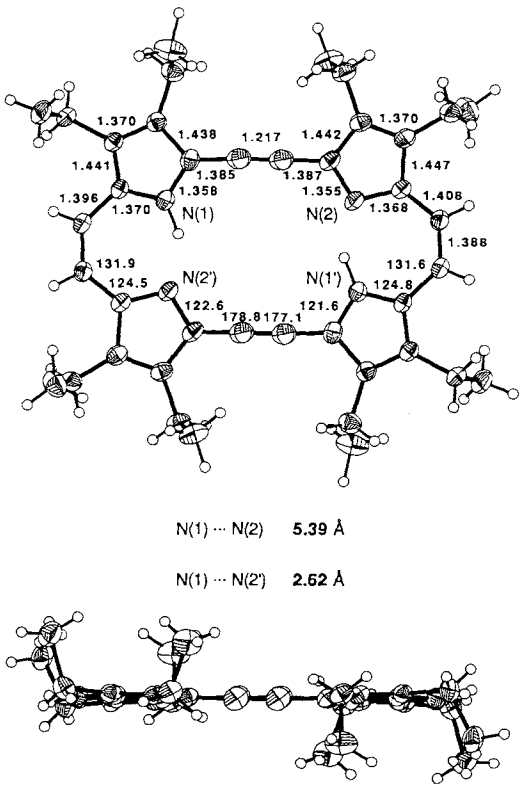

Fig. 2. Molecular structure of **12**. Top: Top view. Bottom: Side view. Selected bond lengths and other distances [Å] and bond angles [°]; standard deviations of ca. 0.002 Å and 0.1°. The thermal ellipsoids are drawn at 40% probability.

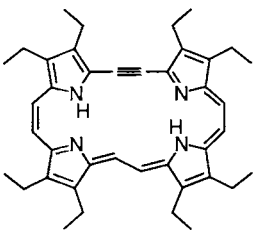
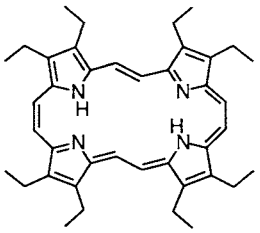
tically planar ring framework (maximal distance of the C and N atoms from the mean ring plane: 0.07 Å). As indicated by the symmetry, the $C_{sp^2}C_{sp}C_{sp}C_{sp^2}$ structural units on opposite sides are equivalent; **12** should therefore be formulated as a resonance hybrid. The geometric parameters of these C_4 units are in excellent agreement with those in **1**[2a] and in 3,9,12,18-tetra-*tert*-butyltetradehydro[18]annulene[2b] with respect to the bond angles at the sp-hybridized carbons (178.8 and 177.1°) and the lengths of the $C_{sp^2}C_{sp}$ and $C_{sp}C_{sp}$ bonds (1.385/1.387 Å and 1.217 Å, respectively). Basically, the macrocycle **12** may be viewed as a "stretched" porphycene. The NH hydrogens in **12**, unlike those in **2**, are not disordered, so that assignment to specific nitrogens (which must be N atoms in diagonal positions owing to symmetry) is possible. The cavity of **12** exhibits N1N2′ and N1N2 distances of 2.62 and 5.39 Å, respectively, and therefore has very unfavorable dimensions for complexation of metals. Conceivably, however, the $C_{sp}C_{sp}$ bonds might assist coordination with suitable metal ions.

The small amounts of byproducts formed on reductive coupling of **10** to give **12** were identified as the acetylenic dihydro compound **14** and the tetrahydro compound **15**. Compound **15**, described in the following communication,[16] represents the first [22]porphyrin(2.2.2.2).



14



15

Experimental Procedure

12: Activated zinc (650 mg, 10 mmol) and anhydrous copper(I) chloride (65 mg, 0.7 mmol) were suspended in 40 mL of absolute tetrahydrofuran (THF) and treated slowly with titanium tetrachloride (0.54 mL, 5 mmol). The mixture was refluxed for 3 h before dialdehyde **10** (162 mg, 0.5 mmol) was added in small portions. After 10 min of further heating, 40 mL of aqueous ammonia was added in order to hydrolyze the reaction mixture, which was then extracted with chloroform. Chromatography on silica gel with carbon disulfide and subsequent recrystallization from benzene afforded 26 mg (18%) of **12** as blue needles with a metallic luster (dec. above 300 °C). Compounds **14** and **15** were isolated as minor products in up to 5% combined yield.

Porphyrin Homologues: [22]Porphyrin(2.2.2.2), a "Stretched Porphycene"

By *Emanuel Vogel,* Norbert Jux, Eduardo Rodriguez-Val, Johann Lex*, and *Hans Schmickler*

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

Porphyrin (**1a**), the parent compound of the biologically most important class of natural dyes and pigments, is a tetrapyrrolic macrocycle whose π-electron structure can be described by various models.[1] In the design and synthesis of novel porphyrinoid ring systems,[2] it has proven useful to regard **1a** as an [18]annulene. Accordingly, **1a** should have homologues derived from [4n+2]annulenes with $n > 4$. These homologues, some of which are already known as dicationic *N,N′,N″,N‴*-tetraalkyl derivatives from the elegant biomimetic syntheses of *Franck* et al.,[3] may be represented (together with **1a**) by the generalized formula **1** (leaving stereochemistry aside).[4]

An obvious variation of formula **1** would be to differentiate the four $(CH)_n$ segments as depicted by formula **2**. In **2**, a $(4n+2)\pi$-electron main conjugation pathway is maintained if the sum of the carbons in the segments is a multiple of 4. The porphyrin homologues are thus complemented by a broad spectrum of porphyrin analogues. Representative examples are [18]porphyrin(2.0.2.0) (porphycene), first synthesized in 1986,[2a] and the [22]porphyrin(3.1.3.1) system, the parent structure of the platyrins,[5] the preparation of which was recently reported.[6]

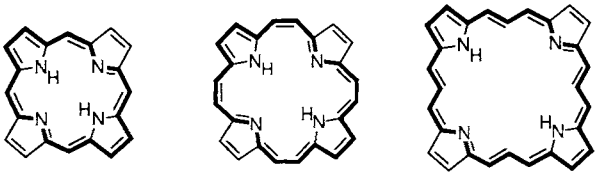
N = 1, 2, 3, etc.

X = NH, NCH_3, O, S, Se

As pointed out earlier,[2c] porphyrin and its homologues bear a close relationship to the dicationic porphyrinoids represented by formula **3**, that is, the *N*,*N*′,*N*″,*N*‴-tetraalkylated porphyrins[2e] and their homologues,[3] and compounds in which the N/NH functions in **1** are replaced by heteroatoms such as oxygen,[2c] sulfur,[2d] and selenium.[2d] A similar relationship linking neutral molecules to charged species applies to the porphyrin analogues **2**.[2b] As regards the charge distribution in the dicationic porphyrinoids, it is not yet clear to what extent resonance structures in which the positive charges reside at the heteroatoms contribute to the hybrid.

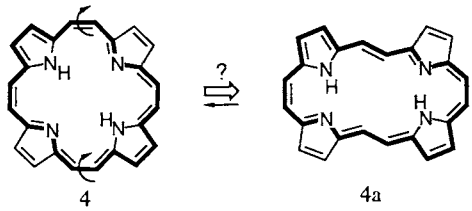


1a 4 5

[18]Porphyrin(1.1.1.1) [22]Porphyrin(2.2.2.2) [26]Porphyrin(3.3.3.3)

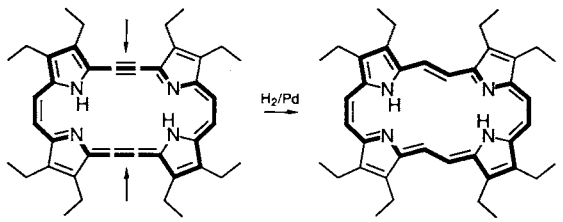
Of the porphyrinoids **1**–**3**, the neutral porphyrin homologues **1b**, **1c**, etc., which are of interest as unusual chromophores, potential ligands, and components of supramolecular structures, still pose a challenge for the synthetic chemist. In pursuing the synthesis of such molecules, it must be kept in mind that the transition from porphyrin to its homologues is accompanied by the occurrence of configurational isomerism.[7] Stereochemical considerations indicate that a distinction should be made between porphyrin homologues with odd and even index n (formula **1**). Whereas a porphyrin-like geometry with D_{2h} symmetry should be favored for **1c**, **1e**, etc., as shown by formula **5** for **1c**—that is, $(CH)_n$ segments with all-*trans*-CH=CH bonds—the existence of a D_{2h}-symmetric molecule is rendered difficult, if not ruled out, for **1b**, **1d**, etc., for steric reasons.

The target molecule of the present work is the *next higher homologue of porphyrin*, termed [22]porphyrin(2.2.2.2) (**1b**), for which, besides the isomer **4** containing four *cis*-CH=CH bonds, isomers with *trans*-CH=CH bonds must be considered. In all probability, **4** is nonplanar, since it should have a relatively high strain, which can hardly be compensated for by the resonance energy of the system. As consistently found by both examination of molecular models and force-field calculations,[8] **4a**, the *cis,trans,cis,trans* isomer of [22]porphyrin(2.2.2.2), is energetically favored over **4** and other isomers. Structure **4a** can adopt a planar conformation with only slight skeletal strain and has the additional advantage that it possesses N-H···N hydrogen bonds tending to stabilize a planar arrangement.



4 4a

Here we describe two syntheses of the porphyrin homologue 2,3,8,9,14,15,20,21-octaethyl[22]porphyrin(2.2.2.2) (**7**), the first one employing the acetylene-cumulene porphyrinoid **6** reported in the preceding communication[9] as starting compound. Hydrogenation of **6** with palladium (Pb-poisoned), carried out until the starting material and dihydro compound were consumed (TLC monitoring), afforded the tetrahydro compound **7** as the major nonpolymeric product.



6 7

Chromatography on silica gel with carbon disulfide followed by crystallization from benzene furnished violet crystals (rhombs; dec. above 285 °C; yield 35%), which, in organic solvents, produced green solutions.

The ^{1}H NMR spectrum of **7** (see Fig. 1 and Table 1) is temperature-dependent and consistent with a *cis,trans,-cis,trans* configuration of the compound. The extreme low- and high-field positions of the resonances of the perimeter protons H-5,11,12 and H-6, respectively, convincingly demonstrate the aromatic porphyrinoid nature of **7**, whereas the resonance of the NH protons at relatively low field (porphyrin NH protons: $\delta = -3.76$[10]), due to the presence of strong N-H···N hydrogen bonds,[11] clearly reveals the structural relationship of **7** to porphycene (NH protons: $\delta = 3.15$[2a]). The changes in the spectrum observed above 70 °C (in $C_2D_2Cl_4$) indicate that rapid exchange occurs between H-5 and H-6, H-11 and H-12, the ethyl groups on C-2 and C-9, and the ethyl groups on C-3 and C-8 and thus suggest that [22]porphyrin(2.2.2.2), in *cis,trans,cis,trans* con-

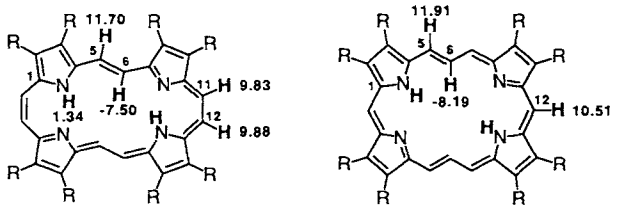
Table 1. Selected physical data for **7** and **9**.

7: ^{1}H NMR (300 MHz, CS_2/CD_2Cl_2, room temperature): $\delta = 11.70$ (d, $^3J_{5,6} = 15.24$ Hz, 2H; H-5,17), 9.88, 9.83 (2 d, $^3J_{11,12} = 11.23$ Hz, 4H; H-11,12,23,24), 4.69, 4.28 (2 q, 8H; H-3a,8a,15a,20a), 4.14 (q, 8H; H-2a,9a,14a,21a), 2.36, 2.14 (2 t, 12H; H-3b,8b,15b,20b), 2.01, 1.99 (2 t, 12H; H-2b,9b,14b,21b), 1.34 (br. s, 2H, NH), −7.50 (d, 2H; H-6,18). ^{13}C NMR (75.5 MHz, CS_2/CD_2Cl_2): $\delta = 147.26$, 145.61, 144.99, 140.48, 140.24, 139.93, 139.85, 139.48, 116.09, 113.84, 111.30, 108.96, 23.10, 20.90, 20.66, 20.46, 19.37, 19.30 (2 C), 16.81. MS (EI, 70 eV): *m/z* 586 ($M^{\oplus}$, 100%), 293 (18). IR (CsI): $\tilde{\nu}$[cm^{-1}] = 2963, 2932, 2871, 1471, 1283, 1195, 1054, 1006, 985, 937, 806, 619. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 270 (14400), 417 (79800) sh, 440 (207900), 464 (104400), 482 (41600) sh, 579 (2200) sh, 618 (4100) sh, 656 (19500) sh, 672 (38900), 685 (26500) sh, 719 (16600) sh, 726 (17100), 790 (57200).

9: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 10.02$ (br.s, 1H), 9.86 (s, 2H), 2.74 (q, 4H), 1.21 (t, 6H). MS (EI, 70 eV): *m/z* 179 ($M^{\oplus}$, 100%). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3261, 1675, 1649, 1470, 1220. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 241 (19300), 320 (1400).

figuration, undergoes an isodynamic transformation involving rotation around the *trans*-CH=CH bonds[12]—corresponding to a transition from C_{2h} to effective D_{2h} molecular symmetry. A detailed line-shape analysis of the temperature-dependent spectrum is still being carried out. However, the coalescence temperature of the signals of the methyl protons of the ethyl substituents on C-3 and C-8 already allows the free energy of activation $\Delta G^{\neq}$ of the isodynamic conformational process to be estimated as about 20 kcal mol^{-1}.

The ^{1}H NMR spectrum of **7** may be compared with that of *Franck*'s compound **8**,[6] derived from [22]porphyrin(1.3.1.3), a porphyrinoid isomeric to [22]porphyrin-(2.2.2.2) (**4a**). An astounding analogy is found between the two types of [22]porphyrin with respect to the ring-current effect. In both **7** and **8**, the difference in the chemical shifts of the inner and outer protons is on the order of no less than $\Delta\delta = 20$ (Fig. 1).



7: R=C_2H_5 8: R=CH_2COOEt

Fig. 1. Comparison of the ^{1}H NMR data (each 300 MHz, room temperature) of **7** (in CS_2/CD_2Cl_2) and **8** (in $CDCl_3$) [6] with respect to the chemical shifts of the protons most influenced by the diamagnetic ring current (no information is available regarding the position of the signal for the NH proton in **8**).

The UV/VIS spectrum of **7** contains a strong Soret band, appearing as a double band at $\lambda = 440/464$ nm ($\varepsilon = 207900/104400$), and Q bands in the region of $\lambda = 672$ to 790 nm. Owing to the shape and position of the bands, this spectrum might be looked upon as a porphycene spectrum shifted to longer wavelength. The IR spectrum of **7** reveals no NH stretching vibration and thus provides an additional argument that this compound, like porphycene, features strong N-H···N hydrogen bonds. In the mass spectrum (EI, 70 eV), the molecular ion (*m/z* 586, 100%) accounts for the base peak and the doubly charged molecular ion (*m/z* 293, 18%) for an additional prominent peak.

An X-ray structure analysis[13] of **7** (Fig. 2) confirms the *cis,trans,cis,trans* configuration of the compound and reveals, in particular, the planarity of the ring framework (maximum distance of the C and N atoms from the mean ring plane: 0.05 Å). Compound **7** is centrosymmetric; accordingly, the imino hydrogens can be assigned to diagonally opposite nitrogens. A parallel observation is that **7** contains two kinds of pyrrolic rings, whose bond lengths and angles agree within the limits of error with those in octaethylporphyrin.[14] Whereas the relationship of **7** to porphyrins is reflected in the structural parameters of the pyrrolic rings, the striking similarities in the partial structures of **7** and porphycene justify regarding **7** as a "stretched porphycene". The presence of strong N-H···N hydrogen bonds in **7** is presumably of decisive importance for the planarity of the ring framework of the molecule as is true for porphycene. The nonbonding interactions between the inner CH hydrogens are too small, in agreement with molecular models, to cause a significant deviation of these hydrogens from the plane of the molecular framework. However, such interactions are reflected by an increase in the CCC angles at C-6

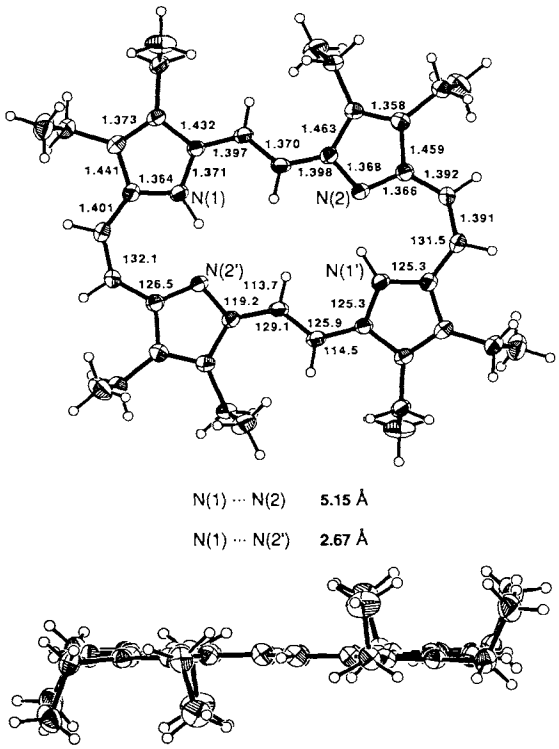


Fig. 2. Molecular structure of **7**. Top: Top view. Bottom: Side view. Selected bond lengths and other distances [Å] and bond angles [°]; standard deviations ca. 0.003 Å and 0.2°. The thermal ellipsoids are drawn at 40% probability.

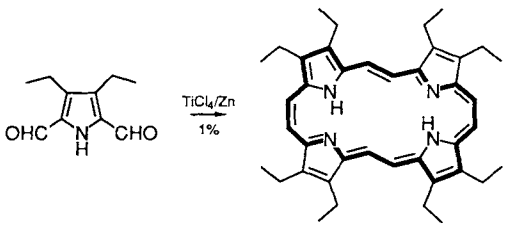
and C-18. The four N atoms in **7** define a parallelogram (N2-N1-N2′ = 78.1°) owing to the presence of the *trans*-CH=CH segments.

The stability of *cis,trans,cis,trans*-octaethyl[22]porphyrin-(2.2.2.2) (**7**) encouraged us to attempt a one-pot synthesis of the compound—comparable to the biomimetic synthesis of porphyrins[15] from α-hydroxy- or α-aminomethylpyrroles—by reductive coupling of dialdehyde **9**[16] with low-valent titanium.[17] Indeed, reaction of **9** with the coupling reagent generated from titanium tetrachloride and zinc-copper in tetrahydrofuran gave the desired compound **7** as the only low-molecular-weight product, although in a preliminary yield of only 1%. In the meantime, we have also



9 **7**

carried out the coupling of 2,5-pyrroledicarbaldehyde under the same conditions to give unsubstituted *cis,trans,cis,trans*-[22]porphyrin(2.2.2.2) (**4a**).[18] In this case, the yield is even lower (0.1–0.2%), presumably owing to solubility problems. A full characterization of the parent compound will therefore require further experimentation.

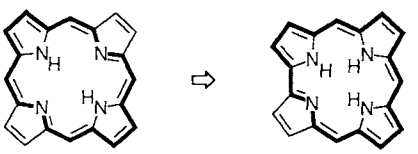
[18] So far obtained as a microcrystalline blue powder with a metallic luster; ^{1}H NMR spectrum (300 MHz, $CDCl_3$, room temperature): $\delta = 11.67$ (H-5), 10.19 (H-3), 9.95 (H-12), 9.86 (H-11), 9.46 (H-8), 9.36 (H-2), 9.30 (H-9), 2.21 (NH), −7.13 (H-6). The couplings of **9** and 2,5-pyrroledicarbaldehyde were carried out by *S. Böhm* and *W. Hennig*.

Isocorroles: Novel Tetrapyrrolic Macrocycles**

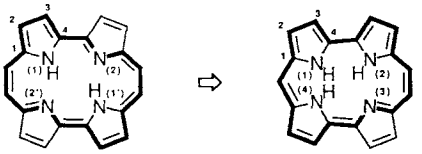
By *Stefan Will, Afssaneh Rahbar, Hans Schmickler, Johann Lex*, and *Emanuel Vogel**

Dedicated to Professor Albert Eschenmoser on the occasion of his 65th birthday

Corrole (**2**), which may be regarded as the aromatic basic structure of the ring framework of vitamin B_{12} [1] and which has been investigated extensively by *A. W. Johnson* and his co-workers,[2] is formally derived from porphyrin (**1**) by contraction of the C_{20} perimeter with expulsion of a *meso* carbon atom. Compound **2**, like **1**, exhibits an 18π-electron main conjugation pathway, but differs from **1** in that it contains three pyrrole-like nitrogen atoms, assumed to be responsible for the ready anion formation in the case of **2**. The spectra of corroles display a close relationship with those of porphyrins, even though the ring framework deviates noticeably from planarity, presumably owing to steric interactions between the NH hydrogens.[3] The chemistry of corroles, which have not yet been found in nature, is dominated by their ability to form complexes (metallocorroles) with metal ions.[2, 4]



1 2



3 4

It occurred to us that the formalism relating **1** and **2** structurally might be extended to the porphyrin isomer porphycene (**3**).[5] Our attention was thereby directed to the previously unknown tetrapyrrolic macrocycle **4**, for which the name isocorrole is proposed. Compound **4**, in a planar conformation, is more strained than **2**, so that it was open to

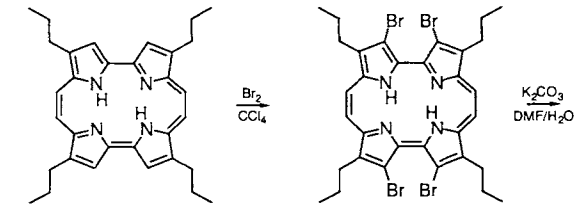
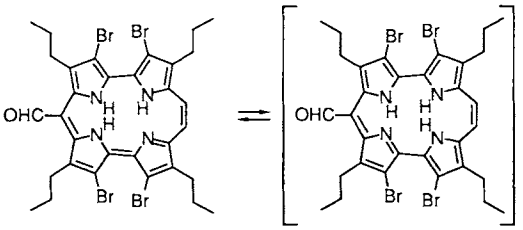
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

question whether the compound would possess an aromatic ring system. In our exploration of the chemistry of 2,7,12,17-tetrapropylporphycene (**5**),[6] we have now discovered a *porphycene–isocorrole rearrangement*, which leads to a stable isocorrole.

Because of its favorable solubility, compound **5**, accessible on a preparative scale, is a good model compound for the study of electrophilic and other substitutions on the porphycene ring system, although the pyrrole rings in **5** each have only one substitutable hydrogen. The expectation that quantum-mechanical calculations would provide reliable information on the course (substitution pattern) of the reaction of **5** with electrophiles has been frustrated so far, since the relative reactivities of the CHCH bridge carbons and the pyrrole carbons determined by the conventional calculational procedures (PPP, CNDO, AM1, and others) are not consistent.[7] The initially studied bromination of **5** with bromine in carbon tetrachloride had the surprising result that halogen substitution occurred at the four available β-pyrrolic positions to form the 3,6,13,16-tetrabromo compound **6** before substitution at the nonpyrrolic carbons took place.[8] If the product of monobromination, 3-bromo-2,7,12,17-tetrapropylporphycene (**8**), is desired, bromine on a polymeric support is best used as the brominating agent (see *Experimental Procedure*).



5 6



7a 7b

The structural proof for **6** and **8** is based on the ^{1}H and ^{13}C NMR spectra; in addition, an X-ray structure analysis[11] was carried out on **6** (Fig. 1). Compound **6** is a centrosymmetric molecule, whose ring framework practically retains the planarity found for **3** and **5**, but whose bromine atoms are markedly displaced from the plane of the framework owing to nonbonding interactions. Thus, compound **6** strikingly differs from 2,3,6,7,12,13,16,17-octaethylporphycene,[12] which has the same substitution pattern, since, in the latter compound, the substituents in the 3,6- and 13,16-positions cause a pronounced ruffling of the ring framework. The "squeezing" of the bromine atoms, revealed in the relatively short Br ··· Br distance of 3.267 Å (sum of the van der Waals radii: 3.9 Å), causes the pyrrole rings to rotate within the plane of the ring framework and results in angle deformations of up to 6° at the positions where the rings are joined. Moreover, a reversal of the relative distances within the N_4 core (now, N1 ··· N2 < N1 ··· N2′) ensues. Because of partial disorder, the two imino hydrogens are distributed with half occupancy over each of the four possible positions.

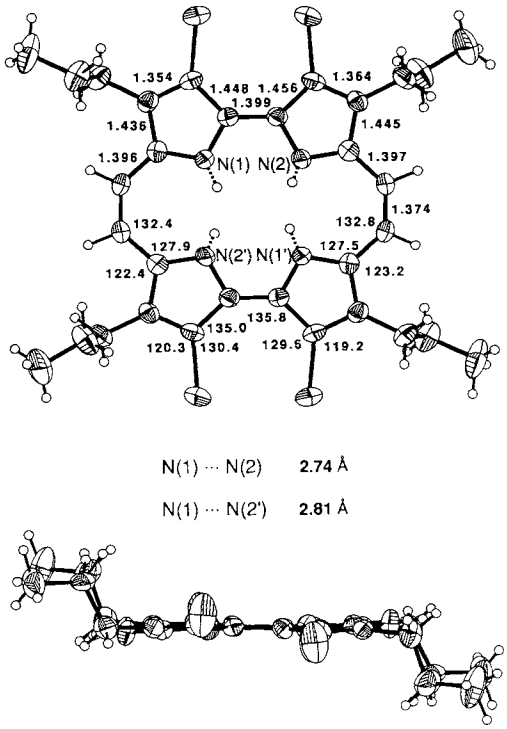


Fig. 1. Molecular structure of **6**. Top: Top view. Bottom: Side view. Selected bond lengths and other distances [Å] and bond angles [°]; standard deviations ca. 0.009 Å and 0.8°. The thermal ellipsoids are drawn at the 40% probability level.

The supposition that steric compression of the bromine atoms in **6** might facilitate nucleophilic substitutions leading to a linkage of C3 and C6 was not borne out. Compound **6** reacts only very sluggishly with nucleophiles, as observed for other halopyrroles.[13] This behavior of **6** allows for the occurrence of a porphycene–isocorrole ring contraction, which requires a basic medium and is apparently associated with the presence of the halogen atoms.[14] When **6** is heated with potassium carbonate in DMF/water (7:1) under argon to 120 °C (4 h) and the resulting products are chromatographed on silica gel (chloroform), two fractions are obtained. The first consists of **6** together with unidentified, decomposable products and the second contains the isocorrole aldehyde **7**. Crystallization from dichloromethane/hexane affords **7** as small black-green needles (dec. above 180 °C; yield 34%).

The ^{1}H NMR spectrum of **7** (Table 1) shows a simple pattern, in agreement with the assumption that **7** undergoes rapid NH tautomerism, which gives the molecule effective C_{2v} symmetry: singlets at $\delta = 11.45$ (aldehyde proton) and 8.77 (H-9,10; $^3J_{9,10} = 12.5$ Hz), six groups of signals in the region of $\delta = 1.0-3.6$ (protons of four pairwise identical propyl groups), and two strongly broadened signals at $\delta = 3.5$ (1 NH; involved in hydrogen bonding) and -2.5 (2 NH), which only become sharp singlets at -50 °C. Consistent with this spectrum, the ^{13}C NMR spectrum shows 17 signals, that at $\delta = 187.72$ (CHO; $^1J_{C,H} = 176.1$ Hz) being assigned to the aldehyde carbon. The aromaticity of the ring system in **7** is apparent from the positions of the resonances for the two perimeter protons and for the two NH protons not involved in hydrogen bonding at relatively low and high field, respectively. The UV/VIS spectrum of **7** contains a moderately intense Soret band at $\lambda = 371$ nm ($\varepsilon = 53\,100$) as well as a relatively complex system of Q bands. In addition, however, there is a short-wavelength band at 260 nm (20 300), which has no counterpart in the spectra of **1**, **3**, and the known corroles. In the IR spectrum, unlike in the corre-

Table 1. Selected physical data for **6**, **7**, and **8**.

8: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 10.11 (s, 1H; H-6), 9.51 (m, 4H; H-9,10,19,20), 9.18 (s, 1H; H-16), 9.08 (s, 1H; H-13), 3.90 (m, 8H; H-2a,7a,12a,17a), 2.32 (m, 9H; H-2b,7b,12b,17b, NH3), 1.98 (br.s, 1H; NH1), 1.31 (m, 12H; H-2c,7c,12c, 17c). ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 148.50, 147.38, 144.86, 144.69, 143.52, 142.40, 138.98, 138.30, 137.79, 133.09, 131.16, 130.57, 123.84, 122.47, 121.66, 114.64, 112.52, 111.83, 109.51, 108.53, 30.47, 30.39, 30.23, 29.63, 25.70, 25.42, 25.11, 24.99, 14.55, 14.49. MS (EI, 70 eV): *m/z* 558/556 ($M^{\oplus}$, 20/18%), 529/527 (7/7), 82 (95), 80 (100). IR (CsI): $\tilde{\nu}$[cm^{-1}] = 2950, 2918, 2855, 1555, 1455, 1210, 1035, 1012, 936, 803. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 372 (121 000), 383 (101 000), 565 (34 000), 608 (28 600), 643 (44 000).

sponding spectra of **3**, **5**, and **6**, an NH stretching band (3415 cm^{-1}) is observed and is presumably due to the imino hydrogens not participating in hydrogen bonding. The EI mass spectrum contains only signals of fragment ions of low mass, whereas FAB ionization results in a single peak, due to the molecular ion.

An X-ray structure analysis of **7**[15] (Fig. 2) reveals the nonplanarity of the isocorrole ring framework, which is mainly due to the steric interactions between the imino hydrogens, and, in addition, confirms the porphyrinoid nature of the compound. Whereas pyrrole rings B and C, which, together with C-9 and C-10, form a porphycene partial structure (dipyrroethene structure), lie in the mean plane of the ring framework, rings A and D are each twisted out of this plane by 23° but in opposite directions. A consequence of the torsion of rings A and D is that the N ··· N contact distances are nearly equal (ca. 2.7 Å). The ring framework of **7** thus deviates more strongly from planarity than that of corroles, since a structure analysis of 8,12-diethyl-2,3,7,13,17,18-hexamethylcorrole (**9**)[3] has shown that, in this molecule, pyrrole rings A, B, and C are arranged in a nearly planar fashion and ring D is twisted by only 8–10°. Interestingly, the imino hydrogens in **7** are not statistically disordered over the four nitrogens, as observed for **9** and the porphycenes **3**, **5**, and **6**, but rather can be localized in compliance with the NH tautomer **7a**. As inferred from the situation for **3** and **5**, a strong N-H ··· N hydrogen bond should exist between N2 and N3. The similar bond lengths in the nonpyrrolic perimeter CC bonds, especially in combination with the length relation C_α-C_β > C_β-C_β,[16] observed for the pyrrole rings, support the aromatic character of **7**. The isocorrole system once again corroborates the finding that the ring frameworks of porphyrins and their analogues can be considerably deformed without a serious loss of aromaticity.[17]

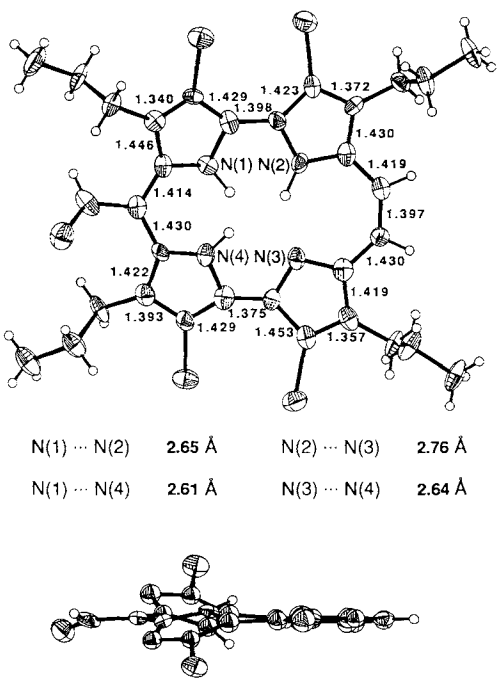

Fig. 2. Molecular structure of **7**. Same projections as in Fig. 1 (standard deviation ca. 0.012 Å). Side view without propyl groups.

Preliminary reactions of **7** with di- and trivalent metal ions led to metal complexes, but these usually decomposed rapidly. An exception was the complex obtained with Co^{II} ions in the presence of pyridine. According to NMR spectroscopic investigations, this complex has the structure of a diamagnetic Co^{III} isocorrole complex with two molecules of coordinatively bound pyridine.

Experimental Procedure

8: Compound **5** (100 mg, 0.2 mmol) in 40 mL of dichloromethane and 40 mL of acetic acid was treated at 0 °C under argon with 260 mg of Amberlyst A-26 (Br_3 form)[9] (corresponding to 0.4 mmol of bromine). The reaction mixture was stirred for 2 h and then filtered. The solvent was removed and the residue chromatographed on silica gel (column: 100 × 5 cm) with hexane/dichloromethane (6:1). The first fraction (also the main fraction) contains the monobromide **8**, which, after crystallization from hexane, was obtained as violet needles with a metallic luster; m. p. 199–200 °C, yield 93 mg (80%).

6: Bromine (225 mg, 1.4 mmol) in 20 mL of carbon tetrachloride was added over 10 min at room temperature to a vigorously stirred mixture of **5** (100 mg, 0.2 mmol) in 40 mL of carbon tetrachloride and a buffer solution (1 g of sodium acetate in 40 mL of water). The resulting reaction mixture was stirred for 1 h. The organic phase was washed with a saturated solution of sodium thiosulfate and with water and then chromatographed on silica gel (column: 100 × 4 cm) with hexane/dichloromethane (6:1). Three fractions were obtained: the first contained a complex mixture of polybromides, the second 3,6,13-tribromo-2,7,12,17-tetrapropylporphycene[10], and the third **6**. Crystallization from hexane/dichloromethane afforded **6** as violet needles with a metallic luster; dec. above 300 °C, yield 67 mg (40%).

[8] In the case of the porphycene parent compound, reaction with bromine also leads exclusively to β-pyrrolic bromination, but the bromine substituent is found in the 2-position, which is occupied by a propyl group in **5**. 2-Bromoporphycene is the only isolated monobromination product (unpublished results with *K. Pramod* and *H.-J. Dünnwald*). This substitution pattern for bromination is different from that of porphyrin, for which regioselective substitution at the methine bridge leads to the formation of 5-bromoporphyrin [H. J. Callot, E. Schaeffer, *J. Chem. Res. (S) 1978* 51; L. R. Nudy, H. G. Hutchinson, C. Schieber, F. R. Longo, *Tetrahedron 40* (1984) 2359], even though PPP calculations indicate that electrophilic attack on the β-pyrrolic carbon should have occurred [J. V. Knop, J.-H. Fuhrhop, *Z. Naturforsch. B 25* (1970) 729]. The β-pyrrolic bromination of porphyrin observed earlier by E. Samuels, R. Shuttleworth, and T. S. Stevens [*J. Chem. Soc. C 1968*, 145] could not be reproduced by *F. R. Longo* et al. (cited above).

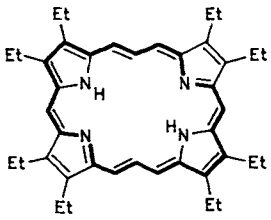
Synthesis of a Bisvinylogous Octaethylporphyrin**

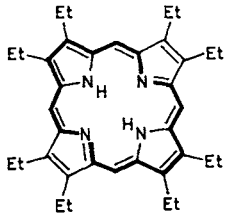
By *Hartmann König, Christian Eickmeier, Manfred Möller, Ute Rodewald*, and *Burchard Franck**

In memoriam Hans Fischer

Octaethylporphyrin (OEP, **2**), first synthesized in 1929 by *Hans Fischer* et al.,[1] is one of the most important and most investigated porphyrins.[2] Here we describe an efficient synthesis of the title compound **1**, which is extremely stable and markedly aromatic. Thus, the crystal structure analysis of the bistrifluoroacetate of **1** revealed that the conjugated perimeter is planar and its bonds largely equal in length. The ^{1}H NMR spectrum indicates an intense diamagnetic ring current. Furthermore, **1** is the first annulene for which the protons inside and outside the aromatic system exhibit a large difference in reactivity. According to the nomenclature for vinylogous porphyrins,[7] **1** is named [22]octaethylporphyrin(1.3.1.3).



1



2

An initial synthetic attempt based on the procedure of *MacDonald* et al.[3] was unsuccessful owing to the low stability of the required pyrromethene and pyrropropene intermediates. However, the "biladiene synthesis path",[4] which is of less general use in porphyrin syntheses, proved to be a more efficient route to **1**. The key compound is the previously unknown bisvinylogous biladiene **5**, which was obtained in 81% yield by condensation of **3**[6] and **4**[5b] (Scheme 1), both of which are readily accessible from 3,4-diethylpyrrole.[5] Condensation of biladiene **5** to give porphyrin **1** was accomplished by heating **5** with CH_2O/MeOH followed by in situ oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (42% yield based on **5**).[8]

The ^{1}H NMR spectrum of **1** in $CDCl_3$/1% trifluoroacetic acid (TFA) (Table 1) shows that the signals for the inner and outer bridge protons are strongly shifted upfield and downfield, respectively; the spectrum spans an unusually broad

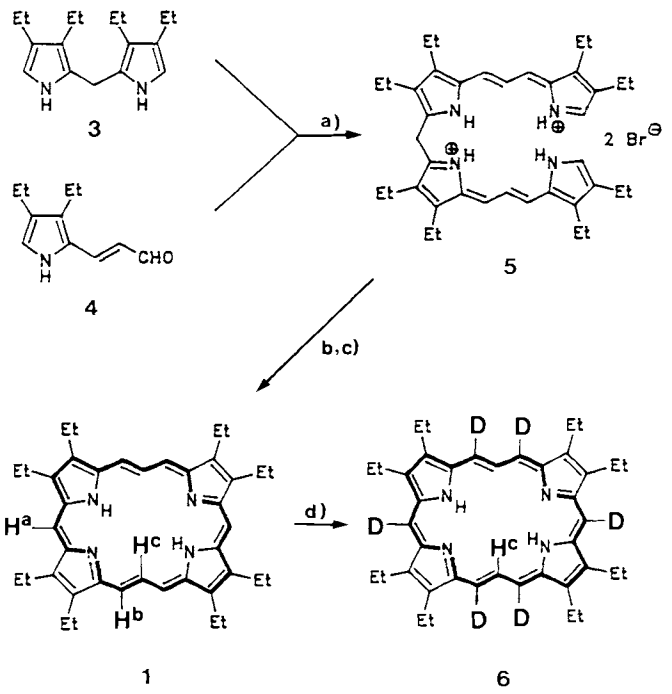
[**] Novel Porphyrinoids, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG (Ludwigshafen). Part 9: [7a].

range of $\Delta\delta = 20.2$. Thus, according to ^{1}H NMR criteria,[9] **1** is a pronouncedly aromatic porphyrinoid.

The electrophilic deuteration carried out in order to investigate the chemical stability and reactivity of [22]octaethylporphyrin **1** (Scheme 1) gave an interesting result: *exclusively*



Scheme 1. Synthesis of [22]octaethylporphyrin **1** and its electrophilic deuteration. Reaction conditions: a) HBr, MeOH, −15 °C, 5 min; 81% **5** (dec. above 160 °C); b, c) aqueous CH_2O, MeOH/HBr, reflux, 30 min, then DDQ/CH_2Cl_2, 20 °C, 2 h; 42% **1** as deep green needles (dec. above 280 °C); d) D_2SO_4/D_2O (9:1), 20 °C, 72 h, **6** (see also text).

the outer protons of the C_1 and C_3 bridges of the conjugated perimeter were exchanged and the deuterated product **6** was formed in high yield (90.3%) as determined by mass spectrometry. Thus, the ^{1}H NMR spectrum of the hexadeuterated [22]octaethylporphyrin **6** (Table 1), in contrast to that of **1**, shows only a two-proton singlet for the inner protons H^c at $\delta = -9.71$. Clearly, the outer protons of the 22π-electron system of **1** readily undergo electrophilic substitution, whereas the inner protons are inert.

Since **1** crystallizes from various solvents as small, strongly intergrown needles, a crystal structure determination of the free base was not possible. Finally, however, we obtained dark green single crystals up to 2 mm in length from the bistrifluoroacetate of [22]porphyrin **1** and were able to perform a crystal structure analysis (Fig. 1).[10]

The [22]porphyrin dication **1**-2H$^\oplus$ has—without the β side chains—a practically planar structure (Fig. 1, bottom). The maximum deviation of the C and N framework atoms from the mean plane is 19.5 pm (**2**-2H$^\oplus$ 9.5 pm[11b]). A trifluoroacetate ion above and below the arene plane can be assigned to the porphyrin dication. The bond lengths and angles (Fig. 1, top) in the pyrrole units correspond to those in the OEP dication (**2**-2H$^\oplus$).[11b] The C–C bond lengths in the bridges between the pyrrole rings (137.5–139.1 pm) also lie in the range observed for **2**-2H$^\oplus$ (136.6–138.8 pm). This holds for the monomethine bridges as well as for the trimethine bridges; if "loss of aromaticity" had occurred on going from **1** to OEP (**2**), bond-length alternation would have been expected in the trimethine bridges.[3] The similarity of the

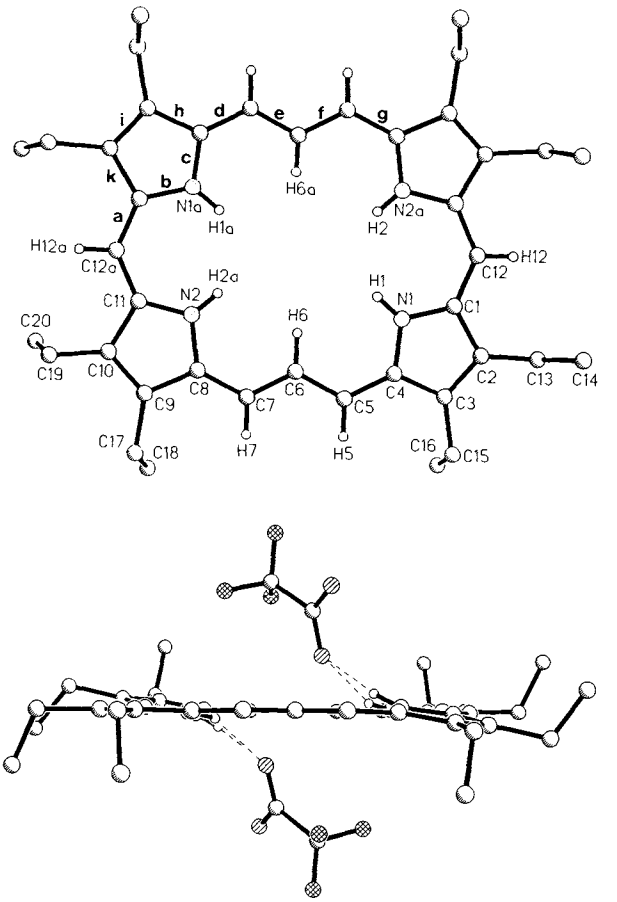


Fig. 1. Molecular structure of the centrosymmetric dication **1**-2H$^\oplus$. Top: View perpendicular to the arene plane. Below: Side view. Important distances [pm]: a = 138.6, b = 136.8, c = 136.7, d = 139.0, e = 138.1, f = 137.5, g = 139.1, h = 143.4, i = 136.7, k = 144.4.

crystal structures of OEP (**2**)[11a] and the OEP dication (**2**-2H$^\oplus$)[11b] justifies the assumption that the structure of the [22]porphyrin dication **1**-2H$^\oplus$ determined here differs only slightly from that of free porphyrin (**1**).

[22]Coproporphyrin II for Photodynamic Therapy **

By *Stefan Beckmann, Thomas Wessel, Burchard Franck,* Wolfgang Hönle, Horst Borrmann,* and *Hans-Georg von Schnering*

Dedicated to Professor Albert Eschenmoser on the occasion of his 65th birthday

Hematoporphyrin (**1a**) and related compounds have found application as photosensitizers for photodynamic tumor therapy (PDT)[1] and for deactivation of viruses in transfusion blood (PDV).[2] The disadvantages of these photosensitizers are their chemical instability, the stereoisomerism of the two secondary hydroxyl groups, and the similarity of the UV/VIS absorption with that of the red blood pigment hemin. The latter property makes it difficult to apply photodynamic therapy to the deeper layers of tumors and transfusion blood. Here we describe the total synthesis of the bisvinylogous coproporphyrin II **2a**, which is free of the above-mentioned disadvantages, as well as its properties as a photosensitizer and the crystal structure analysis of its dihydrochloride.

The lower half of the hematoporphyrin **1a** (enclosed in the formula) has more favorable properties for photomedicinal applications than the upper half: it is chemically stable and contains, instead of stereogenic hydroxyethyl groups, two propionic acid moieties, which promote solubility. Therefore, a porphyrin consisting of two of these lower halves should be a more suitable photosensitizer for photodynamic therapy. To improve still further the photomedicinal properties, we chose the *bisvinylogous* porphyrinoid **2** as our synthetic goal, since it absorbs at longer wavelengths than **1a**. Compound **2** is an enlarged derivative of coproporphyrin II and is therefore structurally related to natural porphyrins in terms of its substitution pattern. In accordance with the nomenclature for vinylogous porphyrinoids,[3] **2a** is named [22]coproporphyrin II(1.3.1.3).

The key step in the synthesis of the [22]coproporphyrin II **2a** is the acid-catalyzed condensation of the bis(carbonylvinyl)dipyrrylmethane **3** with the dipyrrylmethane **4** (Scheme 1). Subsequent dehydrogenation in situ with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) gave **2a**, which forms deep green solutions and could be isolated in analytically pure form in 35% yield by column chromatography (silica gel, Merck, 0.063–0.2 mm, ethyl acetate/methanol 10:1).[4] After addition of HCl, the dihydrochloride hydrate **2b** could be crystallized. The synthesis of **3** was carried out by double vinylogous Vilsmeier formylation[3] of the dipyrrylmethane **4** with dimethylaminoacrolein/$POCl_3$.[4] Compound **4**, in turn, was obtained from the known dipyrrylmethanedicarboxylic acid **6**[5] in two steps by

[**] Novel Porphyrinoids, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG (Ludwigshafen). Part 10: [10].

mild decarboxylation to give the diiodide **5**, which was then catalytically hydrogenated.

The conjugated 22π-electron perimeter in **2a** results in a strong diamagnetic ring-current effect in the ^{1}H NMR spectrum. The difference between the signals for the inner protons (H_a) and those for the outer protons (H_b, H_c) is remarkably large ($\Delta\delta = 20.27$ and 18.88, respectively)[6] and corresponds to that of [22]octaethylporphyrin.[10]

Of particular importance for photomedicinal application of the [22]coproporphyrin **2a** is its photosensitizing effect as well as its UV/VIS absorptions, which are shifted to longer wavelengths and are of greater intensity than those of the blood pigment hemin or hematoporphyrin (**1a**). Figure 1 shows the UV/VIS absorption of **2a** together with that of the isohematoporphyrin (**1b**). The latter compound has the same UV/VIS spectrum as hematoporphyrin (**1a**), which, because it is unstable, is unsuitable for detailed comparison of the spectra.

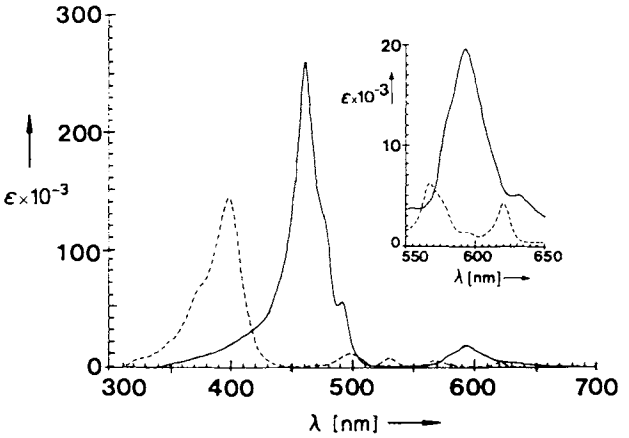

Fig. 1. UV/VIS spectra of [22]coproporphyrin **2a** and the dimethyl ester of isohematoporphyrin (**1b**) in dichloromethane.

A measure of the photosensitizing ability of the [22]coproporphyrin **2a** is singlet oxygen formation, which was determined chemically and compared with that of the excellent photosensitizer Rose Bengal and that of isohematoporphyrin (**1b**). This was accomplished by the cycloaddition of $^1O_2$ to 2,5-dimethylfuran, which is a quantitative reaction, followed by titration of the hydroperoxide formed upon methanolysis.[7, 8] For **2a**, $^1O_2$ formation exceeds that of Rose Bengal and isohematoporphyrin (**1b**) by factors of 1.4 and 1.7, respectively.

The single crystals of the [22]coproporphyrin II dihydrochloride **2b**, in the form of flat parallelepipeds (maximum size $0.26 \times 0.12 \times 0.02$ mm^3), are stable in air and display an anthracite-colored metallic luster even in thin layers. The difficulties in measuring the diffraction intensities were due, on the one hand, to the poor diffractive properties of the crystals and, on the other, to the strong decrease in intensity with θ. Compound **2b** has crystallographic $\bar{1}$ symmetry (Fig. 2). The bond lengths in the 22π-electron perimeter of **2a** (highlighted by bold lines in the formula) are nearly equal and show typical values for porphyrins ($d_{N-C} = 137.8$ pm and $d_{C-C} = 138.6$ pm).[11] The lengths of the C–N and C–C bonds in the conjugated perimeter of **2a** differ by only 0.6%; therefore, **2a**, like the [22]octaethylporphyrin described in the preceding communication,[10] fulfills not only the ring-current criterion but also the second most important criterion for aromaticity.[6] Both [22]porphyrins are thus the largest cyclic π-electron systems so far found in which the largely equal-length bonds prove both aromaticity and the validity of the (4n+2) rule.[12] Further noteworthy is the pronounced planarity of the cyclic conjugated system. Thus, the mean deviation from planarity is only 0.6 pm (Fig. 2).

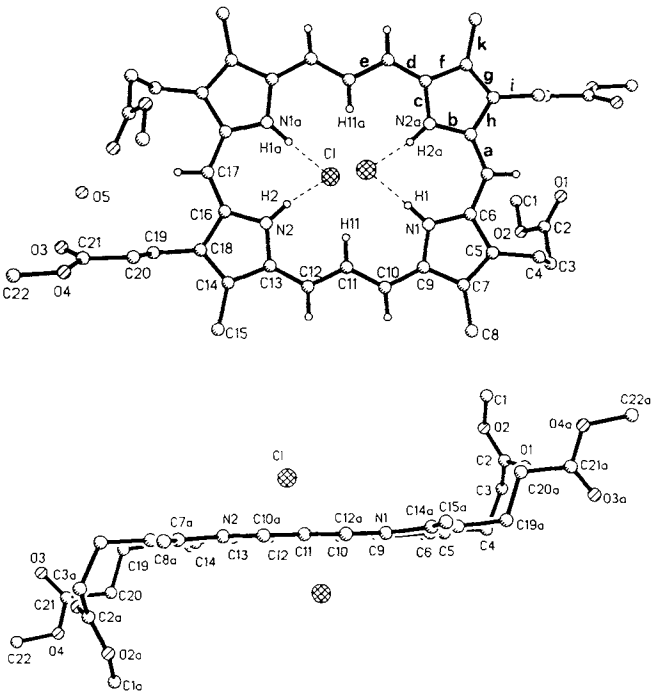

Fig. 2. Structure of **2b** with crystallographic position labeling as viewed from above (top) and from the side (bottom). Important average distances [pm]: a = 138.6, b = 137.9, c = 137.8, d = 139.3, e = 137.9, f = 143.5, g = 137.8, h = 143.1, i = 149.1, k = 148.9.

Ge^{II} and Sn^{II} Complexes of [2.2.2]Paracyclophane with Threefold Internal η^6 Coordination**

By *Thomas Probst, Oliver Steigelmann, Jürgen Riede,* and *Hubert Schmidbaur**

During the last few years π complexes of main-group p-block elements have been ordered in a system which now covers the complete triads (Ga,In,Tl), (Ge,Sn,Pb), and (As,Sb,Bi).[1-3] Though the interactions of these metals with neutral aromatic hydrocarbons are relatively weak, the structural features are amazingly consistent. They include the strong centroid (η^6) coordination above the aromatic rings, which is observed for all nine metals in oxidation states corresponding to an $nd^{10}(n+1)s^2$ electronic configuration. Only for antimony(III) is this mode of coordination avoided by a displacement of the metal away from the central position.[4]

At first only *mono*(arene) complexes were found, but later on a series of *bis*(arene) complexes with interplanar angles of about 60° were also discovered.[1,5-7] The [n.n]paracyclophanes (n = 2, 3), in particular, have shown high donor capacities. However, the metal ions in the resulting systems are coordinated to the benzene rings from the outside.[8,9] Attempts to introduce $Ga^{\oplus}$ into the cavity were finally successful when [2.2.2]paracyclophane with its larger interstice was allowed to react with gallium subhalides, $Ga[GaX_4]$ (X = Cl, Br).[10]

We now report the synthesis and structural characterization of the analogous germanium(II) and tin(II) compounds. They are obtained by allowing the cyclophane (p-$C_6H_4CH_2CH_2)_3$ (= $C_{24}H_{24}$) to react in benzene with one equivalent of $GeCl_2$ and $SnCl_2$, respectively, and two to three equivalents of $AlCl_3$. Upon standing, the resulting yellow to red solutions afford colorless crystals. In the case of the Sn^{II} compound, depending on the molar ratios employed, these crystals contain the expected 1:1:2 adduct (**1**, m.p. 63 °C), with two $AlCl_4^{\ominus}$ anions, or a 1:1:3 adduct (**2**, m.p. 225 °C), with one of the anions extended to the $Al_2Cl_7^{\ominus}$ species [Eqs. (a) and (a'), respectively]. Similarities in the IR and ^1H NMR spectra suggest the presence of the same cationic species in both cases.

$$C_{24}H_{24} + SnCl_2 + 2\,AlCl_3 \longrightarrow [\{(C_{24}H_{24})Sn\}(AlCl_4)]^{\oplus}AlCl_4^{\ominus}\ \mathbf{1} \quad (a)$$

$$C_{24}H_{24} + SnCl_2 + 3\,AlCl_3 \longrightarrow [\{(C_{24}H_{24})Sn\}(AlCl_4)]^{\oplus}Al_2Cl_7^{\ominus}\ \mathbf{2} \quad (a')$$

Crystallization of the Ge^{II} compound is much slower. Single crystals of a product are obtained only over a longer period accompanied by unavoidable slow diffusion of water into the solution. The germanium atoms of the cations are still bound to one chlorine ligand and are associated—in the molar ratio 2:1—with the anions $Al_4O_2Cl_{10}^{2\ominus}$ formed by partial hydrolysis [Eq. (b)]. 1:1:1 complexes were not obtained.

$$2\,C_{24}H_{24} + 2\,GeCl_2 + 4\,AlCl_3 + 2\,H_2O \longrightarrow 4\,HCl + [(C_{24}H_{24})GeCl]_2(Al_4O_2Cl_{10})\ \mathbf{3} \quad (b)$$

^1H NMR spectra of solutions of the three complexes in [D_6]acetone (**1**, **2**) or [D_6]dimethyl sulfoxide (**3**) show only two signals in each case, indicating the preservation of the maximum symmetry of the ligand (ψ-D_{3h}) through unperturbed centroid metal coordination in solution. This observation may however be the result of a shift in anion coordination from one side to the other (see below), which is fast on the NMR time scale, or of solvation by the strongly donating solvents.

The tin(II) bis(tetrachloroaluminate) **1** crystallizes with 1.5 equivalents of benzene (m.p. 63 °C). X-ray analysis[11] revealed that the Sn^{II} ion in **1** is indeed located in the interior of the arene "fence" (Fig. 1). The contact to one of the counterions causes a displacement of the metal away from the center of the cavity. This is accompanied by a tilting of the three benzene rings in such a manner that the positioning of the metal ions above the ring centers is largely retained. The distances of the tin atom from the 18 carbon atoms of the rings span a relatively narrow range (2.817(5)–3.075(6) Å). The $AlCl_4^{\ominus}$ counterion, which shows metal contact, is coordinated only via one chlorine atom (Sn-Cl2 = 3.073(2) Å); the second counterion is not engaged in metal bonding.

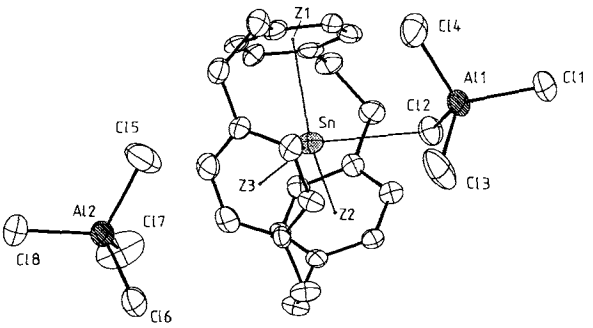

Fig. 1. Structure of **1** (ORTEP, thermal ellipsoids at 50% probability; H atoms omitted).

The distances of the tin atom from the centers of the benzene rings are not exactly the same, but their values (Sn-Z1 = 2.623, Sn-Z2 = 2.666, Sn-Z3 = 2.534 Å) indicate a comparable bonding situation. The sum of the angles Z1-Sn-Z2 = 115.52°, Z1-Sn-Z3 = 119.08°, and Z2-Sn-Z3 = 118.53° is 358.13°. The small deviation from the standard value of 360° for a local trigonal-planar symmetry reflects the only moderate distortional influence of the anion contact.

The germanium(II) compound **3** crystallizes with four molecules of benzene.[11] The anions $Al_4O_2Cl_{10}^{2\ominus}$ do not need any further description, since they are already known as compo-

nents of other salts.[12] As a consequence of the crystallographic center of symmetry, pairs of cations $(C_{24}H_{24})$-$GeCl^{\oplus}$ are structurally equivalent. The geometrical situation in the cations of **1** (Fig. 1) and **3** (Fig. 2) seems to be similar only at first glance. The most important difference is the strong binding of the germanium atom to one chlorine atom, as revealed by the short distance of 2.224(1) Å. Accordingly, a $\tilde{\nu}$(Ge-Cl) vibrational band is found in the IR spectrum at 429 cm^{-1}.

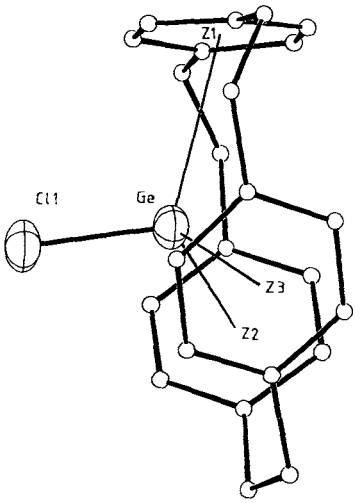

Fig. 2. Structure of the cation in **3** (ORTEP, thermal ellipsoids at 50% probability; arbitrary radii for C atoms, H atoms omitted).

The environment of the germanium atom in **3** can best be described as tetrahedral, consisting of three arene rings and one chlorine atom. The Ge–Z distances (Ge-Z1 = 2.797, Ge-Z2 = 2.722, Ge-Z3 = 2.715 Å) are slightly longer than the Sn–Z distances in **1**, and the Ge–C distances (2.724(7)–3.408(7) Å) are scattered over a broader range than the Sn–C distances in **1**. Tin is thus more strongly coordinated to the arene rings than germanium, which is consistent with the situation met with arsenic and antimony. Stereochemical activity of the lone pair at the metal center is not obvious.

The threefold coordination to neutral aromatic hydrocarbons $(3 \cdot \eta^6)$ found for the compounds **1**–**3** and for the analogous complex of $Ga[GaBr_4]$[10] has not been observed previously for transition metals. The complex $(C_{24}H_{24}) \cdot AgClO_4$[13] is also significantly different, since the metal is coordinated only to one edge of each of three arenes $(3 \cdot \eta^2)$. Centroid (η^6) coordination of transition metals like chromium(0) to [2.2.2]paracyclophane occurs with different stoichiometries and externally.[14] The larger radii of the p-block elements compared to the d-block elements seem to be an essential condition for accomplishing the excessive coordination found with low-valent main-group metals.

Experimental Procedure

1: A slurry of $SnCl_2$ (0.56 g, 2.95 mmol) and [2.2.2]paracyclophane (0.98 g, 2.94 mmol) in 180 mL of benzene was treated with $AlCl_3$ (0.81 g, 6.1 mmol), which was added slowly under reflux conditions via a Soxhlet apparatus. The color of the mixture changed to red. After 30 min the mixture was allowed to cool slowly to room temperature and then filtered. Upon standing at 20 °C, the solution afforded clear colorless crystals (**1**, 2.19 g, 84%), m.p. 63 °C. ^1H NMR ([D_6]acetone): $\delta = 7.36$ (s, 3H, C_6H_6), 6.71 (s, 4H, C_6H_4), 2.94 (s, 4H, CH_2).

2: As described for **1**, reaction of $SnCl_2$ (0.40 g, 2.11 mmol), paracyclophane (0.64 g, 2.05 mmol), and $AlCl_3$ (0.81 g, 6.07 mmol) resulted in a yellow solution above a red oil, which was separated. The solution was heated again, evaporated in vacuo to a volume of 100 mL, and cooled to room temperature. Colorless crystals separated (**2**, 1.59 g, 86%), m.p. 225 °C (dec.). The ^1H NMR spectrum was as observed for **1**.

3: As described for **1**, $GeCl_2$ (0.52 g, 3.62 mmol), cyclophane (0.84 g, 2.69 mmol), and $AlCl_3$ (1.50 g, 11.25 mmol) were allowed to react in 175 mL of benzene under reflux conditions. After 1 h a yellow solution was obtained, which was concentrated to a volume of 85 mL. Upon standing for several weeks, the solution turned green and small colorless crystals separated (**3**, 1.76 g, 44%). (Apparently, some water diffused into the solution during crystallization, though the reasons for this were not obvious.) ^1H NMR ([D_6]DMSO): $\delta = 7.35$ (s, 8H, C_6H_6), 6.65 (s, 4H, C_6H_4), 2.85 (s, 4H, CH_2).

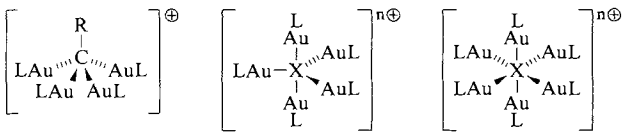
Assembly of the $[CAu_6]^{2\oplus}$ Cluster with a Tailor-made Diphosphane Spanning the Octahedral Edges**

By *Oliver Steigelmann, Peter Bissinger,* and *Hubert Schmidbaur**

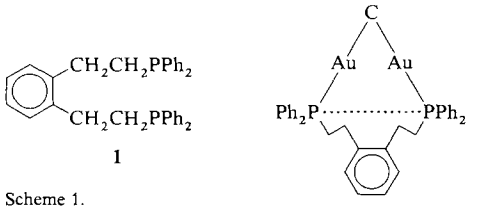
Accumulating experimental and theoretical evidence suggesting the existence of hypercoordination at carbon by gold and related d^{10} elements has led to a systematic search for compounds featuring carbon and other elements completely surrounded by gold atoms ("gilded atoms"). The initial series of investigations resulted in the synthesis and characterization of the extremely stable species $[RC(AuL)_4]^{\oplus}$, $[C(AuL)_5]^{\oplus}$, and $[C(AuL)_6]^{2\oplus}$, containing penta- and even hexacoordinate carbon atoms in the center of square pyramids, trigonal bipyramids, or octahedra of gold atoms, respectively (**A**–**C**).[1–4] This chemistry has meanwhile been extended to include the atoms boron, nitrogen, silicon, and phosphorus as nucleation centers for gold. Pertinent results cover not only more classical species like $[RN(AuL)_3]^{\oplus}$ and $[RP(AuL)_3]^{\oplus}$, but also the unprecedented di- and trications $[N(AuL)_5]^{2\oplus}$, $[N(AuL)_6]^{3\oplus}$, and $[P(AuL)_5]^{2\oplus}$ (**D**–**F**).[1, 5–8]

In all compounds obtained to date the ligand L is monodentate triphenylphosphane. The simple question therefore arose whether the novel element-centered gold clusters could also be prepared with other auxiliary donors, especially chelating ligands. Bidentate ligands, for example, could further stabilize the electron-deficient, hypercoordinate clusters and also impose different symmetry properties and chirality. We now report the assembly of the $[CAu_6]^{2\oplus}$ core triply chelated by a new diphosphane, $(1,2\text{-}C_6H_4)(CH_2CH_2PPh_2)_2$, tailor-made to span the edges of the $[CAu_6]^{2\oplus}$ octahedron.



A **B**: X = C, n = 1 **C**: X = C, n = 2
D: X = N, n = 2 **E**: X = N, n = 3
F: X = P, n = 2

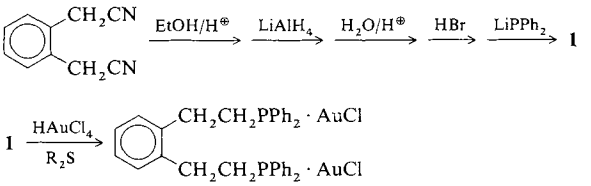
Graphical evaluation of models based on the geometry of the $[C(AuL)_6]^{2\oplus}$ cation[3] has shown that a ligand $R_2P(CH_2)_mPR_2$ should contain a chain with m = 6 in order to bridge the vertices of the metal octahedron if the C–Au–P axes are required to be linear. Molecular modeling suggested that a ligand such as **1** should provide the required P···P distance and acceptor orbital orientation at neighboring gold atoms (Scheme 1).



1

Scheme 1.

1,2-Bis(2-diphenylphosphinoethyl)benzene (**1**) [m.p. 71 °C, $\delta(^{31}P) = -15.1$] was prepared starting from 1,2-bis(cyanomethyl)benzene as shown in Scheme 1. Most of the conversions, involving standard procedures, gave satisfactory yields. Treatment of the ligand **1** with tetrachloroauric acid in the presence of a thioether as a reducing and complexing agent[9] finally afforded the pale-yellow dinuclear complex **2** [m.p. 205 °C (dec.), $\delta(^{31}P) = 29.2$] in ca. 65% yield as the key reagent for assembly of the carbon-centered cluster (Scheme 2).



2

Scheme 2. Synthesis of **2**.

Reaction of the gold complex **2** with tetrakis(dimethoxyboryl)methane[3, 10] in hexamethylphosphoric triamide (HMPT) in the presence of cesium fluoride produced an orange solution. After filtration and precipitation with a benzene/pentane mixture, yellow crystals of **3** were obtained in about 10% yield (m.p. 155 °C with decomposition) [Eq. (a)].

$$3\,\mathbf{2} + C[B(OCH_3)_2]_4 + 8\,CsF \rightarrow 6\,CsCl + 2\,B(OCH_3)_3 + 2\,CsOCH_3 + [\{C_6H_4(CH_2CH_2PPh_2Au)_2\}_3C][BF_4]_2 \quad (a)$$

3

Compound **3** was identified by elemental analysis and field desorption mass spectrometry. The parent peak at *m/z* 1350.7 is readily assigned to the dication in **3** (in CH_2Cl_2). The $^{31}P\{^1H\}$ NMR spectrum (in CD_2Cl_2) shows a single resonance at $\delta = 24.3$. Both the ^1H and the ^{13}C NMR spectra exhibit sets of signals indicating not only virtual threefold symmetry of the dication in solution, but also an internal twofold symmetry of the ligand (C_2) which renders the ligand halves equivalent.[11] The resonance of the central carbon atom could not be observed, but the counterions have been detected through their ^{11}B resonance ($\delta = -17.9$, $^1J(BF) = 17.1$ Hz).

The structure of the new cluster cation was determined by X-ray diffraction.[12] Crystals grown from dichloromethane/benzene/pentane solution (monoclinic, space group $C2/c$, $Z = 4$) contain one molecule of crystal benzene per stoichiometric unit. The dication $[CAu_6(\mathbf{1})_3]^{2\oplus}$ does not obey the high point-group symmetry (D_{3d}) suggested by the NMR spectra of the solutions, but exhibits only crystallographic C_2 symmetry with the twofold axis passing through the central carbon atom and through the centers of two C–C bonds on opposite sides of one of the *ortho*-phenylene rings (Fig. 1). Each dication is a chiral entity, which is related with a neighboring enantiomer by a center of symmetry.

The CAu_6 core can be described as a distorted carbon-centered octahedron of gold atoms with Au···Au distances between 2.942(2) and 3.132(2) Å and with C–Au distances of 2.09(3), 2.15(3), and 2.13(3) Å. The three independent Au–P distances and C–Au–P angles are equal within the limits set by the rather large standard deviations for these parameters.

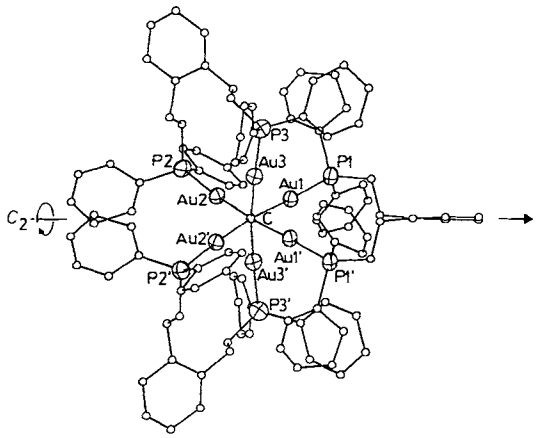

Fig. 1. Structure of the dication of **3** in the crystal [12] (ORTEP, thermal ellipsoids drawn at 50% probability for Au, P; arbitrary radius for C; H atoms omitted for clarity). Selected distances [Å] and angles [°]: Au1-Au1' 2.979(3), Au1-Au2 2.947(2), Au1-Au3 2.942(2), Au1-Au3' 2.985(2) Au2-Au3 3.094(2), Au2-Au3' 2.982(2), Au2-Au2' 3.132(2); C-Au1 2.15(3), C-Au2 2.09(3), C-Au(3) 2.13(3); P1-Au1 2.266(9), P2-Au2 2.267(9), P3-Au3 2.275(9); C-Au1-P1 177.3(3); C-Au2-P2 175.3(9), C-Au3-P3 175.8(9).

The structure of the dication in **3** is thus very similar to that of the parent hexakis(triphenylphosphane) cluster. Though the yields are not really satisfactory, the successful synthesis of the triply chelated cluster **3** and its thermal and chemical stability support the validity of the aurophilicity concept advanced in an attempt to account for formation and bonding of this new type of coordination.[1, 3, 13] It is important to note here that all attempts to prepare clusters of the types $[C(AgL)_6]^{2\oplus}$ and $[C(CuL)_6]^{2\oplus}$ have met with failure, whereas work in progress on other functional or polychelating organophosphane complexes of the $[CAu_6]^{2\oplus}$ unit continue to show promising results.

Experimental Procedure

1 (Scheme 2): a) 1,2-Bis(cyanomethyl)benzene (40.0 g, 0.256 mol) in ethanol (95%, 125 mL) was treated with concentrated H_2SO_4 (100 g) and refluxed for 7 h. Hydrolytic workup afforded the ethyl ester (47.1 g, 73%), b.p. 146–8 °C/1 Torr) [14]. b) This ester (45.0 g, 0.18 mol) in diethyl ether (225 mL) was reduced by $LiAlH_4$ (12.8 g, 0.34 mol, in 850 mL of Et_2O). Workup in aqueous sulfuric acid yielded 10.5 g of the diol (35%, m.p. 61 °C (from benzene)) [15]. c) The diol (5.8 g, 35 mmol) was treated with aqueous HBr (120 mL, 80%) for 5 h at reflux temperature. Extraction with CH_2Cl_2 and distillation gave 7.3 g of the dibromide (72%, b.p. 134 °C/1 Torr) [16]. d) A red solution of $LiPPh_2$ was prepared from Li powder (1.52 g, 220 mmol) and $ClPPh_2$ (11.1 g, 50 mmol) in THF (100 mL) at reflux temperature (30 min) under nitrogen. This solution was treated with the dibromide precursor (7.32 g, 25 mmol) in THF (30 mL) at 0–65 °C. Workup with aqueous HCl (30 mL, 10%) yielded ligand **1** (6.0 g, 48%, m.p. 71 °C (from ethanol)). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 29.3 (d, J(PC) = 18 Hz), 29.8 (d, J(PC) = 14 Hz; CH_2) C_6H_4: δ = 139.2(d, J(PC) = 14 Hz; C1,C2), 129.4 (C3,C6), 126.6 (C4,C5), C_6H_5: δ = 140.6 (d, J(PC) = 13 Hz; *ipso*-C), 133.0 (d, J(PC) = 19 Hz; *o*-C), 128.9 (d, J(PC) = 13 Hz; *m*-C'), 128.9 (*p*-C). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = − 15.1 [17].

2 and **3**: $HAuCl_4 \cdot 3H_2O$ (3.67 g, 9.3 mmol) was dissolved in ethanol (50 mL) and treated with thiodiglycol (3.41 g, 27.9 mmol) in ethanol (20 mL) at 0 °C [9]. As soon as the yellow color had vanished, ligand **2** (2.34 g, 4.66 mmol) was added in acetone (50 mL). The pale yellow precipitate of **2** was collected after 12 h (2.8 g, 62%, dec. at 205 °C). $^{13}C\{^1H\}$ NMR ($CDCl_3$, see **1** for assignments, J(PC) coupling constants in parentheses): 28.2(4), 29.3(36); 137.3(14), 129.3, 127.6; 128.8(60), 133.2(13), 129.5(11), 132.2. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 29.2.

Complex **2** (2.1 g, 2.17 mmol) and CsF (4.32 g, 28.4 mmol) in HMPT (60 mL) were treated with a solution of $C[B(OCH_3)_2]_4$ (0.220 g, 0.725 mmol) in the same solvent (20 mL) for 48 h at 20 °C under N_2. The orange solution was filtered and the product precipitated with pentane/benzene. Repeated extraction with CH_2Cl_2 and reprecipitation with pentane/benzene afforded yellow crystals of **3** (0.20 g, 10%, dec. at 155 °C). For NMR data see [11].

Amine-Template-Directed Synthesis of Cyclic Porphyrin Oligomers**

By *Harry L. Anderson* and *Jeremy K. M. Sanders**

The use of guest molecules as templates for directing the assembly of complementary host structures is a recurrent theme in many areas of biochemistry. It is also an approach widely used in the synthesis of coronands,[1] catenanes,[2] zeolites,[3] functionalized polymers,[4] and biomimetic systems such as models for enzymic catalysis[5] and self-replica-

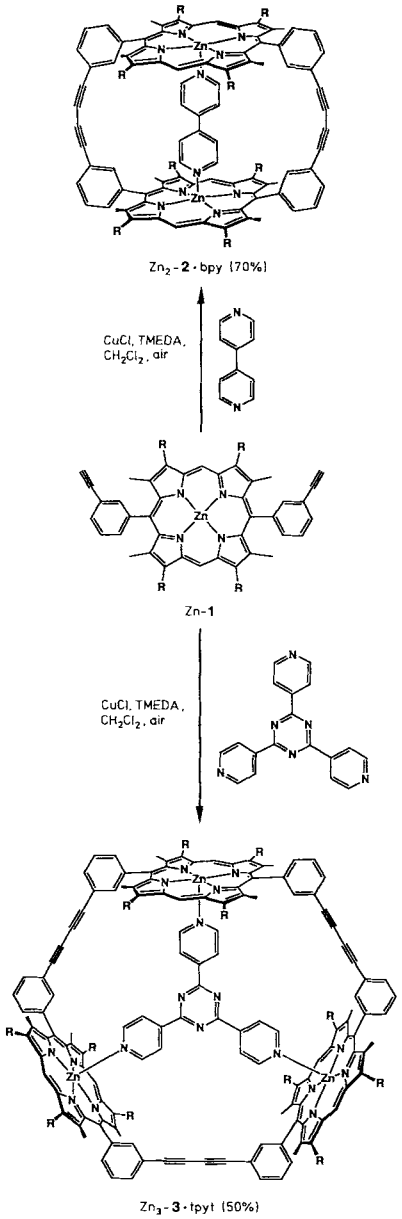
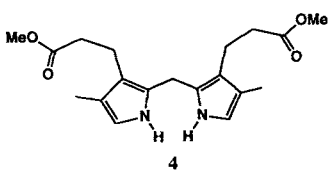
[**] This work was supported by the Science and Engineering Research Council (UK).

tion.[6] Here we describe how this concept can be extended to the ligand-templated synthesis of cyclic porphyrin oligomers. Recently we reported the structure-directed synthesis of a porphyrin trimer.[7] We have now found that, by judicious use of templates, the outcome of this reaction can be directed down either of two quite different pathways (Scheme 1).



Scheme 1. Control of supermacrocyclization by amine templates (R = $CH_2CH_2CO_2Me$).

The ester-functionalized bisacetylenic porphyrin H_2-**1** was synthesized in 55% yield by condensation of **4**[8] (generated in situ) with 3-ethynylbenzaldehyde. We first prepared the



4

functionalized porphyrin dimer and trimer, H_4-**2** and H_6-**3**, by the untemplated oxidative coupling of Zn-**1** using conditions developed for the synthesis of unfunctionalized porphyrin trimer[7] (0.5 mM Zn-**1**/60 mM CuCl/pyridine/air). This reaction yields a mixture of Zn_2-**2** and Zn_3-**3**, which were demetalated, separated by flash chromatography, and isolated in 20–25% and 30–35% yield, respectively.[9] Both cyclic oligomers are readily soluble in chloroform.[10]

Ligands such as 4,4'-bipyridyl (bpy) and s-tri(4-pyridyl)-triazine (tpyt) have no affect on the coupling reaction in coordinating solvents such as pyridine. After screening a wide range of conditions, however, we found that dramatic templating effects are observed in noncoordinating solvents, such as dichloromethane, when air/CuCl/*N,N,N',N'*-tetramethylethylenediamine (TMEDA) is used as the oxidant.[11] This effect is seen most clearly by looking at the *meso* region of the ^{1}H NMR spectra of the crude reaction mixtures after removing copper, bound zinc, and ligands (Fig. 1). The reso-

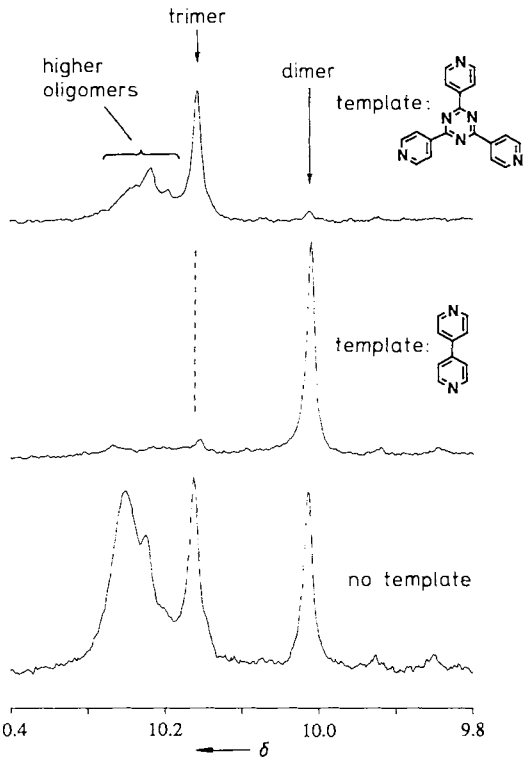


Fig. 1. ^{1}H NMR spectra of crude reaction mixtures demonstrating the effects of amine templates. The conditions used to produce these reaction mixtures differed only in the type of template present.

nances of the *meso* protons of H_6-**3** and H_4-**2** are shifted to progressively lower chemical shift, relative to H_2-**1**, by the ring current effect across the porphyrin cavity, so that the product distribution can be accurately estimated from these spectra. The tpyt ligand clearly enhances formation of Zn_3-**3** and inhibits formation of Zn_2-**2**, whereas bpy has the opposite effect, templating formation of Zn_2-**2**. In our hands, template-directed synthesis is now the most practical preparative route to both **2** and **3**.

The origin of these effects can be understood by comparing the binding properties[12] of a range of ligands with their templating behavior[13] (Table 1). The bpy ligand, which gives a threefold increase in the yield of dimer, shows a remarkable affinity for Zn_2-**2**.[14] The chelation factor (effective molarity) of the Zn_2-**2**·bpy complex (34 M) is higher than

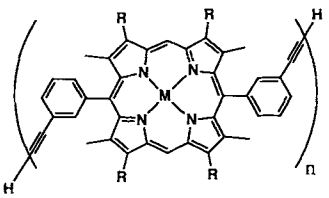
values reported for similar complexes,[15] although it is still much less than the theoretical maximum.[16] The tpyt ligand is the best template for trimer synthesis and binds strongly to Zn_3-**3**, although it appears to be slightly too small to fit this host perfectly and shows an overall chelation factor of only ca. 1 M. The templating and binding properties of 1,3-di(4-pyridyl)propane are almost as effective as those of tpyt; the third binding site of tpyt has only a modest effect on both its binding and its templating. 1,2-Di(4-pyridyl)ethane binds quite strongly to both Zn_2-**2** and Zn_3-**3**, showing little selectivity and exhibiting little template effect.

Table 1. Host affinities and yields for various template ligands[12, 13].

Ligand/Template	lg$K$ Zn-**1**	lg$K$ Zn_2-**2**	lg$K$ Zn_3-**3**	Yield [%] H_4-**2**	Yield [%] H_6-**3**
Pyridine	3.7	3.7	3.6	23	34
4,4'-Bipyridyl	3.9	8.8	4.9[a]	72	4
1,2-Di(4-pyridyl)ethane	4.1	6.1	7.5[a]	27	34
1,3-Di(4-pyridyl)propane	4.2	5.1	8.8[a]	7	43
s-Tri(4-pyridyl)triazine	3.9	3.8	10.0	6	52

[a] These are lgK_1 values. K_2 values were also measured.

