3.5.3.2. Algorithms for Constraint Dynamics in Cartesian Coordinates

Molecular constraints have the form (68) for the case of

$$\sigma_k(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N) = 0 \qquad k = 1, \ldots N_c \tag{68}$$

N_c constraints in a molecule consisting of N atoms. Bond-length and bond-angle constraints can be put in the form of distance constraints between atoms k_1 and k_2, as in (69) where the constraint distance is given by $d_{k_1k_2}$.

$$\boldsymbol{r}_{k_1k_2}^2 - d_{k_1k_2}^2 = 0 \tag{69}$$

When applying constraints in MD or SD, the $3N$ equations of motion (39) or (41) have to be integrated while satisfying the N_c constraints. This can be accomplished by applying Lagrange's method of undetermined multipliers.[122] A zero term (68) is added to the potential energy function V in Equation (40), which yields (70) as the equation of motion.

$$m_i d^2\boldsymbol{r}_i(t)/\mathrm{d}t^2 = -\frac{\partial}{\partial \boldsymbol{r}_i}\left\{V(\{\boldsymbol{r}_i(t)\}) + \sum_{k=1}^{N_c} \lambda_k(t)\,\sigma_k(\{\boldsymbol{r}_i(t)\})\right\} \tag{70}$$

The time-dependent multipliers $\lambda_k(t)$ are determined such that the constraints σ_k are satisfied. The physical interpretation of Equation (70) becomes clear by rewriting it in terms of forces [Eq. (71)]:

$$m_i d^2\boldsymbol{r}_i(t)/\mathrm{d}t^2 = \boldsymbol{F}_i(t) + \boldsymbol{G}_i(t) \tag{71}$$

The total unconstrained force $\boldsymbol{F}_i(t)$ derived from the potential energy function is the first term in Equation (70), while the constraint force $\boldsymbol{G}_i(t)$, which compensates the components of $\boldsymbol{F}_i(t)$ that act along the directions of the constraints, is the second term.

The leap-frog scheme [(56)–(57)] for integration of Equation (71) becomes Equations (72) and (73).

$$\boldsymbol{v}_i(t_n + \Delta t/2) = \boldsymbol{v}_i(t_n - \Delta t/2) + m_i^{-1}\{\boldsymbol{F}_i(t_n) + \boldsymbol{G}_i(t_n)\}\,\Delta t \tag{72}$$

$$\boldsymbol{r}_i(t_n + \Delta t) = \boldsymbol{r}_i(t_n) + \boldsymbol{v}_i(t_n + \Delta t/2)\,\Delta t \tag{73}$$

Separating contributions from $\boldsymbol{F}_i(t_n)$ and $\boldsymbol{G}_i(t_n)$ we find

$$\boldsymbol{r}_i(t_n + \Delta t) = \boldsymbol{r}_i' + \delta\boldsymbol{r}_i \tag{74}$$

with

$$\delta\boldsymbol{r}_i = m_i^{-1}\,\boldsymbol{G}_i(t_n)(\Delta t)^2 \tag{75}$$

where $\boldsymbol{r}_i'$ are the positions after a MD or SD step disregarding all constraints, and $\delta\boldsymbol{r}_i$ are the positional corrections to be made as a result of the constraints. Using the definition of $\boldsymbol{G}_i$ we find

$$\delta\boldsymbol{r}_i = -\,m_i^{-1}(\Delta t)^2 \sum_{k=1}^{N_c} \lambda_k(t_n)\,\frac{\partial}{\partial \boldsymbol{r}_i}\,\sigma_k(\{\boldsymbol{r}_i(t_n)\}) \tag{76}$$

or when using the explicit form (69) for σ_k:

$$\delta\boldsymbol{r}_i = -\,2m_i^{-1}(\Delta t)^2 \sum_{\substack{k=1 \\ (k_1,k_2)=(i,j)}}^{N_c} \lambda_k(t_n)\,\boldsymbol{r}_{ij}(t_n) \tag{77}$$

where the summation extends only over constraints involving atom i. This implies that corrections due to the distance constraint between atoms i and j must be applied in the directions of the vector $\boldsymbol{r}_{ij}$. Corrections to $\boldsymbol{r}_i'$ and $\boldsymbol{r}_j'$ are in opposite directions and weighted by the inverse mass of atoms i and j, as is illustrated in Figure 12. Since the positions $\boldsymbol{r}_i(t_n + \Delta t)$ must satisfy the constraints (68, 69) using (74) we have for each constraint:

$$[\boldsymbol{r}_{k_1}' + \delta\boldsymbol{r}_{k_1} - \boldsymbol{r}_{k_2}' - \delta\boldsymbol{r}_{k_2}]^2 = d_{k_1k_2}^2 \tag{78}$$

These form a set of N_c quadratic equations from which the N_c Lagrangian multipliers λ_k can be determined. After linearization of Equation (78) by neglecting the terms quadratic

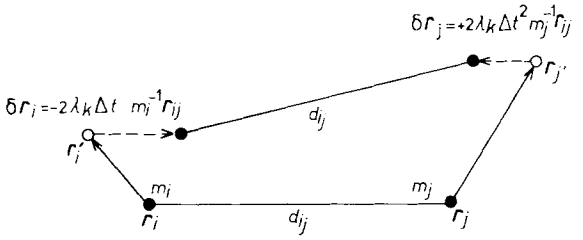

Fig. 12. Application of distance constraints. Atomic coordinate resetting using Lagrangian multipliers λ_k.

in λ_k, a set of linear equations is obtained. The above mentioned matrix methods solve these by a matrix inversion.[138] The iterative methods solve them by treating all constraints in succession, and iterating this procedure until all constraints are satisfied within a specific geometric tolerance.

The so-called SHAKE method, which is much used, is of the iterative type.[138] Its application in various algorithms is denoted by Equation (79). This means that the positions

$$\text{SHAKE}\ (\boldsymbol{r}_i(t_n),\ \boldsymbol{r}_i'(t_n + \Delta t),\ \boldsymbol{r}_i(t_n + \Delta t)) \tag{79}$$

$\boldsymbol{r}_i'(t_n + \Delta t)$ resulting from a non-constraint time step will be reset to give the constrained positions $\boldsymbol{r}_i(t_n + \Delta t)$. When necessary the constraint forces can be determined from Equation (80) and the constrained velocities from Equation (81).

$$\boldsymbol{G}_i(t_n) = m_i[\boldsymbol{r}_i(t_n + \Delta t) - \boldsymbol{r}_i'(t_n + \Delta t)]/(\Delta t)^2 \tag{80}$$

$$\boldsymbol{v}_i(t_n + \Delta t/2) = [\boldsymbol{r}_i(t_n + \Delta t) - \boldsymbol{r}_i(t_n)]/\Delta t \tag{81}$$

3.5.3.3. *Effect of the Application of Constraints*

The effect of constraining bond lengths and bond angles in molecular systems has been evaluated.[126, 139] It turns out that the application of bond-length constraints saves about a factor of 2 in computing effort when bonds to hydrogen atoms are constrained and about a factor of 3 when all covalent bonds are constrained. No evidence was found for a distortion of the physical properties by the rigidity of the bonds.[139] When the bond angles undergo limited variation, which is generally true for molecular systems, metric tensor corrections play an insignificant role when bond-length constraints are applied.[132]

The use of bond-angle constraints is not allowed, since it considerably affects the molecular motion. Macromolecular flexibility and entropy are halved, and the number of torsional angle transitions is dramatically reduced.[139] Moreover, it has been shown that in case of application of bond angle constraints metric tensor corrections, which are nearly impossible to calculate for all but the smallest flexible molecules, are of significant size and may not be ignored.[132] This means that MD or SD of molecular systems should not be performed in torsional space while treating bond lengths and angles as fixed quantities.

3.5.3.4. *Disadvantages of the Application of Constraints*

The advantage of the application of bond-length constraints is clear: at the expense of about 10% extra computing time, longer, time steps Δt can be taken. When simulating macromolecular systems without constraints, a value of $\Delta t = 0.5$ fs is appropriate, whereas with bonds to hydrogen atoms constrained $\Delta t = 1.0$ fs, and with all bonds constrained $\Delta t = 2.0$ fs is appropriate. So, a factor of 2 to 4 in computing effort is saved.

Yet, the application of constraints also has its disadvantages.

1. *Convergence problems for large planar groups.* In practice, procedures like the SHAKE method sometimes fail to converge to a molecular configuration satisfying all constraints. This is often due to the fact that the constraint forces act along the bond directions in the previous MD step (Fig. 12). For a planar group of atoms the constraint forces will act along vectors in the plane. So, when the other forces, e.g. due to charge repulsion, act orthogonally to the plane, it is nearly impossible for the constraint forces to counteract these, since they act orthogonally to each other. A solution to this problem has been proposed in Ref. [140], where virtual atoms lying outside the plane of the planar group are used to obtain constraint forces with sizeable components orthogonal to the plane of the group of real atoms. The implementation of this virtual atom technique would require definition of virtual atoms for each possible type of planar group. This makes this technique not very attractive for application in macromolecules.

2. *Free energy of creation or annihilation of atoms.* When free energy differences are computed using the coupling parameter approach, the application of constraints is a complicating factor. The Hamiltonian, or the potential energy function, is made a function of a coupling parameter λ, which is smoothly changed in the course of a simulation in order to obtain the work done by the system over a reversible change of λ. The problem now is that a constrained bond length cannot be removed from the system as a smooth function of λ. When computing the free energy of breaking a bond one faces the fact that the removal of a constraint is a discontinuous process. Even when only the length of a bond is changed (not removed) as a function of λ, computation of the free energy change due to the work done by the constraint forces is not simple, as is shown in Ref. [141].

3. *Computational bottleneck for parallelization of algorithms.* The constraint forces are generally computed after the other forces have been calculated and an unconstrained integration time step is performed. This makes the application of constraints a computational bottleneck: all other computations have to wait for its termination. Moreover, the most efficient methods for application of constraints, such as the SHAKE method, are of an iterative nature which makes them unsuitable for parallelization on a computer.

4. *Physical model of frozen bonds.* Although no significant effects due to freezing of bonds have been observed for molecular systems in equilibrium, it remains to be seen whether in non-equilibrium situations the finite flexibility of bonds may play a role in the dynamics, e.g. as an energy reservoir.

3.5.4. *Multiple Time Step Algorithms*

An alternative to the application of bond length constraints is the use of a multiple time step (MTS) integration

algorithm.[6, 142] The length of the integration time step is limited by the oscillation or relaxation time of the forces [see Eq. (67)]. In a molecular system three frequency ranges can be distinguished, as shown in Table 5: high-frequency bond-stretching forces $\boldsymbol{F}^{hf}$, low-frequency long-range Coulomb forces $\boldsymbol{F}^{lf}$, and the remaining intermediate frequency forces $\boldsymbol{F}^{if}$. The contribution of the different forces to the atomic trajectories may be integrated using different time steps. An example is the twin range method discussed in Section 3.1.3.4, in which the long-range Coulomb force is kept constant during k time steps Δt, where k lies in the range 5–100.

Table 5. Various relaxation times in macromolecular systems, and force components to be used in multiple time step algorithms.

Type of force	Approximate oscillation or relaxation time (fs)	Force: Application at step $n' = 0,1,2,\ldots$	Force: Update at step	Force: Size of force to be applied
1. high frequency: $\boldsymbol{F}^{hf}$ covalent bond stretching	10	$t_n + n'\Delta t'$	$t_n + n'\Delta t'$	$\boldsymbol{F}_i^{hf}$
2. intermediate frequency: $\boldsymbol{F}^{if}$ bond-angle bending, dihedral angle torsion, van der Waals, shortrange Coulomb	40	$t_n + n'm\Delta t'$	$t_n + n'm\Delta t'$	$m\boldsymbol{F}_i^{lf}$
3. low frequency: $\boldsymbol{F}^{lf}$ long-range Coulomb	1000	$t_n + n'm\Delta t'$	$t_n + n'mk\Delta t'$	$m\boldsymbol{F}_i^{lf}$

A multiple time step scheme could also be applied to the bond-stretching forces.[143] The conventional MD or SD time step Δt is subdivided into m (m = odd) smaller substeps $\Delta t'$, so $\Delta t = m\Delta t'$. The covalent bond forces $\boldsymbol{F}^{hf}$ are evaluated at each time step $t_n + n'\Delta t'$, with $n' = 0,1,2,\ldots$ When n' is a multiple of m, the other forces $\boldsymbol{F}^{if} + \boldsymbol{F}^{lf}$ are applied, but multiplied by a factor m in order to compensate for their omission at the substeps. Application of this MTS algorithm to macromolecules shows that for $m = 3$ or 5 the integration is as accurately performed as when bond-length constraints are used. Since the bond frequencies are about four times the other ones, a value of $m = 4$ would be expected to be large enough to ensure proper integration of the bond forces.

We note that the physical quantities one is interested in should only be evaluated at the conventional time steps Δt, not at the substeps $\Delta t'$. Since the bond stretching forces can be rapidly computed, application of this MTS algorithm is as efficient as the use of the SHAKE method, but it avoids the disadvantages of the latter method which were discussed in the previous section.

3.5.5. *Searching Neighbors*

The bulk (approximately 90%) of the computer time required by a MD or SD simulation is used for calculating the nonbonded interactions, that is, for finding the nearest neighbor atoms and subsequently evaluating the van der Waals and Coulomb interaction terms for the atom pairs obtained. Various schemes for performing this task as efficiently as possible have been proposed.[6, 144]

1. *Neighbor list techniques.* Once the neighbors have been found, either by scanning of all possible atom pairs (operation proportional to N^2), or by using grid-search techniques (proportional to N), the pairs are stored in a neighbor list which is only updated every so many steps, typically every 5 to 100 steps. At each time step the neighbor list is used to calculate the interactions (operation proportional to N).
2. *Grid search techniques.* The computational box is filled with a grid or mesh, and for each grid cell it is determined which atoms lie in it. This operation is proportional to N. The nearest neighbors of an atom can easily be found in the grid cells surrounding the grid cell containing the atom.

An evaluation of the different schemes can be found in Ref. [144]. For small systems ($N \lesssim 1000$) the use of neighbor list techniques will reduce finding the neighbors to a small part of the calculation. For large systems ($N \gtrsim 1000$) the application of grid search techniques will become advantageous.

3.6. Initial Conditions, Equilibration, and Analysis of Simulations

A simulation starts with initial atomic positions and velocities. The results should be independent of these. The initial configuration for a molecular system can be obtained from different sources: X-ray structure, model building, distance geometry calculation, random search techniques, etc. The initial velocities are either taken from a Maxwellian distribution or chosen to be zero, in which case strain in the molecule that is converted into kinetic energy may generate non-zero velocities.

The equilibration period that is required will depend on the relaxation time of the property one is interested in. Some properties, such as the kinetic energy, require short (picoseconds) equilibration times, whereas others, such as dielectric properties, may require longer times of the order of tens of picoseconds. During a simulation a number of quantities, such as the potential and kinetic energy, or the diffusion from the initial structure, are generally monitored to obtain a picture of the stability of the simulation.

The results are generally analyzed by taking time averages or averages over simulations with different initial conditions of the quantities of interest. Fluctuations and correlation functions may be calculated to analyze the mobility and dynamic behavior of the system.[6]

4. Application of Simulations

4.1. Understanding in Terms of Atomic Properties

The obvious utility of computer simulation is the possibility of analyzing molecular processes at the atomic level. Many examples can be found in the literature.[1–9] Here, we briefly mention two recent examples, the atomic interpretation of biochemical data on repressor-DNA operator binding,[26] and the atomic interpretation of biophysical measurements on membrane properties.[37]

4.1.1. Interpretation of Biochemical Data on Repressor-Operator Binding by MD Computer Simulation

In Ref. [26] a 125-ps MD simulation of a Lac repressor headpiece (51 amino acid residues) complexed with its DNA operator (14 base pairs) in aqueous solution was reported. The starting structure for the simulation was obtained from model building and energy minimization based on 169 proton–proton distances for the headpiece and 24 headpiece–DNA proton–proton distances which were available from 2D-NMR measurements.[145] When analyzing the repressor-operator contacts, no evidence was found that a so-called "direct readout" mechanism[146] for recognition is based on direct repressor side-chain–base hydrogen bonds, which is the common view on recognition. The simulation suggested that direct readout occurs rather through non-polar contacts and water-mediated hydrogen bonds. The repressor-operator contacts as observed in the simulation are compatible with the available biochemical data on base-pair or amino acid residue substitution,[147, 148] but do not support the usual interpretation in terms of side-chain–base hydrogen bonds. This illustrates the usefulness of computer simulation studies to obtain an interpretation of biochemical data at the atomic level.

4.1.2. Interpretation of Biophysical Data on Membrane Properties by MD Computer Simulation

In Ref. [37] a 180-ps MD simulation of a bilayered system of 52 sodium ions, 52 decanoate, 76 decanol and 526 water molecules was reported. A detailed analysis of the lipid–water interface was made. The charged (decanoate) head groups lie well within the water layer, but the alcoholic groups are situated more on the lipid side of the interface, which appears to be very diffuse and extends over almost 10 Å. Unexpectedly, the overlap of sodium ion and carboxylic acid distributions suggests a charge compensation rather than an electric double layer as pictured in most textbooks. Water molecule orientation is such that the remaining ion charge distribution is compensated.

Lateral diffusion constants of the lipid molecules as measured in the simulation ($3 \times 10^{-6}\ cm^2\ s^{-1}$) compare well with experiment ($2 \times 10^{-6}\ cm^2\ s^{-1}$) as measured using nitroxide spin labels.[149] Analysis shows that the hydrodynamic interaction of the head groups with the aqueous layer determines the diffusion constant of the lipid molecules, rather than interactions within the lipid layer. This illustrates the usefulness of computer simulation studies to obtain an interpretation of biophysical data at the atomic level.

4.2. Determination of Spatial Molecular Structure on the Basis of 2D-NMR, X-Ray or Neutron Diffraction Data

During the last few years computer simulation has become a standard tool in the determination of spatial molecular structure on the basis of X-ray or neutron diffraction or 2D-NMR data.[150] The goal of structure determination based on experimental NMR or diffraction data is to find a molecular structure that

1. satisfies the experimental data, such as a set of atom–atom distance constraints $\{r_{ij}^0\}$ or torsional angle constraints $\{\varphi_{ij}^0\}$ in the case of NMR, or a set of observed structure factor amplitudes $F_{obs}(hkl)$ and, if available, phases $\alpha(hkl)$ in the case of diffraction data, *and*
2. has a low energy in terms of a molecular potential energy function $V_{phys}(\{r_i\})$ [Eq. (1)].

In order to optimize a structure simultaneously with respect to both criteria, the experimental information is cast into the form of a penalty function or restraining potential V_{restr}, the value of which increases the more an actual structure violates the experimental data. The most simple choice of a function taking into account maximum values for the interatomic distances $\{r_{ij}^{ub}\}$ would be Equation (82), where the force constant is denoted by K_{dr}.

$$V_{restr} = V_{dr} \equiv \tfrac{1}{2} K_{dr} \sum_{\text{all constraints } (ij)} [\max(0, r_{ij} - r_{ij}^{ub})]^2 \qquad (82)$$

The corresponding function which restrains the calculated structure factor amplitudes $F_{calc}(hkl)$ to the observed ones is defined in (83).

$$V_{restr} = V_{sf} \equiv \tfrac{1}{2} K_{sf} \sum_{hkl} [F_{calc}(hkl) - F_{obs}(hkl)]^2 \qquad (83)$$

The optimization problem is to find a molecular structure for which the energy function (84) attains the global

$$V_{opt} = V_{phys}(\{r_i\}) + V_{restr}(\{r_i\}) \qquad (84)$$

minimum. As discussed in Section 3.2, MD simulation is a very powerful method to search configuration space for low energy configurations, due to its ability to surmount energy barriers of the order of $k_B T$ per degree of freedom. Therefore, the application of MD computer simulation in spatial structure refinement of 2D-NMR or X-ray diffraction data has become widespread in recent years.

4.2.1. Refinement of Structures Based on NMR Data

After introduction of the method of MD refinement[151] it has been applied to a variety of molecules using different refinement protocols.[150–154] The penalty function V_{restr} may be chosen in different ways.[154] The relative weight of the restraining term in Equation (84), that is the value of K_{dr}, may be chosen so large as to reduce the distance violations, at the expense of increasing the intramolecular energy V_{phys}. Too large a K_{dr} value will generally lead to a strained (unphysical) molecular structure.[28] The searching of configuration space may be performed at high temperature in order to more easily cross energy barriers.

The standard procedure is to start with a number of distance geometry (DG) type calculations to generate a collection of starting structures, which are subsequently refined by MD simulation. In Ref. [153] it was shown that the best DG structure in terms of distance violations is generally not the best structure after MD refinement. This is due to the crude energy function used in DG which has to be cast in the form of distances, and so favors geometries which are unfavored by more sophisticated energy functions used in simulations.

When the NMR data contain contributions from different molecular conformations it will be impossible to find *one* conformation satisfying the experimental data.[155] This observation led to the introduction of time-dependent constraints[156] which do not force the molecule to satisfy the distance constraints at each time point of the simulation, but only forces the distance constraints to be satisfied on average. This forms a better representation of the measured data.

4.2.2. Refinement of Structure Based on Crystallographic X-Ray or Neutron Diffraction Data

Since its introduction the method of MD refinement of crystallographic data[157] has been applied mainly in protein crystallography. Again, different penalty functions (83) and refinement protocols are used. Generally speaking MD refinement saves a few months work over conventional refinement when applied to proteins. A survey of recent developments is given in Ref. [158].

As in the NMR case, the use of time-dependent structure factor restraints will be a much better representation of the experimental information, which is an average over time and over molecules. Preliminary results (*P. Gros*, private communication) indicate that lower R values and better searching of conformational space are obtained.

4.3. Prediction of Structural Changes by MD Simulation

No reliable approaches are as yet available for the prediction of de novo (macro)molecular structures, and there is no real alternative to experimental structure determination. When structural information on homologous molecules is available, a molecular structure may be predicted starting from the homologous molecules and subsequently changing it to the required composition, either by model building on a graphic device or by more automatic simulation techniques. When additional experimental information from X-ray diffraction or NMR is available the chance of success is greatly increased. An example is the structure determination of the 279-residue protein thermitase, starting from the known structure of subtilisin (275 amino acids).[158,159] These proteins show only 47% homology; residues had to be changed, deleted and inserted when changing subtilisin into thermitase. Subsequent MD refinement using crystallographic X-ray data on thermitase made numerous atoms move over more than 4 Å. Some parts showed a structural change of more than 8 Å.

If only one or a few amino acid side chains in a protein are changed (mutated), the structural change may be predicted by MD simulation without the extra help of X-ray data. In Figure 13 the conformation of the Met-222 → Phe mutant of subtilisin resulting from a MD simulation in which Met-222 was gradually changed into Phe-222[32] is compared with the conformation as obtained from an X-ray diffraction determination of this subtilisin mutant.[160] The predicted conformation is correct. However, this is not always true; especially when hydrogen bond networks, involving bound water molecules, have to be rearranged, the simulation period may be too short compared to the hydrogen bond network relaxation time.[32]

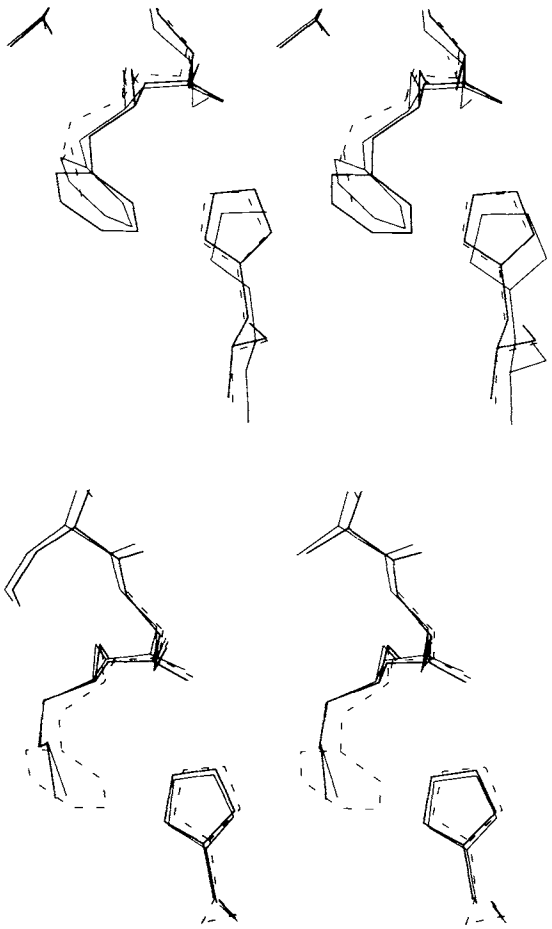

Fig. 13. Stereoview of the hydrophobic binding pocket of subtilisin. Upper part: forward 222 Met → Phe mutation; dashed line: 222 Met (native) starting structure; thick solid line: 222 Phe (mutant) MD predicted structure; thin solid line: 222 Phe (mutant) X-ray structure. Lower part: backwards 222 Phe → Met mutation; dashed line 222 Phe (MD) starting structure; thick solid line: 222 Met MD predicted structure (from 222 Phe mutant); thin solid line 222 Met (native) MD structure (from X-ray).

It is also possible by MD simulation to determine the conformation of a molecule as a function of the type of environment, viz. crystalline, nonpolar solution, aqueous solution, etc. Studies of this type have been performed for different molecules.[161-164] For the immuno suppressive drug cyclosporin A (CPA) the conformational differences found between its crystal conformation and its conformation in a chloroform solution were exactly reproduced by two MD simulations in the corresponding environments (Figure 16).[164]

This application illustrates the power of MD simulation when studying conformational properties of flexible molecules or mutants. However, when large conformational changes are to be expected the length (typically 10^1-10^2 ps) of a MD simulation may be too short to bring these about in the limited time available to surmount possible energy barriers.

4.4. Prediction of Free Energy Changes by MD Simulation

From an MD trajectory the statistical equilibrium averages can be obtained for any desired property of the molec-

ular system for which a value can be computed at each point of the trajectory. Examples of such properties are the potential and kinetic energy of relevant parts of the system, structural properties and fluctuations, electric fields, diffusion constants, etc. A number of thermodynamic properties can be derived from such averages. However, two important thermodynamic quantities, the entropy and the (Gibbs or Helmholtz) free energy, generally cannot be derived from a statistical average. They are global properties that depend on the extent of phase (or configuration) space accessible to the molecular system. Therefore, computation of the absolute free energy of a molecular system is virtually impossible. Yet, the most important chemical quantities like binding constants, association and dissociation constants, solubilities, adsorption coefficients, chemical potentials, etc., are directly related to the free energy. Over the past decade statistical mechanical procedures have evolved by means of which *relative* free energy differences may be obtained. For recent reviews of methodology and applications see Refs. [8, 165].

The most powerful method is the so-called thermodynamic cycle integration technique. The free energy difference between two states A and B of a system is determined from a MD simulation in which the potential energy function $V(\{\boldsymbol{r}_i\})$ [Eq. (1)] is slowly changed such that the system slowly converts from state A into state B. In principle the free enthalpy difference $\Delta G_{BA} = G(B) - G(A)$ is determined as the work necessary to change the system from state A to state B via a reversible path. An example is given in Figure 14, where the free enthalpy of changing one water molecule (state A) in a cube with 216 water molecules into a methanol molecule (state B) is illustrated. The change is carried out over a period of 20 ps and yields $\Delta G_{BA} = 6.1$ kJ mol^{-1}, as compared with an experimental value of 5.2 kJ mol^{-1}.

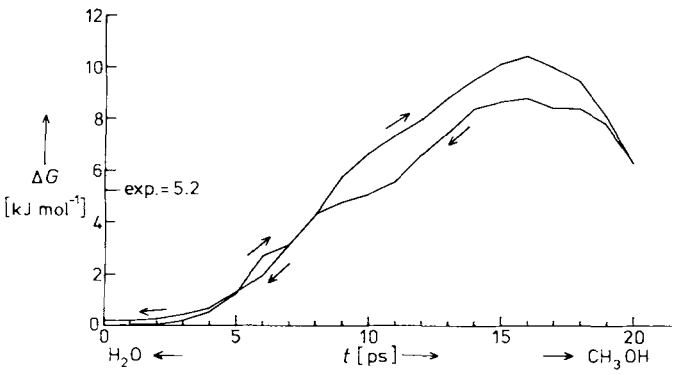

Fig. 14. Free enthalpy change ΔG on changing H_2O into CH_3OH and back again.

The basis on which the thermodynamic cycle approach rests is the fact that the free enthalpy G is a thermodynamic state function. This means that as long as the system is changed in a reversible way the change in free enthalpy ΔG will be independent of the path. Therefore, along a closed path or cycle one has $\Delta G = 0$. This result implies that there are two possibilities of obtaining ΔG for a specific process; one may calculate it directly using the technique sketched above along a path corresponding to the process, or one may design a cycle of which the specific process is only a part, and calculate the ΔG of the remaining part of the cycle. The power of this thermodynamic cycle technique lies in the fact that on the computer also non-chemical processes such as the conversion of one type of atom into another type (H into CH_3, see Fig. 14) may be performed.

The method is outlined in Figure 15 for the process of binding of two different inhibitors, trimethoprim (TMP) and its triethyl analogue (TEP), to the enzyme dihydrofolate reductase (DHFR) from chicken liver[166, 167] in the presence of coenzyme (NADPH) and water. The appropriate thermodynamic cycle is given in Figure 15. The relative

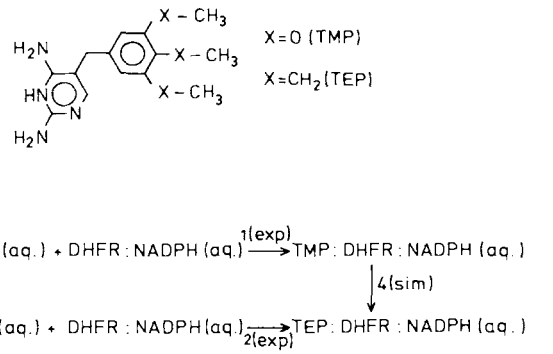

Fig. 15. Thermodynamic cycle for computation of the relative free enthalpy of binding of two inhibitors, trimethoprim (TMP) and its triethyl analogue (TEP), to the enzyme dihydrofolate reductase (DHFR) in the presence of coenzyme (NADPH) in aqueous solution. Complexation is denoted by the symbol ":".

binding constant of the two inhibitors equals $K_2/K_1 = \exp[-(\Delta G_2 - \Delta G_1)/RT]$. However, simulation of processes 1 and 2 is virtually impossible, since it would involve the reversible removal of many solvent molecules from the active site of the enzyme to be substituted by the inhibitor. Since the processes in Figure 15 form a cycle, one has $\Delta G_2 - \Delta G_1 = \Delta G_4 - \Delta G_3$, and the processes 3 and 4 can easily be simulated since they involve the change of three oxygen atoms (TMP) into three CH_2 groups (TEP). MD simulation of process 3 yields $\Delta G_3 = -61 \pm 0.2$ kJ mol^{-1} and of process 4 yields $\Delta G_4 = -65 \pm 10$ kJ mol^{-1}. So, the computed difference in free enthalpy of binding between TEP and TMP is $+4 \pm 10$ kJ mol^{-1} to be compared with an experimental value of $+7$ kJ mol^{-1}.

Although this result seems reasonable, the computed value may only be considered as an order-of-magnitude estimate. This is due to various assumptions and approximations that underlie this type of free energy calculation. Since these have been discussed elsewhere,[141] the most important ones will only be summarized here.

1. *Adequate sampling, or the relaxation time of the environment.* The change from state A to state B has to be carried out in a reversible way, which means that the time period of the change must be much longer than the relaxation time of the environment which has to adapt to the change. The rotational correlation time of a water molecule is about 2 ps and the dielectric relaxation time of water is about 8 ps. This means that a MD simulation of the change from A to B over 20 ps or more is long enough to obtain reasonably accurate ΔG values (see Fig. 14). How-

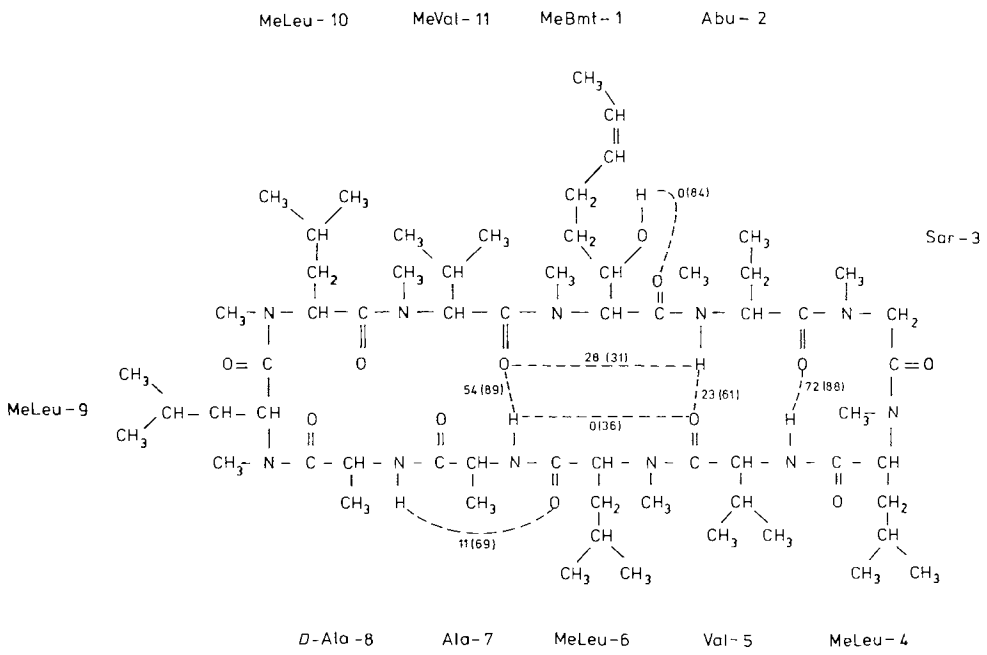

Fig. 16. Hydrogen bonds (dashed lines) occurring in two MD simulations of cyclosporin A. Percentage of occurrence is given, both for a MD simulation in aqueous solution and (in parentheses) for a MD simulation in vacuo.

ever, in process 4 (Fig. 15) the relaxation time of the (protein) environment of the inhibitor is much longer, which results in a large uncertainty of 10 kJ mol^{-1}.

2. *Effect of long-range Coulomb interactions.* Free energy computation involving the creation or annihilation of (full) atomic charges is very dependent on a proper treatment of the Coulomb interaction, which has an r^{-1} distance dependence. For example, when creating an ion in aqueous solution, the contribution of the hydration shell between 9 Å and 12 Å to the free energy of solvation is about 40 kJ mol^{-1},[41] which means that the cut-off radius must be very large to obtain accurate ΔG values. When only dipolar changes play a role, as in the case of Figures 14 and 15, the interaction has an r^{-3} distance dependence, which considerably reduces the need to use a large cut-off radius.
3. *Sensitivity to force field parameters.* Not unexpectedly, the free energy of a molecular system is rather sensitive to the interaction function (1) that is used in the simulation. For example, in the relatively simple case of the free enthalpy of solvation of methanol in water (see Fig. 14), application of force field parameters of established force fields yields values ranging from 0 to 14 kJ mol^{-1},[28] a spread of 2–3 kT around G_{exp} = 5.2 kJ mol^{-1}.

The techniques for computation of (relative) free energy are in many applications not yet sufficiently accurate. However, they are still being improved and are in principle widely applicable in the study of molecular systems.

4.5. Static versus Dynamic Representation of a Molecular System

The common approach to modeling a molecular system on a computer is a static one. For example, quantum calculations yield an equilibrium charge distribution, molecular mechanics calculations one or a few minimum energy conformations of a molecule; on a graphics device, molecules are studied in terms of fixed conformations. However, a molecular system at room temperature is by no means of static character. It should be described in terms of a multidimensional distribution function of all atomic coordinates and its development in time. An example of a dynamic equilibrium between different hydrogen bond patterns is given in Table 6 for crystalline cyclodextrin. The O61 atom is involved in different, mutually exclusive hydrogen bonds. The ones that do exist more than about 20% of the MD simulation are also observed, as expected, in the neutron diffraction

Table 6. Dynamic equilibrium between various hydrogen bond patterns involving the O61 atom in crystalline α-cyclodextrin [a]

Donor [a]	Acceptor	%	MD simulation distance [Å] D···A	MD simulation angle [°] D-H···A	Neutron diffraction distance [Å] D···A	Neutron diffraction angle [°] D-H···A
O61-H61	O63	79	2.79	160	2.81	177
	O65	2	3.04	158		
	O56	1	2.99	158		
	OW3	6	3.04	146		
	OWA	+ 2	2.08	156		
		90				
O21-H21	O61	14	3.06	156		
O63-H63		3	2.84	161		
OWA-HWA1		36	2.97	156	2.97	173
OWA-HWA2		5	3.01	154		
OW3-HW31		8	3.07	153	3.33	107
OW3-HW32		11	3.04	153		
OWB-HWB1		+ 2	2.94	156		
		79				

[a] Abbreviations. D = donor, A = acceptor, W = water atoms [29].

experiment.[168] It is also observed that the lower the occurrence of a hydrogen bond is in the simulation, the more deformed its geometry is when described in terms of one static hydrogen bond, as is the case for the neutron diffraction data (see Table 6).

4.6. The Role of a Solvent in Molecular Simulations

Many (macro)molecular modeling studies involve an isolated molecule without any solvent. This means that solvent effects are completely ignored. The molecular surface will be distorted by the vacuum boundary condition, and certainly no meaningful free energy estimates can be obtained. When a molecular complex is formed, solvent molecules may play a bridging role, as is observed in the repressor–operator complexes.[26, 169] Even intramolecular hydrogen bonding is affected by the competitive presence of water molecules surrounding a solute in aqueous solution. An example is given in Figure 16, where the occurrence of intramolecular hydrogen bonds is given for cyclosporin A, on the one hand simulated in vacuo and on the other in aqueous solution.[164] It is clear that omission of the solvent results in too high a percentage of intramolecular hydrogen bonds. Proper treatment of solvent effects is a necessary condition for a reliable simulation of molecular properties.

4.7. Other Applications of Computer Simulation in Chemistry and Physics

The field of computer simulation of molecular systems has grown so rapidly that a review of all possible applications is hardly feasible. In this section we have chosen examples, mostly of our own work, to illustrate specific aspects of simulation studies. Many other applications may be found in a number of reviews and monographs on computer simulation in physics and chemistry.[1–9] We would like to mention a few recent studies which may lead the reader to areas of application that were not mentioned here. Computer simulation has been applied to the study of electrolytes,[170] ionic conductors,[171] ionic crystals,[172] ionic salts,[10] and, inter alia, to processes like adsorption,[173] sputtering[174] and melting.[175, 176]

5. Future Developments in Computer Simulation

5.1. Quantum Simulations

Classical computer simulation implies a number of restrictions, as mentioned in Section 2.1.3, which are due to the assumption that quantum effects play a minor role. A proper description of low-temperature or light-atom (hydrogen) motion or chemical reactions requires a quantum mechanical treatment. Various quantum methods for application in the area of simulation have been developed and recent years have shown an increasing activity in the area of quantum simulations. Here, we briefly mention a few methods. Quantum effects can be incorporated in simulations in different ways.

A. *Quantum corrections to the results of classical simulations* can be made. Expansion of the partition function in powers of $\hbar$, Planck's constant, leads to correction formulas for thermodynamic quantities like the free energy[177] or structural quantities like the radial distribution function $g(r)$.[178] *Berens* et al. propose a correction formula based on a harmonic approximation of the atomic motion.[179] Also for time-dependent equilibrium quantities, quantum correction formulas are known.[180]

B. *Quantum mechanical treatment of a few degrees of freedom in an otherwise classical simulation* can be implemented in different ways.

1. The *path-integral simulation method*[181–183] yields a quantum mechanical equilibrium distribution. Its name originates from its derivation by a discretization of the path-integral form of the density matrix. A recent application is the treatment of electron transfer reactions.[184]
2. The *Gaussian wave packet method*[185–187] constituted an early attempt to solve the time-dependent Schrödinger equation by computer simulation. A problem inherent in this method is that of arriving at an adequate description of the interaction between a wave packet and its classical environment.
3. In the *density functional dynamic method*[188] an energy functional, as used in density-functional theory, is added to the Lagrangian of the molecular system, and the Lagrangian equations of motion are subsequently integrated using MD techniques. Static and dynamic properties of crystalline silicon were obtained in terms of a self-consistent pseudo potential.[188]
4. In the *adiabatic quantum molecular dynamics method*[189] the time-dependent Schrödinger equation for the excess electrons and Newton's equation of motion for the nuclei plus core electrons are integrated in the Born–Oppenheimer approximation. Electronic states and dynamic properties of dilute liquid K–KCl solutions were studied.[189]

The potential of the different methods has not yet been fully explored, which means that a best methodology has not as yet crystallized. The field is in a state of rapid development and holds much promise for a proper dynamic treatment of quantum degrees of freedom in the future.

5.2. System Size and Time Scale of Simulations

The number of particles in a computer simulation typically lies in the range of 10^2-10^4, although simulations involving more than 10^4 atoms are nowadays feasible.[173] Relatively complex systems like a protein embedded in a membrane will also contain about 10^5 atoms. In practical applications limited system size is much less a concern than the finite time scale of a computer simulation. Due to large energy barriers in the potential energy surface, it may take a molecular system a very long time to cross these barriers and so to sample configuration space efficiently. Typical simulation periods are 10^1-10^2 psec, which is much too short for a proper description of properties which show a much longer relaxation time. Therefore, possibilities to lengthen the time

scale of MD simulations are continuously investigated. Here we mention a few.

1. *Freezing of degrees of freedom.* The basic problem of removing degrees of freedom is that of defining an appropriate interaction function for the remaining degrees of freedom. Moreover, the degrees of freedom removed should play a minor role in the processes one is interested in. Application of bond-length constraints and the twin range method to handle long-range forces fall in this class. An alternative to freezing of degrees of freedom is the use of multiple time step integration methods.
2. *Stochastification of degrees of freedom.* Explicit treatment of degrees of freedom may be replaced by the application of a mean force plus a stochastic force which represent the average effect of the removed or stochastified degrees of freedom on the remaining explicitly treated ones. An example is the use of the Langevin equation to model the solvent or solid-state environment of a molecule.
3. *Scaling of system parameters.* Assume that we are interested in a quantity Q which has a relaxation time τ that is longer than the time period that could be covered by a MD simulation. It may be possible to identify one or more system parameters p for which τ is a (rapidly) changing function $\tau(p)$ of p. In that case the physically correct value of $p = p_{phys}$ can be changed to p_{short} such that $\tau(p_{short})$ becomes shorter than the length of a MD simulation, which can then be carried out to obtain $Q(p_{short})$. Extrapolation of $Q(p)$ for p from p_{short} to p_{phys} will yield an estimate $Q(p_{phys})$. The risk associated with the application of this technique is that by scaling of system parameters, the physical processes are changed such that a process at p_{short} may have nothing to do with one at p_{phys}. For example, when studying the relaxation of vibrational energy of an HCl molecule in an Ar lattice, the relaxation time may be shortened from the μs time scale to the ns time scale by reducing the HCl bond-stretching force constant. This will, however, certainly influence the balance between various relaxation mechanisms that are feasible for this process.
4. *Activated barrier crossing.* In the case of an activated process, methods exist to avoid a full simulation of the rare event of barrier crossing.[115] The procedure consists of three steps: 1) The location of the barrier must be determined. 2) The likelihood that the system will be at the top of the barrier is computed using umbrella sampling techniques. 3) The transition probability is computed by running MD trajectories from the top of the barrier. This technique has been applied to simulate ring flips in proteins.[116]
5. *Mass tensor dynamics.* In the classical partition function the integration over the momenta of the particles can be carried out separately from that over the coordinates, when no constraints are applied. The atomic masses do not appear in the configurational integral, which means that the equilibrium properties of a system will be independent of the masses in the system. The technique of mass tensor dynamics[190] exploits this freedom by choosing the atomic masses such that the high-frequency motions of the molecular system are slowed down, which allows a longer simulation time step to be taken.

None of the above-mentioned methods for lengthening the time scale of a simulation is really satisfactory. Most of the progress in this respect will probably result from the ever increasing power of computers. Yet, a combination of the different techniques mentioned above may yield a considerable reduction of the required computing power in suitable cases.

5.3. Accuracy of Molecular Model and Force Field

As was discussed in Section 3.1.1, there is no best molecular model or force field for all possible applications. The reliability of a particular force field will depend on the type of system and physical quantity it is applied to. Improvement of the quality and extension of the range of applicability is a continual concern in the area of computer simulation. Yet, the improvement of a force field is not a simple exercise for the following reasons.

1. When applying complicated force fields like (1), the exact *relationship* between a *force field parameter* and a *molecular property* is *often not known*. For example, how will the free enthalpy of solvation of methanol in water depend on the geometry and nonbonded interaction parameters?
2. *Force field parameters may be correlated.* For example, the actual barrier for a torsional rotation will depend on the combined effect of the dihedral angle potential energy term in (1) and the third neighbor nonbonded interaction between the first and the last atom defining the torsional angle.
3. There may be *conflicting requirements for improvement.* For example, the van der Waals radii of third neighbor atoms must not be too large in order that the energy of a gauche conformation is not too high in the case of a hydrocarbon chain. However, to obtain the correct density for a hydrocarbon liquid the van der Waals radius must be chosen larger. This conflict may be solved by a separate treatment of third-neighbor and other van der Waals interactions.
4. There is some conflict between the wish to stick to conceptual simplicity of a force field on the one hand, and the wish to extend its range of applicability and accuracy by allowing the force field to become more complex.
5. Approximations inherent in certain force fields may block substantial improvement by changing of the parameters. For example, when applying a cut-off radius to long-range Coulomb forces, it is impossible to obtain a proper representation of electrostatic effects.

The inclusion of polarizability will be essential for an accurate modeling of processes like the binding of charged ligands. Polarizability only allows for a local displacement of charge, not for a transfer of charge. This can be achieved by combining static ab initio or semi-empirical quantum methods to compute charge densities with classical MD simulation in an adiabatic way: the quantum charge density is converted into atomic charges which are used in a number of classical simulation steps, and the new atomic positions are subsequently used to generate a new quantum charge distribution, and so on.[191] This type of treatment is only an improvement over conventional simulation when (i) the quantum Hamiltonian includes the long-range electrostatic

field, and (ii) the classical Hamiltonian accounts in a consistent way for the changing charge distribution.

In view of the limited accuracy of currently available force fields it may be wise in practical applications to check whether the results obtained are force field dependent.

5.4. Non-Equilibrium Molecular Dynamics

In this paper we have considered the computer simulation of systems in equilibrium. It is also possible to change the equations of motion and boundary conditions such that the system is kept in a non-equilibrium state. In such a non-equilibrium molecular dynamics (NEMD) simulation, a non-equilibrium ensemble is sampled. NEMD simulation is an efficient technique to obtain transport coefficients, like viscosity, thermal conductivity, and mobility of molecular systems. An example is the study of the molecular viscosity of *n*-alkanes as a function of the intramolecular interaction function.[192] For an introduction to NEMD methods and their applications see Refs. [6, 7]. It is a rapidly developing field, which is still almost unexplored, with prospects in the area of practical rheology.

5.5. Development of Computing Power

The growth of the field of computer simulation of fluid-like systems has been made possible by the steady and rapid increase of computing power over the last couple of decades. Figure 2 suggests an increase of an order of magnitude every 5–7 years. This trend will continue in the near future, since the present growth of computing power is based on the introduction of massive parallelism. The possibilities of parallel computation can be exploited rather easily in MD simulations, since the most time-consuming part is the force calculation, which can be carried out in parallel for all atoms in the system. Also the integration step can easily be performed in parallel. The required computing time for a MD simulation depends linearly on the simulation period and the number of particles (in case of forces of finite range). Therefore this type of calculation can optimally benefit from the continuous growth of computing power. In contrast, quantum mechanical calculations extend their range much more slowly, due to the fact that the required computing power is approximately proportional to N_e^3 in the case of semi-empirical or local density functional calculations, to N_e^4 in the case of Hartree-Fock calculations, or even to N_e^5 in the case of configurational interaction calculations. Here, N_e is the number of *electronic* degrees of freedom. In classical simulations the required computing power is proportional to N_a, or in the case of inclusion of long-range forces or polarizability to at most N_a^2, where N_a denotes the number of *atomic* degrees of freedom.

6. Summary and Outlook

Dynamic computer simulation is just a branch of computational chemistry and physics in which a mathematical model of the real world is formulated and its consequences for the various physical or chemical quantities are evaluated

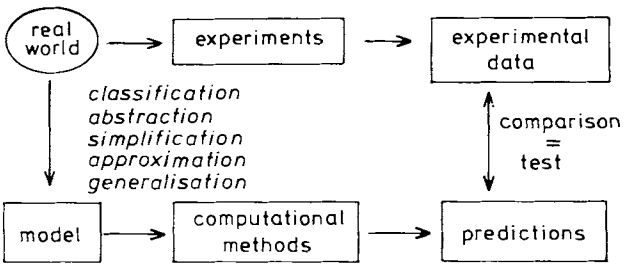

Fig. 17. Computational physics and chemistry involve formulation and testing of a (mathematical) *model* of the *real world*.

by numerical methods. This is illustrated in Figure 17. In this paper much attention has been devoted to methodology, because the core of any model is the approximations, assumptions and simplifications that are used in its formulation. Only an understanding of the basics of a particular model may lead to sensible application or improvement of its performance. Secondly, attention has been focussed on comparison of model predictions with experimental data, which may reveal flaws in the model (or experiment). Due to the complexity of the systems of chemical interest, theoretical methods only became of practical interest with the advent and development of computers. With the continuous progress of methodology and computing power, computational methods, especially computer simulation methods, will find wider and wider application in the different areas of chemistry.

In Table 7 we have listed our thoughts about the possible development of various aspects of (molecular dynamics)

Table 7. Development of various aspects of molecular dynamics computer simulation methods in chemistry.

Aspect	Past (1980)	Present (1990)	Future (2000)
accuracy			
– atomic positions	≈3 Å	≈1 Å	≈0.5 Å
– free energy	–	≈4 k_BT	≈2 k_BT
force field	united atoms	all atoms	polarizability
environment	vacuo	solvents	membranes
time scale	≈10 ps	≈100 ps	≳1 ns
system size	≈1000 atoms	≈10 000 atoms	≈100 000 atoms
quantum (MD) degrees of freedom	–	simple models	enzyme reactions
non-equilibrium simulations	atomic fluids	simple polymers	rheology of molecular mixtures

computer simulation methodology and application in chemistry. From the contents of this paper it will be clear that there are still a number of very difficult problems, such as protein folding or crystallization, which are well beyond the reach of simulation methods owing to the size of the configurational space involved, the time scale of the process, and the small free energy differences between folded and unfolded state or between crystalline and liquid state.

We would like to thank all our co-workers and colleagues who contributed to the work described here. This work was

supported by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organisation for Scientific Research (NWO). The GROMOS (GROningen MOlecular Simulation) program library, which can be used for applying the methods discussed here, is available at nominal cost from the authors.

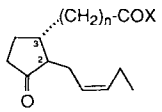
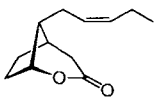
Building Blocks for the Synthesis of Enantiomerically Pure Jasmonoids: Synthesis of (+)-Methyl Epijasmonate**

By *Günter Helmchen,* Andreas Goeke, Gilbert Lauer, Matthias Urmann*, and *Jürgen Fries*

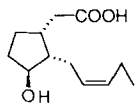
Jasmonoids of type **1** (n = 1,3,5) and their reduction products are widespread in the plant world.[1a] The best-known compound is ester **1**, n = 1, X = OCH_3, a valued fragrance,[1b] found in jasmine and rosemary oil. This ester and the corresponding carboxylic acid (**1**, n = 1, X = OH) are endogenous growth regulators in plants.[1a]



1



2

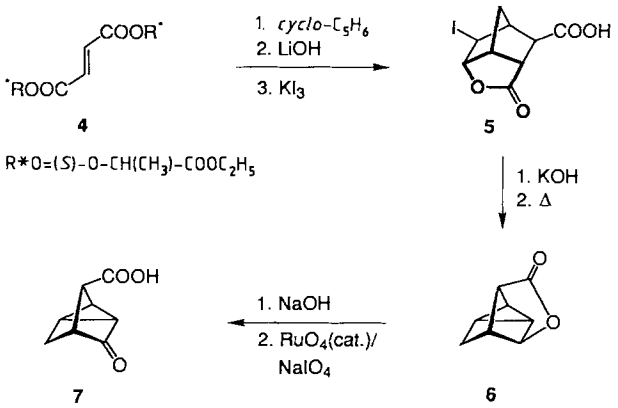


3

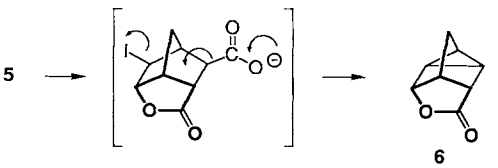
a: n = 1, X = OCH_3, 2,3 - *cis*

b: n = 1, X = OCH_3, 2,3 - *trans*

Recent investigations raised the question as to the relative configuration of the biologically active substances. Thus, *Acree* and *Nishida* et al. obtained the pure stereoisomers **1a,b** and their enantiomers by tedious separation procedures.[2] Only **1a** (methyl epijasmonate), which readily isomerizes to **1b** (methyl jasmonate), is fragrant.[2] The above-mentioned plant oils contain only 5% of **1a** together with **1b** (equilibrium mixture). Furthermore, **1a** acts as a pheromone, whereas **1b** is inactive.[3] Finally, cyclopentanes with *cis* configuration have been shown to be the biogenetic precursors of jasmonoids;[4] notably, this also holds true for all reduced compounds such as lactone **2**[5] and cucurbic acid (**3**),[6] neither of which can undergo epimerization at C-2. We have now developed a synthetic strategy that makes available large quantities of enantiomerically pure, structurally diverse *cis* jasmonoids in a stereoselective fashion. Although several syntheses of nonracemic compounds of the *trans* series are known,[7a] only two unselective syntheses of *rac*-**1a** have been described.[7b]



Our starting point is the asymmetric Diels–Alder reaction. Several years ago, we found that the uncatalyzed reactions of the fumarates of (*S*)-ethyl lactate and (*R*)-pantolactone proceed with high diastereoselectivity.[8] For example, ester **4**, readily available in kilogram quantities, and cyclopentadiene react with a diastereoselectivity of 98:2. The crude product is hydrolyzed with LiOH in THF/water to give the salt of 5-norbornene-2,3-dicarboxylic acid, which is then converted directly, without purification, into the iodolactone **5**. Recrystallization affords enantiomerically pure[9] **5** in 70–80% yield. Heating a solution of the dried K salt of **5** in dimethyl sulfoxide (DMSO) (9 h, 175 °C) gives lactone **6** in 84% yield. We assume that this new cyclization is a decarboxylative 1,3 elimination.



Conversion of **6** to the ketocarboxylic acid **7** [m.p. 123.5–124.5 °C, $[\alpha]_D^{20}$ = 95.5 (*c* = 3, 95% EtOH)] is accomplished in 91% yield by oxidation with RuO_4 (cat.)/$NaIO_4$.[10] In analogy to the C-7 epimer, a key intermediate in prostaglandin synthesis,[11] **7** can be selectively opened at the cyclopropane ring with mineral acids.[12] Heating with concentrated hydrogen iodide leads to 5-iodonorbornanecarboxylic acid (**8a**, 84%), which can be reduced with zinc (THF/KH_2PO_4 buffer) to give the ketocarboxylic acid **8b** (93%).

Whereas C-3 undergoes migration in norbornanones with *syn* (relative to the carbonyl group) halogen or alkyl substituents at position 7,[13] C-1 migrates when the carboxylic acid **8b** is treated with *m*-chloroperbenzoic acid (MCPBA)[14] or peracetic acid. Reaction of the resulting lactone **9** (83%) with oxalyl chloride followed by Rosenmund reduction and treatment of the resulting aldehyde with the phos-

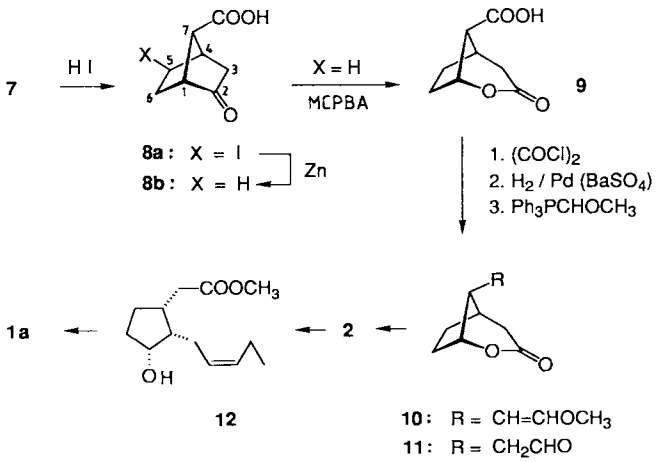
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results were presented at the 11th International Symposium Synthesis in Organic Chemistry (Oxford, June 26, 1989). We thank Dr. *J. Weetman* and *T. Lobreyer* for preliminary studies and Prof. *K. Weinges*, whose group independently carried out a synthesis of (+)-**1a**, for exchanging information.



phorane PPh_3CHOCH_3 affords enol ether **10** (66%) as a *Z*/*E* mixture. Hydrolysis of **10** ($THF/H_2O/CH_3COOH$ 1:1:3) leads to aldehyde **11**. Reaction of unpurified **11** with propylidenetriphenylphosphorane in a "salt-free" Wittig reaction results in highly selective[15] formation of lactone **2**, $[\alpha]_D^{20} = -73.0$ ($c = 3.0$, $CHCl_3$),[16] in 72% yield.

Hydrolysis (NaOH) of **2** followed by esterification of the resulting hydroxy acid (CH_2N_2) gives ester **12** (95%). The absence of epimerization had to be ensured for both the oxidation of **12** to the target compound **1a** and the subsequent analysis. HPLC analysis using silica gel columns[17] proved suitable, but gas chromatography on capillary columns did not.[18] The best oxidation results were obtained with pyridinium dichromate in CH_2Cl_2 (**1a**:**1b** = 99.4:0.6, 70% yield). The optical rotation $[\alpha]_D^{20} = 57.3$ ($c = 2.5$, CH_3OH) of HPLC-pure **1a** agrees with the literature value.[2] Whereas a very intense, typical "jasmonate fragrance" is found for **1a**, HPLC-pure **1b** is odorless (cf. Ref. [7a]). The method described here allows methyl epijasmonate (**1a**) to be prepared on a multigram scale and thus makes it available for investigations in plant physiology. Furthermore, intermediates **8** and **11** are building blocks for the EPC synthesis of almost all jasmonoids (about 20 compounds).

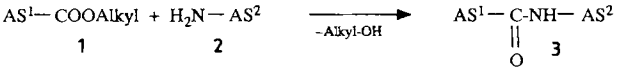
Peptide Synthesis under High Pressure

By *Joachim Gante,* Ulrike Kalthof, Frank-Gerrit Klärner,** and *Thomas Weber*

Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

A long-cherished wish of peptide chemists is to carry out peptide couplings with nonactivated amino acid alkyl esters as partners in the reaction **1** + **2** → **3** (Scheme 1). The advantages of this reaction would include a simplified procedure, more readily accessible and more inexpensive starting materials, and the easy removal of byproducts (volatile alcohols).



Scheme 1. AS^1, AS^2 = amino acid residues.

Up to now, a practical procedure of this kind could not be developed owing to the low degree of activation of the alkyl esters.[1] Only the addition of large amounts of activating substances—like imidazole as solvent (80 °C!)[2] or complex-forming metal salts[3, 4]—has made possible such a reaction, which requires considerable preparative work.

We have now found a solution to this problem by the use of high pressure (10-kbar range). High pressure has already proved useful in many areas of organic chemistry and has allowed reactions that, under normal conditions, can be carried out only inadequately or not at all.[5] The preparation of

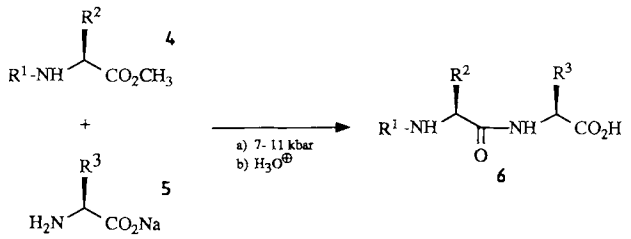
peptides in this way has not yet been described. The only example of a powerful pressure-induced enhancement of the rate and yield of a reaction known to us in amino acid chemistry deals with the reaction of *N*-protected amino acid hydroxysuccinimide esters (that is, "conventionally" activated esters) with poorly reactive imino bis(carboxylic esters) at 10 kbar.[6]

Reaction of various *N*-protected L-amino acid methyl esters **4** with L-amino acid Na salts **5** in methanol[7] at room



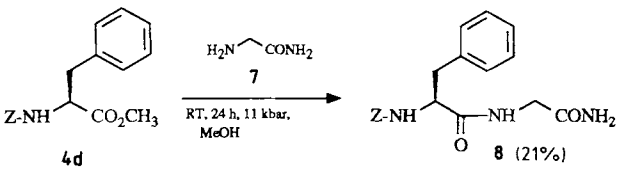
temperature and a pressure of 7–11 kbar leads to formation of the corresponding dipeptide derivatives **6** with loss of methanol (Table 1).

Table 1. High-pressure synthesis of dipeptide derivatives **6** from protected amino acid methyl esters **4** at room temperature.

6	R^1	R^2	R^3	Reaction time [h]	Pressure [kbar]	Yield [%]	M.p. [°C]	$[\alpha]_D^{20}$ ($c = 1$, MeOH)
a	Ph-CO	CH_3	H	17	10	64	178–180	−6.7
b	Ph-CO	CH_3	CH_3	66	10.5	76	201	−13.0
c	Boc[a]	Ph-CH_2	H	66	7	42	158	−4.3
d	Z[b]	Ph-CH_2	CH_3	19	10.6	47	174	−7.3

[a] Boc = *t*Bu-O-CO. [b] Z = Ph-CH_2-O-CO.

The reaction of the methyl esters is also feasible with other amino acid derivatives, as shown by the 1:1 reaction of **4d** with H-Gly-NH_2 (7) to give the protected dipeptide derivative **8** (m.p. 123–124 °C, $[\alpha]_D^{20} = -3.2$ ($c = 1$, MeOH)).



^{1}H NMR and GC analysis of peptides **6a–d**[8] established that, for the benzoylated derivatives **6a** and **6b**, 5 to 8% racemization occurred in the ester-derived component during coupling (corresponding to the tendency also observed in conventional coupling methods), whereas the carbamate-protected products **6c**, **6d**, and **8** were formed without detectable racemization.

The high-pressure method described here thus allows peptide coupling between *N*-terminal-protected amino acid methyl esters and simple amino acid derivatives. The use of amino acid Na salts **5** as "amine component" is a further advantage of the method, since this obviates the additional steps (esterification, saponification) required in the usual techniques involving ester protecting groups.[9]

General Experimental Procedure

A solution of 1.0 mol each of **4** and **5** in 10 mL of dry MeOH was compressed in a sealed polytetrafluoroethylene (PTFE) shrinkage tube according to the conditions given in Table 1[10]. The solution was then evaporated and the residue dissolved in 10 mL of water. The resulting solution was extracted with ethyl acetate, the aqueous phase was acidified to pH ≈ 1 with diluted hydrochloric acid very carefully (since the Boc group is acid labile), and the product **6** was extracted with ethyl acetate. After drying over Na_2SO_4, the organic extract was evaporated and/or petroleum ether was added to give **6** in pure form. The reaction times and yields given in Table 1 are not optimized.

How Do Two C–C Double Bonds Add to One M–M Triple Bond? Structure and Bonding in Bis(η^2-ethylene)hexakis(neopentoxy)ditungsten **

By *Roger H. Cayton, Stephanie T. Chacon, Malcolm H. Chisholm,** and *John C. Huffman*

Dedicated to Professor F. A. Cotton on the occasion of his 60th birthday

The symmetry rules that are so powerful in predicting forbidden reactions in organic chemistry[1] are not as straightforward in inorganic and organometallic chemistry. Thus, [2+2] cycloaddition reactions may be thermally allowed in certain instances. For example, the reversible coupling of two $[W_2(O\mathit{i}Pr)_6]$ to give $[W_4(O\mathit{i}Pr)_{12}]$ occurs with an enthalpy of activation of 10 kcal mol^{-1} and is predicted by a theoretical analysis to be a symmetry-allowed $[\pi_s^2 + \pi_s^2]$ cycloaddition reaction.[2] *Norton* et al.[3] have observed the facile reversible elimination of ethylene from $[Os_2(CO)_8(\mu\text{-}\eta^1\text{:}\eta^1\text{-}C_2H_4)]$ and shown that the stereochemistry at carbon is maintained during this *formal* [2+2] addition/elimination reaction involving C–C and Os–Os double bonds and a 1,2-

diosmacyclobutane. In our studies of the reactions of $[W_2(OR)_6]$ with ethylene we have observed facile ($T < 22$ °C, $p < 1$ bar) C–C bond formation and subsequent C–H activation [Eq. (a)].[4]

$$[W_2(OR)_6] + 3C_2H_4 \longrightarrow [W_2(OR)_6(\mu\text{-}CCH_2CH_2CH_2)] + C_2H_6 \qquad (a)$$

In the specific reaction between $[W_2(OCH_2tBu)_6]$ and ethylene we observed an *initial* reversible equilibrium involving a bisethylene adduct, $[W_2(OCH_2tBu)_6(\eta^2\text{-}C_2H_4)_2]$ (**1**). From considerations of the ^1H and ^{13}C NMR data, we proposed one of two structures for the $W_2O_6(C_2)_2$ skeleton of **1** (Fig. 1), either **I** or **II**.[5] We have now determined the structure in the solid state[6] and find that, contrary to our predictions, **1** adopts the unprecedented structure **III** (Scheme 1).

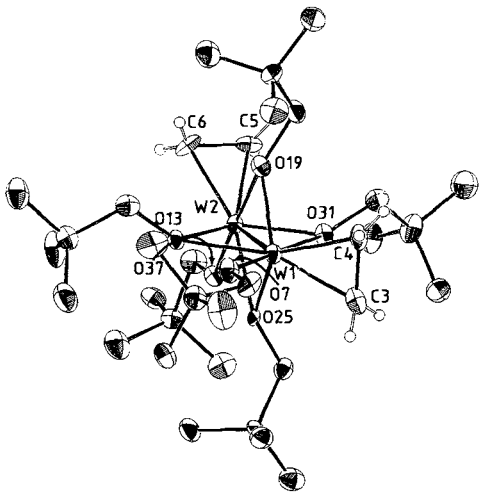

Fig. 1. ORTEP drawing of **1** emphasizing the presence of the four alkoxide bridges and the relative orientation of the ethylene ligands. Important distances [Å]: W-W 2.5331(9), W1-O7 1.89(1), W1-O13 2.28(1), W1-O19 2.00(1), W1-O25 2.31(1), W1-C3 2.13(1), W1-C4 2.14(1), W2-O13 1.98(1), W2-O19 2.32(1), W2-O25 2.32(1), W2-O31 2.00(1), W2-O37 1.88(1), W2-C5 2.15(1), W2-C6 2.15(1), C3-C4 1.45(2), C5-C6 1.45(2).

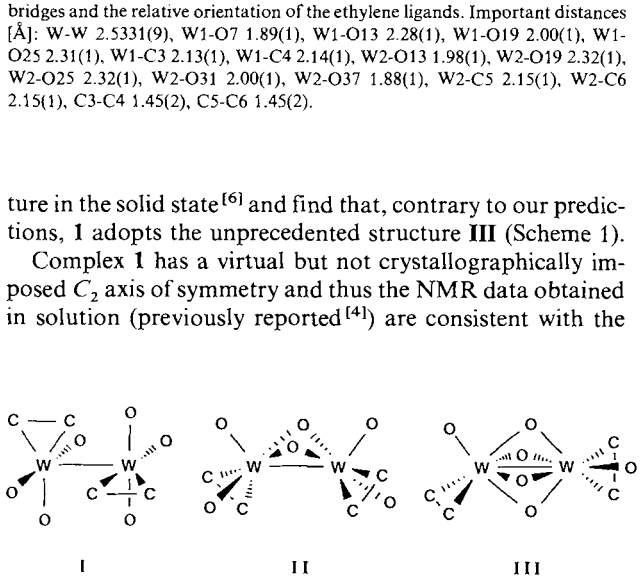
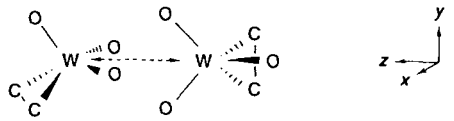
Complex **1** has a virtual but not crystallographically imposed C_2 axis of symmetry and thus the NMR data obtained in solution (previously reported[4]) are consistent with the solid-state structure. Note that all the methylene protons of the OCH_2tBu ligands are diastereotopic and all four ethylene protons are inequivalent. The W–C and C–C distances associated with the $W(\eta^2\text{-}C_2H_4)$ structural unit imply extensive $W(d_\pi)$-to-$C_2(\pi^*)$ bonding and conform to the metallacyclopropane valence bond description for a coordinated ethylene. The W–W distance (2.533(1) Å) is notably longer than that in $[W_2(OR)_6]$ compounds[7] (ca. 2.30 Å, average), implying that $W(d_\pi)$-to-$C_2(\pi^*)$ bonding has occurred at the expense of $W(d_\pi)$-$W(d_\pi)$ bonding. It is, however, the presence of the four bridging ligands and the specific orientation of the terminal ligands that require most attention. Note, too, the gross asymmetry in the W–O distances to the bridging OR ligands. Each tungsten has two short (2.00(1) Å, average) and two long (2.31(1) Å average) W–O bonds. If the ethylene is considered as a monodentate ligand, the structure of **1** bears a resemblance to the $S_2V(\mu\text{-}S)_4VS_2$ skeleton seen in $[V_2(edt)_4]^{2\ominus}$ (edt = ethylenedithiolate), though the latter has more symmetrical V–μ-S bridges.[8–10]



Scheme 1. Possible structures for **1**.

The bonding in **1** can be most easily understood by a Hoffmann frontier molecular orbital approach.[11] Two pseudotetrahedral d^3-$W(OR)_3(C_2H_4)$ fragments are brought together in the manner shown in Scheme 2. As the W–OR bridges are formed, the long W–O bridging distances are *trans* to the terminal OR and η^2-C_2H_4 ligands. The d-orbital splitting for a tetrahedral ML_4 fragment is t_2 above e. Replacement of one L by the single-faced π-acceptor ligand C_2H_4 to give a d^3-$ML_3(C_2H_4)$ fragment will remove the degeneracy of the e orbitals, since one is stabilized by $W(d_\pi)$-to-$C_2(\pi^*)$ bonding. If the d_{z^2} orbital is not allowed to interact with the ethylene, it will be available for M–M bonding (Scheme 2).



Scheme 2. Formation of **1** from two d^3-$W(OR)_3(C_2H_4)$ fragments.

We have carried out Fenske–Hall MO calculations[12] on the model compound $[W_2(OH)_6(\eta^2\text{-}C_2H_4)_2]$ with metric

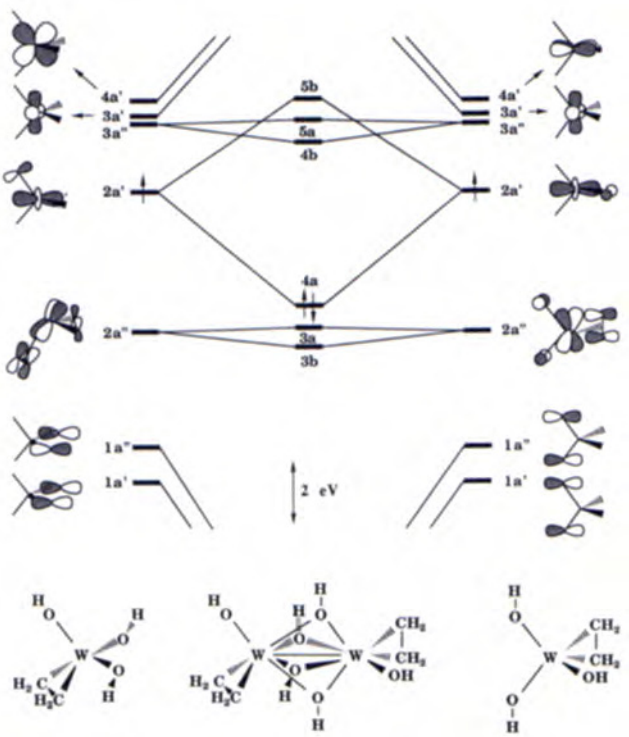


Fig. 2. Frontier molecular orbital diagram for $[W_2(OH)_6(\eta^2\text{-}C_2H_4)_2]$ viewed as the sum of two pseudotetrahedral d^3-$W(OH)_3(C_2H_4)$ fragments (see Scheme 2).

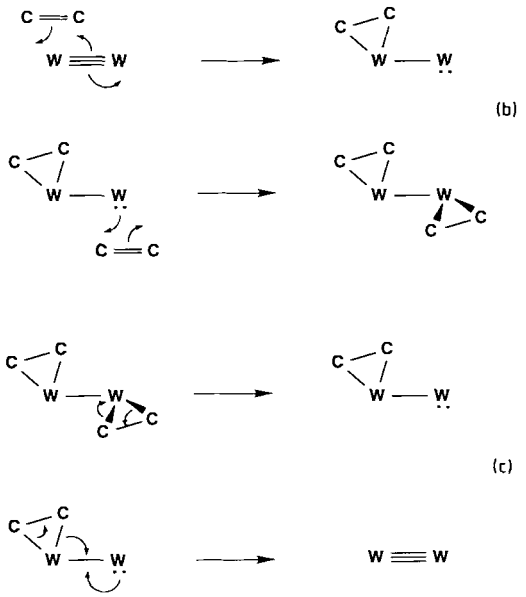
parameters taken from the observed structure of **1**. Although there is additional π bonding involving $W(d_\pi)$ and $O(p_\pi)$ orbitals, the essential features of the bonding are as anticipated from the above considerations. The frontier molecular orbitals are shown in Figure 2. The HOMO is the W–W σ bond formed from the d_z^2–d_z^2 interaction. The M–M δ and δ* orbitals (3a and 3b) are lower in energy and filled, but these orbitals have in reality little M–M bonding character, being essentially localized $M(d_\pi)$-to-$C_2(\pi^*)$ orbitals. The electronic barrier to olefin rotation and the specific orientation of the ethylene ligands arise because M–M and $M(d_\pi)$-to-$C_2(\pi^*)$ bonding compete for use of d_z^2 and d_{xy} orbitals (with the axes shown in Scheme 2).

The relative instability and kinetic lability of a monoethylene intermediate in the reversible reaction between $[W_2(OR)_6]$ and ethylene can also be understood in terms of the competitive nature of M–M d_π–d_π and $M(d_\pi) \rightarrow C_2(\pi^*)$ bonding. Addition of ethylene to one tungsten center effectively activates the other tungsten center by generating a $W(d_\pi)$ electron pair that is poised for uptake of the second ethylene. Schematically, this is shown in Equation (b). Loss of one ethylene from **1** triggers the reverse reaction in



which M–M and C–C π bonds are reformed as shown in Equation (c).

Perchlorinated and Highly Chlorinated *meso*-Tetraphenylporphyrins **

By *Tilak Wijesekera, Akiteru Matsumoto, David Dolphin,** and *Doris Lexa*

meso-Tetraphenylporphyrins (TPPs) are widely used to study metalloporphyrin chemistry because they are usually readily prepared by simple synthetic sequences. However, since their phenyl and porphyrin rings are sterically constrained to lie essentially perpendicular to each other, the electronic effects of substituted phenyl rings can only be inductively transmitted to the porphyrin ring. Thus, the redox potentials (for the one-electron reduction of the porphyrin ring) for a diverse group of phenyl-substituted TPPs vary by only 130 mV.[1] The effect on a coordinated metal is even less. When directly substituted on the porphyrin ring itself, however, electron-withdrawing groups can have a more pronounced effect on the porphyrin redox chemistry. Indeed, with β-tetracyano-*meso*-tetraphenylporphyrin[2] and *meso*-tetranitro-β-octaethylporphyrin,[3] the anodic shifts resulting from substitution are almost 1 V. In order to expand the versatility of the tetraphenylporphyrins, we have examined β-chlorination reactions and report here on the synthesis and electrochemistry of the iron complexes of TPP and phenyl-ring-chlorinated TPPs.

Although β-polybromination of *meso*-tetraphenylporphyrin derivatives has been successfully accomplished using *N*-bromosuccinimide,[4, 5] the analogous chlorinations using *N*-chlorosuccinimide produced mainly the monosubstituted product.[6] Our attempts to polychlorinate *meso*-tetra(2,6-dichlorophenyl)porphyrin[7] (Cl_8TPPH_2) or its Zn^{II} or Fe^{III} complexes using excess *N*-chlorosuccinimide failed, the starting material being recovered even after heating for 5 h at 140 °C. However, in the presence of anhydrous $FeCl_3$, the Fe^{III} complex **3** in *o*-dichlorobenzene underwent facile perchlorination of the porphyrin ring when treated with chlorine gas. The reaction mixture was maintained at 140 °C following an initial slow bubbling of Cl_2 gas for 5 min and

Perchlorinated and Highly Chlorinated *meso*-Tetraphenylporphyrins **

By *Tilak Wijesekera, Akiteru Matsumoto, David Dolphin,** and *Doris Lexa*

meso-Tetraphenylporphyrins (TPPs) are widely used to study metalloporphyrin chemistry because they are usually readily prepared by simple synthetic sequences. However, since their phenyl and porphyrin rings are sterically constrained to lie essentially perpendicular to each other, the electronic effects of substituted phenyl rings can only be inductively transmitted to the porphyrin ring. Thus, the redox potentials (for the one-electron reduction of the porphyrin ring) for a diverse group of phenyl-substituted TPPs vary by only 130 mV.[1] The effect on a coordinated metal is even less. When directly substituted on the porphyrin ring itself, however, electron-withdrawing groups can have a more pronounced effect on the porphyrin redox chemistry. Indeed, with β-tetracyano-*meso*-tetraphenylporphyrin[2] and *meso*-tetranitro-β-octaethylporphyrin,[3] the anodic shifts resulting from substitution are almost 1 V. In order to expand the versatility of the tetraphenylporphyrins, we have examined β-chlorination reactions and report here on the synthesis and electrochemistry of the iron complexes of TPP and phenyl-ring-chlorinated TPPs.

Although β-polybromination of *meso*-tetraphenylporphyrin derivatives has been successfully accomplished using *N*-bromosuccinimide,[4, 5] the analogous chlorinations using *N*-chlorosuccinimide produced mainly the monosubstituted product.[6] Our attempts to polychlorinate *meso*-tetra(2,6-dichlorophenyl)porphyrin[7] (Cl_8TPPH_2) or its Zn^{II} or Fe^{III} complexes using excess *N*-chlorosuccinimide failed, the starting material being recovered even after heating for 5 h at 140 °C. However, in the presence of anhydrous $FeCl_3$, the Fe^{III} complex **3** in *o*-dichlorobenzene underwent facile perchlorination of the porphyrin ring when treated with chlorine gas. The reaction mixture was maintained at 140 °C following an initial slow bubbling of Cl_2 gas for 5 min and

the progress of the reaction was monitored by UV spectroscopy (Soret shifts from 420 to 442 nm in approximately 30 min). The product (**4**)[8] was isolated in 85% yield after chromatography and recrystallization.

meso-Tetra(pentachlorophenyl)porphinatoiron(III) chloride[7] (**5**) was chlorinated under the conditions described above to give perchloro-TPP (**6**) in 70% yield. However, attempted chlorination of the unsubstituted hemin, **1**, with $Cl_2/FeCl_3$ resulted in destruction of the macrocycle. When *N*-chlorosuccinimide was used as the chlorinating agent, the hemin as well as the free-base porphyrin $TPPH_2$ could only be partially chlorinated prior to decomposition. The Ni^{II} complex (TPPNi), on the other hand, reacted with 10–12 equivalents of *N*-chlorosuccinimide in *o*-dichlorobenzene (140 °C) to give *meso*-tetraphenyl-β-octachloroporphinatonickel(II) (β-Cl_8TPPNi), isolated in 75% yield. Demetalation with concentrated H_2SO_4 gave the free-base porphyrin β-Cl_8TPPH_2 (90%), which was converted into the corresponding hemin (**2**) in 85% yield by the standard $FeCl_2$/DMF procedure.[9] Attempted chlorination of Zn- or CuTPP gave several products including ring-opened materials, indicating that the centrally coordinated metal exerts an influence on peripheral electrophilic substitution.[10]

Three successive reductions and two oxidations were observed for the porphyrin chloroiron(III) complexes. In order to determine the effect of the counterion on the redox potential,[11] $E_{1/2}$ measurements were also carried out in the presence of $AgClO_4$ ($Cl^\ominus$ removed as AgCl). In general, the electron-withdrawing chloro substituent produced anodic shifts of potentials, but the effect was more pronounced for pyrrolic substitution (Table 1). For the first reduction of **3** (reversible wave obtained with added $Cl^\ominus$), the positive shift of $E_{1/2}$ compared with that for **1** was marginal, whereas for **2** the corresponding shift was 0.41 V. A shift of similar magnitude was also observed when comparing **3** with **4**, but the largest change (0.64 V) from that of **1** was observed for the perchloro system **6**.

The second reduction of the chloroiron(III) complexes of β-octachlorinated porphyrins **2**, **4**, and **6** produced reversible waves only when the counterion was removed with $AgClO_4$. Observed shifts of $E_{1/2}$ due to β-octachlorination (0.45 V for E_{2-1} and 0.47 V for E_{4-3}) were comparable with that reported for the corresponding redox couple of the tetracyano derivative β-$(CN)_4$TPPFe[12] ($\Delta E = 0.51$ V) but significantly higher than the value reported for the β-tetrabromo analogue β-Br_4TPPFe[13] ($\Delta E = 0.174$ V). As shown in Table 1, addition of $Ag^\oplus$ made no change in the $E_{1/2}$ values for the third reduction, suggesting that in no case is the [Fe-TPP]$^\ominus$

[a] Irrversible wave. [b] Quasi-irreversible wave, very close to the reduction of $Ag^\oplus$. [c] Peaks ill-defined. [d] Due to the high concentration of $AgNO_3$ used, the large $Ag^\oplus/Ag$ wave masked that of the metalloporphyrin.

complexed by axial $Cl^{\ominus}$. The anodic shifts observed for β-octachlorination were once again on the order of 0.5 V.

Analysis of current–voltage curves and half-wave potentials,[11] as well as spectroelectrochemistry,[14] have shown that ferrous TPPs can complex with anions. The highly electron-deficient systems described here have been examined spectroelectrochemically. The weak binding of $Cl^{\ominus}$ to Cl_8TPPFe^{II} compared to unsubstituted $TPPFe^{II}$ (K_A; Table 2) may be due to steric effects of the bulky *ortho*-chloro substituents. The β-chlorinated porphyrins, on the other hand, exhibited high stability constants, suggesting that the electronegativity of the β-substituents far outweighs the steric effects of phenyl substitution.

Preliminary studies have shown that these highly electronegatively substituted hemins are robust and effective catalysts for cytochrome-P450-related biomimetic studies.

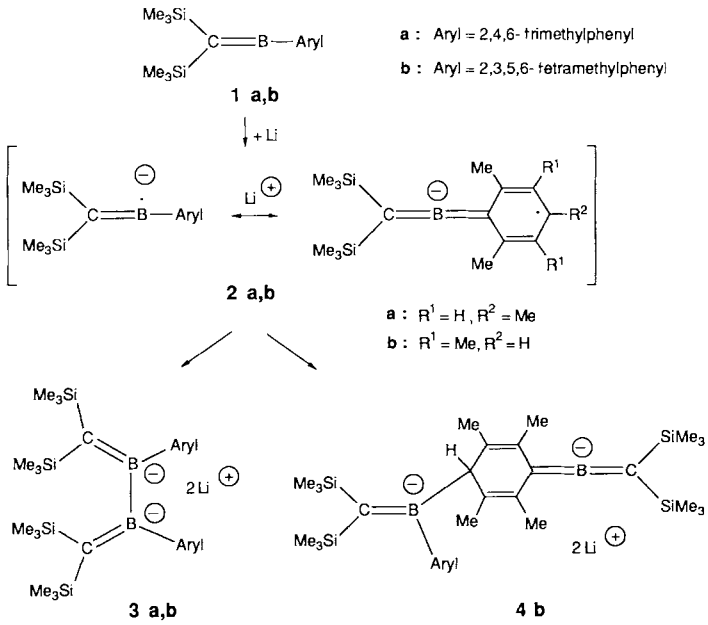
2,3-Diboratabutadienes and 2-Borataallenes**

By *Monika Pilz, Jürgen Allwohn, Peter Willershausen, Werner Massa*, and *Armin Berndt**

Dedicated to Professor Karl Dimroth on the occasion of his 80th birthday

The methyleneborane **1a**[1] reacts with lithium (powder containing 2% sodium) in toluene at 25 °C to give the 2,3-diboratabutadiene **3a**, the symmetrical dimer of its radical anion **2a**. Under the same conditions, **1b** yields the 2-boratraallene **4b**, the unsymmetrical dimer of **2b**, as major product together with **3b** as minor product.[2] The structure[3] of **3a** is shown in Figure 1.



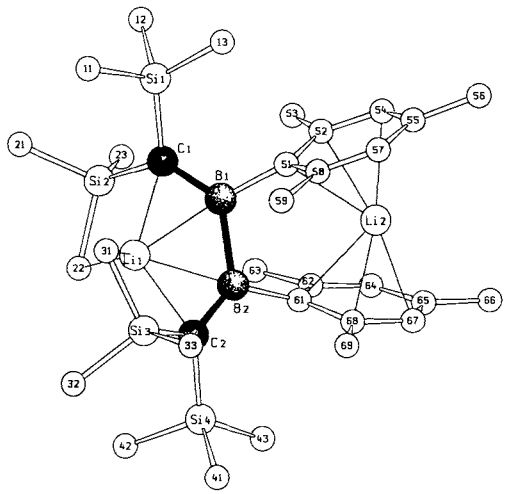


Fig. 1. Schakal drawing of the molecular structure of **3a**. Projection onto the plane B1, B2, Li1, Li2. Important distances [pm] and angles [°]: B1-B2 185.9(8), C1-B1 150.9(8), C2-B2 147.5(8), Li1-C1 213(1), Li1-B1 217(1), Li1-B2 217(1), Li1-C2 214(1), Li1-C22 235(1), Li1-C31 234(1), Li2-C61 238(1), Li2-C68 227(1), Li2-C67 229(1), Li2-C51 234(1), Li2-C52 224(1), Li2-C54 232(1); C1-B1-B2 129.5(5), C2-B2-B1 130.1(5), Si1-C1-B1 119.1(4), Si3-C2-B2 128.4(4), C51-B1-B2 108.7(4), C61-B2-B1 107.4(4); C1-B1-B2-C2 −45.3(8), C1-B1-B2-C61 135.9(5), C2-B2-B1-C51 138.1(5), C51-B1-B2-C61 −40.7(5), Si1-C1-B1-B2 159.1(4), Si1-C1-B1-C51 −24.7(6), Si2-C1-B1-B2 −34.9(8), Si2-C1-B1-C51 141.3(4), Si3-C2-B2-B1 −35.4(8), Si3-C2-B2-C61 143.2(4), Si4-C2-B2-B1 158.7(4), Si4-C2-B2-C61 −22.6(7).

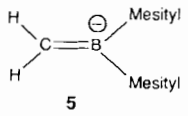
In **3a**, only one lithium ion (Li1) is coordinated to the charge-bearing framework atoms C1, B1, B2, and C2; the other lithium ion (Li2) is found between the mesityl substituents. Li1 displays remarkably short[4] distances to B1 and B2 (217 pm) and short distances to C1 and C2 (213 and 214 pm) as well as to C22 and C31 (235 and 234 pm). Li2 exhibits three short distances to the *ipso*, *ortho*, and *meta* C

[*] Prof. Dr. A. Berndt, Dr. M. Pilz, J. Allwohn, P. Willershausen, Prof. Dr. W. Massa
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

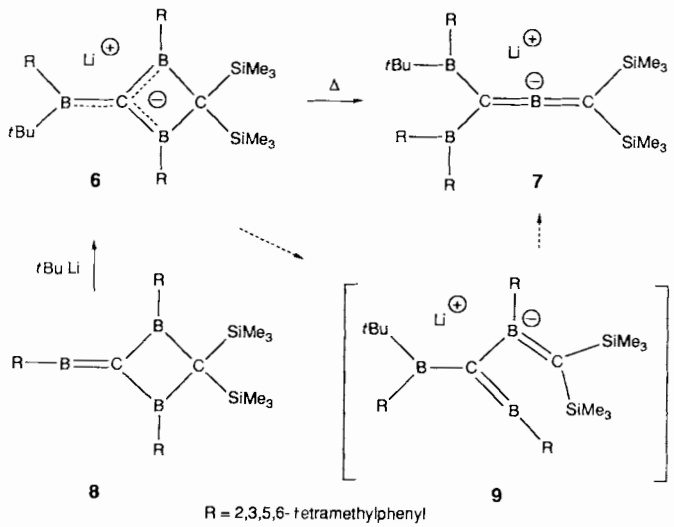
atoms of the mesityl rings. The 2,3-diboratabutadiene dianion is twisted at the C–B bonds by about 30 and 29° and at the B–B bond by about 43°.

The C1–B1 and C2–B2 bonds (151 and 148 pm, respectively) are longer than the C–B bond in planar **5** (144 pm),[5]



5

and the B1–B2 bond (186 pm) is markedly longer than the B–B bond in uncharged diborane(4) derivatives (171–175 pm).[6] This is presumably due to the electrostatic repulsion of the π charges on the boron atoms. The twisting of the



heterobutadiene framework and the resulting chirality[7] explain the diastereotopism of the groups bonded to the *ortho* and *meta* C atoms[8] (see Table 1).

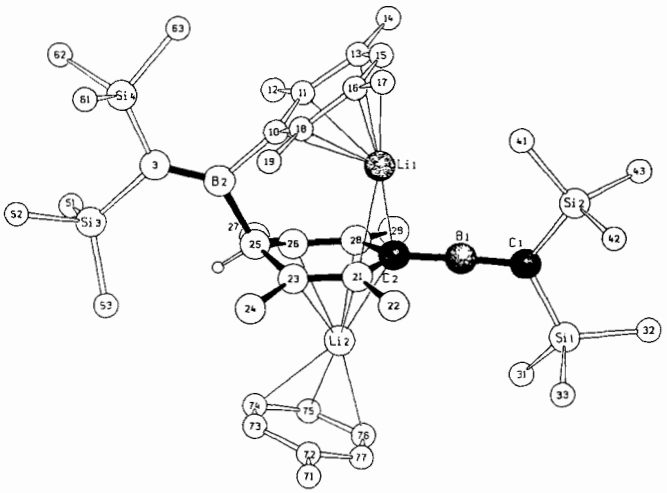


Fig. 2. Schakal drawing of the molecular structure of **4b** · toluene. Projection by 45° onto the plane C1,B1,C2,B2,C3. Important distances [pm] and angles [°]: C1-B1 139(2), C2-B1 142(2), C3-B2 140(2), B2-C25 166(2), B2-C10 163(2), C2-Li1 211(2), C2-Li2 224(2), C10-Li1 232(2), C11-Li1 242(3), C13-Li1 249(2), C15-Li1 243(2), C16-Li1 240(2), C18-Li1 233(2), C21-Li2 226(2), C28-Li2 228(2), C23-Li2 244(2), C26-Li2 237(2); Si1-C1-Si2 117.7(6), C1-B1-C2 177(1), C3-B2-C10 123(1), C3-B2-C25 132(1), C10-B2-C25 105.1(9); Si3-C3-B2-C25 6(2); Si1, Si2, C1-C2, C21, C28 86.4(12).

The structure of **4b** is discussed together with that of the 2-borataallene **7**, formed by heating the 2-boryl-1,3-diboretanide **6** at 200 °C. Presumably, this reaction initially involves a ring-opening to give **9**, a process typical of 1,3-diboretanes.[1] Then, one aryl group undergoes a 1,3-migration from a tri- to the dicoordinated boron atom.[9] Compound **6** is accessible from the methyleneborane **8**[10] and *tert*-butyllithium.

The lithium ions Li1 in **4b** (Fig. 2),[3] which crystallizes with one molar equivalent of toluene, and in **7** (Fig. 3)[3] display short distances to the ring C atoms of the aryl ring on B2 (**4b**, 232–249 pm; **7**, 233–240 pm) and to C2 (211 pm) and C1 (217 pm). In **4b**, Li2 is coordinated by C2 (224 pm), the other sp^2 C atoms of the cyclohexadienyl ring (226–244 pm), and the C atoms C74–C76 (247–253 pm) of the toluene molecule.