In general, there is a close correspondence between the templating properties of each ligand and its trimer/dimer binding selectivity, which indicates that the transition state for acetylene coupling has a geometry closely resembling that of the product. The criteria for an efficient trimer-producing template are more stringent than those for a dimer template: a trimer-producing template must both bind the linear dimer intermediate **5**[17] in a conformation which prevents it from cyclizing and bind linear trimer **6** in the correct conformation for accelerating ring closure; in contrast, a dimer-producing template has only to accelerate the cyclization of linear dimer **5**. The tpyt ligand appears to be very efficient at inhibiting cyclization of **5** but less good at accelerating the closure of **6**.



5 (n = 2), **6** (n = 3)

This templating approach not only provides a good practical route to potentially catalytic molecules but also elucidates some of the design principles required. When designing templates for the assembly of more complex hosts, it will be important to remember that the template must be able to bind strongly to early intermediates and prevent them from following undesired pathways, and that it must be able to bind later intermediates and hold them in conformations resembling that of the desired product. Importantly, a good template does not need to show perfect product complementarity.

Experimental Procedure

H_2-**1**: Palladium on carbon (10%, 140 mg) was added to a solution of 5,5'-dibenzyloxycarbonyl-3,3'-di(2-methoxycarbonylethyl)-4,4'-dimethyl-2,2'-dipyrrylmethane [18] (4.0 mmol) in THF (100 mL) containing 1% triethylamine and the mixture was stirred under hydrogen. After 1 h, the catalyst was filtered off and the filtrate was evaporated and redissolved in trifluoroacetic acid (TFA, 25 mL) under argon at 0 °C to generate a solution of **4**[8]. After 20 min, a solution of 3-ethynylbenzaldehyde (4.0 mmol) in methanol (100 mL) was added and the mixture was stirred for 2 h. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (6 mmol) in THF (50 mL) was added and the mixture was stirred for a further 2 h and then evaporated. The product was purified by flash chromatography ($SiO_2/CHCl_3$, $R_f = 0.18$) and recrystallized from chloroform/methanol. Yield 55% (1.005 g). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = -2.48$ (s, 2H), 2.52 (s, 12H, 3.15 (t, 8H), 3.18 (s, 2H), 3.65 (s, 12H), 4.36 (t, 8H), 7.73 (t, 2H), 7.95 (d, 2H), 8.04 (d, 2H), 8.20 (s, 2H), 10.28 (s, 2H). IR ($CHCl_3$): $\tilde{\nu}$[cm^{-1}] = 3304 (C-H), 1732 (C=O). UV/VIS (CH_2Cl_2): λ_{max}[nm] = 408, 506, 539, 574, 627. FAB MS (Xe$^{\oplus}$, 8 KV): m/z 911 ($M^{\oplus}$).

H_4-**2**: A solution of Zn-**1** (0.20 mmol, 200 mg) in anhydrous dichloromethane (500 mL) was treated with copper(I) chloride (14 mmol), TMEDA (14 mmol), and 4,4'-bipyridyl (1.2 mmol) and stirred under dry air. After 24 h, the reaction mixture was washed with water (3 × 500 mL) and treated with methanolic TFA (10%, 100 mL), then washed again with water (4 × 500 mL) and evaporated. (The ^{1}H NMR of the crude material was recorded at this stage.) The product was purified by flash chromatography (SiO_2/1:1 $CH_2Cl_2/CHCl_3$, $R_f = 0.13$ in $CHCl_3$). Yield 65–75% (120–135 mg). ^{1}H NMR: $\delta = -2.63$ (s, 4H), 2.34 (s, 4H), 2.34 (s, 24H), 2.95 (t, 16H), 3.53 (s, 24H), 4.17 (t, 16H), 7.08 (s, 4H), 7.74 (m, 8H), 8.49 (d, 4H), 10.01 (s, 4H). IR: $\tilde{\nu}$[cm^{-1}] = 1732 (C=O). UV/VIS: λ_{max}[nm] = 315, 336, 407, 507, 540, 575, 627. FAB MS: m/z 1818 ($M^{\oplus}$).

H_6-**3**: The procedure was identical to that described above, except that s-tri(4-pyridyl)triazine (1.2 mmol) was used instead of 4,4'-bipyridyl. Yield 50–55% (90–100 mg). $R_f = 0.11$ in $CHCl_3$. ^{1}H NMR: $\delta = -2.66$ (s, 6H), 2.43 (s, 36H), 3.04 (t, 24H), 3.55 (s, 36H), 4.23 (t, 24H), 7.72 (t, 6H), 7.98 (d, 6H), 8.02 (d, 6H), 8.07 (s, 6H), 10.16 (s, 6H). IR: $\tilde{\nu}$[cm^{-1}] = 1733 (C=O). UV/VIS: λ_{max}[nm] = 314, 334, 408, 506, 539, 574, 627. FAB MS: m/z 2727 ($M^{\oplus}$), 1364 ($M^{2\oplus}$).

All products were spectroscopically pure. Free-base porphyrins were metalated with zinc in near quantitative yield by treatment with excess zinc acetate in chloroform.

[9] The ester groups of these compounds can be hydrolyzed to give water-soluble hosts.
[10] It appears that some unfunctionalized cyclic porphyrin dimer is also formed during the synthesis[7] of unfunctionalized trimer, but that it is extremely insoluble and is lost during workup.
[11] No reaction occurs in dichloromethane in the absence of TMEDA, but this ligand has no effect on the reaction in pyridine. The use of TMEDA to promote Glaser coupling in noncoordinating solvents was first reported by *A. S. Hay* (*J. Org. Chem. 27* (1962) 3320).
[12] Binding constants were determined by simulation analysis of UV titration curves in CH_2Cl_2 at ambient temperatures: see C. A. Hunter, P. Leighton, J. K. M. Sanders, *J. Chem. Soc. Perkin Trans. 1 1989*, 547. The lgK_1 values are reproducible to within ± 1%, except for values greater than 8 which are only accurate to ± 5%. Zn-**1** and Zn_3-**3** have similar binding constants to those of their unfunctionalized analogues, some of which have already been published [7].
[13] The templated yields of dimer and trimer in Table 1 were determined by integrating the *meso* regions of ^{1}H NMR spectra of crude reaction mixtures obtained using 1.7 mM template (see *Experimental Procedure*).

Yields can be estimated accurately in this way because all the products are soluble and no porphyrin units are destroyed during reaction; values are reproducible within ± 5% and compare well with isolated yields.

[14] The Zn_2-**2**·bpy complex exchanges slowly with excess bpy on the ^1H NMR time scale at ambient temperatures and its ^1H NMR spectrum has been fully assigned using 2D NMR techniques (NOEs are detected between internal *ortho*-aromatic protons of the host and both guest protons). The 1:1 complex can also be observed directly by FAB MS.

Synthesis and Structure of $[Et_2OZn(SC_6H_2tBu_3)_2]$, the First T-Shaped Zinc Complex**

By *Philip P. Power** and *Steven C. Shoner*

Considerable effort has been devoted to the study of zinc thiolates in the search for structural models for the metal–sulfur bonding in zinc-cysteine metalloproteins.[1–3] In addition, recent results concerning the structure of the so-called zinc finger centers in nucleic acid binding proteins have provided added impetus to this area of research.[4, 5] A characteristic feature of many of the zinc thiolate complexes synthesized to date has been their tendency to form aggregates or cages comprised of $[ZnS_4]$ units.[1–3] It has been shown recently that association can be prevented by the use of bulky ligands, as seen in $[Zn(2,3,5,6\text{-}Me_4C_6HS)_3]^{\ominus}$,[6] a monomeric ion having trigonal-planar coordination at zinc and Zn–S distances near 2.23 Å. In sharp contrast to these data, there is little structural information currently available for neutral zinc thiolate species. Normally, $Zn(SR)_2$ complexes are polymeric with tetrahedrally coordinated zinc linked by SR bridges.[7] Monomeric species are observed only when ancillary or chelating ligands are used, as exemplified by $Zn(SCH_2CH_2NMe_2)_2$, which has four-coordinate zinc.[8] As part of our work on the synthesis of the quasi-aromatic ring systems $(RZnSR')_3$ (R and R′ = bulky alkyl or aryl groups),[9, 10] we have become interested in the reactions of zinc alkyls with bulky thiols. Here we describe the synthesis and structure of the unusual compound $[Et_2OZn(SAr)_2]$ (**1**, Ar = 2,4,6-$tBu_3C_6H_2$), which has approximately T-shaped coordination at zinc.

Compound **1** was synthesized by reaction of $Zn(CH_2SiMe_3)_2$[11] with two equivalents of HSAr in the presence of ether. In the absence of Et_2O, a white precipitate of $Zn(SAr)_2$ (**2**) was formed. This species dissolves in warm toluene and is sparingly soluble in warm hexane. ^1H NMR spectroscopy and cryoscopy indicate a monomeric structure in C_6D_6. Unfortunately, crystals of **2** suitable for X-ray crystallography have not been obtained to date. The apparent monomeric nature of **2** in solution is in agreement with the recently reported solution data for $Cd(EAr)_2$ (E = S or Se).[12] These compounds have dimeric structures in the solid with EAr bridges.

The monomeric structure of **1** (Fig. 1) features a planar, three-coordinate Zn center. The angles observed at zinc justify the description of the coordination as T-shaped. The Zn–S distances (ca. 2.196 Å) are the shortest thus far observed for a Zn–S bond and, in fact, approach the value of 2.133(5) Å observed for the Zn–OEt_2 bond. The short Zn–S bonds suggest that the Zn–S bonding orbitals probably have approximate sp hybridization. The relatively long Zn–O bond (cf. ca. 2.077 Å for Zn-O_{thf} in four-coordinate $[Zn(2,6\text{-}tBu_2C_6H_3O)_2(thf)_2]$[14]) is consistent with this view and is indicative of the involvement of a p-like Zn orbital in the Zn–O bond. The weaker nature of the Zn–O bond is reflected in the relative ease with which Et_2O may be removed under reduced pressure and moderate temperature (100 °C).

The unusual geometry of this molecule is probably the result of a combination of factors. For example, it is notable that the aromatic rings are almost parallel, both to each other and to those of neighboring molecules. The approximately parallel stacking of the Ar groups and the ca. 102.9° Zn–S–C angles result in a S–Zn–S angle of ca. 160°. Owing to its low coordination and relative electron deficiency, the Zn center can behave readily as an acceptor toward one Et_2O molecule.

Coordination of a second ether is disfavored for steric reasons and because it would probably destroy the advantageous packing arrangement. The T-shaped geometry is unknown for Zn species and has only been authenticated in a few transition-metal complexes.[15–17]

Experimental Procedure

Under anaerobic and anhydrous conditions, 2,4,6-$tBu_3C_6H_2SH$ (1.11 g, 4 mmol) [18] in pentane (20 mL) was added dropwise to $Zn(CH_2SiMe_3)_2$ (0.48 g, 2 mmol) [11] in pentane (5 mL). The solution was refluxed for 1 h, and a white precipitate was formed. The volatile materials were removed under reduced pressure and the residue was dissolved in Et_2O (7 mL). Cooling slowly to −25 °C resulted in formation of colorless crystals of **1** in 70–80% yield. ^1H NMR (300 MHz, C_6D_6): δ = 1.08 (t, 6H; Et_2O), 1.33 (s, 18H), 1.65 (s, 36H), 3.26 (q, 4H; Et_2O), 7.45 (s, 4H). The crystals became yellow upon heating above 150 °C. They melt at 202–205 °C. It is possible, however, that the fusible species may not be **1**. Probably, it is **2** or the thioether $S(Ar)_2$.

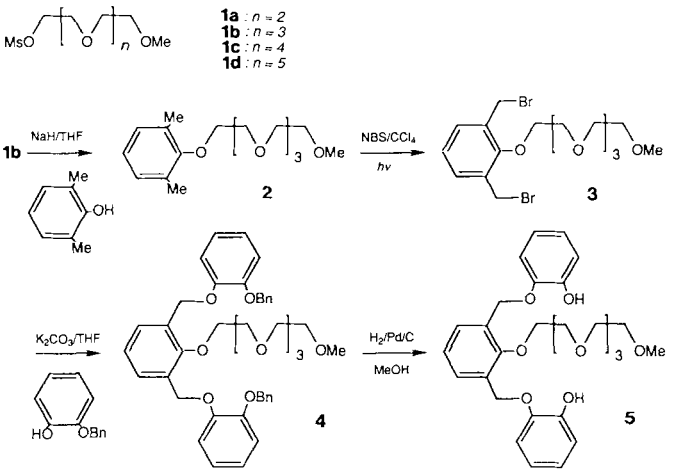
A New Mode of Metal Encapsulation**

By *John S. Bartlett, James F. Costello, Shrock Mehani, S. Ramdas, Alexandra M. Z. Slawin, J. Fraser Stoddart** and *David J. Williams*

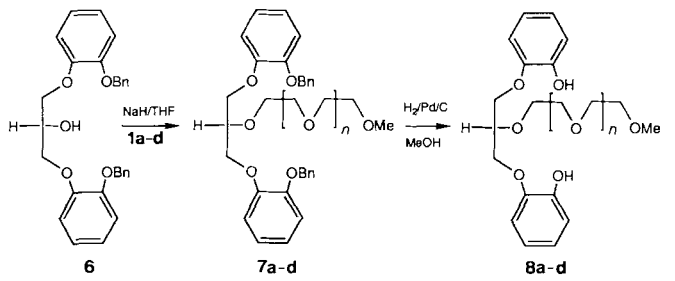
Highly organized, synthetically derived molecular architectures, such as those comprising macrocycles,[1] bridged polymacrocycles[2] and cyclophanes,[3] have enjoyed much attention in the investigation of noncovalent bonding interactions in supramolecular systems.[4] By comparison, their acyclic analogues have received only modest attention as they are considered to be poorly preorganized[5] for the recognition event. Nonetheless, interest in noncyclic hosts has resulted in both elegant[6-10] and spectacular[11] examples of the unquestionable potential of such systems. Previous studies[12] on the encapsulation of alkali metal cations by functionalized acyclic oligoethers[13] encouraged us to re-examine this approach towards the design[14] of ligands capable of achieving both kinetically fast and thermodynamically selective complexation of alkaline earth metal dications.[15] We anticipated that the elaboration of both an oligoether *tail* and a pair of nucleophilic *pincers* into the same acyclic molecular framework would generate a new class of ligands capable of exercising both fast and selective formation of strong *scorpion-like*[16] dicationic chelates.

Here we report the synthesis of a series of scorpion-like ligands capable of metal encapsulation and the characterization of their mode of interaction with metal ions, both in solution and in the solid state. Initially **4** and **7b**, based on planar and tetrahedral tripodal constitutions respectively, were chosen as synthetic targets. Important intermediates in the synthesis of scorpion-like ligands such as **5** and **8a–d** are the mesylated monomethyl ethers **1a–d**.



Reaction of **1b** with sodium 2,6-dimethylphenoxide generated **2**, which upon bromination with N-bromosuccinimide (NBS) and subsequent reaction with potassium *o*-benzyloxyphenoxide afforded **4**, the dibenzyl ether of **5**.

Treatment of the sodium alkoxide of **6**[18] with the appropriate mesylate (**1a–d**) produced the range of compounds **7a–d**, the dibenzyl ethers of **8a–d**.



Strong evidence in support of the encapsulation of $Ba^{2\oplus}$ ions came from 250 MHz ^1H NMR spectroscopic studies in [D_6]acetone of **4** · $Ba(SCN)_2$ and **7b** · $Ba(SCN)_2$. Marked ion-induced downfield chemical shifts were observed, which resulted in the dispersion and simplification of certain spin systems, most notably for those attributable to the protons arising from (i) the catechol residues of both **7b** and **4** (especially those protons *ortho* to the oxygen substituents, where $\Delta\delta \approx 0.20$), and (ii) the glycerol residue of **7b** (where the methylene and methine protons have $\Delta\delta$ values of ca. 0.25 and 0.10, respectively). It is apparent that many of the ligand oxygen atoms are participating in the metal ion coordination. Table 1 records the relative affinities of the neutral ligands **4** and **7b**, among others, toward alkali and alkaline

earth metal picrates.[19] As far as selectivity is concerned, it is clear that **7b** and **4** show a size selectivity for ionic radii of about 1.3 Å ($K^{\oplus}$ and $Ba^{2\oplus}$). It is noteworthy that **7b** appears to bind more tightly to $K^{\oplus}$ ions than does **4**. More importantly, the ligand **7b**, which is based on tetrahedral geometry, associates with the harder $Ba^{2\oplus}$ ion approximately 16 times more strongly than does ligand **4** with its planar structure. In order to probe further the mode of association of **7b** with $Ba^{2\oplus}$ ions in solution, the effect of complexation upon the ^1H spin-lattice relaxation time[20] of the ligand was investigated. In the presence of the dication, the rates of relaxation of the protons of the bismethylene and methyl units in the oligoether chain increase by 70–85%. This effect may be the result of a decrease in the mobility of the chain, when it wraps itself about the metal dication.

Table 1. Association constants K_a [M^{-1}] in $CHCl_3$ of a range of neutral acyclic oligoether ligands [a] with alkali metal and alkaline earth metal cations as measured by the picrate extraction technique [19].

Ligand	$Li^{\oplus}$	$Na^{\oplus}$	$K^{\oplus}$	$Rb^{\oplus}$	$Cs^{\oplus}$	$Mg^{2\oplus}$	$Ca^{2\oplus}$	$Sr^{2\oplus}$	$Ba^{2\oplus}$

[a] K_a values $\lesssim 1000\ M^{-1}$ are subject to an uncertainty of ca. 10%

Computer-aided molecular modeling[21] provided an insight into the reasons for the superior complexing ability of **7b** over **4** and the ion selectivity exhibited by the ligands. **7b** resembles a noncyclic[22] cryptand[23] with carbon as bridgehead atoms and as a consequence can define a pseudo-cavity for a metal ion of the appropriate size more efficiently than **4**, which is based on planar geometry. In the presence of a metal ion, **7b** attempts to maximize the number of stabilizing ion–dipole interactions by forming such a pseudo-cavity around the metal ion. Molecular modeling shows that when the metal ion is small (i.e. $Li^{\oplus}$, $Na^{\oplus}$) the severe steric crowding experienced by the oligoether tail and the benzylic moities of **7b** during complexation probably leads to destabilizing intramolecular interactions of a steric nature, and consequently fewer stabilizing electronic interactions result. The lower binding affinities (Table 1) of **4** and **7b** toward the larger ions ($Rb^{\oplus}$, $Cs^{\oplus}$) is possibly a result of the inability of these ligands to satisfy completely the normal coordination number of these softer cations.

In order to investigate further the interplay between ionic size and intramolecular crowding, we synthesized ligands **7a**, **7c** and **7d**, and related trends in selectivity to those of the corresponding diphenols **8a–d**. It is noteworthy (Table 1) that the general affinity for ions of radii around 1.3 Å persists and that the strength of $Ba^{2\oplus}$ ion complexation increases by a factor of two with the sequential addition of an oxygen atom to the homologous series of ligands. Interestingly, **7d** appears to have an anomalously higher affinity towards $Sr^{2\oplus}$ ions than does its lower homologues. One would expect that a scorpion-like complex of **7d** with the smaller (radius 1.1 Å), harder $Sr^{2\oplus}$ ion would be extremely crowded. A different mode of encapsulation may therefore operate in order to avoid intramolecular crowding.

The diphenols **8a–d** were obtained in good yields by catalytic hydrogenolysis (H_2/Pd/C) of the corresponding dibenzyl ethers **7a–d**. Ligand **5** could be obtained in a similar manner from **4**, but only in modest yields because of the presence of two other benzylic centers. In addition to the significant ion-induced chemical shifts, a feature common to the ^1H NMR spectra ([D_6]acetone) of the ligands **8a–d** and **5** in the presence of one equivalent of $Ba(SCN)_2$ is the significant downfield shift ($\Delta\delta \approx 2.5$) of the phenolic protons. We ascribe the observation to a thiocyanate–hydrogen bond, because no such downfield chemical shift is observed when picrate is the counterion.

Removal of the sterically demanding benzyl ether groups is expected to facilitate tighter metal encapsulation, as the intramolecular repulsion involved in such a process would decrease. In an NMR experiment irradiation of the resonance of the oligoether methyl group in the complex **8b** · $Ba(SCN)_2$ resulted in a nuclear Overhauser enhancement of the resonance for the proton *ortho* to the phenolic hydroxyl group. The spatial proximity implied for these nuclei is a direct consequence of encapsulation.

Fortunately, single crystals of **8c** · $Ba(SCN)_2Me_2CO$ which were suitable for X-ray crystallographic analysis[24] were obtained. The solid-state structure (Fig. 1) confirms the

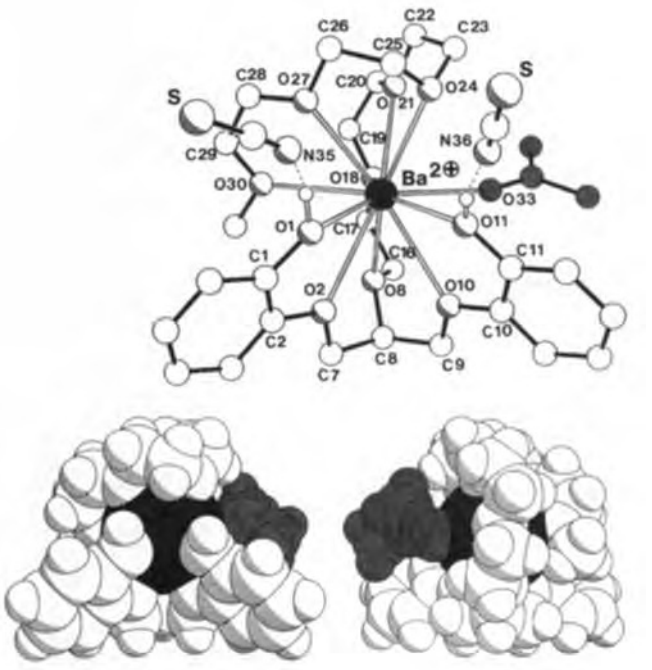

Fig. 1. Ball-and-stick representation of the structure of **8c** · $Ba(SCN)_2.Me_2CO$ in the crystal. Top: Crystal data: orthorhombic, $a = 11.925(2)$, $b = 13.267(2)$, $c = 23.295(5)$ Å, $V = 3685$ Å^3, space group $P2_12_12_1$, $Z = 4$, $\varrho_{calcd} = 1.48$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 101$ cm^{-1}, 2646 independent observed absorption-corrected reflections [$|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 116°$], $R = 0.035$, $R_w = 0.035$. $Ba^{2\oplus}$–O bond lengths [Å]: Ba–O1 2.871(5), Ba–O2 2.985(5), Ba–O8 2.815(5), Ba–O10 2.973(5), Ba–O11 2.860(5), Ba–O18 2.907(5), Ba–O21 2.925(5), Ba–O24 2.816(5), Ba–O27 2.867(6), Ba–O30 2.862(6), Ba–O33 2.762(7). Hydrogen bond lengths [Å]: O1···N35 2.74(1), O11···N36 2.70(1). Torsion angles [°]: O2–C7–C8–C9 70.2(8), C7–C8–C9–O10 −63.4(8), O8–C16–C17–O18 50.5(10), O18–C19–C20–O21 −40.2(12), O21–C22–C23–O24 −50.6(10), O24–C25–C26–O27 48.7(10), O27–C28–C29–O30 −10.5(19). Bottom: Space-filling model, on the left viewed from the same vantage point as the ball and stick model, and on the right viewed from the opposite direction. The $Ba^{2\oplus}$ ion is highlighted in black and the acetone molecule of solvation is featured in gray.

scorpion-like character of the complex in which the barium ion is 11-coordinate. All ten oxygen atoms of **8c** coordinate to the metal at distances ranging between 2.81 and 2.99 Å. The remaining eleventh coordination site is occupied by an acetone molecule of solvation (Ba–O, 2.76 Å). The complexation of the barium ion by all the oxygen atoms of the

polyether chain is achieved—with the exception of the 'flattening' of the terminal bismethylenedioxy unit—without any significant perturbation of the characteristic *gauche*-O–C–C–O- and *anti*-C–C–O–C-conformations. Each phenolic hydroxyl group forms a strong O–H···N hydrogen bond to a thiocyanate counterion.

The results described here have established the superiority of the ligands based on the tetrahedral tripodal constitution (**7a–d** and **8a–d**) over those (**4** and **5**) based on the planar constitution.

Experimental Procedure

2: Reaction of 2,6-dimethylphenol (NaH/THF/66 °C) with the mesylate **1b** (1 mol equiv.) afforded, after chromatography (SiO_2, EtOAc/$CHCl_3$), an oil (62%), which was characterized as **2** (EI-MS): *m/z* 312 ($M^{\oplus}$); ^{1}H NMR ($CDCl_3$): δ = 2.27 (s, 6H), 3.35 (s, 3H), 3.51–3.98 (m, 16H), 6.83–6.92 (m, 3H).

3: A stirred suspension of NBS (12.5 g, 70 mmol) and **2** (10 g, 32 mmol) in CCl_4 (200 mL) was irradiated (Hanovia photochemical reactor) for 1 h. The resulting crude mixture afforded as oils, after chromatography (SiO_2, $CHCl_3$/MeOH) in order of elution, the monobromide and **3**: 3.7 g (24%), CIMS *m/z* 488 ($[M + NH_4]^{\oplus}$); ^{1}H NMR ($CDCl_3$): δ = 3.38 (s, 3H), 3.53–3.59 (m, 2H), 3.64–3.81 (m, 10H), 3.82–3.93 (m, 2H), 4.23–4.31 (m, 2H), 4.64 (s, 4H), 7.14 (t, J = 7 Hz, 1H), 7.52 (d, J = 7 Hz, 2H)].

4: A solution of **3** (0.6 g, 1.2 mmol) in dry THF (50 mL) was added dropwise under reflux to a solution of *o*-benzyloxyphenol (0.61 g, 3 mmol) and K_2CO_3 (1.2 mol equiv.) in dry THF (100 mL) during 2 h under N_2. The solution was heated for a further 72 h, cooled to room temperature and concentrated in vacuo. Chromatography on SiO_2 ($CHCl_3$/Et_2O: 4/1 v/v) afforded 0.42 g (46%) of a clear colorless oil, characterized as **4**: FAB MS *m/z* 731 $[M + Na]^{\oplus}$; ^{1}H NMR ([D$_6$]acetone): δ = 3.23 (s, 3H), 3.39–3.42 (m, 2H), 3.48–3.55 (m, 10H), 3.65–3.69 (m, 2H), 4.17–4.20 (m, 2H), 5.12 (s, 4H), 5.24 (s, 4H), 6.87–6.92 (m, 4H), 7.03–7.07 (m, 2H), 7.12–7.19 (m, 2H), 7.17 (t, J = 7 Hz, 1H), 7.27–7.38 (m, 6H), 7.45–7.49 (m, 4H), 7.55 (d, J = 7 Hz, 2H).

5: Hydrogenolysis (H_2/Pd/C) of **4** (150 mg, 0.2 mmol) in dry MeOH (25 mL) at room temperature afforded, after chromatography on SiO_2 ($CHCl_3$/EtOAc: 4/1 v/v), an oil, which was characterized as **5**: 20 mg (18%) FAB MS *m/z* 551 $[M + Na]^{\oplus}$; ^{1}H NMR ([D$_6$] acetone): δ = 3.23 (s, 3H), 3.39–3.44 (m, 2H), 3.49–3.62 (m, 10H), 3.72–3.81 (m, 2H), 4.12–4.19 (m, 2H), 5.23 (s, 4H), 6.73–6.88 (m, 6H), 7.07–7.20 (m, 2H), 7.15 (t, J = 7 Hz, 1H), 7.54 (d, J = 7 Hz, 2H), 7.73 (br. s, 2H).

7c: A solution of 6 [18] (3.30 g, 7.23 mmol) in dry THF (40 mL) was added dropwise with stirring over 0.5 h to a suspension of NaH (600 mg, 50% dispersion in oil, 12.5 mmol) in dry THF (50 mL) under N_2. The mixture was heated under reflux for a further 2 h. The mesylate **1c** (2.62 g, 7.94 mmol) dissolved in THF (10 mL) was added within 1 h and the mixture was stirred under reflux for a further 16 h. After cooling and subsequent standard work-up, the crude product was subjected to column chromatography (SiO_2, $CHCl_3$/EtOAc: 4/1 v/v) and gave a clear oil, characterized as **7c**: 2.22 g (47%); FAB MS: *m/z* 713 ($[M + Na]^{\oplus}$); ^{1}H NMR ([D$_6$]acetone): δ = 3.26 (s, 3H), 3.41–3.47 (m, 2H), 3.49–3.58 (m, 16H), 3.84–3.89 (m, 2H), 4.12–4.3 (m, 5H), 5.09 (s, 4H), 6.85–6.95 (m, 4H), 6.98–7.07 (m, 4H), 7.24–7.37 (m, 6H), 7.45–7.51 (m, 4H).

8c: A solution of **7c** (1.62 g, 2.35 mmol) and 10% Pd/C (160 mg) in dry MeOH (100 mL) was subjected to hydrogenolysis at 40 °C and atmospheric pressure. After 60 min, the solution was cooled, filtered (Celite), and concentrated in vacuo. Column chromatography on SiO_2 ($CHCl_3$) furnished a clear oil, which was characterized as **8c**: 0.78 g (65%); FAB MS: *m/z* 511 ($[M + H]^{\oplus}$); ^{1}H NMR ([D$_6$]acetone): δ = 3.26 (s, 3H), 3.41–3.47 (m, 2H), 3.51–3.67 (m, 16H), 3.87–3.91 (m, 2H), 4.16–4.32 (m, 5H), 6.73–6.85 (m, 6H), 6.97–7.13 (m, 2H), 7.66 (br. s, 2H). Single crystals of **8c** · $Ba(SCN)_2$ · Me_2CO (m.p. 140–141.5 °C), suitable for X-ray crystallography, were obtained by the slow evaporation of equimolar amounts of **8c** and $Ba(SCN)_2$ from acetone.

[14] The rational approach towards the design of ligands for the selective complexation of metals has been reviewed recently. See, R. D. Hancock, A. E. Martell, *Chem. Rev. 89* (1989) 1875.

[15] The clogging of oil wells as a result of $BaSO_4$ scale formation has proved both a vexatious and costly problem (O. J. G. Vetter, *J. Petr. Techn. 1975*, 1515; *ibid. 1976* 1402). In the prevention and dissolution of such scales, the application of acyclic ethylenediaminetetraacetic acid and macrocyclic chelating agents (F. de Jong, D. N. Reinhoudt, G. J. Torny, A. van Zon, *Recl. J. R. Neth. Chem. Soc. 102* (1983) 164) is a very useful approach. Scorpion-like molecules offer a unique opportunity to include flexibility, selectivity, and chelate stability into the same compounds.

[16] "The wrapping of linear polyetheneglycol ligands around metal cations is dependent upon their length" (W. Saenger, I.-H. Suh, G. Weber, *Isr. J. Chem. 18* (1979) 253). To our knowledge, the scorpion-like mode of encapsulation represents an addition to the circular, helical, and S-like (where two metal ions are bound) modes of metal encapsulation.

[17] The synthesis of **1a** has been reported (M. Schmidt, R. Amstutz, G. Crass, D. Seebach, *Chem. Ber. 113* (1980) 1691). The higher homologues **1b–d** were synthesized in a similar manner.

[18] D. G. Parsons, *J. Chem. Soc. Perkin Trans. 1, 1978*, 451.

[19] a) The solvent extraction of aqueous metal picrates provides a facile technique for the rapid screening of the cation binding ability of neutral acyclic polyether ligands (K. E. Koenig, G. M. Lein, P. Stuckler, T. Kaneda, D. J. Cram, *J. Am. Chem. Soc. 101* (1979) 3553). Since the extracting ability of such ligands is generally low in comparison to that of their macrocyclic analogues, the technique was modified to increase the sensitivity of the detection of extracted picrate anion by UV spectrophotometry. In a typical experiment, a 5 mM solution of the appropriate aqueous metal picrate was partitioned with a 60 mM solution ($CHCl_3$) of the ligand. Interpretation and comparisons of K_a values should be confined to this closely related series of neutral acyclic polyether ligands. b) The assumed 1:1 stoichiometries of all the complexes were supported by FAB MS investigations. An expression for calculating K_a values from the experimental data obtained for extractions of divalent alkaline earth metal picrates was derived in a similar manner to that previously described for monovalent metal picrates (J. M. Timko, S. S. Moore, D. M. Walba, P. C. Hiberty, D. J. Cram, *J. Amer. Chem. Soc. 99* (1977) 4207). Values for distribution constants (K_d) for the alkaline earth metal picrates between chloroform and water were taken from the literature (T. Maeda, K. Kimura, T. Shono, *Fresenius Z. Anal. Chem. 313* (1982) 407).

[20] The T_1 measurements were carried out by the inversion recovery technique (Bruker AM 250 spectrometer). An equimolar solution (15 mM) of **7b** and $Ba(SCN)_2$ was used in this experiment. We thank Dr. *J. R. Bales* (BP Research, Sunbury, UK) for his assistance in obtaining these ^{1}H-NMR spectra.

[21] CHEMX (Chemical Design Limited, Oxford), the general purpose molecular modeling software, was used in our studies. Molecular mechanics calculations upon such highly flexible ligands would be inappropriate. We have, therefore, relied upon a multi-disciplinary approach, in which conformational analysis, distance geometry information (^{1}H NMR experiments, NOE, and T_1 measurements) and X-ray crystallographic data (especially Ba–O bond distances) have allowed us to develop a three-dimensional model with low resolution for **7b** · $Ba^{2\oplus}$ and **8b** · $Ba^{2\oplus}$ which were not wholly at variance with the solid state structure of **8c** · $Ba(SCN)_2$ · Me_2CO.

[22] F. Vögtle, W. M. Müller, W. Wehner, E. Buhleier, *Angew. Chem. 89* (1977) 564; *Angew. Chem. Int. Ed. Engl. 16* (1977) 548.

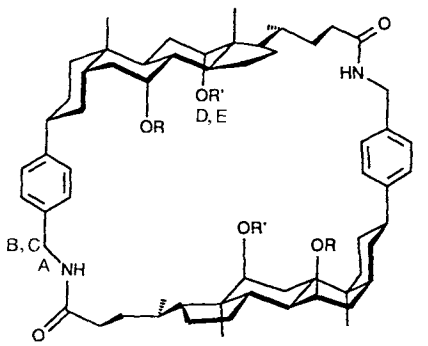
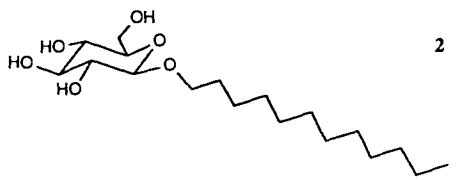
Artificial Receptors for Carbohydrate Derivatives**

By *Richard P. Bonar-Law, Anthony P. Davis,** and *Brian A. Murray*

There is widespread interest in the recognition and binding of neutral, polar molecules in organic solvents. Particular attention has been paid to derivatives of amino acids[1] and nucleobases,[2] but little has been published on the binding of the third major class of natural building blocks, the carbohydrates.[3] This is possibly because of the three-dimensional complexity of carbohydrate structures. In order to take full advantage of the potential binding sites on, for example, the pyranose nucleus, it is necessary to design receptors which can surround the nucleus on all sides with hydrogen-bond donor and/or acceptor functionality.[4] We have recently published syntheses of a series of "cholaphanes" **1a–e**.[5] Noting that their common framework is able to enclose a pyranose, and that **1a** in particular bears six functional groups with hydrogen-bond donor/acceptor properties (four hydroxyl and two secondary amide groups), we undertook to investigate these macrocycles as receptors for carbohydrate derivatives. We now report evidence that **1a** and **1e** bind to the lipophilic glucoside **2** in $CDCl_3$ with stability constants (K_a) in the region of 10^3 M^{-1}.[6]



1a: R,R' = H
1b: R,R' = Ac
1c: R = Ac, R' = Bn
1d: R = Ac, R' = H
1e: R = H, R' = Bn



2

When glucoside **2** was added incrementally to a ca. 1 mM solution of the tetrahydroxycholaphane **1a** in $CDCl_3$, the ^1H NMR spectrum of the latter underwent a number of changes. Initially, the region from $\delta = 4.2$ to 5.8 contained a signal corresponding to the two amide NH protons (broad triplet) and an AB quartet corresponding to the four benzylic CH_2-N protons, each of which is further coupled to the amide protons (see Fig. 1a and Table 1). As **2** was added, the amide and the lower-field benzylic resonances moved downfield, the higher-field benzylic resonances moved upfield,

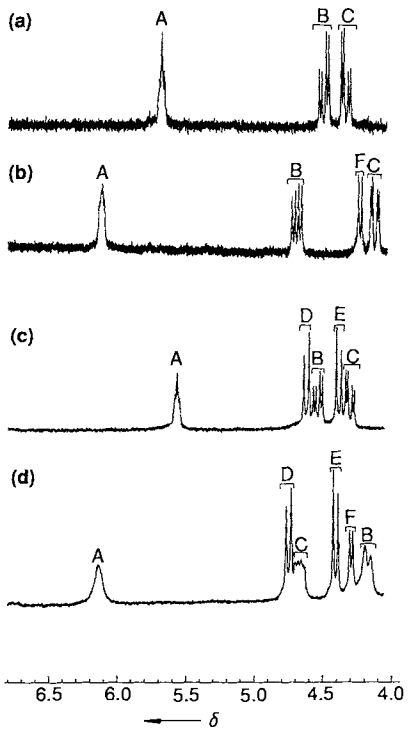


Fig. 1. Partial ^1H NMR spectra in $CDCl_3$ of a) **1a** (1.1 mM). b) **1a** (1.1. mM) + **2** (0.88 mM). c) **1e** (5.6 mM). d) **1e** (5.2 mM) + **2** (7.8 mM). Assignments: A = NH; B,C = CH_2N; D,E = CH_2 of the OBn group (**1e** only); F = anomeric CH (see also formulas **1** and **2**).

and there were substantial changes in the coupling constants between the amide and benzylic protons (Fig. 1b). The changes were analyzed using an iterative least-squares curve-fitting program with weighting of data points according to the error analysis of *Deranleau*.[7] They were found to be consistent with the formation of a 1:1 complex between **1a** and **2** with $K_a = 1740(\pm 200)$ M^{-1}. The calculated binding curve and chemical shifts for the amide resonance are shown in Figure 2, and the limiting values for the chemical shifts are given in Table 1.

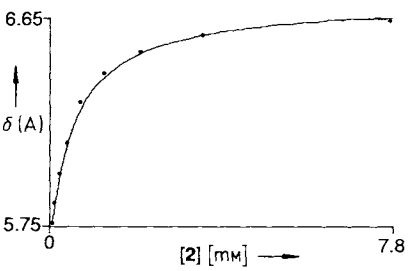

Fig. 2. Downfield shifts of the NH NMR signal of **1a** on incremental addition of **2**; experimental points and calculated binding curve.

Analysis of the carbohydrate resonances was less informative, because of overlap between the signals due to host and guest. However, the anomeric CH proton of **2** does stand out clearly as a sharp doublet F and can be seen to shift up field by $\Delta\delta > 0.1$ on complex formation. To confirm that we could discount self-association of host and guest, we recorded ^1H NMR spectra of each at various concentrations. As anticipated, for both cases there was virtually no change within the concentration range important for the binding experiment.

Table 1. Selected ^{1}H NMR data for hosts **1a** and **1e**, and corresponding values for complexes with **2** (by extrapolation; see text). A,B,C: see formula for **1**.

	δ(A)	δ(B/C)	(J(A,B/C), [Hz])	δ(CH_2O)		δ (21-Me)
1a	5.67	4.48(5.9)	4.34(5.1)			1.01
1a + **2**	6.75	4.8(>8.1)	3.9(<3.3)			0.97
1e	5.58	4.27(4.8)	4.51(6.0)	4.6	4.36	0.99
1e + **2**	6.37	4.71(>7)	4.04 [a]	4.75	4.37	0.75

[a] Signal broadened; J too small to be discernible.

Similar experiments were used to investigate the interaction of **2** with **1b–e** in $CDCl_3$. On addition of **2** the ^{1}H NMR spectra of **1b–d** underwent no significant changes, but the dibenzyl derivative **1e** showed evidence of binding in much the same manner as **1a** (Fig. 1c, 1d and Table 1). New features were the movement of the signals due to the $PhCH_2$-O protons and the doublet corresponding to the methyl group (21-Me) in the steroidal side chain (Table 1). Again, analysis of the data indicated that a 1:1 complex had been formed, with a binding constant of 700($\pm$100) M^{-1}.

We believe that the glucoside is located inside the macrocycle in both the above complexes for the following reasons: 1) The changes in the $H_{B,C}$ signals on complex formation clearly suggest a major alteration in the conformational properties of the macrocycles, probably the "freezing out" of one or a limited number of conformations (see below). This is most easily accommodated by the inclusion of the carbohydrate molecule in the macrocyles. 2) In the case of **1e**, the changes in the $PhCH_2$-O resonances and the 21-Me provide further support. They imply that conformational changes are occurring in widely separated regions of the macrocycle, and it is hard to see how such changes could be induced other than by an inclusion process. 3) The binding constants are sufficiently large to suggest that multiple hydrogen bonding interactions are involved. As a comparison, in a recent study by *Rebek* et al. involving the binding of adenine derivatives, association constants in the range 100 to 400 M^{-1} were measured for complexes in which two hydrogen bonds and one π-stacking interaction were postulated.[2a]

The association between **1e** and **2** was also studied by IR spectroscopy. Initially the IR spectrum of **1e** in $CHCl_3$ (7.26 mM) showed a single band in the N–H stretching region at 3446 cm^{-1}, and bands at 1662 cm^{-1} (C=O) and 1513 cm^{-1} (amide II). On incremental addition of **2** the carbonyl stretching band was only marginally affected, broadening somewhat and shifting to a slightly lower frequency (up to 10 cm^{-1}). In contrast the intensities of the N–H stretching and amide II bands decreased steadily and in concert with each other. These results are significant in that, when combined with the shift in the NH resonance, they suggest strongly that the amide groups act as hydrogen bond donors in complex formation.[8]

We have attempted to interpret our results with the assistance of computer-based molecular modeling.[9] Calculations on **1a** suggest that the cholaphane framework does have considerable flexibility; thus, 36 different conformations have been found within 4.5 kcal mol^{-1} of the baseline (which is as represented by **1**), and their structural variety is such as to suggest that there are many more. However, although their shapes vary considerably (e.g. NH···HN distances from 11.1 to 14.9 Å), all have open conformations with substantial cavities.

On addition of methyl β-D-glucopyranoside (a model for **2**), it becomes clear that there are many possibilities for formation of multiple hydrogen bonds between host and guest.

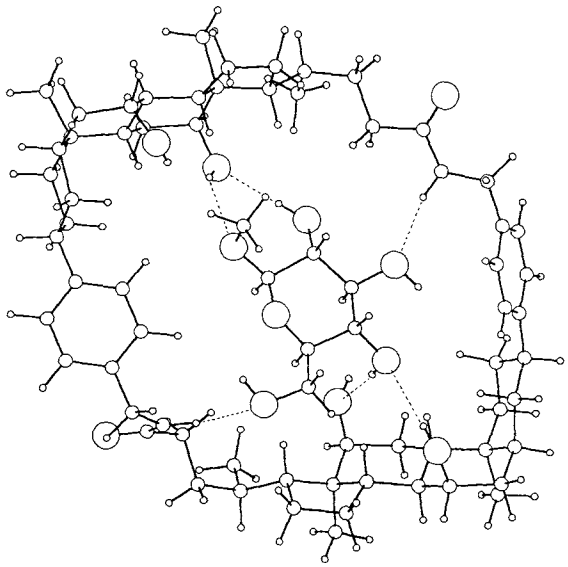

Fig. 3. A possible conformation for **1a** and methyl β-D-glucopyranoside, minimized within the CHARMm force field. Dotted lines represent intermolecular hydrogen bonds, ranging in length from 2.06 to 2.32 Å.

One example which is consistent with the IR data is shown in Figure 3. It is derived from a conformer of the macrocycle which is 3.4 kcal mol^{-1} above the baseline. Complex formation requires a further slight distortion of the macrocyclic framework (3.2. kcal mol^{-1}), but is promoted by the formation of six hydrogen bonds, as illustrated. Although this specific structure may not be important, it does demonstrate the ability of the glucoside to enter the cavity of **1a** and to form multiple hydrogen bonds with its host without causing undue distortion.

Similar studies on **1e** support the idea that complex formation would substantially reduce the conformational options of the O-benzyl groups, accounting for the movement of the CH_2-O NMR resonances. The shift of the 21-Me resonance probably results from the same process, the effect being transmitted via the diamagnetic anisotropy of the benzyl group.

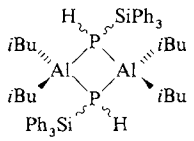
An Aluminaphosphacubane, a New Aluminum Phosphide Precursor

By *Alan H. Cowley*,** *Richard A. Jones*,* *Miguel A. Mardones, Jerry L. Atwood*,* and *Simon G. Bott*

There is a heightened interest in the chemistry of cubanes and their isolobal analogues. In the context of phosphorus-containing cubanes, salient developments include the syntheses of $[t\mathrm{BuE}(\mu_3\text{-P})]_4$ (E = C[1], Si[2]) **1**, $[\mathrm{PhSn}(\mu_3\text{-P})]_4$[3] **2**, and several organometallic derivatives of the general type $[(L_nM)_x(P)_{4-x}]$.[4] Conceptually, these novel compounds can be regarded as derivatives of the hypothetical cubane P_8.[5] Alternatively, cubanes **1** and **2** can be viewed as tetramers of triply-bonded monomers, RE≡P. In principle, a different class of phosphorus-containing cubane should be possible by tetramerization of monomers of the type RM≒PR′ where M represents a group 13 element. We report the first aluminaphosphacubane.

Treatment of equimolar quantities of $i\mathrm{Bu_2AlH}$ and $\mathrm{Ph_3SiPH_2}$[6] in toluene at 25 °C for 12 h resulted in the evolution of H_2 and the formation of white, crystalline **3**.



3

The dimeric nature of **3** was established by mass spectrometry (MS) which revealed a parent peak at *m/z* 864 followed by fragment ions corresponding to $[\mathrm{MH^{\oplus}} - i\mathrm{Bu} - \mathrm{Ph_3Si}]$ and $[\mathrm{M^{\oplus}} - 2i\mathrm{Bu} - \mathrm{Ph_3Si}]$. Like $[(\mathrm{Me_3Si})_2\mathrm{AlP(Ph)(SiMe_3)}]_2$,[7] **3** exists as a mixture of *syn* and *anti* isomers in approximately 1:2 abundance as evidenced by the presence of two ^{31}P-NMR peaks.[8] Compound **3** starts to melt at 80 °C; however, melting is accompanied by gas evolution (MS: isobutane) followed by resolidification. Refluxing **3** in toluene solution for 12 h, followed by concentration and cooling to − 20 °C, resulted in the isolation of white, crystalline $[i\mathrm{BuAl}(\mu_3\text{-}\mathrm{PSiPh_3})]_4$ (**4**) in 83% yield. Mass spectroscopy was not very useful for the characterization of **4**; the highest mass peak in EI or CI experiments occurred at *m/z* 259 and corresponds to $[\mathrm{Ph_3Si^{\oplus}}]$. The ^{31}P-NMR spectrum comprised a singlet at $\delta = -213.0$ and the ^{1}H- and ^{13}C{^{1}H}-NMR spectra were indicative of the presence of equal numbers of *i*Bu and $\mathrm{Ph_3Si}$ groups. The ^{27}Al-NMR signal for **4** was very broad ($\Delta W_{1/2}$ 4700 Hz) and no ^{31}P coupling was discernible. Elemental analytical data corresponded to the empirical composition $i\mathrm{BuAlPSiPh_3}$. An X-ray crystallographic study[9] revealed that **4** possesses a cubane structure (Fig. 1). There are no short intermolecular contacts and each molecule resides on a site of S_4 symmetry. As in the case of the recently isolated tetraphosphacubanes, $[t\mathrm{BuC}(\mu_3\text{-P})]_4$[1] and $[t\mathrm{BuSi}(\mu_3\text{-P})]_4$[2] the cube of **4** is distorted in the sense that the internal bond

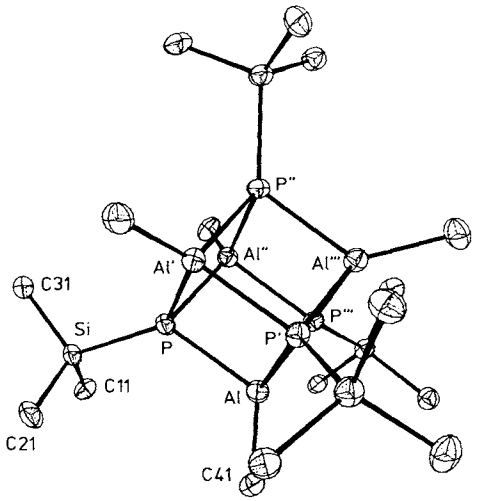


Fig. 1. View (ORTEP) of **4** showing the atom numbering scheme. Important bond distances [Å] and bond angles [°]: P–Al 2.409(4), P–Al′ 2.415(4), P–Al″ 2.417(4), P–Si 2.236(4), Al–C41 1.96(1), Al–P–Al′ 89.0(2), Al–P–Al″ 87.8(2), Al′–P–Al″ 87.7(2), Al–P–Si 127.3(2), Al′–P–Si 125.6(2), Al″–P–Si 126.8(2), P–Al–P′ 90.9(2), P–Al–P‴ 92.3(2), P′–Al–P‴ 92.2(2), P–Al–C41 120.6(4), P′–Al–C41 127.7(4), P‴–Al–C41 123.6(4).

angles at phosphorus are less than 90° (av. 88.2(2)°). The average Al–P bond distance in **4** (2.414(4) Å) is slightly less than those observed in Al_2P_2 dimers which span the range 2.433(4) to 2.475(1) Å.[7] The P–Si distance in **4** (2.236(4) Å) is slighly shorter than that in the diphosphene 2,4,6-$t\mathrm{Bu_3C_6H_2P}$ = $\mathrm{PSiPh_3}$ (2.269(2) Å).[6]

Preliminary work indicates that an analogous gallaphosphacubane $[t\mathrm{BuGa}(\mu_3\text{-}\mathrm{PSiPh_3})]_4$ ($\delta_{^{31}\mathrm{P}} = -185$) can be prepared by treatment of $[t\mathrm{BuGaCl_2}]_2$ with $\mathrm{Ph_3SiPLi_2}$ in $\mathrm{Et_2O}$. Interestingly, we have not been able to isolate cubanes when phosphorus substituents other than $\mathrm{Ph_3Si}$ are employed.

Cubane **4** is reactive toward both electrophiles and nucleophiles. For example, reaction of **4** with eight equivalents of EtOH affords $\mathrm{Ph_3SiPH_2}$[6] and $i\mathrm{BuAl(OEt)_2}$.[10] Even when less than eight equivalents are employed, complete cage degradation occurs and a proportionate quantity of unchanged **4** is left over. Similar results are obtained with H_2O. Treatment of **4** with four equivalents of MeLi in $\mathrm{Et_2O}$ also causes rupture of the Al_4P_4 cage. The NMR data for the MeLi reaction product correspond to those anticipated for the anion $[i\mathrm{BuMeAlPSiPh_3}]^{\ominus}$ **5**.[8] This was confirmed by the reaction of **5** with EtOH, which produced $[i\mathrm{BuMeAlOEt}]$.[10]

Thermolysis studies reveal that the new Al_4P_4 cubane **4** represents a potentially interesting precursor to aluminum phosphide. Temperature-programmed EI or CI mass spectrometry demonstrates that the decomposition of the cubane starts as low as 150 °C. The major volatiles are identified as $\mathrm{Ph_3SiH}$ and isobutylene. XPS (X-ray Photoelectron Spectroscopy) analysis[11] and X-ray diffraction of the residue that remained after heating to 500 °C indicates that it is aluminum phosphide.

Experimental Procedure

3: A toluene solution (25 wt.%) of $i\mathrm{Bu_2AlH}$ (13.4 mL, 20 mmol) was added to 5.84 g (20 mmol) of $\mathrm{Ph_3SiPH_2}$. The resulting clear solution, which evolved hydrogen, was stirred for 12 h at room temperature. Solvent evaporation afforded white, crystalline **3** in virtually quantitative yield (m.p. = 80 °C, decomp.). **4**: A toluene solution of **3** was refluxed for 12 h. The solvent and volatiles were removed in vacuo, following which the resulting white residue was redissolved in toluene. After filtration and concentration of the filtrate, colorless crystals of **4** formed in 83% yield by cooling to − 20 °C.

The Structure of Cyclic C_6S_6 and C_6O_6**

By *Gernot Frenking**

Dedicated to Professor Karl Dimroth on the occasion of his 80th birthday

Sülzle et al.[1] recently reported on the mass spectrometric investigation of benzo[1,2-*d*:3,4-*d'*:5,6-*d''*]-tri(1,3-dithiol-2-one) **1**, in which, after cleavage of three molecules of CO from the radical anion $\mathbf{1}^{\bullet\ominus}$ and subsequent charge exchange reactions, the fragments $C_6S_6^n$ (n = + 1, 0, − 1) were detected. The experimental findings provided no information about the structure of the $C_6S_6^n$ fragments, but, owing to the low tendency of radical anions to rearrange,[2] it was presumed that the six-membered ring structure of **1** remains intact. As possible structures the valence isomers **2a** and **2b** were proposed.[1]

2a and **2b** are not only aesthetically attractive, their relative stability is also of considerable interest for theoretical studies of molecular structures, since they afford important information about the influence of aromatic stabilization,

ring strain and the strength of the C–S double bond. We have therefore calculated the geometries and energies of the C_6S_6 isomers **2a** and **2b** as well as of the quinoid form **2c**.[3, 4] The optimized geometries are depicted in Figure 2, and the relative energies are listed in Table 1.[5] In addition, we report our results of theoretical studies on the analogous oxygen compound C_6O_6 in the isomeric forms **3a**, **3b**, and **3c**.

[a] Energy calculation with 3-21G*-optimized geometries. [b] Optimization leads to the structure **3a**.

[*] Prof. Dr. G. Frenking
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, W-3550 Marburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and Convex and Silicon Graphics.

The optimization of the geometries of **2a–2c** were first carried out with the MNDO method and at the ab initio level with the STO-3G basis set. The calculation of the frequency of the optimized structure **2a** with D_{6h} symmetry yielded in both cases three imaginary frequencies, whose coordinates correspond to non planar modes. An optimization of the geometry without enforced planarity led to the chair-shaped structure **2d**, which is respectively 5.2 kcal mol^{-1} (STO-3G) and 11.9 kcal mol^{-1} (MNDO) energetically more favorable than **2a**. The calculation of the force constant matrix identified **2d** as minimum on the potential hypersurface. **2b**, however, is predicted by MNDO and STO-3G to be the energetically most favorable form (Table 1).

We have also optimized the geometries of **2a–2d** with the 3-21G* basis set. The data in Figure 2 and Table 1 show an increase in the stability of **2d** compared with **2a**; the chair form **2d** is now calculated to be 23.9 kcal mol^{-1} more favorable than the planar form **2a** and the bending angle θ is 43.5°. The energetically most favorable isomer at the 3-21G* level is still the aromatic form **2b**. However, the quinoid structure **2c** is calculated as lying only 3.2 kcal mol^{-1} higher (Table 1). A calculation of the energy with the 6-31G* basis set using the 3-21G*-optimized geometries changes this result only very slightly. The difference in the stability of **2b** and **2c** is still only 1.1 kcal mol^{-1}. However, inclusion of the correlation energy leads to a marked preference of structure **2c**. At the MP2/6-31G*//3-21G* level the quinoid form **2c** is calculated as lying 10.1 kcal mol^{-1} lower energetically than the aromatic form **2b**. If the zero-point energy (ZPE) is also taken into consideration this energy difference increases to 10.9 kcal mol^{-1}.[6] At the same theoretical level, i.e. MP2/6-31G*//3-21G* + ZPE, the aromatic form **2b** and the chair structure **2d** are energetically almost degenerate; **2b** is calculated as being 0.3 kcal mol^{-1} more favorable than **2d**. Our results are in agreement with the theoretical studies on dithial HSC–CSH, according to which the four-membered valence isomer is energetically almost degenerate with the dithial form.[7]

Table 1 also lists our calculated energies for the structurally analogous oxygen compounds C_6O_6 **3a–3d**, whose geometries are shown in Figure 3. Here the question of the energetically most favorable structure is clearly answered in favor of the hexaketo form (Table 1). The MNDO calculation again predicts the chair form **3d** as being the energetically most favorable minimum,[8] which, however, lies only 6.5 kcal mol^{-1} lower than the planar structure **3a**, whereas the ab initio calculations indicate the D_{6h} form **3a** as being the most stable isomer. The difference in energy between **3a** and **3b** or **3c** is more than 100 kcal mol^{-1} (Table 1).

The differences in energy of the series of C_6O_6 isomers relative to those of the C_6S_6 isomers can be explained quite easily. The ring strain of the four-membered rings in **3b** and **3c** is substantially greater than in **2b** and **2c** since the O–O bond is much shorter than the S–S bond. Moreover, the use of standard values for the bonding increments[9] of C–C, C–O, C–S, O–O, and S–S bonds gives an exothermic balance of -8 kcal mol^{-1} for the formation of **2c** from **2a** or **2d**, whereas the corresponding transition from **3a** to **3c** is 80 kcal mol^{-1} and endothermic.

These results show that of the three C_6S_6 isomers of **2a–2d** investigated, the quinoid form **2c** is the energetically most favorable,[6] and that the hexathioketone isomer prefers the nonplanar chair form **2d**. Although it cannot be ruled out that, under the experimental conditions of the neutralization-reionization mass spectrometry (NRMS),[10] the more energetic isomers **2b** or **2d** are generated from **1** in a kinetically controlled process,[1] it appears likely that the indirectly observed species C_6S_6 has the structure **2c**.

How great are the chances of generating from the precursor analogous to **1** but with oxygen instead of sulfur ("benzene tricarbonate") a fragment C_6O_6 which has structure **3c**? We have calculated (MP2/3-21G*//3-21G* + ZPE[11]) the reaction enthalpies of the decomposition into six molecules of CS and CO respectively for each of the most stable C_6S_6 and C_6O_6 isomers **2c** and **3a**.

$$\mathbf{2c} \rightarrow 6\,CS + 221.8 \text{ kcal mol}^{-1} \quad (a)$$

$$\mathbf{3a} \rightarrow 6\,CO + 27.5 \text{ kcal mol}^{-1} \quad (b)$$

The reaction enthalpies for the reactions (a) and (b) show that the decomposition of **2c** into six molecules of CS is not favored thermodynamically. In contrast, an extremely low C–C bond strength of 27.5/6 = 4.6 kcal mol^{-1} is calculated for **3a**. It appears unlikely that the same method by which C_6S_6 could be observed[1] also leads to indirect detection of C_6O_6 in the case of the analogous precursor benzene tricarbonate. In this instance other strategies should be examined.[12]

[12] From ethylenetetracarboxylic acid derivatives a bis-anhydride of the formula C_6O_6 with two five-membered rings can be formed, which according to our calculations is 45.5 kcal mol^{-1} (MP2/3-21G*//3-21G* + ZPE) more stable than **3a** [13]. This anhydride is structurally related to the known anhydride of mellitic acid $C_{12}O_9$: N. N. Greenwood, A. Earnshaw: *Chemie der Elemente*, VCH, Weinheim 1988, p. 362.

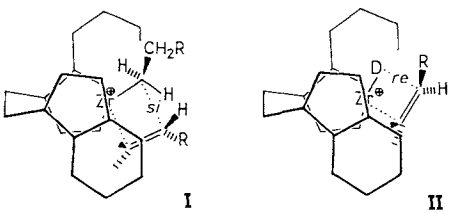
[13] In the meantime the detection of C_6O_6 in the gas phase by NRMS experiments starting from ethylenetetracarboxylates has been made. The author thanks Dr. *D. Sülzle* for this information and for interesting discussions.

Isotope Effects Associated with α-Olefin Insertion in Zirconocene-Based Polymerisation Catalysts: Evidence for an α-Agostic Transition State**

By *Helmuth Krauledat* and *Hans-Herbert Brintzinger**

In memoriam Piero Pino

Efficient catalysts for the stereospecific polymerization of α-olefins are obtained from chiral *ansa*-zirconocene complexes by activation with methyl alumoxane (MAO).[1] A useful model for the stereochemical course of this catalysis has been derived by *Pino* et al.[2] from studies on the MAO-activated hydrooligomerization of olefins in the presence of H_2, which is catalyzed by a resolved *ansa*-zirconocene enantiomer, (*R*)-[ethylene bis(4,5,6,7-tetrahydro-1-indenyl]zirconium dichloride (*R*)-**1**. The absolute configuration of the hydrotrimer was found to be that expected from an insertion path in which the CH_2R alkyl chain of the $ZrCH_2CH_2R$ unit points into an open segment of the chiral ligand framework, while the olefin approaches with that enantioface[3]—*si* for the complex with (*R*) configuration—which places the two alkyl substituents at the incipient C–C bond in *trans* positions to each other (**I**). This model has been confirmed by *Kaminsky* et al. in a recent study on the enantioselective oligomerization of α-olefins with this catalyst system.[4]



I II

An olefin approach with opposite enantiofacial preference—*re* for (*R*)-**1**—was indicated, however, by the prevailing product configuration for (*R*)-**1**-catalyzed α-olefin deuteration (**II**).[5] Here, the olefin substituent appears to take up the position which was occupied by the CH_2R group in **I**.

To test these models we studied the zirconocene/MAO-catalyzed hydrodimerization of 1-hexene, labeled with deuterium in its 1-*trans* position: the hydrodimerization product 6-deuterio-5-deuteriomethylundecane **2** must arise from two consecutive olefin insertions and final hydrogenolysis in the form of its *threo* isomer if both insertions proceed with opposite enantiofacial olefin orientation, and in the form of the *erythro* isomer if the two olefin insertions proceed with identical enantiofacial orientation.

Such a hydrodimerization, carried out with 0.1 mol-% rac-**1**, activated by MAO (200:1) under 20–15 atm of H_2 at -5 °C, affords ca. 10% 1-deuteriohexane, 5% hydrodimer **2** and 85% of higher hydrooligomers.[6] The D-NMR spectrum of **2** shows the signals of the *threo* ($\delta = 1.09$) and *erythro* ($\delta = 1.28$) diastereomers in a ratio of $(2.30 \pm 0.03):1$.[7] With (*Z*)- instead of (E)-1-deuterio-1-hexene, this ratio is inverted to $1:(2.55 \pm 0.10)$ in favor of the *erythro* isomer. These results confirm that olefin insertions into Zr–H and $Zr–CHDCH_2R$ units occur preferentially with opposite enantiofacial orientation.

For catalysis of the same reactions by MAO-activated $(C_5H_5)_2ZrCl_2$ one would expect that this achiral catalyst cannot induce any enantiofacial bias of the two α-olefin insertions. Yet repeated runs of these experiments consistently lead to a significant excess of the *erythro* product, with *threo*/*erythro* ratios of $1:(1.30 \pm 0.03)$.[8]

This surprising result is explained, in line with considerations of *Grubbs* et al.,[9] as outlined in Scheme 1: the asymmetric orientation of H and D atoms at the α-C atom of the first insertion product must influence the sense of insertion of the second olefin by a primary kinetic isotope effect,[10] when the $ZrCHDCH_2R$ unit is folded into an α-agostic bridge—either to $\overbrace{Zr \leftarrow H–CDCH_2R}$ or to $\overbrace{Zr \leftarrow D–CHCH_2R}$—in the transition state of the olefin insertion. Preference for H over D atoms in such an agostic bridge, together with preferentially *trans*-positioned alkyl groups at the incipient C–C bond, would indeed predict a preference for identical olefin orientations in both insertion steps for such an achiral catalyst.

Assuming a strict *trans* arrangement of the two alkyl residues and an energy lower by 500–600 J mol^{-1} for a metal–H–C- than for a metal–D–C-bridged species, as determined e.g. for $[HOs_3(CO)_{10}CH_2D]$ from temperature-dependent ^{1}H-NMR shifts of the CH_2D group,[11] Scheme 1 would yield, at a reaction temperature of 268 K, exactly the observed *threo*/*erythro* ratio of 1:1.3. The tenet of Scheme 1 is further supported by the observation that the $(C_5H_5)_2ZrCl_2$/MAO-catalyzed hydrodimerization of (Z)-1-deuterio-1-hexene gives the same *threo*/*erythro* ratio as that of its E isomer. This documents the chemical equivalence of the α-H/D positions in the first insertion product and distinguishes the isotopic differentiation in such an achiral catalyst from the stereotopic differentiation found for catalysis with rac-**1**, where inverted diastereomer ratios were observed for (*E*) and (*Z*) deuterated olefins.

That olefin insertions in Ziegler-Natta catalysis pass through a transition state involving an α-agostic distortion

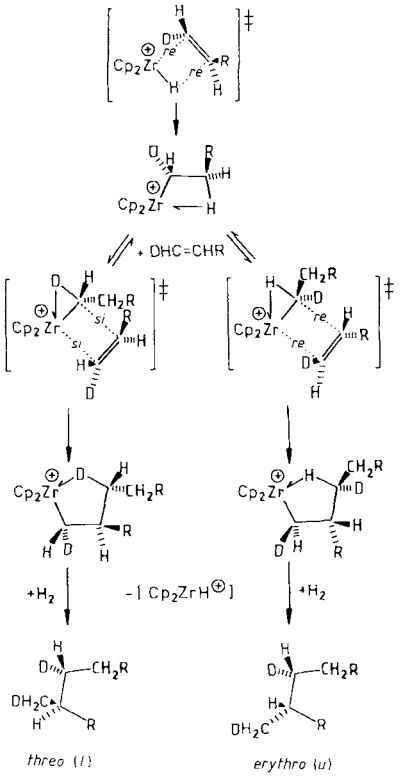
Grubbs* (California Institute of Technology, Pasadena, USA) for communication of unpublished results [13] and helpful discussions.



Scheme 1. Reaction paths with alternative α-agostic transition states leading to *threo*-**2** (left) and *erythro*-**2** (right) via two consecutive olefin insertions with opposite and identical olefin orientations, respectively.

of the migrating alkyl unit, has been proposed by *Brookhart* and *Green*.[12] The observations reported here constitute the first experimental evidence for such an α-agostic transition state in zirconocene-catalyzed olefin polymerizations.[13]

Experimental

(*E*)-1-deuterio-1-hexene: Reaction of 1-hexyne with 1 equiv. diisobutylaluminum hydride in toluene at 0 °C; cleavage with D_2O and fractional distillation [G. Wilke, H. Müller, *Justus Liebigs Ann. Chem. 629* (1960) 222; G. Zweifel, R. L. Miller, *J. Am. Chem. Soc. 92* (1970) 6678]; the ^{1}H-NMR spectrum (doublet of triplets, $\delta = 4.98$, $^3J = 17.1$, $^4J = 1.5$ Hz, 1H; symmetric multiplet, $\delta = 5.82$, 1H[14]) indicates that (*E*)-1-deuterio-1-hexene is the only olefin present. (*Z*)-1-deuterio-1-hexene: Cleavage with H_2O of the hydroalumination product of 1-deuterio-1-hexyne [G. W. Kabalka, R. J. Newton, J. Jacobus, *J. Org. Chem. 43* (1978) 1567]. ^{1}H NMR: $\delta = 4.91$ (d, $^3J = 10.4$ Hz), 5.80(m). The presence of ca. 15% [D_2]hexane, 10% toluene and 5% [D_1]butane, indicated by gas chromatography does not interfere with the catalysis or with the isolation of the hydrodimer **2**; traces of 1-hexyne have to be removed by prolonged stirring with and distilling from solvent-free *n*-butyllithium.

Hydrodimerizations: 3.5 mL (33 mmol) of (*E*)- or (*Z*)-1-deuterio-1-hexene, 430 mg MAO (6.6 mmol CH_3AlO, Schering AG, $M_r \approx 1300$, in 4.5 mL toluene) and 33 μmol of either rac-**1** or $(C_5H_5)_2ZrCl_2$ in 0.5 mL toluene (all under N_2) were exposed in a 50 mL autoclave at − 5 °C to initial H_2 pressures of 20 and 15 atm, respectively, for 16–20 h; during this time H_2 pressures fell by ca. 5 atm. After quenching with 10 mL 1.5 M aq. HCl and separation of the organic layer, **2** was isolated by fractional distillation. Admixtures of ca. 5% 6,7-[D_2]-*n*-dodecane (the tail-to-tail mis-insertion product) gave weak D-NMR signals just separable from the adjacent signal of *erythro*-**2**.

[6] Determined by gas chromatography with toluene as internal standard. Under 100 atm H_2, the respective yields are 61%, 10% and 29%. For **2** obtained from this reaction, the *threo*/*erythro* ratio is still 2.30:1, i.e., equal to that obtained with 20 atm H_2.
[7] Measured in C_6H_6 solution relative to $\delta(C_6H_5D) = 7.15$ on Bruker AMX-600 and AMX-500 NMR spectrometers operated at 92.1 and 76.8 MHz respectively with broad-band ^{1}H decoupling. The assignment of the signal at $\delta = 1.09$ to *threo*-**2** and that at $\delta = 1.28$ to *erythro*-**2** is based on closely similar D-NMR shifts for the *threo* ($\delta = 1.07$) and *erythro* ($\delta = 1.28$) diastereomers of 2-deuterio-3-methylpentane, prepared by hydroboration and subsequent deuterolysis with CH_3COOD from the (*Z*) and (*E*) isomers, respectively, of 3-methyl-2-pentene (c.f. G. W. Kabalka, R. J. Newton, J. Jacobus, *J. Org. Chem. 44* (1979) 4185).
[8] This reaction yields 35% 1-deuteriohexane, 45–50% **2** and 15–20% of hydrotrimer plus higher hydrooligomers.

[13] A similar kinetic isotope effect due to α-CHD asymmetry has recently been observed for the hydrocyclization of (*E*,*E*)-1,6-dideuterio-1,5-hexadiene to 2-deuterio-1-deuteriomethylcyclopentane for which an achiral scandiocene catalyst gave, at − 10 °C, a *cis*/*trans* diastereomer ratio of 1:1.26 (J. E. Bercaw, W. E. Piers, *J. Am. Chem. Soc.*, in press). For the analogous cyclization reaction catalyzed by MAO-activated $(C_5H_5)_2ZrCl_2$, we find a *cis*/*trans* ratio of 1.01 ± 0.02, i.e. no indication for any α-agostic interaction. A *cis*/*trans* ratio of 1.0 has also been reported for the $Al(C_2H_5)Cl_2$-induced, stoichiometric cyclization of Cp_2TiCl–CHD–$(CH_2)_3$–$CH=CH_2$ to Cp_2TiCl–CH_2–$\overline{CH}$–$(CH_2)_3$–$\overline{CH}$D [9].

2-Pentylcyclopent-2-en-1-one by Catalytic Pauson-Khand Reaction**

By *Valentin Rautenstrauch,** *Patrick Mégard, José Conesa*, and *Wilhelm Küster*

We report the preparation of 2-pentylcyclopent-2-en-1-one **1**, a precursor of methyl *trans*-dihydrojasmonate (Hedione®),[1] an important perfumery chemical, from hept-1-yne **2**, ethylene **3** and CO, by catalytic Pauson-Khand reaction (PKR) (Scheme 1).

Conventionally, PKRs are carried out by heating the complexes $[Co_2(CO)_6(alkyne)]$ (intramolecular PKRs: $[Co_2(CO)_6(alkenyne)]$) with alkenes (for exceptions, see below),[2] and **1** was obtained via this stoichiometric PKR, from $[Co_2(CO)_6(hept\text{-}1\text{-}yne)]$ **4** and **3**. The yields were 31–47% based on **4** (35–70% in the presence of 1 mol-equiv. of tributylphosphane oxide), but were irreproducible.[3] The complexes are prepared in a separate step, from the alkynes

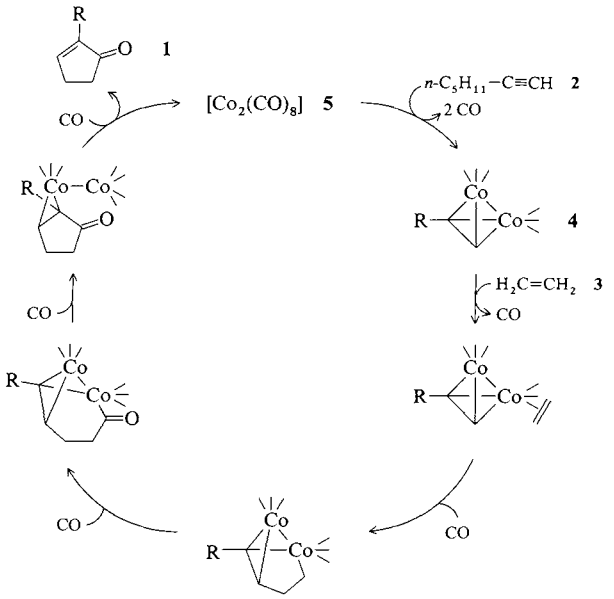
or alkenynes and $[Co_2(CO)_8]$ **5**.[2] The yield of **4** was 80–85% (1 mol-equiv. or slight excess of **2**[3]).

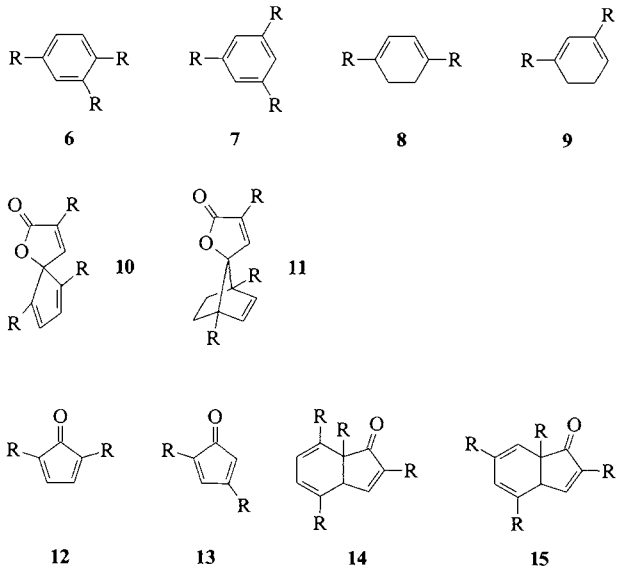
A catalytic PKR that would instead allow the use of free alkyne and CO would be of great interest, especially for industrial applications. This has often been attempted,[4] but the only truly catalytic reactions described so far[4a] involve the strained, reactive alkenes norbornene and norbornadiene, in combination with acetylene and CO. The turnover numbers achieved were small (8 and 11) and the amounts of (pre)catalyst **5** used rather high (9.4 and 3.7 mol-% of the alkenes).



Scheme 1. Hypothetical mechanism for the synthesis of the cyclopentenone **1** via a catalytic Pauson-Khand reaction. R = n-C_5H_{11}. The CO ligands are indicated by dashes.

Our process is based on the fact that PKRs involving a 1-alkyne and **3** are uniquely favorable. The complexes $[Co_2(CO)_6$(1-alkyne)] react highly regioselectively and in the right sense, whereas 1-alkenes react completely unselectively.[2] As concerns regioselectivity, combination of **4** (or of **2** in a catalytic process) with **3** is therefore the best possible choice. **3** is also very reactive.[3] Kinetic data are lacking, but one can assume that **3** is the most reactive unstrained alkene component, and that alkene reactivity is a key factor. In view of the known catalytic reactions,[4a] it is certain that **3** is also the best possible choice with respect to reactivity. In the alternative combination of $[Co_2(CO)_6(C_2H_2)]$ (or acetylene) with hept-1-ene and CO, the regioselectivity with respect to, and the reactivity of, hept-1-ene are both unfavorable. Moreover, the reactivities of the alkynes towards cyclotrimerization, one of the prominent side reactions, also favor the first combination, **2** cyclotrimerizing less readily than acetylene. The second combination would be an alternative because it would produce 5-pentyl- along with 4-pentylcyclopent-2-en-1-one, and the former can be readily isomerized to **1**.[5]

Four types of prominent side reactions compete in our process: cyclotrimerization (CT) (**2** → **6** + **7**), cocyclotrimerization (CCT) (**2** + **3** → **8** + **9**), formation of **10** (spirofuranone (SF)-formation), which is trapped in situ by **3** as the Diels-Alder adduct **11**, and formation of the cyclopentadienones (CPs) **12** and **13** (→ → **14** + **15**, see below)].[6] None of these side reactions has previously been identified in PKRs, although CT had been suggested as an obvious possibility.[7]

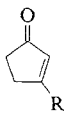


Our process is further based on the identification of three parameters that strongly affect the PKR and side reactions: 1) the concentration of **2**—CT, CCT and CP formation were all more or less suppressed at low concentrations of **2**. 2) The CO pressure—at high CO pressure, the PKR was favored, catalyst recycling improved, and CP formation favored at the expense of CT, but SF formation not favored; 3) the pressures of **3**—high pressures were needed, but the catalytic system broke down beyond a certain limit. The primary parameters are the concentrations of CO and **3** in the liquid phase. These are determined by the partial pressures and solubilities, but the solubility of **3** is much higher than that of CO.

In terms of statistical analysis, these parameters appear to interact.[8] We carried out two long series of experiments (some 40 runs in each) in which these and some other parameters were varied, and which led to the above deductions. The experiments were not statistically designed,[8] because other, unidentified and/or difficult-to-control parameters seem to play a role. This is suggested by the fact that we were unable to reproduce exactly the first series in the second series (about 5 months later, see below), although we could reproduce experiments when they were successive or close in time within each series. One of these parameters is clearly autoclave conditioning.

In one of our best experiments, we used a 0.80 M toluene solution of **2** (40 mmol, about 50 mL solution), 0.088 mmol **5** (0.0022 mol-equiv., 0.22 mol-%), partial pressures (room temperature) of 40 bar **3** and 100 bar CO [100 mL stainless steel autoclave, magnetically-linked high speed stirrer; about 9 mol-equiv. of **3** and 6 mol-equiv. of CO]. We heated to 150 °C for 16 h (310–360 bar total pressure at 150 °C) and obtained **1** in 47–49% isolated yield based on **2**. The conversion of **2** was ≥ 98% (GC), the overall turnover number about 220, the overall turnover rate about 0.04 s^{-1}, and the initial turnover rate about 0.2 s^{-1}. The regioselectivity was 98–99% (1–2% of **16**). All four side reactions were largely suppressed, but CCT and CP formation less than the other two. Based on the yield of **1** and approximate product ratios determined by gas chromatography, we estimate yields[9] of

about 8% for **8** + **9**, 7% for **14** + **15**, and 1% each for **6** + **7**, and **11**. The sum of these yields and that of **1**, about 65%, is a material balance with respect to **2**, which is clearly incomplete. Apart from the prominent side products, we also detected a background of trace products (GC) and may have overlooked products of high molecular weight.

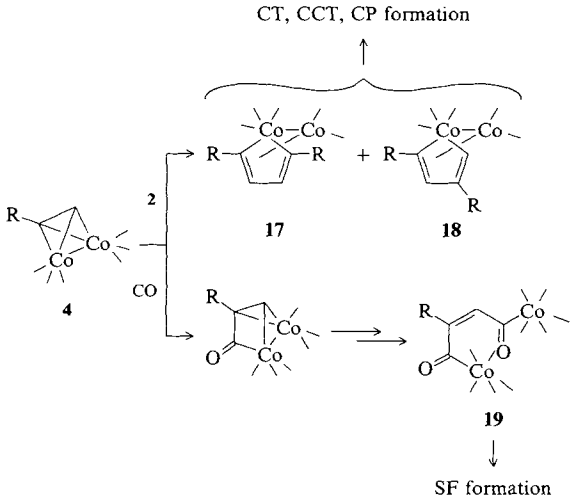


16

The irreproducibilities mentioned above were as follows: the maximum yield of **1** was close to 50% in the second series (the results above are from the second series), but close to 60% in the first; furthermore, small amounts of acetonitrile and $[Fe(CO)_5]$ had apparently improved the yield in the first series, which we were unable to reproduce exactly in the second.

Scheme 1 shows a working hypothesis for the mechanism of the catalytic PKR, which is based on the Schore-Magnus mechanism for the stoichiometric reaction.[10] There is little experimental evidence to support either one of these hypotheses, but they at least permit a first discussion. The kinetics of the first step, the reaction between **5** and alkynes, have been studied and a mechanism proposed[11b] which involves loss of a CO ($\rightarrow [Co_2(CO)_7]$), addition of the alkyne ($\rightarrow [Co_2(CO)_7(\text{alkyne})]$), and loss of the second CO (the sequence is not explicitly formulated).

How the Co_2 fragment is liberated from the cyclopentenone and recycled is unknown, but the ultimate fate of the fragment in the stoichiometric reaction is known: in isooctane as the solvent $[Co_4(CO)_{12}]$ was isolated,[4a] and in aromatic solvents the clusters $[Co_4(CO)_9(\text{arene})]$ ($[Co_4(CO)_{12}]$ reacts with arenes to give $[Co_4(CO)_9(\text{arene})]$).[2a, 12] The same clusters are primary products when **5** is thermolyzed (at or above room temperature) in the absence of CO; the end product is metallic Co.[11c, 12] In contrast, in the presence of CO, but effectively only at high CO pressures, an equilibrium favoring **5** is established (little $[Co_4(CO)_{12}]$, no decomposition to metallic Co); the kinetics of the back reaction $[Co_4(CO)_{12}] + 4\,CO \rightarrow 2\,\mathbf{5}$ have been investigated and a mechanism deduced.[11c, 13] All of this suggested that catalyst recycling in the PKR might only be efficient at high CO pressure. No systematic investigation of the PKR at high CO pressure is in the literature, but it has been established that CO at atmospheric pressure has little or no effect on the stoichiometric reaction.[2c] As reaction **5** + **2** → **4** + 2CO involves CO dissociation (see above), and the same is assumed in the next step, the insertion of **3** (Scheme 1), one might have expected that high CO pressure would block these dissociations.



Scheme 2. Hypothetical reaction pathways to the prominent side products in the synthesis of **1**. R = n-C_5H_{11}. Dashes = CO ligands.

Scheme 2 shows the two pathways presumed to lead to the side reactions. One pathway involves the reaction of **4** with **2** to give **17** and **18**,[14] thought to be common intermediates in CT,[15] CCT[16] and CP formation. The other involves the reaction of **4** with CO to **19**, considered to be an intermediate in SF formation (for details, see [17]). Once the free CPs **12** and **13** are generated, they undergo mainly two Diels-Alder reactions, **12** + **12** and **12** + **13**, and the resulting adducts then decarbonylate to **14** and **15**.[17–19]

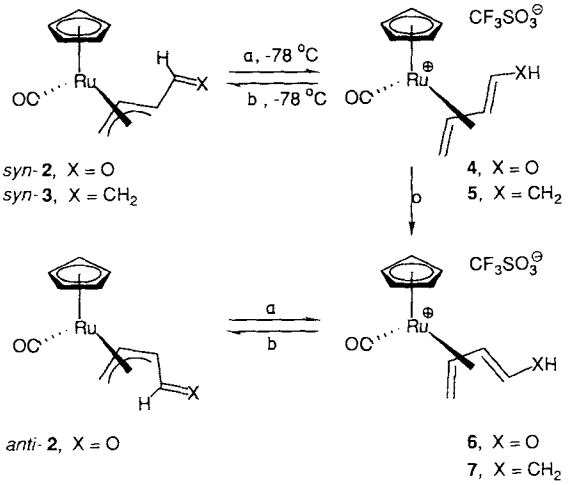
s-trans-1,3-Dienes as Ligands for Cationic Group 8 Metal Centers**

By *Stephen A. Benyunes, Jeremy P. Day, Michael Green*, Abdul Wahab Al-Saadoon*, and *Tracey L. Waring*

Conjugated dienes, as ligands, have been of paramount importance during the development of organotransition metal chemistry.[1] Structural studies have long since established that, in contrast to the solution behavior of the free ligand, upon coordination to a metal center a 1,3-diene almost invariably adopts an *s-cis* conformation. Species in which the coordinated diene defies this generalization were first reported in 1980 by *Erker* et al.[2] Since then a variety of thermally stable neutral *s-trans*-diene complexes has been described.[3] Examples of these, however, are confined to the early transition metals in which the L_nM-diene moiety may be viewed as being predominantly metallacyclic in character. More recently we have described the first examples of species containing an *s-trans*-diene coordinated at a cationic molybdenum center.[4] Complexes of type $[Mo(\eta^4\text{-}C_4H_5R)(CO)_2(\eta\text{-}C_5Me_5)][CF_3SO_3]$ were generated at low temperature, and were found to undergo irreversible isomerization to their *s-cis* counterparts above − 30 °C. In extending our synthetic methodology to an analogous ruthenium system we have discovered that cationic *s-trans*-1,3-diene complexes of this type are surprisingly more stable, and with this insight we have selectively trapped *s-trans*-1,3-dienes with a $[Ru(CO)(\eta\text{-}C_5H_5)]^{\oplus}$ fragment.

As a continuation of the synthetic approach established for molybdenum, the reaction of 1-trimethylsilyloxybuta-1,3-diene with $[Ru(NCMe)_2(CO)(\eta\text{-}C_5H_5)][BF_4]$ **1**[5] was investigated. This gave, upon prolonged stirring, the oxo-functionalized allyl complex **2** as an *exo-syn*:*endo-syn* isomeric mixture[6] (4:1), which was purified by column chromatography. Reaction of **2** with the Wittig reagent $Ph_3P{=}CH_2$ resulted in a smooth transformation into the corresponding η^3-pentadienyl species **3** (Scheme 1). Characterization of *exo-syn*-**2** by means of a single-crystal X-ray diffraction analysis[7] revealed an unexpectedly short C^1–C^2 interatomic distance in the allyl ligand (1.46 Å). This observed increase in the bond order implies the presence of considerable π delocalization throughout the ligand, and hence a high degree of stereochemical rigidity. This latter feature was reflected accordingly in the low-temperature protonation of **2**: treatment of *syn*-**2** with CF_3SO_3H (CD_2Cl_2, −78 °C) gave only the *s-trans*-diene complex **4**, thereby demonstrating retention of the stereochemical integrity of the transoid C_4 ligand. In similar fashion, protonation of *syn*-**3** afforded exclusively the *s-trans*-diene complex **5** (Scheme 2). Complexes **4** and **5**



Scheme 2. a) CF_3SO_3H, CH_2Cl_2; b) NEt_3.

were not isolated, and were characterized in situ by comparison of their ^{1}H-NMR data with those of the known[5] *s-cis* isomerization products **6** and **7**. Identification as such was based on two spectroscopic features associated with the *s-trans* geometry: a) a higher value for $^3J(H^b\text{–}H^c)$ across the central C–C single bond and b) a marked upfield shift of the signals arising from the exposed protons H^a and H^e, both criteria being relative to the isomeric *s-cis* species (Table 1). In contrast with the analogous molybdenum complexes, the rate of isomerization of **4** and **5** was relatively slow, their stability in CH_2Cl_2 solution at 25 °C corresponding to a $t_{1/2}$ of 2 and 48 h, respectively. Reaction of the hydroxydiene cations **4** and **6** with NEt_3 gave only *syn*-**2** and *anti*-**2**, respectively, thus demonstrating again the previously established

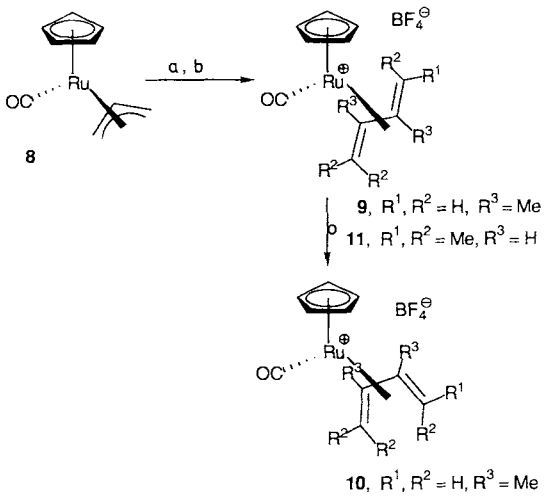
structural relationship (*syn*-allyl $\rightleftharpoons$ *s-trans*-diene, *anti*-allyl $\rightleftharpoons$ *s-cis*-diene) inherent in the protonation of **2** and **3**.

The unexpectedly high degree of thermal stability displayed by the cations **4** and **5** suggested that it might actually be possible to prepare such species by the selective capture of an *s-trans*-1,3-diene with an appropriate metal fragment. This was achieved via a simple extension of an existing procedure.[8] Addition of $HBF_4 \cdot OEt_2$ to allyl complex **8** (CH_2Cl_2, $-78\,^\circ C$) followed by an excess of 2,3-dimethylbuta-1,3-diene afforded a mixture of the *s-trans* and *s-cis* cations **9** and **10** (Scheme 3). Complex **9** proved unstable in



Scheme 3. a) $HBF_4 \cdot OEt_2$, CH_2Cl_2, $-78\,^\circ C$; b) Diene

solution at 25 °C, undergoing slow rearrangement to the *s-cis* isomer **10**. Substitution, in the above sequence of the more sterically demanding 2,5-dimethylhexa-2,4-diene gave only a single species **11** isolated as orange-yellow crystals. As was the case for **9**, the asymmetry present in the diene ligand, highlighted by ^{1}H and ^{13}C NMR, allowed **11** to be unequivocally assigned the predicted *s-trans* geometry. Solution studies show a complete absence of isomerization at 25 °C, and thus **11** can be regarded as an unprecedented example of a stable cationic *s-trans* diene complex. It is also the first example of an *s-trans*-1,3-diene complex of a metal from the right-hand side of the periodic table. Our studies might thus suggest that *s-trans*-1,3-dienes as ligands are less unusual than was originally thought.

Experimental

2: A solution of **1** (0.50 g, 1.38 mmol) in CH_2Cl_2 (30 mL) was treated with 1-trimethylsilyloxybuta-1,3-diene (0.50 g, 3.5 mmol) and the resulting mixture stirred for 3 d at 25 °C. After removal of solvent, the residue was chromatographed on alumina with Et_2O. **2** (0.18 g, 50%), was obtained as an orange-yellow solid in the form of a 4:1 *exo-syn*:*endo-syn* mixture.

exo-syn-**2**: IR (CH_2Cl_2): $\tilde{\nu}$ (C=O) = 1950 vs, 1650 s cm^{-1}; ^{1}H NMR (CD_2Cl_2): δ = 9.00 (d, 1H, CHO, J = 6.7 Hz), 4.30 (s, 5H, C_5H_5), 4.22 (ddd, 1H, CH, J = 11.1, 9.2, 7.0 Hz), 2.77 (dd, 1H, CH_2, J = 7.0, 1.4 Hz), 2.46 (dd, 1H, CH, J = 9.2, 6.7 Hz), 1.53 (dd, 1H, CH_2, J = 11.1, 1.5 Hz); MS: m/z 263 ($M^\oplus$).

3: A solution of **2** (250 mg, 0.95 mmol) in THF (40 mL) was cooled to $-78\,^\circ C$, and treated with a THF solution of $Ph_3P{=}CH_2$ (0.8 g, 2.9 mmol). The mixture was warmed to ambient temperature and stirred for 15 h. Solvent was then removed under reduced pressure, and the solid residue purified by column chromatography. Elution with Et_2O/hexane (1:1) afforded a bright yellow band, which following concentration and recrystallization from hexane gave yellow crystals of **3** (145 mg, 58%).

exo-syn-**3**: IR (CH_2Cl_2): $\tilde{\nu}$ (C=O) = 1940 vs cm^{-1}; ^{1}H NMR ($CDCl_3$): δ = 5.88 (dt, 1H, CH, J = 17.0, 10.1 Hz), 5.17 (dd, 1H, $=CH_2$, J = 16.9, 1.5 Hz), 4.97 (s, 5H, C_5H_5), 4.80 (dd, 1H, CH, J = 10.1, 1.5 Hz), 4.23 (ddd, 1H, CH, J = 10.3, 9.9, 6.9 Hz), 2.84 (t, 1H, =CH, J = 9.9 Hz), 2.81 (dd, 1H, CH_2, J = 6.8, 1.9 Hz), 1.29 (dd, 1H, CH_2, J = 10.5, 1.9 Hz); MS: m/z = 263 ($M^\oplus$).

4: A slight excess of CF_3SO_3H (8 µL, 0.09 mmol) was added slowly to a cooled ($-78\,^\circ C$) solution of **2** (21 mg, 0.08 mmol) in CD_2Cl_2 (0.5 mL) contained within a septum capped 5-mm NMR tube. This was transferred immediately to the pre-cooled ($-70\,^\circ C$) probe of the NMR spectrometer. Spectra were recorded whilst warming at 10 °C intervals, showing the instantaneous and quantitative generation of **4** as the only species present in solution.

exo-s-trans-**4**: ^{1}H NMR ($-40\,^\circ C$): δ = 8.05 (d, 1H, H^a, J_{ab} = 10.4 Hz), 5.59 (s, 5H, C_5H_5), 4.46 (ddd, 1H, H^c, J_{ce} = 11.5, J_{cb} = 8.1, J_{cd} = 6.9 Hz), 3.82 (dd, 1H, H^b, J_{ba} = 10.5, J_{bc} = 8.0 Hz), 3.65 (d, 1H, H^e, J_{ec} = 11.4 Hz), 3.32 (d, 1H, H^d, J_{dc} = 6.9 Hz). Warming the sample to 25 °C gave rise to a second set of signals corresponding to *endo-s-cis*-**6**: ^{1}H NMR: δ = 5.92 (ddd, 1H, H^c, J_{ce} = 11.2, J_{cd} = 8.2, J_{ch} = 6.4 Hz), 5.60 (dd, 1H, H^b, J_{ba} = 9.2, J_{bc} = 6.2 Hz), 5.55 (s, 5H, C_5H_5), 5.48 (d, 1H, H^a, J_{ab} = 9.2 Hz), 3.30 (dd, 1H, H^d, J_{dc} = 8.2, J_{de} = 2.1 Hz), 1.64 (dd, 1H, H^e, J_{ec} = 11.4, J_{ed} = 2.1 Hz).

5: The low-temperature protonation of **3** gave, in similar fashion, *exo-s-trans*-**5**. ^{1}H NMR: ($-40\,^\circ C$) δ = 5.65 (s, 5H, C_5H_5), 4.94 (dq, 1H, H^a, J_{ab} = 11.5, $J_{a\text{-}Me}$ = 6.4 Hz), 4.58 (dd, 1H, H^b, J_{ba} = 11.5, J_{bc} = 7.7 Hz), 4.31 (d, 1H, H^e, J_{ec} = 12.7 Hz), 4.22 (d, 1H, H^d, J_{dc} = 6.8 Hz), 4.15 (dt, 1H, H^c, J_{ce} = 12.7, $J_{ch \approx cd} \approx 7.0$ Hz), 1.86 (d, 3H, Me, $J_{Me\text{-}a}$ = 6.4 Hz).

11: To a cooled ($-78\,^\circ C$) solution of **8** (50 mg, 0.21 mmol) in CH_2Cl_2 (5 mL) was added successively $HBF_4 \cdot OEt_2$ (85%, 21 µL, 0.23 mmol) and 2,5-dimethylhexa-2,4-diene (70 mg, 0.64 mmol). The mixture was then allowed to warm to ambient temperature. Stirring was continued for 4 d, accompanied by a gradual change in color from orange to dark green. The resulting solution was filtered through celite and concentrated under reduced pressure. Addition of Et_2O gave a pale green powder, which upon recrystallization from CH_2Cl_2 ($-40\,^\circ C$) afforded orange-yellow crystals of **11** (53 mg, 64%). IR (CH_2Cl_2): $\tilde{\nu}$ (C=O) = 2004 vs cm^{-1}; ^{1}H NMR (CD_2Cl_2): δ = 5.36 (s, 5H, C_5H_5), 4.89 (d, 1H, CH, J = 9.4 Hz), 4.24 (d, 1H, CH, J = 9.4 Hz), 2.14 (s, 6H, 2 Me), 2.10 (s, 3H, Me), 2.02 (s, 3H, Me); ^{13}C-{^{1}H} NMR (CD_2Cl_2): δ = 119.5 (CMe_2), 110.0 (CMe_2), 90.8 (C_5H_5), 86.4 (CH), 75.3 (CH) 32.0 (Me), 31.5 (Me), 25.3 (Me), 24.7 (Me).

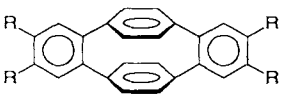
A Synthetic Equivalent for [2.2]Paracyclophane-1,9-diyne: Octaphenyl-1:2,9:10-dibenzo[2.2]paracyclophane-1,9-diene and Its Reduction to the Hexaanion**

By *Armin de Meijere,* Jürgen Heinze, Klaus Meerholz, Oliver Reiser*, and *Burkhard König*

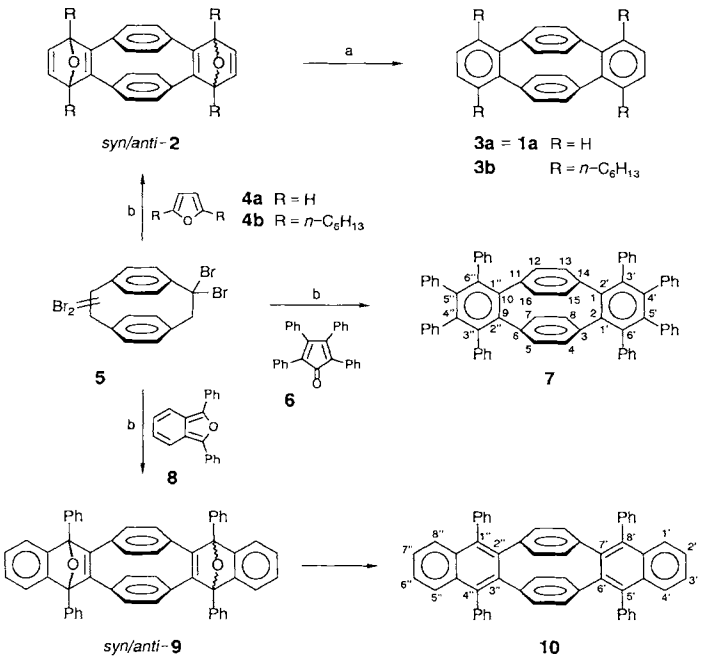
Dedicated to Professor Marit Traetteberg on the occasion of her 60th birthday

The synthesis of unusual molecules that are not naturally occurring is not just a challenge, but often an opportunity to discover new properties and phenomena. 1:2,9:10-Dibenzo[2.2]paracyclophane-1,9-diene (**1a**), first synthesized by *Wong*,[1] contains two biphenyl units that are nonconjugated in the classical sense because the phenyl rings are mutually orthogonal. Reduction of **1a** with alkali metals gives a radical anion, $\mathbf{1a}^{\bullet\ominus}$, whose unpaired electron resides in the phane benzene rings.[2] The tetraphenyl derivative **1b**, which we synthesized,[3] behaves differently; the first two additional electrons reside in the lateral *ortho*-terphenyl units.[4] Compound **1c** can be reversibly reduced to the tetraanion.[5] Thus, octaphenyl-1:2,9:10-dibenzo[2.2]paracyclophane-1,9-diene (**7**), described here, was expected to extend this trend still further.



1a R = H
1b R = C_6H_5
1c R = p-$C_6H_4C(CH_3)_3$

The synthesis of **1a** developed by *Wong*[1] starts with 9,9-dibromo-1:2-benzo[2.2]paracyclophan-1-ene, which is obtained in five steps from *o*-terphenyl in only poor yield (0.3%). This route is therefore hardly suitable for a synthesis of **1a** in preparative quantities. However, we found that the concept of double dehydrobromination of a geminal dibromide can be applied to the isomeric mixture of 1,1,9,9- and 1,1,10,10-tetrabromo[2.2]paracyclophane (**5**), easily obtained in large amounts (90% yield) from commercially available [2.2]paracyclophane.[6] In this way, not only **1a** but also a series of interesting derivatives, such as **3b**, **7**, and **10**, are now readily available for the first time in large amounts. Treatment of **5** with potassium *tert*-butoxide in tetrahydrofuran (THF) results, via fourfold dehydrobromination, in the stepwise formation of a triple bond in each bridge of [2.2]paracyclophane. In the presence of furan (**4a**), the highly strained alkynes are immediately trapped and afford the two diastereomeric bis-endoxides *syn/anti*-**2a** (23% yield) in a ratio of about 1:1 (Scheme 1). The bis-endoxides *syn/anti*-**2a**[7] undergo facile deoxygenation upon treatment with low-valent titanium ($TiCl_4/LiAlH_4$) to give **3a** (= **1a**) (75%). Dibenzo[2.2]paracyclophanediene (**1a**) can thus be prepared in three steps in gram amounts from [2.2]paracyclophane. Use of 2,5-disubstituted furans **4b**[8] as trapping agents in this sequence leads, via the corresponding bis-endoxides **2b**,[7] to 3′,6′,3″,6″-tetrasubstituted dibenzo[2.2]paracyclophanedienes such as **3b**.[7]



Scheme 1. a) $TiCl_4/LiAlH_4$, NEt_3, THF, room temperature 0.5 h; b) KO*t*Bu/THF, 22 °C, 4–5 h.

Analogously, reaction with 2,5-diphenylisobenzofuran (**8**) affords the dibenzo bis-endoxides *syn/anti*-**9**, which are deoxygenated by $TiCl_4/LiAlH_4$ to give dinaphtho[2.2]paracyclophane-1,9-diene (**10**).[7] Dropwise addition of a solution of potassium *tert*-butoxide in THF to a mixture of **5** and tetraphenylcyclopentadienone (tetracyclone, **6**) furnishes octaphenyldibenzo[2.2]paracyclophanediene (**7**)[7] in a yield of 69%. The high efficiency with which the ring-strained alkyne generated here is trapped by tetracyclone (**6**), a diene with inverse electron demand, is also known for other highly strained cycloalkynes.[9]

Compound **7** has a centrosymmetric structure in the crystal (Fig. 1). The interplanar angles in each of the four

biphenyl units formed by the two lateral benzene rings and their four phenyl substituents increase sequentially from 63.2° to 81.4°, presumably owing to intermolecular effects in the crystal. The same phenomenon has also been observed for hexaphenylbenzene,[10] for which the average value of the interplanar angle (67.2°) is slightly, but significantly, smaller than that in **7** (average value 73.2°). The geometry of the central framework in **7** corresponds to that in the parent compound **1a**.[12]

Whereas **1a** can be reduced to a dianion in two steps and the tetraphenyl derivative **1c** can be reduced to a tetraanion in four steps,[5] the cyclovoltammogram of the octaphenyl derivative **7**[13] shows three reversible two-electron reduction waves at $E^0 = -2.61$, -2.76, and -3.13 V versus Ag/AgCl. Only a few examples of reversibly formed hexaanions have been reported so far.[14] As expected, the reduction potentials of **7** are all more positive than those of hexaphenylbenzene, which is reduced in three steps at $E^0 = -2.73$, -3.10, and -3.23 V to only a trianion. Even in **1c**, the potential differences between mono- and dianion formation and tri- and tetraanion formation (70 and 85 mV, respectively) are very small owing to the weak interaction between the two substituted, lateral benzene rings.[5] It is not surprising, therefore, that formal 2e processes with $\Delta E^0 < 50$ mV are observed for **7**, which has still larger conjugated systems. Also noteworthy is the formation of the hexaanion over an extremely small potential range ($\Delta E^0 = 0.52$ V). Compound **7** is thus an efficient storer of charge, since Coulomb repulsions between the six excess charges are minimized by the unusual structure.

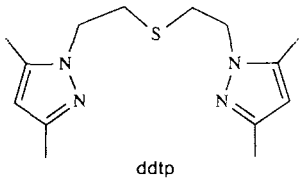
$[Cu_4(ddtp)_2Br_4]$, a Unique Tetranuclear Copper(I) Complex with Bridging Thioethers and Bridging Bromides**

By *Adrianus L. E. Stoffels, Willem G. Haanstra, Willem L. Driessen,** and *Jan Reedijk*

The ligand 1,5-bis(3′,5′-dimethylpyrazolyl)-3-thiapentane (ddtp), which has three potential donor atoms, forms coordination compounds with a 1:1 stoichiometry, namely $M(ddtp)X_2$, with divalent first row transition metals and anions.[1] In contrast, when reacting $CuBr_2$ with ddtp in warm ethanol/acetone in air,[2] the solution decolorizes almost immediately. On cooling, colorless air-stable crystals of stoichiometry $Cu_2(ddtp)Br_2$ separate. Apparently a reduction to a Cu^I species has occurred. Cu^{II} compounds exhibit a d-d transition band in the VIS-NIR region and usually give rise to an EPR signal. Both phenomena were absent in the resulting ddtp copper bromide compound. The same compound was also prepared by reacting ddtp with CuBr in a nitrogen atmosphere,[3] as confirmed by a comparison of IR spectra and X-ray powder patterns.



ddtp

Single-crystal X-ray structure analysis[4] shows that each copper ion resides in a distorted tetrahedral environment provided by a nitrogen, a bridging thioether and two bridging bromides (see Fig. 1). Two copper ions are linked by two bromides forming a Cu_2Br_2 fragment. The Cu···Cu distance

[**] We thank *S. Gorter* for providing the data set for the X-ray structure analysis and *R. A. G. de Graaff* for assistance in solving the X-ray structure. Further we also thank *M. van Roon* for providing an alternative reaction path to the title compound.—ddtp = 1,5-bis(3′,5′-dimethylpyrazolyl)-3-thiapentane

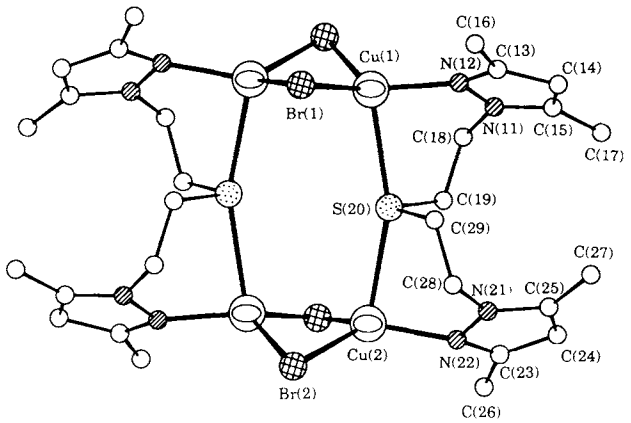

Fig. 1. Structure of the tetranuclear Cu^{I} complex $[Cu_4(ddtp)_2Br_4]$ (PLUTO projection [5]; hydrogen atoms are omitted for clarity).

(270 pm) is somewhat smaller than the Cu···Cu distances in other Cu^{I} compounds with comparable bridges (e.g. 274 and 286 pm[6]; 288 and 284 pm[7]). This distance and the acute Cu–Br–Cu angles (54.4 and 57.8°) suggest some $Cu^{I}\cdots Cu^{I}$ interaction. Two Cu_2Br_2 fragments are linked together by two ddtp ligands, bringing the four copper atoms into a rectangular arrangement. The ligand links the Cu_2Br_2 fragments together through its two ligating nitrogen atoms as well as through the thioether sulfur, which bridges two copper ions of different Cu_2Br_2 fragments. Thus Cu···Cu distances of 270 and 524 pm are observed in this complex. A striking feature is that the Cu–S–Cu angle (160.6°) is significantly larger than any other Cu–S–Cu angle reported so far. Some angles found in other X-ray structures are 79.4[7], 109.8[8], 112.2[8], 116.2[8] and 118.6°[9]. The C–S–Cu angles are 96.9 and 97.0° respectively. The Cu···S distances are 264 and 268 pm. The occurrence of both bromide and thioether bridges in a tetranuclear Cu^{I} compound, together with the relatively short Cu···Cu distances, make this air-stable compound truly unique.

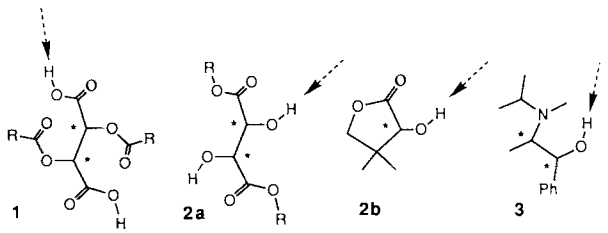
Asymmetric Protonation of Enolates**

By *Dominique Potin, Kevin Williams*, and *Julius Rebek, Jr.**

An effective, chiral proton source is a desirable goal of modern organic synthesis, since it could lead to asymmetric carbonyl compounds from readily available enolates. Progress in this areas has been made by several groups, especially those of *Duhamel*,[1] *Hünig*[2] and *Fehr*,[3] using the chiral proton sources **1, 2** and **3**, respectively. If proton transfer



from these materials takes place along the expected trajectories (indicated by arrows), it would appear that the asymmetric centers are less than ideally placed to influence the course of the reaction. Even if intramolecular hydrogen bonding is involved (as seems to be a common feature of these sources), the enolate carbon could be quite remote from the asymmetric environment in the transition structure. We have prepared some new structures in which the proton is buried within an asymmetric environment; they have been useful as chiral auxiliaries in cycloadditions[4] and alkylation reactions.[5] Here we report their application to the asymmetric protonation of enolates.

The compounds are derivatives of Kemp's tricarboxylic acid **4**[6] and they are readily prepared as previously described.[4] Condensation of **4** with urea, followed by reaction with $SOCl_2$ gives the acid chloride **5a**, with which optically active amines can be acylated with formation of **5b**. Reduction with $NaBH_4$ followed by acid treatment gives the tricyclic lactams **6**. The diastereomers are obtained as an easily separable mixture,[7] and the X-ray crystal structure[8] of one of the diastereomers **6a** of the (*R*)-naphthylethyl series is shown in Figure 1. This reveals that the acidic NH bond

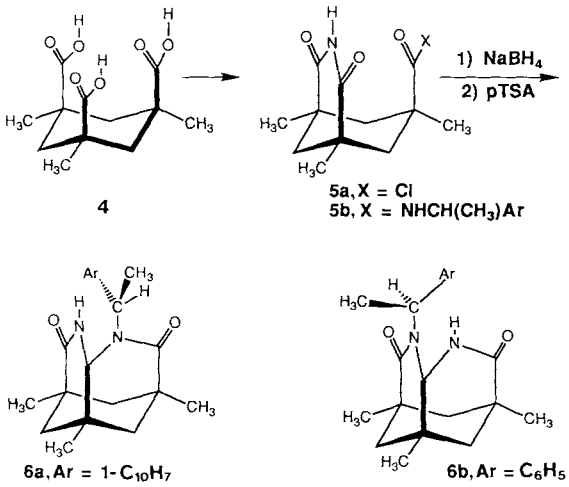
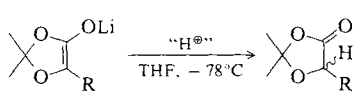
[**] This work was supported by Hoechst Celanese and Rhône-Poulenc Sauté (Fellowship to *D. P.*).



is buried within an asymmetric microenvironment; the NH signal in the ^{1}H-NMR spectrum of this diastereomer is shifted upfield ($\delta = 3.5$ in $CDCl_3$), indicating shielding by the aromatic surface. From (*S*)-phenethylamine the diastereomer **6b** was obtained.

Fig. 1. X-ray crystal structure of **6a** [8].

Initially, the test enolate **8a** described by *Hünig* et al.[2] in which the enolate geometry is fixed by means of a cyclic arrangement was protonated. An enantiomeric excess (*ee*) of up to 53% had been observed with the α-hydroxycarbonyl compound **2b**. The relatively weak basicity of **8a** and the weak acidity of the dilactams **6** led to unreproducible results.[9] However, a series of alkyl substituted enolates, **8b**–**8f**, were successfully protonated (Table 1).



8 **9**

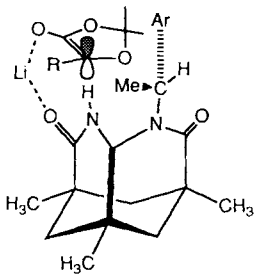
a, R = Ph; **b**, R = Me; **c**, R = Et; **d**, R = *n*Bu; **e**, R = *i*Pr; **f**, R = *t*Bu; **g**, R = Bn

In relating the stereochemistry of the product to the shape of the dilactam, a reasonable transition structure, **10**, can be proposed. The lithium is likely to be chelated between the two oxygens in the structure shown, and the second point of contact is at the proton to be transferred. Finally, steric interactions in **10** were also significant:[11] Larger groups R remain outside of the cavity, with selectivity according to their sizes; small groups, e.g. **8b**, show negligible preference. These considerations lead to the absolute stereochemistry observed for the products **9**.

Table 1. Asymmetric protonation of the enolates **8** with **6a** and **6b**.

Enolate	Proton source	*ee* [%] [a]/ Configuration [b]
8a	**6a**	0
8b	**6a**	9/(*R*)
8c	**6a**	28/(*S*)
8d	**6a**	33/(*S*)
8e	**6a**	76/(*S*)
8f	**6a**	91/(*S*)
8f	**6b**	72/(*R*)
8g	**6a**	50/(*S*)

[a] Determined by ^{1}H-NMR spectroscopy with (*S*)-1-(9-anthryl)-2,2,2-trifluoroethanol as the chiral shift reagent [10]. [b] Determined by polarimetry on **9**; cf T. Polonski, *Tetrahedron 39* (1983) 3131.



10

Experimental

In a typical experiment, the dioxolanone [12] (1 mmol) was added to a solution of lithium diisopropylamide (1.3–1.5 mmol) in THF (5 mL) at −78 °C. After the reaction mixture had been stirred for 20 min (−78 °C to −30 °C), the solution was cooled to −78 °C and transferred to a flask containing a suspension of the dilactam (1.7–7.8 mmol) in THF (5 mL) at −78 °C. After 10 min, the reaction mixture was allowed to warm to room temperature. It was then treated with 10 mL of CH_2Cl_2 and 3 mL of saturated NH_4Cl solution. The organic layer was washed with HCl (10%) and saturated $NaHCO_3$ solution, and dried over $MgSO_4$. After concentration, the dilactam was precipitated by addition of pentane (1 mL) and the supernatant solution was evaporated and the products **9** were distilled (yield > 80%).

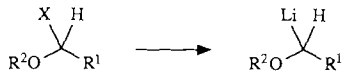
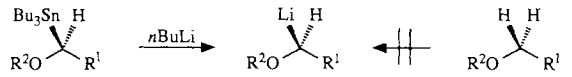
Chiral Lithium-1-oxyalkanides by Asymmetric Deprotonation; Enantioselective Synthesis of 2-Hydroxyalkanoic Acids and Secondary Alkanols**

By *Dieter Hoppe,* Folker Hintze*, and *Petra Tebben*

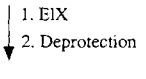
α-Lithiated ethers **4a** and acetals **4b** are of great preparative importance as umpoled synthetic building blocks[1] for the nucleophilic introduction of 1-oxyalkyl groups. As long as R^1 is not a stabilizing group like aryl, 1-alkenyl or 1-alkynyl, the lithium compounds **4** cannot be generated by simple deprotonation of **3** at low temperature. The reagents **4a** or **4b** are therefore prepared, in general, by transmetalation[3] of the stannanes **1** or by reductive cleavage of the monothioacetals **2**.[4] Some racemic α-lithioalkyl benzoates with sterically shielded carbonyl groups, such as **4c**, were generated by deprotonation;[5] however, the subsequent cleavage of the aroyl group presents difficulties.



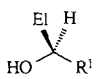
1, X = $SnBu_3$
2, X = SAr
3, X = H



(*S*)-**1** (*S*)-**4** **3**

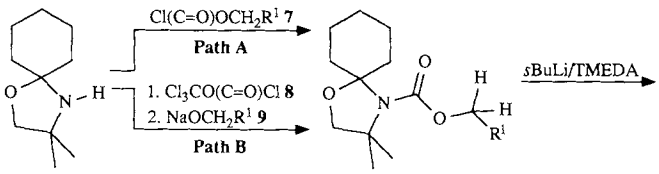


R^1 = Alkyl
a, R^2 = Alkyl
b, R^2 = 1-Alkoxyalkyl
c, R^2 = (2,4,6-*i*Pr)$_3$$C_6H_2C(=O)$

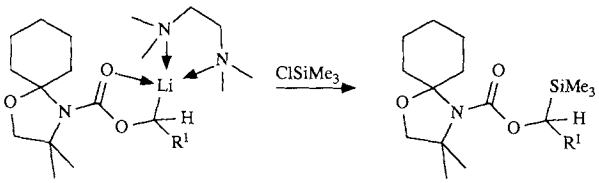


(*R*)- or (*S*)-**5**

The lithiodestannylation of (*S*)-**1** and subsequent electrophilic substitutions to (*R*)- or (*S*)-**5** proceed with retention of configuration,[6] i.e. the intermediate (*S*)-**4** is configurationally stable. The required non-racemic stannanes (*R*)- or (*S*)-**1** were obtained by optical resolution,[6a, b] asymmetric reduction of acylstannanes,[6d, e] or oxidation of α-trialkylstannyl boronates.[6f] We now report on the hitherto simplest entry to chiral synthetic building blocks of type **3**; it comprises an enantiotopically differentiating deprotonation of the precursor **3** in the presence of (-)sparteine[7] and is made possible by a protecting group R^2 of the carbamate type[9], which activates through chelate and dipole stabilization and which is cleavable under mild conditions.[8] We obtained the carbamates **10**[10] from the spirocyclic oxazolidine[11] **6** by acylation with the corresponding alkoxycarbonyl chlorides **7** (route A) or via the carbamoyl chloride (ClC=O for H in **6**) and reaction with sodium alkoxides **9** (route B) in yields of 87 to 95%. Treatment of the esters **10** with *sec*-butyllithium in ether/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) at −78 °C leads to the persistent lithium compounds *rac*-**11** · TMEDA, which were trapped as silanes[9] *rac*-**12** (Table 1).



6 **10**



rac-**11**•TMEDA *rac*-**12**

Experimental

A solution of 2.8 mmol of *s*BuLi (in cyclohexane/isopentane) in 8 mL of ether was cooled to −78 °C and treated with 2.9 mmol of (−)-sparteine, (−)-**13**. After 10 minutes' stirring and injection of a solution of 2.0 mmol of the carbamate **10** in 2 mL ether, the mixture was stirred for 5–6 h at −78 °C. After introduction of carbon dioxide (excess) into the solution of (*S*)-**11** · (−)-**13** (for the synthesis of **14**) or addition of 3.5 mmol of trimethyltin chloride or methyl iodide (for the synthesis of **15** or **16**), the reaction mixture was stirred for 16 h at −78 °C. Work-up was carried out as usual with 10 mL of ether/10 mL of 2N HCl, and the crude product was purified by flash chromatography on silica gel with ether/pentane mixtures. The racemates *rac*-**11** · TMEDA were generated in the same way, but with 2.9 mmol of TMEDA instead of (−)-sparteine.

For cleavage of the *Cbx* group a solution of 2 mmol of **16** in 10 mL of methanol was heated under reflux with 0.1 mL of methanesulfonic acid for 16 h. Finally, 1.0 g of $Ba(OH)_2 \cdot 8H_2O$ was added to the mixture, which was heated under reflux for a further 4 h before workup in the usual way in aqueous medium and purification of the crude product on silica gel by flash chromatography.

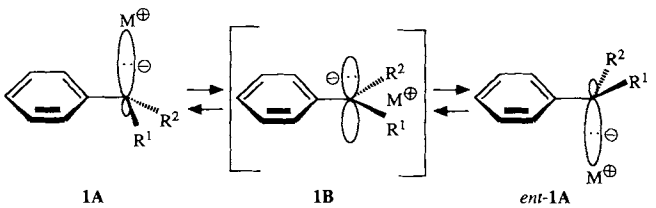
Generation of a Configurationally Stable Chiral Benzyllithium Derivative, and the Capricious Stereochemistry of Its Electrophilic Substitution**

By *Dieter Hoppe,** *Axel Carstens*, and *Thomas Krämer*

Dedicated to Professor Jürgen Bestmann on the occasion of his 65th birthday

Chiral benzyl alkali metal derivatives **1A** undergo rapid racemization in solution via an ion pair **1B** with planar configurated carbanion; hence, the chiral information of the optically active precursor is generally lost during its generation.[1] Some α-sulfonylbenzyl anions constitute an exception.[2]



1A **1B** *ent*-**1A**

Short-lived benzyl anions have been trapped in situ with high enantiomeric excesses by deprotonation/reprotonation of optically active phenyl alkanes[1] as well as in the Haller-Bauer cleavage of tertiary benzyl phenyl ketones.[3] Chiral α-oxybenzyl anions are trapped as short-lived intermediates in the Brook[4] and reverse Brook rearrangement.[5]

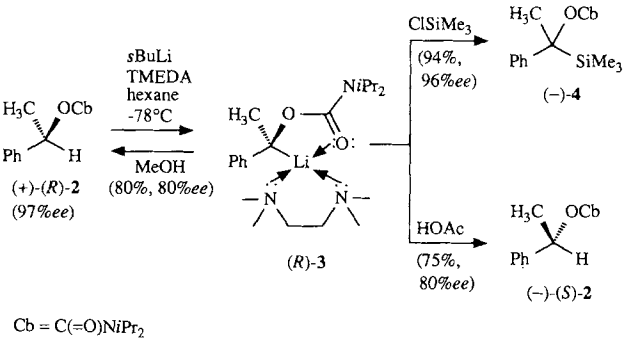
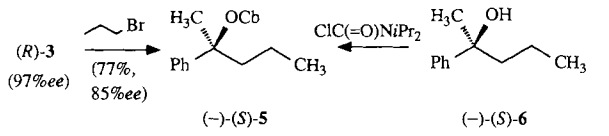
Although non-racemic, heterosubstituted benzyllithium derivatives, e.g. carbanions derived from tetrahydroisoquinolines,[6,7] play an important role in enantioselective synthesis, knowledge of the stereochemical course of their electrophilic substitution is very limited. The reason for this is that the extent to which the chiral auxiliary influences the properties of the carbanionic center is unknown.[8] We now report on the generation of an enantiomerically enriched benzyllithium derivative which is practically configurationally stable at low temperatures, and which, like some allyllithium derivatives synthesized by us,[9] is free of such complications. Furthermore, we have investigated the stereochemistry of some important substitution reactions.

The *N*,*N*-diisopropyl carbamate[10,11] (*R*)-**2**, obtained from (*R*)-1-phenylethanol[12] (97% *ee*[13]), was deprotonated with *sec*-butyllithium/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) in hexane below −70 °C,[14] and after 30 min the intermediary lithium alkanide (*R*)-**3**[15,16] was trapped with chlorotrimethylsilane. The silane (−)-**4**[17] of unknown absolute configuration was obtained with 96% *ee*.[18] This means that maximally 1% racemization occurs over the two reaction steps. Protonation of (*R*)-**3** with methanol leads to the initial carbamate (*R*)-**2** again, whereas with acetic acid inversion takes place with formation of (*S*)-**2**.

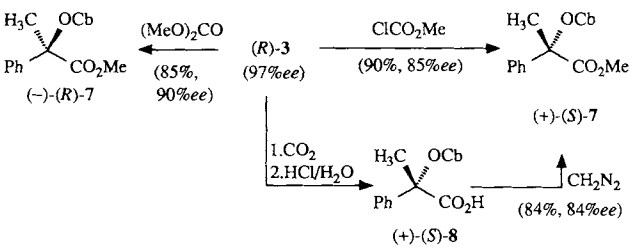


Cb = C(=O)N*i*Pr$_2$

The alkylation of (*R*)-**3** with *n*-propyl bromide proceeds with retention of the configuration; the tertiary carbamate[17,18] (−)-(*S*)-**5** was correlated stereochemically with the known carbinol (−)-(*S*)-**6**.[19]



(*R*)-**3** reacts with dimethyl carbonate with retention of configuration, but with methoxycarbonyl chloride with inversion, to give the methyl ester[17,18] (−)-(*R*)-**7**[20] and (+)-(*S*)-**7**, respectively. Surprisingly, carbon dioxide like-



wise adds with inversion and furnishes the acid (+)-(*S*)-**8**; normally, the carboxylation of alkyllithium compounds proceeds with retention.[21]

A particularly unexpected result was that of the stannylation-lithiodestannylation sequence starting from (*R*)-**3**: it leads via (+)-(*R*)-**9**[17, 22] to the lithium compound (*S*)-**3** (detected by trapping with dimethyl carbonate as (+)-(*S*)-**7** or with chlorotrimethylstannane as (−)-(*S*)-**9**); i.e. one of the two reaction steps proceeds with inversion, the other with retention.

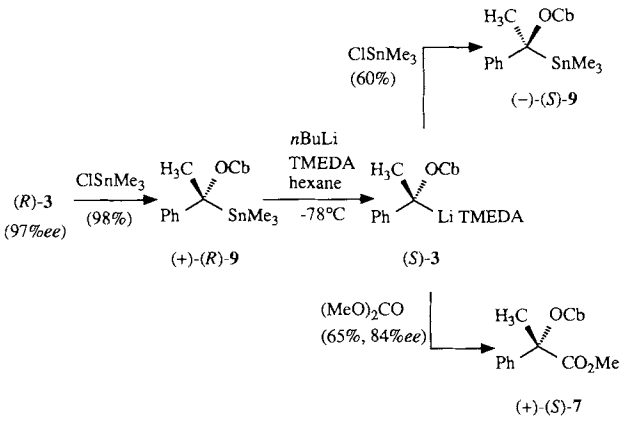


Table 1. Selected physical data of the new compounds **2**–**9**.

(*R*)-**2**: colorless oil; 97% *ee*; $[\alpha]_D^{20}$ + 5.1 (CH_2Cl_2, *c* = 1.2); ^{1}H NMR ($CDCl_3$): δ = 1.20 [d, *J* = 6.8 Hz, NCH(CH_3)$_2$], 1.55 (d, *J* = 6.6 Hz, 1-CH_3), 3.94 (m, NCH), 5.85 (q, 1-H), 7.22–7.44 (m, Ph)

(−)-**4**: colorless oil; 96% *ee*; $[\alpha]_D^{20}$ = − 17.3 (CH_2Cl_2, *c* = 1.0); ^{1}H NMR ($CDCl_3$): δ = 0.01 [s, Si(CH_3)$_3$], 1.24 [m, NCH(CH_3)$_2$], 1.90 (s, 1-CH_3), 3.93 (m, NCH), 7.07–7.30 (m, Ph)

(*S*)-**5**: colorless oil; 85% *ee*; $[\alpha]_D^{20}$ − 29.9 (CH_2Cl_2, *c* = 1.2); ^{1}H NMR ($CDCl_3$): δ = 0.87 (t, $J_{3,4}$ = 7.2 Hz, 4-CH_3), 1.15–1.32 [m, NCH(CH_3)$_2$ 3-H_2), 1.84 (s, 1-CH_3), 1.85–2.14 (m, 2-H_2), 3.77 and 4.04 (each m, NCH), 7.16–7.37 (m, Ph)

(*R*)-**7**: colorless crystals; m.p. 80 °C (ether/pentane); 90% *ee*; $[\alpha]_D^{20}$ −7.5 (CH_2Cl_2, *c* = 1.04); ^{1}H NMR ($CDCl_3$): δ = 1.28 [d, *J* = 6.6 Hz, NCH(CH_3)$_2$], 1.98 (s, 1-CH_3), 3.69 (s, OCH_3), 3.93 (m, NCH), 7.23–7.52 (m, Ph)

(*S*)-**7**: 85% *ee*; $[\alpha]_D^{20}$ + 6.9 (CH_2Cl_2, *c* = 1.05)

(*R*)-**9**: colorless crystals; m.p. 68 °C (ether/pentane); $[\alpha]_D^{20}$ +76.3 (CH_2Cl_2, *c* = 1.0); ^{1}H NMR ($CDCl_3$): δ = − 0.03 [s, Sn(CH_3)$_3$], 1.25 [m, NCH(CH_3)$_2$], 1.83 (s, 1-CH_3), 3.79 and 4.17 (each m, NCH), 7.05–7.34 (m, Ph)

Our experimental findings confirm the theoretical predictions of *Schleyer* et al.,[26] according to which the activation energies of front-side and back-side attack lie close to each another. Apparently the extent of the interaction of electrofugal and nucleofugal leaving groups as well as steric effects have a decisive influence thereby on the competing reaction paths. The energy difference between the two reaction channels could shrink further, and the antarafacial attack gain more significance by the mesomeric flattening of the carbanionic center in the benzyl position.[27] Besides insights into the course of electrophilic substitution reactions which chiral α-oxybenzyllithium of type **3** provides, they also facilitate principally new routes for the enantioselective synthesis of tertiary benzyl alcohols. In the preceding communication we report on a carbamoyl group cleavable under mild conditions.[24]

[14] A solution of (*R*)-**2** (1 mmol) and TMEDA (1.1 mmol) in hexane (2 mL) was treated dropwise at −78 °C with a ca. 1.4 M solution of *sec*-butyllithium (1.1 mmol) in cyclohexane/isopentane and the mixture stirred for 30 min at this temperature. The resulting yellow solution of (*R*)-**3** was treated at −78 °C with 1.1 mmol of the electrophile, stirred for 30 min, allowed to warm to room temperature, neutralized with 2 mL of 2N HCl, and extracted three times with ether. Purification was performed by flash chromatography on silica gel with ether/pentane (1:4 to 1:8).
[15] We assign the lithium compound **3** the (*R*)-configuration, since we assume a deprotonation with retention of configuration. Although this assumption is plausible [9a] and finds theoretical support [16], it has to our knowledge, never been proven, since the absolute configuration of the trapping product was always determined and not that of the organometallic intermediate. For simplification an equilibrium of monomeric **3** with dimeric or tetrameric aggregates has not been taken into consideration; cf. references cited in [27].

[22] The (*R*)-configuration of the stannane (+)-**9** is not strictly confirmed; it follows from the observed rotation using Brewsters rule [23]. In the sequence (+)-**9** → (*S*)-**3** → (−)-**9** only one of the two steps can proceed with inversion, and according to the derived assignment of configuration it must be the delithiostannylation. This is also supported by the fact that retention has always been established for lithiodestannylations of α-oxyalkylstannanes [24, 25].

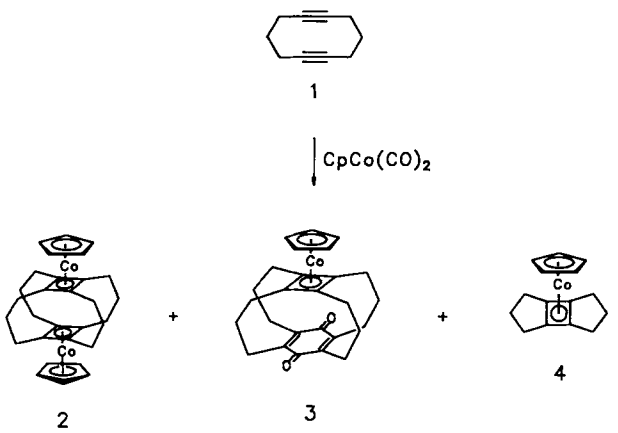
Building Up Metal-Stabilized Fourfold Bridged Cyclobutadienophanes**

By *Rolf Gleiter** and *Volker Schehlmann*

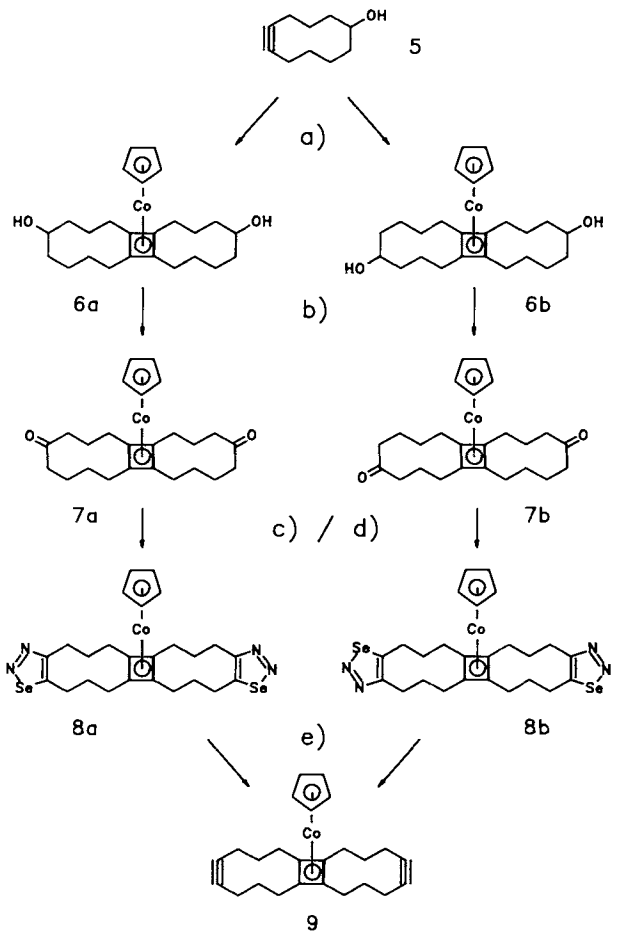
The metal-induced [2+2] and [2+2+2] cycloaddition of two or three triple bonds is a very important method of synthesizing metal-stabilized cyclobutadienes,[1] benzenes[2] or 6π-heterocycles.[3] Using α,ω-diynes provides access to bicyclic aromatic systems.[2] A reaction between cyclic diynes and $[CpCoL_2]$ yields tricyclic cyclobutadiene complexes or, in one case, a fourfold bridged cyclophane of cyclobutadiene, capped by a CpCo unit on each side. Thus, while such a superphane (**2**) occurred as major product (together with **3** and **4**) when cyclodeca-1,6-diyne, **1**, was heated with $[CpCo(CO)_2]$,[4, 5a] no analogue could be detected when other medium-sized cyclic diynes were used.[5b, 6] We report here a new concept in the superphane synthesis based on a construction principle that uses masked cycloalkynes as building blocks.[6]



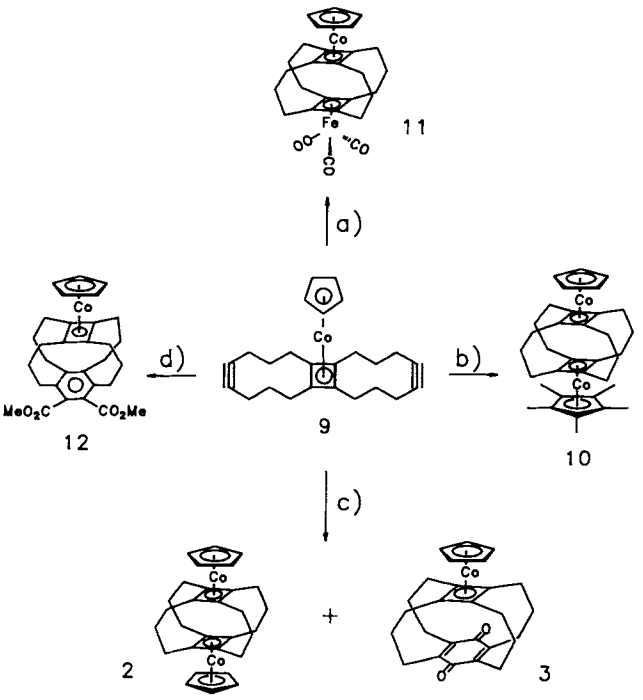
The starting point for our synthesis is 5-cyclodecynol **5**.[7] It can be transformed into a mixture of tricyclic cyclobutadiene complexes **6** in 40% yield by heating a very dilute solution in decalin with [CpCo(cod)] at 150–160 °C (Scheme 1). The alcohols **6** are oxidized to the isomeric ketones **7a** and **7b** in 83% yield via an Oppenauer oxidation with acetone. The isomers may be separated on silicagel using CH_2Cl_2 as eluent (Table 1). The structure of **7b** was determined by X-ray analysis.[8]

In the next step the mixture of diketones is transformed into the bisselena-diazoles **8a** and **8b** via a method first devised by *Lalezari* et al.[9] Without further purification the mixture **8a/8b** is treated with *n*BuLi at −40 °C to give the diyne **9** (Table 1, X-ray analysis[8]) in 70% yield. The reaction shown in Scheme 1 allows the preparation of 1–2 g of **9** in one synthetic run.

Scheme 2 shows that diyne **9** is the key compound in the synthesis of several metal-protected fourfold bridged cyclobutadienophanes. When **9** is heated in cyclooctane with $[CpCo(CO)_2]$ the superphane **2** is obtained in 80% yield. This reaction occurs relatively fast; this supports our earlier



Scheme 1: a) [CpCo(cod)], decalin, 150–160 °C, high dilution, 7 d; b) Oppenauer oxidation, acetone/toluene, $Al(OiPr)_3$, 14 h reflux; c) Semicarbazide · HOAc, ethanol, 45 min. reflux; d) SeO_2, CH_3COOH, 4–5 h, 30–40 °C; e) BuLi, THF, −40 °C.



Scheme 2: a) $Fe(CO)_5$, toluene, 18 h reflux; b) $[Cp^*Co(CO)_2]$, decalin, 150–160 °C, 24 h; c) $[CpCo(CO)_2]$, cyclooctane, 2 h reflux; d) $[CpCo(CO)_2]$, DMAD, toluene, 24 h reflux.

12: m.p. 175–179 °C; ^{1}H NMR (300 MHz, C_6D_6): δ = 4.38 (s, 5H), 3.50 (s, 6H), 3.06–3.19 (m, 2H), 2.79–2.88 (m, 2H), 2.52–2.62 (m, 2H), 2.26–2.43 (m, 4H), 2.06–2.11 (m, 4H), 1.66–1.99 (m, 10H); ^{13}C NMR (75.46 MHz, C_6D_6): δ = 169.9(s), 141.2(s), 135.6(s), 130.2(s), 80.5 (d, Cp), 80.4(s), 77.8(s), 51.8(q), 27.9(t), 26.8(t), 26.2(t), 24.9(t), 23.4(t), 22.1(t); IR ($CDCl_3$): $\tilde{\nu}$ [cm^{-1}] = 2928, 2848, 1737, 1707, 1432, 1266, 1220, 1195, 1177; MS (70 eV): *m/z* 530(35%), 249(27), 165(25), 153(20), 141(29), 128(36), 124(65), 115(41), 104(20), 91(56), 77(30), 65(21), 59(100), 55(34), 44(50), 41(38); UV (CH_3CN): λ_{max} [nm] (lgε) = 196(4.15), 266(4.06), 294(3.25).

assumption that **9** is an intermediate in the reaction **1** → **2**.[4] As a side product of this reaction we isolated the donor-acceptor-phane **3**[5] (1% yield). The reaction with [Cp*Co-$(CO)_2$][10] in decalin at 150–160 °C yields **10** (84%) and heating **9** with $Fe(CO)_5$ in toluene[11] leads to **11** (8%). Compound **11** is related to the recently synthesized [2,2](1,3)cyclobutadienophane which is capped with an $Fe(CO)_3$ unit on each side.[12] The structure of **11** has been confirmed by an X-ray study on single crystals.[8] Finally, heating with dimethylacetylenedicarboxylate (DMAD) and $[CpCo(CO)_2]$ gives the mixed cyclophane **12** in 5% yield.

Calculations using the AM1 method[14] on a model of **9** which does not contain the CpCo unit but allows minimization of all geometrical parameters[13] of the remaining hydrocarbon reproduces the molecular parameters calculated in the X-ray studies for the hydrocarbon unit very well. Besides the global minimum **A**, in which the acetylene units are 6.3 Å apart, the calculations predict two local minima, **B** and **C**, in which the triple bonds are separated by 3.9 and 4.6 Å, respectively (Scheme 3).

The calculated energy difference between **A** and **C** is 8.3 kcal mol^{-1} and between **A** and **B** 10.0 kcal mol^{-1}.

	B	A	C
d [Å]	3.9	6.3	4.6
$E_{rel.}$ [kcal mol^{-1}]	10.0	0.0	8.3

Scheme 3.

Doubly Bridged Prismanes, Dewar Benzenes and Benzene Derivatives from Cyclooctyne and 1,8-Cyclotetradecadiyne: En Route to Propella[n_3]prismanes**

By *Rolf Gleiter** and *Björn Treptow*

Starting from 1,6-cyclodecadiyne we recently synthesized propella[3_4]prismane **1**.[1] En route to the homologous propella[n_3]prismane **2** we have now succeeded in the synthesis of **3** and **4**, each with two of the three methylene bridges. To

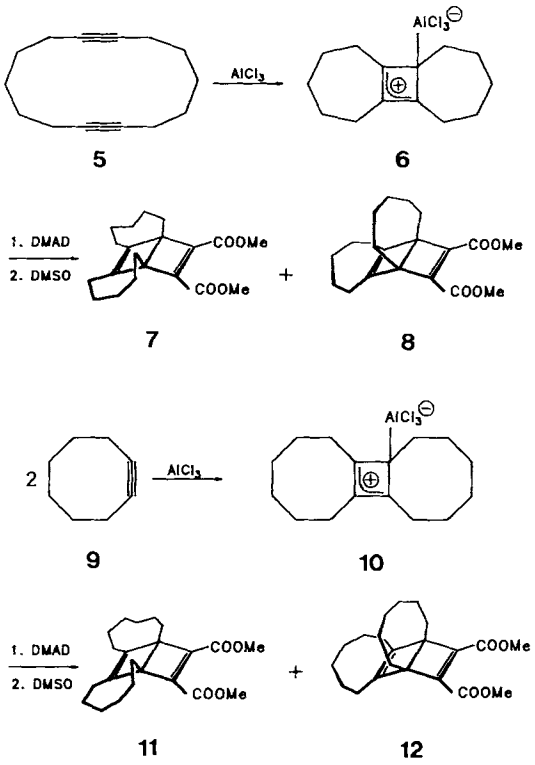
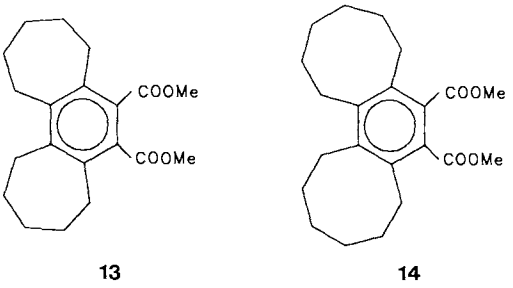
our knowledge these are the first doubly bridged prismane derivatives.

As starting material we chose for **3** 1,8-cyclotetradecadiyne[2] **5** and for **4** cyclooctyne **9**.[3] The reaction with $AlCl_3$ in CH_2Cl_2 yields, as expected, the cyclobutadiene–$AlCl_3$ σ-complexes **6** and **10**, respectively. Addition of dimethyl acetylenedicarboxylate (DMAD) and dimethyl sulfoxide (DMSO) results in the formation of the two isomeric doubly bridged Dewar benzene derivatives **7**, **8** and **11**, **12**, respectively, as shown in Scheme 1.

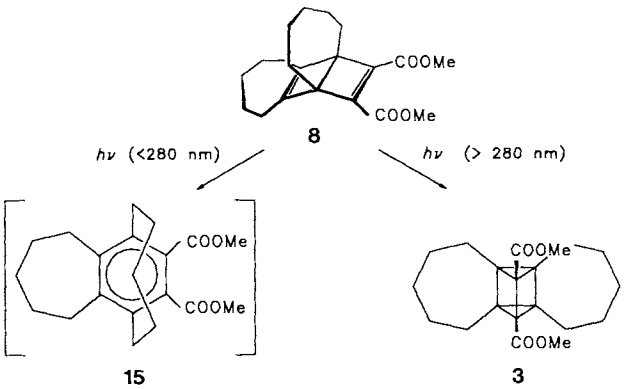


Scheme 1.

This route to Dewar benzenes was discovered in 1971[4], and the reaction has been thoroughly studied since then.[5] *Hogeveen* and et al. only briefly mentioned the reaction leading to the Dewar benzenes **7** and **8**.[5] If the reaction is carried out at low temperature (−50 °C) the addition of DMSO is necessary to release the cyclobutadiene,[6, 7] which now reacts in a Diels–Alder reaction with DMAD to form a 1:1 mixture of the isomeric products. At higher temperatures (0° to 10 °C) this ratio is shifted to 3:7 in favor of **8** and **12**, respectively. Separation of the isomeric Dewar benzenes by column chromatography is difficult and tedious. The Dewar-benzene isomers are characterized by NMR spectroscopy as follows (cf. Table 1): in the ^{13}C-NMR spectra of **7** and **8** with the pentamethylene chains we observe six methylene signals for **8**, two of them with lower intensity and five signals for **7**, all of them showing equal intensity. The characterization of **11** and **12** is more difficult and can only be achieved via the corresponding aromatic isomers **14** and **16**, which show different dynamic behaviors. Compound **14** shows the expected sharp ^{13}C-NMR signals. In **16**, however, the signals for the benzene ring and the *para* methylene chain exhibit considerable line broadening due to bridge flipping. This phenomenon is typical for [6]paracyclophanes and was thoroughly studied by *Tochtermann* and co-workers.[8] A low-temperature ^1H-NMR spectrum (253 K) of **16** reveals two signals at $\delta = -0.51$ and -0.75. They are assigned to the central protons of the *para* bridge, which point towards the aromatic ring. These resonances are in good agreement with those found for similar systems.[8] The assignment is also supported by the UV spectrum, which shows a bathochromic shift of about 30 nm relative to the transitions for the flat systems **13** and **14**. This shift is characteristic for a bent aromatic system[9]



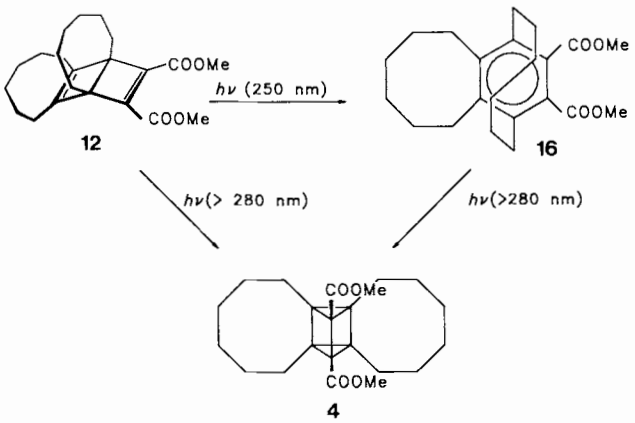
Irradiation[11] of **7** and **11** either at 250 nm or 300 nm leads quantitatively to the aromatic isomers **13** and **14**,[10] whereas irradiation[11] of **8** at 250 nm yields only polymeric material. We suggest that the corresponding [5]paracyclophane **15** is formed but decomposes immediately, because these compounds are unstable at temperatures above 0 °C.[12] The prismane **3** is isolated in 15% yield after 72 h when **8** is irradiated at 280 nm[11] (Scheme 2). Longer irradiation leads only to polymeric by-products and does not increase the yield.



Scheme 2.

When **12** is irradiated[11] at 250 nm a rapid isomerization (100% after 1 h) to the [6]paracyclophane **16** takes place;[13] increasing the wavelength to 280 nm leads to prismane **4** (30% after 24 h).[13, 14] Monitoring by ^1H-NMR spectroscopy shows that at first a major part of **12** is transformed into the [6]paracyclophane **16** while the formation of the prismane commences slowly. A solution of **16** irradiated under similar conditions also led to the prismane[15] (Scheme 3).

There are two possible explanations for this behavior. First our prismanes may not be generated directly from the Dewar benzenes but via the paracyclophanes. This would also explain the unexpectedly low yield of prismane **3**, because the intermediate [5]paracyclophane **15** partly decomposes before it can react to the corresponding prismane. Second a photochemical equilibrium may exist between



Scheme 3.

Dewar benzene and paracyclophane, both of which can isomerize to the corresponding prismane. We are continuing our irradiation experiments to clarify the kinetics of the process.

The prismanes **3** and **4** can easily be characterized by ^{13}C-NMR spectroscopy. A change from a Dewar benzene or a paracyclophane to a prismane creates a second plane of symmetry and thus reduces the number of ^{13}C signals. For both prismanes we observe one low field resonance assigned to the carboxyl groups and six further signals below $\delta = 60$ belonging to the core and the methylene chains (Table 1).

Table 1. Important spectroscopic data of **3, 4, 7, 8, 11–14**, and **16**.

Spontaneous Formation of Stable Phosphino(silyl)-carbenes from Unstable Diazo Compounds

By *Gregory R. Gillette, Antoine Baceiredo*, and *Guy Bertrand**

The ability of transition metals to stabilize electron-deficient species such as carbenes, nitrenes, and phosphinidenes is now well established. More seldomly, it has been shown that a similar role could be played by heavier main group elements.[1] We previously utilized this property in the synthesis of the first stable compound featuring all the characteristic reactions of simple carbenes, i.e. cyclopropanation, carbon-hydrogen insertion and carbene-carbene coupling.[2] However, the preparation of this species, namely the [bis(diisopropylamino)phosphanyl](trimethylsilyl)carbene **1b**, was rather tricky due to the drastic conditions used (250 °C under 10^{-2} torr) and to the narrow utilizable temperature range: below 240 °C the starting diazo **1a** is not decomposed and above 260 °C the carbene inserted into a C–H bond of a diisopropylamino substituent affording heterocycle **1c**. As a result of efforts to extend the chemistry of these carbene-like derivatives, we now report the surprisingly facile synthesis of new stable compounds of this type.

Several phosphinodiazomethanes[3] have previously been studied, but until now only the combination of two

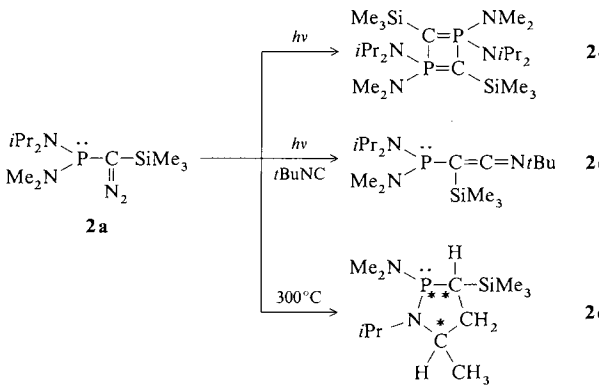
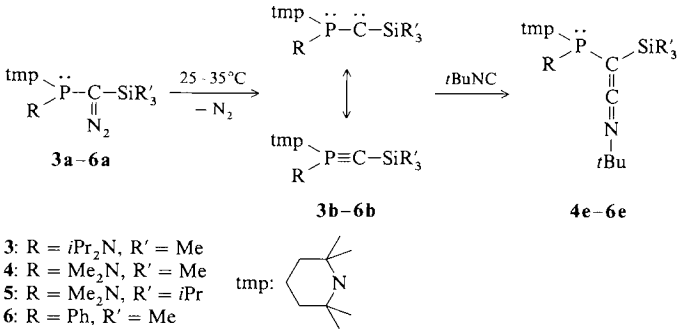
diisopropylamino substituents at phosphorus and a trimethylsilyl group at carbon led to a stable "carbene" after elimination of N_2.[2] It was of interest to know to what extent we could vary the nature of the substituents while retaining the kinetic stabilization of the carbene. We first chose to replace one of the diisopropylamino groups by a dimethylamino group. The diazo derivative **2a** was easily available from the lithium salt of the trimethylsilyldiazomethane[4] and the corresponding phosphorus chloride.[5] Photolysis of **2a** did not lead to the desired carbene but to its [2+2] cyclic dimer **2d** (involving its λ^5-phosphaacetylene form) as had already been observed by *Regitz* et al. for the bis(dimethylamino) analogue.[3d] However, the carbene-like nature of the intermediate was confirmed by a trapping experiment with *tert*-butylisocyanide, affording ketenimine **2e**. Diazo **2a** is stable up to 250 °C under vacuum, while thermolysis at 300 °C under 10^{-2} torr gave rise to a mixture of five-membered ring diastereoisomers **2c**, formally resulting from a CH insertion of the carbene.



From these results the influence of the steric hindrance was obvious and thus we attempted to synthesize the [diisopropylamino(2,2,6,6-tetramethylpiperidino)phosphino](trimethylsilyl)diazomethane **3a** by the usual procedure. Surprisingly, after work-up we isolated the "carbene" **3b** in near quantitative yield. It appeared that the diazo compound **3a** was only stable for a short time at room temperature but could be spectroscopically characterized in solution. In marked contrast, "carbene" **3b** was perfectly stable for weeks in solution at room temperature, but appeared to be very poorly reactive (it did not react with *tert*-butylisocyanide).

A good compromise was found using both tetramethylpiperidino- and dimethylamino-substituents at phosphorus. In this case, we have i) a diazo compound **4a** which decomposed over a few days at room temperature or after 1 hour at 35 °C; ii) a "carbene" **4b**, stable for weeks at room temperature but also quite reactive, as demonstrated by its immediate reaction with *tert*-butylisocyanide at 20 °C to give **4e**. In other words, **4a** allows straightforward access to multi-gram quantities of a synthetically useful "carbene".

The generality of the influence of the tetramethylpiperidino group on the decomposition temperature of the diazo and on the stability of the "carbene" is shown by the results obtained with compounds **5** and **6**. No dramatic change was



3: R = iPr$_2$N, R′ = Me
4: R = Me$_2$N, R′ = Me
5: R = Me$_2$N, R′ = iPr
6: R = Ph, R′ = Me

observed when the trimethylsilyl was replaced by a triisopropylsilyl group except for a decrease in reactivity of the carbene: reaction of **5b** with *t*BuNC required two days at room temperature. **6b** is of special interest since it is the first example of a relatively stable "carbene" (one day at room temperature, but weeks at −20 °C) with only one amino group at phosphorus.

All the carbenes are easily characterized by multinuclear NMR spectroscopy (Table 1). The most striking features are

[a] **2b** was not characterized. [b] **3b** does not react with *t*BuNC.

certainly the high-field chemical shift in ^{31}P (δ = −24.1 to −49.7), and in ^{29}Si (δ = −2.8 to −21.3), the low-field ^{13}C resonances (δ = 120.7 to 145.5), and the large $^1J_{PC}$ (147 to 203 Hz) and $^2J_{PSi}$ (27 to 70 Hz) coupling constants.

In summary, given the right set of substituents, it appears that phosphino(silyl)carbenes can be more "stable" than their corresponding diazo precursors!

Experimental

In a typical experiment, 4.72 mL of a solution of 1.6 M *n*BuLi in hexane (7.6 mmol) was added to a THF solution (10 mL) of trimethylsilyldiazomethane (0.86 g, 7.6 mmol), at −78 °C. The mixture was stirred, at −78 °C for 30 min, then chlorodimethylamino(2,2,6,6-tetramethylpiperidino)phosphane (1.92 g, 7.6 mmol) was added neat, via a syringe. The resulting solution was

slowly (3 h) warmed to room temperature and then the volatiles were removed in vacuo. Following treatment with pentane, filtration, and evaporation, 2.4 g (96%) of diazo **4a** was obtained. Carbene **4b** was prepared by heating a toluene solution (10 mL) of 2.4 g of diazo **4a**, at 35 °C for 1 h.

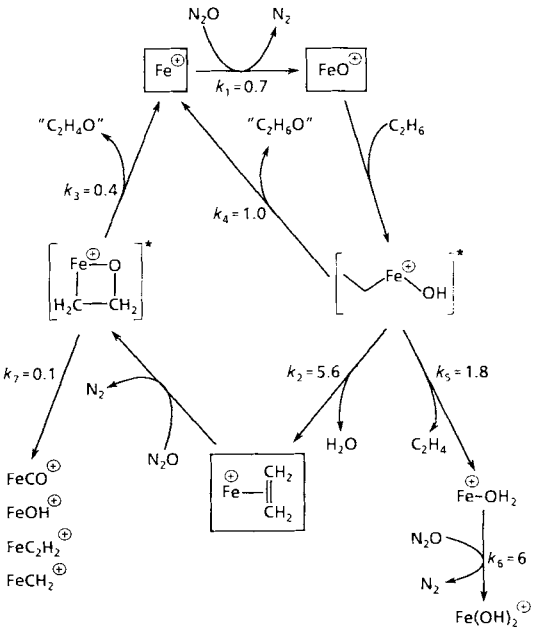

Scheme 1. Catalytic cycle for the $Fe^{\oplus}$-mediated oxidation of C_2H_6 by N_2O. The rate constants k_i, given in cm^3 molecule^{-1} s^{-1}, have to be multiplied by 10^{-10}.

$Fe^{\oplus}$-Catalyzed Gas-Phase Oxidation of Ethane by N_2O**

By *Detlef Schröder* and *Helmut Schwarz**

Dedicated to Professor Albert Eschenmoser on the occasion of his 65th birthday

Although thermodynamically favored, many oxidation reactions do not occur at room temperature unless the kinetic barriers are lowered by catalysts. This fact is a prerequisite for the origin and maintenance of life,[1] but it also poses an obstacle to the in vitro transformation of simple substrates to "more valuable" products.

Here we describe a model reaction in which oxidation of ethane by N_2O [Eq. (a)] is catalyzed by $Fe^{\oplus}$. Although the process is strongly exothermic ($\Delta H_r = -121$ kcal mol^{-1}), it does not occur in the absence of $Fe^{\oplus}$.

$$C_2H_6 + 2\,N_2O \rightarrow CH_3CHO + H_2O + 2\,N_2 \qquad (a)$$

The oxidation takes place in the gas phase and the individual steps of the $Fe^{\oplus}$-catalyzed cycle (Scheme 1) can be studied by Fourier transform ion cyclotron resonance (FT-ICR).[2]

The following observations were made concerning the individual reactions:

1. In the reaction of $FeO^{\oplus}$ with C_2H_6, already investigated by *Freiser* et al.,[7] the encounter complex $[FeO/C_2H_6]^{\oplus *}$ is not observed. Instead, the products of three reaction paths were found [Eq. (b)]. The corresponding rate constants k_i are given in Scheme 1. All processes are strongly exothermic.[8]

$$\begin{array}{lllll} FeO^{\oplus} + C_2H_6 & & & & \Delta H_r \\ \downarrow & & & & [\text{kcal mol}^{-1}] \\ & \xrightarrow{67\%} & Fe(C_2H_4)^{\oplus} + H_2O & -36 & \\ [FeO/C_2H_6]^{\oplus *} & \xrightarrow{21\%} & Fe(OH_2)^{\oplus} + C_2H_4 & -31 & (b) \\ & \xrightarrow{12\%} & Fe^{\oplus} + CH_3CH_2OH & -13 & \end{array}$$

A double resonance experiment demonstrates that $FeO^{\oplus}$ is the direct precursor of all products shown in Equation (b): irradiation at the resonance frequency of $FeO^{\oplus}$ results in suppression of the reactions. Collisional activation and labeling experiments provide indications of the structures of the $Fe(C_2H_4)^{\oplus}$ and $Fe(OH_2)^{\oplus}$ ions. The iron–hydrocarbon complex at m/z 84 specifically loses C_2H_4 upon collisional activation with argon; this finding is consistent with an Fe(ethylene)$^{\oplus}$ structure. The dominating reaction of the ion at m/z 74 with argon is loss of H_2O; in addition, ca. 10% loss of H$^{\bullet}$ or OH$^{\bullet}$ is observed. If, instead of an $Fe(OH_2)^{\oplus}$ complex, an $Fe(H)OH^{\oplus}$ structure were present, preferential H$^{\bullet}$ loss would be expected owing to the dissociation energies $D(M^{\oplus}\text{-}X)$ (X = H, OH).[9] Moreover, the thermochemical data favor the structure $Fe(OH_2)^{\oplus}$ over $Fe(H)OH^{\oplus}$ by more than 14 kcal mol^{-1}.[8] The role of $Fe(OH_2)^{\oplus}$ as a "sink" in the catalytic cycle will be discussed in greater detail later.

The encounter complex $(FeO/C_2H_6)^{\oplus *}$ presumably corresponds to $Fe(C_2H_5)OH^{\oplus *}$, as indicated by the product distribution obtained from the reaction of $FeO^{\oplus}$ with CH_3CD_3: decomposition of $(FeO/CH_3CD_3)^{\oplus *}$ yields almost exclusively HDO and $C_2H_2D_2$ as neutral molecules.

2. Reaction of "isolated" $Fe(C_2H_4)^{\oplus}$ with N_2O results in liberation of N_2 [Eq. (c)]. Since the liberated N_2 takes away

[*] Prof. Dr. H. Schwarz, Dipl.-Chem. D. Schröder

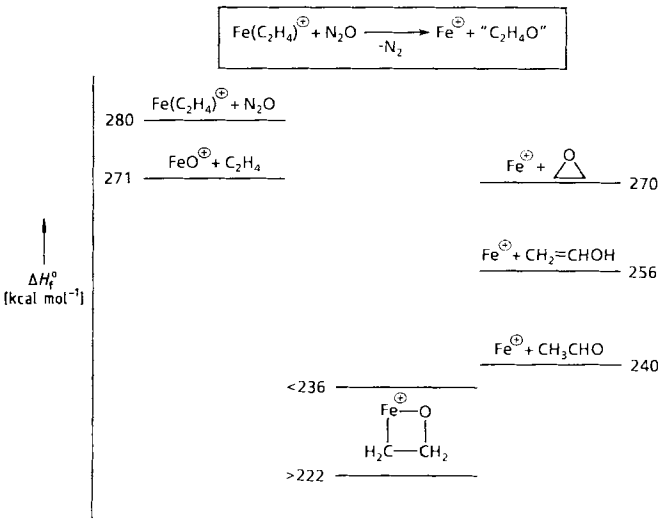
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der Technischen Universität Berlin.

part of the excitation energy as translational and vibrational energy, it is not surprising that a signal for $Fe(C_2H_4O)^{\oplus}$ is observable. However, the main products are $Fe^{\oplus}$ and "C_2H_4O". The two reactions account for 88% of the product distribution; the products corresponding to k_7 in Scheme 1 ($\Sigma < 12\%$) are formed in nearly equal amounts ($X = CO, OH, C_2H_2, CH_2$).

$$Fe(C_2H_4)^{\oplus} + N_2O \xrightarrow{-N_2} \begin{cases} \xrightarrow{16\%} Fe(C_2H_4O)^{\oplus} \\ \xrightarrow{72\%} Fe^{\oplus} + C_2H_4O \\ \xrightarrow{<12\%} FeX^{\oplus} \end{cases} \quad (c)$$

3. The ion $Fe(C_2H_4O)^{\oplus}$ is most likely a ferraoxacyclobutane, since, upon collisional activation, the "isolated" ion decomposes practically exclusively to $FeCH_2^{\oplus}/CH_2O$ and $Fe^{\oplus}/C_2H_4O$. The formation of $FeCH_2^{\oplus}$ would not be possible from either an $Fe(CH_3CHO)^{\oplus}$ or an $Fe(CH_2=CHOH)^{\oplus}$ complex. That the metallacycle does not decompose to $FeO^{\oplus}/C_2H_4$ upon collisonal activation is due to the product stability for the two other conceivable cycloreversions; $FeO^{\oplus}/C_2H_4$ is at least 20 kcal mol^{-1} less favorable than $FeCH_2^{\oplus}/CH_2O$.

4. The central question posed by the reaction $FeC_2H_4^{\oplus} + N_2O \rightarrow Fe^{\oplus} + C_2H_4O$ [Eq. (c)] concerns the constitution of "C_2H_4O". Chemically reasonable structures for the neutral compound include oxirane, vinyl alcohol, and acetaldehyde. As shown by Scheme 2, the formation of each



Scheme 2.

of the three isomers starting from $Fe(C_2H_4)^{\oplus}/N_2O$ would be exothermic. Since neutral species cannot be directly observed in ICR experiments, indirect evidence is necessary. Nonetheless, the appearance of a weak-intensity signal at m/z 43 ($CH_3CO^{\oplus}$) proves that, in the course of this reaction, oxygen must have been transferred to the C_2H_4 unit.

The enthalpy of formation ΔH_f° of the metallacycle $Fe(C_2H_4O)^{\oplus}$ can be estimated from the occurrence or absence of the ligand displacement reactions (d) and (e): $222 < \Delta H_f^{\circ}(FeC_2H_4O)^{\oplus} < 236$ kcal mol^{-1}.