The 2-borataallene frameworks in **4b** and **7** are nearly linear (177 and 176°, respectively); the plane Si1, C1, Si2 forms angles of 86 and 85° with the planes C21, C2, C28 and B2, C2, B3, respectively. The C–B distances in the 2-borataallene framework (139 and 145 pm) lie in the range found for the B–C double bonds of the isoelectronic

Table 1. Selected physical data for compounds **3a**, **b**, **4b**, **6**, and **7**. Standard for ^1H and ^{13}C NMR spectra, TMS; for ^{11}B NMR spectra, $BF_3 \cdot OEt_2$.

tions on the highest level.[2] Here we present evidence supporting a true boron–carbon triple bond in the deprotonated borylborataalkynes **2**.[1, 3]

The molecular structure of the bis(diethyl ether) adduct of **2b** is shown in Figure 1. The B1–C2 bond (132.3(9) pm) is exactly as long as that calculated on the highest level for the unsubstituted borataalkyne **4** (132.3 pm).[2, 5] However, be-

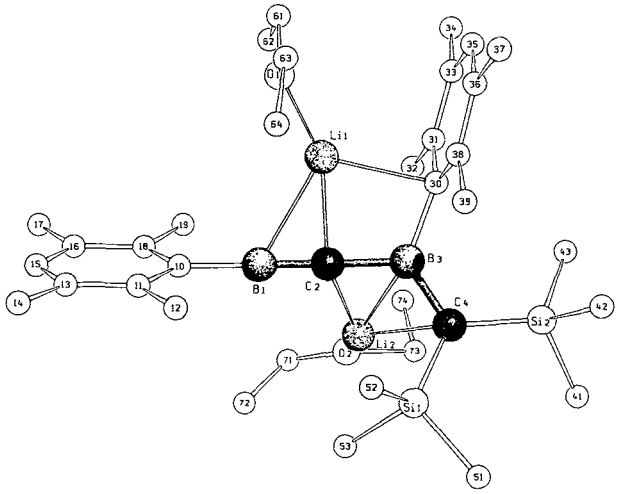

Fig. 1. Schakal drawing of the molecular structure of **2b** · $2Et_2O$. Projection roughly onto the plane C2-C4-C30. Important distances [pm] and angles [°]: B1-C2 132.3(9), C2-B3 154.6(9), B1-C10 156(1), B3-C4 150.5(9), B3-C30 162.8(9), B1-Li1 245(1), C2-Li1 210(1), C30-Li1 228(1), C2-Li2 215(1), B3-Li2 228(1), C4-Li2 226(1); B1-C2-B3 177.2(6), C2-B1-C10 176.3(7), C2-B3-C4 121.9(5), C2-B3-C30 111.7(5), C4-B3-C30 126.3(5), B1-C2-Li1 88.5(5), B3-C2-Li1 91.3(5), C2-Li1-O1 154.1(6), B1-C2-Li2 104.3(5), B3-C2-Li2 74.2(4), C2-Li2-O2 140.4(6) Li1-C2-Li2 142.4(5); C2-B3-C4-Si1 −32.6(8), C2-B3-C4-Si2 169.3(5), C30-B3-C4-Si1 146.5(5), C30-B3-C4-Si2 −11.6(8), Li1-C2-B3-C30 −6.2(6), Li2-C2-B3-C30 138.6(6).

cause of the relatively large standard deviation and the small difference in the B_{sp}–C_{sp} bond lengths in **2b** (132.3 pm) and **1a** (133.9 pm)[1] as well as in **4** (132.3 pm)[2] and **3** (133.8 pm),[2] this agreement alone is not sufficient to prove the existence of a boron–carbon triple bond in **2b**. Also necessary is to show that a delocalization involving resonance structure **B**, which characterizes **1a** as a system with only *partial* B–C triple bond, does not play a significant role in **2b**. This is established by the bond lengths and NMR shifts.

The C2–B3 distance in **2b** (154.6(9) pm) is significantly longer than the corresponding distance in **1a** (149.2(6) pm). In **5a**, whose bond lengths show no evidence of delocalization,[6] the C_{sp}–B_{sp^2} distance is 152.9(6) pm. Furthermore, a delocalization in **2b** should lead to a weakening of the π bond between B3 and C4. The B3–C4 bond in **2b** (150.5(9) pm), however, is relatively short and exhibits only a small twisting (22°), as observed for the B–C double bonds in **6a** (150.9(8) and 147.5(8) pm, 30 and 29°).[7] Additional evidence disfavoring localization of negative π charge on C4, which would be expected for **2B**, is provided by the chemical shifts of C4 (δ = 58.3 for **2a** and 57.9 for **2b**), which are similar to the shift of the corresponding sp^2 C atom in the borataalkene **7b** (δ = 65.3).[8] For *localized* π charge, as in **8**, a value of $\delta(^{13}C)$ = 10.2 is found for the tricoordinated C atoms.[9] The absence of significant delocalization in **2** is also indicated by the greater shielding ($\Delta\delta$ = 15) of the sp boron atoms in **2a, b** (δ = 26) compared with that in **1a, b** (δ = 41).

A Compound with a Boron–Arsenic Double Bond**

By *Mark A. Petrie, Steven C. Shoner, H. V. Rasika Dias,* and *Philip P. Power**

In comparison to boron–nitrogen compounds, species with bonds between boron and the heavier elements of the fifth main group are relatively poorly studied. Nonetheless, recent results have suggested that the variety of boron–phosphorus compounds is potentially as great as that found for their boron–nitrogen counterparts.[1] These new developments have not, however, encompassed heavier congeners with B–As, B–Sb, or B–Bi bonds. In fact, well-characterized compounds having such moieties are extremely rare. Apart

from boron arsenide, BAs,[2] the structures of only two compounds having B–As bonds have been reported to date.[3, 4] Here we describe the synthesis and structural characterization of **1** (Mes = mesityl) and the ion pair **2** (tmeda = *N,N,N',N'*-tetramethylethylenediamine). Both **1** and **2** have a B–As double bond and dynamic ^{1}H NMR studies demonstrate that the B–As rotation barrier is about 21 kcal mol^{-1}.

$[Li(thf)_3PhAsBMes_2]$ **1**

$[Li(tmeda)_2][PhAsBMes_2]$ **2**

The structures of **1** (Fig. 1) and **2** (Fig. 2) were determined by X-ray crystallography.[5] They are interesting for a number of reasons. For example, they are the first structures

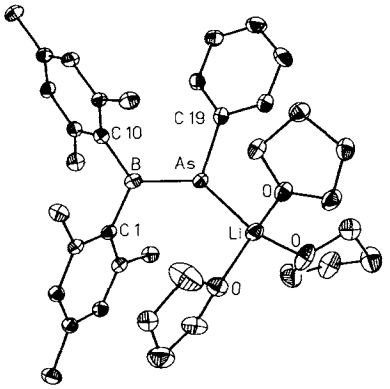

Fig. 1. View of the crystal structure of **1** (H atoms are omitted for clarity). Important bond distances [A°] and angles [°]: B–As 1.926(6), As–C19 1.957(5), As–Li 2.670(9), B–C1 1.613(7), B–C10 1.588(7), Li-O 1.939(9)–1.945(10); 1.945(9), B–As–C19 107.8(2), B–As–Li 122.7(2), Li–As–C19 110.9(2), C1–B–C10 120.3(4), C1–B–As 115.1(3), C10–B–As 124.6(4).

involving bonds between three-coordinate planar boron and approximately sp^2-hybridized arsenic centers. In this respect they resemble their phosphorus counterparts.[6] The B–As bond lengths are 1.926(6) Å (**1**) and 1.936(11) Å (**2**), which

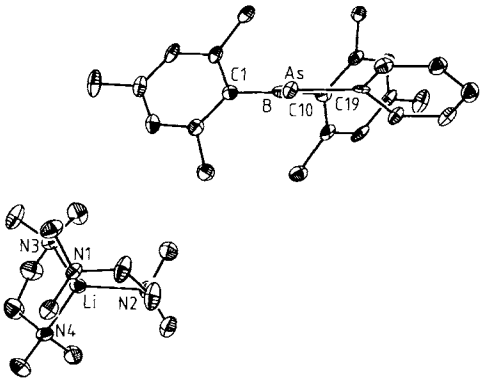

Fig. 2. View of the crystal structure of **2** (H atoms are omitted for clarity). Important bond distances [Å] and angles [°]: B–As 1.936(11), As–C19 1.925(9), B–C1 1.612(16), B–C10 1.595(13), Li–N 2.085–2.146(19), B–As–C19 107.1(4), C1–B–C(10) 118.7(8), C1–B–As 114.8(6), C10–B–As 126.4(8).

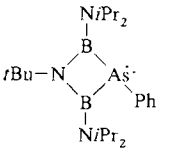
are considerably shorter than the previously reported B–As distances in boron arsenide (2.069 Å)[2] and in the cyclic species **3** (2.063(4) Å).[3] They are longer, however,



3

than the B–As bonds in the Zintl compound K_3BAs_2 wherein the boron is two coordinate in the linear array [As–B–As]$^{3\ominus}$ and the B–As bonds are 1.868 Å long.[4] The difference between this value and those in **1** and **2** can be accounted for mainly in terms of the dissimilarity in the hybridization (sp vs. sp^2) and coordination number of boron (2 vs. 3). The longer distances (ca. 2.06–2.07 Å) in boron arsenide and **3** are consistent with a bond order of 1 since the sum of the radii of B and As is about 2.06–2.07 Å.[7]

Other aspects of the structures of **1** and **2** support B–As double bonding. In both compounds the empty boron p orbital is aligned (interplanar angle between the B-C10-C1 and As–B–C19 planes = 1.1°) with the arsenic p orbital bearing the lone pair so that overlap is maximized. In **1**, although the arsenic center has a nonplanar coordination (sum of angles at arsenic = 341.4°), the As–C19 bond is in the eclipsed configuration with respect to the BC_2 array and it is the Li–As vector which deviates from the molecular plane. The long Li–As distance and the ease with which the $Li^{\oplus}$ ion may be removed to give **2** suggest that the Li–As interaction is mainly ionic. Furthermore, the B–As bond length is virtually unaffected by the removal of the $Li^{\oplus}$ ion and the ^{11}B NMR chemical shift also remains unchanged. This picture of the bonding receives support from theoretical calculations[8] on the related phosphorus species $LiPHBH_2$ in which the $Li^{\oplus}$ cation is also out of the $[PHBH_2]^{\ominus}$ plane.

Variable-temperature ^{1}H NMR data afforded conclusive proof of the multiple-bond nature of the B–As bond. The ^{1}H NMR spectra[9] of **1** and **2** in $[D_{10}]$xylene at ca. 297 K clearly displayed two distinct sets of peaks attributable to the mesityl hydrogens.[10] Heating of this solution, in the case of **1**, to higher temperatures resulted in the coalescence of the *m*-H resonances at 400 K and of the *o*–Me H resonances at 421 K. Substitution of these values and the values for the peak separations measured 10 °C below coalescence ($\Delta\nu$ = 13.8 Hz for *m*–H and 64 Hz for *o*–Me) into an approximate formula[11] afforded the consistent result of 20.9 kcal mol^{-1} for the energy barrier to the dynamic process. This unexpectedly high value is comparable to those found in aminoboranes.[12] The barriers for the corresponding boron phosphorus species—for example, **4**[6]—are not yet accurately known. However, variable-temperature ^{1}H NMR studies[13]

$[Li(Et_2O)_2PhPBMes_2]$ **4**

indicate that the rotation barrier at the B–P bond in **4** is at least 24 kcal mol^{-1}. Work on these and other compounds containing multiple bonds between boron and elements of the fifth main group is continuing.

Experimental Procedure

Compound **1** was prepared, under anaerobic and anhydrous conditions, by the addition of Mes_2BF[14] (1.00 g, 3.72 mmol) to a solution of Li_2AsPh[15] (0.617 g, 3.72 mmol) in THF (50 mL). The red solution was stirred for 3 h and the solvent was removed under reduced pressure. The residue was dissolved in Et_2O (25 mL); the solution was filtered and the filtrate cooled in a −20 °C freezer over 10 h. The resulting orange-red crystals of **1** were isolated by filtration. Yield 59%; m.p. 111–114 °C. ^{11}B NMR: δ = 74.6. Compound **2** was prepared, also under anaerobic and anhydrous conditions, by the addition of two equivalents of TMEDA (0.815 g, 0.24 mL, 3.2 mmol) to an Et_2O (20 mL) solution of **1** (0.99 g, 1.59 mmol). After stirring for 5 min, a finely divided

yellow precipitate appeared. Addition of THF (3–4 mL) resulted in a clear solution and cooling in a −20 °C freezer for 10 h gave the product **2** as orange-red crystals. Yield 0.37 g, 36%; m.p. 140 °C (dec. slow). ^{11}B NMR: $\delta = 74.9$.

[10] It is possible to propose that the inequivalence of the mesityl resonances could be due to a restricted rotation around the B–C bonds. Thus, if the mesityls were locked into a position perpendicular to the boron-C10-C1 plane and if the As–C bond were in the mirror plane (i.e., no B–As π interaction), inequivalent *ortho*-H and *meta*-H resonances would also be observed. This scenario is unlikely because (1) related studies [1] with B–P compounds fail to show any locking in of the mesityl orientations until a very low temperature (−80 °C) is reached, (2) the barrier observed, 20.9 kcal mol^{-1}, is extremely high and incompatible with a rotation barrier around a B–C bond, (3) two *para* peaks are observed for the mesityl groups in the ^{1}H NMR spectrum of **2**, and (4) the X-ray structure supports π interaction.

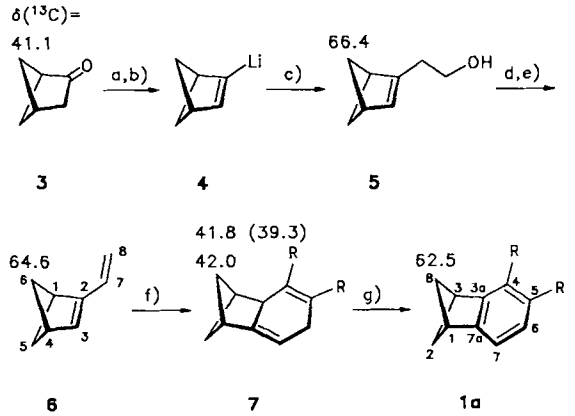
Synthesis and NMR Spectra of 2,3-Dihydro-1,3-methanoindene Derivatives and 1,2,3,5-Tetrahydro-1,3-methanopentalene**

By *Manfred Christl** and *Horst Reuchlein*

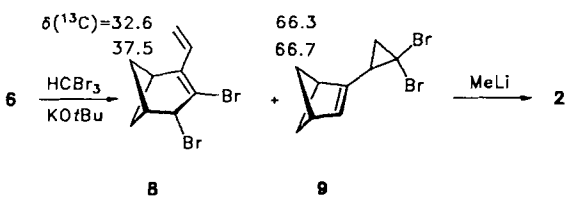
1,3-Bridged cyclobutanes are interesting models for theoretical[1] and spectroscopic[1b, c, 2] studies as well as for comparisons of reactivity.[1c, 3] Nonetheless, little is known about bicyclo[2.1.1]hexene and its derivatives, since they are accessible only with difficulty. The benzo derivative **1** (2,3-dihydro-1,3-methanoindene) is formed as minor product in the reaction of bicyclo[1.1.0]butane with dehydrobenzene[4a] and has also been synthesized in seven steps from benzonorbornadiene.[4b] Its ^{13}C NMR data are still unknown; however, they were recently calculated.[5]

Here we report a route to this system and to 1,2,3,5-tetrahydro-1,3-methanopentalene (**2**). The relatively readily accessible bicyclo[2.1.1]hexan-2-one (**3**)[6] can be converted, via 2-vinylbicyclo[2.1.1]hexene (**6**), into the dimethyl dicarboxylate **1a**, as shown in Scheme 1. The key intermediate is 2-lithiobicyclo[2.1.1]hexene (**4**), formed by reaction of the 2,4,6-triisopropylbenzenesulfonyl hydrazone of **3** with *n*-butyllithium.[7]



Scheme 1.[8] a) 2,4,6-(iPr)$_3$C$_6$H$_2$SO$_2$NHNH$_2$, MeOH, HCl (cat.), 20 °C, 54%. b) 2 equiv. nBuLi, hexane/tetramethylethylenediamine (1:1), −55 to 20 °C. c) 1 equiv. ethylene oxide, 0–20 °C, 49% based on the hydrazone. d) TosCl, pyridine, 90%. e) KOtBu, DMSO, 75 °C, 20 Torr, 82%. f) R-C≡C-R (R = CO_2CH_3), $CHCl_3$, 20 °C, 75%. g) 1 equiv. 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, C_6H_6, 80 °C, 89%.

To synthesize **2**, we first added dibromocarbene to **6** ($CHBr_3$, KOtBu, pentane, −30 °C, 90%; endocyclic: exocyclic addition 1:3) and obtained the rearranged product **8** together with unrearranged **9**.[8] As expected,[9a] reaction of **9** (containing **8**) with methyllithium in ether resulted in a Skattebøl rearrangement to give **2**[8] (4% yield, isolation by preparative gas chromatography).



If the behavior of isodicyclopentadiene and related compounds[9b] can be extrapolated to **2**, then 1,4 additions to the 1,3-cyclopentadiene system of **2** should lead to polycyclic

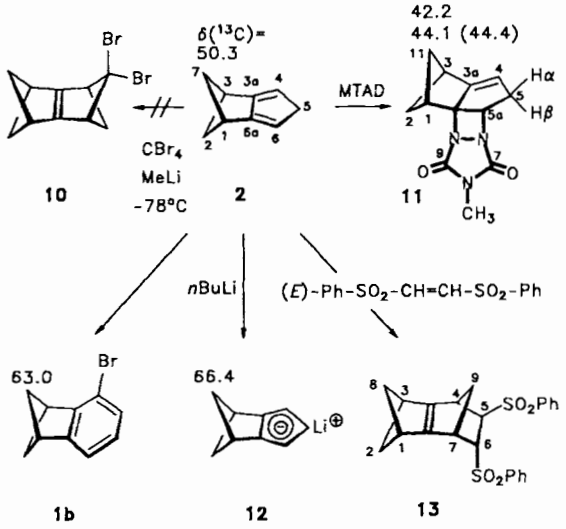
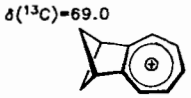
olefins with a strongly pyramidalized double bond between two bridgehead C atoms. An interplanar angle of 145°, instead of 180° as found for normal olefin geometry, was calculated for the parent hydrocarbon of **10**.[10] The hope that, owing to steric hindrance of [2 + 1] cycloaddition by the CH_2 groups of the bicyclohexane system, **2** and dibromocarbene (CBr_4, MeLi, −78 °C) might undergo rare, but known,[11] [4 + 1] cycoladdition to **10** was not fulfilled. Instead, we isolated the bromo derivative **1b**[8] in 23% yield. Compound **1b** is presumably formed by [2 + 1] cycloaddition and ring expansion of the resulting dibromocyclopropane derivative followed by elimination of HBr. Compound **2** also undergoes 1,2 addition with 4-methyl-1,2,4-triazole-3,5(4*H*)-dione (MTAD) (**2** → **11**)[8] as well as with tetracyanoethylene. However, (*E*)-1,2-bisphenylsulfonylethylene undergoes slow Diels–Alder reaction with **2** to give **13**, which, because of its lability, could not be isolated and was only characterized by an ^1H NMR spectrum.



Of particular interest is the ^{13}C NMR spectrum of the cycopentadienyl anion **12**, which we generated by treatment of **2** with *n*-butyllithium. C-2,7 ($\delta = 66.4$) absorb at lower field than C-2,7 of **2** ($\Delta\delta = 16.1$) and than C-2, C-11 of **11** ($\Delta\delta = 22.3$ and 24.2). The latter effect resembles that observed for the C-2, C-8 signals when **7** is converted into **1a**. Remarkably, the methylene C atoms of the tropylium ion **14** ($\delta = 69.0$[12]) are only slightly more deshielded than those of **12** despite the difference in two units of charge.



14 [12]

The annelation of arenes to bicyclo[2.1.1]hexane (C-5: $\delta = 39.4$[2b]) thus causes the methylene C atoms to be strongly deshielded by an amount similar to the difference between the chemical shifts of C-5 in bicyclo[2.1.1]hexane and -hexene ($\Delta\delta = 28.7$).[2b] This effect is correctly reproduced by calculations using the IGLO method.[13] The result of the above-mentioned calculation for the value of C-2 in **1**[5] is 30% too small if **1a**, **b** are accepted as models.

Table 1. Selected physical data for **1a**, **2**, **6**, and **11**–**13**; 200- or 400-MHz ^1H NMR spectra and 50- or 100-MHz ^{13}C NMR spectra (δ values, coupling constants in Hz). H*a* = H*anti*, H*s* = H*syn*, H*c* = H*cis*, H*t* = H*trans*.

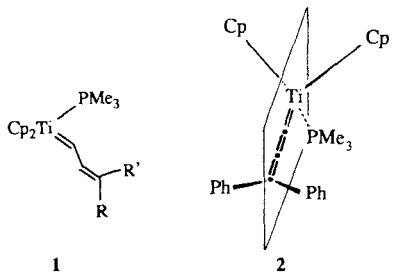
(3,3-Diphenylallenylidene)trimethylphosphanetitanocene: The First Titanocene Carbene Complex with Three Cumulative Double Bonds

By *Paul Binger,* Patrik Müller, Regine Wenz,* and *Richard Mynott*

Titanocene carbene complexes are of interest in organic synthesis, especially for carbonyl olefination. Their use is limited, however, by a lack of suitable syntheses for substituted titanocene carbene complexes.[1] We recently reported a novel method for preparing the titanocene vinylcarbene complexes **1a–c** from 3,3-disubstituted cyclopropenes and bis(trimethylphosphane)titanocene.[2]

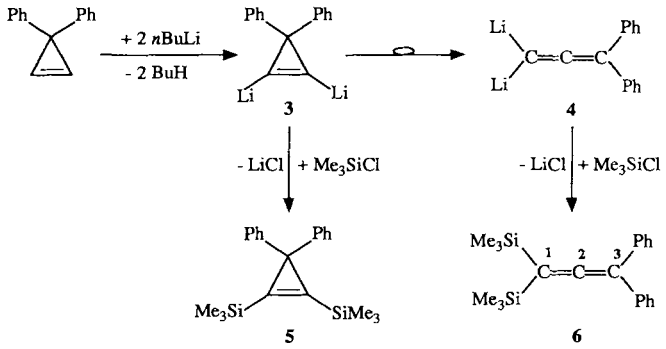
On attempting to carry out a one-pot synthesis of **1a** by treating $[Cp_2TiCl_2]$ with two equivalents of *n*-butyllithium at $-78\,^{\circ}C$ and then allowing the solution to warm up in the presence of PMe_3 and 3,3-diphenylcyclopropene, we found that, in addition to the vinylcarbene complex **1a**, (3,3-diphenylallenylidene)trimethylphosphanetitanocene (**2**) is also formed.[3]



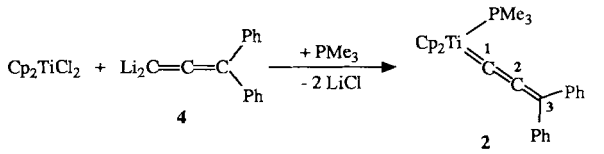
1 **2**

a: R = R' = Ph, **b**: R = Ph, R' = Me, **c**: R = R' = CH_3

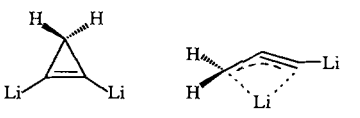
Closer examination of this result showed that *n*-butyllithium lithiates 3,3-diphenylcyclopropene under the conditions chosen.[4] Reaction of the two starting materials in a molar ratio of 2:1 at 0 °C for 1 h gives a mixture of the two dilithiated compounds **3** and **4** in a ratio of 14:86. At 25 °C, only the immediate formation of **4** (90% purity) is observed; **4** slowly decomposes at room temperature to unidentified products. Apparently, the dilithiocyclopropene derivative **3** rapidly rearranges to the dilithioallene derivative **4**. The lithium derivatives **3** and **4** have not yet been isolated as pure substances; they were trapped by reaction with trimethylchlorosilane to give the corresponding trimethylsilyl derivatives **5** and **6**, which were then characterized.



1,1-Dilithio-3,3-diphenylallene (**4**), prepared at 0 °C, reacts at this temperature with titanocene dichloride and trimethylphosphane to give the (3,3-diphenylallenylidene)-titanocene complex **2** in 71% yield. The route of formation of complex **2** is thereby elucidated. At the same time, these results open up a way of synthesizing as yet unknown allenylidenetitanocene complexes.



Also new is the selective rearrangement of a 1,2-dilithiocyclopropene to the corresponding 1,1-dilithiopropadiene. Previously, it was known only that both acidic olefinic hydrogen atoms undergo ready lithiation, although almost all preparative applications have used the monometalated cyclopropene.[4, 5] Dilithiated 3,3-dimethylcyclopropene, prepared from 3,3-dimethylcyclopropene and lithium diisopropylamide/tetramethylethylenediamine (LDA/TMEDA) at $-60\,^{\circ}C$ to $+20\,^{\circ}C$, can be trapped as 3,3-dimethyl-1,2-bis(trimethylsilyl)cyclopropene by reaction with trimethylchlorosilane,[6] even though calculations show that, for the parent compound, structure **B** is 51.3 kcal mol^{-1} more stable than 1,2-dilithiocyclopropene (**A**).[7, 8]



A **B**

Rearrangements of tetrasubstituted cyclopropenes to allenes occur upon irradiation[9] or upon heating at about 150 °C.[5]

The structures of allenylidene derivatives **2** and **6** were established unambiguously by spectroscopy. The IR spectra show strong bands characteristic of both organic[10]

[*] Prof. Dr. P. Binger, Dr. P. Müller, Dipl.-Chem. R. Wenz, Dr. R. Mynott

and organometallic allene systems (**2**, $\tilde{\nu} = 1870$; **6**, $\tilde{\nu} = 1895\ cm^{-1}$).[11] The ^{13}C NMR spectrum of **2** contains three signals for the three C atoms of the cumulene system: $\delta = 264.9$ (C1, $J_{PC} = 31.4$ Hz); 168.3 (C2, $J_{PC} = 7.8$ Hz), 94.0 (C3, $J_{PC} = 13.2$ Hz). C3 was identified by observation of ^3J (C3, H_{ortho}) in the proton-coupled spectrum, whereas C1 and C2 were assigned by taking into consideration the chemical shifts and J_{PC}. Cooling the sample to $-105\,^{\circ}C$ results in no significant changes in the spectrum, thereby excluding dynamic processes The appearance of only one cyclopentadienyl signal (40 °C, $\delta_C = 103.3$., $J_{CH} = 173$ Hz; $\delta_H = 5.66$) and just one set of phenyl signals is consistent with a tetrahedral arrangement of the ligands around the metal atom, such that the molecule has C_s symmetry with P, Ti, and the three C atoms of the cumulene system lying in the mirror plane. The allene resonances of **6** at $\delta = 93.7$ (C1, $^1J_{SiC} = 48.6$ Hz), 210.6 (C2), and 98.0 (C3, $^3J_{SiC} = 5.7$ Hz) lie in the expected range.

Transition-metal allenylidene complexes have so far been described only for metals of the 6th (M = Cr, W),[11] 7th (M = Mn),[12a] and 8th (M = Ru)[12b] subgroups. All these metal complexes have been synthesized via other routes, however. The existence of a 1,1-dilithioallene derivative has not yet been demonstrated unequivocally; for example, dilithiation of allene gives a dilithium derivative, which, after derivatization with trimethylchlorosilane, affords 1,3-bis(trimethylsilyl)propyne.[13] Reaction of dilithiated 3-methylbutyne with trimethylchlorosilane yields 1,3-bis(trimethylsilyl)-3-methylbutyne.[14] We are currently studying the synthetic possibilities offered by the new compounds **2** and **4**.

Experimental Procedure

2: 11 mL (1.8 mmol) of a 0.16 M solution of *n*-butyllithium in hexane was added to a solution of 3,3-diphenylcyclopropene (0.17 g, 0.9 mmol) in 10 mL of THF at −45 °C. The orange solution was allowed to warm to 0 °C and stirred at this temperature for 1 h. Trimethylphosphane (0.2 mL; 0.27 g, 3.5 mmol) and a solution of titanocene dichloride (0.22 g, 0.9 mmol) in 10 mL of THF were then added in succession. The violet reaction solution was stirred at 13 °C for 6 h, the solvent mixture removed at 10^{-3} torr, the residue dissolved in 25 mL of toluene, the LiCl removed by filtration, and the filtrate concentrated to dryness at 10^{-3} torr. Washing the product with pentane and drying at 10^{-3} torr afforded 0.28 g (71%) of **2** as a dark violet powder (dec. above ca. 70 °C).

6: In analogy to the above procedure, a solution of 3,3-diphenylcyclopropene (96 mg, 0.5 mmol) in 10 mL of THF at 0 °C was allowed to react with 7 mL (1.1 mmol) of a 0.16 M solution of *n*-butyllithium in hexane for 1 h. The resulting orange-yellow solution was then treated with trimethylchlorosilane (120 mg, 1.1 mmol) in 5 mL of THF. The reaction mixture was stirred for 1 h and the solvent then removed at 10^{-3} torr. The product consisted of 269 mg (80%) of a yellow oil having the following composition (GC): **5** (13%), **6** (80%), and six unidentified compounds (7%).

An Efficient Route to Linear Conjugated Triepoxides: *allo-*, *galacto-*, and *altro*-Type Trianhydrohexitols **

By *Jürgen Kammerer*, *Grety Rihs*, and *Horst Prinzbach**

The *cis/trans*-isomeric tris-σ-homobenzenes, like the benzene trioxides **1**[1,2] and **2**,[3,4] differ in their thermal stability, that is, in their propensity to undergo [σ2 + σ2 + σ2] cycloreversion.[5] For the mechanistically relevant assessment of kinetic parameters, the thermochemical data[6] for **1** and **2**, as well as those for the linear conjugated 3,4-*cis*-triepoxyhexanes **3**–**5**, 1,2:3,4:5,6-trianhydro derivatives of *meso*-allitol, *meso*-galactitol (dulcitol), and *rac*-altritol,[7] are of interest.

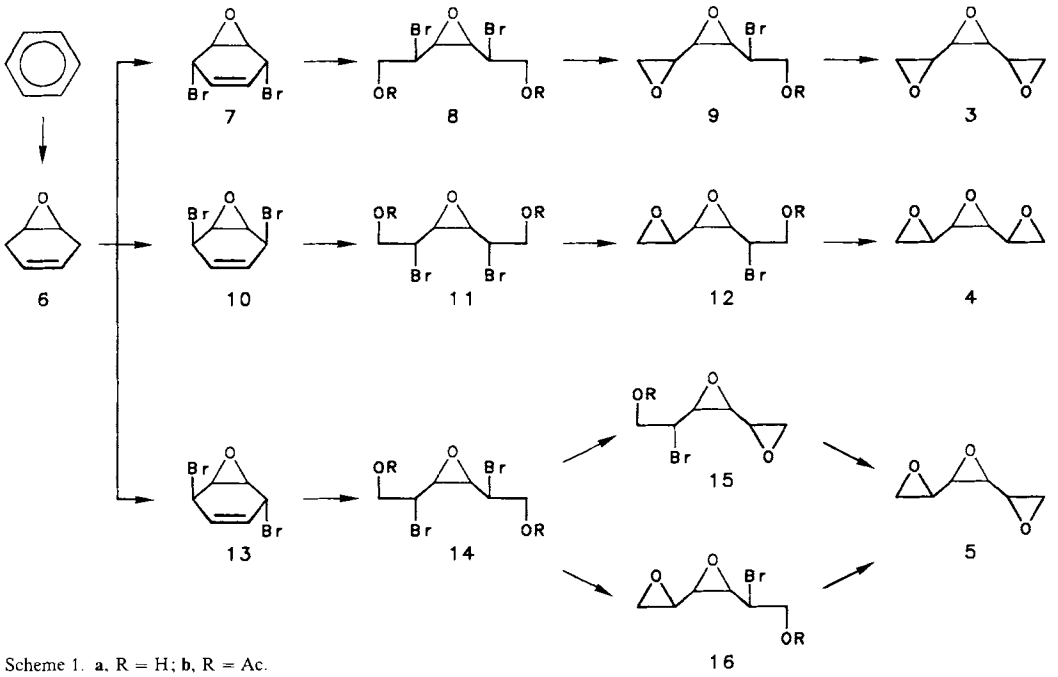

Scheme 1. a, R = H; b, R = Ac.

Triepoxides **3**–**5**, which, like **1**,[5, 8] are attractive as C_6 building blocks, are not yet accessible from sugar precursors. We prepared them in close analogy to the synthesis of **1**[1] (Scheme 1).[9, 10] Starting materials are the dibromides **7**, **10**, and **13**, interconvertible by equilibration and thus directly and efficiently accessible from epoxycyclohexene (**6**).[11] Their oxidative cleavage with ozone (**13** reacts only slowly) leads, after reductive workup,[12] to consistently high yields (85–92%) of the 2,5-dibromo-3,4-epoxy-1,6-hexanediols **8a** (*meso-galacto*, m.p. 97–99 °C, $J_{2,3(4,5)} = 7$ Hz, $CDCl_3$), **11a** (*meso-allo*, m.p. 115°–117 °C, $J_{2,3(4,5)} = 9$ Hz), and **14a** (*rac-altro*, m.p. 78 °C, $J_{1,2} = 5.3$, $J_{1',2} = 4.5$, $J_{2,3} = 9.8$, $J_{3,4} = 3.9$, $J_{4,5} = 9.8$, $J_{5,6} = J_{5,6'} = 4.8$ Hz); they were also characterized as diacetates **8b**, **11b**, and **14b**.

In carrying out the epoxide cyclizations to **3**–**5**, competing cyclizations (including 6-*exo*-pyran formation) and, above all, the reactivity of the intermediates and end products must be considered a priori. Indeed, reaction of **8a**, **11a**, and **14a** in protic solvents in the presence of various bases leads to very complex mixtures of products. However, in aprotic medium (ca. 10^{-2} M THF solutions) with NaH as base and at a reaction temperature of 0–20 °C or under phase-transfer conditions (CH_2Cl_2, nBu$_4$NBr, KOH, room temperature), the epoxide cyclizations proceed with almost no competing reactions; continuous TLC and ^{1}H NMR monitoring reveals no products other than 2-bromo-3,4:5,6-diepoxy-1-hexanols **9a** (*altro*),[14] **12a** (*talo*), **15a** (*galacto*), and **16a** (*allo*), formed with inversion, as well as triepoxyhexanes **3** (*allo*), **4** (*galacto*), and **5** (*altro*). The use of 2.1 equivalents of NaH results in practically exclusive formation of triepoxides **3** (m.p. ca. 30 °C), **4** (m.p. 74 °C), and *rac*-**5** (oil) (0.1 M runs, yields 82–95%). On the other hand, the direct preparation of the diepoxy intermediates is, as expected, problematic: only in the case of **8a** does the use of 1.0 equivalent of NaH lead to selective formation of the diepoxide (**9a**, 90%, oil; $J_{2,3} = 9.5$, $J_{4,5} = 5.5$ Hz);[9] from **11a** or **14a**, however, ca. 1:1 mixtures containing **4** and **12a** or **5** and **15a**/**16a** are obtained. The kinetic and thermodynamic details of these reactions are not known.

Unlike **1** and **2**, triexpoxides **3**–**5** are readily soluble in chloroform, dichloromethane, water, acetonitrile, ethanol, acetone, and tetrahydrofuran; they are sparingly soluble in benzene and tetrachloromethane and nearly insoluble in petroleum ether. The ^{1}H and ^{13}C NMR spectra, which are invariant between +30 and −65 °C (Fig. 1), indicate (average) C_s symmetry for **3** and **4**. Moreover, the hardly differing ^{1}H and ^{13}C NMR chemical shifts and $J_{2,3(4,5)}$ coupling constants (5–6 Hz) are an indication that the "open" unsymmetrical conformations (H–C2(5)–C3(4)–H torsion angle of >150°) generally predominate. The ^{1}H NMR spectra—unlike those of **1**[15]—are not significantly affected by addition of metal ions. The X-ray structure analysis of **4** reveals only approximate C_s symmetry in the crystal (Fig. 2)[16] and manifests, especially with respect to the C–C bond lengths, overall agreement between the linear conjugated triepoxide **4** (average *exo*/*endo* 1.473/1.461 Å) and the cyclic conjugated **1** (*exo*/*endo* 1.487/1.471 Å[17]).

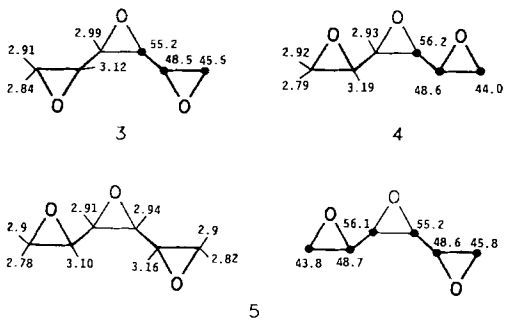

Fig. 1. ^{1}H and ^{13}C NMR chemical shifts for **3**–**5** (400 MHz, $CDCl_3$, ca. 30 °C).

The preparative potential of these linear conjugated triepoxides as C_6 building blocks was demonstrated by the following model reactions. Terminal S_N2 nucleophilic addition to **3** gives the dianhydrohydroxylates **17**. The 5-*exo* ring closure of **17** to give **18** was expected in principle to be highly favored kinetically over the main competing reactions, epoxide migrations (Payne rearrangements). Indeed, in buffered

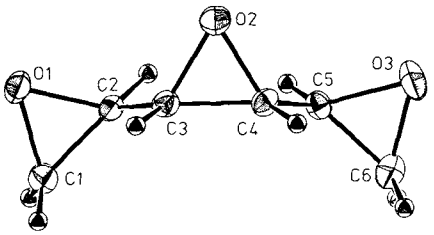

Fig. 2. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: C1-C2 1.460(6), C2-C3 1.481(5), C3-C4 1.468(5), C4-C5 1.465(5), C5-C6 1.455(6), C1-O1 1.443(6), C2-O1 1.450(4), C3-O2 1.444(5), C4-O2 1.451(5), C5-O3 1.441(4), C6-O3 1.434(6); C1-C2-O1 59.5(2), C1-O1-C2 60.6(2), O1-C1-C2 59.9(3), C3-C4-O2 59.3(2), C3-O2-C4 61.0(3), O2-C3-C4 59.7(3), C5-C6-O3 59.8(2), C5-O3-C6 60.8(3), O3-C5-C6 59.4(3); H2-C2-C3-H3 171.3(4.3), H4-C4-C5-H5 −178.2(2.9), O1-C2-C3-O2 −96.5(0.4), O2-C4-C5-O3 96.0(0.3).

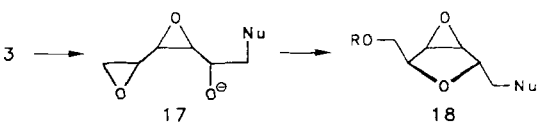
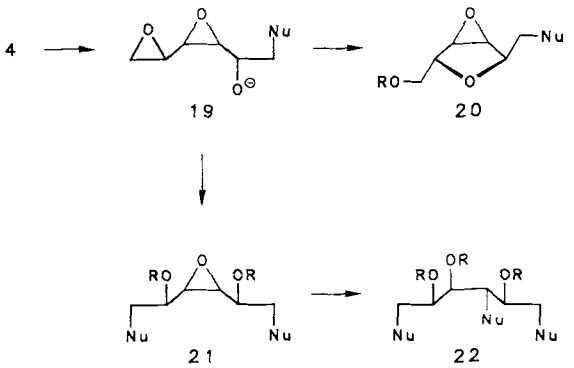
aqueous solution (pH 7–8, 50 °C, Na_2HPO_4/KH_2PO_4), exclusively diol **18a** is formed; reaction with 1.0 equivalent each of NaN_3 (70 min), $NaSCH_2C_6H_5$ (3.5 h), or NaCN (5 h) affords derivatives **18b–d**, respectively (>90%). Even a very large excess of nucleophile (50.0 equivalents) does not result in significant double terminal addition (C1, C6); instead, **18** increasingly undergoes subsequent reaction.



R = H: **a**, Nu = OH; **b**, Nu = N_3; **c**, Nu = $SCH_2C_6H_5$; **d**, Nu = CN

The conformational situation for furan formation (**20**) is predictably less favorable for the primary hydroxylates **19** (obtained from **4**) than for **17**. As a result, an increase in the concentration of nucleophile and the reaction time (under otherwise identical conditions) allows 1,6-bis (**21**) and 1,3,6-



R = H: **a**, Nu = N_3; **b**, Nu = NH_2

tris (**22**) adducts to be prepared directly. For example, reaction with 1.0 equivalent of NaN_3 (3 h) results in a mixture of 70% **20a** and 30% **21a**; with 10.0 equivalents of NaN_3 (40 min), 10% **20a**, 85% **21a**, and 5% **22a** are obtained; with 50.0 equivalents of NaN_3 (70 h), **22a** is formed quantitatively. The latter can be reduced catalytically to give exclusively triaminotriol **22b**.

On the other hand, 1,3-diphenyl-1,3-propanedione (**1a**) is known to react smoothly with **2a** in diethyl ether to give 4-benzoyl-2,3-dioxo-5-phenyl-2-3-dihydrofurans **4a**.[2] Under the same conditions, we obtained 5-*tert*-butyl-2,3-dioxo-4-pivaloyl-2,3-dihydrofuran (**4b**) from **1b** and **2a** (Table 1).

Facile Synthesis of 4-Acyl-5-alkyl-2,3-dioxo-2,3-dihydrofurans and Alkylidenebutenolides**

By *Rolf W. Saalfrank** and *Thomas Lutz*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 65th birthday

Earlier we obtained the tetranuclear metal chelate complexes **3** by reaction of diethyl malonate with methylmagnesium iodide or the system methyllithium/metal dichloride and with oxalyl chloride (**2a**) at −78 °C in tetrahydrofuran followed by workup with aqueous ammonium chloride solution.[1] Our attempts to generalize this concept have failed so far. Under the conditions employed, α, γ-dicarbonyl compounds with alkyl or aryl substituents do not undergo *spontaneous self-assembly* to form *adamantanoid* chelate complexes of type **3**.

Apparently, the situation is completely different for α,γ-diketones **1c–f** containing at least one α-hydrogen in R^1 and/or R^2. *Ziegler* et al.[2] have reported that they were unsuccessful in preparing the analogous furan-2,3-diones **4** by reaction of acetylacetone (**1c**), benzoylacetone (**1f**), etc, with **2a**. In principle, however, it should be possible for the reaction of such α,γ-diketones and **2a** either to give tetranuclear chelate complexes of type **3** via template coupling or to afford furan-2,3-diones **4** via intramolecular ring-closure.

[**] 4-Acyl-5-alkyl-2,3-dioxo-2,3-dihydrofurans, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Our experience with metal-assisted synthesis of tetranuclear chelate complexes **3** made it reasonable to attempt the reaction of α,γ-diketones containing an α-hydrogen with **2a** in diethyl ether in the presence of magnesium chloride.[3] Under these conditions, we obtained the previously unknown compound 4-acetyl-5-methyl-2,3-dioxo-2,3-dihydrofuran (**4c**) from **1c** and **2a**. According to the ^{1}H NMR spectrum, **4c** exists exclusively in the keto form in deuterochloroform at −55 °C (Table 1). At 27 °C, however, **4c** is in equilibrium with approximately 10% of the corresponding enol **5a**.

Surprisingly, the magnesium chloride-induced reaction of the unsymmetrically substituted diketones **1d, e** with **2a** proceeds both *regio-* and *stereospecifically* and affords exclusively enols **5b, c** (Table 1). The information provided by an *NOE* difference spectrum of the silyl enol ether **6b** supports the *Z* configuration proposed for the alkylidenebutenolides **5b, c**. Enols **5a–c** react readily with bromotrimethylsilane in the presence of hexamethyldisilazane to give the corresponding silyl enol ethers **6a–c**; compound **6a** is very sensitive, whereas **6b** and **6c** can be easily purified by kugelrohr distillation (Table 1).

Table 1. Data for the compounds **4b, c, f, 5b, c**, and **6a–c**[a].

4b: 7.7 g (65%), m.p. 94 °C (from $CHCl_3$). MS: *m/z* 240 ($M^{\oplus}$)

6c: 2.4 g (91%), b.p. 91 °C/0.04 Torr. IR: $\tilde{\nu}$ = 1760, 1680 (C=O), 1600 cm^{-1} (C=C). ^{1}H NMR: δ = 0.18 (s, 9H, $Si(CH_3)_3$), 1.18 (d, 6H, CH_3), 2.45 (s, 3H, CH_3), 2.85 (m, 1H, CH), 5.88 (d, 1H, =CH). ^{13}C NMR: δ = 0.82 ($Si(CH_3)_3$), 22.67, 31.72 (CH_3), 25.72 (CH), 122.67, 123.36, 141.12, 145.75 (=C), 164.95, 193.21 (C=O). MS: *m/z* 268 ($M^{\oplus}$)

[a] IR spectra: IR-5 instrument (Beckman), in KBr, except for **6b, c** (neat) ^{1}H/^{13}C NMR spectra: JNM GX-400 instrument (Jeol); solvent, $CDCl_3$, TMS int., except for **4f** ([D_6]acetone). Mass spectra: Varian MAT-CH-4B, direct inlet, 70 eV.

The reaction of benzoylacetone (**1f**) with **2a** in the presence of magnesium chloride is much more complicated and gives a mixture of substances that is very difficult to separate. On the other hand, reaction with oxalyl bromide (**2b**) under otherwise identical conditions smoothly leads to 4-acetyl-2,3-dioxo-5-phenyl-2,3-dihydrofuran (**4f**) (Table 1). Moreover, we found that the use of the more reactive **2b** obviates the necessity of activating **1f** by addition of magnesium chloride. The new procedure is a considerable extension of the methods previously used for the synthesis of 2,3-dioxo-2,3-dihydrofurans[2, 4] and is strikingly simple to carry out.

Experimental Procedure

4b: A solution of **2a** (6.35 g, 50 mmol) in 20 mL of *n*-hexane was added dropwise over 0.5 h to a solution of **1b** (9.2 g, 50 mmol) in 30 mL of diethyl ether. Yellow crystals of **4b** were collected after 3 d.

4c, 5b, c: Magnesium chloride (1.2 g) was added to a solution of **1c–e** (50 mmol) in 50 mL of diethyl ether and the resulting mixture was added over 0.5 h to a vigorously stirred solution of **2a** (6.35 g, 50 mmol) in 25 mL of *n*-hexane at 0 °C (−10 °C for **4c**). After a reaction time of 3 h at 20 °C (−10 °C for **4c**), 25 mL of *n*-hexane was added, the reaction solution was filtered, the filtrate was concentrated to 30% using a rotory evaporator (water bath temperature 20 °C for **4c**), and the crystals were isolated (in the dark for **4c**).

Compound **4f** was obtained analogously (addition of magnesium chloride was not necessary) from **1f** (8.11 g, 50 mmol) and **2b** (10.79 g, 50 mmol).

6b, c: Hexamethyldisilazane (1.78 g, 11 mmol) and bromotrimethylsilane (1.84 g, 12 mmol), each in 5 mL of diethyl ether, were added in succession to a solution of **5b, c** (10 mmol) in 30 mL of diethyl ether at −78 °C. The resulting reaction mixture was allowed to warm over 20 h to 20 °C and filtered. The solvent was removed with a rotory evaporator and the product distilled.

Tetraphenylallylsodium Diethyl Ether: A Contact Ion Pair with an Intramolecular $Na^{\oplus}$ Sandwich**

By *Hans Bock,* Klaus Ruppert, Zdenek Havlas*, and *Dieter Fenske**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The successful growth of a single crystal of the paramagnetic contact ion pair $[(fluorenone^{\bullet\ominus})\{Na^{\oplus}(dme)_2\}]_2$ (dme = dimethoxyethane)[2] has been our starting point in the use of MNDO energy hypersurface calculations to discover other organic salts in which positive or negative charges bring about similarly amusing perturbations, such as the twisting of the two molecular halves in ethene di-

[**] Structures of Perturbed π Systems, Part 4, and Electron Transfer and Ion Pair Formation, Part 19. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Alexander von Humboldt-Stiftung (*Z. H.*), and the State of Hesse. Parts 3 and 18: [1a] and [1b].

cations $((H_3C)_2N)_2^{\oplus}C\text{–}C^{\oplus}(N(CH_3)_2)_2$[3] and dianions $(H_5C_6)_2{}^{\ominus}C\text{–}C^{\ominus}(C_6H_5)_2$.[1a] For molecular anions, one observes, in addition, that infinite contact-ion-pair strings[1a] or even three-dimensional networks[4] are formed around the countercations with their usually high-coordination-number dimers;[2] these structures may contain rather surprising connecting links, such as intermolecular "dibenzene sodium sandwich" double cones.[1a]

Our procedure for semiempirical "molecule screening" will be illustrated by the twisted π-hydrocarbon allene, for which MNDO calculations[5] support the sequence of electron transfers and protonation shown in Figure 1 as a speculative redox pathway for formation of contact ion pairs. Obviously, the gas-phase structure of allene[2] is satisfactorily reproduced by the lowest-energy MNDO structure and the single electron transfer to its radical anion should reduce the dihedral angle by about half. The second reduction to the dianion should require considerably more energy (Fig. 1: $\Delta\Delta H_f^{MNDO}$ $(D_2 \rightarrow C_{2v}) \approx 660$ kJ mol^{-1}) and cause dramatic

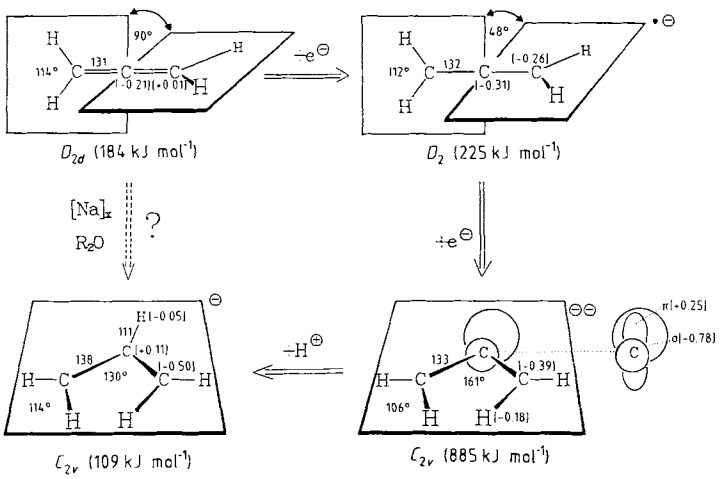

Fig. 1. MNDO geometry-optimized structures of allene, its radical anion and dianion, and the protonation product of the latter, allyl anion, together with MNDO enthalpies of formation ΔH_f° [kJ mol^{-1}] and MNDO charge distributions q_μ (bond lengths in pm).

structural changes: thus, the molecular skeleton should be flattened and bent (Fig. 1: $\sphericalangle$ CCC = 161°), thereby forming a nonstabilized and therefore extremely basic carbon σ lone pair (Fig. 1: $q_{C,\sigma}^{MNDO} = -0.78$). Its protonation (e.g., by the ether solvent) may then result in an allyl anion with each half of the negative charge at the outer carbon centers (Fig. 1: $q_C^{MNDO} = -0.50$).

Well invented? Reacting tetraphenylallene in diethyl ether, which had been dried over Na/K ($c_{H^{\oplus}} < 1$ ppm), at room temperature and under Ar with a sodium mirror produced by vacuum distillation[7] (cf. Ref. [1a]) generates a dark red solution,[8] from which black crystals with a metallic luster deposit.[9] The crystal structure of tetraphenylallylsodium diethyl ether (**1**) (Fig. 2) largely corresponds to that calculated for the allyl anion (Fig. 1): C–C distances of approximately 139 pm and a C–C–C bending angle of approximately 130° are found.

A striking feature of the structure of **1** (Fig. 2) is the intramolecular cage of the two phenyl rings facing each other: it encapsulates the $Na^{\oplus}$ countercation and is sealed by a "solvate plug" consisting of a coordinated diethyl ether in W conformation. A literature search for analogous compounds with a similar "intramolecular alkali-metal-cation sandwich" proved fruitless.

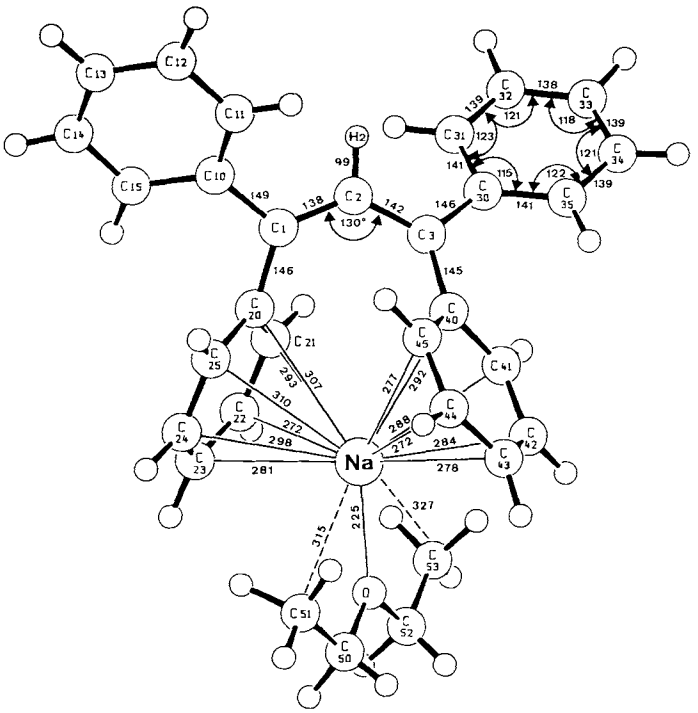

Fig. 2. Molecular structure of **1** [9]. Significant distances [pm, ±0.8] and angles [°, ±0.3]: C1-C2 138, C2-C3 142, C2-H2 99, C1-C(ring) 145, C3-C(ring) 149, C-C(ring) 139, Na···C(ring) 272–310, Na-O 225, O-C50 144; C1-C2-C3 130, C10-C1-C20 117, C30-C3-C40 120, (C50-O-C52 113, C10-C1-C20)/(C30-C3-C40) 46, (C11-C10-C15)/CC1-C2-C3) 40, (C31-C30-C35)/(C1-C2-C3) 49, (C21-C20-C25)/(C1-C2-C3) 58, (C41-C40-C45)/(C1-C2-C3) 55.

Extensive MNDO energy hypersurface calculations for the model compound diphenylallylsodium diethyl ether,[5, 11] the energy minimum of which is represented by the computed structure in Figure 3a, plausibly explain the formation of the intramolecular sodium sandwich: the diphenylallyl anion in its energy-favored C_2 structure, with the opposing phenyl rings each turned around their C_{allyl}–C_{phenyl} axes by 41°, exhibits a total negative charge of $\Sigma q_C = -0.47$ at the five "outer" ring carbons; this charge exceeds that calculated for one of the allyl carbons (−0.36) (Fig. 3b). If the $Na^{\delta\oplus}$ countercation is fixed in the calculations at one of the charge-bearing allyl anion centers, therefore, it moves along a barrier-free path on the MNDO hypersurface to the point of maximum contact-ion-pair interaction between the two phenyl rings facing each other at an acute angle (Fig. 3b). The calculated total charge at the Na center amounts to +0.34; that is, for the $Na^{\oplus}$ allyl anion salt described here, predominantly covalent complexation is predicted. The largest single contribution to the MNDO enthalpy of formation is made by the ether solvate plug in W conformation.

Altogether, the structure determination of carefully grown single crystals of organic salts is of current interest for two reasons.[1] Novel bonding possibilities,[1] such as the intramolecular $Na^{\oplus}$ sandwich, are discovered and hints con-

[9] Crystal structure analysis: $C_{27}H_{21}Na \cdot O(C_2H_5)_2$, $a = 898.1(6)$, $b = 1666.8(19)$, $c = 1660.6(9)$ pm, $\beta = 92.41(3)°$, $V = 2483.7 \times 10^6$ pm^3 (200 K), space group $P2_1/n$, $Z = 4$, $\mu(Mo_{K\alpha}) = 0.7$ cm^{-1}, STOE STADI IV four-circle diffractometer, 2θ region: 3–56°, ω scan, 5955 reflections found, of which 3364 are independent with $I > 2\sigma(I)$, structure determination by Patterson methods, SHELXS-86, SHELX-76, SCHAKAL, $R = 0.066$, $R_w = 0.042$; C, O, Na positions anisotropically refined, all H positions found and isotropically improved. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54698, the names of the authors, and the journal citation.

[10] Known are numerous "alkali-cation half-sandwich" compounds (cf. the reviews by W. N. Setzer, P. von R. Schleyer, *Adv. Organomet. Chem. 24* (1985) 353; C. Schade, P. von R. Schleyer, *ibid. 27* (1987) 169) as well as our *inter*molecular "$Na(C_6H_5)_2$ complex" between each two tetraphenylethene dianion–$Na^{\oplus}$ contact ion pairs [1a]. *Intra*molecular bis(μ^3-benzylidene)phosphonium complexes of $Na^{\oplus}$ and $K^{\oplus}$ are reported by H. Schmidbaur, U. Deschler, B. Milewski-Mahrla, B. Zimmer-Gasser, *Chem. Ber. 115* (1981) 608. Also important in this context is the structure determination of $C_3H_5Li \cdot$ pmdta by E. Weiss, U. Schürmann, H. Dietrich, W. Mahdi, *J. Organomet. Chem. 332* (1987) 299, $C_3H_5Li \cdot$ tmeda by H. Köster, E. Weiss, *Chem. Ber. 115* (1982) 3422, and of 1,3 diphenylallyllithium diethyl ether by G. Boche, H. Etzrodt, M. Marsch, W. Massa, G. Baum, H. Dietrich, W. Mahdi, *Angew. Chem. 98* (1986) 84; *Angew. Chem. Int. Ed. Engl. 25* (1986) 104.

[11] The MNDO calculations have been performed using the program SCAMP IV/1 kindly provided by *T. Clark* (Universität Erlangen-Nürnberg) and the VAX 11/750 of our group; the Na parameters used are specified in [5]. From the experimentally determined structure only the data of the phenyl rings have been adopted, all other bond lengths and angles are optimized. The MNDO enthalpies of formation ΔH_f° [kJ mol^{-1}] are: diphenylallyl anion, +211; diphenylallylsodium, −218; diphenylallylsodium diethyl ether, −539. Experimental (Fig. 2) and calculated structure data (Fig. 3b) agree satisfactorily with the exception of the too short Na–C_{phenyl} distances and the exaggerated Na–O coordination bond length, resulting from the accompanying steric overcrowding.

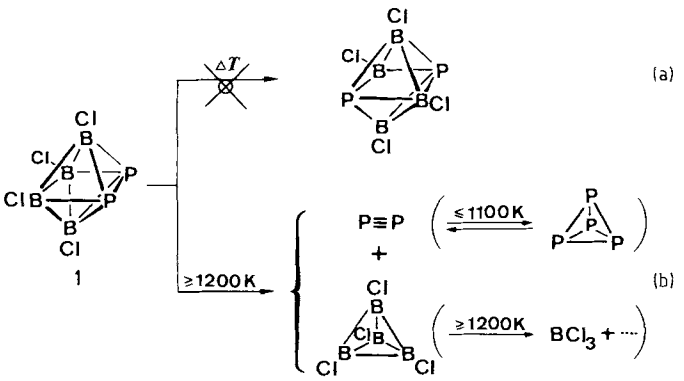
[**] Gas-Phase Reactions, Part 79. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the States of Hesse and Baden-Württemberg. Part 78: H. Bock, M. Bankmann, *Phosphorus, Sulfur, Silicon Relat. Elem.* (1990), in press; cf. also Part 77, *ibid. 49* (1990) 3.

can presently neither be imagined nor rationalized, owing to the prohibitive number of internal degrees of freedom $(3n-6)$,[1, 2b] according to which a 10-center molecule fills a 24-dimensional hyperspace. Nevertheless, chemists can contribute partial solutions to this fundamental problem, for example, by synthesizing suitable precursors for thermolytic fragmentations, which allow the identification of short-lived[2c] and sometimes "chemically activated"[2d] intermediates. Based on the experimental data, additional energy hypersurface calculations along selected molecular-dynamics coordinates afford approximative insight into the microscopic reaction pathways.

The title compound, $(ClB)_4P_2$, a *closo*-1,2-diphosphahexaborane, recently prepared by copyrolysis of Cl_2BBCl_2 and PCl_3,[3a] is selected as a model, because electron-deficient clusters can be transformed in competing thermal reactions by either rearrangement [Eq. (a)] or elimination of "leaving molecules" [Eq. (b)], thereby improving the electronic configuration. Textbook examples are the *ortho* → *meta* → *para* isomerization of the icosahedral carborane $B_{10}C_2H_{12}$ and the pyrolytic dehydrogenation of B_2H_6 to $B_{10}H_{14}$.[3b] Upon gas-phase thermolysis under close to unimolecular conditions in a white-hot flow-pyrolysis tube (Fig. 1: $p \approx 10^{-4}$ mbar, $T > 1200$ K, PE-spectroscopic real-time analysis[2]), the nonmetal octahedron investigated here, **1**, chooses selective expulsion of the diphosphorus molecule, P≡P [Eq. (b)], analogous to N_2. The dimerization to the phosphorus tetrahedron, $2P_2 \rightleftarrows P_4$, has already been investigated by PE spectroscopy under similar flow conditions[4a] and becomes quantitative only below 1100 K. The other fragmentation product, the B_4Cl_4 tetrahedron,[4b] disproportionates largely to BCl_3 and boron[4] at these rather high pyrolysis temperatures (Fig. 1).



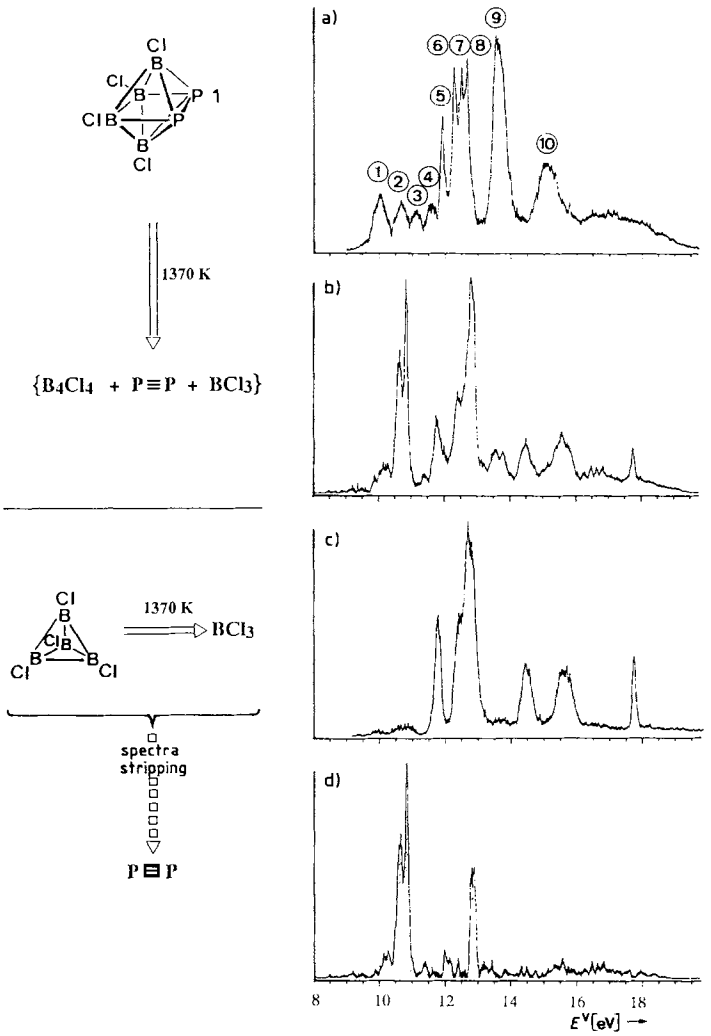


Fig. 1. He(I) PE spectra of $(ClB)_4P_2$, **1** (a), and its 1370 K pyrolysis mixture (b) as well as that of B_4Cl_4 (c) at the same temperature and the one resulting after digital subtraction (d) [2c], which satisfactorily resembles that of P_2 [4a]. E^V = vertical ionization energy. For the assignment of ①–⑩, see [5].

The selective thermal expulsion of an octahedral edge to give a tetrahedron [Eq. (b)] is surprising and novel. Topologically, six bonds have to be broken—as also on fragmentation into two three-membered ring radicals, $(ClB_2)P^{\bullet}$—that is, two more than on elimination of an octahedral center, for example, of BCl to yield the presumably trigonal-bipyramidal *closo*-$(ClB)_3P_2$. An energetically favored decomposition of **1** into B_4Cl_4 and P_2 is in accord with the assumed distribution of the 14 skeletal electrons over one σ_{pp}, two σ_{BBB}, and four σ_{BBP} bonds[5] as well as with the prediction that the reaction pathway, starting from the known C_{2v} molecular structure of **1**[3a] and proceeding in the direction of an internal a_2 coordinate, should be allowed by (orbital) symmetry.[6] These arguments are further supported by a MNDO enthalpy of formation hypersurface (cf. Ref. [2] and especially Ref. [4a]), although its calculation is based on the rather risky assumption that the essential dynamic coordinates for the reaction pathway (b) of the 10-center molecule with altogether 24 internal degrees of freedom[6] may be approximated by the distance changes $\Delta d_{(B_4)(P_2)}$ and Δd_{PP}.

The extensive approximative calculations predict an activation barrier of about 300 kJ mol^{-1} for reaction (b), qualitatively corresponding to the rather high pyrolysis temperature necessary. The reaction products, B_4Cl_4 and P_2, are located in a shallow minimum only about 60 kJ mol^{-1} below the saddle point; that is, in decomposition equilibrium (b), the subsequent thermal disproportionation $B_4Cl_4 \rightarrow BCl_3 + (B)_\infty$ will be responsible for the irreversible process. The geometry-optimized MNDO calculations suggest that the structure at the saddle point is a slightly bent B_4 ring, which only later on forms a tetrahedron along coordinate ζ. The elimination of the relatively electron-rich P_2 donor from the B_4P_2 cluster dramatically changes the charge distribution, especially at the axial B centers (from −0.25 to +0.16; Fig. 2).

The thermal elimination of the P_2 octahedral edge from the nonmetal octahedron **1**, as well as the experimental details such as the high pyrolysis temperature and the at first

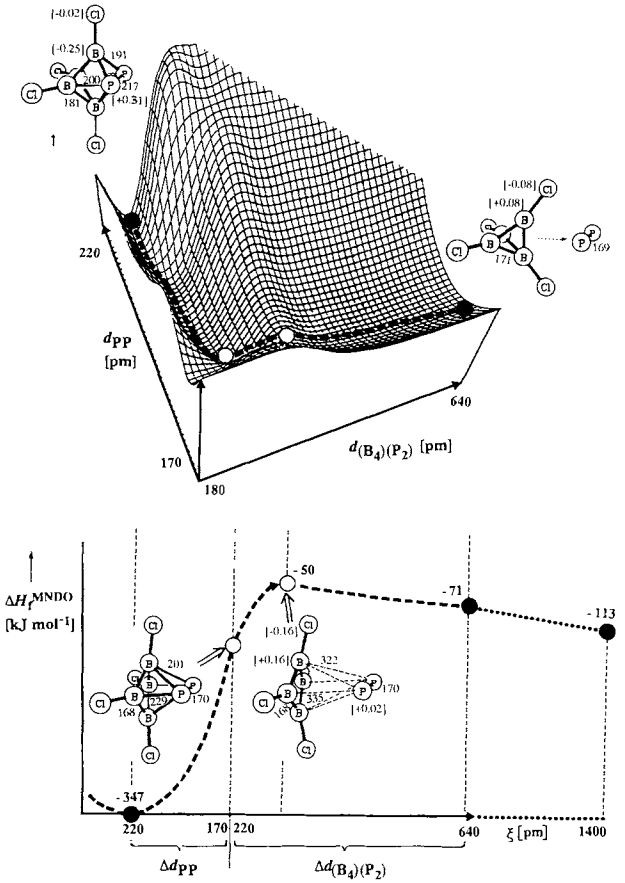

Fig. 2. Top: Simplified ΔH_f^{MNDO} hypersurface along the coordinates $d_{(B_4)(P_2)}$ and d_{PP}, containing the structural data of educts and products reported in the literature [3] (●, local minima; ○, coordinate change as well as saddle point). Bottom: The reaction profile along the hypersurface cut (– – –) defined by the selected coordinates ζ together with the calculated structures at points ○ (bond lengths in pm; representative MNDO charge distribution in brackets).

sight surprising selectivity of the decomposition, can be plausibly rationalized by the calculated MNDO hypersurface—despite the drastic approximations used. Obviously, a potential fracture site is introduced by the P_2 donor group into the otherwise rather electron-poor octahedral borane and constitutes a potentially interesting synthesis principle for the preparation of unknown strained nonmetal tetrahedra.

[5] Within the He(I) measuring region, according to the rule of thumb $\Sigma(1s_H + np_F)/2$ (cf. [2c, 3]), about 15 of a total of 25 valence ionizations are expected; these generate the respective radical-cation states of irreducible representations $\Gamma(C_{2v}) = 10a_1 + 3a_2 + 6b_1 + 6b_2$. This is based on the assumption that the formal skeletal electrons of the cluster $(4 \times 2(B) + 2 \times 3(P) = 14)$ are approximately distributed over one σ_{PP} two-center bond and two σ_{BBB} and four σ_{BBP} three-center bonds. The PE-spectroscopic ionization bands of **1** (Abb. 1a) are assigned by Koopmans' correlation with MNDO eigenvalues as follows: ①, 10.1 eV (σ_{BP}, $3A_2$); ②, 10.6 eV (n_P, $6B_1$); ③, 11.2 eV (n_P, $10A_1$); ④, 11.6 eV (σ_{BP}, $6B_2$); ⑤, 11.9 eV (σ_P, $9A_1$); ⑥, 12.3 eV (n_{Cl}, $5B_1$ and $2A_2$); ⑦, 12.5 eV (n_{Cl}, $5B_2$); ⑧, 12.7 eV (n_{Cl}, $8A_1$ and $4B_2$); ⑨, 13.6 eV (n_{Cl}, $4B_1/1A_2/3$ B_1 and $7A_1$); ⑩, 15.1 eV (σ_{BP}, $6A_1$ and $3B_2$); 17.3 eV (σ_{BCl}, $5A_1$).

[6] For the orbital correspondence analysis in maximum symmetry (OCAMS), see E. A. Halevi, *Angew. Chem. 88* (1976) 664; *Angew. Chem. Int. Ed. Engl. 15* (1976) 593. For analogous OCAMS arguments for the D_{3d} symmetry-forbidden dimerization $2P_4 \rightleftarrows P_8$, cf. E. A. Halevi, H. Bock, B. Roth, *Inorg. Chem. 23* (1984) 4376. For the reaction discussed here, one simplifingly proceeds as follows: Comparison of the localized [5] orbitals of $(HB)_4P_2$ ($\Gamma(C_{2v}) = 5a_1 + 2a_2 + 3b_1 + 3b_2$) with those of B_4H_4 ($\Gamma(C_{2v}) = 3a_1 + 1a_2 + 2b_2$) and P_2 ($\Gamma(C_{2v}) = 3a_1 + 1b_1 + 1b_2$) results in the difference $a_1 \times a_2 = a_2$. Correspondence, therefore, can be accomplished along an internal a_2 coordinate, which reduces the symmetry to that of the subgroup C_2. The $3n-6 = 24$ internal symmetry coordinates of $(HB)_4P_2$ transform in C_{2v} according to $(10a_1 + 2a_2 + 5b_1 + 7b_2)$; that is, they also contain the irreducible representation $a_2(R_z)$ and, therefore, the dissociation into $B_4H_4 + P_2$ is (orbital) symmetry allowed.

The Proton Catalyzed Transformation of a Cobaltacyclopentadiene into a η^4-Cyclobutadiene Complex**

By *Lutz Brandt, Michael Green,*and Adrian W. Parkins*

Metallacyclopentadienes of the transition metals have been implicated in both the cyclotrimerization of alkynes and in the cyclocotrimerization of nitriles, and other unsaturated molecules.[1] Kinetic studies[2] with **1** (Me instead of Ph) suggest that an initial dissociative loss of PPh_3 is important. A similar loss of PPh_3 is involved in the reaction of **1** with B_2H_6[3] or N_2CHCO_2Et[4] forming respectively $[Co(\eta^5\text{-}C_4Ph_4BH)(\eta^5\text{-}C_5H_5)]$ and $[Co(\eta^4\text{-}C_4Ph_4\text{-}CHCO_2Et)(\eta^5\text{-}C_5H_5)]$, an excess of the Lewis acid serving to scavenge the triphenylphosphane. In attempting to gain access to the coordinatively unsaturated cobaltacyclopentadienes implicated in these reactions we have examined the reaction of **1** with strong proton acids. However, this has led to

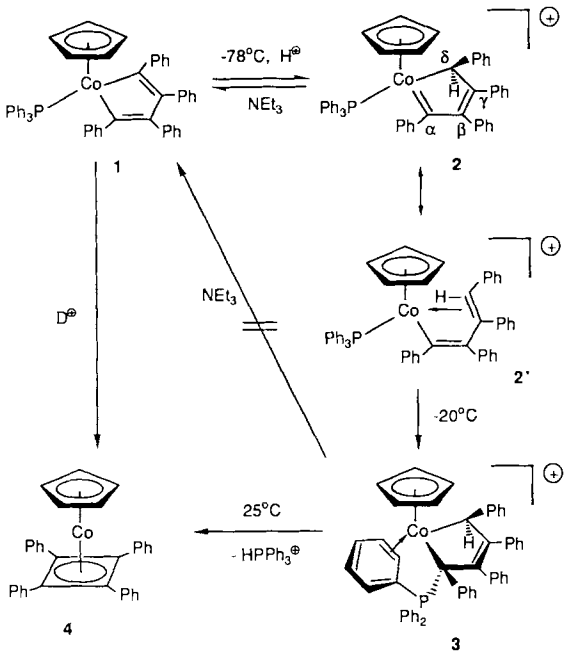
1

the discovery of unusual ring-opening and ring-closure reactions.

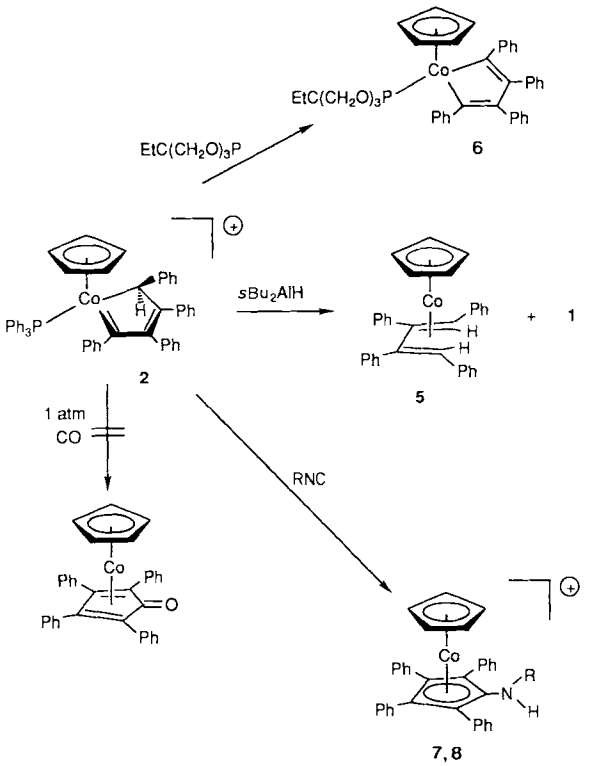
Rapid protonation occurred on addition (−78 °C, CH_2Cl_2) of a slight excess of $HSbF_6$ or CF_3CO_2H to **1**,[5] column chromatography (silicagel, CH_2Cl_2/THF, −30 °C) affording 70% yield of the thermolabile green cation **2** (Scheme 1), which can be precipitated from CH_2Cl_2 by addition of Et_2O. Examination of the ^{1}H-, ^{13}C- and ^{31}P-NMR spectra[6] as well as chemical evidence suggested that protonation proceeds with stereofacial selectivity on a carbon of the metallacycle, probably from the face opposite to the η^5-C_5H_5 ligand, to form a cationic species whose structure in solution can be represented by contributions[7–10] from the resonance forms **2** and **2'**. Interestingly, treatment of **2** with triethylamine in CH_2Cl_2 at low temperature results in the quantitative regeneration of **1**.



Scheme 1. Counterions of the cationic complexes **2**, **2'** and **3**: $SbF_6^\ominus$ or $CF_3CO_2^\ominus$.

The cation **2** rearranges irreversibly in CH_2Cl_2 on warming to −20 °C to form the cation **3**, which can be purified by column chromatography (silica gel, CH_2Cl_2/THF, −30 °C) as a red-brown, moderately air and moisture sensitive salt (78% yield). Salts of **3** are reasonably thermally stable and their composition has been confirmed by elemental analysis. This new isomeric cation cannot be deprotonated to regenerate **1**, and examination of the NMR spectra[11] of **3** suggested that the triphenylphosphane ligand has migrated from the cobalt to the original α-carbon of the butadienyl fragment to form a metallacyclopent-3-ene with the hydrogen and phosphorus substituents adopting a relative *cis*-configuration. Thus, the ^{13}C-NMR spectra of **3** reveals the disappearance of the carbenoid character associated with the metallacyclic moiety in **2** as indicated by the absence of any low field signals in the spectrum. The presence of a phosphorus coupled doublet at $\delta = 44.7$ (d, J(CP) = 36.6 Hz) is consistent with the proposed structure. The signals due to the three remaining carbon atoms of the metallacyclic moiety are likewise shifted to higher field. Two of these three signals [δ = 99.8(s), 96.9(s)] indicate the presence of two vinylic carbon centers whilst the remaining signal at $\delta = 58.9$(s) correlates with a ^{1}H resonance at $\delta = 2.96$ (d, J(HP) = 2.9 Hz) confirming the presence of a CoCH(Ph) moiety. The ^{1}H-NMR spectrum of the cation **3** also shows unusual signals at $\delta = 5.44$ (d, $J = 7.8$ Hz) and 5.86(d) each integrating for a single proton. Both signals correlate to resonances at $\delta = 134.2$(d, J(CP) = 4.2 Hz) and $\delta = 131.0$(s) in the arene region of the spectrum, and it is suggested that these high field ^{1}H shifts, which are also seen with η^2-bonded arene complexes,[12, 13] are due to a phenyl group of the migrated triphenylphosphane becoming bonded in a η^2-mode to the cobalt center. Connectivity data obtained from a 2D-COSY spectrum and an examination of models support this argument and suggest the illustrated site of coordination of the arene ring (Scheme 1), although coordination involving a different arene C–C bond cannot be ruled out.

When a solution of **3** is allowed to warm to room temperature a further unexpected reaction occurs. The products (6 h, CH_2Cl_2) are the corresponding phosphonium salt [$HPPh_3$]X and the η^4-cyclobutadiene complex **4** previously prepared by thermolysis (194 °C) of **1**.[14] Of particular interest is the observation that in contrast with **2**, treatment of **3** with Et_3N does not regenerate **1**, but instead accelerates the formation of **4**. This implies that the rate determining step in this process corresponds to the deprotonation step. In agreement with the reaction path shown in Scheme 1, when **1** was protonated in the presence of D_2O and allowed to transform into **4** there was no evidence of deuterium incorporation.



Scheme 2. RNC: R = 2,6-$Me_2C_6H_3$ or *t*Bu. **7**: R = 2,6-$Me_2C_6H_3$. **8**: R = H. Counterion in **7** and **8**: $SbF_6^\ominus$.

The cation **2** undergoes a number of other interesting reactions (Scheme 2). Thus, treatment with a slight excess of sBu_2AlH (CH_2Cl_2, $-78\,^{\circ}C$) affords a 2:3 mixture of the starting material and the known[15] η^4-buta-1,3-diene complex **5**, which could be separated by column chromatography (Al_2O_3 grade II, benzene/hexane, 25 °C). This finding can be rationalized in terms of a competitive reaction involving delivery of "$H^{\ominus}$" to the carbenoid or α-carbon of **2** and proton abstraction from the δ-carbon. In contrast, reaction of **2** (CH_2Cl_2, $-78\,^{\circ}C$) with $EtC(CH_2O)_3P$ does not lead to nucleophilic attack on the α-carbon, but instead deprotonation occurs and the triphenylphosphane is replaced by the cage phosphite to form (column chromatography, silica, MeCN, $-30\,^{\circ}C$) the pink solid **6**.[16]

Although **2** does not react with carbon monoxide, treatment (CH_2Cl_2/THF, $-78\,^{\circ}C$ to $+25\,^{\circ}C$ and chromatography on silica/MeCN) with a two-fold excess of the isocyanides RNC (R = 2,6-$Me_2C_6H_3$, *t*Bu) resulted in the formation of red-orange **7** and yellow **8** respectively as slightly air-sensitive solids. Compound **7** was identified as the hexafluoroantimonate salt by comparison of the ^{1}H-NMR and IR spectra with those of the fluoroborate species described by *Yamazaki*.[17] The corresponding spectroscopic data[18] for **8** suggested that an unexpected reaction had occurred involving loss of the *t*Bu substituent, and this has now been confirmed[19] by single crystal X-ray crystallography. Such a fragmentation reaction has not been previously obtained.

The Structure of Vicinal Pentaketones—X-Ray Structure Investigations and Calculations**

By *Rolf Gleiter,* Edwin Litterst, Thomas Oeser,* and *Hermann Irngartinger**

Dedicated to Professor Tetsuo Nozoe on the occasion of his 88th birthday

The recently prepared vicinal pentaketones[1] are ideally suited as models for describing the electronic and steric requirements of a keto group. Each CO moiety possesses a strong local dipole moment and provides two lone pairs at the oxygen as well as a π- and a π^*-orbital. So far, only a few structural data on open chain vicinal di-,[2] tri-[3,4] and tetraketones[3,4] are available. Empirical calculations (MM2[5]) predict the dihedral angles of α-diketones[6] and triketones but fail to do so for those of tetra- and pentaketones. Older semiempirical methods,[7] as well as more recent ones[8] and ab initio calculations with a minimal basis (STO 3G),[9] give unsatisfactory results with respect to the torsional angles of vicinal CO groups in polyketones.[8] In this communication we report on the structural parameters of vicinal pentaketones and present a simple model which reproduces the torsional angles properly.

1, R = *t*Bu; **2**, R = Ph

In Figure 1 we show the conformation and most significant bond lengths of *tert*-butylphenylpentaketone (**1**).[10] An X-ray investigation on single crystals of diphenylpentake-

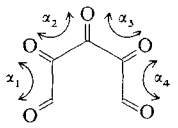
show a transoid conformation. The recorded torsional angles for **1** and **2** are given in Table 2.

It is interesting to note that the distances between O5 and C1 and C2 are relatively short (see Table 2). This interaction leads to a slight pyramidalization of the keto groups at C1 and C2. The deviation of C1 and C2 in **1** and **2** from the plane defined by its three neighbor atoms amounts to 0.014 Å/0.063 Å in **1** and 0.006 Å/0.064 Å in **2**. This deviation occurs



Scheme 1. Definition of the torsional angles in Table 2.

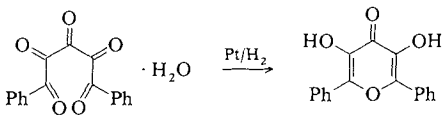
in the direction of O5. Corresponding changes at the other side of the molecule cannot be detected since the C···O distances are larger (see Table 2). The proximity of the terminal CO groups is also in line with the finding that the reduction of **2** gives exclusively 3,5-dihydroxy-2,6-diphenyl-4*H*-pyran-4-one (**3**).[11]



1 · H_2O **3**

On applying current force field methods to calculate the torsional angles between the CO groups by assuming the usual dipole–dipole forces as well as torsional and van der Waals forces, we were unable to reproduce the geometry of the pentaketones satisfactorily. However, upon neglecting torsional and van der Waals forces, assuming the dipole moment of each CO group to be 2.3 D,[5b] the bond distances between the adjacent carbon atoms to be fixed at 1.54 Å, and those between C and O at 1.20 Å, as well as bond angles of 120°, we were able to reproduce the torsional angles between CO groups of vicinal polyketones. The minima found on the corresponding hypersurface show remarkable agreement with experimental data: For 1,2-diketones a dihedral angle of 180° results, for 1,2,3-triketones both dihedral angles are 127°. For vicinal tetraketones we find one broad minimum with two *trans* 1,2-diketone units ($\alpha_1 \approx 180°$, $\alpha_2 \approx 90°$, $\alpha_3 \approx 180°$). A helical structure with $\alpha_1 \approx \alpha_2 \approx \alpha_3 \approx 130°$ also fits well into this minimum.

In Figure 2 we show the dipole-energy of a vicinal pentaketone as a function of α_2 and α_3. For each point of the

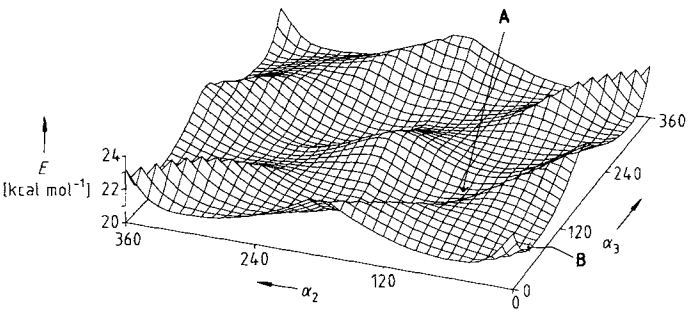


Fig. 2. Dipole energy hypersurface for five vicinal CO groups as a function of α_2 and α_3.

surface the energy was minimized for α_1 and α_4. The surface is symmetrical with respect to the diagonal $\alpha_2 = \alpha_3$. Two nearly equal minima are found at **B** ($\alpha_2 \approx \alpha_3 \approx 25°$, $\alpha_1 \approx 180°$, $\alpha_4 \approx 180°$) at 20.9 kcal mol^{-1} and at **A** ($\alpha_2 \approx \alpha_3 \approx 129°$, $\alpha_1 \approx \alpha_4 \approx 140°$) at 20.0 kcal mol^{-1}. Minimum **B** corresponds to the structures found for **1** and **2**. An analysis of the interactions between the CO groups in **B** shows that the unfavorable cisoid arrangement of the central $(CO)_3$ unit allows the peripheral CO groups to come into a conformation so that their dipole moments are nearly compensated (see Fig. 1). Semiempirical calculations on **1** and **2** suggest an electron transfer from the lone pairs at O5 and—to a lesser extent—from O1 to the π^* level. A further stabilization of minimum **B** with respect to **A**, which is not included in our simple model, is due to the better overlap between the CO groups in **B**. Our simple model suggests that the dipole moment determines the conformation of the $(CO)_x$ moiety. In the current force fields the interplay between torsional, van der Waals and dipole-dipole forces of CO groups is not treated properly.

Experimental

The synthesis of **1** was carried out analogously to that of **2** [1]. **1**: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.9–8.0 (m, 2H), 6.8–7.15 (m, 3H), 1.15 (s, 9H); ^{13}C NMR (66, MHZ, $CDCl_3$): δ = 205.6 (s), 191.0 (s), 189.1 (s), 183.3 (s), 182.7 (s), 136.7 (d), 131.8 (s), 131.3 (d), 129.9 (d), 43.5 (s), 25.8 (q); IR (CH_2Cl_2): $\tilde{\nu}$ = 3148 (w), 1728 (s), 1664 (s), 1594 (s) cm^{-1}; UV (CH_2Cl_2): λ_{max} (ε): 431 (207), 542 (136) nm.

The reduction of **2** (hydrate) was carried out with PtO_2/H_2 in ethanol at room temperature (32% yield) or in ethanol/water (3:1) with L-ascorbinic acid (55% yield). **3**: m.p. 249 °C; IR (cm^{-1}): $\tilde{\nu}$ 3250 (br), 1572 (s), 1390 (s); ^{1}H NMR (300 MHz, d_8THF): δ = 7.37–7.56 (6H, m), 8.2–8.7 (4H, m), 8.93 (2H, br); ^{13}C NMR (200 MHz, [D_6]DMSO): δ = 126.97 (d), 128.59 (d), 129.34 (d), 131.35 (s), 140.96 (s), 144.44 (s), 169.45 (s). The structure of **3** was confirmed by an X-ray investigation on the 3,5-bisacetyl-derivative of **3**.[11]

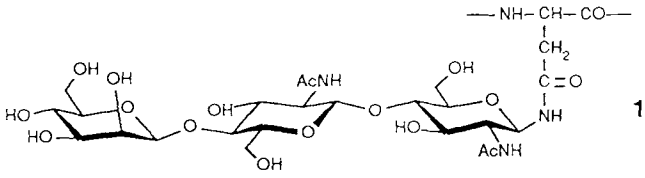
Synthesis of a β-Mannosyl-Chitobiosyl-Asparagine Conjugate—a Central Core Region Unit of the *N*-Glycoproteins**

By *Wolfgang Günther* and *Horst Kunz**

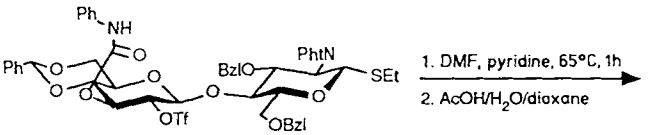
N-Glycoproteins are widespread in living organisms as membrane and serum constituents; some, e.g. the immunoglobulins and transferrin, carry functionalities important for biological selectivity.[1] As a rule, *N*-glycoproteins are characterized by an *N*-glycosidic bond between an *N*-acetylglucosamine unit and the amide function of an asparagine unit. On the carbohydrate side there follow a further *N*-acetylglucosamine unit and a mannose unit as building blocks. The linkages are β(1 → 4) glycosidic, so that this section of the core region and binding region has the structure Manβ1 → 4GlcNAcβ1 → 4GlcNacβ1 → Asn **1**.



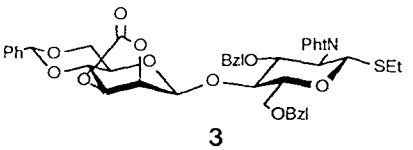
1

The β-glycosidically linked mannose unit in **1** is a central element in the oligosaccharide side chains of the *N*-glycoproteins, since it is the starting point of branching in the antennary saccharide side chains via binding of α-mannoside units.

The especially difficult synthesis of β-mannosides (neighboring group participation and thermodynamic control strongly favor the formation of α-mannosides) was effectively achieved by use of silver silicate catalysts[2] or via oxidation/reduction at the C-2 center of glucosides.[3] In both cases, however, undesirable anomers or epimers are obtained as by-products, which must be separated. In 1988 we developed a directed synthesis of β-mannosides which was based on the inversion of the configuration at C-2 of glycosides (Scheme 1).[4] The β-mannosylglucosamine **3** was obtained in an overall yield of 85% via the glucosylglucosamine **2** by intramolecular nucleophilic substitution.



2



3

Scheme 1. DMF = dimethylformamide. Pht = phthaloyl.

The thioglucoside **3** was now activated according to the method described by *Lönn*[5] using phenylselenyl triflate[6], and coupled with the glucosamine **4** (Scheme 2).

The carbonate group was removed from the β-mannosyl-chitobiose derivative **5**, obtained in 76% yield after chromatographic purification, by treatment with sodium methoxide/methanol, and then the *N*-phthaloyl protecting groups were removed by treatment with hydrazine/ethanol. After acetylation of the deblocked amino and hydroxy functions to give the trisaccharide **6**, the benzylic protecting groups were removed hydrogenolytically. Further acetyla-

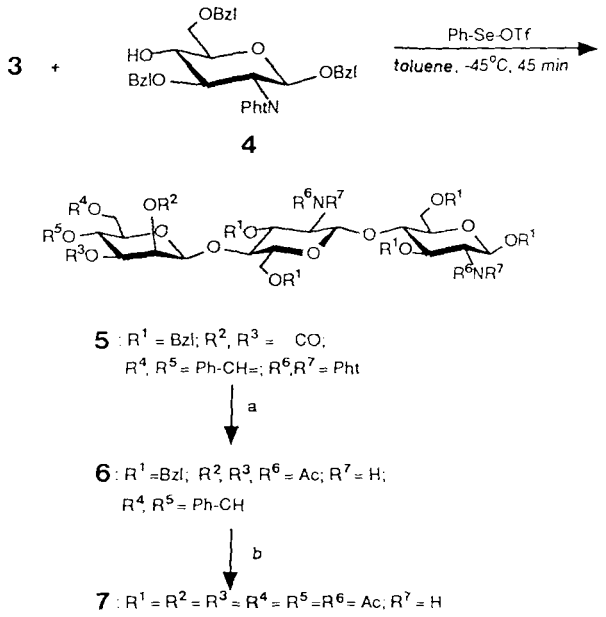
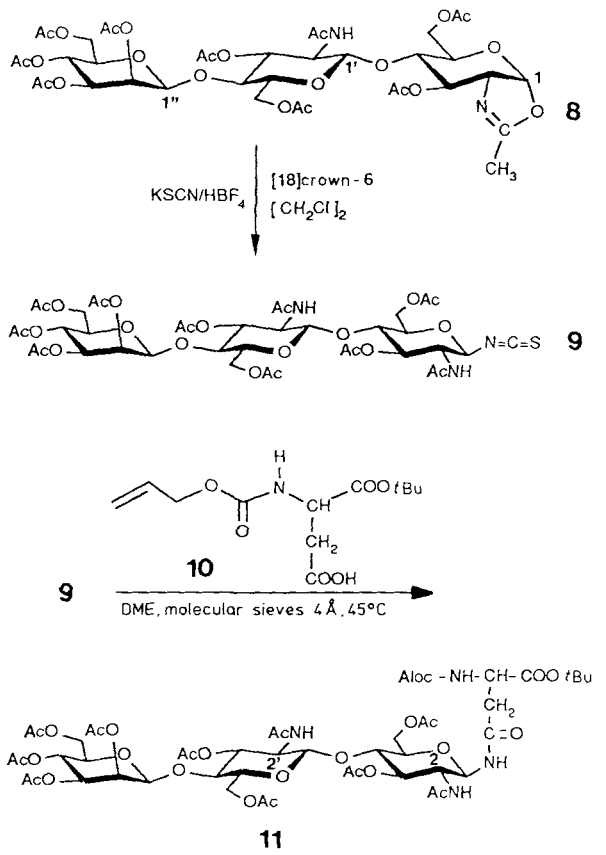


Scheme 2. a) 1. NaOMe, MeOH, 2. H_2N-NH_2, EtOH; 3. Ac_2O/pyridine. b) 1. H_2/Pd-C; 2. Ac_2O/pyridine.

tion then furnished the peracetylated trisaccharide **7** as an anomeric mixture in 85% yield based on **5**.