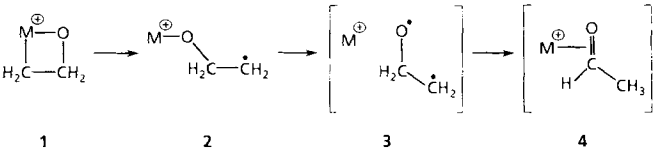
The observation of the metallacycle $Fe(C_2H_4O)^{\oplus}$ despite the strong exothermicity of the reaction [Eq. (c)] must be due to the fact that the simultaneously formed nitrogen carries

$$Fe(C_2H_4)^{\oplus} + H_2C\overset{O}{\diagup\diagdown}CH_2 \longrightarrow \begin{matrix} {}^{\oplus}Fe-O \\ | \quad | \\ H_2C-CH_2 \end{matrix} + C_2H_4 \quad (d)$$

$$Fe(butadiene)^{\oplus} + H_2C\overset{O}{\diagup\diagdown}CH_2 \dashrightarrow \begin{matrix} {}^{\oplus}Fe-O \\ | \quad | \\ H_2C-CH_2 \end{matrix} + C_4H_6 \quad (e)$$

away a considerable part of the energy as kinetic energy. This assumption is supported by the observation that an encounter complex is *not* detectable in the reaction $FeO^{\oplus} + C_2H_4 \rightarrow Fe(C_2H_4O)^{\oplus}$, although this process is 9 kcal mol^{-1} less exothermic; instead, only subsequently formed products are observed. If at least 9 kcal mol^{-1} of internal energy is transferred to N_2 as translational energy on formation of $Fe(C_2H_4O)^{\oplus}$ from $Fe(C_2H_4)^{\oplus}$ and N_2O, however, then oxirane is necessarily ruled out for thermochemical reasons as the oxidation product of C_2H_4. This supposition is supported by an independent experiment: $Fe^{\oplus}$, thermalized with argon ($p \approx 5 \times 10^{-8}$ mbar) for about 20 s, reacts with added oxirane to give, among other products, $FeO^{\oplus}$ and C_2H_4 (25%); this means that $Fe(C_2H_4)^{\oplus}/N_2O$ would react via $Fe^{\oplus}/C_2H_4O$ to give $FeO^{\oplus}/C_2H_4$ if C_2H_4O corresponded to oxirane. This is not observed in the experiment [Eq. (c)].

The decision in favor of acetaldehyde is facilitated by a "mechanistic criterion". *Armentrout, Beauchamp* et al.[6, 10] have indicated that the weakest bond in a metallacycle of type **1** is the metal–carbon bond. Cleavage of this bond could lead, via diverse ion/dipole complexes, to a "metal-bound" diradical **3** (Scheme 3). Experimental data and MO



1 2 3 4

Scheme 3.

calculations[11] indicate that a free diradical $\dot{O}CH_2\dot{C}H_2$ should isomerize to CH_3CHO. If this also holds true in the presence of $M^{\oplus}$, then complex **4** would be formed in the present case. It should be mentioned that the side product $Fe(CO)^{\oplus}$ (4%) in reaction (c) could be formed from **4** by reductive elemination of CH_4. The main path, however, would be loss of CH_3CHO and regeneration of $Fe^{\oplus}$, which, in turn, could initiate a new cycle. *Beyond any doubt, $Fe^{\oplus}$ functions as a catalyst in reaction (a).* From the rate constants given in Scheme 1, each $Fe^{\oplus}$ ion is estimated to convert about 2.5 molecules of C_2H_6. Where are the "sinks" that keep the turnover number so small? (1) The metallacycle **1** (M = Fe) not only decomposes to $Fe^{\oplus}$ and CH_3CHO with a rate constant of $k_3 = 0.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, but also affords other side products ($k_7 = 0.1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}); common to all is the loss of $Fe^{\oplus}$. (2) A strong sink is the reaction path with the rate constants k_5: $Fe(OH_2)^{\oplus}$ undergoes rapid further reaction with N_2O to give $Fe(OH)_2^{\oplus}$, which, however, only reacts with C_2H_6/N_2O at an unmeasurably slow rate; thus, $Fe(OH)_2^{\oplus}$ represents a dead end. It is noteworthy that $FeO^{\oplus}$ reacts with C_2H_6 whereas $Fe(OH)_2^{\oplus}$ reacts only sluggishly: although both iron-containing ions have a formal oxidation state of + 3, the oxidation state of the metal is not the only governing factor for an efficient activation.

Finally, the result of a further test should be mentioned. This test my be regarded as a measure of the reliability of the k_i values in Scheme 1 (which themselves were derived from the reaction of "isolated" intermediates). Use of the so-derived rate constants for determination of the time dependence of the ions $Fe^{\oplus}$, $FeO^{\oplus}$, $Fe(C_2H_4)^{\oplus}$, and $Fe(OH)_2^{\oplus}$ appearing in the catalytic cycle gives the data shown in Figure 1. Theory (solid line) and experiment are in good agreement in view of the known errors involved in FTICR intensity measurements. Comparison of theory with experiment reveals the following: (1) No noticeable excitation occurs on "isolation" of the intermediates. (2) Additional intermediates need not be considered in modeling the catalytic cycle.

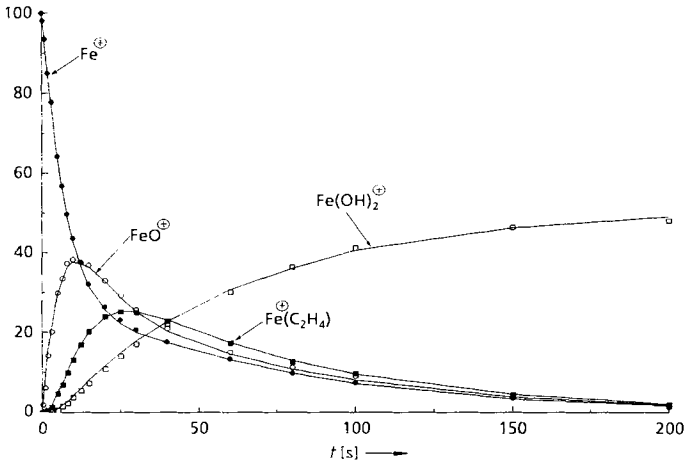


Fig. 1. Time dependence of ion abundance for $Fe^{\oplus}$, $FeO^{\oplus}$, $Fe(C_2H_4)^{\oplus}$, and $Fe(OH)_2^{\oplus}$ in the range $0 < t < 200$ s. The solid lines are based on a numerical solution of the respective differential equations using the k_i values given in Scheme 1 (see text). ●,■,○,□ = measured values.

[1] A. Eschenmoser, *Angew. Chem. 100* (1988) 5; *Angew. Chem. Int. Ed. Engl. 27* (1988) 5.

[2] Conditions: $Fe^{\oplus}$ ions were generated from a stainless steel target in the external ion source of a Spectrospin CMS 47X mass spectrometer[3] by laser desorption/ionization using an Nd-YAG laser (Spectron Systems; $\lambda = 1064$ nm)[4]. The metal ions were transferred to the actual ICR cell by means of a system of electrical potentials and lenses. After deceleration, they were trapped in the magnetic field of a superconducting magnet (Oxford Instruments; maximum field strength 7.05 T). The isotope $^{56}Fe^{\oplus}$ was "isolated" by a double resonance experiment and allowed to react with N_2O ($p = 8 \times 10^{-8}$ mbar) to give $FeO^{\oplus}$[5]. Since this reaction is strongly exothermic (1.8 eV)[6], the products were formed with considerable excitation energy, which, however, was removed by collisions with the environment. $FeO^{\oplus}$ was "reisolated" and allowed to react with C_2H_6 ($p = 1.2 \times 10^{-8}$ mbar) as described by *Freiser*[7]. The main product was $FeC_2H_4^{\oplus}$ (70%), which, after renewed "isolation", was allowed to react again with N_2O. Mainly (>80%) "C_2H_4O" and $Fe^{\oplus}$ were thereby formed. The regenerated $Fe^{\oplus}$ completes the catalytic cycle and is available for a new cycle. It should be noted that the rate constants k_i are independent of the "age" of $Fe^{\oplus}$ within the error limits of ± 15%.

$FeO^{\oplus}$ Activates Methane**

By *Detlef Schröder* and *Helmut Schwarz**

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

The metal-mediated activation of methane is the most important of all CH bond activations.[1] This is due not only to the great economic interest in the direct conversion of methane to "valuable" products such as methanol, but also to the inherent scientific challenge, which still remains to be met in a general way. The approach used succesfully for many substrates, namely, to obtain information on the detailed steps of the activation of CH/CC bonds by "naked" transition-metal ions,[2] has failed for the simple reason that the oxidative addition of most metal ions $M^{\oplus}$ (M = Ti, V, Co, Fe, Nb, Rh, Sc, Y, La, Lu, Co, Ni, Zn, and U)[3] to CH_4 [Eq. (a)] is endothermic.[4]

$$CH_4 + M^{\oplus} \rightarrow H\text{-}M^{\oplus}\text{-}CH_3 \rightarrow \text{products} \qquad \text{(a)}$$

The only exceptions are those cases where either $M^{\oplus}$ is electronically excited (e.g., $Ti^{\oplus}$ [5] or $Cr^{\oplus}$ [6]) or the barrier to oxidative addition is overcome by kinetic excitation of $M^{\oplus}$.[2b, 7] The reaction of "naked" metal atoms M (M = Mn, Fe, Co, Ni, Zn) with CH_4 in a noble-gas matrix is also only possible after photochemical excitation of M.[8] The often useful approach of activating CH/CC bonds not by single metal ions but rather by homo- or heteronuclear ionic clusters[9] has also proved fruitless.[10]

A conceivable way of favorably influencing the reaction enthalpy for activation of methane is the use of $MO^{\oplus}$ instead of $M^{\oplus}$.[11] Indeed, *Freiser* et al.[12] were able to increase the propensity of alkanes to react by use of $FeO^{\oplus}$ instead of $Fe^{\oplus}$. The authors reported, however, that "cold" $FeO^{\oplus}$ did *not* react with CH_4 in the gas phase, even though all processes shown in Equation (b) are exothermic.[13]

We have not been able to confirm this result.[12] $FeO^{\oplus}$, generated under FTICR (Fourier transform ion cyclotron resonance) conditions[14] from $Fe^{\oplus}$ and N_2O, *affords all the products shown in Equation (b) in a ratio of 57:2:41.*[19] The possibility that excited $FeO^{\oplus}$ might be generated[20] and

[*] Prof. Dr. H. Schwarz, Dipl.-Chem. D. Schröder
Institut für Organische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie.

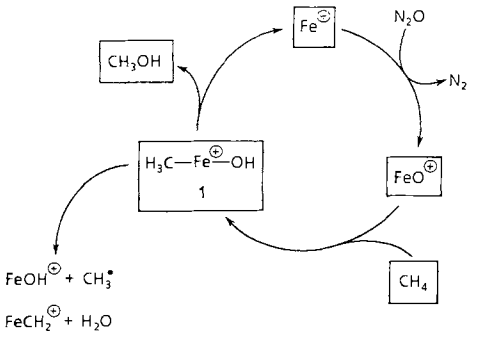
$$\begin{array}{lll} & & \Delta H_r \\ & & [\text{kcal mol}^{-1}] \\ \text{FeO}^{\oplus} + \text{CH}_4 \xrightarrow{k_1} & \text{FeOH}^{\oplus} + \text{CH}_3^{\bullet} & -2 \\ & \text{FeCH}_2^{\oplus} + \text{H}_2\text{O} & -21 \\ & \text{Fe}^{\oplus} + \text{CH}_3\text{OH} & -7 \end{array} \quad \text{(b)}$$

thus be responsible for the activation of CH_4 is unsupported. This is directly shown by control experiments in which $FeO^{\oplus}$ was allowed to react with CH_4 under diverse conditions (variation of the trapping time or the quenching partner); no change in the product distribution or the rate constants k_1 was found. We obtained a value of $k_1 = 2.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. Although this value is significantly smaller than that for the analogous reaction of $FeO^{\oplus}$ with C_2H_6 ($k = 8.4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} [12, 21]), it is still two orders of magnitude greater than the rate constants for association reactions of $M^{\oplus}$ with CH_4.[3b]

The product distribution[22] obtained from the reaction of $FeO^{\oplus}$ with CH_2D_2 and with CD_4 [Eq. (c)] allows conclusions to be drawn concerning the reaction mechanism. A small isotope effect ($k_H/k_D = 4.6$) is found by comparing the rate constants for formation of $FeOD^{\oplus}$ and $FeOH^{\oplus}$ (reaction with CH_2D_2). Comparison of the distribution of the products $FeOX^{\oplus}$ (X = H, D) and $Fe^{\oplus}$ for CH_4, CH_2D_2, and CD_4 reveals that the formation of $Fe^{\oplus}$, which, for thermodynamic reasons, is necessarily coupled with the generation of CH_3OH, is likewise favored by an isotope effect.

$$\begin{array}{lll} & & \text{rel. amount [\%]} \\ \text{FeO}^{\oplus} + \text{CH}_2\text{D}_2 \longrightarrow & \text{FeOD}^{\oplus} + \text{CH}_2\text{D}^{\bullet} & 9 \\ & \text{FeOH}^{\oplus} + \text{CHD}_2^{\bullet} & 41 \\ & \text{Fe}^{\oplus} + \text{CH}_2\text{D}_2\text{O} & 50 \\ \text{FeO}^{\oplus} + \text{CD}_4 \longrightarrow & \text{FeOD}^{\oplus} + \text{CD}_3^{\bullet} & 35 \\ & \text{Fe}^{\oplus} + \text{CD}_3\text{OD} & 65 \end{array} \quad \text{(c)}$$

The observed isotope effects can be easily explained if the species $CH_3FeOH^{\oplus}$ (**1**) is postulated as central intermediate. Several paths for the formation of **1** are conceivable.



Scheme 1.

Although $Fe^{\oplus}$ is used in "equimolar" amounts in the experiments described here,[23] the chances of achieving a *catalytic* activation of CH_4 by $FeO^{\oplus}$ are not small, since $Fe^{\oplus}$ generated in the course of the reductive elimination of CH_3OH could be easily reintroduced into the cycle after reaction with, for example, N_2O (Scheme 1).[24]

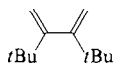
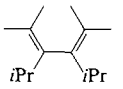
Sterically Hindered Internal Rotation in an Acyclic α,β-Unsaturated Ketone. 2,2,5-Trimethyl-4-isopropylhex-4-en-3-one**

By *John M. Nuss,* Steven J. Bark, Daniel B. Borchardt,* and *Thomas Hellmann Morton**

Sterically hindered internal rotation has been widely studied in a variety of organic compounds. Surprisingly, such effects in the simplest conjugated systems have been detected in a comparatively small number of cases. Among hydrocarbons, only two examples of acyclic skew dienes have been reported, 2,3-di-*tert*-butyl-1,3-butadiene (**1**)[1] and 2,5-dimethyl-3,4-diisopropyl-2,4-hexadiene (**2**).[2] The former



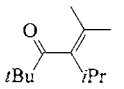
1



2

was characterized by the λ_{max} value of its $\pi \rightarrow \pi^*$ absorption, while hindered rotation in the latter was characterized by the chemical nonequivalence of its isopropyl methyl groups in the ^{1}H NMR spectrum and by its He(I) photoelectron spectrum.[3] From the absence of any line broadening in the ^{1}H NMR spectrum of **2** at low frequency (60 MHz) and high temperature (195 °C), an experimental barrier to planarization of $\Delta G > 110$ kJ mol^{-1} (26 kcal mol^{-1}) has been calculated.[2] From the photoelectron spectrum, the dihedral angle between the two double bonds of **2** is estimated to be $\theta = 90 \pm 5°$.[3]

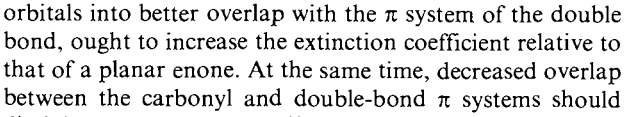
To date no example of sterically hindered internal rotation about the sp^2–sp^2 single bond in an acyclic enone has been reported. We describe here the synthesis and spectroscopic properties of α,β-unsaturated ketone **3**, which exhibits a barrier to planarization of its π system. The following alter-



3

ations of the electronic spectrum might be anticipated as the result of preventing the carbonyl from being coplanar with the carbon–carbon double bond. Since $n \rightarrow \pi^*$ transitions are spatially forbidden, skewing, which brings the lone pair orbitals into better overlap with the π system of the double bond, ought to increase the extinction coefficient relative to that of a planar enone. At the same time, decreased overlap between the carbonyl and double-bond π systems should diminish the extinction coefficient of the $\pi \rightarrow \pi^*$ transition.

Compound **3** was synthesized from the vinyl iodide **4**.[4] Conversion to the corresponding vinyllithium **5** by addition of two equivalents of *tert*-butyllithium proceeds in good yield, as evidenced by recovery of the vinyltributylstannane **6** in 80% yield when the reaction mixture is quenched with tributyltin chloride. When pivaloyl chloride is added to a solution of **5** in THF at −78 °C and the mixture allowed to warm to room temperature, **3** is produced, but in a lower yield (55%) along with di-*tert*-butyl ketone as the major impurity. Purification of **3** by distillation and column chromatography affords a colorless liquid with a camphoraceous odor reminiscent of cineole (b.p. 104–105 °C at 25 Torr, $[n]_D^{20} = 1.4522$).[5]



4, X = I
5, X = Li
6, X = Bu_3Sn

3 (a)

^{1}H NMR spectra at −99 °C and 25 °C are shown in Figure 1. By fitting[6] the observed spectra at eleven temperatures over the range, we calculated the following Arrhenius parameters for interconversion of the nonequivalent isopropyl methyl groups: $E_a = 45 \pm 3$ kJ mol^{-1}, $\lg A = 14.4 \pm 0.7$, where the experimental errors represent 95% confidence limits.

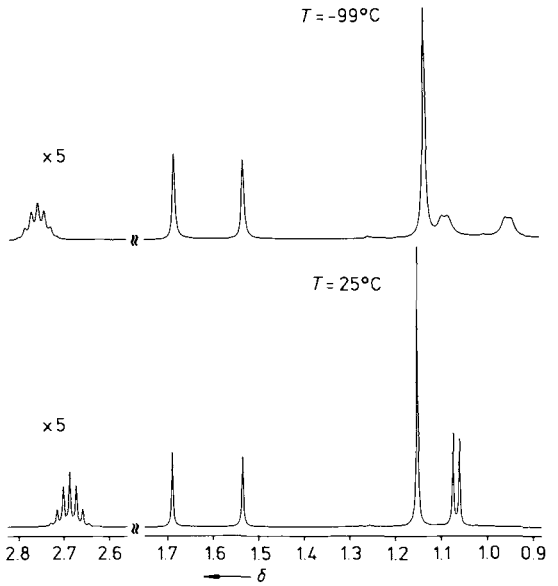


Fig. 1. 500-MHz ^{1}H NMR spectrum of **3** in $CFCl_3$. The doublets corresponding to the nonequivalent isopropyl methyl groups at $\delta = 0.95$ and 1.1 coalesce at −75 °C and sharpen to a doublet at $\delta = 1.08$ in the room temperature spectrum.

We infer that the nonequivalence of the isopropyl methyl resonances results from the chirality of the nonplanar enone. This inference is corroborated by the UV spectrum. The $n \rightarrow \pi^*$ transition of **3** ($\lambda_{max} = 318$ nm, $\varepsilon = 80$) has an extinction coefficient twice as large as that of mesityl oxide and exhibits partially resolved vibrational fine structure (six bands between 290 and 345 nm with a separation of 1100 cm^{-1}). The $\pi \rightarrow \pi^*$ transition of **3** ($\lambda_{max} = 242$ nm, $\varepsilon = 960$) is an order of magnitude less intense than the corresponding band in mesityl oxide.

Planarization of the enone is required in order for the isopropyl methyl groups to become chemically equivalent, and the barrier for **3** is much lower than for **2**. We have examined a number of molecular mechanics calculations of the relative planarization barriers and cannot find an obvious explanation. Although torsional potentials for aliphatic sp^2–sp^2 single bonds have not been well parameterized for force-field computations, we are nevertheless surprised that such calculations inevitably predict a planarization barrier for **2** that is less than twice as large as that for **3**, contrary to our experimental findings. The large preexponential A factor (which corresponds to a positive $\Delta S^{\ddagger}$) is also unusual. Although positive activation entropies have been reported for

some conformational changes (e.g., six-member ring interconversions in the gas phase), solution-phase values of $\Delta S^{\neq}$ (from NMR studies) tend to be close to zero.[7] The hindered rotation in 2,2'-dimethylbiphenyl exhibits a negative activation entropy,[8] as do nearly all other hindered rotations for which activation parameters have been reported. Additional insight will be gained from studying homologues of compounds **1**–**3**.

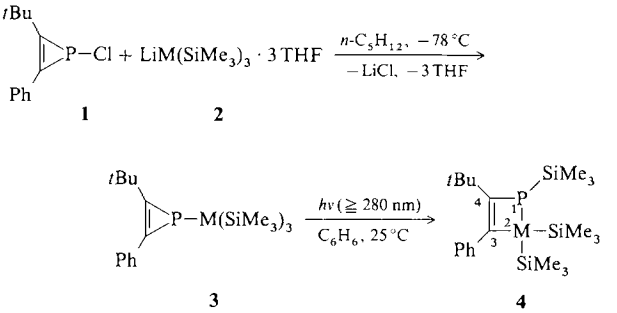
Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

1-Chloro-1*H*-phosphirenes such as **1** are readily accessible by [2 + 1] cycloaddition of chlorocarbenes (thermally generated from chlorodiazirines) to phosphaalkynes followed by [1,3] Cl shift.[1] We have used **1** to obtain the tris(trimethylsilyl)silyl-1*H*-phosphirene **3a**, which, via a previously unknown photochemical rearrangement, gives the dihydrophosphasilete **4a**. Compound **4a** provides an entry to the still unexplored chemistry of heterocycles containing 2-phospha-1,3-diene units.

The starting point for this sequence of reactions is the 1-chloro-1*H*-phosphirene **1**,[1] which undergoes smooth nucleophilic substitution with the lithiated silane **2a**[2] to give the 1-silyl-1*H*-phosphirene **3a**. Irradiation of **3a** in benzene results in ring expansion at the phenyl-substituted carbon of the three-membered ring and (Si → P) silyl shift to give the dihydrophosphasilete **4a**.[3] Dihydrodiphosphetes and dihydrometallaphosphetes (**4**, RP and metal complex fragments, respectively, instead of $M(SiMe_3)_2$) with comparable structures have already been prepared from 1*H*-phosphirenes by intermolecular insertion reactions.[4] The 1-germyl-1*H*-phosphirene/dihydrophosphagermete rearrangement (**3b** → **4b**), also previously unknown, can be carried out photochemically.[5]



2a–**4a**: M = Si
2b–**4b**: M = Ge

The ring expansion **3a** → **4a** is accompanied by a downfield shift of the ^{31}P NMR signal (see Table 1). The signal of the C atom bearing the *t*Bu group (C4) in **4a** is also shifted downfield relative to that in **3a** and exhibits a $^1J(^{31}P,^{13}C)$ coupling of only 22.1 Hz, as also observed for 1,2-dihydro-1,2-diphosphetes.[6] In the ^1H NMR spectrum, the (Si → P) silyl shift is revealed by splitting of the $SiMe_3$ signal ($^3J(P,H)$ = 4 Hz).[7] These findings also hold true for **4b**.[5] The spectroscopic observations were confirmed by crystal structure analysis of **4a**.[8]

The 1,2-dihydro-1,2-phosphasilete ring is nearly planar, as shown by the torsional angles (see caption to Fig. 1). Notably, the exocyclic P–Si bond (2.259(1) Å) is significantly shorter than the P–Si bond in the ring (2.283(1) Å).

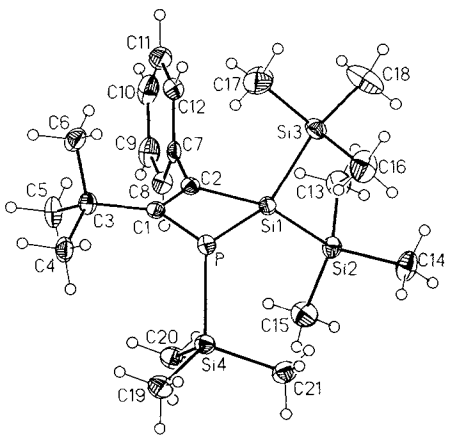


Fig. 1. Molecular structure of **4**[8]. Selected bond lengths [Å] and angles [°]: C1-C2 1.348(3), C1-P 1.879(2), C2-Si1 1.881(2), P-Si1 2.283(1), P-Si4 2.259(1), C1-C3 1.532(3), C2-C7 1.487(3), Si1-Si2 2.356(1), Si1-Si3 2.348(1); C1-P-Si1 73.5(1), P-Si1-C2 77.7(1), Si1-C2-C1 100.8(1), C2-C1-P 108.0(2), Si1-P-Si4 103.0(1), C1-P-Si4 103.7(1). Torsional angles: C1-C2-Si1-P 0.4, P-C1-C2-Si1 0.5, Si4-P-Si1-C2 –101.0, Si4-P-C1-C2 –100.1.

The reactivity of the silylphosphane component of **4a** may be exploited preparatively. Reaction with chlorobis(trimethylsilyl)methylenephosphane gives **5** (80%). Methyl pro-

[**] Phosphorus Compounds with Unusual Coordination, Part 45. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 44: M. Ehle, O. Wagner, U. Bergstraßer, M. Regitz, *Tetrahedron Lett. 31* (1990), in press.

piolate undergoes insertion into the P–Si bond to afford **6** (95%);[9] likewise, diphenylketene yields **7** (70%).

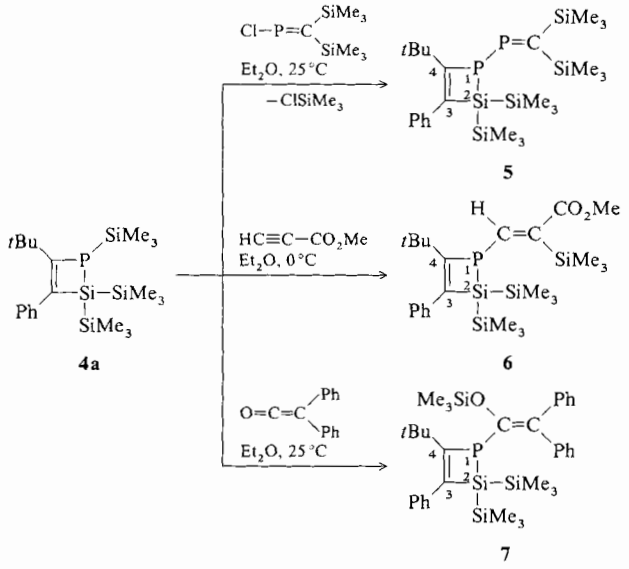

Table 1. Selected physical data for compounds **3**–**7** and **10**[a].

3a: bright yellow oil, b.p. 150 °C/10^{-3} mbar [b]; ^{1}H NMR: $\delta = 0.4$ (s, 27H, $SiMe_3$), 1.4 (s, 9H, *t*Bu), 7.1–7.9 (m, 5H, arene H). ^{13}C NMR: $\delta = 2.4$ (s, $Si(CH_3)_3$), 29.7 (s, $C(CH_3)_3$), 33.9 (d, ^2J(P,C) = 6.7 Hz, $C(CH_3)_3$), 111.5 (d, ^1J(P,C) = 45.3 Hz, =*C*-Ph), 130.9 (d, ^1J(P,C) = 56.2 Hz, =*C*-*t*Bu). ^{31}P NMR: $\delta = -205$.

4a: colorless crystals, m.p. 75 °C; ^{1}H NMR(CD_2Cl_2): $\delta = 0.2$–0.4 (broad, 18H, $Si(SiMe_3)_2$), 0.45 (d, ^3J(P,H) = 4.0 Hz, 9H, P-$SiMe_3$), 1.10 (s, 9H, *t*Bu), 7.0–7.2 (m, 5H, arene H). ^{13}C NMR: $\delta = 0.1$, 1.2 (each broad, Si-Si(CH_3)$_3$), 2.0 (d, ^2J(P,C) = 10.3 Hz, P-$Si(CH_3)_3$), 31.5 (d, ^3J(P,C) = 5.0 Hz, $C(CH_3)_3$), 40.9 (d, ^2J(P,C) = 13.7 Hz, $C(CH_3)_3$), 149.3 (d, ^2J(P,C) = 13.3 Hz, C3), 166.2 (d, ^1J(P,C) = 22.1 Hz, C4); ^{31}P NMR: $\delta = -130.7$.

5: bright yellow, nondistillable oil. ^{13}C NMR: $\delta = 0.35$, 1.4 (each s, $Si(CH_3)_3$), 1.9 (d, ^3J(P,C) = 12.4 Hz, $Si(CH_3)_3$), 3.0 (d, ^3J(P,C) = 8.9 Hz, $Si(CH_3)_3$), 31.6 (d, ^3J(P,C) = 4.7 Hz, $C(CH_3)_3$), 41.5 (d, ^2J(P,C) = 11.8 Hz, $C(CH_3)_3$), 152.4 (dd, ^2J(P,C) = 14.6 Hz, ^3J(P,C) = 5.8 Hz, C3), 168.9 (dd, ^1J(P,C) = 23.7, ^2J(P,C) = 6.8 Hz, C4), 211.2 (d, ^1J(P,C) = 96.4 Hz, P=C); ^{31}P NMR: $\delta = 459$, −38 (each d, each ^1J(P,P) = 270.5 Hz).

6: bright yellow oil, b.p. 200 °C/10^{-3} mbar [b]. ^{1}H NMR: $\delta = 0.4$, 0.5, 0.6 (each s, each 9H, $SiMe_3$), 1.2 (s, 9H, *t*Bu), 3.6 (s, 3H, CO_2Me), 7.0–7.3 (m, 5H, arene H), 8.7 (d, ^2J(P,H) = 5.0 Hz, 1H, CH-olefin). ^{13}C NMR: $\delta = -0.2$ (s, $Si(CH_3)_3$), 0.5 (s, $Si(CH_3)_3$), 1.0 (d, J(P,C) = 8.8 Hz, $Si(CH_3)_3$), 31.3 (d, ^3J(P,C) = 4.8 Hz, $C(CH_3)_3$), 41.4 (d, ^2J(P,C) = 12.7 Hz, $C(CH_3)_3$), 51.1 (s, CO_2CH_3), 142.9 (d, ^2J(P,C) = 28.5 Hz, =*C*-ester), 151.3 (d, ^2J(P,C) = 20.1 Hz, C3), 164.6 (d, ^1J(P,C) = 46.3 Hz, ^1J(C,H) = 154.0 Hz, =C-H), 169.2 (d, ^3J(P,C) = 14.6 Hz, CO_2CH_3), 169.7 (d, ^1J(P,C) = 17.0 Hz, C4). ^{31}P NMR: $\delta = -82$.

7: bright yellow oil, b.p. 220 °C/10^{-3} mbar [b], ^{1}H NMR(CD_2Cl_2): $\delta = 0.05$, 0.15, 0.40 (each s, each 9H, $SiMe_3$), 1.10 (s, 9H, *t*Bu), 7.0–7.4 (m, 15H, arene H). ^{13}C NMR(CD_2Cl_2): $\delta = 0.2$ (d, J(P,C) = 3.0 Hz, $Si(CH_3)_3$), 1.6 (s, $Si(CH_3)_3$), 2.5 (s, $Si(CH_3)_3$), 31.4 (d, ^3J(P,C) = 4.6 Hz, $C(CH_3)_3$), 41.5 (d, ^2J(P,C) = 15.0 Hz, $C(CH_3)_3$), 134.1 (d, ^2J(P,C) = 38.1 Hz, =CPh_2), 153.3 (d, ^1J(P,C) = 62.0 Hz, =*C*-$OSiMe_3$), 153.4 (d, ^2J(P,C) = 20.4 Hz, C3), 166.5 (d, ^1J(P,C) = 19.6 Hz, C4). ^{31}P NMR(CD_2Cl_2): $\delta = -58$.

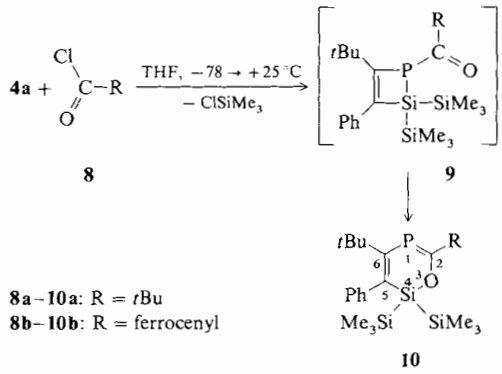
10a: colorless crystals, m.p. 85 °C. ^{1}H NMR(CD_2Cl_2): $\delta = 0.15$ (s, 18H, $SiMe_3$), 1.15 (s, 9H, *t*Bu), 1.3 (d, ^4J(P,H) = 2.0 Hz, *t*Bu), 7.0–7.4 (m, 5H, arene H). ^{13}C NMR(CD_2Cl_2): $\delta = -0.62$ (s, $Si(CH_3)_3$), 29.1 (d, ^3J(P,C) = 13.7 Hz, $C(CH_3)_3$), 32.8 (d, ^3J(P,C) = 14.0 Hz, $C(CH_3)_3$), 42.8 (d, ^2J(P,C) = 27.3 Hz, $C(CH_3)_3$), 43.1 (d, ^2J(P,C) = 24.1 Hz, $C(CH_3)_3$), 125.6, 127.9, 128.2, 145.1 (each s, arene C), 134.6 (d, ^2J(P,C) = 7.3 Hz, C-5), 161.5 (d, ^1J(P,C) = 58.2 Hz, C6), 217.6 (d, ^1J(P,C) = 79.3 Hz, C2). ^{31}P NMR(CD_2Cl_2): $\delta = 91$.

10b: dark red crystals, m.p. 135 °C. ^{1}H NMR: $\delta = 0.40$ (s, 18H, $SiMe_3$), 1.5 (s, 9H, *t*Bu), 4.2–4.5 (m, 7H, Cp-H), 5.1 (m, 2H, Cp-H), 7.1–7.4 (m, 5H, arene H). ^{31}P NMR: $\delta = 92$.

[a] 90-MHz ^{1}H, 100.64-MHz ^{13}C, and 80.8-MHz ^{31}P NMR spectra in C_6D_6 (TMS(int.) or 85% H_3PO_4(ext.)). [b] Oven temperature for kugelrohr distillation.

The dihydrophosphasilete framework is still intact in **5**–**7**, as shown by comparison of the NMR chemical shifts of the ring carbon atoms (as well as their P coupling constants) and phosphorus atoms with the corresponding values for **4a** (Table 1).

Reaction of **4a** with the acyl chlorides **8a, b** undoubtedly results in initial formation of the *P*-acyl dihydrophosphasiletes **9a, b**, which, in contrast to **5**–**7**, are not isolable. Instead, they undergo spontaneous isomerization by 1,3-silyl shift[10] to give the dihydrooxaphospasilines **10a, b**, the first cyclic compounds containing a 2-phospha-1,3-diene partial structure.



The transition from a $\lambda^3\sigma^3$ to a $\lambda^3\sigma^2$ phosphorus (**4a** → **10a,b**) is accompanied by a marked downfield shift of the ^{31}P NMR signal (Table 1). Otherwise, the NMR data for the 2-phospha-1,3-diene system of **10a,b** are in very good agreement with those for open-chain compounds containing the same structural unit, although in *s-trans* arrangement.[11, 12]

Experimental Procedure

4a: A solution of the 1-silyl-1*H*-phosphirene **3a** (1.5 g, 3.4 mmol) in 5 mL of benzene was irradiated in an NMR tube (diameter 10 mm) for 40 h (Heraeus TQ 150 high-pressure mercury lamp, ^{31}P NMR monitoring). After removal of the solvent, the crude product, a red-brown oil, was purified by kugelrohr distillation (150 °C oven temperature/10^{-3} mbar). Recrystallization from pentane at −78 °C afforded 0.5 g (34%) of colorless crystals of **4a** (m.p. 75 °C).

10b: A solution of **4a** (150 mg, 0.34 mmol) in 1 mL of tetrahydrofuran was treated slowly with a solution of **8b** (87 mg, 0.36 mmol) in 1 mL of tetrahydrofuran. After thawing, the solution was stirred for 24 h at 25 °C. Evaporation followed by column-chromatographic workup of the crude product on 12 g of silica gel (dried under vacuum) with 250 mL of pentane/ether (5/1) as eluent and recrystallization from pentane at −78 °C afforded 140 mg (70%) of dark red crystals of **10b** (m.p. 135 °C).

Vanadium(-I) Dinitrogen Complexes with N_2 Coordinated End-on: Functional Models for the "Alternative Nitrogenase"**

By *Claus Woitha* and *Dieter Rehder**

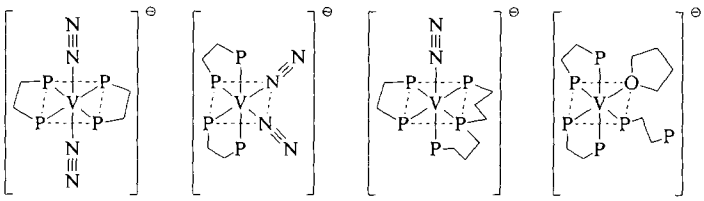
Recently, the nitrogen-fixing bacterium *Azotobacter* was found to code not only for a molybdenum nitrogenase but also for "alternative nitrogenases" containing vanadium[1] or iron[2] instead of Mo in the active site. It has already been known for more than half a century that vanadium can play a role in the in vivo fixation of nitrogen.[3] However, the in vitro reduction of N_2 to NH_3 and/or N_2H_4 also occurs, for example, in alkaline $V^{2\oplus}$- and $Mg^{2\oplus}$-containing solutions[4] or in the system $V^{2\oplus}$/dicarboxylate.[5] In the latter case, a binuclear, N_2-bridged intermediate has been postulated. The structure of an N_2-bridged V^{II} complex, [(*o*-$Me_2NCH_2C_6H_4)_2V(NC_5H_4)]_2(\mu\text{-}N_2)$, was recently determined.[6] We have now synthesized and isolated a series of V^{-I} nitrogen complexes which contain N_2 coordinated in an end-on fashion and which are stable at room temperature.

Such complexes have only been identified previously in low-temperature matrices (e.g., $V(N_2)_6$[7] and $[CpV(NO)_2N_2]$[8]) or in solution below 220 K ($[V(CO)_5N_2]^{\ominus}$[9]). Multidentate phosphanes were used as supporting ligands to provide stabilization, as was the case for the comparable complexes of Mo^0 regarded as functional models of Mo nitrogenase.

The anionic vanadium complexes **2a–f** (Scheme 1), which have the composition $[Vp_n(N_2)_{6-n}]^{\ominus}$ (n indicates the number of *coordinated* phosphorus functions of one or more multidentate phosphanes p) are formed as their Na salts on reduction of $[VCl_3p_n(thf)_{3-n}]$[10] (**1**) with sodium sand in the presence of the phosphane under N_2 (see Eq. (a) for p_n = bis(dimethylphosphino)ethane, dmpe), when catalytic amounts of naphthalene are added.

$$VCl_3(thf)_3 + dmpe \longrightarrow [VCl_3dmpe(thf)] \xrightarrow[dmpe,\ Na]{N_2} \mathbf{2a}\text{-Na} + \mathbf{2c}\text{-Na} \qquad (a)$$

1a



2a(b) **2c(d)** **2e(f)** **3**

Scheme 1. The formula numbers **2b,d,f** refer to the analogous $^{15}N_2$ complexes.

The composition of the reaction solution obtained according to Equation (a) can be determined from its ^{51}V NMR spectrum (Fig. 1, spectrum A).[11,12a] The main product is the *trans* complex **2a**, characterized by a quintet ($^1J(^{31}P,^{51}V)$ = 314 Hz) at $\delta(^{51}V)$ = – 1123. Also present is the *cis* isomer **2c** ($\delta(^{51}V)$ = – 978, A_2B_2X spin system, $J(^{31}P^A,^{51}V)$ = 316, $J(^{31}P^B,^{51}V)$ = 253 Hz). Carrying out the reaction at temperatures around 240 K results in an increase

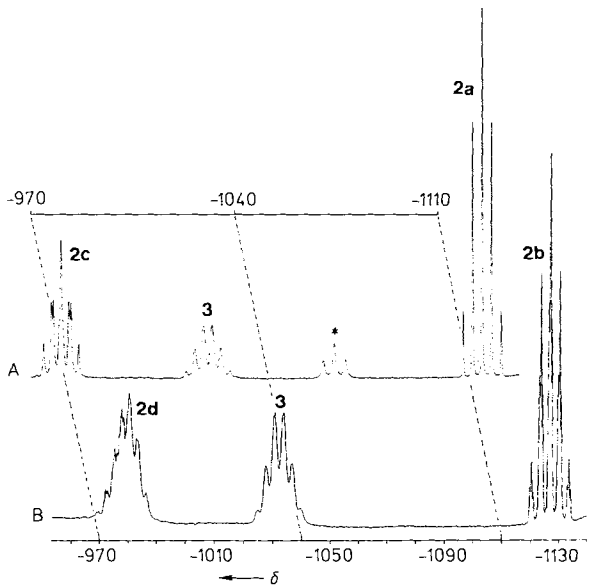


Fig. 1. 94.7-MHz $^{51}V\{^1H\}$ NMR spectrum of the reaction mixture formed on reduction of **1a** with Na under $^{14}N_2$ (A) and $^{15}N_2$ (B) at 273 K. In A, only a coupling pattern corresponding to $^{31}P,^{51}V$ coupling is observed. In B, $^{15}N,^{51}V$ coupling is also observed for the two nitrogen complexes **2b** and **2d**. Compound **3** (L = THF, preliminary formula) contains no nitrogen. The triplet marked with an asterisk is not assigned.

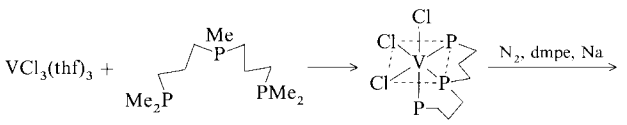
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

in the amount of the *cis* isomer **2c**. In the IR spectrum of its solution in THF, **2a** is characterized by an intense, broad band for ν(NN) at 1763 cm^{-1} (Nujol: 1759 cm^{-1}). Complex **2c**, which can be precipitated from hexane at low temperatures as the pure Na salt, exhibits two equal-intensity bands (1791 and 1674 cm^{-1}) in the IR spectrum (Nujol).

Direct proof for the formation of N_2 complexes is provided by the reduction [Eq. (a)] under $^{15}N_2$. In the ^{51}V NMR spectrum, each component of the multiplet is further split into a triplet (Fig. 1, spectrum B: *trans*-$^{15}N_2$ complex **2b**, $J(^{15}N,^{51}V) = 57(1)$ Hz; *cis*-$^{15}N_2$ complex **2d**, $J(^{15}N,^{51}V) = 67(6)$ Hz).[12b] In the IR spectrum, the ν(NN) absorption for the *trans* complex is shifted to $\tilde{\nu} = 1695\ cm^{-1}$.

The values for the $^{31}P,^{51}V$ couplings lie in the region observed for other low-valent alkylphosphane complexes of vanadium.[14] $^{14/15}N,^{51}V$ coupling constants on the order of those determined here have only been observed sporadically so far and exclusively for V^V compounds.[15] The absence of fine splitting in the sextet observed at $\delta = -1032$ in the ^{51}V NMR spectrum of **3** (Fig. 1) shows that, in this case, no N_2 is coordinated. Compound **3** probably has the composition $[V(dmpe)_3(thf)]^{\ominus}$, five of the available P functions being coordinated to vanadium.[12c]

Nonetheless, it was also possible to prepare an anionic nitrogen complex containing only one N_2 ligand (**2e**) [Eq. (b)]. The tridentate phosphane bdpm (bis(3-dimethylphosphinopropyl)methylphosphane)[16] and dmpe were used.



2e-Na ⟶ **2a**-Na

The complex anion **2e**, initially formed on reduction of **1b**, exhibits a characteristic N–N stretching vibration at $\tilde{\nu} = 1725\ cm^{-1}$ in the IR spectrum (THF). For the analogous $^{15}N_2$ complex, **2f**, ν(NN) is found at $\tilde{\nu} = 1678\ cm^{-1}$ in the IR spectrum (THF). Figure 2 shows the ^{51}V NMR spectrum of **2e**. The A_5BX spin system ($^1J(^{31}P^A,^{51}V) = 291$ Hz, $^1J(^{31}P^B,^{51}V) = 222$ Hz) clearly shows that the coupling pattern is governed not so much by the chemical nonequivalence of alkylphosphane functions in the end and middle positions but rather by their position with respect to the N_2 ligand. A similar argument explains the coupling pattern in the NMR spectrum of the hydrido complexes $HM_p(CO)_{6-n}$ (M = V, Nb, Ta; n = 2–4).[17] Compound **2e**-Na is soluble, but not stable, in hexane. Upon standing for several days, the hexane solution affords a precipitate of the pure Na salt, **2a**-Na.

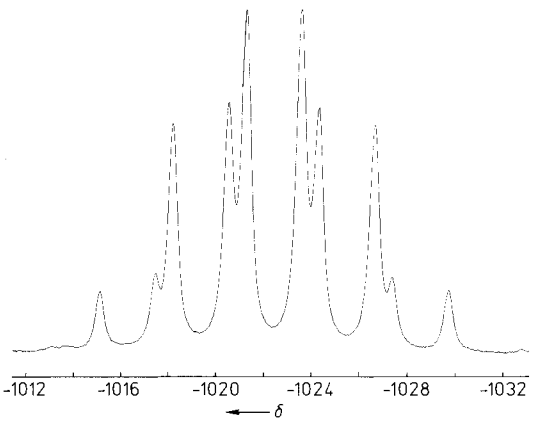


Fig. 2. 94.7-MHz $^{51}V\{^1H\}$ NMR spectrum of the anionic nitrogen complex **2e**.

The phosphane-stabilized V^{-1} dinitrogen complexes show spectroscopic similarities with the valence-isoelectronic Mo^0 complexes (e.g., *trans*-$[Mo(Et_2PCH_2CH_2PEt_2)_2(N_2)_2]$[13]), but also exhibit the differences expected for an anionic versus a neutral complex. For example, ν(NN) for the Mo complex lies at $\tilde{\nu} = 1928\ cm^{-1}$, about 170 cm^{-1} higher than for the V complex **2a**. The ^{15}N nucleus in the Mo complex ($\delta(^{15}N) = +338$[13]) is more strongly shielded than in **2b** ($\delta(^{15}N) = +423$[18]). Interestingly, the N_2 ligand in complexes **2a(b)** can be transformed into ammonia by reductive protonation, as observed for Mo complexes: When dry HCl gas is admitted into a THF solution of **2a**-Na at −30 °C, about 30% of the N_2 is converted into NH_4Cl (hydrazine is formed in only trace amounts). In addition, still not fully characterized chloro complexes, probably of V^{III}, are formed.

Experimental Procedure

$VCl_3(thf)_3$ (1 mmol)[19] was dissolved in 10 mL of THF. After addition of dmpe (2 mmol), the solution was stirred under inert atmosphere. The green solution of **1a** that was immediately formed was cooled to 273 K and then treated with sodium sand (8 mmol) and naphthalene (5 mg) and stirred for 5 h under N_2. The resulting brown solution contained, in addition to the main product **2a**, compounds **2c** and **3** (as well as a not further identified V^{-1} complex containing only one dmpe ligand, $\delta(^{51}V) = -1072$, $J(P,V) = 360$ Hz; cf. Fig. 1, A). Addition of about 100 mL of *n*-hexane resulted in precipitation of **2a**-Na as a pyrophoric, brown-black powder, which, however, was not completely homogeneous. When the reaction was carried out at 220–240 K, the main product was **2c**-Na, which could be precipitated from hexane at low temperatures as a pure substance. Compounds **2a**-Na and **2c**-Na are stable under N_2 at room temperature. The yields of **2a**-Na and **2c**-Na were 40%. In solution, **2c** is slowly transformed into **2a**. In vacuum, both complexes lose N_2. To synthesize the $^{15}N_2$ complexes **2b**, **2d**, and **2f**, $^{15}N_2$ (99%, Campro Scientific) was used.

Pure **2a**-Na was also obtained by an indirect route: $VCl_3(thf)_3$ (1 mmol) was dissolved in 20 mL of THF and treated with bdpm (1 mmol) and the reaction mixture was stirred for 1 h. The resulting solution, containing **1b**, was concentrated to 5 mL and then treated with dmpe (1 mmol), sodium sand (200 mg), and naphthalene (20 mg), after which it was stirred for one day at 198 K and one more day at 230 K under N_2. The main product was the nitrogen complex **2e**. Filtration through a short Celite column (2.5 × 1 cm) and treatment (at 198 K) with a large excess of *n*-hexane resulted in precipitation of small amounts of **2c**-Na. Microcrystalline **2a**-Na was obtained when the solution was allowed to stand for longer periods at room temperature.

[11] The ^{51}V NMR spectra were recorded with a Bruker AM 360 spectrometer at 94.726 MHz in 10-mm NMR tubes (THF solutions; total concentration c(V), ca. 0.05 M) at 298(1) K. Typical measurement parameters: sweep width 125 kHz, time domain 8200 K, pulse angle 20°, no relaxation delay, number of scans 25000. All $\delta(^{51}V)$ values are given with respect to $VOCl_3$ as external standard.

[12] a) The ^{31}P NMR spectra show signals of several kHz width due to the only partially relaxed scalar $^{51}V,^{31}P$ coupling ($J(^{51}V) = 7/2$); b) The $^{2}J(^{15}N,^{51}V)$ coupling is not resolved. In nitrogen complexes of W and Rh, it is several Hz[13]; c) Noncoordinated phosphorus: $^{31}P\{^{1}H\}$ NMR (32.4 MHz, THF, H_3PO_4): $\delta = -53.8$ (d, $^{3}J(P,P) = 26$ Hz); cf. uncomplexed dmpe: $\delta = -52.9$ (s).

Lewis-Base-Dictated Structural Variations in Sodium Amide Chemistry: X-Ray Crystal Structures of Phenyl(2-pyridyl)amidosodium with Hexamethylphosphoric Triamide (HMPA) and with Pentamethyldiethylenetriamine (PMDETA)**

By *Philip C. Andrews, William Clegg*, and *Robert E. Mulvey**

Since their discovery nearly two centuries ago, sodium amides have been much utilized as reagents in, for example, amide transfer, metalation, and polymerization initiation.[1] Except for some silylated derivatives,[2] such as $[(Me_3Si)_2NNa]_\infty$,[2a] and for two adducts of *N*-sodioindole,[3] structural characterization of such species by X-ray diffraction has hitherto proved elusive. This dearth is in marked contrast to the recent growth in the number of lithium amide crystal structures.[4] Such an imbalance may reflect the greater sensitivity (to both moisture and oxygen) of heavier alkali-metal amides compared with their lithium counterparts. Reported here are the preparations and crystal structures of two adducts of the sodium amide $[Ph(2\text{-}NC_5H_4)NNa]_n$. The donor in **1** is hexamethylphosphoric triamide (HMPA) and in **2** pentamethyldiethylenetriamine (PMDETA).

$[Ph(2\text{-}NC_5H_4)N]Na \cdot 3\,HMPA \cdot Na[N(2\text{-}NC_5H_4)Ph]$ **1**

$[\{Ph(2\text{-}NC_5H_4)N\}Na \cdot PMDETA]_2$ **2**

The crystal structure of **1** determined by X-ray diffraction[5] reveals that the metal atoms are formally attached to the amido nitrogens (N(12) and N(22), Fig. 1), but that there are additional (anchimeric) coordinations with the pyridyl nitrogen atoms N(11) and N(21). These bidentate

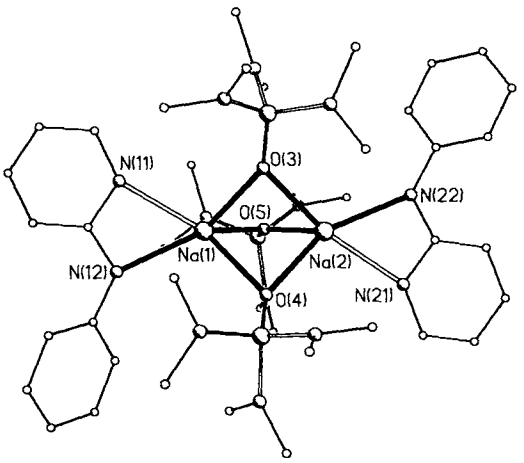

Fig. 1. Molecular structure of **1** without hydrogen atoms. Key distances [Å] and angles [°]. Na(1)-N(11) 2.459(5), Na(2)-N(21) 2.446(5), Na(1)-N(12) 2.439(7), Na(2)-N(22) 2.439(8), Na(1)-O(3) 2.381(6), Na(2)-O(3) 2.426(6), Na(1)-O(4) 2.436(5), Na(2)-O(4) 2.374(6), Na(1)-O(5) 2.347(5), Na(2)-O(5) 2.345(5), Na(1)···Na(2) 2.996(3); Na(1)-O(3)-Na(2) 77.1(2), Na(1)-O(4)-Na(2) 77.0(2), Na(1)-O(5)-Na(2) 79.4(2), N(11)-Na(1)-N(12) 55.4(2), N(21)-Na(2)-N(22) 55.1(2), O(3)-Na(1)-O(4) 78.7(2), O(3)-Na(1)-O(5) 87.1(2), O(4)-Na(1)-O(5) 87.3(2), O(3)-Na(2)-O(4) 79.1(2), O(3)-Na(2)-O(5) 86.1(2), O(4)-Na(2)-O(5) 88.8(2).

$[Ph(2\text{-}NC_5H_4)N]^{\ominus}$ anions occupy terminal positions and the oxygens of three neutral HMPA molecules each bridge the two metal centers. This donor usually binds to alkali metals in a terminal manner,[6] though it occasionally bridges in lithium systems.[7] However, this is the first example of μ_2-(HMPA)O–Na bonding. Four HMPA equivalents were available to every two equivalents of the metal in the reaction mixture producing **1**, but, by adopting bridging positions, only three HMPA equivalents are needed in order to render both sodium cations five-coordinate.

In keeping with the unpredictable structures of alkali-metal organometallics,[8] **2** prefers a dimeric arrangement that offers each metal atom an additional (sixth) coordination. Figure 2 shows that this crystal structure[9] is best viewed as a planar, centrosymmetric, rhomboidal $(N\text{-}Na)_2$ cyclic ring having nitrogen-bound phenyl and 2-pyridyl substituents. The *trans* positioning of these substituents above and below the ring plane allows each pyridyl nitrogen atom to interact with both cations through unsymmetrical Na–N–Na bridges. Overall, therefore, the six core atoms (Na,Na',N(1),N(1)',N(2),N(2)') generate a distorted octahedron. Each of its N–Na bonds is longer (by distances ranging from 0.040 to 0.346 Å) than the N–Na bonds in **1**, where the metal cations are only five-coordinate. Association appears preferential to complexation in **2** since PMDETA chelation here is incomplete with only two of its three potential donor

atoms connecting to the metal. The crystal structure of **2** represents the first example where PMDETA binds to sodium in this bidentate manner. Even with the appreciably smaller lithium cation, such "partial" bonding has been reported only in the monomeric cyclopentadienyl derivative $(Me_3Si)_3C_5H_2Li \cdot PMDETA$.[10]

Experimental Procedure

1: One molar equivalent of phenyl(2-pyridyl)amine was added to a chilled suspension of PhNa in hexane under a dry, oxygen-free argon atmosphere. Stirring this mixture at 25 °C caused the precipitation of a solid, which redissolved on addition of HMPA (two molar equivalents per sodium). Cooling of the resulting orange solution afforded pale yellow plates which had 1.5 HMPA molecules per sodium and were identified as **1** [yield 72% based on amine, m.p. 100–102 C; satisfactory analyses (C,H,N,P,Na)].

2: One molar equivalent of PMDETA was added to a suspension of phenyl(2-pyridyl)amidosodium in chilled hexane under a dry, oxygen-free argon atmosphere. Stirring gave a pale brown solution which deposited pale brown crystals on refrigeration at −20 °C. These crystals were washed with hexane and identified as **2** [yield 84%, m.p. 89–91 °C; satisfactory analyses (C,H,N,Na)].

Single crystals of both **1** and **2** suitable for X-ray crystallography were sealed under argon in Lindemann capillary tubes prior to data collection.

Decameric and Dodecameric Sodium Amides and an Organosodium Amide with Stack Structures: $[Na_{10}(NMe_2)_{10}(tmeda)_4]$, $[Na_{12}(NMe_2)_{12}(tmeda)_4]$, and $[Na_{12}(NMe_2)_{10}(CH_2C_6H_4Me)_2(tmeda)_4]$**

By *Nis Peter Lorenzen, Jürgen Kopf, Falk Olbrich, Uwe Schümann*, and *Erwin Weiss**

Dedicated to Professor Fausto Calderazzo on the occasion of his 60th birthday

Alkali-metal organometallics exhibit a pronounced tendency to form oligomeric aggregates. Depending on the spatial demands of the organic groups, the ionic radius of the metal ion, and possible solvation (for example, by ethers or amines), various types of structures are found.[1] The alkali-metal amides, which are also synthetically valuable, show many structural similarities, as revealed particularly by recent investigations on lithium amides. Monomeric, dimeric, trimeric, tetrameric, and also ladder structures are known;[1c, 2] furthermore, a hexameric Li-Na imide with a stack structure was described recently.[2c]

Here we describe novel stack structures of sodium dimethylamide with aggregation numbers of 10 and 12 (**1**–**3**) the preparation of these oligomeric amides was not our actual goal; they were obtained in attempts to metalate hydrocarbons (4-methylbiphenyl, 1,2,4,5-tetramethylbenzene (durene), and *p*-xylene) by treating them with *n*-butylsodium in the presence of the chelating ligand tetramethylethylenediamine (TMEDA).

$[Na_{10}(NMe_2)_{10}(tmeda)_4]$ **1**

$[Na_{12}(NMe_2)_{12}(tmeda)_4]$ **2**

$[Na_{12}(NMe_2)_{10}(CH_2C_6H_4Me)_2(tmeda)_4]$ **3**

In this method,[3] TMEDA is used to transform *n*BuNa, which is insoluble in hydrocarbons, into a soluble form and to complex the resulting products. In addition, the activation energy is considerably lowered by the solvating ligand, re-

[**] Metal-Alkyl and Metal-Aryl Compounds, Part 45. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dipl.-Chem. *Volker Jordan* for experimental help. Part 44: E. Weiss, S. Corbelin, J. K. Cockcroft, A. N. Fitch, *Chem. Ber. 123* (1990) 1629.

sulting in markedly shorter reaction times. The fragmentation of the ligand by highly reactive *n*-butylsodium partly counters these advantages in the reaction conditions.

The metalation of TMEDA by organolithium compounds and the subsequent fragmentation have already been investigated.[4] They require increased temperatures and proceed with preferential metalation of a terminal methyl group. We observed, in contrast, that treatment of TMEDA with *n*-butylsodium results to a large extent in amide formation and decomposition even at room temperature (yields of sodium dimethylamide: **1**, 34%; **2**, 48%). The limits of applicability of this metalation reaction are thus clearly evident. Here, the decomposition reaction apparently proceeds analogously to the ether cleavage, whereby the *N*-ligand in α position first is metalated and then decomposes with elimination of the amide [Eq. (a)].

$$Me_2NCH_2\text{-}CH_2NMe_2 + NaBu \xrightarrow[-BuH]{} Me_2NCH_2\text{-}CH(Na)NMe_2 \longrightarrow Me_2NCH{=}CH_2 + NaNMe_2 \quad (a)$$

The resulting amides **1** and **2** (Figs. 1, 2) have remarkable structures. They are oligomeric and correspond to the dode-

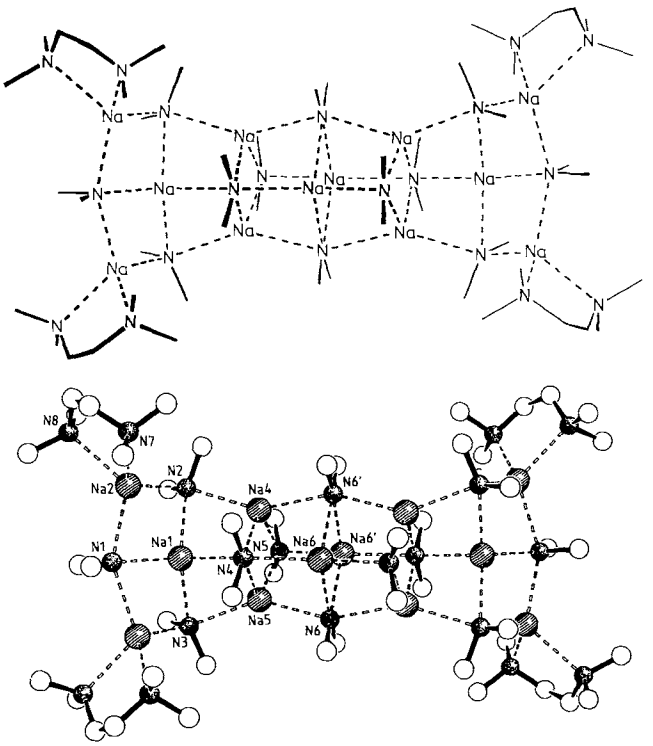

Fig. 2. Crystal structure of **2**. The unit cell contains two non-symmetry-related, but very similar molecules 1 and 2, each of which has a center of inversion at its center of gravity. Only molecule 1 is shown [7], but not the localized hexane molecule it contains [13]. Important distances [pm] and angles [°] for molecule 1 (the values for molecule 2 are very similar): Na1-N1 238, Na-N2 244, Na1-N3 245, Na1-N4 249, Na2-N1 248, Na2-N2 245, Na2-N7 259, Na2-N8 256, Na4-N4 255, Na4-N5 238, Na4-N2 252, Na4-N6' 260 Na5-N4 256, Na5-N5 242, Na5-N3 250, Na5-N6 250, N-C (NMe_2, average) 143.9; N1-Na1-N2 104.3, N1-Na1-N3 102.7, N1-Na1-N4 118.3, N2-Na1-N4 96.4, N2-Na1-N3 138.8, N1-Na2-N2 100.9, N7-Na2-N8 72.9, N4-Na4-N5 106.6, Na4-N4-Na5 71.0, N6'-Na6-N6 97.6, Na6-N6-Na6' 71.1.

sterically demanding. The terminal metal atoms of the stack are coordinatively saturated by solvent ligands (in this case, THF).

$[(LiC{\equiv}CtBu)_{12}(thf)]_4$ **4**

In a similar way, **1** and **2** could conceivably be formed by stacking of $Na_2(NR_2)_2$ rings. Here, however, the stacks are only ordered in their central portions with two roughly parallel rings (heterocubane system) in **1** and three parallel rings in **2**. At the ends of the stacks, the structures become more unsymmetric, although here, too, ring-shaped Na_2N_2 units

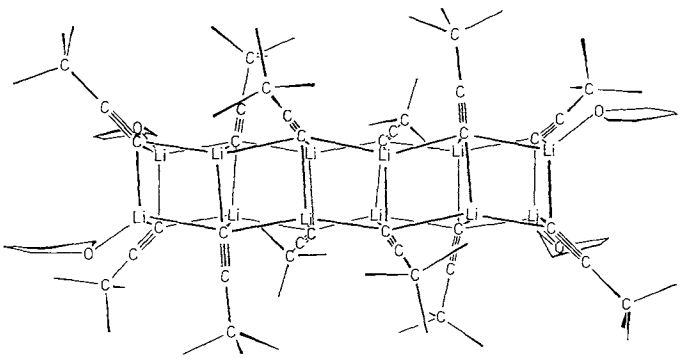

Fig. 3. Crystal structure of **4** [14].

are found and each Na atom is tetracoordinated by N atoms. The terminal Na atoms are coordinatively saturated by chelating TMEDA ligands. These ligands are sterically more demanding than THF and may therefore be responsible for the lower symmetry compared with **4**. Moreover, this results in more equal angles for the terminal pseudotetrahedral NaN_4 structural units of **1** and **2**, with strong deviations from tetrahedral angles occurring in the region of the four-membered ring stacks. In any case, the terminal structural units $Na_3(NMe_2)_3(tmeda)_2$ are particularly stable and are present in all the amide structures described here.

Further systematic investigations showed that solvated metal amides could be formed in high yields by direct synthesis from dimethyl-, diethyl-, or diphenylamine and *n*-butylsodium (or *n*-butyllithium) in the presence of TMEDA (or PMDTA = pentamethyldiethylenetriamine). The compounds characterized so far by X-ray analysis consist almost exclusively of dimers: for example, $[Na_2(NEt_2)_2(tmeda)_2]$, $[Na_2(NMe_2)_2(pmdta)_2]$, $[Na_2(NPh_2)_2(tmeda)_2]$, and $[Li_2(NPh_2)_2(tmeda)_2]$. The use of dimethylamine in excess results in formation of an oligomer $[Na_8(NMe_2)_8(HNMe_2)_2(pmdta)_2]$ with a complicated structure ($HNMe_2$ coordinated to a central $Na_2(NMe_2)_2$ four-membered ring).[8]

A further variant is offered by $[Na_{12}(NMe_2)_{10}(CH_2C_6H_4Me)_2(tmeda)_4]$ (**3**), which, in addition to amido groups, contains two *p*-xylyl moieties. Complex **3** was formed in an attempt to metalate *p*-xylene with *n*BuNa in the presence of TMEDA. Its structure is largely similar to that of **2** (Fig. 4). To the best of our knowledge, it is the first example of an alkali-metal complex containing organo and amido ligands; on the other hand, several mixed aggregates consisting of alkali amide and enolate[15a] or nitrile[15b] are known.

The compounds described here show that sodium amides can also have structures based on the "ring stacking principle". Similarly structured lithium amides have not yet been found. Based on theoretical model calculations, the suggestion has been made that further aggregation of lithium amide rings should lead preferentially to ladder structures and not to stacks. The results presented here indicate that this postulate is not valid for sodium amides.

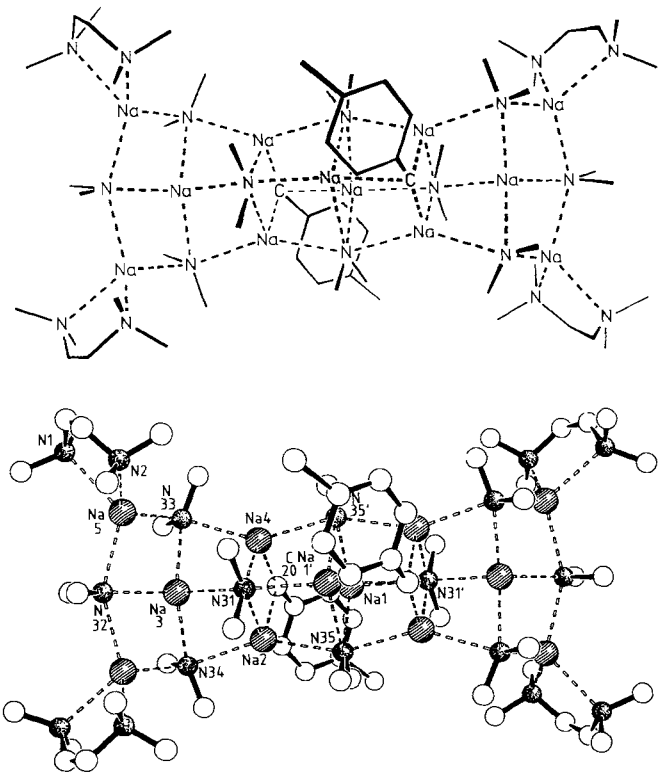

Fig. 4. Crystal structure of **3**. The *p*-xylyl and TMEDA groups are disordered. Therefore, the atomic positions are not exact [9, 13]. Important distances [pm] and angles [°]: Na1-C20 258, Na2-C20 259, Na4-C20 250, Na1-N35 253, Na1-N35′ 257, Na1-N31′ 244, Na2-N31 260, Na2-N35 254, Na3-N31 251, Na3-N33 245, Na3-N34 244, Na4-N35′ 252, Na4-N33 246, Na5-N33 241, Na5-N32 248, Na5-N1 256, Na5-N2 254; N35-Na1-N35′ 108.6, Na1-N35-Na1′ 71.5, C20-Na4-N31 108.2, C20-Na2-N31 103.5, Na2-N31-Na4 73.8; the other values are similar to those of **1** and **2**.

Experimental Procedure

1 · $C_{10}H_{14}$ ($C_{10}H_{14}$ = 1,2,4,5-tetramethylbenzene, durene): *n*-Butylsodium (1.2 g, 15 mmol) was suspended in 100 mL of hexane under inert atmosphere and largely dissolved by addition of TMEDA (9 mL, 60 mmol, dried over CaH_2). 1,2,4,5-Tetramethylbenzene (1.3 g, 10 mmol) was added to the dark brown, turbid solution, which was then stirred for a further 30 min at 20 °C. Clearing of the solution was accompanied by a lightening of the color. A yellow, finely crystalline precipitate formed and was collected by filtration. The filtrate was cooled to − 30 °C and afforded, after a few days, **1** as colorless, air-sensitive cubes with 1-cm edges; yield 0.74 g (34% based on *n*BuNa), correct elemental analyses for Na, C, H, N.

2 · 0.5 C_6H_{14} (C_6H_{14} = hexane): *n*-Butylsodium (0.8 g, 10 mmol) was suspended in 60 mL of hexane and largely dissolved by addition of TMEDA (6 mL, 40 mmol). 4-Methylbiphenyl (0.7 g, 4 mmol), dissolved in 20 mL of hexane, was added to the dark brown, stirred solution. The color lightened and an orange solid (0.5 g) precipitated and was removed by filtration. The filtrate was cooled to − 30 °C and afforded, after a few days, **2** as colorless cubes; yield 0.53 g (48%), correct analyses for Na, C, H, N.

3: *n*-Butylsodium (1.6 g, 20 mmol) was dissolved in 100 mL of benzene by addition of TMEDA (3 mL, 20 mmol) and the resulting solution was stirred overnight. Addition of *p*-xylene (2.4 mL, 19.4 mmol) resulted in transformation of the yellow-brown solution to an orange suspension. The reaction mixture was stirred overnight and the heterogeneous, brown-green precipitate (2.2 g) was removed by filtration. Upon long standing at 8 °C, the red-brown filtrate afforded **3** as brown cubes; yield 0.16 g (1.2%), correct analyses for Na, C, H, N; the heterogeneous main product has a different composition.

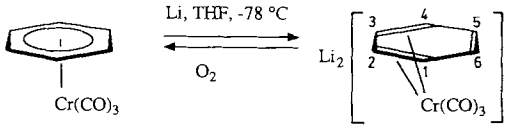
Synthesis and Direct NMR Spectroscopic Observation of $[(\eta^4\text{-Arene})Cr(CO)_3]$ Dianions**

By *Hans G. Wey* and *Holger Butenschön**

Although a change in hapticity from η^6 to η^4 has not been achieved by reaction of $[(arene)Cr(CO)_3]$ complexes with bidentate phosphanes,[1] $[(\eta^4\text{-arene})Cr(CO)_3]$ dianions are known and have been used for the synthesis of functionalized cyclohexadienyl complexes[2] and for $Cr(CO)_3$ transfer under mild conditions.[3] The only compound of this type to be fully characterized so far is the $[(\eta^4\text{-naphthalene})Cr(CO)_3]$ dianion,[4] which is stable at room temperature and for which the η^4 coordination is facilitated by involvement of the decomplexed double bond in an aromatic system—a stabilization similar to the "indenyl effect".[5] The $[(\eta^4\text{-benzene})Cr(CO)_3]^{2\ominus}$ dianion has already been obtained by reaction of benzenetricarbonylchromium(0) (**1**) with naphthalenepotassium.[2, 3] However, its characterization was based only on its IR data and chemical reactivity. Here we describe the synthesis of $[(\eta^4\text{-arene})Cr(CO)_3]$ dianions by a method that does not involve paramagnetic naphthalenepotassium. This approach avoids contamination of the product by and undesired ligand exchange reactions with naphthalene.

Reaction of **1**[6] with lithium sand in THF at $-78\,^\circ C$ results in a color change from yellow to red to brown. Filtration to remove the excess lithium sand affords a solution that is stable for several days at $-78\,^\circ C$, but which decomposes above $-40\,^\circ C$ to give a black solid and benzene. Exposure to atmospheric oxygen results in re-formation of **1** (ca. 50%) with partial decomposition.



1 **2**

The solution could be easily investigated at $-80\,^\circ C$ by ^1H and ^{13}C NMR spectroscopy.[7] The starting material **1** was no longer detectable. The only signals observed were those fully consistent with the formation of **2**. Particularly useful is a comparison of the ^{13}C NMR data of **2** with those of **1** and benzene (**3**) (Table 1). In agreement with the corresponding

Table 1. Comparison of the ^{13}C NMR data for **1**, **2**, and **3** (75.5 MHz, $[D_8]THF$).

	C-1(4)	C-2(3)	C-5(6)	CO
δ (**3**)	128.0	128.0	128.0	-

δ (**2**) − δ (**3**)	−72.4	−40.5	−3.5	-

values for $[(\eta^4\text{-naphthalene})Cr(CO)_3]^{2\ominus}$,[4] the chemical shifts of the terminal C atoms of the coordinated diene in **2** (C-1(4)) differ from those of benzene by $\Delta\delta = -72.4$; for the internal C atoms (C-2(3)), $\Delta\delta = -40.5$. The similarity of the data for **2** with those for the $[(\eta^4\text{-naphthalene})Cr(CO)_3]$ dianion, which also extends to the $^1J_{CH}$ couplings of C-3 and C-4, poses the question whether the benzene ligand in **2**, like the naphthalene ligand, is bent.[4]

In our work on cyclobutabenzene complexes,[8] we were also interested in the question of which double bond in the η^6-cyclobutabenzene complex **4**,[9] whose cyclovoltammogram exhibits an irreversible reduction at 2.45 V (vs. SCE, mercury drop electrode, 0.1 M nBu_4NClO_4 in THF, 100 mV s^{-1}) at 25 °C, is preferentially decomplexed upon reduction. Reaction of **4** with lithium sand gives a brown-yellow solution, which no longer contains **4** and which de-

[a, b] Interchangeable assignment. [c] The signals in the gated spectrum are clearly differentiated as singlet (C-6a) and doublet (C-3).

composes above −60 °C to give a metal-containing solid and cyclobutabenzene (**6**). Exposure to atmospheric oxygen resulted in reoxidation to **4**.

NMR spectroscopic analysis shows that the solution contains one main component, whose ^{13}C NMR data are most consistent with **5**. Also present are at least two minor components, whose signals partly correspond to isomers of **5**. This is in agreement with the reoxidizability of the products to **4**. Because of the isomeric side products, the ^1H NMR spectrum is of little value. The η^4 coordination in **5** is shown, however, by comparing its ^{13}C NMR data with those for cyclobutabenzene (**6**) (Table 2). For **5** and **2**, the changes in the chemical shifts of the terminal C atoms ($\Delta\delta = -77.3$ and -72.5, respectively) and the inner C atoms ($\Delta\delta = -49.3$ and -33.8, respectively) of the coordinated diene unit relative to those of the free ligand are similar. Apparently, the most strained double bond of the ligand remains preferentially in the coordination sphere of the metal. Similar observations were made earlier for 4,7-dihydroacepentalene complexes.[10]

IR spectra of **2** and **5** in THF at −30 °C and of **2** at −100 °C in KBr were recorded.[11] Owing to the increase in electron density at the metal atom, the carbonyl bands display lower wave numbers than those in the starting materials. Small deviations from the data obtained by *Cooper* et al.[2] for $K_2[(\eta^4\text{-benzene})Cr(CO)_3]$ and by *Rieke* et al.[4] for $Na_2[(\eta^4\text{-naphthalene})Cr(CO)_3]$ may be due to differing measurement conditions and counterions.

This work thus represents the first synthesis and spectroscopic characterization of naphthalene-free solutions of $[(\eta^4\text{-arene})Cr(CO)_3]$ dianions whose decomplexed double bond is not stabilized by an aromatic system. In order to check whether the absence of stabilization facilitates the transfer of the $Cr(CO)_3$ group to other arenes, **2** was allowed to react with *ortho*-xylene and **6**, both in excess. However, the $Cr(CO)_3$ group was not transferred. Therefore, the transfer to naphthalene[3] presumably occurs because naphthalene readily undergoes η^4 coordination.

Experimental Procedure

2: Lithium sand (40 mg, 5.7 mmol) was activated on the surface by vigorous stirring under argon. It was then cooled to −78 °C and combined, under a stream of argon, with a solution of **1** (214 mg, 1.0 mmol) in 4 mL of $[D_8]$THF cooled to −78 °C. The initially yellow reaction solution turned red after a few minutes and then brown. The suspension was stirred for 16 h at −78 °C and then filtered at −78 °C to remove excess lithium sand. The brown-yellow solution is stable for several days under argon at −78 °C.

[11] Only the positions of the carbonyl bands are given. **2**: IR (THF, −30 °C): $\tilde{\nu}$[cm^{-1}] = 1845 m, 1810 m, 1790 s, 1765 s, 1765 m, 1735 m, 1710 m, 1665 m. The bands at 1845, 1735, and 1665 cm^{-1} disappear after only a few seconds, whereas the other bands given here as well as those of the starting material at 1960 and 1885 cm^{-1} become more intense. IR (KBr, −100 °C): $\tilde{\nu}$[cm^{-1}] = 3500 br, 3020 m, 2920 m, 2740 m, 1792 s, 1759 s, 1724 s, 1510 w, 1480 w, 1445 m, 1300 m, 1180 m, 1155 m, 1025 s, 750 m, 678 m, 635 m, 535 m. **4**: IR (THF, −30 °C): $\tilde{\nu}$[cm^{-1}] = 1842 m, 1795 m, 1790 m, 1750 m, 1735 m, 1708 m, 1665 m. The bands at 1842, 1790, 1735, and 1665 cm^{-1} disappear after only a few seconds, whereas the other bands given here as well as those of the starting material at 1957 and 1878 cm^{-1} become more intense.

Organoosmium Oxides: Efficient Syntheses and Structures**

By *Wolfgang A. Herrmann,* Stefan J. Eder, Paul Kiprof, Kristin Rypdal*, and *Petra Watzlowik*

The little explored organometallic oxides[1] offer application in homogeneous and heterogeneous catalysis, for example in the oxidation and metathesis of olefins and in aldehyde olefination.[2] The synthesis of compounds of general formula $R_aM_bO_c$ has so far been left largely to chance, since the usual oxide and halide precursors are not easily alkylated because they are strong oxidants. An exception is the methylation of dirhenium heptaoxide,[3] although extension to

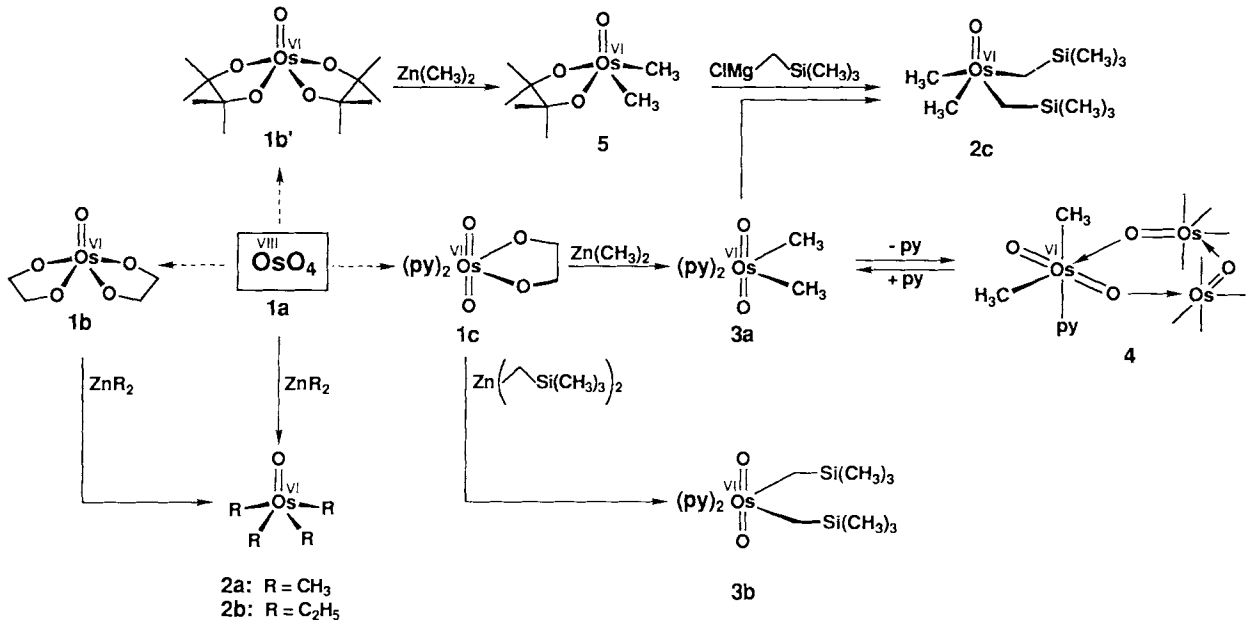
[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 84. This work was supported by the Fonds der Chemischen Industrie (doctoral fellowship to *S. J. E.*) and the Deutsche Forschungsgemeinschaft. Part 83: I. A. Degnan, W. A. Herrmann, E. Herdtweck, *Chem. Ber. 123* (1990) 1347.



Scheme 1. Synthesis of selected new organoosmium oxides. All compounds were characterized by elemental analysis; for further data see [7–9, 11, 12].

even closely related osmium tetraoxide is not possible. Here we describe a simple, generalizable synthetic procedure, as exemplified by organoosmium oxides. It is based on the selective alkylation of glycolate complexes of metals in high oxidation states.

Alkylosmium oxides of unpredictable composition are formed in poor yields upon direct alkylation of osmium(VIII) oxide.[4] For example, treatment of OsO_4 (**1a**) with dimethylzinc affords tetramethyl(oxo)osmium(VI) (**2a**) in only 19% yield (Scheme 1).[4g] Only recently was a more efficient synthesis of a tetraalkylosmium oxide described.[5]

On the other hand, reaction of dimethylzinc and the air-stable glycolate complex **1b**, obtained by treatment of **1a** with 1,2-ethanediol (> 95% yield),[6] affords the methyl compound **2a** in 60% yield as a red solid that sublimes under vacuum without decomposition.[7a] Compound **2a**, the simplest alkylosmium oxide so far, has a square-pyramidal molecular structure of symmetry C_4 in the gas phase (Fig. 1). It is resistant to both oxidation and reduction: the cyclovoltammetric half-wave potentials are 2.2 V (irreversible) and −1.58 V (reversible), respectively, versus Ag/AgCl in acetonitrile. Diethylzinc reacts with **1a** to give the ethyl compound **2b**, which decomposes above −60 °C and preferentially loses *n*-butane, ethane, and ethylene at room temperature.[7b]

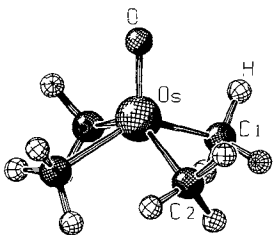


Fig. 1. Gas-phase structure of tetramethyl(oxo)osmium(VI) determined by electron diffraction. Selected bond lengths [pm] and angles [°]: Os-C 209.6(3), C-H 111.0(4), Os-O 168.1(4); C1-Os-C2 81.8(4), C1/C2/C3/C4-Os-O 112.2(5), Os-C-H 109(1); O-Os-C-H 24.(8).