Reaction of **7** with trimethylsilyl trifluoromethanesulfonate, or even with acetyl chloride/HCl and other activating agents, led exclusively to the dihydrooxazole **8**.[7] All attempts to convert **8** into the anomeric azide with trimethylsilyl azide/$SnCl_4$ according to the procedure of *Jeanloz* et al.[8] met without success. Even the phase transfer procedure, known to be productive in the case of the corresponding chitobiosyl chloride,[9] did not afford the desired trisaccharide. Nevertheless, in order to achieve the coupling of the trisaccharide **7** with asparagine, **8** was first converted into the trisaccharide isothiocyanate **9** in 85% yield by reaction with potassium rhodanide/HBF_4 in the presence of [18]crown-6 as catalyst[10] (Scheme 3).



Scheme 3.

This reaction led initially to the anomeric rhodanide, which then rearranged to **9**. Reaction of the isothiocyanate **9**[11] with α-*tert*-butyl *N*-allyloxycarbonyl-L-asparaginate requires strict exclusion of water. Nevertheless, the interfering formation of *N,N'*-bisglycosylthiourea cannot be completely avoided. The target compound, the β-mannosyl-chitobiosyl-asparagine derivative **11**, is obtained in 75% yield.[12] Thus, for the first time, a core region unit of the *N*-glycoproteins which contains the hitherto problematic coupling of the β-mannoside unit to the chitobiosyl-asparagine unit in correct stereochemistry, was synthesized.

A Novel Type of Ring Contraction as Non-Enzymatic Step in the Later Stages of the Biosynthesis of Urdamycin H**

By *Jürgen Rohr**

The biosynthesis of secondary metabolites is generally characterized by an enzymatic anabolism of highly complex molecules from compounds that stem from the primary metabolism.[1,2] Unsuccessful screening attempts for special biosynthetic enzymes, as well as the small size of certain enzymes which are assumed to be responsible for a great

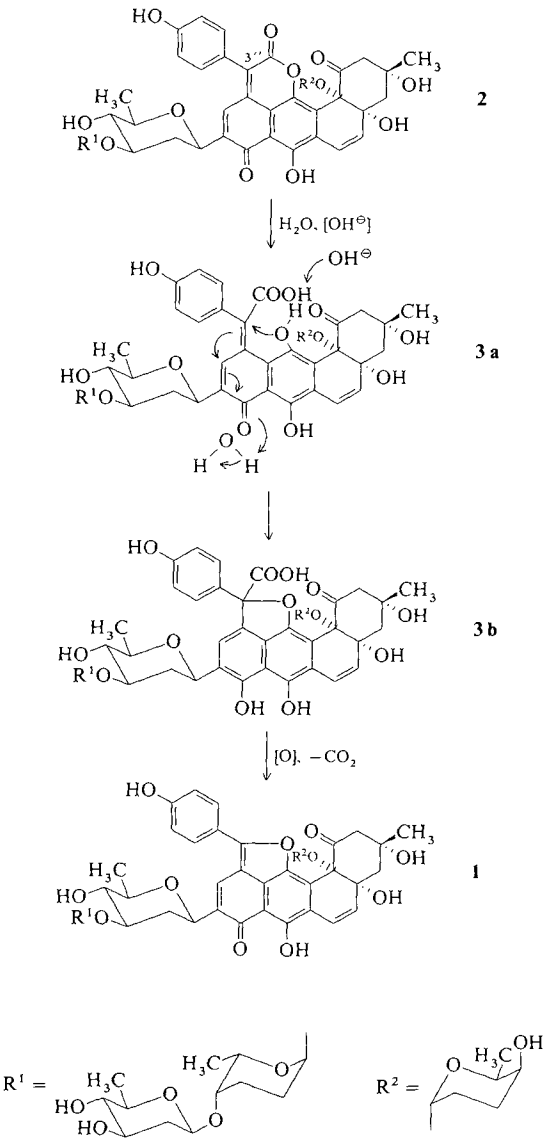
number of reaction steps,[3] are reasons for the speculation that non-enzymatic steps are more involved in natural product formation than generally accepted. Our investigations on the later steps of the biosynthesis of the angucycline antibiotic[4] urdamycin complex support this hypothesis. Recently we reported on the involvement of non-enzymatic reactions in the later stages of the biosynthesis of the urdamycins C, D, and E.[5] This communication deals with another non-enzymatic reaction step, which is responsible for the formation of urdamycin H **1**.

Urdamycin H **1** was discovered as the latest congener of the urdamycin family[6] during a screening for intermediates between urdamycin A and urdamycins C/D before the non-enzymatic interconversion mechanisms could be deduced.[5] Its structure resembles urdamycin C **2**; only the tetracyclic ring frame of this angucycline is enlarged by a (4-hydroxyphenyl)furan moiety instead of the (4-hydroxyphenyl)-δ-lactone moiety of urdamycin C. Thus, **1** is smaller by one C=O than **2**.[7]

Preliminary biosynthetic studies showed that the 4-hydroxyphenyl moiety of **1**, like that of **2**, derives from tyrosine and not from (4-hydroxyphenyl)glycine. This finding and the structure of **1** rule out **1** being the biosynthetic intermediate between urdamycin A and **2**. Even the converse, namely the possibility of **2** being a precursor of **1**, was probable, but no obvious rearrangement mechanism for the excision of a C=O-unit from **2** to give **1** could support the latter hypothesis.[7]

Based on the observation that the fermentation of the urdamycin H-producing mutant shifted earlier into the alkaline than the wild strain, it was evident that the initiation of the rearrangement cascade could be the opening of the δ-lactone moiety of urdamycin C **2**. An intramolecular nucleophilic attack of the liberated 12-OH group at the olefinic carbon in the α-position of the 4-hydroxyphenyl ring (formerly C-3″ of **2**), followed by synchronic H-rearrangements and an oxidative decarboxylation, completes the formation of urdamycin H **1** (Scheme 1). That the reaction described by this mechanism is non-enzymatic, could be proven in vitro by stirring urdamycin C **2** in 0.1 M phosphate buffer/DMSO (1:1) at pH 8.0 for 24 h at 28 °C in an open Erlenmeyer flask; this yielded, besides unchanged **2**, about 30% of urdamycin H **1**, which, with respect to all physicochemical data, is identical with **1** obtained from *Streptomyces fradiae*.[7] An intermediate such as **3** (Scheme 1) could not be isolated. Since DMSO can be replaced by THF or methanol as solvent, and since no reduced **2** can be found in the reaction mixture, molecular oxygen remains the best oxidizing agent for the reaction.

Since a weak alkaline pH and atmospheric oxygen are essential for the formation of **1** under conditions comparable to the last 24 hours of the fermentation process (pH 7–8), one could assume urdamycin H **1** as being an artifact. Obviously its formation can be limited by a pH barrier if the fermentation were to be carried out in a fermentor. Since Erlenmeyer flasks in a shaker are used for the normal fermentation process of *Streptomyces fradiae*, i.e. without pH control, the formation of **1** cannot be avoided. This is in complete contrast to avoidable artifacts which are due to the working-up procedure, as was recently described, e.g., for the vasodilator FK 409.[8] Independently of whether urdamycin H **1** might be considered being an artifact or not, the discovered ring contraction from an arene δ-lactone into a furan is unusual and novel, and is certainly dependent on the quinomethane system of the chromophore which enables the H-rearrangements and oxidation processes shown in Scheme 1.



Scheme 1. Mechanism of the non-enzymatic interconversion of urdamycin C **2** into urdamycin H **1**. R^1 = L-rhodinose-D-olivose; R^2 = L-rhodinose.

The formation of urdamycin H **1** from urdamycin C **2** is the third non-enzymatic interconversion reaction which was discovered during investigations on the later steps of the biosynthesis of the urdamycin complex. Thus, this reaction lends further support to the above mentioned hypothesis, namely the involvement of important non-enzymatic reactions in the biosynthesis of natural products. This should always be considered in future biosynthetic studies and increased interest should be shown in the later biosynthetic steps, since one can also discover unexpected new reactions. There is some evidence in the literature for non-enzymatic reactions in the biosynthesis of other antibiotic complexes, e.g., some ansamycins,[9] some naphthocyclinones,[10] and the esmeraldins[11]

Direct Electron Transfer between Carbon Electrodes, Immobilized Mediator and an Immobilized Viologen-accepting Pyridine Nucleotide Oxidoreductase**

By *Helmut Günther, Antonios S. Paxinos, Michael Schulz, Cees van Dijk*, and *Helmut Simon**

Dedicated to Professor Ivar Ugi on the occasion of his 60th birthday

Electrons from an electrode constitute an inexpensive, residue-free reagent for redox reactions whose redox potential can be adjusted over wide ranges to the desired reaction. They could be especially valuable in combination with specific redox enzymes. However, the direct transfer of electrons between redox active prosthetic groups of oxidoreductases and electrodes is far too slow for preparative conversions. Usually recourse to synthetic redox mediators, for example viologens or metallo cage complexes, has to be made in order to achieve satisfactory rates for the electron transfer. Preparative electromicrobial and electroenzymatic systems with dissolved mediator and dissolved enzyme[1] have been reported, as have also systems in which either the mediator or the enzyme was immobilized on the electrode surface.[2, 3] For analytical purposes, a ferrocene derivative was deposited on a graphite electrode and subsequently covalently bound to glucose oxidase.[4] We have now tried to bind both the mediator as well as the enzyme covalently to a functionalized carbon surface in order to check whether electrons flow from the cathode via the mediator, acting as "molecular wire," to the prosthetic group of the enzyme.

For the immobilization, an enzyme discovered by us in thermophilic bacilli was chosen which transfers redox equivalents between viologens [Eq. (1); V = viologen] or Co-cage complexes [Eq. (2); Co-diamser, cf. Fig. 1] and pyridine nucleotides.[5] Viologen-accepting pyridine nucleotide oxidoreductases (VAPORs) are present in numerous cells.

$$2V^{\cdot\oplus} + NAD(P)^{\oplus} + H^{\oplus} \rightleftharpoons NAD(P)H + 2V^{2\oplus} \quad (1)$$

$$2Co^{2\oplus}\text{-diamsar} + NAD(P)^{\oplus} + H^{\oplus} \rightleftharpoons NAD(P)H + 2Co^{3\oplus}\text{-diamsar} \quad (2)$$

The VAPOR from the thermophilic *Bacillus spec.* DSM 466 was immobilized together with viologen, and then the reactions shown in Scheme 1 were carried out. It was not

modified VAPOR was then checked in an optical test (Table 1). Upon covalent binding of DAPV to the enzyme with carbodiimide, not only is the enzyme activity retained, or even increased under certain conditions, but also the K_m value for the binding of NAD changes only negligibly compared to the unmodified enzyme from 0.054 mM to 0.07 mM (80 mol DAPV per mol VAPOR).

Table 1. Enzyme activity in dependence of method of immobilization. EDC = *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide. HCl. Solutions of DAPV in 10–100 µL of 0.1 N NaOH and of EDC in 100–500 µL of H_2O were added to 5–8 mL VAPOR in TRIS/HCl buffer [TRIS = tris(hydroxymethyl)aminomethane] (0.02 M, pH 7.0) and adjusted to the respective pH with 0.1 N HCl, which was kept constant during the reaction time of 6 min. Finally, unbound DAPV and other low-molecular substances were removed by repeated ultrafiltration.

[a] Specific activity of the modified VAPOR compared to the native enzyme. [b] With additional 8.6 µmol *N*-hydroxysuccinimide. [c] The reaction time in this case was 2.5 h.

Similar results are to be expected upon immobilization of VAPOR on a carbon surface modified with viologens according to the carbodiimide method (route 2). This was also indicated by experiments in which the stability of such immobilizates was checked. The respective viologen was first covalently bound to carbon felt and thereafter a monomolecular layer of the enzyme was applied. A solution of NAD and $MV^{\bullet\oplus}$ (MV = *N*,*N'*-dimethyl-4,4'-bipyridinium) was now pumped through the carbon felt and the NADH formed was measured samplewise in an optical test with L-lactate dehydrogenase (L-LDH, E.C 1.1.1.27) and pyruvate. The results for various viologens are shown in Figure 2. The non-linearity of the reaction rate is in this case mainly determined by the progressive consumption of the starting materials and the increasing concentration of the products.

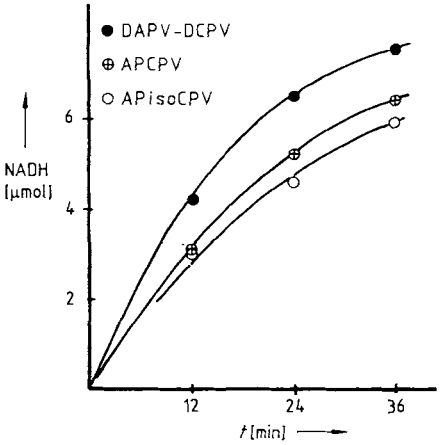

Fig. 2. NADH formation of the immobilized VAPOR as a function of time. DAPV-DCPV, APCPV or APisoCPV was bound covalently to 50 mg carbon felt (ca. 12 cm^2, Type RVG 4000, Carbone Lorraine); a monomolecular layer of VAPOR was then immobilized on the modified felt. For the test, a solution of NAD (10 µmol) and $MV^{\bullet\oplus}$ (25 µmol) in potassium phosphate buffer (0.1 M, pH 7.0) was circulated through the felt at 2.7 mL min^{-1} for about 40 min.

The immobilizates are, after a rapid drop to ca. 50% of the initial activity, very stable. The starting activity is ca. 40% of the activity of the dissolved enzyme.

The functionalization of the glassy carbon electrode and the covalent coating of the electrode surface with a bifunctional viologen will be described elsewhere.[6] By varying the sequence of the immobilization steps for viologen and VAPOR, differently coated electrode surfaces can be prepared (Fig. 3). The electrodes were tested as cathodes in potentiostatically-controlled, electrochemical cells as shown in Scheme 1. All experiments were carried out with strict exclusion of oxygen; anolyte and catholyte were therefore separated by a diaphragm. The initial rate of NADH formation was determined by the bioluminescence method[7] using a calibration curve (Fig. 4). The following conclusions can be drawn: 1) all electrodes without VAPOR (a, b) or without mediator (c, d) show no NADH formation (measured values in the region of that of the blank). 2) Monomolecular layers of VAPOR on a cathode with viologen layer reduce NAD to NADH (e–g). 3) In the case of electrodes modified with DAPV and coated with a multilayer of enzyme (h), the enzyme layers reachable by the substrate no longer have ample electronic contact with the electrode. 4) If, however, DAPV is covalently incorporated in the enzyme layer in the case of such an electrode, a modified electrode (i) is formed which reduces NAD to biologically active NADH). 5) Charge and bonding conditions influence the rate of reaction (e–i).

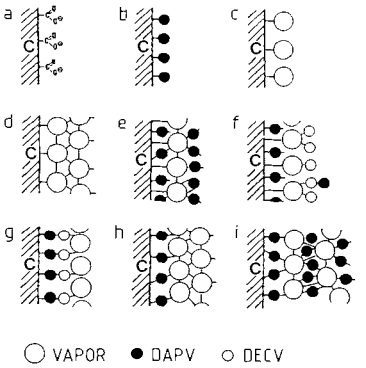

Fig. 3. Schematic representation of the various electrode surfaces. Electrode: glassy carbon (SIGRADUR G), area 1 cm^2. a) Functionalized surface. b) DAPV layer bound via the carboxy groups of (a). c) Monomolecular VAPOR layer: the carboxy groups on an electrode of type (a) were activated by 2 µmol *N*-cyclohexyl-*N'*-[2-(*N*-methylmorpholino)ethyl]carbodiimide · *p*-toluenesulfonate (CMC) in 100 µL 0.1 M potassium phosphate buffer pH 4.5 for 2 h and the so modified electrode treated with 1 U VAPOR in 100 µL 0.05 M TRIS/HCl buffer pH 7.0. d) Multimolecular layer of VAPOR: as (c), but treated simultaneously with 1 µmol CMC in 50 µL 0.1 M potassium phosphate buffer pH 5.5 and the enzyme. e) Monomolecular layer of VAPOR, doped with DAPV: as (c), then both the carboxy groups still available at the electrode surface as well as the enzyme were re-activated and DAPV immobilized thereon. f) Monomolecular layer of VAPOR, doped with DECV: as (c), then DECV was activated with EDC in the molar ratio 1:1.2 and transferred onto the enzyme layer. After 7 min this solution was treated with an additional 2 µmol of DAPV. g) Monomolecular layer of VAPOR, immobilized on a DAPV-DECV layer: as (b), then DECV was treated with EDC analogously to (f) and, after renewed activation of the resulting DAPV-DECV layer with EDC, VAPOR was added. h) Multimolecular layer of VAPOR on DAPV: as (b), then 1 U VAPOR in 100 µL 0.05 M TRIS/HCl buffer pH 7.0 and 1 µmol CMC in 50 µL 0.1 M potassium phosphate buffer pH 5.5 added simultaneously. i) Multimolecular layer of VAPOR and DAPV, cross-linked by DAPV: as (b), then 1 U VAPOR in 100 µL 0.05 M TRIS/HCl buffer pH 7.0, 1 µmol EDC, and 1 µmol DAPV each in 50 µL 0.1 M potassium phosphate buffer pH 5.5 added simultaneously.

The rate of NADH formation decreases significantly over a period of 20 h. The coupling of a reaction rapidly consuming NADH (Scheme 1) increases the rate and stabilizes the reaction, even over a longer period of time. The coupled reaction was the reduction of pyruvate to L-lactate (catalyzed by L-LDH). The lactate formation at the electrode of type (i) was 148 nmol cm^{-2} in 20 h compared to 13.5 nmol cm^{-2} NADH in 19.5 h with a comparable electrode without coupling of an NADH-consuming reaction. In control experiments it was established that all the lactate originates

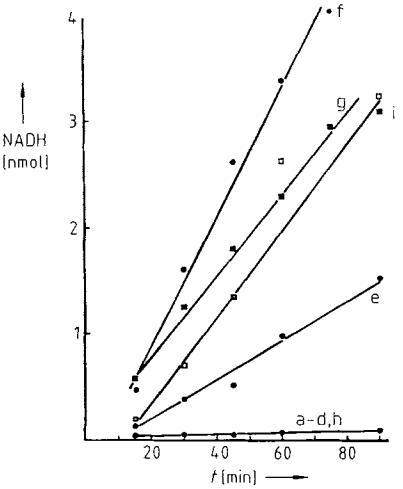

Fig. 4. Time course of NADH formation at carbon electrodes modified as described in Figure 3. Electrode surface: 1 cm^2 (glassy carbon), potential: −407 mV vs. NHE, 6 mL oxygen-free catholyte (TRIS/HCl buffer, 0.1 M, pH 7.0); 18 μmol NAD. (a)–(i) as in Fig. 3). Bioluminescence-NADH test: 250 μL potassium phosphate buffer (25 mM, pH 7.0) contained 25 μmol dithiothreitol, 1.25 μg luciferase EC 1.14.14.3, 9.5 mU flavin mononucleotide (FMN) oxidoreductase EC 1.6.8.1, 0.6 μmol FMN, 10 μg TRITON X-100, 5 μmol myristinaldehyde, 150 μmol NAD, and 50 μL sample. Apparatus: BIOLUMAT LB 9500 T, Berthold, D-7547 Wildbad (FRG).

from the NADH-dependent LDH-catalyzed reaction. A further experiment was carried out with such an electrode in order to clarify the influence of the NADH decomposition during the 19.5 h. First the NADH formation was measured over 90 min according to the bioluminescence method, then, after addition of pyruvate (20 μmol) and L-LDH (7 U), the increase in lactate was determined after a further 17 h. The NADH formation slowed down in the first 30 min from 3.6 nmol cm^{-2} h^{-1} to 1.2 nmol cm^{-2} h^{-1}, but the lactate formation was 9 nmol cm^{-2} h^{-1} over 17 h. In a further analogous experiment with the same electrode the lactate formation was 8.4 nmol cm^{-2} h^{-1} after 2 days.

The higher lactate formation compared to the NADH formation in the absence of an NADH-consuming reaction can be explained in terms of the pyrurate/lactate diffusing more rapidly than NAD/NADH and of an absorption of LDH at the electrode.[8] The NAD concentration in the reaction layer is also increased through the dehydrogenation of the NADH.

According to the above results, current densities lying in the lower range of the current densities of industrial processes can be expected on using carbon felts with larger internal surfaces (referred to the macroscopic surface).[9]

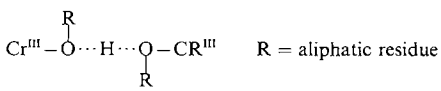
Dependence of the Magnetic Superexchange on the Cr···Cr Distance in Dinuclear Chromium(II) Complexes**

By *Ursula Bossek, Karl Wieghardt,* Bernhard Nuber,* and *Johannes Weiss*

The spins of the unpaired electrons of a transition metal ion in a dinuclear complex can be oriented intramolecularly parallel (ferromagnetism) or antiparallel (antiferromagnetism) through the mediation of bridged, non-magnetic anions. This phenomenon is referred to as superexchange.[1] Generally speaking, the extent of this spin-spin coupling is satisfactorily described by the isotropic Heisenberg–Dirac–vanVleck model (HDVV model), whereby the form of the isotropic spin-Hamilton operator is given by $H = -2JS_1S_2$, where J is the exchange coupling constant (in cm^{-1}) and S_1 and S_2 give the total spin of the metal ions **1** and **2**, respectively; J is negative in the case of antiferromagnetic and positive in the case of ferromagnetic spin coupling. The question of whether J is a function of the distance r between the two paramagnetic centers in a bridged, dinuclear complex is still a matter of controversy.[2] Experimentally most convincing is such a dependence with $-J \approx r^{-12}$ in the case of solid-state structures of the type XMF_3 and X_2MF_4 (X = K, Rb, Tl; M = Mn^{II}, Co^{II}, Ni^{II}).[2b] However, the M···M distances vary only by ca. 0.020 Å. Such a dependence on distance has not been observed for the intramolecular spin coupling in dinuclear complexes, since the distance between the metal ions changes with changing type of bridge ligand, and this results in the superexchange mechanism changing.

We have now synthesized dinuclear $Cr^{III}(d^3)$ complexes containing H-bridges as common structural feature:



R = aliphatic residue or H

The Cr···Cr distance varies because two octahedrally coordinated Cr^{III} ions are coupled intramolecularly to each

other via one, two or three such bridges. The Cr···Cr distance varies between 4.46 and 5.64 Å. The temperature-dependent susceptibilities of these compounds were measured on powdered solid samples in the range 4–298 K with a Faraday balance[3] and then fitted to the isotropic HDVV model.[4]

In the complex $[L(acac)CrOH]PF_6 \cdot H_2O$ **1** (L = 1,4,7-trimethyl-1,4,7-triazacyclononane; acac = 2,4-pentanedionate(1−)) the octahedrally coordinated Cr^{III} ions are not coupled to each other (Fig. 1).[5] The Cr–OH group is bound via

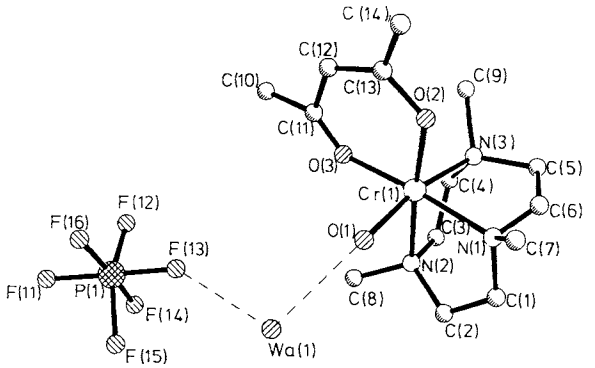

Fig. 1. Structure of **1** in the crystal. Important distances [Å]: Cr1–O1 1.90(2), O1–Wa1 2.66(3), F13···Wa1 2.87(3); Wa = water.

a strong H-bridge to a water molecule; the shortest intermolecular Cr···Cr distance is 8.38 Å. A temperature-independent magnetic moment of 3.79 μ_B was found (Curie behavior), which corresponds to the spin-only value of three unpaired electrons of a Cr^{III} ion. That is **1** shows no spin coupling; an effective superexchange mechanism is lacking.

Crystals of $[(L(acac)Cr)_2(\mu\text{-}H_3O_2)](PF_6)_3$ **2** were obtained from aqueous solutions of **1** at pH = 5. The crystal structure analysis[5] shows that two $[L(acac)Cr\text{-}OH]^{\oplus}$ units are coupled via a strong (O-H···O)-bridge (Fig. 2). Complexes with $(H_3O_2^{\ominus})$-bridges have been the subject of intensive studies in the past few years.[6] Measurements of the temperature-dependent susceptibility of **2** indicate that the spins of the two Cr^{III} ions are coupled weakly antiferromagnetically (Table 1).[7]

Ardon et al.[8] have recently observed a somewhat stronger coupling in two dinuclear Cr^{III} complexes, in each of which there are two $(H_3O_2^{\ominus})$-bridges, namely in β-*cis*-$[(bispictn)_2Cr_2(H_3O_2)_2]I_4 \cdot 4H_2O$ **3** and α-*cis*-$[(pico)_4Cr_2(H_3O_2)_2]I_4 \cdot H_2O$ **4**. The Cr···Cr distances in **3** and **4** are shorter than those in **2**.

Finally, we have obtained the dinuclear, triply bridged complex $[Cr_2^{III}L'_2H_3](PF_6)_3$ **5**[9] by reaction of 1,4,7-tris(2-hydroxyethyl)-1,4,7-triazacyclononone[12] (L′) with $CrCl_3 \cdot 6H_2O$ in ethanol. The structure analysis[5] clearly shows that three O atoms of one ligand are bound via very

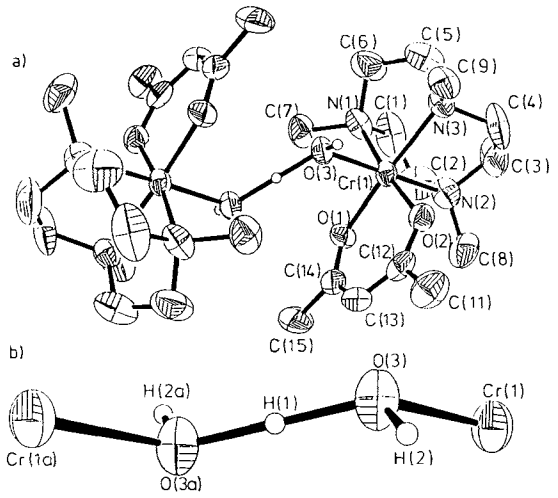

Fig. 2. Structure of the trication of **2** in the crystal. Important distances [Å] and angles [°]: Cr(1)-O(3) 1.969(4), O(3)···O(3)′ 2.496(6), Cr···Cr 5.583(2); O(3)-H(1)-O(3)′ 180.0, Cr(1)-O(3)-H(2) 107.4(2), H(1)-O(3)-H(2) 115.2(3), H(1)-O(3)-Cr(1) 118.8(3). b) structure of the Cr-OH(H)HO-Cr-bridge.

short H-bridges (O···O ≈ 2.47 Å) with the corresponding O atoms of a second ligand (Fig. 3). The Cr···Cr distance could be determined quite reliably as 4.458(6) Å. The temperature dependence of the susceptibility of **5** is typical for an antiferromagnetic spin coupling (Table 1).

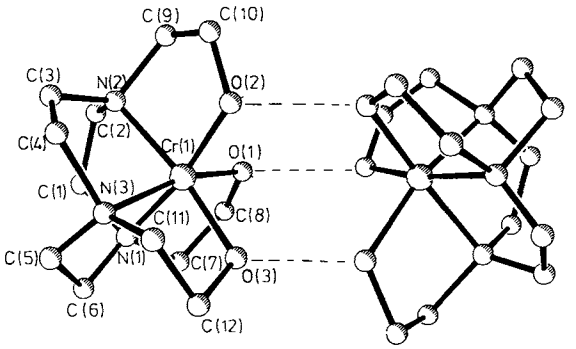

Fig. 3. Structure of the trication of **5** in the crystal. Important distances [Å]: mean O···O distance: 2.47, Cr···Cr 4.458(6), mean Cr-O distance 1.95.

Thus, in each of the complexes **2**–**5** two Cr^{III} ions are coupled via one, two or three O–H···O bridges to give dinuclear units, and the spins are intramolecularly coupled antiferromagnetically. The plot of log $|2J|$, where $-2J$ gives the energy difference between the singlet and the triplet state, versus the logarithm of the Cr···Cr distance yields a straight line of slope −12.1(2) (Fig. 4). That is $-J$ varies proportionally with r^{-12}. Interestingly, the O–H···O distance[13]

Table 1. Structural data and magnetic properties of the μ(ROHOR)-bridged complex. L = 1,4,7-trimethyl-1,4,7-triazacyclononane; acac = 2,4-pentanedionate; bispictn = *N*,*N*′-bis(2-pyridylmethyl)-1,3-propanediamine; pico = 2-picolylamine; L′ = 1,4,7-tris(2-hydroxyethyl)-1,4,7-triazacyclononane(−3H).

and the mean Cr–O distance do not correlate with the strength of the spin-exchange coupling; both quantities are about constant in the series **2**–**5**. It has already been experimentally observed that a superexchange mechanism can be facilitated via H-bridges.[10]

It must be pointed out that the straight line in Figure 4 is no limiting function for the dependence of the antiferromagnetic superexchange on the distance between the metal ions, like that suggested by *Coffman* and *Buettner*.[2d] It is possible, of course, that strong intramolecular couplings occur over considerably greater Cr···Cr distances than would be implied by Figure 4 if other bridge ligands bind the magnetic orbitals symmetry allowed with larger overlap constants. Indeed, in the case of $[LCu^{II}(H_2O)(\mu\text{-terephthalato})Cu^{II}L(H_2O)](ClO_4)_2$, for example, there is a strong spin coupling over 11.25 Å.[11] The correlation found here thus implies that, with unchanging superexchange mechanism but with differing distances between the paramagnetic centers in a series of complexes, the strength of the spin coupling decreases with the twelth power of the distance between the metal ions.[14]

Experimental

1: A suspension of $LCrBr_3$ (2.0 g) in H_2O (50 mL) and sodium acetylacetonate (2.0 g) was stirred for 1 h at 70 °C until a clear solution was obtained. After addition of 1.0 g of KPF_6 and cooling to 5 °C, violet crystals of **1** (0.90 g) separated.

2: When the above reaction solution was treated with HPF_6 until the pH was 5, after subsequent addition of 1 g of KPF_6 red crystals of **2** precipitated (1.2 g), which were recrystallized from a minimum of H_2O (pH = 5).

5: A solution of $CrCl_3 \cdot 6H_2O$ (0.27 g) in ethanol (10 mL) was treated under an argon atmosphere with granulated zinc (2–3 pieces). After 15 minutes' stirring at 45 °C an Ar-purged solution of 1,4,7-tris(2-hydroxyethyl)-1,4,7-triazacyclononane(L') (0.26 g) in ethanol (10 mL) was added dropwise and stirring continued for another further 45 min at 45 °C (dark violet solution). After removal of solvent the residue was dissolved in 20 mL of H_2O and the resulting solution treated with 0.55 g of KPF_6 and a few drops of HPF_6 (pH 4). Within a few hours, violet crystals of **5** separated out. Recrystallization from a CH_3CN/H_2O mixture (4:1) furnished single crystals suitable for an X-ray structure analysis.

All the complexes gave correct elemental analyses (C,H,N,Cr); the UV-VIS spectra are typical for octahedral Cr^{III} complexes.

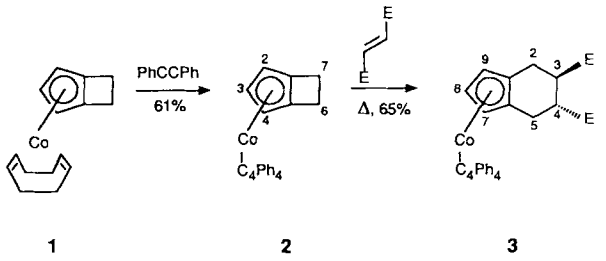
[**] *H. B.* thanks the Verband der Chemischen Industrie e.V. for a Liebig fellowship, Prof. Dr. *G. Wilke* for generous support, and Herrn *G. Schroth* for help with the NMR investigations. The results of this work were delivered in a lecture at the Chemiedozenten-Tagung 1990 in Ulm.

posed by *Basolo* et al. to explain associative ligand exchange processes.[1] Since then, η^3-cyclopentadienyl complexes have often been postulated as intermediates.[2] *Brintzinger* et al. were the first to succeed in isolating and structurally characterizing an η^3-cyclopentadienyl complex.[3] Herein we report the first case of a ring slippage reaction in which the η^5-cyclopentadienyl ligand being used is altered by breakage and reformation of C–C bonds.

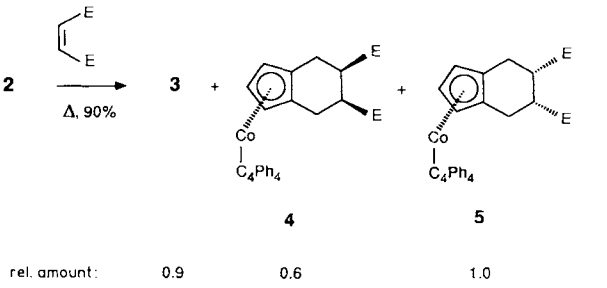
The DSC analysis (differential scanning calorimetry) of the η^5-bicyclo[3.2.0]hepta-1,3-dienylcobalt(I) complex **1** shows a reaction above 200 °C, which, however, does not involve the desired opening of the four-membered ring, but cleavage of the electroneutral cycloocta-1,5-diene (COD).[4] Apparently, the opening of the four-membered ring requires a higher activation energy than the COD cleavage. Therefore COD must be replaced by a less easily cleavable ligand. **1** reacts with diphenylethyne in boiling *ortho*-xylene to give the tetraphenylcyclobutadiene complex **2**, cleavage of which is first expected to take place at higher temperatures.[5, 6] The DSC analysis of **2** also shows a reaction above 200 °C. In order to check whether it involves thermal opening of the four-membered ring, **2** was allowed to react with dimethyl fumarate at 200 °C for 13 h. The cycloadduct **3** was obtained in 65% yield (C_4Ph_4 = tetraphenylcyclobutadiene, E = $COOCH_3$).



1 **2** **3**

This result suggests formation of an η^3-(4,5-dimethylenecyclopentenyl)cobalt(I) complex[7] (see Scheme 1), an analogue of an *ortho*-quinodimethane complex, as intermediate. Replacement of dimethyl fumarate by dimethyl maleate leads to a less clear result, which nevertheless permits further insights into the course of the reaction.

3 (rel. amount 0.9) and the *cis*-substituted complexes **4** (0.6) and **5** (1.0) are obtained in an overall yield of 90%. The assignment of the structures followed from the spectroscopic data of the mixture (IR, ^1H NMR, ^{13}C NMR, MS) and, in the case of **4** and **5**, also from NOE measurements (irradiation at OCH_3 shows NOE of the *ortho*-H in the case of **5**, and vice versa).

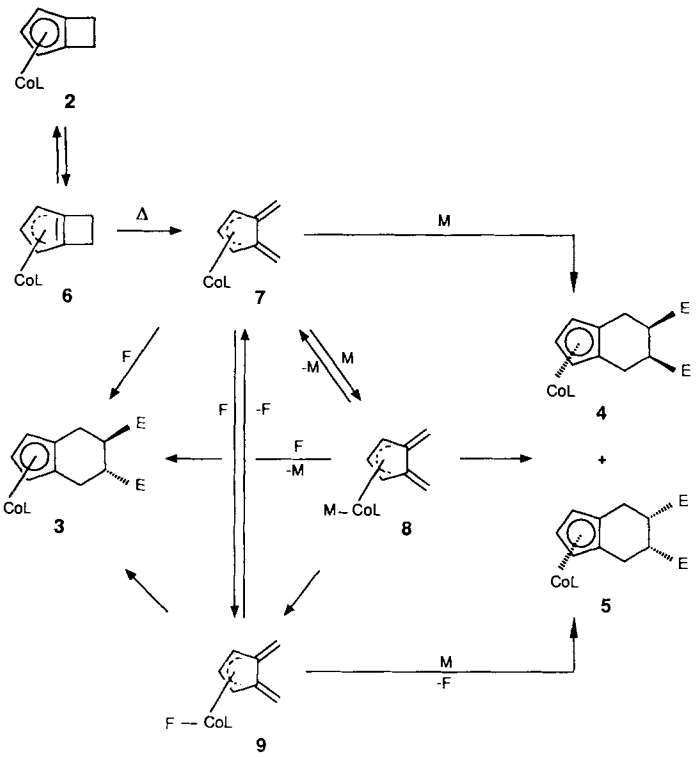


2 **3** **4** **5**

rel. amount: 0.9 0.6 1.0

Some further observations must be taken into consideration in order to explain the course of the reaction: The dimethyl maleate employed contains 0.3% of dimethyl fumarate before the reaction, whereas the dimethyl maleate recovered by distillation after the reaction contains 3.9% of dimethyl fumarate (GC). Apparently an isomerization takes place,[8] as has already been observed previously in the reaction of **1** with dimethyl maleate. In the absence of **2** under otherwise unchanged reaction conditions a comparable isomerization is not observed, and not up to 180 °C even in the presence of **2**. Nor does a comparable isomerization take place under the same conditions with η^5-(cyclopentadienyl)-η^4-(tetraphenylcyclobutadene)cobalt(I).[6] It may therefore be concluded that the *cis-trans* isomerization is transition-metal-catalyzed at a vacant coordination site during the course of opening of the four-membered ring.

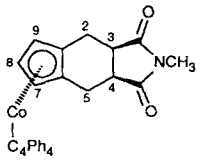
These findings would suggest a reaction as depicted in Scheme 1. As a result of the thermal ring-opening, which is best described in therms of an allyl-ene structure such as **6**, the η^5-bicyclo[3.2.0]hepta-1,3-dienyl complex **2** is converted into an η^3-4,5-dimethylenecyclopentenyl complex **7**, which reacts with dimethyl maleate with reformation of the stable η^5-coordination to give the cycloadducts **4** and **5**. Besides the direct cycloaddition, dimethyl maleate can coordinate to the free coordination site and subsequently be isomerized to dimethyl fumarate; from **7**, the complexes **8** and **9** could be formed, which then react with the coordinated dimethyl fumarate or with the dimethyl fumarate present in the reaction mixture (according to *Sauer* this should be more reactive than dimethyl maleate[9]) to give the *trans*-cycloadduct **3** as a stable η^5-cyclopentadienyl complex. That the formation of the *cis-endo* cycloadduct **5** is favored over that of **4**, could be due to an intramolecular transfer of the coordinated dimethyl maleate in **8** to the diene unit.



2 **3** **4** **5** **6** **7** **8** **9**

Scheme 1. L = C_4Ph_4; E = $COOCH_3$; F = dimethyl fumarate; M = dimethyl maleate.

Since the course of the reaction with dimethyl maleate was largely influenced by its coordination and the isomerization to dimethyl fumarate, **2** was also allowed to react with the cyclic, poorly coordinating *N*-methylmaleimide. The reaction carried out in *n*-dodecane gave as sole product (93%) the *exo*-cycloadduct **10** corresponding to **4**,[5] whose *exo*-



10

configuration was confirmed by an NOE experiment. Apparently, the attack of the non-coordinating dienophile takes place exclusively from the side of the diene away from the metal atom, which is consistent with the postulated reaction course (Scheme 1).

The reactions of the cobalt complex **2** presented here represent the first cases in which a ring-slippage reaction ($\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$) leads to breakage of one, and formation of two new C–C bonds. The driving force behind this reaction could be the ring strain in the educt and the individual transformations of π-bonds into σ-bonds of each Diels-Alder reaction. The similarity to the chemistry of cyclobutabenzene is unmistakable; an essential difference lies, however, in the breaking of a symmetry plane in the educt and in the *ortho*-quinodimethane-analogous intermediates by coordination to a transition metal. Recent findings by *Kündig* et al. are also of interest in this connection.[10]

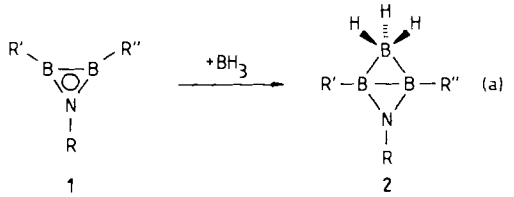
Azadiboriridine-Borane: a Non-Classical Acid-Base Adduct**

By *Peter Paetzold,* Burkhard Redenz-Stormanns, Roland Boese,* Michael Bühl*, and *Paul von Ragué Schleyer**

In the reaction of the azadiboriridine **1a**[1] with THF · BH_3 we expected the Lewis acid BH_3 to add at the N atom. Surprisingly, however, **1a** displays its Lewis basicity across the B–B bond, and as a consequence the bicyclic **2**, a colorless liquid, was obtained in accordance with Equation (a).



1 **2**

a, R = R' = R'' = *t*Bu
b, R = R' = *t*Bu, R'' = *i*Pr
c, R = R' = R'' = H
d, R = H, R' = R'' = Me

The constitution of **2a** in solution follows from the NMR spectra.[2] The ^{11}B-NMR signal at $\delta = 51.9$ would have been shifted to lower field if the ring π-electron pair had been employed for the formation of a B-N adduct, but actually a high field shift to $\delta = 32.9$ was observed with retention of the equivalence of both B-atoms. Moreover, it can be concluded from the 2D-COSY-^{11}B-^{11}B-NMR spectrum that the B atom of the BH_3 group directly interacts with each of the two other B atoms. A notable feature of **2a** is the rigid conformation of the BH_3 group, which leads to two quartets (1:1:1:1) in the ^{1}H-NMR spectrum and to a doublet/triplet pattern with coupling constants of 131 Hz (BH) and 68 Hz (BH_2) in the ^{11}B-NMR spectrum. The 2:1 non-equivalence of the BH_3 protons is retained even at 90 °C in toluene. The NMR findings in solution are also confirmed for the solid state by an X-ray structure analysis at 120 K (Fig. 1).[3]

The almost equilateral triangles B1–B2–B3 and N–B2–B3 enclose an angle of 42.6°. The markedly large ring angle of 78.1° at the N atom provides optimal clearance for the bulky ligands. The NB_3 skeleton can be regarded as a *nido*-fragment of a trigonal bipyramid, and, indeed, **2a** fulfills the electron count rules for a *nido*-compound. The B1–H12 and B1–H13 distances (each 1.16 Å) are significantly greater than B1–H1 (1.10 Å), but the B2–H12 and B3–H13 distances (ca. 1.67 Å) are too large to assume a bridge position of H12 and H13. The structure of **2a** is, in principle, reminiscent of that of the anion $[Fe(CO)_4B_7H_{12}]^{\ominus}$, which is formed by the addition of BH_3 to a B–B bond of the anion $[Fe(CO)_4B_6H_9]^{\ominus}$ in the pentagonal base of the pyramidal B_6 structure.[4]

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The azadiboriridine **1b** can be prepared analogously to **1a** from Cl–B(*t*Bu)–N(*t*Bu)–B(*i*Pr)–Cl[11] by dehalogenation with Na/K if the reaction is carried out at −78 °C; on allowing to warm to room temperature, **1b** dimerizes to the *nido*-cluster compound $N_2B_4tBu_4iPr_2$.[11] If, however, **1b** is treated with THF · BH_3 at −78 °C, **2b** can be isolated in 34% yield as a colorless liquid, and can be characterized NMR spectroscopically.[5] The ^{11}B-NMR signal of the BH_3 group, at room temperature a doublet-triplet pattern at $\delta = -17.8$ ($J = 131$ and 69 Hz, respectively), is converted into a quartet at $\delta = -17.2$ ($J = 88$ Hz) upon heating to 90 °C in toluene, an indication that the conformational rigidity of the BH_3 group in **2a** has, inter alia, steric origin.

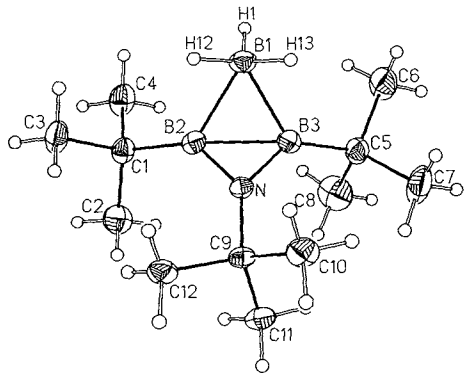

Fig. 1. Molecular structure of **2a** in the crystal. Selected bond lengths, angles, and torsion angles ([Å] and [°], resp., standard deviations in brackets): B1–B2 1.770(2), B1–B3 1.752(2), B2–B3 1.785(2), B1–N 2.484(2), B2–N 1.412(2), B3–N 1.421(2), B2–C1 1.590(2), B3–C5 1.592(2), N–C9 1.480(2), B1–H1 1.098(17), B1–H12 1.158(17), B1–H13 1.155(15), B2–H12 1.686(18), B3–H13 1.653(17); B2–B1–B3 60.9(1), B1–B2–B3 59.1(1), B1–B3–B2 60.0(1), N–B2–B3 51.2(1), N–B3–B2 50.7(1), B2–N–B3 78.1(1), B1–B2–C1 120.9(1), N–B2–C1 136.9(1), B1–B3–C5 120.9(1), N–B3–C5 135.8(1), B2–N–C9 140.8(1), B3–N–C9 140.3(1), H1–B1–B2 127.2(8), H1–B1–B3 124.8(8), H1–B1–H12 119.6(11), H1–B1–H13 118.3(11); H1–B1–B2–N 142.4, H1–B1–B3–N −145.9, H1–B1–B2–B3 113.5, H1–B1–H12–B2 120.8, H1–B1–H13–B3 −117.9, C1–B2–B3–C5 −2.7, C1–B2–N–C9 27.7, C5–B3–N–C9 −33.2, H12–B2–B3–B1 −25.8, H13–B1–B2–B3 −44.2.

Table 1. Comparison of measured (**2a**) and calculated (**2c, d**) distances and ^{11}B-NMR chemical shifts.

	Distances [Å] [a]				δ (^{11}B) [b]	
	B1-B2 B1-B3	B2-B3	B2-N B3-N	B2-H12 B3-H13	B1	B2/B3
2a	1.770 1.752	1.785	1.421 1.412	1.653 1.686	−14.1	32.9
2c	1.716	1.758	1.421	1.599	−15.5	22.1
2d	1.724	1.766	1.424	1.627	−18.9	28.8

[a] MP2/6-31G*-optimized (**2c, d**). [b] IGLO (Individual Gauge for Localized Orbitals) [8]; Double-Zeta Basis (**2c, d**).

Ab initio calculations[6] on the model systems **2c** and **2d** confirm the experimental findings. Optimizations in C_s symmetry satisfactorily reproduce both the geometry[7] as well as the ^{11}B-NMR chemical shifts of **2a** (Table 1). The influence of the alkyl substituents on the ^{11}B-NMR signals of B2/B3 is made clear on going from **2c** ($\delta = 22$) to **2d** ($\delta = 29$).—Based on the calculated bond order of 0.19 a weak B2···H12 interaction becomes apparent in **2c**, in spite of the relatively long distance of more than 1.6 Å.[6] This may be a further explanation for the observed conformational rigidity of the complexed BH_3 group in addition to steric reasons. The enthalpy of formation of −45.7 kcal mol^{-1} for the formation of **2c** from BH_3 and NB_2H_3 is significantly greater than the value of −28.5 kcal mol^{-1} calculated for the formation of H_3B–NH_3 from BH_3 and NH_3 [calculated for both at MP4sdtq(FC)/6-31G**//MP2//(Full)/6-31G* + ZPE(6-31G*) level]. Hence, azadiboriridines are stronger bases towards BH_3 than amines, but the weak B–B bond[9] and not the nitrogen represents the basic center. This is also true for the protonation: the proton affinity of −211.5 kcal mol^{-1} calculated for NB_2H_3 (with formation of a three-center B–H–B bond) is greater than that for ammonia, with a value of −206.8 kcal mol [calculated for both at MP4sdtq(FC)/6-31 + G**//6-31G* + ZPE(6.31G*) level].

Experimental

1,2,3-Tri-*tert*-butyl-*nido*-1-azatetraborane(6) (tri-*tert*-butylazadiboriridineborane) **2a**: A solution of **1a** (1.08 g) in THF (15 mL) was treated at 0 °C with 5.9 mL of a 0.83 M solution of BH_3 in THF. The mixture was stirred for 30 min at room temperature. After removal of solvent and distillation at 45 °C (0.3 torr) we obtained 1.10 g (95%) of **2a**, m.p. −10 °C.

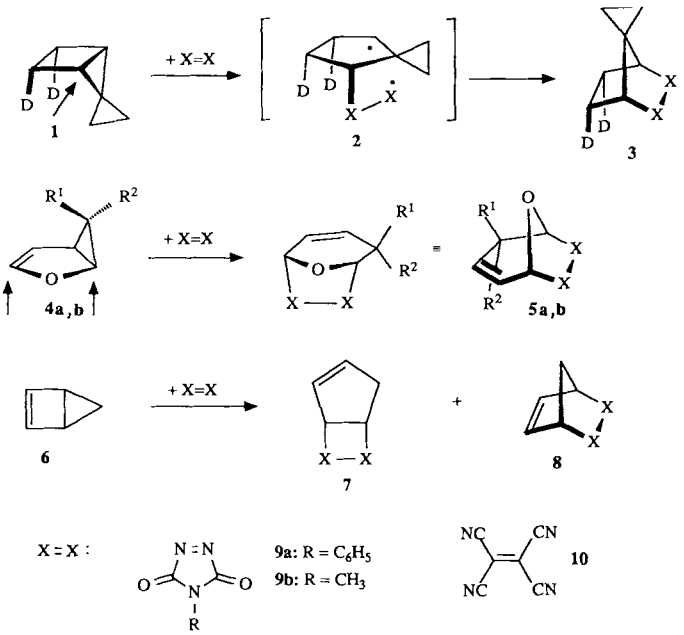
Mechanism of the Cycloaddition of Bicyclo[2.1.0]pent-2-ene: a Non-concerted Homo-Diels-Alder Reaction**

By *Frank-Gerrit Klärner** and *Manfred Naumann*

Dedicated to Professor Wolfgang R. Roth on the occasion of his 60th birthday

Roth and *Martin*[1] have interpreted the *endo*-stereospecific course of the $[_\sigma2+_\pi2]$-cycloaddition of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione **9a** to the bicyclo[2.1.0]pentane derivative **1** as characteristic of a two-step process. As first step, the authors postulate, in line with MO considerations,[2] an electronically favored backside attack of **9a** at the strained, central cyclopropane bond of **1** with formation of the reactive diradical intermediate **2**, which then closes in the second step to give the stable cycloadduct **3**. An analogous *endo*-stereospecificity is also observed in the addition of olefins such as maleic anhydride, fumaronitrile and maleonitrile to bicyclo[2.1.0]pentane,[3] of **9a** to tricyclo[3.2.0.0^{2,4}]heptane,[4] and of **9b** to bicyclo[1.1.0]butane.[5] In contrast, *exo*-stereospecificity is observed in the case of the homo-Diels-Alder reaction of tetracyanoethylene **10**, *N*-phenylmaleimide or fumaronitrile with the 6-methylhomofurans **4a**, **b**,[6] in which a concerted $[(_\sigma2_s + _\pi2_s) + _\pi2_s]$-cycloaddition could be involved due to the stereospecific *cis*-addition of the dienophiles (fumaro- and maleonitrile). Bicyclo[2.1.0]pent-2-ene **6** reacts with **10** predominantly in the sense of a homo-Diels-Alder reaction to give an adduct of type **7**[7] and with **9a**, **b** in the sense of a $[_\sigma2+_\pi2]$-cycloaddition to give adducts of type **8**.[8] We report here on the surprising stereochemical



4a, **5a**: $R^1=CH_3$, $R^2=H$; **4b**, **5b**: $R^1=H$, $R^2=CH_3$

course of the bicyclo[2.1.0]pentene cycloaddition, which shows that the homo-Diels-Alder reaction also takes place in two steps in this case.

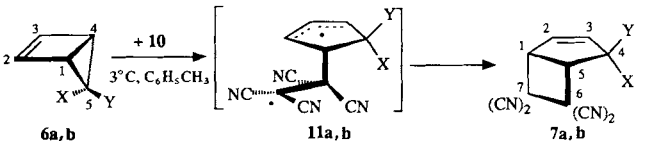
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We have solved the problem of which side the dienophile attacks the bicyclo[2.1.0]pentene system by using the known bicyclopentene esters **6a**, **b**[9] as model compounds. The separated diasteromers **6a** and **6b** each react quantitatively and stereospecifically with **10**, even at 3 °C (overnight in toluene), to give the formal homo-Diels-Alder adducts **7a** and **7b** respectively. The structure and the stereochemical arrangement of the substituents on C-4 in the diastereomers **7a**, **b** could be determined ^{1}H-NMR spectroscopically. With the given assignment[10] the hydrogen atom 5-H *cis* to the methyl group on C-4 of **7b** absorbs at higher field ($\delta = 3.81$) than the corresponding *trans* hydrogen atom 5-H of **7a** ($\delta = 4.30$), in agreement with the hydrogen atoms 1,4-H_2 *cis* and *trans* to the methyl group on C-5 of **6b** ($\delta = 2.03$) and **6a** ($\delta = 2.38$).[9] This assignment can be checked independently by means of NOE ^{1}H-NMR difference spectra. Upon irradiation of the resonance frequency of the 4-methyl signal, the increase in intensity of the signal of 5-H (relative to 3-H) in the spectrum of **7b** brought about by the nuclear Overhauser effect is, as a result of the smaller steric $\{CH_3\cdots H\}$ distance (2.90 Å), about double that of the corresponding signal in the spectrum of **7a**, in which 5-H and the 4-CH_3 group are *trans* to each other, and their steric separation is 3.84 Å.[11]

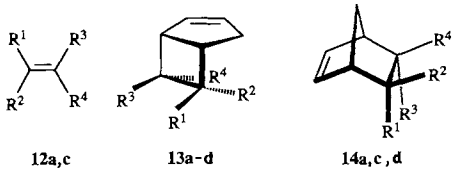


a: X = CH_3, Y = CO_2CH_3; **b**: X = CO_2CH_3, Y = CH_3

The cycloaddition of **10** to the bicyclo[2.1.0]pentenes **6a**, **b** proceeds stereospecifically *endo* with respect to the cyclopropane ring. Thus, the stereochemical course of this reaction is exactly the opposite to that of the homo-Diels-Alder reaction of the homofurans **4a**, **b** and consistent with that of the $[_\sigma2+_\pi2]$-cycloaddition of the bicyclo[2.1.0]pentane system (e.g. **1**). It may be assumed therefore that the formal homo-Diels-Alder reaction of the bicyclo[2.1.0]pentene proceeds, just like the cycloaddition of the bicyclo[2.1.0]pentane, in two steps via a diradical intermediate **11a**, **b**.[12]

To check this assumption we have investigated the stereochemical course of the reaction with respect to the olefinic components using the dicyanofumaric and maleic acid esters **12a**, **c**[13] as model compounds. Reaction of a 93:7 mixture of bicyclopentene **6** and 1,3-cyclopentadiene with **12a** (3 h, 0 °C, THF) led to the formation of three products in the ^{1}H-NMR spectroscopically determined ratio of 55:30:15. The by-product formed in 15% yield is identical with the Diels-Alder adduct **14a** of 1,3-cyclopentadiene and **12a**. The two main products, of which the isomer formed in 55% yield could be enriched by fractional crystallization to 80%, could, according to a comparison of their spectral data[10] with those of the tetracyanoethylene adduct 7,[7] be the bicyclo[3.2.0]heptene derivatives **13a**, **b**. An unequivocal stereochemical assignment of the substituents on C-6 and C-7 is not possible here. The reaction of **6** (purity > 99%) with **12c** leads at 0 °C (48% conversion of **12c** after 15 min) to a mixture of seven products in the ratio 31:22:19:11:10:5:3. Of the three main products, two, which are formed in 31 and 19% yield, are identical with **13a** and **13b**, the products of the reaction of **6** with **12a**. The spectral data of three by-products (formed in 5, 10 and 3% yield) are identical with those of **14a**, **c** and **d**, the Diels-Alder adducts of 1,3-cy-

clopentadiene and **12a** and **12c** respectively.[14] We assign to the remaining products (22 and 11%) the structures of the still missing *cis*-diastereomers **13c, d**. No significant *cis-trans* isomerization **12c** → **12a** (<5%) takes place under the reaction conditions.[15] It is demonstrated therefore, that the cycloaddition of bicyclo[2.1.0]pentene **6** proceeds non-stereospecifically, as expected in the case of a two-step process.



12a,c **13a-d** **14a,c,d**

a: $R^1=R^4=CN$, $R^2=R^3=CO_2CH_3$; **b**: $R^1=R^4=CO_2CH_3$, $R^2=R^3=CN$; **c**: $R^1=R^3=CO_2CH_3$, $R^2=R^4=CN$; **d**: $R^1=R^3=CN$, $R^2=R^4=CO_2CH_3$

Finally, there remains the question of which factors are responsible for the different course of the homo-Diels-Alder reaction of homofuran **4** and bicyclopentene **6**. The two systems have very different strain energies. In the homofuran **4**, the strain energy is essentially determined by the cyclopropane ring, whereas in the bicyclopentene **6** it is composed of the three- and four-membered ring strain as well as the negative resonance energy, which is attributed to the antiaromatic character of **6** as homocyclobutadiene.[16] In the transition state of the two-step process, the central cyclopropane bond could be opened further than in the concerted homo-Diels-Alder reaction. The reaction of **6** profits in particular from this bond opening, since the total strain of the bicyclopentene is released in one step.

[11] The average $CH_3\cdots H$ distances were taken from MMX force field calculations: J. J. Gajewski, K. E. Gilbert, Serena Software 1988.
[12] Owing to the high polarity of the olefins **10** and **12a, c** the reactive intermediates of type **11** could also have dipolar structures.
[13] C. J. Ireland, K. Jones, J. S. Pizey, S. Johnson, *Synth. Commun. 6* (1976) 185; T. Gotoh, A. B. Padias, H. K. Hall, Jr., *J. Am. Chem. Soc. 108* (1986) 4920.
[14] Since the Diels-Alder reaction of 1,3-cyclopentadiene with **12c** (0°C, 3 h, THF) yields only the *cis*-adducts **14c** and **14d** in the ratio 87:13, the *trans*-adduct **14a** must be formed directly from **6** in the reaction of **6** with **12c**. This result indicates that the $[_\pi 2 + _\pi 2]$-cycloaddition also proceeds non-stereospecifically and thus, as expected, in two steps.
[15] After 2 h the ratio of unchanged **12c** to **12a** is 90:10 and after 3 h 77:23. In a control experiment the extent of *cis-trans* isomerization **12c** → **12a** without addition of **6** was determined as 28% after 3 h at 0°C. It can therefore be ruled out that **6** catalyzes the *cis-trans* isomerization **12c** → **12a**. From the time-dependence of seven measurements (between 15 and 180 min) the product ratio of the reaction of **6** with **12c** was extrapolated to the time $t = 0$: $[\mathbf{13a}:\mathbf{13b}:\mathbf{13c}:\mathbf{13d}:\mathbf{14a}:\mathbf{14c}:\mathbf{14d}]_{t\to 0} = 29:18:24:12:3:11:4$.

Nickel-Catalyzed Cyclodimerization of Hexapentaenes: [4]Radialenes and [5]Radialenones with Cumulated Double Bonds**

By *Masahiko Iyoda,* Yoshiyuki Kuwatani, Masaji Oda, Yasushi Kai,* Nobuko Kaneshisa*, and *Nobutami Kasai**

Although cumulenic double bonds[1] have a wide variety of potential reactive sites, which can lead to novel cyclic dimers, trimers, and oligomers, great difficulty in controlling the reactivity has prevented the utilization of cumulenes in organic synthesis. We recently reported the nickel-catalyzed cyclooligomerization of [3]cumulenes (butatrienes)[2] and the cyclodimerization of [5]cumulenes (hexapentaenes)[3] to give various types of radialenes, and demonstrated the synthetic utility of this type of reaction. We report here the nickel-mediated synthesis of novel [4]radialenes and [5]radialenones[4] based on the same synthetic strategy.

Tetramethyl- and tetra-*tert*-butyl[5]cumulenes dimerize thermally to give octamethylcyclododeca-1,3,7,9-tetrayne[6] and tetrakis(di-*tert*-butylvinylidene)cyclobutane.[7] However, nickel-catalyzed cyclodimerization of tetraarylhexapentaene yields 1,2-bis(diarylmethylene)-3,4-bis(diarylpropadienylidene)cyclobutane as the head-to-head dimer.[3] Thus, the known thermal and nickel-catalyzed dimerizations of [5]cumulenes occur regioselectively. In order to investigate the difference in the reactivity of these double bonds, we carried out reactions of the [5]cumulenes **5** with nickel catalysts.

The [5]cumulenes **5a-c** were prepared according to the procedure outlined in Scheme 1. Ethynylation of the ketones

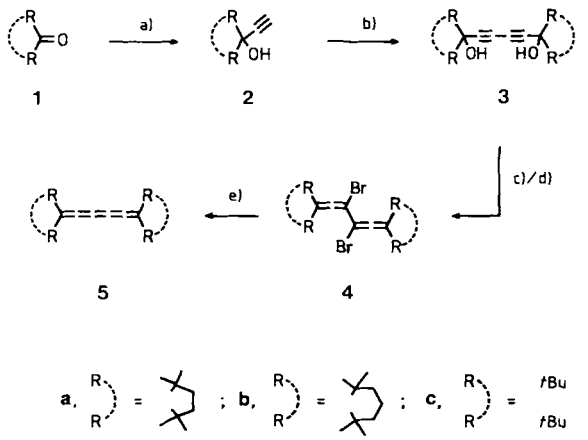
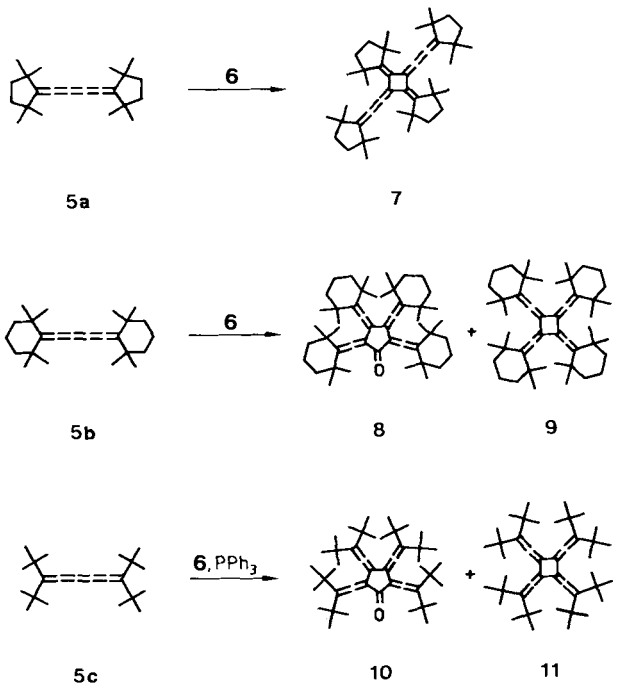
1a and **1b** with lithium acetylide in THF gave **2a** and **2b** in 91 and 89% yields, respectively. The oxidative coupling of **2a** and **2b** with $Cu(OAc)_2 \cdot H_2O$ in pyridine-methanol at 55 °C afforded the diols **3a** (90%) and **3b** respectively[8]. Treatment of **3a** with conc. hydrobromic acid in acetic acid furnished the corresponding dibromide **4a** (90%). Reduction of **4a** with zinc in THF gave the desired [5]cumulene **5a** (95%). The conversion of **3b** into **5b** was carried out by a previously reported method.[8] The cumulene **5c** was prepared according to the procedure shown in Scheme 1 [a) 88.5%; b) 89%; d) 84%; e) 81%].[9]



Scheme 1. a) $LiC \equiv CH$, THF, −78 °C → RT. b) $Cu(OAc)_2 \cdot H_2O$, pyridine-methanol (1:1), 55 °C. c) HBr, AcOH, RT. d) PBr_3, benzene, 50 °C. e) Zn, THF, sonication.

Although **5a–c** are less reactive than tetraarylhexapentaenes, which react smoothly with $[Ni(CO)_2(PPh_3)_2]$ **6** in refluxing benzene to afford the dimers, their reactions with stoichiometric amounts of **6** in benzene at the same temperature lead very slowly to the cyclic dimers. Thus, treatment of **5a** with 0.5 equivalents of **6** in refluxing benzene under argon for 24 h gave the head-to-tail dimer **7** in 82% yield. Interestingly, the reaction of the more bulky-substituted **5b** with 1 equivalent of **6** in refluxing benzene for 2 days resulted in the formation of the [5]radialenone **8** in 32% yield, together with the corresponding [4]radialene **9** in 36% yield. The difference in the reactivity of **5a** and **5b** towards the nickel(0) complex may be due to steric factors. Furthermore, treatment of the most bulkily-substituted **5c** with 1 equivalent of **6** in the presence of 3 equivalents of triphenylphosphane in refluxing benzene for 8 days gave the [5]radialenone **10** as the main product (74%), together with a small amount of **11** (6%). Since the starting [5]cumulenes **5** described here can be prepared easily by the route shown in Scheme 1, the [4]radialenes **7** and **9** and the [5]radialenones **8** and **10** can be synthesized in only a few steps.

The *[4]radialenes and [5]radialenones* reported here are very stable towards light and air. Molecular models show that **7** can have a planar structure with D_{2h} symmetry. The ^1H- and ^{13}C-NMR spectra (Table 1) reflect its highly symmetrical structure. The electronic spectra of **7** show absorptions up to 450 nm, indicating elongation of π-conjugation, whereas the electronic spectrum of **9** shows absorption only up to 350 nm, corresponding to its spiro-oriented allenic π bonds. The ^1H- and ^{13}C-NMR spectra of the [5]radialenones **8** and **10** show symmetrical structures. The IR spectra contain two characteristic bands for α,β,γ-unsaturated ketones



Scheme 2. **6** = $[Ni(CO)_2(PPh_3)_2]$.

at 1940–1910 cm^{-1} (C=C=C) and 1690 cm^{-1} (C=O). The adsorption of the ketones **8** and **10** on silica gel results in a bright yellow coloration, and the electronic spectra of **8** and **10** in CF_3COOH show a marked bathochromic shift tailing up to 700 nm with a deep violet coloration.

Table 1. Selected physical data of compounds 7–**10**.

7: Yellow needles (from CH_2Cl_2-hexane), m.p. = 281–282 °C; MS (70 eV): *m/z* 592 ($M^{\oplus}$); ^1H NMR (400 MHz, $CDCl_3$, 30 °C, TMS): δ = 1.23 (s, 24H; CH_3), 1.45 (s, 24H; CH_3), 1.65 (s, 8H; CH_2), 1.68 (s, 8H; CH_2); ^{13}C NMR (100 MHz, $CDCl_3$, 30 °C, TMS): δ = 27.8(q), 30.3(q), 40.6(s), 41.6(s), 46.1(t), 48.0(t), 118.5(s), 136.7(s), 145.2(s), 148.9(s), 155.2(s), 155.9(s); UV/VIS (cyclohexane): λ_{max} [nm] (log ε) = 253 (4.46), 260 sh (4.42), 285 (4.22), 323 sh (4.73), 334 (4.98), 406 (3.93), 431 sh (3.82); Raman (KBr): $\tilde{\nu}$ [cm^{-1}] = 2005 (C=C=C=C), 1637, 1610 (C=C).

8: Yellow needles (from EtOH), m.p. = 226–227 °C; MS: *m/z* 676 ($M^{\oplus}$); ^1H NMR (400 MHz, $CDCl_3$): δ = 1.12 (s, 12H; CH_3), 1.14 (s, 12H; CH_3), 1.17 (s, 12H; CH_3), 1.19 (s, 12H; CH_3), 1.34–1.47 (m, 16H; CH_2), 1.58–1.69 (m, 8H; CH_2); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 19.0(t), 19.3(t), 30.8(q), 30.9(q), 31.4(q), 31.5(q), 35.7(t), 35.9(t), 40.8(s), 41.7(s), 101.4(s), 107.7(s), 126.9(s), 128.1(s), 191.9 (s, CO), 196.7(s), 202.4(s); UV/VIS (cyclohexane): λ_{max} [nm] (log ε) = 215 (4.78), 246 (4.70), 263 sh (4.22), 298 (3.64), 313 (3.47), 378 (3.39), 408 sh (3.26); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1941, 1919 (C=C=C), 1691 (C=O).

9: Colorless needles (from Et_2O-EtOH), m.p. = 315 °C (sublimed); MS: *m/z* 648 ($M^{\oplus}$); ^1H NMR (90 MHz, $CDCl_3$): δ = 1.12 (s, 48H; CH_3), 1.25–1.80 (m, 24H; CH_2); ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 19.2(t), 31.7(q), 35.5(t), 40.9(s), 109.4(s), 127.6(s). 192.5(s); UV/VIS (cyclohexane): λ_{max} [nm] (log ε) = 215 (5.13), 252 sh (4.27), 259 (4.28), 268 sh (4.19), 300 (3.38), 318 (3.42); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1957, 1917 (C=C=C).

10: Yellow prisms (from Et_2O-MeOH), m.p. = 220 °C (sublimed); MS: *m/z* 628 ($M^{\oplus}$); ^1H NMR (400 MHz, $CDCl_3$): δ = 1.24 (s, 36H, *t*-Bu), 1.25 (s, 36H; *t*-Bu); ^{13}C NMR (100 MHz, $CDCl_3$): δ: 32.2(q), 32.5(q), 36.6(s), 36.7(s), 100.7(s), 107.0(s), 129.0(s). 130.6(s), 192.2 (s, CO), 199.2(s), 205.1(s); UV/VIS (THF): λ_{max} [nm] (log ε) = 244 (4.67), 270 sh (4.15), 300 sh (3.75), 315 sh (3.36), 378 (3.36), 408 (3.27); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1908 (C=C=C), 1691 (C=O).

In order to elucidate the unique molecular structure of [5]radialenone **10**, its crystal structure was determined by X-ray diffraction analysis.[10] The crystal lattice contains two crystallographically independent molecules, which are found to have essentially the same structure, including the

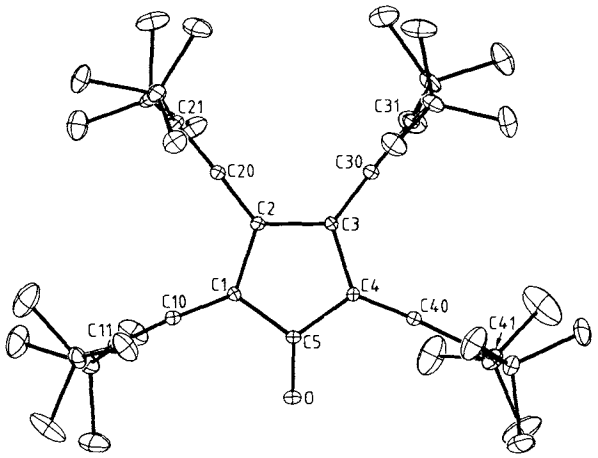


Fig. 1. Molecular structure of **10** in the crystal (ORTEP) with the thermal ellipsoids at the 10% probability level for the non-hydrogen atoms. The estimated standard deviations are 0.009–0.011 Å and 0.7–0.8° for bond distances and angles: C1-C2 1.492, C2-C3 1.483, C3-C4 1.490, C4-C5 1.488, C5-C1 1.476, C5-O 1.206, C1-C10 1.322, C10-C11 1.302, C2-C20 1.318, C20-C21 1.312, C3-C30 1.320, C30-C31 1.310, C4-C40 1.325, C40-C41 1.286; C1-C2-C3 107.8, C2-C3-C4 107.8, C3-C4-C5 108.1, C4-C5-C1 107.7, C5-C1-C2 108.4, C1-C2-C20 123.9, C20-C2-C3 128.4, C2-C3-C30 126.4, C30-C3-C4 125.7, C40-C4-C5 122.0, C4-C5-O 126.2, C2-C1-C10 129.2, C3-C4-C40 129.9, O-C5-C1 126.0, C5-C1-C10 122.4, C1-C10-C11 175.4, C2-C20-C21 177.7, C3-C30-C31 179.2, C4-C40-C41 175.4.

conformations of the *tert*-butyl groups. Figure 1 shows the molecular structure of **10** in the crystal; particularly noteworthy is the high coplanarity of the cyclopentanone ring, the maximum atomic deviation from the least-squares plane of the central five-membered ring being 0.03 Å. The planar structure extends to the exocyclic allenic bonds with a maximum deviation of 0.24 Å. The bond distances in the carbonyl and allene moieties of the molecule are normal, while the bond angles C(2)–C(1)–C(10) [129.2(6)°] and C(3)–C(4)–C(40) [129.9(7)°] are significantly larger than the expected value of 126° in spite of the large distance between the methyl groups of the neighboring *tert*-butyl substituents. A similar angular deformation was found in tetrakis(1,3-dithiaindanylidene)cyclopentanone[11] due to significant non-bonded repulsion between the substituents of exocyclic bonds. In comparison with the half-chair conformation of the molecule, the planar structure of **10** may be due to the absence of steric strain between the *tert*-butyl substituents as a result of the extension of the exocyclic bonds by a cumulenic structure.

Nickel-catalyzed reactions provide the possibility of preparing highly unsaturated compounds containing functional groups.[12] The results reported here demonstrate the utility of nickel-catalyzed cyclooligomerization for the synthesis of highly unsaturated unique molecules.

[10] Crystal data of **10**: $C_{45}H_{72}O$, $m = 629.1$, monoclinic, space group $P2_1/n$, $a = 16.400(2)$, $b = 21.176(1)$, $c = 28.087(3)$ Å, $\beta = 116.07(1)°$, $V = 8762.0(16)$ Å^3, $Z = 8$, $D_x = 0.953$ g cm^{-3}. The transformation $100/0\bar{1}0/\bar{1}0\bar{1}$ gives a reduced cell of $P2_1/c$. X-Ray intensity data were measured on a Rigaku four-circle diffractometer with nickel-filtered $Cu_{K\alpha}$ radiation using a $0.3 \times 0.3 \times 0.3$-mm crystal. A collodion coating was necessary to prevent decomposition of the crystal. 11 023 reflections were collected up to $2\theta = 120°$, of which 7355 had $|F_o| > 3\sigma(F_o)$ and were used in the refinement. The intensity data were corrected for Lorentz and polarization effects but not for absorption [$\mu(Cu_{K\alpha}) = 3.8$ cm^{-1}]. The crystal structure was solved by direct method (SHELXS-86) and refined by full-matrix least-squares (XRAY-76). Anisotropic refinement revealed the abnormally large thermal vibration of the *tert*-butyl substituents, all the hydrogen atoms connecting to those methyl carbons were difficult to locate in the difference Fourier maps. The weighting scheme used was $w = [\sigma^2(F_o) + 0.003(F_o)^2]^{-1}$. The final R and R_w indices were 0.118 and 0.161, respectively. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.

Golfomycin A, a Novel Designed Molecule with DNA-Cleaving Properties and Antitumor Activity**

By *K. C. Nicolaou,** *Golfo Skokotas, S. Furuya, H. Suemune*, and *D. Colette Nicolaou*

Due to their fascinating structures and biological activities, natural products have been capturing the interest and imagination of isolation, synthetic, and medicinal chemists for a very long time.[1] Designed molecules with predefined chemical and biological properties could enrich and compliment this arsenal of substances and sharpen the capability of chemistry to deliver biologically and therapeutically useful compounds. Described herein are the design, synthesis, and chemical and biological activities of a novel agent with DNA-cleaving[3] and antitumor properties, golfomycin A(**1**).[2]

Detailed in Scheme 1 is the mechanistic rationale that led to the design of compound **1** as a potential DNA-cleaving

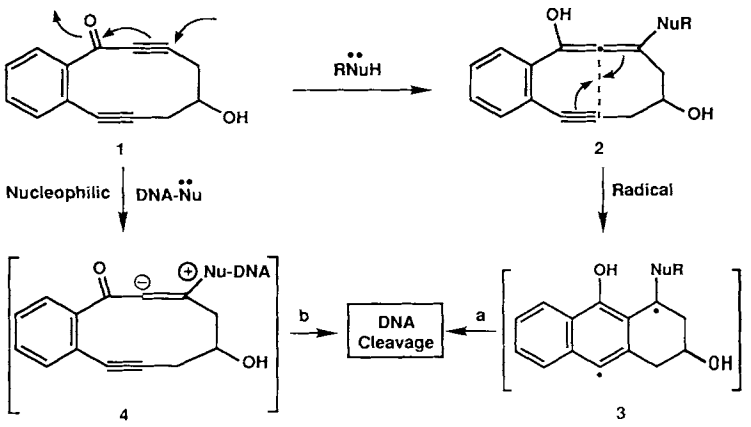
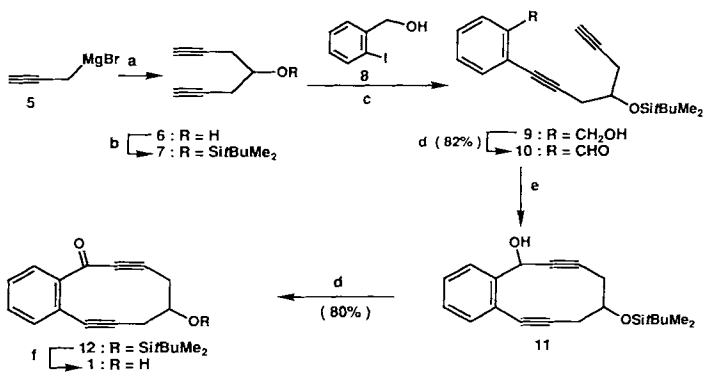
[**] We wish to thank Drs *Dee H. Huang* of the Research Institute of Scripps Clinic and *Raj Chadha* of the University of California, San Diego for their help with the NMR and X-ray crystallographic investigations, respectively. We also wish to thank Professor *B. Snider* of Brandeis University for valuable discussions regarding the chemistry of conjugated allenes.

molecule. Two alternative modes of action were considered plausible: A nucleophilic attack (e.g., from a cofactor or DNA) on the ynone function would lead to the allene-ene-yne structure **2**, which was expected, on the basis of previous results,[4] to undergo a facile cyclization to the diradical **3**. Species **3** was then expected to cleave DNA by a radical mechanism (path a, Scheme 1). Alternatively, nucleophilic addition by DNA on **1** could generate species **4**, which was projected to undergo chemistry leading to DNA cleavage via a nucleophilic mechanism (path b, Scheme 1). The highly strained nature of **1** was expected to facilitate the postulated reactions shown in Scheme 1.



Scheme 1. Mechanism-based design of molecule **1**. Plausible mechanism of DNA cleaving action of **1**, a: radical mechanism, b: nucleophilic mechanism.

The synthesis of golfomycin A (**1**) is detailed in Scheme 2. Thus, reaction of excess Grignard reagent **5** with ethyl formate led to the diacetylenic compound **6**[5] (80%), which was silylated to afford compound **7** (95%). Coupling of **7** with aromatic iodide **8** under the catalytic influence of $Pd(PPh_3)_4$-CuI[6] gave compound **9** (70%), which was oxidized with MnO_2 to furnish the acetylenic aldehyde **10**



Scheme 2. Synthesis of golfomycin A(**1**). Reagents and conditions. (a) 1.0 eq HCOOEt, THF, 0 °C, 2 h, 80%; (b) 1.2 eq tBuMe$_2$SiCl, 1.2 eq imidazole, DMF, 25 °C, 8 h, 95%; (c) 0.6 eq **5**, 0.03 eq $(Pd(PPh_3)_4$, 0.1 eq CuI, nBuNH$_2$ 0 °C, 3 h, 70%; (d) excess MnO_2, CH_2Cl_2, 25 °C, 4 h, 82%; (e) 1.0 eq $KN(SiMe_3)_2$, THF, −78 °C, 45 min, 51%; (f) 4.0 eq HF-CH_3CN, 25 °C, 3 h, 89%.

(82%). Intramolecular addition of the acetylide derived from **10** and $KN(SiMe_3)_2$ to the aldehyde function led to the ten-membered ring alcohol **11** (51%) which was smoothly oxidized (80%) and desilylated (89%) to afford the desired product **1** via its silyl ether **12**.

Golfomycin A(**1**) was found to cleave DNA in a pH-dependent manner as shown in Figure 1. Addition of methyl

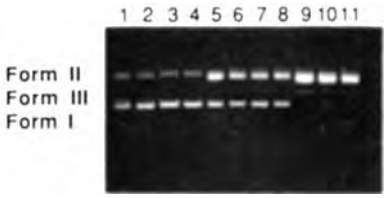


Fig. 1. DNA cleavage by golfomycin A(**1**) at various pH's. $\Phi \times 174$ form I DNA (50 μM per base pair) was incubated for 20 h at 37 °C with golfomycin A(**1**) 1000 μM) in various pH buffers and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1, DNA alone at pH 8.5; lanes 2-11 correspond to pH 5.0, 6.0, 7.0, 7.4, 8.0, 8.5, 9.0, 9.5, 10.0 and 10.7 respectively. Forms I, II and III correspond to supercoiled, relaxed, and linear DNA respectively. Control experiments at the above pH's in the absence of agent demonstrated no DNA cleavage.

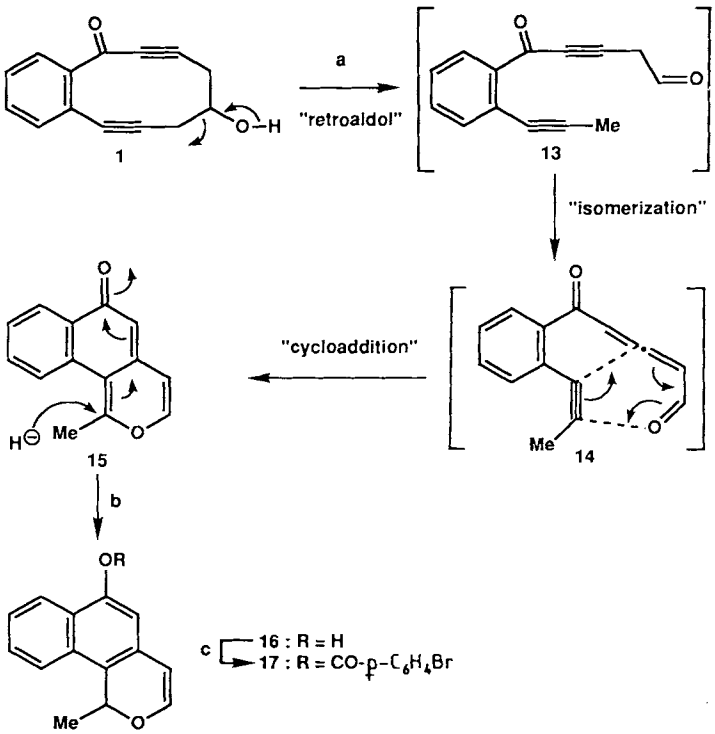
thioglycolate as a cofactor inhibited, rather than enhanced the activity of **1**, whereas, the presence of catalase did not have any measurable effect on the cleavage.

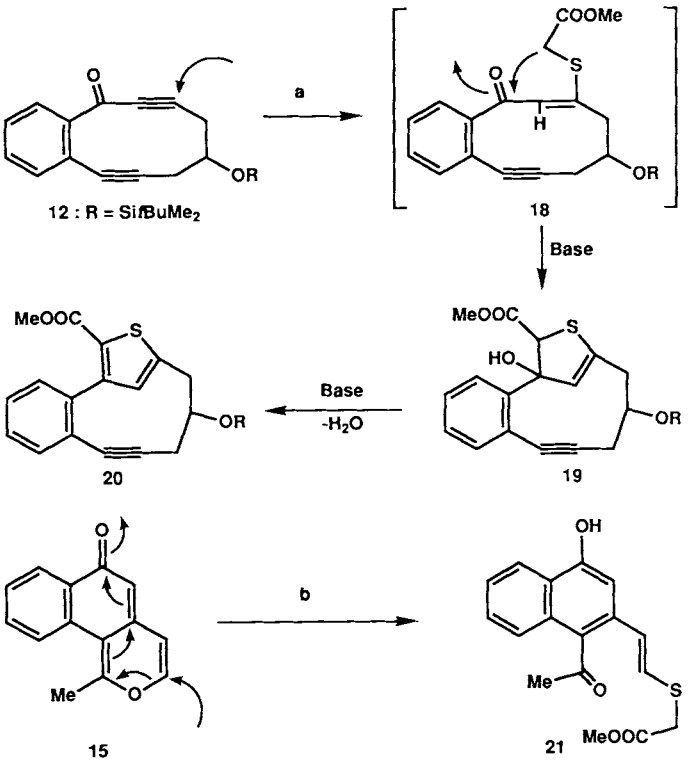
The chemistry of **1** was then investigated in order to gain insight into its mode of action. Thus, **1** was swiftly converted by 1,8-diazabicyclo[5.4.0]undec-7-ene(DBU) into an intensely fluorescent compound (75%) whose structure was assigned as **15** (coined golfomycin B, Scheme 3) on the basis of its spectral and chemical properties. Golfomycin B(**15**) reacted rapidly with $NaBH_4$ at 0 °C, leading quantitatively to compound **16** whose structure was confirmed by X-ray crystallographic analysis[7] on its p-bromobenzoate **17** (prepared from **16** in 80% yield).



Scheme 3. Chemistry of golfomycin A (**1**). (a) 1.0 eq DBU, benzene-THF, 25 °C, 0.5 h, 75%; (b) 4.0 eq $NaBH_4$, MeOH, 0 °C, 15 min, 97%; (c) 1.5 eq p-bromobenzoyl chloride, 2.0 eq Et_3N, CH_2Cl_2, 25 °C, 2 h, 80%.

To explain the formation of **15** from **1** under the basic conditions, the following events were assumed: a) retroaldol reaction (**1** → **13**); b) base-induced isomerization (**13** → **14**); and c) intramolecular [4+2]-cycloaddition (**14** → **15**).[8] Low temperature ^{1}H-NMR studies revealed the transient presence of **13** [−20 → 25 °C, δ = 9.77 (t, J = 2.5 Hz, C*H*O)] in the reaction mixture, but no signals corresponding to **14** were detected under those conditions (presumably due to the fast nature of the cycloaddition reaction).

The chemistry of golfomycin A(**1**) and B(**15**) towards nucleophiles was then investigated using methyl thioglycolate as a model reagent (Scheme 4). Thus, the silyl ether **12** reacted smoothly with excess reagent at 10 °C under basic conditions to afford compounds **19** (55%, single isomer, stereochemistry unassigned) and **20** (20%), presumably via the intermediacy of the initially formed adduct **18**.[9] Under similar conditions compound **15** furnished the 1,6-adduct **21** in 67% yield and with opposite regioselectivity[10] from the hydride reduction of **15** to **16** (Scheme 3). The propensity of both **12** and **15** to undergo facile nucleophilic attack is presumably due to strain relief (for **12** and **15**) and aromaticity gains (for **15**). Indeed, an open chain analog of **1** did not show the same reactivity, nor did it cleave DNA under the same conditions. The results presented above strongly support a nucleophilic mechanism (path b, Scheme 1) rather than a radical mechanism (path a, Scheme 1) for DNA cleavage by golfomycin A(**1**) [similarly for golfomycin B(**15**)].



Scheme 4. Addition of methyl thioglycolate to golfomycins A (**1**) and B (**15**). (a) 5.0 eq $HSCH_2COOMe$, 5.0 eq DBU, THF, 10 °C, 75%; (b) 5.0 eq $HSCH_2COOMe$, 1.5 eq DBU, THF, 25 °C, 67%.

The properties of golfomycins A(**1**) and B(**15**) prompted us to test the hypothesis that they might show antitumor activity. Indeed, preliminary in vitro tests show that golfomycin A(**1**) inhibits the growth of MB49 murine bladder carcinoma cells with IC_{50} of 3.4 μmol L^{-1} during 4 days of exposure (37 °C, 7% CO_2).[11, 12]

The described chemistry and biology of golfomycin A(**1**) demonstrate the power of design and synthesis in the preparation of molecules with specific chemical and biological properties. In vivo antitumor studies with golfomycin A(**1**) and further studies in the area of designed molecules are continuing.

[7] Details of the crystallographic analysis will be given elsewhere.

[8] The observed second wave of DNA cleavage at pH ≥9 may signal the initiation of this reaction cascade.

[9] Apparently the -SH group from methyl thioglycolate is adding to the acetylene in a *trans* fashion giving **18**, otherwise the following step **18** → **19** would be geometrically impossible. In accordance with this observation, MM 2 calculations revealed that **18** is ca. 4.9 kcal/mol less strained than its geometrical isomer. The stereochemistry of **19** was not assigned.

[10] This striking difference in regioselectivity may be the result of combined steric effects (nucleophile size and electrophilic center environment).

[11] Golfomycin B(**15**) also exhibited DNA-cleaving properties and antitumor activity although with lower potency (ca. 10 times less) than golfomycin A(**1**). These studies were carried out in collaboration with Dr. *D. Rideout* of the Research Institute of Scripps Clinic.

[12] Although it is tempting to relate DNA cleavage with cytotoxic activity this relationship must be viewed with caution pending further investigations.

Synthesis and Cycloadditions of Monomeric Selenobenzophenone **

By *Gerhard Erker,* Regina Hock, Carl Krüger, Stefan Werner, Frank-Gerrit Klärner,* and *Uwe Artschwager-Perl*

Dedicated to Professor Wolfgang R. Roth on the occasion of his 60th birthday

The higher homologues of the aldehydes and ketones are concomitantly more nucleophilic ("higher" HOMO) and more electrophilic ("lower" LUMO) than the normal organic carbonyl compounds,[1] and therefore exhibit a different reaction behavior.[2] Whereas the chemistry of the thiocarbonyl compounds is well documented,[3] only few stable selenoketones are known; all of these carry *tert*-alkyl substituents on the carbonyl carbon atom.[4] Simple selenoketones, e.g. selenobenzophenone **2**, as well as seleno- and telluroaldehydes were considered to be so reactive that they were previously only generated in situ and were detected by the formation of characteristic trapping products.[5] We have now prepared selenobenzophenone **2** and spectroscopically characterized it as the monomeric compound in solution. The stereochemistry of the [4 + 2]-cycloaddition to conjugated dienes frequently used as trapping reaction could be elucidated for the first time with this simple selenoketone. The result was surprising.

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Alfried-Krupp-von-Bohlen-und-Halbach Foundation.

2 is formed in the Staudinger chalcogenation[5c, 6] of the phosphorus ylide $Ph_3P{=}CPh_2$ **1** with elemental selenium in toluene at 85 °C (2 h). After sublimation (75 °C, $< 10^{-3}$ bar) and recrystallization, the cyclodimer **3** of the selenobenzophenone **2** can be isolated in two yellow-green crystal modifications **3a**, **3b**. Crystal structure analyses were carried out on both modifications.[7] 2,2,4,4-Tetraphenyl-1,3-diselenacyclobutane with planar C_2Se_2 ring is present, both in the triclinic form **3b** with two independent molecules in the unit cell, as well as in the monoclinic form **3a** (Fig. 1) (Z = 2). The molecules differ only in the interplanar angles between the phenyl rings and the four-membered ring. The averaged data from all independent molecules were as follows: Se–C 2.002(9), Se···Se* 2.901(6) Å; Se–C–Se* 92.9(8), C–Se–C* 87.1(8)°.

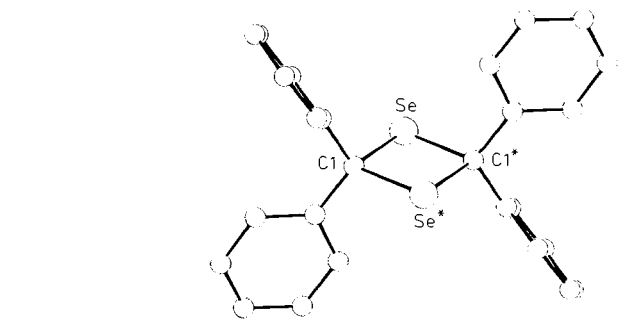

Fig. 1. Structure of the diselenacyclobutane **3** in the crystal (modification **3a**).

In solution, **3** rapidly dissociates with formation of monomeric selenobenzophenone **2**. The transformation **3** → **2** can be monitored quite well on the basis of characteristic NMR spectra.[7] **2** is intense green in solution[7] (λ_{max} = 741 nm, $n \rightarrow \pi^*$[1b]). The cleavage of **3** with formation of **2** is acid-catalyzed in many solvents. In the presence of traces of $H^{\oplus}$ and at concentrations of **3** of ca. 0.1 mol L^{-1} an equilibrium is rapidly established between **3** and **2** (3:2 ≈ 1.9 at room temperature). We have measured the rate of the uncatalyzed, thermally induced cleavage of **3** ^{1}H-NMR spectroscopically at 323 K in C_6D_6 (which was distilled with ca. 1% tetramethylenediamine to remove traces of acid). With an initial concentration of **3** of c = 0.13 mol L^{-1} a first-order rate of $k(\mathbf{3} \rightarrow \mathbf{2}) = 1.73 \times 10^{-4}\ s^{-1}$ [$\Delta G^{\neq}$(323 K) = 24.4 ± 0.3 kcal mol^{-1}] was measured.

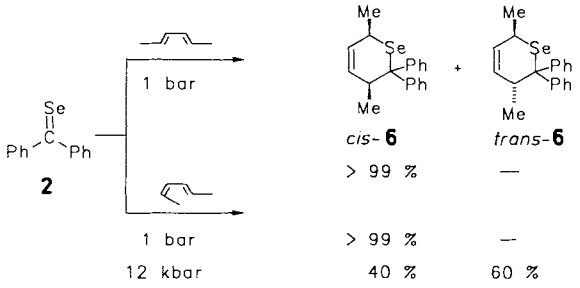
Like the reactive selenoaldehydes and selenoketones generated in situ, selenobenzophenone **2** forms [4 + 2]-cycloaddition products with conjugated dienes.[5] With 2,3-dimethylbutadiene, 2,3-dimethoxybutadiene, cyclopentadiene or 1,3-cyclohexadiene the addition compounds **4** and **5** are obtained in good yields at room temperature.[8]

4a, R = CH_3
4b, R = OCH_3

2

5a, n = 1
5b, n = 2

To check whether these cycloadditions are concerted hetero-Diels-Alder reactions we have investigated their stereochemistry by allowing **2** to react with *trans,trans*-hexa-2,4-diene in toluene at room temperature. The reaction was monitored ^{1}H-NMR spectroscopically. A single product was formed and was isolated in 82% yield. According to the spectroscopic data the product is *cis*-3,6-dimethyl-2,2-diphenyl-3,6-dihydro-2*H*-selenapyran *cis*-**6**.[9a] Only *cis*-**6** is found as product also in the analogous reaction of **2** with *cis, trans*-hexa-2,4-diene. That is, the selenapyran is formed with loss of the stereochemical information of the conjugated diene.



Concerted [4 + 2]-cycloadditions are characterized by strongly negative activation volumes. Consequently, at higher pressures they are favored over the alternative multistep reaction paths.[10] We therefore carried out the reaction of **2** with *cis, trans*-hexa-2,4-diene in toluene at room temperature again but this time at a pressure of 11–12 kbar; we now obtained, besides *cis*-**6**, the stereoisomeric *trans*-**6**[9b] (ratio ca. 40:60). Apparently, in the case of the [4 + 2]-cycloaddition of **2**, the alternative reaction routes — concerted and multistep process — are energetically so widely separated that kinetic acceleration by high pressure is necessary for the concerted hetero-Diels-Alder reaction to be competitive with the multistep addition sequence. We assume that this is true for many of the "Diels-Alder reactions" of non-stabilized chalcogeno-ketones and -aldehydes.[5]

Serendipity: Accidental Discoveries in Science. By *R. M. Roberts*. Wiley, New York 1989. xviii, 270 pp., paperback $ 12.95.—ISBN 0-471-60203-5

Serendipity is a relatively old word; it was coined in 1754 by the English writer *Horace Walpole* to describe accidental discoveries that are not the result of a deliberate search, but which nevertheless often have far-reaching consequences. An example of serendipity par excellence is the discovery of America by *Columbus*, who, as is well known, began his voyage in a search for a new sea route to India. Not far from India lies Serendip—now called Sri Lanka—where, according to an oriental tale with which *Walpole* was familiar, many centuries ago three princes continually made accidental discoveries of this sort during their extensive journeyings.

For over 200 years serendipity remained a word used only in learned literary circles—for example, *Merton* uses it frequently in his guide through the labyrinth of learned writings "On the Shoulders of Giants"—until about 1970 when a writer who was probably looking for another word at the time came across this one (through serendipity?), and initiated its rapid climb to the status of a fashionable word, though one which is already showing the first signs of being worn out—such is the nature of these things.

That chance discoveries, luck, a "golden hand", or whatever else one may call it, have played a major role in the development of knowledge and continue to do so, is well known. *R. M. Roberts*, Professor of Chemistry at Austin, Texas, has for many years collected stories of lucky chances of this kind, and from these has produced a collection of anecdotes from many different fields of science and technology, from the Rosetta stone to the Velcro fastener, with a definite emphasis on chemical discoveries (ranging from *Wöhler*'s synthesis of urea through *Pasteur*'s separation of racemates and *Perkin*'s mauve dye to *Ziegler*'s synthesis of polyethylene, the determination of the DNA structure, the crown ethers, etc.)—anecdotes whose quality varies between wide extremes. The truth content of such stories can hardly be checked, and to try to do so would perhaps be pointless—one recalls the endless controversy about *Kekulé*'s dreams, which is of course referred to by the author.

However, whether accurate or not, the stories are in every case well told, and they therefore stick in one's memory. And for this reason it may be that their value is often more pedagogic than historical in nature, in view of their usefulness as colorful gems to include in a lecture, or to illustrate to a layman that scientists are anything but rational and "cold" in their thinking, apart from the planning of experiments which is always precise and detailed. Also the anecdotes demonstrate again and again the extent to which "chance favors the prepared mind" (*Pasteur*), thus giving at least a partial answer to the question "Why didn't *I* make that discovery?". "The essential part of any discovery comes by chance, but chance passes most people by" (*F. Nietzsche*). Unfortunately the pleasure of reading the book is slightly marred by a great number of printing and other errors; one could well do without serendipity of this sort in a revised edition.

Inorganic Chemistry. By *D. F. Shriver, P. W. Atkins* and *C. H. Langford*. Oxford University Press, Oxford 1990. xiii, 706 pp., paperback, £ 16.50.—ISBN 0-19-855231-9

"Inorganic Chemistry" is a typical anglo-american textbook. It is intended to be used mainly as a text in undergraduate courses in Canada, Great Britain and the USA and it is constructed accordingly. The individual chapters are treated briefly but precisely, with a generous quantity of clear and lucid illustrations. In addition, the reader is offered a large number of exercise problems, the solutions to which are given in the book.

As noted by the authors in the preface, the book cannot enter into as detailed a treatment of inorganic chemistry as the well-known textbooks "Cotton and Wilkinson", "Holleman and Wiberg", or "Greenwood and Earnshaw".

In five sections with altogether 19 subchapters, the authors do justice to the objectives of the book in an outstanding fashion. New research results as well as the application of modern spectroscopic methods are also included.

In the first main section the structures of atoms, molecules and solids are discussed. Notable features are the early introduction to symmetry analysis, the related classification of point-groups and the application of MO theory and of isolobal analogies. Physico-chemical methods of analysis are described using illustrative examples at appropriate places in the text. Even a section on one-dimensional conductors and superconductivity is included.

The second main section is entitled "Reactions". Four sections treat the concepts of Brønsted acids and bases, the Lewis acid-base principle, complexes of the d-metals and redox reactions. Here again the linking-up of basic knowledge and the physico-chemical background has succeeded remarkably well.

The third main section which concerns the s- and p-block elements is a successful introduction to the organometallic chemistry of main group elements. Included here are H, B, C, N, the halogens and the noble gases as well as compounds of these elements. Topics discussed include the preparation and structures of organometallic compounds, of compounds with element–element multiple bonding and of boranes. Polyanions and -cations, band gaps and conductivity, and "Chemical Vapour Deposition" are treated in shorter chapters. Two display boxes on manipulations under inert atmospheres are an original contribution.

The fourth main section is devoted to transition metal complexes of the d- and f-block elements. Term diagrams, UV-VIS spectroscopy, luminescence phenomena, EPR spec-

troscopy, reaction mechanisms of the d-block transition metal complexes and the organometallic chemistry of the transition metals are discussed here.

In the last main section entitled "Interdisciplinary Topics" the reader will find those aspects of inorganic chemistry which in the last few years have grown in importance and which have for the most part already developed into their own areas of activity: homogeneous and heterogeneous catalysis, the structure and properties of solids (crystal defects, ionic conduction, structure and magnetic characteristics) and not least bioinorganic chemistry.

The work is rounded off with an appendix which also includes character tables and information on the symmetry of orbital groups, as well as a formula and key-word index. For further reading there are ample references to the current literature; however, all these are English language journals and books.

Only a few errors could be found. The figure referring to $Cl_2B{=}N(iPr)_2$ (p. 338) is incomplete. On p. 340 a method for the preparation of Ga^{II} halides is cited, whereas only on the next page is it correctly pointed out that "$Ga^{II}Cl_2$" is in reality $Ga^{I}[Ga^{III}Cl_4]$. The comparison of a 3z, 2e-bond in the Al_2CH_3 bridge of $Al_2(CH_3)_6$ with the 3z,4e-bond in an Al_2Cl bridge of $(CH_3)_2AlCl_2Al(CH_3)_2$ (p. 316, Fig. 10.3) is also confusing, as the latter is described as a 2z,2e-bridge.

Nonetheless these minor defects cannot tarnish my overall positive impression of the book. Its approach, which differs from that of traditional textbooks, and the fact that new areas of inorganic chemistry are included (even though the choice is subjective), makes it a valuable supplement for students after their prediploma or first degree. It can also be recommended for diplomands and doctorate (graduate) students. Also worth mentioning is the pleasing appearance of the paperback version; it is very good value for the price.

Bernhard Neumüller [NB 1081 IE]

der Universität Marburg (FRG)

The Chemistry of Enones. Parts 1 and 2. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester 1989. xvi, 1267 pp., hard cover, £ 285.00.—ISBN 0-471-91563-7 (Part 1)/ 0-471-92289-7 (Part 2)

α,β-Unsaturated carbonyl compounds are among the most important functional groups of organic chemistry, a fact which has now been recognized by the publication of the book "The Chemistry of Enones", edited by *S. Patai* and *Z. Rappoport*, in the series "The Chemistry of Functional Groups". The authors of the 22 individual contributions which make up this two-part work have not assumed an unduly narrow definition of the term "enone", and where the context is appropriate they have also included unsaturated aldehydes, esters or ketenes. In accordance with the aims of the "Patai" series, the authors have not attempted an exhaustive treatment of their individual topics; instead there is a clear emphasis on reviewing recent results. However, the topics are in most cases introduced in such a general way as to result in self-contained, easily readable, chapters that have the character of monographs. To give just one example, Chapter 17 on oxygenation reactions is introduced by a general description of active oxygen-containing species. The resulting unavoidable instances of overlapping between chapters are generally kept within acceptable limits.

In contrast to other handbooks such as "Houben and Weyl", the pattern generally adopted by *Patai* is to present the chemistry of the functional groups in a broad framework ranging from theory through spectroscopic properties to synthetic applications. Accordingly the first chapter by *A. Y. Meyer* (Jerusalem) deals with the general and theoretical aspects of enones. There have been very few recent quantum chemical studies concerned exclusively with enones, and the author therefore takes the opportunity to include in his article a number of his own unpublished studies, and presents a general discussion of the relationships between conformational and spectroscopic properties. The next two chapters, on structural chemistry (*B. Schweizer*, Zürich) and on conformational and optical rotational properties (*J. K. Gawronski*, Poznán) follow logically after the theoretical chapter. The many structural formulas with bond lengths and angles are useful, even though half a page each on cyclobutenone and cyclopentenone (pp. 39, 40) seems rather excessive. In the following review of the thermochemistry (*J. F. Liebman* and *R. M. Pollack*, Baltimore), the most important parts are the tables. The chapter on NMR spectroscopy (*H. E. Gottlieb*, Ramat Gan, Israel) includes detailed conformational analyses as a central topic, and the comparison with the theoretical predictions of the preceding chapters is very instructive. The next article, on the chemistry of ionized enones in the gas phase (*F. Turecek*, Prague), contains a good discussion of the rules governing the mass-spectrometric fragmentation behavior. In this context quinones are also mentioned as an important related class of compounds, which also have a separate volume devoted to them in the *Patai* series.[*]

However, the main emphasis of the work (occupying about 1000 of the 1200 pages) is on the various aspects of chemical reactivity, which are covered in the following 14 chapters. There is not space here to discuss every chapter in detail, but the wide range of subjects provides clear evidence of the many-faceted reactivity of the enones as ambidentate functional groups (Ch. 7, synthesis: *C.* and *Y. Thebtaranonth*, Bangkok; Ch. 8, general synthetic applications: *G. V. Boyd*, Jerusalem; Ch. 9, acid-base behavior: *R. I. Zalewski*, Poznán; Ch. 10, nucleophilic attack: *D. Duval* and *S. Géribaldi*, Nizza; Ch. 11, addition of electrons or radicals: *G. A. Russell*, Ames; Ch. 12, reactions with electrophiles: *K. Müllen* and *P. Wolf*, Mainz; Ch. 13, enzymic transformations: *R. M. Pollack, P. L. Bounds* and *C. L. Bevins*, Baltimore; Ch. 14, electrochemistry: *R. D. Little* and *M. M. Baizer*, Santa Barbara; Ch. 15, photochemistry: *D. I. Schuster*, New York; Ch. 16, radiation chemistry: *P. Neta* and *M. Dizdaroglu*, Maryland; Ch. 17, oxygenation reactions: *A. A. Frimer*, Ramat Gan, Israel; Ch. 18, reductions: *E. Keinan* and *N. Greenspoon*, Haifa; Ch. 19. organometallic derivatives: *J. A. S. Howell*, Keele; Ch. 20, enolizations: *B. Capon*, Hongkong; Ch. 21, asymmetric syntheses: *M. R. Peel* and *C. R. Johnson*, Detroit; Ch. 22, dimerizations and polymerizations: *C. R. Theocharis*, Uxbridge).

The detailed sub-division of the extensive subject matter enables the reader to easily find the topic of immediate interest. Overlapping occurs in some areas, however; thus, for example, the reader looking for information on asymmetric syntheses would be well advised not to limit his attention to Chapter 21. Again, important oxygenation reactions are found not only in Chapter 17 but also under reactions with electrophiles (Chapter 12).

The authors have, without exception, aimed to cover work published up to the beginning of 1988, but the overwhelming

[*] Cf. *Angew. Chem. 101* (1989) 649; *Angew. Chem. Int. Ed. Engl. 28* (1989) 933.

majority of the references are to papers from earlier years. Some random checks showed that modern developments in, for example, enantioselective *cis*-hydroxylation using osmium tetraoxide, polarity reversal of the reactivity in enones and enals, free radical addition to enones (e.g. for synthesizing *C*-glycosides) and modern variants of the Khand-Pauson, Sakurai and Nazarov reactions are all included. It is true that in several of these areas there have been further rapid advances since the volume appeared, but the reader will nevertheless find here a good introduction to these topics. This reviewer was disappointed to note that some important contributions to enones chemistry from the carbohydrates field were not included. The neglect of this aspect is regrettable in view of the use now being made of renewable raw materials for synthesizing enantiomerically pure natural substances.

There is now an increasing level of interest in the safety and toxicity aspects of chemical substances and reagents, and editors of comprehensive handbooks will probably need to give more thought to this in the future. In the present volume such information is only rarely included, e. g. the warning about the possible explosive risk with some molybdenum oxodiperoxy complexes (p. 548).

Now some comments regarding the formulas. The convenient small page format used in "Patai" has advantages for the user, but occasionally, for typographical reasons, it necessitates moving a formula scheme on to the next page. The formulas are generally clear and well set out (except for the fact that the stereo-arrows are too thick, especially in the representation of cyclopentene on p. 255).

The idea of constructing the handbook as a collection of self-contained monographs means that it is particularly important to have comprehensive author and subject indexes. It would perhaps have been useful to make the subject index even a little more comprehensive, at the expense of some duplication. To give just one example, the Sakurai reaction cannot be found in the index under this name; it is (very correctly) indexed as the Hosomi-Sakurai reaction.

No library which already contains parts of the *Patai* series can afford to be without this volume. Because of the importance of the functional groups that it deals with, it will also be a useful and worthwhile addition to the private collections of preparative organic chemists.

The Chemistry of Linear Oligopyrroles and Bile Pigments. By *H. Falk*. Springer, Vienna 1989. xii, 261 pp., hardcover, DM 270.00.—ISBN 3-211-82112-0

There is hardly another class of compounds in organic chemistry that has held more fascination for investigators of successive generations than the pyrrole pigments. Since the pioneering work of *Hans Fischer* and his school, pyrrole derivatives in the widest sense have for several decades been the subject of studies by many renowned laboratories throughout the world. One recalls, for example, such celebrated studies as that which led to the determination of the structure of the vitamin B_{12} coenzyme (*D. C. Hodgkin*), those on the total syntheses of chlorophyll *a* (*R. B. Woodward*) and of cyanocobalamine (*A. Eschenmoser* and *R. B. Woodward*), the biosynthesis of the corrinoids (*A. Battersby, A. I. Scott* and others), the development of models for oxygen fixation (*J. P. Collman, J. E. Baldwin* and others), and many more. However, whereas the chemistry and biology of the macrocyclic pyrrole pigments and the chemistry of pyrrole and its derivatives have been reviewed more than once during the past fifteen years, since the publication of the classic work by *R. Lemberg* and *J. W. Legge* ("Hematin Compounds and Bile Pigments") and of the mainly medically orientated book by *T. B. With* ("Bile Pigments", 1968) there has been no comparable monograph covering the bile pigments and the related linear oligopyrroles. This is probably due to the fact that bile pigments occur as breakdown products of the biologically important porphyrin chromophores, and consequently in the past it is their clinical significance that has been emphasized. Although *Lemberg* discovered as long ago as 1933 that the substances responsible for the colors of cyanobacteria and red algae belong to the class of bile pigments, the renaissance in the chemistry of these compounds did not occur until the early 1950s, following the pioneering work of *H. Fischer* and his school, when a chromophore of the bile pigment type was also shown to be present in phytochrome, the photoreceptor which controls plant morphogenesis. Since then there have been some important milestones in the new era of bile pigment chemistry, such as the elucidation of the structures of the chromophores mentioned above (*J. J. Katz, H. Rapoport, W. Rüdiger, H. W. Siegelman* and others) and of a bioluminescent bile-type pigment found in marine organisms (*Y. Kishi* et al., 1988), and particularly the recently published X-ray structural analysis of the photoreceptor proteins of cyanobacteria (*R. Huber* et al., 1986), and these successes have stimulated a continued growth in activity in this area.

The book "The Chemistry of Linear Oligopyrroles and Bile Pigments", by *H. Falk*, thus closes the existing gap in the literature at an opportune moment, and it does this admirably. The eight chapters of this 534-page work deal exhaustively with the physical and chemical properties of the various members of this class of compounds. After a short introductory chapter, the troublesome question of the nomenclature of linear oligopyrroles is critically discussed in Chapter 2, and suggestions for a rational system of nomenclature are offered. Since moves to resolve this problem at an international level are still in their beginnings, the reader is strongly recommended to read this chapter right at the start. The account in Chapter 3 of the occurrence, formation and importance of linear tetrapyrroles in nature is rather brief (20 pp.), although it is true that further information on these topics is given in the chapters that follow (for example, the latest papers on the enzymic synthesis of tetrapyrroles are cited on p. 352, and the structures of the bile pigments present in butterfly wings are given on pp. 203–205, 231, 318 etc.). The reader whose main interest concerns the clinical aspects of bile pigments is referred to several relevant recent monographs. Chapter 4 collects together some very instructive information about the historical development of pyrrole chemistry; the connection between this and the human intellect is illustrated by drawings from the *papyrus Ebers* of the 17th century B.C., and by the oboe passages of *Mozart*'s Magic Flute (which is even cited in the index).

Chapter 5 covers more than half the book (293 pp.), and deals with the structure and stereochemistry of pyrroles (including MO methods). The majority of the work described here comes from the author's own scientific papers, and the reader thus has the benefit of getting the required information directly from the present leading chemist in this area of research. Non-specialists will also appreciate the short general description in Section 5.1.3 of the physical methods used for the structural analysis of pyrroles, and the references to relevant literature. Chapter 6 describes the synthetic meth-

ods used for preparing linear oligopyrroles with two to six units in the chain, using the "synthone approach", and these are illustrated by appropriate examples. Chapter 7 deals with the physical (mainly spectroscopic) properties of oligopyrroles. Although there is some overlapping here with the contents of Chapter 5, the reader is unlikely to consider this as a disadvantage. Finally, in Chapter 8, the reactivity of oligopyrroles and bile pigments is discussed under the different types of reactions (photochemical rearrangements, the formation of metal chelates, substitution and addition reactions, etc.). The bibliography and the author and subject indexes, which have been very carefully compiled, reinforce the excellent impression obtained from this book. The figures, which have been prepared using an Apple-Macintosh computer program, are excellent and essentially error-free. In the few exceptions to this (Figs. 3.17, 5.96, 6.197–198) the attentive reader should have no difficulty in correcting the mischief of the "printer's devil". Altogether this is an excellent book, which will be indispensable to every chemist working in this field, and to those wishing to become involved.

Albert Gossauer [NB 1028 IE]

Carbon-13 NMR of Flavonoids. (Series: Studies in Organic Chemistry, Vol. 39). Edited by *P. K. Agrawal*. Elsevier, Amsterdam 1989. 564 pp., hardcover, DFl 350.00.—ISBN 0-444-87449-6

Flavonoids occur widely in plants as pigments and other constituents, and are very important not only in food technology, pharmacology and chemotherapy, but also as key substances in the chemotaxonomy of plants. Because of their wide variety of structures their identification and structural elucidation requires unambiguous spectroscopic methods. To the earlier monograph and data compilation *The Flavonoids*, edited by *J. B. Harbone* and *T. J. Mabry* and published in 1975, is now added this volume by *P. K. Agrawal* and coauthors on the ^{13}C NMR data, which supplements and updates the earlier work.

The introduction briefly describes and compares the most important spectroscopic methods that have been used to determine flavonoid structures (IR, UV, MS, ^{1}H NMR), then leads into the subject of the book by revising the structures of a few well-known flavonoids on the basis of their ^{13}C NMR spectra. A useful guide is provided by tables listing typical ^{1}H and ^{13}C NMR chemical shift ranges and coupling constants. Chapter 2 deals very briefly with the most important one- and two-dimensional NMR techniques, including decoupling procedures and correlation spectroscopy and with chemical aids for assigning ^{13}C NMR signals (shift reagents, labeling methods, derivatizations). Even the off-resonance decoupling method, now completely superseded by more sensitive and unambiguous methods for determining CH multiplicities (notably DEPT), is revived yet again.

Chapters 3 to 9 (altogether 414 pp.) constitute the largest and most useful part of the book, in which over 800 literature references are reviewed. These chapters provide a survey, in the form of tables accompanied by a concise commentary, of ^{13}C chemical shifts for flavonoids and anthocyanidines (Chapter 3), isoflavonoids, coumarins, pterocarpanoids and rotenoids (Chapter 4), neoflavonoids, auronoides and homoisoflavonoids (Chapter 5), flavonoid-glycosides (Chapter 6), chalconoides (Chapter 7), and flavanoids and flavanoid-glycosides (Chapter 9). The final chapter of the book gives useful advice on using ^{13}C chemical shift data to distinguish between the different classes of flavonoids, and to recognize functional groups and determine their position. Regrettably, though, the chapter omits to explain that, by analyzing contour diagrams from two-dimensional correlation experiments such as CH-COSY and CH-COLOC, a complete and precise structure elucidation can be obtained even with only a small amount of substance.

The literature up to 1987 is covered. Unfortunately the clarity of the presentation is marred by the fact that the formulas (usually without numbering of the carbon nuclei) are widely separated from the data tables, necessitating constant leafing back and forth. A more user-friendly arrangement would have been to give the chemical shift values directly alongside the carbon nuclei in the formulas, a form of presentation that could have been achieved by using commercially available text-graphics software. This would also have enabled the $\delta(^{1}H)$ values to be clearly shown as complementary data, especially as it is nowadays possible to rapidly determine $\delta(^{13}C)$ and $\delta(^{1}H)$ values in a single correlation experiment (CH-COSY). It would also have been useful to include details of the use of $^{3}J_{CH}$ values for determining substitution patterns (pp. 509f).

The subject and compound indexes have been badly printed in a 9-point matrix format. In the compound index it would have been better to use the Chemical Abstracts method of classification (basic skeleton and substituents). Lastly, the formulas have evidently been reproduced from the authors' hand-drawings; the use of such technically inferior methods is inappropriate in such a highly priced book. Nevertheless, the book is a useful work of reference for all those concerned with identifying flavonoids and elucidating their structures.

Chemistry of Tin. Edited by *P. J. Harrison*. Blackie, Glasgow 1989. xi, 461 pp., hardcover, £ 75.00—ISBN 0-216-92496-0.

Organotin Chemistry. (Series: Journal of Organometallic Chemistry Library, Vol. 21). By *I. Omae*. Elsevier, Amsterdam 1989, viii, 356 pp., hardcover, DFl 270.00.—ISBN 0-444-87456-9

Organotin Compounds in Organic Synthesis. Edited by *Y. Yamamoto*. Tetrahedron Symposia-in-Print 36, Vol. 45, No. 4, pp. 909–1230. Pergamon, Oxford 1989.—ISBN 0040-4020

"Tin for organic synthesis" is the best way of describing the rapid developments that have occurred in organotin chemistry. These developments were initiated by acknowledged masters of the art of dealing with complex organic molecules and their subtle stereochemistry, chemists such as *E. J. Corey, D. H. R. Barton, G. Stork* and *J. K. Stille*. The irony of this development is that most of the basic organotin reactions now used had been known in the literature for twenty years or more, though without having been exploited to such an extent. The rift that had developed between "pure" organic chemistry and organometallic chemistry, and had almost become a tradition—although such a rift did not yet exist in the days of *Victor Grignard, Karl Ziegler* and *Georg Wittig*—was only closed again when the great "back to synthesis" movement began.

Thus we now have four books on the subject. The first, by *Pereyre, Quintard* and *Rahm*, which was reviewed by the unforgettable *J. K. Stille* (*Angew. Chem. 100* (1988) 314; *Angew. Chem. Int. Ed. Engl. 27* (1988) 445), had the misfortune to appear just at the beginning of the phase of most rapid development (it covered literature up to early 1985). Important advances occurred soon afterwards, and a thoroughly revised new edition would be welcome.

The book edited by *Phil Harrison*, covering the literature up to 1987, has the encyclopedic layout of a classic monograph. It contains good thorough compilations of relevant material on the spectroscopy, structure, formation and breakdown of tin compounds, on the basic reactions involving tin, and on its biochemistry, industrial applications, etc. A great deal of information has been carefully compiled and critically evaluated with clear figures and tables. Printing errors are rare, except possibly in the names of authors, e.g. in the preface (*Poller*), while on page 17 two references have become jumbled together under (i), and the name of this reviewer got lost. The formulas are easily legible, and the presentation is attractive. The main emphasis is on structural chemical aspects, in accordance with the interests of the editor. Preparative applications, on the other hand, are relegated to the background. In some places the editor has not succeeded in fully coordinating the contributions of the different authors, as often happens in works of this kind, despite the fact that all are British. For example, overlapping occurs between Chapter 9 (Radical Chemistry of Tin, *A. G. Davies*) and Chapter 10 (The Uses of Organotin Compounds in Organic Synthesis, *J. L. Wardell*), despite the fact that these contain only 20 and 43 pages respectively. One could have wished for both these authors to be given more space, but it is not obvious to the reviewer where economies of space could be made elsewhere in the book without a sacrifice of information that would detract from the encyclopedic value of the book. Thus it is fortunate for readers interested in preparative aspects (and the number of these has increased in the last few years) that there also exist the two other books discussed below.

The book by *I. Omae* covers the literature up to 1987, and partly that of 1988. Although it deals with the classical principles of syntheses and reactions involving the tin atom (including, for example, a good treatment of the direct synthesis of organotin compounds from elemental tin), greater emphasis is put on the important developments of the last few years, e.g. palladium catalyzed reactions using organotin reagents are covered in detail. However, aspects that can be criticized are a degree of unevenness in the treatment, and some arbitrariness in the choice of topics emphasized. For example, whereas free radical reactions using R_3SnH are adequately covered in total in Sections 5.3 and 5.4 of Chapter 5 ("Reactions of Organotin Compounds") and 6.9 of Chapter 6 ("Organic Synthesis with Organotin Compounds", meriting a full chapter of 47 pages), intramolecular coordination in β-carbonylstannanes is given a disproportionately large amount of space in Chapters 3, 6 and 7, despite the fact that a book on this topic by the same author appeared in the same series of monographs in 1986. This leads to quite a lot of repetition. In Chapter 6 under aryl stannanes one fails to find the early electrophilic scission reactions (studied by *C. Eaborn* and others) which are the foundation of modern syntheses. In view of current public concerns it is surprising not to find the keyword "toxicity", even though there are individual mentions of this scattered through the book, e.g. under "Biological Activities". Under environmental aspects the outstanding analytical studies by *F. Brinckman* deserved to be mentioned. However, these comments should not be allowed to detract from the author's achievement in having provided a lucid survey of the rapidly growing knowledge in this field. The book is mainly intended for organic, organometallic, pharmaceutical and industrial chemists involved in research, and is also suitable for advanced students.

However, the publishers must be reproached for the poor standard of production at such an inflated price. The presentation of the text in typescript form, unedited and without any emphases, variations of typography, or bold or italic type, and the clumsy formulas etc., are not reader-friendly. The user will find the book reminiscent of a hand-produced doctoral thesis of 30 years ago. And this in a book which is also recommended for use by students! Any modern program for printing text and formulas on a standard desk computer offers better readability than this.

The Tetrahedron Symposium-in-Print edited by *Yoshinori Yamamoto* is devoted entirely to the use of organotin compounds in organic synthesis, and covers the literature up to 1988. An excellent treatment of the subject is given, with original laboratory recipes, under a number of very well chosen sub-areas. There are 28 articles by expert authors, most of whom are leading participants in the current rapid developments in the field. To meet ideal criteria the book should perhaps also have included contributions by *M. Reetz* and *G. E. Keck*—and from the editor himself! However, this is a very good, timely and relevant report on a rapidly expanding field.

Which of these books ought one to buy? In most cases two are needed. No true student textbook is available. *Harrison*'s book is the encyclopedia of the subject, but is too short on detail for organic synthetic purposes. The book by *Omae* is better in this respect, but contains less information of a general nature. *Yamamoto*'s book is aimed especially at synthetic chemists. One must choose according to one's point of view and objectives.

Wilhelm Paul Neumann [NB 1064 IE]
Institut für Organische Chemie
der Universität Dortmund (FRG)

Leukotrienes and Lipoxygenases. Chemical, Biological and Clinical Aspects. (Series: Bioactive Molecules, Vol. 11). Edited by *J. Rokach*. Elsevier, Amsterdam 1989. xxxii, 518 pp., hardcover, DFl 360.00.—ISBN 0-444-87464-X

The importance that the arachidonic acid derivatives have earned as highly effective, physiologically and pharmacologically active mediators of intercellular communication has led to the coining of the collective term "eicosanoids". Whilst the initial main interest was in the prostaglandins, the new eicosanoid research has shifted to the area of lipoxygenases and leukotrienes. The elucidation of their chemical structures and the biochemical characterization of their biosynthesis and mode of action provided the key for the development of inhibitors for which high hopes are held out, since the lipoxygenase products are involved in the activation of the immune system. Pioneering studies have mainly been carried out by three groups (Harvard, Quebec and Stockholm). Of their publications, this one by *J. Rokach* (Merck Frosst, Canada), in Volume 11 of the "Bioactive Molecules" series, has attempted to collect and critically review all the information obtained to date.

This first attempt at the task has been an outstanding success. Together with 15 coauthors, *Rokach* has systematically brought together all aspects of this material, from

chemical to medical. The main emphasis is on the structural elucidation and chemical syntheses of the lipoxygenase products, tasks which have proved very demanding due to the complex stereochemistry. The many structural formula schemes that are needed are clearly set out, and for the essential syntheses are almost of textbook style, being additionally provided with literature references. A second strong point of the book is the full explanation of the analytical methods, which spares the newcomer in this area from the troublesome study of the primary literature. The biochemistry, pharmacology and pathophysiology of the leukotrienes are also discussed in the light of the latest knowledge. Evidence that the area is still scientifically expanding is apparent from the chapter by *Ford-Hutchinson*, in which only fifteen pages are devoted to the association of the leukotrienes with various illnesses, even though the conditions covered, in which leukotrienes are responsible for many symptoms, include inflammations, asthma, allergies, shock and cardiovascular diseases. A chapter about inhibitors and antagonist receptors is modestly placed at the end of the book. It does not yet include the success of the Merck-Frosst group, who have discovered the most promising 5-lipoxygenase inhibitor to date, which operates by a new principle and is likely to replace the antioxidant type inhibitors that were previously tested. This has demonstrated at the same time how broadly-structured chemical and pharmacological research has consistently led to results both for clinical practice and biochemical theory. When in addition such a book results as a spin-off, both the company and the authors should be equally congratulated.

As this is the first book of its kind on the subject, and against the background of the increasing importance of the leukotrienes in pathophysiology, it is indispensible for researchers in medicine. The book is typographically excellent, but its price (DM 360.—) means that students of chemistry, pharmacy, medicine or biochemistry must be satisfied with only borrowing it.

der Universität Konstanz (FRG)

Transition Metal Oxides: Surface Chemistry and Catalysis. (Series: Studies in Surface Science and Catalysis, Vol. 45). By *H. H. Kung*. Elsevier, Amsterdam 1989. x, 282 pp., hardcover, DFl 215.00.—ISBN 0-444-87394-5

At a time when transition metal oxides are becoming increasingly important, especially in high technology applications such as superconductors, high performance ceramics, microelectronics and sensors, this book on one of the longer-established applications of these oxides is particularly welcome. *Harold H. Kung* here deals with the heterogeneous catalysis and surface chemistry of transition metal oxides, a field in which he has been engaged for many years. The amount of fundamental research that has been carried out in this area during the last two decades is so large that to cover every aspect would appear impossible. This book restricts itself to new developments in the preparation and characterization of catalysts, their reaction mechanisms and catalytic functions, and a limited selection of reactions. Thermodynamic and kinetic aspects are not treated.

Following a short introduction (Chapter 1 and part of Chapter 2), the author continues Chapter 2 with a discussion of the structures of metal oxides. Chapter 3 deals with the physical and electronic properties of metal oxides and their surfaces. The actual charges on the metal ions in the oxides can show considerable differences from those corresponding to their formal oxidation states. A discussion of the importance of the electronic structure at the surface in relation to catalysis leads into the next chapter, which highlights the role of coordinative unsaturation at the surface. *Kung* points out that most studies up to now have been concerned with the electronic structure of clean surfaces, and relatively little is known about the interaction of these surfaces with adsorbed molecules.

The following chapter discusses how the free coordination sites of the surface metal ions depend on the orientation of the surface and on the extent of dehydration. The possibilities for coordinative, dissociative, reductive or abstractive adsorption are explained, taking as examples small molecules such as H_2, CO, NO_x and alkenes.

An important characteristic for heterogeneous catalysis by metal oxides is the surface acidity due to Lewis and Brønsted sites. For adsorbed molecules on metal oxide surfaces the acidity scale for their aqueous solutions can be used. Many mixed metal oxides have strongly acidic surface sites and detailed studies of such materials are described. Methods for the qualitative and quantitative characterization of surface acidity, such as pyridine and ammonia adsorption measurements, determination of the isoelectric point, or the use of indicators, are discussed.

Chapter 6 deals with the reduction of metal oxides, an important pretreatment process for their use as catalysts. In many cases the catalytically active sites are not formed until the surface reduction is carried out. Here it is argued that this involves not only the generation of free coordination sites by reductive removal of surface oxygen atoms, but also a cooperative effect between the metallic and oxide regions of the surface. The effect of the support material on the reducibility of the surface is also discussed. However, the picture given here is not fully up-to-date, since much new knowledge has been gained on this subject in the last four years (e.g. the concept of "strong metal support interaction", SMSI).

Chapter 7 describes the characterization of the various oxygen species and their reactivities at metal oxide surfaces; regrettably, however, there is no corresponding chapter on hydrogen species.

The description of the constitutions and structures of oxide catalysts and their surfaces concludes with Chapter 8, which deals with the preparation of metal oxide catalysts. The different preparative methods are summarized at the beginning of the chapter, and the influence of the choice of method on the activity and morphology of the catalysts is clearly and concisely described. Catalysts consisting of a single component, mixed catalysts and supported catalysts are each discussed separately. However, the micro-, meso- and macroscopic pore distribution in these metal oxide catalysts, which are often of crucial importance to the activity and stability of the catalyst, are not mentioned. The remaining chapters are concerned with a number of reactions that are catalyzed by transition metal oxides.

The catalysts mainly used for the metathesis of olefins are reduced oxides of Mo, W and Re, while the isomerization of olefins is catalyzed by a wide variety of metal oxides through cationic and anionic mechanisms.

For the dehydrogenation and dehydration of alcohols the most common catalysts are oxides of Zn, Cr, Cu, Ti and Ni. The decomposition of N_2O and the reduction of NO are catalyzed by many different metal oxides. This chapter also includes accounts of some relatively old and frequently cited results on hydrogenation and H/D exchange in hydrocarbons on oxide catalysts.

Some representative selective oxidation reactions are briefly discussed from various angles in Chapters 11 and 12. Chapter 13 deals with aspects of CO and CO_2 hydrogenation reactions, ranging from the synthesis of methanol through hydrocarbons synthesis to the water-gas reaction, although there is no mention of the Fischer-Tropsch reaction.

In the final chapter photocatalytic processes, which are observed particularly on oxides of Mo, Ti and W, are again discussed. Reactions whose rates are increased by irradiating with photons of the correct energy include the catalytic oxidation of hydrocarbons, alcohols, CO and NH_3, as well as H_2/D_2 and other isotope exchange reactions.

Although the book appeared as recently as 1989, it corresponds essentially to the state of knowledge in the literature up to 1986. The inclusion of literature references in several different forms is confusing—as well as being listed at the end of each chapter, they also appear in tables with separate numbering or in alphabetical order. Methods for characterizing metal oxide surfaces, particularly surface physics and surface chemistry techniques, are not treated in enough detail, and are usually only mentioned as abbreviations (NEXAFS, HREEL etc.).

The book contains important information for specialists, but its structure makes it also entirely suitable for beginners and students as an introduction to transition metal oxide catalysts.

Wilhelm F. Maier [NB 1067 IE]
Institut für Technische Chemie
der Universität-Gesamthochschule Essen (FRG)

Calixarenes. By *C. D. Gutsche*. Edited by *J. F. Stoddart*. Royal Society of Chemistry, London 1989. xii, 222 pp., hardcover, £ 39.50.—ISBN 0-85186-916-5

This book inaugurates the "Monographs in Supramolecular Chemistry", a series edited by *J. F. Stoddart*. To deal with calixarenes the editor has chosen one of the experts in this field, Professor *C. D. Gutsche*; his fundamental and numerous contributions in the development of calixarene chemistry are widely recognized. The book is subdivided into seven chapters.

The first one describes in detail the long history (covering more than a century) of phenol-formaldehyde chemistry. It is fascinating to notice: i) how many first class scientists have been involved in this area (*Baeyer, Baekeland, Zinke, Cornforth,* to mention just a few); ii) the wealth of reaction possibilities between two rather simple reactants; iii) that the structures of many compounds isolated in the old days have been elucidated only in the last few decades (due to the introduction of improved X-ray and NMR techniques) and revealed to be of primary importance for the development of the calixarenes field.

Chapter 2 deals with the syntheses of calixarenes. The two main procedures, the one-step and the multi-step processes, are thoroughly discussed and exemplified. Syntheses of compounds closely related to calixarenes (homocalixarenes, oxacalixarenes, etc.) are also described.

The third chapter is devoted to the characterization and properties of calixarenes. The X-ray crystallography of several calix[*n*]arenes ($n = 4-6, 8$) is described and discussed. All the typical features of this class of compounds are mentioned: melting points, solubilities, dissociation constants of the OH groups, IR, UV, NMR, MS.

The large fourth chapter focusses on the conformation of calixarenes in both solid state and solution. It starts with the conformational studies of the flexible calixarenes, and goes on to describe the various methods capable of freezing some conformations, so as to obtain compounds with a definite and permanent cavity able to accept guest molecules.

Chapter 5 gives an account of the rich chemistry of calixarenes. The presence of several OH groups allows the preparation of many functionalized derivatives. Thus by appropriate chemical tailoring the simple calixarene can be transformed into a sophisticated compound containing both a binding site, the cavity, and a reactive entity able to react with a bound substrate.

Chapter 6 describes the formation of calixarene complexes. This fundamental aspect of supramolecular chemistry concerns a large variety of substrates. In the solid state, X-ray studies support the existence of complexes with many simple guests (chloroform, benzene, toluene, methanol, anisole, etc.). In some cases formation of these types of complexes is also observed in solution. Calixarenes also form complexes with metal cations, chiefly with the group I cations; extractions and transport are also described. Several water soluble sulfonatocalixarenes form very stable and highly selective complexes with $UO_2^{2\oplus}$. Complexation of organic cations is discussed in this chapter.

The last chapter concentrates on calixarene patents and industrial applications or potential uses of these compounds. At present there does not appear to be a large involvement of calixarenes in the industrial sector, but this is sure to change in the future.

The book is eloquently written and *C. D. Gutsche* has the talent to attract the reader in the calixarenes saga; he is particularly attentive to the history of this field and he has accomplished his preface purpose "by taking the reader inside the house of one small family". Thus all the major contributors in this field are acknowledged by a short biographical note and a picture. However, the most important feature of the book is its account of the state-of-the-art in calixarene chemistry. Since the *Gutsche* review in 1984 (*Topics in Current Chemistry 127*, 1) the number of groups working in this area has greatly increased; this expansion appears in the literature citations (about half of the references are form the period after 1984). The bibliography is large and the literature reviewed is up-to-date (through late 1988) and in addition many unpublished studies and observations are mentioned. The book is well illustrated with many figures (some in colour) and it contains three copious indexes (subject index; phenol-derived and resorcinol-derived calixarenes).

I warmly recommend this book as an excellent work of reference for the chemists actively engaged in this field. For scientists who are preparing to undertake research in calixarene chemistry the reading of this monograph is essential.

Computer-Aided Molecular Design. Edited by *W. G. Richards*. IBC Technical Services, London 1989. vii, 266 pp., hardcover, £ 95.00.—ISBN 1-85271-054-3

Computer-aided design of protein molecules is a topic in which there has been much interest both in industry and the academic world in the last few years. Fascinating possibilities are opened up here, both in applications ("drug design") and in basic research (aimed at understanding structure-activity relationships). While there has up to now been no

book that deals with the topic as a whole, there are already several reports on relevant symposia, although their coverage is necessarily incomplete and selective. In this book an attempt is made to treat the subject comprehensively by means of articles by various authors drawn from several "European Conferences on Computer-Aided Molecular Design" organized by IBC, However, this approach means that quite a number of the articles are several years old and do not include the latest developments.

It is stated in the preface that the book is intended both for newcomers to the field and for experienced scientists who wish to broaden the scope of their work. This is an oblique reference to the fact that the authors of the articles have adopted widely differing approaches. Whereas in some of the contributions (e.g. Chapters 1 and 2) the aim is to give an overview of a particular sub-area, others (e.g. Chapters 9 and 11) deal with specialized topics in a way which is far from comprehensive. The same applies to the literature citations in the individual articles, which in some cases extend only slightly beyond the authors' own publications, whereas in others they give a representative overview.

The book's 21 chapters do in fact cover quite large areas of the subject of molecular design. Thus Chapter 1 (*Murray-Rust*) gives a survey of the structural data banks that exist throughout the world, and in Chapter 2 the reader finds an excellent introduction to force field methods of calculation. Applications of quantum mechanical methods, especially for simulating activated enzyme complexes, are described in Chapter 3, and Chapter 4 describes applications of "free energy perturbation" methods.

Chapter 5 gives a brief sketch summarizing the "distance geometry" method, which is nowadays often used in connection with NMR spectroscopic studies of proteins to develop an initial structure model. Chapter 17 (*Clore, Gronenborn* et al.) gives a general survey of the applications of NMR spectroscopy for determining three-dimensional structures of proteins, and special aspects of this are described in the short Chapter 16 (*Wüthrich* et al.).

Chapter 6 discusses some aspects of the methods, at present only used by a relatively small number of research groups, based on the symbolic description and analysis of molecular conformations.

In Chapter 8 *Marshall* gives an excellent review of the main approaches being used in drug design, while in Chapter 10 *Müller* et al. describe an interesting alternative approach to this problem. Methodological aspects are also discussed in Chapter 12 by *Goodford*.

In the prediction of structures and in the design of proteins, which must still at present be based on already known three-dimensional structures of homologous proteins, the problems encountered are entirely different from those that apply for small molecules. In this regard the book has large gaps. Unfortunately the methods used are only described incompletely and in summary form in Chapter 13. Some aspects of displaying protein structures using fast graphics workstations are discussed in Chapter 14, and a procedure for identifying and classifying antigen sites in proteins is described in Chapter 15.

The last few articles deal with applications of molecular design in areas where the use of this method is very recent, namely in materials science (microporous materials, Chapter 18, and materials in general, Chapter 21) and catalytic research (zeolites, Chapter 19, and heterogeneous catalysis, Chapter 20).

At the end of the book, disconnected from the articles to which they belong, are 16 pages of color plates. Although this arrangement is no doubt more economical from a printing standpoint, it is rather awkward for the reader.

The articles that have not been mentioned here, Chapters 7, 9 and 11, really do not fit into the overall scheme of the book, as they describe specialized applications and software that is not generally available.

The book is certainly not the thorough treatment according to a standard pattern that this subject deserved; some of the articles are no longer fully up-to-date, some important aspects, such as the determination of molecular structures by X-ray crystallography and certain sub-areas of protein design, are not included, but on the other hand many topics are treated comprehensively by experts. Taking into account also the fact that there is virtually no other book which reviews such a wide range of molecular design topics, the present book can be recommended to everyone who wishes to learn about this systematic modern method for developing substances with new properties.

Complexes of Carbon Monoxide and Its Relatives: An Organometallic Family Celebrates Its Birthday**

By Helmut Werner*

Dedicated to Professor Max Schmidt on the occasion of his 65th birthday

Nickel tetracarbonyl was discovered one hundred years ago. Its hundredth birthday deserves to be celebrated not only by metal carbonyl chemists. The pioneering work of *Mond, Langer*, and *Quincke* has led to developments which, particularly in the last 30 years, have had consequences in many areas outside that of metal carbonyl chemistry. The parent ligand of the family, CO, has been joined by a series of relatives which are isoelectronic with it and which in some cases are even more effective as π acceptors. These are in the main extremely reactive molecules such as CS, CNH, and $C{=}CH_2$, which, though very short-lived in the free state, form very stable complexes with transition metals. This article documents the family relationships by structure and reactivity comparisons; attention is also drawn to the synthetic potential of the metal carbonyl analogues, which is still virtually untapped. The final section ventures a look towards the next 100 years, which promise to be just as exciting as the past century.

1. Introduction

An organometallic family celebrates its hundredth birthday this year. In August 1890 an article by *Ludwig Mond, Carl Langer*, and *Friedrich Quincke* appeared in the *Journal of the Chemical Society* with the title "Action of Carbon Monoxide on Nickel"; in this paper the authors described the synthesis of nickel tetracarbonyl.[1] Although this compound, isolated as a colorless, clear, extremely toxic liquid, was not the first metal compound containing carbonyl ligands—the first, $[Pt(CO)_2Cl_2]$, had already been synthesized by *Schützenberger* in 1868[2]—its remarkable properties and its industrial applicability to the preparation of ultrapure nickel were immediately recognized by *Mond*. This serendipitous discovery[3] started a development which reached its first peak in the work of *Walter Hieber*[4] and which, during the last 40 years, has played a very important role in the often-cited "renaissance of inorganic chemistry".

This review will not focus, however, on the chemistry of metal carbonyls, which remains just as fascinating and as topical as it has always been (see Fig. 1). Nickel tetracarbonyl and other stable binary carbonyls, some of them already described by *Ludwig Mond*,[3] have been joined in recent years by very labile carbonyls such as $[Cu_2(CO)_6]$, $[Ag_2(CO)_6]$, $[Pt(CO)_4]$, and $[Ti(CO)_6]$.[5] Thanks in great part to the pioneering work by *Chini, Longoni, Dahl* et al.[6] and *Lewis* et al.,[7] carbonylmetal clusters have achieved a degree of importance undreamed of twenty years ago, in particular as cage frameworks for both smaller and larger metal and nonmetal atoms.[8] Moreover, carbonyl metalates have found an important place in synthetic chemistry—not only because of the importance of *Collman*'s reagent, $Na_2[Fe(CO)_4]$.[9] There are still unmarked areas on the metal carbonyl map, however, as shown, for example, by the fact that the synthesis of salts of the hexacarbonyltitanate dianion, $[Ti(CO)_6]^{2\ominus}$, the first stable binary carbonyl compound

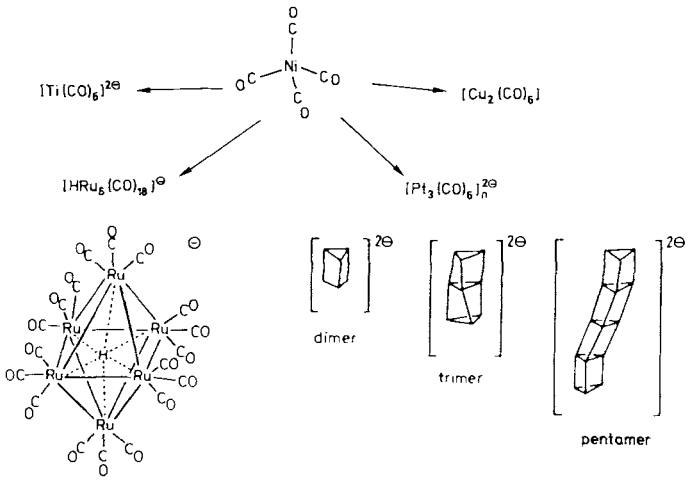

Fig. 1. $[Ni(CO)_4]$ and other, much later synthesized metal carbonyls.

of titanium, was described by *Ellis* only in 1988, that is, almost 100 years after the discovery of nickel tetracarbonyl.[10]

The metal carbonyls have meanwhile been joined by "relatives", which are the subject of this article. Remarkably, their history is almost as long as that of their "ancestor". Soon after the publication of *Mond*'s results,[11] *Sabatier* et al. in Toulouse attempted to bond NO, NO_2, C_2H_4, and C_2H_2 to nickel and similar metals; although they were unsuccessful, their attempts did in fact lead to the discovery that nickel could be used as a catalyst in hydrogenation.[11] There was then a gap of 75 years before *Wilke* et al. were successful in preparing $[Ni(C_2H_4)_3]$,[12] a compound similar to $[Ni(CO)_4]$ although structurally different. It was then used in the synthesis of further nickel(0) complexes, some of which are catalytically extremely active.[13]

Here, however, ethylene will not be regarded as a relative of carbon monoxide. Although there are indeed close relationships between metal carbonyls such as $[Ni(CO)_4]$ and compounds such as $[Ni(C_2H_4)_3]$,[12] $[Ni(PCl_3)_4]$,[14] $[Ni(PPh_3)_4]$,[15] and $K_4[Ni(C\equiv CH)_4]$,[16] only those molecules or fragments that are valence-isoelectronic with CO will be considered relatives. Such ligands resemble CO not only formally but also in their coordination properties and thus form a family with it. For example, the bonding of the parent molecule to one or several metal atoms can be either end-on or via μ_2 or μ_3 bridges (Fig. 2). This is also true for the relatives.

The family of CO-like molecules has two separate branches: the first includes the molecules formed from CO by substitution of the *carbon atom* by a homologous element of the fourth main group or by an isoelectronic ion ($B^{\ominus}$, $N^{\oplus}$). The second contains the molecules derived from CO by replacing

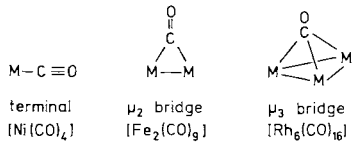

Fig. 2. Coordination possibilities for CO.

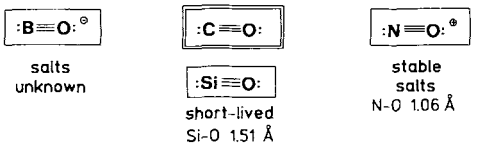
the *oxygen atom* by S, Se, or Te or by an isoelectronic fragment such as NH or CH_2. The corresponding classes of compounds will not be discussed in detail; instead, this article will make clear the relationships within the family as well as the particular features of the various members of the family.

2. The Relatives of the Type [X≡O]: Known and Unknown Examples

The closest relative of CO, at least from the point of view of the preparative chemist dealing with this type of molecule, is surely SiO (Scheme 1). This molecule is formed when SiO_2 is heated with Si under vacuum at 1250 °C and can be detected both in the gas phase and at low temperatures in a suitable matrix. The Si–O bond length of 1.51 Å agrees well with the theoretical value of 1.50 Å and shows that SiO is isosteric with CO.[17]



Scheme 1.

Helmut Werner was born in 1934 in Mühlhausen (Thüringen). He studied chemistry at Jena, where he received his "Diplom" under Franz Hein, and at the Technische Hochschule in Munich, where he received his doctorate under E. O. Fischer. After postdoctoral research under J. H. Richards at the California Institute of Technology in Pasadena (1962–1963), he completed his "Habilitation" at the end of 1966 on kinetic investigations of substitution reactions of organometallic complexes. In 1968, he began work in inorganic chemistry at the Universität Zürich, where he became a full professor in 1970. At the end of 1975, he moved to the Universität Würzburg. Helmut Werner has received numerous prizes and honors, including the Alfred-Stock-Gedächtnispreis of the German Chemical Society; since 1988, he has been a full member of the Deutsche Akademie der Naturforscher Leopoldina.

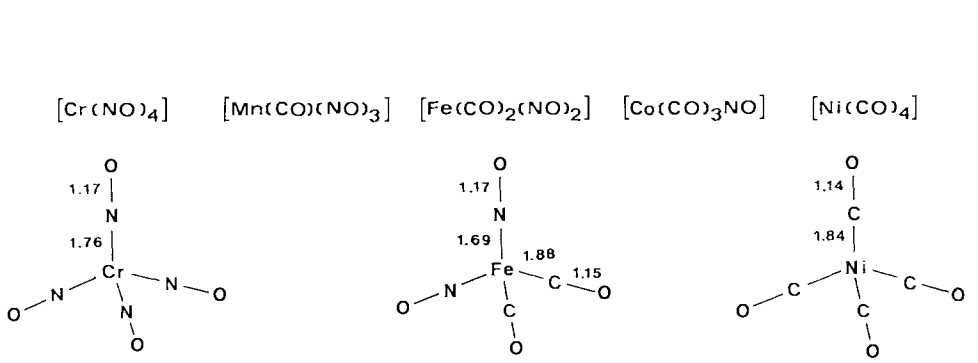


Fig. 3. The $[M(CO)_n(NO)_{4-n}]$ family (n = 0–4).

Metal complexes with SiO as a ligand are still unknown. Although it has been possible during the last 30 years, starting with the synthesis of the first metal cyclobutadiene complexes by *Criegee* et al.[18] and *Hübel* et al.,[19] to bind many molecules that are extremely short-lived in the free state ("nonexistent" molecules) within the coordination sphere of a metal and thus to investigate them, corresponding attempts to isolate or detect complexes of the type $[M(SiO)L_n]$ have so far been unsuccessful. Even matrix studies have provided no evidence for their existence.[20]

The situation with regard to the anion $BO^{\ominus}$ is similar. The protonated molecule HBO has been detected experimentally;[21] however, salts derived from it such as MBO (M = Na, K, etc.) still do not exist. *Rosmus*[22] recently showed from SCF calculations that the potential energy functions of KBO and KCN are very similar, so that the molecule would probably be quasi-linear. This structural prediction also applies to methyl boroxide, which is formally derived from $BO^{\ominus}$ by methylation; this molecule was first prepared as an intermediate by *Paetzold* et al.[23] and was characterized very recently by its PE spectrum.[24] In view of the vast scope of the chemistry of metal carbene complexes $[M(=CXY)L_n]$ it seems remarkable that only very little is known about comparable (isoelectronic or isosteric) compounds of the type $[M'(=BXY)L_n]$.[25]

The picture becomes completely different on moving to the right of CO, that is, to $NO^{\oplus}$. Not only are many salts of this cation known (the N–O distance of 1.06 Å corresponds exactly to that of a triple bond, as in CO) but a great deal is also known about its coordination properties.[26] In fact, the first nitrosyl complex, the dication $[Fe(NO)(H_2O)_5]^{2\oplus}$, was discovered in 1790 by *Priestley*! Although carbonyl and nitrosyl metal compounds have many similarities, very little is known about species of the type $[M(NO)_n]$ or about the corresponding cations or anions. Only $[Cr(NO)_4]$ has been characterized: *Herberhold* and *Razavi* obtained this complex as a brown, low-melting solid by photolysis of $[Cr(CO)_6]$ in an NO atmosphere.[27] The species $[Co(NO)_3]$ has also been reported;[28] however, clear evidence for the existence of this compound is still wanting. Binary metal nitrosyl clusters are still an unknown class of substances; they would be of general interest in connection with the bonding of NO at metal surfaces.

Mixed carbonyl-nitrosyl metal complexes are better known. As early as 1922, *Robert Mond* (the son of *Ludwig Mond*) et al. described the compound $[Co(CO)_3(NO)]$;[29] *Hieber* et al. and later *Lewis* et al. prepared the isoelectronic molecules $[Fe(CO)_2(NO)_2]$[30] and $[Mn(CO)(NO)_3]$.[31] The formal analogy between such compounds, which was later confirmed on a structural basis (Fig. 3), prompted *Seel* in 1942 to propose the "nitrosyl shift relationship",[32] which is still of importance today as a heuristic principle. According to this postulate, it is possible to replace Ni in $[Ni(CO)_4]$ by Co when one of the CO ligands (two-electron donor) is simultaneously replaced by the three-electron donor NO. The metal atoms in the ML_4 series (Fig. 3) thus act as "pseudonickel atoms". Only one analogue of iron pentacarbonyl, the manganese complex $[Mn(CO)_4(NO)]$,[33] has been described; the remaining members of the ML_5 series, $[Cr(CO)_3(NO)_2]$, $[V(CO)_2(NO)_3]$, and $[Ti(CO)(NO)_4]$ still remain to be discovered.

$NO^{\oplus}$ is a stronger π acceptor than CO, as can be seen both from the stretching vibration frequencies in the IR spectra and from the bond distances determined by *Hedberg* and co-workers[34] (see Fig. 3). In particular, the differences in the Fe–C and Fe–N bond distances in the compound $[Fe(CO)_2(NO)_2]$ confirm that the nitrosyl ligands are more strongly bound; this is also documented by the easier exchange of CO (e.g., for PR_3) in substitution reactions of carbonyl–nitrosyl metal complexes.

Although, as already mentioned, binary metal nitrosyl *clusters* do not yet exist, bi- and polynuclear compounds with NO as a ligand are already known;[26] they show the same possibilities for coordination of NO (or, to be more precise, $NO^{\oplus}$) as for CO in the corresponding metal carbonyl complexes (see Fig. 4). When cyclopentadienyl is used

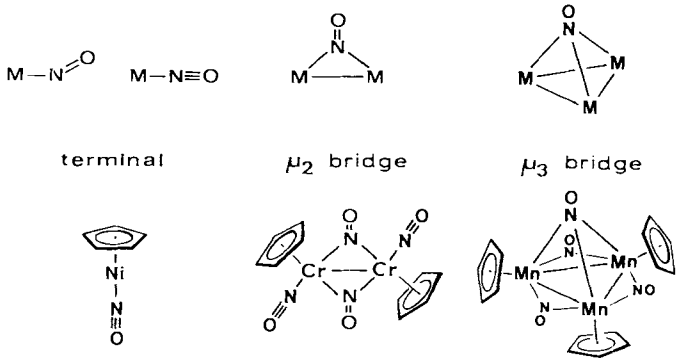

Fig. 4. Coordination possibilities for NO.

as the coligand, an end-on (linear) M–N–O arrangement is found in [CpNi(NO)],[35] whereas μ_2 and μ_3 bridges exist in $[Cp_2(NO)_2Cr_2(\mu\text{-}NO)_2]$[36] and $[Cp_3Mn_3(\mu_2\text{-}NO)_3(\mu_3\text{-}NO)]$,[37] respectively. The structural relationship with CO is extremely obvious here.

Until a few years ago almost nothing was known about analogies in reaction behavior between CO and NO in the coordination sphere of a metal. In particular, it was unclear whether one of the most typical reactions of coordinated CO, insertion into a M–C bond in the presence of an alkyl or aryl ligand (which is also the key step in important catalytic processes such as the oxo process or the Monsanto acetic acid process[38]) is also possible for NO. *Bergman* et al.[39] were the first to show that an alkyl(nitrosyl)metal complex, formed in the same way as an alkyl(carbonyl) compound by alkylation of the corresponding anion, reacts with PPh_3 to give a nitrosoalkane derivative via N–C bond formation (Fig. 5). The coordination number of the metal remains unchanged. In a very similar manner the same group has synthesized and structurally characterized the complex $[C_5Me_5Ru(N(O)Et)(Ph)PMe_2Ph]$ starting from PMe_2Ph and $[C_5Me_5Ru(NO)(Et)Ph]$.[40] On the basis of mechanistic studies,[39b] there is no doubt that the "NO insertion" is in fact an alkyl migration to the nitrosyl ligand, as is the case for the "CO insertion".[41] *Legzdins* et al.[42] and *Vollhardt* et al.[43] have shown very recently that this process occurs not only with neutral donors such as tertiary phosphanes but also with $NO^{\oplus}$ itself.

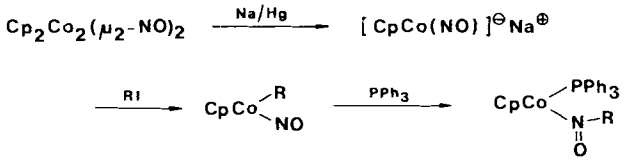

Fig. 5. NO insertion. R = alkyl.

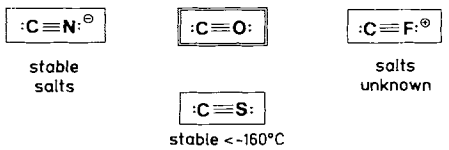
3. The CO Homologues CS, CSe, and CTe: Unstable Molecules with a Rich Coordination Chemistry

Whereas CO and CO_2 are both thermodynamically stable, for the homologous sulfur compounds this is only true for CS_2. The molecule CS, which can be formed from CS_2 by photolysis, thermolysis, or cold electrical discharge, is stable only below −160 °C (Scheme 2) and polymerizes very rapidly at higher temperatures;[44] this process can occur in an explosive manner. In spite of its extreme reactivity, the spectroscopic data for CS are known very precisely, and clear evidence on the mechanism of its formation from CS_2 is available.[44c] Much less is known about CSe,[45] and practically nothing about CTe; the latter has so far resisted all attempts to detect it, so that it still belongs to the group of "nonexistent" diatomic molecules.



Scheme 2.

The extreme tendency of CS to polymerize makes it understandable that so far almost all attempts to synthesize thiocarbonyl metal complexes from *free* CS and a metal or metal compound have been unsuccessful. Only the cocondensation of CS with nickel atoms in an argon matrix at 10 K gives a product whose IR spectrum indicates it to be $[Ni(CS)_4]$.[46] In contrast to $[Ni(CO)_4]$, it is unstable at room temperature, decomposing to give a black solid which is difficult to characterize.

In the case of iron and chromium, whose carbonyl complexes $[Fe(CO)_5]$ and $[Cr(CO)_6]$ are much more stable than $[Ni(CO)_4]$, the corresponding binary metal thiocarbonyls $[M(CS)_n]$ are still unknown. Mixed carbonyl-thiocarbonyl complexes are however known (Fig. 6). In the 1970s *Angelici* et al. and *Butler* et al. synthesized the $[Cr(CO)_6]$ analogues $[Cr(CO)_5(CS)]$ and $[Cr(CO)_5(CSe)]$,[47] and somewhat later *Petz* reported the preparation of the $[Fe(CO)_5]$ analogue $[Fe(CO)_4(CS)]$.[48] These complexes, which are stable under normal conditions, are volatile and can even be handled in air; their other properties are also very similar to those of the parent compounds $[M(CO)_n]$.

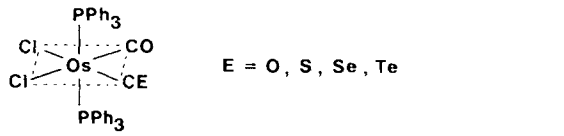


Fig. 6. Metal carbonyls and mixed CO–CE metal complexes.

The characterization of a complete series of the general composition $[M(CE)L_n]$ with E = O, S, Se, and Te was carried out by *Roper* and co-workers, who obtained the complexes $[OsCl_2(CE)(CO)(PPh_3)_2]$ by reaction of $[OsCl_2(CCl_2)(CO)(PPh_3)_2]$ with $EH^{\ominus}$.[49] Exact structural data are available for all the members of the series; $[OsCl_2(CTe)(CO)(PPh_3)_2]$ was the first metal tellurocarbonyl compound to be described.

Since free CS, CSe, and CTe are not available as starting materials, it is necessary to find suitable precursors for the synthesis of complexes with carbon monochalcogenides as ligands. As is shown in Figures 7–9 for CS, three routes for the preparation of compounds of the type $[M(CS)L_n]$ have so far proved generally applicable.[50] In each case, the thiocarbonyl ligand is generated *at the metal* and remains without exception strongly bonded to it.

The oldest and with hindsight most obvious synthetic method starts from CS_2; its discovery is, so to speak, a "by-product" of the trailblazing work of the *Wilkinson* school on the catalytic abilities of $[RhCl(PPh_3)_3]$. When studying the behavior of this compound in various solvents, *Baird* and *Wilkinson* noticed that it reacted with CS_2 to give the square-planar complex *trans*-$[RhCl(CS)(PPh_3)_2]$ via an unstable intermediate with a presumably π-bonded and a σ-bonded CS_2 ligand.[51] In a similar manner (see Fig. 7) *Butler* and co-workers were able several years later to obtain the manganese thiocarbonyl compound $[CpMn(CO)_2(CS)]$, which is

homologous to $[CpMn(CO)_3]$, and also to isolate the intermediate $[CpMn(CO)_2(\eta^2\text{-}CS_2)]$.[52] It reacts with PPh_3 to give $SPPh_3$ and $[CpMn(CO)_2(CS)]$; presumably, the phosphane attacks the sulfur atom bound to the metal and not the exocyclic sulfur atom. The same principle has been applied to prepare further thiocarbonyl and selenocarbonyl complexes (the latter starting from CSe_2),[50] whereby the isolation of $[CpMn(CO)(CS)_2]$ as the first compound with *two* CS ligands deserves particular mention.[52]

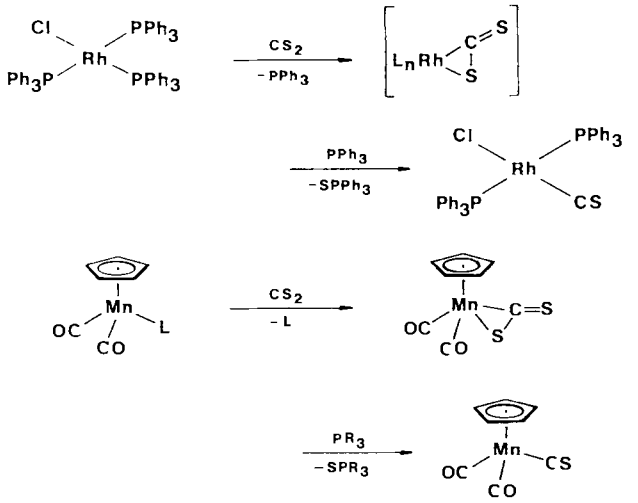

Fig. 7. Synthesis of metal thiocarbonyl complexes from CS_2.

The second likely source for thiocarbonyl ligands is thiophosgene. As shown in Figure 8, its reaction with $[Fe(CO)_4]^{2\ominus}$ and $[M_2(CO)_{10}]^{2\ominus}$ (M = Cr, Mo, W) gives the complexes $[Fe(CO)_4(CS)]$ and $[M(CO)_5(CS)]$, although the yields are not particularly good.[47a, 48] Another synthesis of $[Cr(CO)_5(CS)]$ starts from the metal arene compounds $[(C_6H_5R)Cr(CO)_2(CS)]$ (R = H, CO_2Me), which can be formed from $[(C_6H_5R)Cr(CO)_2(thf)]$ and CS_2; the aromatic ring ligand is then displaced by CO.[47b]

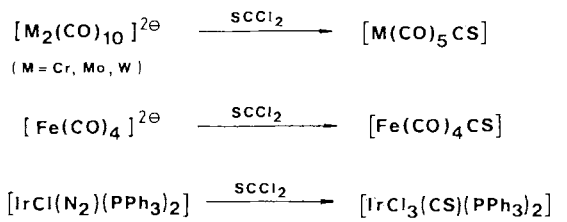

Fig. 8. Synthesis of metal thiocarbonyl complexes from $SCCl_2$.

$SCCl_2$ reacts with square-planar rhodium(I) and iridium(I) complexes such as $[RhCl(PPh_3)_3]$ and $[IrCl(N_2)(PPh_3)_2]$ via oxidative addition to give the corresponding thiocarbonylrhodium(III) and -iridium(III) compounds.[53] The presumed intermediate contains the unit M[C(=S)Cl](Cl), which forms the stable final product via a 1,2 shift of chlorine from carbon to the metal. Treatment of $[Ru_3(CO)_{12}]$ with thiophosgene followed by fragmentation of the cluster results in a similar reaction, leading to $[RuCl_2(CS)(CO)_3]$.[54]

A third method for the synthesis of CS complexes starts from heteroallenes such as CSSe (Fig. 9). In the course of our initial work on the coordination chemistry of CS_2, we found that the compounds $[CpM(PMe_3)(\eta^2\text{-}CS_2)]$ (M = Co, Rh) are formed readily and in good yields starting from $[CpCo(PMe_3)_2]$ and $[CpRh(PMe_3)(C_2H_4)]$; however, the former do not undergo sulfur abstraction with PR_3.[55] At the same time we observed that the reaction of $[CpCo(PMe_3)_2]$ with COS gives the carbonyl complex $[CpCo(PMe_3)(CO)]$, so that we expected that reaction with CSSe would form the thiocarbonyl compound $[CpCo(PMe_3)(CS)]$. This is in fact the case, although, depending on the reaction conditions, its formation may be accompanied by that of the corresponding thiocarbonylselenide complex $[CpCo(PMe_3)(\eta^2\text{-}CSSe)]$.[56] The latter reacts quantitatively with PPh_3 to give $[CpCo(PMe_3)(CS)]$. In the case of rhodium, the conversion of $[Rh](C_2H_4)$ to $[Rh](\eta^2\text{-}CSSe)$ and [Rh](CS), where [Rh] = $[CpRh(PMe_3)]$, can be readily carried out stepwise; here, as for the case where cobalt is the central atom, the reaction of $[Rh](\eta^2\text{-}CSSe)$ with PPh_3 leads solely to [Rh](CS) and not to [Rh](CSe).[56]

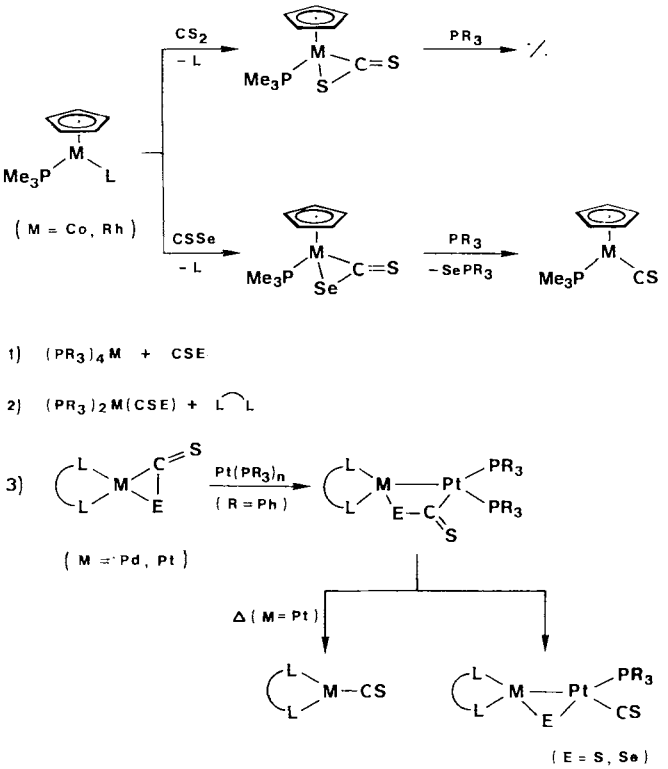

Fig. 9. Synthesis of metal thiocarbonyl complexes from heteroallenes.

A fragmentation of coordinated CS_2 to give CS and S or of CSSe to give CS and Se can be caused not only by PR_3 but also by nucleophilic metal complexes. In earlier studies we had already observed that the cobalt compound $[CpCo(PMe_3)(\eta^2\text{-}CS_2)]$ reacts with the metal base $[CpCo(PMe_3)_2]$ to give the trinuclear cluster $[(CpCo)_3(\mu_3\text{-}CS)(\mu_3\text{-}S)]$ in almost quantitative yield.[57] A similar metal-initiated cleavage of CS_2 or CSSe takes place when either $[Pt(PPh_3)_4]$ or $[Pt(C_2H_4)(PPh_3)_2]$ is allowed to react with the chelate phosphane complexes [(L-L)M(η^2-CSE)] (M = Pd, Pt; E = S,

Se; L-L = $Ph_2PC_2H_4PPh_2$, o-$C_6H_4(CH_2PPh_2)_2$).[58] The products (Fig. 9) are the binuclear sulfido- or selenido-bridged thiocarbonyl compounds [(L-L)M(μ-E)Pt(CS)-(PPh_3)]; it seems likely that the complexes [(L-L)M(μ-CSE)Pt(PPh_3)$_2$] are formed as intermediates. In the case where L-L = o-$C_6H_4(CH_2PPh_2)_2$, M = Pd or Pt, and E = S or Se, products with this composition can be isolated.[58b] Surprisingly, the addition of the ligands $Ph_2PC_2H_4PPh_2$ or o-$C_6H_4(CH_2PPh_2)_2$ to the complexes [(L-L)M(μ-E)Pt(CS)-(PPh_3)] leads not only to the displacement of PPh_3 but also to a recombination of the fragments CS and E to give CSE, so that the final product is an unsymmetrical binuclear complex of the type [(L-L)M(μ-CSE)Pt(L-L)] with two chelating phosphane ligands. There are no other known examples of such a process (fragmentation of a triatomic molecule and its re-formation under the influence of the same metal). The thermolysis of [$(PPh_3)_2$Pt(μ-CS_2)Pt(PPh_3)$_2$] and [(L-L)Pt(μ-CS_2)Pt(PPh_3)$_2$] (L-L = o-$C_6H_4(CH_2PPh_2)_2$) leads to the formation of the compounds [Pt(CS)(PPh_3)$_2$] and [Pt(CS)(L-L)]; these are the first *mono*nuclear thiocarbonyl complexes of platinum(0).[59]

There are only small differences between the modes of coordination adopted by CS and CO. As shown in Figure 10,

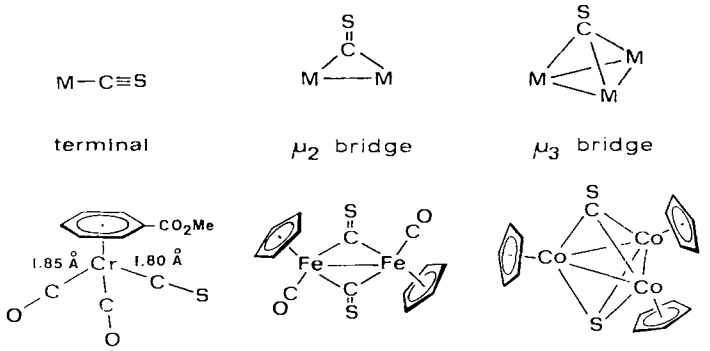

Fig. 10. Coordination possibilities for CS.

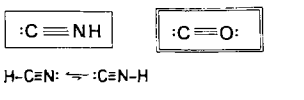
the thiocarbonyl ligand can be coordinated both end-on or in a bridging manner (between two or three metal atoms); it should be noted that, when CO and CS are both present in the same molecule (as, for example, in [$Cp_2Fe(CO)_2$-$(CS)_2$][60]), the formation of CS rather than CO bridges is observed.

CS is a stronger π acceptor than CO; this is shown not only by MO calculations[61] but also by the structural data of mixed carbonyl thiocarbonyl metal complexes. For example, the Cr–CS distance in [($C_6H_5CO_2Me$)Cr($CO)_2$(CS)] is shorter by 0.05 Å than the Cr–CO distance (mean value)[62], and a similar difference is observed in the cation [Ir-($CO)_2$(CS)(PPh_3)$_2$]$^{\oplus}$ (as the PF_6 salt).[63] This behavior indicates a stronger synergistic interaction between the metal and the thiocarbonyl ligand. Interestingly, the sulfur atom is clearly nucleophilic in all coordination modes of CS; it can not only undergo alkylation but also add 16-electron fragments such as [$Cr(CO)_5$] or [$CpMn(CO)_2$]. The resulting complexes have a bent arrangement for $(M)_nC$-S-M′, the exact structure of which has been determined for both n = 1 (e.g., in [(C_6H_5Me)Cr($CO)_2$CSCr($CO)_5$][64]) and n = 2 and 3 (e.g., in [Cp(PMe_3)Co(μ-CO){μ-CSMn($CO)_2$Cp}Mn(CO)-Cp][65] and [($CpCo)_3$(μ_3-S){μ_3-CSCr($CO)_5$}], respectively)[57] by X-ray structural analyses. Thus, CS is considerably superior to the parent molecule CO with respect to this additional bonding type and offers a synthetic potential for heterometal multinuclear complexes which has so far hardly been used.

4. Isocyanides as Ligands: CO Analogues with Advantages and Disadvantages

The molecule CNH is strictly isoelectronic with CO; like CS, it is extremely labile in the free state, isomerizing very rapidly to HCN.[66] However, it can be readily generated in the coordination sphere of a metal, where it is stable (a further analogy to CS). The formation of a CNH ligand can be carried out most simply by protonation of anionic cyano complexes; for example, treatment of [$M(CO)_5(CN)$]$^{\ominus}$ with HCl or [(C_5H_4R)Mn($CO)_2$(CN)]$^{\ominus}$ with H_3PO_4: in this manner, the neutral compounds [$M(CO)_5$(CNH)] (M = Cr, Mo, W)[67] and [(C_5H_4R)Mn($CO)_2$(CNH)] (R = H, Me)[68] are formed. Both the spectroscopic properties and the behavior of the complexes [$M(CO)_5$(CNH)] (M = Cr, W) leave no doubt that the M–CNH bond is considerably stronger than the M–NCH bond in the corresponding isomers [$M(CO)_5$(NCH)], which are formed by allowing [$M(CO)_5$(thf)] to react with HCN.[67b]



Scheme 3.

Alkyl and aryl isocyanides, which can be prepared in various ways, are much more stable than the parent compound CNH.[69, 70] They are generally stronger σ donors than CO; as a consequence, numerous binary ("homoleptic") *cationic* complexes can be isolated as the corresponding salts (see Table 1): examples are [$M(CNR)_7$]$^{2\oplus}$ (M = Cr, Mo, W), [$Fe(CNR)_6$]$^{2\oplus}$, [$Ni(CNR)_4$]$^{2\oplus}$, [$Ag(CNR)_2$]$^{\oplus}$, and [$Co_2(CNR)_{10}$]$^{4\oplus}$.[71] Comparable carbonyl metal compounds are not yet known.

Table 1. Metal isocyanide complexes of 3d transition metals.

[$Cr(CNR)_6$]	[$Fe(CNR)_5$]	[$Co_2(CNR)_8$]	[$Ni(CNR)_4$]	[$Cu(CNR)_4$]$^{\oplus}$
[$Cr(CNR)_6$]$^{\oplus}$	[$Fe_2(CNR)_9$]	[$Co(CNR)_5$]$^{\oplus}$	[$Ni_4(CNR)_7$]	
[$Cr(CNR)_6$]$^{2\oplus}$	[$Fe(CNR)_6$]$^{2\oplus}$	[$Co(CNR)_5$]$^{2\oplus}$	[$Ni(CNR)_4$]$^{2\oplus}$	
[$Cr(CNR)_7$]$^{2\oplus}$		[$Co_2(CNR)_{10}$]$^{4\oplus}$		

Like CO, isocyanides (CNR) are good π acceptors; not only have various metal(0) complexes of the type [$M(CNR)_n$] (n = 6, M = Cr, Mo, W; n = 5, M = Fe, Ru, Os; n = 4, M = Ni) been synthesized,[71] but also very recently the first *anionic* complex, [$Co(CNR)_4$]$^{\ominus}$ (R = 2,6-$Me_2C_6H_3$)[72] (i.e., an analogue of [$Co(CO)_4$]$^{\ominus}$). Binuclear complexes such as [$Co_2(CNR)_8$] and [$Fe_2(CNR)_9$], which resemble the corre-

sponding metal carbonyls not only in molecular formula but also structurally, are also known.[71] As a historical reminiscence, we may mention that the most direct relatives in this series to the parent $Ni(CO)_4$), the compounds $[Ni(CNR)_4]$ ($R = C_6H_5$, p-$EtOC_6H_4$), were obtained exactly 40 years ago in the same city (Munich) by two groups working fully independently of one another, in both cases via ligand substitution reactions starting from $[Ni(CO)_4]$.[73]

$$[Ni(CO)_4] \xrightarrow[-4\,CO]{4\,CNR} [Ni(CNR)_4]$$

In the case of L = CNR, however, this synthetic method (formation of $[ML_n]$ from $[M(CO)_n]$ and L) is extremely unusual and can only be used in the absence of a catalyst when a labile starting material is available. Under purely thermal conditions, the reaction of metal hexacarbonyls, $[M(CO)_6]$ (M = Cr, Mo, W), and of iron pentacarbonyl, $[Fe(CO)_5]$, with isocyanides often leads only to monosubstitution even at higher temperatures and with long reaction times.[71e] The use of phase-transfer catalysts can improve the situation.[74] However, it is even more favorable to carry out the reaction of $[M(CO)_6]$ or $[Fe(CO)_5]$ with CNR in the presence of a *heterogeneous* catalyst such as $CoCl_2$, activated carbon, or metallic platinum on an oxide support. This method, developed by *Coville* and co-workers,[75] has made it possible to replace *all* the CO ligands in the otherwise inert $Fe(CO)_5$ by CNR and also to substitute more than half of the carbonyl groups in metal clusters such as $[Ir_4(CO)_{12}]$. Apart from metal carbonyls, arene and cyclodi- and -triene complexes have been used as starting materials for reactions with isocyanides; the synthesis of $[Cr(CNR)_6]$ from bis(naphthalene)chromium and CNR ($R = n$Bu, C_6H_{11}) is a good example.[76]

$$[Cr(\eta^6\text{-}C_{10}H_8)_2] \xrightarrow[-2\,C_{10}H_8]{6\,CNR} [Cr(CNR)_6]$$

The coordination properties of CO and isocyanides are similar. The most generally encountered bonding situations are compared in Figure 11, top; it should be mentioned that,

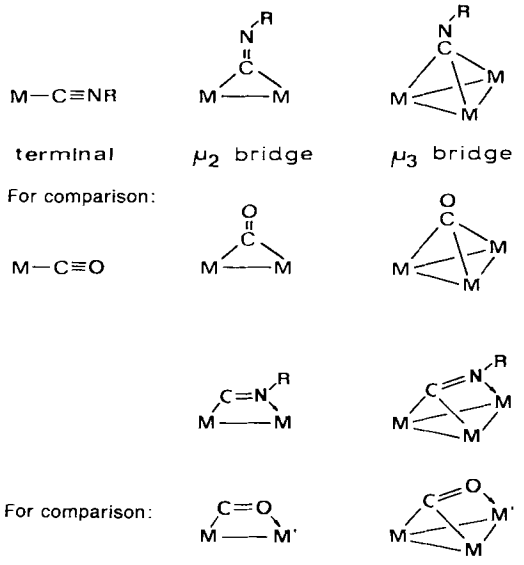


Fig. 11. Coordination possibilities for CNR.

in some cases, terminally bonded isocyanide ligands can be bent at the N atom.[71]

The ligand CNR can also bridge two or three metal atoms, in the manner shown in Figure 11, bottom. A good example of the μ_2-C,N form is the nickel cluster $[Ni_4(CNtBu)_7]$ described by *Muetterties* et al.[77] A comparable interaction of CO with two or three metallic centers has been discussed for the adsorption of carbon monoxide at surfaces;[78] the possible threefold bridging seems particularly likely when M is a transition metal and M′ an electropositive metal such as K, Mg, or Al.

CO and CNR are also closely analogous in their reactions. Both isocyanide and carbonyl ligands are able to undergo insertion into M–C σ bonds; this process can take place either spontaneously or in the presence of a Lewis base L (see Fig. 12). Whether the acyl or imidoyl residue formed is bonded in a mono- or bidentate manner depends ultimately on the electronic configuration and the required coordination geometry of the metal.

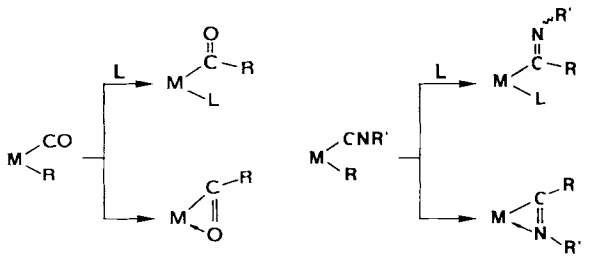

Fig. 12. Insertion of CO and CNR into M–C σ bonds.

There is one interesting reactivity difference between structurally analogous acyl and imidoylcobalt complexes of the half-sandwich type formed by CO and CNR insertion, respectively (see Fig. 13). While the compound [CpCoMe(CO)(PMe_3)]I, obtained from [CpCo(CO)(PMe_3)] and methyl iodide in toluene, undergoes only isomerization to [CpCo{C(O)Me}(PMe_3)I] when acetone is added,[79] a cycloaddition reaction takes place when the corresponding methyl isocyanide complex is dissolved in this solvent. A five-membered metallaheterocycle is formed, probably via an intermediate with the partial structure Co-C(Me) = NCH_3; the final product has been characterized by an X-ray structural analysis.[80] Furthermore, [3 + 2] cycloaddition reactions occur with acetaldehyde and benzaldehyde as well as with a number of nitriles R′CN (R′ = Me, Ph, *cyclo*-C_3H_5, $CH=CH_2$, $CMe=CH_2$, $CH=CHMe$, NH_2, NMe_2, SMe); the five-membered ring of the type [Co]-$C(CH_3)$=NR-CR′=N shown in Figure 13 is thermodynamically unstable and isomerizes to [Co]-$C(=CH_2)$-NR=CR′-NH, independent of the nature of the group R′.[81] With CS_2 it is even possible to realize a *double* cycloaddition, leading to the dimetallaspiroheterocycle depicted in Figure 13; this compound has been structurally characterized.[82] The difference in behavior between coordinated CO and CNR documented by this and other results[83] is probably due to the basicity of the CNR nitrogen atom being higher than that of the oxygen in CO; moreover, the building block [M]-C(Me) = NR formed by a methyl shift is a better 1,3 dipole than the corresponding unit [M]-C(Me) = O.

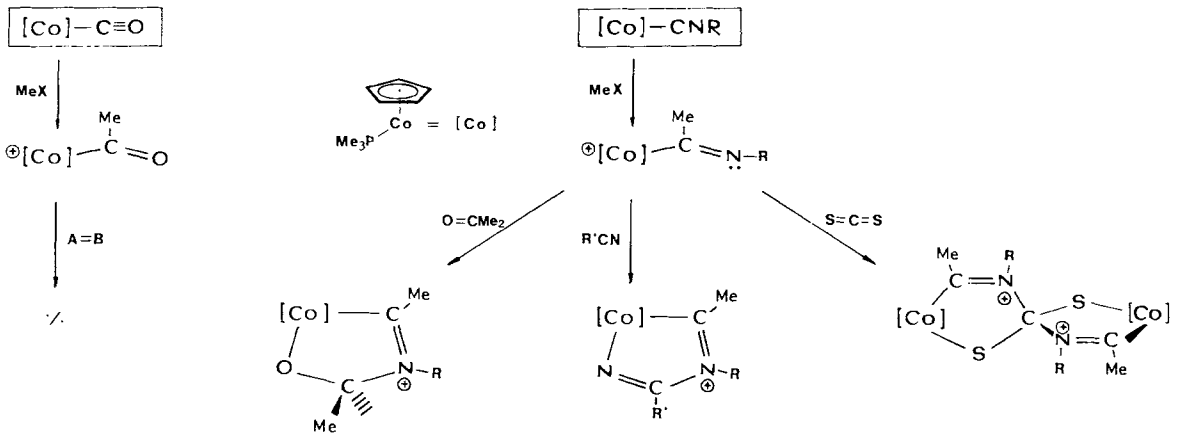

Fig. 13. Reactivity of [CpCo(CO)(PMe$_3$)] and the CNR analogue.

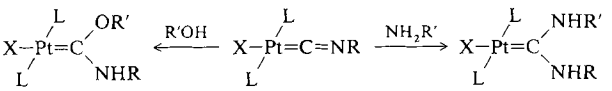
The greater polarity of the C≡NR bond compared with the C≡O bond causes metal isocyanide compounds to be suitable starting materials for the formation of aminocarbene complexes. The pioneering work in this area was done by *Chatt* and co-workers[84], who showed that platinum(II) isocyanide compounds of the type *cis*-[PtX$_2$(L)(CNR)] (X = Cl, Br, I; R = Me, Et, Ph, *p*-Tol; L = PMe$_2$Ph, PEt$_3$, PEt$_2$Ph) react with primary alcohols and amines even under very mild conditions to give *cis*-[PtX$_2$(L){C(NHR)(OR')}] and *cis*-[PtX$_2$(L){C(NHR)(NHR')}], respectively. Somewhat later, this synthetic principle was extended to isocyanide complexes of iron,[85] nickel,[86] palladium,[87] rhodium,[88] ruthenium,[89] osmium,[90] and gold;[91] a large number of carbene complexes of these metals could thus be obtained.[92] The observations (confirmed by kinetic studies) that both primary and secondary amines react faster than alcohols and that electron-withdrawing groups R at the isocyanide nitrogen atom accelerate the reaction indicate that the formation of the carbene ligands C(NHR)(NHR') and C(NHR)(OR') occurs via an initial attack of the amine or alcohol at the carbon atom of the isocyanide.



A similar conversion of a coordinated carbonyl group to an amino(hydroxy)carbene ligand C(OH)(NHR) or C(OH)(NR$_2$) is not known; the nucleophilicity of a primary or secondary amine is apparently not sufficient to make this possible. However, *Fischer* and *Kollmeier* showed almost simultaneously with the work carried out by *Chatt* and coworkers (see Fig. 14) that lithium dialkylamides do undergo

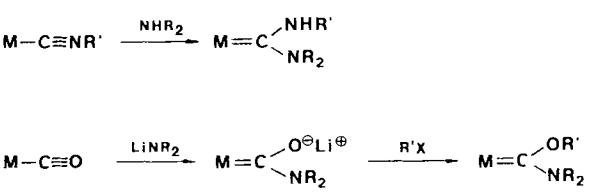


Fig. 14. Nucleophilic addition to CNR and CO metal complexes.

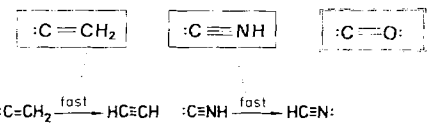
nucleophilic attack at a CO group bound to a metal (e.g., in [Cr(CO)$_6$]); subsequent alkylation gives an alkoxy(amino)-carbene ligand.[93] This variation of the classical Fischer method for the formation of metal carbene complexes has found further application[92] and has proved useful in organic synthesis.[94]

5. The Completion of the Series CO, CNH, CCH$_2$: Vinylidenes as Building Blocks for Metal Complexes

Like CNH, vinylidene (CCH$_2$) is in a strict sense isoelectronic with CO; in addition, it is similarly labile in the free state, in analogy to its nitrogen relative. The energy barrier for the conversion of C=CH$_2$ to its isomer acetylene HC≡CH has been calculated by *Schaeffer* et al. to be only ca. 4 kcal mol^{-1} and could in fact be even lower because of zero point energy effects.[95] The lifetime of C=CH$_2$ can thus be estimated to be 10^{-11} to 10^{-12} s; this is in good agreement with the results of trapping experiments.[96]



Scheme 4.

In contrast to isocyanides (CNR), vinylidene derivatives of the general type C=CHR and C=CR$_2$ are also unstable and thus not available as starting materials for synthesis of complexes. It is therefore *absolutely necessary* to generate the ligand C=CH$_2$, C=CHR, or C=CR$_2$ at the metal; as will be shown below there are various methods for doing so.

The first results in this direction were obtained only two years after the discovery of the carbene complexes; again, as so often, luck played an important role. *Mills* and *Redhouse*[97] had attempted to prepare an iron carbene complex by irradiating a benzene solution of [Fe(CO)$_5$] and diphenylketene; however, they obtained a product with the molecular formula [Fe$_2$(CO)$_8$(C$_2$Ph$_2$)], the X-ray structural analysis of which showed it to be a bridged vinylidene complex. The first *mononuclear* compound with a vinylidene ligand was de-

scribed in 1972 by *King* and *Saran*, who isolated the compounds $[CpM\{C=C(CN)_2\}L_2Cl]$ (M = Mo, W; L = PPh_3, $AsPh_3$, $SbPh_3$, etc.) in the course of studies on the reactivity of 1-chloro-2,2-dicyanovinyl complexes of molybdenum and tungsten.[98] The extremely high thermodynamic stability of the vinylidene–metal bond observed by them has also been confirmed for many other examples; it is thus not surprising that today vinylidene complexes of almost all the transition metals are known.[99]

Very exact information on the structures and bonding modes of these complexes is available. As can be seen from the comparison in Figure 15, not only vinylidene and carbonyl complexes but also vinylidene and isocyanide com-

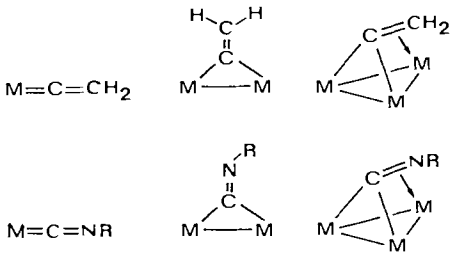


Fig. 15. Coordination possibilities for $C=CH_2$.

plexes show common structural features. The vinylidenes as terminally bonded ligands have excellent π-acceptor properties, which according to a comparative spectroscopic investigation are better than those of CO and only a little worse than those of CS and SO_2.[100] It is remarkable that the rotational barrier for the M=C bond is very small for both isocyanide and vinylidene complexes,[101] so that optical isomers have not yet been detected for allene analogues of the type [LL'M=C=CRR'].[102]

A large number of compounds with doubly bridging vinylidene ligands are known; these can be obtained both directly (see the iron complex $[Fe_2(CO)_8(\mu\text{-}C=CPh_2)]$ already mentioned)[97] and stepwise via addition of a coordinatively unsaturated metal compound to an M=C=CRR' unit.[99] The latter method is important for the formation of binuclear complexes with *two different* metal atoms. The μ_3-C,C bridges (Fig. 15) are also by no means unusual and are found in particular in ruthenium and osmium trinuclear clusters.[103]

The aforementioned extraordinary lability of the compounds C=CRR' leads naturally to the question *how* complexes containing the structural unit M=C=CRR' can be prepared. Two methods have so far proved generally useful; these start either from alkynylmetal compounds or from coordinatively unsaturated or substitution-labile metal complexes and 1-alkynes. Other methods, which employ vinylidene sources such as ketenes,[97] 1,1-dichloroolefins,[104] diazoolefins,[106] and α-(chlorovinyl)silanes,[107] can be used in special cases but have not attained general importance.[99]

The road to vinylidene complexes starting from alkynylmetal compounds was opened in particular by *Davison* and co-workers[108] and *Bruce* and co-workers[109] (see Fig. 16). Cyclopentadienyl iron and ruthenium compounds of the general composition $[CpML_2(C\equiv CR)]$ can undergo not only protonation but also alkylation [using $MeOSO_2F$ or $[OR_3]BF_4$ (R = Me, Et)]; the yields are practically quantitative, indicating that the β-C atom of the alkynyl ligand and not the metal is the preferred site for attack by the electrophile (even for $L=PMe_3$). The observation that anionic alkynyl compounds can undergo electrophilic addition reactions even more readily than neutral compounds corresponds to expectations; it has been used by *Berke* and coworkers, in particular, for the synthesis of the vinylidene manganese complexes $[CpMn(CO)_2(C=CRR')]$.[110]

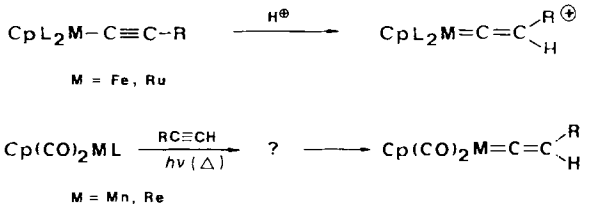

Fig. 16. Synthesis of vinylidenemetal complexes from alkynylmetal compounds and 1-alkynes.