The synthetic principle—exchange of a glycolate chelating ligand for two alkyl groups R—can be extended in a straightforward fashion to complex **1c**. As shown in Scheme 1, this reaction affords the dimethylosmium(VI) compound **3a** in 55% yield.[8a] Complex **3a** has a nearly undistorted octahedral molecular structure in the crystal with *trans* oxo and *cis* methyl groups (Fig. 2.) It is resistant to alkylzinc com-

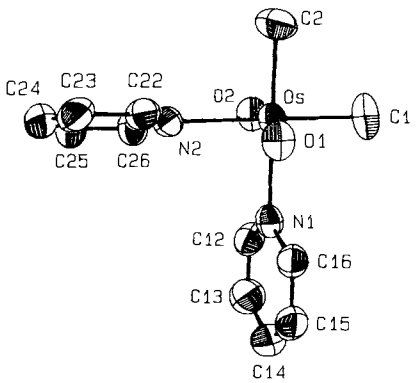

Fig. 2. Molecular structure of dimethyl(dioxo)bis(pyridine)osmium(VI) (**3a**) in the crystal (ORTEP plot without H atoms). Selected bond lengths [pm] and angles [°]: Os-O1 172.3(3), Os-O2 171.5(3), Os-C1 207.8(6), Os-C2 208.4(6), Os-N1 232.8(5), Os-N2 233.2(4); O1-Os-O2 164.8(2), C1-Os-C2 87.3(2), N1-Os-N2 88.9(1)[13].

pounds, but undergoes smooth alkylation on treatment with the Grignard reagent Me_3SiCH_2MgCl in a redox-neutral fashion and with retention of the *cis* configuration (!) (70% yield).[9] Organometallic oxides with *different* alkyl ligands are thus accessible for the first time by a direct and stereoselective reaction. Reaction of **1c** with bis(trimethylsilylmethyl) zinc gives complex **3b**[8b] (Scheme 1), which was also characterized by X-ray structure analysis.[10]

In vacuum, complex **3a** loses one molar equivalent of pyridine and affords the formally fivefold coordinated com-

plex $[OsO_2(CH_2)_3(py)]$. In the solid state, the latter complex forms the trinuclear compound **4**, which is octahedrally coordinated at osmium and has the same empirical formula (45% yield). The crystal structure (Fig. 3) is unusual in that an unsymmetrical, nearly planar Os_3O_3 six-membered ring, held together by O→Os donor bonds, is present.[11] However, these bonds stabilize only the solid-state structure. They are so weak that, even in chloroform or benzene, only monomers are present (vapor pressure osmometry). Addition of pyridine results in conversion of **4** back to **3a**.

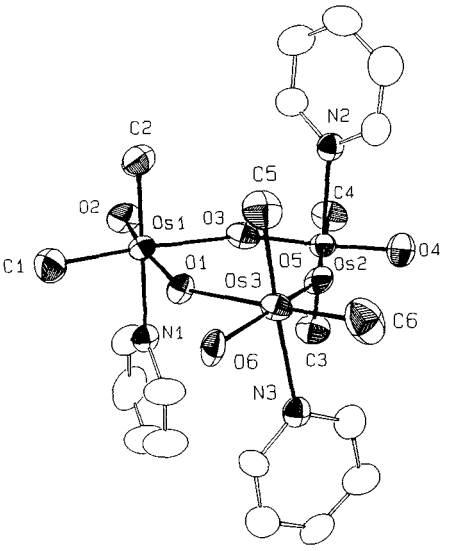

Fig. 3. Structure of trimeric dimethyl(dioxo)(pyridine)osmium(VI) (**4**) in the crystal (ORTEP plot without H atoms). Selected bond lengths [pm] and angles [°]: Os1-O1 173.5(3), Os1-O2 171.7(4), Os1-O3 231.2(4), Os3-O1 244.5(4), Os1-N1 232.4(6), Os1-C1 203.3(8), Os1-C2 207.0(7); O1-Os1-O2 164.3(2), C1-Os1-C2 89.1(3), O1-Os1-O3 81.9(2), Os1-O1-Os3 153.1(3)[13].

The constitution of the glycolate ligands may be used to control the selectivity of alkylation. The bulky bispinacolate complex **1b'** reacted with $Zn(CH_3)_2$ to give the dimethyl compound **5**, also characterized by an X-ray structure analysis,[10] in 55% yield.[12] The second chelating ligand here is only removed upon treatment with Grignard reagents (Scheme 1). This approach represents a second way to obtain mixed alkylated osmium oxides.

The glycolate derivatization—possibly with *reduction* (Scheme 1)—has proven useful in the efficient synthesis of alkyl(oxo) complexes of osmium in medium and high oxidation states. It is superior to the methods used so far with respect to yield, selectivity, and generizability. The route to a thorough exploration of this class of substances is thus open, and we have applied this technique to metals other than osmium.[14]

$CsF{\cdot}Br_2$, an Alkali-Metal Halide Intercalation Compound**

By *Darryl D. DesMarteau,* Thomas Grelbig, Sun-Hee Hwang,* and *Konrad Seppelt*

Cesium fluoride is one of the strongest fluoride catalysts, since it combines a very large cation and a very small anion in a simple NaCl-type lattice. Therefore, the salt has a strong tendency to "increase" the size of its anion by forming intermediate or permanent anionic fluoride complexes. There are a large number of complex cesium fluorides $Cs_x^{\oplus}AF_y^{\ominus}$, where A can be almost any element of the periodic system. Many of their structures are known.

In the reactions of fluorinated nitriles with bromine in the presence of CsF, the CsF was found to absorb bromine, which was not readily removed at room temperature.[1, 2] Subsequent investigation revealed that CsF can absorb both Br_2 and I_2 to form complexes in which the ratio $CsF:X_2$ is 1:1 and 2:1.[3] The $CsF{\cdot}Br_2$ complex is very effective in oxidizing fluorinated nitriles and imines to *N*-bromo derivatives as well as in converting N–Cl bonds into N–Br bonds in *N,N*-dichloroamines.[1–3] This reactivity, combined with the novelty of the CsF–halogen complexes, made their structure determination of interest.

The halogen-rich 1:1 phases are formed with excess halogen at room temperature, and the 2:1 materials can be prepared by prolonged pumping at 10^{-2} mbar on the 1:1 phases. The supposition that the 1:1 materials might contain the polyhalide ions [Br-Br-F]$^{\ominus}$ and [I-I-F]$^{\ominus}$ (cf. $Br_3^{\ominus}$, $BrF_2^{\ominus}$, $ICl_2^{\ominus}$, $Cl_2F^{\ominus}$) was not in accord with the Raman spectra of $CsF{\cdot}Br_2$, since it shows only one line at $\tilde{\nu} = 292.5\ cm^{-1}$, which is almost unchanged from the Raman line of elemental Br_2 (317 cm^{-1}). No BrF stretching vibration could be seen.

In the case of $CsF \cdot Br_2$, we succeeded in growing single crystals and carrying out an X-ray analysis (Fig. 1). Much to our surprise the compound is a cesium fluoride intercalation compound with Br_2 as guest. The NaCl-type cesium fluoride lattice has opened along the (100) planes and the Br_2 molecules are stacked between the planes. The cesium and fluorine atoms are arranged in an eclipsed manner along [100], resulting in a primitive tetragonal cell. The Br–Br distance of 232.4 pm is only slightly longer than that in elemental bromine (228 pm) and the $Br \cdots F^{\ominus}$ contacts (252.1 pm) are about 40% longer than a normal Br–F bond (180 ± 10 pm). Any covalent bonding here must be very weak.

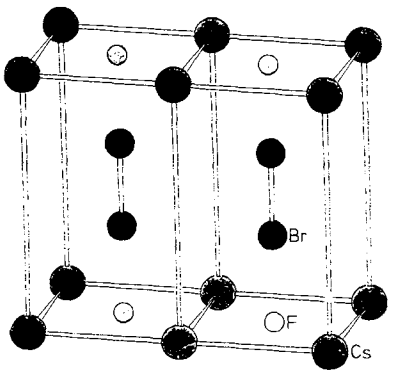

Fig. 1. Crystal structure of $CsF \cdot Br_2$ (two adjacent unit cells). The orange crystals were grown from CsF in a large excess of elemental bromine at 80 °C in a glass ampoule over four weeks. Enraf-Nonius CAD-4 diffractometer, $T = -153$ °C, $Mo_{K\alpha}$, graphite monochromator, $\omega/2\theta$ scan, DIFABS absorption correction. SHELX, full matrix, *P4/mmm* (No. 123), $a = 417.7(2)$, $c = 736.4(2)$ pm, $V = 128.5 \times 10^6$ pm^3, $Z = 1$. Reflections: 886 measured, 287 independant, 264 with $I \geq 3\sigma(I)$ within $2 \leq \theta \leq 40°$. $R = 3.15$, $R_w = 2.6$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftliche und technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54259, the names of the authors, and the journal citation.

If one considers the NaCl lattice to be very stable, this reaction is very surprising. But Madelung lattice energy calculations (MAPLE)[4] on CsF show that cleavage along (100) results in loss of only 6% of the energy; which explains the cleavability parallel to (100) for such crystals. If entropic terms are disregarded, this small loss of electrostatic energy could be compensated for by even very weak $Br \cdots F^{\ominus}$ interactions, which could amount to only a few kJ mol^{-1}.

The coordination of the $Cs^{\oplus}$ ions is square planar and the $Cs^{\oplus} \cdots F^{\ominus}$ distance of 300.1 pm in cesium fluoride is reduced to 294.0 pm in $CsF \cdot Br_2$. This is virtually identical to the $Cs^{\oplus} \cdots F^{\ominus}$ distance of 293.6 pm in the high-pressure CsF (CsCl-type) modification (48 kbar).[5] If the bromine atoms at a distance of 388 pm are included in the coordination of $Cs^{\oplus}$, the coordination number is 12 and the coordination polyhedron a square-based column.

Whether these features are retained in $CsF{\cdot}I_2$ and whether the 2:1 phases are intercalates where only every second layer is filled remain speculation until structural data are available.

$(NBu_4)[Sn\{Pt(\mu\text{-}Cl)(C_6F_5)_2\}_3]$, an Unusual Cluster with Three $Pt^{II} \rightarrow Sn^{II}$ Bonds**

By *Rafael Usón,* Juan Forniés, Milagros Tomás,* and *Isabel Usón*

The insertion of $SnCl_2$ into M–Cl bonds to give $Cl_3Sn \rightarrow M$ bonds is well documented.[1] Adducts of the general type $[Cl_2Sn\{M(PMe_3)_3Cl\}_2]$ (M = Rh, Ir), displaying two $M \rightarrow SnCl_2$ bonds have been prepared recently and the structure of the rhodium complex has been solved by X-ray crystallography.[2] But, to the best of our knowledge, no complexes with bonds from a Pt^{II} moiety to an otherwise bare Sn^{II} center have, so far, been reported.

During the last few years we have shown that anionic pentahalophenyl complexes of platinum(II) are suitable precursors for the synthesis of heteronuclear complexes containing $Pt \rightarrow Ag$ bonds, since the basic platinum centers enable them to act as donor atoms to the electrophilic silver ions in silver salts ($AgClO_4$, $AgNO_3$) or silver complexes such as $[O_3ClOAgPPh_3]$.[3] Therefore, we have explored the use of anionic platinum(II) derivatives as Pt-donor ligands towards other electrophiles. Here we describe the synthesis of an unprecedented tetranuclear cluster containing three $Pt^{II} \rightarrow Sn^{II}$ bonds unsupported by any covalent bridging ligands; the Sn^{II} center is only linked to three Pt^{II} atoms and additionally displays short contacts to several *o*-F atoms of pentafluorophenyl groups.

Addition of $SnCl_2$ and $AgClO_4$ to a THF solution of the Pt complex **1**[4] at room temperature leads to precipitation of AgCl. The tetranuclear complex **2** can be obtained from the filtrate in 75% yield [Eq. (1)].

$$1.5(NBu_4)_2[Pt_2(\mu\text{-}Cl)_2(C_6F_5)_4] + SnCl_2 + 2\,AgClO_4 \xrightarrow{THF} \underset{\mathbf{1}}{} \quad (1)$$

$$2\,AgCl\downarrow + 2NBu_4ClO_4 + \underset{\mathbf{2}}{(NBu_4)[Sn\{Pt(\mu\text{-}Cl)(C_6F_5)_2\}_3]}$$

It is important to strictly maintain the given stoichiometry, since an excess of $AgClO_4$ also precipitates the bridging chloride ligands between the Pt^{II} atoms, leading to decomposition.

The structure of **2** has been established by a single-crystal X-ray study.[5] The unit cell (space group *Cc*) contains, in addition to the corresponding cations, two types of independent anions of the same composition (A and B) with very similar central cores but different orientations of the C_6F_5 groups (Fig. 1).

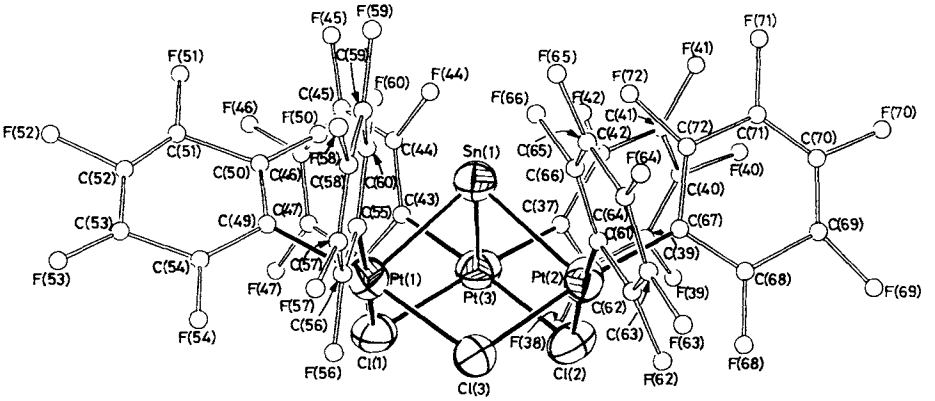

Fig. 1. Molecular structure of the anion in **2**. Selected bond lengths [Å] and bond angles [°]: anion A: Sn(1)-Pt(1) 2.732(2), Sn(1)-Pt(2) 2.742(3), Sn(1)-Pt(3) 2.704(2), Pt(1)-Cl(1) 2.414(6), Pt(1)-Cl(3) 2.373(7), Pt(2)-Cl(3) 2.401(7), Pt(2)-Cl(2), 2.415(6), Pt(3)-Cl(2) 2.372(7), Pt(3)-Cl(1) 2.426(8), Pt(1)-C(49) 2.029(23), Pt(1)-C(55) 2.068(23), Pt(2)-C(61) 1.943(19), Pt(2)-C(67) 1.968(23), Pt(3)-C(37) 1.981(24), Pt(3)-C(43) 2.028(24); Pt-Sn-Pt 87.7(30); Sn(1)-F(42) 2.9996(150), Sn(1)-F(44) 3.2526(166), Sn(1)-F(50) 2.9706(184), Sn(1)-F(60) 3.0491(132), Sn(1)-F(66) 3.0882(138), Sn(1)-F(72) 3.0946(153). anion B: Sn(2)-Pt(4) 2.733(2), Sn(2)-Pt(5) 2.703(3), Sn(2)-Pt(6) 2.734(2), Pt(4)-Cl(4) 2.439(7), Pt(4)-Cl(6) 2.417(7), Pt(5)-Cl(4) 2.386(7), Pt(5)-Cl5 2.404(7), Pt(6)-Cl(5) 2.422(7), Pt(6)-Cl(6) 2.396(7), Pt(4)-C(25) 1.989(25), Pt(4)-C(31) 1.960(23), Pt(5)-C(1) 2.007(23), Pt(5)-C(7) 2.048(23), Pt(6)-C(13) 1.957(23), Pt(6)-C(14) 1.962(27); Pt-Sn-Pt 88.1(9); Sn(2)-F(6) 2.8887(137), Sn(2)-F(8) 3.1309(132), Sn(2)-F(18) 3.0643(161), Sn(2)-F(24) 3.1668(133), Sn(2)-F(26) 3.0035(160), Sn(2)-F(32) 3.1930(136).

The cluster can be described as a $[Pt_3(\mu\text{-}Cl_3)(C_6F_5)_6]^{3\ominus}$ unit with a six-membered, puckered Pt_3Cl_3 ring in which the three Pt atoms are interconnected by three chloride bridges and linked to the Sn^{II} atom by platinum-to-tin donor–acceptor bonds. Thus, the Pt_3Cl_3 moiety acts as a tridentate ligand to the Sn atoms. Each platinum atom has square-pyramidal coordination with an apical Sn atom; the basal plane is defined by the *ipso*-C atoms of two C_6F_5 groups and two chloride ligands and the Pt–Sn bonds form angles of 10.63–

13.66° with the perpendicular to each basal plane.[6] The Pt–Sn distances (2.703(3) to 2.742(3) Å) are within the expected range of 2.5[1] to 2.8[7,8] Å. Finally, short contacts between several *o*-F atoms and the Sn atom are present. As in the case of previously reported *o*-F···Ag contacts,[3] they are presumably responsible for the structure and stability of the cluster. The comparison parameter ρ (= experimental distances/sum of covalent radii)[9] has values between 1.42 and 1.59, which lie at the high end of the range found for *o*-F···Ag contacts, implying weak *o*-F···Sn interactions. Complex **2** behaves as 1:1 electrolyte in acetone solution; that is, the Pt → Sn bonds resist cleavage by this solvent.

We are studying the feasibility of preparing similar clusters. By substituting $PbCl_2$ for $SnCl_2$ in Equation (1), we have isolated a compound having the expected composition, but structural information is still lacking.

Experimental Procedure

A mixture of **1** (0.3 g, 0.1858 mmol), anhydrous $SnCl_2$ (0.0235 g, 0.1239 mmol), and $AgClO_4$ (0.0513 g, 0.2478 mmol) in THF (40 mL) was stirred at room temperature for 30 min. The suspension was evaporated to dryness and the residue treated with diethyl ether (50 mL). After filtration, a white residue (AgCl + NBu_4ClO_4) and a yellow solution were obtained. The solution was evaporated to dryness, the resulting oily residue was dissolved in CH_2Cl_2 (10 mL), and **2** (75% yield) was precipitaed by addition of pentane. Correct C,H,N analysis; m.p. 170 °C (dec.); molar conductivity (acetone $c \approx 5 \times 10^{-4}$ M), 128 S m^2 mol^{-1}. IR (Nujol), $\tilde{\nu}$ in cm^{-1}: C_6F_5 groups 1638 w, 1611 w, 1511 s, 1067 s, 964 s; X-sensitive [10] 813 s, 805 s; $NBu_4^{\oplus}$ 885; ν(Pt-Cl) 296 m,br.

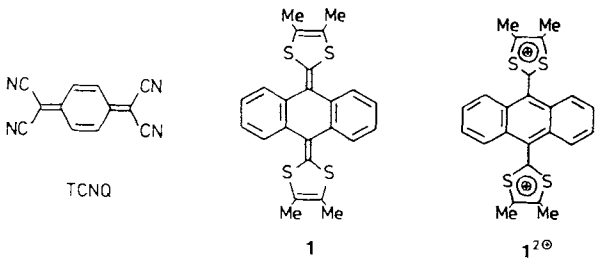
Electrical and Magnetic Properties and X-Ray Structure of a Highly Conductive 4:1 Complex of Tetracyanoquinodimethane and a Tetrathiafulvalene Derivative**

By *Martin R. Bryce,* Adrian J. Moore, Masihul Hasan, Geoffrey J. Ashwell,* Alexander T. Fraser, William Clegg, Michael B. Hursthouse*, and *A. I. Karaulov*

Extended tetrathiafulvalene (TTF) derivatives have been identified by several groups to be promising donor molecules for the formation of new organic metals.[1–6] These large donors may be expected to form nonstoichiometric complexes with 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) (by virtue of size mismatch) and they are known to form stable dication species; this is in marked contrast to TTF itself, for which the dication is destabilized by intramolecular Coulombic repulsion.[7] Although many extended TTF derivatives having alkenic, acetylenic, and quinonoid linking groups are known,[1–6] single crystals of neutral donors and their salts have been very difficult to obtain. Consequently, very little solid-state data are available for these materials. We now report the single-crystal X-ray structure of the donor 9,10-bis(4,5-dimethyl-1,3-dithiole)-2-ylidene-9,10-dihydroanthracene (**1**); we have recently reported the synthesis of this donor from anthraquinone.[8] *Yamashita* et al. have also synthesized analogues of this system.[5] We also present electrical, magnetic, and single-crystal X-ray data for a highly conducting 1:4 complex of **1** with TCNQ.



The crystal structure of the neutral donor **1** is shown in Figure 1a.[9] The molecule is butterfly-shaped with the central quinonoid ring severely distorted into a boat form.[10] Nonetheless, **1** forms a highly conductive 1:4 complex[11] with TCNQ, which is isolated from acetonitrile solution in 48% yield, and an insulating 1:2 salt with 2,5-dibromo-TCNQ. The 1:2 salt is diamagnetic with $\chi = -5.7 \times 10^{-4}$ emu mol^{-1}, the value being temperature-independent and consistent with that obtained from Pascal's constants. In contrast, the 1:4 TCNQ complex is paramagnetic. The susceptibility at 300 K, corrected for core diamagnetism, $\chi = 2.5 \times 10^{-3}$ emu mol^{-1}, corresponds to an effective mo-

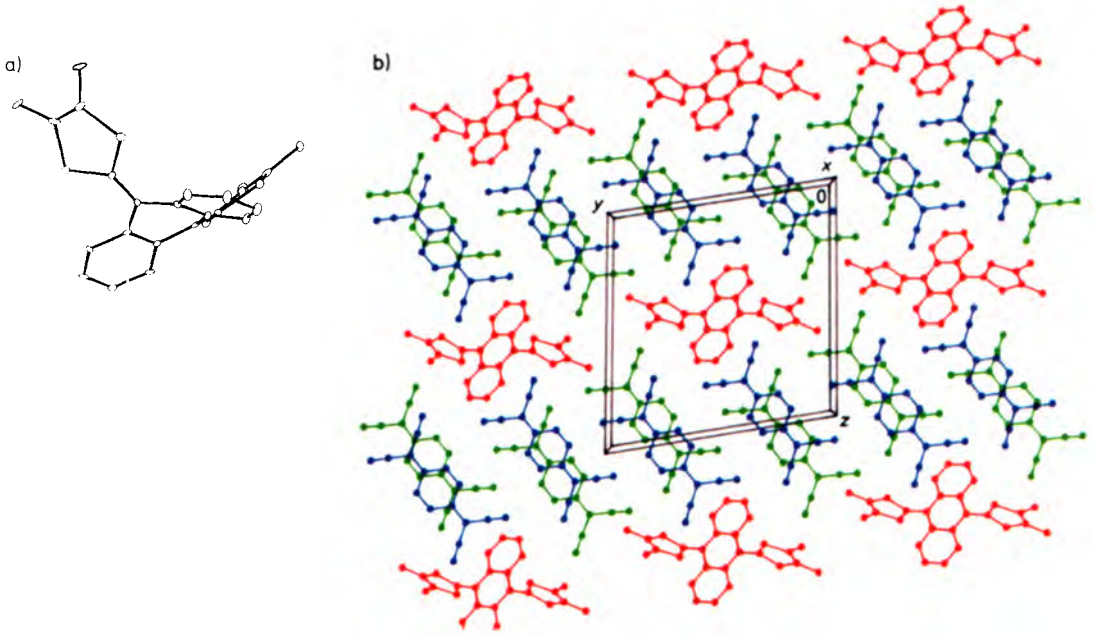

Fig. 1. Crystal structure of **1** (a) and the 1:4 complex $\mathbf{1}^{2\oplus}[(TCNQ)_4]^{2\ominus}$, projected along *a* (b).

ment of 2.45 μ_B. This value is lower than the 2.828 μ_B required of a triplet but is in close agreement with $\mu_{eff} = 2.449\ \mu_B$ for two independent spins per TCNQ formula unit. However, there is some uncertainty regarding the mechanism, since the effective moment is constant for a limited temperature range only.

The crystal structure of the 1:4 complex $\mathbf{1}^{2\oplus}[(TCNQ)_4]^{2\ominus}$, projected along *a*, is shown in Figure 1b.[12] The donor, in the dication form, adopts a dramatically different conformation from that of the neutral species, with dihedral angles of 86.0° between the planar anthracene group and the two dithiole rings. The dication is located on a center of symmetry. The TCNQ molecules stack plane-to-plane, parallel to *a*, with favorable ring-over-bond overlap and a uniform intermolecular spacing of 3.36 Å. The dimensions of the crystallographically independent molecules indicate that there is partial localization of charge onto alternate TCNQ molecules along the stacks.

$\mathbf{1}^{2\oplus}[(TCNQ)_4]^{2\ominus}$ is the first semimetallic TCNQ complex to be formed by a TTF-type donor that adopts such a nonplanar conformation.[13] The conductivity, $\sigma_{300K} = 60\ S\ cm^{-1}$, varies only slightly upon cooling to ca. 90 K but then decreases abruptly with a plateau between 50 and 70 K (Fig. 2a). This is mimicked by the susceptibility data, which show a plateau between ca. 40 and 80 K (Fig. 2b). In this temperature region, one sample showed an anomalous transition to a higher susceptibility state which persisted for several heating/cooling cycles. The effective moments, before and after switching, conformed to values for *two* and *four* spins per formula unit, respectively, signifying an unpairing of spins on the $\mathbf{1}^{2\oplus}$ stacks. Thus, we attribute the high conductivity to delocalized electrons on the uniform TCNQ stacks and the electrical and magnetic behavior in the 40–90 K region to structural transitions.

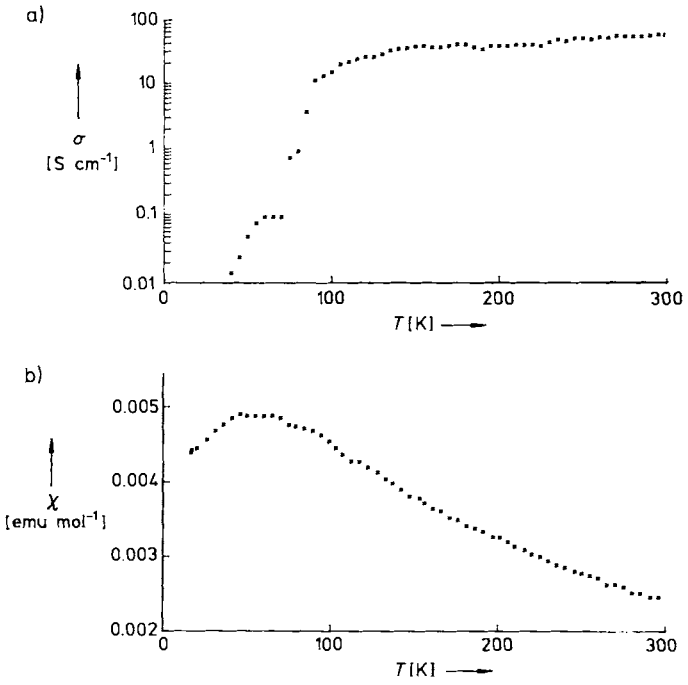

Fig. 2. Temperature dependence of the electrical conductivity σ (a) and the magnetic susceptibility corrected for core diamagnetism (b) of $\mathbf{1}^{2\oplus}[(TCNQ)_4]^{2\ominus}$. The data depicted correspond to cooling runs.

New Copper Clusters Containing Se and PEt_3 as Ligands: $[Cu_{70}Se_{35}(PEt_3)_{22}]$ and $[Cu_{20}Se_{13}(PEt_3)_{12}]$**

By *Dieter Fenske** and *Harald Krautscheid*

Dedicated to Professor Klaus Krogmann on the occasion of his 65th birthday

We recently reported on the reaction of CuCl with $Se(SiMe_3)_2$ in the presence of tertiary phosphanes such as $PtBu_3$ and $PiPr_3$.[1] High yields of clusters **1**–**3** were thereby obtained.

$[Cu_{29}Se_{15}(PiPr_3)_{12}]$ **1**

$[Cu_{30}Se_{15}(PiPr_3)_{12}]$ **2**

$[Cu_{36}Se_{18}(PtBu_3)_{12}]$ **3**

Apparently, the structures of the resulting cluster complexes are influenced by the phosphane used. We have therefore investigated which cluster complexes are formed on reaction of CuCl with $Se(SiMe_3)_2$ and PEt_3. Carried out in THF or toluene, this reaction results in a deep brown solution from which no crystalline products are isolable. On the other hand, crystals suitable for crystal structure analysis are obtained when the starting compounds are dissolved at -80 °C in diethyl ether and the reaction temperature is raised over several days to 20 °C. The resulting needles of **4** (yield ca. 60%) display a metallic luster. Although we have performed this reaction repeatedly, in only one case did we obtain black, octahedral crystals of composition **5**.[2]

$$CuCl + PEt_3 + Se(SiMe_3)_2 \rightarrow \underset{\mathbf{4}}{[Cu_{70}Se_{35}(PEt_3)_{22}]} + \underset{\mathbf{5}}{[Cu_{20}Se_{13}(PEt_3)_{12}]}$$

The IR spectra of **4** and **5** show the vibrational bands characteristic of PEt_3 ligands. Only one resonance signal ($\delta = -10$), providing no structural information, is found in the ^{31}P NMR spectrum (121.5 MHz, C_6D_6, 25 °C, H_3PO_4) of **4** owing to rapid exchange of the phosphane ligand.

The structures of **4** and **5** were determined by single-crystal investigations.[3] Cluster **5** (Fig. 1) consists of an undistorted

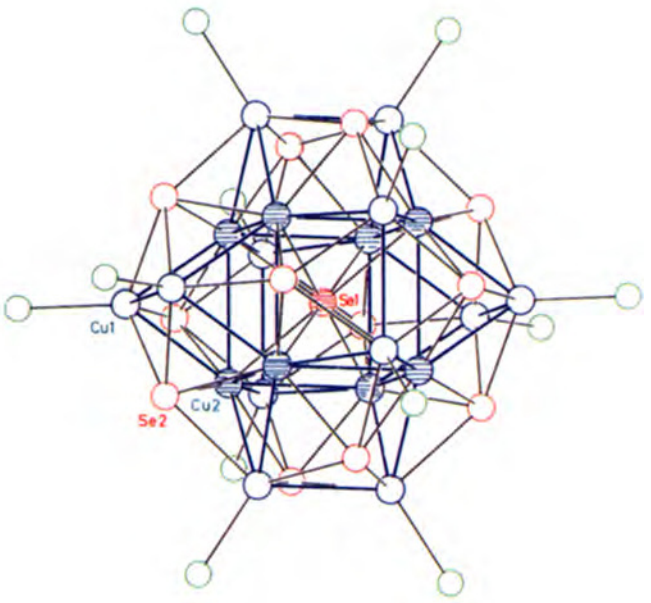

Fig. 1. Molecular structure of the cluster $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**5**) (C atoms omitted; Cu, blue; Cu1, open circles; Cu2, hatched; Se, red; Se1, hatched; Se2, open circles; P, green).

Cu_8 cube (Cu2, blue, hatched; Cu2-Cu2 300.8(3) pm), each of whose edges is bridged by a Cu1 atom (Cu1, blue, open circle; Cu1-Cu1 282.1(3) pm). The P atoms (green) of the PEt_3 ligands are bonded to each of these peripheral Cu1 atoms. In the resulting 20-atom Cu polyhedron, the shortest separations are those between Cu1 and Cu2 (267.8(3) pm). The μ_8-Se ligand Se1 (red, hatched; Se1-Cu2 260.5(3) pm) lies at the center of **5** and twelve μ_5-Se2 ligands cap all faces of the polyhedron (Se2, red, open circles; Cu1-Se2 247.7–260.1, Cu2-Se2 244.8(3) pm).

Alternatively, the Cu framework can be described in terms of six trigonal prisms, linked through common edges. Planes consisting of six Cu atoms result thereby. The Cu cluster is surrounded by twelve Se2 ligands, which form a nearly undistorted icosahedron (Se2 $\cdots$ Se2 392–415 pm). This structural principle is clearly illustrated in Figure 2 in which the faces of the Se icosahedron are drawn. However, the conceivable interpenetration of two dual polyhedra, an Se_{12} icosahedron and a Cu_{20} pentagonal dodecahedron, is only

Popp* for help in producing the figures.

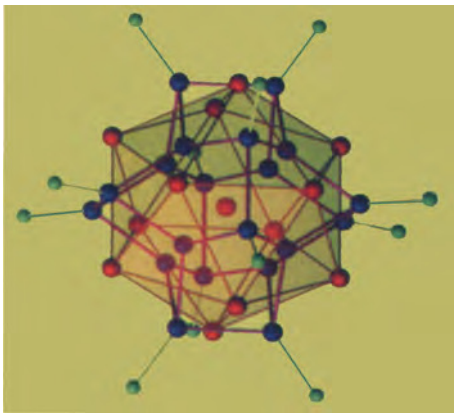

Fig. 2. Structure of the Se_{12} icosahedron (red) and the interpenetrating Cu_{20} polyhedron (Se, red; Cu, blue; P, green; Se–Cu bonds not shown).

realized in part, since, owing to the Cu–Cu interactions, the twelve Cu1 atoms lie above and the eight Cu2 atoms below the faces of the Se icosahedron.[12]

Thus, the bonding in **5** is different from that in the structurally related cluster $[Pd_{20}As_{12}(PPh_3)_{12}]$, in which the cluster center is unoccupied.[4] Consequently, the Pd–Pd bonds in the Pd_8 cube are significantly shorter (278.5–291.7 pm). The electron count in **5** gives 298 valence electrons. Assuming that all Cu–Cu distances less than 290 pm are bonding, the 18-electron rule is exceeded by only two electrons.

Comparison of the structures of **1**–**3** and **5** clearly reveals that use of PEt_3 ligands, which are not very sterically demanding, apparently can lead to a new cluster composition. In our attempts to isolate further copper complexes by reaction of CuCl with $Se(SiMe_3)_2$ and PEt_3, we were surprised to find only the $Cu_{70}Se_{35}$ cluster **4**, the largest cluster to be characterized so far by X-ray structure analysis.

Figure 3 shows that **4** contains a twofold axis through Se9, Se13, Cu31, Cu34, and Se19. The description of the structure of the Cu framework is problematic. Notable is the structural fragment shown in violet in Figure 4. It consists of two trigonal bipyramids that share a common vertex and in which two faces are bridged by Cu_2 units. Figure 4 clearly reveals that these Cu_{13} units (Cu6–Cu18 and Cu27–Cu33) are present three times in the Cu_{70} cluster and are linked through nearly planar layers of six (Cu21–Cu23) and seven (Cu19, Cu20, Cu23–Cu26) Cu atoms, respectively. Fifteen Cu atoms (Cu1-Cu5 and Cu34-Cu36) are bonded to the periphery of this structural fragment.

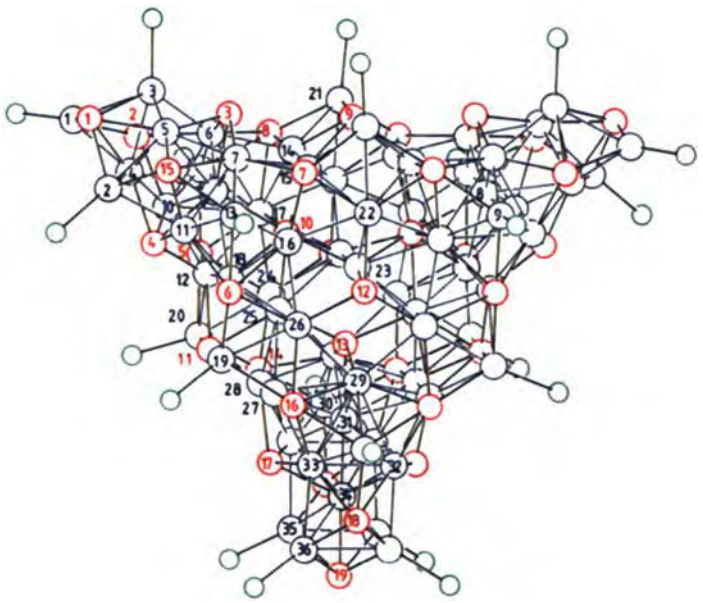

Fig. 3. Molecular structure of the cluster $[Cu_{70}Se_{35}(PEt_3)_{22}]$ (**4**) (C atoms omitted; Cu, blue; Se, red; P, green). Cu–Cu bonds up to 290 pm long and Cu–Se bonds up to 275 pm long are drawn. For clarity, the Cu atoms are labeled with blue numbers, the Se atoms with red numbers.

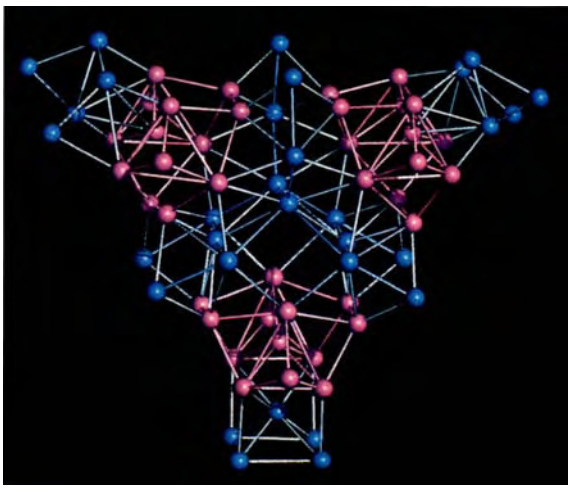

Fig. 4. Structure of the Cu_{70} framework in **4**.

The Se ligands are involved in different kinds of bonding. Se12 (Fig. 3) is present as a μ_4 bridge (Cu-Se12 233.6–240.1(5) pm). Se1, Se3, Se13, Se15, Se18, and Se19 serve as μ_5 ligands with Cu–Se distances of 236.4–268.8(5) pm. Se2, Se4–Se9, Se14, Se16, and Se 17 are μ_6-Se ligands (Cu-Se 234.2–273.2(5) pm). Se11 (Cu-Se 243.3–273.5(5) pm) and Se10 (Cu-Se 246.1–270.9(5) pm) function as μ_7 and μ_8 bridges, respectively.

The peripheral Cu atoms (Cu1–Cu3, Cu9, Cu13, Cu19–Cu21, Cu30, Cu35, and Cu36) are bonded to the P atoms of the PEt_3 ligands, which completely shield the surface of the cluster. Cu2, Cu35, and Cu36 are additionally surrounded by two Se and three Cu atoms (Cu-Cu 255.9–271.2(5) pm). Cu9, Cu13, Cu19–Cu21, and Cu30 form bonds to three Cu atoms (Cu-Cu 256.3–268.2(5) pm) and three Se atoms. Only Cu1 and Cu3 are bonded to two Cu and two Se atoms and to four Cu and three Se atoms (Cu-Cu 255.7–269.2(5) pm), respectively. All other Cu atoms inside the Cu cluster have coordination number 9 or 11. They are each bonded to three Se and six Cu atoms or to three Se and eight Cu atoms (Cu-Cu 242.5–289.6(5) pm). Similar Cu-Cu distances to those in **4** and **5** are also found in **1**–**3** and in other multinuclear copper complexes; they are indicative of only weak Cu-Cu interactions.[1, 5]

Cluster **4** contains 960 valence electrons. A comparison with the electron count calculated by rules such as the 18-electron rule is not possible, since the spectrum of Cu-Cu distances shows no clear boundary for possible Cu-Cu bonds. Overall, 210 Cu–Cu distances lie in the range 240–330 pm and 141 of these lie between 240 and 280 pm.

In the $Cu_{70}Se_{35}$ cluster, Cu has a formal charge of + 1. Accordingly, diamagnetic behavior would be expected. In fact, we find $\chi_{mol} = -2.73 \times 10^{-3}$ emu mol^{-1} at room temperature. Taking into consideration the diamagnetic increments for $Cu^{\oplus}$, $Se^{2\ominus}$, and PEt_3, a weak temperature-inde-

pendent paramagnetism of $\chi_{mol} = +1.77 \times 10^{-3}$ emu mol^{-1} [6] is obtained. This result is in agreement with the magnetic properties of Cu_2Se.[7]

The Cu:Se ratio is 2:1 in both **4** and Cu_2Se. Heating **4** to above 160°C results in loss of PEt_3 and formation of a (previously) unknown phase, which, on further warming, transforms into β-Cu_2Se (cubic). Cooling to below about 130°C affords α-Cu_2Se (monoclinic).[8] Accordingly, **4** may be regarded as a molecular precursor for the formation of binary copper selenides. This is consistent with findings made by *Steigerwald* et al. on the formation of NiTe from $[(cod)_2Ni]$ and Et_3PTe.[9]

Apparently, **4** and **5** are formed via a previously unknown and rather complex reaction path. Remarkably, however, **4** contains a Cu_9 unit (Fig. 3: Cu32–Cu36) whose structure is nearly identical with that of a Pd cluster of composition $[Pd_9As_8(PPh_3)_8]$. This compound is formed on reaction of $[PdCl_2(PPh_3)_2]$ with $As(SiMe_3)_3$ as part of a mixture also containing $[Pd_{20}As_{12}(PPh_3)_{12}]$, the Pd analogue of **5**.[4, 10] Possibly, the nine-atom metal cluster is an intermediate in the condensation to very large clusters. Further examples of metal clusters containing a large number of metal atoms are $[Au_{18}Ag_{19}Br_{11}(P\textit{p}\text{-}Tol_3)_{12}]^{2\oplus}$, $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n\ominus}$, $[Pd_{38}(CO)_{28}(PEt_3)_{12}]$, $[Au_{55}(PPh_3)_{12}Cl_6]$, $[Au_{13}Ag_{12}Br_8(P\textit{p}\text{-}Tol_3)_{10}]^{\ominus}$, and $[Ni_{34}Se_{22}(PPh_3)_{10}]$.[11]

New Benzyl(β-oxido)phosphorus and -arsenic Ylides: Reactivity and Stereoselectivity in the Wittig Reaction**

By *Benaissa Boubia, André Mann, François D. Bellamy,* and *Charles Mioskowski**

Owing to its convenience and efficiency, the Wittig reaction is one of the most useful olefination methods used in organic chemistry. Generally, high selectivity for *E* or *Z* alkenes is achieved depending on the reaction conditions.[1] Furthermore, if the phosphorus atom bears other substituents than phenyl, the *E*/*Z* ratio can be increased or inverted.[2] Oxidophosphoranes show an increase in *E* selectivity.[3, 4] Particulary interesting are the β-oxido ylides, which were first prepared by *M. Schlosser* et al.[5] and subsequently developed by *E. J. Corey* et al.[6] and which have been used in the synthesis of natural compounds.[7] Depending on the order of addition of the aldehydes, trisubstituted olefins with controlled geometry are accessible. In general, the second aldehyde promotes the formation of the double bond, its oxygen atom being eliminated during the reaction as triphenylphosphane oxide. An exception is formaldehyde, which does not participate in the olefin formation.[1]

In view of the fact that Wittig condensation of semi-stabilized ylides gives mixtures of *E* and *Z* isomers, and taking into consideration the above-mentioned data, we have developed new benzyl ylides in order to form stereoselectively *E* isomers.[8] Since phosphorus and arsenic ylides behave differently in the Wittig condensation,[9] we have designed two new β-oxido benzyl ylides, **2a, b**, where the oxido and the ylide parts are two different appendages of P and As. The corresponding salts **1a, b** were easily prepared from the

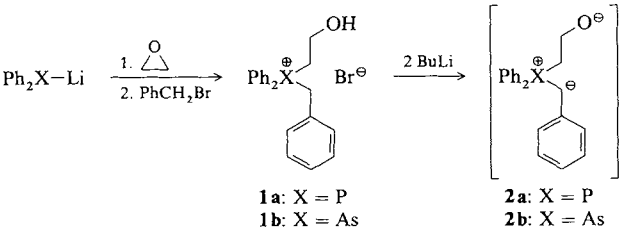
[**] This work was funded by the CNRS and the Laboratoires Fournier, Dijon. We thank Prof. *M. Schlosser* for suggesting the experiment described in [12].

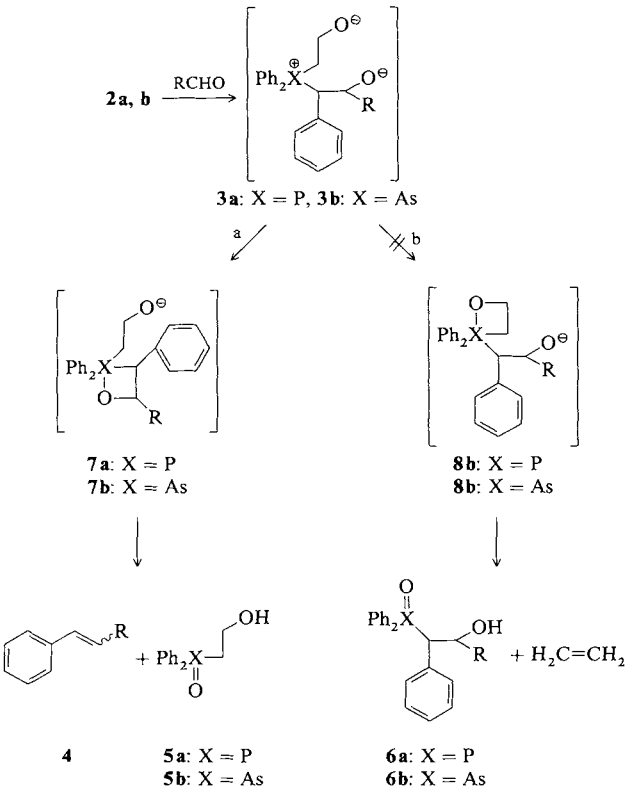
known lithiodiphenylphosphane[10] and -arsane[11] by condensation with ethylene oxide followed by reaction with benzyl bromide. The ylides **2a, b** were obtained by addition of two equivalents of BuLi to the salts **1a, b** in THF or in a mixture of THF and HMPA (hexamethylphosphoramide) (85/15) at $-20\,^{\circ}C$.



1a: X = P
1b: X = As

2a: X = P
2b: X = As

The reaction of these ylides with aldehydes (piperonal or hexanal) leads to the di(β-oxido) ylides **3a, b**, which can react further to give either olefins **4** and oxides **5** (pathway a) or ethylene and oxides **6** (pathway b) via oxaphosphetanes or oxaarsetanes **7a, b** and **8a, b**.



7a: X = P
7b: X = As

8b: X = P
8b: X = As

4

5a: X = P
5b: X = As

6a: X = P
6b: X = As

The ylides used here led only to products formed via pathway a. In the case of phosphorus ylide **2a**, the yields are high but the selectivities modest (see Table 1). In presence of HMPA, a slight increase in the *E*/*Z* ratio is observed. For the arsenic ylide **2b**, the reaction occurs only in the presence of HMPA; the yields are slightly lower, but the reaction is highly stereoselective with both piperonal and hexanal.[12]

No epoxidation occurs, in accord with observations made earlier with semi-stabilized arsenic ylides.[13] Moreover, the β-hydroxy oxides formed during the reactions are easier to remove from the reaction mixture than triphenylphosphane or -arsane oxides. This study shows that the arsenic ylide **2b** is a useful reagent for the stereoselective preparation of *E*-styrene derivatives **4**.

Table 1. Reaction conditions, yields, and *E*/*Z* ratio in the reaction of **2a, b** with hexanal or piperonal.

Ylide	Aldehyde	Solvent	*T* [°C]	*E*/*Z*	**4** [%]
2a	hexanal	THF	−78	65/35	91
2a	piperonal	THF	−78	75/25	73
2a	hexanal	THF/HMPA [a]	−78	85/15	87
2b	hexanal	THF	−78	–	–
2b	hexanal	THF	−20	–	–
2b	piperonal	THF/HMPA [a]	−78	100/0	65
2b	hexanal	THF/HMPA [a]	−78	100/0	65

[a] 85/15 (v/v).

Experimental Procedure

1a/b: Ph_2PLi [9] or Ph_2AsLi [10] (freshly prepared from triphenylphosphane or -arsane and Li in THF) were allowed to react with ethylene oxide at 0 °C. After extractive workup, the resulting phosphane or arsane was purified by chromatography on silica gel (ether/dichloromethane 5/95) (yield 65%). (β-Hydroxyethyl)diphenylphosphane: ^1H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 7.50-7.39$ (m, 10H; Ar-H), 3.79 (td, 2H, $J = 7.0$, 9.0 Hz; CH_2-P), 2.41 (t, 2H, $J = 7.0$ Hz; CH_2-OH), 2.22 (s, 1H; OH). (β-Hydroxyethyl)diphenylarsane: ^1H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 7.51-7.33$ (m, 10H; Ar-H), 3.85 (t, 2H, $J = 7.5$ Hz; CH_2-As), 2.36 (t, 2H, $J = 7.5$ Hz; CH_2-OH), 2.20 (s, 1H; OH).

Benzyl bromide (5.5 mmol) was added to a solution of the phosphane or arsane (5 mmol) dissolved in 20 mL of acetonitrile, and the mixture was refluxed for about 12 h under argon. The solvent was removed in vacuo and the resulting solid was taken up in dichloromethane. Addition of ether afforded white crystals in 75% yield for **1a** and 65% for **1b**.

1a: m.p. 172–174 °C. ^1H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 7.76-7.52$ (m, 10H, Ar-H), 7.16–6.93 (m, 5H; Ar-H), 4.60 (d, 2H, $J = 15$ Hz; CH_2-Ar), 3.90 (td, 2H, $J = 5.5$, 20.0 Hz; CH_2-OH), 3.25 (td, 2H, $J = 5.5$, 12.0 Hz; CH_2-P).

1b: m.p. 146–148 °C. ^1H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 7.66-7.48$ (m, 10H; Ar-H), 7.12–7.02 (m, 5H; Ar-H), 4.72 (s, 2H; CH_2-Ar), 4.05 (t, 2H, $J = 6$ Hz; CH_2OH), 3.48 (t, 2H, $J = 6$ Hz; CH_2-As).

Wittig olefination reaction: BuLi (2.2 mmol, 1.6 M in hexane) was added to a suspension of **1b** (1 mmol) in THF (10 mL) and HMPA (1.5 mL) at −20 °C. A yellow color appeared immediately and changed progressively to deep red. After 1 h, the mixture was chilled to −78 °C, the aldehyde (0.9 mmol) in THF (2 mL) was added, and the reaction mixture was allowed to warm up overnight. After extractive workup, the oily residue was purified by chromatography on silica gel and analyzed by gas chromatography to determe the stereoisomer composition.

[12] On account of the basicity of the arsenic ylides, we checked carefully that no isomerization of the final products had occurred under the reaction conditions. The Wittig reaction of **2b** and hexanal was performed in the presence of (*Z*)-1-(1,3-dioxaindan-5-yl)-1-heptene (purity > 99%). Gas-chromatographic analysis showed no trace of the *E* isomer.

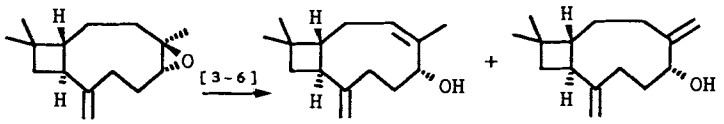
A Stereoselective π Cyclization to a Combined Bridgehead Olefin–Bridgehead Alcohol**

By *Uwe Vogt, Ulrike Eggert, Alexandra M. Z. Slawin, David J. Williams,* and *H. M. R. Hoffmann**

Bridgehead structure and bridgehead reactivity have contributed substantially to the evolution of concepts in organic chemistry. Starting from naturally occurring (−)-caryophyllene oxide (**1**), we describe a simple route to enantiomerically pure cage compounds in which the two bridgehead carbons are differentiated functionally.

Owing to the variety of its characteristic transformations and molecular rearrangements, caryophyllene has been considered unique among sesquiterpenes.[1, 2] The isomerization of its epoxide **1** has been investigated frequently in the past and shown to furnish allylic alcohols **2** and **3** in addition to



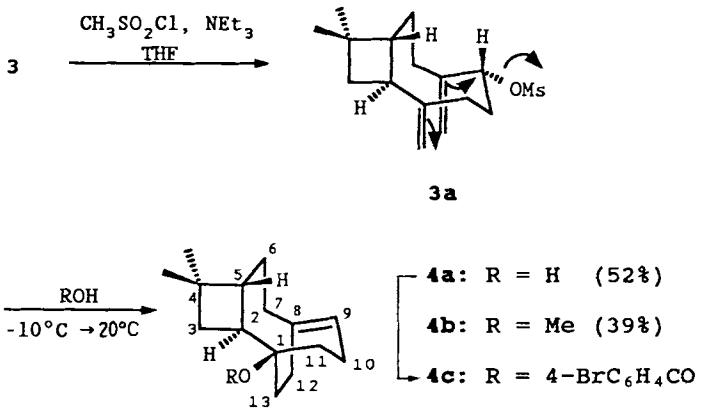
1 **2** **3**

unidentified products (Table 1).[3–6] Unfortunately, separation of the two isomers and isolation of pure **3** by chromatography are tedious, a situation not uncommon in caryophyllene chemistry. Further experiments to isomerize **1** with $Al(OiPr)_3$ in refluxing toluene[7] and with $KOtBu$ in refluxing pyridine[8] furnished both isomers (thin layer chromatography), with an increase in byproducts.

Table 1. Reported conversions of **1** into **3**.

Experimental conditions	2 [%]	3 [%]	Other products [%]	Ref.
PyHBr, pyridine, Δ	mixture			[3]
Al_2O_3	little	much		[4]
BuLi, Et_2O, Δ	8	58	34	[5]
Al_2O_3	4	50		[6]

Remarkably, treatment of **1** with $LiNiPr_2$ in refluxing THF gave the desired alcohol **3** in a clean, regio- and stereoselective reaction (90% yield). When **3** was treated with CH_3SO_2Cl/NEt_3 at −40 °C, a reactive secondary allylic mesylate, **3a**, was formed, which decomposed on attempted chromatography. However, **3a** could be isolated by crystallization at −20 °C in petroleum ether/ether. Hydrolysis of **3a** in H_2O/THF (1/10) gave a tertiary alcohol in 52% yield. Similarly, methanolysis afforded a tertiary methyl ether (39% yield). ^{13}C and ^1H NMR spectra (solvent $(CD_3)_2SO$) suggested structure **4a**[9] for the alcohol and **4b** for the methyl ether.



Structural assignment and absolute stereochemistry[10] were corroborated by preparation[11] of the crystalline *p*-bromobenzoate **4c** and X-ray diffraction analysis (Fig. 1). The NMR spectra and X-ray structure indicate that the cyclization is diastereoselective, giving enantiomerically pure **4a**, **b**.[10] Both **4a** and **4b** contain a *trans*-cyclononene moiety within the tricyclic framework. They also contain a (*Z*)-bicyclo[4.3.2]undec-1(9)-ene substructure, which has been calculated to be a "hyperstable" olefin.[12a]

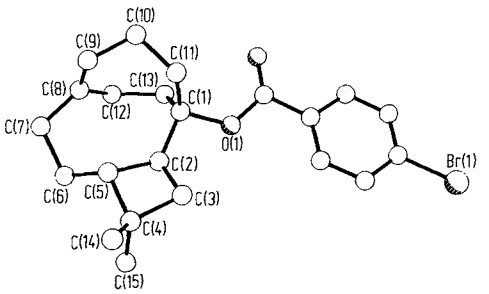


Fig. 1. Structure of one of the two independent molecules of **4c** in the crystal

The transformation of **3a** into **4a** and **4b** proceeds with ease and must have considerable driving force. Models show

that the reaction is stereoelectronically and also sterically favored. The leaving mesylate group in **3a** can adopt a quasi-axial position with respect to the allylic double bond. Transannular formation of the new carbon–carbon σ bond, which is antiperiplanar with respect to the departing mesylate group[10] involves two readily accessible, unsubstituted methylene termini. Nonetheless, it is a *bridgehead* cation that must be solvated and captured by the external nucleophile. The necessary stabilization of this tertiary cation is probably provided by a propellane-like interaction of the vacant p orbital with the π bond at the other bridgehead (estimated distance between bridgeheads[13] ca. 2.4 Å in the cation and 2.9 Å in **4c**).[14]

Although electrophilically induced π cyclization of polyenes is ubiquitous for building up natural products, both enzymatically and in vitro, the spontaneous formation of **4a, b** from **3a** is, to our knowledge, the first cyclization in which a bridgehead cation and a bridgehead olefin are simultaneously formed in a surprising, transannular fashion.

[8] Z. Rykowski, K. Burak, *Rocz. Chem. 50* (1976) 1709; *Chem. Abstr. 86* (1977) 140258.

[9] Our route to **4a** could be biomimetic, since **4a** has been detected by GC-MS in clove oil and hop oil, used for flavoring beer; see T. Uchida, Y. Matsubara, A. Adachi, *Agric. Biol. Chem. 50* (1986) 1903.

[10] Absolute configuration of **4a**: 1*S*,2*S*,5*R*. The 1*R*,2*S*,5*R* epimer would have been detected in the NMR spectrum. Its formation is stereoelectronically unfavorable. For a concerted cyclization with transannular π participation to occur, the C–OMs σ bond would have to be cleaved in the nodal plane of the π system, generating an orthogonally twisted allyl cation. Other conformations of **3a**, which would cyclize to a very strained *trans*-cycloheptene substructure, can be excluded by the *trans*-cycloalkene rule [12b].

[11] *Experimental Procedure*: **3**: A solution (1.6 M in hexane) of *n*BuLi (12.4 mL, 19.8 mmol) was added dropwise to a solution of dry $HNiPr_2$ (2.0 g, 19.8 mmol) in absolute THF (50 mL) at 0 °C and stirred for 30 min. Compound **1** (3.96 g, 18 mmol) in absolute THF (15 mL) was added dropwise and the mixture was refluxed. After complete reaction, the solvent was evaporated, the residue taken up in *tert*-butyl methyl ether (MTBE), washed with cold dilute HCl, and dried ($MgSO_4$). Flash chromatography gave 3.56 g (90%) of a colorless oil. ^1H NMR (200 MHz, $CDCl_3$): δ = 5.05, 4.96 (s, C(2) = CH_2), 4.78, 4.76 (s, C(6) = CH_2), 4.08 (dd, J = 2, 7 Hz, H-5), 2.60–1.43 (m, 13H), 0.98 (s, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 152.38/151.26 (s, C-2, C-6), 113.29/109.03 (t, 2 = CH_2), 75.08 (d, C-5), 54.21/43.67 (d, C-1, C-9), 33.35 (s, C-10), 29.95/21.91 (q, C-14, C-15), 37.03/32.74/32.54/32.49/30.54 (t, 5C). **3a**: Allylic alcohol **3** (3.3 g, 15 mmol) in absolute THF (100 mL) was mixed with dry NEt_3 (2.9 mL, 21 mmol) and cooled to −40 °C. CH_3SO_2Cl (1.4 mL, 18 mmol) was added dropwise at −40 °C and the temperature was allowed to rise to −10 °C within 2 h. After filtration and removal of the solvent, the residue was taken up in 20 mL of petroleum ether/diethyl ether (1/1). Crystallization at −20 °C gave white crystals (3.32 g, 70%), m.p. 56–58 °C (dec.). **4a**: **3a** (0.6 g, 1.9 mmol) and K_2CO_3 (0.5 g) in THF/H_2O (22 mL, 10/1) were stirred for ca. 12 h at room temperature. After removal of solvent, the residue was taken up in H_2O and extracted with MTBE, and the organic phase was dried ($MgSO_4$). Column chromatography gave a white solid (220 mg, 52% based on **3a**), m.p. 140–143 °C. $[\alpha]_D^{22}$ = 15.7 ($CHCl_3$, c = 0.3 g per 100 mL). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3365 (OH). ^1H NMR (200 MHz, $(CD_3)_2SO$): δ = 5.33 (bt, J = 6 Hz, H-9), 3.71 (s, OH), 2.38–1.22 (m, 16H), 0.93 (s, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 138.05 (C-8), 126.09 (C-9), 75.14 (C-1), 51.97, 47.74 (C-2, C-5), 29.99, 21.82 (C-14, C-15), 37.56/36.42/35.39/33.49/33.32/26.17/24.54/23.64 (8C). **4b**: Mesylate **3a** (157 mg, 0.5 mmol) and K_2CO_3 (50 mg) in MeOH (2 mL) were strirred for 2 h. Column chromatography gave 46 mg (39% based on **3a**) of white crystals, m.p. 65–66 °C. $[\alpha]_D^{22}$ = 49.7 ($CHCl_3$, c = 0.944 g per 100 mL). ^1H NMR (80 MHz, $CDCl_3$): δ = 5.41 (br. t, J = 7 Hz, H-9), 3.12 (s, OCH_3), 2.63–1.18 (m, 16H), 0.99, 0.98 (each s, CH_3). **4c**: A solution (1.6 M in hexane) of *n*BuLi (0.14 mL, 0.23 mmol) was added to **4a** in absolute THF (1 mL) and the solution was stirred for 0.5 h at room temperature. 4-BrC_6H_4COCl in absolute THF (1 mL) was added dropwise and the mixture was refluxed for 4 h. Flash chromatography and recrystallization (petroleum ether) gave white crystals (40 mg, 59%), m.p. 103–105 °C, which were used for X-ray crystallography [15].

[14] The strained cyclobutane segment may also contribute to stabilization in that the *trans* junction, that is, the C(2)–C(5) σ bond, and the vacant p orbital of the bridgehead cation lie approximately in one plane and parallel to each other (models); see also I. Erden, A. de Meijere, *Tetrahedron Lett. 21* (1980) 3179.

[15] Nicolet R3m diffractometer, ω scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically. Crystal data: orthorhombic, a = 8.233(2), b = 9.886(3), c = 48.210(12) Å, V = 3924 Å^3, space group $P2_12_12_1$, Z = 8 (there are two crystallographically independent molecules), ϱ = 1.37 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 29 cm^{-1}. 2632 independent observed reflections with $|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 116°$, R = 0.036, R_w = 0.037. The fused ring systems of the two independent molecules have virtually identical conformations with a maximum deviation of 0.1 Å for C(3) (from a least-squares fit of the two independent molecules). The absolute stereochemistry was confirmed by refinement of a free variable η, which multiplies all f''; this parameter was refined to a value of 1.06(4). Further details of the crystal structure investigation can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), by quoting the full journal citation.

The 3-(3-Pyridyl)allyloxycarbonyl (Paloc) Moiety—a Stable, Amino-Protecting Group for Peptide Syntheses in Organic Media and in Water That Is Cleavable under Neutral Conditions**

By *Karsten von dem Bruch* and *Horst Kunz**

Peptides and peptide mimetics are currently attracting increasing interest as natural and natural-product-like active substances which exhibit selective biological activity and at the same time are biologically degradable.[1] The same applies in the case of glycopeptides, which embody partial structures of natural glycoproteins.[2] Since these compounds have a tendency to undergo transpeptidation or glycoside cleavage their synthesis requires methods which allow exactly specified transformations under very mild conditions. Enzymatic peptide synthesis[3] would undoubtedly be of interest for this purpose. A further prerequisite for the successful synthesis of such peptide-type substances are protecting groups which are stable in use and which, at the same time, can readily be removed under mild neutral conditions.

We report here on a novel amino protecting group, namely the 3-(3-pyridyl)allyloxycarbonyl (Paloc) residue, which combines the advantages of stability under various reaction conditions, cleavability under neutral conditions, and solu-

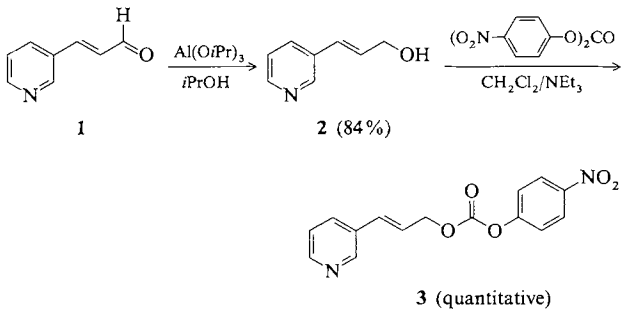
bility in water. The Paloc group is so resistant towards trifluoroacetic acid that *tert*-butyl esters or ethers can be removed selectively. Moreover, it is stable under the conditions of the rhodium(I)-catalyzed isomerization and cleavage of allyl esters.[4] Nevertheless, like the allyl ester and the allyloxycarbonyl (Aloc) group,[6] it can be removed from the blocked amino function under neutral conditions by palladium(0)-catalyzed allyl transfer to weakly basic or neutral nucleophiles.

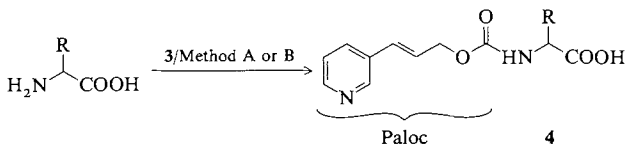
A suitable reagent for the introduction of the Paloc group is obtained by Meerwein-Ponndorf reduction of 3-(3-pyridyl)propenal **1**[7] to the 3-(3-pyridyl)allyl alcohol **2** and its subsequent reaction with bis-(4-nitrophenyl) carbonate[8] to give the 3-(3-pyridyl)allyl(4-nitrophenyl) carbonate (Paloc-ONp) **3** (Scheme 1).



1 **2** (84%) **3** (quantitative)

Scheme 1.

When **3** is allowed to react with amino acids in water/dioxane under pH-stat conditions at pH 10 (Method A)[9] or with the amino acid trimethylsilyl esters (formed from the respective amino acids and equivalent amounts of trimethylchlorosilane) in the presence of two equivalents of ethyldiisopropylamine in chloroform/acetonitrile, the Paloc amino acids **4** are obtained in high yields (see Scheme 2 and Table 1). The Paloc compounds show characteristic UV absorption and IR and NMR spectra.[11]



Scheme 2. A: H_2O/dioxane, pH-stat at pH 10, 4N NaOH; B: 1) 2 equiv. Me_3SiCl/2 equiv. *i*PrEtN in $CHCl_3$/MeCN (1:1); 2) **3**, reflux.

Table 1. Synthesis of 3-(3-pyridyl)allyloxycarbonyl (Paloc) amino acid **4** according to Scheme 2 [9, 10].

Compound	Amino acid	Method	Yield (%)	M.p. [°C]	$[\alpha]_D^{22}$ ($c = 2$, MeOH)
4a	Ala	A	82	115	−5.6

4c	Asp(OH)-O*t*Bu	A	68	oil	−13.0
4d	Gly	B	72	161	–
4e	Ile	A	89	oil	+8.3
4f	Leu	A	77	108	−11.1
4g	Lys(Z)	B [a]	65	99–101	−1.8
4h	Phe	B	72	102–104	−8.0
4i	Thr	A	80	Öl	+5.2
4j	Val	A	83	101–103	+3.2

[a] Twice the solvent volume.

Paloc amino acids **4** react smoothly with amino acid *tert*-butyl or allyl esters[4, 5] to form the Paloc dipeptide esters **5**. The solubility-promoting properties of the Paloc group permit the peptide condensations (Scheme 3) to be carried out both in an organic medium in the presence of condensation reagents such as ethyl-2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ),[12] as well as in water, e.g. with 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide (DAEC)/1-hydroxybenzotriazole (HOBt) (Scheme 3 and Table 2).

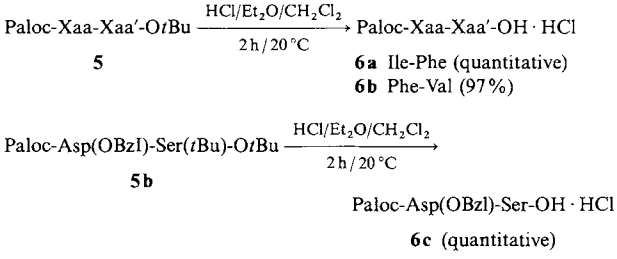
4 **5**

Scheme 3. A: EEDQ, CH_2Cl_2, 20 °C/20–60 h; B: DAEC/HOBt, H_2O/pH 5–6, 20 °C, 4 d.

Table 2. Synthesis of Paloc dipeptide esters **5** according to Scheme 3.

Compound	Xaa-Xaa′	OR	Method	Yield (%)	$[\alpha]_D^{22}$ ($c = 2$, MeOH)
5a	Ala-Gly	OAll	A	73	−15.7
			B	77	
5b	Asp(OBzl)-Ser(*t*Bu)	O*t*Bu	A	81	−0.8
5c	Gly-Thr	OAll	A	79	−3.5
5d	Gly-Thr(*t*Bu)	OAll	A	81	+10.4
5e	Ile-Leu	O*t*Bu	A	69	−39.3
			B	72	
5f	Ile-Thr(*t*Bu)	OAll	A	66	+0.5
5g	Leu-Ile	O*t*Bu	A	86	−22.5
5h	Phe-Val	O*t*Bu	A	90	−12.1
5i	Val-Ile	O*t*Bu	A	78	−24.0

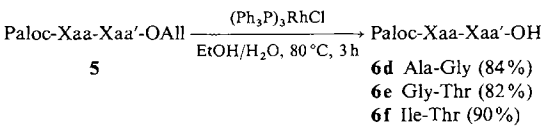
Both in the case of the synthesis of the polar dipeptide ester **5a**, as well as in that of the unpolar, sterically hindered dipeptide ester **5e** a higher yield was obtained when the reaction was carried out in water. The high stability of the Paloc group towards acids is caused by protonation at the pyridine nitrogen atom and the resultant shielding against further proton attack. It enables *tert*-butyl protecting groups to be selectively removed from Paloc-protected peptides, e.g. with HCl in ether/dichloromethane (Scheme 4).



5 **5b**

Scheme 4.

The Paloc group is also stable during the cleavage of peptide allyl esters by rhodium(I)-catalyzed isomerization and subsequent hydrolysis of the resulting propenyl ester (Scheme 5). Not only the Paloc group but also protecting groups of the *tert*-butyl type are stable under these neutral conditions.



5

Scheme 5.

The Paloc group can be removed selectively and in high yield from the blocked amino functions of the peptides by palladium(0)-catalyzed allyl transfer to neutral or weakly basic nucleophiles, e.g. *N*-methylaniline (Scheme 6). Protected cysteine and methionine residues do not interfere with these reactions.[6] This deblocking requires longer reaction times than the cleavage of the unsubstituted Aloc group.[6] The very mild reaction conditions leave benzyl- and tert-*butyl*-type protecting groups intact (cf. **7d**). Furthermore, **7d** demonstrates that no transpeptidation of aspartic acid peptides occurs under the conditions of the Paloc cleavage.

Paloc-Xaa-Xaa'-O*t*Bu **5** $\xrightarrow[C_6H_5NHCH_3,\ THF,\ 20\,^\circ C,\ 10\,h]{(Ph_3P)_4Pd}$ H-Xaa-Xaa'-O*t*Bu

7a Val-Ile (89%)
7b Gly-Val (84%)
7c Ile-Leu (80%)
7d Asp(OBzl)-Ser(*t*Bu) (74%)

Scheme 6.

The solubilizing properties and stability of the Paloc group are advantageous for the synthesis of peptides by fragment condensation. As shown in Scheme 7 for the two Paloc tetrapeptide esters **8**, sterically hindered condensation agents such as isobutyl-2-isobutoxy-1,2-dihydroquinoline-1-carboxylate IIDQ[14] can be applied for this purpose. However, longer reaction times are necessary. Nevertheless, owing to the stability of the Paloc group no further undesired side reactions occur.

6a + **7b** $\xrightarrow[CH_2Cl_2,\ 3\,d]{IIDQ}$ Paloc-Ile-Phe-Gly-Val-O*t*Bu
8a (79%)

6d + **7a** $\xrightarrow[CH_2Cl_2,\ 3\,d]{IIDQ}$ Paloc-Ala-Gly-Val-Ile-O*t*Bu
8b (71%)

Scheme 7.

Stability, solubility properties, and cleavability under neutral conditions establish the Paloc group as valuable tool for the synthesis of demanding, sensitive peptide derivatives.

[9] *Method A:* A solution of amino acid (25 mmol) in water (30 mL) was treated dropwise at constant pH 10 (addition of 4N NaOH) with a solution of **3** (7.5 g, 25 mmol) in dioxane (30 mL), the mixture stirred for 1 h, then adjusted to pH 4 with 6N HCl, and finally evaporated to dryness. The residue was digested with 250 mL of ethyl acetate, the mixture filtered over a small amount of silica gel and, after evaporating down, purified by flash chromatography on 100 g of silica gel (0.040–0.063 mesh) in ethyl acetate/glacial acetic acid (200:1). After removal of the solvent in vacuo and redistillation from toluene the Paloc amino acids **4** were obtained as colorless crystals or oils.
[10] *Method B:* A mixture of the amino acid (25 mmol) and trimethylchlorosilane (3.2 g, 25 mmol) in 100 mL of chloroform/acetonitrile (1:1) was heated under reflux for 2 h. After cooling, the mixture was treated with 8.7 mL of diisopropylethylamine (50 mmol) and stirred for 30 min. **3** (7.5 g, 25 mmol) was then added and the mixture refluxed for 12 h. After concentration in vacuo the concentrate was worked up as in **9**.

Synthesis and Transmission Electron Microscopic Investigation of Bi(Pb)–Sr–Ca–Cu–O Superconductors **

By *Jan-Henrik Müller, Martin Schwarz,* and *Reginald Gruehn* *

The preparation and investigation of ceramic high-temperature superconductors of the Bi(Pb)–Sr–Ca–Cu–O system are considerably more time-consuming and expensive than the preparation and characterization of specimens of the Y–Ba–Cu–O system. To obtain information, otherwise inaccessible, about the real structure of such specimens we resorted to the technique of high-resolution transmission electron microscopy.

For the synthesis of $Bi_2Sr_2Ca_2Cu_3O_{12-x}$ (Sample **A**, prepared from the oxides) the composition reported by *Endo* et al.[1] was chosen (nominal composition $Bi_{0.8}Pb_{0.2}Sr_{0.8}CaCu_{1.4}O_x$; T_c (R = 0) = 100 K). The phase purity was checked with X-ray powder patterns (Fig. 1, top) and the composition analytically. Measurements of the magnetic susceptibility on rod-shaped samples (2 × 2 × 10 mm) revealed a predominant superconducting domain (Fig. 1, bottom). The synthesis and characterization of the samples **B** (nominal composition as in the case of Sample

A; $T_c(R=0) = 105$ K) and **D** (nominal composition, $Bi_{4.3}Sr_{3.5}Ca_{3.5}Cu_6O_x$; T_c ($R=0$) = 95 K) were carried out in the same way as for Sample **A**. Sample **C** (composition $Bi_2Sr_{1.8}Ca_{0.2}Cu_2O_x$; $T_c \approx 90$ K (midpoint)[2] was characterized X-ray crystallographically by the Guinier method and was found to consist predominantly of the compound $Bi_2Sr_2CuO_x$.

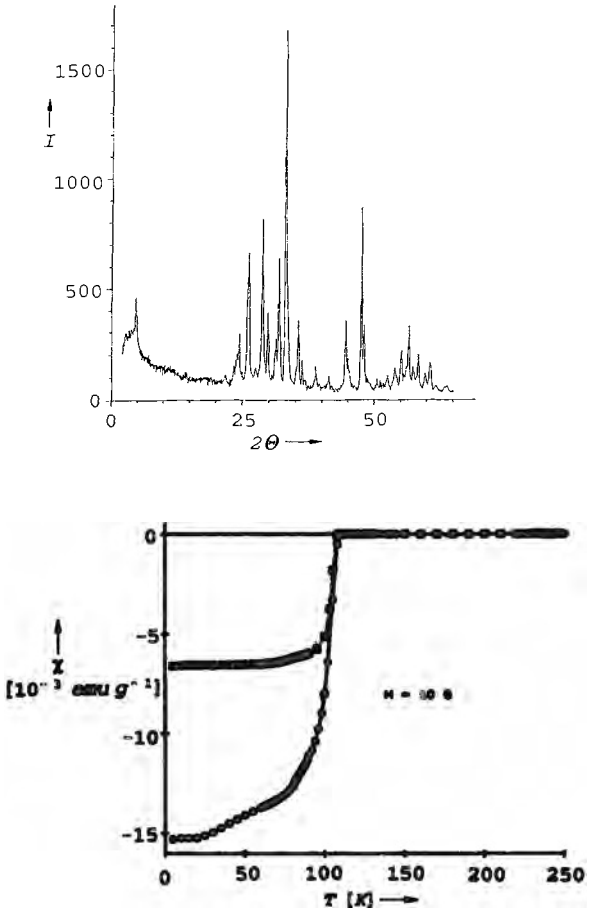

Fig. 1. Characterization of Sample **A**. Top: powder diffractogram; bottom: SQUID susceptometer measurement, shielding curve: —o—; Meissner curve: ··□·· (SQUID-VTS susceptometer, SHE Corp.).

Sample **A**: The layer structure to be expected on the basis of other investigations[3] is clearly recognizable *electron microscopically* upon viewing along [110] (transmission photograph Fig. 2a; corresponding electron diffraction pattern, Fig. 2b). However, the successive half unit cells staggered along [001] have different lengths, which can be characterized by the respective number (2 or 3) of the O–Cu–O layers. The contrasts change drastically on varying the defocus (Fig. 2d, e). The bright lines running perpendicular to the *c* direction appear to split. The layer pattern of Figure 2a is least pronounced in Figure 2e; instead finer details with a point resolution of about 3 Å are discernable. The Figures 2a, d, and e demonstrate the problem of assigning the structural units (e.g. half unit cells) or strongly diffracting heavy atoms (Bi) to the electron microscopically recorded contrasts: owing to the dependence of the contrasts on the defocusing, an unequivocal assignment of the structural details is not always possible. However, transmission images together with the electron diffraction can yield valuable information about the symmetry of the structure, as could also be shown by image simulation calculations (multi-slice method).[4]

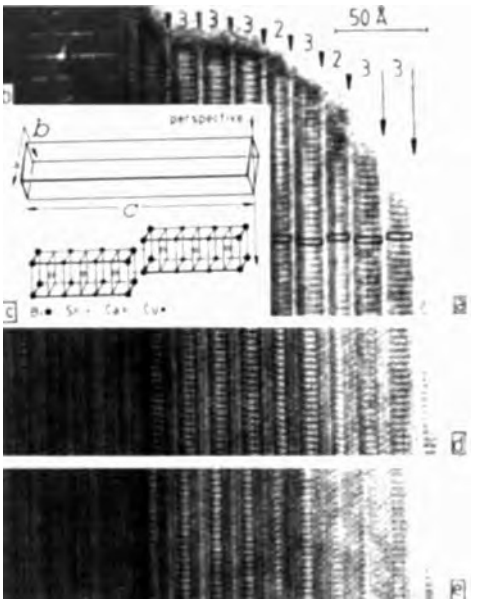

Fig. 2. Crystal fragment of Sample **A**; view along [110]. a) Transmission image with half unit cells indicated; b) corresponding electron diffraction pattern; c) structural model (after [3]) with two Cu "layers" in every half unit cell; d) and e) transmission images but, compared to (a), at different defocus values and with changed contrast.

A sequence of half unit cells with two, three and four O–Cu–O layers in another region of Sample **A** (Fig. 3) can also be interpreted in terms of substitution of three-layer half unit cells ($3 + 3 + 3 \rightarrow 2 + 3 + 4$). To this sequence are then attached further unit cells containing three O–Cu–O layers.

Fig. 3. Transmission photograph along [110] (other crystal fragment of Sample **A**).

A crystal fragment of Sample **B**, on the other hand (Fig. 4), shows extended regions of an undisturbed three-layer structure (three O–Cu–O layers per half unit cell); defects as are seen in Figures 2 and 3 are not found.

On viewing along [100], transmission and diffraction images (Fig. 5a and 5b, resp.) show a complicated superstructure (Sample **C**). Superstructures[8, 9] ("modulation"), which are possibly due to differences in the occupation and location of the oxygen positions adjacent to the Bi layers, have been observed in superconductors of the type $(BiO)_2Sr_2Ca_{n-1}Cu_nO_{2n+2}$ ($n \geq 1$).[3, 5-7] An influence on the positions of the metal atoms is assumed.[10] The electron microscopic photographs cannot as yet be satisfactorily evaluated, because, for example, a detailed model of the real structure of such a crystal is not accurately known. An attempt at a tentative interpretation of the modulated structure is described in Ref. [10].

A highly resolved transmission photograph along [001] (Fig. 6a) of an especially thin sample of **D** reveals a periodic change (superstructure with $5b \approx 27$ Å) of the contrast in the

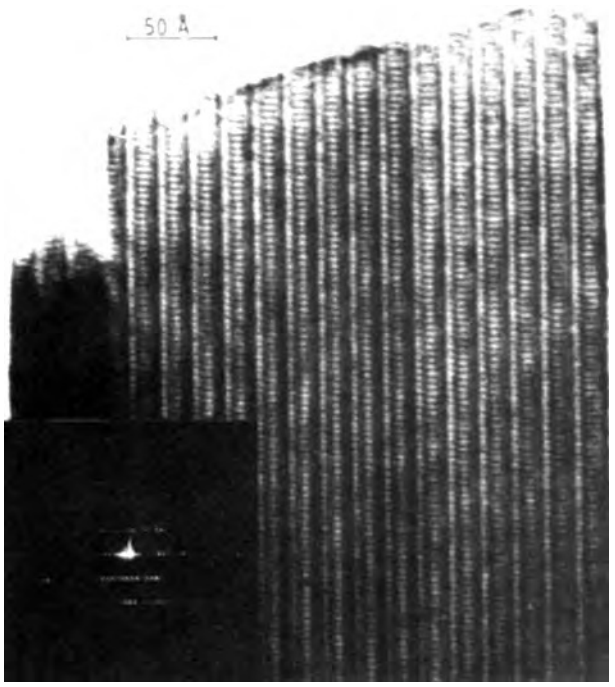

Fig. 4. Transmission and electron diffraction photographs along [110] (Sample **B**).