The pioneering work on the conversion of the thermodynamically much more stable 1-alkynes (HC≡CR) into the isomeric vinylidenes (C=CHR) in the coordination sphere of a metal was done by *Antonova, Kolobova*, and their coworkers.[100, 111] They found that the photochemical reaction of $[CpM(CO)_3]$ (M = Mn, Re) with phenylacetylene does not give the expected alkyne metal compounds $[CpM(CO)_2(\eta^2\text{-}PhC\equiv CH)]$ but instead the isomeric vinylidene complexes $[CpM(CO)_2(C=CHPh)]$. The IR spectra recorded during the reaction indicated that the alkyne is first coordinated, but attempts to isolate the intermediate $[CpM(CO)_2(\eta^2\text{-}PhC\equiv CH)]$ in an analytically pure form were unsuccessful[100, 111]. Similar results were obtained later in the reactions of the systems $[CpML_2]^{\oplus}$ (M=Ru, Os), $[Cr(CO)_5]$, and $[W(CO)_3(R_2PC_2H_4PR_2)]$ (all of which are related to $[CpM(CO)_2]$ (M=Mn, Re)) with 1-alkynes reported by *Bruce*,[109b, 112] *Berke*,[113] and *Templeton*[114] and their co-workers. In each case vinylidene rather than 1-alkyne complexes were formed.

The question thus raised regarding the *mechanism* of the conversion of 1-alkynes to metal-bound vinylidenes could at first be answered only in a speculative manner. The suggestion made by various authors, in particular by *Antonova* and co-workers[111] (see Fig. 17), was that subsequent to the coordination of the alkyne an intramolecular oxidative addition takes place, the alkynyl(hydrido) intermediate then un-

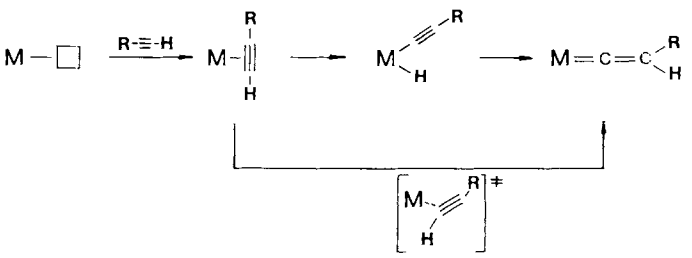

Fig. 17. Proposed mechanisms for vinylidene formation from 1-alkynes.

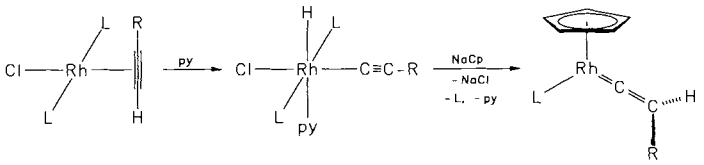
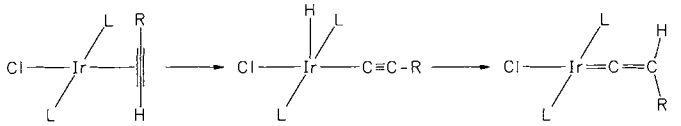
dergoing a 1,3-H shift to give the vinylidene complex. Although this appeared plausible, there was at first no experimental evidence for it. In addition, a very detailed study by *Silvestre* and *Hoffmann*[115] showed that the isomerization of $[L_nMH(C\equiv CR)]$ to $[L_nM(C=CHR)]$ would have a very high activation energy, so that the stepwise conversion of the alkyne to the vinylidene complex shown in the upper part of Figure 17 would be improbable. They suggested that a slippage of the 1-alkyne into a position in which only *one* carbon atom of the triple bond interacts with the metal should be more favorable; this is reminiscent of the bonding situation in a vinylcarbenium ion (see Fig. 17).

Evidence that a stepwise interconversion is possible after all and that, with the correct choice of ligands, the *three possible isomers* can be isolated was produced in the course of our own work on the reactivity of coordinatively unsaturated triisopropylphosphane rhodium and iridium complexes. In the initial stages we were able (see Scheme 5) to trans-



Scheme 5. L = $P\mathit{i}Pr_3$.

form the square-planar alkyne compounds *trans*-$[RhCl(RC\equiv CH)(P\mathit{i}Pr_3)_2]$ into the octahedral alkynyl(hydrido) complexes $[RhHCl(C\equiv CR)(P\mathit{i}Pr_3)_2(py)]$ by adding pyridine and to treat these with CpNa to give the half-sandwich compounds $[CpRh(C=CHR)(P\mathit{i}Pr_3)]$;[116] a little later, using iridium as the central atom, we were able to synthesize the complete series of isomers shown in Scheme 6.[117] According to more recent studies, there is no doubt that an analogous stepwise conversion of $HC\equiv CR$ to $C=CHR$ also occurs for rhodium.[102, 118]



Scheme 6. L = $P\mathit{i}Pr_3$. Middle: $\delta(IrH) \approx -43$.

These results seem at first to be in complete disagreement with the MO calculations of *Silvestre* and *Hoffmann*.[115] However, these authors started from complex building blocks $[ML_n]$ such as $[CpMn(CO)_2]$ (or more simply $[MnH_5]^{4\ominus}$) in which the metal has a 16-electron configuration; thus, addition of the alkyne gives a filled shell with 18 electrons. This requirement is not met, however, by the fragment $[MCl(P\mathit{i}Pr_3)_2]$ (M = Rh, Ir): here, the metal has only a 14-electron configuration, so that a free coordination site is still present after addition of the alkyne. For this reason the hydride transfer from the metal to the β-C atom of the alkynyl ligand in the intermediate $[MHCl(C\equiv CR)(P\mathit{i}Pr_3)_2]$ could occur *inter*molecularly; this is in agreement with preliminary kinetic data (for the example M = Ir).[119]

The final reaction products shown in Schemes 5 and 6 behave in part very similarly to their CO relatives. For example, reaction of both the compounds *trans*-$[IrCl(C=CHR)(P\mathit{i}Pr_3)_2]$ and the Vaska complex *trans*-$[IrCl(CO)(PPh_3)_2]$ with HBF_4 results in protonation at the metal,[120] whereas the half-sandwich compounds $[CpRh(C=CHR)(P\mathit{i}Pr_3)]$ (R = H, Me, Ph) and $[CpRh(CO)(PMe_3)]$ react with benzoyl azide to give the same type of five-membered metallaheterocycles.[121]

The parallels in reactivity are even closer for *isocyanide* and *vinylidene* complexes, however. The method discovered by *Chatt* and co-workers for the preparation of metal alkoxy(amino)- and diaminocarbene compounds (see Section 4), which is based on the nucleophilic attack of a Lewis base such as ROH or RNH_2 on the carbon atom of the isocyanide,[84] can readily be extended to vinylidene complexes, in particular when these are cationic. The α-carbon atom of the vinylidene ligand is then even more electrophilic than in comparable neutral compounds, so that, for example, starting from $[CpFe(C=CH_2)(CO)(PPh_3)]^{\oplus}$ and alcohols, amines, mercaptans or hydrogen halides, it is possible to obtain various types of iron carbene complexes. Figure 18 contains a summary of the results described by *Hughes* et al.[122]

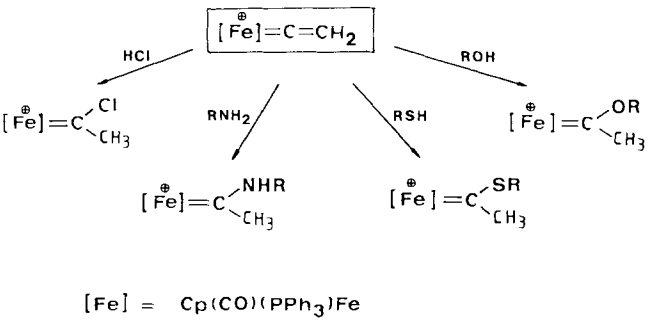


Fig. 18. Reaction of $[CpFe(C=CH_2)(CO)(PPh_3)]^{\oplus}$ with nucleophiles.

Another feature common to the parent compound CO and its near relatives CS and $C=CH_2$ should be mentioned. Since the beginning of this century it has been known that metal carbonyls react with thermally or photochemically generated 16-electron complex fragments to give binuclear compounds in which the CO acts as a bridge; the prototype of this reaction is the formation of $[Fe_2(CO)_9]$ from $[Fe(CO)_5]$ and $[Fe(CO)_4]$.[123] Using the isostructural series $[CpRh(CX)(PR_3)]$ with X = O, S and CH_2 as an example, we were able to show that these three complexes react in exactly the same way with the 16-electron species $[CpMn(CO)_2]$ generated by irradiation of $[CpMn(CO)_3]$ and stabilized by THF (Fig. 19).[65, 124] It is remarkable that not only

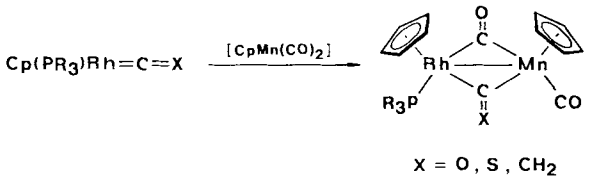

Fig. 19. Reaction of the isostructural compounds $[CpRh(CX)(PR_3)]$ with $[CpMn(CO)_2]$.

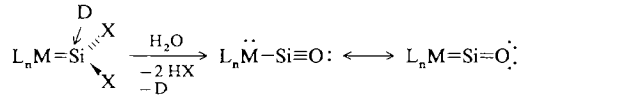
the CO but also the CS and $C=CH_2$ bridges occupy an unsymmetrical position between the two metal atoms; this is presumably due to the dissimilar electron configurations at rhodium and manganese.

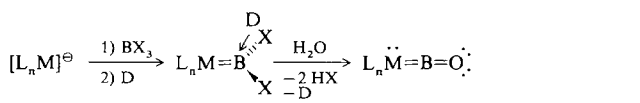
6. On to the Second Century: The Search for the Missing Relatives

What does the future look like? Will the organometallic family which is now celebrating its birthday increase in size, and in which direction could this perhaps take place? Which will be the next metal-bonded relative of CO?

One very promising candidate is certainly SiO. On the basis of earlier work by *Schmid* et al.,[125] *Zybill* et al. have very recently shown that dichlorosilylene, $SiCl_2$, can be generated at a 16-electron complex fragment just as can a carbene and that the M–$SiCl_2$ bond can be stabilized by means of adduct formation with suitable Lewis bases such as hexamethylphosphoric triamide (HMPT).[126] The X-ray structural analyses of $[(CO)_5CrSiCl_2(hmpt)]$ and $[(CO)_4FeSiCl_2(hmpt)]$ show that the M–Si distance is relatively short and that the HMPT molecule is only weakly bonded.[126] If it were possible to displace the HMPT molecule and replace it by H_2O and thus to eliminate two molecules of HCl, one could generate the CO analogue SiO. A very similar conversion of CCl_2 coordinated at osmium to CO has been described by *Roper* and co-workers.[49] In order to fix the silicon monoxide ligand it may be necessary to use an electron-richer complex building block such as $[C_5Me_5Re(PR_3)_2]$, $[Os(PMe_3)_4]$, or $[C_5Me_5Ir(PMe_3)]$ rather than $[Cr(CO)_5]$ or $[Fe(CO)_4]$; such building blocks could stabilize the M–SiO bond by means of stronger π back-bonding.



If it were possible to fix SiO, then why not also $BO^{\ominus}$? In Section 2, we referred to the existence of the extremely short-lived species CH_3BO, which is isoelectronic with BH_3CO; the former can be thought to be built up from $CH_3^{\oplus}$ and $BO^{\ominus}$. According to *Hoffmann*,[127] $CH_3^{\oplus}$ is isolobal with $[Mn(CO)_5]^{\oplus}$ and $[Co(CO)_4]^{\oplus}$, so that compounds such as $[Mn(CO)_5(BO)]$ and $[Co(CO)_4(BO)]$ (i.e., analogues of $[Cr(CO)_6]$ and $[Fe(CO)_5]$) would be plausible synthetic goals. Attempts to synthesize these complexes could build on the work of *Nöth* and *Schmid*, who reported the preparation of the readily decomposing compound $[(CO)_4CoBCl_2]$ as early as 1966.[128] Addition of a Lewis base such as HMPT would give an intermediate similar to that formulated above for SiX_2. Careful protolysis could then convert an ElX_2 ligand into an ElO ligand (El = B). Boron compounds with a coordination number of two are no longer curiosities today, as has been shown clearly in the last decade, in particular by *Nöth, Parry, Paetzold*, and *Berndt*.[129]



What other possibilities are there apart from SiO and $BO^{\ominus}$? What is the situation regarding $CF^{\oplus}$, which we have already mentioned in Scheme 2, or BF, which is also isoelectronic with CO? Is it realistic to think of such ligands becoming available? If intuition is not deceiving, a compound of the type $L_nM(CF)$ will soon be described in the literature. The question will then be only whether this molecule is better described as a carbyne complex $[L_nM\equiv C-F]$ than as a carbonyl analogue $[L_nM=C=F]$; this question can only be answered by an X-ray structural analysis, together with MO calculations. The signposts on the way to $[L_nM(CF)]$ have probably already been set up by *Roper*, who, during the course of extremely interesting studies, has been able to synthesize several compounds containing the fragments $M(CCl_2)$ and $M(CF_2)$.[130] Although compounds such as $[RuCl_2(CF_2)(CO)(PPh_3)]$ and $[Os(CF_2)(CO)_2(PPh_3)_2]$ have not yet led to products containing an OsCF unit,[131] the compound $[OsCl(CPh)(CO)(PPh_3)_2]$ obtained by the same group[132] shows that the goal of synthesizing a neutral complex $[OsCl(CF)(CO)(PPh_3)_2]$ or a cation $[Os(CF)(CO)_2(PPh_3)_2]^{\oplus}$ is quite realistic. The existence of trinuclear clusters with μ_3-CF bridges such as $[\{(CO)_3Co\}_3(\mu\text{-}CF)]$[133] and $[\{(CO)_3Fe\}_3(\mu_3\text{-}CF)_2]$[134] is also encouraging in this respect. These complexes resemble the corresponding carbonyl compounds with triply bridging CO ligands in both their structure and their bonding features.

A complex such as $[Fe(CO)_4(BF)]$ or $[(C_6R_6)Os(L)(BF)]$ also seems attainable. *Schmid, Petz*, and *Nöth*[135] described compounds of the formula $[Fe(CO)_4(BNR_2)]$ (R = Me, Et) as early as 1970; while these are extremely thermally labile, there is no doubt that they do exist. Although the road from $[Fe(CO)_4(BNR_2)]$ to $[Fe(CO)_4(BF)]$ will not be an easy one, it does appear passable. Reactions at osmium also appear feasible; the building blocks $[C_6H_6Os(PR_3)]$,[136] $[C_6H_6Os(CO)]$,[137] and $[(C_6H_3Me_3)Os(CO)]$,[138] used by us, could well prove suitable for the attachment of a BF ligand.

One hundred years have passed and a new era lies before us. One does not really need to be a prophet to forecast that the second century will also be an exciting one, that further surprises await us, and that the present survey will certainly not be the last occasion on which the serendipitous discovery made by *Ludwig Mond* will be remembered with reverence.

I thank Heinrich Vahrenkamp for suggesting this subject and Ernst Otto Fischer for valuable information regarding the material to be consulted. Oliver Nürnberg helped in the preparation of the reaction schemes, figures, etc., and I thank him heartily for this help.

Aspartic and Glutamic Acid as Ligands to Alkali and Alkaline-Earth Metals: Structural Chemistry as Related to Magnesium Therapy

By Hubert Schmidbaur,* Hans Georg Classen, and Joachim Helbig

Dedicated to Professor Max Schmidt on the occasion of his 65th birthday

Magnesium and other alkaline-earth and alkali metals play an important role in the biochemistry of virtually all living organisms. In contrast to "trace elements", these "common metals" are distributed in most cells and tissues, often in considerable concentrations, and a constant supply is indispensable for unrestricted performance of biological functions. In contemporary medicine, various forms of magnesium therapy are recommended in order to compensate for magnesium deficiency due to certain dysfunctions as well as to loss from excessive transpiration. In addition, there are numerous indications for prophylaxis. Magnesium is usually administered orally in the form of "complexes" with "natural" anions derived from L-aspartic, L-glutamic, L-pyroglutamic (pidolic), citric, and orotic acid. Analytical, electrochemical, and spectroscopic investigations of aqueous solutions of these pharmaceuticals, together with X-ray diffraction studies of crystalline samples, have given a detailed knowledge of these coordination compounds. Only certain combinations can be addressed as magnesium complexes, whereas others are only present as aquo complexes both in aqueous solutions and in the solid state. Thus, a delicate balance of metal complexation and hydrogen bonding exists for the components of the drugs, which is relevant for the metal carrier functions of the organic ligands. Compared with the more flexible stereochemistry of Ca, Sr, Ba, Mn^{II}, Zn, Li, Na, and K complexes, which have coordination numbers between 4 and 9, octahedral hexacoordination is found exclusively for magnesium, the most stereoselective of these metals.

1. Introduction

Terms like "inorganic biochemistry" or "bioinorganic chemistry" have been coined for an area of interdisciplinary research where interest is focused largely on the role of metals in biological systems.[1-7] It was recognized very early that a deficiency of common minerals or mineral components in food and drink may greatly affect the health of animals and humans,[8,9] with "salt" (sodium chloride) perhaps being the most prominent example in the history of mankind. Regular uptake of demineralized water is an injurious diet not only due to, for example, the lack of buffer anions like (bi)carbonate, phosphate, or sulfate, but also owing to depletion of the concentrations of standard metals in the body, leading to a breakdown of most osmotic systems and to mal- or dysfunction of most enzymes, biological signal processing, and biomineralization.

For many body functions some of the "essential metals" are required in relatively high quantities and have to be provided by a regular intake in order to secure standard performance. Bioinorganic chemists classify these elements as "common metals", as opposed to "trace elements" for which only minute quantities are required, and for which a constant supply is less mandatory owing to, for example, storage capabilities of the body (which is particularly true for first-row transition metals like iron). The rest of the metals in the periodic table are biologically "nonessential metals", whose absence appears to be of little or no immediately obvious consequence, but for which concentrations above certain limits may be found to be either toxic or, in certain cases, of therapeutic use.

In biological systems, the most prominent common metals are the alkali and alkaline-earth metals sodium, potassium, magnesium, and calcium (Table 1).[9-16] On the other hand, lithium[15] is considered a nonessential metal, but with considerable therapeutic value and low toxicity. The bioinor-

Table 1. Distribution and significance of some alkali and alkaline-earth metals in biological systems and recommended daily intake.

Element	Total (adult)	Serum (plasma level)	Essential	Recommended daily intake (adults)
Li	2–3 mg	2–3 μmol L^{-1}	no	–
Na	85 g	134–141 mmol L^{-1}	yes	2 g
K	120–150 g	3.8–4.5 mmol L^{-1}	yes	3–4 g
Mg	24–26 g	0.76–1.10 mmol L^{-1}	yes	0.3–0.45 g
Ca	750–1100 g	2.15–2.55 mmol L^{-1}	yes	0.8–1.2 g
Sr	140–1000 mg	1.6–5.0 μmol L^{-1}	questionable	–
Mn	10–40 mg	1.8–20 μmol L^{-1} [a]	yes	2–5 mg
Zn	1.4–2.1 g	12–17 μmol L^{-1}	yes	15–25 mg

ganic chemistry of the very rare elements rubidium and cesium has remained largely unexplored.[4, 5, 9] Beryllium is considered highly toxic, at least in respiratory uptake, but less so when administered orally.[17–19] Strontium is rated nontoxic, and traces of it appear to be "essential", though the reason for this is not yet known. Barium causes typical "heavy-metal poisoning" even at low concentrations if soluble compounds are applied.[4]

Apart from diseases involving resorptive, storage, or excretion malfunction, deficiency syndromes associated with the most common metal cations in humans and animals, $Na^{\oplus}$, $K^{\oplus}$, $Mg^{2\oplus}$, and $Ca^{2\oplus}$, have been rare phenomena for many years. Virtually all standard diets appeared to guarantee a sufficient supply of these cations owing to their high abundance. This situation has changed in modern society, where, for example, animals are raised in a controlled environment with special growth-regulating diets, and humans may be subject to rapid loss of electrolyte due to stress, excessive recreational activities, or highly irregular and selective eating and drinking habits. Food processing and conservation, which result in depletion of some elements, are other origins. This is particularly true for *magnesium*, which is most likely to be deficient owing to its somewhat lower abundance compared with that of sodium, potassium, or calcium. Magnesium therapy has therefore become an important issue in contemporary medicine, including veterinary medicine. The enormous increase in the consumption of mineral water from bottles labeled with a complete analytical inventory probably also reflects contemporary attitudes and concern.

One of the most relevant questions arising in this context is the optimum administration of magnesium, that is, the selection of compounds (salts or complexes) which lead to rapid and efficient resorption without upsetting the pH or the ionic equilibria in body fluids. If possible, side effects from the anionic and/or ligand components should be negligible or, if possible, therapeutically beneficial.

Among the many possibilities for a "magnesium formulation", the natural amino acids and their derivatives are preferred candidates. The acidic members of the amino acid series, L-aspartic and L-glutamic acid as well as L-pyroglutamic acid (pidolic acid), were therefore chosen at an early stage of the development of magnesium drugs, though only preliminary information was available on pertinent acid/base and complex equilibria in aqueous media resembling the situation in body fluids. The present article summarizes the results of more recent research in this area and also deals with other "common" and "trace elements".

Hubert Schmidbaur was born in Landsberg/Lech in 1934 and studied chemistry at the University of Munich from 1953 to 1960 (Dissertation with Max Schmidt). He became a lecturer at the University of Marburg in 1964 and was Professor of Inorganic Chemistry at the University of Würzburg from 1965 to 1973, when he was appointed Professor of Inorganic and Analytical Chemistry at the Technical University of Munich. Hubert Schmidbaur has received many honors and is a member of the Göttingen Academy of Sciences and the Leopoldina Academy in Halle. He currently has research interests in the chemistry of silicon and germanium (as related to solar cell and sensor technology), the chemistry of gold (as related to microelectronics and electrical engineering), the coordination chemistry and organometallic chemistry of the p-block metals (e.g., gallium), the synthetic and structural chemistry of organophosphorus compounds, and the bioinorganic chemistry of magnesium (magnesium therapy).

Joachim Helbig was born in Rabenstein near Chemnitz in 1929 and studied biology at the University of Dresden and veterinary medicine at the Humboldt University in Berlin. He received his doctorate degree (med. vet.) at the Free University of Berlin in 1957 and worked for the Spitzner Company (Ettlingen) and for Grünenthal Inc. as a research associate. Since 1962, he has been head of the Clinical Research and Development Division of Verla-Pharm (Tutzing). Joachim Helbig is a member of numerous national and international scientific societies and editor of "Magnesium Bulletin".

Hans Georg Classen was born in Schatensen near Uelzen in 1936 and studied medicine at the University of Göttingen from 1955 to 1960 (Dr. med. in 1962). In 1964 he started as a research assistant at the Institute for Experimental Therapy of the University of Freiburg and became a lecturer in toxicology and pharmacology there in 1971. Since 1976, Hans Georg Classen has been head of the division of Pharmacology and Toxicology of Nutrition at the University of Hohenheim. His main research interests are the metabolism of magnesium, cadmium, and nitrate/nitrite, mainly as related to stress conditions and their pharmacological treatment.

1.1. The Role of Magnesium and Other Alkaline-Earth Metals in Biological Systems

Magnesium is one of the most important elements in biological systems. The many facets of its action can therefore only be summarized here very briefly. Magnesium is present solely as the solvated or complexed dication $Mg^{2\oplus}$, basically as part of the osmotic equilibria in- and outside of cells and in all tissues.[20, 21] It is readily transported through membranes, including the blood/brain barrier.[22] In purely "inorganic" form it is accumulated (stored) in invertebrate "granules" as the carbonate, phosphate, or citrate, mostly along with the calcium salt as the main matrix constituent, from which it can be remobilized.[23-25] In vertebrate bone and teeth it plays only a minor role (again next to calcium). Magnesium cations available from these sources or from direct intake bind to various sites on protein (or pectin) surfaces to induce or stabilize tertiary structures (e.g., membranes[22]) or to enhance certain functionalities. This is particularly true for enzyme activities, with ATP and ADP hydrolysis perhaps being one of the most significant examples. For example, $Mg^{2\oplus}$ and $K^{\oplus}$ are indispensable cofactors of ribonuclease activity.[22] Careful investigation of the magnesium (or calcium) binding sites on proteins has shown that the acidic groups of L-aspartic and L-glutamic acid are the key anchoring positions for these cations.[23-25]

In the above processes, magnesium competes successfully for certain coordination sites with the other common metal ions, some of which are antagonists through a different specificity. Since ion–ion and ion–dipole interactions are the main binding forces, this specificity is predominantly governed by the charge and size of the individual cation, as well as by the resulting effective coordination number and geometry. An improved understanding of the function of biological cations is thus to be expected from a detailed study of the coordinating properties of the metals competing for the ligand sites of a given matrix. However, the specific contributions from cation- and anion-based Coulomb forces may be obscured, for example, by the effect of ubiquitous hydrogen bonding, which energetically can be of the same order of magnitude. Thus, only a complete picture of the structural situation allows individual contributions to be distinguished.

Table 2. Oral toxicity of M(L-AspH)Cl (M = Mg, Ca, Sr, Mn, Zn); Sprague–Dawley rats, empty stomach. Except for the insoluble Mg(L-Asp) · $3H_2O$ reference, all compounds were dissolved in water. LD_{50}: dosis resulting in the death of 50% of the animals.

Compound	% Weight		LD_{50} [g kg^{-1}]
	M	Cl	(95% reliability)
Mg(L-AspH)Cl	9.55	14.26	10.69 (9.82–11.70)
Mg(L-Asp) · $3H_2O$	8.68	–	36.01 (22.70–57.15)
Ca(L-AspH)Cl	18.35	15.90	6.04 (4.96–7.37)
Sr(L-AspH)Cl	31.50	12.94	ca. 14
Mn(L-AspH)Cl	22.80	14.80	3.42 (2.28–5.15)
Zn(L-AspH)Cl	28.39	14.77	1.91 (1.50–2.42)

The (oral) toxicity of alkaline-earth metals, like that of other metals, is strongly dependent on the anions present in the drug. This dependence may be due to different "bioavailability", as well as to the specific effects of the anions. As pertinent examples, the oral toxicities of M(L-AspH)Cl (M = Mg, Ca, Sr, Mn^{II}, Zn) are listed for comparison in Table 2.[14, 26] Since the same anions are present in all cases, these data reflect relative metal toxicities for the given system. Magnesium toxicity is recognized to be a minimum in this series. LD_{50} values as high as 10 g kg^{-1} (!) are tolerated.

1.2. The Metal-Binding Role of L-Aspartic and L-Glutamic Acid in Biological Systems

As already pointed out, the common metals become attached predominantly to the carboxylate groups of L-aspartate and L-glutamate residues. Particularly striking cases are the matrices for biomineralization in general and for shell, bone, and dental growth in particular. For example, aspartic acid, along with (phospho)serine, is the main component of the calcium carbonate biomineralization matrices of mollusks and of phosphophoryns in dentin fractions.[23]

In polysaccharide and other matrices the cations become primarily associated with sulfonate or phosphate groups, but carboxylate coordination via L-aspartic acid is also retained. Soluble glycoproteins were found to become attached to the surface of common metal carboxylates like fumarate or maleate through their aspartate residues, and intercrystalline proteins of biomineralized material ($CaCO_3$, $Ca_5(PO_4)_3OH$, CaC_2O_4, $CaSO_4$, $SrSO_4$, $BaSO_4$) were invariably shown to contain extremely high concentrations of L-aspartate.[23]

Whereas the key role of L-aspartate and, to a lesser extent, L-glutamate in the binding of metals to polymeric biomatrices is thus well established, the metal-cation affinity of low-molecular-weight peptides and free amino acids in aqueous solutions is much less well documented. Only very few complexes have been isolated, and—owing to the complexity of the equilibria involved—other physical measurements in vitro and in vivo have not always given conclusive results.

2. Dissociation Equilibria of Aspartic and Glutamic Acid in Aqueous Solution

Aspartic acid ($AspH_2$) and glutamic acid ($GluH_2$) can dissociate in aqueous solution [Eqs. (1), (2), (4), and (5)] to form monoanions ($AspH^{\ominus}$, $GluH^{\ominus}$) and dianions ($Asp^{2\ominus}$, $Glu^{2\ominus}$).

$$AspH_2 + H_2O \rightarrow AspH^{\ominus} + H_3O^{\oplus} \quad (1)$$

$$AspH^{\ominus} + H_2O \rightarrow Asp^{2\ominus} + H_3O^{\oplus} \quad (2)$$

$$AspH_2 + H_3O^{\oplus} \rightarrow AspH_3^{\oplus} + H_2O \quad (3)$$

$$GluH_2 + H_2O \rightarrow GluH^{\ominus} + H_3O^{\oplus} \quad (4)$$

$$GluH^{\ominus} + H_2O \rightarrow Glu^{2\ominus} + H_3O^{\oplus} \quad (5)$$

$$GluH_2 + H_3O^{\oplus} \rightarrow GluH_3^{\oplus} + H_2O \quad (6)$$

At very low pH, both acids can be further protonated [Eqs. (3) and (6)] to give the species $AspH_3^{\oplus}$ and $GluH_3^{\oplus}$, but these two cations (with both carboxylate groups and the amino group protonated) are of very limited biological relevance. By contrast, all four anionic species have to be considered, since the corresponding equilibrium constants suggest

significant concentrations in neutral and weakly basic media: $pK = 1.88$ ($AspH_3^{\oplus}$), 3.65 ($AspH_2$), 9.60 ($AspH^{\ominus}$); 2.16 ($GluH_3^{\oplus}$), 4.32 ($GluH_2$), 9.96 ($GluH^{\ominus}$).

Figure 1 shows the distribution of the three species derived from L-$AspH_2$ as a function of pH. The monoanion $AspH^{\ominus}$ is clearly the dominant species in the biologically most relevant pH range 5–9.[25]

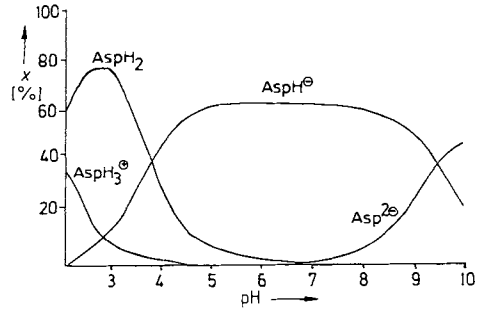

Fig. 1. Dissociation of L-aspartic acid in water as a function of pH.

The monoanions $AspH^{\ominus}$ and $GluH^{\ominus}$ (with protonated amino groups) are potentially bidentate ligands with either two carboxylate groups or the amino group together with one of the two (nonequivalent) carboxylate groups as the donor sites. For pure, dilute aqueous solutions, the amino group is assumed to be protonated, but, in the presence of metal ions, a proton transfer from N to O (α or β/γ) can generate N,O(α) or N,O(β/γ) chelate ligands. Upon coordination, these ambidentate aspartate and glutamate monoanions can form five-, six/seven-, and seven/eight-membered rings and are therefore very adaptable to the conditions of size and charge imposed by the metal.

The dianions are potential N,O(α),O(β) tripod ligands. In such mononuclear complexes, the resulting bicyclic systems have the ring sizes mentioned above.

The free acids $AspH_2$ and $GluH_2$ feature only one carboxylate group; in the protonated forms, no basic sites are left. However, more than one oxygen atom per carboxylate group may be involved in coordination in condensed solid-state structures, where even oxygen bridging of metals may occur (see below). In aqueous solutions, the high donor ability of water molecules generally overrules the donor capacity of carbonyl oxygen atoms (C=O), but not necessarily of the carboxylate oxygen atoms ($C-O^{\ominus}$).

3. Metal-Ion Complexation by Aspartate and Glutamate Ligands in Aqueous Solution

Aspartate and glutamate anions are known to coordinate with many metals, but characterization of these complexes is often still not satisfactory. This is particularly true for those metals whose complexation is "weak", meaning that the complexes are strongly dissociated in dilute aqueous solution. The stability constants of a number of complexes have been determined, largely by potentiometric titration.[27–32]

Although the values indicate relatively stable complexes for the later first-row transition metals (e.g., divalent Fe, Co, Ni, and Cu), this is not true for the common metals (e.g., Mg, Ca, Sr, and Zn or the alkali metals).

The values $\lg K = 2.45$ for Mg(L-AspH)$^{\oplus}$ and $\lg K = 1.90$ for Mg(L-GluH)$^{\oplus}$, as determined in classical studies by *Martell* et al. for dilute aqueous solutions, are a measure of the extensive dissociation of the two basic magnesium complexes. Figure 2 shows the distribution of magnesium aspartate complexes in water as a function of pH.[33]

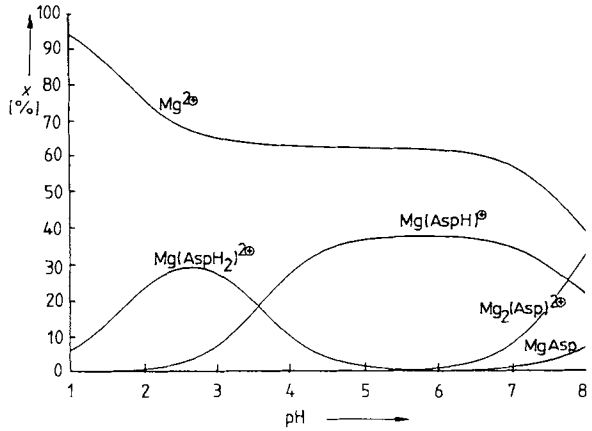

Fig. 2. Distribution of magnesium L-aspartate complexes in water as a function of pH.

These data have recently been confirmed by titrations using ion-sensitive electrodes with ion-selective membranes. The $Mg^{2\oplus}$ concentrations detected over the most important pH range are in good agreement with those calculated from previous measurements.[34]

This dissociation does not mean that these complexes are inherently unstable, but rather indicates that water molecules are able to compete favorably with the amino acids for metal complexation. The energy balance in the system is maintained by a redistribution of hydrogen bonding between the amino and carboxylate functions and the water molecules. The resulting reversibility makes aspartate and glutamate amenable as carriers, or auxiliary carriers, for metals in biological systems. Methods for the determination of structural features of the species present in solution are discussed below.

4. Influence of Aspartate and Glutamate on Transport and Distribution of Magnesium and the Effect of Auxiliary Anions

To compensate for loss of magnesium by structural incorporation (cells, skeleton, etc.) and excretion (perspiration, urine, feces), the body is dependent on regular uptake of magnesium. Should a deficiency arise, as easily revealed by lower magnesium concentrations in serum and tissue, the uptake has to be increased. Moreover, an increase in the magnesium concentration beyond the standard level can also be therapeutically useful in conditions as different as premature labor, eclampsia, or heart attack, where antagonism with $Ca^{2\oplus}$ is important.[20, 35]

The kind of administration (enteral or parenteral) is determined by the galenic form, the dose, and the specific indications. For parenteral administration of a magnesium compound (intramuscular, intravenous), high solubility (no oxide, carbonate, oxalate, orotate) and tissue compatibility (no magnesium chloride!) are of prime importance. For oral administration, maintenance of the acid/base equilibrium is particularly critical if larger doses of magnesium are necessary: anions of weak acids are strong buffers, which lead to a rapid increase in gastrointestinal pH.[20, 36]

Although neutralization of stomach acid by oxides, hydroxides, or carbonates is a standard procedure in gastroenterology, alkalotic metabolic conditions may arise with large quantities of these magnesium compounds. On the other hand, acidosis may occur in treatment with $MgCl_2$. Shifts of the acid/base equilibria are biologically very significant: the action of catecholamines, typical stress hormones, is greatly enhanced under alkalotic conditions, whereas it is reduced under acidotic conditions.[37] Secondary shifts in the electrolyte equilibria (e.g., hypopotassemia under alkalosis) are likely to aggravate the symptoms. Aspartic and glutamic acid have intermediate acid/base properties and therefore do not seriously affect the proton equilibria in the stomach or in body fluids.

Aspartic acid is converted into oxaloacetate through metabolic transamination or oxidative deamination and then fed into the citric acid cycle.[10] Together with glutamic acid, it is thus classified as a glucoplastic amino acid. Glutamic acid plays a key role in transamination processes and in the formation of urea. In the brain, the neurotransmitter γ-aminobutyric acid (GABA) is generated. Drugs based on magnesium complexes of the two acidic amino acids are therefore designed in such a way that both cationic and anionic components play active roles in therapy.

Monitoring of serum and bone magnesium levels, which are transport and storage indicators, in animal tests with rats and cats have shown that enteral availability of magnesium is clearly greater for Mg(L-AspH)Cl than for $Mg(L\text{-}AspH)_2$ or $MgSO_4$. $MgCl_2$ turned out to be significantly more toxic, probably owing to accompanying acidosis.[38] Administration of the complex $Mg(L\text{-}AspH)Cl \cdot 3H_2O$ was more effective than simultaneous administration of $Mg(L\text{-}AspH)_2$ and KCl.[39a] The magnesium uptake was even more rapid using Mg(L-AspH)Br, but interfering bromism makes application for magnesium supplementation inappropriate. In therapeutical dosage, the compound can be used as a daytime seditive showing tranquilizing and thymoleptic effects. In long-term experiments, no bromide intoxication could be observed for this medication, in clear contrast to inorganic bromides.[39b, c]

In agreement with the resorption studies, Mg(L-AspH)Cl proved to be superior to $MgSO_4$ in the treatment of experimental animal heart necrosis models, in that it also lowered adrenalin-induced high blood pressure.[40] These positive effects are ascribed to high magnesium availability, the absence of a dependence on acid/base equilibria,[36, 40] and inhibition of the hypothalamus–hypophysis–adrenalin gland axis activated in acute stress.[41]

The results of the initial animal experiments have been confirmed in tests with livestock.[41, 42] A pronounced protective effect against transport-induced stress, secondary sterility, and cannibalism was observed for a community of 6000 hogs, and stress reactions were also greatly reduced in groups of 1500 cattle and horses. Similar results are to be expected for the corresponding glutamate. However, since resorption processes from the gastrointestinal tract are exceedingly complex (pH range as wide as 2.0–9.5, active and passive mechanisms, liver clearance, enterohepatic cycles, etc.), no detailed knowledge can be claimed as yet regarding the individual mechanistic steps for either the aspartate or the glutamate complex.

5. Approaches to Structure Elucidation of Species in Solution and Matrices

Colligative properties, as measured, for example, by electrochemical methods (potentiometry, conductivity) or by osmometry, can serve to determine stoichiometry, charge, and distribution of species in solution (cf. Figs. 1 and 2), but give no clue as to the structure of the individual components. Other approaches therefore had to be chosen in order to clarify the mode of complexation of metals by aspartate and glutamate.

IR and Raman studies met with only limited success owing to the complexity of the system; the difficulties encountered are mainly due to the comparable effects of metal complexation and hydrogen bonding on molecular vibrations. Similar problems arose in the evaluation of optical rotation and circular dichroism.[43]

NMR spectroscopy is a more promising technique, at least for the elucidation of the aspartate and glutamate conformations through the determination of chemical shifts, coupling constants, and relaxation times as a function of pH, concentration, and temperature.[44] Three ground-state conformations have been proposed for the two amino acids and their complexes[45] (Fig. 3). When acid titrations of magnesium

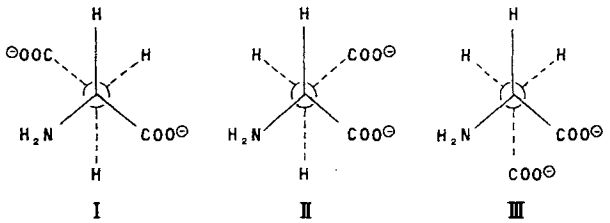

Fig. 3. Proposed ground-state conformations of L-aspartic (L-glutamic) acid, determined by NMR spectroscopy. I, N,O chelate; II, O,O chelate; III, N,O,O tripod.

aspartate (glutamate) solutions are monitored by ^1H and ^{13}C NMR spectroscopy, the resulting curves for the δ and J values are in good agreement with potentiometric measurements. The transition from one prevailing species to the other (cf. Fig. 2) is shown by similar inflections in the curves. NMR spectroscopy is a "slow" method, however, and only yields time-averaged parameters for all species present in solution.

Nevertheless, for pH ranges where one species is dominant in solution, the J values can give a clear indication as to the

structure of the ligand. For magnesium aspartate and glutamate solutions at pH = 8, conformation **III** (Fig. 3) appears to prevail; at lower pH, conformation **I** becomes important.[34] This result indicates that the dianion $Asp^{2\ominus}$ functions as a tripod ligand for $Mg^{2\oplus}$, whereas $AspH^{\ominus}$ is N,O(α)-bidentate.

For other metals, with an even more extensive dissociation (e.g., the alkali metals), evaluation of the spectra is less straightforward. ^{7}Li NMR spectroscopy shows differences in the δ values and line widths for lithium aspartate and glutamate solutions, but the pH dependence is not very pronounced. Although the variations in the line widths indicate differences in the environment of the metal, no detailed information can be deduced.[34] This situation is not unlike the results of related NMR studies with the quadrupolar nucleus ^{23}Na.[46]

By contrast, NMR studies using the nucleus ^{113}Cd have recently attracted considerable interest. The δ values of Cd are strongly dependent on the metal environment and thus a good indicator of the coordination number and/or geometry. Since $Cd^{2\oplus}$ can replace $Ca^{2\oplus}$ ions in their specific binding sites, this technique can also be used to probe the coordination sphere of $Ca^{2\oplus}$. X-ray results seem to confirm the assignments made on the basis of NMR experiments.[47–49] It is no coincidence that, in the proteins investigated in this important study, aspartate groups are the main contact sites for the metals!

6. The Structures of Crystalline Materials

Crystal structure studies of metal aspartate and glutamate complexes have recently been renewed and intensified for several reasons: (1) Investigations of aqueous solutions of the compounds have not yielded fully satisfactory information on the mode of coordination of the amino acids. (2) Solid-state structures may give at least a clue regarding the structures to be expected in solution. (3) In the light of the low equilibrium constants, it had been questioned whether the species present in solution and/or isolated as solids were true coordination compounds of the amino acid and not just aquo complexes with aspartate or glutamate as the counterions. (4) For economical and galenic reasons the formulations for magnesium therapy are often amorphous binary or ternary compositions (e.g., $Mg(L\text{-}AspH)_2 \cdot 4H_2O$ or $Mg(L\text{-}AspH)Cl \cdot 3H_2O$), with the stoichiometry adjusted by spray-drying of solutions with the desired quantities of the components; it was therefore of prime importance to prove that the latter products, for example, were not just mixtures of $Mg(L\text{-}AspH)_2 \cdot aq$ and $MgCl_2 \cdot aq$, but discrete ternary phases.

Unfortunately, many metal aspartate and glutamate phases are extremely difficult to crystallize. Prolonged (literally year-long) efforts were often required to isolate suitable single crystals. But for some phases this has never been possible, and therefore there are still gaps in the systematics of these complexes. The following inventory covers the literature until early 1990, when structural studies were still under way in several laboratories; the results of these studies may make important additions to the present picture of metal binding by amino acids.

Most of the studies refer to species derived from the L-amino acids, which are the dominant species in biological systems and are used exclusively for medication. Although the crystal structures of the D forms would only be mirror images, the racemic compounds have entirely different crystal structures, with serious implications for biological matrices.

6.1. Magnesium Aspartates and Glutamates

6.1.1. *Magnesium L-Aspartate Trihydrate*

A compound of the composition $Mg(L\text{-}Asp) \cdot 3H_2O$ is isolated from strongly alkaline solutions (pH > 10) of magnesium aspartate (cf. Fig. 2), regardless of the initial composition.[50] Crystal growth from concentrated solutions (containing KOH) may require several months. The structure of the material consists of chains composed of individual mononuclear complexes, where the $Asp^{2\ominus}$ dianion acts as an N,O(α),O(β) tripod ligand. The environment of the magnesium atom is octahedral with two (of the three) hydrate water molecules and a carbonyl oxygen atom of a neighboring unit occupying the remaining three vertices (Fig. 4). The strands of complex units are interconnected by hydrogen bonds involving the third hydrate water molecule.

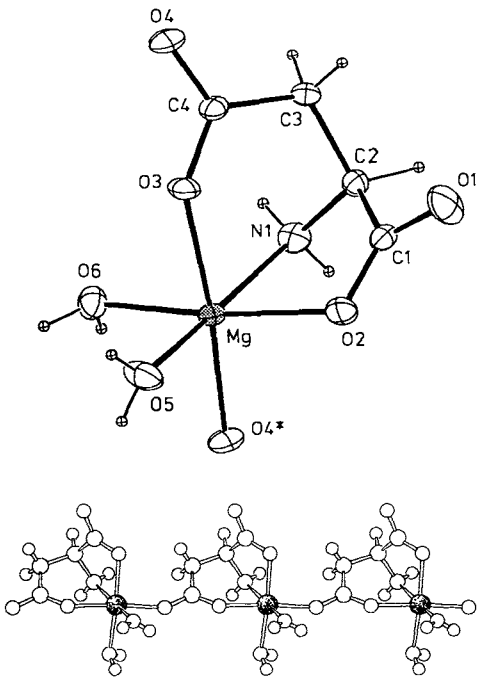

Fig. 4. Crystal structure of $Mg(L\text{-}Asp) \cdot 3H_2O$. Top: Individual complex unit. Bottom: Coordination polymer. (Interstitial water molecules are not shown.)

The crystal structure of $Mg(L\text{-}Asp) \cdot 3H_2O$ clearly shows the chelating ability of the aspartate dianion for $Mg^{2\oplus}$ ions and the preference of the latter for octahedral coordination. The compound dissolves only slowly in cold water. It is tempting to propose that, in this solvation process, individual complexes are released from the chains through substitution of the carbonyl oxygen donor by a water molecule. Further hydrolysis may remove one of the three donor func-

tions from the metal, converting the tripod into a bidentate ligand. Such a process would account for the alkaline reaction of the compound (pH = 9), since protonation of the liberated functional group leads to an increase in the $OH^{\ominus}$ concentration.

6.1.2. *Magnesium L-Glutamate Tetrahydrate*

From alkaline (KOH) solutions of magnesium glutamate, the species Mg(L-Glu) can be obtained as the dihydrate or the tetrahydrate, depending on the reaction conditions. The crystal structure of the tetrahydrate[51] has been determined, since, owing to its higher water content, it should resemble more closely the solution state of the complex. Crystalline Mg(L-Glu) · $4H_2O$ is built from individual complex units, in which the magnesium atom is N,O(α)-chelated by the L-$Glu^{2\ominus}$ dianion. The γ-carboxylate function is not engaged in metal coordination, and the remaining four vertices of the octahedron are occupied by water molecules (Fig. 5). Hence,

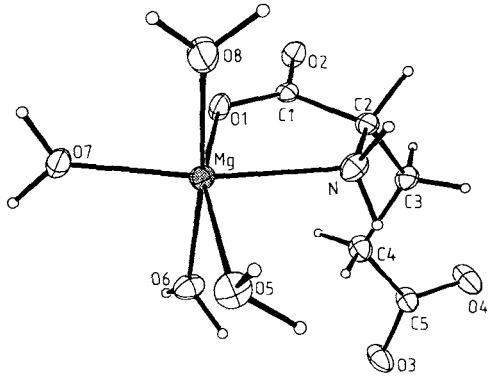

Fig. 5. Crystal structure of Mg(L-Glu) · $4H_2O$.

whereas all three possible ring systems, including a seven-membered heterocycle, are present in the tripod of the aspartate analogue, the largest (eight-membered) chelate ring is avoided in the glutamate complex. Instead, the "dangling" γ-carboxylate group is engaged in hydrogen bonding with water molecules of neighboring complexes.

6.1.3. *Magnesium Bis(Hydrogenaspartate) and Bis(Hydrogenglutamate) Hydrates*

Neutralization of MgO, $Mg(OH)_2$, or $MgCO_3$ with aspartic acid or glutamic acid yields the bis(hydrogenaspartates) or bis(hydrogenglutamates) in quantitative yield.[52] The products generated from the pure L or D forms of aspartic or glutamic acid have to date only been obtained in microcrystalline form, and their structures are unknown. By contrast, racemic aspartic acid yields the complex Mg(D,L-$AspH)_2$ · $4H_2O$, which can be readily crystallized from aqueous methanol. This product is also formed in the racemization of Mg(L-$AspH)_2$ in basic medium at elevated temperature.

In the crystal lattice the compound again shows octahedral coordination around magnesium, with four water molecules occupying equatorial positions and β-carboxylate oxygen atoms of the two anions in the (*trans*) axial positions (Fig. 6). The two amino acids are optical antipodes and structurally related by a center of symmetry (at Mg). The structure of the tetrahydrate is a caveat in that it shows that the aspartate monoanions, unlike the dianions, do not necessarily act as bidentate ligands towards magnesium, their interactions with the metal being reduced in this case to a single, monodentate contact. In the dihydrate, the aspartate will have to coordinate in a multidentate fashion, of course, owing to the reduced number of hydrate water molecules available. In dilute aqueous solution, however, the aspartate anions may even fully dissociate from the magnesium center, as indicated by the dissociation equilibria.

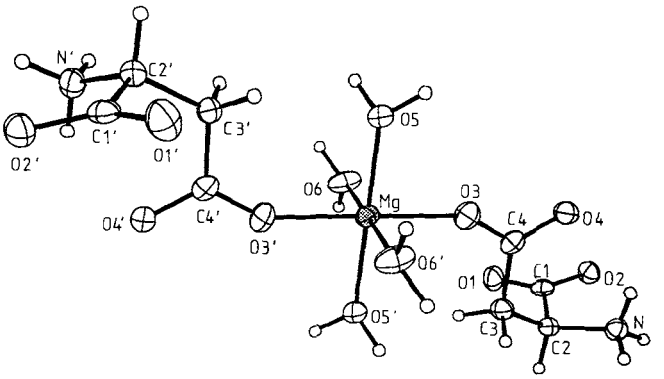

Fig. 6. Crystal structure of Mg(L, D-$AspH)_2$ · $4H_2O$.

Clearly, the delicate balance between enthalpy and entropy terms related to metal coordination/solvation and aspartate protonation (in hydrogen bonds), already advanced in the discussion of the colligative properties of the solutions, also shows up in the structural features of the crystalline compounds.

6.1.4. *Magnesium L-Hydrogenaspartate Chloride Trihydrate*

A compound of the stoichiometry Mg(L-AspH)Cl · $3H_2O$ is produced by spray-drying of aqueous solutions containing the components $Mg^{2\oplus}$, $AspH^{\ominus}$, $Cl^{\ominus}$ in the molar ratio 1:1:1. This preparation must be carried out under carefully controlled conditions in order to avoid racemization of the amino acid, condensation with formation of diketopiperazines, and other side reactions leading to contamination of the product. Mg(L-AspH)Cl is an established drug for magnesium therapy. The spray-dried trihydrate material is X-ray amorphous. In very tedious experiments it has recently been possible to crystallize the compound and to determine its structure.[53]

Mg(L-AspH)Cl · $3H_2O$ has a layer structure, where the chloride anions and one of the three water molecules are found between sheets of the composition $[Mg(L\text{-}AspH)(H_2O)_2^{\oplus}]_n$. The layers represent cationic coordination polymers with the magnesium atoms in an octahedral environment. The hydrogen aspartate anions function as O(α),O(β)-chelating ligands through their α- and β-carboxylate groups; the amino group is protonated and has no metal contact

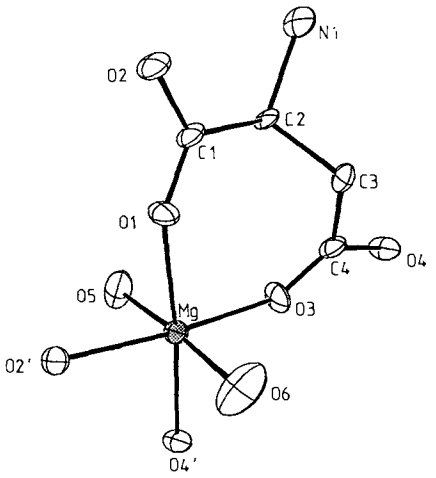

Fig. 7. Crystal structure of Mg(L-AspH)Cl · $3H_2O$; one of two crystallographically independent, but similar moieties.

(Fig. 7). Two hydrate water molecules and two carbonyl oxygen atoms of neighboring complex units occupy the remaining coordination sites of the octahedron. A network of hydrogen bonds connects the layers and the interstitial water molecules. The chlorides form distinct hydrogen bonds to the ammonium groups. Two adjacent layers are crystallographically nonequivalent, but the structural differences are almost negligible. Figure 8 shows a projection of one of these layers and the corresponding chloride ions and hydrate water molecules.

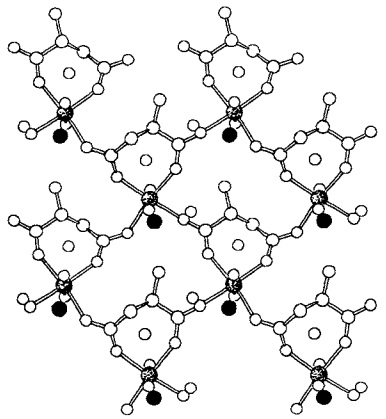

Fig. 8. Layer structure of Mg(L-AspH)Cl · $3H_2O$. Filled circles, Cl; small empty circles, interstitial water; dotted circles, Mg.

Mg(L-AspH)Cl · $3H_2O$ is thus a discrete phase and not a mixture of two or more components. Its special structure shows yet another mode of coordination between magnesium and aspartate ions as far as the individual complex units are concerned (cf. Fig. 7). In addition, the bulk structure suggests novel features in the degradation (hydration, hydrolysis) and resorption (ion complexation and transport) of the compound. Layer structures of this kind are likely to exhibit ion-exchange properties until the (slow) degradation of the sheets leads to a breakdown of the framework. Moreover, the degradation need not lead immediately to mononuclear complex units; instead, it can yield di- or polynuclear species with differing transport behavior. Probably, therefore, the distinct pharmacological properties of this compound are partly of structural origin. Ca(L-GluH)Cl · H_2O has a similar structure (see Section 6.2).

6.2. The Structures of Crystalline Calcium, Strontium, and Barium Analogues

Aspartates and glutamates of the heavier alkaline-earth metals were found to crystallize more readily than their magnesium analogues. Roughly the same number of structures with calcium has been determined, but most of the results were available earlier than for magnesium.

Like magnesium, calcium forms crystalline complexes of the types Ca(L-Asp), Ca(L-AspH)$_2$, and Ca(L-AspH)Cl. Depending on the reaction conditions, Ca(L-Asp) is obtained in the form of two hydrates. A tetrahydrate is generated on neutralization of $Ca(OH)_2$ with L-$AspH_2$. On the other hand, $CaCO_3$ and $AspH_2$ first yield the hydrogen aspartate Ca(L-AspH)$_2$, which can be converted into Ca(L-AspH)Cl in a redistribution reaction with $CaCl_2$. In strong alkali (KOH), the latter finally affords a precipitate of the dihydrate of Ca(L-Asp). Calcium L-glutamate, Ca(L-Glu), obtained like Ca(L-Asp) · $4H_2O$, was found to crystallize as the trihydrate.

Aspartate and glutamate structures have also been determined for strontium and barium. Sr(L-Glu/L-Asp) and Ba(L-Glu/L-Asp) are available from the metal dihydroxides and glutamic/aspartic acid and are crystallized as tetra- and hexahydrates, respectively.

6.2.1. Calcium L-Aspartate Tetrahydrate and Dihydrate

In Ca(L-Asp) · $2H_2O$, the aspartate anion functions as an N,O(α),O(β) tripod ligand. The individual complex units (Fig. 9) are arranged in double strands with a peculiar pattern of metal bridging by carbonyl oxygen atoms (Fig. 10).[54] The coordination number of the calcium atoms is eight: apart from the tripod ligand, two hydrate water molecules and three O(β) oxygen atoms of two neighboring complex units are part of the inner coordination sphere. The polymeric strands are cross-linked by hydrogen bonds.

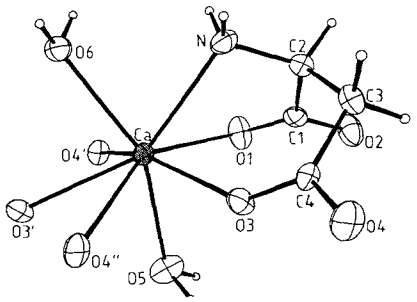

Fig. 9. Crystal structure of Ca(L-Asp) · $2H_2O$.

In Ca(L-Asp) · $4H_2O$, the aspartate anion is present only as an N,O(α) chelate ligand in the individual complex unit

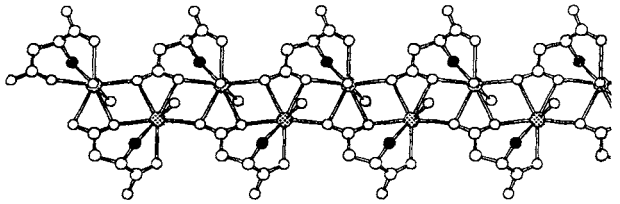

Fig. 10. Double-chain structure of Ca(L-Asp) · $2H_2O$. Dotted circles, Ca; filled circles, N.

(Fig. 11), but the β-carboxylate group is coordinated to a neighboring unit. Through these contacts, the complexes are again associated into chains, which, however, feature a single

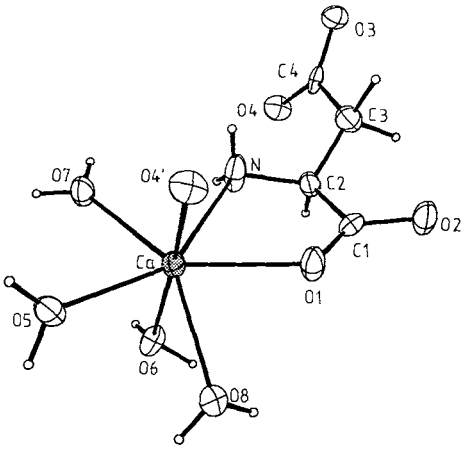

Fig. 11. Crystal structure of Ca(L-Asp) · $4H_2O$.

metal strand (Fig. 12). The coordination number of the calcium atoms is again eight, with all four hydrate water molecules attached to the metal. There are two crystallographically independent complex units in the crystal, but with only minor geometrical differences. Hydrogen-bonding connects the polymeric strands into a three-dimensional network.

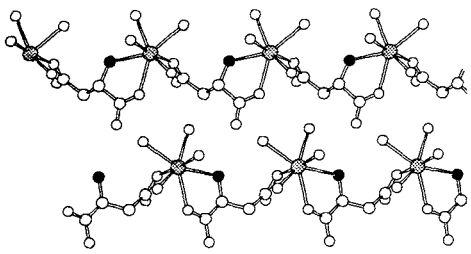

Fig. 12. Chain structure of Ca(L-Asp) · $4H_2O$.

6.2.2. *Calcium* L-*Glutamate Trihydrate*

The individual units of crystalline Ca(L-Glu) · $3H_2O$[55] closely resemble those in the aspartate dihydrate. The amino acid is N,O(α)-chelating, and the γ-carboxylate groups of two neighboring molecules, together with two hydrate water molecules, are part of the inner coordination sphere. Since both oxygen atoms of each of the γ-carboxylate groups have about the same Ca–O(γ) distance, the coordination number of the calcium atom is again eight. The bulk structure is a true three-dimensional coordination polymer, not only based on hydrogen bonding as in the chain and layer structure of the aspartate analogues.

6.2.3. *Strontium and Barium* L-*Aspartate Trihydrates and* L-*Glutamate Hexahydrates*

The strontium and barium aspartates, as well as the two glutamates, are isomorphous.[51, 56] Differences arise from the lengthening of the chain by one CH_2 group on going from aspartate to glutamate; surprisingly, this change is simply compensated for by inclusion of three more interstitial water molecules for the glutamates. Owing to the difference in the atomic radii of Sr and Ba, there are small deviations in the bond distances and angles, but the general features are the same. The metals are nine-coordinate (Fig. 13), with four

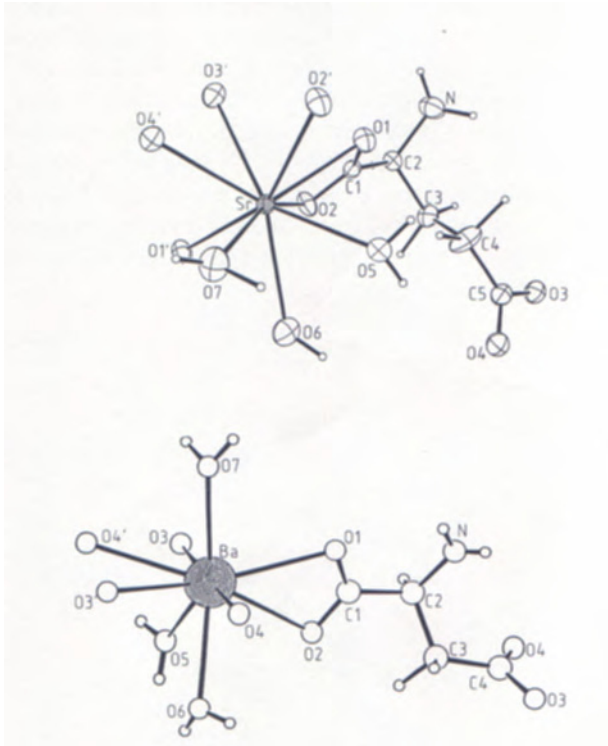

Fig. 13. Crystal structures of Sr(L-Glu) · $6H_2O$ (top) and Ba(L-Asp) · $6H_2O$ (bottom).

α-carboxylate and two β/γ-carboxylate oxygen atoms (of three different anions) and three water molecules as nearest neighbors. The metals are arranged in double strands and bridged via the O(α) atoms. These double strands are bridged by the O(β/γ) contacts to give the layer structures (Fig. 14). In the glutamate structure, the remaining three crystal water molecules are part of the hydrogen-bonding system connecting the layers.

High coordination numbers, as found for the aspartate and glutamate complexes of strontium and barium, are rare in the coordination chemistry of amino acids. Important parallels are found with the large cations from the lanthanoid series, however. A typical example is Ho(L-AspH)-Cl_2 · $6H_2O$. Here, the Ho atoms are eight-coordinate. In the

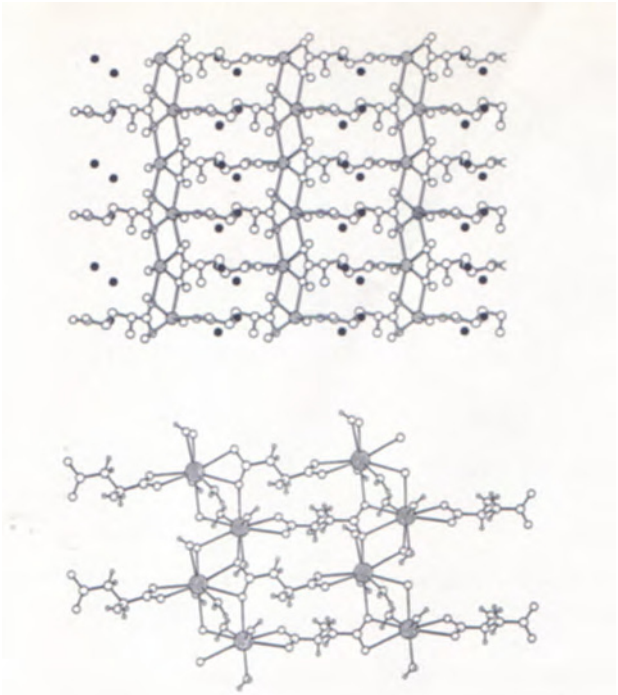

Fig. 14. Layer structures of Sr(L-Glu) · $6H_2O$ (top; filled circles, H_2O) and Ba(L-Asp) · $6H_2O$ (bottom); interstitial water molecules not shown.

binuclear praseodymium complex Pr_2(L-GluH)$_2(ClO_4)_4 \cdot 11H_2O$, the metal atoms are even nine-coordinate.[57, 58]

6.2.4. Calcium Bis(L-Hydrogenglutamate) Tetrahydrate and Calcium L-Hydrogenglutamate Chloride Monohydrate

The compounds Ca(L-GluH)Cl · H_2O and Ca(L-GluH)$_2$ · $4H_2O$ are readily obtained by following a procedure similar to that used for the magnesium hydrogen aspartate chloride and magnesium hydrogen aspartate complexes.

Ca(L-GluH)Cl · H_2O again features a layer structure. The chloride ions are eclipsed between sheetlike cationic coordination polymers of the composition $[Ca(L\text{-}GluH)^{\oplus}(H_2O)]_n$. In the complex unit the calcium atoms are hexacoordinate with five oxygen atoms from five different $(L\text{-}GluH)^{\ominus}$ anions and the water molecule directly attached to the metal. There are thus no chelating interactions. The amino group is protonated and hydrogen-bonded to the chloride counterion.

Ca(L-GluH)$_2$ · $4H_2O$ has a structure with a three-dimensional coordination network consisting of alternating layers of $GluH^{\ominus}$ anions and $Ca^{2\oplus}$ cations. The calcium atoms are hexacoordinate with four equatorial contacts to carboxylate oxygen atoms of four different anions [$2 \times O(\alpha)$, $2 \times O(\gamma)$] and two axial water molecules. The amino groups are protonated and, together with the remaining two interstitial water molecules, are engaged in hydrogen-bonding.

6.3. Beryllium, the Missing Link

Very surprisingly, there is very little information on the structural chemistry of beryllium complexes of amino acids. No beryllium aspartates or glutamates have been isolated in the crystalline state, and information on the nature of their aqueous solutions is very limited.[61–63] The known structural chemistry of beryllium complexes indicates that $Be^{2\oplus}$ ions will probably strictly adhere to coordination number four in amino acid complexes. On this basis alone, the coordination chemistry of beryllium with aspartate and glutamate anions will be entirely different from that of its heavier alkaline-earth congeners. It is also tempting to suggest that beryllium toxicity is directly associated with this change in coordination chemistry towards amino acids, peptides, and proteins, as well as polysaccharides and related natural polyfunctional ligands. Work in this direction is in progress. Parallels in the coordination chemistry of lithium, which also has a very small ionic radius, should be noted.

6.4. Structural Relations with Complexes of the First-Row Transition Metals

Divalent first-row transition elements form aspartate and glutamate complexes with a stoichiometry similar to that of the alkaline-earth metals. In the intermediate pH range (5–9), the composition M(L-Asp/L-Glu) prevails. Structurally, the aspartate compounds are found to be isomorphous for M = Mn, Fe, Co, Ni, and Zn.[64–66] The complex units contain the $(L\text{-}Asp)^{2\ominus}$ dianion as an N,O(α),O(β) tripod to the hexacoordinated metals. These units are arranged in chains with a connectivity pattern not unlike that found for Mg(L-Asp) · $3H_2O$ (cf. Fig. 3), except for a difference in the positioning of the carbonyl oxygen atom originating from a neighboring molecule. In the magnesium complex, this occurs *trans* to O, whereas it is *trans* to N in transition-metal complexes (Fig. 15).

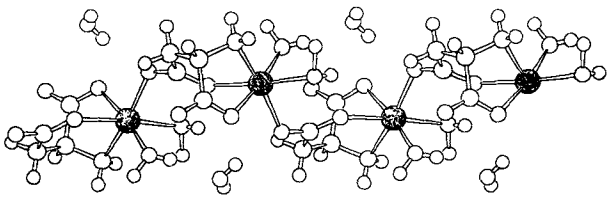

Fig. 15. Chain structure of Mn(L-Asp) · $3H_2O$.

Hydrogen aspartate and glutamate complexes of first-row transition metals are less well represented. The product obtained from ZnO and L-glutamic acid was shown not to be the expected Zn(L-GluH)$_2$, but to contain zinc associated with two L-pyroglutamate anions.[67] In Zn(L-pGlu)$_2$ ·

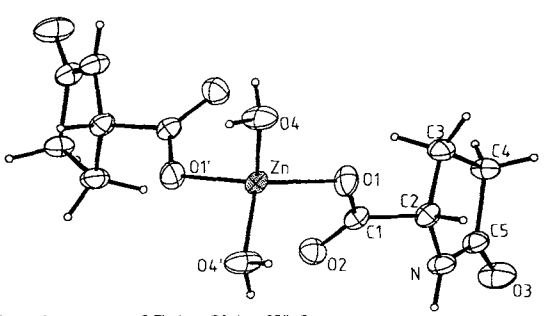

Fig. 16. Crystal structure of Zn(L-pGlu)$_2$ · $2H_2O$.

$2H_2O$, zinc has coordination number four and the two L-pGlu units are related by a twofold axis (Fig. 16).

Zinc bis(L-hydrogenaspartate) and zinc dichloride form a crystalline ternary phase, Zn(L-AspH)Cl, which contains no hydrate water.[68] The structure of the compound features a three-dimensional network in which the zinc atoms are again tetracoordinate. Three oxygen atoms (of three different hydrogen aspartate anions) and the chloride anion are ligands to the metal (Fig. 17). This situation is unique in comparison to the structures of the corresponding compounds of Mg or

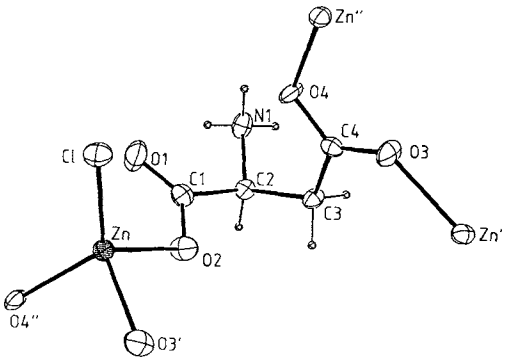

Fig. 17. Environment of the zinc and aspartate units in the three-dimensional network of Zn(L-AspH)Cl.

Ca, where coordination numbers are six or seven and the chloride counterions are not part of the inner coordination sphere of the metals. Though higher coordination numbers are known, the obvious preference of zinc for low coordination and for halide contacts is noteworthy and probably reflects the completely different biochemical activity of the metal.

6.5. Alkali Aspartate and Glutamate Complexes

A few representative aspartate and glutamate complexes of lithium, sodium, and potassium have been structurally characterized by X-ray diffraction studies. A comparison of the results shows variations similar to those encountered with the alkaline-earth analogues. With the small lithium cation, the coordination number is restricted to four, whereas sodium and potassium allow higher coordination numbers, but are obviously less selective.

6.5.1. *Lithium L-Hydrogenaspartate Monohydrate*

Neutralization of LiOH or Li_2CO_3 with L-$AspH_2$ yields a crystalline monohydrate, which has a layer structure.[69] The four-coordinate lithium centers are arranged in double strands with carboxylate oxygen atoms as bridging units (Fig. 18). The amino group is protonated and not coordinated to lithium. Together with the interstitial water molecule, it is responsible for extensive hydrogen bonding between the layers.

The compounds Li_2(L-Asp) · $2H_2O$, Li(L-GluH), and Li_2(L-Glu) have also been prepared, but their structures are unknown.

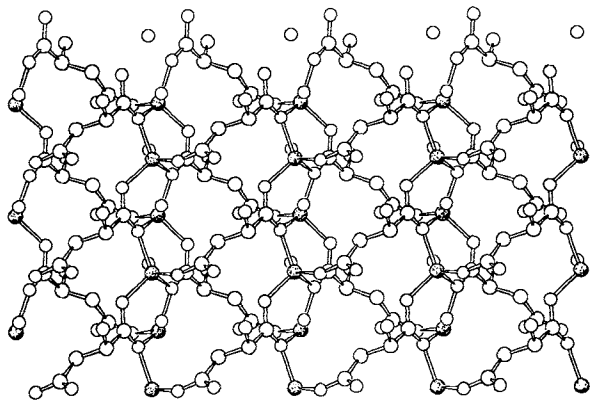

Fig. 18. Three-dimensional network of Li(L-AspH) · H_2O.

6.5.2. *Sodium and Potassium L-Hydrogenaspartates and -glutamates*

For crystalline sodium aspartates and glutamates only limited and preliminary information is available. Sodium L-hydrogenglutamate is reported to crystallize as a monohydrate, Na(L-GluH) · H_2O, in which sodium is hexacoordinate. Carboxylate oxygen atoms bridge adjacent metal atoms.[70]

Potassium L-hydrogenaspartate,[69] obtained as the dihydrate K(L-AspH) · $2H_2O$ upon neutralization of KOH with L-$AspH_2$, has a chain structure reminiscent of the structures of Sr/Ba(L-Glu) · $6H_2O$. The metal atoms are arranged in double strands, bridged by carboxylate oxygen atoms. As a special feature, the potassium compound also shows metal-bridging water molecules. The coordination number of the potassium atoms is only seven, since the α-carboxylate and the amino groups are not coordinated to the metal (Fig. 19).

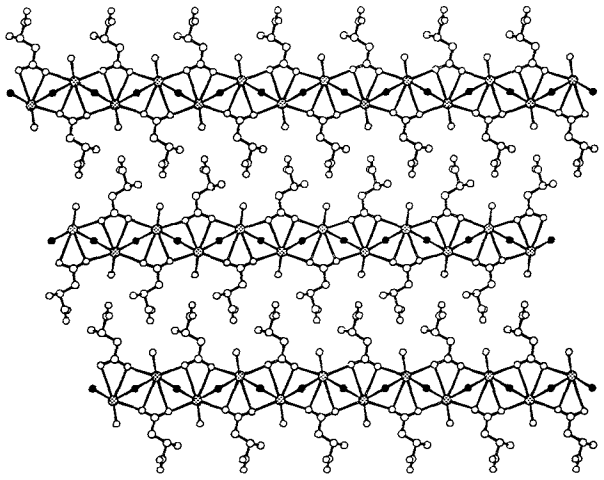

Fig. 19. Double-chain structure of K(L-Asp) · $2H_2O$; shaded circles, K; filled circles, H_2O.

Potassium L-hydrogenglutamate,[71] obtained similarly as a monohydrate, K(L-GluH) · H_2O, has a layer structure in which the potassium atoms are arranged in parallel strands and interconnected by the hydrogenglutamate anions (Fig. 20). The potassium atoms are hexacoordinate with the

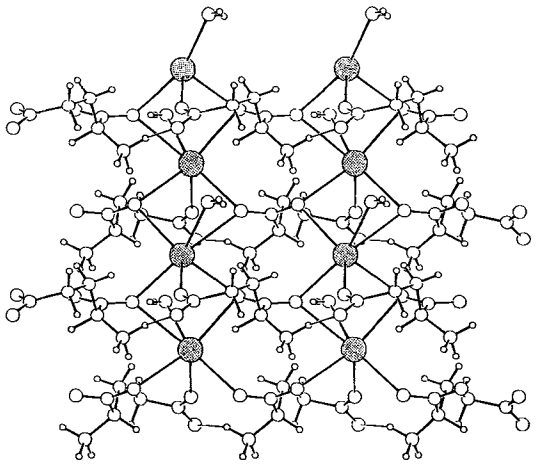

Fig. 20. Layer structure of K(L-GluH) · H_2O.

coordination polyhedron in the form of a distorted trigonal prism. The L-$GluH^{\ominus}$ anion is O(α),O(γ)-chelating, giving rise to an eight-membered ring, with carboxylate atoms also in a metal-bridging position. The amino group of the ligand is protonated and hydrogen-bonded, but not metal-coordinated.

No stoichiometric or structural data are available on related rubidium or cesium compounds.

7. "Complexation" of Magnesium and Other Cations by Related Counterions

Among formulations used for magnesium therapy, the orotates also have a special position.[72] For these compounds, in particular, it had remained an open question whether the (hydrogen)orotate anions would really form complexes with magnesium or just function as counterions for the hexaaquamagnesium cation.

The magnesium salt $Mg(OrH)_2$ of 6-uracilic acid (orotic acid, OrH_2) can be crystallized in the form of several hydrates. Of these, the octahydrate, with the highest number of water molecules, was chosen for structural studies, since its structural situation would perhaps most closely resemble the solution structure.[73] The *octa*hydrate was also found to crystallize from solutions obtained from samples with a smaller number of hydrate water molecules in the stoichiometric unit.

7.1. Magnesium Bis(Hydrogenorotate) Octahydrate

$Mg(OrH)_2 \cdot 8H_2O$[73] is generated by neutralization of MgO, $Mg(OH)_2$, or $MgCO_3$ with orotic acid or by metathesis of magnesium salts and alkali orotates, followed by crystallization. Single-crystal X-ray diffraction studies showed the compound to consist of hexaaquamagnesium dications and two hydrogenorotate anions, which are associated through hydrogen-bonding (Fig. 21). Crystallographically, the two anions are related by a center of symmetry (at Mg). This rules out the classification of magnesium orotates as "complexes", since it is extremely unlikely that, upon dissolution in water, the orotate anions would enter the magnesium coordination sphere by substitution of water molecules. For a rationalization of the therapeutic effects of the magnesium orotate drugs, an auxiliary or independent anion-based mechanism must be considered.

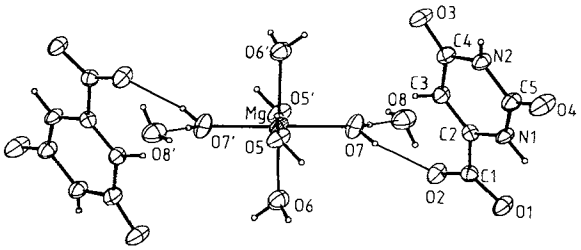

Fig. 21. Stoichiometric unit $Mg(OrH)_2 \cdot 8H_2O$.

The structures of ammonium hydrogenorotate monohydrate,[74] nickel(II) orotate tetrahydrate,[75] and *cis*-diaminoplatinum(II) orotate[76] were determined earlier. With the transition metals nickel and platinum, true complexes are formed, whereas the ammonium salt is a hydrogen-bonded network.

Lithium hydrogenorotate was recently found to crystallize as the monohydrate, which has a very simple layer structure (space group $P\bar{1}$). The lithium atoms are tetracoordinated to three orotate oxygen atoms and one water oxygen atom (Fig. 22).

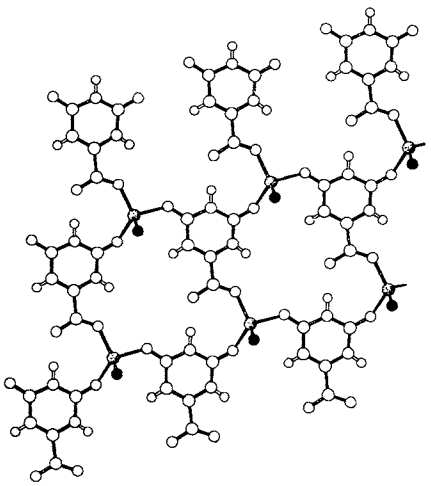

Fig. 22. Layer structure of lithium hydrogen orotate monohydrate.

Electrochemical studies have also shown that alkaline-earth orotates are "weak" complexes with β values decreasing in the series Mg (2.41), Ca (2.34), Sr (1.91), and Ba (1.62) under standard conditions.[77]

7.2. Magnesium Citrate and L-Pyroglutamate Compounds

Apart from the aspartate/glutamate and orotate complexes described above, magnesium citrate and L-pyroglutamate hydrates (pidolates) have been employed in magnesium ther-

apy. Some years ago X-ray diffraction studies on the citrate complex (as a decahydrate) showed the magnesium atoms to be only partially present as part of a true citrate complex: one of the three magnesium ions is found as part of a hexaaquo complex (Fig. 23).[78a]

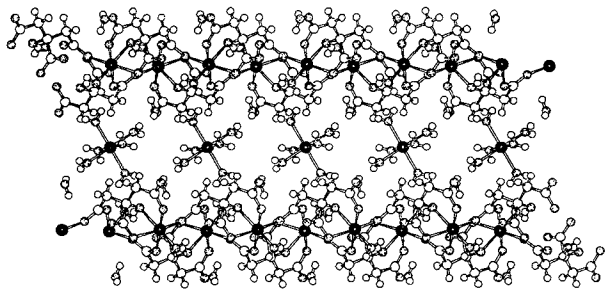

Fig. 23. Stoichiometric unit of $[Mg(H_2O)_6][MgC_6H_5O_7(H_2O)]_2 \cdot 2H_2O$.

The whole structure can be described as a coordination polymer network composed of triple strands of metal complexes and hydrates. The citrate anion acts as a multidentate ligand with tripod and bridging functions. The constitution can be best accounted for by the formula $[Mg(H_2O)_6]^{2\oplus}$ $2[MgC_6H_5O_7(H_2O)]^{\ominus} \cdot 2H_2O$.

Magnesium bis(L-pyroglutamate) hydrates, also known as magnesium pidolates, can be obtained either by dehydration of magnesium bis(L-hydrogenglutamate) or by metathesis reactions with L-pyroglutamates. These methods have recently turned out to be very efficient processes.[78b]

The structures of the magnesium derivatives are still unknown, but a zinc[67] (Fig. 16) and a sodium[78c] complex have been characterized, as already mentioned above. They show totally different coordinative features.

8. Scope and Problems of "Magnesium Therapy"

The therapeutic advantages of parenteral administration of magnesium for compensation of a deficiency or as a $Ca^{2\oplus}$ antagonist are unquestionable for treatment of disorders such as eclampsia, preeclampsia, or premature labor. In several placebo-controlled studies, positive effects in the treatment of acute myocardial infarction (reduction in mortality and in frequency of arrhythmias) and digitalis intoxication have been demonstrated.[21, 79] Other indications, such as ethanol withdrawal symptoms, extracellular calcification, angina pectoris, and asthma, need further study.

Oral administration would of course be the preferred form of medication, especially for lighter, nonacute forms of magnesium deficiency. Since these are difficult to monitor by standard laboratory techniques—cellular deficiency may not necessarily be associated with hypomagnesemia—and often are accompanied by secondary shifts of Na, K, and/or Ca levels, leading to complex clinical symptoms, the success of an oral therapy has to be cross-checked very thoroughly against placebos. Particular attention should again be given to the fact that different magnesium compounds may lead to entirely different results.

The following indications appear to be amenable to magnesium therapy at least for oral application of higher doses, predominantly of Mg(L-AspH)Cl preparations:

- Hypomagnesemia (< 0.76 mmol L^{-1} serum), caused by Mg-deficient diet, disturbances of enteral absorption, high (mainly renal) loss, or increased demand for magnesium and accompanied by corresponding symptoms
- Constipation, in particular with spastic symptoms.[80]
- Tetanic syndrome, with or without hypomagnesemia[21, 81]
- Premature labor and nocturnal calf cramps during pregnancy[82, 83]
- Diuretic-induced disorder associated with treatment of arterial hypertension[84–86]
- Stress-induced hypertension[87]
- Cardiac arrhythmias[88, 89]

Positive effects on other indications need further confirmation, and pertinent studies are in progress.[90–92]

G. B. Weiss has summarized the present knowledge (1986) as follows: "Thus, the possible therapeutic applications of an orally effective magnesium salt like magnesium (hydrogen)-aspartate chloride include established indications in frank hypomagnesemic states. In addition, Mg(AspH)Cl has a potentially broad range of therapeutic activity as an orally effective $Ca^{2\oplus}$-like membrane stabilizer and a physiological cellular $Ca^{2\oplus}$ antagonist."[93]

Because of this medical interest, basic research in the area of alkaline-earth and alkali aspartate and glutamate chemistry has been given renewed attention in recent years, with a focus mainly on magnesium complexes. It is to be expected, however, that similar therapeutic perspectives will emerge for the corresponding calcium compounds, for example, since availability, distribution, and biological effects depend so strongly on the nature of the individual chemical and its galenic formulation. In addition, there is the advantage that no "artificial" auxiliary carrier ligand needs to be introduced with a completely unknown spectrum of side effects.

The research reported in this article has been supported by the Deutsche Forschungsgemeinschaft (Leibniz-Programm), the Fonds der Chemie und Biologischen Chemie, and the Alexander von Humboldt-Stiftung (D.L.W.). Synthetic and analytical studies have been carried out mainly by Dr. Ina Bach, Dipl.-Chem. Patrizia Mikulcik, and Dr. Annette Schier (TU München), as well as by Dr. G. Manninger and G. Hopf (Verla-Pharm). The structural studies were performed, in the X-ray laboratory of TU München, by Prof. Dr. G. Müller, Dr. D. L. Wilkinson, J. Riede, Dipl.-Chem. P. Mikulcik, and, last but not least, Dipl.-Chem. O. Kumberger, who also has been particularly helpful in providing the drawings of the structures. Their cooperation is gratefully acknowledged.

Complexes with Substituent-free Acyclic and Cyclic Phosphorus, Arsenic, Antimony, and Bismuth Ligands

By Otto J. Scherer*

Dedicated to Professor Max Schmidt on the occasion of his 65th birthday

Until recently, phosphorus, arsenic, antimony and bismuth ligands were nearly always understood to be molecules such as R_3E, $R_2E(CH_2)_nER_2$, and $RC[(CH_2)_nER_2]_3$(E = P, As, Sb, Bi) in which the lone pair of the atom E functions as a 2e donor. Current research interests, however, increasingly involve substituent-free E_n ligands (n = 1–6), the various types of which are mainly accessible via EX_3 (X = F,Cl,Br,Ph), $E(SiMe_3)_3$, $(RAs)_n$, P_4S_3, As_4S_4, gray arsenic, and especially P_4 and As_4; these ligands can be stabilized in the coordination spheres of certain transition metal fragments. P_1, As_1 and Sb_1 units with multiple M–E bonds are found in bi- and trinuclear complexes; E_1 units can also be encapsulated (partially or completely) in cavities of a variety of metal cluster frameworks. Metallatetrahedranes with up to three E atoms are especially common. Besides E_1 units, the greatest variety of coordination modes is exhibited by E_4 ligands, which are found as intact tetrahedra and also as parts of chains, polycycles, cubes and a trigonal prism. The phosphorus and arsenic species *cyclo*-E_n, isoelectronic to the carbocyclic $(CH)_n$ species, are suitable ligands for forming sandwich complexes (n = 3, 4, 5) and triple-decker sandwich complexes (n = 3, 5, 6). In addition to the wide variety of chemical reactions, remarkable parallels are found in organic chemistry as well as in solid-state chemistry for many of these substance classes. Some of the molecules have received lively interest from theoretical chemists.

1. Introduction

In a fascinating review article "Homonuclear Bonds Involving Main Group Elements" published in 1981,[1] *H. G. von Schnering* pointed out that insights into general chemical principles can be hindered by too narrow a view of demarcated research interests. Links between the various chemical disciplines of inorganic (solid state, main group, transition metal chemistry), organic, and theoretical chemistry have been forged as a result of two breakthroughs: first, the successful isolation in the 1980s of an unexpectedly wide variety of molecules with (p–p)π multiple bonds (both between elements of the first octet of main group elements and heavier elements, and among the heavier elements alone), and secondly the concept of isolobal analogy (published by *R. Hoffmann* in 1982[2]) and its applications in organometallic chemistry.[3] Such unifying concepts have proved ever more powerful and have facilitated views of chemistry as an indivisible whole. A further useful heuristic principle is the diagonal relationship between carbon and phosphorus (C ↘ P); the expertise of *Baudler* and co-workers[4] was applied in the synthesis of polyphosphanes P_nH_{n+2} and $(PH)_n$, the analogues of alkanes C_nH_{2n+2} and cycloalkanes $(CH_2)_n$, and the structurally impressive polycyclic organophosphanes with P- and PR-units, which are in turn isoelectronic and isolobal to the fragments CH and CH_2 ($CH_3 \triangleq PH_2$).

Since the N_2 analogue P_2 ($P{\equiv}P \triangleq HC{\equiv}CH$) had been well-known and spectroscopically characterized and the first kinetically stabilized diphosphene derivative, *trans*-R–P=P–R (R = 2,4,6-tBu$_3$C$_6$H$_2$), had been isolated by *Yoshifuji* et al.,[5] and since *cyclo*-E_3 (E = P,As) had been stabilized in sandwich complexes by *Sacconi*'s group in Florence,[6] and *cyclo*-P_6 (hexaphosphabenzene) in similar fashion by *H. Sitzmann* in this Institute,[7] hope was nourished that other E_n units (E = P,As,Sb,Bi), in particular E_n rings isoelectronic to carbocyclic π systems $(CH)_n$, could be stabilized in the coordination spheres of transition metal fragments. This review article describes the properties of ligands composed of "naked" acyclic and cyclic E_n structural units (E = N homologues) and aims to give an impression of the momentum of research[8] in this novel and multidisciplinary area.

2. E_1 Ligands

2.1. Terminal Coordination (η^1-E)

Phosphaalkynes R–C≡P have been isolated and thoroughly studied.[9] In contrast, there is only indirect evidence and speculation to support the existence of molecules with a metal–phosphorus (or arsenic) triple bond (coordination type **I**).

$L_nM{\equiv}E$ **I** (E = P, As)

The trimetallaphosphatetrahedrane $[W_3(\mu_3\text{-P})(\mu\text{-OR})_3(OR)_6]$ (**10c**), R = CH_2tBu, may be formed from $W_2(OR)_6$ and $(RO)_3W{\equiv}P$.[10a] The co-photolysis of the Mo_3As tetrahedrane $[As\{Mo(CO)_2Cp\}_3]$ (**10d**) and $[CpM(CO)_2]$, M = Co,[10b] Rh[10c] (cf. Section 2.2.2.3) allows the identification of, inter alia, the products $[Cp(CO)_2Mo{\equiv}Mo(CO)_2Cp]$ and

[*] Prof. Dr. O. J. Scherer
Fachbereich Chemie der Universität
Erwin-Schrödinger-Straße, D-6750 Kaiserslautern (FRG)

$[Cp_2(CO)_4Mo_2(\mu,\eta^2\text{-}As_2)]$ (**33g**). The formation of **33g** has been postulated to be the result of a fragmentation of **10d** into the two triple bond systems $LMo \equiv MoL$ ($L = Cp(CO)_2$) and $LMo \equiv As$ ($LMo \leftrightarrow CH,P,As$), isolobal to acetylene. $LMo \equiv As$ could then give the isolated Mo_2As_2 tetrahedrane **33g** by dimerization.[10b,c]

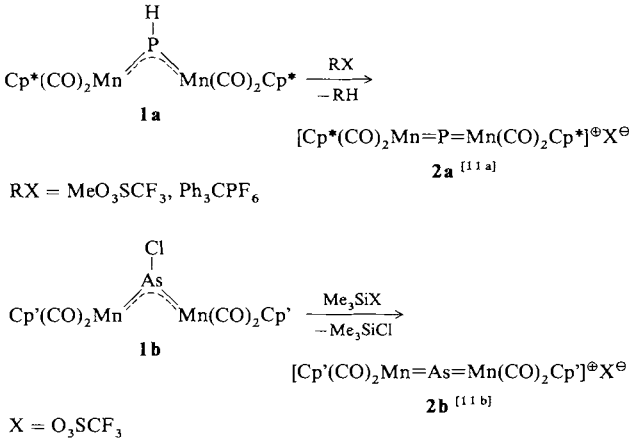
2.2. Bridging Coordination

2.2.1. *Doubly Bridging (μ-E, Allene-like)* [*]

The unusual linear two-coordination of type **II** was recently reported for the first time by *Huttner* et al.[11]

$[L_nM{=}E{=}ML_n]^{\oplus}$ **II** (E=P, As)

The extremely hydrolysis-sensitive dimetallaphospha- and -arsacumulenes **2a**[11a] and **2b**[11b] are obtained from the phosphinidene or arsinidene complexes **1a** and **1b** by removal of hydride or chloride.

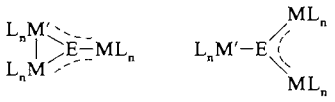


Substances **2** are typified by a shift of the π–π* transition of starting material **1** to lower wavelength (**1a** → **2a**: 522 → 411 nm,[11a] **1b** → **2b**: 512 → 380 nm[11b]). Parallel to this, one observes a drastic high-field shift in the ^{31}P-NMR spectrum (**1a** → **2a**: $\delta = 816 \rightarrow \delta = 172$[11a]). Both observations point to a strengthening of the Mn–E π-bond on going from **1** to **2**. The X-ray structure analysis of the Cp* derivative of **2b**[11b] confirms both the stronger bond ($\bar{d}$(Mn–As) for **1b**(Cp′) → **2b**(Cp*) = 2.223 → 2.147 Å) and the linear geometry (Mn–As–Mn = 176.3(1)°), and thus, also the formulation of the cation as an allene analogue, the $Cp^*(CO)_2Mn$ moieties of which are rotated by 88.5° from each other with respect to the Mn–As–Mn axis.