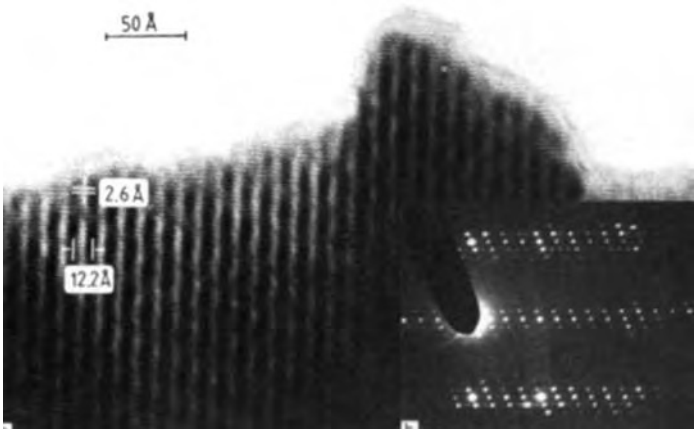

Fig. 5. Crystal fragment of Sample C; view along [100]. a) Transmission image; b) electron diffraction pattern.

direction of the *b* axis (horizontally in the image, "modulation"). The image contrast changes slightly every five unit cells (arrows in Fig. 6a). Periodic changes in contrast are also observed vertical to the *b* axis.

The electron diffraction pattern (Fig. 6b) shows intense reflections and very weak reflections which appear to be arranged crosswise. In Figure 6c, the reflections which illustrate the pattern of the superstructure in the direction b^* are shown (immediately adjacent reflections in the vertical direction have been omitted). The pattern (Fig. 6c) can be generated by rotation through 90° in the image plane and superposition with the original diagram ("rotated" twin in Fig. 6d). This type of defect, which differs markedly from the microtwinning in $YBa_2Cu_3O_{7-x}$,[11] has often been observed. This indicates that two or several crystal platelets (view perpendicular to {110}) have *not* rotated through 90° and, after that, superimposed coincidentally.

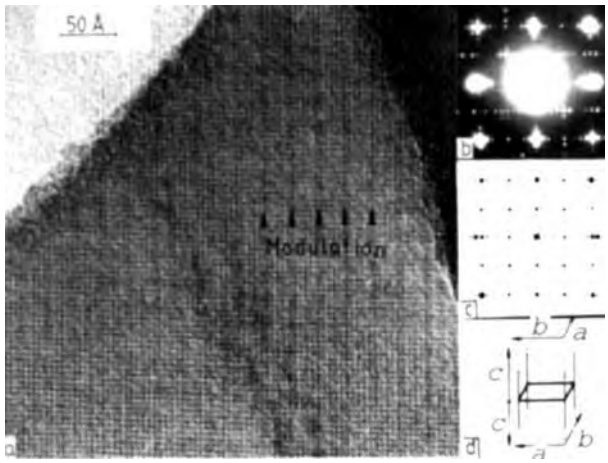

Fig. 6. Crystal fragment of Sample **D**; view along [001]. a) Transmission image; b) electron diffraction pattern; c) schematic diagram of the reflections of Figure 6 (cf. text); d) schematic drawing of a "rotated twin".

The electron microscopic investigation reveals the complicated real structure of the Bi(Pb)–Sr–Ca–Cu–O superconductor. A relationship between the observed structural defects and the preparative prehistory cannot be established on the basis of the present studies, since only a small number of crystal fragments found by chance have been examined. For example, according to the electron microscopic findings, sample **A**, which was characterized by X-ray powder patterns as a "three-layer compound", also contains crystal fragments which are made up by the "one-layer" compound and the "two-layer" compound.

Experimental

Synthesis of superconductors of the system Bi(Pb)–Sr–Ca–Cu–O: To suppress decomposition reactions, strontium was used in small excess and a part of the bismuth was substituted by lead. After preliminary reaction of the mixture at $T = 800$ °C, the powder was pressed to a tablet (13 mm × 3 mm; pressure $p =$ 50 bar) and sintered on a MgO support for 80 h at 846 °C (Sample **D**: 870 °C). Finally, the mixture was tempered a total of six times alternately for 3 h at 600 °C and 3 h at 846 °C (**D**: 870 °C), then cooled at a rate of 100 Kh^{-1} to room temperature. The samples were gently crushed and suspended in ethanol. One drop of the slurry was put on a Cu grid covered with a carbon coated perforated foil.[12]

Electron microscopic investigation: The electron microscopic investigation was carried out with a Philips EM-400-HMG (LaB_6 cathode, 120 kV; primary magnification of 4.4×10^5). With the help of electron diffraction, suitable crystals were so adjusted that the desired crystallographic direction lay in the direction of transmission. The crystal fragments had mainly the form of thin platelets (basal plane $\{110\}$[13]), so that normally only the view perpendicular to the basal plane, [001], could be used. Views along a diagonal of the unit cell were more difficult to obtain, and only in exceptional cases could an observation along one of the short axes be accomplished.

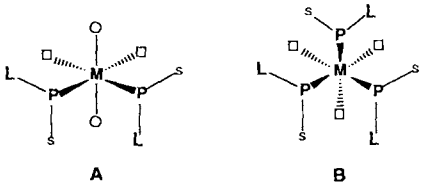
New Chiral C_3-Symmetric Tripodal Phosphanes**

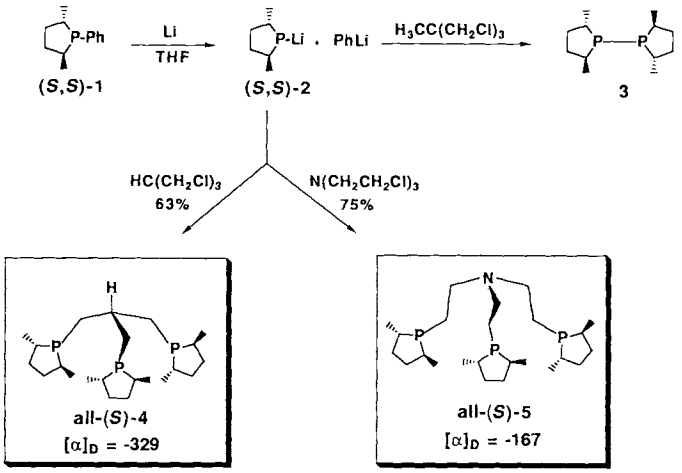
By *Mark J. Burk** and *Richard L. Harlow*

Chiral ligands possessing a C_2 symmetry axis are known to induce a high degree of stereocontrol in a variety of transition-metal-catalyzed reactions.[1, 2] Despite the great success with C_2-symmetric ligands, chiral ligands possessing elements of higher symmetry[3] have been ignored to a large extent. The proper introduction of chirality into polydentate ligands should offer the opportunity to explore systems with higher order symmetry. Our objective has been the rational design of new chiral C_3-symmetric tris(phosphane) ligands which may be used in asymmetric catalysis.

The high optical yields obtained with catalysts bearing C_2-symmetric ligands have been attributed to a reduction in the number of possible diastereomeric transition states because of equivalent asymmetric environments imposed along the z axes (+ and −) of an intermediate square-planar metal complex.[1, 2] In addition to square-planar species, octahedral intermediates are known to be involved in many transition-metal-catalyzed reactions.[4] An octahedral intermediate bearing a chiral bidentate C_2-symmetric ligand (**A**) offers two nonequivalent (diastereotopic) coordination sites (axial and equatorial) for substrate binding. In contrast, a similar octahedral intermediate with a chiral tridentate C_3-symmetric ligand (**B**) offers only one type of site for substrate coordination; all the sites opposite a C_3-symmetric tripod ligand are equivalent (homotopic). The reduced number of competing asymmetric environments should lead to high enantioselectivity in catalytic reactions involving metal centers bearing chiral tripodal C_3-symmetric ligands. Furthermore, conformationally rigid polydentate ligands possessing a C_3 symmetry axis may provide a high degree of stereochemical control in notoriously difficult asymmetric catalytic reactions, such as those involving nonchelating or unfunctionalized substrates. We now report the first examples of homochiral C_3-symmetric polydentate phosphanes, as well as the preparation and structural characterization of several transition metal complexes bearing these ligands.



We recently described[5] an efficient route to (*R,R*) and (*S,S*)-2,5-disubstituted phospholanes such as **1**. Treatment of **1** with lithium metal was found to cleave the P–Ph bond of the phospholane selectively, providing a mixture of the lithium phosphide **2** and phenyllithium. As we wished to prepare chiral tripodal phosphanes, we examined the reaction between **2** and 1,1,1-tris(chloromethyl)ethane. The major product of this reaction, however, was the P–P coupled diphospholane dimer, **3**, presumably produced via initial lithium/halogen exchange. The desired C_3-symmetric triphospholane all-(*S*)-**4**[6] was obtained as a colorless crystalline solid upon reaction between the less hindered 1,3-dichloro-2-chloromethylpropane[7] and (*S,S*)-**2**. Analogously, either enantiomer of the C_3-symmetric triphospholanamine **5**[6] was readily prepared by treatment of the corresponding lithium phosphide (*R,R*) or (*S,S*)-**2** with tris(2-chloroethyl)amine. The high symmetry of **4** and **5** was indicated by the ^{31}P NMR spectra, which exhibited singlets at $\delta = -8.0$ and -3.4, respectively. The chiral nature of these phosphanes was confirmed by the large optical rotations, $[\alpha]_D^{20} = -329$ and $[\alpha]_D^{20} = -167$ (**c** = 1, hexane) for all-(*S*)-**4** and all-(*S*)-**5**, respectively.



The C_3-symmetric rhodium complex $[(NP_3)Rh(CO)]^{\oplus}Cl^{\ominus}$ all-(*R*)-**6**[8] (NP_3 = **5**) was obtained as a bright yellow precipitate upon reaction of all-(*R*)-**5** with $[(CO)_2RhCl]_2$ in toluene. Its trigonal bipyramidal structure was ascertained by X-ray crystallography[9] (Fig. 1). The Rh atom is located 0.2 Å below the equatorial plane defined by the three P atoms. As is apparent from the view in Figure 1 (bottom), the molecule possesses a crystallographic C_3 symmetry axis which coincides with the apical N–Rh–CO axis of the complex; the chloride counterion also lies on this axis. Similarly, the chiral C_3-symmetric ligand, all-(*S*)-**4**, was reacted with $[(cod)_2Rh]^{\oplus}SbF_6^{\ominus}$ (cod = cyclooctadiene) to give the rhodium complex $[(cod)Rh(C_3P_3)]^{\oplus}SbF_6^{\ominus}$ (C_3P_3 = all-(*S*)-**4**), all-

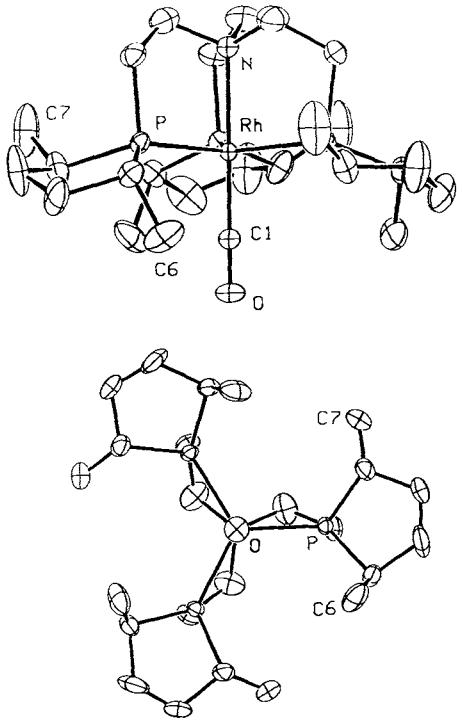

Fig. 1. ORTEP drawings of rhodium complex all-(*R*)-**6**. Hydrogen atoms and $Cl^{\ominus}$ anion are omitted for clarity. Top: Side view. Bottom: View looking down the crystallographic C_3 symmetry axis (N-Rh-CO axis).

(*S*)-**7**,[8] which was characterized by X-ray crystallography.[10] The ORTEP diagram (Fig. 2) reveals the C_3-symmetric environment imposed by the tripodal ligand all-(*S*)-**4**. These structural studies indicate that the electron-rich chiral C_3-symmetric tripodal phosphanes **4** and **5** produce a highly asymmetric environment when complexed to transition metal centers.

In preliminary studies the rhodium complex all-(*S*)-**7** was shown to act as a catalyst precursor for the enantioselective hydrogenation of methyl (z)-α-acetamidocinnamate (50 °C, 72 h, 89% *ee*) and dimethyl itaconate (50 °C, 20 h, 95% *ee*). Although activation of the catalyst through hydrogenation of the cod ligand of all-(*S*)-**7** occurs at 25 °C and 2 atm H_2, substrate hydrogenation was very slow under these conditions. The higher temperature required for reasonable reduction rates suggests that dissociation of one arm of the chelating substrates or the phosphane ligand in a five-coordinate (18-electron) intermediate is necessary for reaction with hydrogen. Further studies aimed at using the new C_3-symmetric chiral ligands **4** and **5** in asymmetric catalysis are in progress.

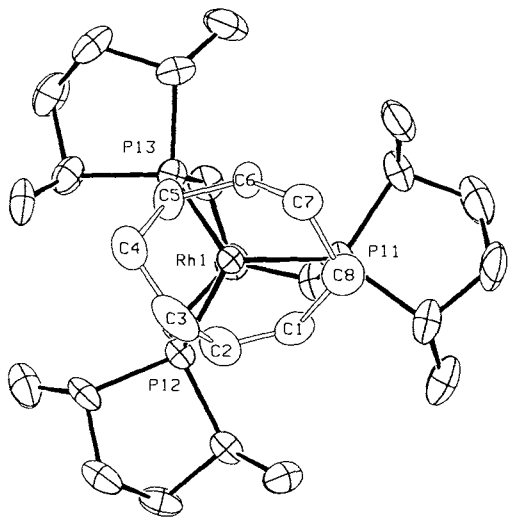

Fig. 2. ORTEP drawing of all-(*S*)-**7**. Hydrogen atoms and $SbF_6^{\ominus}$ anion are omitted for clarity.

Experimental Procedure

Preparation of all-(*S*)-**4**: Clean Li ribbon (0.55 g, 79 mmol) was added to a solution of (*S,S*)-**1** [5] (6.07 g, 32 mmol) in THF (200 mL) at 25 °C under Ar, and the mixture stirred for 15 h. The resulting brown/orange mixture was treated dropwise with a solution of 1,3-dichloro-2-(chloromethyl)propane [7] (1.70 g, 10.5 mmol) in THF (15 mL) at 25 °C. The reaction remained brown throughout the addition, and after stirring for 30 min, MeOH (3 mL) was added to quench the remaining PhLi. The mixture was stirred for a further 15 min and then filtered to remove precipitated lithium methoxide. The filtrate was concentrated in vacuo. The resulting solids were extracted with pentane (125 mL), and the pentane layer was filtered and concentrated to ca. 15 mL, during which time a colorless crystalline solid formed. Rapid filtration of the cold mixture afforded the product (1.0 g), which was dried in vacuo. The pentane filtrate was then evaporated down, and yielded a pale yellow solid, which was dissolved in a minimum amount of Et_2O (3 mL). This solution was treated with MeOH (15 mL), and the mixture was cooled to − 20 °C for 12 h. The resulting colorless crystals of all-(*S*)-**4** were filtered, washed with cold MeOH and dried in vacuo (1.65 g). Combined yield 2.65 g (63%).

Preparation of all-(*R*)-**5**: Clean Li ribbon (0.27 g, 39.0 mmol) was added to a solution of (*R,R*)-**1** [5] (3.0 g, 15.6 mmol) in THF (100 mL) at 25 °C under Ar, and the reaction mixture stirred for 15 h. To the resulting brown/orange mixture was added dropwise a solution of tris(2-chloroethyl)amine (1.06 g, 5.2 mmol) in THF (15 mL) at 25 °C. The procedure for isolation of the colorless crystalline product all-(*R*)-**5** was exactly as described above for all-(*S*)-**4**. Combined yield 1.73 g (75%).

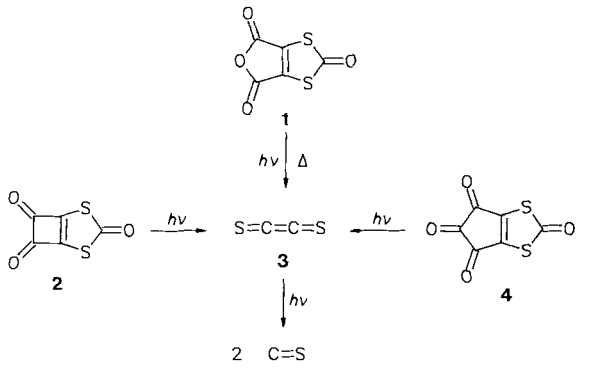
C_2S_2(Ethene-1,2-dithione), an Example for the Violation of Hund's Rule?**

By *Günther Maier,* Hans Peter Reisenauer, Jürgen Schrot,* and *Rudolf Janoschek*

Dedicated to Professor Karl Dimroth on the occasion of his 80th birthday

Of the open-chain oxides and sulfides of carbon having the general formula (S)O=(C_x)=O(S),[1] those with an even number of C atoms are characterized by the fact that only two instead of the four electrons required for a closed shell are available for the pairwise degenerate, highest occupied molecular orbitals in a linear atomic arrangement ($D_{\infty h}$). The electronic situation therefore resembles that in the O_2 and S_2 molecules, and should, according to Hund's rule, lead to a triplet ground state. The associated high reactivity is probably the reason why the first spectroscopic detection of a compound of this series (C_4O_2) (in a matrix) has been accomplished only recently.[2, 3] We now report on the synthesis and identification of matrix-isolated C_2S_2 **3**, and on quantum chemical calculations regarding its structure, the multiplicity of its ground state, and its electron-excitation and vibrational spectra.

As C_2S_2 precursors we chose the molecules **1**, **2** and **4**, made up exclusively of C, S and O atoms, and subjected these to a high-vacuum flash pyrolysis, with subsequent isolation of the products in an argon matrix, or to a direct photolysis in the matrix.



Brief irradiation of **1** with a mercury low-pressure lamp (254 nm) leads, as shown by the IR spectrum of the photolysis products (Fig. 1), to formation of CO_2, CO and small amounts of C_3OS,[4] COS, CS_2 and CS, as well as an unknown species showing an intense band at 1179 cm^{-1}. This

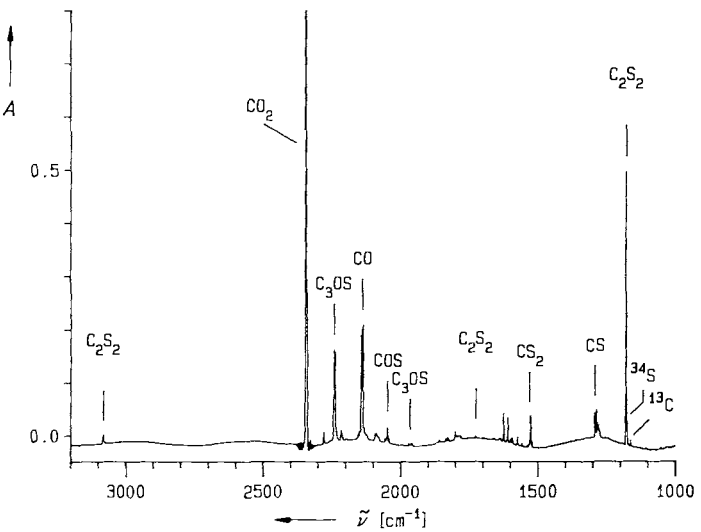


Fig. 1. IR spectrum of the photoproducts of **1** (Ar matrix, 12 K, after 15 min irradiation with λ = 254 nm). A = absorbance.

species also gives rise to a UV band with pronounced vibrational fine structure between 392 and 350 nm and to an additional intense end absorption beginning at about 230 nm (Fig. 2). On continuing the irradiation with 254-nm light these absorptions decrease only slowly, on irradiation with longer wavelength light (λ > 300 nm) very rapidly and in both cases in favor of the band characteristic for CS (Fig. 2). This observation in itself leaves little doubt that the photoproduct of **1** is C_2S_2 **3**.[14]

The IR spectrum is also as would be expected for C_2S_2. With $D_{\infty h}$ symmetry only one of the three stretching vibra-

[**] Heterocumulenes, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 4: [2].

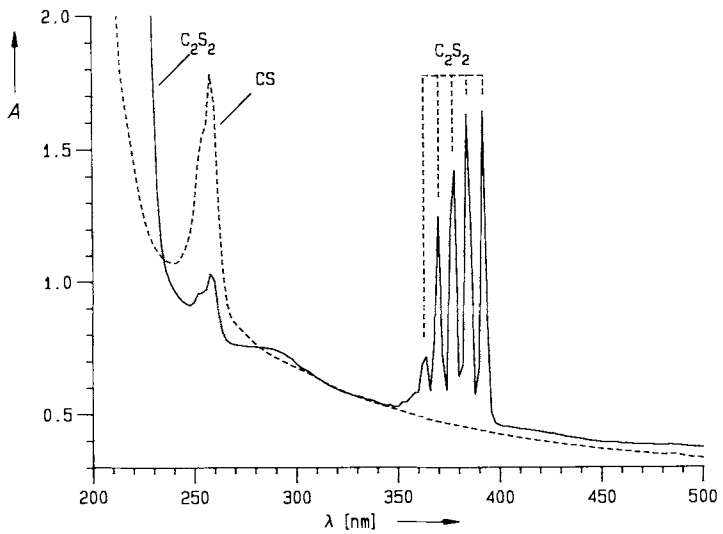

Fig. 2. UV/VIS spectra of the photoproducts of **1** (Ar matrix, 12 K); —— after 5 min irradiation with $\lambda = 254$ nm; --- after a further 6 min irradiation with $\lambda = 392 \pm 10$ nm.

tions (out-of-phase CS stretching vibration) and one of the two degenerate bending vibrations of C_2S_2 **3** are IR active. Since the latter is expected in the far IR region, only a single fundamental vibration should be observable above 300 cm^{-1}.

As indicated in Table 1 the observed position of the band at 1179 cm^{-1} ($\tilde{\nu}_3$) is in good agreement with the results of semiempirical PM3[5] and ab initio calculations.[6] Also informative are the weak bands of the ^{34}S and ^{13}C isotopomers at 1175 and 1162 cm^{-1}, respectively. From their relative intensities, which correspond to about double the natural abundances, and the fact that in each case only one isotope band is observable, if follows that two symmetry-equivalent atoms each of sulfur and carbon are present. In addition, the magnitude of the isotopic shift is in excellent agreement with the calculated values (Table 1). Two further weak absorptions which appear at 3083 and 1725 cm^{-1} and are best interpreted as combination bands ($\nu_1 + \nu_3$) and ($\nu_2 + \nu_3$) can also be assigned to C_2S_2 **3**. The position of the non-IR-active stretching vibrations which can be derived therefrom (1904 and 546 cm^{-1}) is also in agreement with the calculations. The experimental IR spectrum thus fits very well for a C_2S_2 **3** with linear or at least centrosymmetric structure.

Table 1. Observed IR spectrum and calculated fundamental vibrations [cm^{-1}] of C_2S_2.

	Experiment	Calculation		
		PM3		ab initio [6]
		$^1\Delta_g$	$^3\Sigma_g^-$	$^3\Sigma_g^-$
$\nu_1\ \Sigma_g$	(1904) [a]	2004	1984	2104
$\nu_2\ \Sigma_g$	(546) [a]	560	560	595
$\nu_3\ \Sigma_u$	1179.3	1160.5	1160.4	1262
^{34}S	1174.5	1155.8	1155.8	
^{13}C	1161.9	1143.1	1143.1	
$\nu_4\ \pi_g$	-	600	608	485
$\nu_5\ \pi_u$	-	219	217	199
$\nu_1 + \nu_3$	3082.8			
$\nu_2 + \nu_3$	1725.4			

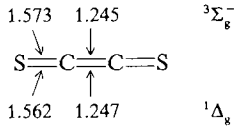
[a] Calculated from combination bands.

The characteristic IR and UV bands of **3** can also be recorded after irradiation of the matrix-isolated precursor compounds **2** and **4**. In both cases, however, the yields of **3** are lower. Apparently the competing fragmentation, which leads to C_3OS and COS, gains more significance here. This is also true in general for the thermal cleavage of all three precursor molecules. In the pyrolysis of **1**, C_3OS and CS are the main products, and C_2S_2 **3** is formed in minor amounts only, while in the case of **2** and **4** the thermolysis leads exclusively to C_3OS and COS, and **3** is no longer detectable.

C_2S_2 **3** is a very reactive molecule. Without isolating matrix material it is incapable of existing at 77 K, as has been shown by pyrolysis of **1** and condensation of the products on a spectroscopic window cooled with liquid nitrogen. Under these conditions **3** polymerizes to a brown solid. Also its lifetime in the gas phase is apparently extremely short. After a flight of 30 cm in a 1 cm thick quartz tube at a pressure of about 10^{-4} mbar only ca. 10% of the C_2S_2 molecules formed are still detectable.

The experimental findings reported here give no answer to the important question of the multiplicity of the ground state of **3**.[7] What does theory say?—The C_2S_2 molecule with $D_{\infty h}$ symmetry has in the ground configuration $(\cdots(2\pi_g)^4(3\pi_u)^2(3\pi_g)^0(8\sigma_g)^0)$ 18 π-electrons, for which Hund's rule predicts a triplet ground state. Therefore, in the investigations carried out so far the lowest singlet state was disregarded.[3b, 6] Since we were recently unable to unequivocally rule out a singlet ground state for C_4O_2 (with $D_{\infty h}$ symmetry 14 π-electrons)[2] the ground state problem must also be very carefully investigated in the case of C_2S_2.

For the calculation of the structure of the lowest triplet and singlet states we used the MCSCF (*m*ulti*c*onfiguration *s*elf*c*onsistent *f*ield) method with a 3-21G(d) basis.[8] The configurations were chosen by the CAS(6,4) method, i.e. for the given spin multiplicity, all configurations were constructed (*c*omplete *a*ctive *s*pace) which are possible upon distribution of six electrons over four orbitals ($2\pi_g$, $3\pi_u$). In both states C_2S_2 is linear ($D_{\infty h}$) with bond lengths that hardly differ (Scheme 1). The almost identical structures of the two states are reflected in the frequencies calculated for harmonic vibrations according to the semiempirical PM3 method (Table 1): the singlet and the triplet state exhibit very similar vibrational spectra. The measured IR spectrum fits both equally well.



Scheme 1. Ab initio CAS (6,4)/3-21G(d) bond lengths [Å] for **3** in the lowest triplet state and in the lowest singlet state.

The calculation of the singlet–triplet energy difference of a molecule such as C_2S_2 **3** requires a well-balanced consideration of the electron correlation. Single calculations using conventional methods such as SCF-MP2 or extremely short MCSCF approaches are generally questionable. We have therefore repeated the calculation of the S–T difference in the MCSCF approximation with an increasing number of configurations, and using CAS(6,4) structures in all cases. As can be seen in Table 2 the S–T difference steadily decreases; with the CAS(6,6) *ansatz* (the active space consists of the six orbitals $2\pi_g$, $3\pi_u$, $3\pi_g$ of the above quoted electron configu-

Table 2. CASSCF-(3-21G(d)-basis) and RHF-CI(SD) calculations (6-31G(d)) of the singlet-triplet energy difference $\Delta E(S\text{-}T) = E(^1\Delta_g) - E(^3\Sigma_g^-)$ of **3**. For comparison: RMP2 ($^1\Delta_g$ with complex π-orbitals) and UMP2 ($^3\Sigma_g^-$, 6-31G basis set) yields 7.6 kcal mol^{-1}.

	Configurations used T	S	ΔE(S-T) [kcal mol^{-1}]
CAS(2,2)	1	3	11.9
CAS(6,4)	6	10	8.2
CAS(6,6)	189	175	−0.7
RHF	1	1	14.0
RHF-CI(SD)	ca. 20000		−2.1

ration) the singlet state is finally 0.7 kcal mol^{-1} more stable than the triplet state.

We have also carried out calculations for both states by the RHF-CI(SD) (*r*estricted *H*artree-*F*ock-*c*onfiguration *i*nteraction (*s*ingles *d*oubles)) method (6-31G(d)basis), whereby the active space for the configuration interaction consists of 9 occupied and 21 virtual orbitals.[9] The results showed that the singlet state is 2.1 kcal mol^{-1} more stable than the triplet state. The desirable combination CASSCF-CI(SD), a method in which the dynamic correlation (CI) is based on a variationally determined reference wave function (CASSCF), generally cannot be carried out because of the limited computer word length in systems with 44 electrons. Such a theoretical effort, however, was also not necessary for the previously reported examples of the violation of Hund's rule.

To our knowledge C_2S_2 **3** would thus provide the first example for the violation of Hund's rule in an equilibrium structure (geometry in the potential minimum). This would mean that also experimental evidence of a violation of Hund's rule could be found for the first time. Previously known violations of Hund's rule relate to highly symmetric transition structures of equilibrium reactions between structures with lower symmetry (square cyclobutadiene (D_{4h}), twisted ethylene(D_{2d})). In the case of these examples the violation of Hund's rule could be explained in terms of the dynamic spin polarization. A further special electronic property of C_2S_2 **3** concerns the near-degeneracy of the two states $^1\Delta_g(\cdots(2\pi_g)^4(3\pi_u)^2)$ and $^1\Delta_g^*(\cdots(2\pi_g)^2(3\pi_u)^4)$, which lie only 0.3 kcal mol^{-1} apart. This also explains the unusual sensitivity of the S–T difference to the size of the CAS and failure of the Møller-Plesset approximation.

For the MCSCF calculation of vertically excited electronic states the 3-21G(d) basis was extended by diffuse sp sets at all centers. The lowest symmetry-allowed electronic transitions for singlet and triplet terms are reproduced in Table 3.

Table 3. MCSCF calculations of the symmetry allowed vertical electronic transitions of **3**.

Initial state	$^3\Sigma_g^-$	$^3\Sigma_g^-$	$^3\Sigma_g^-$	$^1\Delta_g$	$^1\Delta_g$	$^1\Delta_g$
Final state	$^3\Pi_u$	$^3\Sigma_u^-$	$^3\Sigma_u^-$	$^1\Pi_u$	$^1\Delta_u$	$^1\Delta_u$
λ [nm]	212	275	567	229	295	687

The pattern is similar in both cases and is reconcilable within computational accuracy (44 electrons!) with the experimental spectrum. Accordingly the end absorption beginning at 230 nm can be assigned to a transition to a Π_u state with Rydberg character ($3\pi_u \rightarrow 8\sigma_g$) and the longer wavelength bands between 350 and 392 nm to a $3\pi_u \rightarrow 3\pi_g$ transition ($^3\Sigma_u^- \leftarrow {}^3\Sigma_g^-$ or $^1\Delta_u \leftarrow {}^1\Delta_g$). We have found no experimental evidence for the calculated $2\pi_g \rightarrow 3\pi_u$ transition ($^3\Sigma_u^- \leftarrow {}^3\Sigma_g^-$ or $^1\Delta_u \leftarrow {}^1\Delta_g$) at about 600 nm (the region up to 2600 nm was checked). Apparently this band has a very low intensity.

Summarizing: C_2S_2 **3** is a very reactive molecule, but capable of existence under matrix conditions. Upon photochemical excitation it decomposes into two molecules of CS. Its electronic structure is unusual. According to the calculations the $^1\Delta_g$ state and not the $^3\Sigma_g^-$ state is, contrary to Hund's rule, of lowest energy.

Experimental

1: A mixture of 1,3-dithiol-2-one-4,5-dicarboxylic acid monohydrate (5.20 g, 23 mmol) and thionyl chloride (25 mL) was heated at 50 °C for 1 h. After removal of the solvent by vacuum distillation and subsequent sublimation of the residue 2.50 g (57%) of **1** was obtained; m.p. 89 °C.—^{13}C NMR ($CDCl_3$): δ = 137.5, 155.5, 186.9.—IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 1860, 1774, 1550, 1270, 1053, 880.—MS(70 eV): *m/z* 187.9208 ($M^{\oplus}$), 160, 116, 88, 84, 72, 56.—UV(CH_2Cl_2): λ_{max} [nm] (lg ε) = 342 (3.50), 240 (3.90).—Correct elemental analysis.

2: A suspension of dipotassium 1,2-dithioquadratate monohydrate (530 mg 2.2 mmol) [12] in acetonitrile (15 mL) was treated at 0 °C with a solution of phosgene in toluene (3 mL, 1.93 M) and the mixture stirred for 1 h at room temperature. After removal of the solvent by distillation and subsequent sublimation of the residue 130 mg (34%) of **2** was isolated; m.p. 124 °C (decomp.).—IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 1800, 1765, 1755, 1732, 1713, 1665, 1150, 1125, 889.—UV(CH_3CN): λ_{max} [nm] (lg ε) = 270 (4.11), 218 (3.93).—MS(70 eV): *m/z* 171.9285 ($M^{\oplus}$), 144, 116, 88, 84, 56.—^{13}C NMR (CD_2Cl_2, Cr(acac)$_3$): δ = 182.7, 186.2, 190.9.

4: Analogously as described for **2**: 270 mg (1.0 mmol) of disodium 4,5-disulfido-4-cyclopentene-1,2,3-trione trihydrate [13] gave 85 mg (43%) of **4** as orange crystals; m.p. 140 °C (in a sealed tube).—^{13}C NMR (CD_3CN, Cr(acac)$_3$): δ = 159.6, 174.7, 182.9, 186.0.—IR(Nujol): $\tilde{\nu}$ [cm^{-1}] = 1770 (sh.), 1755 (sh.), 1710, 1260, 1240, 1160, 1095, 870, 725.—UV(CH_3CN): λ_{max} [nm] (lg ε) = 328 (4.04), 238 (3.98).—MS(70 eV): *m/z* 199.9236 ($M^{\oplus}$), 172, 144, 116, 88, 84, 56.

[1] The names carbon oxide/carbon sulfide should be reserved for such open-chain systems. A simple naming would then be: C_2O = dicarbon oxide, C_2O_2 = dicarbon dioxide etc. A general extension of these names to compounds of the elemental composition C_nO_x makes little sense. Mellitic anhydride ($C_{12}O_9$) also consists of only C and O atoms but chemically it is more appropriate to classify this compound in the group of "normal" anhydrides.

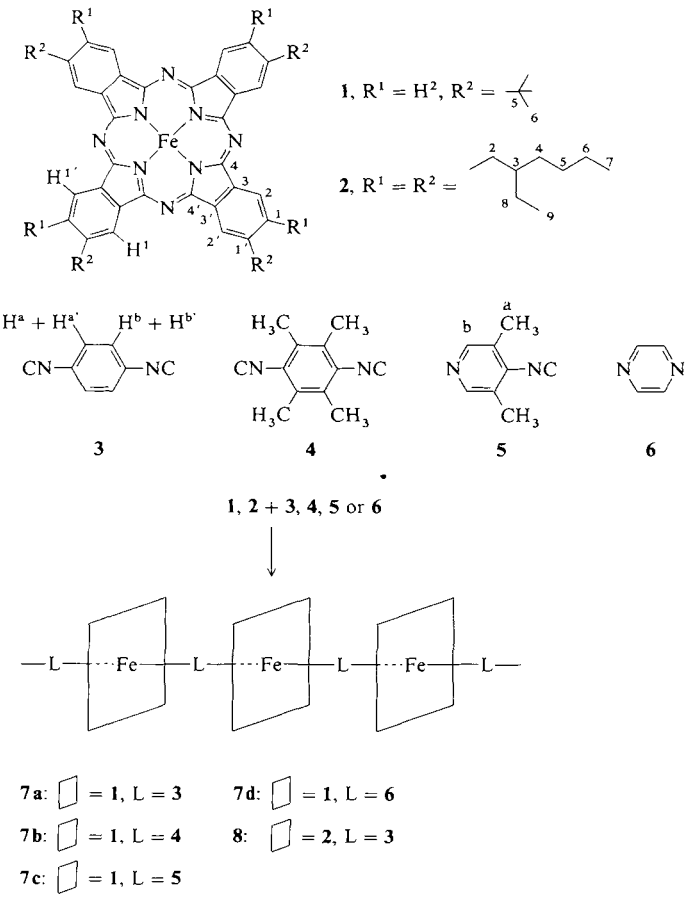
Soluble, Oligomeric Bridged Phthalocyaninatoiron(II) Complexes

By *Michael Hanack*,* *Andreas Hirsch*, and *Helmut Lehmann*

Macrocyclic transition metal complexes can be linked by bidentate ligands to form axially bridged, stacked structures. A number of systems of this kind have been synthesized by us and have been the subject of intensive investigations, particularly with regard to their conductivity.[1] As macrocycles, we used, in particular, phthalocyanine (Pc),[1] tetrabenzoporphyrin (TBP)[2] and 2,3-naphthalocyanine (2,3-Nc);[1] as metal atoms we used Fe, Ru or Co. Besides neutral molecules such as pyrazine (pyz), tetrazine (tz) and 1,4-diisocyanobenzene (dib), anions such as cyanide or thiocyanate are suitable as bridging ligands L. Some compounds of this class also exhibit a relatively high electric conductivity without additional doping.[3] Most of the systems synthesized by us are practically insoluble in organic solvents. We have however, already been able to show, with $[t\mathrm{Bu_4PcMO}]_n$ (M = Si, Ge, Sn) as examples, that when peripherally substituted macrocycles are used the corresponding oligomers are soluble. This was corroborated with other examples.[5] We have also been able for the first time to synthesize soluble oligomers with a central transition metal atom.[6]

We report here on the synthesis and properties of soluble, bridged phthalocyaninatoiron complexes. As metallomacrocycles we used ($t\mathrm{Bu_4Pc}$)Fe **1** (mixture of the constitutional isomers) and ($\mathrm{R_8Pc}$)Fe **2** (R = 2-Et-$\mathrm{C_6H_{12}}$). Compounds **1** and **2** are readily soluble in almost all organic solvents. The metallocycles ($\mathrm{R_8Pc}$)Fe (R = $\mathrm{C_5H_{11}}$, $\mathrm{C_8H_{17}}$) prepared for comparison are more sparingly soluble, i.e. to achieve high solubilities the metallocycle should either be tetrasubstituted or have a branched alkyl chain.



Scheme 1. Arbitrary position numbers.

Compounds **1** and **2** can be be converted into the bridged complexes **7a–d** and **8** by reaction with dib **3**, $\mathrm{Me_4}$dib **4**, $\mathrm{Me_2}$pyNC **5** and pyz **6** in acetone under reflux (Scheme 1). In contrast to the uncoordinated metallomacrocycles, **1** and **2**, and short-chain oligomers, the systems **7a–d** and **8** are sparingly soluble in acetone and can therefore be readily separated from short-chain oligomers. **7a–c** and **8** are soluble in $\mathrm{CHCl_3}$, whereas **7d** is relatively sparingly soluble.

The coordination of the isocyanides to the central iron atom of the phthalocyanine results in a characteristic shift of the NC valence vibration frequency compared to that of the uncoordinated ligand. The NC valence vibration frequency in **7a–c** and **8** is lowered by 20–30 $\mathrm{cm^{-1}}$ by the strong π-acceptor ability of **3–5** (Table 2).

The hexacoordination of the central iron atoms of **7a–d** and **8** is verified by their ^{57}Fe Mössbauer spectra. The measured isomer shifts δ and quadrupole splittings ΔE_Q (Table 1) correspond to the typical values for hexacoordinated $\mathrm{PcFe^{II}}$ complexes[7] and all insoluble systems $[\mathrm{PcFeL}]_n$ previously synthesized by us.[8] As reference compound the hexacoordinated monomer ($t\mathrm{Bu_4Pc}$)Fe(tBuNc)$_2$ **9** was prepared by reaction of **1** with *tert*-butyl isocyanide. Smaller isomer shifts and quadrupole splittings than in the pyz–bridged system **7d** were found for the dib-bridged oligomers **7a** and **8**, and the $\mathrm{Me_4}$dib-bridged oligomer **7b**. This can be explained in terms of a shorter M–L bond length in the isocyanide complex and a resulting higher electron density at the iron atoms along the z-axis.[8, 9] **7d** has hyperfine parameters which are characteristic for $\mathrm{PcFe^{II}}$ complexes coordinated biaxially with N-heterocycles.[7] In **7c**, both the heterocycle N-atom as well as the isocyanide group of the ambidentate bridging ligand **5** is coordinated to the central iron atom. Thus, **7c** has an intermediate ΔE (Table 1). The presence of identical iron centers, i.e. a regular head-to-tail arrangement of the bridging ligands is confirmed by the occurrence of only one doublet in the case of **7c**. Independent confirmation of this is also provided by the ^{1}H NMR spectra. In the formation of **7c** the strong *trans*-effect of the isocyanide ligand favors attachment of the heterocycle N-atom of **5** at the second axial position.

Table 1. ^{57}Fe Mössbauer spectroscopic data of **7a–d**, **8**, and **9**.

Compound		δ [a] [mm $\mathrm{s^{-1}}$]	ΔE_Q [mm $\mathrm{s^{-1}}$]
$[(t\mathrm{Bu_4Pc})\mathrm{Fe(dib)}]_n$	**7a**	0.09	0.72
$[(t\mathrm{Bu_4Pc})\mathrm{Fe(Me_4dib)}]_n$	**7b**	0.13	0.72
$[(t\mathrm{Bu_4Pc})\mathrm{Fe(Me_2pyNC)}]_n$	**7c**	0.12	1.24
$[(t\mathrm{Bu_4Pc})\mathrm{Fe(pyz)}]_n$	**7d**	0.24	1.99
$[\{(2\text{-Et-}\mathrm{C_6H_{12}})_8\mathrm{Pc}\}\mathrm{Fe}(dib)]_n$	**8**	0.11	0.67
$[(t\mathrm{Bu_4Pc})\mathrm{Fe}(t\mathrm{BuNC})]_2$	**9**	0.13	0.73

[a] Referred to α-iron.

Thermogravimetric measurements of **7a–d** and **8** showed that the ratio of macrocycle to L is 1:1 in all oligomers.[10] Since hexacoordinated complexes are present in each case the bridged structure of the oligomers is confirmed. Finally, the ^{1}H NMR spectra prove the bridged structure of the oligomers **7a–d** and **8**. The signals of the macrocycles **7a–d** and **8** are shifted upfield compared to those of the monomer **9** (Table 2). The signals of the inner macrocycle are shifted

Table 2. Selected spectroscopic data of **7a–d**, **8**, and **9** [a].

7a IR: ν [cm^{-1}] = 2099 (C ≡ N); ^{1}H NMR: δ = 1.49–1.62 (ns: n = number > 1, s = singlet; CH_3), 3.90–4.13 (m; H^a), 5.93 (s, H^a), 7.70–7.95 (m; H-2), 8.70–9.20 (m; H-1,1′); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 31.8 (C-6), 35.4 (C-5), 117.1 (C-2′), 120.3 (C-2), 123.0 (C^b), 124.7 (C^a), 125.3 (C-1), 138.1 (C-3), 140.3 (C-3′), 146.4 (C-4, C-4′), 151.2 (C-1′), 158.9 (C^c).

7b IR: ν [cm^{-1}] = 2096 (C ≡ N); ^{1}H NMR: δ = – 0.97–0.80 (m; H$^{a\prime}$), 1.46–1.62 (ns; CH_3), 7.65–7.90 (m; H-2), 8.70–9.20 (m; H-1,1′).

7c IR: ν [cm^{-1}] = 2083 (C ≡ N); ^{1}H NMR: δ = – 1.89– – 1.63 (m; H$^{a\prime}$), – 0.18 (s; H^a) 0.42–0.87 (m; H$^{b\prime}$), 1.36–1.57 (ns; CH_3), 7.12 (s; H^b), 7.53–7.85 (m; H-2), 8.37–9.00 (m; H-1,1′).

7d ^{1}H NMR: δ = – 3.36–3.23 (ns, 2d; H$^{a\prime}$) 1.30–1.76 (nd; CH_3), 7.61 (d, ^3J (H,H) = 4.48 Hz; H^a), 7.49–7.85 (nd, ^3J (H,H) 7.92 Hz; H-2), 8.30–9.00 (nm; H-1,1′).

8 IR: ν [cm^{-1}] = 2097 (C ≡ N); ^{1}H NMR: δ = 0.73, 0.7 (2t; H-7,9), 1.0–1.5 (m; H-5,6,8), 1.69 (m; H-3), 2.74, 2.81 (d; H-2), 4.0 (m; H$^{a\prime}$), 8.55 (ns; H-1,1′, chain phthalocyanines), 8.8 (ns; H-1,1′, end-group phthalocyanines).

9 IR: ν [cm^{-1}] = 2143 (C ≡ N); ^{1}H NMR: δ = – 0.51 (s, 18H; CH_3), 1.76 (t, 36H; CH_3), 8.02 (d, ^3J (H,H) = 7.92 Hz, 4H; H-2), 9.22 (m, 4H; H-1), 9.34 (2s, 4H; H-1′).

[a] IR: KBr. ^{1}H NMR: 250 MHz, 400 MHz, $CDCl_3$. The bridge ligand protons marked with a prime correspond to the signals of inner units.

even further upfield by $\Delta\delta$ = 0.2–0.7 compared to those of the terminal macrocycles. This phenomenon is explained by the strong mutual influence of the phthalocyanine rings in close proximity through the ring current effect.[11] The magnitude of the upfield shift thus depends on the interplanar distance prescribed by the size of the bridging ligands. This increases along the series pyz < Me_2pyNC < dib, Me_4dib. Thus, the upfield shift of the inner compared to the terminal Pc-H 1,1′-protons is up to $\Delta\delta$ = 0.7 in the case of [(tBu$_4$Pc)Fe(pyz)]$_n$ **7d** and, in constrast, up to $\Delta\delta$ = 0.5 in the case of [(tBu$_4$Pc)Fe(Me_4dib)]$_n$ **7b**. Also the signals of inner bridging ligand protons are shifted upfield compared to those of terminal bridging ligand protons. Since the bridging ligands are situated between the aromatic systems of the macrocycles, the upfield shift in this instance is much more dependent on the interplanar distance. For example, in **7d** in the case of bridging dib ligands it is $\Delta\delta$ = 2 and in the case of bridging pyz ligands it reaches values of up to $\Delta\delta$ = 10. Due to the characteristic differences in the positions of the signals of terminal groups and bridging units, the average chain length in **7a–d** and **8** can be determined by the relevant intergration ratios. In **7d**, the average chain length is 4, longer chain oligomers are sparingly soluble. In the isocyanide-bridged systems **7a–c** the average chain lengths lie between 10 and 16, but can be increased by further boiling in $CHCl_3$. With an average number of at least 110 bridged phthalocyanine units, **8** represents the longest chain system in this series.

The ^{13}C NMR spectra of **7a–c** were recorded. Exemplary data, namely for **7a**, are collected in Table 2. The signals of terminal units are shifted downfield compared to those of the inner units and are seen in the spectra merely as shoulders of weak intensity. Spectra of short chain species show the signal splitting due to bridging much more clearly. The carbon atoms most strongly affected by the upfield shift of inner phthalocyanines are C4/4, C3, and C3′.

Experimental

2: A mixture of 4,5-dicyano-1,2-diisooctylbenzene (950 mg, 27 mmol) and $FeSO_4 \cdot H_2O$ (250 mg) in freshly distilled *N,N*-dimethylaminoethanol (7 mL) was boiled under reflux for 24 h in a nitrogen atmosphere. After completion of the reaction the mixture was treated with 70 mL of ethanol and the suspension heated to boiling.

The mixture was filtered and the residue boiled successively in 0.1N HCl and 0.1N NaOH, refiltered, washed thoroughly with H_2O, and finally taken up again in ethanol. The solvent was then removed under reduced pressure and the residue dried. 4,5-Dicyano-1,2-diisooctylbenzene was obtained from *o*-diisooctylbenzene, which was prepared via a Grignard reaction [12, 13]. *o*-Diisooctylbenzene was brominated in the 4- and 5-positions and the product transformed in a Rosenmund–von-Braun reaction into the desired compound.

7a–d and **8**: A mixture of 1 mmol of the relevant isocyanide **3**, **4**, or **5** or 3 mmol of pyrazine **6** in 50 mL of acetone was stirred under reflux for 2d in an N_2 atomosphere. After filtration, the residue was washed with acetone until the solution was colorless. The residue was then dried for 6 h at 70 °C in vacuo.

Amino Acid Esters as Chiral Auxiliary Groups in Lewis Acid Catalyzed Reactions of Electron-rich Siloxydienes with Imines**

By *Herbert Waldmann,** *Matthias Braun*, and *Martin Dräger*

Reactions of compounds containing C–N double bonds with dienes, particularly the Lewis acid catalyzed reactions of imines with electron-rich butadiene derivatives such as the Brassard diene **1**[1] and the Danishefsky diene **2**[2], open up a wide variety of possibilities for the synthesis of heterocycles and natural products.[3] Despite the great potential of this synthetic method only isolated efforts have thus far been made to carry out corresponding transformations asymmetrically using chiral auxiliary groups. In the case of **2**, highly diastereoselective tandem Mannich–Michael reactions have been reported to take place with chiral Schiff bases derived from a galactosylamine.[4] However, asymmetric aza-Diels–Alder reactions with imines, which, for instance, occur if **1** is treated with these heterodienophiles in the presence of Lewis acids[3b] have been the subject of very few investigations.[5]

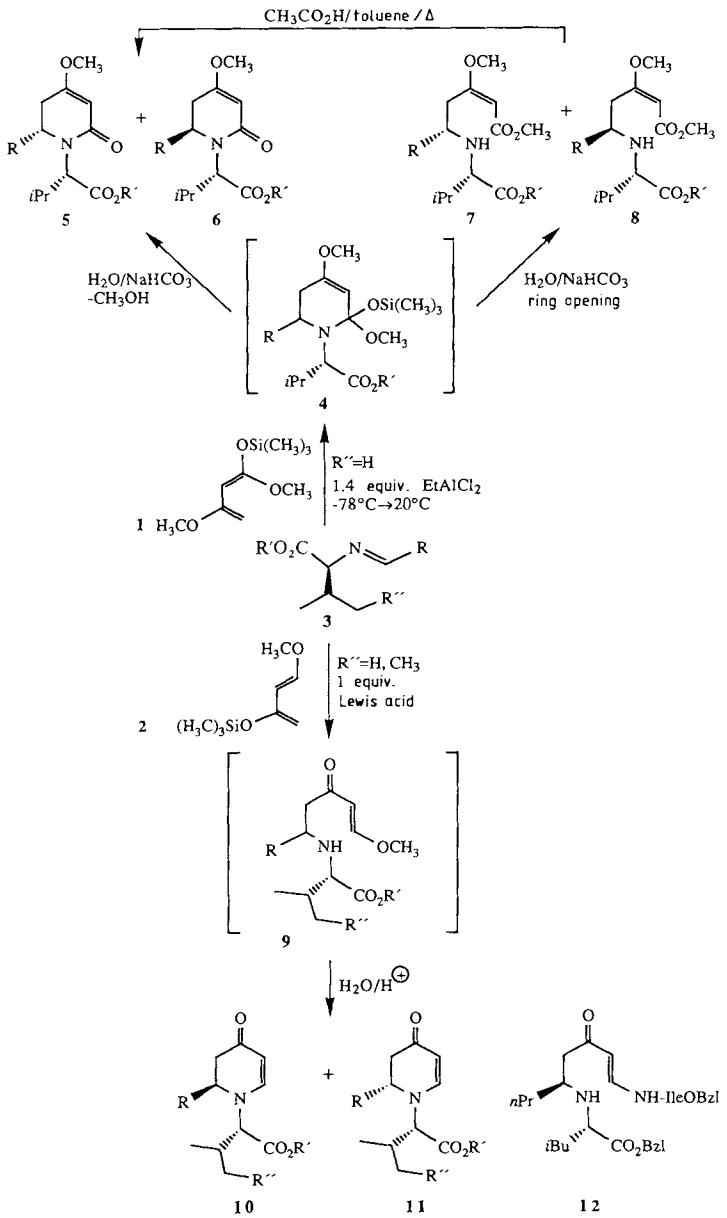
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

We report here on the use of readily available amino acid esters as mediators of the chirality in the reactions of Schiff bases with the electron-rich siloxydienes **1** and **2**. These esters have already proven useful as chiral auxiliary groups in asymmetric Diels–Alder reactions,[5, 6] 1,3-dipolar cycloadditions,[7] and radical additions to carbonyl groups.[8]

The Brassard diene **1** undergoes cycloadditions with the amino acid ester imines **3** of aromatic and aliphatic aldehydes in the presence of Lewis acids ($TiCl_4$, $SnCl_4$, $EtAlCl_2$, $ZnCl_2$, $BF_3 \cdot OEt_2$) to form the α,β-unsaturated lactams **5/6** and the α,β-unsaturated esters **7/8** in good yields and with high diastereomeric excesses (Scheme 1, Table 1). The best results are achieved with 1.4 equivalents of $EtAlCl_2$ at −78 °C and with *tert*-butyl valinate as chiral auxiliary.



Scheme 1.

The primary adducts **4** with orthoester structure, expected to be formed as intermediates, could not be detected. Depending upon the nature of the imine substituents, hydrolysis with $NaHCO_3$ solution leads via elimination of methanol to the lactams **5/6** or via ring opening to the methyl esters **7/8**. Starting from aromatic aldehydes, only the esters **7/8** are always formed, while the imines of aliphatic aldehydes give mixtures of **5/6** and **7/8**. The methyl esters can, however, be converted into the lactams subsequently by simply warming in toluene in the presence of acetic acid. The absolute configuration of the major diastereomer was unequivocally established by an X-ray crystal structure analysis of the lactam **5d**, which revealed that, in this case, the (6*R*)-isomer is preferentially formed.[9] When the Danishefsky diene **2** is allowed to react with the amino acid ester imines **3** of aromatic and aliphatic aldehydes in the presence of an equimolar amount of different Lewis acids ($TiCl_4$, $BF_3 \cdot OEt_2$, $MeAlCl_2$, $EtAlCl_2$, Me_2AlCl, Et_2AlCl), the enaminones **10** and **11** are formed in good yields and with good diastereomeric excesses (Scheme 1, Table 2). The Schiff bases of aliphatic aldehydes give the best results when aluminum compounds are used as

Table 1. Yields and diastereomeric ratios *ds* in the synthesis of the cycloadducts **5/6** and **7/8**[a].

[a] All reactions with $ZnCl_2$ were carried out in THF, all reactions with aluminum Lewis acids in CH_2Cl_2. Imine, diene and Lewis acid were employed in the ratio 1:1.3:1. [b] All enaminones **10**/**11** were obtained as yellowish oils and identified on the basis of their ^1H and ^{13}C NMR spectra [14]. The elemental analyses are in good agreement with the calculated values. [c] Determined from the crude reaction mixtures by HPLC.

catalyst and dichloromethane as solvent (see **10d/11d** in Table 2). In the case of imines of aromatic aldehydes the best catalyst system is zinc chloride in tetrahydrofuran.

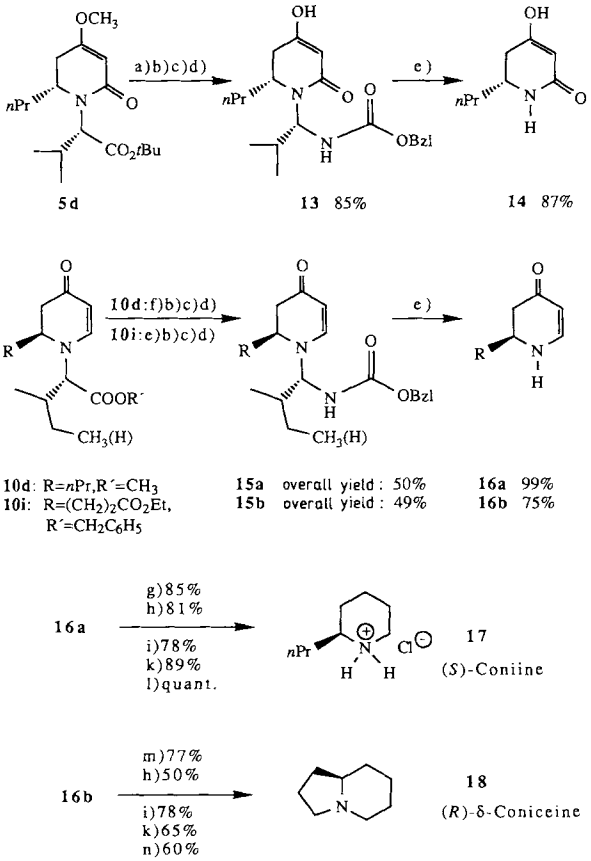
Particularly striking, and also unexpected, is that the chelating $ZnCl_2$ yields the same diastereomer in excess as the aluminum compounds, which generally are only capable of tetracoordination. An indication that the reactions of the Schiff bases **3** with the Danishefsky diene **2** proceed, in accord with the findings for the carbohydrate imines,[4] as tandem Mannich–Michael reactions is provided by the observation that, in the synthesis of **10e** with $ZnCl_2$, the vinylogous amide **12** can also be isolated (Scheme 1). This amide must be formed by nucleophilic attack of amino acid ester (present in the reaction mixture because of incomplete formation of imine) at the Mannich base intermediate, **9**.

In the asymmetric syntheses presented here the sterically demanding amino acids valine and isoleucine have proven to be especially suitable as chiral auxiliary groups. The size of the ester group has only a subordinate influence on the stereoselection; however, in the reactions with **1** the *tert*-butyl esters give the highest yields.

For the cleavage of the chiral auxiliary groups from the heterocycles we have used the principle of converting the α-C-atom into an acetal center, which liberates the desired heterocycle on treatment with aqueous acid or base.[10] Therefore the *tert*-butyl ester group and the enol ether structure on the α,β-unsaturated amides **5**/**6** were first removed simultaneously by treatment with trifluoroacetic acid (Scheme 2). The carboxylic acid formed in this way, e.g. from **5d**, is then converted with diphenylphosphorylazide[11] into the acid azide, which after heating to 80 °C undergoes a Curtius rearrangement. The isocyanate formed thereby is trapped as urethane **13** by added benzyl alcohol. After hydrogenolytic removal of the benzyl group and hydrolysis of the aminal structure the free amide **14** is formed.[12]

The same procedure has also proven useful in the case of the enaminones **10**/**11**. Thus **10d** and **10i**, after selective ester cleavage and Curtius rearrangement, furnished the aminals **15a**, **b** in ca. 50% yield, from which the vinylogous amides **16a**, **b** were released after hydrogenolysis. Enaminones such as **16a**, **b** are versatile intermediates for the synthesis of alkaloids.[4, 13] Thus, the indolizidine alkaloid (*R*)-δ-coniceine **18** could be synthesized from **16b** by lactam formation and subsequent reduction and deoxygenation of the enaminone system by known methods (Scheme 2).[4] In an analogous way, the *n*-propyl substituted vinylogous amide **16a**, after acylation at the nitrogen with Z-chloride in a similar sequence, affords the piperidine alkaloid (*S*)-coniine **17**. A comparison of the specific rotations measured for **17** and **18** with those given in the literature[14] confirmed the absolute configuration of the enaminones **10**/**11**.

The different steric courses of the reactions of the imines **3** with the dienes **1** and **2** in the presence of $EtAlCl_2$ indicate that these reactions proceed via different mechanisms (Scheme 1). In the tandem Mannich–Michael reactions with **2**, the amino acid esters should, in analogy to the Felkin–Anh model, assume the conformation shown in formula **A**, in which the *Re* side of the C=N bond is more freely accessible. The chelating $ZnCl_2$, which additionally coordinates the ester carbonyl group, is expected to reverse the direction of induction. NMR spectroscopic investigations, however, confirm that, in this case, the imine double bond isomerizes under the reaction conditions (− 20 °C to 0 °C), as previously observed by *Ojima* et al.[15] The resulting *cis*-imine is again preferentially attacked from the *Re* side. The Brassard diene **1** appears to undergo a cycloaddition with the imines **3** in the presence of $EtAlCl_2$, with the diene attacking the *Si* side of the C=N bond (formula **B**). The amino acid ester in B is actually present in an anti-Felkin–Anh conformation. However, in this arrangement the unfavorable steric interactions between the bulky substituents on C1 of the diene and the voluminous amino acid side chain are minimized.



Scheme 2. a) CF_3CO_2H/H_2O (9:1), 81%, b) $(PhO)_2P(O)N_3$, c) toluene 80 °C, d) $PhCH_2OH$, e) H_2/Pd-C, f) NaOH/CH_3OH, g) Z-Cl, BuLi, h) L-selectride, THF, i) $HS(CH_2)_2SH/BF_3{\cdot}OEt_2$, k) Raney-Ni/ethanol/Δ, l) HCl/CH_3OH, m) DBU/benzene/Δ, n) $LiAlH_4$/THF.

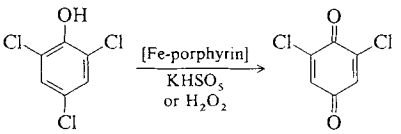
Oxidative Degradation of Aromatic Pollutants by Chemical Models of Ligninase Based on Porphyrin Complexes**

By *Gilles Labat, Jean-Louis Seris* and *Bernard Meunier**

Microorganisms in soils and waters convert many man-made organic chemicals into inorganic products.[1] However, some molecules are recalcitrant and are subject to biomagnification and accumulation in the tissues of plants and animals. Among these compounds, organohalide pollutants (e.g. DDT, lindane[2]) resist microbial destruction.[1, 3] The lack of penetration, coupled with the absence of a suitable extracellular enzyme (often a peroxidase rather than a monooxygenase), is the accepted basis for a molecule being recalcitrant. *Phanerochaete chrysosporium* is able to degrade not only lignin, the oxidation-resistant component of woody plants, but also organohalides, via an extracellular peroxidase, ligninase.[4] We recently developed a chemical ligninase model based on the association of a single oxygen atom donor with water-soluble iron and manganese porphyrin complexes.[5] This inorganic peroxide is also soluble in water at pH 7 and is an efficient oxidant for the generation of oxo-metalloporphyrin species.[6]

Here we report the high catalytic activity of the "metalloporphyrin/$KHSO_5$" system in the oxidation of 2,4,6-trichlorophenol[7] **1** (Table 1) and various substituted arenes



1 **2**

(Table 2). The data in the tables were obtained under the following experimental conditions: To 20 μmol of substrate and 60 nmol of metalloporphyrin[9] in 500 μL of acetonitrile and 1 mL of a buffer solution (0.1 M citrate-phosphate buffer for reactions at pH 3.0 or 0.5 M phosphate buffer at pH 6.0) were added 100 μmol of $KHSO_5$[11] (30.7 mg) in 500 μL of the required buffer (final volume: 2 mL). In some experiments, we replaced potassium monopersulfate by hydrogen peroxide as primary oxidant (12 μL of a 8.6 M solution of H_2O_2 in water). Catalysts adsorbed on Amerlite® were also used, namely FeTPPS-Ad and FeTMPS-Ad.[12] In that case, 2 μmol of metalloporphyrin adsorbed onto 100 mg of resin was added to the reaction mixture. Quinone formation was monitored by high-pressure liquid chromatography (HPLC) on a C_{18} μ-Bondapak analytical column (eluent: methanol/water, 1:1 v/v, flow rate 1 mL/min; UV detection at 280 nm).

Table 1. Oxidation of **1** to **2** catalyzed by iron porphyrins [9].

Run	Catalyst	% Catalyst per Substrate	pH	Oxidant	Yield of **2** [%] within 1 min	15 min
1	FeTPPS	0.3	3.0	$KHSO_5$	95[a]	-
2	FeTPPS	0.3	3.0	H_2O_2	11	68
3	FeTPPS	0.1	3.0	$KHSO_5$	90	92
4	FeTMPS	0.3	3.0	$KHSO_5$	95	-
5	FeTMPS	0.3	6.0	$KHSO_5$	25[b]	10[b]
6	FeTDCPPS	0.3	3.0	$KHSO_5$	92	-
7	FeTPPS-Ad	10	3.0	$KHSO_5$	11	30
8	FeTMPS-Ad	10	3.0	$KHSO_5$	15	36
9	MnTPPS	10	6.0	$KHSO_5$	25[b]	-

[a] 89% of **2** in 15 s: catalytic activity = 20 cycles per second. [b] **2** polymerizes at pH 6.0.

1 was oxidized to 2,6-dichloro-1,4-benzoquinone **2** by iron porphyrin catalysts (0.3% catalyst with respect to **1**) within 1 min at room temperature (Table 1 runs 1, 3 and 4). In run

1 with FeTPPS, 89% of the maximum yield of **2** formed within 15 s, corresponding to a catalytic activity of 20 cycles per second. The same oxidative dechlorination[4a] is performed by ligninase at only 1.5 cycles per second. At pH 6.0, the quinone tends to polymerize. So, the isolated yield of **2** is 25% after a reaction time of 1 min and only 10% after 10 min (run 5). With hydrogen peroxide, a non-pollutant oxidant, the reaction at pH 3 is slower than with $KHSO_5$, but **2** is still isolated with 68% yield after 15 min (run 2). A highly robust water-soluble porphyrin catalyst such as FeTDCPPS is also very efficient (run 6) and only 5% of the catalyst is lost at the end of the reaction. Supported metalloporphyrins can also be used although they are less active: a catalyst concentration of 10% of the substrate concentration is required to obtain 30–36% of **2** in 15 min (runs 7 and 8). Manganese complexes are apparently less active than iron complexes (run 9).

The high redox potential of **1** ($E_{1/2} = 1.7$ V; Ag/AgCl) indicates that the "FeTPPS/$KHSO_5$" peroxidase model is able to oxidize other oxidation-resistant molecules. We therefore investigated a series of methoxylated arenes as substrates (Table 2), some of which are oxidized by ligninase[13].

Table 2. Activity of the system FeTPPS/$KHSO_5$ in the oxidation of methoxyarenes to quinones for a 3:1000 catalyst:substrate ratio (reaction time: 5 min).

Substrate	$E_{1/2}$ [a]	Quinone	Yield [%]
anisole **3**	1.69	1,4-benzoquinone	20[b]
1,2-dimethoxybenzene **4**	1.36	2-methoxy-1,4-benzoquinone	30[b]
1,4-dimethoxybenzene **5**	1.25	1,4-benzoquinone	32[b]
2-methoxyphenol-(guaiacol) **6**	1.23	2-methoxy-1,4-benzoquinone	45
3,4,5-trimethoxyphenol **7**	0.96	2,6-dimethoxy-1,4-benzoquinone	63(43[c])
1,3,5-trimethoxybenzene **8**	1.45	2,6-dimethoxy-1,4-benzoquinone	55
5-chloro-1,3-dimethoxybenzene **9**	0.96	2-chloro-6-methoxy-1,4-benzoquinone	28[b]
1-methoxynaphthalene **10**	1.30	1,2- and 1,4-naphthoquinones[d]	22[b]

[a] $E_{1/2}$ [V] (Ag/AgCl) obtained by linear voltamperometry. [b] Other products are observed. [c] With H_2O_2 as oxidant. [d] The 1,4- to 1,2-quinone ratio is 1.75:1.

Reactions were performed as indicated above with the concentration of FeTPPS 0.3% that of the substrate at pH 3.0 and room temperature. Yields indicated in Table 2 correspond to the yield of isolated quinone after a reaction time of 5 min. All compounds were identified by their ^1H NMR, ^{13}C NMR, and UV-VIS spectra. All methoxylated arenes (**3–5**, **7–10**) are converted into quinones. In the case of horseradish peroxidase[14] or ligninase[13] such *O*-demethylation reactions have been shown to occur via a radical cation followed by the addition of a water molecule. Quinone yields range from 20 to 63% in 5 min (yield maxima are reached within 20–30 min). H_2O_2 can be used as the oxygen donor, as illustrated in the case of 3,4,5-trimethoxyphenol, with only a small decrease in the quinone yield (43% instead of 63%).

It must be noted that methoxylated benzene derivatives with an oxidation potential above 1.4 V are oxidized by FeTPPS/$KHSO_5$ ($E_{1/2}$ values referred to Ag/AgCl are listed in Table 2). We considered five methoxylated arenes, **6**, **5**, **4**, **8** and **3** (listed in order of increasing $E_{1/2}$ values) to scale the oxidation potential of this peroxidase model and to compare its oxidizing power with that of ligninase and horseradish peroxidase (Table 3). Horseradish peroxidase is only able to oxidize **6**, and ligninase **6** and dimethoxybenzenes (both substrates with $E_{1/2}$ values below 1.4 V), whereas "FeTPPS/$KHSO_5$" is able to oxidize all five compounds. This suggests that the redox potential of the high-valent iron–oxo species is above 1.7 V. The $E_{1/2}$ value for the corresponding active iron–oxo entity in cytochrome P-450 was recently estimated at 1.7–2.0 V (vs. calomel electrode, the difference of 45 mV between the two reference systems used is negligible compared to the values discussed here).[15] A value of 1.6 V was found in the case of a high-valent manganese–oxo porphyrin complex.[16]

Table 3. Comparison of the redox activity of the FeTPPS/$KHSO_5$ system and the peroxidases LiP or HRP in the catalytic oxidation of methoxybenzene derivatives [a].

Substrate	$E_{1/2}$ [b]	Oxidation by: FeTPPS/$KHSO_5$ [c]	LiP [d]	HRP
anisole **3**	1.69	+	–	–
1,3,5-trimethoxybenzene **8**	1.45	+	–	–
1,2-dimethoxybenzene **4**	1.36	+	+	–
1,4-dimethoxybenzene **5**	1.25	+	+	–
guaiacol **6**	1.23	+	+	+

[a] LiP = Ligninase, HRP = Horseradish peroxidase; + Oxidation, – no activity. [b] $E_{1/2}$ [V] (Ag/AgCl). [c] 0.3% catalyst, citrate-phosphate buffer at pH 3.0. [c] According to *Kirk* et al. [13].

To conclude, the "Fe-porphyrin/$KHSO_5$" system based on sulfonated porphyrin ligands is able to catalyze the oxidative dechlorination of phenols and the *O*-demethylation of methoxylated arenes which are usually considered as being recalcitrant to many microorganisms, except those producing ligninase. Since ligninase is a rather fragile enzyme (see [17] for the inactivation of ligninase by an excess of hydrogen peroxide), the peroxidase model described here might have a future in the oxidative degradation of organic pollutants.

π/σ Equilibria in Metal Complexes of Organic Carbonyl Compounds; Synthesis and Structure of Chiral Rhenium Complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(O{=}CHAr)]X$ **

By *N. Quirós Méndez, Atta M. Arif,* and *J. A. Gladysz* *

Interactions between metal fragments and organic carbonyl compounds pervade chemistry and biology.[1] Both π (η^2) and σ (η^1) binding modes have been recognized. However, few quantitative data on π/σ equilibria are available.[2] We have previously shown that the chiral rhenium fragment **1** binds aliphatic aldehydes to give the π complexes **2**,[3] and ketones to give the σ complexes **3**.[4, 5] Although we have

$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^{\oplus}$ **1**
$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}O{=}CHR)]^{\oplus}\ BF_4^{\ominus}$ **2**
$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^1\text{-}O{=}CRR')]^{\oplus}\ BF_4^{\ominus}$ **3**

previously suggested a rationale for this dichotomy[4b], we sought a series of compounds that would exhibit *both* binding modes and allow a rigorous study of equilibrium trends. In this communication, we report the synthesis and characterization of complexes of *aromatic* aldehydes, **4**. Depending

$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(O{=}CHAr)]^{\oplus}\ BF_4^{\ominus}$ **4**

upon the aryl substituents, the temperature, and the solvent, either π or σ binding can dominate.

Reactions of dichloromethane complex **5**[6] with the aromatic aldehydes **6a–o** (2–3 equiv., Scheme 1) gave the substitution products **4a–o** (80–97%).[5] These exhibited different NMR properties. Some resembled π complexes, some resembled σ complexes, and others had peaks between the chemical shifts expected for these extremes. This behavior suggested rapidly equilibrating mixtures of π/σ isomers.

Low-temperature NMR spectra (CD_2Cl_2) did not show the decoalescence of π and σ isomers, although chemical shifts of some resonances changed markedly.[7] However, we noted earlier that the IR absorptions ν_{NO} of π complexes **2** (1740–1729 cm^{-1}) and σ complexes **3** (1697–1680 cm^{-1}) differ. Significantly, **4d–o** exhibited ν_{NO} in *both* regions, as illustrated by the representative spectra in Figure 1.[8] Area measurements gave the π/σ ratios in Scheme 1.[9]

Next, IR spectra of the benzaldehyde, *p*-methylbenzaldehyde, and *p*-methoxybenzaldehyde complexes **4i**, **l**, **o** were

Scheme 1. Synthesis of aromatic aldehyde complexes **4**.

recorded in CH_2Cl_2 at temperatures ranging from 303 to 233 K. The π/σ ratios increased markedly at lower temperatures. Van't Hoff plots gave ΔH values of 3.6, 2.8, and 1.8 (±0.2) kcal mol^{-1}, and ΔS values of 9.2, 9.5, and 9.1 (±0.7) eu, respectively. Thus, π coordination is favored enthalpically, and σ coordination entropically.

The solvent dependence of these equilibria was investigated. First, IR spectra of **4i** were recorded in CH_2Cl_2/hexane (50:50 v/v). The π/σ ratio *decreased* to 1:1. Under identical conditions, aliphatic aldehyde complexes **2** exhibited small ν_{NO} shoulders suggestive of σ isomers. Next, IR spectra of **4o** in nitromethane showed an *increased* π/σ ratio of 36:64. Other complexes showed similar IR behavior in these sol-

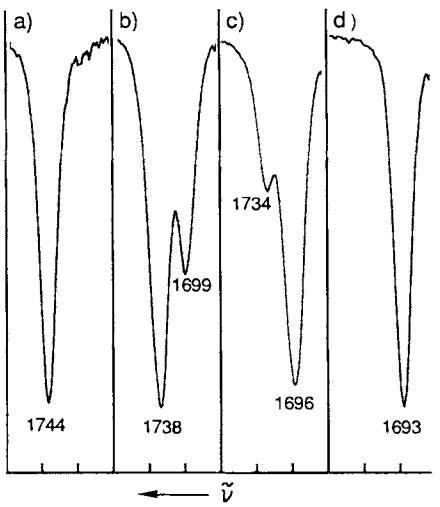

Fig. 1. IR spectra (1800 – 1650 cm^{-1}, CH_2Cl_2, 299 K; ν_{NO}) (a) of **2** with R = H, b) of **4l**, (c) of **4o**, and (d) of **3** with R = R' = Me.

vents. Thus, less polar solvents favor σ bonding, whereas more polar solvents favor π bonding. We attribute this to a greater resonance delocalization of the positive charge in the σ isomers.

The UV/VIS spectrum of **4a** (and the aliphatic ketone complexes **3**) in CH_2Cl_2 showed no visible absorptions. However visible absorptions were observed for **4b**, **i**, **l**, **o** (400–580 nm) and intensified as the proportion of σ isomers increased. Conjugated metal–ligand assemblies frequently give metal-to-ligand charge transfer absorptions.[10] **4o** exhibited a unique and intense UV band at 313 nm.

Finally, structures of **4b** and **4o** were determined (Fig. 2).[5b] Complex **4o** crystallizes as a σ isomer, with (1) conjugated aryl and C=O moieties (the angle between the plane of the ring and the C24–O bond is 6°), and (2) an eclipsed Re–O conformation that directs the aldehyde proton toward the nitrosyl ligand (N1,Re,O2 and C24 are coplanar). This orientation maximizes overlap of the HOMO, a d orbital, of **1** (Scheme 1) and the C=O π* acceptor lobes on oxygen (Fig. 2b). Accordingly, **4o** exhibits a low IR $\nu_{C=O}$ value[8b] and a considerably longer C=O bond length (1.271(8) Å) than those in other σ aldehyde and ketone complexes.[4] Complex **4b** crystallizes as a π isomer, with a Re–(C=O) conformation that allows a high degree of overlap of the HOMO of **1** and the C=O π* orbital. The geometric features of **4b** are similar to those previously found in the analogous phenylacetaldehyde complex,[3] but with somewhat more "slippage" of the carbonyl carbon away from the rhenium (Fig. 2d). Presumably, this distortion is yet more pronounced in π isomers of **4** without electron withdrawing substituents on the aryl ring.

In summary, these data clearly establish the importance of electronic effects in π/σ equilibria of aldehyde and ketone complexes. To a first approximation, electron-withdrawing arene substituents in **4** favor π binding, and electron-donating arene substituents favor σ binding. The acceptor substituents enhance π acidity and lower σ basicity, while the donor substituents have opposite effects.[11] Similar trends have been documented for selenobenzaldehyde complexes.[2b] However, other factors that may affect the equilibrium deserve emphasis. For example, complex **4e**, which has donor substituent in the *ortho* position of the arene ring, shows a much a higher π/σ ratio than the *para* substituted analog **4o**. In σ isomers, interactions are also possible between the arene ring and the phenyl rings of PPh_3.[4] Finally, stabilizing arene/C=O–Re conjugation as in **4o** (Fig. 2a) cannot occur with aliphatic aldehyde ligands. This accounts, at least in part, for the much higher π/σ ratios found for **2**. Future studies will probe other equilibria of π isomers of **4**,[7] and the effect of the binding mode on chemical reactivity.

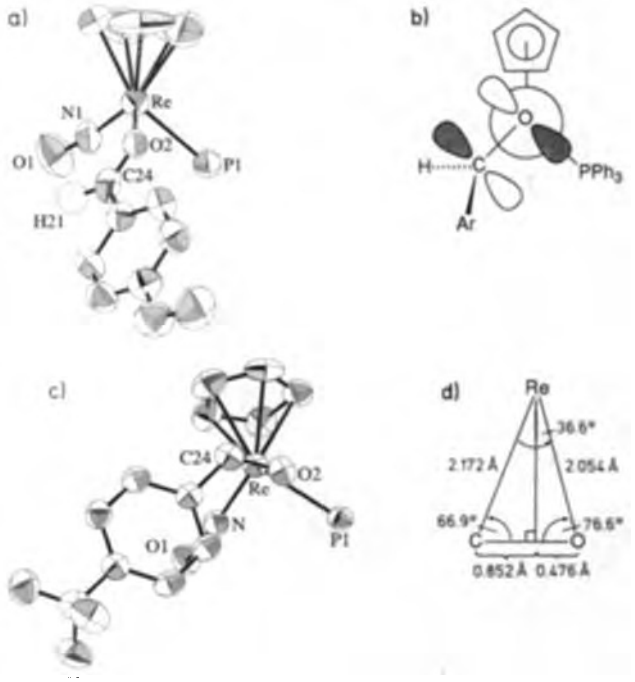

Fig. 2. Partial structures of **4o** (a, b) and **4b** (c, d) as $PF_6^\ominus$ salts, with phenyl rings omitted. [11] An interesting consequence is that the values of ν_{NO} decrease nearly monotonically in the series **4a–o** for *both* binding modes (π, $\tilde{\nu} = 1745–1733$; σ, $\tilde{\nu} = 1701–1692$ cm^{-1}).

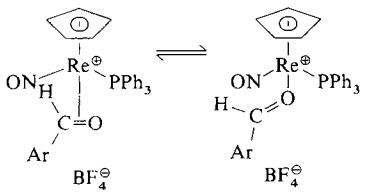
Thermodynamic Aldehyde Enantioface Binding Selectivities in Complexes of Chiral Metal Fragments; Mechanism of Interconversion of Diastereomeric π-Aldehyde Complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}O{=}CHAr)]BF_4$ **

By *N. Quirós Méndez, Charles L. Mayne,* and *J. A. Gladysz* *

One of the most fundamental issues in asymmetric syntheses and separations is the "chiral recognition" event.[1] For example, a chiral receptor might selectively bind one enantioface of a prochiral organic molecule such as an aldehyde or monosubstituted alkene, giving predominantly one of two possible π diastereomers. In order for mechanisms of enantioselection to be fully delineated, data on kinetic and thermodynamic substrate binding selectivities, and diastereomer interconversion rates, are required.[2] In this communication, we report the first thermodynamic data on aldehyde enantioface binding selectivities in complexes of chiral metal fragments, as well as 2D-NMR experiments which show that the resulting π diastereomers interconvert by a novel intramolecular mechanism. Electronic effects evident in these data are probably broadly applicable to asymmetric transformations that proceed via metal π complexes.

Solution IR spectra show that the *p*-methoxybenzaldehyde complex **1f** is a temperature-dependent mixture of π and σ isomers.[3,4] Thus, variable temperature NMR spectra of **1f** were recorded. No signals decoalesced in CD_2Cl_2



1

a, Ar = C_6F_5; **b**, Ar = 4-$CF_3C_6H_4$; **c**, Ar = 4-ClC_6H_4; **d**, Ar = C_6H_5; **e**, Ar = 4-$CH_3C_6H_4$; **f**, Ar = 4-$H_3COC_6H_4$

($^1H/^{13}C/^{31}P$), although some resonances broadened near the freezing point of the solution. However, ^{31}P NMR spectra in a lower-freezing solvent, $CDCl_2F$, showed decoalescence into *three* PPh_3 resonances (Figure 1; 136 K: δ = 22.8, 12.9, 9.4; areas 28:58:14). From data reported earlier,[3,5] the downfield resonance was assigned to σ isomer **III** (Scheme 1).[4a] The two upfield resonances were characteristic of π isomers, and were assigned to diastereomers of idealized structures **I** and **II** (81:19).[6] These differ in the enantioface of the aldehyde bound to the chiral rhenium fragment $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]^{\oplus}$ **2**.

Low-temperature ^{31}P NMR spectra (CD_2Cl_2) were acquired for analogous pentafluorobenzaldehyde, 4-trifluoromethylbenzaldehyde, 4-chlorobenzaldehyde, benzaldehyde, and 4-methylbenzaldehyde complexes **1a–e**.[3] These exhibit much higher π/σ isomer ratios than **1f**.[4b] No peaks attributable to σ-isomers were observed. Resonances for π isomers **I** and **II**, however, decoalesced in each case, as summarized in Table 1.

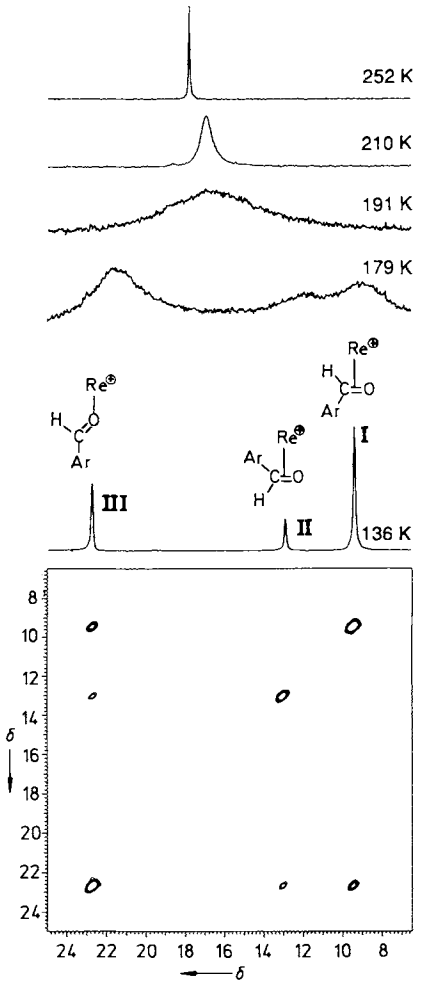


Fig. 1. ^{31}P NMR spectra of **1f** in $CDCl_2F$. Top: 1D spectra at several temperatures. Bottom: Chemical exchange map (mixing time 50 ms, 143 K).

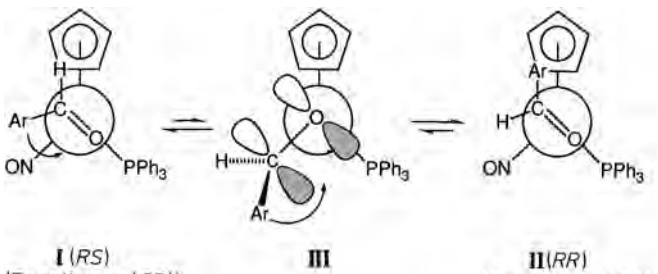
Application of standard formulas[9] gave values for $\Delta G^{\neq}$ (T_c, **I** → **II**) of 9.8 to greater than 15.2 kcal mol^{-1}. Peak areas gave ΔG values (183 K, **I** → **II**; from **I**/**II** ratios) of 0.6 to 1.2 kcal mol^{-1}. The cyclopentadienyl ^1H and ^{13}C NMR resonances of isomers **I** and **II** also decoalesced, and gave nearly identical $\Delta G^{\neq}$ and ΔG (Table 1). The isomer ratios for **1a**, **b** were constant over the temperature range 273–183 K, as assayed by ^{31}P and ^1H NMR.



Scheme 1. Mechanism of interconversion of π diastereomers (**I**, **II**) of complexes of type **1**.

The data in Table 1 show several significant trends. First, enantioface binding selectivities increase as the π acidities of

[a] Cyclopentadienyl resonance [b] The first value refers to isomer **I**, the second to isomer **II** [c] The diastereomer ratios were determined by integration; error limits—88:12 ≙ (88 ± 2):(12 ± 2). [d] For conversion of **I** to **II**, determined from ^{31}P, ^{1}H, and ^{13}C NMR data. [e] No decoalescence observed in ^{1}H and ^{13}C NMR spectra; the **I**:**II** ratio and limiting chemical shifts are taken from data in $CDCl_2F$ (see text).

the aldehydes increase (**1a** > **1b** > **1c** > **1d** > **1e** > **1f**).[3] Crystal structures show that aldehydes that are poorer π acceptors exhibit progressively greater "slippage" of the carbonyl carbon from the rhenium fragment **2**.[3, 7] This moves the carbon and rhenium stereocenters further apart, attenuating chiral recognition. Second, $\Delta G^{\neq}$ for the interconversion of π isomers (e.g., **I** → **II**) *increases* from **1f** to **1a** as ΔG for isomerization to σ isomers (**I** → **III**) *increases*.[3, 4b] We have previously shown that benzaldehyde does not readily dissociate from **1d** at room temperature.[7] These observations suggest that π isomers interconvert via σ isomers, as shown in Scheme 1.

This mechanistic possibility was probed via 2D ^{31}P NMR experiments. Complex **1f** gave the ^{31}P chemical exchange correlation map[10] shown in Figure 1. The diagonal peaks correspond to isomers **III**, **II** and **I**. Significantly, off-diagonal peaks are found *on σ/π intercepts, but not π/π intercepts*. Since the mixing time is quite short (50 ms), this indicates that π isomers **I** and **II** interconvert exclusively (within detection limits) via σ isomer **III**, as shown in Scheme 1. Analogous spectra with other mixing times corroborate these results, and analyses that will yield rates and activation parameters are in progress.

Some extensions of these experiments have been briefly investigated. First, low temperature ^{31}P and ^{1}H NMR spectra of complexes of **2** and aliphatic aldehydes O=CHR (R = CH_3, $CH(CH_3)_2$)[7] have been acquired and carefully analyzed in view of the new chemical shift data in Table 1. These show the reproducible decoalescence of small resonances that can be assigned to π isomers of the type **II** (**I**/**II** ca. 99/1). Thus, aliphatic aldehydes exhibit considerably greater thermodynamic enantioface binding selectivities than aromatic aldehydes. Accordingly, the corresponding crystal structures show less aldehyde ligand slippage.[7] Similarly, preliminary data suggest that aliphatic alkenes exhibit higher thermodynamic enantioface binding selectivities to **2** than styrene.[8, 11] The diastereomeric alkene complexes of **2** also interconvert by an intramolecular pathway (90–100 °C), and we have proposed a mechanism that is conceptually related to the mechanism in Scheme 1.[11]

In summary, this study has established (1) that a striking electronic effect, which is probably general for many π complexes of chiral metal fragments, influences the thermodynamic aldehyde enantioface binding selectivities, and (2) that the facile intramolecular equilibration of diastereomeric π aldehyde complexes proceeds via σ complexes. Both π aldehyde and σ ketone complexes of **2** undergo highly diastereoselective nucleophile additions.[5, 7] Future studies will investigate the relative reactivities of the π and σ isomers toward nucleophiles.

Enantio- and Regiocontrolled Synthesis of a Central Ionophoric Antibiotic Building Block by Sequential Opening of Two Epoxide Rings with Cuprate Reagents**

By *Johann Mulzer** and *Bernd Schöllhorn*

Dedicated to Professor Helmut Vorbrüggen on the occasion of his 60th birthday

The synthesis of complex ionophoric antibiotics of the polypropionate type has been highly topical for several years

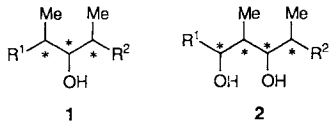
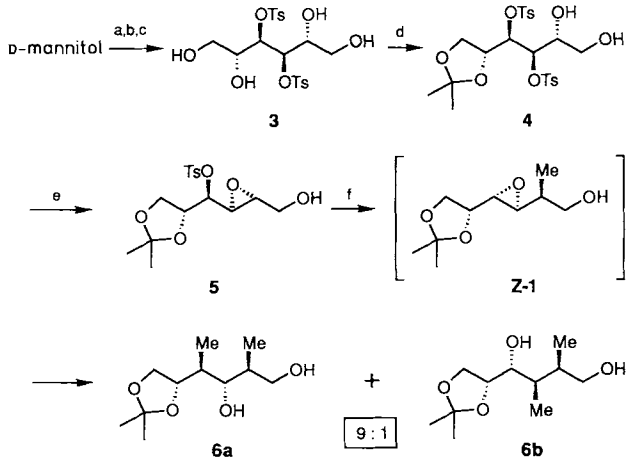
now.[1] For such syntheses the availability of central chiral fragments (so-called "stereotriads" **1**[1] or "stereotetrads" **2**) is of decisive importance. Whereas numerous direct methods have been developed for the synthesis of triads, so far the tetrads have mainly been obtained by attachment of a further stereocenter to a triad.[1, 2] The simplest and more attractive access to such tetrads, however, would be the alternating substitution of hydroxy by methyl groups in polyols of the chiral pool, particularly if this can be achieved in a single synthetic operation.



1 **2**

R^1, R^2 = CH_2OH, CH=O, $CH=CH_2$ etc.

This concept has been realized in the completely regio- and stereocontrolled synthesis of the stereotetrads **6a** and **9**. These tetrads are contained, e.g., in the ionophoric antibiotics zincophorin,[3] denticulatin A and B,[4] and, in enantiomeric form, also in ionomycin.[5] The key step in the synthesis is the sequential opening of two neighboring epoxide rings with cuprate reagents, which we use in two variants A and B. In both cases the ditosylate **3**, accessible in few steps from D-mannitol, serves as starting material. In variant A (Scheme 1) **3** is cyclized via **4** to give the epoxide **5**, which in



Scheme 1. a) Acetone/$ZnCl_2$, 22 °C, 4 h, 60%; b) *p*-toluenesulfonic acid chloride/dimethylaminopyridine (DMAP)/pyridine, 60 °C, 24 h, 85%; c) trifluoroacetic acid (TFA)/H_2O/MeOH, 50 °C, 12 h, 82%; d) 2,2'-dimethoxypropane (DMP)/*p*-toluenesulfonic acid/dimethylformamide (DMF), 22 °C, 12 h, 85%; e) K_2CO_3/MeOH/CH_2Cl_2, 22 °C, 1–2 h, 93%; f) $Me_2CNCuLi_2/Et_2O$, −78 °C, 3 h, **6a**: 72%, **6b**: 8%.

a tandem reaction with Lipshutz dimethyl cuprate,[6] immediately affords—presumably via the intermediate **Z-1**[7]—the tetrad **6a** (72%) (Table 1). Separation of **6a** from the regioisomer **6b** (8%) is unproblematical. The regiochemical control of the cuprate attack on **5** could be determined by the steric repulsion of the tosylate group. Possibly the primary hydroxyl group also steers the organometal into the neighboring position by complexation. In **Z-1** the steric repulsion by the methyl groups already present is presumably decisive for the site of the second attack by the cuprate. Lithium-

Table 1. Analytical data of some key compounds (correct combustion analyses for all compounds; ^1H and ^{13}C NMR spectra at 270 or 68 MHz with internal TMS standard, 25 °C)

6a: ^1H NMR ($CDCl_3$): δ = 0.80 (d, 3H, J = 6.8 Hz; 4-CH_3), 1.16 (d, 3H, J = 6.8 Hz; 2-CH_3), 1.38 (s, 3H; isopropylidene-CH_3), 1.42 (s, 3H; isopropylidene-CH_3), 1.86 (m, 1H; 2-H), 1.92 (m, 1H; 4-H), 3.15 (dd, 1H, J = 8.0, 2.8 Hz; 1-OH), 3.54–3.63 (m, 2H; 1-H_A, 3-H), ABM system: δ_A = 3.68, δ_B = 4.14, δ_M = 4.02 (J_{AB} = 8.1 Hz, J_{AM} = 8.1 Hz, $J_{M,4}$ = 8.6 Hz, J_{BM} = 5.9 Hz; 5-H, 6-H), 3.91 (dd, 1H, ^2J = 10.8 Hz, ^3J = 2.7 Hz; 1-H_B), 4.36 (s, broad, 1H; 3-OH); ^{13}C NMR ($CDCl_3$): δ = 13.0, 15.1, 25.8, 26.7, 35.9, 40.1, 65.4, 69.0, 80.2, 81.5, 109.6; $[\alpha]_D^{20}$ = + 24.0 (c = 1.8, $CHCl_3$)

7: ^1H NMR ([D_6]acetone): δ = 2.80 (s, 2H; 3-H, 4-H), 3.08 (m, 2H; 2-H, 5-H), AB-system: δ_A = 3.52, δ_B = 3.75 (2ddd, 4H, $^2J_{AB}$ = 11.3 Hz, $^3J_{A,OH}$ = $^3J_{B,OH}$ = 5.7 Hz, ^3J_B = 3.2 Hz, ^3J_A = 1.9 Hz; 1-H, 6-H), 3.92 (t, 2H, J = 5.7 Hz; OH); ^{13}C NMR ([D_6]DMSO): δ = 54.3, 56.1, 60.7; m.p. 91–93 °C; $[\alpha]_D^{20}$ = + 65.1 (c = 2.2, methanol)

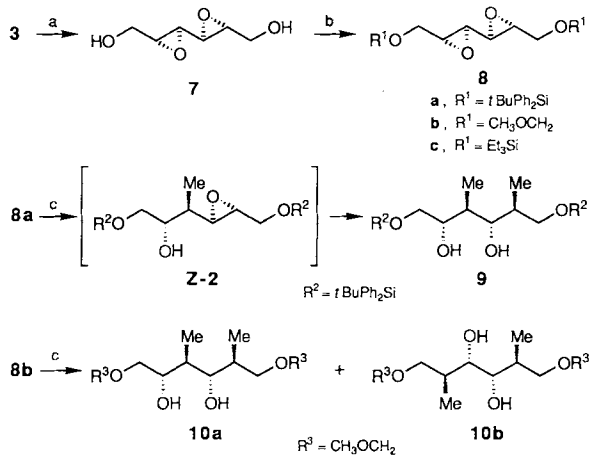
8a: ^1H NMR ($CDCl_3$): δ = 1.07 (s, 18H; *t*Bu-CH_3), 2.93 (s, 2H; 3-H, 4-H), 3.11 (mc, 2H; 2-H, 5-H), 3.83 (ddd, 4H, ^2J = 15.0 Hz, ^3J = 4.0 Hz, ^3J = 3.0 Hz), 7.38 (mc, 12H; *o*- and *p*-arene-H), 7.66 (mc, 8H; *m*-arene-H); ^{13}C NMR ($CDCl_3$): δ = 19.3, 26.6, 53.4, 59.9, 62.8, 127.7, 129.8, 133.0, 133.2, 135.5; $[\alpha]_D^{20}$ = + 20.7 (c = 1.2, $CHCl_3$)

9: ^1H NMR ($CDCl_3$): δ = 0.76 (d, 3H; J = 7.0 Hz; CH_3), 1.00 (d, 3H, J = 7.0 Hz; CH_3), 1.05 (s, 9H; *t*Bu-CH_3), 1.08 (s, 9H; *t*Bu-CH_3), 1.85–2.03 (m, 2H; 3-H, 5-H), 3.52 (mc, 2H; 6-H), 3.64 (m, 2H; 1-H), 3.76 (d, 1H, J = 4.9 Hz; OH), 3.80 (m, 2H; 2-H, 4-H), 4.20 (s, broad, 1H; OH), 7.38 (m, 12H; *o*- and *p*-arene-H), 7.68 (m, 8H; *m*-arene-H); ^{13}C NMR ($CDCl_3$): δ = 13.7, 15.3, 19.2, 19.4, 27.0, 37.4, 38.7, 66.4, 67.1, 75.2, 80.5, 127.6, 129.6, 132.7, 133.0, 135.3; $[\alpha]_D^{20}$ = + 3.8 (c = 1.8, $CHCl_3$)

11: ^1H NMR ([D_6]DMSO): δ = 0.80 (d, 3H, J = 6.8 Hz; CH_3), 0.89 (d, 3H, J = 7.0 Hz; CH_3), 1.72 (mc, 1H; CH_3CH), 1.80 (mc, 1H; CH_3CH) 3.25 (m, 3H), 3.42 (mc, 1H), 3.53 (mc, 1H), 3.64 (mc, 1H), 4.32 (t, 1H, J = 5.1 Hz; OH), 4.52 (t, 1H, J = 5.4 Hz, OH), 4.56 (d, 1H, J = 4.3 Hz; OH), 4.76 (d, 1H, J = 5.7 Hz; OH); ^{13}C NMR ([D_4]methanol): δ = 13.1, 15.4, 38.9, 40.2, 64.4, 65.1, 75.2, 79.7; $[\alpha]_D^{20}$ = −7.0 (c = 2.1, methanol)

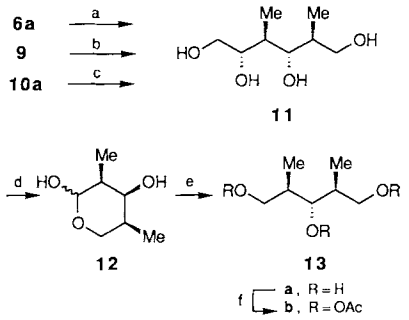
dimethyl homocuprate reacts less regioselectively (**6a**:**6b** = 7:1).

Variant B (Scheme 2) is used for the transformation of **3** into the C_2-symmetric bisepoxide **7** (Table 1). Decisive for the regiocontrol in the opening of the secondary product **8** with cuprate reagents are the two hydroxy protecting groups. Only the bulky *tert*-butyldiphenylsilyl moiety directs the attack to one of the two equivalent "inner" epoxide positions, and the unintercepted intermediate **Z-2** is formed. The attack of the second cuprate moiety is steered, as before, by the presence of the first methyl group, whose influence markedly dominates over that of the silyl group. As expected the transformation of **3** into **7** proceeds without Payne rear-



Scheme 2. a) K_2CO_3/MeOH, 22 °C, 3 h, 93%; b) **8a**: *t*$BuPh_2SiCl$/imidazole/DMF, 22 °C, 12 h, 95%; **8b**: CH_3OCH_2Cl/EtN(*i*Pr)$_2$/THF, 30–40 °C, 30 h, 86%; **8c**: Et_3SiCl/imidazole/DMF, 22 °C, 2 h, 96%; c) $Me_2CNCuLi_2/Et_2O$, −78 °C, 3 h, **9**: 67%, **10a**: 55%, **10b**: 28%.

rangement, since in this case a *cis*-epoxide would have been formed. Furthermore, in the course of the formation of **9** (Table 1) from **8a** (Table 1) a possible cyclization to give the tetrahydrofuran ring does not take place. Access to the enantiomeric tetrad *ent*-**9** was accomplished analogously by using the enantiomer *ent*-**7**, which is also accessible in few steps from D-mannitol.[8] From the bismethoxymethyl ether **8b**, on the other hand, two regioisomers **10a** and **10b** are obtained in the ratio 2:1 upon reaction with the cuprate. **7** and **8c** react in a regio-uncontrolled fashion. The configurations of **6a**, **9**, and **10a** were verified by degradation via **11** (Table 1) and **12** to the well-documented *meso* compound **13b**[9] (Scheme 3).



Scheme 3. a) TFA/H_2O/MeOH, 22 °C, 24 h, 88%; b) nBu_4NF/THF, 22 °C, 12 h, 92%; c) HCl(cat.)/MeOH, 60%, 12 h, 82%; d) H_5IO_6/THF, 22 °C, 1 h, 96%; e) $NaBH_4$/MeOH, 22 °C, 1–2 h, 87%; f) Ac_2O/DMAP/pyridine, 22 °C, 3 h, 96%.

Synthesis of the otherwise difficultly accessible *anti-anti*-triads **1**, which occur, e.g., in rifamycin **S**[10] or tirandamycin,[11] is possible via the semiacetal **12**. The structures of **6b** and **10b** were established by ^{1}H-^{1}H-COSY measurements.

The variants A and B complement each other with regards to the pattern of the protecting groups of the tetrads: In **6a** the 1,2-OH are differentiated from the 3,6-OH groups; in **9**, on the other hand, the 1,6-OH are distinguished from the 2,4-OH groups. In a further communication we shall report on the incorporation of both tetrads into polypropionate antibiotics and on the reaction of **5** and **8** with other nucleophiles.

Induction and Variation of Chirality in Discotic Liquid Crystalline Polymers **

By *Mark M. Green, Helmut Ringsdorf,* Jürgen Wagner,* and *Renate Wüstefeld*

Cholesteric[1] and chiral smectic phases[2] are of great importance, both scientifically and technologically. The chirality of these phases manifests itself in helical superstructures and in special physical properties such as selective reflection of polarized light[3] or ferroelectricity.[4] The influence of chirality has been studied in detail on calamitic (rod-shaped)[1–4] and lyotropic[5] liquid crystals. Chiral discotic (disk-shaped) liquid crystals, on the other hand, have scarcely received any attention, although chiral discotic compounds[6a–d] and phases are known. Special interest attaches to discotic-columnar phases, in which the chirality of the individual molecules can be enhanced first within the individual columns, and second by the arrangement of the columns (e.g. N_c phase) (Fig. 1). The helical order of disks[6a, c] or their side chains[7] is considered responsible for the first reinforcing effect. The helical order of columns leads to the second reinforcing effect that has so far only been demonstrated on lyotropic liquid crystals.[5]

The present work outlines several routes to chiral discotic-columnar phases (Fig. 2). To strengthen the interactions between the columns, main-chain polymers are synthesized in which chiral disk-shaped molecules are linked covalently (a in Fig. 2). If, in addition, these chiral polymers have electron-donor properties they can be doped with electron acceptors to form charge-transfer (CT) complexes;[8] as a consequence the interactions within the columns are strengthened (b in Fig. 2). If achiral polymers are used as starting material, chirality can be introduced by doping them with acceptor molecules (c in Fig. 2).

The chiral monomers for the *synthesis of the main chain polymers* were obtained analogously as described for achiral monomers with pentyloxy side chains.[9a] Triphenylene hexaacetate was allowed to react with (*S*)-(−)-2-methylbutyl

[**] Part of this work was conducted at the IBM Almaden Research Center (San Jose, California) and at Osaka University (Osaka, Japan). *R. W.* is grateful to her hosts Dr. R. Twieg and Dr. C. G. Wilson (Almaden Research Center); J. W. and M. M. G. are grateful to Prof. Okamoto and Prof. Hatada (Osaka University).

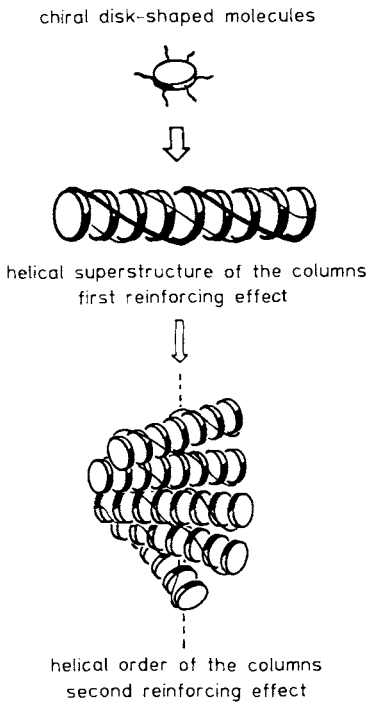

Fig. 1. Chirality in discotic columnar liquid crystals. Other than in the case of conventional calamitic (rod shaped) liquid crystals the chirality of the individual disk-shaped molecules can be doubly reinforced: by the helical superstructure of the columns and, e.g., in nematic columnar phases, and also by the helical ordering of the columns.

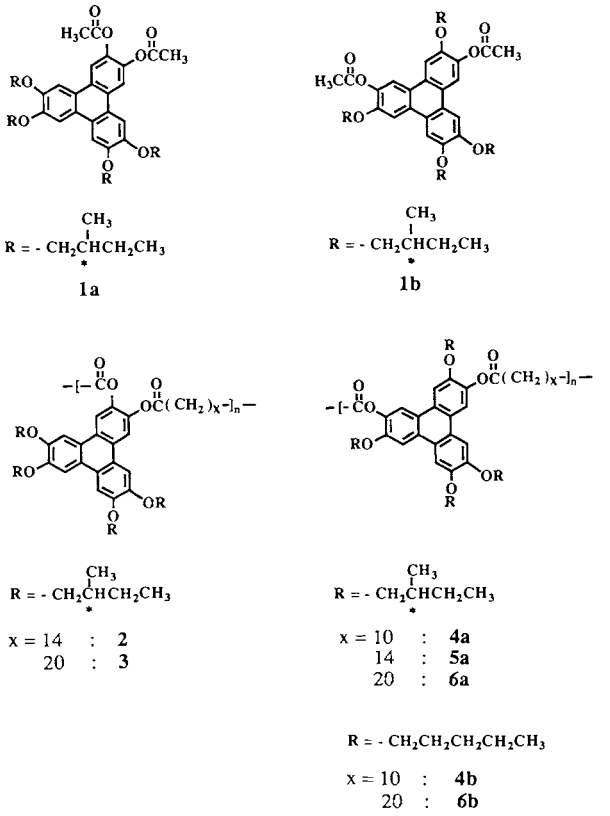

tosylate/K_2CO_3 to give a mixture of completely and incompletely etherified triphenylene acetates. The yield of diacetates (64 mol-%) was comparatively high (hexaether: 2 mol-%, monoacetate: 15 mol-%), since, with more than four side chains, the etherification is sterically hindered. For the first time, also the diacetate **1a** with two ortho acetyl groups was obtained which could be separated chromatographically from the remaining isomers **1b–d**.[10] For polymer synthesis both the *o*-diacetate **1a** (polymers **2** and **3**) as well as the mixture of the remaining isomers **1b–1d** (polymers **4a–6a**) were employed. Polycondensation was carried out in the melt by transesterification with the corresponding 1,ω-dicarboxylic acids (catalyst = *p*-toluenesulfonic acid).[9b]

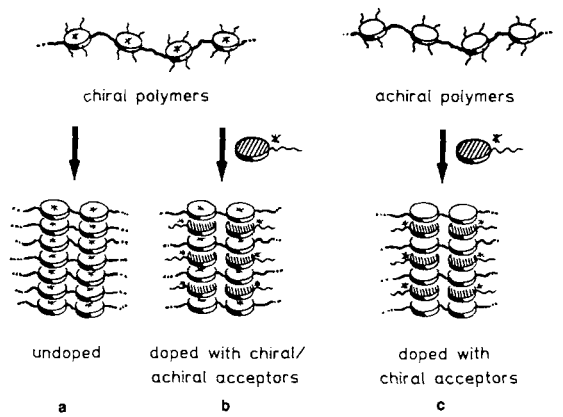

Fig. 2. Routes to chiral discotic-columnar polymer systems. a) The chiral polymer is liquid crystalline. b) The chiral polymer is not liquid crystalline, but can be converted by doping with achiral or chiral electron acceptors into a discotic liquid crystalline system. c) Chirality is introduced into an achiral polymer via doping with chiral electron acceptors.

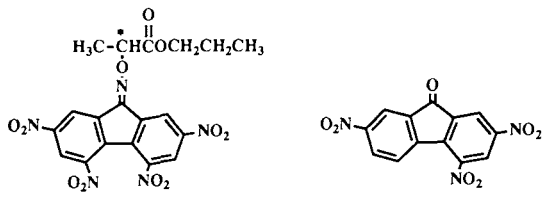
The *phase behavior* of the monomeric diacetates and their polycondensates is shown in Table 1. Of all the compounds, only the main chain polymer **4a** (shortest spacer length) proved to be liquid crystalline. Analogously to the achiral polymers,[9a, b] the ratio of spacer length to side-chain length decides the mesomorphic properties. The structure of the starting monomer is, in contrast, less important: **2** and **5a** as well as **3** and **6a**, which were obtained from the *o*-diacetate **1a** and the diacetate mixture **1b–d** respectively, are amorphous and hardly differ in their glass temperatures.

Table 1. Characterization and phase behavior of the monomers **1a–d** and the polymers **2–6a**.

Compound	x [a]	M_r [b]	Phase behavior [c]
1a	–	689	k_1 180 k_2 195 i
1b–d	–	689	k 203 i
2	14	17000	g 105 i
3	20	15000	g 75 i
4a	10	19000	g 140 D_{ho} 192 i
5a	14	16000	g 108 i
6a	20	18000	g 79 i

[a] x = number of the CH_2 groups of the 1,ω-dicarboxylic acids used as spacers. [b] Relative molecular weight from gel-permeation chromatographic measurements versus polystyrene standards (UV detection, $CHCl_3$). [c] Phase transition temperatures [°C] from differential calorimetric measurements; g = glassy state; D_{ho} = *d*iscotic *h*exagonal *o*rdered phase; i = isotropic melt; k_1, k_2 = crystalline phases [12].

When the main chain polymers **2**, **3**, and **4a–6a** are treated with electron acceptors such as 2,4,7-trinitrofluorenone (TNF) or the enantiomeric 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid propyl esters (−)- and



(−)-TAPAE
(+)-TAPAE

TNF

(+)-TAPAE, colored CT complexes (brownish red, violet, and green—depending on the dopant and polymer) and predominantly liquid crystalline phases are formed (see Table 2). Noticeably it is the first time that, besides the highly ordered D_{ho} and D_{ro} phases (in the case of **4a**, **5a**, **4b**), also a nematic-columnar N_c phase has been found for a chiral discotic system (**6a**/TNF) (cf. Fig. 1).[11]

Table 2. Phase behavior [a] of the chiral CT complexes.

Donor polymer	x	Undoped	Doped with electron acceptors TNF	TAPAE(+) [b]	TAPAE(−) [b]
4a	10	g 140 D_{ho} 192 i	g 118 D_{ho} 256 i	lc 235 i	lc 237 i
5a	14	g 108 i	g 83 D_{ro} 180 i	lc 157 i	lc 157 i
6a	20	g 79 i	g 60 N_c 116 i	amorph.	amorph.
4b	10	g 50 D_{ho} 195 i	g 40 D_{ho} 246 i	lc 220 i	lc 220 i

[a] Cf. [c] in Table 1; D_{ro} = *d*iscotic *r*ectangular *o*rdered phase; N_c = *n*ematic-*c*olumnar phase; lc = *l*iquid *c*rystalline [11]. [b] Glass point and mesophase type have not yet been determined.

Figures 3 and 4 show typical *UV and CD spectra* of thin films[12] of undoped and doped polymers in the region of $\lambda = 200-400$ nm. Doping was carried out with the chiral acceptors (+)-TAPAE or (−)-TAPAE, in each case in a molar ratio donor/acceptor of 3:1. None of the films shows anisotropy, so that orientational effects do not have to be considered upon interpreting the spectra. Instead, information is obtained about the chiral interactions between neighboring molecules within the columns (first reinforcement effect). Information about the chiral interactions between the columns (second reinforcement effect) cannot be gained from these measurements.

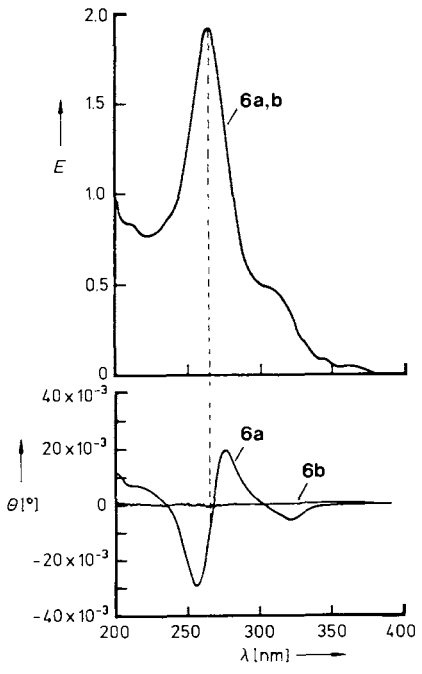


Fig. 3. UV (top) and CD spectra (bottom) of thin films of the *undoped* polymers; here as example, the chiral polymer **6a** and the achiral polymer **6b** with equal spacer lengths. The chiral polymers **4a** and **5a**, like **6a**, show an exciton splitting: the UV transition at $\lambda = 265$ nm splits in the CD spectrum into two transitions. UV absorption as extinction E, CD absorption as ellipticity θ in degrees [13].

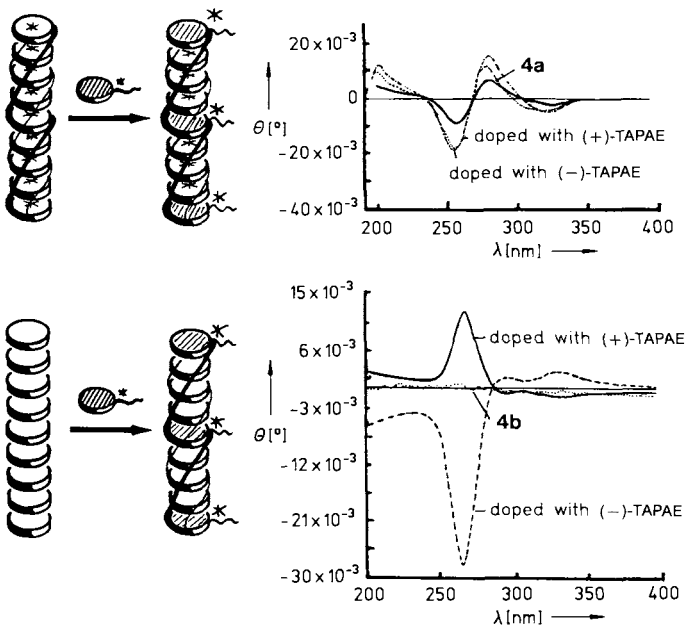

Fig. 4. CD spectra of thin films of *doped* polymers, and schematic representation of the acceptor's influence. Top: chiral polymer **4a**, undoped and doped with (−)-TAPAE or (+)-TAPAE. Doping leads, independently of the handedness of the acceptor, always to a slight increase in CD intensity. The acceptor is inserted into the column without noticeably influencing the interactions between the chiral triphenylene disks. Bottom: Polymers **4b**, undoped and doped with (−)-TAPAE or (+)-TAPAE. The doping leads to high CD intensities; the optical antipodes give mirror-image spectra. The acceptor induces chirality, which is enhanced via the cooperative interactions along the columns. In addition it now determines the handedness of the helix. CD adsorption as ellipticity θ in degrees [13].

The UV spectra of all polymer films are characterized by a broad band at $\lambda = 265$ nm with a shoulder at $\lambda = 310$ nm. They differ very little for chiral and achiral polymers. Larger differences appear only in the CD spectra, in which, as expected, only the chiral polymer systems—doped or undoped—show CD activity. Monomer **1a** was also investigated in solution (3 mM); it is not CD active. This lets us conclude that the CD activity of the polymers does not derive from individual triphenylenes, but from the resulting columnar superstructures that are present in the films. An indication of helical superstructures follows from the exciton splitting. The $\pi \rightarrow \pi^*$ transition of the UV absorption maximum at $\lambda = 265$ nm is split into two transitions in the CD spectrum, as is also found for $\pi \rightarrow \pi^*$ chromophores in helical polymers.[15]

If the *chiral* polymer is doped with the likewise chiral acceptors (−)-TAPAE or (+)-TAPAE, the structures of the CD spectra do not change. In the liquid crystalline systems **4a**/(+)-TAPAE and **4a**/(−)-TAPAE, the CD intensity increases slightly, and by the same amount for both optical antipodes (−)-TAPAE and (+)-TAPAE (Fig. 4, top). The following picture emerges: along the columns there are

strong interactions between the chiral methylbutyloxy side groups and thus also between the triphenylene chromophores, which are arranged in a helix. When (−)-TAPAE or (+)-TAPAE is added the CD spectrum does not change qualitatively, i.e. the CD activity still arises from the twisted triphenylene chromophores and not from the acceptors or triphenylene-acceptor pairs. Quantitatively the CD activity is increased only slightly by acceptor addition; (−)-TAPAE and (+)-TAPAE thus insert into the columns without substantially influencing the chiral interactions.[16]

If, however, the *achiral* polymers are doped with chiral acceptors, a completely different chiroptical behavior is observed (Fig. 4, bottom). Remarkable in this case is the high induced CD intensity, which, once again, arises from the triphenylene chromophores.[17] For the first time the CD spectra differ in the case of the optical antipodes (+)-TAPAE and (−)-TAPAE, namely in their sign. This difference is already known from induced cholesteric phases of enantiomeric calamitic or lyotropic liquid crystals.[18] The structure of the CD spectra is, there as also here in the case of **4b**/(+)-TAPAE and **4b**/(−)-TAPAE, virtually identical to that of the UV absorption spectra. Thus, the chiral acceptors induce—comparably with chiral dopants in calamitic liquid crystals—helical superstructures and, in addition, determine even the handedness of the helices. High CD intensities are obtained since the chirality of the acceptor is enhanced by cooperative interactions along the columns. Chiral doping thus signals a route on which the chiral discotic polymers with high optical activities are accessible at little synthetic expense. Due to CT interactions the chiral acceptor dopants can also be added in high concentrations (often up to molar ratios of 1:1) without destroying the LC phase. Moreover, the acceptors are incorporated into the columns and can, although not liquid crystalline themselves, be oriented with the mesogenic donors.

These first CD investigations show that the chiral discotic polymers prepared via various methods (see Fig. 2) are all optically active and that the high optical activities arise from the superstructures of the columns. The chirality can, as shown, be considerably influenced by the structure of the donor and of the acceptor. Furthermore, the temperature and the ratio donor/acceptor and thus concentrations of chiral groups can be varied. Via all three factors it should be possible to selectively influence the pitch of the helices along the columns. This is of fundamental importance for helical polymers. Moreover, in the case of discotic liquid crystals the connection between the helical superstructure of individual columns and the helical ordering of the columns is of interest (see Fig. 1.). This question is currently being investigated for the N_c phase of system **6a**/TNF. It also refers to helical polymers which may exhibit liquid crystalline ordering in nature as well.[19]

[10] Composition of the isomeric mixture 73 mol-% **1b** and 27 mol-% **1c**/**1d** (**1c** and **1d** cannot be differentiated on the basis of the ^{1}H and ^{13}C NMR data).
[11] The phase types were determined by X-ray investigations: C. Baehr, M. Ebert, J. H. Wendorff, H. Ringsdorf, R. Wüstefeld, 19. Freiburger Arbeitstagung Flüssigkristalle, April 4–6, 1990, Tagungsband, P12.
[12] Preparation by spin coating of the polymer solutions (10 wt.-%) in cyclohexanone, 2d dry in vacuo. Film thickness 0.4–0.5 μm. CD and UV spectra were recorded at room temperature; the polymers are present either as liquid-crystalline or as completely amorphous glasses.
[13] The ellipticity is given by: $\theta = \theta_m cd \sim \Delta\varepsilon cd$; θ_m = molar ellipticity c = concentration, d = film thickness, and $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$ with $\varepsilon_L, \varepsilon_R$ = molar extinction coefficient for left and right circularly polarized light respectively. Differences in the film thickness d play a role only in quantitative considerations and were taken into account by also comparing the intensity ratio I_{CD}/I_{UV}.
[14] Small differences are observed in the range 330 nm $< \lambda <$ 370 nm: the absorption bands of the chiral systems (λ = 345 nm, λ = 362 nm) are shifted hypsochromically compared to those of the achiral systems (λ = 350 nm, λ = 367 nm). It is not important whether the chirality is present in the polymer itself or first introduced via doping.
[15] a) Concerning exciton splitting in copolymers of styrene and chiral olefins: F. Ciardelli, P. Salvadori, *Pure Appl. Chem. 57* (1985) 931, and references cited therein; b) concerning exciton splitting in general: N. Harada, K. Nakanishi (Eds.): *Circular Dichroic Spectroscopy—Exciton Coupling in Organic Chemistry*, Oxford Univ. Press, Oxford 1983. c) For the first time an exciton splitting has also been found in the CD spectrum of a lyotropic liquid crystalline system: J. Wagner, M. Green, unpublished results from studies on chiral poly-2,6-dimethylheptylisocyanates and chirally doped polyhexylisocyanates.
[16] In the *amorphous* systems **6a**/(−)-TAPAE and **6a**/(+)-TAPAE the CD intensity is lower than in the undoped polymer **6a**. Insertion of the acceptor prevents the formation of helices and thus reduces the chiral interactions.
[17] The CD activity does not derive from the TAPAE acceptors. They show only slight CD activity, and their CD spectra differ significantly from those of the doped discotic polymers.

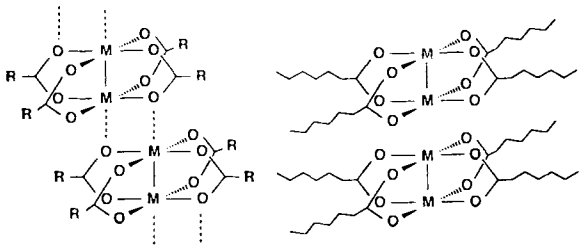
structure, reactivity, and electronic properties for some 25 years.[1] However, the field of macromolecular chemistry based on M–M multiple bonds is still in its infancy. We are interested in exploring the way in which chemical manipulations on a molecular level affect the macroscopic properties of bulk materials derived from dinuclear transition metal complexes containing electronically tunable M–M multiple bond systems. We describe here our preparation and characterization of the first examples of liquid crystalline compounds containing M–M quadruple bonds.[2]

Dimetal tetracarboxylates, $[M_2(O_2CR)_4]$, are known for numerous transition elements, and for certain MO configurations M–M multiple bonds result, e.g. $\sigma^2\pi^4\delta^2$ (M≡M) for M = Cr, Mo, W, and $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$ (M=M) for M = Ru. In the absence of axial donor ligands these compounds form ladder structures **I** in the solid state, whereby the oxygen atom from one carboxylato ligand forms a weak intermolecular bond to the metal atom of a neighboring $[M_2(O_2CR)_4]$ unit.[3] In addition, for suitable substituents R, we believed that these compounds should exhibit thermotropic discotic liquid crystalline phases, **II**, wherein macroscopic order of the "disks" would be maintained by substituent interaction rather than the intermolecular M···O bonds. Discotic mesophases have been reported for $[Rh_2(O_2CR)_4]$ (M–M),[4] $[Cu_2(O_2CR)_4]$ (M···M),[5] and only just recently for $[Ru_2(O_2CR)_4]$ (M=M),[6] (R = C_nH_{2n+1}).



I II

We prepared a series of compounds of the composition $[Mo_2(O_2C(CH_2)_nCH_3)_4]$ where n = 1–11 and 16 by reaction of $[Mo(CO)_6]$ with the appropriate carboxylic acid in diglyme as solvent.[7] All the compounds were crystalline at room temperature and stable at temperatures up to 250 °C in an inert atmosphere. The phase behavior of these compounds was examined by differential scanning calorimetry (DSC) in the temperature range 22 °C–250 °C. The compounds for which n = 3 to 9 exhibit a liquid crystalline phase between their crystalline and isotropic liquid phases. The onset point, as well as the temperature range of the mesophase was found to vary significantly with hydrocarbyl chain length, as is evident in the phase–temperature profile for the series (Fig. 1). The shortest chain to exhibit a liquid crystal phase is for n = 3 (pentanoate), in which the mesophase first exists at 152 °C and is stable up to 174 °C. For n = 4 (hexanoate) the onset temperature is only 108 °C and the mesophase is stable over a range of 64 °C. With increasing chain length the onset temperatures vary only slightly, whereas the mesomorphic range decreases until n = 10 (dodecanoate), at which point the compound melts directly from its crystalline form to an isotropic liquid.

As shown by investigations with the polarizing microscope, a significant degree of order is maintained in the mesophase. Figure 2 shows $[Mo_2(O_2C(CH_2)_7CH_3)_4]$ in its mesomorphic temperature region as obtained by cooling the

isotropic liquid. The fan-like domains > 200 microns are indicative of a discotic mesophase.[8]

The endotherm associated with the crystal → liquid crystal transition is significantly larger than the liquid crystal → isotropic liquid endotherm (see Table 1). We were puzzled as to the interpretation of this phenomenon and in particular how it might relate to the weak metal–oxygen binding in the ladder structure. Accordingly we prepared the octanoates $[M_2(O_2C(CH_2)_6CH_3)_4]$ for the series of metals M = Cr, W, Ru and Rh. The tungsten complex was found to melt with-

out showing a mesophase. The chromium, ruthenium and rhodium complexes (the latter being one previously shown to have a discotic phase) underwent a crystal–liquid crystal transition but did not melt before decomposition. Similar behavior was observed for the laurates (M = Cr, Ru, Rh) and stearates (M = Cr, Ru). It is known that axial ligation is stronger for M = Cr ≫ Mo > W, and in related compounds such as $M_2(O_2CMe)_2(CH_3CN)_6^{2\oplus}$[9] the axial binding to M = Rh is much stronger than that to M = Mo, as evidenced by the metal–ligand distances. The magnitude of the endotherms for the crystal–liquid crystal phase transition and the phase-transition temperature is very similar for all the octanoates. Thus we believe that in the liquid crystalline phase the axial M · · · O interactions are maintained, which is contrary to our initial expectations (see proposed structure **II**).

Given the redox activity and electronic tunability of the M–M manifold, these liquid crystalline materials based on dinuclear transition metal complexes should have interesting electronic, magnetic, and photophysical properties. Further studies are in progress.

[7] In a typical preparation, 1.00 g (3.8 mmol) of $[Mo(CO)_6]$ was slurried in 15 mL of diglyme (dried and oxygen-free) under an N_2 atmosphere. To this mixture was added 3 equivalents of the carboxylic acid and the solution heated to reflux for 3 h. During this time, sublimed $[Mo(CO)_6]$ was continually shaken back into solution. The diglyme was removed in vacuo and the resulting yellow residue was recrystallized from hot toluene. ^{1}H NMR data indicate that all compounds are free from coordinated solvent.

Synthesis and Structure of $[Ba_3(OSiPh_3)_6(THF)] \cdot 0.5$ THF, a Trinuclear Barium Siloxide Containing Low-Coordinate Barium Ions

By *Kenneth G. Caulton,* Malcolm H. Chisholm, Simon R. Drake*, and *William E. Streib*

Alkoxides of barium are of interest as molecular precursors to solid-state materials such as the superconducting ternary oxide $YBa_2Cu_3O_{7-x}$.[1] Recently, we have shown that the reactions between barium metal and alcohols or phenols give oxo alkoxides and oxo aryloxides, respectively.[2, 3] Reasoning that the oxo group in these derivatives was derived from a C–O bond cleavage, we turned our attention to the use of a silanol for which Si–O bond cleavage by either a radical or cationic mechanism is less likely.[4] However, triphenyl silanol, which is known to form compounds with several alkali metals,[5, 6] failed to react with Ba granules in THF under conditions previously employed in the synthesis of barium alkoxides and aryloxides. Neither prolonged reflux nor the use of an ultrasonic gun had significant effect. The addition of trace amounts of $HgCl_2$ or I_2 (known to activate metal surfaces) or strong Lewis bases such as $Me_2NCH_2CH_2NMe_2$ or $(Me_2N)_3PO$ similarly failed to produce a reaction.

The alkaline-earth metals are known to dissolve in NH_3 to yield amide complexes,[7] which, though poorly characterized, have provided active systems for reactions with organic ligands containing acidic protons.[8, 9] Furthermore, NH_3-saturated solutions (rather than liquid NH_3) have found synthetic utility.[10] Barium metal granules in THF and triphenylsilanol react readily when gaseous ammonia is

passed into the solution.[11] It is possible that a labile amido species is formed and leads by facile reaction with Ph_3SiOH to the title compound, siloxide **1**, though a radical pathway cannot be discounted. In any event, the reaction between barium and Ph_3SiOH is catalyzed by ammonia. Compound **1**, which is soluble in toluene, yielded crystals suitable for a single-crystal X-ray analysis from a toluene solution carefully layered with *n*-pentane.[12] The molecular structure of **1** and a ball-and-stick drawing of the M-OSi framework are shown in Figure 1.

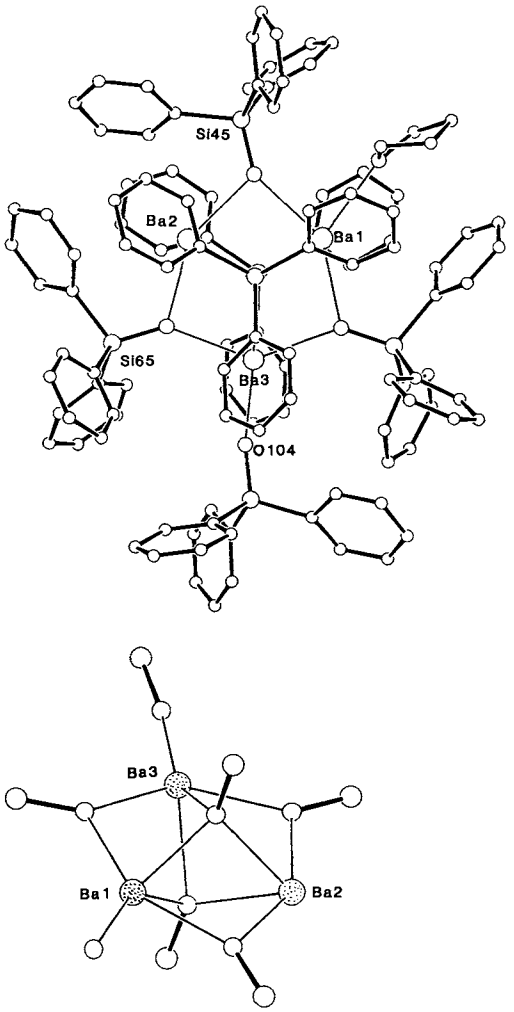

Fig. 1. Crystal structure of **1**. Top: Selected distances [Å], averaged where appropriate: Ba(1–3)-μ_3-$OSiPh_3$ 2.69(9), Ba(1-3)-μ_2-$OSiPh_3$ 2.64(4), Ba3-O104 2.472(4), Ba1-O(THF) 2.75(1). Bottom: Structure of $[Ba_3(OSi)_6O]$ core. ○ = O,Si; ⊜ = Ba.

In contrast to the recently reported structures of phenoxide, *tert*-butoxide, and methoxy-ethoxide complexes,[2, 3] there is no hydroxy or oxo ligand present in the compound. This is in accord with the prediction that the Si–O bond is stronger than the C–O bond.[4] Also worthy of mention is the low Lewis base (THF) content of **1**, which may be attributed to the steric bulkiness of the triphenylsilanol ligands and the solubility which these ligands impart to the resulting complex.

The three barium atoms form a triangle that is capped by two μ_3-$OSiPh_3$ ligands and further linked by three μ_2-$OSiPh_3$ moieties around the belt of the triangle. To achieve electrical neutrality (with Ba in a + 2 oxidation state), a sixth triphenylsiloxide ligand is terminally bonded to Ba3. In addition, one terminal THF molecule is ligated to Ba1. The barium atom coordination in **1** is exceptionally low for a dipositive cation as large as $Ba^{2\oplus}$.[13] Thus, Ba1 and Ba3, which are both ligated by terminal ligands (THF and Ph_3SiO, respectively), are five-coordinate, while Ba2 has the unprecedented coordination number 4 and a coordination geometry which constrains all four siloxide ligands into less than a hemisphere. The shortest Ba2–C(phenyl) distance is 3.31 Å, which is notably longer than the average Ba–C distance of 2.98 Å in Cp^*_2Ba($Cp^* = \eta^5$-C_5Me_5).[14] Moreover, Ba–C(phenyl) distances as short as 3.36 Å for Ba1 and Ba3 indicate that no significant phenyl–Ba2 interaction is operative. Four coordination of one of the barium metal centers in **1** represents the first observation of such a low coordination number (no such examples were found in a search of the Cambridge Crystallographic Data Base).[15] For barium, coordination numbers of 6–9 or greater are common.[13, 15, 16] Because the bonds between Ba2 and the oxygens of the μ_2- and μ_3-siloxide ligands are so short, the adjacent μ_2-siloxides (those containing Si45 and Si65) bend into the region of the empty hemisphere of Ba2. Whereas the terminal Ba–O104 bond is short (with a nearly linear Ba–O104–Si angle of 167.1°), the Ba–O(THF) bond is very long.

The ^1H and ^{13}C NMR spectra of **1** in $[D_8]$toluene reveal only one type of phenyl ring at ambient temperature.[17] Even at − 60 °C, only one phenyl group is identified by ^1H NMR spectroscopy. This suggests that the molecule may be fluxional, although the phenyl protons may not be sensitive probes for Ba–O interactions. Evidently, ^{29}Si NMR spectroscopy is more discriminating because the ^{29}Si NMR spectrum of **1** in $[D_8]$toluene shows two resonances in the integral ratio 2:4.[17] A plausible explanation for the 2:4 ^{29}Si NMR signals would be that the terminal $OSiPh_3$ is involved in a selective exchange with the μ-$OSiPh_3$ groups that lie in the Ba_3 plane. This $OSiPh_3$ exchange would not involve the μ_3-$OSiPh_3$ ligands that lie above and below the plane of the metal atoms.

Rather surprisingly, **1** is volatile and may be sublimed at 200–220 °C (10^{-2} Torr) to yield the THF-free compound, $[Ba(OSiPh_3)_2]_n$, which may also be obtained by stripping a toluene solution of **1** to dryness. This material is insoluble in nondonor media, but dissolves in THF, to regenerate **1** after crystallization from toluene.

[11] All reactions were carried out under an argon atmosphere in dried and carefully deoxygenated solvents. **1**: Ba (1.37 g, 10 mmol) and Ph_3SiOH (5.56 g, 20 mmol) were weighed into a Schlenk tube in a glove box. After removal of the Schlenk tube from the glove box, 20 mL of THF was added, and ammonia gas was bubbled slowly into the reaction mixture for 7 min. The evolution of gas bubbles and the appearance of a pink color indicated that the barium metal was reacting. The solution was then stirred for 5 h, during which time all the metal was consumed, to yield a cloudy pink solution. The solvent and excess ammonia were removed under vacuum to yield a waxy solid, which was redissolved in 20 mL of THF. The solvent was removed once more, and the white powdery solid was redissolved in toluene (15 mL) and filtered. The filtrate was carefully layered with *n*-pentane (15 mL) and left to crystallize at 20 °C. Yield 6.15 g, 77% based on Ba. A small amount (< 30 mg) of a solid purple precipitate formed in the reaction was readily separated from the product by filtration.

[12] Crystal data for **1** at −169 °C: $a = 16.560(3)$, $b = 22.586(3)$, $c = 15.244(3)$ Å, $\alpha = 104.22(1)$, $\beta = 115.71(1)$, $\gamma = 88.82(1)°$, $Z = 2$, $\varrho_{calcd} = 1.456$ g cm^{-3}, space group $P\bar{1}$. Of the 15190 reflections collected ($Mo_{K\alpha}$, $6 \le 2\theta \le 45$), 13035 were unique and the 11231 having $F > 3\sigma(F)$ were used in the full-matrix least-squares refinement. Non-hydrogen atoms were refined anisotropically. The unit cell also contains a molecule of THF which is at a center of symmetry and is therefore disordered. Hydrogen atoms, except those on the disordered THF, were placed in calculated positions with d(C-H) = 0.95 Å and the thermal parameters were set to one plus the isotropic thermal parameter of the parent atom. The final residuals are $R = 0.041$ and $R_w = 0.045$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH. D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54798, the names of the authors, and the journal citation.

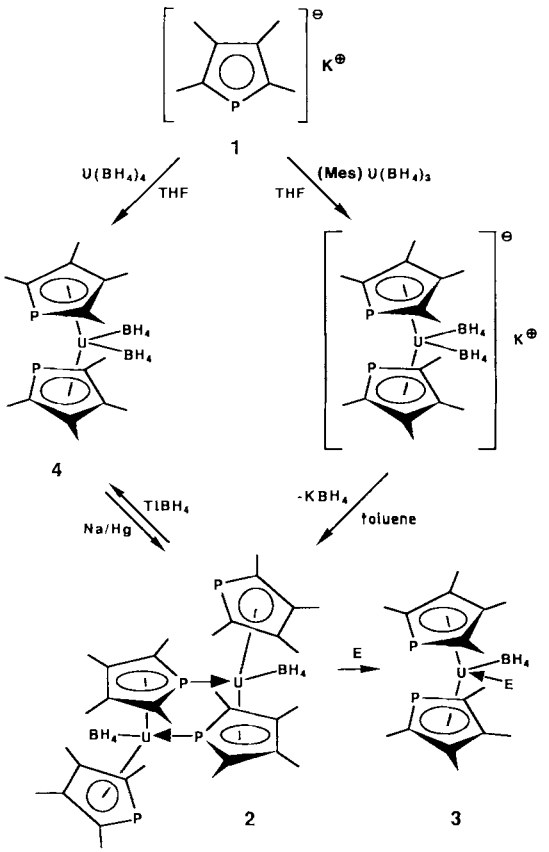
Synthesis of Phospholyltetrahydroboratouranium Complexes. Crystal Structure of $[(\eta^5\text{-}C_4Me_4P)_2U(BH_4)_2]$

By *Denise Baudry,* Michel Ephritikhine, François Nief,* Louis Ricard,* and *François Mathey*

The phospholyl group is a heterocyclopentadienyl ligand that has recently been found capable of η^5-coordination to main group metals[1] as well as to rare earth[2] and early transition metals.[3] This ligand was of special interest to us in uranium chemistry because of its ability to bridge two metal centers.[4] Related pyrrolyl azacyclopentadienyl complexes of uranium have only recently appeared in the literature.[5] We report here the first synthesis of monomeric and dimeric uranium phospholyl complexes.

The phospholyl compounds were prepared similarly to other η^5-dienyltetrahydroborato complexes of uranium[6] (see Scheme 1). Thus, reaction of donor-free potassium 2,3,4,5-tetramethylphospholide **1**[7] (hereafter abbreviated as L) in THF with $[(Mes)U(BH_4)_3]$ (Mes = η^6-1,3,5-$(CH_3)_3C_6H_3$)[6a] afforded a red solution of $[L_2U(BH_4)_2]K$;[8] after removal of the solvent, a dark brown solution of $[(L_2UBH_4)_2]$ **2**[9] was obtained by extraction with toluene. The ^{31}P NMR spectrum of **2**,[10] which exhibited two signals at $\delta = 727$ and 3471, revealed the presence of two nonequivalent L ligands, whereas the ^{1}H NMR spectrum showed that the eight methyl groups in **2** are chemically nonequivalent. The neutral complex **2** adopts the dimeric structure shown in Scheme 1. We suppose that in this symmetric structure the phosphorus atom, which is σ–π bonded to uranium, gives rise to the large paramagnetic shift at $\delta = 3471$. The eight methyl groups of each L_2UBH_4 moiety are nonequivalent because of the chirality of the metal centers.



Scheme 1. Mes = η^6-1,3,5-$(CH_3)_3C_6H_3$. E = THF, PPh_3O.

Dimeric organouranium complexes are very rare,[11] and it is noteworthy that the phospholyl ligands rather than the borohydride groups are bridging in **2**. These bridges can be broken by dissolution of **2** in THF or by addition of one equivalent of PPh_3O in toluene, resulting in the formation of $[L_2U(BH_4)(OPPh_3)]$ **3**.[12]

Compound **2** was oxidized with $TlBH_4$ to the neutral U(IV) derivative $[L_2U(BH_4)_2]$ **4**,[13] which was also formed on reaction of $U(BH_4)_4$ with **1**. Reduction of **4** with sodium amalgam gives **2**.

The pseudotetrahedral structure of **4** in the crystal (Fig. 1)[14] shows that the phospholyl ligand is pentahapto bonded to the uranium atom. The ring geometry differs very little from that of related complexes of Li[1] or Zr.[3] The short U–B distance (255 pm) is typical for bonds with a tridentate BH_4 ligand.[6c] Finally, we should emphasize that,

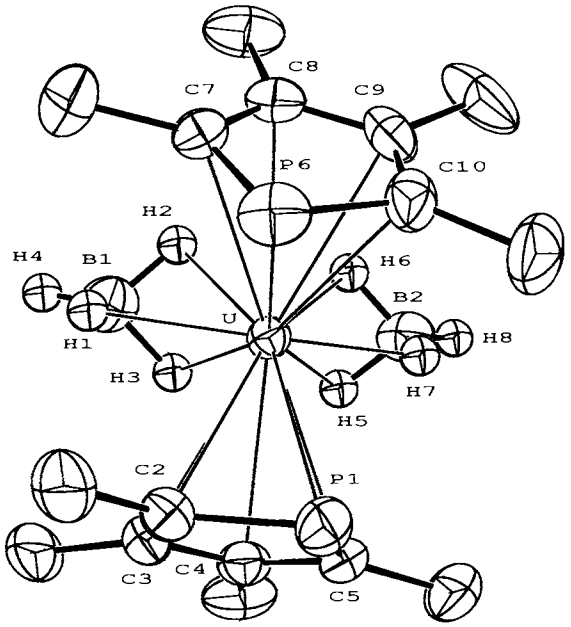

Fig. 1. Structure of **4** in the crystal. Selected mean bond lengths [pm] and angles [°]: U-P, 290.5 ± 0.8; U-C, 281.1 ± 4.3; U-B, 255.3 ± 0.1; U-H, 229 ± 20; P-C, 176.4 ± 1; C-C (cycle), 140.4 ± 2.1; B-H, 110 ± 15; B-U-B, 100.4(2); C-P-C, 90.4 ± 0.3; P-C-C (ring) and C-C-C (ring) 112.3 ± 0.7.

in contrast to two previous reports,[15, 16] we could detect the ^{31}P NMR signals for all the described compounds without major difficulty. We could also observe a resonance at $\delta = 2515$ ($W_{1/2} \approx 200$ Hz) for Cp_3UPPh_2.[15] Therefore, although there is not enough data available to establish correlations between ^{31}P NMR parameters and coordination modes of phosphorus, ^{31}P NMR should prove a valuable tool for the study of phosphorus-containing uranium compounds.

Experimental

^1H NMR (TMS int.): Bruker WP60 (60 MHz) and Bruker AC200 (200 MHz); ^{31}P NMR (85% H_3PO_4 int.): Bruker WP80 (32.4 MHz) and Bruker AM400 (162 MHz).

1: A solution of 1,4-bis(tetramethylphospholyl)butane [17] (5.16 g, 15.4 mmol) in dimethoxyethane (100 mL) was treated with K (1.8 g) at 50 °C for 3 h. After cooling, the reaction mixture was filtered and evaporated to dryness. The residue was rinsed with THF (2 × 50 mL) and dried in vacuo. Yield 3.20 g (17.9 mmol, 58%) of **1** as a white solid.—**2**: THF (20 mL) was condensed at −78 °C onto a mixture of [(Mes)U(BH_4)$_3$] (277 mg, 0.69 mmol) and **1** (245 mg, 1.37 mmol). After warming to room temperature, the solution was evaporated to dryness and extracted with toluene. The toluene solution was concentrated and **2** crystallized out on addition of cold (−78 °C) pentane (118 mg, 0.22 mmol, 32%).—**3**: A solution of **2** (150 mg, 0.28 mmol) and Ph_3PO (78 mg, 0.28 mmol) in toluene was stirred for 10 min at room temperature, then filtered. Evaporation of the cooled solution led to separation of microcrystals of **3**; these were washed with cold (−78 °C) toluene and pentane (84 mg, 0.11 mmol, 40%).—**4**: A mixture of U(BH_4)$_4$ (173 mg, 0.58 mmol) and **1** (207 mg, 1.16 mmol) in toluene (15 mL) was stirred of 2 h at room temperature. The solvent was then removed and the residue extracted with pentane. Upon cooling to −50 °C, dark brown crystals of **4** separated out (188 mg, 0.34 mmol, 59%).

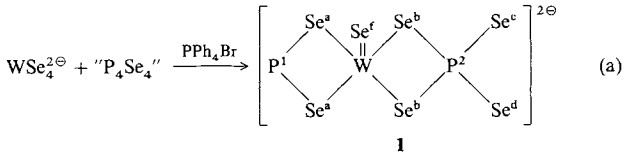
gation.[1] Part of the motivation for studies in this sector has derived from some obvious differences in chemistry from that of metal sulfides, as well as their use in generating new solids.[2] We are interested in using these elements to generate new three-dimensional cages which have novel structural and electronic characteristics.[3] However, since chalcogen atoms are generally divalent, the occurrence of true cages and clusters is somewhat limited. In contrast, compounds containing trivalent atoms of group 15 have recently been reported which possess extraordinary structural diversity.[4]

Cage compounds such as P_4S_3 are useful for generating novel three-dimensional clusters, either as a unit,[5] or as a source of unusual fragments.[6] In this communication we report the preparation of a tungsten phosphorus selenide cluster which displays several unusual features. The easily accessible $[Ph_4P]_2[WSe_4]$[7] readily reacts with phosphorus selenide glass, "P_4Se_4", and in reasonable yield to give the



(a)

1

dianion **1** [Eq. (a)], which has been crystallized as its tetraphenylphosphonium salt with one DMF molecule per cluster. It has been characterized by a variety of spectroscopic methods and a single-crystal X-ray diffraction.[8] The structure of **1** is unusual in many respects (see Fig. 1). It

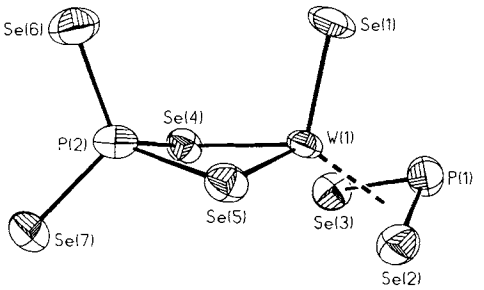


Fig. 1. Structure of **1** in the crystal (ORTEP), ellipsoids at the 50% probability level with important distances [pm]: W1-Se1 226.0(3), W1-Se2 252.6(3), W1-Se3 252.9(3), W1-Se4 248.9(3), W1-Se5 249.6(3), W1-P1 248.3(7), P1-Se2 222.9(7), P1-Se3 223.3(9), P2-Se4 228.0(7), P2-Se5 229.9(8), P2-Se6 212.7(6), P2-Se7 213.6(6).

contains a tetrahedral $PSe_4^{3\ominus}$ ligand coordinated in bidentate fashion to the metal center. This is in contrast to the metal phosphates which usually form bridges between different metal centers, but is common for dithiophosphate esters.[9] However, the coordination chemistry of the heavier phosphorus chalcogenides is not well developed and most examples are solid-state compounds derived from the sulfosalt class of minerals.[9]

The most interesting feature of the molecule is the very unusual bent PSe_2 moiety bound to the tungsten center. The group can be assigned a formal charge of -1, which would make it isoelectronic and isolobal with the allyl anion and $NO_2^{\ominus}$. The bond distances of 252.7(3) pm between tungsten and the $PSe_2^{\ominus}$ selenium atoms corresponds quite well with the length of a single bond. It is not much longer than the W–Se distances to the $PSe_4^{3\ominus}$ ligand (average 249.3(3) pm), but considerably longer than the double bond to the terminal selenide (226.0(3) pm). The distance between the tungsten and the phosphorus atom of the $PSe_2^{\ominus}$ ligand is 248.3(7) pm, which is clearly a bonding interaction.[10] The P–Se distances in the $PSe_2^{\ominus}$ group average 223.1(8) pm, which is between the formally double bonded terminal P–Se distances (213.2(6) pm), and the single bonded bridging distances (229.0(7) pm) of the coordinated $PSe_4^{3\ominus}$ group. In addition, the Se–P–Se angle is 102.3(3)° implying the existence of a stereoactive lone pair on the phosphorus atom.

Thus we can postulate a pseudo-allylic resonance structure which is coordinated to the tungsten center in a side bonded fashion. The single negative charge on the ligand implies a formal oxidation state of IV on the tungsten atom. The chemistry of low-coordinated phosphorus ligands has been extensively investigated,[11] but to our knowledge, the $PSe_2^{\ominus}$ group has not been reported in its free or complexed state.

We have performed multinuclear NMR characterization of this molecule and were able to assign all ^{31}P and ^{77}Se resonances on the basis of coupling and satellite peaks (see *Experimental* and Fig. 2). In the ^{31}P NMR spectrum the P(1)

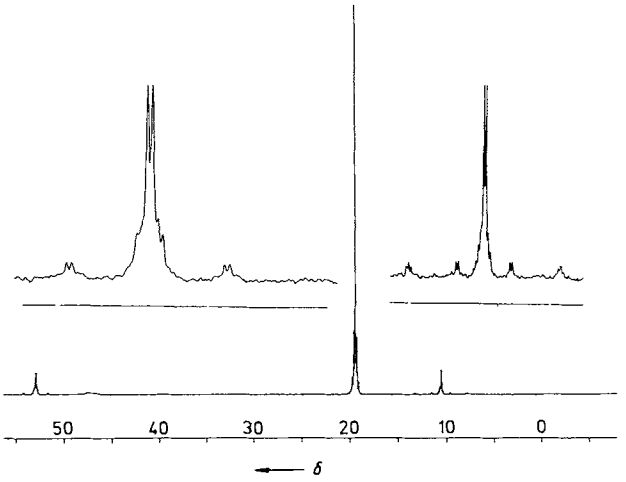

Fig. 2. ^{31}P NMR spectrum of $(PPh_4)_2 \cdot$ **1**, showing an expanded view of the satellites due to ^{77}Se coupling.

resonance appears 10.49 ppm upfield of the tetraphenylphosphonium signal. It has doublet satellite peaks with J_{P-Se} of 227.8 Hz and J_{P-Se} of 654.5 Hz. (All peaks are doublets due to long range coupling with the other phosphorus.) The satellites with the larger coupling can be assigned as the terminal phosphorus selenides. Since the two selenides are in a slightly different environment, their satellites show up as two superimposed doublets or a pseudo triplet. The resonance of P(1) (of the "$PSe_2^{\ominus}$ phosphorus") is downfield at $\delta = 52.85$ (with $J_{P-Se} = 309.4$ Hz). On the basis of these coupling constants, all of the selenium shifts, which show up as doublets due to coupling with the phosphorus, can be assigned with confidence. The terminal selenium bound to the tungsten appears far downfield, as is common with these groups.[12]

Experimental

The mixed polychalcogenide of stoichiometry P_4Se_4 was prepared by heating a mixture of equimolar amounts of red phosphorus and gray selenium in a quartz tube for 16 h at 450 °C followed by slow cooling to room temperature.

This was ground up and stored in an argon atmosphere. The "P_4Se_4" powder (0.40 g, 0.91 mmol) was added to a solution of 0.56 g (0.48 mmol) $[(C_6H_5)_4P]_2[WSe_4]$ in 10 mL DMF. The resulting red solution was stirred for 24 h at room temperature, then filtered, layered with 10 mL THF, and stored at 4 °C. Lustrous red crystals suitable for an X-ray diffraction analysis separated out. Yield 70%, correct analysis.—IR: ν [cm^{-1}] = 495(s), 441(s), 328(m), 123(m).—NMR data [for the designation of the P and Se atoms see Equation (a)]: ^{31}P NMR (DMF, H_3PO_4 ext.): δ = 52.85 (d, 1 P, P(1)) J(P(1)–P(2)) 9.8 Hz, J(P(1)–Se(a)) 309 Hz), δ = 10.49 (d,1 P, P(2)) J(P(2)–Se(b)) 227.8 Hz, J(P(2)–Se(c,d)) 654.5 Hz), 19.37 (s, 2 P, $Ph_4P^{\oplus}$), ^{77}Se NMR (DMF rel. to Me_2Se): δ = 1073 (d, 2 Se, Se(a)), 1210 (d, 2 Se, Se(b)), 993 (d, 2 Se, Se(c,d)), 2288 (s, 1 Se, Se(f)).

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Poets in the Laboratory

Cantor's Dilemma. By *C. Djerassi*. Doubleday, New York 1989. 230 pp., hardcover $ 18.95.—ISBN 0-385-26183-7

It is unusual for scientists to write fiction, the most familiar example being *C. P. Snow*, the Cambridge University chemist–spectroscopist, best known for his "Strangers and Brothers" series of novels and his influential and controversial book "The Two Cultures and the Scientific Revolution." *Carl Djerassi*, Professor of Chemistry at Stanford University, recipient of the US National Medal of Science and the first Wolf Prize in Chemistry and synthesizer of the first oral contraceptive, has followed *Baron Snow*'s example; he is the author of "The Futurist and Other Stories", and his short stories, essays, and poems have appeared in various magazines. As related in "Steroids Made It Possible", an autobiographical volume in *Jeffrey I. Seeman*'s "Profiles, Pathways and Dreams" series, following a cancer operation in 1985, *Djerassi* decided "to test the seriousness of [his] intellectual commitment to a new literary career... [proceeding] concurrently along two paths—one fictional, the other autobiographical."

The accelerating pace of research and increasing size of research groups has rendered more difficult the traditional mode of transmitting the methods, values, and ethics of science to scientific novices by personal contact with experienced researchers. One indirect but quite artistic means for accomplishing this goal is the medium of fiction, a method chosen by *Djerassi* in "Cantor's Dilemma," his first novel.

First and foremost, "Cantor's Dilemma" is an absorbing mystery that kept us engrossed through the final pages. We won't spoil the fun for potential readers by disclosing the outcome. It is a cautionary tale about I. C. Cantor, an internationally renowned "superstar" cell biologist and, like *Djerassi* himself, a true renaissance man, who pushes his best postdoc, Jeremiah Stafford, a young scientist with flawless laboratory technique into performing an *experimentum crucis* to prove Cantor's new theory of tumor formation. The

initial failure of one of the researchers in the laboratory of Kurt Krauss, a fellow cancer researcher and competitor of Cantor's, to replicate Stafford's work as well as an anonymous letter cause Cantor to doubt Jerry's results, so Cantor devises a second and simpler experimental proof, which he carries out himself. Cantor and Stafford jointly receive the Nobel Prize, and many of the later pages of the book are devoted to the elaborate Stockholm ceremonies. In the end Krauss attempts to blackmail Cantor into nominating him for the Nobel Prize.

The book reads like a veritable "Who's Who" of science. The names of familiar leading researchers, editors, and historians of science, historical and contemporary, appear on almost every page. *Djerassi* even slyly introduces an oblique reference to himself (p. 167). While telling his story, he deals with many personal and professional issues that researchers encounter in their work, issues neglected in traditional science courses, e.g., choosing a Ph.D. mentor, role models, hiring and tenure policies, laboratory notebooks, grantsmanship, refereemanship, the status of women in science, teacher-student relationships including sexual relations, nominations and awards, patents, competition, priority, jealousy, fraud, replication of experiments, credibility, retraction of published work, seminars, and lectures. Also unobtrusively and skillfully integrated into the story are countless other fascinating esoteric minutiae ranging from antique furniture and *Boccherini* string quartets to Nobel protocol and European dining habits.

After we each had read the book separately, we exchanged and compared our impressions. As a chemist, one reviewer marveled at the authoritative way in which *Djerassi* accurately presents a "behind the scenes" view of how science is done and how the scientific community works. He also admired the seemingly effortless manner in which the author dispenses nuggets of wisdom that should be invaluable to budding scientists. As a humanist, the other was disappointed at the picture of the scientific enterprise as predominantly award-oriented rather than as the idealistic search for truth generally perceived by the public. She also thought that the characters, especially the women, lacked depth. As we continued to discuss the book, more and more ambiguities surfaced; in particular, Cantor's final dilemma—whether or not to recommend Krauss—is unresolved. Nevertheless, we both enjoyed the book immensely and could not put it down until we had finished it.

According to *Djerassi*, "Publications, priorities, the order of the authors, the choice of the journal, the collegiality and the brutal competition, academic tenure, grantsmanship, the Nobel Prize, *Schadenfreude*... are soul and baggage of contemporary science. To illustrate them, I had Cantor and Stafford work on a totally fictitious theory of tumorigenesis.... Only by giving myself... the assurance that their science is pure fiction could I write about behavior and attitudes surely more common than we like to admit."

While *Djerassi*'s novel will be avidly read by chemists, it will also reach a wider audience. In view of the current rampant epidemic of antiscientific attitudes and chemophobia, many scientists may question the wisdom of washing science's dirty linen in public by giving the public an inside view of the darker side of science with Cromwellian warts. *Stephen G. Brush* has written an article, "Should the History of Science Be Rated X?" (*Science 183* (1974) 1164), subtitled "The way scientists behave (according to historians) might not be a good model for students." The same question might be raised with respect to "Cantor's Dilemma" and the nonscientific public. We recommend that you read it and answer the question yourself.

Gaps and Verges. By *R. Hoffmann*. University of Central Florida Press, Orlando 1990. Distributed by University Presses of Florida, 15 NW 15th St., Gainesville, FL 32603. x, 88 pp., hardcover, $ 14.95.—ISBN 0-8130-0943-X

As in *Hoffmann*'s first poetry volume ("The Metamict State", 1987), these poems are characterized by striking metaphors and vivid images, many drawn from scientific ideas and concepts: "disordered silica chains, rings and structural frustration"; "oxygenated salty soups, lightning-lit, when molecules swam to be shaped"; "membranes, assemblies of proteins and lipids that define the outer walls of cells"; and "lipid-tailored confinements, warm prisons where enzyme brews gel."

Not only do scientific and chemical metaphors and images occur in poems dealing with events from *Hoffmann*'s everyday life, but entire poems deal with scientific and academic themes. "Jerry-Built Forever" deals with an automobile exhaust suicide by describing in poetic but scientifically accurate detail the oxygen-carrying mechanism of hemoglobin and the competition between oxygen and carbon monoxide. "Modes of Representation" describes the artistic line cuts of laboratory experiments in old chemistry books. *Hoffmann* contrasts these simple but lucid drawings with the modern photoengraved illustrations in full color that grace the pages of the latest chemistry textbooks (and add tremendously to the cost!), whose introduction he connects with "a deterioration in the students' ability to follow a simple experimental procedure." "What we have learned about the Pineal" describes the functions and secretions of the pineal gland in animals and in humans. "Thèse pour Obtenir le Grade de Docteur ès-Sciences" depicts an oral thesis defense, a common academic rite of passage.

Many of the selections will appeal to nonscientists as well as to scientists. A number derive from *Hoffmann*'s frequent travels, e.g., "Svoloch" depicts his encounter with customs officials at Sheremetovo Airport and the confiscation of the cassette of a *Haydn* cello concerto played by *Mstislav Rostropovich*, who was then still *persona non grata* in his Russian homeland. "Eschatology" recalls the bishops' rooms at Maynooth, the Irish Pontifical Seminary where *Hoffmann* and other invited speakers at a scientific meeting were housed.

Although we found the meaning of a few of the poems obscure, particularly in Sections 1 and 6 of this six-part book, *Hoffmann*'s poignant autobiographical recollections of the Holocaust are readily accessible to Jew and non-Jew alike. "June 1944" recalls his escape after 15 months' hiding in an attic as a six-year-old with his mother to the Russian lines and the family home, while "Believing" sketches his experiences in Kraków at the age of eight as a Catholic, including confession and first communion (his family pretended to have converted during World War II).

The volume concludes with "Corral", a poem for *Carlos Fuentes* that portrays Sor *Juana Inés de la Cruz* (1651–1695), the intellectual prodigy, poet, scholar, and scientist, who retired to the convent of San Jerónimo because "it was not a time for learned women in Mexico". In this slim volume, which we heartily recommend to aficionados of *Hoffmann*'s verse, he masterly presents to a wider audience the image of a chemist both as a professional scientist and as a human being.

Heats of Vaporization of Fluids. By *V. Majer, V. Svoboda* and *J. Pick*. Elsevier, Amsterdam 1988. 344 p., hard cover DFl 295.00.—ISBN 0-444-98920-X

The heat of vaporization is a thermodynamic quantity which plays an important part in the design of many chemical engineering processes. This book gives a very good survey of the methods now available for estimating or experimentally determining the heats of vaporization of pure substances and mixtures, with the emphasis on organic liquids.

It consists of eight chapters on pure substances, a further eight on mixtures, and four appendices, and covers all important aspects of the subject. First the fundamental thermodynamic relationships between the heat of vaporization and the vapor pressure, the specific heats, the phase composition and the p,V,T data are summarized briefly but in an easily comprehensible form. The various experimental methods based on these relationships for determining the heat of vaporization, either by direct calorimetric measurements or indirectly, are then described, together with many different experimental arrangements and their respective advantages and disadvantages. The empirical methods and correlations used for calculating heats of vaporization are discussed in detail, their application being illustrated by examples in every case. Azeotropic mixtures, mixtures containing non-volatile components, and those with components which associate, are given special treatment and the special points to be noted in these cases are explained. In addition there is a critical survey of the purposes to which heats of vaporization of pure substances can be applied. The appendices give details of methods recommended as suitable for calculating the p,V,T data that are usually needed in applying heats of vaporization in practical situations. Extensive bibliographies are appended to all the chapters.

The book aims to be a useful resource for all scientists and process development engineers who need data on heats of vaporization, and it fulfills this objective very well, though it assumes that the user already has a basic knowledge of thermodynamics. However, the price is very high, which could result in copies of the book being mainly confined to libraries.

Physikalisch-chemisches Institut
der Universität Heidelberg (FRG)

C_4 Hydrocarbons and Derivatives—Resources, Production, Marketing. By *J. Schulze* and *M. Homann*. Springer, Berlin 1989. xi, 239 pp., hardcover, DM 228.00.—ISBN 3-540-19470-3

This book by *Schulze* and *Homann* offers a good and detailed insight into the industrial chemistry of C_4 compounds and their derivatives. The first half of the book is devoted to the chemistry and process technology of the compounds, and the second is concerned more with economic aspects such as the competitive situation and price structure for these chemicals. The book contains a great deal of detailed information and numerical data, since both authors have excellent connections with the chemical and petrochemicals industries; in fact one of them works in industry.

The book is divided into seven chapters. After an introductory chapter dealing with fundamentals such as the properties and specifications of the C_4 hydrocarbons, Chapter 2 describes the processes currently used for the separation or synthesis of C_4 hydrocarbons and the corresponding aldehydes and alcohols. This chapter is very concisely written and assumes that the reader already has some basic knowledge. For example, the several variants of the Mobil process are described in only a few sentences, the latest developments of the Fischer-Tropsch synthesis are covered in one short paragraph, and the production of 1-butene by the SHOP process is only mentioned in one sentence. By contrast Chapter 3, which describes processes for separating C_4 hydrocarbons and the wide-ranging chemistry based on these, including the latest developments, is very detailed. In Chapter 4 the industrial processes based on butane, butenes and butadiene are summarized in clear reaction schemes, supported by production figures. Chapter 5 is concerned with the market situation for C_4 products, and Chapter 6 evaluates the market prospects for derivatives of C_4 hydrocarbons, taking as examples motor fuels and C_4-based polymers. Chapter 7 then gives a further short survey of the most important cross-relationships and recent developments in industrial C_4 chemistry.

This book is an unqualified must for everyone who is involved with C_4 products and their marketing. The clear product charts and process flow diagrams, the extensive bibliography (over 350 references, covering publications up to 1987 in some parts), and the remarkably detailed numerical data make this book one of the most important available works of reference on C_4 chemicals. However, it is not very suitable for use as a student textbook, since considerable previous knowledge is assumed.

Düsseldorf (FRG)

Rings, Clusters and Polymers of Main Group and Transition Elements. Edited by *H. W. Roesky*. Elsevier, Amsterdam 1989. 560 pp., hardcover DFl 350.00. – ISBN 0-444-88172-7

This volume, edited by a leading authority in the field, *H. W. Roesky*, features 11 chapters on a variety of topics broadly described by the title. The book is in the type offset format, presumably to effect savings on the costs and on the time of the production process. Unfortunately, this has not resulted in a price that would tempt many chemists, even those active in the field, into a purchase. Nevertheless, the authors have maintained a standard of presentation of the material that is uniformly high, and there are only a few errors. A brief subject index is also provided. As might be expected the material is very much up to date (1989) and this is a very positive feature of the volume. In some respects, this collection of topics brings up to date and expands the relevant material for some of the chapters in the recently published two volume review monograph edited by *Haiduc* and *Sowerby* entitled "The Chemistry of Inorganic Homo- and Heterocycles".[*] The extremely rapid developments in some of the published areas described are readily apparent in a comparison of the two publications.