2.2.2. *Triply Bridging (μ_3-E)*

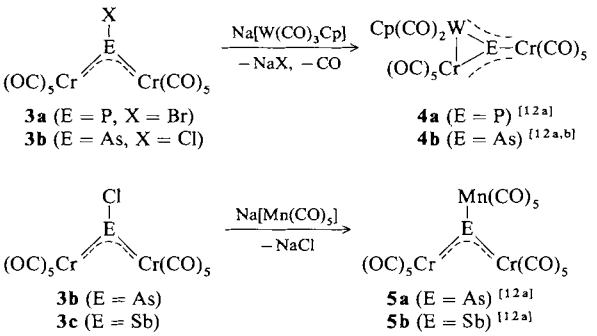
2.2.2.1. *Trigonal Planar EM_3 Framework*

The trigonal planar geometry at an E_1 atom (E = P,As,Sb) has been found in complexes of coordination type **III** and **IV**.



III (E = P, As) **IV** (E = As, Sb)

Characteristic for this bonding mode is an sp^2-hybridized E atom and ML_n moieties capable of π bonding. Ideal starting compounds, which satisfy these conditions, are the halogen-containing phosphinidene, arsinidene, and stibinidene complexes **3a–c**, which give complexes of classes **4** and **5** by substitution of the halogen on reaction with an organometallic nucleophile.[12]

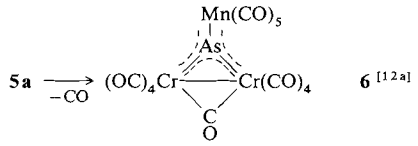


The five valence electrons of the E atom (E = P,As,Sb) in the cyclic trinuclear clusters **4a, b** are involved in bonding

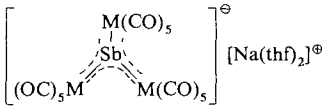
[*] Abbreviations: Cp = η^5-C_5H_5, Cp* = η^5-C_5Me_5, Cp′ = η^5-C_5H_4Me, Cp″ = η^5-C_5HiPr_4 Cp‴ = η^5-1,3-$tBu_2C_5H_3$, Cp^x = η^5-C_5Me_4Et, triphos = $MeC(CH_2PPh_2)_3$, np_3 = $N(CH_2CH_2PPh_2)_3$, py = pyridine; VE = valence electrons, SEP = skeletal electron pairs.

Otto J. Scherer, born 1933 in Amberg (Bavaria), studied chemistry from 1955 through 1959 at the Technische Hochschule Aachen and at the Universität München, where he gained his doctorate in 1962 under the supervision of Max Schmidt. He then went as scientific assistant with his supervisor to Marburg and to Würzburg. After his habilitation in 1967 at the Universität Würzburg there followed an appointment as dozent (1968) and the offer of a chair at the newly founded Universität Kaiserslautern. His research activities center on the study of the ligand properties of lower coordinated phosphazenes and the coordinative stabilization of "naked" phosphorus and arsenic ligands.

with two 16e fragments and one 15e fragment. To satisfy the 18e rule, a W–Cr bond is formed and CO eliminated. In the acyclic complexes **5**, the five electrons are distributed amongst two 16e fragments and one 17e fragment. Complexes **5** correspond to a classical methylarsinidene or -stibinidene complex[13] in which the CH_3 group is replaced by the isolobal $Mn(CO)_5$ fragment. The extreme low-field shift of the ^{31}P-NMR signal ($\delta = 945$[12a]), induced by the planar μ_3-coordination of the phosphorus by three metal atoms, is characteristic of **4a**. X-ray structure analysis confirms for **4a, b**[12a,b] and **5a**[12a] that the strongest E–M bonds (**4a, b**: d(E–W) $\approx d$(E–Cr_{exo}) < d(E–Cr_{endo}); **5a**: d(As–Cr) = 2.44/2.42 Å, d(As–Mn) = 2.52 Å) are those between E = P,As and the less electron-rich ML_n fragment. In solution, **5a** forms the cyclic trinuclear cluster **6** by decarbonylation, slowly at room temperature but rapidly at 80 °C.[12a]



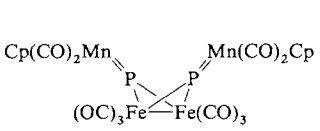
If **3c** is allowed to react with the decacarbonyldimetalates $Na_2[M_2(CO)_{10}]$ of the sixth subgroup (Group 6) in CH_2Cl_2, the extremely air-sensitive salts **7** are obtained on removal of the solvent and treatment with tetrahydrofuran.[12a]



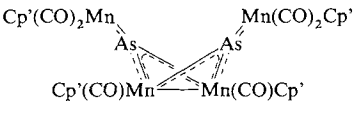
7 (M = Cr, Mo, W) [12a]

The structural parameters of the chromium compound, together with the intense color of the complexes **7**,[12a] show the existence of a Sb–M(d − p)π-multicenter interaction.

The same planar μ_3-E coordination with E–M π-bonding is observed in the E_2M_2 butterfly frameworks of complexes **8a**[14] and **8b**,[12a] obtained from $[Cp(CO)_2Mn(PBr_3)]$ and $Fe_2(CO)_9$ or photochemically from the Cp′ derivative of complex **42**,[27h] respectively (see Section 3.3).



8a [14]

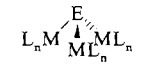


8b [12a]

A comparison of the X-ray structures of the isoelectronic molecules **8a** and **8b**, which contain different 14e ML_n-fragments along the hinge, shows that the π-bonding component in **8a** is clearly more strongly localized in the exocyclic double bond ($\bar{d}$(P–Mn) = 2.10, $\bar{d}$(P–Fe) = 2.18 Å). Like **4a**, **8a** also shows a ^{31}P-NMR signal shifted to extremely low field ($\delta = 977$).[14]

2.2.2.2. *Trigonal Pyramidal EM_3 Framework*

This geometrical variant of μ_3-E coordination can be subdivided into complexes with or without metal–metal bonding between the ML_n fragments. If each CH_3 group of the main group molecules $E(CH_3)_3$ (E = P,Sb,Bi) is formally replaced by an isolobal 17e ML_n fragment, then the substance class **9** is obtained.



9 (E = P, Sb, Bi)

9	E	ML_n (17e)	Ref.
a	P	$Mo(CO)_3Cp$	[15a]
b	Sb	$Mo(CO)_3Cp$	[15b]
c[*]	Sb	$Fe(CO)_2Cp$	[15b, c]
d[*]	Bi	$Mo(CO)_3Cp(')$	[15d]
e	Bi	$Mn(CO)_5$	[15e]
f	Bi	$Fe(CO)_2(PPh_3)(NO)$	[15f]
g[*]	Bi	$Fe(CO)_2Cp(')$	[15g]
h[*]	Bi	$Co(CO)_4$	[15f, h]

[*] X-ray structure analysis

The preferred synthesis of **9**[15] involves the reaction of EX_3 (X = F, most commonly Cl, or Br) with the corresponding carbonylmetalates Na(K) $[ML_n]$. In isolated cases,[15f,h] the binuclear complexes $L_nM–ML_n$ (e.g. $Co_2(CO)_8$) can be used as the source of the 17e ML_n fragment. The remaining lone pair on *E* in **9** can react with S_8, $BF_3 \cdot OEt_2$[15a] and $M(CO)_5$(thf) (M = Cr,W[15c]). Photochemical[15g] or thermal CO elimination[16h] can convert the "open" Bi clusters **9g** and **9h** into the closed clusters **10**, involving tetrahedrane geometry and 15e ML_n fragments.

$$[Bi\{Fe(CO)_2Cp^{(')}\}_3] \xrightarrow[-3\,CO]{h\nu} [Bi\{Fe(\mu\text{-}CO)Cp^{(')}\}_3]$$

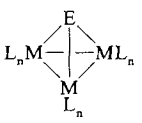
9g → **10g** [15g]

$$[Bi\{Co(CO)_4\}_3] \xrightarrow[-3\,CO]{\Delta} [Bi\{Co(\mu\text{-}CO)(CO)_2\}_3]$$

9h → **10h** [16h]

2.2.2.3. *Tetrahedranes with EM_3 Core*

All clusters of coordination type **10** possess 50 VE (valence electrons) and can be formally derived either from the tetrahedral 60 VE molecule $[Ir(CO)_3]_4$ or from the $P_4(E_4)$ tetrahedron (20 VE) by exchange of the isolobal units $P(E) \leftrightarrow Ir(CO)_3$ (in general a 15e ML_n fragment).

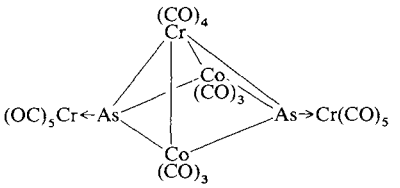


10 (E = P, As, Sb, Bi)

10	E	ML_n(15e)	Ref.
a	P	$Ir(PF_3)_3$	[16a]
b	P	$Co(CO)_3$	[16b]
c[*]	P	$W(OCH_2tBu)_3$	[10a]
d	As	$Co(CO)_3$	[16c]
e[*]	As	$Mo(CO)_2Cp$	[16d]
f[*]	Bi	$Ir(CO)_3$	[16g]
h[*]	Bi	$Fe(CO)Cp(')$	[15g]
g[*]	Bi	$Co(CO)_3$	[16h, i]

[*] X-ray structure analysis

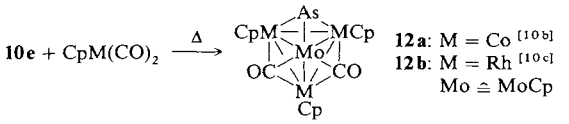
The preparation of clusters **10** (for **10g** and **10h** see substance class **9**) involves the use of PF_3,[16a] P_4, or EX_3 (X = Cl,Br,I; E = P,[10a,16b] As,[16c] Bi[16g]) or grey arsenic[16d] as the source of the element E. The 15e ML_n fragments are obtained from $IrCl_3$,[16a] $[Ir(CO)_4]^{\ominus}$,[16g] $Co_2(CO)_8$ or $[Co(CO)_4]^{\ominus}$,[16b,c] $[Cp(CO)_3Mo]_2$[16d] or $[W_2(OCH_2tBu)_6(HNMe_2)_2]$.[10a] With antimony, only anionic complexes of type **10** are known, such as $[(OC)_4Fe \leftarrow Sb\{Fe(CO)_3\}_3(\mu\text{-}H)]^{2\ominus}$ (**10i**),[16e] in which the Sb lone pair is additionally coordinated to an $Fe(CO)_4$ fragment. Starting materials for this synthesis are $[Sb\{Fe(CO)_4\}_4]^{3\ominus}$ (**16a**) and CF_3SO_3H.[16e] The structurally related 50 VE cluster anion $[Bi\{Fe(CO)_3\}_3(\mu_3\text{-}CO)]^{\ominus}$ (**10j**),[16f] which displays an extra μ_3-CO cap, is formed from $NaBiO_3$ and $Fe(CO)_5$ in methanol; its alkylation with $CH_3SO_3CF_3$ gives $[Bi\{Fe(CO)_3\}_3(\mu_3\text{-}COCH_3)]$, an uncharged $BiFe_3$ tetrahedrane with a μ_3-methoxyalkylidyne ligand as 3e donor.[17a] A large number of complexes **10** have been studied with respect to an extension of their coordination to the μ_4 type $[(L_nM)_3E \rightarrow M'L_n]$.[16b,17b-f] Such clusters can be constructed in completely different ways, namely by reaction of $[Cp(CO)_2Mn(PBr_3)]$ with $Co_2(CO)_8$ or of $[\{(OC)_5Cr\}_2AsCl]$ with $Na[Co(CO)_4]$; the products are the trimetallatetrahedranes $[\{(OC)_3Co\}_3E \rightarrow M'L_n]$, E = P, $M'L_n = Mn(CO)_2Cp$ and E = As, $M'L_n = Cr(CO)_5$.[17e] A slight alteration of the reaction conditions between the arsinidene complex and $Na[Co(CO)_4]$ leads to the cluster **11**, for which the idealized square-pyramidal geometry of the As_2Co_2Cr core was confirmed by X-ray crystallography[17e] (cf. complex **14**).



11 [17e]

In the anion $[(\mu\text{-}CO)\{Fe(CO)_3\}_3P \rightarrow Fe(CO)_4]^{\ominus}$, prepared from $[Fe_4(CO)_{13}]^{2\ominus}$ and PCl_3, the 50 VE of the tetrahedrane core are provided by three 14e $Fe(CO)_3$ fragments, one bridging CO, the P atom, and the negative charge.[17f]

10b[16b] and **10d**[16c] tend to cyclotrimerize, retaining the tetrahedral EM_3 core and eliminating three molecules of CO. **10e**[16d] gives the cluster **12a, b**, which has a trigonal bipyramidal core, on co-thermolysis with $CpM(CO)_2$ (M = Co,Rh).[10b,c]



12a: M = Co [10b]
12b: M = Rh [10c]
Mo ≙ MoCp

12b additionally contains a CpRh(CO) fragment coordinated to the As lone pair.

2.2.2.4. *Trigonal Bipyramids with EM_3E Core*

The M_3 plane of the *closo* cluster type **13**[18a] is generally composed of three 14e $Fe(CO)_3$ fragments. In order to introduce the μ_3-E caps (E = As and Sb as well as P) into the clusters **13**,[18a] compounds **3** are treated with $Na_2[Fe(CO)_4]$; only in the case of **13a** is a terminal $Cr(CO)_5$ ligand replaced by $Fe(CO)_4$.

$$[\{(OC)_5Cr\}_2ECl] \xrightarrow{Na_2[Fe(CO)_4]} \mathbf{13}$$

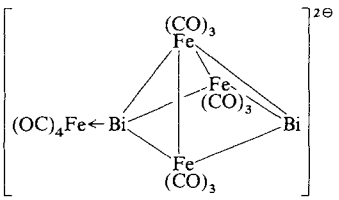
[*] X-ray structure analysis

13a–c are obtained in better yield from $(OC)_5M(PX_3)$ (M = Cr,Mo,W; X = Cl,Br) and $Fe_2(CO)_9$.[18a] The remarkable conversion of trigonal planar coordinated μ_3-P into μ_4-P is observed in the formation of **13d**[18a] from **8a** and $Fe_2(CO)_9$. **13d** can be formally derived from **8a** by bridging the two butterfly wingtips with an $Fe(CO)_3$ fragment and forming two additional Fe–Fe bonds. The ML_n-free compound **13f** has been known for a long time; it is obtained from AsF_3 and $Fe(CO)_5$ or from AsX_3 (X = Cl,Br)[18c] and $Na_2[Fe(CO)_4]$. Starting materials for the cluster **13h**,[18d] isoelectronic with **13f**, and also for $[Bi\{M(CO)_3\}_3Bi]$ (M = Ru,Os),[18e] are $NaBiO_3$ and $Na[HFe(CO)_4]$ or $M_3(CO)_{12}$ (M = Ru,Os).

The reaction between $[Bi\{Fe(CO)_3\}Bi]$ (**13h**)[18d] and $[Fe(CO)_4]^{2\ominus}$ leads to opening of an Fe–Fe bond and formation of $[Bi_2Fe_4(CO)_{13}]^{2\ominus}$ **14**,[18f] a cluster anion of the *nido* type (cf. complex **11**) with a square-pyramidal Bi_2Fe_3 core (by X-ray analysis) and a terminal $Fe(CO)_4$ group.

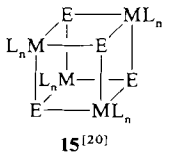


14 [18f]

2.2.2.5. *Cubanes with E_4M_4 Core*

Molecules whose core corresponds to a cubane (slightly or considerably distorted) occupy a key position among transition metal clusters.[19] With elements of the fifth main group (group 15), cubanes of the type A_4B_4 are preponderant (substance class **15**).

Such molecules were discovered in 1970 by *Dahl* et al.,[20c] who prepared **15e** from $Co(OAc)_2 \cdot 4H_2O$ and $SbCl_3$ in methanol under CO/H_2 pressure. **15d**[78d] and **15f**[20d] are



15[20]

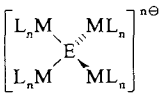
15	E	ML_n	Ref.
a	P	CoCp	[20a]
b	P	NiCp′	[20b]
c	As	NiCp′	[20b]
d	As	MoCp	[78d]
e	Sb	$Co(CO)_3$	[20c]
f	Bi	$Co(CO)_3$	[20d]

formed in the thermolysis of $[\{CpMo(CO)_2\}_2\{\mu\text{-}(AsMe)_5\}]$ or $[Bi\{Co(CO)_4\}_3]$ (**9h**); **15a**[20a] and **15b, c**[20b] in the co-thermolysis of $CpCo(CO)_2$ or $[Cp'Ni(CO)]_2$ (Cp′ = C_5H_4Me) with E_4 (E = P,As). 15e fragments isolobal to E are the preferred ML_n fragments. Of the cubanes characterized by X-ray structure analysis (**15a**,[20a] **15e**,[20c] **15f**[20d]), **15a** with its 14e CoCp fragment shows, as expected, the most pronounced distortion. Four short P···P distances (av. 2.57 Å) are observed in addition to the two very short Co···Co distances (av. 2.50 Å).[20a]

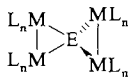
2.2.3. *Quadruply Bridging (μ_4-E)*

2.2.3.1. *Tetrahedral EM_4 Core*

This coordination type can be subdivided into polynuclear complexes without (substance class **16**) or with M–M bonds (spirocyclic complexes, **17**).



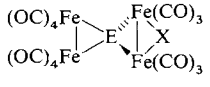
16



17

In the case of the anionic complexes **16**, in the examples known so far E is restricted to Sb and Bi, and ML_n to $Fe(CO)_4$ and $Co(CO)_4$. $[Sb\{Fe(CO)_4\}_4]^{3\ominus}$ (**16a**)[16e] can be prepared from, e.g., $SbCl_3$ or $SbCl_5$ and $Na_2[Fe(CO)_4]$, $[Bi\{Fe(CO)_4\}_4]^{3\ominus}$ (**16b**)[21a] from $NaBiO_3$ and $Fe(CO)_5$ in methanolic KOH. $[Bi\{Co(CO)_4\}_4]^{\ominus}$ (**16c**)[21b] is formed from $BiCl_3$ and $[Co(CO)_4]^{\ominus}$ and in the reaction of $[Cp_2Co][Co(CO)_4]$ with $[Bi\{Co(CO)_4\}_3]$ (**9h**) to form $[Cp_2Co][Bi\{Co(CO)_4\}_4]$ (**16d**),[21c] a paramagnetic complex with ten electrons at bismuth. The tetrahedral environment of Sb and Bi in **16a–16d** was proved by X-ray structure analysis. The structures of the cationic complexes[15f] $[Sb\{Fe(CO)_2(NO)(PPh_3)\}_4]^{\oplus}$ and $[Sb\{Co(CO)_3(PPh_3)\}_4]^{\oplus}$, however, have not yet been determined.

Preferred ML_n fragments in the substance class **17** are $Fe(CO)_n$ units. Thus, PX_3 (X = Cl, Br), $AsCl_3$, and *i*Pr(H)PCH_2PH_2 react with $Fe_2(CO)_9$ to form the spirocyclic complexes **17a–d**.



17a–d

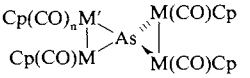
a[*]	P	Cl	[22a]
b[*]	P	Br	[18a]
c	P	PMe*i*Pr	[22b]
d[*]	As	Cl	[22a]

[*] X-ray structure analysis

If the pnicogen E is replaced by its heaviest homologues Sb and Bi, complexes with different structures are obtained. The reaction of $SbCl_3$ with $[Fe(CO)_4]^{2\ominus}$ or $[Fe_2(CO)_8]^{2\ominus}$ leads to the multinuclear bispiro cluster $[\{(OC)_8Fe_2(\mu_4\text{-}Sb)\}_2\{Fe(CO)_3\}_2]$ (**17e**),[22c] the structure of which can be formally derived from that of **17a** by replacing the 3e ligand X of the latter by another 3e donor fragment, $\{(OC)_4Fe\}_2Sb$. **17e** possesses an $SbFe_2Sb$ core with butterfly geometry. The spirocyclic core is also preserved in the Bi multinuclear cluster $[\{(OC)_8Ru_2\}(\mu_4\text{-}Bi)(\mu\text{-}H)Ru_3(CO)_{10}]$ (**17f**),[22d] which is synthesized from $Bi(NO_3)_3 \cdot 5H_2O$ and $Na[Ru_3H(CO)_{11}]$ in methanol. The role of 3e bridging donor is here assumed by μ-H and an $Ru(CO)_4$ fragment of the original Ru_3 starting material.[22d]

The uncharged arsa-spirocycles **18a, b** arise in the co-photolysis of $[\{Cp(CO)_2Mo\}_3(\mu_3\text{-}As)]$ (**10e**)[16d] and $[CpM(CO)_2]$ (M = Co,Rh),[10b,c] the related cation **18c** in the reaction of $[CpCo(CO)_2]$ with AsF_3.[22e] In these inorganic



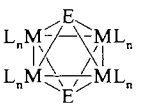
18

18a: M = Co, M′ = Mo, n = 2 [10b]
18b: M = Rh, M′ = Mo, n = 2 [10c]
[18c]$^{\oplus}$: M = M′ = Co, n = 1 [22e]

spiropentane analogues, characterized by X-ray analysis, the "extra" electron of **18a, b** at the spiro junction (As instead of C) can be removed to the 15e molybdenum fragment; the symmetric cation **18c** has an $As^{\oplus}$ spiro junction isoelectronic and isolobal to C.

2.2.3.2. *Square Bipyramidal EM_4E Core*

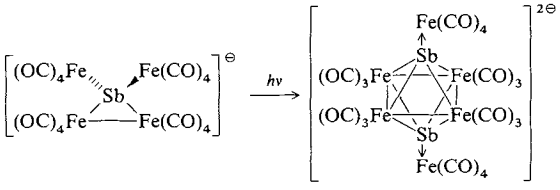
If the *trans* positions of an octahedron with six 14e ML_n fragments are replaced by Sb or Bi atoms, the *closo* cluster **20b** is obtained; this is the prototype of square pyramidal μ_4-E coordination and possesses 7 SEP (skeletal electron pairs).



20

20a: E = Sb, ML_n = $Fe(CO)_3$; dianion [23a]
20b: E = Bi, ML_n = $Ru(CO)_3$ [18e, 23b]

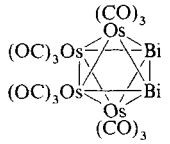
The dianion **20a**, with additional terminal coordination at Sb, is formed, inter alia, photochemically from **19**, the μ_4-Sb atom of which is coordinated by four Fe atoms in a distorted tetrahedron.



19[23a] **20a**[23a]

Whereas the four ruthenium atoms of **20b**, synthesized from $Bi(NO_3)_3 \cdot 5H_2O$ and $Ru_3(CO)_{12}$, lie in a plane,[18e,23b]

the electron-richer anion **20a** (8 SEP = n + 2 type) displays a folded Fe_4 ring.[23a] The *cis* isomer of substance class **20** can be realized for the heaviest homologue of group 8.[18e]



20c [18e]

The cluster core of **20c** consists of an Os_4 butterfly bridged by a Bi_2 unit (d(Bi–Bi) = 3.017(2) Å, cf. Section 3). In the cubic body-centered clusters **21a**, **b** (characterized by X-ray analysis) all the faces are capped by μ_4-As ligands.[24a,b]

The starting materials for the syntheses are $[NiCl_2(PPh_3)_2]$ and $PhAs(SiMe_3)_2$ or $[Pd_3(\mu_3\text{-}S)_2Cl_2(PPh_3)_4]$ and $As(SiMe_3)_3$, respectively.

$[Ni_9(\mu_4\text{-}As)_6(PPh_3)_5Cl_3]$ **21a** [24a]

$[Pd_9(\mu_4\text{-}As)_6(PPh_3)_8]$ **21b** [24b]

In the structurally more complicated macroclusters **22a**, **b**, not only μ_4-As coordination but also face-linking μ_5-As and connected tetrahedra with μ_6-As are observed.

$[Pd_8\{\mu\text{-}Pd(PPh_3)\}_{12}(\mu_5\text{-}As)_{12}]$ **22a** [24b]

$[Co_8\{\mu_6\text{-}As)(\mu_4\text{-}As)(\mu_4\text{-}AsPh)_2(CO)_{16}]_2$ **22b** [24c]

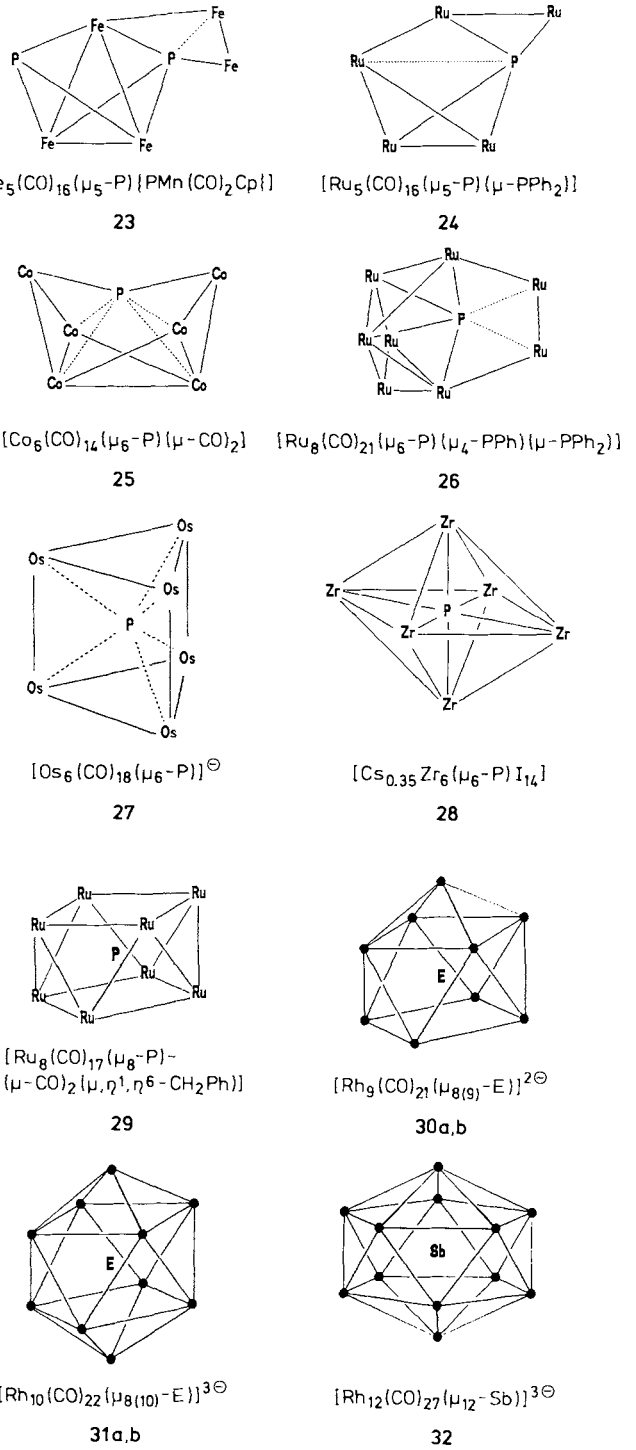
The source of the "naked" As atom is $As(SiMe_3)_3$ for **22a** and $(PhAs)_6$ for **22b**, which are allowed to react with $[PdCl_2(PPh_3)_2]$ or $[Co_2(CO)_8]$, respectively.

2.2.4. *Clusters with Semi-interstitial P and Interstitial E Atom (E = P,As,Sb)*

The partial or complete incorporation of E_1 structural units into open or closed metal polyhedra leads in the case of P_1 to the clusters **23**–**32**, which display a fascinating structural diversity (Scheme 1). If P_1 is replaced by its larger homologues (covalent radii: P 110, As 121, Sb 141, Bi 146 pm), then sufficient space is only available for As_1 in the singly or doubly capped square antiprism of Rh atoms (complexes **30b**, **31b**) and for Sb_1 in the distorted Rh_{12} icosahedron (complex **32**). In all clusters with semi-interstitial P, butterfly fragments are present.

The solid-state structures of metal-rich phosphides[26] offer many parallels to the coordination polyhedra of **27**–**31**. X-ray structure analysis of the clusters $[Os_6(CO)_{18}(\mu_6\text{-}P)(\mu\text{-}AuPPh_3)]$ (**27a**)[25d] and $[Os_6(CO)_{18}(\mu_6\text{-}P)(\mu\text{-}Cl)]$ (**27b**),[25k] prepared from **27** and $Ph_3PAu^{\oplus}$ or $FeCl_3$ respectively, reveals that an intact triangle edge of **27** is bridged in **27a**, but in **27b** an opened edge. Fenske–Hall calculations on Ru model analogues of **27** and **27b** show the interaction of the tangential Cl atomic orbital with the antibonding Ru–Ru LUMO of $[Ru_6(CO)_{18}P]^{\ominus}$ to be crucial; the cluster electron count of **27b** is raised to 92.[25k] The longer metal–phosphorus bonds, as determined by X-ray methods, are indicated by dotted lines in the diagrams of clusters **23**–**26**. In **30** and **31**, these are the Rh–P bonds to the caps.[25g–i] Temperature-dependent multinuclear NMR studies[25l] show that both the CO ligands and the polyhedral core are subject to fluxional processes; for **32** in solution, these dynamic processes are rapid even at − 97 °C.

Sources of the E_1 units are: $[Cp(CO)_2MnPCl_3]$ (for **23**),[18a] $[Ru_3(CO)_n(PPh_2)(H)]$ (for **24**, **26**),[25a,c] PCl_3 (for **25**),[25b] $[Os_6H_2(CO)_{21}(PH)]$ (for **27**),[25d] red phosphorus (for **28**),[25e] $HPPh_2$ (for **29**)[25f] and Ph_3E (E = P,As,Sb) (for **30**–**32**).[25g–j]



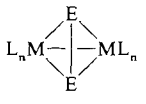
Scheme 1. Schematic representations of the polyhedral skeletons of clusters with semi-interstitial P(**23**–**26**) and interstitial P, As, and Sb atom (**27**–**32**).

3. E_2 Ligands

3.1. μ,η^2 Coordination (4e Donor)

3.1.1. Tetrahedranes with E_2M_2 Core

The E_2 ligands P_2, As_2 and Bi_2 (isoelectronic to acetylene $HC\equiv CH$) tend to form the tetrahedral clusters **33** with side-on coordinated E_2 ligands and 15e L_nM fragments.



33 (E = P, As, Bi)

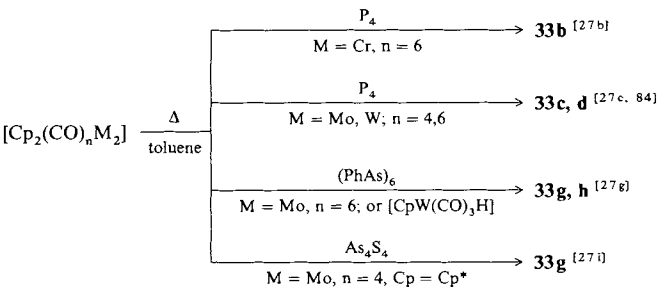
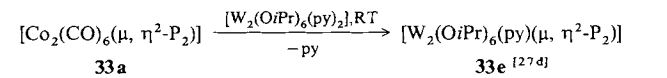
[*] Contains another py ligand

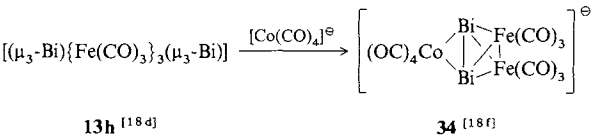
$[\{(OC)_3Co\}_2(\mu,\eta^2\text{-}As_2)]$ (**33f**), the first representative of this substance class, was prepared as early as 1969 from $[Co_2(CO)_8]$ and $AsCl_3$[27e] and characterized by X-ray structure determinations of its derivatives $[Co_2(CO)_{6-n}(PPh_3)_n(\mu,\eta^2\text{-}As_2)]$ (**33f'**, n = 1, **33f''**, n = 2) (Table 1).[27f] The sources of E_2 were (for phosphorus) P_4[16b, 27b, c] and PX_3 (X = Cl,Br,I)[16h] and (for arsenic) *cyclo*-$(PhAs)_6$,[27g] the μ_3-As trinuclear clusters **4b, c**[12a, b] (in **4c**, W is replaced by Mo) and As_4S_4.[27i] **33i** is formed photochemically from $[Bi\{Mo(CO)_3Cp'\}_3]$ (**9d**).[15d] The 15e ML_n fragments of Cr, Mo, and W can conveniently be obtained by the following thermolysis reactions:



The transfer of an E_2 unit of **33** is a remarkable reaction type, for which only one example is known.[27d]

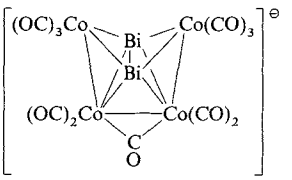


If the trigonal bipyramidal cluster **13h** is allowed to react with $[Co(CO)_4]^{\ominus}$, the edge-bridged tetrahedrane anion **34** is obtained, formally by replacing an $Fe(CO)_3$ fragment by $Co(CO)_4$ and simultaneously forming a Bi–Bi bond[18f] (cf. complex **14**).



13h [18d] **34** [18f]

A tetrahedrane with two capped faces constitutes the Bi_2Co_4 core of the paramagnetic anion **35**,[16i] which is obtained, inter alia, by reaction of $BiCl_3$ with $[Co(CO)_4]^{\ominus}$.



35 [16i]

The characteristic valence electron count of 40 for tetrahedranes **33** (*nido* type with n + 2 SEP) is attained in **34** with the help of two electrons from the $[Co(CO)_4]^{\ominus}$.

3.1.2. Compounds with E_2M_2 Butterfly Cores

14e and 16e ML_n fragments are typical of this type of E_2M_2 core **36**.

36 (E = P, As)

36	E	ML_n	Ref.
a	P	$Ni(Et_2PCH_2)_2$	[28a]

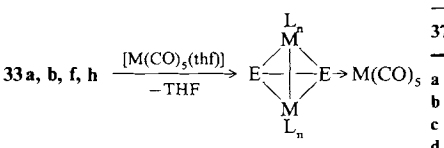
c	P	$Pt(PEt_3)_2$	[28c]
d	As	$Pd(PPh_3)_2$	[24b]
e	As	$Mn(CO)_2Cp^*$	[28d]

Whereas **36e** is formed by thermolysis of the arsinidene complex $[\{Cp^*(CO)_2Mn\}_2AsH]$,[28d] other representatives of this substance class are synthesized from $[Cl_2M(PR_3)_2]$ (M = Ni,Pt; R = Et;[28b, c] M = Pd, R = Ph[24b]) or $[Cl_2Ni(Et_2PCH_2)_2]$[28a] and $E(SiMe_3)_3$ (E = P,As) or $LiP(SiMe_3)_2$.[28b, c]

3.2. 6e-Donor E_2-Ligands

As well as the complexes **37**, with additional terminal coordination of an E_2M_2 tetrahedrane **33**, star-shaped molecules **38** are known, in which the unusual μ_3-η^2-E_2 coordination type has been verified.



37

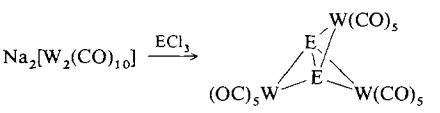
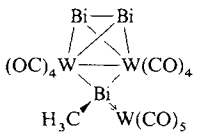
d	As	W	$W(CO)_2Cp$	[27h]



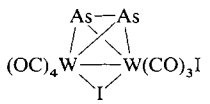
38

38a: E = As[30a]; **b**: E = Sb[30b]; **c**: E = Bi[30c]

38c is formed in the reaction of $(Me_3Si)_2CHBiCl_2$ with $Na_2[W(CO)_5]$; this reaction also gives rise to the edge-bridged Bi_2W_2 tetrahedrane **39a**.[30d] The related As_2W_2 cluster **39b** (d(As–As) = 2.305(10) Å), with an iodine bridge, is obtained from **38a** and iodine.[27h]



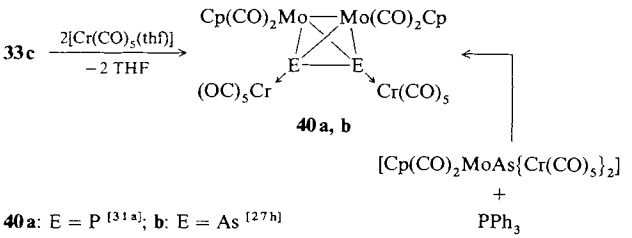
39a [30d]



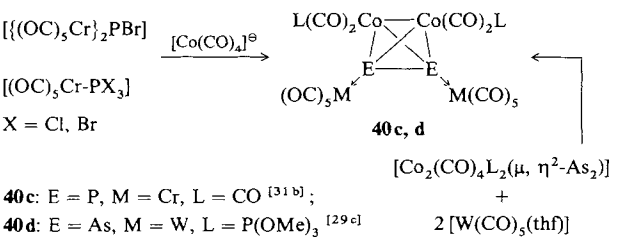
39b [27h]

3.3. 8e-Donor E_2 Ligands

Numerous complexes of type **40** are known; some examples are shown in the diagrams. The E_2M_2 core coordinates additionally through both E atoms to terminal transition metal fragments. The complexes **40** can either be obtained from the tetrahedrane precursor **33**, or can be formed directly in the coordination sphere of the transition metals.

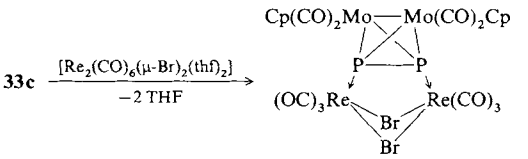


40a: E = P [31a]; **b**: E = As [27h]



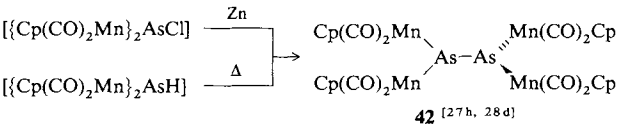
40c: E = P, M = Cr, L = CO [31b];
40d: E = As, M = W, L = $P(OMe)_3$ [29c]

The variant with bridging coordination is so far confined to complex **41**.



41 [31a]

Complex **42**, in which an As_2 ligand is coordinated to four 16e fragments, is formed by reductive coupling.[27h, 28d]



42 [27h, 28d]

X-ray structure analysis of **42** shows that both 3c,4e-Mn⋯As⋯Mn halves are rotated by 75.9° with respect to each other and are thus incapable of conjugation. The As–As bond length of 2.445(4) Å (single bond) (cf. Table 1) and the planar geometry at As indicate the presence of a diarsinidene ligand ⋮As–As⋮.[27h]

3.4. Structural and Theoretical Aspects

The X-ray data (Table 1) show clearly that the E–E and M–M bond lengths of the E_2M_2 tetrahedrane unit undergo only slight changes on going from a 4e(μ,η^2)- to an 8e(μ,$\eta^{2:1:1}$)-E_2 donor ligand (e.g. **33a'**/**40c**, **33c**/**41** and **33g**/**40b**). The Bi–Bi bond becomes appreciably longer on going from the uncharged tetrahedranes **33i** (2.838(1) Å)[27j] and **39a** (2.796(1) Å)[30d] to the anions **34** (3.092(2) Å)[18f] and **35** (3.088(1) Å)[16i].

The side-on coordination of an E≡E ligand leads, as expected (and as was shown by EH calculations on N_2 com-

Table 1. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz, 85% H_3PO_4 ext.) and E–E and M–M bond lengths [Å] of selected examples with E_2M_2 core.

plexes)[32] to a lengthening of the E–E bond. In the tetrahedrane **33e** (Table 1) the P–P bond is 0.26 Å longer than in uncomplexed P≡P [d(P≡P)$_{exp}$ = 1.894, d(P≡P)$_{calc}$ = 1.896 Å[33]]. The corresponding bond length in metal phosphides with $P_2^{4\ominus}$ "dumbbells" is ca. 2.23 Å.[34]

By means of EH calculations on the model substance types $[Co_2(CO)_6E_2]$ (E = P,PH and $PCr(CO)_5$), the criteria determining the choice of tetrahedrane or various butterfly geometries were analyzed (compare **36** with **8a**).[35] Analogous calculations for $(L_5W)_3As_2$, L = CO, suggest plausibly that the E_2 ligand in complexes of type **38** uses its σ bond pair as well as the 4π electrons in bonding to transition metals.[30a]

4. E_3 Ligands

4.1. Mononuclear Complexes with *cyclo*-E_3 Ligands

The substance class **43**, the least metal-rich respresentative of the tetrahedrane series $[(L_nM)_{4-n}E_n]$ (n = 1,2,3), contains a *cyclo*-E_3 unit. The complexes **43a–h** represent typical examples with widely differing ML_n fragments (mostly 15e).

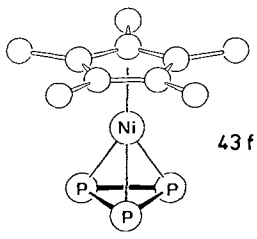
g	As	$Mo(CO)_2Cp^*$	[27i]
h	As	$Co(CO)_3$	[36c]

[a] Cation

As with the E_2M_2 tetrahedranes, it was *Dahl*'s group that succeeded in the pioneering studies of this type of complex; they synthesized $[(OC)_3Co(\eta^3\text{-}As_3)]$ (**43h**)[36c] from $(MeAs)_5$ and $[Co_2(CO)_8]$ at 200 °C under high CO pressure. **43a, c, g**. **43b**[10a] and **10c** are products of the thermolysis of $[W_2(OCH_2tBu)_6(HNMe_2)_2]$ with P_4, which is also (along

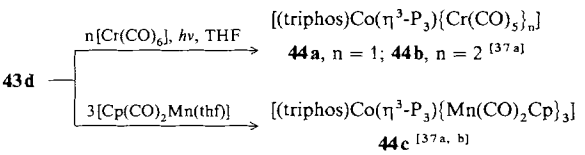


43f

with P_4S_3) the source of P_3 for **43d, e**; the (triphos)M moieties are obtained from $[M(H_2O)_6][BF_4]_2$ (M = Co,Ni) and triphos.[6, 36b] Starting materials for the classical sandwich complex **43f**[20b] are $[Cp^*Ni(\mu\text{-}CO)]_2$ and P_4.

4.1.1. *Reactivity of the cyclo-P_3 Ligand*

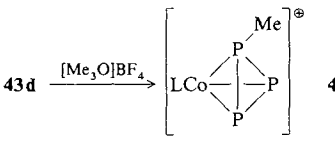
The lone pair of each atom of the P_3 ring is, as expected, capable of further coordination.[37a, b]



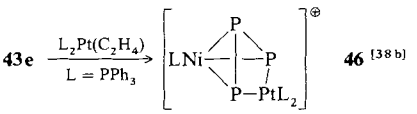
$[Cp^*(CO)_2W(\eta^3\text{-}P_3)\{Mn(CO)_2Cp\}_3]$ **44d**[37c]

$[Cp^*Ni(\eta^3\text{-}P_3)\{Cr(CO)_5\}_3]$ **44e**[20b]

In the complex $[Cp^*(CO)_2W(\eta^3\text{-}P_3)\{Mn(CO)_2Cp\}_3]$ (**44d**) (analogous to **44c**), restricted rotation of the *cyclo*-P_3 disk ($T_c \approx 330$ K, $\Delta G^{\neq}_{T_c}$ = ca. 56 kJ/mol) was demonstrated by ^{31}P-NMR spectroscopy.[37c] Complex **43f** reacts with excess $[Cr(CO)_5(thf)]$ to form $[Cp^*Ni(\eta^3\text{-}P_3)\{Cr(CO)_5\}_3]$ (**44e**).[20b] While the P_3 ring remains intact when **43d** is alkylated,[38a] one P–P edge is opened when the cationic complex **43e** reacts with $L_2Pt(C_2H_4)$.[38b]

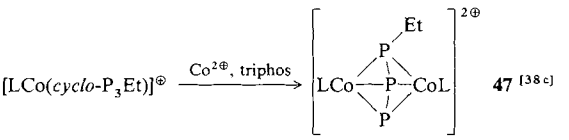


L = triphos



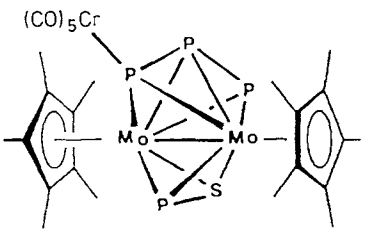
L = triphos

If the ethyl derivative of **45** is allowed to react with $Co^{2\oplus}$ and triphos, the binuclear product **47** contains EtP_3, the phosphorus analogue of ethyl azide, stabilized by coordination.[38c]



L = triphos

47 shows a certain parallel to **48**, which is formed (together with $[Cp^*(CO)_2Mo(\eta^3\text{-}P_3)]$, $[\{Cp^*(CO)_2Mo\}_2(\mu,\eta^2\text{-}P_2)]$

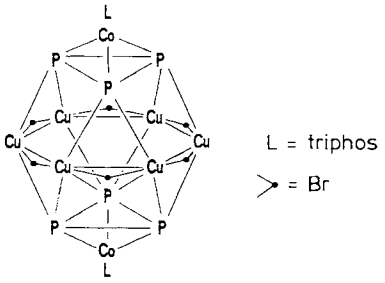


48

and $[Cp^*_2Mo_2P_2S_3]$) during the co-thermolysis of $[Cp^*(CO)_2Mo]_2$ and P_4S_3.[39]

Characteristic for complexes **45**–**48** are the marked differences (as shown by X-ray methods) in the P–P and M–P bond lengths (Table 2). The EtP_3 ligand displays a remarkable dynamic ring opening and closing behavior, as shown by temperature dependent ^{31}P-NMR spectroscopy.

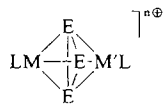
A particularly striking example of a cluster assembly reaction is seen in the reaction of [(triphos)Co(η^3-P_3)] (**43d**) with CuBr, which results in the impressive multilayer sandwich structure **49**.[40] The Cu_6P_6 core, which may also be regarded as a cuboctahedron, consists of a Cu_6 central deck and two *cyclo*-P_3 decks ($\bar{d}$(P–P) = 2.03(1) Å).[40]



49

4.2. Binuclear Complexes with *cyclo*-P_3 Ligands

The discovery by *Sacconi* et al. of the triple-deckers **50**, with a central *cyclo*-E_3 deck (E = P,As) was a milestone in the studies of complexes with "naked" E_n ligands.[6] Typical examples are **50a**–**f**.[6]



50: E = P, As, L = triphos

50	E	M	M'	n	VE	Ref.
a	P	Co	Co	2	31	[6]

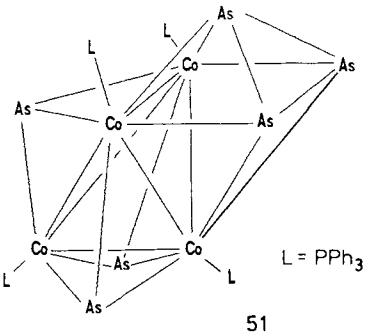
c	P	Pd	Pd	1	34	[6, 41]
d[a]	P	Co	Fe	2	30	[6]
e	P	Co	Ni	2	32	[6]
f	As	Co	Co	2	31	[6]

[a] L = $MeC(CH_2PEt_2)_3$ to the Fe

The homonuclear representatives **50a**, **b**, **c**, **f** are prepared from $[M(H_2O)_6]^{2\oplus}$ (M = Co,Ni) or $[PdCl_2(PBu_3)_2]$, triphos and E_4 (E = P,As)[6] or As_4S_3.[42] [(triphos)Co(η^3-P_3)] (**43d**) can be extended to a triple-decker sandwich **50e** by reaction with the $[(triphos)Ni]^{2\oplus}$ moiety (generated as just described); this is an impressive demonstration of the π-donor properties of the *cyclo*-P_3 ligand. Some of these complexes can be reduced to the monocation with $NaBH_4$.[6] Complex **50a** can be oxidized (30 VE) or reduced (32,33 VE) cyclovoltammetrically.[6] Complexes with 31 to 33 VE are[6], with the exception of $[(triphos)Ni(P_3)Rh(triphos)]^{2\oplus}$, a 32 VE complex with a strongly distorted P_3 central deck [d(P–P) = 2.15–2.31 Å[6]], paramagnetic. In this complex and the edge-opened 32 VE binuclear complex **47**,[38c] the double degeneracy of the HOMO is removed by a Jahn–Teller distortion, changing the ground state from a triplet to a singlet state.[6, 38c]

If the Wade–Mingos electron counting rules for *closo* deltahedra[44] are applied to the triple-deckers **50** (which conform to the classical 30/34e rule[43]), then it is obvious that only the 30e species **50d** possesses the necessary 6 SEP for a trigonal bipyramid (n + 1 type).

Cyclo-As_3 can also form part of a polynuclear cluster. In $[Co_4(\mu_3\text{-}As)_3(\mu_3,\eta^3\text{-}As_3)L_4]$ (**51**), synthesized from [Co-



51

Cl_2L_2] and $PhAs(SiMe_3)_2$,[46] the cluster core consists of a Co_4 tetrahedron with three faces capped by As atoms and with the fourth face extended to an octahedron by an As_3 ligand [d(As–As) = 2.463(2) Å].

4.3. Spectroscopic, Structural, and Theoretical Aspects

In the mononuclear complexes **43**, the strongest deshielding of the ^{31}P-NMR signal is observed for **43f** (Table 2) and [(triphos)Pd(η^3-P_3)]BF_4 (**43i**), δ = – 132.9(q).[36b] The signal is shifted by ca. 200 ppm to high field in the binuclear complex **50c** (Table 2). The very small ^1J(MP) coupling constants [**43b**: $^1J(^{183}W^{31}P)$ = 16 Hz,[10a] [(triphos)Rh(η^3-P_3)] (**43j**): $^1J(^{103}Rh^{31}P)$ = 13 Hz[36b]] indicate an essentially π-bonded η^3-P_3 ligand.

The X-ray structure analyses show that the average P–P bond lengths of the mononuclear complexes **43** lie in a narrow range, 2.100–2.155 Å, and that the extension of the clusters to triple-deckers with a μ,η^3-P_3 central deck leads only to a small increase in the bond length; this trend is also recognizable in the few values available for the As complexes (Table 2). The P–P bond length (2.183 Å) in the bent, symmetric P_3 chain of the 19e radical anion $P_3^{4\ominus}$ (in K_4P_3[47]) does not differ greatly (in contrast to the P–P–P angle) from the average P–P bond length of the P_3 ligand in **47** (2.16 Å[38c]) and **48** (2.20 Å[39]). The M···M distances of the binuclear complexes **50**, with a central E_3 deck, lie in the non-bonding range (Table 2).

Ab initio calculations for the 16e anion $P_3^{\ominus}$ (an analogue of azide, $N_3^{\ominus}$) indicate that the bent isomer is only slightly less stable than the linear form.[48]

EH calculations,[6, 49a] carried out for the model systems $[LM(\mu,\eta^3\text{-}P_3)ML]^{n\oplus}$, suggest that the interactions between the xz and yz metal orbitals (e″ combinations of the LM···ML system) and the z orbitals of the phosphorus (e″ set of the *cyclo*-P_3 fragment) are crucial. Analogous calculations were also carried out for the 32 VE model compounds $[(H_3P)_3M(E_2S)M(PH_3)_3]^{n\oplus}$ (E = P,As).[50]

Table 2. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz, 85% H_3PO_4 ext.) and E–E and M–M bond lengths [Å] of selected examples with $E_3M_{1(2)}$ core.

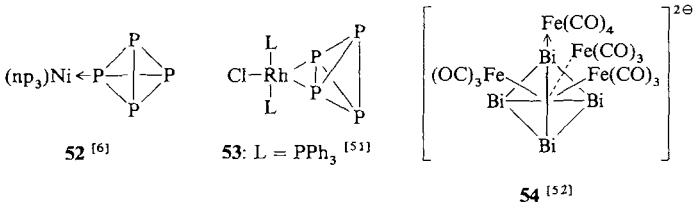
5. E_4 Ligands

5.1. E_4 Tetrahedra (E = P,Bi) as Ligands

Of the three conceivable coordination modes of an E_4 tetrahedrane, the terminal η^1-P_4 and edge-bridging (side-on) η^2-P_4 coordination have been realized for phosphorus and the face-capped variant η^3-Bi_4 for bismuth. Starting materials for **52**[6] and **53**[51] (apart from P_4) are the complexes $[(np)_3Ni]$ and $[ClRh(PPh_3)_3]$; **54** is formed in the reaction between $[Bi\{Fe(CO)_3\}_3(\mu_3\text{-}CO)]^{\ominus}$ (**10j**)[16f] and CO.[52]



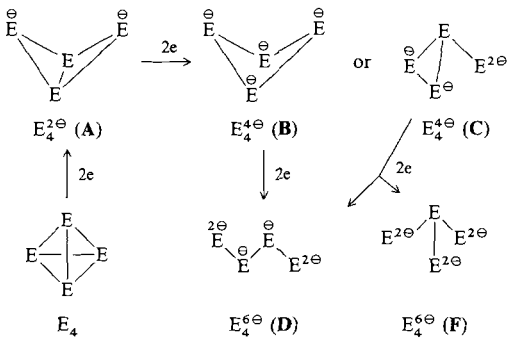
52 [6] **53**: L = PPh_3 [51] **54** [52]

X-ray structure analysis reveals characteristic differences in the E–E bond lengths. Whereas the average $P_{ap.}$–$P_{bas.}$ bond length in **52** is 2.20 Å, 0.1 Å longer than the mean $P_{bas.}$–$P_{bas.}$,[6] the difference in **54** is as high as 0.3 Å (mean $Bi_{ap.}$–$Bi_{bas.}$ 3.47, $Bi_{bas.}$–$Bi_{bas.}$ 3.16 Å). This trend is consistent with the results of EH calculations for $[Bi_4(\mu_3\text{-}FeL_3)_3]^{2\ominus}$.[52] The side-on coordination of the P_4 edge in **53**, almost perpendicular to the $[(Ph_3P)_2ClRh]$ plane, leads to an increased bond length of 2.462 Å, while the opposite bond is significantly the shortest (2.188 Å), and the others (mean P–P 2.21 Å) correspond to those of the P_4 molecule.[51] EH calculations for the model complexes $[(H_3P)_3Ni(\eta^1\text{-}P_4)]$[6] and $[(H_3P)_2ClRh(P_4)]$[51,53] do not allow a clear distinction between an intact η^2-P_4 edge or one opened by oxidative addition (cf. complexes **55** and **56**).[53]

The cluster-like particles M_6Sb_4 (M = Na,Cs), detected in the gas phase, are suggested to possess a tetrahedral Sb_4 core, surrounded by an alkali metal octahedron.[54]

5.2. E_4 Ligands Formally Derived by Opening Edges of an E_4 Tetrahedron

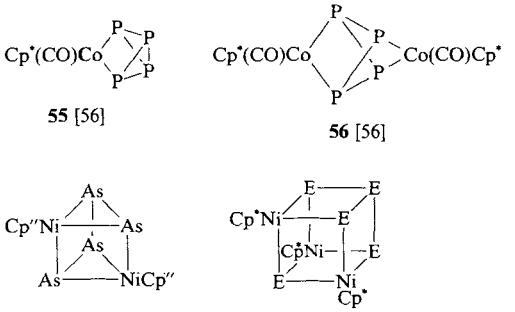
If one imagines three edges of an E_4 tetrahedron being successively opened by 2e reduction, then the Zintl ions[1,55] $E_4^{n\ominus}$ (n = 2,4,6) are formally obtained (E = P,As,Sb,Bi).



$E_4^{2\ominus}$ **(A)** $E_4^{4\ominus}$ **(B)** $E_4^{4\ominus}$ **(C)** E_4 $E_4^{6\ominus}$ **(D)** $E_4^{6\ominus}$ **(F)**

Scheme 2. $E_4^{n\ominus}$ units derived from the E_4 tetrahedron. ≡E denotes one, $=E^{\ominus}$ two, and $-E^{2\ominus}$ three lone pairs.

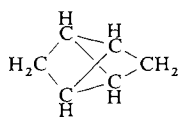
If covalent bonding is assumed, the successive homolytic bond cleavage of an E_4 tetrahedron leads to the uncharged species corresponding formally to **A**–**F** ($=\ddot{E}\cdot$ forming two bonds, $-\ddot{\underset{\cdot}{E}}\cdot \triangleq -\ddot{\underset{\cdot}{\ddot{E}}}$ forming one bond).

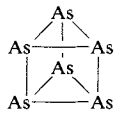


55 [56] **56** [56]

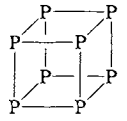
57 [57] **58a**: E = P [20b] **58b**: E = As [20b]

Of the $E_4^{n\ominus}$ units in Scheme 2, it has so far proved possible to stabilize **A**, **B**, **D** and **F** in the coordination compounds **55** (**A**),[56] **56** (**B**),[56] **57** (**D**),[57] and **58** (**F**).[20b] According to the principle of isolobal analogy[2] the complexes **56**–**58** can be formally derived from tricyclo[2.2.0.$0^{2,5}$]hexane and the hypothetical molecules hexaarsaprismane and E_8-cubane (E = P,As) respectively [Cp(CO)Co $\leftrightarrow\sigma\rightarrow$ CH_2, P $\leftrightarrow\sigma\rightarrow$ CH; CpNi $\leftrightarrow\sigma\rightarrow$ P,As].





As_6



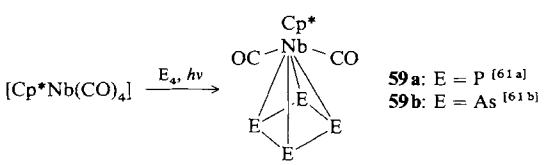
P_8

The ^{31}P-NMR[56] and X-ray data for the cobaltatetraphosphatricycloalkanes **55** [$\bar{d}$(P···P) = 2.61 Å] and **56** [$\bar{d}$(P···P) = 2.58 Å] show, in comparison with **53**,[51] that a single (to $P_4^{2\ominus}$) or double oxidative addition (to $P_4^{4\ominus}$) of P_4[56] has taken place. The suggested $P_4^{2\ominus}$ butterfly structure (**A** in Scheme 2) for K_2P_4 (detected by mass spectroscopy)[58a] was proved for $HP_4^{\ominus}$[58b] by ^{31}P-NMR spectroscopy.

The mean As–As bond length of 2.40 Å in the distorted dinickelatetraarsaprismane **57**[57] is slightly shorter than the value of 2.44 Å in the distorted trinickelapentaarsacubane **58b**.[20b] The most remarkable feature of the structures of the cubanes **58** is the tripod-like E_4 ligand, corresponding to an E_4 tetrahedron with three bonds broken. This leads, as expected, to a widening of the E–E–E angle from 60° to ca. 82°; the mean E–E bond lengths of 2.21 (**58a**) and 2.44 Å (**58b**)[20b] are however identical to those of P_4 or As_4 respectively. **58a** displays an interesting similarity to the solid-state structure of $La_6Ni_6P_{17}$,[59] in which sixteen P atoms formally constitute four trigonal pyramidal $P_4^{6\ominus}$ units and the seventeenth functions as $P^{3\ominus}$. The relevant Ni–P and P–P distances in both structures are essentially identical. The chemical bonding topology of binary and ternary transition metal polyphosphides has been studied on the basis of edge-localized models.[60]

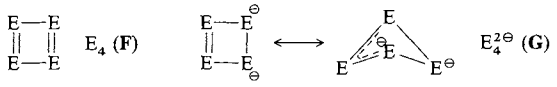
The synthesis of **56**–**58** is achieved by thermolysis of $[Cp^*M(\mu\text{-}CO)]_2$ (M = CO,[56] Ni[20b]) and $[Cp''Ni(\mu\text{-}CO)]_2$[57] with P_4 or As_4.

The only fragment so far capable of coordinatively stabilizing tetraphospha- or tetraarsacyclobutadienes is the 14e fragment $Cp^*Nb(CO)_2$. The Wade–Mingos electron counting rules[44] for the slightly distorted square pyramid E_4Nb in **59** lead to the necessary number of SEP (n + 2 = 7) for the *nido* structure; the average E–E bond lengths (**59a** 2.16 Å,[61a] **59b** 2.38 Å[61b]) lie in the expected range for a *cyclo*-E_4 ligand with sandwich-like coordination.



59a: E = P [61a]
59b: E = As [61b]

The analogy to cyclobutadiene,[62] C_4H_4, and to the allyl-like distortion of the dianion,[63] $C_4H_4^{2\ominus}$, would lead one to postulate the structures **F** and **G** for $E_4^{0/2\ominus}$ (E = P,As $\leftrightarrow\sigma\rightarrow$ CH) (Scheme 3).



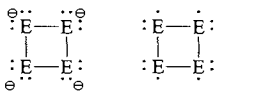
E_4 (**F**) $E_4^{2\ominus}$ (**G**)

Scheme 3. E = CH,P,As.

A slight distortion of the planar P_4 base of **59a** to a kite shape is observed (the two P–P bonds approximately parallel to the CO groups are slightly shorter).[61] It is not clear whether this is evidence for a formulation as *cyclo*-$P_4^{2\ominus}$ ligand **G** (d^2-Nb), because the distortion of an uncharged *cyclo*-P_4 ligand **F** (d^4-Nb) could be caused by the different ligands at the Nb atom.

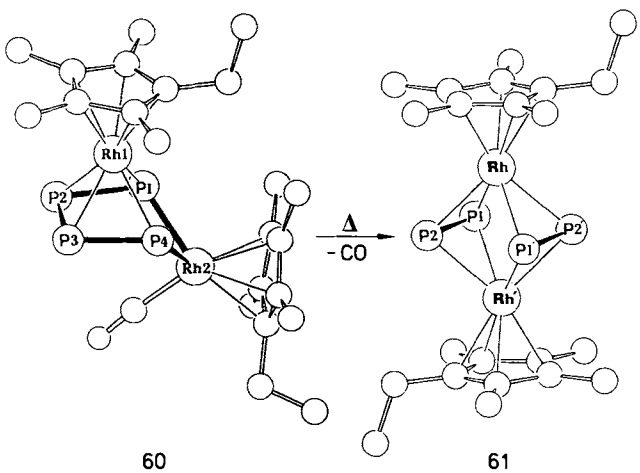
Theoretical investigations suggest[64] that *cyclo*-P_4, the "antiaromatic" phosphorus analogue of cyclobutadiene, should prefer the square arrangement with a P–P bond length (6-31G* value) of 2.143 Å (average value in **59a** 2.16 Å[61a]).

In the series of square planar Zintl anions *cyclo*-$E_4^{2\ominus}$ (E = As,[65] Sb and Bi[66]), an As–As bond length of 2.35 Å was found[65] for *cyclo*-$As_4^{2\ominus}$ (characterized by EXAFS studies), which is in equilibrium with *cyclo*-$As_6^{4\ominus}$ (cf. 2.38 Å mean As–As in **59b**[61b]). Similar planar *cyclo*-E_4 units are found in the solid-state structures of (e.g.) CoE_3 (E = P,As; skutterudite-type),[67] where the E_4 rectangles display appreciably longer E–E bonds (CoP_3,[67a] 2.24/2.34 Å, $CoAs_3$,[67b] 2.47/2.56 Å). This type of molecule can be described either as an ionic or a covalent form.



$(Co^{3\oplus})_4(E_4^{4\ominus})_3 \equiv CoE_3 \equiv Co_4(E_4)_3$

If $[Cp^xRh(CO)_2]$ and P_4 are thermolyzed, then **61**[68b] and the binuclear complex **60**[68a] are formed; in the latter, the



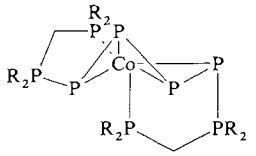
60 61

Scheme 4. Conversion of **60** into **61** at elevated temperature.

metallatetraphosphacyclopentadiene moiety itself acts as an η^4 ligand. **60** can be converted at 150 °C in xylene with cleavage of CO into **61** (Scheme 4).

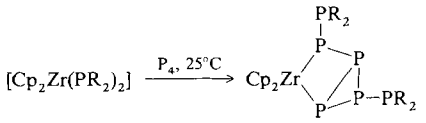
The X-ray structure analysis of **60** shows that the planar P_4 unit and the top Cp^x deck are arranged parallel to each other, as in a sandwich.[68a] The almost equal P–P distances (av. 2.15 Å) contrast with those of the P_4 rectangle in the binuclear sandwich complex **61**,[68b] with a short (2.052(2) Å; cf. Table 1) and a very long (2.845(2) Å P···P) P–P distance (Rh···Rh = 3.324(1) Å).

The mononuclear complex **62**, prepared from $[Co(H_2O)_6]^{2\oplus}$, P_4 and $R_2PCH_2PR_2$,[69] contains a zig-zag-shaped η^4-tetraphosphabutadiene central ligand moiety with P–P bond lengths in the range 2.171–2.197(3) Å.



62 [69]: R = Ph

White phosphorus undergoes a ready insertion into the Zr–P bonds of a bis(phosphido)zirconium complex under very mild conditions, leading to the complex **63**.[70] The four remaining edges of the original P_4 tetrahedron have bond



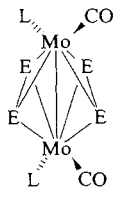
63 [70]

R = $SiMe_3$

lengths of 2.213 Å (mean value for the P_3 triangle) and 2.241(4) Å.[70]

5.3. $(E_2)_2$ Ligands (E = P,As)

As well as the rectangular arrangement of two P_2 units already discussed for the sandwich complex **61**,[68b] the alternative trapezium form of $(E_2)_2$ has been realized in the binuclear molybdenum complexes **62**. Single crystals of **62a** suitable for an X-ray structure determination were obtainable



62

62	E	L	Ref.
a	P	Cp*	[7]
b	As	Cp*	[71a, 85]
c	As	Cp′	[71b]

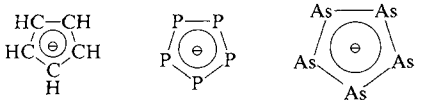
only in the case of the derivative **62a′**, $[Cp^*(CO)MoP_2\{Cr(CO)_5\}]_2$.[71a] In **62a′** and **62c**[71b] the plane of the E_4 trapezium is perpendicular to the Mo–Mo axis [d(Mo–Mo) = 2.905(1) (**62a′**), 2.950(1) Å (**62c**)], which forms the common edge of two Mo_2E_2 tetrahedranes. The E_2 units [d(P–P) = 2.063(5)/2.071(5), d(As–As = 2.279(2)/2.300(2) Å, cf. Table 1] approach each other in the phosphorus compound to within 2.849(5) Å and in the arsenic complex **62c** to 3.051(2) Å. The bonding and nonbonding P–P distances of **62a′** and **61** are thus comparable. The structure of **62** throws light on the synthesis[71a] of the triple-decker complex $[\{Cp^*Mo\}_2(\mu,\eta^6\text{-}P_6)]$ (**68a**)[7] from **62a** and white phosphorus (see Section 7.1).

62a–c are formed together with other products in the thermolysis of $[Cp^*(CO)_2Mo]_2$ or $[Cp'(CO)_3Mo]_2$ and E_4 (E = P, **62a**[7] As **62b**[71a, 85]) or *cyclo*-$(MeAs)_5$ **62c**.[71b]

6. *cyclo*-E_5 Ligands (E = P,As)

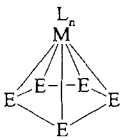
6.1. Sandwich Complexes

In 1987 the pentaphosphacyclopentadienide ion *cyclo*-$P_5^\ominus$, isoelectronic to the classical cyclopentadienide ion $C_5H_5^\ominus$, was synthesized from white phosphorus P_4 and stabilized in the sandwich complex $[Cp^*FeP_5]$ (**63a**)[72a]



At about the same time[73a] *Baudler* et al. succeeded in preparing stable solutions of MP_5 (M = Li,Na) from P_4 and sodium in diglyme or from P_4 and $LiPH_2$ in THF (NaP_5/[18]crown-6/THF[73a, c]). The products were characterized by ^{31}P-NMR and UV spectroscopy and by negative-ion mass spectroscopy[73b] (the same method demonstrated the presence of $P_5^\ominus$ in the spectrum of red phosphorus at 325 °C[74]) and by conversion into **63a**[73b].

The anion *cyclo*-$As_5^\ominus$, prepared from yellow arsenic As_4, is to date the largest known 6π five-membered ring ligand, and is suitable for constructing the sandwich complexes **63**.[75]



63

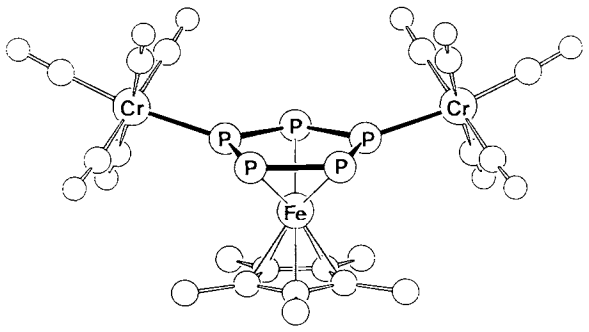
The metallocenes **63**, with a *cyclo*-E_5 deck, are mostly stable thermally and towards air; like ferrocene, they are typical *nido* compounds (n + 2 = 8 SEP) with a pentagonal pyramidal core.

63a reacts with $[Cr(CO)_5(thf)]$ or $[CpMn(CO)_2(thf)]$ in such a way as to utilize two (in **64**[76]) or even four (in **65**[76]) of its lone pairs for further coordination.



64

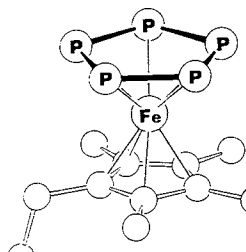
65: $[Cp^*FeP_5\{Mn(CO)_2Cp\}_4]$

The decamethylferrocene stacking reaction, discovered by *Rybinskaya* et al. for the synthesis of the 30 VE triple-decker sandwich complex $[(C_5H_5)Fe(C_5Me_5)Fe(C_5Me_5)]PF_6$[77] can also be applied to **63b** and **63e**.

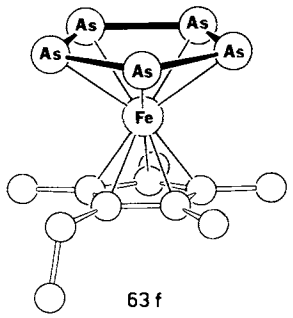
63b, e $\xrightarrow[-C_6H_6]{[CpFe(C_6H_6)]PF_6,\ h\nu}$ $[CpFe(E_5)Fe(C_5Me_4R)]PF_6$

66g: E = P, R = Et [76]
66h: E = As, R = Me [75a]

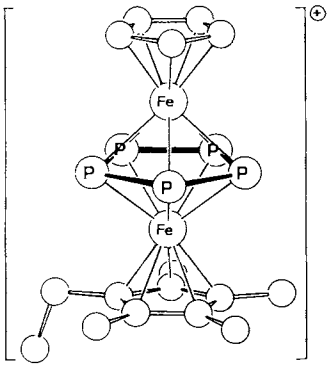
The mixed sandwich complexes **63** are formed by cothermolysis of E_4 (E = P,[72] As[75]) with $[\eta^5\text{-}C_5Me_4R)M(CO)_2]_2$ (M = Fe,Ru) or $[(\eta^5\text{-}C_5Me_4R)Ru(CO)_2Br]$ (R = Me,Et).



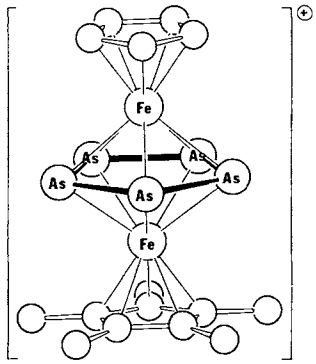
63b



63f

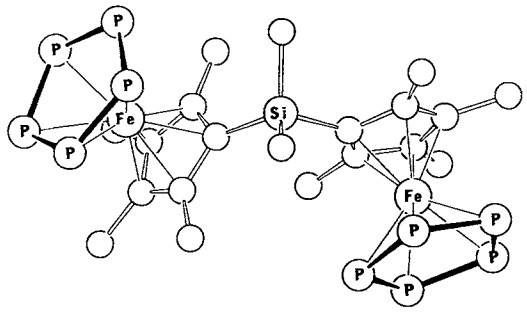


66g



66h

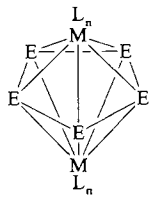
The reaction of the Me_2Si-bridged binuclear complex $[\{(C_5Me_4)_2SiMe_2\}Fe_2(CO)_2(\mu\text{-}CO)_2]$ with P_4 in decalin (12 h, 190 °C) leads to the "double sandwich" structure **67**, which can also, analogously to **66g**, be further "stacked up" at both P_5 rings.[79]



67

6.2. Triple-Decker Sandwich Complexes

Whereas the stacking up of **63** leads to the cationic, diamagnetic 30 VE complexes, the synthetic approach according to the following methods has so far only yielded the



66

66	E	ML_n	Ref.

e	As	$CrCp^\times$	[78c]
f	As	MoCp	[78d]

27 VE species **66a–f**. Possibly the preparation of **66f**,[78d] the only molybdenum compound of the series, depends on the use of *cyclo*-$(MeAs)_5$ instead of P_4[78a] and As_4,[78b,c] which served as sources for the E_5 deck in the chromium complexes (cf. the triple-decker complexes with *cyclo*-P_6 middle deck). In both cases different Cp-substituted binuclear complexes of the type $[CpM(CO)_3]_2$ (M = Cr,Mo) are used to generate the ML_n fragments of **66** in the thermolysis reaction. The photochemical conversion of $[Cp^\times(CO)_2Cr(\eta^3\text{-}As_3)]$ into **66e**[78c] is also known.

Cyclovoltammetric studies[78a] show that the mixed-valence (d^4/d^5-Cr), paramagnetic (μ = 2.07 μB[78e]) 27 VE triple-decker complex **66a** can readily be reversibly reduced (28 VE species, E_{red} = − 0.97 V) and oxidized (26 VE species, E_{ox} = + 0.07 V); the latter is possible even on the preparative scale with $[Cp_2Fe]^\oplus$.[78f]

6.3. Spectroscopic, Structural, and Theoretical Aspects

^{31}P-NMR studies show that the signal for the *cyclo*-P_5 ring undergoes a continuous high-field shift upon conversion of LiP_5[73a,b] (δ = 470) into the sandwich and triple-decker sandwich complexes (Table 3; e.g. **63a**, **b** and **66g**). The average P–P bond lengths (see Table 3; determined by electron diffraction in the gas phase for $[Cp^*Fe(P_5)]$ (**63a**),[80] by X-ray methods for all other *cyclo*-P_5 sandwich complexes) are all very similar and agree well with values from ab initio calculations for *cyclo*-$P_5^\ominus$ [2.081 Å (3-21 G*), 2.093 Å (DZ + P)][81a,b] and NaP_5 [2.093 Å (3-21 G*)].[81a] EH calculations for the model complexes $(C_6H_6)_2Cr$, $(C_6H_6)CrP_6$, $[(C_5H_5)_2Cr]^{2\ominus}$, $[(C_5H_5)CrP_5]^{2\ominus}$, $(C_5H_5)_2Fe$ and (C_5H_5)-

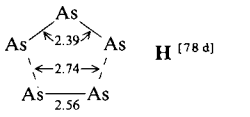
[a] Average value. [b] Electron diffraction. [c] AMM'XX' spin system. [d] Values for one of the two independent molecules in the unit cell. VE = number of valence electrons.

FeP_5 indicate that the compounds with *cyclo*-$P_{5(6)}$ ligands are at least as stable as their carbocyclic analogues;[82] this result has so far only been confirmed for $[Cp^*FeP_5]$ (**63a**) and other P_5 metallocenes with highly alkylated Cp ligands (Table 3).

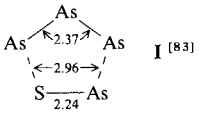
In all the sandwich and triple-decker sandwich complexes, the five-membered rings are planar and parallel to each other. $[Cp^\times FeP_5]$ (**63b**) and $[Cp^\times FeAs_5]$ (**63f**) display nearly identical pairs of distances from the iron atom to the centers of the five-membered rings (Table 3). The appreciably shorter M–M distances (ca. 2.73–2.78 Å) in the less electron-rich 27 VE triple-deckers (cf. ca. 3.05 Å in the 30 VE species) lead to a compression of the pentagonal bipyramidal ME_5M framework (the angles M–E–M are ca. 8° narrower), accompanied by a lengthening of the average E–E bond length by ca. 0.09 Å (cf. **66g** with **66a**, and **66h** with **66d**, **e** in Table 3).

EH calculations for triple-decker compounds $[CpM(\mu,\eta^n\text{-}E_n)MCp]$ (n = 5, E = P,As; n = 6, E = P) with bonding M–M distances suggest[49] that 28 VE should be the magic number (cf. the 30/34e rule[43]). If the electron count is increased to 30, then two electrons must occupy the antibonding a_2'' (σ^*) orbital,[49] which explains the experimentally established lengthening of the M–M bond length by ca. 0.3 Å (see Table 3).

$[CpMo(As_5)MoCp]$ (**66f**)[78d] occupies a special position among the triple-decker complexes **66d–f** with a central As_5 deck. The distortion **H** of the As_5 ring to an "allyl–ene" system, of which this is surprisingly the only known example, can be attributed to Jahn–Teller effects, as shown by EH calculations.[49] In the 28 VE triple-decker $[(CpMo)_2(\mu,\eta^3\text{-}As_3)(\mu,\eta^2AsS)]$ (**67**),[83] the As_4S middle deck (the AsS



H [78d]



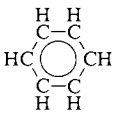
I [83]

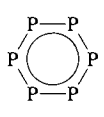
part is disordered) displays the distortion in **I**, also consistent with theory[49a] (cf. the analogous triple-decker **48**[39] with a central P_4S deck).

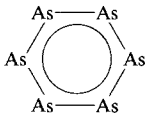
If the Wade–Mingos electron-counting rules[44] are applied to substance class **66**, then only the 30 VE triple-deckers **66g**[76] and **66h**[75a] have the necessary number of skeletal electron pairs for a pentagonal bipyramid (n + 1 = 8 SEP).

7. *cyclo*-E_6 Ligands (E = P,As)

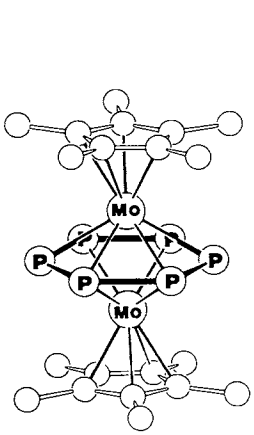
7.1. Triple-Decker Sandwich Complexes



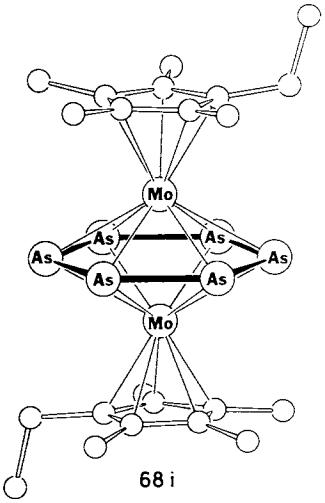




The molecules *cyclo*-P_6 (hexaphosphabenzene) and *cyclo*-As_6 (hexaarsabenzene), isoelectronic to benzene (CH ≙ P,As) were first coordinatively stabilized in 1985[7] and 1989[85] respectively, as the central decks of the triple-decker sandwich complexes **68a** and **68i**.

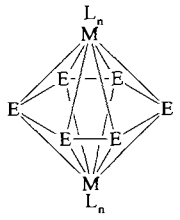


68a



68i

The synthesis of **68** can involve the thermolysis of E_4 (E = P,As) with $[Cp_2^{*(x)}M_2(CO)_n]$ (n = 4,6; M = Mo,[7, 85] W[84]) or $[Cp^{*(x)}M(CO)_4]$ (M = V,[84] Nb,[61a, 87]) or the photolysis of $[Cp^{*(x)}(CO)_2Mo(\eta^3\text{-}E_3)]$ (E = P,[86] As[85]).



68

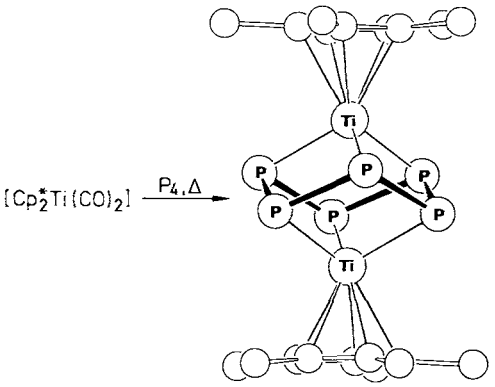
g	P	NbCp'''	[87]
h	As	MoCp*	[85]
i	As	$MoCp^x$	[85]

For group 4 metals, the synthesis of **69**[88] involves not only CO elimination but also the removal of a Cp* ligand from the mononuclear Ti complex.



69

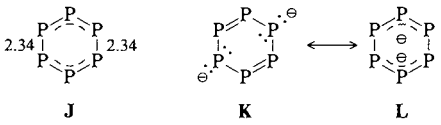
68 and **69** are thermally very stable and can be handled in air.

Cyclovoltammetric studies[84] show that the triple-decker complexes **68a–c**, with 28 or 26 VE, have a strong tendency to form 27 VE complexes (open-shell configuration) by reduction (V complex **68c**) or oxidation (W complex **68b**). The 24 VE complex **69** is irreversibly oxidized to the 23 VE cation and reversibly reduced to the 25 VE anion.[88]

Attempts to prepare cubic P_8 from **69** and two moles of PX_3 (X = Cl,Br) have proved unsuccessful.[88]

7.2. Spectroscopic, Structural, and Theoretical Aspects

The lowering of the valence electron number from 28 to 24 leads to an increasing low-field shift in the ^{31}P-NMR signals of the *cyclo*-P_6 group in **68** and **69** (Table 4). Parallel to this, an increasing distortion of the *cyclo*-P_6 ligand is observed by X-ray methods. The separation of the benzene π system into two allyl-like 3e units, just observable in the 26 VE triple-decker $[CpV(C_6H_6)VCp]$,[89] is particularly marked in the *cyclo*-P_6 ligand of **68g**; the central deck here (**J**) shows four short (2.104(2)–2.116(3) Å) and two very long (2.345(3) Å) P–P bonds (Table 4; cf. complex **68f**[61a]). The presence of a *cyclo*-$P_6^{2\ominus}$ ligand is also formally conceivable (resonance forms **K** and **L**). LCAO-MO calculations[90] for the series *cyclo*-$P_6^{n\ominus}$ (n = 0,2,4,6) with idealized symmetry 6/*mmm* indicate the greatest stability for *cyclo*-$P_6^{2\ominus}$.



J **K** **L**

The 28 VE triple-deckers **68a**, **b** and **68i** display within experimental error regular phosphorus or arsenic hexagons; the average E–E bond lengths are only slightly different from those of the polyphosphides M_4P_6[90] (M = K,Rb 2.15 Å; Cs 2.14 Å) and the polyarsenide Rb_4As_6[1] (2.37 Å), which also possess a regular hexagonal ring, $E_6^{4\ominus}$ (10π system). The marked enlargement of the central E_6 deck on going from E = P (**68a**, **b**) to E = As (**68i**), coupled with the almost constant Mo–Mo distance (Table 4), causes a flattening (decrease of Mo–E–Mo angle) of the hexagonal bipyramidal $Mo(E_6)Mo$ framework.

If the chair-shaped P_6 ring in the distorted Ti_6P_6 cubane framework of **69**[88] is attributed the formal charge *cyclo*-$P_6^{6\ominus}$ (isoelectronic with *cyclo*-S_6), an interesting analogy to the μ,η^3,η^3-*cyclo*-$P_6^{6\ominus}$ moiety of Th_2P_{11}[91] arises; the average P–P bond length and P–P–P angles of the latter compound are essentially the same as in **69** (2.23 Å, 105.9°).[88]

EH calculations[49] for the model compound [CpMo(P_6)MoCp], as for the triple-decker complexes with a central P_5 deck, indicate that the magic number of electrons should be 28; the HOMO–LUMO gap (ca. 0.7 eV) is much smaller here. The crystallographically determined average P–P bond length of **68a**, **b** (Table 4) is ca. 0.07 Å longer

Table 4. $^{31}P\{^1H\}$-NMR data (δ values, 85% H_3PO_4 ext.) and selected bond lengths [A] and angles [°] for triple-decker complexes with a central *cyclo*-E_6-deck.

than indicated by ab initio calculations (6-31G*, 2.096 Å)[64, 81b, 92a, b] for uncoordinated hexaphosphabenzene, *cyclo*-P_6. Whereas *cyclo*-$P_5^{\ominus}$ proves in every respect to be the all-phosphorus analogue of $C_5H_5^{\ominus}$, *cyclo*-P_6 differs from benzene mainly in the σ framework properties (rather than the π electronic effects).

8. Prospects

The coordinative stabilization of numerous substituent-free E_n units of phosphorus, arsenic, antimony and bismuth has proved in some cases to be surprisingly simple. This has led to a rapid growth of the interdisciplinary research area within a short time. Parallel to these developments is an increase in the number of examples that support the original hopes of forging links to organic and solid-state chemistry.

It remains to be seen whether suitable synthetic strategies can be developed (a) to stabilize *cyclo*-P_6 in sandwich complexes and *cyclo*-$P_{7(8)}$ analogously or in triple-decker complexes and (b) to prepare polydecker sandwich complexes[93] or to stabilize coordinatively the uncharged As building blocks of the interesting anions $[As_7Cr(CO)_3]^{3\ominus}$[94] and $^1_\infty[Rb\{NbAs_8\}]^{2\ominus}$.[95] It is not too wild a prediction that clusters and cage molecules with cyclic and acyclic E_n frameworks will soon be discovered with ever increasing frequency. The attempts to illuminate the mechanistic aspects[27b] should be continued, the cyclovoltammetric and magnetic measurements intensified, and the study of catalytic properties taken in hand. The continued active interest of the theoreticians will be a great advantage.

My particular thanks are due to the proficient and dedicated co-workers, whose names are given in the references, and who have worked in this (for us) new research area. We also thank Prof. Kaim (Stuttgart) for spontaneously assenting to collaboration and Dr. G. Wolmershäuser for constant and rapid assistance, readily given, in determining the many X-ray structures. Both have decisively influenced the progress of our research. The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie gave generous financial assistance.

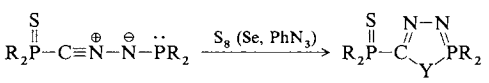
An *N*-Phosphino *C*-Thiophosphinoyl Nitrilimine as a Formal 1,4 Dipole: Synthesis of 1,2,3λ^5-Diaza- and 1,2,4,3λ^5-Triazaphosphinines**

By *Michel Granier, Antoine Baceiredo, Martin Nieger,* and *Guy Bertrand**

Compared to the other known nitrilimines,[1, 2] the stability of the *N*-phosphino *C*-thiophosphinoyl nitrilimine **1** (m.p. 100 °C)[3] was striking. Thus, the question arose as to whether it was possible to use the tricoordinated trivalent phosphorus as a second center of functionality of the molecule. Here, we report that reactions specific to $\sigma^3\lambda^3$ phosphorus can occur and that the phosphorus center can even react faster than the nitrilimine moiety with dipolarophiles, affording new families of heterocycles.

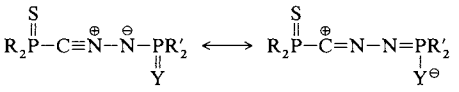
One of the classic reactions of phosphanes is sulfurization with S_8. When **1** was treated with an excess of elemental sulfur at 20 °C, a clean reaction took place and was complete after a few minutes. After workup, 1,3,4,2λ^5-thiadiazaphosphole **2a** was isolated in 85% yield. The disappearance of the nitrilimine skeleton was obvious from the IR spectrum and the cyclic structure was established from the NMR spectra.[4] Addition of selenium led to a similar product **2b**,[4] in 84% yield. The coupling constants $^1J_{P(ring)Se} = 474.7$ Hz and $^2J_{PSe} = 61.7$ Hz provided strong evidence for the structural assignment. Reaction of phenyl azide with **1** resulted in evolution of nitrogen and formation of the 1,2,4,3λ^5-triazaphosphole **2c**[4] in 74% yield.



1: R = iPr$_2$N

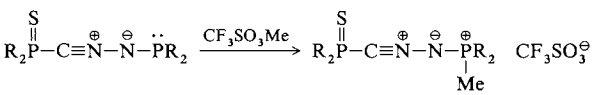
2a, Y = S
2b, Y = Se
2c, Y = NPh

Although adducts **2** formally result from a [4 + 1] cycloaddition process, a two-step mechanism is most likely involved: electrophilic attack of sulfur, selenium, or phenyl azide on the phosphorus lone pair, activated by the electron-rich nitrilimine skeleton, leads to intermediates **3**, which undergo 1,5 electrocyclization.[5] The formation of 1,3,4-thiadiazoles and 1,3,4-triazoles from unstable *N*-thiocarbonyl[6] and *N*-imino nitrilimines,[7] respectively, has already been reported.



3

Definitive proof for primary attack on the phosphorus lone pair was provided by the reaction of **1** with a stoichiometric amount of methyl triflate. A clean reaction led to the new nitrilimine **4**, which was isolated as white crystals (m.p. 100–102 °C, 87% yield) after recrystallization from a THF–ether solution. In contrast with **1**, nitrilimine **4** is poorly soluble in nonpolar solvents and therefore presumably has an ionic structure. The presence of the methyl group at phosphorus was obvious from the ^{1}H NMR spectrum ($\delta = 2.12$, d, $J_{PH} = 13.3$ Hz, 3H) and the ^{13}C NMR spectrum ($\delta = 16.71$, d, $J_{PC} = 87.9$ Hz). The rather high-field ^{31}P NMR chemical shift of the λ^5 phosphorus ($\delta = 28.75$),[3c] the small phosphorus–phosphorus coupling constant ($^4J_{PP} = 6.7$ Hz), and the ^{13}C NMR signal of the quaternary carbon ($\delta = 69.83$, dd, $J_{PC} = 90.3$ and 17.7 Hz) were consistent with the nitrilimine structure.



1 **4**

R = iPr$_2$N

With all the reagents mentioned above, the nitrilimine moiety was not able to compete with the phosphorus lone pair. In contrast, a dipolarophile such as dimethyl acetylenedicarboxylate should react with the 1,3 dipole. In fact, the reaction of **1** with a stoichiometric amount of this alkyne afforded the 1,2,3λ^5-diazaphosphinine **5** as orange crystals (m.p. 147 °C, 90% yield).[4] Although the synthesis of 1,2,4λ^5-diazaphosphinines was recently described[8] and several examples of 1,3,2λ^5-diazaphosphinines are known,[9] no derivatives of type **5** have yet been reported. Thus, an X-ray crystal study was carried out (Fig. 1).[10]

Particularly interesting are the bond lengths in the ring, all of which have a value halfway between a single and a double bond. Moreover, the ring is nearly planar as shown by the values of the deviations from the best plane: P1, 0.078; N2, −0.064; N3, −0.009; C4, 0.064; C5, −0.025; C6, −0.043 Å. The six-membered ring **5** formally results from a [4 + 2] cycloaddition process. However, as mentioned above, an alternative mechanism involving an electrophilic attack of the electron-poor reagent on the phosphorus lone pair of **1**, followed by a 1,6 ring closure of intermediate **6**, seems more likely. Although no examples of 1,6 electrocyclization involving nitrilimine are known, it has been shown that electron-poor alkynes react with phosphanes to give 1,3 dipolar species,[11] and this hypothesis

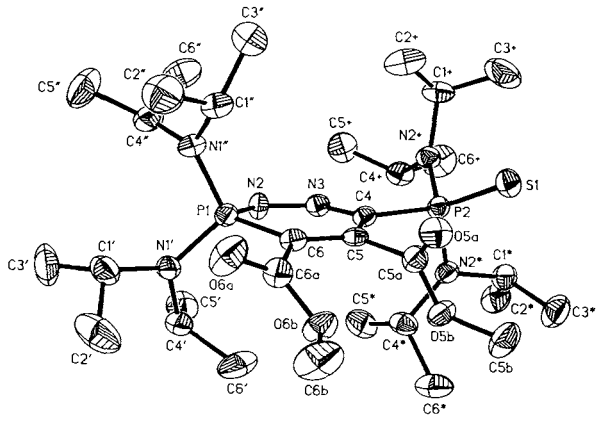

Fig. 1. Molecular structure of **5**. Important bond lengths [Å] and angles [°]: P1-N2 1.650 (4), N2-N3 1.316 (5), N3-C4 1.353 (6), C4-C5 1.421 (6), C5-C6 1.377 (6), C6-P1 1.765 (5), P1-N1' 1.640 (3), P1-N1'' 1.642 (3), C4-P2 1.829 (4), C5-C5a 1.510(7), C6-C6a 1.475 (7); C6-P1-N2 104.8 (2), N1'-P1-C6 115.0 (2), N1''-P1-C6 113.0 (2), N1'-P1-N2 105.9 (2), N1''-P1-N2 110.0 (2), N1''-P1-N1' 107.8 (2), P1-N2-N3 124.3 (3), N2-N3-C4 124.3 (4), N3-C4-C5 123.5 (4), N3-C4-P2 109.6 (3), P2-C4-C5 126.7 (3), C4-C5-C6 123.0 (4), C4-C5-C5a 120.3 (4), C5a-C5-C6 116.7 (4), C5-C6-P1 118.7 (3), C5-C6-C6a 123.1 (4), C6a-C6-P1 117.7 (3).