However, it would be a mistake to characterize this volume as solely an updated version of the *Haiduc* and *Sowerby* monograph. The majority of the topics are either unique or only have partial overlap with material previously published. Examples are the chapters on "Boron Hydride Clusters" by *N. N. Greenwood*, "Polysilanes" by *E. Hengge* and *H. Stüger* (which complements the corresponding chapter on "Cyclopolysilanes" in the previous monograph), "Germanium-

[*] *Angew. Chem. 100* (1988) 1017; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1107

Carbon Rings" by *P. Mazerolles*, and "Rings with Phosphorus Carbon Multiple Bonds" by *E. Fluck* and *B. Neumüller*. Other chapters deal with the very active interface between main group and transition metal chemistry. Included in this category are "Multiple Bonds between Transition and Main Group Element Atoms" by *W. A. Herrmann*, "Organometallic π Systems" by *G. Huttner* and *H. Lang*, and "Clusters of Metals and Nonmetals" by *K. H. Whitmire*. A significant portion of this material has been reviewed earlier by these three authors but is here updated and expanded. Also included is a chapter by the editor on "Unsaturated 4,6 and 8-membered Metalloheterocycles and Metal Polymers". The timeliness of this chapter, in the light of recent developments in this field, can be gauged from the references, most of which date from the 1980's. Phosphorus-nitrogen ring systems are represented in a chapter entitled "Azaphospholes" by *A. Schmidpeter* and *K. Karaghiosoff*. The vast array of structural types and many novel classes of compound encompassed within the heading "Polynuclear Transition Metal Complexes with Sulfur Ligands" are reviewed by *B. Krebs* and *G. Henkel*. The review includes both sulfide and thiolate ligands. The huge scope of this chapter is reflected in over 400 references, even though 1,1-dithiolate and 1,2-dithiolenes, complexes with partial chalcogen spheres, and abiotic dithio ligands are excluded.

In summary, this book covers the very rapid developments in selected modern topics in the general area of inorganic rings, clusters and polymers. The distinguished list of authors who are all major contributors to their respective fields has ensured that the coverage is thorough. It is a book which every research library should have.

Philip P. Power [NB 1074 IE]
Department of Chemistry
University of California
Davis, CA (USA)

Fusarium Mycotoxins, Taxonomy and Pathogenicity. (Series: Topics in Secondary Metabolism, Vol. 2). Edited by *J. Chelkowski*. Elsevier, Amsterdam 1989. xiv, 492 pp., hardcover DFl 325.00.—ISBN 0-444-87468-2

This book of about 500 pages is based on a seminar on the topic named in the title which took place in September 1987 in Warsaw. It contains 26 contributions on various topics relating to molds of the genus *Fusarium* and their toxic metabolites. The emphasis in over half the articles is on the phytopathological aspects, whereas the chemical and analytical aspects are not adequately covered.

The problems of *Fusarium* taxonomy are discussed in detail, though it is regrettable that in Chapter 10 only the European species of *Fusarium* are treated. For those who are not experts in taxonomy Table 1 of this chapter is very useful, as this lists the different names used in the three "schools" for a given species. However, the list of *Fusarium* metabolites given in Chapter 1 is incomplete; it does not include the apotrichothecenes, nor fumonisin B_1 which is mentioned in Chapters 2 and 12. Not all the calonectrin derivatives are listed. In the bibliography one searches in vain for the "Natural Products Database" produced by *Berdy* et al.; on the other hand there are unnecessary references to many of the older original papers. For many compounds only the trivial name is given, not the systematic name nor the numbering. Instead of log ε the symbol ε_{mol} is used, although the values given for this are the same as those given in the literature for log ε. Chapter 2 gives a competent treatment of fusarin C. One wishes that all the chapters were so well written. Chapters 3 and 4—in very bad English and with many typographical errors—deal with the occurrence of *Fusarium* and mycotoxins in maize, wheat oats and rye, with special reference to Poland, while Chapter 5 contains a detailed discussion of problems in Mediterranean countries. Chapters 17 to 19 deal with subject matter which is similar, and in some cases is even the same. In Chapter 6 a new variant of the *Artemia-salina* bioassay procedure is described. The following chapter is a survey of the literature on trichothecene poisoning in fish. The chapters on the metabolism of trichothecenes in animals are lucid and comprehensible. Also interesting are the chapters on the hyperparasitism of *Fusarium* on some species of *Claviceps*, and the role of cutinase and cell-wall destroying enzymes in the process whereby plants become infected with *Fusarium*. A very nice conclusion is provided by the final chapter on the occurrence of *Fusarium* toxins in cereal crops and animal feeds in Europe. The latest literature (up to 1988) is covered, and the tables contain a great deal of clearly presented information.

Taken as a whole this multi-author volume is very non-uniform and is not well balanced. The treatments of many of the topics could have been shortened by leaving out all the information that is duplicated from one chapter to another. This editing should have been possible during the interval of two years between the seminar and the appearance of the book.

In my view the book can only be recommended for phytopathologists, since that is where the main emphasis of the contributions lies. Food chemists, biochemists and chemists will benefit little from it, especially as there is already a good choice of books on the mycotoxins field, including some that are better than this one.

Heidrun Anke [NB 1083 IE]

der Universität Kaiserslautern (FRG)

Thermochemical Data of Pure Substances. Parts I and II. By *I. Barin*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. Part I: x, 87 pp. Index, pp. 1–816; Part II: vi, pp. 817–1739; hardcover DM 680.00.—ISBN 3-527-27812-5/0-89573-866-X

Anyone who had the experience of using a thermochemical data collection such as "Barin, Knacke and Kubaschewski" (1973, 1977) for everyday reference, whether for calculating reaction equilibria, estimating the ranges of conditions under which species exist, or determining the cell potentials of electrochemical chains, will welcome this updated work, with *I. Barin* as sole author.

Almost 2400 substances are covered, including 100 organic materials and, among inorganic substances, exotic species such as C_3, $PuC_{0.88}$ and Th_2N_2O. The wealth of compounds listed undoubtedly makes this collection of tables the most complete data compilation of its kind in existence, and when one also takes into account the attractive presentation, the relatively high price of DM 680 becomes justified. It is also of interest to the user to know that the thermodynamic information is also available in computer-readable form (though this is unfortunately not included in the price). Comparing this work with "Barin, Knacke and Kubaschewski", not only have some data been revised and new compounds included (thus confirming the need for this new version), but also a number of previously listed substances have been omitted. It would have been useful to give the reasons in these cases, since even a rejection of earlier data contains useful information.

A typical table lists the various thermochemical data for temperatures increasing in steps of 100 K above room temperature (extending up to 5000 K in the case of B_2O_3 for example), for the phase stable at each temperature at a pressure of 1 bar. The data listed include specific heats, enthalpies and entropies, and the auxiliary functions $(G\text{-}H_{298})/T$ and $(H\text{-}H_{298})$. A commendable feature is the inclusion also of the enthalpies of formation and free enthalpies of formation, and of the corresponding equilibrium constants; in the previous work the definition of these functions led to a serious potential source of error. Whereas the "Janaf" tables, for example, consistently use energies of formation (so that the values for elements are, by definition, zero at all temperatures), in "Barin, Knacke and Kubaschewski" the enthalpies of the elements are normalized to zero only at room temperature, and consequently the values at other temperatures differ from zero by amounts determined by their specific heats. The present work also lists at the top of each table the units employed, an arrangement which, although clumsy, is user-friendly. At the foot of each table the sources of the data are given; carefully checked sources such as the "Janaf" tables have been used wherever possible.

The precision and reliability of the listed data is a tiresome but unavoidable subject. The experienced themodynamicist is no doubt well aware that for important calculations one must consult the original papers. However, the occasional user may be tempted to assume precision values of up to 1 part in 10^6. For example, H-values are given to within 10^{-3} kJ mol^{-1}, whereas in the literature one frequently finds discrepancies of the order of 10 kJ mol^{-1}.

It is unreasonable to expect that error limits, reliability of data and inconsistencies in the thermodynamic literature can be taken into account and evaluated in every case, but the reader should certainly be given appropriate warnings on these points.

Much space (87 pages of Part I) is devoted to introductory explanations and comments to accompany the tables, including much useful information and worked examples. However, I preferred the introductory chapter on "Basic Principles" in the earlier work, as it was more concise and more appropriate to the book's purpose. In the present work this has been replaced by essentially a collection of formulas. One should not quarrel with the convention of introducing units into equations, but it is unfortunate that the logical notation of the physical-chemical literature has not been followed, particularly in a work of this nature: expressions of the form "t_c[°C] = T[K] -273.15" should really now be a thing of the past. Also the logical definitions in the chapter on "Entropy" are open to misunderstanding; the condition $\Delta S = 0$ does not necessarily imply a reversible adiabatic process, but can also apply to an (irreversible) steady state. The chapters on the pressure dependence of equilibrium constants and on normal potentials could lead to misunderstandings, and are—in view of the rigor of the statements—partly incorrect.

The electronic index comes with the search module of the literature-management program, VCH Biblio. You can use this index on all PCs running with MS-DOS.

ANGEWANDTE CHEMIE
International Edition in English

Soon available

At the press of a button

The annual index of "Angewandte" is soon available on 5 1/4" and 3 1/2" diskettes.

Yearly updates will keep this invaluable electronic library complete. You can search the cumulative contents in mere seconds.

Price: ca. DM 34.00 plus shipping and handling.

Special news! In honor of the 30th anniversary of "Angewandte Chemie I.E." the cumulative index will also be available on diskette.

INDEX OF AUTHORS AND REVIEWERS OF BOOKS

This index lists separately the names of Authors/Editors and Reviewers, respectively, of books reviewed in *Angew. Chem. Int. Ed. Engl. 29* (1990).

Bookauthors

Agrawal, P. K. 1072
Allen, G. 699
Andersson, S. 1368
Andriska, V. 324
Ashfold, M. N. R. 936
Atkins, P. W. 1069
Atta-ur-Rahman 935
Baggott, J. E. 936
Barin, I. 1491
Bevington, J. C. 699
Birks, J. W. 436
Brandsma, L. 562
Brückner, R. 702
Büchel, K. H. 110
Büchner, W. 110
Buckingham, J. 561
Burguera, J. L. 819
Chanon, M. 704
Chelkowski, J. 1491
Cheng, X.-M. 435
Corey, E. J. 435
Cox, M. 701
Cox, P. A. 822
Datta, T. 111
Djerassi, C. 1488
Dugas, H. 815
Elschenbroich, C. 438
Emsley, J. 700
Falk, H. 1071
Farach, H. A. 111
Fox, M. A. 704
Friedrich, W. 112
Gale, R. J. 699
Glass, R. S. 815

Gutsche, C. D. 1075
Hahn, O. 219
Haines, A. H. 563
Harrison, P. J. 1072
Hellinger, U. 937
Hill, C. L. 700
Hill, M. J. 220
Hoffmann, R. 1489
Homann, M. 1490
Hyde, B. G. 1368
Iddon, B. 111
Ioffe, I. I. 222
Ismail, M. I. 817
Jaffe, H. W. 702
Kropf, H. 327
Kučera, A. 936
Kung, H. H. 1074
Laatsch, H. 560
Lachmann, H. 562
Langford, C. H. 1069
Larock, R. C. 435
Lindberg, T. 326
Lipatov, Y. S. 563
Lown, J. W. 559
Luckenbach, R. 109
Maier, J. P. 437
Mainzer, K. 821
Majer, V. 1490
Malhotra, R. 820
Martin, J. C. 820
Matolcsy, G. 324
Moore, G. L. 703
Moore, W. 697
Nádasy, M. 324
Narang, S. C. 820
Olah, G. A. 820
Omae, I. 1072
Otsuka, C. I. 327
Patai, S. 221, 821, 1070
Pick, J. 1490
Polster, J. 562
Poole, C. P. 111
Price, D. 111
Rabideau, P. W. 698
Rappoport, Z. 221, 1070
Regitz, M. 1369
Remers, W. A. 818
Richards, W. G. 1075
Roberts, R. M. 1069
Roesky, H. W. 1490
Rokach, J. 1073
Salzer, A. 438
Scheffold, R. 819
Schliebs, R. 110, 1490
Schulze, J. 1490
Shriver, D. F. 1069
Southon, I. W. 561
Sposito, G. 817
Stoddart, J. F. 1075
Struve, W. S. 816
Svoboda, V. 1490
Tullius, T. D. 1175
Verkruijsse, H. D. 562
Vögtle, F. 323
Wakefield, B. J. 111
Walker, J. M. 701
White, C. M. 325
Winter, G. 110
Woollins, J. D. 110
Yamamoto, Y. 1072
Yamanaka, T. 327

SUBJECT INDEX

(A second page number to an entry indicates an erratum to the corresponding article.)

(R) = Review Article (C) = Short Communication (B) = Book Review (L) = Correspondence

Ab initio calculations
- Application of the Combined ab initio/IGLO/NMR Method to Resolve the B_6H_{12} Structural Question (C) 886
- C_4O_2 (1,2,3-Butatriene-1,4-dione), the First Dioxide of Carbon with an Even Number of C Atoms (C) 905
- C_2S_2(Ethene-1,2-dithione), an Example for the Violation of Hund's Rule? (C) 1464
- Lithium-Ion-Catalyzed Epoxidation by Triplet Dioxygen: An ab initio Study (C) 648
- On the Nature of Pyrazolylborane. An Ab Initio/IGLO/NMR Study (C) 304
- [PhLiNCH$_2$CH$_2$NLiPh] · 3HMPA, a Monomeric Dilithiumethylenediamide Complex with N_2Li_2 Double Bridging: Synthesis, Crystal Structure, and Model MO Calculations (C) 410
- The Structure of Cyclic C_6S_6 and C_6O_6 (C) 1410

Acetals
- Dependence of Anomeric Stabilization on Structure in Acetals (C) 320

Acetonitrile
- CH Activation of Acetonitrile by Alkyl Compounds of the Early Lanthanoids: Dimeric Cyanomethyl-Lanthanoid Complexes with CH_2CN Bridges (C) 420

Acrylamide
- Catalytic Hydration of Acrylonitrile to Acrylamide under Mild Conditions (C) 523

Acylation
- Asymmetric Nucleophilic Acylation via Metalated Chiral Amino Cyanides: Enantioselective Synthesis of 3-Substituted 4-Oxoesters by Asymmetric Michael Addition (C) 179

Adamantanes
- The First Clamped and Strongly Deformed Adamantane (C) 902

Aldol reactions
- A Novel Pyrrole Synthesis (C) 777

Alkali metal compounds
- About the $Li^{\oplus}$ Gegenion Effect on α-Sulfonyl Carbanions (C) 100
- Aspartic and Glutamic Acid as Ligands to Alkali and Alkaline-Earth Metals: Structural Chemistry as Related to Magnesium Therapy (R) 1090
- Borole Dianions: Metalation of 1-(Dialkylamino)-2,5-dihydro-1*H*-boroles and the Structure of $Li_2(C_4H_4BNEt_2)$ · TMEDA (C) 317
- Carbonylation of Doubly Lithiated *N*-Pivaloyl-anilines. A Novel Approach to Dioxindoles via Intramolecular Trapping of Aromatic Acyllithiums (C) 282
- Chiral Lithium-1-oxyalkanides by Asymmetric Deprotonation; Enantioselective Synthesis of 2-Hydroxyalkanoic Acids and Secondary Alkanols (C) 1422
- CsF · Br_2, an Alkali-Metal Halide Intercalation Compound (C) 1448
- $CsNa_2(OH)_3 \cdot 6H_2O$: Structural Differentiation in the Hydrate of a Ternary Alkali-Metal Hydroxide (C) 904
- Decameric and Dodecameric Sodium Amides and an Organosodium Amide with Stack Structures: $[Na_{10}(NMe_2)_{10}(tmeda)_4]$, $[Na_{12}(NMe_2)_{12}(tmeda)_4]$, and $[Na_{12}(NMe_2)_{10}(CH_2C_6H_4Me)_2(tmeda)_4]$ (C) 1441
- Generation of a Configurationally Stable Chiral Benzyllithium Derivative, and the Capricious Stereochemistry of Its Electrophilic Substitution (C) 1424
- Lewis-Base-Dictated Structural Variations in Sodium Amide Chemistry: X-Ray Crystal Structures of Phenyl(2-pyridyl)amidosodium with Hexamethylphosphoric Triamide (HMPA) and with Pentamethyldiethylenetriamine (PMDETA) (C) 1440
- Lithium Bis(di-*tert*-butylfluorosilyl)-amide as Contact Ion Pair with Linear Si–$N^{\ominus}$–Si Unit and as Ion Pair without $Li^{\oplus}$-Anion Contact (C) 209
- $Na_{10}\{Li_2[MnO_4]_4\}$, a Compound in Which LiO_4 and MnO_4 Tetrahedra Form Chains Consisting of Six- and Eight-Membered Rings (C) 800
- [*n*BuLi · LiO*t*Bu]$_4$, Solid-State Structure of an *n*-Butyllithium–Lithium *tert*-Butoxide Complex (C) 308
- [PhLiNCH$_2$CH$_2$NLiPh] · 3HMPA, a Monomeric Dilithiumethylenediamide Complex with N_2Li_2 Double Bridging: Synthesis, Crystal Structure, and Model MO Calculations (C) 410
- Preparation of an Enantiomerically Enriched Allyllithium Derivative by Deprotonation with Kinetic Resolution of Enantiomers (C) 296
- Reductive Scission of a Cyclopropane σ-Bond During the Action of Elemental Lithium on Cyclopropylacetylenes – A *cis*-1,2-Dilithioalkene as Intermediate (C) 667
- Structure Determination of $NaCD_3$ Powders at 1.5 and 300K by Neutron and Synchrotron–Radiation Diffraction (C) 650
- Synthesis and Structure Determination of Bicyclic $[Li(tmeda)]_2[S_6]$ (C) 422
- Synthesis and Structure of a Dimeric Lithium Diphenylcuprate: $[\{Li(OEt)_2\}(CuPh_2)]_2$ (C) 300
- 2,3,4,5-Tetramethyl-1-sodiopyrrole: An Azacyclopentadienyl Ligand in a Novel Bridging Function (C) 1143
- Tetraphenylallylsodium Diethyl Ether: A Contact Ion Pair with an Intramolecular $Na^{\oplus}$ Sandwich (C) 1042

Alkaline-earth metal compounds
- Aspartic and Glutamic Acid as Ligands to Alkali and Alkaline-Earth Metals: Structural Chemistry as Related to Magnesium Therapy (R) 1090

Alkaloids

- High-Pressure NMR Studies of $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)Cr(CO)_2]$. Evidence for Concerted Ring Interchange (C) 194
- μ-Hydroxobis(μ-formato)hexaaquadichromium(III), an Intermediate in the Formation of Basic Chromium Carboxylates (C) 811
- Intramolecular Interconversion of *syn*- and *anti*-Tricarbonyl(1-ethoxy-1,2-dihydrocyclobutabenzene)chromium. Trapping of the *ortho*-Quinodimethane Intermediate (C) 407
- Synthesis and Direct NMR Spectroscopic Observation of $[(\eta^4\text{-Arene})Cr(CO)_3]$ Dianions (C) 1444
- Synthesis of Nitrogen Heterocycles by Diastereoselective Intramolecular Aminocarbene Annelation (C) 176

CIDNP
- NMR Study of Nuclear Spin Polarization during Chemical Reactions with Ortho Hydrogen (C) 58

Clusters
- Lewis-Acid-Induced Transformation of a Terminal Carbonyl Ligand: Synthesis and Structure of the Alkyne-Cluster-Analogue $[(\mu\text{-}H)_3Os_3(CO)_9\{\mu_3,\eta^2\text{-}C(OBC_8H_{14})B(Cl)\}]$ (C) 309
- New Copper Clusters Containing Se and PEt_3 as Ligands: $[Cu_{70}Se_{35}(PEt_3)_{22}]$ and $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (C) 1452
- $[Ni_3(\mu_3\text{-}CNMe)(\mu_3\text{-}I)(CNMe)_2(Ph_2PCH_2PPh_2)_2]I$, a *triangulo* Nickel Cluster with an Unprecedented Symmetric Linear μ_3-η^1 Isocyanide Ligand (C) 395
- Nonmolecular Metal Chalcogenide/Halide Solids and Their Molecular Cluster Analogues (R) 840
- Novel Bonding Mode for a Cyanometalate Ligand: Synthesis and Crystal Structure of the Mn_4Pd_4 Cluster $[(OC)Pd(\mu\text{-}NC)Mn(\eta\text{-}C_5H_4Me)(CO)_2]_4$

Containing an Orthogonal Arrangement of Helical Units (C) 1140
- $[(Ph_3P)_2N]_2[Os_{18}Hg_2C_2(CO)_{42}]$ a Photochemically Generated High-Nuclearity Cluster Which Reversibly Incorporates Metallic Mercury into Its Metal Core (C) 1137
- Preparation and Structure of $[Se=W(PSe_4)(PSe_2)]^{2\ominus}$; a Cluster Containing a Heteroallylic $PSe_2^{\ominus}$ Unit (C) 1486
- Rings, Clusters and Polymers of Main Group and Transition Elements (B) 1490
- Synthesis and Structure of $(NBu_4)[Sn\{Pt(\mu\text{-}Cl)(C_6F_5)_2\}_3]$, an Unusual Cluster with Three $Pt^{II}\rightarrow Sn^{II}$ Bonds (C) 1449
- Synthesis and Structure of Novel Cu-Clusters: $[Cu_{30-x}Se_{15}(PiPr_3)_{12}]$ (x = 0,1) and $[Cu_{36}Se_{18}(PtBu_3)_{12}]$ (C) 796
- Topologically Interesting Cages for Negative Ions with Extremely High "Coordination Number": An Unusual Property of V-O Clusters (C) 926

Cobalt compounds
- Building Up Metal-Stabilized Fourfold Bridged Cyclobutadienophanes (C) 1426
- Catalytic Hydration of Acrylonitrile to Acrylamide under Mild Conditions (C) 523
- Cycloaddition Reactions of CpCo-Stabilized Cyclobutadiene Derivatives (C) 276
- Dicobalt Complexes with *syn*- and *anti*-Coordinated μ-Cycloheptatriene Bridges (C) 686
- Formation of Tetranuclear Chelate(4-) Ions of Divalent Metals (Mn, Co, Ni) with Idealized *T* Symmetry by Spontaneous Self-assembly (C) 311
- Heteronuclear Complexes Containing $CuCo(CO)_4$ Structural Units and Nitrogen Ligands (C) 783
- Ring-Opening of a Bicyclo[3.2.0]hepta-1,3-dienylcobalt(I) Complex Followed by Cycloaddition (C) 1057
- The Azide Homologues Et–PPP and Ph–AsAsAs as Bifacially Coordinated Ligands in Tripod-Cobalt Complexes: Synthesis, Structure and Molecular Dynamics (C) 929
- The Proton Catalyzed Transformation of a Cobaltacyclopentadiene into a η^4-Cyclobutadiene Complex (C) 1046
- The Tri-μ-amidobis[triammine-cobalt(III)] Cation: The First Triply Amido-bridged Complex (C) 1158
- *trans*-1,2-Difluoro-1,2-bis[(tetracarbonyl)cobaltio]ethene, a Difluoroethyne Complex with μ_2-η^1-η^1-Coordination (C) 315

Cobyrinic acid
- Hydrogenobyrinic Acid: Isolation, Biosynthesis, and Function (C) 884

Cocondensations
- Highly Reactive Intermediates from the Cocondensation Reactions of Iron, Cobalt and Nickel Vapor with Arenes (R) 126

Collisions
- Bimolecular Collisions (B) 936

Colloids
- Colloid Chemistry of Polymers (B) 563

Complexes with aldehyde ligands
- π/σ Equilibria in Metal Complexes of Organic Carbonyl Compounds; Synthesis and Structure of Chiral Rhenium Complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(O=CHAr)]X$ (C) 1473
- Thermodynamic Aldehyde Enantioface Binding Selectivities in Complexes of Chiral Metal Fragments; Mechanism of Interconversion of Diastereomeric π-Aldehyde Complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}O=CHAr)]BF_4$ (C) 1475

Complexes with arsenic ligands
- The Azide Homologues Et–PPP and Ph–AsAsAs as Bifacially Coordinated Ligands in Tripod-Cobalt Complexes: Synthesis, Structure and Molecular Dynamics (C) 929

Complexes with carbon ligands
- CH Activation of Acetonitrile by Alkyl Compounds of the Early Lanthanoids: Dimeric Cyanomethyl-Lanthanoid Complexes with CH_2CN Bridges (C) 420
- Complexes of Carbon Monoxide and Its Relatives: An Organometallic Family Celebrates Its Birthday (R) 1077
- (3,3-Diphenylallenylidene)trimethylphosphanetitanocene: The First Titanocene Carbene Complex with Three Cumulative Double Bonds (C) 1037
- $[\{Ni_2(\mu\text{-}CNMe)(CNMe)_4(Ph_2PCH_2PPh_2)\}_2Hg][NiCl_4]$, a Spirocyclic Ni_4Hg Cluster with an Hg^{II}-Center (C) 396
- $[Ni_3(\mu_3\text{-}CNMe)(\mu_3\text{-}I)(CNMe)_2(Ph_2PCH_2PPh_2)_2]I$, a *triangulo* Nickel Cluster with an Unprecedented Symmetric Linear μ_3-η^1 Isocyanide Ligand (C) 395
- Synthesis of Two Tl^{III} Diacetonyl Compounds and Crystal Structure of $[Tl\{CH_2C(O)Me\}_2(\mu\text{-}CF_3SO_3)(bpy)]_2$ (C) 1125
- The Proton Catalyzed Transformation of a Cobaltacyclopentadiene into a η^4-Cyclobutadiene Complex (C) 1046

Complexes with chalcogen ligands
- Low-Dimensional Compounds Incorporating Polychalcogenide Ligands. The Unusual Polymeric Structures of $[AuSe_5]_n^{n\ominus}$ and $[AuSe_{13}]_n^{3n\ominus}$ (C) 914
- Synthesis, Structure, and Gas-Phase Decomposition of $[Cd(EC_6H_2tBu_3)_2]_2$ (E = S, Se): First Examples of Low-Coordinate Volatile Cadmium Chalcogenolato Complexes (C) 638

Complexes with diene ligands
- *s-trans*-1,3-Dienes as Ligands for Cationic Group 8 Metal Centers (C) 1417

Complexes with hydrido ligands
- Synthesis and 2D-(^1H,^{103}Rh)-NMR Study of the First "Non-Classical" Polyhydrido Complex Stabilized by a Nitrogen Donor Ligand (C) 548

Complexes with nitrogen ligands
- Functional Tetrahedral Zinc Complexes (C) 898
- Heteronuclear Complexes Containing $CuCo(CO)_4$ Structural Units and Nitrogen Ligands (C) 783
- Ketenimine Complexes from Metal Isocyanides and Diazoalkanes (C) 275
- On a (1,4-Diazabutadiene)bis(ethene)-nickel(0) Complex and Related Compounds (C) 298
- $[PhLiNCH_2CH_2NLiPh]\cdot 3HMPA$, a Monomeric Dilithiumethylenediamide Complex with N_2Li_2 Double Bridging: Synthesis, Crystal Structure, and Model MO Calculations (C) 410
- Platinum in the Unusual Oxidation State +2.75: A Linear Tetranuclear Complex with the Model Nucleobase 1-Methylthymine (C) 84
- Synthesis and Structure of $Ph_2P(S)N=TiCl_2\cdot 3C_5H_5N$, the First Imidotitanium Complex (C) 669
- Synthesis, Structure, and Reactivity of Aryloxo(imido)titanium Complexes (C) 664
- The Tri-μ-amidobis[triamminecobalt-(III)] Cation: The First Triply Amido-bridged Complex (C) 1158
- Ytterbium(II) Benzamidinates, a New Class of Highly Reactive Lanthanoid(II) Complexes (C) 894

Complexes with oligocyclopentadienyl ligands
- On the Way to Ligating Oligocyclopentadienyls: Synthesis and Preliminary Reactions of the Two Isomeric Tercyclopentadienyls and Their Transition Metal Complexes (C) 549

Complexes with oxygen ligands
- Alkyltechnetium Oxides: First Examples and Reactions (C) 189
- Asymmetric Heterodinuclear $[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2ML]^{2\oplus}$ Complexes (M = Fe, Mn, V): Electronic Structure and Magnetic Properties (C) 645
- Coordination Chemistry of Polyoxomolybdates: The Structure of a Dodecanuclear Molybdate Cage Incorporating Hydrogen Squarate Ligands, $[(C_4H_9)_4N]_4[Mo_{12}O_{36}(C_4O_4H)_4]\cdot 10Et_2O$ (C) 70
- Formation of Tetranuclear Chelate(4-) Ions of Divalent Metals (Mn, Co, Ni) with Idealized *T* Symmetry by Spontaneous Self-assembly (C) 311
- μ-Hydroxobis(μ-formato)hexaaquadichromium(III), an Intermediate in the Formation of Basic Chromium Carboxylates (C) 811
- $[n\text{BuLi}\cdot \text{LiO}t\text{Bu}]_4$, Solid-State Structure of an *n*-Butyllithium–Lithium *tert*-Butoxide Complex (C) 308
- Organometallic Macrocycles: Synthesis and Molecular Structure of Trimeric Tartratodiruthenium Complexes (C) 429
- Structure–Magnetism Relationship in $[Ti^{III}\text{-}O\text{-}Ti^{III}]^{4\oplus}$ Complexes (C) 68
- Synthesis and Characterization of the Linear Trinuclear Complexes $[M^{II}_3(O_2CCH_3)_6(biphme)_2]$, M = Mn, Fe (C) 812
- Synthesis, Structure, and Catalase-Type Activity of a Novel Oxo-Bridged Tetranuclear Manganese Aggregate Exhibiting Short O···O Interactions (C) 1156
- The Coordination Chemistry and Organometallic Chemistry of Tridentate Oxygen Ligands with π-Donor Properties (R) 627
- The Re–Re Bond in Binuclear Di-μ-oxorhenium Complexes Containing the 1,4,7-Triazacyclononane Ligand (C) 787

Complexes with phosphorus ligands
- Assembly of the $CAu_6^{2\oplus}$ Cluster with a Tailor-made Diphosphane Spanning the Octahedral Edges (C) 1399
- Epoxidation of the P=C Double Bond of Phosphaalkene Complexes: X-Ray Crystal Structure Analysis of a Stable Oxaphosphirane Complex (C) 1166
- New Chiral C_3-Symmetric Tripodal Phosphanes (C) 1462
- Novel Diphosphinoiridium Catalysts for the Enantioselective Hydrogenation of *N*-Arylketimines (C) 558
- Synthesis of Phospholyltetrahydroboratouranium Complexes. Crystal Structure of $[(\eta^5\text{-}C_4Me_4P)_2U(BH_4)_2]$ (C) 1485
- The Azide Homologues Et–PPP and Ph–AsAsAs as Bifacially Coordinated Ligands in Tripod-Cobalt Complexes:

Synthesis, Structure and Molecular Dynamics (C) 929
- Water-Soluble Metal Complexes of the Sulfonated Triphenylphosphane TPPTS: Preparation of the Pure Compounds and their Use in Catalysis (C) 391
- $Zn^{II}Fe^{III}$ and $Fe^{II}Fe^{III}$ Complexes Containing a Novel (μ-Phenoxo)bis(μ-diphenylphosphato)dimetal(II,III) Core as Model Complexes for Active Sites of Purple Phosphatases (C) 531

Complexes with pnictogen ligands
- Complexes with Substituent-free Acyclic and Cyclic Phosphorus, Arsenic, Antimony, and Bismuth Ligands (R) 1104

Complexes with sulfur ligands
- Bis(1,4,7-trithiacyclononane)gold Dication: A Paramagnetic, Mononuclear Au^{II} Complex (C) 197
- $[Cu_4(ddtp)_2Br_4]$, a Unique Tetranuclear Copper(I) Complex with Bridging Thioethers and Bridging Bromides (C) 1419
- Oxygen Activation with Transition Metal Complexes: Nickel-Catalyzed Oxidation of a Pentacoordinated Substrate (C) 106
- Synthesis and Structure of $[Et_2OZn(SC_6H_2tBu_3)_2]$, the First T-Shaped Zinc Complex (C) 1403

Computer
- Computer Simulation of Molecular Dynamics: Methodology, Applications, and Perspectives in Chemistry (R) 992
- Organic Synthesis in the Age of Computers (R) 1286
- VCH TransDict, Übersetzersoftware, Version 2.2 (B) 937

Concanavalin A
- Concanavalin A Binds Pyranosides and Their Tetraacetates Stereoselectively (C) 672

Conformation
- On the Conformation and Structure of Organometal Complexes in the Solid State: Two Studies Relevant to Chemical Synthesis (R) 256
- Peptides as Conformational Switch: Medium-Induced Conformational Transitions of Designed Peptides (C) 185
- Restricted Rotation of an Unsubstituted η^5-Cyclopentadienyl Group in Solution Demonstrated by ^{13}C NMR Spectroscopy (C) 289

Conformational analysis
- Conformational Analysis of Medium-Sized Heterocycles (B) 815
- The Conformational Analysis of Cyclohexenes, Cyclohexadienes and Related Hydroaromatic Compounds (B) 698

Conformer separation
- Isolation of Conformational Isomers of α- and β-Ionones by Inclusion Complex Formation (C) 662

Coordination
- π/σ Equilibria in Metal Complexes of Organic Carbonyl Compounds; Synthesis and Structure of Chiral Rhenium Complexes $[(\eta^5\text{-}C_5H_5)\text{-}Re(NO)(PPh_3)(O=CHAr)]X$ (C) 1473
- A New Mode of Metal Encapsulation (C) 1404
- Complexes with Substituent-free Acyclic and Cyclic Phosphorus, Arsenic, Antimony, and Bismuth Ligands (R) 1104
- Cp*Ru(acac)--A Coordinatively Unsaturated, Stable 16-Valence-Electron Complex (C) 773
- Dicobalt Complexes with *syn*- and *anti*-Coordinated μ-Cycloheptatriene Bridges (C) 686
- Functional Tetrahedral Zinc Complexes (C) 898
- Ge^{II} and Sn^{II} Complexes of [2.2.2]Paracyclophane with Threefold Internal η^6 Coordination (C) 1397
- $[H_2Ru_6(CO)_{16}(\mu\text{-}C_6H_4O)]$: Binding of Five Metal Atoms to a Phenol Molecule (C) 198, (L) 938
- Lithium Bis(di-*tert*-butylfluorosilyl)-amide as Contact Ion Pair with Linear $Si\text{-}N^{\ominus}\text{-}Si$ Unit and as Ion Pair without $Li^{\oplus}$-Anion Contact (C) 209
- Novel Bonding Mode for a Cyanometalate Ligand: Synthesis and Crystal Structure of the Mn_4Pd_4 Cluster $[(OC)Pd(\mu\text{-}NC)Mn(\eta\text{-}C_5H_4Me)(CO)_2]_4$ Containing an Orthogonal Arrangement of Helical Units (C) 1140
- Ring-Opening of a Bicyclo[3.2.0]hepta-1,3-dienylcobalt(I) Complex Followed by Cycloaddition (C) 1057
- Synthesis and Direct NMR Spectroscopic Observation of $[(\eta^4\text{-Arene})Cr(CO)_3]$ Dianions (C) 1444
- Synthesis and Structure of $[Ba_3(OSiPh_3)_6(THF)] \cdot 0.5\ THF$, a Trinuclear Barium Siloxide Containing Low-Coordinate Barium Ions (C) 1483
- 2,3,4,5-Tetramethyl-1-sodiopyrrole: An Azacyclopentadienyl Ligand in a Novel Bridging Function (C) 1143
- Thermodynamic Aldehyde Enantioface Binding Selectivities in Complexes of Chiral Metal Fragments; Mechanism of Interconversion of Diastereomeric π-Aldehyde Complexes $[(\eta^5\text{-}C_5H_5)\text{-}Re(NO)(PPh_3)(\eta^2\text{-}O=CHAr)]BF_4$ (C) 1475
- Topologically Interesting Cages for Negative Ions with Extremely High "Coordination Number": An Unusual Property of V-O Clusters (C) 926

Cope rearrangements
- Stereocontrolled Construction of Complex Cyclic Ketones via Oxy-Cope Rearrangement (R) 609

Copper compounds
- Correlations between Magnetism and Structure in Dinuclear $Cu^{II}Fe^{III}$ Complexes with Integer Spin EPR Signals (C) 921
- $[Cu_4(ddtp)_2Br_4]$, a Unique Tetranuclear Copper(I) Complex with Bridging Thioethers and Bridging Bromides (C) 1419
- Heteronuclear Complexes Containing $CuCo(CO)_4$ Structural Units and Nitrogen Ligands (C) 783
- Highly Selective Synthesis of (*E*)-Alkene Isosteric Dipeptides With High Optical Purity via $RCu(CN)Li \cdot BF_3$ Mediated Reaction (C) 801
- New Copper Clusters Containing Se and PEt_3 as Ligands: $[Cu_{70}Se_{35}(PEt_3)_{22}]$ and $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (C) 1452
- Structure of a Synthetic Trefoil Knot Coordinated to Two Copper(I) Centers (C) 1154
- Synthesis and Structure of a Dimeric Lithium Diphenylcuprate: $[\{Li(OEt)_2\}\{CuPh_2\}]_2$ (C) 300
- Synthesis and Structure of Novel Cu-Clusters: $[Cu_{30-x}Se_{15}(PiPr_3)_{12}]$ ($x = 0,1$) and $[Cu_{36}Se_{18}(PtBu_3)_{12}]$ (C) 796

Correspondence (L) 938

C-Si activation
- Novel Platinum Complexes Enable Selective C-H and C-Si Activation of Tetramethylsilane at Room Temperature (C) 880

Cumulenes
- Acetylene-Cumulene Porphyrinoids (C) 1385
- (3,3-Diphenylallenylidene)trimethylphosphanetitanocene: The First Titanocene Carbene Complex with Three Cumulative Double Bonds (C) 1037
- Nickel-Catalyzed Cyclodimerization of Hexapentaenes: [4]Radialenes and [5]Radialenones with Cumulated Double Bonds (C) 1062
- Ruthenium-containing Cumulenes: Generation of 2,3,4-Pentatrienylidene- and 3-Oxo-1,4-pentadienyl-Complexes (C) 215

Cyanines
- Vinylogous Cyanine-like Dications of Tetrakis(dimethylamino) Compounds (C) 211

Cyanohydrins
- Enzyme-Catalyzed Synthesis of (*S*)-Cyanohydrins (C) 386

Cycloadditions

Enantioselectivity
- Enantioselective Catalysis with a New Zirconium Trichloride Lewis Acid Containing a "Dibornacyclopentadienyl" Ligand (C) 512
- Novel Diphosphinoiridium Catalysts for the Enantioselective Hydrogenation of *N*-Arylketimines (C) 558
- Optically Active Deltacyclanes and Deltacyclenes by Enantioselective Catalysis (C) 652
- Synthesis of Enantiomerically Pure Heterosteroids by Intramolecular Hetero-Diels-Alder Reaction (C) 527
- Thermodynamic Aldehyde Enantioface Binding Selectivities in Complexes of Chiral Metal Fragments; Mechanism of Interconversion of Diastereomeric π-Aldehyde Complexes $[(\eta^5\text{-}C_5H_5)\text{-}Re(NO)(PPh_3)(\eta^2\text{-}O = CHAr)]BF_4$ (C) 1475
Energy storage
- Active MgH_2–Mg Systems for Reversible Chemical Energy Storage (R) 223
Enols
- Asymmetric Protonation of Enolates (C) 1420
- New Chiral Auxiliaries for Enolate Alkylations (C) 555
- Stability and Cyclization of Enol Radical Cations: A Mechanistic Study of

One-Electron Oxidation of β,β-Dimesityl Enols (C) 541
Enones
- The Chemistry of Enones. Parts 1 and 2 (B) 1070
Enzyme catalysis
- Combined Chemoenzymatic Synthesis of *N*-Glycoprotein Building Blocks (C) 80
- Enzyme-Catalyzed Synthesis of (*S*)-Cyanohydrins (C) 386
- Enzymic Reaction Selectivity by Negative Catalysis or How Do Enzymes Deal with Highly Reactive Intermediates? (R) 355
- Isolation of an L-Stereospecific *N*-Acyl-L-proline-Acylase and its Use as Catalyst in Organic Synthesis (C) 417
Enzymes
- Bioorganic Chemistry. A Chemical Approach to Enzyme Action (B) 815
- Direct Electrical Communication between Graphite Electrodes and Surface Adsorbed Glucose Oxidase/Redox Polymer Complexes (C) 82
- Direct Electron Transfer between Carbon Electrodes, Immobilized Mediator and an Immobilized Viologen-accepting Pyridine Nucleotide Oxidoreductase (C) 1053
- Oxidative Degradation of Aromatic Pollutants by Chemical Models of Ligninase Based on Porphyrin Complexes (C) 1471
Epoxidation
- Epoxidation of the P = C Double Bond of Phosphaalkene Complexes: X-Ray Crystal Structure Analysis of a Stable Oxaphosphirane Complex (C) 1166
- Lithium-Ion-Catalyzed Epoxidation by Triplet Dioxygen: An ab initio Study (C) 648
Epoxides
- An Efficient Route to Linear Conjugated Triepoxides: *allo*-, *galacto*-, and *altro*-Type Trianhydrohexitols (C) 1038
- Enantio- and Regiocontrolled Synthesis of a Central Ionophoric Antibiotic Building Block by Sequential Opening of Two Epoxide Rings with Cuprate Reagents (C) 1476
ESR spectroscopy
- A Stable Triradical Compound and its Unusual Magnetic Properties (C) 415
- Ambident Behavior of the "New Vitamin" Methoxatin (Cofactor PQQ) towards Metals: Coordinative Stabilization of the Pyrrolide Form and the Semiquinone Form (C) 78
- Asymmetric Heterodinuclear $[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2ML]^{2\oplus}$ Complexes (M = Fe, Mn, V): Electronic Structure and Magnetic Properties (C) 645
- Bis(1,4,7-trithiacyclononane)gold Dication: A Paramagnetic, Mononuclear Au^{II} Complex (C) 197
- Correlations between Magnetism and Structure in Dinuclear $Cu^{II}Fe^{III}$ Complexes with Integer Spin EPR Signals (C) 921
- Structure–Magnetism Relationship in $[Ti^{III}\text{-}O\text{-}Ti^{III}]^{4\oplus}$ Complexes (C) 68
Ester cleavage
- Switching Reaction Mechanism by Monolayer Compression: An Ester Hydrolysis (C) 306
Esters
- Synergic Destabilization by Geminal Ester Groups (C) 674
Ethane
- $Fe^{\oplus}$-Catalyzed Gas-Phase Oxidation of Ethane by N_2O (C) 1431
Ethylene
- Transition-Metal-Induced Generation of C_2H_4 from 1,7-Octadiene: Regiospecific Activation of Internal C–C Bonds instead of Metathesis-like Coupling of Terminal CH_2 Groups (C) 402
Ethynol
- Reversible Photoisomerization of Ketene to Ethynol (C) 411
Ethynylethenes
- Novel Planar π-Systems (C) 393
Extracellular matrix
- Biologically Active Analogues of the Extracellular Matrix: Artificial Skin and Nerves (R) 20

Fenestins
- What Are the Structures of Fenestin A and Fenestin B? (C) 514
Flavonoids
- Carbon-13 NMR of Flavonoids (B) 1072
Fluorescence spectroscopy
- Electron Transfer between Covalently Linked Porphyrin and Quinone Units: Synthesis, Magnetic Resonance and Picosecond Fluorescence Spectroscopy (C) 670
- Fluorescence "Off–On" Signalling upon Linear Recognition and Binding of α,ω-Alkanediyldiammonium Ions by 9,10-Bis{(1-aza-4,7,10,13,16-pentaoxacyclooctadecyl)methyl}anthracene (C) 1173
Fluorine compounds
- Inverse Amine-Stabilized Sulfenes $F_2C = SO_2$ and $FHC = SO_2$ (C) 60
- Isomerization of Benzoylalkylidene Sulfur Tetrafluorides $C_6H_5\text{-}CO\text{-}CR = SF_4$ to Dihydrooxathietes (C) 1128
- Lithium Bis(di-*tert*-butylfluorosilyl)-amide as Contact Ion Pair with Linear $Si\text{–}N^{\ominus}\text{–}Si$ Unit and as Ion Pair without $Li^{\oplus}$-Anion Contact (C) 209
- Surprising Basicity of Low Valent Transition Metal Carbonyl Fluorides; Crystallographic Characterization of an $sp^2\text{-}CH\cdots F$ Hydrogen Bond (C) 888
- The Monofluorooxonium(0) Hexafluorometalate(VI)s $H_2OF^{\oplus}MF_6^{\ominus}$ (M = As,Sb) (C) 688
- *trans*-1,2-Difluoro-1,2-bis[(tetracarbonyl)cobaltio]ethene, a Difluoroethyne Complex with $\mu_2\text{-}\eta^1\text{-}\eta^1$-Coordination (C) 315
- Vanadium Tetrafluoride (C) 406
Force field calculations
- Computer Simulation of Molecular Dynamics: Methodology, Applications, and Perspectives in Chemistry (R) 992
- The Structure of Vicinal Pentaketones—X-Ray Structure Investigations and Calculations (C) 1048
Fractals
- Fractals and Related Hierarchical Models in Polymer Science (R) 113
Fragmentation
- Mesolytic Cleavage of C–C Bonds. Comparison with Homolytic and Heterolytic Processes in the Same Substrate (C) 283
Fulvalenes
- Electrical and Magnetic Properties and X-Ray Structure of a Highly Conductive 4:1 Complex of Tetracyanoquinodimethane and a Tetrathiafulvalene Derivative (C) 1450
Fulvenes
- Gas-Phase Thermolysis of 6-Cyclopropyl- and 6-Oxiranylpentafulvenes: Novel Routes to Dihydroindenes and Vinylcyclopentadienes (C) 803
- The Tautomeric Equilibrium between Cyclopentadienyl-1-carboxylic Acid and Fulvene-6,6-diol in Aqueous Solution (C) 790
Functional groups
- Patai's Guide to the Chemistry of Functional Groups (B) 821
Future of chemistry
- Chemistry for the Future—State of the Art and Perspectives (R) 1177
- Organic Synthesis—Where now? (R) 1320
- What Will Chemistry Do in the Next Twenty Years? (R) 1209

Gallium compounds
- Synthesis and Structure of a Diphosphadigalletane: A Novel Base-Stabilized Ga_2P_2 Ring System (C) 1150
Gas chromatography
- Gas Chromatographic Separation of Enantiomers on Cyclodextrin Derivatives (R) 939
- Permethyl-β-cyclodextrin, Chemically Bonded to Polysiloxane: a Chiral Stationary Phase with Wider Application Range for Enantiomer Separation by Capillary Gas Chromatography (C) 427
Gas-phase reactions
- Thermal Decomposition of the Nonmetal Octahedron $(ClB)_4P_2$ by Elimination of Its PP Octahedral Edge (C) 1044
Germanium compounds
- An Intramolecularly Lewis-Base-Stabilized Ge = N-Compound and a Related Ge-Fe Complex (C) 216
- Anions Isosteric with $CO_3^{2\ominus}$ in Cs_5SiP_3, Cs_5SiAs_3, Cs_5GeP_3, and Cs_5GeAs_3 (C) 87
- Ge^{II} and Sn^{II} Complexes of [2.2.2]Paracyclophane with Threefold Internal η^6 Coordination (C) 1397
Glycopeptides
- Facile Synthesis of a β(1-3)-Linked galgalactal Disaccharide and Its Use in *N*-Iodosuccinimide-Activated *O*-Glycopeptide Synthesis (C) 425
- Solid-Phase Synthesis of Glycopeptide Amides under Mild Conditions: Morphiceptin Analogues (C) 291
Glycoproteins
- Combined Chemoenzymatic Synthesis of *N*-Glycoprotein Building Blocks (C) 80
- Syntheses, Conformations and X-Ray Structure Analyses of the Saccharide Chains from the Core Regions of Glycoproteins (R) 823
- Synthesis of a β-Mannosyl-Chitobiosyl-Asparagine Conjugate—a Central Core Region Unit of the *N*-Glycoproteins (C) 1050
Glycosidase inhibitors
- Cyclization of *N*-Protected 1-Amino-4-pentene-2,3-diols to *lyxo*-Configurated Deoxyimino Sugars (*cis*-Dihydroxypyrrolidines); Synthesis of Potential Glycosidase Inhibitors (C) 1171
Glycosylation
- Semisynthetic Rhodomycins: Novel Glycosylation Methods for the Synthesis of Anthracycline Oligosaccharides (C) 809
Gold compounds
- Assembly of the $CAu_6^{2\oplus}$ Cluster with a Tailor-made Diphosphane Spanning the Octahedral Edges (C) 1399
- Bis(pentamethylcyclopentadienyl)silylene as Ligand in Gold(I) Chloride Complexes (C) 893
- Bis(1,4,7-trithiacyclononane)gold Dication: A Paramagnetic, Mononuclear Au^{II} Complex (C) 197
- Low-Dimensional Compounds Incorporating Polychalcogenide Ligands. The Unusual Polymeric Structures of $[AuSe_5]_n^{n\ominus}$ and $[AuSe_{13}]_n^{3n\ominus}$ (C) 914

Golfomycin A
- Golfomycin A, a Novel Designed Molecule with DNA-Cleaving Properties and Antitumor Activity (C) 1064
Grahamine
- Grahamine, an Unusual Tropane Alkaloid from *Schizanthus grahamii* (C) 385
Grob fragmentation
- X-Ray Structure Analysis of an Iminium Ion Generated by Grob Fragmentation (C) 188

Halogen compounds
- $CsF \cdot Br_2$, an Alkali-Metal Halide Intercalation Compound (C) 1448
- Ethynyl(phenyl)iodonium Triflate, $[HC \equiv CIPh][OSO_2CF_3]$: Preparation, Spectral Properties, Mechanism of Formation and X-Ray Molecular Structure (C) 287
- Facile Synthesis of 3-(ω-Haloalkyl)thiophenes as Key Building Blocks for Functionalized Thiophenes and Polythiophenes (C) 419
Heats of vaporization
- Heats of Vaporization of Fluids (B) 1490
Helicenes
- Helicene Dianions: Paratropicity of Twisted Phenanthrene Dianions (C) 919
Heteroallenes
- A Carbonyliron Complex of an Amino-9-fluorenylideneborane with Coordination at a Borabutadiene Unit (C) 199
- Preparation and Structure of $[Se = W(PSe_4)(PSe_2)]^{2\ominus}$; a Cluster Containing a Heteroallylic $PSe_2^{\ominus}$ Unit (C) 1486
Heteroarenes
- A First Step toward the Phosphorus Analogues of Polythiophenes (C) 655
- A Wagner–Meerwein Rearrangement as Intermediate Step in the Formation of Dihydroindolones from 2-Diazoacetoacetanilides (C) 86
- 5-Methyl-1,1,3,3-tetraphenyl-1λ^5,3λ^5-diphosphabenzene (C) 516
- Some Valenes of Benzannelated Five-Membered Heteroarenes – Synthesis and NMR Spectra (C) 675
- The Synthesis and Structure of Stibaindoles (C) 771
- Torand Synthesis by Trimerization—New Receptors for Guanidinium (C) 923
Heterocycles
- A Monocyclic Selenepine: Synthesis and Characterization of Diethyl 2,7-Di-*tert*-butyl-4,5-selenepinedicarboxylate (C) 424
- A 1-Silyl-1*H*-phosphirene/1,2-Dihydro-1,2-phosphasilete Rearrangement—The Decisive Step in the Synthesis of Heterocycles Containing 2-Phospha-1,3-diene Units (C) 1436
- Amino Acid Esters as Chiral Auxiliary Groups in Lewis Acid Catalyzed Reactions of Electron-rich Siloxydienes with Imines (C) 1468
- Application of Titanacycles to Heterocycle Synthesis: Phospha- and Arsacyclobutenes (C) 75
- Conformational Analysis of Medium-Sized Heterocycles (B) 815
- 4,7-Dimethyl-4,7-dihydro[1,2,5]thiadiazolo[3,4-*b*]pyrazine, a Novel Electron Donor with a 12π-Electron Ring System (C) 643
- Imidazo[1,2-*e*][1,3,5]triazepine Derivatives: First Representatives of a New Heterocyclic System (C) 933
- Novel S-Heteroquinoid Electron Acceptors. Synthesis of 2,5-Bis(cyanoimino)-2,5-dihydrothieno[3,2-*b*]thiophenes (DCNTTs) and Conductive Charge Transfer Complexes (C) 204
- Rings, Clusters and Polymers of Main Group and Transition Elements (B) 1490
- Synthesis and Structure of a 1λ^5,4λ^5-Diphosphapentalene (C) 799
- Synthesis of Nitrogen Heterocycles by Diastereoselective Intramolecular Aminocarbene Annelation (C) 176
- Unsaturated C_3B_2 Rings with Neighboring Boron Atoms: Derivatives of 4-Methylene-1,2-diboracyclopentane, Dilithium 2,3-diboratafulvene, and 1,2-Dibora-3-cyclopentene (C) 912
Heteropolyanions
- $[H_6As_{10}Mo_{24}O_{90}]^{8\ominus}$, a Heteropolyanion Comprising Two Linked Spherical Fragments, and Reduced Keggin Anions as Its Degradation Products (C) 88
Hexaalkynyltriphenylene
- Hexaalkynyltriphenylene: A New Type of Nematic-Discotic Hydrocarbon (C) 177
Hexapentaenes
- Nickel-Catalyzed Cyclodimerization of Hexapentaenes: [4]Radialenes and [5]Radialenones with Cumulated Double Bonds (C) 1062
Hexatrienes
- Macrocyclically Fixed Diarylhexatrienes (C) 1162
High pressure chemistry
- Peptide Synthesis under High Pressure (C) 1025
Hindered rotations
- Sterically Hindered Internal Rotation in an Acyclic α,β-Unsaturated Ketone 2,2,5-Trimethyl-4-isopropylhex-4-en-3-one (C) 1435
History of chemistry

Hiyama addition
- Doubly Stereodifferentiating Hiyama Addition with Mismatched Reactants; Enantio- and Diastereo-controlled Synthesis of Dihydrocanadensolide (C) 679
Homo-Diels-Alder reactions
- Mechanism of the Cycloaddition of Bicyclo[2.1.0]pent-2-ene: a Non-concerted Homo-Diels-Alder Reaction (C) 1061
Hormaomycin
- Elucidation of the Structure of Hormaomycin (C) 64
Host-guest chemistry
- A New Mode of Metal Encapsulation (C) 1404
- A Spacious Cyclophane Host for Inclusion Complexation of Steroids and [m.n]Paracyclophanes (C) 769
- A Synthetic Allosteric System with High Cooperativity between Polar and Hydrophobic Binding Sites (C) 1159
- Amine-Template-Directed Synthesis of Cyclic Porphyrin Oligomers (C) 1400
- Biomimetic Catalysis of an S_N2 Reaction Resulting from a Novel Form of Transition-State Stabilization (C) 915
- Catalytic Cyclophanes: A Porphyrin-Bridged Cyclophane as a Model for Cytochrome P-450 Enzymes (C) 191
- Host-Guest Complexes with Closed, Half-open, and Stretched Receptors: Hydrophobic Cavity Effects and Induced Pole-Dipole Interactions (C) 1161
- Molecular Recognition with Model Systems (R) 245
- Organometallic Host–Guest Systems Representing Novel Charge-Transfer "Ion Pairs" with Three-Dimensional Electron-Donor Networks (C) 1126
- Supramolekulare Chemie (B) 323
- Torand Synthesis by Trimerization—New Receptors for Guanidinium (C) 923
Houben-Weyl
- Houben-Weyl. Methoden der Organischen Chemie. Band E13, Teil 1 und 2: Organische Peroxo-Verbindungen (B) 327
Hydration
- Catalytic Hydration of Acrylonitrile to Acrylamide under Mild Conditions (C) 523
Hydride transfer
- Iron(II)-Mediated Hydride and Methanide Transfer to Carbonyl Groups (C) 910
Hydroaromatic compounds
- The Conformational Analysis of Cyclohexenes, Cyclohexadienes and Related Hydroaromatic Compounds (B) 698
Hydrogen bonds
- Characterization by Microwave Spectroscopy of a Transient Hydrogen-Bonded Complex of Oxirane and Hydrogen Chloride Isolated in a Pulsed Jet (C) 72
- Cooperative Interactions in Molecular Recognition—the Binding of Diamines to a Tetracarboxylic Acid (C) 1148
- Surprising Basicity of Low Valent Transition Metal Carbonyl Fluorides; Crystallographic Characterization of an sp^2-CH $\cdots$ F Hydrogen Bond (C) 888
Hydrogen storage
- Active MgH_2–Mg Systems for Reversible Chemical Energy Storage (R) 223
Hydrogen transfer
- Reactivity in Intramolecular Radical Reactions: A Comparison of Hydrogen Transfer with Alkene Addition (C) 653
Hydrogenation
- Catalytic Hydrosilylation or Hydrogenation at One Coordination Site of [Cp'Fe(CO)(X)] Fragments (C) 1131
- Facile Hydrogenation of the Central Cyclohexatriene of Tris(benzocyclobutadieno)benzene: Synthesis, Structure, and Thermal and Photochemical Isomerization of all-*cis*-Tris(benzocyclobuta)cyclohexane (C) 1151
- Novel Diphosphinoiridium Catalysts for the Enantioselective Hydrogenation of *N*-Arylketimines (C) 558
Hydrogenobyrinic acid
- Hydrogenobyrinic Acid: Isolation, Biosynthesis, and Function (C) 884
Hydrosilylation
- Catalytic Hydrosilylation or Hydrogenation at One Coordination Site of [Cp'Fe(CO)(X)] Fragments (C) 1131
Hyperconjugation
- Strong C–Sn Hyperconjugation in a Distannylmethyleneborane (C) 401
Hypnophilin
- Synthesis of Enantiomerically Pure (−)-Hypnophilin (C) 680
Hypofluorous acid
- The Monofluorooxonium(0) Hexafluorometalate(VI)s $H_2OF^{\oplus}MF_6^{\ominus}$ (M = As,Sb) (C) 688

Imidazoles
- 1-Amino- and 1,3-Diaminoimidazolium Salts (C) 556

Imidazotriazepines
- Imidazo[1,2-*e*][1,3,5]triazepine Derivatives: First Representatives of a New Heterocyclic System (C) 933

Iminium ions
- X-Ray Structure Analysis of an Iminium Ion Generated by Grob Fragmentation (C) 188

Inclusion complexation
- Isolation of Conformational Isomers of α- and β-Ionones by Inclusion Complex Formation (C) 662

Indenes
- Gas-Phase Thermolysis of 6-Cyclopropyl- and 6-Oxiranylpentafulvenes: Novel Routes to Dihydroindenes and Vinylcyclopentadienes (C) 803
- Synthesis and NMR Spectra of 2,3-Dihydro-1,3-methanoindene Derivatives and 1,2,3,5-Tetrahydro-1,3-methanopentalene (C) 1035

Indoles
- A Wagner–Meerwein Rearrangement as Intermediate Step in the Formation of Dihydroindolones from 2-Diazoacetoacetanilides (C) 86
- Carbonylation of Doubly Lithiated *N*-Pivaloylanilines. A Novel Approach to Dioxindoles via Intramolecular Trapping of Aromatic Acyllithiums (C) 282

Industrial chemistry
- Industrial Inorganic Chemistry (B) 110
- Mathematical Modeling of Chemical Reactors—Development and Implementation of Novel Technologies (R) 1235
- Molecular Thermodynamics for Chemical Process Design (R) 1246
- What Does the Chemical Industry Expect from Physical and Industrial Chemistry? (R) 1228

Inorganic chemistry
- Industrial Inorganic Chemistry (B) 110
- Inorganic Chemistry (B) 1069

Intercalation compounds
- $CsF \cdot Br_2$, an Alkali-Metal Halide Intercalation Compound (C) 1448

Interfaces
- The Quartz Microbalance: A Novel Approach to the In-Situ Investigation of Interfacial Phenomena at the Solid/Liquid Junction (R) 329

Interstellar chemistry
- The Chemistry of Interstellar Space (R) 595

Ion traps
- Electromagnetic Traps for Charged and Neutral Particles (Nobel Lecture) (R) 739
- Experiments with an Isolated Subatomic Particle at Rest (Nobel Lecture) (R) 734

Ionones
- Isolation of Conformational Isomers of α- and β-Ionones by Inclusion Complex Formation (C) 662

Ions
- Ion and Cluster Ion Spectroscopy and Structure (B) 437

IR spectroscopy
- Experimental and Theoretical IR Spectra of the 2-Norbornyl Cation (C) 183
- The Monofluorooxonium(0) Hexafluorometalate(VI)s $H_2OF^{\oplus}MF_6^{\ominus}$ (M = As,Sb) (C) 688

Iridium compounds
- Coupling of an Iridium Vinylidene Complex with Aluminum Alkyls; Carbon-Carbon Bond Formation via Migratory Insertion of a Vinylidene Unit (C) 73
- Novel Diphosphinoiridium Catalysts for the Enantioselective Hydrogenation of *N*-Arylketimines (C) 558
- Synthesis and Structure of Annelated Carbon Rings Containing a Bridgehead Transition Metal (C) 543

Iron compounds
- A Carbonyliron Complex of an Amino-9-fluorenylideneborane with Coordination at a Borabutadiene Unit (C) 199
- Catalytic Hydrosilylation or Hydrogenation at One Coordination Site of [Cp'Fe(CO)(X)] Fragments (C) 1131
- Correlations between Magnetism and Structure in Dinuclear $Cu^{II}Fe^{III}$ Complexes with Integer Spin EPR Signals (C) 921
- Iron(II)-Mediated Hydride and Methanide Transfer to Carbonyl Groups (C) 910
- Soluble, Oligomeric Bridged Phthalocyaninatoiron(II) Complexes (C) 1467
- Synthesis and Characterization of the Linear Trinuclear Complexes $[M^{II}_3(O_2CCH_3)_6(biphme)_2]$, M = Mn, Fe (C) 812
- Synthesis and Structure of the Novel μ_2-Carbido Complex [(TPP)Fe = C = $Re(CO)_4Re(CO)_5$] (C) 318
- $Zn^{II}Fe^{III}$ and $Fe^{II}Fe^{III}$ Complexes Containing a Novel (μ-Phenoxo)bis(μ-diphenylphosphato)dimetal(II,III) Core as Model Complexes for Active Sites of Purple Phosphatases (C) 531

Isocorroles
- Isocorroles: Novel Tetrapyrrolic Macrocycles (C) 1390

Isocyanates
- A Novel Palladium-Catalyzed Carbonylation of Aromatic *N*-Chlorosulfonamidates to Arylsulfonyl Isocyanates (C) 1147

Isosterism
- Anions Isosteric with CO_3^{2-} in Cs_5SiP_3, Cs_5SiAs_3, Cs_5GeP_3, and Cs_5GeAs_3 (C) 87
- Highly Selective Synthesis of (*E*)-Alkene Isosteric Dipeptides With High Optical Purity via $RCu(CN)Li \cdot BF_3$ Mediated Reaction (C) 801

Isotope effects
- Kinetic Isotope Effects as a Mechanistic Tool for the Elucidation of the Rate-Determining Step(s) in the Transition-Metal-Ion-Mediated Activation of CH/CC Bonds. Ethylene Loss from Metastable 4-Octyne/$M^{\oplus}$ Complexes in the Gas Phase (C) 509

Jasmonoids
- Building Blocks for the Synthesis of Enantiomerically Pure Jasmonoids: Synthesis of (+)-Methyl Epijasmonate (C) 1024

Kaolinites
- Clays Direct Aromatic Nitration (C) 535
- Solid-State NMR Studies of the Structure and Reactivity of Metakaolinite (C) 553

Keggin anions
- $[H_6As_{10}Mo_{24}O_{90}]^{8\ominus}$, a Heteropolyanion Comprising Two Linked Spherical Fragments, and Reduced Keggin Anions as Its Degradation Products (C) 88

Ketenes
- Reversible Photoisomerization of Ketene to Ethynol (C) 411

Ketenimines
- A Cyclodimeric Silaketenimine (C) 90

Keto/enol equilibrium
- Stability and Cyclization of Enol Radical Cations: A Mechanistic Study of One-Electron Oxidation of β,β-Dimesityl Enols (C) 541
- The Enol of Mandelic Acid, Detection, Acidity in Aqueous Solution, and Estimation of the Keto-Enol Equilibrium Constant and Carbon Acidity of Mandelic Acid (C) 792
- The Tautomeric Equilibrium between Cyclopentadienyl-1-carboxylic Acid and Fulvene-6,6-diol in Aqueous Solution (C) 790

Ketones
- Stereocontrolled Construction of Complex Cyclic Ketones via Oxy-Cope Rearrangement (R) 609
- α-Umpolung of Ketones via Enol Radical Cations: A Mechanistic Study (C) 1144

Kinetics
- Bimolecular Collisions (B) 936

Knot compounds
- Structure of a Synthetic Trefoil Knot Coordinated to Two Copper(I) Centers (C) 1154

Kolbe electrolysis
- Mixed Kolbe Electrolyses with Sugar Carboxylic Acids (C) 195

β-Lactams
- A Facile Synthesis of β-Selenolactams (C) 530

Lanthanoid compounds
- CH Activation of Acetonitrile by Alkyl Compounds of the Early Lanthanoids: Dimeric Cyanomethyl-Lanthanoid Complexes with CH_2CN Bridges (C) 420
- The Ammonium Salt Route to Oligomeric Lanthanum Salt Complexes: Synthesis and X-Ray Crystal Structure of $La(NCS)_3 \cdot 4HMPA$ (C) 285
- Ytterbium(II) Benzamidinates, a New Class of Highly Reactive Lanthanoid(II) Complexes (C) 894

Leukotrienes
- Leukotrienes and Lipoxygenases. Chemical, Biological and Clinical Aspects (B) 1073

Lipids
- Specific Interactions of Proteins with Functional Lipid Monolayers—Ways of Simulating Biomembrane Processes (R) 1269

Lipoxygenases
- Leukotrienes and Lipoxygenases. Chemical, Biological and Clinical Aspects (B) 1073

Liquid crystals
- Advanced Materials: Trends and Possibilities in Liquid Crystalline Polymers (R) 1256
- Hexaalkynyltriphenylene: A New Type of Nematic-Discotic Hydrocarbon (C) 177
- Induction and Variation of Chirality in Discotic Liquid Crystalline Polymers (C) 1478
- Multiple Bonds Between Metal Atoms in Ordered Assemblies: Liquid Crystals Containing Mo–Mo Quadruple Bonds (C) 1481

Macrocycles
- A New Type of Double Calix[4]arenes by Linkage via the Phenolic Hydroxy Groups (C) 280
- Fluorescence "Off–On" Signalling upon Linear Recognition and Binding of α,ω-Alkanediyldiammonium Ions by 9,10-Bis{(1-aza-4,7,10,13,16-pentaoxacyclooctadecyl)methyl}anthracene (C) 1173

- Interfaces between Molecular and Polymeric "Metals": Electrically Conductive, Structure-Enforced Assemblies of Metallomacrocycles (R) 857
- Isocorroles: Novel Tetrapyrrolic Macrocycles (C) 1390
- Macrocyclically Fixed Diarylhexatrienes (C) 1162
- Organometallic Macrocycles: Synthesis and Molecular Structure of Trimeric Tartratodiruthenium Complexes (C) 429
- Soluble, Oligomeric Bridged Phthalocyaninatoiron(II) Complexes (C) 1467
- The First Clamped and Strongly Deformed Adamantane (C) 902
- Torand Synthesis by Trimerization—New Receptors for Guanidinium (C) 923

Macromolecular chemistry
- Starburst Dendrimers: Molecular-Level Control of Size, Shape, Surface Chemistry, Topology, and Flexibility from Atoms to Macroscopic Matter (R) 138

Magnesium compounds
- A Surface Organometallic Approach for Controlling the Pore Opening Size of Zeolites: the Case of Mordenite Modified via Grafting of Dineopentylmagnesium (C) 805
- Active MgH_2–Mg Systems for Reversible Chemical Energy Storage (R) 223

Magnesium therapy
- Aspartic and Glutamic Acid as Ligands to Alkali and Alkaline-Earth Metals: Structural Chemistry as Related to Magnesium Therapy (R) 1090

Magnetic resonance
- Experiments with Separated Oscillatory Fields and Hydrogen Masers (Nobel Lecture) (R) 725

Magnetic superexchange
- Dependence of the Magnetic Superexchange on the Cr···Cr Distance in Dinuclear Chromium(II) Complexes (C) 1055

Magnetism
- A Stable Triradical Compound and its Unusual Magnetic Properties (C) 415

Maillard reaction
- Formation of an Aminoreductone from Glucose (C) 536
- New Aspects of the Maillard Reaction in Foods and in the Human Body (R) 565

Mandelic acid
- The Enol of Mandelic Acid, Detection, Acidity in Aqueous Solution, and Estimation of the Keto-Enol Equilibrium Constant and Carbon Acidity of Mandelic Acid (C) 792

Manganese compounds
- First Coupling of a Metal Atom with Four Ethene Molecules to give a Metallaspiroalkane (C) 322
- $Na_{10}\{Li_2[MnO_4]_4\}$, a Compound in Which LiO_4 and MnO_4 Tetrahedra Form Chains Consisting of Six- and Eight-Membered Rings (C) 800
- Novel Bonding Mode for a Cyanometalate Ligand: Synthesis and Crystal Structure of the Mn_4Pd_4 Cluster $[(OC)Pd(\mu\text{-}NC)Mn(\eta\text{-}C_5H_4Me)(CO)_2]_4$ Containing an Orthogonal Arrangement of Helical Units (C) 1140
- Synthesis and Characterization of the Linear Trinuclear Complexes $[M^{II}_3(O_2CCH_3)_6(biphme)_2]$, M = Mn, Fe (C) 812
- Synthesis, Structure, and Catalase-Type Activity of a Novel Oxo-Bridged Tetranuclear Manganese Aggregate Exhibiting Short O···O Interactions (C) 1156

Mannich bases
- A Novel Synthesis of 2-Aminomethyl-1,3-butadienes from *N,O*-Acetals (C) 932

Masers
- Experiments with Separated Oscillatory Fields and Hydrogen Masers (Nobel Lecture) (R) 725

Mass spectrometry
- $Fe^{\oplus}$-Catalyzed Gas-Phase Oxidation of Ethane by N_2O (C) 1431
- $FeO^{\oplus}$ Activates Methane (C) 1433
- Identification of Butatrienedione, Its Radical Anion, and Its Radical Cation in the Gas Phase (C) 908
- Ionic Isomer Distinction by Neutralization-Reionization Mass Spectrometry (NRMS): Carbonic Acid Radical Cations, $(HO)_2CO^{\bullet\oplus}$ versus $(H_2O/CO_2)^{\bullet\oplus}$ Clusters (C) 404
- Iron(II)-Mediated Hydride and Methanide Transfer to Carbonyl Groups (C) 910
- Kinetic Isotope Effects as a Mechanistic Tool for the Elucidation of the Rate-Determining Step(s) in the Transition-Metal-Ion-Mediated Activation of CH/CC Bonds. Ethylene Loss from Metastable 4-Octyne/$M^{\oplus}$ Complexes in the Gas Phase (C) 509

Surface chemistry
- Transition Metal Oxides: Surface Chemistry and Catalysis (B) 1074
Symmetry
- Symmetrien der Natur. Ein Handbuch der Natur- und Wissenschaftsphilosophie (B) 821
Synergic interactions
- Synergic Destabilization by Geminal Ester Groups (C) 674
Synthesis design
- Organic Synthesis in the Age of Computers (R) 1286
Synthetic methods
- Activation and Functionalization of Alkanes (B) 700
- Highly Reactive Intermediates from the Cocondensation Reactions of Iron, Cobalt and Nickel Vapor with Arenes (R) 126
- Methods for the Oxidation of Organic Compounds—Alcohols, Alcohol Derivatives, Alkyl Halides, Nitroalkanes, Alkyl Azides, Carbonyl Compounds, Hydroxyarenes and Aminoarenes (B) 563
- Modern Synthetic Methods. Vol. 5 (B) 819
- Stereocontrolled Construction of Complex Cyclic Ketones via Oxy-Cope Rearrangement (R) 609
- Synthesis of a β-Mannosyl-Chitobiosyl-Asparagine Conjugate—a Central Core Region Unit of the *N*-Glycoproteins (C) 1050
- The Directed Synthesis of Biaryl Compounds: Modern Concepts and Strategies (R) 977
Synthetic strategy
- Starburst Dendrimers: Molecular-Level Control of Size, Shape, Surface Chemistry, Topology, and Flexibility from Atoms to Macroscopic Matter (R) 138
- The Logic of Chemical Synthesis (B) 435

Tautomerism

- The Enol of Mandelic Acid, Detection, Acidity in Aqueous Solution, and Estimation of the Keto-Enol Equilibrium Constant and Carbon Acidity of Mandelic Acid (C) 792
- The Tautomeric Equilibrium between Cyclopentadienyl-1-carboxylic Acid and Fulvene-6,6-diol in Aqueous Solution (C) 790
Technetium compounds
- Alkyltechnetium Oxides: First Examples and Reactions (C) 189
Tellurium compounds
- Synthesis and Structure of the Stable Tellurium Nitride $(ClTeNSN)_3N$ (C) 61
- $Te_8^{2\oplus}$, a New Tellurium Polycation (C) 293
Terbium compounds
- Nonradioactive Assay of DNA Hybridization by DNA-Template-Mediated Formation of a Ternary Tb^{III} Complex in Pure Liquid Phase (C) 1167
Tercyclopentadienyls
- On the Way to Ligating Oligocyclopentadienyls: Synthesis and Preliminary Reactions of the Two Isomeric Tercyclopentadienyls and Their Transition Metal Complexes (C) 549
Terrein
- Synthesis of (+)-Terrein from L-Tartaric Acid (C) 67
Tetracarboxylic acids
- Cooperative Interactions in Molecular Recognition—the Binding of Diamines to a Tetracarboxylic Acid (C) 1148
Tetrachloroammonium hexafluoroarsenate
- Synthesis of Tetrachloroammonium Hexafluoroarsenate, $NCl_4^{\oplus}AsF_6^{\ominus}$ (C) 181
Tetraphenylallylsodium diethyl ether
- Tetraphenylallylsodium Diethyl Ether: A Contact Ion Pair with an Intramolecular $Na^{\oplus}$ Sandwich (C) 1042
Tetrasilylmethane
- Tetrasilylmethane, $C(SiH_3)_4$, the Si/C-Inverse of Tetramethylsilane, $Si(CH_3)_4$ (C) 201
Tetrazoles
- Zwitterions as Intermediates of the 1,3-

Dipolar Cycloaddition of Electrophilic Azides to 5-Alkylidenedihydrotetrazoles – the Other Non-Concerted Limiting Case (C) 695
Thallium compounds
– Synthesis of Two Tl^{III} Diacetonyl Compounds and Crystal Structure of $[Tl\{CH_2C(O)Me\}_2(\mu\text{-}CF_3SO_3)(bpy)]_2$ (C) 1125
Theoretical chemistry
– Experimental and Theoretical IR Spectra of the 2-Norbornyl Cation (C) 183
– Fractals and Related Hierarchical Models in Polymer Science (R) 113
Thermochemistry
– Thermochemical Data of Pure Substances. Parts I and II (B) 1491
Thiadiazolopyrazines
– 4,7-Dimethyl-4,7-dihydro[1,2,5]thiadiazolo[3,4-*b*]pyrazine, a Novel Electron Donor with a 12π-Electron Ring System (C) 643
Thienothiophenes
– Novel S-Heteroquinoid Electron Acceptors. Synthesis of 2,5-Bis(cyanoimino)-2,5-dihydrothieno[3,2-*b*]thiophenes (DCNTTs) and Conductive Charge Transfer Complexes (C) 204
Thin films
– Two-Dimensional Model Networks (R) 439
Thiophenes
– Facile Synthesis of 3-(ω-Haloalkyl)thiophenes as Key Building Blocks for Functionalized Thiophenes and Polythiophenes (C) 419
Tin compounds
– Chemistry of Tin (B) 1072
– Ge^{II} and Sn^{II} Complexes of [2.2.2]Paracyclophane with Threefold Internal η^6 Coordination (C) 1397
– Organotin Chemistry (B) 1072
– Organotin Compounds in Organic Synthesis (B) 1072
– Strong C–Sn Hyperconjugation in a Distannylmethyleneborane (C) 401
– Synthesis and Structure of $(NBu_4)[Sn\{Pt(\mu\text{-}Cl)(C_6F_5)_2\}_3]$, an Unusual Cluster with Three $Pt^{II}\rightarrow Sn^{II}$ Bonds (C) 1449
Titanium compounds
– Application of Titanacycles to Heterocycle Synthesis: Phospha- and Arsacyclobutenes (C) 75
– Base-Free Cationic 14-Electron Titanium and Zirconium Alkyls: In situ Generation, Solution Structures, and Olefin Polymerization Activity (C) 780
– (3,3-Diphenylallenylidene)trimethylphosphanetitanocene: The First Titanocene Carbene Complex with Three Cumulative Double Bonds (C) 1037
– Structure–Magnetism Relationship in $[Ti^{III}\text{-}O\text{-}Ti^{III}]^{4\oplus}$ Complexes (C) 68
– Synthesis and Structure of $Ph_2P(S)N = TiCl_2 \cdot 3C_5H_5N$, the First Imidotitanium Complex (C) 669
– Synthesis, Structure, and Reactivity of Aryloxo(imido)titanium Complexes (C) 664
Torands
– Torand Synthesis by Trimerization—New Receptors for Guanidinium (C) 923
Translation
– VCH TransDict, Übersetzersoftware, Version 2.2 (B) 937
Transmission electron microscopy
– Synthesis and Transmission Electron Microscopic Investigation of Bi(Pb)–Sr–Ca–Cu–O Superconductors (C) 1459
Transuranics
– Five Decades Ago: From the "Transuranics" to Nuclear Fission (R) 481
Triepoxides
– An Efficient Route to Linear Conjugated Triepoxides: *allo*-, *galacto*-, and *altro*-Type Trianhydrohexitols (C) 1038
Trimethylisopropylhexenone
– Sterically Hindered Internal Rotation in an Acyclic α,β-Unsaturated Ketone 2,2,5-Trimethyl-4-isopropylhex-4-en-3-one (C) 1435
Triquinanes
– Synthesis of Enantiomerically Pure (−)-Hypnophilin (C) 680
Tris(benzocyclobutadieno)benzene
– Facile Hydrogenation of the Central Cyclohexatriene of Tris(benzocyclobutadieno)benzene: Synthesis, Structure, and Thermal and Photochemical Isomerization of all-*cis*-Tris(benzocyclobuta)cyclohexane (C) 1151
Tropanes
– Grahamine, an Unusual Tropane Alkaloid from *Schizanthus grahamii* (C) 385
Tungsten compounds
– Alkyne Cleavage as a Novel Route to Low-Valent Carbyne-Metal Complexes (C) 207 (–)
– How Do Two C–C Double Bonds Add to One M–M Triple Bond? Structure and Bonding in Bis(η^2-ethylene)hexakis(neopentoxy)ditungsten (C) 1026
– Preparation and Structure of $[Se = W(PSe_4)(PSe_2)]^{2\ominus}$; a Cluster Containing a Heteroallylic $PSe_2^{\ominus}$ Unit (C) 1486
– Surprising Basicity of Low Valent Transition Metal Carbonyl Fluorides; Crystallographic Characterization of an sp^2-CH···F Hydrogen Bond (C) 888

Umpolung
– α-Umpolung of Ketones via Enol Radical Cations: A Mechanistic Study (C) 1144
Uranium compounds
– Synthesis of Phospholyltetrahydroboratouranium Complexes. Crystal Structure of $[(\eta^5\text{-}C_4Me_4P)_2U(BH_4)_2]$ (C) 1485
Urdamycins
– A Novel Type of Ring Contraction as Non-Enzymatic Step in the Later Stages of the Biosynthesis of Urdamycin H (C) 1051

Valenes
– Some Valenes of Benzannelated Five-Membered Heteroarenes – Synthesis and NMR Spectra (C) 675
Vanadium compounds
– Topologically Interesting Cages for Negative Ions with Extremely High "Coordination Number": An Unusual Property of V-O Clusters (C) 926
– Vanadium Tetrafluoride (C) 406
– Vanadium(-I) Dinitrogen Complexes with N_2 Coordinated End-on: Functional Models for the "Alternative Nitrogenase" (C) 1438
Viologenes
– Direct Electron Transfer between Carbon Electrodes, Immobilized Mediator and an Immobilized Viologen-accepting Pyridine Nucleotide Oxidoreductase (C) 1053
– Organometallic Host–Guest Systems Representing Novel Charge-Transfer "Ion Pairs" with Three-Dimensional Electron-Donor Networks (C) 1126
Vision
– The Chemistry of Vitamin A and Vision (R) 461
Vitamin A
– The Chemistry of Vitamin A and Vision (R) 461
Vitamins (B) 112

Wagner–Meerwein rearrangements
– A Wagner–Meerwein Rearrangement as Intermediate Step in the Formation of Dihydroindolones from 2-Diazoacetoacetanilides (C) 86
Wittig reactions
– New Benzyl(β-oxido)phosphorus and -arsenic Ylides: Reactivity and Stereoselectivity in the Wittig Reaction (C) 1454

Ylides
– New Benzyl(β-oxido)phosphorus and -arsenic Ylides: Reactivity and Stereoselectivity in the Wittig Reaction (C) 1454

Zeolites
– A Surface Organometallic Approach for Controlling the Pore Opening Size of Zeolites: the Case of Mordenite Modified via Grafting of Dineopentylmagnesium (C) 805
Zinc compounds
– Functional Tetrahedral Zinc Complexes (C) 898
– Synthesis and Structure of $[Et_2OZn(SC_6H_2tBu_3)_2]$, the First T-Shaped Zinc Complex (C) 1403
– $Zn^{II}Fe^{III}$ and $Fe^{II}Fe^{III}$ Complexes Containing a Novel (μ-Phenoxo)bis(μ-diphenylphosphato)dimetal(II,III) Core as Model Complexes for Active Sites of Purple Phosphatases (C) 531
Zintl anions
– $[BP_2]^{3\ominus}$ and $[BAs_2]^{3\ominus}$, Zintl Anions with Propadiene Structure (C) 65
Zirconium compounds
– Base-Free Cationic 14-Electron Titanium and Zirconium Alkyls: In situ Generation, Solution Structures, and Olefin Polymerization Activity (C) 780
– Enantioselective Catalysis with a New Zirconium Trichloride Lewis Acid Containing a "Dibornacyclopentadienyl" Ligand (C) 512
– Isotope Effects Associated with α-Olefin Insertion in Zirconocene-Based Polymerisation Catalysts: Evidence for an α-Agostic Transition State (C) 1413
– Stereo- and Regioselectivity of Chiral, Alkyl-substituted *ansa*-Zirconocene Catalysts in Methylalumoxane-activated Propene Polymerization (C) 279
Zwitterions
– Zwitterions as Intermediates of the 1,3-Dipolar Cycloaddition of Electrophilic Azides to 5-Alkylidenedihydrotetrazoles – the Other Non-Concerted Limiting Case (C) 695