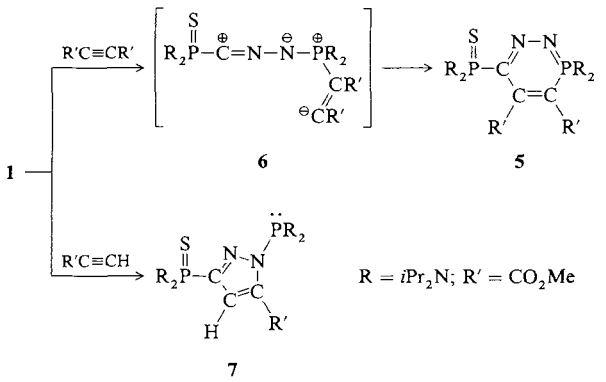
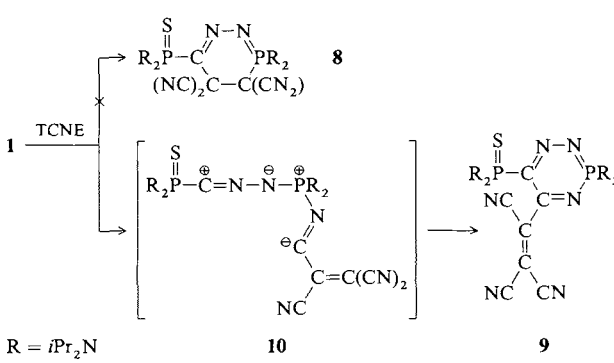
well rationalizes the difference in reactivity observed between dimethyl acetylenedicarboxylate and methyl acetylenecarboxylate, the latter of which led to **7** via a classical cycloaddition process.[3a]



Another example of a reaction where the phosphorus lone pair reacts faster than the 1,3 dipole is the reaction of **1** with tetracyanoethylene (TCNE). Moreover, although addition and cycloaddition reactions of tetracyanoethylene usually proceed with high selectivity at the carbon–carbon double bond,[12] we did not obtain the expected adduct **8** but instead the 1,2,4,3λ⁵-triazaphosphinine **9** (80% yield).[4] This six-membered ring formally results from a [4 + 2] cycloaddition reaction involving a nitrile group of the reagent. Very few examples of [3 + 2][13] and [4 + 2][14] cycloaddition with the carbon–nitrogen triple bond of this electron-poor olefin have been reported. On the other hand, the attack of the phosphorus lone pair on the nitrogen of the nitrile, instead of at carbon, can be explained by the structure of intermediate **10**, where the negative charge can be delocalized. The only previous examples of triazaphosphinines were the 1,3,5,2λ⁵-triazaphosphinines.[15]



It is clear from these results and those of *Regitz* et al.[8] that the scope of application of dipoles having nitrilium betaine structure can be enlarged enormously by introducing the phosphanyl group.

Synthesis of Two Tl^{III} Diacetonyl Compounds and Crystal Structure of $[Tl\{CH_2C(O)Me\}_2(\mu\text{-}CF_3SO_3)(bpy)]_2$ **

By *José Vicente,* José-Antonio Abad, Gabriel Cara,* and *Peter G. Jones**

Despite the interest in thallation reactions in organic chemistry,[1] those involving ketones have only recently been studied;[2] the synthesis in aqueous solutions of Tl^{III} monoketonyl species, $[Tl\{CH_2C(O)R\}X_2]$, was reported, but not their structures. Diketonyl species, $[Tl\{CH_2C(O)R\}_2]^{\oplus}$, could also be detected in solution, but they were always accompanied by the monoketonyl species.

During our work on the synthesis of Tl^{III} monoaryl compounds,[3] some evidence was obtained for the formation of Tl acetonyl(aryl) compounds; this prompted us to attempt to isolate acetonyl derivatives starting from Tl^{III} salts. We had already obtained Au^{III} acetonyl complexes by C–H activation of acetone with Au^{III} 2-(phenylazo)phenyl complexes.[4] There is, as far as we are aware, only one previous report (which did not involve an X-ray structure) of the isolation of a metal diacetonyl complex.[5–7] We report here the isolation of two Tl^{III} diacetonyl derivatives and the X-ray structural characterization of one of them, a diacetonyl complex. An additional unusual structural feature is the presence of coordinated triflate ions.

Addition of trifluoromethanesulfonic acid to a solution of thallium(III) trifluoroacetate in acetone (1.25:1) at room temperature results in formation of the diacetonyl complex **1**,[8] which reacts with 2,2′-bipyridine (bpy) to give **2**.[9] The solid-state IR spectra of the two complexes show bands at similar wave numbers in the regions expected for ν(CO), $\nu(CF_3)$, and $\nu(SO_3)$.[8–10] The ^1H NMR spectra show a singlet (Me) and a doublet (CH_2), the latter coupled with ^{203}Tl and ^{205}Tl nuclei with $^2J(Tl, H)$ values consistent with the presence of two acetonyl groups C-bonded to the Tl atom.[2] Both complexes behave as 1:1 electrolytes in acetone solution, probably because of formation of the solvent complexes $[Tl\{CH_2C(O)Me\}_2(Me_2CO)_n](CF_3SO_3)$ and $[Tl\{CH_2C(O)Me\}_2(bpy)(Me_2CO)_n](CF_3SO_3)$.

$$Tl(CF_3CO_2)_3 + CF_3SO_3H + 2\,Me_2CO \rightarrow 3\,CF_3COOH + [Tl\{CH_2C(O)Me\}_2(CF_3SO_3)]\quad \mathbf{1}$$

$$\mathbf{1} + bpy \rightarrow [Tl\{CH_2C(O)Me\}_2(\mu\text{-}CF_3SO_3)(bpy)]_2\quad \mathbf{2}$$

The crystal structure of **2** reveals distorted six-coordination of the thallium atom (Fig. 1). The ligand sphere may conveniently be regarded as consisting of three components: (1) strong, almost linear (160.8°) coordination by the acetonyl carbons [Tl-C4 216.1(8), Tl-C1 217.1(7) pm] in a manner reminiscent of dimethylthallium(III), (2) longer contacts to the N atoms of the bipy ligand [Tl-N1 245.6(5), Tl-N2 250.0(4) pm], and (3) weak coordination by the oxygen atoms of two triflate ions [Tl-O3 273.9(6), Tl-O5′ 280.6(4) pm]. These weak contacts involve the formation of centrosymmetric dimers. The bond lengths in the acetonyl groups [C=O 122.2, 122.7(8) pm, H_3C-C 148.6(10), 151.1(9) pm, H_2C-C 147.4(9), 148.1(8) pm] strongly indicate the C-bonded nature of the ligand, and this was confirmed by direct location of all H atoms except those at C3. The more usual type of ketone–metal interactions involve metal–oxygen bonds.[12]

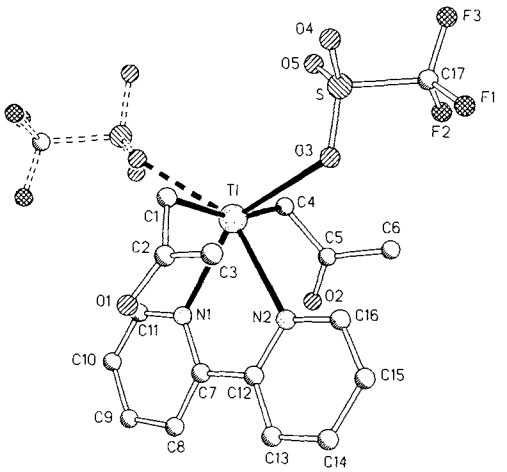

Fig. 1. The structure of **2** in the crystal. Radii are arbitrary; H atoms omitted for clarity. The coordination sphere at thallium is completed by a symmetry-generated triflate ion (indicated by dashed bonds).

The similar IR spectra of **1** and **2** indicate that the triflate ligand also acts as a bridging ligand in **1**.

Experimental Procedure

1: A solution of $Tl(CF_3CO_2)_3$ (500 mg, 0.92 mmol) in acetone (8 mL) was stirred with CF_3SO_3H (2 drops, ca. 1.15 mmol) at room temperature for 1 h. On partial evaporation of the solvent and addition of diethyl ether, **1** precipitated as a white solid (satisfactory elemental analyses). Yield 320 mg (76%).
2: 2,2′-bipyridine (26 mg, 0.16 mmol) was added to **1** (75 mg, 0.16 mmol) in acetone (8 mL). The resulting mixture was stirred at room temperature for 15 min and the solution evaporated to ca. 2 mL. Addition of diethyl ether resulted in precipitation of complex **2** as a white solid (satisfactory elemental analyses). Yield 83 mg (81%).

Organometallic Host–Guest Systems Representing Novel Charge-Transfer "Ion Pairs" with Three-Dimensional Electron-Donor Networks**

By *Stefan Eller, Martin Adam*, and *R. Dieter Fischer**

Dedicated to Professor Helmut Behrens on the occasion of his 75th birthday

Recently, we described several examples of compounds of type A, a widely variable new class of three-dimensional (3D) host–guest systems involving guest cations $G^{\oplus}$ like

$$[(G^{n\oplus})_{1/n}(Me_3Sn^{IV})_3M^{II}(CN)_6]_\infty \quad M = Fe, Ru \quad \text{(type A)}$$

$NR_4^{\oplus}$ (R = alkyl), $[(C_5H_5)_2Co]^{\oplus}$, and even $Me_3Sn^{\oplus}$.[1] Here, we wish to present the first type-A[2] systems with $G^{2\oplus}$ = methyl- and benzylviologen ($MV^{2\oplus}$ and $BV^{2\oplus}$, respectively), as well as with their reduced forms $G^{\oplus} = MV^{\bullet\oplus}$ and $BV^{\bullet\oplus}$.[3] Rod-shaped $MV^{n\oplus}$, and even more $BV^{n\oplus}$ (n = 1,2), requires a maximum of space in just *one* direction. Moreover, $MV^{2\oplus}$ and $BV^{2\oplus}$ display notable electron affinities and thus a tendency to form charge-transfer (CT) adducts with numerous anionic[4] and uncharged[5] electron donors.[3b]

Compounds **1** ($G^{2\oplus} = MV^{2\oplus}$) and **2** ($G^{2\oplus} = BV^{2\oplus}$) are accessible in high yields via ion exchange[1, 6] according to Equation (a). The "alloyed" host–guest systems **3** may be

$$[(Me_3Sn)_4M(CN)_6]_\infty \xrightarrow[-[Me_3Sn(H_2O)_2]^{\oplus}]{0.5\,G^{2\oplus}/H_2O} \underset{\mathbf{1,\ 2}}{[(G^{2\oplus})_{0.5}(Me_3Sn)_3M(CN)_6]_\infty} \quad \text{(a)}$$

a, M = Fe; **b**, M = Ru; **c**, M = Os

prepared correspondingly from the well-characterized precursors $[(Me_3Sn)_4Fe_{1-x}Ru_x(CN)_6]_\infty$.

$$[(MV^{2\oplus})_{0.5}(Me_3Sn)_3Fe_{1-x}Ru_x(CN)_6]_\infty \quad \mathbf{3a},\ x = 0.50;\ \mathbf{3b},\ x = 0.25$$

Suspension of **1** and **2** in an aqueous $Na_2S_2O_4$ solution affords within a few minutes the likewise insoluble, pure type-A systems **4** and **5**, respectively, containing $G^{\bullet\oplus}$ guest ions [Eq. (b)].[6, 8] Alternatively, **4** and **5** may be prepared by

$$2\underset{\mathbf{1,\ 2}}{[(G^{2\oplus})_{0.5}(Me_3Sn)_3M(CN)_6]_\infty} \xrightarrow[-7\,HSO_3^{\ominus}]{7/2\,S_2O_4^{2\ominus}} \underset{\mathbf{4,\ 5}}{[(G^{\bullet\oplus})(Me_3Sn)_3M(CN)_6]_\infty} + [M(CN)_6]^{4\ominus} + 3\,Sn^{2\oplus} + \text{organic products} \quad \text{(b)}$$

"ion exchange"[6] starting from $[(G^{\oplus})(Me_3Sn)_3M(CN)_6]_\infty$ (G = NH_4, Et_4N, Me_3Sn,[1] and even 1/2 MV) and $MV^{\bullet\oplus}$ or $BV^{\bullet\oplus}$ radical ions generated in situ. The NIR/VIS absorption spectra of **4** and **5** strongly resemble those of $(MV^{\bullet\oplus})(PF_6)$ and $(BV^{\bullet\oplus})(PF_6)$, respectively (Table 1). The ESR spectrum of polycrystalline **4b**[9] reflects the involvement of only *one* type of radical ion. Exposure of pure **4a** and **4b** to air results in less abrupt changes[10] than for the apparently more sensitive, blue host–guest system "{zeolite Y/$MV^{\bullet\oplus}$}".[11]

A single-crystal X-ray study of **1b**,[12] the first well-crystallizing type-A species,[13, 14] indicates that all $MV^{2\oplus}$ guest ions are encapsulated in equally shaped cavities of "finite dimensions" spanned by a 3D network of nonlinear $\{Ru-C\equiv N-Sn-N\equiv C\}_\infty$ chains regularly interlinked by the octahedrally coordinated Ru^{II} ions (Fig. 1). The short-

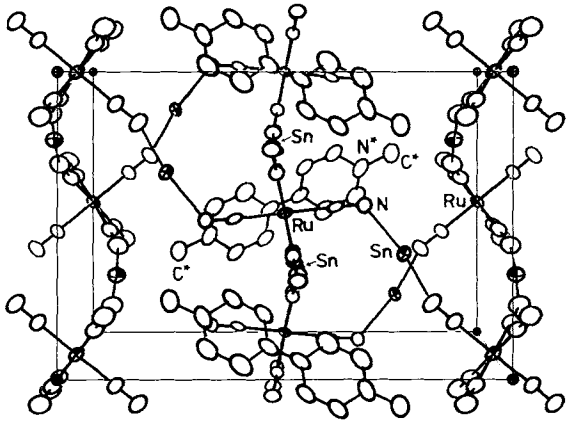

Fig. 1. Unit cell [12] of **1b** (ORTEP). Some atoms of the $MV^{2\oplus}$ guest ion have been marked by an asterisk; the CH_3 groups of all Sn atoms have been omitted.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank *S. Schaugsdat* for her assistance, for example, in the growing of single crystals, Prof. *J. Voß* for measuring an ESR spectrum, and Prof. *U. Behrens* for critical discussion of the X-ray analysis.

est host···guest separations may be deduced from the smallest interatomic distances found, that is, 2.5 ± 0.2 Å for C(CN)···C(MV) and N(CN)···C(MV) (Sn···C(MV) and Ru···C(MV) > 3.5 Å). In view of the different spatial demands of $MV^{n\oplus}$ and $BV^{n\oplus}$ and the variable host/guest ratio (2 for **1** and **2**, but 1 for **4** and **5**), the architecture of the polymeric host network of **1**, **2**, **4**, and **5** is expected to undergo characteristic variations.

Whereas the host–guest system "{zeolite Y/$MV^{2\oplus}$}" has been reported[5] to incorporate spontaneously various π-electron-rich arenes D to form "{zeolite Y/($MV^{2\oplus}$·D)}" with colored CT complexes $MV^{2\oplus}$ · D as guests, **1** and **2** do not react in a corresponding fashion. The pronounced tendency of dissolved $MV^{2\oplus}$ and $[Fe(CN)_6]^{4\ominus}$ ions, for example, to associate to give comparatively stable CT "ion pairs"[4] suggests that the strikingly colored solids **1**–**3** (Table 1) are indeed genuine CT complexes.

Table 1. Properties of the solids **1**–**5** and of some dissolved samples of spectroscopic relevance.

Compd	$G^{n\oplus}$	M	Color	CT maximum [a, b] $\tilde{\nu}$ [cm^{-1}]	System for comparison	CT maximum [a] $\tilde{\nu}$ [cm^{-1}]
1a	$MV^{2\oplus}$	Fe	blue	15870		18870 [4]
1b	$MV^{2\oplus}$	Ru	brick-red	21740		24040 [4]
1c	$MV^{2\oplus}$	Os	violet	20000	$G^{2\oplus}$/	22730
2a	$BV^{2\oplus}$	Fe	lime green	17860	$[M(CN)_6]^{4\ominus}$/	18180

4a	$MV^{\cdot\oplus}$	Fe	dark blue	25000 and		25320 and
4b	$MV^{\cdot\oplus}$	Ru	dark blue	16000	$G^{\cdot\oplus}$ (PF_6)	16540
5a	$BV^{\cdot\oplus}$	Fe	dark violet	26670 and	/$NCCH_3$	25420 and
5b	$BV^{\cdot\oplus}$	Ru	dark violet	17860		16260

[a] **1**–**3**, *inter*molecular electron transfer; **4**–**5**, *intra*molecular excitations of $G^{\cdot\oplus}$ (principal bands). [b] Solid samples (KBr pellets). [c] Solution of $(MV)Cl_2 \cdot H_2O$ or $(BV)Br_2$ and $K_4[M(CN)_6]$ (1/1) in H_2O. [d] Solution of $(MV)Cl_2 \cdot H_2O$, $K_4[Fe(CN)_6]$, and $K_4[Ru(CN)_6]$ (1/1/1) in H_2O. [e] Salt **6b** dissolved in H_2O.

Actually, the NIR/VIS absorption spectra of **1a**–**1c** (Fig. 2), as well as those of **2a**–**2c** (Table 1), display one distinct potential CT band which is absent in the spectra of their components. The λ_{max}(CT) values of **1** and **2** may reasonably be correlated with the oxidation/reduction potentials of the couples $[M^{II}(CN)_6]^{4\ominus}/[M^{III}(CN)_6]^{3\ominus}$ [15a] and $G^{\cdot\oplus}/G^{2\oplus}$,[15b] respectively. However, the *bathochromic* shift of λ_{max}(CT) of **1** and **2** (compared with λ_{max}(CT) of corresponding ion pairs in aqueous solution[4]) is surprising. It is well documented[16] that, for example, the Lewis acid/base neutralization shown in Equation (c) causes a notable de-

$$[M^{II}(CN)_6]^{4\ominus} + 6L^q \rightarrow [M^{II}(CNL)_6]^{6q-4} (0 \le q \le 1) \quad (c)$$

crease in the electron-donor strength of the central d^6 metal ion. The influence of the Lewis acid L^q present in **1** and **2** (formally, L = 1/2 $Me_3Sn^{\oplus}$ with $q = 1/2$) should thus favor a *hypso*chromic shift of λ_{max}(CT). Further insight has so far been hampered by the poorly structured solid-state absorption spectra[17] of the easily accessible new salts $(BV^{2\oplus})_2[M^{II}(CN)_6] \cdot 3H_2O$ (**6a**–**c**), and the appearance of no more than one broad CT absorption band also in the spectra of the "alloyed" systems **3** (Table 1, Fig. 2).

Interestingly, the transition from the "CT sandwich" "bis(*p*-phenylene)-[34]crown-10/$MV^{2\oplus}$" ≙ {DAB/$MV^{2\oplus}$/DAB} (DAB = *p*-dialkoxybenzene)[18] to the "inverted" (with respect to the donor and acceptor components) CT sandwich {$MV^{2\oplus}$/DAB/$MV^{2\oplus}$}(i.e., "cyclobis(methylviologen-*p*-phenylene)/DAB" with DAB = *p*-dimethoxybenzene[19]) is also accompanied by a strong *bathochromic* shift of the main CT band (436 vs. 478 nm[20]). Possibly, *collective phenomena* may operate not only in the latter cyclodimer[21] but likewise in the 3D polymers **1**–**3**, strengthening both the acceptor (coupled pair of $MV^{2\oplus}$ ions) and donor (coupled $[M^{II}(CN)_6]^{4\ominus}$ units) capacity. One illustrative example of an ensemble of six arene units that can be *collectively* oxidized in spite of the "isolation" of each individual π system by CH_2 and $(CH_2)_3$ bridges is "spheric cryptophane".[22] The *spontaneously* occurring ion exchange[6] [Eq. (d), see

$$\mathbf{1}(\text{solid}) + MV^{\cdot\oplus} \xrightarrow{H_2O} \mathbf{4}(\text{solid}) + 0.5\ MV^{2\oplus} \quad (d)$$

above[6, 23]] suggests some extra stabilization of the $MV^{\cdot\oplus}$ ions encapsulated in **4**.[24] This feature is also likely to contribute to the bathochromic shift of the CT excitation (e).

$$\mathbf{1} \xrightarrow{x\,h\nu} [(MV^{\cdot\oplus})_x(MV^{2\oplus})_{0.5-x}(Me_3Sn)_3M^{III}_xM^{II}_{1-x}(CN)_6]_\infty \quad (e)$$

$x \ll 0.5$.

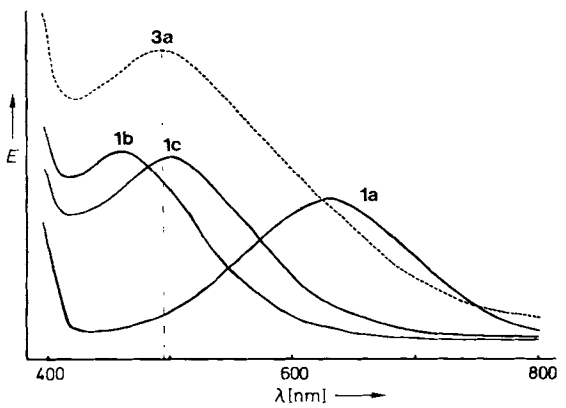

Fig. 2. Absorption spectra of **1a**–**1c** and of **3a** within the range of their CT bands (samples, KBr pellets; Cary 17 spectrophotometer). E = extinction.

Experimental Procedure

1–**3** (typical procedure): 0.3 mmol of $[(Me_3Sn)_4M(CN)_6]_\infty$ (cf. [1]) was suspended in a solution of 0.3 mmol of $(MV)Cl_2 \cdot H_2O$ (Fluka) or $(BV)Br_2$[7] in 40 mL of H_2O. After stirring (room temperature, 12 h), filtration, washing with H_2O, and drying under high vacuum, analytically pure products were obtained (correct elemental analyses for C, H, N, Sn, and Fe in all cases). Yields between 82 (**1a**) and 90% (**2b**, **2c**); decomposition temperatures between 200 (**1a**) and 245 °C (**2b**).

$[(Me_3Sn)_4Fe_{0.5}Ru_{0.5}(CN)_6]_\infty$ (**3a**): Addition of a solution of Me_3SnCl (0.85 g, 4.26 mmol) in 10 mL of H_2O to a solution of $K_4[Fe(CN)_6]$ (0.19 g, 0.53 mmol) and $K_4[Ru(CN)_6]$ (0.22 g, 0.53 mmol) in 15 mL of H_2O; after stirring (5 h), filtration, washing with H_2O, and drying (high vacuum, room temperature), 0.90 g (0.93 mmol) of analytically pure product was obtained (correct elemental analyses for C, H, N, Sn, and Fe; yield 87%; decomposition temperature, 230 °C).

4 and **5** (typical procedure): Suspension of 0.3 mmol of **1** or **2** in a solution of ca. 3.0 mmol of $Na_2S_2O_4$ (Merck-Schuchardt) in 30 mL of O_2-free H_2O under an atmosphere of N_2 resulted in a color change to dark blue and dark violet, respectively, within a few minutes. Analytically pure products were isolated in practically quantitative yields (when referred to $MV^{\cdot\oplus}$ and $BV^{\cdot\oplus}$, respectively) after prolonged stirring (3 h, room temperature), filtration, washing with a small amount of H_2O, and drying (high vacuum, 8 h); correct elemental analyses for C, H, N, Sn and Fe. The filtrate, which still contained $S_2O_4^{2\ominus}$ anions, was free of any $MV^{\cdot\oplus}$ or $BV^{\cdot\oplus}$ ions, but not of the anions $[Fe(CN)_6]^{4\ominus}$ or $[Ru(CN)_6]^{4\ominus}$.

$(BV^{2\oplus})_2[Ru(CN)_6] \cdot 3H_2O$, **6b**: A solution of $(BV)Br_2$ (0.24 g, 0.48 mmol) [7] in 15 mL of H_2O was added to a solution of $K_4[Ru(CN)_6]$ (0.10 g, 0.24 mmol) in 5 mL of H_2O. The instantaneously resulting violet precipitate was separated from the filtrate, washed with a small amount of H_2O, and dried (high vacuum, 8 h). Yield, 74%; correct elemental analyses for C, H, N, and O.

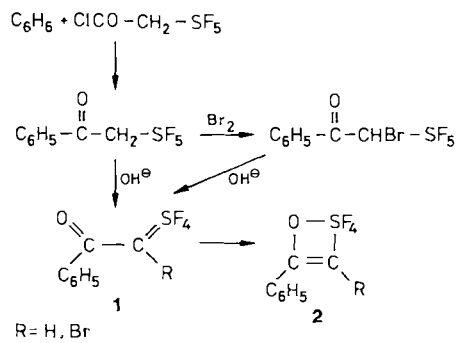
[20] Even concentrated solutions of $(MV)Cl_2$ and *p*-dimethoxybenzene in $NCCH_3$ (2:1) do not show any clear CT band.
[21] In the former cyclodimer, the two DAB units are linked via fairly long, and thus optimally "isolating", $(CH_2)_n$ bridges.
[22] A. Renault, D. Talham, J. Canceill, P. Batail, A. Collet, J. Lajzerowicz, *Angew. Chem. 101* (1989) 1251; *Angew. Chem. Int. Ed. Engl. 28* (1989) 1249.
[23] For M = Ru (**1b** → **4b**), the reaction is accompanied by the following color changes: red → blue (suspended solid) and blue → colorless (aqueous solution).
[24] The redox potential E° of the pair $MV^{\cdot\oplus}/MV^{2\oplus}$ is also known to vary with the solvent: see C. L. Bird, A. T. Kuhn, *Chem. Soc. Rev. 10* (1981) 49.

Isomerization of Benzoylalkylidene Sulfur Tetrafluorides C_6H_5-CO-CR=SF_4 to Dihydrooxathietes**

By *Thomas Henkel, Thomas Krügerke*, and *Konrad Seppelt**

Of the six known alkylidene sulfur tetrafluorides RR'C=SF_4, only F-CO-CH=SF_4 bears a C-functional group.[1] In the crystal at −168 °C, this compound has a fully planar molecular framework with C–S and C–O double bonds arranged in a *cis* fashion.[2] Like most alkylidene sulfur tetrafluorides, it exhibits considerable stability. In attempts to prepare the benzoyl-substituted compounds C_6H_5-CO-CR=SF_4 (**1**), however, they could only be detected as intermediates by ^{19}F NMR (R = H) or were not observed at all (R = Br), since they isomerize immediately to the isolable oxathietes **2**. Because the ^{19}F NMR spectra of



isomers **1** and **2** reveal an A_2BC system in each case, signal assignment requires plausible assumptions regarding the chemical shifts and coupling constants. This is possible for the alkylidene sulfur tetrafluorides, but reference spectra are lacking for the new *S*-tetrafluorodihydrooxathietes. The X-ray structure analysis (Fig. 1) unambiguously established the presence of the unsaturated four-membered ring.[3]

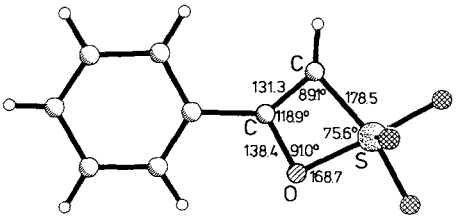


Fig. 1. Molecular structure of **2**, R = H, at −153 °C (XP plot).

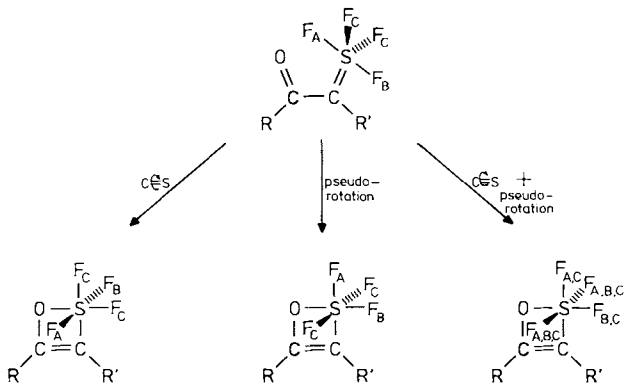
Owing to the special geometry of alkylidene sulfur tetrafluorides such as **1**, where the substituents at carbon lie in the plane defined by the sulfur and the axial fluorines, an approach of the carbonyl oxygen to the sulfur requires that one axial fluorine be pushed aside. The necessary twisting around the C–S double bond can occur in three ways (Scheme 1): rotation, pseudorotational[4] pairwise interchange of axial and equatorial positions, or a combination of

[*] Prof. Dr. K. Seppelt, Dipl.-Chem. T. Henkel, Dr. T. Krügerke
Institut für Anorganische und Analytische Chemie der Freien Universität
Fabeckstrasse 34–36, D-1000 Berlin 33

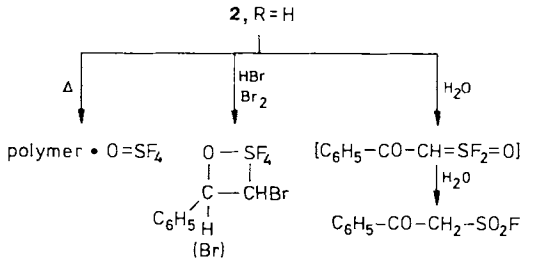
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

both mechanisms. The last possibility is assumed in unsubstituted $H_2C{=}SF_4$ for the methylene torsion, which, owing to the high barrier of 100 kJ mol^{-1}, cannot be observed by NMR spectroscopy.[1]



Scheme 1. Possible mechanism for the isomerization **1** → **2**. The displacement of the axial fluorine can occur by twisting around the C–S double bond (left), by Berry pseudorotation of the fluorines (middle), or by a combination of the two mechanisms (right). The mechanisms could be distinguished if labeling of fluorine were experimentally possible.

The ready isomerization **1** → **2** contrasts with the fact that the butadiene–cyclobutene isomerization, which almost always occurs in the opposite direction, proceeds by conrotatory twisting around the two double bonds for symmetry reasons and therefore requires a high activation energy (130–155 kJ mol^{-1}).[5, 6] 1,2-Dithiones undergo reversible



transformation to dihydro-1,2-dithietes without any symmetry change and with about half of this activation energy.[7]

The four-membered ring is not opened upon addition of HBr or Br_2 to **2**, but it is cleaved by water. Thermolysis of **2** results in elimination of SOF_4.

Experimental Procedure

C_6H_5-CO-CH_2-SF_5: $AlCl_3$-catalyzed acylation of C_6H_6 with ClCO-CH_2-SF_5 at 0 °C followed by classical workup, distillation at 63 °C/0.6 mbar, sublimation under high vacuum at −30 °C; 38% yield, colorless solid, m.p. 38 °C. ^{19}F NMR (84.25 MHz, $CFCl_3$): AB_4X_2 spectrum, δ = 82.2(A), 73.8(B), ^2J(AB) = 153.0, ^3J(BX) = 7.4 Hz. ^1H NMR (90 MHz, TMS): δ = 5.4(CH_2), 7.7–8.6 (C_6H_5).

C_6H_5-CO-CHBr-SF_5: Bromination of C_6H_5-CO-CH_2-SF_5 at 30 °C in CCl_4 under UV irradiation in Pyrex; yield 23%, colorless solid, m.p. 52 °C. ^{19}F NMR: AB_4Xspectrum, δ = 77.4(A), 65.1(B), ^2J(AB) = 148.7, ^3J(BX) = 5.5 Hz. ^1H NMR: δ = 7.0(CH), 7.8–8.6(C_6H_5).

2: C_6H_5-CO-CHR-SF_5 (1 g) in 50 mL of pentane was stirred with NaOH (5 g) at room temperature for 2–3 d. The reaction was monitored by ^{19}F NMR spectroscopy. For R = H, **1** was detected as an intermediate (A_2BCX spectrum: δ = 63.3(A), 58.2(B), 57.8(C), ^2J(AB) = 166.1, ^2J(AC) = 168.5, ^2J(BC) = 9.9, ^3J(AX) = 8.8, ^3J(BX) = −39.4, ^3J(CX) = −13.3 Hz). After complete reaction, the mixture was filtered, the filtrate cooled to −78 °C, and the pentane removed under oil-pump vacuum. **2**, R = H: Colorless solid, which slowly decomposes at 0 °C; recrystallized from ether. IR(CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 1636 (C=C), 877, 810, 788 (S-F). ^{19}F NMR: A_2BCX spectrum, δ = 66.9 (A), 70.2 (B), 57.5 (C), ^2J(AB) = 137.4, ^2J(AC) = 112.1, ^2J(BC) = 135.4, ^3J(AX) = 1.7, ^3J(CX) = 4.7 Hz. ^1H NMR: δ = 7.1(CH), 8.0 (C_6H_5). **2**, R = Br: Colorless solid. ^{19}F NMR: A_2BC spectrum, δ = 61.8(A), 66.5(B), 39.5(C), ^2J(AB) = 147.5, ^2J(AC) = 119.2, ^2J(BC) = 133.1 Hz. MS (80 eV, EI): *m/z* 304, 306 ($M^{\oplus}$, 21%), 105 ($C_7H_5O^{\oplus}$, 27), 89 ($SF_3^{\oplus}$, 100) and smaller fragments.

C_6H_5-CO-CH_2-SO_2F: **2**, R = H, was hydrolyzed by heating it in aqueous acetone at 56 °C. An ^{19}F NMR spectrum assignable to C_6H_5-CO-CH=SF_2=O was recorded during the reaction (δ = 59.7 (S-F), ^3J(HF) = 2.7 Hz). Removal of the solvent and recrystallization from CCl_4 gave C_6H_5-CO-CH_2-SO_2F in quantitative yield. Colorless solid, m.p. 83–86 °C. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 689(C=O), 1413, 1201 (S=O) 801 (S-F). MS (80 eV, EI): *m/z* 202 ($M^{\oplus}$, 31%), 105 ($C_7H_5O^{\oplus}$, 100) and smaller fragments. ^{19}F NMR: δ = 64.0 (S-F), ^3J(HF) = 2.4 Hz. ^1H NMR: δ = 5.5(CH_2), 7.9–8.6 (C_6H_5)

Stereospecific Insertion of the Carbene Ligand of a Fischer Carbene Complex into Olefinic C–H Bonds**

By *Anette Wienand* and *Hans-Ulrich Reissig**

The addition of the C(OMe)Ph ligand of **1** to α,β-unsaturated esters **2** to give cyclopropanes **3** was first described 20 years ago.[1] The synthetic potential of donor–acceptor-substituted cyclopropanes,[2] like **3**, prompted us to investigate the scope of this cyclopropanation method[3] as well as the mechanism of the carbene transfer.[4] We have found that, in

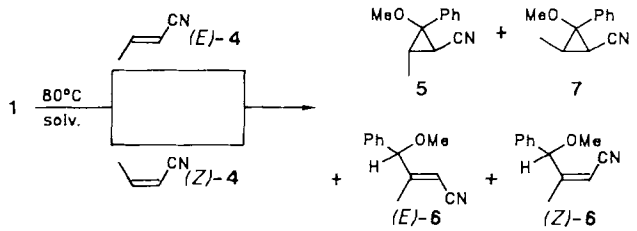
reactions of **1** with *E*- and *Z*-crotononitrile, *E*-**4** and *Z*-**4**, respectively, the carbene ligand of **1** undergoes unprecedented stereospecific[5] insertion into the β-C–H bond of the olefin with inversion of double-bond configuration.

Heating a solution of **1** and *E*-**4** in cyclohexane (80 °C, 23 h) affords a mixture of four products (yield 71 %). More than 90 % of the mixture consists of the insertion product *E*-**6**,[6] whereas *Z*-**6** and the expected cyclopropanes **5** and **7**



are only formed in small amounts (Table 1). On the other hand, use of *Z*-**4** gives *Z*-**6**[6] as the main product (60 % of the mixture). The remaining products consist of only 4 % of the configurationally isomeric insertion product *E*-**6** and, according to NMR spectroscopy, 15 and 21 % of the cyclopropanes **5** and **7**, respectively.

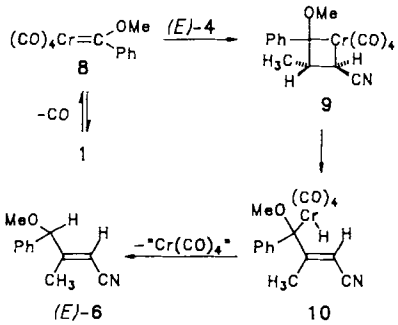
Table 1. Reactions of chromium carbene complex **1** with the crotononitriles *E*-**4** and *Z*-**4** in cyclohexane or acetonitrile (80 °C, 13–28 h, nitrogen atmosphere, ca. 0.5 M[a]).

Olefin	Solvent[b]	Product distribution [%] 5	*E*-6	*Z*-6	7	Overall yield [%]
E-4	C_6H_{12}	3	92	2	3	71
E-4	CH_3CN	77	16	–	7	35
Z-4	C_6H_{12}	15	4	60	21	67
Z-4	CH_3CN	24	2	9	65	32

[a] The product distribution was determined by ^1H NMR spectroscopy (300 MHz; estimated error ± 3 %); the components were separated or enriched by HPLC, so that an unambiguous structural assignment could be made from the ^1H and ^{13}C NMR spectra. Only one of the possible isomers of **5** is formed; **7** is obtained as a mixture of diastereomers (position of Ph/OMe); all chiral products are racemic mixtures. [b] When **1** is allowed to react with *E*-**4** or *Z*-**4** in the absence of solvent (ca. 4 h, 90 °C), the resulting product distribution lies between those found in C_6H_{12} and CH_3CN. No fundamental changes are found with respect to the stereospecificity of the formation of **6**.

The insertion of the carbene ligand into the olefinic β-C–H bond is also highly stereospecific in acetonitrile as solvent: *E*-**6** is obtained preferentially from *E*-**4**, and *Z*-**6** from *Z*-**4**. However, the proportion of cyclopropanes obtained in this solvent is much greater and the overall yield much lower (Table 1). Control experiments established that, under the reaction conditions, (1) the olefins are practically configurationally stable (maximally 5 % $Z \rightarrow E$ isomerization), (2) cyclopropanes **5** and **7** are not transformed into their acyclic isomers *E*/*Z*-**6**, and (3) no hydrogen is abstracted from the solvent (no D incorporation from C_6D_{12} as solvent).

The product distribution in Table 1 clearly shows that the insertion reaction is stereospecific with > 90 % inversion of the olefin configuration, whereas the cyclopropane formation is largely nonstereospecific. Therefore, these two reactions of **1** presumably proceed via different pathways. We will describe elsewhere a cyclopropanation mechanism that is consistent with these findings.[4] Here, we wish to make a (speculative) proposal regarding the mechanism of the stereospecific carbene insertion reaction. Loss of a CO ligand from **1** gives **8**, which reacts with *E*-**4**—presumably via a metal–olefin complex—to afford the chromacyclobutane **9**. Rearrangement of **9** to give the hydridochromium complex **10** may be regarded as a syn elimination of the β-H atom[7] and results in the observed inversion of olefin configuration. Finally, reductive elimination affords *E*-**6**.



Semmelhack and *Tamura* postulated a corresponding mechanism for the reactions of the iron carbene complexes $[(CO)_4FeC(OEt)R]$, which are analogous to **1**, with methyl acrylate and styrene.[8] However, neither their examples nor the observation of CH insertion products as minor compounds in previously reported reactions of olefins with **1** or other chromium carbene complexes[9] allow a prediction of the stereochemical course of the reaction. The inversion of olefin configuration described here is a strong indication for the involvement of metallacyclobutanes such as **9** and for a β-syn elimination. If the formation of the insertion product **6** occurred by direct attack of **8** on the C–H bond, then retention of the olefin configuration would have been expected.[10] Still unanswered is the question why insertion of the carbene ligand of **1** into the crotononitriles *E*/*Z*-**4** so strongly predominates over cyclopropanation. Presumably, the nitrile group plays a decisive, yet still unexplained, role.

Table 2. ^1H and ^{13}C NMR data (300 and 75.5 MHz, respectively, $CDCl_3$) for *E*-**6** and *Z*-**6**.

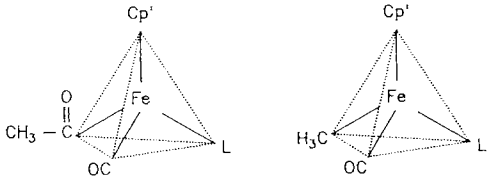
Catalytic Hydrosilylation or Hydrogenation at One Coordination Site of [Cp'Fe(CO)(X)] Fragments**

By Henri Brunner and Konrad Fisch*

The mechanisms proposed for the hydrosilylation of olefins and ketones require that the catalytically active transition-metal complex have three coordination sites, two for oxidative Si–H addition and one for binding of the unsaturated substrate.[1–3] These reactions often result in formation of byproducts, for example, silyl enol ethers from enolizable ketones.[4, 5] Here we describe the use of iron complexes as homogeneous catalysts for the hydrosilylation of acetophenone with diphenylsilane. The reaction takes place at one coordination site and does not lead to byproducts.

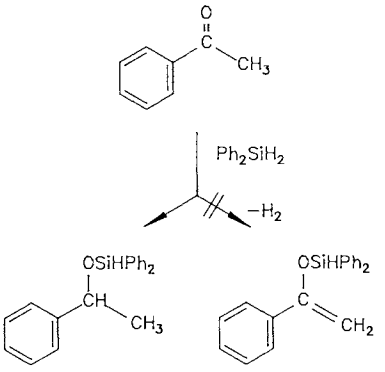
The acetyl complexes (+)- and (−)-**1**/**2**,[6] the methyl complexes (+)- and (−)-**3**–**5**,[7] and $[CpFe(CO)_2(CH_3)]$ were used as catalysts.[8]



1,2 **3-5**

1,3: Cp' = cyclopentadienyl (Cp)
2,4: Cp' = indenyl (Ind)
5: Cp' = 1-*t*Bu-indenyl
L = (*S*)-(+)-$(C_6H_5)_2P-N(CH_3)-CH(CH_3)C_6H_5$

When equimolar amounts of acetophenone and diphenylsilane are heated in the presence of 0.5–1.0 mol % of the iron complex, the hydrosilylation begins after an induction period.[9] The temperatures at which the reaction proceeds at a measurable rate differ considerably, depending on the catalyst. Surprisingly, they correlate with the temperatures necessary for the epimerization at the Fe atom of the catalyst (80 and 60 °C for acetyl complexes **1** and **2**,[10] respectively; 70 and 50 °C for methyl complexes **3** and **4**,[11] respectively). Reaction for 24 hours at these temperatures always results in quantitative formation of the silylated 1-phenylethanol **6**. In no case was silylated enol **7** detected.



6 **7**

Presumably, loss of the phosphane ligand from complexes **1**–**4** is the rate-determining step for both the epimerization and the formation of the catalytically active species.[13] This assumption is supported by the fact that small trialkylphosphanes inhibit the reaction. On the other hand, the complex $[CpFe(CO)_2(CH_3)]$ is activated by methyl group migration,[14] which results in formation of the same intermediate, $[CpFe(CO)(COCH_3)]$, as that obtained by loss of the phosphane ligand from **1**. In the presence of 1.0 mol % of $[CpFe(CO)_2(CH_3)]$ at 70 °C, the catalytic hydrosilylation is also complete within 24 hours.

The acetyl complexes **1** and **2** can be recovered at the end of the catalytic reaction by chromatography on Al_2O_3 with pentane/diethyl ether (4/1) as eluent. The complex $[CpFe(CO)_2(CH_3)]$, however, is consumed during the catalysis.

A possible mechanism for the catalytic hydrosilylation involves initial addition of diphenylsilane to the 16-electron fragment formed by thermal loss of the phosphane ligand or methyl migration. The adduct then reacts with acetophenone to form coordinated **6**, release of which re-forms the 16-electron fragment. There are two possibilities for the addition of silane to the coordinatively unsaturated complex fragment: (1) oxidative addition with cleavage of an Si–H bond and (2) formation of an M–Si–H three-center bond, like that already found for $[CpMn(CO)_2(silane)]$ complexes.[15–17]

We rule out addition of the Si–H bond to the acetyl group of the complexes, since this addition would require additional catalysts[18] and since the methyl complexes **3** and **4** also catalyze the hydrosilylation. We explain the absence of silyl enol ether **7** by a hydrosilylation mechanism involving an Fe–Si–H three-center bond rather than an Fe–H species. By contrast, the hydrosilylation of acetophenone with diphenylsilane catalyzed by hydridorhodium complexes always affords enol ether **7** (in varying amounts) in addition to silyl ether **6**.[4, 5] The different induction periods found for the catalysts are presumably due to deactivation of the catalytically active species at the start of the reaction by traces of impurities.

[**] Optically Active Transition-Metal Complexes, Part 101. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen. Part 100: H. Brunner, H. Peter, *J. Organomet. Chem.*, in press.

The lack of optical induction when the optically active catalysts **1**–**4** are used is the result of rapid racemization of the catalytically active species. Surprisingly, optical induction is still not observed with the optically active complex **5**, whose planar chiral structure does not isomerize even at 200 °C. We interpret this result to mean that acetophenone attacks the coordinated diphenylsilane from the side not facing the complex. The newly formed asymmetric center is thus too far from the planar chiral group.

The complex $[CpFe(CO)_2(CH_3)]$ and also the complex $[IndFe(CO)_2(CH_3)]$ can be used as hydrogenation catalysts. For example, they catalyze the hydrogenation of α-methylstyrene to isopropylbenzene at 100 °C under H_2 (50 bar) in THF.[19] However, owing to rapid deactivation of the complexes employed—formation of the dimeric compounds $[Cp'Fe(CO)_2]_2$, which are catalytically inactive—only a few catalytic cycles are achieved. The phosphane complexes **3** and **4** decompose during hydrogenation of α-methylstyrene (90 °C, bar H_2, THF) so rapidly that only a few percent of hydrogenated product is formed. We explain the catalytic hydrogenation by formation of an η^2-H_2 complex from the unsaturated intermediate $[Cp'Fe(CO)(COCH_3)]$ under the reaction conditions; this complex, formed in competition with THF and olefin complexes, reacts with α-methylstyrene similarly to the reaction of the Fe-bonded SiH group with acetophenone. Such η^2-H_2 complexes have also been postulated to be formed during decomposition of $[CpFe(CO)_2(CH_3)]$ and $[IndFe(CO)_2(CH_3)]$ in the presence of hydrogen.[20]

The majority of the reactions of organometallic compounds proceed via intermediates containing a free coordination site at the metal. It should be possible to use these free coordination sites for catalysts of known structure.[21]

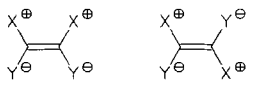
Electrostatic Control of the Molecular and Crystal Structure of an Olefinic Double Betaine **

By *Robert Weiss,* Reinhardt Roth, Rainer H. Lowack,* and *Matthias Bremer*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 65th birthday

E/*Z*-isomeric olefinic double betaines of the type **1**/**2** were previously unknown. The quadrupole system **2**, which has an alternating charge pattern, should be significantly more stable than system **1**, because of the more favorable electrostatic interactions between the charged substituents in **2**. Model calculations have shown that, depending on the substituents, this difference in stability can be up to 40 kcal mol^{-1}.[1] Here we describe the first synthesis of a stable compound of type **1** as well as its unusual molecular and crystal structure.



1 **2**

The starting point of the synthesis was our observation that, in structure-determined analogy to *p*-chloranil,[2] dichloromaleic anhydride (**3**) can be substituted in a bis-onio fashion by 4-dimethylaminopyridine (DMAP, **6**). The yellow

dication salt **4**, obtained in good yields as an analytically pure CH_2Cl_2 adduct, was fully characterized.[3]

The salt **4** can be converted, without loss of an onio substituent, into the corresponding maleic acid **5** by treatment with a small excess of H_2O in CH_2Cl_2.[3] Reconversion of **5** to anhydride **4** by reaction with $SOCl_2$ confirms that the energetically unfavorable *Z* configuration of the two onio moieties is not affected by the hydrolysis. Double deprotonation of **5** finally yields the dihydrate of the *Z* double betaine **1a**.[4] Recrystallization from boiling H_2O affords the hexahydrate of **1a** as crystals suitable for X-ray analysis.[5] Figure 1 shows the molecular structure of **1a** · $6H_2O$ in the crystal.

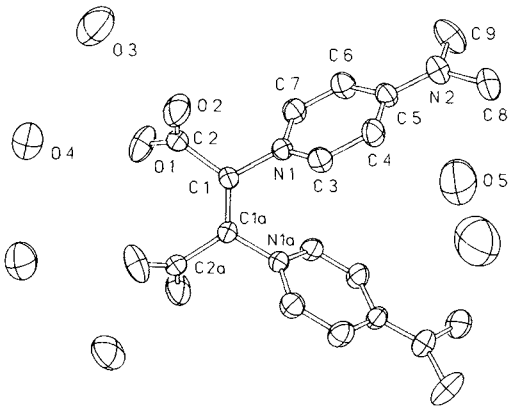

Fig. 1. Structure of **1a** · $6H_2O$ in the crystal. Selected distances [pm], angles [°], and torsion angles [°]: C1-C1a 133.4(7), C1-C2 151.3(5), C2-O2 125.1(5), C2-O1 122.8(5), C1-N1 144.8(4), N1-C3 136.0(5), N1-C7 136.5(5), C3-C4 135.9(6), C6-C7 135.4(6), C4-C5 140.6(6), C5-C6 142.1(6), C5-N2 133.1(5), N2-C8 146.8(6), N2-C9 146.8(6); C1a-C1-C2 125.2(2), C1a-C1-N1 120.1(2), C2-C1-N1 114.5(3); C1a-C1-C2-O2 125.5, C1a-C1-C2-O1 52.4, C3-N1-C1-C1a 62.9, C7-N1-C1-C1a 118.6, C8-N2-C5-C6 174.3, C9-N2-C5-C4 175.5, N1-C1-C1a-N1a −3.8, C2-C1-C1a-C2a 4.7.

The two carboxylate and the two pyridinium substituents are twisted in a *conrotatory* fashion from coplanarity with the central double bond. The torsion angles of the pyridinium moieties (e.g., C3-N1-C1-C1a) are 63°, those of the carboxylate moieties (e.g., C1a-C1-C2-O1) 52°. The molecule has overall C_2 symmetry (twofold axis perpendicular to the double bond in the plane of the double bond). Thus, the double betaine is *chiral* in the crystalline state. Undoubtedly, the electrostatic repulsion of the identically charged substituents in *Z* arrangement is responsible for the observed deconjugation. X-ray structure analyses of alkali-metal maleates show that, in those cases, one carboxylate group remains coplanar with the double bond, while the other is oriented almost orthogonally.[6] AM1 calculations, performed by us, predict that all substituents in **1a** should be twisted by 90° from coplanarity. The flattened form of this double betaine observed in the crystal, however, is presumably the result of a compromise between intramolecular minimization of charge repulsion and intermolecular maximization of charge attraction in the crystal lattice.

Owing to this electrostatic attraction of oppositely charged substituent pairs, **1a** forms a novel stacked structure in the crystal lattice. The basic motif is shown in Figure 2.

The structure displays the following characteristic features:

1. The asymmetric structural units form a racemate by *alternating* stacking of enantiomers along the *c* axis.
2. The charged ligands are each located within the electrostatic attraction region of an oppositely charged ligand of the neighbor in the stack.
3. The midpoints of the central double bonds are separated by 481 pm in the stack. Along the *c* axis, the projection of each of these double bonds relative to the two identically positioned neighboring systems is shifted parallel to the *b* axis by 94 pm (cf. also Fig. 3). A direct interaction of the olefinic double-bond moieties is not expected for this spatial arrangement.
4. The shortest intrastack contacts (225 pm) are formed between two carboxylate oxygen atoms of a given quadrupole **1a** and a partially positively charged DMAP α-H atom of each of the two nearest neighbors in the stack. Both the short distances and the spatial arrangement of the interacting centers (linear O···H-C sequence, C–O···H angle) show that these contacts must involve hydrogen bonds.[7] As revealed in Figure 2, each molecule of **1a** in the stack is anchored by four H-bond systems. As shown by more detailed analysis using molecular models, this favorable situation for interaction is due to the alternating stacking of enantiomers of **1a** to form the racemate.

In the projection along the *c* axis, the stacks of **1a** are approximately X-shaped. In the crystal, these structural units, containing lipophilic end groups (methyl groups of the NMe_2 substituents) are joined together as shown in Figure 3. The remarkable novel solid-state structure thereby resulting contains as structural elements both an undulating layer lat-

tice (distance between layers 0.33 nm) and rhomboidal channels (shorter diameter 0.7 nm, longer diameter 1.4 nm).

In the present case, as shown in Figure 3, the cavities are filled with H_2O molecules. Thus, it appears that this intriguing host lattice should be able to accept other polar and ionic guest molecules as well. Corresponding investigations have already been initiated.

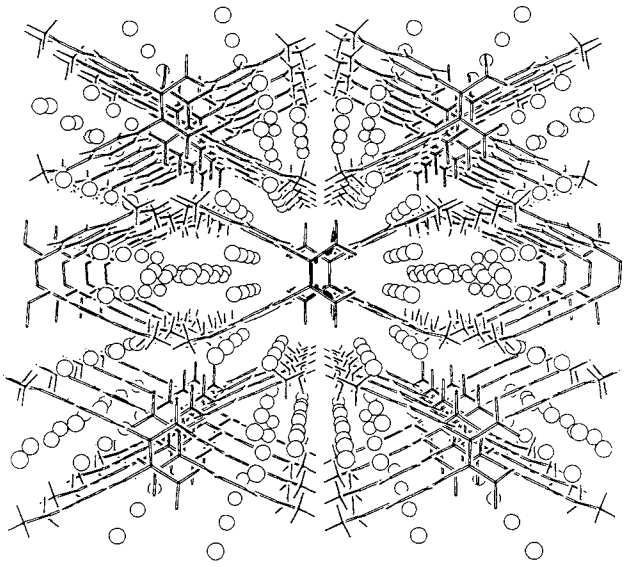

Fig. 3. Perspective drawing of the packing of the stacks of **1a** (projection along the *c* axis) with the oxygen atoms of the molecules of crystal water.

Phenyl-Linked Quinone-Substituted Porphyrin Trimers **

By *Jonathan L. Sessler** and *Vincent L. Capuano*

Long-distance photoinduced electron-transfer (ET) reactions have attracted considerable attention due to their importance in many biological processes as well as their significance in solar energy conversion devices.[1] Of notable interest are those ET reactions which occur upon photoexcitation of the bacterial photosynthetic reaction centers (RC's).[2] However, the complexity surrounding the reactive components in the RC's poses a significant challenge to the understanding of the mechanisms operating throughout the charge separation process.

While experiments performed on native RC's[2–4] and on model systems[5, 6] have helped to clarify those factors, such as distance, orientation, energetics, and medium, which control long-distance ET reactions, the unification of experiment with theory[7, 8] has proven problematic. A particular area of ambiguity concerns the role, if any, of the intermediate monomeric bacteriochlorophyll (BChl) in mediating the initial ET step from the photoexcited special pair (SP*) donor to the bacteriopheophytin (Bph) acceptor.[7] An attractive, but as yet experimentally unconfirmed, mechanism casts this BChl prosthetic group in the role of a "superexchange" mediator, facilitating the long-range (17-Å center-to-center) SP*-to-Bph ET process.[7–9]

Given the controversial nature of this hypothesis we have over the past few years sought to develop a series of acceptor-substituted porphyrin-type model systems which contain a variety of chromophores held in well-defined rigid arrangements. We have recently reported the synthesis and study of several elaborated quinone-substituted porphyrin dimers in which evidence for apparent porphyrin-based "superexchange"-mediated ET behavior was obtained.[6] More sophisticated systems, however, might allow for a further probing of this behavior as well as other related mechanistic questions. We have recently turned our attention, therefore, to the development of model systems containing more than two porphyrin subunits.

In this communication we wish to report the synthesis and photophysical properties of the bis-quinone phenyl-linked trimeric porphyrin **1**, which, to the best of our knowledge, represents the first acceptor-substituted porphyrin trimer.[10] In addition, we report the synthesis of the quinone-free control system **2**.[11]

The syntheses of the title compounds **1** and **2** are based on the condensation between the α-unsubstituted dipyrrylmethane **7** and the functionalized porphyrins **9** and **11**, respectively, using a modified procedure for formation of porphyrin trimers.[12] The central porphyrin is constructed in the final bond-forming sequence. The starting materials **7**, **9**, and **11** were prepared using modifications of methods which we and others have recently reported.[5, 6] Specifically, dipyrrylmethane **3** was prepared by the acid-catalyzed condensation of 4-(hydroxymethyl)benzaldehyde (introduced in the form of its diethyl acetal)[13] with ethyl 3-ethyl-4-methyl-2-pyrrolecarboxylate (75% yield) and was saponified and decarboxylated in boiling ethylene glycol to give **4** as a pale tan solid (m.p. 149–151 °C, 95% yield).[14] Compound **4** was

then condensed with the known di(formylpyrryl)methanes **5** and **6** under conditions of acid catalysis in THF/MeOH (2/1) to give the hydroxymethylphenyl-substituted porphyrin monomers **8** (λ_{max} ($CHCl_3$) = 410, 507, 540, 574, 625 nm)[14] and **10** (λ_{max} ($CHCl_3$) = 404, 502, 537, 571, 623 nm),[14] the direct precursors to **9** and **11**, in 50 and 55% yield, respectively, following *o*-chloranil oxidation and chromatographic purification (silica gel, 2% MeOH in $CHCl_3$). The key formylphenyl-substituted monomers **9** (λ_{max}($CHCl_3$) = 410, 507, 538, 572, 624 nm)[14] and **11** (λ_{max} ($CHCl_3$) = 407, 504, 539, 572, 624 nm)[14] were then obtained from **8** and **10** in almost quantitative yield as bright violet crystals following oxidation with pyridinium dichromate in CH_2Cl_2 and subsequent recrystallization from chloroform/hexanes.

The acid-catalyzed trimer-forming condensation between **11** and **7**, which gave, after *o*-chloranil oxidation, the control compound **2a**, was found to be highly sensitive to the reaction conditions, particularly to the choice of catalyst and reactant concentration. The best yields, roughly 50%, were obtained using reactant concentrations of exactly 1.0×10^{-2} M in CH_2Cl_2 with trifluoroacetic acid (10^{-3} M) as the acid catalyst. These conditions are quite similar to those recently reported by *Lindsey* for use in an optimized porphyrinogen-based tetraphenylporphyrin-forming procedure,[15] suggesting that in this case the critical yield-determining step also involves the formation of an intermediate porphyrinogen-like species. In fact, the use of dipyrrylmethanes and aryl aldehydes requires the formation of half the number of C–C bonds as the Lindsey procedure, which involves monomeric pyrroles.

Using the same conditions as above, the condensation of **9** and **7** gave the bis(hydroquinone methyl ether) trimer **12** (λ_{max}($CHCl_3$) = 409, 507, 541, 573, 625 nm)[14] in over 60% yield after chromatographic purification (silica gel, 2% MeOH in $CHCl_3$) and recrystallization ($CHCl_3$/hexanes). The conversion of **12** to the diquinone trimer **1a** (obtained as a pale burgundy solid[14]) was then accomplished in roughly 40% yield by deprotecting the methyl ethers with BI_3 in CH_2Cl_2[16] (to give **13**[14]) and subsequently oxidizing with dichlorodicyano-*p*-benzoquinone (DDQ) in CH_2Cl_2.

As is true for the 1,4-phenyl-linked dimers **16** and **17**,[6] the phenyl-linked trimers **1** and **2** show evidence for intersubunit excitonic interactions in the ground-state absorption spectra. In the case of the free-base systems **1a** (λ_{max}($CHCl_3$) = 415, 509, 535, 572, 626 nm) and **2a** (λ_{max}($CHCl_3$) = 412, 508, 538, 574, 624 nm), this is only apparent in terms of a slight broadening of the Soret band in the trimers as compared to monomeric, phenyl-substituted porphyrins (e.g., 5,15-diphenylporphyrin[17] (λ_{max}($CHCl_3$) = 408, 506, 541, 573, 624 nm)). However, in the case of the trizinc complexes **1b** and **2b** (obtained by treatment of **1a** and **2a** with excess $Zn(OAc)_2$ in MeOH/$CHCl_3$), which possess strong absorption bands, this excitonic coupling is manifest in terms of a significant bathochromic shifting of the Soret transition along with a dramatic splitting of the absorption into two equally intense peaks. On the basis of simple exciton theory calculations performed on these systems and earlier 1,4-phenyl-linked dimers,[18] such shifts can be readily explained in terms of a point dipole approximation.

The steady-state fluorescence spectrum of **1a** recorded in benzene solution shows substantial quenching relative to **2a** (λ_{max} = 630, 695 nm) upon irradiation at 410 nm. From quantitative analyses, the ratio of the emission intensities of

1a and **2a** was found to be ≤ 0.02. This suggests that the various porphyrin excited states in **1a** are quenched by electron transfer to the quinone acceptors.[5, 6, 19] The excited singlet-state behavior of **1a** is thus very different from that of the simpler quinone-substituted monomeric and dimeric systems **14** and **16**, which show no detectable fluorescence ($\Phi_f < 10^{-5}$) when irradiated under identical conditions.[6] Therefore, the residual fluorescence observed for **1a** can be ascribed to the central porphyrin. However, the fluorescence quantum yield of **1a** ($\Phi_f \leq 0.002$[20]), although substantially higher than that of **14** and **16**, is still considerably reduced relative to the acceptor-free systems **2a**, **15**, and **17**. This indicates that the excited singlet state of the central porphyrin in **1a** is quenched by the presence of the distant "outer" quinones. This in turn indicates that a very efficient porphyrin-to-quinone electron-transfer process is occurring for the inner porphyrin subunit as well as for the outer two porphyrin components. From the measured fluorescence lifetime for the unsubstituted system **2a** (9.09 ns) and standard data analyses,[6c] a lower limit of $5 \times 10^9\ s^{-1}$ for the overall rate of ET from the porphyrin trimer **1a** to the quinones may be determined.[21]

The efficiency with which the net ET process in **1a** occurs over what is a distance nearly comparable to that found in the natural photosynthetic reaction centers, suggests that systems such as **1** and **2** may be well suited for studying long-range ET mechanisms in multicomponent systems. Accordingly, the syntheses of more elaborate analogues in which the acceptor is bound to only one terminus of the system and where metal cations are selectively complexed into two or fewer porphyrin subunits are currently under way.

Experimental Procedure

12: A 50-mL three-necked, round-bottomed flask equipped with an argon inlet, reflux condensor, and septum port was charged with **9** (212 mg, 0.295 mmol, 10^{-2}M), **7** (85 mg, 0.297 mmol, 10^{-2}M), and 30.0 mL of CH_2Cl_2. The solution was then bubbled with argon for 15 minutes. Trifluoroacetic acid (22.7 μL) was added via syringe and the reaction was allowed to stir in the dark for 3.5 h under a blanket of argon. *o*-Chloranil (109 mg, 0.449 mmol) was added and the reaction was placed in a preheated 40 °C oil bath and allowed to stir for an additional 3 h. Thin layer chromatography (2% MeOH/$CHCl_3$, silica gel) indicated the complete absence of the starting porphyrin aldehyde and the appearance of a new spot at lower R_f ascribed to the porphyrin trimer. The solvent was removed in vacuo and the trimeric porphyrin was purified by chromatography on silica gel (2% MeOH/$CHCl_3$, eluent) and recrystallization from $CHCl_3$/hexanes to yield 201 mg (0.0892 mmol, 60.4%) of **12** as a pale purple solid. UV-VIS ($CHCl_3$): λ_{max} (ε) = 409 (630 000), 507 (54 600), 541 (16 200), 573 (20 100), 625 (4010) nm). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = -1.84$ (3H, br. s, NH), $-1,47$) (3H, br. s, NH), 1,24 (12H, t, $J = 7.26$ Hz, $CH_2CH_2CH_2CH_3$), 1.86 (8H, m, $CH_2CH_2CH_2CH_3$), 1.93 (12H, t, J = 7.59 Hz, 12″,18″-CH_2CH_3), 1.96 (12H, t, J = 7.33 Hz, 2″,8″-CH_2CH_3), 2.37 (8H, m, $CH_2CH_2CH_2CH_3$), 2.68 (12H, s, 13″,17″-CH_3), 3.22 (12H, s, 3,7,13,17-CH_3), 3.23 (12H, s, 3″,7″-CH_3), 3.73 (6H, s, OCH_3), 3.89 (6H, s, OCH_3), 4.11 (16H, m, CH_2CH_3), 4.21 (8H, m, $CH_2CH_2CH_2CH_3$), 7.29 (6H, m, aryl), 8.17 (8H, dd, aryl), 10.34 (4H, s, 10″,20″-H), 10.47 (2H, s, 10,20-H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 13.64, 14.41, 17.33, 17.45, 17.69, 17.78, 20.02, 20.16, 23.61, 26.82, 35.72, 56.05, 56.12, 96.61, 97.34, 111.89, 113.68, 115.12, 117.89, 118.06, 120.25, 131.66, 133.30, 133.41, 133.47, 135.38, 135.74, 135.98, 140.77, 141.22, 143.37, 144.51, 144.56, 144.67, 145.55, 145.66, 146.04, 153.70, 153.93. MS (FAB, 79 eV): *m/z* 2255 ($M^{\oplus}$), 2118 ($M^{\oplus} - 137$).

1a: The protected dihydroquinone trimer **12** (50 mg, 0.022 mmol) was dissolved in 10 mL of freshly distilled CH_2Cl_2 and bubbled with Ar for 15 min. A freshly prepared solution of BI_3 (1.3 mL of a 0.81 M solution in CH_2Cl_2) was then added dropwise over 30 s at 0 °C. The reaction was allowed to stir in the dark at 0 °C for an additional 15 min. The vessel was then removed from the ice bath and allowed to warm to room temperature over the course of 30 min. The excess BI_3 was quenched with H_2O and the reaction neutralized with dilute ammonia and extracted with $CHCl_3$ (3 × 30 mL). The organic layer was separated and dried over Na_2SO_4 and the solvent was removed under reduced pressure to give a final volume of approximately 50 mL. DDQ (25 mg, 0.11 mmol) was added and the reaction stirred at room temperature, in the dark, for 2.5 h. The reaction mixture was washed with aqueous Na_2CO_3 and H_2O and dried over Na_2SO_4. The product **1a** was purified by column chromatography on silica gel (2% MeOH/$CHCl_3$) to yield 18 mg (0.0095 mmol, 43.2%). UV-VIS ($CHCl_3$): λ_{max} (ε) = 415 (501 000), 510 (41 700), 535 (13 000), 572 (16 800), 627 (5910) nm. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = -1.99$ (2H, s, NH), -1.88 (2H, s, NH), $-1,46$ (2H, s, NH), 1.28 (12H, t, $CH_2CH_2CH_2CH_3$), 1.88–1.97 (32H, m, 2,8,12,18-$CH_2CH_2CH_2CH_3$, 2″,8″,12″,18″-CH_2CH_3), 2.39 (8H, q, $CH_2CH_2CH_2CH_3$), 3.09 (24H, s, 3,7,13,17-CH_3, 3″,7″-CH_3), 3.17 (12H, s, 13″,17″-CH_3), 4.14–4.23 (24H, m, 2″,8″,12″,18″-CH_2CH_3, 2,8,12,18-$CH_2CH_2CH_2CH_3$), 7.34 (8H, dd, H_{phenyl}), 8.42 (6H, m, $H_{quinone}$), 10.39 (4H, s, 10″,20″-H_{phenyl}), 10.49 (2H, 10,20-$H_{quinone}$). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 14.39, 16.37, 17.33, 17.49, 17.71, 20.04, 20.11, 23.60, 26.82, 29.70, 35.71, 97.23, 97.39, 110.23, 117.94, 119.28, 133.31, 133.38, 133.50, 135.92, 136.13, 137.17, 137.93, 139.53, 141.17, 141.33, 141.96, 142.26, 143.46, 144.67, 144.90, 145.71, 146.05, 187.34, 189.00. MS (FAB, 70 eV): *m/z* 1913 ($M^{\oplus}$ + 3), 1912 ($M^{\oplus}$ + 2), 1911 ($M^{\oplus}$ + 1).

$[(Ph_3P)_2N]_2[Os_{18}Hg_2C_2(CO)_{42}]$ a Photochemically Generated High-Nuclearity Cluster Which Reversibly Incorporates Metallic Mercury into Its Metal Core**

By *Eleni Charalambous, Lutz H. Gade, Brian F. G. Johnson, Thomas Kotch, Alistair J. Lees, Jack Lewis,** and *Mary McPartlin**

The majority of studies into the photochemical properties of transition-metal cluster compounds have so far been conducted in the context of ligand activation or substitution in triatomic clusters,[1] while investigations of light-induced transformations of the metal core are comparatively rare.[2] Mixed-metal clusters incorporating transition or main-group metals with significantly different electronic properties to those of the principal core metal, and consequently containing polar metal–metal bonds, have intrinsic sites where bond cleavage may preferentially occur, either by chemical or photochemical means. The latter, in particular, would permit the generation of metal-frame structures which are inaccessible via conventional synthetic routes.

An ideal model system for the study of these anticipated properties of large mixed-metal clusters is the dianion $[Os_{18}Hg_3C_2(CO)_{42}]^{2\ominus}$ (**1**), which we recently reported along with a variety of other high-nuclearity Os-Hg clusters.[3] Cluster **1** contains a triangular Hg_3 subcluster, sandwiched by two tricapped-octahedral $Os_9C(CO)_{21}$ fragments and therefore clear-cut interfaces between different metallic domains. In the course of our investigation of the chemical reactivity of **1**, we have found that, when the deep purple solution of $[PPN]_2 \cdot$ **1** [PPN = $(Ph_3PNPPh_3)^{\oplus}$] was exposed to light, the compound underwent a clean photochemical conversion to an unknown burgundy red product **2**, which is markedly less deeply colored than **1**. Simultaneously, metallic mercury was generated and precipitated. The light-induced loss of Hg was confirmed by the negative-ion FAB mass spectrum (FAB = fast atom bombardment) of the product **2**, which displayed the same basic pattern as the spectrum of **1** but was shifted by $\Delta(m/z)$ 200 to lower mass.[4] The similarity of the IR absorption band patterns of **1** and **2** in the CO stretching region and the signal patterns in the ^{13}C NMR spectra of both compounds[5] suggested similar overall symmetries. The reaction product **2** was therefore formulated as $[Os_{18}Hg_2C_2(CO)_{42}]^{2\ominus}$, with a metal core consisting of an Hg_2 fragment fusing the two $Os_9C(CO)_{21}$ units already present in the starting material.[6]

In order to substantiate this proposal and to obtain detailed information about the structural environment of the two remaining Hg atoms, a single-crystal X-ray structure analysis of the PPN salt of **2** was carried out.[7] It revealed that the open Os_3 triangles of the $Os_9C(CO)_{21}$ units are staggered, with each of the two Hg atoms linking an edge of one triangle with the corner of the other, the two halves of the molecule being related by a crystallographic center of symmetry at the midpoint of the Hg–Hg vector (Fig. 1). The Hg–Hg distance of 2.744(5) Å is considerably shorter than

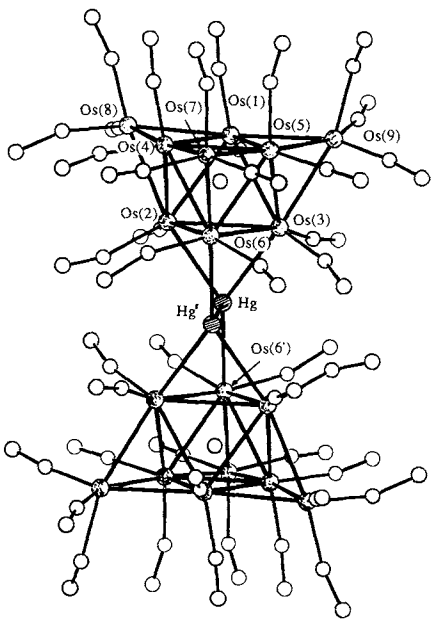

Fig. 1. Molecular structure of **1**. Principal bond distances [Å] (maximum standard deviation 0.005 Å): Os(1)-Os(2) 2.872, Os(1)-Os(3) 2.870, Os(1)-Os(4) 2.862, Os(1)-Os(5) 2.855, Os(1)-Os(8) 2.755, Os(1)-Os(9) 2.772, Os(2)-Os(3) 3.009, Os(2)-Os(4) 2.875, Os(2)-Os(6) 3.038, Os(2)-Os(8) 2.816, Os(3)-Os(5) 2.877, Os(3)-Os(6) 3.001, Os(3)-Os(9) 2.792, Os(4)-Os(5) 2.841, Os(4)-Os(6) 2.842, Os(4)-Os(7) 2.778, Os(4)-Os(8) 2.743, Os(5)-Os(6) 2.836, Os(5)-Os(7) 2.761, Os(5)-Os(9) 2.755, Os(6)-Os(7) 2.798, Os(2)-Hg 2.822, Os(3)-Hg 2.907, Os(6')-Hg 2.636, Hg-Hg' = 2.744(5).

the mean Hg–Hg distance in the triangular mercury unit of **1** (2.918(5) Å), but comparable to that in the recently described $(Hg_3)^{4/3\oplus}$ clusters in $[Hg_3(dppm)_3(SO_4)_2]$ (d(Hg-Hg) = 2.764–2.802 Å, dppm = diphenylphosphinomethane)[8] or the mineral terlinguaite, $Hg_4Cl_2O_2$ (2.703 Å).[9] The Hg_2 fragment is embedded in the metal frame in a uniquely compact way in comparison to other examples of mixed-metal compounds containing Hg_2 units.[10]

The ^{13}C NMR spectrum of **2**, recorded at 295 K, has four sharp carbonyl resonances, which correspond to a higher symmetry (C_{3v}) with respect to a molecular axis through the centers of both Os units than that displayed in the solid-state structure. We attribute this to a fast rotation of the two Os_9 subclusters relative to each other on the NMR time scale in solution. This is not unexpected, since fluxional cores are commonly observed in high-nuclearity Os-Hg clusters.[11]

If, under exclusion of light, **2** is exposed to metallic mercury, thermal reinsertion of an Hg atom into the structure occurs, regenerating **1** almost quantitatively. This means that the photoreaction from **1** to **2** is thermally fully reversible.

The observed retention of sharp isosbestic points in a sequence of UV-VIS spectra, recorded after successive irradiation of the solution of **1** in CH_2Cl_2 with the 458-nm line of an Ar-ion laser, suggests that the photochemical Hg extrusion proceeds without interference from secondary photoprocesses (Fig. 2). The intensity of the absorption band

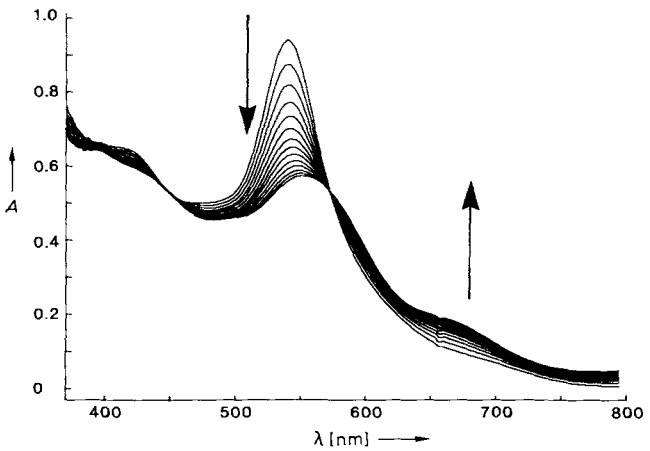

Fig. 2. UV spectra obtained after 458-nm photolysis (Ar-ion laser) of 2.15×10^{-5} M solutions of $[PPN]_2 \cdot$ **1** in deoxygenated CH_2Cl_2 at 20 °C. Spectra were recorded at irradiation intervals of 30 s. A = absorbance. The arrows indicate the direction of spectral change.

of the starting material at 540 nm ($\varepsilon = 4.38 \times 10^4$ L mol^{-1} cm^{-1}) decreases significantly during the reaction with a concomitant shift of the maximum by ca. 10 nm to longer wavelengths. The initial step in this reaction is thought to be a metal-to-metal charge-transfer (MMCT) transition, which is then followed by the extrusion of an Hg atom and subsequent rearrangement of the metal core. The low quantum efficiency of 0.004–0.005 for this process on irradiation in the range of 458–514 nm[12] is probably a consequence of the large number of nonreactive deactivation pathways for the cluster, but it may also reflect the efficiency of the thermal back-reaction that regenerates the starting material during the period of irradiation.

The dianions **1** and **2** can be oxidized by silver salts, yielding the corresponding radical monoanions $[Os_{18}Hg_3C_2(CO)_{42}]^{\ominus}$ (**3**) and $[Os_{18}Hg_2C_2(CO)_{42}]^{\ominus}$ (**4**), which are extremely air-sensitive and immediately regenerate the dianions when exposed to moist air.[5a] Both monoanions are related to each other by a set of similar photochemical Hg extrusion and thermal reinsertion reactions as found for **1** and **2**. Thus, the clusters **1**–**4** are part of a reversible redox and photochemical cycle (Fig. 3).

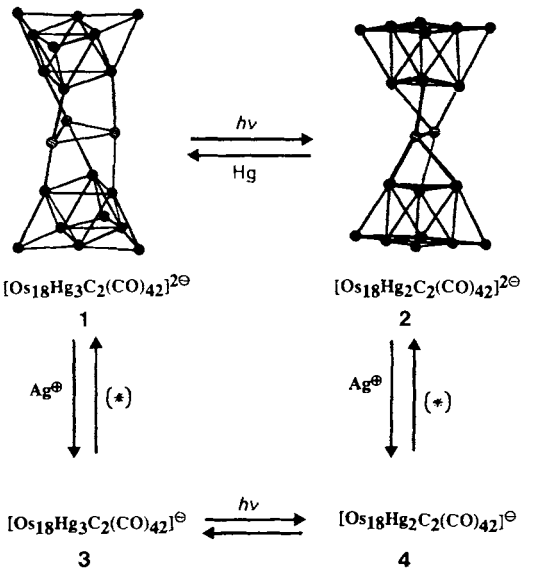

Fig. 3. The photo- and redox chemical cycle linking **1**–**4**. (*): standing in moist air.

[4] The negative-ion FAB mass spectra of the salts of dianionic clusters display a characteristic peak pattern: dianion, monoanion, {dianion + cation}, and, in exceptional cases {dianion + 2 × cation}. For **1** and **2** the most abundant isotopomers for the cluster anions were found at: **1** dianion m/z 2615 (simulated 2615), monoanion m/z 5228 (simulated 5230), **2** dianion m/z 2514 (simulated 2514.5), monoanion m/z 5028 (simulated 5029).

[5] a) IR (CH_2Cl_2) [cm^{-1}]: **1**: $\tilde{\nu}$ = 2072 (m), 2057 (s), 2005 (s); **2**: 2064 (s), 2057 (vs), 2007 (s). **3**: $\tilde{\nu}$ = 2085 (m), 2072 (s), 2022 (s); **4**: $\tilde{\nu}$ = 2081 (s), 2073 (vs), 2022 (s). b) ^{13}C NMR (50% ^{13}C enriched Samples, CD_2Cl_2, 295 K): **1**: δ = 185.7 (6 CO), 184.9 (6 CO), 177.7 (12 CO, $^2J(^{199}Hg^{13}C)$ = 56 Hz), 175.6 (18 CO, the carbonyls on the Os(CO)$_3$ vertices are equivalent on the NMR time scale at 295 K) **2**: δ = 185.8 (6 CO), 185.7 (6 CO), 179.7 (12 CO, $^2J(^{199}Hg^{13}C)$ not resolved), 176.0 (18 CO), 411 (interstitial carbide).

[6] *Experimental Procedure*: A stirred solution of $[PPN]_2 \cdot$ **1** (50 mg, 0.0082 mmol) in CH_2Cl_2 was irradiated with a 250-W tungsten lamp, the reaction vessel being cooled externally with water. After ca. 10 min, precipitation of metallic mercury was observed and the reaction was complete after 40–50 min as judged by IR spectroscopy. During this time, the color of the solution changes from deep purple to a much less intense burgundy red. After separation of the mercury by filtration, the solvent volume was reduced to 20 mL and the product crystallized by slow vapor diffusion with diethyl ether. Black crystals, yield 45.5 mg (92%).

[7] Crystal data for $[PPN]_2 \cdot 2$: ($C_{116}H_{60}O_{42}Hg_2N_2Os_{18}P_4$) triclinic, space group $P\bar{1}$ (No. 2), $a = 18.711(4)$, $b = 16.379(3)$, $c = 11.724(2)$ Å, $\alpha = 111.242(2)$, $\beta = 84.284(1)$, $\gamma = 105.994(2)°$, $M = 6102.41$, $V = 3220.08$ Å^3, $Z = 1$, $\varrho_{calcd} = 3.147$ g cm^{-3}, $F(000) = 2694$, $R = 0.0938$ for 3537 reflections with $I/\sigma(I) > 3.0$ corrected for absorption [$\mu(Mo_{K\alpha}) = 201.6$ cm^{-1}]. The only crystals which could be obtained diffracted rather weakly due to marked disorder of the [PPN] counterions. Relatively high thermal parameters for Os(9) and Hg appear to be due to slight disorder of the cluster dianion, which could not be resolved. Nonetheless, the structural features of the cluster are well established. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the full journal citation.

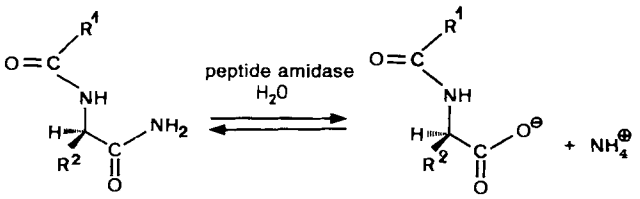
Selective Deamidation of Peptide Amides**

By *Dörte Steinke* and *Maria-Regina Kula**

The choice of protecting groups is crucial in the synthesis of peptides.[1, 2] The selective removal of certain protecting groups is often desirable, but difficult to realize. For example, the selective cleavage of the amide bond of peptide amides has not yet been accomplished without at least partial hydrolysis of the chemically similar peptide bonds. For this reason, the amide function has found little use as a C-terminal protecting group in peptide synthesis, even though it offers several advantages, including a lower pK_i value than for the corresponding free amino acids, increased solubility of the peptide, and good chemical stability. We have now isolated and characterized an enzyme which can be used to hydrolyze peptide amides of apparently any length to give peptides having a free C terminus without cleavage of peptide bonds. A highly selective C-terminal deprotection is thus possible (Scheme 1).



Scheme 1. Amide cleavage by the peptide amidase. R^1 = amino acid residue, peptide residue, or N-terminal protecting group of an amino acid amide. R^2 = side chain of an amino acid.

[**] This work was supported by the Bundesministerium für Forschung und Technologie (project No. 031 900 713) and by Degussa AG. We thank Dr. *Drauz* (Degussa AG) and Dr. *Berndt* (Deutsches Wollforschungsinstitut, Aachen) for providing substrates.

The peptide amidase was isolated and characterized from the flavedo of oranges. The pH dependence of the enzymatic hydrolysis of Z-Gly-Tyr-NH_2, for example, is shown in Figure 1. The broad pH optimum from pH 6.8 to 8.4, as well as the broad range of substrates (see Table 1), makes the enzyme universally applicable. The peptide amidase accepts both N-terminal protected peptides and peptides with a free N terminus as substrates. The side chains of the C-terminal amino acids appear to be of secondary importance. Of the forty peptide amides so far investigated, only those with C-terminal D-amino acids were not converted by the peptide amidase. Table 1 lists a selection of substrates employed.

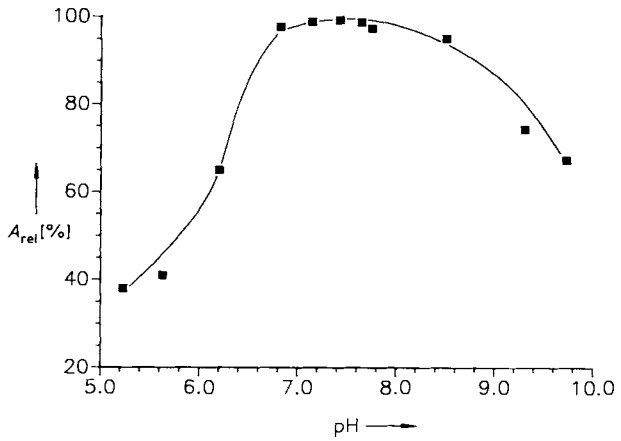

Fig. 1. The pH dependence of the enzymatic deamidation of Z-Gly-Tyr-NH_2. Reaction conditions: 10 mM Z-Gly-Tyr-NH_2, 50 mM Na citrate, Na phosphate, or Na carbonate buffer, 40 μg mL^{-1} peptide amidase, 30 °C. A_{rel} = relative activity of the peptide amidase.

The enzyme is therefore markedly nonspecific with respect to the amino acid side chains of the peptide, and its stereose-

Table 1. Substrate spectrum of the peptide amidase.

H-Gly-Phe-D-Phe-NH_2	0 [c]	80/20	7.3	11.4
H-Arg-Pro-D-Ala-NH_2	0 [c]	99/1	2.4	
Z-Arg-Arg-*p*Na	0 [c]			

[a] The substrates were supplied by Bachem, Heidelberg, or by Dr. *Drauz* or Dr. *Berndt*. [b] TBA = $Bu_4N(HSO_4)$. [c] No conversion in 12 h (no decrease in the area of the amide peak). Ac = acetyl, Bz = benzoyl, Boc = *tert*-butyloxycarbonyl, Z = benzyloxycarbonyl, *p*Na = *para*-nitroanilide, Trt = trityl. Unless otherwise indicated, the amino acids had L configuration (2*S*-amino acids).

lectivity appears to be restricted to the C-terminal amino acid: the substrate H-Gly-D-Phe-Tyr-NH_2 is deamidated, whereas H-Gly-Phe-D-Phe-NH_2 and H-Arg-Pro-D-Ala-NH_2 do not react.

Amino acid amides with free α-amino groups are not hydrolyzed, whereas N-protected amino acid amides are accepted as substrates (see the first three entries in Table 1). Substituted amides, such as peptide anilides, which are frequently used in analysis of proteases, are not cleaved.

The enzyme can be readily used in enzymatic peptide syntheses, since it does not cleave the amino acid amides preferentially used as nucleophiles.[1, 3, 4] Therefore, these are always available for reaction, whereas the resulting peptide amide is deamidated. Thus, a peptide synthesis with simultaneous deamidation of the product is possible.[5]

When amino acid amides are used instead of esters as nucleophiles in enzymatic peptide syntheses, a much lower excess of nucleophile is required,[2] thereby facilitating workup of the peptide. For some carboxypeptidases, amides are obligatory substrates as nucleophiles for peptide synthesis.[6]

Because of the poor solubility of many peptide substrates in water, the effect of water-miscible organic solvents on the stability of the peptide amidase was investigated. The results are shown in Figure 2. The least loss of activity was observed

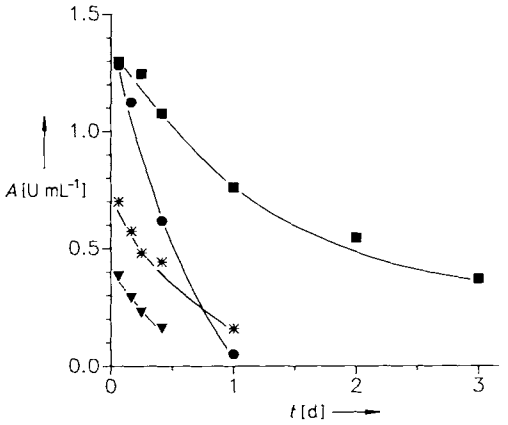

Fig. 2. Effect of organic solvents on the stability of the peptide amidase. Reaction conditions: 40 μg mL^{-1} enzyme was preincubated at 30 °C in 50 mM Tris buffer (pH 7.5) containing 30% organic solvent. The reaction was started at $t = 0$ by addition of substrate (Z-Gly-Tyr-NH_2). In the corresponding control (enzyme in 50 mM Tris/HCl, pH 7.5, without organic solvent), the activity remained unchanged. ■ = DMF, ● = acetone, * = ethanol, ▼ = acetonitrile.

with dimethylformamide (DMF): after three days of incubation in DMF/H_2O (30/70) at 30 °C, 30% of the original activity was still present.

Experimental Procedure

The enzyme preparation was obtained from the flavedo of oranges, that is, from the outermost colored layer of the peel, by a two-step purification involving fractionating salt precipitation and ion exchange chromatography. The peptide amidase had an activity of 2 to 100 U mg^{-1}, depending on the substrate, whereby an activity of 1 U corresponds to the formation of 1 μmol of product per minute at 30 °C and pH 7.5. Unless otherwise stated, 10–50 mM peptide amide in 50 mM Tris/HCl buffer at pH 7.5 was treated with 20–40 μg mL^{-1} of the peptide amidase. The determination and quantification of the peptide was accomplished by HPLC on an RP-18 column, which was eluted isocratically with various compositions of TBA/acetonitrile at a rate of 1.0 mL min^{-1}. The UV detector was set to the absorption maximum of the respective substrate. The eluent compositions are given in Table 1. In all experiments, only one new peak was observed in the chromatogram; its area remained unchanged even after 24–48 h of incubation and its retention time was identical with that of a reference sample (if available). The following reference substances, obtained from Bachem, Heidelberg, were used for product identification: Ac-Trp-OH, Bz-Arg-OH, Z-Gly-Tyr-OH, H-Asp-Phe-OH, H-Ala-Phe-OH, H-Arg-Met-OH, H-Val-Phe-OH, Z-Pro-Leu-Gly-OH, Z-Gly-Gly-Leu-OH, and H-Gly-Phe-Phe-OH.

Novel Bonding Mode for a Cyanometalate Ligand: Synthesis and Crystal Structure of the Mn_4Pd_4 Cluster $[(OC)Pd(\mu\text{-}NC)Mn(\eta\text{-}C_5H_4Me)(CO)_2]_4$ Containing an Orthogonal Arrangement of Helical Units**

By *Pierre Braunstein,* Benoît Oswald, Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*

Cyanide complexes attract increasing interest in synthetic and physical chemistry owing to the ability of the cyanide ligand to link different organometallic units, to stabilize unusual electron counts and mixed-valence systems, to act as a charge-transfer mediator,[1] and to form catalytically active transition-metal complexes.[2] The fact that the cyanide ligand is isosteric with CO has also made it a model for CO chemistry,[3] though it is a poorer π acceptor and better σ donor than CO. Although the donor strength of the cyanide ion is the dominant property of this ligand in $[Cp'Mn(CN)(CO)_2]^{\ominus}$ ($\mathbf{1}^{\ominus}$, Cp' = η-C_5H_4Me), the title complex represents the first example of a polynuclear complex displaying both direct metal–metal bonding and M–CN–M' bridge formation, which result in a novel molecular architecture.

Here we compare the reactivity of $\mathbf{1}^{\ominus}$ [5] with that of the isosteric[6] anion $[CpMo(CO)_3]^{\ominus}$ ($\mathbf{2}^{\ominus}$) towards palladium complexes. The reaction of *trans*-$[PdCl_2(PPh_3)_2]$ with two equivalents of Na · **1** (THF, 0.5 h, 25 °C) led to chloride substitution and formation of the red-violet complex *trans*-$[Pd\{(\mu\text{-}NC)Mn(CO)_2Cp'\}_2(PPh_3)_2]$ (**3**) in 89% yield.

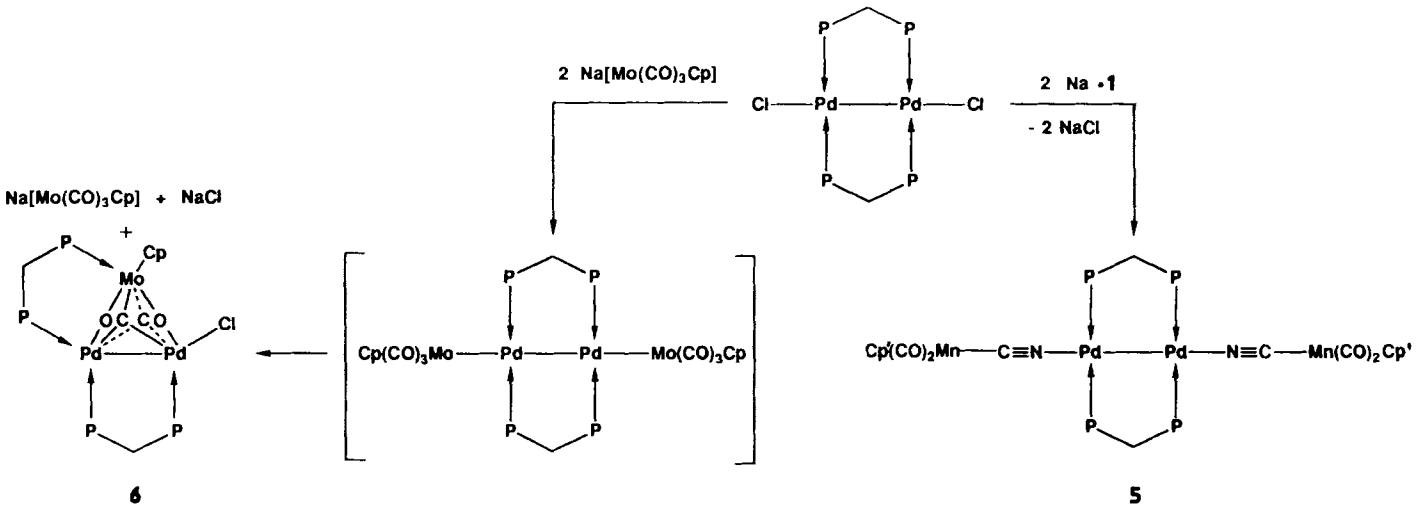

Scheme 1.

Under similar conditions, Na · **2** afforded the planar cluster $[Pd_2Mo_2Cp_2(CO)_6(PPh_3)_2]$ (**4**), in which the metal atoms form two edge-sharing triangles and Pd^{II} has been reduced to Pd^{I}.[6] This difference is steric in origin, since the *trans*-Mo–Pd–Pd–Mo chain structure is not stable when two PR_3 ligands are bonded to Pd.[6]

The reaction of the Pd^{I}–Pd^{I} dinuclear complex $[Pd_2Cl_2(\mu\text{-}CO)(PPh_3)_3]$ with $\mathbf{1}^{\ominus}$ (toluene, 5 h, 0 to 25 °C) led to disproportionation to **3** (44% yield) and Pd metal, but reaction with $\mathbf{2}^{\ominus}$ gave **4**.[7] The reasons for the instability of the primary reaction product resulting from simple substitution of the chloride ligand by $\mathbf{1}^{\ominus}$ or $\mathbf{2}^{\ominus}$ must be electronic in the first case and again steric in the second since one Pd–Mo bond would be *cis* with respect to the two PPh_3 ligands.

The dppm-stabilized dinuclear complex $[Pd_2(\mu\text{-}dppm)_2Cl_2]$ (dppm = $Ph_2PCH_2PPh_2$) reacted with two equivalents of $\mathbf{1}^{\ominus}$ (THF, 1 h, 25 °C) to form the stable eight-atom chain complex $[Pd_2(\mu\text{-}dppm)_2\{(\mu\text{-}NC)Mn(CO)_2Cp'\}_2]$ (**5**) in 91% yield (Scheme 1). The spectroscopic data for **5** are consistent with the symmetrical structure shown: the singlet observed in the $^{31}P\{^1H\}$ NMR spectrum has a chemical shift of $\delta = -5.33$, similar to that of other $[Pd_2(\mu\text{-}dppm)_2X_2]$ complexes,[8] and the IR $\tilde{\nu}$(CN) and $\tilde{\nu}$(CO) absorptions are, as in **3**, similar to those observed when this or analogous fragments are bonded through nitrogen to a metal center.[1,4] In a formal sense, **3** and **5** may also be viewed as "isocyano" Pd complexes[9] stabilized by the 16-electron fragment $Cp'Mn(CO)_2$. In contrast, $\mathbf{2}^{\ominus}$ reacted with $[Pd_2(\mu\text{-}dppm)_2Cl_2]$ to give the *triangulo* cluster $[Pd_2MoClCp(CO)_2(\mu\text{-}dppm)_2]$ (**6**), formed by phosphorus migration from Pd to an adjacent Mo atom in the sterically crowded and therefore unstable Mo–Pd–Pd–Mo intermediate chain complex $[Pd_2(\mu\text{-}dppm)_2\{Mo(CO)_3Cp\}_2]$[10] (Scheme 1).

The tetranuclear Pd^{I} complex $[Pd_4(CO)_4(OAc)_4](AcOH)_2$ reacted quantitatively with four equivalents of Na · **1** (toluene, 3 h, −40 to 25 °C) to form a deep violet solution of the new, air-stable cluster **7** ("Mn_4Pd_4"). The structure of the ethanol solvate **7** · C_2H_5OH has been fully elucidated by an X-ray study.[11] Neglecting the Cp' ligands, this cluster has approximate S_4 symmetry. It consists of two nearly orthogonal, bent Mn–Pd–Pd–Mn metal chains, *s-trans* connected by four Mn–(μ-CN)–Pd bridges (Figs. 1 and 2). A terminal CO completes the approximately square-planar coordination of each Pd atom. One of the Mn-bound CO ligands is semibridging, as indicated by the rather short contact with the Pd atom (Pd–C distances in the range 2.35(3)–2.41(3) Å) and by the slightly bent Mn–C–O angle (in the range 162(3)–165(3)°). Of note is that each μ-CN ligand also makes short contacts with a Pd atom in the neighboring Mn–Pd–Pd–Mn chain: the Pd–C distances are in the range 2.49(2)–2.56(3) Å, while the corresponding Pd–N distances (3.09(2)–3.14(2) Å) are in a range consistent with the weak interactions between the filled π orbitals of the nitrile functions and the empty 5p orbitals of the palladium atoms.[13]

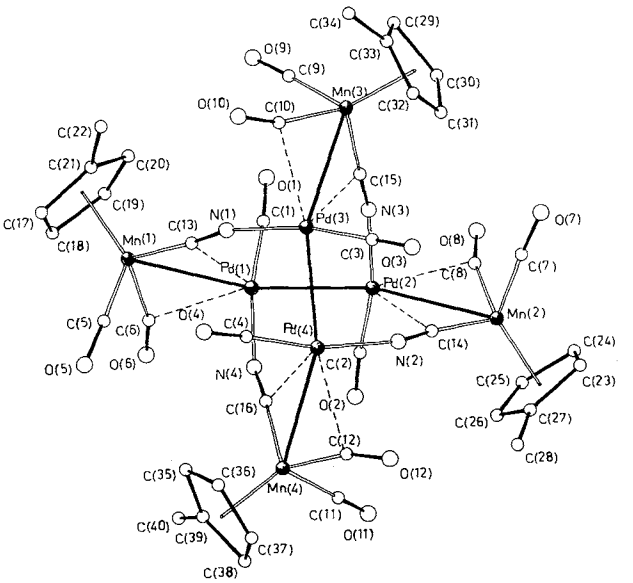

Fig. 1. View of the molecular structure of **7**. Selected bond distances [Å] and angles [°]: Pd(1)-Pd(2) 2.591(3), Pd(3)-Pd(4) 2.612(3), Pd(1)-Mn(1) 2.791(4), Pd(2)-Mn(2) 2.810(4), Pd(3)-Mn(3) 2.788(5), Pd(4)-Mn(4) 2.800(5), Pd(1)-C(1) 1.78(4), Pd(1)-C(6) 2.39(2), Pd(1)-C(13) 2.49(2), Pd(1)-N(4) 2.05(3), Pd(2)-C(2) 1.82(3), Pd(2)-C(8) 2.35(3), Pd(2)-C(14) 2.50(3), Pd(2)-N(3) 2.01(2), Pd(3)-C(3) 1.81(3), Pd(3)-C(10) 2.38(2), Pd(3)-C(15) 2.56(3), Pd(3)-N(1) 2.06(2), Pd(4)-C(4) 1.87(2), Pd(4)-C(12) 2.41(3), Pd(4)-C(16) 2.52(3), Pd(4)-N(2) 2.05(2), Mn(1)-C(13) 1.90(3), Mn(2)-C(14) 1.93(3), Mn(3)-C(15) 1.97(2), Mn(4)-C(16) 1.97(3), C(13)-N(1) 1.18(3), C(14)-N(2) 1.16(3), C(15)-N(3) 1.15(3), C(16)-N(4) 1.12(4); Mn(1)-Pd(1)-Pd(2) 161.6(2), Pd(1)-Pd(2)-Mn(2) 161.1(2), Mn(3)-Pd(3)-Pd(4) 153.3(2), Pd(3)-Pd(4)-Mn(4) 154.9(2), Pd(1)-Mn(1)-C(13) 60.5(7), Pd(2)-Mn(2)-C(14) 60.3(7), Pd(3)-Mn(3)-C(15) 62.3(8), Pd(4)-Mn(4)-C(16) 61.0(8), Mn(1)-C(13)-N(1) 173(2), C(13)-N(1)-Pd(3) 160(2), Mn(2)-C(14)-N(2) 173(2), C(14)-N(2)-Pd(4) 161(2), Mn(3)-C(15)-N(3) 175(2), C(15)-N(3)-Pd(2) 164(2), Mn(4)-C(16)-N(4) 173(2), C(16)-N(4)-Pd(1) 162(2).

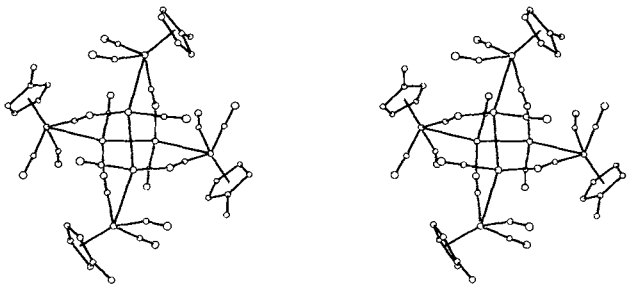

Fig. 2. Stereoview of the structure of 7.

No redox reaction has occurred in the course of the synthesis, and it could be considered that $1^{\ominus}$ has formally replaced an acetate ligand of the precursor complex, thus acting as an overall four-electron donor ligand. Of note is that the Pd_4 core of **7** contains two short metal–metal bonds (2.591(3) and 2.612(3) Å), as in the rectangular, 60-electron, Pd^I clusters $[Pd_4(CO)_4(OAc)_4]$ (2.663(1) Å) and $[Pd_4(\mu\text{-}Cl)_2(\mu\text{-dppm})_4](PF_6)_2$ (2.594(2) Å).[14] The topology of the $Pd_4Mn_4(CN)_4$ core is that of a tetrahedron, which is colored (the Pd–Pd edges are different from the Pd–Mn–CN–Pd ones) and oriented (through the Mn–CN–Pd vector) (Fig. 3).[15] The structure may be viewed as formed by two helices of opposite chirality whose axes are orthogonal, thus resulting in an overall *meso* structure.[16] The shape is largely

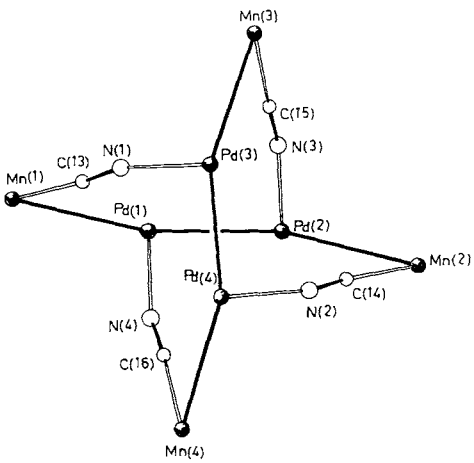

Fig. 3. Top: Core structure of 7 showing the Pd(1)N(4)C(16)Mn(4)Pd(4)Pd(3)-Mn(3)C(15)N(3)Pd(2) and Pd(3)N(1)C(13)Mn(1)Pd(1)Pd(2)Mn(2)C(14)N(2)Pd(4) *M* and *P* whorls of helices whose axes are orthogonal to each other, resulting in a *meso* arrangement [21]. Bottom: Schematic drawing of the structure.

controlled by the coordination geometry about the metals, in particular with $Pd–Mn–C_{cyanide}$ angles ranging from 60.3(7) to 62.3(8)°. Cluster **7** remained the only product observed when the stoichiometry of the reaction was changed, thus providing an interesting example of molecular self-assembly.

The Pd-bound CO ligands of **7** (Pd^I) are readily displaced by, for example, PPh_3, resulting in quantitative disproportionation to **3** (Pd^{II}) and Pd^0. The reaction of $[Pd_4(CO)_4(OAc)_4]\cdot(AcOH)_2$ with $2^{\ominus}$ was recently shown[17] to afford the anionic cluster $[Pd_4\{MoCp(CO)_3\}_4]^{2\ominus}$, in which each $MoCp(CO)_3$ fragment bridges a Pd–Pd edge of the central Pd_4 square in a manner similar to that encountered in **4**.[6] The latter reaction occurs with formal reduction of Pd^I to $Pd^{1/2}$. Whereas the ability of $[CpMo(CO)_3]^{\ominus}$ to act as a bridging metallo ligand is now well documented,[18] the first examples of $1^{\ominus}$ acting as a bridging ligand via the N atom have only recently been reported.[4b]

Reactions with $1^{\ominus}$ afford di-, tri-, and tetranuclear mixed-metal complexes, in which the metals are only linked by M–(μ-NC)–Mn bridges (CN-centered donor ability), and the octanuclear title cluster, the first cyanometalate complex with additional metal–metal interactions. Whereas most of the electron density in $1^{\ominus}$ is localized on the nitrogen atom, sufficient electron density must remain at the metal for further metal–metal bonding. These results provide an interesting contrast with the bonding behavior of $2^{\ominus}$, where metal–metal bond formation is usual (metal-centered donor ability) and M–(μ-OC)–Mo bridge formation much less common.[19] It is noteworthy that the metal-centered basicity of $CpCo(CO)_2$ was recently found to account for the formation of the Lewis acid–base complexes $[Cp(OC)_2Co \rightarrow HgX_2]$, whereas, with the stronger base $[CpCo(CN)(CO)]^{\ominus}$, the corresponding complex is unstable with respect to further electron transfer and elemental mercury is formed.[20]

Experimental Procedure

Reactions were performed under purified nitrogen, using standard Schlenk-type techniques. All compounds have been fully characterized by elemental analysis and spectroscopy. Unless otherwise noted, IR spectra were measured (Bruker IFS 66 spectrometer) in CH_2Cl_2 and ^1H and $^{31}P\{^1H\}$ NMR spectra in C_6D_6 (δ values in ppm relative to TMS) and THF/C_6D_6 (δ values in ppm relative to external H_3PO_4), respectively. Selected data: **3**: deep red crystals. IR: $\tilde{\nu}$(CN) = 2074 s, $\tilde{\nu}$(CO) = 1918 vs, 1865 vs cm^{-1}. IR (Nujol): $\tilde{\nu}$(CN) = 2070 vs, $\tilde{\nu}$(CO) = 1918 vs, 1909 vs, 1849 vs, br cm^{-1}. ^1H NMR: δ = 7.83–7.11 (m, 30H, C_6H_5), 3.71–3.66 (m, 8H, CH_3-C_5H_4), 1.54 (*s*, 6H, CH_3-C_5H_4). $^{31}P\{^1H\}$ NMR: δ = 19.17 (s). **5**: IR: $\tilde{\nu}$(CN) = 2067 s, $\tilde{\nu}$(CO) = 1913 vs, 1846 vs cm^{-1}. IR (Nujol): $\tilde{\nu}$(CN) = 2075 vs, $\tilde{\nu}$(CO) = 1916 vs, 1905 vs, 1834 vs cm^{-1}. ^1H NMR: δ = 7.43–7.07 (m, 40H, C_6H_5), 4.26–3.66 (m, 8H, CH_3-C_5H_4), 3.68 (m, 4H, ^{2+4}J(P,H) = 5 Hz, PCH_2), 1.71 (s, 6H, CH_3-C_5H_4). $^{31}P\{^1H\}$ NMR: (THF/C_6H_6): δ = − 5.33 (s). **7**: Deep violet crystals. IR: $\tilde{\nu}$ = 2055 w, 2018 s, 1932 vs, 1876 w cm^{-1}. IR (Nujol): $\tilde{\nu}$(CO) = 2061 m, 2048 m, 2023 w, 1938 vs, 1925 vs, 1870 m, 1855 m, br cm^{-1}. ^1H NMR: δ = 4.37–4.14 (m, 16H, CH_3-C_5H_4), 1.65 (s, 12H, CH_3-C_5H_4).

[11] Crystal structure determination of $7 \cdot C_2H_5OH$: $C_{40}H_{28}Mn_4N_4O_{12}Pd_4 \cdot C_2H_5OH$, $M = 1448.10$, triclinic, space group $P\bar{1}$, $a = 13.324(6)$, $b = 18.377(8)$, $c = 10.954(6)$ Å, $\alpha = 101.90(2)$, $\beta = 109.90(2)$, $\gamma = 90.98(2)°$, $V = 2457(2)$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.958$ g cm^{-3}, graphite-monochromated, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $\mu = 24.28$ cm^{-1}. The intensity data were collected on a Philips PW 1100 diffractometer, using the ω-2θ scan technique at room temperature. A decay of about 30% of the initial intensity of a standard reflection, measured after 50 reflections, was observed during the data collection and corrected. 7135 unique reflections, $3 < \theta < 25°$, 2635 with $I > 2\sigma(I)$ used in the refinement. The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares fit procedures, with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms except the carbon atoms of the methylcyclopentadienyl rings and the atoms of the molecule of solvation. The hydrogen atoms were introduced in calculated positions, but their parameters were not refined. The SHELX-76 and SHELXS-86 system of computer programs was used[12]. The R and R_w values were 0.0578 and 0.0852, respectively. Further details of the crystal structure analysis may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54 697, the names of the authors, and the journal citation.

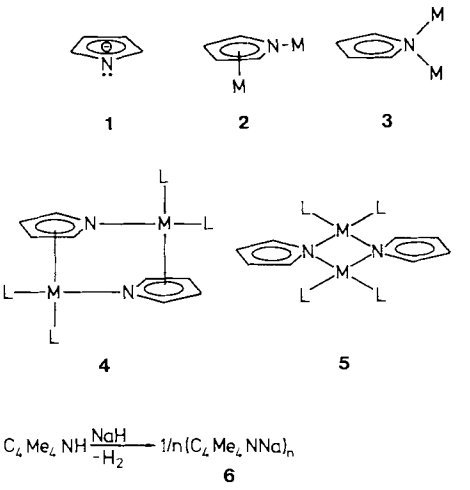
2,3,4,5-Tetramethyl-1-sodiopyrrole: An Azacyclopentadienyl Ligand in a Novel Bridging Function**

By *Norbert Kuhn,* Gerald Henkel,* and *Jörg Kreutzberg*

Dedicated to Professor Max Schmidt on the occasion of his 65th birthday

The structure and reactivity of pyrrolides (**1**) exhibit features of cyclopentadienides as well as of pyridines and amides. These similarities are reflected in the coordination of structure **2** and **3**, which have been identified in dimeric carbazolides of the alkali metals (**4** and **5**)[1, 2] (Scheme 1).



1 2 3 4 5

6

Scheme 1.

The structure of 2,3,4,5-tetramethyl-1-sodiopyrrole (**6**)[3] combines the characteristic features of amide bridges[4] with the π coordination of dienyl ligands.[5] In Figure 1, the double chain structure, consisting of alternating sodium and nitrogen atoms, shows that each pyrrolyl ligand[6] bridges three sodium atoms; the unusual coordination numbers 7 and 5 are thereby attained for sodium and nitrogen, respectively. As observed for lithiocarbazole,[1a] the two Na–N bonds involving η^1 bonding are of different lengths (Na-N^j 2.411(2), Na-N^k 2.351(1) Å); however, since the two η^1-bonded sodium atoms in **6** lie outside the plane of the linking pyrrolyl ligand to the same extent (the angle Na^i-N-Na^l is roughly bisected by the ring plane), a differentiation between σ and π bonding makes no sense in this case. On the other hand, the Na-N bond involving η^5 bonding (2.694(1) Å) is clearly longer and lies in the range observed for π bonding.[7] A comparison of the Na–C bonds (Na-C1 2.660(2), Na-C2 2.631(2), Na-C3 2.635(2), Na-C4 2.666(2) Å), also lying in the expected range,[5] shows that the sodium atom is displaced toward the carbon atoms in β position; this finding is in agreement with the structure calculated for lithiopyrrole.[1a] The bond lengths in the pyrrole ring (N-C1 1.387(2), N-C4 1.384(2), C1-C2 1.386(2), C2-C3 1.432(2), C3-C4 1.387(2) Å) are markedly longer than those of noncoordinat-

[**] Heterocycles as Ligands, Part 6. This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *P. Sartori* for his support. Part 8: N. Kuhn, E.-M. Lampe, *J. Organomet. Chem. 385* (1990) C9–C12.

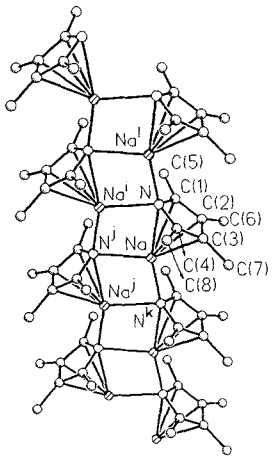

Fig. 1. Structure of **6** in the crystal (hydrogen atoms omitted). Selected interatomic distances [Å] and bond angles [°]: N···N^j 3.724(2), Na···Na^i 3.229(1); Na^i-Na-Na^j 101.3(1), N-Na-N^k 163.6(1), N-Na-N^j 93.5(1), N^k-Na-N^j 102.9(1), Na-N-Na^l 163.6(1), Na-N-Na^j 78.2(1), Na^l-N-Na^i 85.4(1).

ed tetramethyl pyrrole, but not as long as those in the fragment $(\pi\text{-}C_4Me_4N)Fe$.[8, 9] The Na_2N_2 quadrilaterals formed by the double chains (interatomic distances and bond angles shown in Fig. 1) are planar within the limits of experimental error and form angles of 0.8° with each other, resulting in a layer structure resembling a distorted rope ladder.

Unlike the analogous lithium compound, **6** is readily soluble in THF and is present in solution as a dimer. In the ^{13}C NMR spectrum, the signals of the ring carbon atoms (δ = 124.84 and 111.77) are only slightly shifted compared with those of tetramethylpyrrole (δ = 119.96 and 113.33); this finding indicates that the π bonding is disrupted upon dissolution with formation of structure type **5** (L = THF).

The unique structural features of 2,3,4,5-tetramethyl-1-sodiopyrrole confirm that the azacyclopentadienyl ligand displays versatile coordination properties, which were until now only presumed. In view of the rich structural chemistry of cyclopentadienyl compounds of the main-group elements,[10] the coordination chemistry of this heteroarene should offer promising applications.

Experimental Procedure

6: NaH (0.57 g, 23.7 mmol) and 2,3,4,5,-tetramethylpyrrole (2.93 g, 23.7 mmol) were allowed to react in 100 mL of refluxing THF for 18 h. The reaction mixture was then filtered, the solvent removed, and the residue extracted with 30 mL of diethyl ether. Yield after recrystallization of the residue from THF/diethyl ether: 1.28 g (43%) of colorless crystals. ^{13}C NMR (75.43 MHz, [D_8]THF, TMS int.): δ = 124.84 (C2,5), 111.77 (C3,4), 13.70 (C2,5-CH_3), 10.43 (C3,4-CH_3). MS (70 eV): *m/z* 145 ($M^{\oplus}$, 1%), 122 ($M^{\oplus}$ − Na], 100%). Molecular mass: found 265 (vapor pressure osmometry in THF at 45 °C), calcd 145.2 (monomeric formula unit).

α-Umpolung of Ketones via Enol Radical Cations: A Mechanistic Study**

By *Michael Schmittel,* Ahmed Abufarag, Olaf Luche,* and *Michael Levis*

Numerous MO calculations[1] and mass-spectrometric studies[2] have confirmed that simple enol radical cations are much more stable than the tautomeric keto ions in the gas phase, in distinct contrast to the order of stability of the neutral species[3] (Fig. 1).

Reversal of the thermodynamics of the keto/enol equilibrium by one-electron oxidation is also found in solution, as exemplified by studies on stable enols.[4] For example, the radical cations of β,β-dimesityl-substituted enols are up to 25 kcal mol^{-1} more stable than those of the tautomeric ketones in acetonitrile.

This finding opens up interesting possibilities for new synthetic procedures. Starting from the ketone, the small amount of enol present in equilibrium can be selectively oxidized by suitable choice of oxidizing agent and the resulting radical cation can be trapped by nucleophiles. If enolization is sufficiently fast (acid or base catalysis), the carbonyl com-

[**] Enol Radical Cations in Solution, Part 2. This work was supported by the Deutsche Forschungsgemeinschaft, the Land Baden-Württemberg (Fr-NW 31), and the Fonds der Chemischen Industrie (Liebig-Stipendium for *M. S.*). We thank Prof. *C. Rüchardt* for supporting our work and *D. Morat* for her dedicated assistance. Part 1: [4].

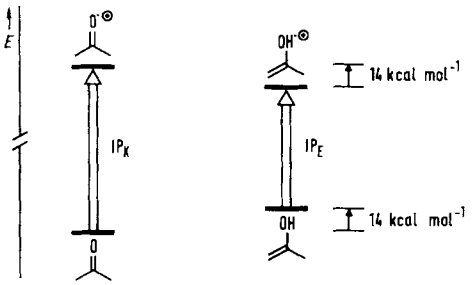

Fig. 1. Relative energies of acetone and the tautomeric propen-2-ol as neutral molecules and as radical cations in the gas phase [2].

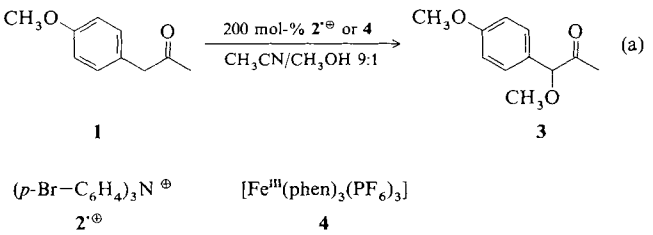
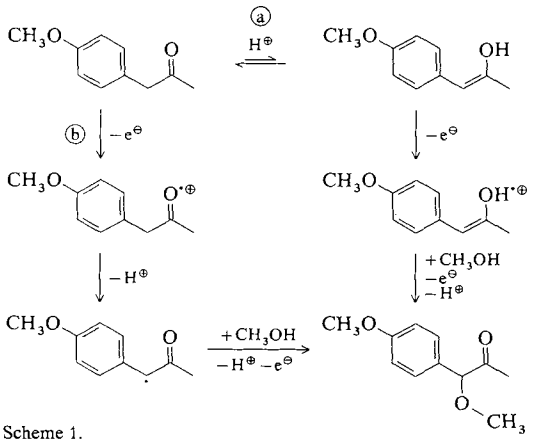
pound could react quantitatively via enol radical cation intermediates.

To investigate this possibility, we first studied the reaction of 1-(*p*-methoxyphenyl)propan-2-one (**1**), which has an enol content of only about 10^{-4}% 1-(*p*-methoxyphenyl)propen-2-ol,[5] with tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate ($\mathbf{2}^{\bullet\oplus}$). The direct one-electron oxidation of **1** (E_p = 1.67 V[6]) by $\mathbf{2}^{\bullet\oplus}$ (**2**: $E_{1/2}$ = 1.06 V[7]) is so strongly endergonic that, even for rapid subsequent reactions of $\mathbf{1}^{\bullet\oplus}$, reactions should occur only slowly. On the other hand, the oxidation potential of the enol of **1** should be less than 1 V,[8] ensuring its rapid oxidation by $\mathbf{2}^{\bullet\oplus}$. Reaction of **1** with 200 mol% of $\mathbf{2}^{\bullet\oplus}$ in acetonitrile/methanol (9:1) for 14 min gave **3**[9] (56%) [Eq. (a)]. In addition, *p*-anisaldehyde (<9%) and 1-(*p*-methoxyphenyl)propane-1,2-dione (<5%) were formed.



Comparable yields of **3** (49%) are obtained when 200 mol% of tris(*o*-phenanthroline)iron(III) tris(hexafluorophosphate) (**4**) is used. This finding supports the assumption of one-electron oxidation steps in the reaction mechanism, since **4** ($E_{1/2}$ = 1.09 V) is known to be an outer-sphere oxidizing agent according to the work of *Kochi* et al.[10]



Scheme 1.

The products obtained are consistent with the assumed course of the reaction. The acid released during the reaction catalyzes the enolization of **1** and the enol is selectively oxidized and then trapped by methanol (Scheme 1, path a). Also plausible would be the route involved in oxidative functionalization of alkylarenes[11] (path b). This reaction is known to proceed effectively despite strongly endergonic electron-transfer steps.

Control experiments allow a distinction to be made between the two reaction hypotheses. According to path b, a strongly endergonic electron-transfer step is followed by deprotonation of the keto radical cation. The rate of the overall reaction should therefore increase, or at least remain constant, upon addition of a base. In fact, however, the reaction of **1** with $\mathbf{2}^{\bullet\oplus}$ proceeds much slower in the presence of 200 mol% of 2,6-di-*tert*-butylpyridine: after 5 h, only 8% of **3**, together with 58% of unreacted **1**, is obtained.[12] This finding rules out path b but is consistent with path a, since the acid-catalyzed enolization should be suppressed by addition of base.[13]

Additional arguments against path b are provided by the reaction of 3-(*p*-methoxyphenyl)butan-2-one (**5**, E_p = 1.69 V) with ammoniumyl salts. The direct oxidation of **5** can be suppressed or enhanced relative to acid-catalyzed enolization by the use of ammoniumyl salts having various oxidizing strengths (Table 1) [Eq. (b)].

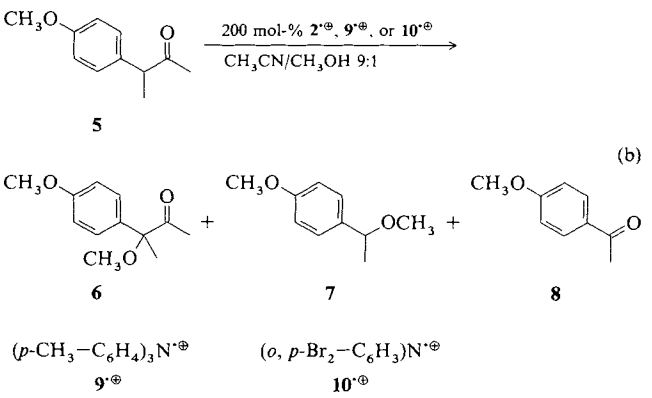


Table 1. Products of the reaction of **5** with ammoniumyl salts (200 mol%) in acetonitrile/methanol (9:1) at room temperature. The yields and reaction times are average values from at least three independent experiments.

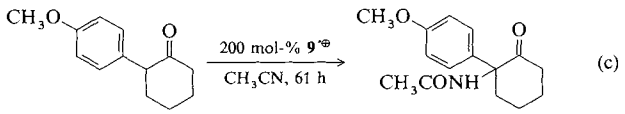
Ammoniumyl salt	$E_{1/2}$ (SCE)[14] [V]	**6** [%]	**7** [%]	**8** [%]	**5** [%]	*t* [12]
$\mathbf{9}^{\bullet\oplus}$ [a]	0.76	78	<1	<1	5	33 h
$\mathbf{2}^{\bullet\oplus}$ [a]	1.06	30	10	6	29	153 min
$\mathbf{10}^{\bullet\oplus}$ [a]	1.50	<1	7	6	41	25 s

[a] As hexachloroantimonate.

The product analysis clearly shows that the use of strong ammoniumyl salts results in a large decrease in the amount of **6** and an increase in the formation of cleavage products such as **7** and **8**.[9, 15] Apparently, $\mathbf{5}^{\bullet\oplus}$ is not deprotonated under the reaction conditions, as required according to path b, but instead undergoes C–C bond cleavage. On the other hand, the use of a weakly oxidizing ammoniumyl salt leads to high yields of **6**; in this case, the direct oxidation of **5** can no longer compete with the acid-catalyzed enolization and subsequent oxidation of the enol.

The use of alcohols as nucleophiles necessitates the consideration of further reaction pathways in addition to those discussed above, since, besides ketones and tautomeric enols, small equilibrium concentrations of enol ethers and acetals may also be present.[16] However, acetals and enol ethers need not be intermediates in the umpolung reaction, as shown by treatment of 2-(*p*-methoxyphenyl)cyclohexanone (**11**, E_p = 1.63 V) with 200 mol% of $\mathbf{9}^{\bullet\oplus}$ in pure acetonitrile: **12** is formed in 74% yield [Eq. (c)].



11 **12** (c)

The investigations show that ketones such as **1** and **5**, which exhibit a low tendency toward enolization, can be methoxylated in the α position via their enol radical cations. It is still unclear how the enol radical cations react further to give the products.[17] Elucidation of the mechanistic details and scope of application of this novel umpolung reaction of ketones, especially in comparison with known methods,[18] is in progress.

[6] The oxidation potentials given here refer to the saturated calomel electrode (SCE); they were measured in acetonitrile (100 mV s^{-1}): 2–3 mM **1** or **5**, 0.1 M tetra-*n*-butylammonium hexafluorophosphate, ferrocene as reference.
[7] W. Schmidt, E. Steckhan, *Chem. Ber. 113* (1980) 577.
[8] The oxidation potentials of β,β-dimesityl-substituted enols [4] are about 1 V below those of the tautomeric ketones. Assuming identical differences in oxidation potential for **1** in enol and keto form, E_p (enol) should be much less than 1 V (SCE).
[9] A 30 mM solution of the ketone in acetonitrile/methanol (9:1) was stirred with 20 mol% of $\mathbf{2}^{\bullet\oplus}$ at room temperature until the blue color of the ammoniumyl salt vanished. The products were characterized by spectroscopy and by comparison with authentic substances.

[11] E. Baciocchi, A. Dalla Cort, L. Eberson, L. Mandolini, C. Rol, *J. Org. Chem. 51* (1986) 4544; C. J. Schlesener, J. K. Kochi, *ibid. 49* (1984) 3142; L. Eberson, *J. Am. Chem. Soc. 105* (1983) 3192; E. Baciocchi, C. Rol, G. V. Sebastiani, B. Serena, *Gazz. Chim. Ital. 113* (1983) 853.
[12] As a measure of the reaction rate, the time required for color change from blue (color of $\mathbf{2}^{\bullet\oplus}$) to brown was determined.
[13] Addition of 200 mol% of trifluoromethanesulfonic acid to the reaction mixture gave **3** in 78% yield after 10 min.
[14] E. Steckhan, *Top. Curr. Chem. 142* (1987) 1.
[15] The low conversion of **5** upon oxidation with $\mathbf{10}^{\bullet\oplus}$ is due to rapid reaction of $\mathbf{10}^{\bullet\oplus}$ with the solvent mixture. Furthermore, competition experiments showed that, when $\mathbf{10}^{\bullet\oplus}$ was used as oxidizing agent, **6** did not react faster than **5**.

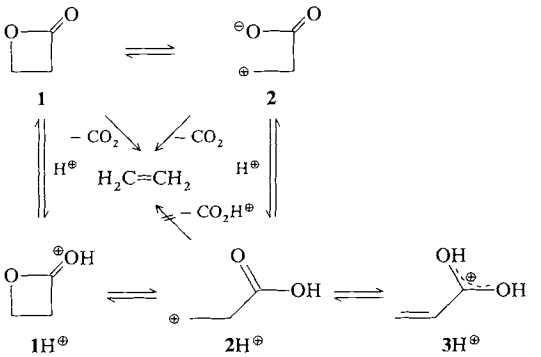
Isomerization versus Decarboxylation of Protonated Oxetanone: Comparison between Experimental Results and Theoretical Calculations

By *Gregorio Asensio,* Miguel A. Miranda,* Julia Perez-Prieto, Maria J. Sabater,* and *Antonio Simón-Fuentes*

Decarboxylation of 2-oxetanones is a general and useful method for the stereospecific synthesis of olefins, proceeding with complete stereoretention in neutral organic solvents.[1] Conversely, upon addition of an acid catalyst, *cis*-3,4-disubstituted 2-oxetanones undergo carbon dioxide elimination with almost total inversion of configuration and a marked increase in the reaction rate.[2] Recent theoretical calculations[3] on the decarboxylation of 2-oxetanone protonated at the carbonyl oxygen atom ($\mathbf{1H}^{\oplus}$) as a model for the acid-catalyzed thermolysis appear to support the intermediacy of a carbenium ion ($\mathbf{2H}^{\oplus}$), which is assumed to undergo fragmentation affording ethylene and protonated carbon dioxide. Hence, we decided, as a part of our work on the thermolysis of protonated carbonyl compounds,[4] to study the behavior of the parent 2-oxetanone (**1**) in concentrated sulfuric acid in order to determine the role of cationic species in the decarboxylation and to check the feasibility of the suggested C3–C4 fragmentation of $\mathbf{2H}^{\oplus}$ to ethylene and protonated carbon dioxide.



The protonated lactone $\mathbf{1H}^{\oplus}$ [5] was studied over a temperature range of 30 to 150 °C, during a period of up to several days, by keeping the corresponding sulfuric acid solutions in thermostated baths and recording periodically the ^{1}H NMR

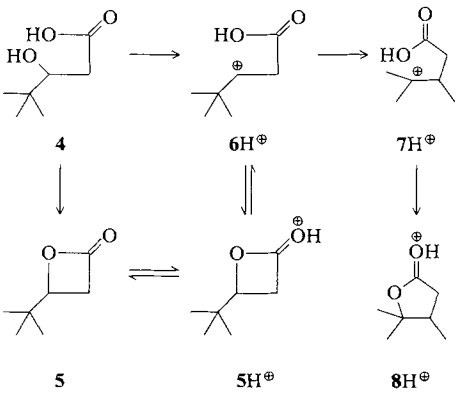
spectra. Surprisingly, formation of ethylene could not even be detected.[6] Instead, an equilibrium[7] was established between O-protonated 2-oxetanone ($1H^{\oplus}$) and O-protonated acrylic acid ($3H^{\oplus}$).[8] Alternatively, $3H^{\oplus}$, generated directly by protonation of **3** in concentrated sulfuric acid, was heated in the same temperature range to afford equilibrium mixtures of $1H^{\oplus}$ and $3H^{\oplus}$ with the same composition as starting from $1H^{\oplus}$. Even after prolonged heating at 150 °C, the transformations were clean[9] in that no polymers were formed, as shown by adding a known amount of methanesulfonic acid as internal standard for ^1H NMR integration. These results strongly suggest the intermediacy of the cation $2H^{\oplus}$, which does not decarboxylate at all, in clear disagreement with theoretical calculations.[3]

To rule out the possibility of alternative reaction pathways not involving the intermediacy of $2H^{\oplus}$ (i.e., E_2 elimination from $1H^{\oplus}$ or conjugate addition to $3H^{\oplus}$), we studied the *tert*-butyl-substituted oxetanone **5** and its β-hydroxy acid precursor **4**.[10] We anticipated that the corresponding C-protonated species $6H^{\oplus}$, if formed, would rearrange to the more stable tertiary cation $7H^{\oplus}$. As expected, compounds **4** and **5**, when dissolved in sulfuric acid at room temperature, gave O-protonated 4,5,5-trimethyl-γ-butyrolactone ($8H^{\oplus}$)[11] in quantitative yield.



Since the value of ΔG° for the conversion of O-protonated oxetanone ($1H^{\oplus}$) to O-protonated acrylic acid ($3H^{\oplus}$) is very small,[7] it is easy to understand why the observed isomerization $1H^{\oplus} \rightleftharpoons 3H^{\oplus}$ takes place. On the other hand, the predicted fragmentation of $1H^{\oplus}$ to ethylene and protonated CO_2 would be strongly endothermic.[3]

Nonetheless, it must be taken into account that our results have been obtained in solution, whereas the theoretical calculations refer to the gas phase. For this reason, we recorded the CI mass spectrum of **1**, since fragmentation of the $(M+1)$ peak, corresponding to the protonated molecule, is highly relevant in terms of gas-phase ion chemistry.[4] In this spectrum, the peak with *m/z* 73, resulting from the isobaric ions $1H^{\oplus}$ and $3H^{\oplus}$, was most intense. Dehydration of $3H^{\oplus}$ to the corresponding acylium ion would account for the presence of a fragment with *m/z* 55 (5%). A minor peak with *m/z* 45 (5%), assignable to protonated carbon dioxide, was observed, thus indicating that the predicted cleavage of $1H^{\oplus}$ can indeed occur to a small extent under the very energetic conditions inherent to mass spectrometry. Moreover, the alternative pathway for the formal [2+2] cycloreversion, involving formation of protonated ketene (*m/z* 43 (21%)), appears to be more important. This fragmentation was also detected in solution.[9]

In summary, we have shown that the only significant process undergone by protonated 2-oxetanone ($1H^{\oplus}$) in concentrated sulfuric acid solution is the isomerization to O-protonated acrylic acid ($3H^{\oplus}$) via the C-protonated intermediate $2H^{\oplus}$, which does not decarboxylate as predicted earlier.[3] These results might be interesting in connection with the reported inverted stereospecificity and rate enhancement in the decarboxylation of 3,4-disubstituted 2-oxetanones in the presence of catalytic amounts of acid.[2] Under these conditions, $2H^{\oplus}$ (or the corresponding substituted species) would be in equilibrium with the zwitterion **2**. It is reasonable to assume, therefore, that a fast rotation around the C–C bond will occur in $2H^{\oplus}$, where 1,4 interactions are weaker, whereas decarboxylation should take place from **2**, as postulated for the neutral compound **1**.[1b,c]

A Novel Palladium-Catalyzed Carbonylation of Aromatic *N*-Chlorosulfonamidates to Arylsulfonyl Isocyanates**

By *Gábor Besenyei, Sándor Németh*, and *László I. Simándi**

Catalytic hydroformylation and related carbonylations at carbon atoms affording aldehydes, carboxylic acids and esters are well known and widely used in laboratory and industry. Other important types of carbonylation are those occurring at the nitrogen atoms of aromatic amines and nitro compounds, leading to the formation of isocyanates and their derivatives like ureas and carbamates,[1,2] which find

application as components of polyurethane resins and plant protecting agents. Owing to the drastic conditions, expensive catalysts, and sometimes inadequate selectivities the best methods of isocyanate synthesis remain those based on the phosgenation of amines.

In the course of searching for new possibilities concerning the synthesis of arylsulfonyl isocyanates, we have discovered that sodium and potassium salts of aromatic *N*-chlorosulfonamidates (**1**) can be catalytically carbonylated to arylsulfonyl isocyanates (**2**) at 20–100 °C and a CO pressure of 20–50 bar in CH_2Cl_2 or 1,2-dichloroethane as solvent [Eq. (a), M = Na, K]. Suitable catalysts are palladium salts and complexes like $[PdCl_2(CH_3CN)_2]$, $[PdCl_2(PhCN)_2]$, $[PdCl_2(Ph_3As)_2]$ and $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone). The starting compounds **1a–e** are listed in Table 1 together with typical yields of the product isocyanates **2a–e**. The latter were identified by the strong N=C=O stretching

$$\underset{\textbf{1a-e}}{[ArylSO_2NCl]M} + CO \xrightarrow{\text{Pd-catalyst}} \underset{\textbf{2a-e}}{ArylSO_2NCO} + MCl \qquad (a)$$

Table 1. Yields of arylsulfonyl isocyanates **2** by catalytic carbonylation of *N*-chloroarylsulfonamidates ($p(CO)$ = 40 bar; solvent CH_2Cl_2). Right-hand column: molecular masses of the corresponding arylsulfonylureas **3** determined by FAB-MS.

1 Aryl	M	*T* [°C]	Catalyst/Additive	Yield of **2** [%]	($M^{\oplus}$ + H) of **3**
a Phenyl	$K^{\oplus}$	20	$[PdCl_2(Ph_3As)_2]$	76	311

band at $\tilde{\nu}$ = 2250–2230 cm^{-1} readily observed in the diluted product mixture. Upon addition of some ethanol, the N=C=O band disappears and new bands appear at $\tilde{\nu}$ = 3600 and 1750 cm^{-1}, which are due to excess ethanol and ethyl *N*-arylsulfonylcarbamate. The yields in Table 1 were determined by treating the reaction mixture with the theoretical amount of 2-chloroaniline (2-CA), followed by isolation of the *N*-arylsulfonyl-*N'*-(2-chlorophenyl)ureas **3a–e** formed [Eq. (b)], which were identified by FAB-MS, IR spectroscopy, and elemental analysis.

$$\underset{\textbf{2a-e}}{ArylSO_2NCO} + 2\text{-CA} \longrightarrow \underset{\textbf{3a-e},\ Aryl' = 2\text{-chlorophenyl}}{ArylSO_2NHC(O)NHAryl'} \qquad (b)$$

Currently the best method available for the synthesis of arylsulfonyl isocyanates involves phosgenation of *N*-arylsulfonyl-*N'*-butylureas.[3] Reaction (a) constitutes a new and convenient phosgene-free route to arylsulfonyl isocyanates, which are important intermediates in the synthesis of sulfonylurea type herbicides and pharmaceuticals.

Two kinds of mechanisms are conceivable for reaction (a), namely those involving an arylsulfonylcarbamoyl chloride and those involving an arylsulfonylnitrene as intermediate. To our knowledge the only N-Cl carbonylation reported thus far is the reaction of *N*-chloroamines with CO, resulting in the formation of substituted carbamoyl chlorides.[4] We could not detect a carbamoyl band ($\tilde{\nu}$ = 1760–1810 cm^{-1}) in the reaction mixture, which rules out accumulation of a carbamoyl chloride intermediate. If this intermediate is formed, it should immediately decompose with elimination of the alkali metal chloride to give the isocyanate. The possibility of a nitrene intermediate receives some support from a claim that *N*-chloro-*p*-toluenesulfonamidate may be a potential source of tosylnitrene.[5] It is reasonable to assume that nitrene, if involved, should coordinate to the palladium ion, which may also bind a carbonyl ligand, thus providing a path for nitrene carbonylation in the coordination sphere. Work is in progress in our laboratory to elucidate the mechanism of this new reaction.

Experimental

A 45-mL stainless steel reactor (Parr Model 4712) was charged with 10 mL of dry CH_2Cl_2, 2.7 g (0.01 mol) of potassium *N*-chloro-2-chlorobenzenesulfonamidate **1c** [6], 70 mg of $PdCl_2$ and 1 mL of CH_3CN. After flushing with CO, the reactor was pressurized to 40 bar with CO. The mixture was stirred for 6 h at ambient temperature. The pressure was released, and 0.5 mL of the reaction solution was diluted with CH_2Cl_2 to 20 mL for the IR measurement. The intense band observed at 2230 cm^{-1} disappeared upon treatment with EtOH. The rest of the mixture was treated dropwise with 1.2 g (0.01 mol) of 2-chloroaniline under N_2. A violent reaction took place, which required external cooling. Evaporation to dryness afforded 3.54 g of a pale yellow crude product, which, besides KCl and the catalyst, contained 76% of *N*-(2-chlorophenylsulfonyl)-*N'*-(2-chlorophenyl)urea (**3c**), and 10% 2-chlorobenzenesulfonamide, as shown by HPLC. IR (KBr) (cm^{-1}): **2c**: $\tilde{\nu}$ = 2230 (ν_{as}NCO); **3c**: $\tilde{\nu}$ = 1690 (νCO), 1535(amide II), 1435, 1335(ν_{as} SO_2), 1155(ν_s SO_2), 755(γCH), 745(γCH); the 3370–2820 region is dominated by free and associated νNH vibrations. MS (FAB): *m/z* 345 ($M^{\oplus}$ + H, 10%).

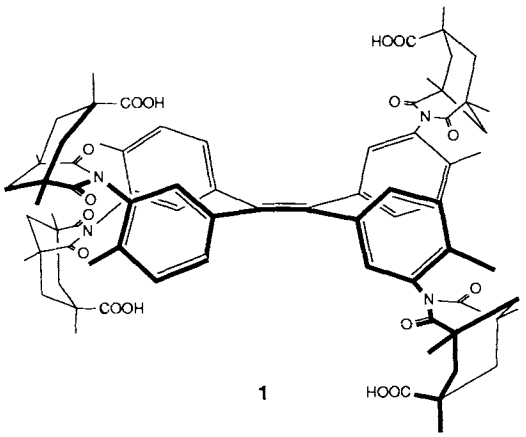
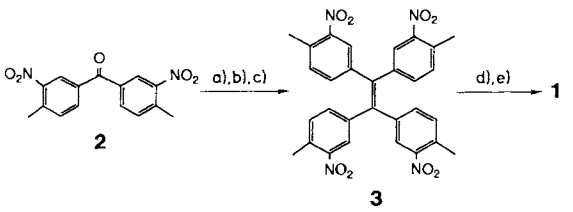
high affinities result when the conformation of the free host approaches that of the complex.[1] However, it has been hard to dissect the enthalpic contributions of ground state destabilization from those involving entropic factors, such as restricted motions. In this work, we use an allosteric effect as a means of preorganization and provide a measure of what enhanced affinity may be expected from such remote interactions.

The system involves the Kemp triacid derivative **1**, in which the acidic OH bonds of up to four carboxy groups can converge toward the center of the structure.



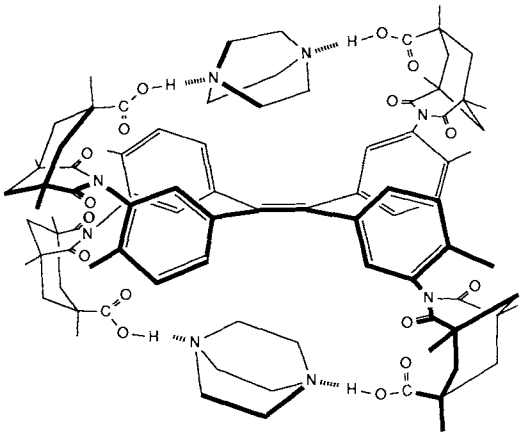
1

1 was synthesized from the dinitrobenzophenone **2**[2] via its hydrazone. Oxidation of the hydrazone with $Pb(OAc)_4$ in CH_2Cl_2 gave the diazo compound **4**, which was decomposed in hot benzene using $Cu(acac)_2$ as a catalyst to give the tetraphenylethylene derivative **3**, along with the corresponding ketazine and the ketone **2** as side products. Reduction of **3** with Raney nickel in dioxane gave the tetramine from which **1** was prepared by condensation with four equivalents of Kemp's triacid (Scheme 1).[3]



Scheme 1. a) hydrazine, ethanol, 82%; b) $Pb(OAc)_4$, CH_2Cl_2, 96%; c) $Cu(acac)_2$, benzene, 35%; d) H_2, Raney-Ni, dioxane, 3 bar, 95%; e) anhydride acid chloride of Kemp's triacid, pyridine, dimethylaminopyridine (DMAP), 30%.

Molecular modeling suggested that several diamines would be suitable guests for **1**. Hydrazine, ethylenediamine, 1,4-diazobicyclo[2.2.2]octane (DABCO) and 2-aminopyrimidine were selected for study and proton NMR titrations of **1** with these diamines in $CDCl_3$ were performed. The downfield shifts ($\delta = 0.15-0.60$) of the aromatic host protons in the 2,2',2'' and 2''' positions were followed. The titration curves obtained showed the formation of a 1:2 complex; 1:1 models such as Eadie-Hofstee-plots[4] did not fit the experimental data, but Hill plots gave appropriate sigmoid shapes. While rapid exchange was observed at room temperature, the DABCO complex showed slow exchange at 213 K in $CDCl_3/CD_2Cl_2$ mixtures. Signals for the 1:1, the 1:2 complex and the free host were resolved. Further, irradiation of the DABCO resonance in a 1:2 mixture of **1** and DABCO in $CDCl_3$ results in a homonuclear intermolecular NOE effect of +30% for the aromatic host protons near the imide groups (2,2',2'',2'''-positions). The results are consistent with the structure shown in Scheme 2. FAB mass spectra (matrix: *m*-nitrobenzyl alcohol, 8 kV-Xe-bombardment) of mixtures of **1** with the chosen guest molecules show intense signals for the 1:1 complexes; signals for the 1:2 complexes could not be observed. The statistically corrected association constants (Table 1) were obtained from Hill plots.[5]



Scheme 2. Proposed structure of the 1:2 complex of **1** with DABCO.

Table 1. Statistically corrected association constants for the 1:1 and 1:2 complexes of **1** with various diamines[a].

Guest	$K(1:1)$ [L mol^{-1}]	$K(1:2)$ [L mol^{-1}]
Hydrazine	630	35000
Ethylendiamine	9	1700
DABCO	150	360
2-Aminopyrimidine	1400	90

[a] $T = 25\,^{\circ}C$; $c_{host} = 1 \times 10^{-3}$ mol L^{-1}, $c_{guest} = 5 \times 10^{-3}$ mol L^{-1}. Errors are estimated to be 10%.

Hydrazine and ethylenediamine show extensive positive cooperativity. DABCO shows reduced cooperativity, whereas 2-aminopyrimidine features negative cooperativity. It is likely that intramolecular hydrogen bonds between adjacent carboxy groups stabilize the unbound state. Chelation of one molecule of either hydrazine or ethylenediamine by nonadjacent acid groups of **1** forces the remaining acid groups to the other side of the ethylene planes in a conformation where they are poised (preorganized) for chelation of a second amine. This could lead to the 55 to nearly 200-fold increase of the association constants for the second binding event. DABCO has a somewhat longer N–N distance (2.6 Å) than is ideal for the cavity, and binding on one site could result in buttressing effects that reduce the cooperativity of the system. The chelation of 2-aminopyrimidine probably involves two adjacent sites, but we are unable to distinguish just which isomer this is. If a third carboxy group makes binding contact in the 1:1 complex, negative cooperativity would be the result.

In conclusion, the results show that binding cooperativity in these systems is much larger than those previously ob-

served with crown ether derivatives;[6] whether they arise from lost rotational degrees of freedom or exposure of buried sites is a matter for future research.[7]

Synthesis and Structure of a Diphosphadigalletane: A Novel Base-Stabilized Ga_2P_2 Ring System**

By *Alan H. Cowley,* Richard A. Jones,* Miguel A. Mardones, Jaime Ruiz, Jerry L. Atwood,** and *Simon G. Bott*

The search for new semiconductor precursors provides much of the impetus for a rekindled interest in the synthetic chemistry of the heavier group 13 and 15 elements. Apart from Lewis acid-base adducts, most of the current emphasis has been placed on compounds of the general type $(R_2MER'_2)_n$ (M = Ga,In; E = P,As,Sb).[1] However, we have recently turned our attention to species of empirical composition RMER'. Such compounds are of interest because of the potentially rich variety of structural forms and the possibility of novel bonding modes. Previous examples of compounds of the type $(RMER')_n$ have been confined to cases where M = B, Al and E = N.[2] We report the first instance in which both M and E are heavier main group elements.

Our initial attempts to prepare the desired compounds focussed on base-promoted dehydrochlorination reactions of $[t$Bu(Cl)GaP(H)Ar'$]_2$ which, in turn, was prepared via the methathetical reaction of $(t$BuGaCl$_2)_2$ with Ar'PHLi (Ar' = 2,4,6-tBu$_3$C$_6$H$_2$).[3] However, these efforts were thwarted by the strong Lewis acidity of Ga. As a consequence, we decided to explore the possibility of intramolecular Lewis base stabilization of the desired structure. The monoanionic ligand $[2,6\text{-}(Me_2NCH_2)_2C_6H_3]^{\ominus}$ seemed well suited for this purpose because of its demonstrated ability to stabilize unusual transition metal intermediates.[4]

Treatment of $Li[2,6\text{-}(Me_2NCH_2)_2C_6H_3]$[5] with an equimolar quantity of $GaCl_3$ in toluene solution at −78 °C affords **1** which was characterized spectroscopically[6] and by an X-ray analysis.[7] The geometry around Ga in **1** is approximately trigonal bipyramidal (Fig. 1): the two N atoms

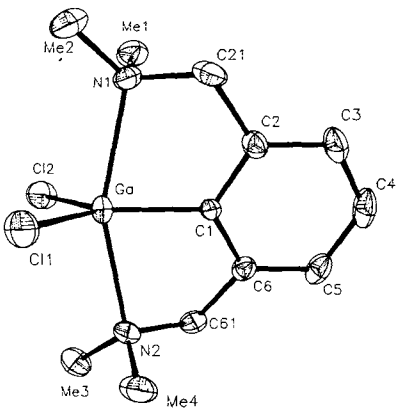

Fig. 1. The structure of **1** in the crystal. Selected bond lengths [Å] and bond angles [°]: Ga-Cl1 2.189(1), Ga-Cl2 2.189(2), Ga-N1 2.359(4), Ga-N2 2.351(4), Ga-C1 1.924(4), Cl11-Ga-Cl2 111.01(8), N1-Ga-N2 158.2(1), Cl1-Ga-C1 124.5(1), Cl2-Ga-C1 124.4(1).

adopt axial sites while the equatorial positions are occupied by two Cl atoms and the aryl group. There is, however, considerable distortion from the ideal angles, for example Cl-Ga-Cl = 110.01(8)° and N-Ga-N = 158.2(1)°.

Treatment of Ph_3SiPH_2[8] with 2.0 equivalents of tBuLi in Et_2O affords Li_2PSiPh_3 which, in turn, reacts with **1** at −78 °C to give **2**. The ^{1}H- and ^{13}C{^{1}H}-NMR data for **2**[6] establish equal abundances for the aryl and Ph_3Si substituents, and the high-resolution mass spectrum for the most intense $M^{\oplus}$ peak (found 1102.295630, calculated for $C_{60}H_{68}{}^{69}Ga^{71}GaN_4P_2Si_2$ 1102.296064) corresponds to a dimer of composition $[\{(Me_2NCH_2)_2C_6H_3\}GaPSiPh_3]_2$. Detailed structural information was provided by an X-ray analysis (Fig. 2). The central Ga_2P_2 core of **2** comprises a rhombus which resides on a center of symmetry. The bond angle at Ga (94.25(5)°) is somewhat larger than at P (85.75(5)°). The Ga–P bond length (2.338(1) Å) is over 0.1 Å shorter than those found in dimers or trimers of empirical composition RR'GaPR"R"'.[1] While it is tempting to suggest a modicum of P → Ga dative π-bonding, it should be noted that the phosphorus geometry is pyramidal (sum of angles at P = 325.52°). Clearly if there is any delocalization in the Ga_2P_2 ring, it is considerably less than that in diazadiboretidines[2] which are therefore much closer analogues of cyclobutadiene. Note also that each Ga is tetracoordinate due to the coordination of one dimethylamino group on each aryl ligand. In solution at ambient temperature there is evidently an exchange between free and coordinated Me_2N moieties since only one set of resonances is apparent in the

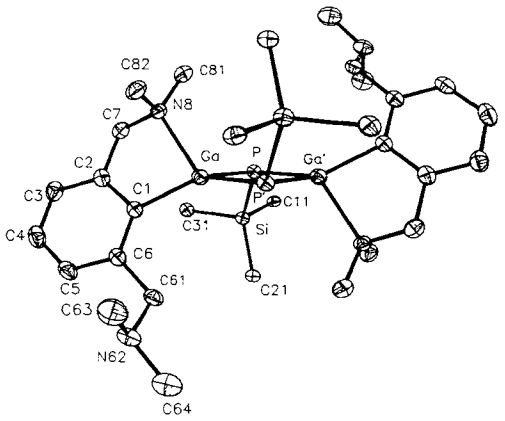

Fig. 2. The structure of **2** in the crystal. Selected bond lengths [Å] and bond angles [°]: Ga-P 2.388(1), P-Si 2.210(2), Ga-N8 2.139(4), Ga-C1 1.982(4), P'-Ga-P 94.25(5), P'-Ga-C1 129.4(1), P-Ga-N8 119.1(1), Ga'-P-Ga 85.75(5), Ga-P-Si 125.21(6), Ga'-P-Si 114.56(6), C1-Ga-N8 84.2(2), P-Ga-N8 119.1(1).

^{1}H- and ^{13}C{^{1}H}-NMR spectra.[6] No significant spectral changes were detectable down to −78 °C.

The thermolysis of **2** has been examined by temperature-programmed EI and CI mass spectrometry. When the temperature of the sample is increased at 20 °C/minute, a cluster of peaks appear at ca. 130 °C which are attributable to the monomer, e.g. at 200 °C for $C_{30}H_{34}{}^{69}GaN_2PSi$, found 550.147365, calculated 550.148472. No peaks corresponding to the dimer are evident at this temperature.

Experimental

1: A solution of 7.38 mmol of Li[2,6-$(Me_2NCH_2)_2C_6H_3$] [5] in 30 mL of toluene was added dropwise to a cooled (−78 °C) solution of $GaCl_3$ (1.3 g, 7.38 mmol) in 25 mL of toluene. The reaction mixture was allowed to warm to ambient temperature, after which it was stirred for a further 24 h. Filtration, followed by solvent evaporation, afforded a turbid liquid from which colorless crystals of **1** (m.p. 58 °C) were obtained in 61% yield by the addition of benzene. MS(EI, 70 eV): 332 ($M^{\oplus}$, 32.20%), 297 ($M^{\oplus}$ − Cl, 8.76%), 289 ($M^{\oplus}$ − NMe_2, 42.14%), 191 ($M^{\oplus}$ − $GaCl_2$, 99.71%), 105 (GaCl, 26.32%), 58 (CH_2NMe_2, 100%).
2: A suspension of Li_2PSiPh_3 was prepared by the addition of 1.8 mL of *t*BuLi (1.7 M in pentane) to a cooled (−78 °C) suspension of Ph_3SiPH_2 [8] (0.44 g, 1.5 mmol) in 25 mL of Et_2O. The stirred suspension was allowed to warm to ambient temperature, following which it was added to the suspension of **1** (0.73 g, 1.5 mmol) in 25 mL of Et_2O at −78 °C. The reaction mixture was allowed to reach ambient temperature and stirring was continued for 3 h. After filtration and concentration of the filtrate, colorless crystals of **2** (m.p. 234–237 °C), formed in 43% yield by cooling to −20 °C. Compound **2** is soluble in Et_2O, THF and toluene, but only slightly soluble in *n*-hexane.

Facile Hydrogenation of the Central Cyclohexatriene of Tris(benzocyclobutadieno)benzene: Synthesis, Structure, and Thermal and Photochemical Isomerization of all-*cis*-Tris(benzocyclobuta)cyclohexane **

By *Debra L. Mohler, K. Peter C. Vollhardt,** and *Stefan Wolff*

We describe the first chemical reaction of hydrocarbon **1**,[1] namely its facile and stereoselective hydrogenation to **2**, whose X-ray structural analysis reveals the presence of an unusually bond-fixed, planar cyclohexane ring. The latter undergoes stereospecific thermal retrocyclization exclusively to the hexaene **3**, a feature that, in conjunction with the associated kinetic data, suggests the occurrence of an unprecedented all-disrotatory process.[2] In contrast, irradiation of **2** effects the rearrangement to the new hydrocarbon **4** and, ultimately, phenanthrene and naphthalene, whereas **3** photoisomerizes to **5** (Scheme 1). The reported chemistry expands significantly the range of the transformations recorded for the benzocyclobutene nucleus and the tribenzo-$(CH)_{12}$-manifold.

The hydrogenation of **1** to **2a** proceeded under extraordinarily mild conditions,[3] a finding ascribable to the high degree of bond localization and strain in the system. On the other hand, the 2,3,6,7,10,11-hexakis(trimethylsilyl) derivative of **1**[1] was inert even at elevated hydrogen pressures (80 atm, THF, Pd-C).

The stereochemistry of **2a** was first assigned on the basis of its ^{1}H-NMR spectrum, particularly the signal for the central ring hydrogens (a singlet at δ = 4.19), the ^{13}C-NMR spectrum (4 lines) and the analogous behavior of the related angular and linear [3]phenylenes.[4] Because of its novelty and unexpected chemistry (see below), and also for comparison with **1**, an X-ray structural investigation was carried out

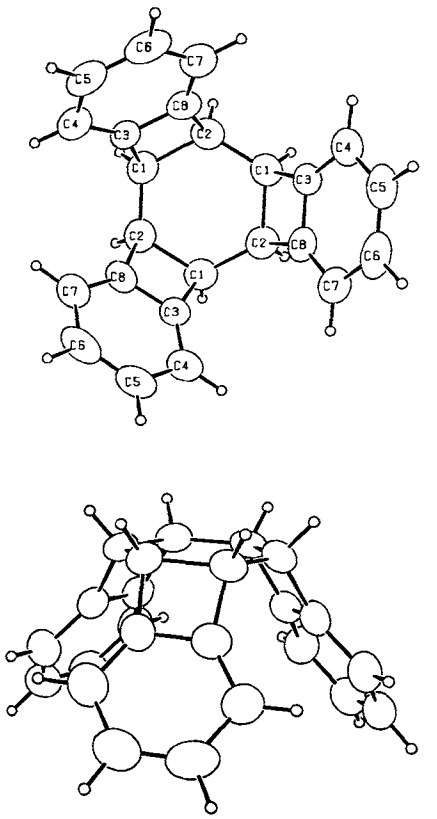

Figure 1. ORTEP drawings of the top and side views of **2a**. Ellipsoids are scaled to represent the 50% probability surface and hydrogen atoms are given as arbitrary small spheres. Selected bond lengths [Å] and angles [°]: C1-C2 1.599(4), C1-C2′ 1.511(4), C1-C3 1.516(3), C2-C8 1.526(3), C3-C4 1.393(4), C3-C8 1.379(4), C4-C5 1.394(4), C5-C6 1.379(5), C6-C7 1.391(4), C7-C8 1.376(3); C2-C1-C2′ 119.8(2), C2-C1-C3 85.6(2), C1-C2-C8 86.0(2), C4-C5-C6 122.2(3), C5-C6-C7 121.9(2), C6-C7-C8 116.1(3), C2-C8-C3 93.5(2), C3-C8-C7 122.5(2).

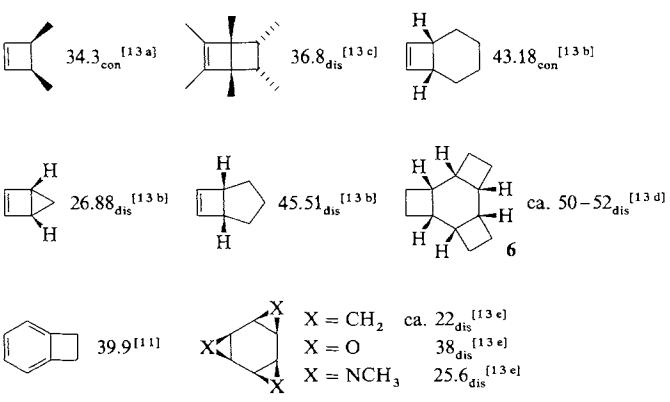
(Fig. 1).[5] The central cyclohexane ring is planar, a geometry enforced by the three fused benzocyclobutenes. The average dihedral angle between the plane of the former and those of the latter is 54.5°, giving rise to a strongly cup-shaped molecule. Most remarkable are two features: 1) There is strong bond alternation in the cyclohexane frame (C1–C2, 1.60 Å; C1–C2′, 1.51 Å), to a degree that is unprecedented,[6] and 2) the geometry of the benzene rings is changed very little relative to those of its precursor **1**,[1, 7] both comparing well to those of model benzocyclobutenes,[8] an aspect also reflected in the ^{1}H- and ^{13}C-NMR data. The first characteristic could be a trigger to the thermal chemistry of **2** (see below), the second may further corroborate recent theoretical findings that σ-effects play an important role in the bond-fixation observed in **1** (and, presumably, other benzenoid hydrocarbons of this type).[9]

Hydrocarbon **2** may be viewed as a trishomolog of the extensively investigated all-*cis*-tris-σ-homobenzenes[10] and as being endowed with sufficient ring strain (>100 kcal mol^{-1})[11] to undergo an analogous retro-[2+2+2]cycloaddition unraveling the cyclohexane moiety. However, the tenuous nature of this notion becomes apparent when one considers that the benzofusion in **2** renders (a least strained) disrotatory four-ring opening unfavorable on the basis of orbital symmetry considerations,[12] that any concerted path may be inhibited by the development of the antiaromatic circuit of a [12]annulene system, and that the saturated debenzo relative of **2**, *cis*-tris[2.2.2]-σ-homobenzene **6**, is stable to high temperatures, when it decomposes through radical intermediates to a complex mixture of products.[13d] These caveats notwithstanding, on heating (C_6D_6, sealed tube, 125–160 °C, several days), **2a** was isomerized cleanly and stereospecifically to **3a**,[3] following first order kinetics [$\Delta H^{\neq}$ = 29.4 (4.7) kcal mol^{-1}, $\Delta S^{\neq}$ = – 12.7(11.3) cal K^{-1} mol^{-1}]. NMR, in particular, highlighted not only the symmetrical nature of the product but also its dissimilarity to the corresponding *E,E,E* form,[14] including J_{cis} = 12 Hz for the former vs. J_{trans} = 18 Hz for the latter (obtained from the respective ^{13}C-satellite ^{1}H-NMR signals). The ease and specifity of the formation of **3a** from **2a** provide strong evidence for the occurrence of a concerted, all-disrotatory mechanism. For comparison, Table 1 summarizes the activation parameters of some model systems.

Table 1. Activation energies E_a (kcal mol^{-1}) for thermal ring-opening reactions of selected model compounds [a].



[a] Stereochemistry of the reaction indicated by subscripts.

Support for the two cornerstones of this claim was assembled as follows. Stereochemistry: **3** cannot be preceded by one of its double bond isomers, as those with either *E,E,E*[14] or *E,Z,Z* configuration[2] are inert to the reaction conditions, while that containing the *E,E,Z* structure has been convincingly demonstrated to furnish stable **5** through homo-Diels-Alder cycloaddition of the *cis*-π-bond to the other two (see also below).[14] Concertedness: both directly competitive and independent kinetic runs, employing **2a** and its hexadeuterated relative **2b** [$k_H(125\,°C) = 3.11(\pm 0.08) \times 10^{-6}\,s^{-1}$; $k_D(125\,°C) = 1.98(\pm 0.06) \times 10^{-6}\,s^{-1}$] revealed the same α-secondary deuterium isotope effect of $k_H/k_D(D_6) = 1.57$! This figure translates into $k_H/k_D(D_1) = 1.08$, the same as that observed for concerted cyclobutene openings.[15] The absence of any relatively long-lived intermediates was ascertained by transforming **2a** into **3a** in molten *cis*-2-butenedioic anhydride (160 °C, 7 d) without change in the outcome of the reaction.

In view of the above findings, one might (naively) expect that photochemical activation of **2** would, by an all-conrotatory pathway (producing initially either or both of the *E,E,E* or *E,Z,Z* isomers of **3**) result in **5**.[14] However, upon photolysis of **2a** (or **2b**) with 254-nm UV lamps (Rayonet, Et_2O, − 2 °C, 3.5 h), **4a** (or **4b**) was formed in 45% yield, together with starting material (32%) and small amounts of phenanthrene (or 9,10-dideuteriophenanthrene) and naphthalene (or [D_4]naphthalene, the position of the label was not ascertained). The new compound **4a** was characterized by spectroscopy[3] and X-ray analysis (Fig. 2).[16]

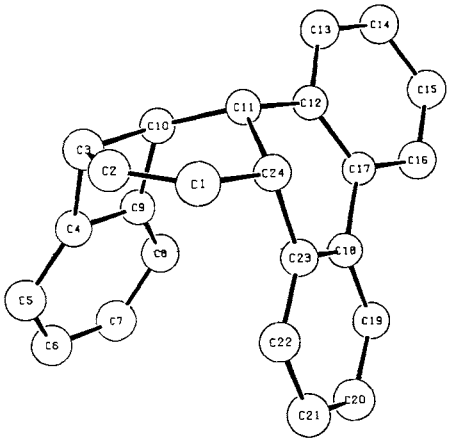


Fig. 2. ORTEP drawing of **4a**. Ellipsoids are scaled to represent the 50% probability surface and hydrogen atoms are given as arbitrary small spheres. Selected bond lengths [Å] and angles [°]: C1-C2 1.351(5), C1-C24 1.526(6), C2-C3 1.512(6), C3-C4 1.542(6), C3-C10 1.590(6), C4-C5 1.392(5), C4-C9 1.376(5), C5-C6 1.426(6), C6-C7 1.413(6), C7-C8 1.407(6), C8-C9 1.401(5), C9-C10 1.539(5), C10-C11 1.527(5), C11-C12 1.514(5), C11-C24 1.549(5), C12-C17 1.386(5), C17-C18 1.482(5), C18-C23 1.415(6), C23-C24 1.525(5); C2-C1-C24 123.1(4), C1-C2-C3 122.3(4), C2-C3-C4 112.9(3), C2-C3-C10 116.2(3), C4-C3-C10 85.8(3), C3-C4-C5 142.3(4), C3-C4-C9 94.1(3), C5-C4-C9 123.6(4), C4-C5-C6 114.8(4), C5-C6-C7 121.2(4), C6-C7-C8 122.6(4), C7-C8-C9 114.7(4), C4-C9-C8 123.1(4), C4-C9-C10 93.8(3), C8-C9-C10 143.1(4), C3-C10-C9 86.2(3), C3-C10-C11 113.9(3), C9-C10-C11 122.7(3), C10-C11-C12 113.2(3), C10-C11-C24 113.8(3), C12-C11-C24 109.2(3), C11-C12-C13 118.4(4), C11-C12-C17 121.3(4), C12-C17-C18 119.4(4), C17-C18-C19 121.5(4), C17-C18-C23 118.9(4), C18-C23-C24 117.8(4), C22-C23-C24 122.5(4), C1-C24-C11 110.6(3), C1-C24-C23 113.3(4), C11-C24-C23 110.9(3).

A control experiment revealed that irradiation of **3a** with 254-nm UV lamps at − 22 °C for 4.5 h leads to **5** almost quantitatively. It is therefore clear that the photochemistry of **2** is associated with a new mechanistic manifold.[14] While delineation of its details are premature, there are topologically analogous transformations in the literature.[12b, c, 17]

Structure of a Synthetic Trefoil Knot Coordinated to Two Copper(I) Centers**

By *Christiane O. Dietrich-Buchecker, Jean Guilhem, Claudine Pascard,** and *Jean-Pierre Sauvage**

Although knotted forms of DNA are relatively common, as shown by recent results of molecular biology,[1, 2] knotted compounds in chemistry have only been envisaged and discussed as hypothetical objects.[3–5]. A year ago, the first synthetic trefoil knot was reported.[6] The preparation of this topologically novel molecular system was made possible by the use of a double three-dimensional template effect. Two coordinating molecular threads were interlaced on two copper(I) centers, forming a double helix, the precursor of a knotted system.

Although convincing evidence for the knotted topology of the molecule was obtained from mass and ^{1}H-NMR studies, in particular by taking advantage of the chirality of a trefoil knot, it was of utmost importance to obtain an X-ray structure of the molecule. In the meantime this has been achieved, and we now report the molecular structure of the compound. This study removes the last uncertainty regarding the knotted structure of the molecule obtained. It also provides interesting data on the fine structure and conformation. Moreover, it demonstrates that the knotted compound undergoes spontaneous resolution, which is very encouraging for a future separation into right- and left-knotted enantiomers.[7]

The chemical representation of the molecule is given in Figure 1. The organic skeleton is made up of a single 86-membered molecular chain, whose ends are tied with formation of a trefoil knot. The molecule still contains the two copper(I) centers used as templating species during the synthesis.

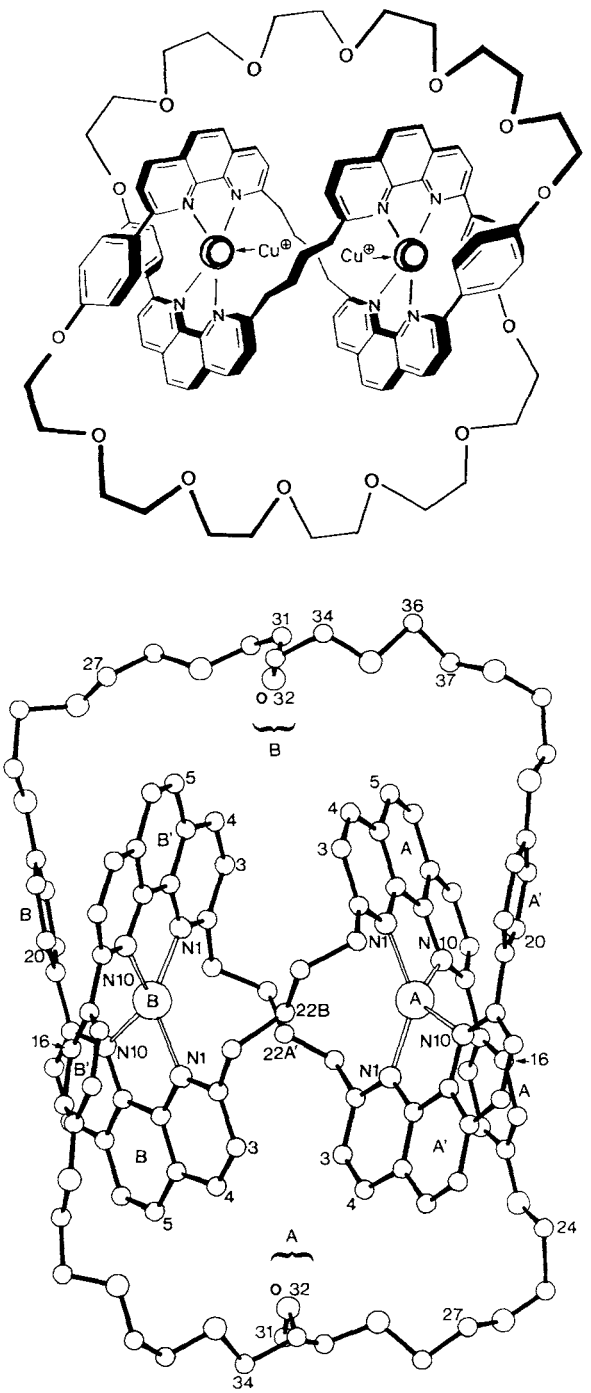

Fig. 1. Structural formula (top) and ORTEP of the knotted compound. For sake of clarity, the written symbols corresponding to the crystallographic numbering have all been omitted, those of O partly omitted. A denotes CuA and B denotes CuB.

The X-ray crystallographically determined molecular structure is shown in Figure 1 (bottom).[8] The molecule has effective D_2 symmetry, with three mutually perpendicular pseudo-twofold axes, one joining the two copper cations, one passing through the middle of the two $(CH_2)_4$ bridges, and the third one passing through the central oxygens of the two polyoxyethylene chains. The symmetry places the two complexes around CuA and CuB, with their respective 1,10-phenanthroline rings (CuA with phen A and phen A′ and CuB with phen B and phen B′) in superimposed fashion: A over B′, and A′ over B. Starting from phen A, the molecular

ribbon goes along the $(CH_2)_4$ bridge joining phen A to phen B, turns around CuB with phen B, follows the long oxy chain B back to phen A', turns around CuA with phen A', goes along the second $(CH_2)_4$ bridge to phen B', and, following the oxy chain A, ends up at the starting point phen A.

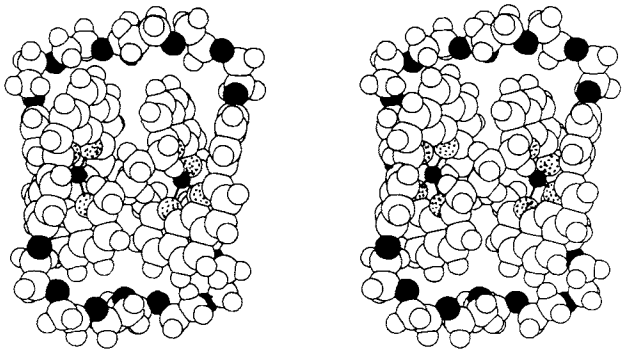

Fig. 2. Stereoview of the knotted compound.

The stereoview (Fig. 2) shows how the two metal atoms are located 6.3 Å apart inside a double helix. The two complexes, around CuA and CuB face each other with similar coordination angles (see Table 1), the wider angle (141° average) opening towards the center of the knot.

Table 1. Structural data of the Cu centers

Cu A environment		Cu B environment	
Distances [Å]			
Cu-N1A	2.00(3)	Cu-N1B	2.08(2)
Cu-N10A	2.14(2)	Cu-N10B	2.06(3)
Cu-N1A'	1.95(2)	Cu-N1B'	2.11(2)
Cu-N10A'	2.11(2)	CuN10B'	2.13(3)
Angles [°] ($\sigma \approx 1°$)			
N1A-Cu-N10A	83	N1B-Cu-N10B	80
N1A'-Cu-N10A'	83	N1B'-Cu-N10B'	79
N10A-Cu-N10A'	128	N10B-Cu-N10B'	135
N10A-Cu-N1A'	113	N10B-Cu-N1B'	112
N1A-Cu-N10A'	114	N1B-Cu-N10B'	120
N1A-Cu-N1A'	143	N1B-Cu-N1B'	140

The general molecular shape of the knotted complex can be compared with that of the chemically related dicopper(I) [3]-catenate consisting of two peripheral 30-membered rings separately interlocked with a central 44-membered ring.[9, 10] In the [3]-catenate, the Cu···Cu distance is noticeably longer than in the knot (8.0 Å instead of 6.3 Å), although better π-stacking is observed in the [3]-catenate than in the knot (see Table 2). In the [3]-catenate[10] the superimposed

Table 2. Relevant dihedral angles [°] between aromatic rings.

	Phenyl A	phen A'	Phenyl A'	phen B	Phenyl B	phen B'	Phenyl B'
phen A	43	64	29	60	19	24	45
Phenyl A		25	37	16	26	52	23
phen A'			43	20	46	60	22
Phenyl A'				50	20	18	22
phen B					42	67	32
Phenyl B						28	38
phen B'							39

phenanthroline rings are roughly parallel (dihedral angle 7°), whereas in the knotted compound they are inclined toward each other (24° and 20°) with their tip ends in proximity: average distance between H3 and H4 of each pair of phenanthrolines (A–B' and A'–B): 3.5 Å. On the other hand, the coordination sphere of each copper(I) ion in the knotted compound is only very slightly distorted compared to that in the [3]-catenate.

Within the complex units of the knotted compound, the dihedral angle between the two phenanthroline rings is 64 and 67° respectively, which reflects the strong distortion of each coordination polyhedron from a tetrahedral geometry. Furthermore, each phenyl ring forms a dihedral angle of approximately 42° with its bonded phenanthroline.

All the oxygen atoms of the polyoxyethylene chains are turned inward, and the molecule has a rectangular hydrophobic feature. The chains are actually a little too long, as can be seen by the folded fragments around the central oxygens O32A and O32B.

The centers of the short $(CH_2)_4$ bridges are very close together, with short distances between the hydrogens of the methylenic carbon atoms C22B and C22A'. Many other short distances exist, in particular between the hydrogen atoms of the hexaethyleneoxy chains and the aromatic groups. The most important data have been collected in Table 3.

Table 3. Shortest intramolecular H-H distances [Å] ($\sigma \approx 0.1$ Å).

Between superimposed phenanthroline rings	*Between phenyl rings*
	H16A-H20A' 2.4
H4A-H4B' 3.5	H16B'-H20B 2.5
H4B-H4A' 3.4	*Between $(CH_2)_4$ bridges*
H4B-H3A' 3.4	H_a22B-H_b22A' 2.3
Between phenanthroline rings and polyoxyethylene chains [a]	*Between the methylene groups in a chain* [a]
H5A-H_b37B 2.8	H_b24A-H_a27A 2.4
H4A'-H_a27A 2.6	H_b31A-H_b34A 2.2
H5B-H_a31A 2.7	H_a31B-H_b34B 2.2
H5B'-H_b27B 2.4	H_a31B-H_b36B 2.5

[a] H_a and H_b are the two H atoms of a given CH_2 group.

Further, the X-ray structure analysis revealed that the chiral dicopper(I) knotted compound crystallizes as a conglomerate of enantiomers, i.e. a given crystal contains only one enantiomer: Figure 3 shows a stereoview of the unit cell with two left knotted enantiomers.

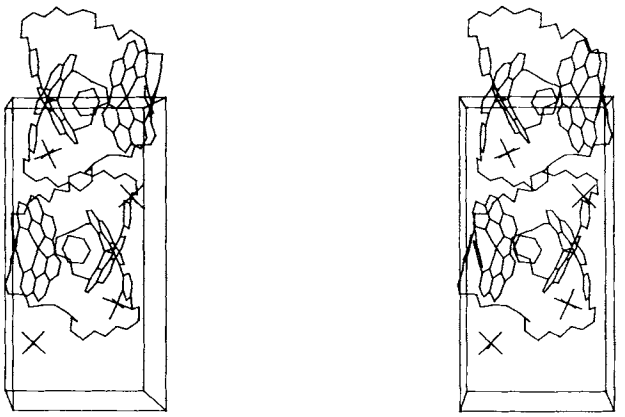

Fig. 3. Stereoview of the unit cell. Shown are two complexes, four anions ($PF_6^{\ominus}$), and two solvent molecules (benzene).

Experimental

Crystals of $[C_{104}H_{104}N_8O_{14}Cu_2](PF_6)_2 \cdot C_6H_6$ were grown from CH_2Cl_2/C_6H_6 by vapor diffusion of benzene. The dark-red, well-shaped crystals obtained ($0.8 \times 0.3 \times 0.1$ mm) were sealed in a capillary tube. Intensity data were collected at 1.1 Å resolution ($\theta_{max} = 45°$) with an automatic Philips PW1100 diffractometer, wavelength $Cu_{K\alpha}$ ($\lambda = 1.5418$ Å), graphite monochromator. From 7925 unique measured reflections, only 2967 independent reflections with $I \geq 2\sigma(I)$ were kept in the calculations. $M = 2183$, monoclinic, space group $P2_1$, $a = 13.462(6)$, $b = 27.841(14)$, $c = 13.912(7)$ Å $\beta = 93.66(4)°$, $V = 5204$ Å^3 $Z = 2$. $\varrho_{calc} = 1.39$ g cm^{-3}. Structure solved by direct methods [11]. High pseudo symmetry rendered the crystallographic study very difficult. Low resolution and thermal agitation led to rigid block refinement of the aromatic parts (except in the last refinement cycle) and constraints in the long chains. The final R factor is 12.8%. Further details of the crystal structure will be published elsewhere and will be available from the Director of the Cambridge Crystllographic Data center, University Chemical Laboratory, Lensfield Road, Cambridge CB2 IEW (UK), on quoting the names of the authors and the journal citation.

Synthesis, Structure, and Catalase-Type Activity of a Novel Oxo-Bridged Tetranuclear Manganese Aggregate Exhibiting Short O···O Interactions

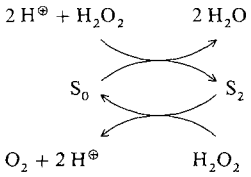
By *Robert T. Stibrany* and *Sergiu M. Gorun**

Dedicated to Professor Stephen J. Lippard on the occasion of his 50th birthday

Due to their relevance to the catalytic center of the photosynthetic water splitting apparatus of green plants and cyanobacteria, tetranuclear manganese aggregates have become a subject of intensive research.[1] A Mn_4 unit is essential for the coupling of two water molecules and liberation of dioxygen [Eq. (a)] in photosystem II (PSII).[2]

$$2H_2O \rightarrow O_2 + 4H^{\oplus} + 4e^{\ominus} \qquad (a)$$

During this process the Mn_4 aggregate passes through five oxidation states, S_0 to S_4, S_0 representing the most reduced state.[3] The S_0 state is believed to comprise one Mn^{II} and three Mn^{III} centers.[1] EXAFS and EPR spectroscopy suggest that the Mn ions are primarily ligated by O donor atoms.[1, 2] Oxo, hydroxo or alkoxo groups are believed to bridge the metals. Two hydroxo groups (to be evolved as O_2 after deprotonation and coupling) have been postulated to be present in the S_0 state.[4] Calcium has also been shown to be essential for activity but its function is not understood.[5] Interestingly, in the absence of light the PSII reaction center can evolve O_2 when H_2O_2 is added as a substrate, a process believed to involve the S_0 and S_2 states [Eq. (b)].[6]



(b)

Despite great efforts no structurally characterized model for the S_0 state exists.[1c, 7] Furthermore, tetranuclear manganese aggregates associated with the biologically relevant calcium ions are not known, and, to our knowledge, biomimetic activity has not been reported thus far for the inorganic models.

We report here the synthesis and structural characterization of the mixed valence $Mn^{II}Mn^{III}_3$ complex **1**,[8] which contains an unprecedented $(Mn_4O_2H)^{8\oplus}$ core. We also report the catalytic biomimetic decomposition of H_2O_2 by **1**.

$(Ba,Ca)_2[Mn_4(\mu\text{-}O)(\mu\text{-}OH)(O_2CCH_3)_2L_2]$ **1**

L = 1,3-Diamino-2-hydroxypropane-*N*,*N*,*N'*,*N'*-tetraacetic acid.

In the anion of **1**, shown in Figure 1, the four manganese ions describe a trapezoid. A crystallographically imposed

mirror plane intersects the atoms C2a, C1a, O1b, H, O2b, C3a and C4a. The structure can be viewed as a dimer of dimers. The unique Mn1 and Mn2 are bridged by the alkoxo groups of the ligand and the $(O_2H)^{3\ominus}$ unit. Reflection across the mirror plane gives the symmetry-related Mn1′, Mn2′ dimer. The two dimers are linked by the $(O_2H)^{3\ominus}$ and acetato groups. Alternatively, Mn1 and Mn1′ bridged by O1b and one carboxylate could define one dinuclear fragment while Mn2 and Mn2′ bridged by O2b and another carboxylate could form another one. The two dinuclear fragments are linked covalently, by alkoxo groups, and by hydrogen bonding interactions via the hydrogen atom H.

The bridging $(O_2H)^{3\ominus}$ unit is of special interest. The hydrogen atom H, located in the difference Fourier map and subsequently refined (its position was not fixed), is shared by the two bridging oxo groups. The unusually short O1b···O2b contact, 2.467(5) Å, indicates a strong hydrogen bond.[9] We suggest that this unit could represent an intermediate stage in the deprotonation and coupling of two water molecules at the metal center [see Eq. (a)]. The stability of **1** would be enhanced by the formation of two six-membered metallocycles by the $(O_2H)^{3\ominus}$ core, the manganese ions and the bridging alkoxo groups.

The stoichiometry of **1** requires that the average charge per Mn atom be + 2.75, suggesting most likely one Mn^{II} and three Mn^{III} ions in the complex. Furthermore, redox titration of **1** with $KI/Na_2S_2O_3$ indicates a 2.9 ± 0.1 electron reduction process per manganese aggregate, i.e., complete reduction from the $Mn^{II}Mn^{III}_3$ oxidation level to the Mn^{II}_4 level.[10, 12]

The average Mn1–ligand distance, 2.037 Å, is typical for Mn^{III};[13] the average Mn2–ligand distance, 2.102 Å, is longer. The Mn–OR bridges are asymmetric: Mn1–O1 = 1.954(3) Å, is within the 1.88–1.96 Å range found for Mn^{III}–OR; Mn2–O1 = 2.108(3) Å, falls short of the 2.120–2.386 Å range known for the Mn^{II}–OR bond length. This asymmetry is typical for localized mixed valence dinuclear complexes.[1a] The symmetry and interatomic distances argue against the presence of oxidation states > III. Thus, **1** is formulated as a $Mn^{II}Mn^{III}_3$ complex.

Based on the above metrical parameters, we assign Mn1 as Mn^{III}. A Jahn-Teller compression of the axial O1b–Mn1–N1 bonds is observed: $Mn–X_{axial} = 1.969$ Å vs. $Mn–X_{eq} = 2.071$ Å. This compression is somewhat alleviated by the *trans* oxo π donation of O1b along the Mn1–N1 vector. A similar phenomenon encountered in dinuclear Mn^{III} complexes has been discussed recently.[14] The Mn1–O1b bond (1.817(2) Å) is slightly longer than 1.78 ± 0.02 Å, the range known for oxo-bridged dinuclear Mn^{III} complexes, but lower than ≃1.95 Å, a typical value encountered for μ-OH and μ-OR bridges.[1, 15] This intermediate value may reflect the presence of partial H-bonds in the O···H···O group since it is known that protonation of μ-oxo bridges results in elongation of the metal–oxygen bonds.

The average + 2.5 oxidation state of the Mn2/Mn2′ pair could arise from valence delocalization or crystallographic disorder. The thermal ellipsoids of Mn2 are equal to or larger than their Mn1 counterparts. In particular, B_{eq} for O2a (80(2)) is clearly different, namely twice as large as B_{eq} for O1a, (36(1)). Also, B_{eq} for O2b (49(2)) is significantly larger than B_{eq} for O1b (33(2)). Moreover, the Mn2–O1 bond length is intermediate between Mn^{II}–OR and Mn^{III}–OR (see above). These observations can be rationalized if the Mn2 site is disordered, half of the time Mn^{II} and the other half Mn^{III}.

The spatial relationship between the Mn_4 complex anion and the barium/calcium ions is shown in Figure 2. Interestingly, the smaller $Ca^{2\oplus}$ ions are located on the Mn^{III} side of the aggregate, the larger $Ba^{2\oplus}$ ions on the $Mn^{II,III}$ side.[16] The water molecules present in the coordination spheres of $Ba^{2\oplus}$ and $Ca^{2\oplus}$ are hydrogen bonded to the carboxylic groups of the ligand.

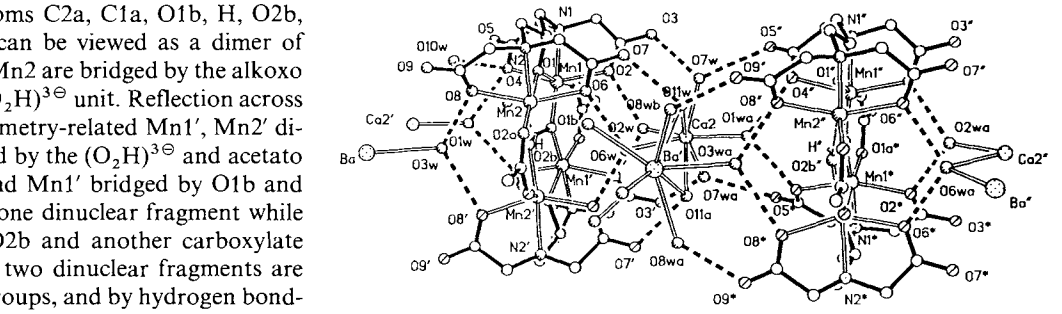

Fig. 2. Section of the structure of the crystal assembly of **1** showing alternating Mn_4 aggregates and bridging calcium and barium ions. View along the O1b–O2b axis. Hydrogen bonds between carboxylate oxygens and calcium/barium bound waters are represented by dashed lines. Only the non-hydrogen atoms are shown.

The above results demonstrate for the first time that a Mn-Ca aggregate can be assembled outside a protein environment and suggest that hydrated Ca ions could play both structural (protein side chains binding) and functional (facilitation of H_2O access to the Mn site) roles in PSII.

The biomimetic activity of our S_0 state model was tested by using H_2O_2 as substrate [see also Eq. (b)]. Complex **1** decomposes H_2O_2 catalytically at high rates.[17] This activity suggests that **1** may be a *functional* model for the S_0 state of PSII. The decomposition of H_2O_2 by **1** lends further support to the "dimers of dimers" view of **1**, since dinuclear Mn^{III} centers (unknown coordination) are present at the active sites of catalases and pseudo-catalases whose main function in vivo is H_2O_2 decomposition.[1a, 18]

Experimental

A solution of the ligand L (268 mg, 0.83 mmol) in H_2O (15 mL) was adjusted to pH 7.0 with an equimolar amount of $Ba(OH)_2$ and $Ca(OH)_2$. After addition of 406 mg (1.66 mmol) of $Mn(OAc)_2 \cdot 4H_2O$ dissolved in 1 mL methanol the pH of the stirred solution was adjusted to 8.5. Bubbling of air through the solution or addition of 1 mL of 25% H_2O_2 (**caution:** heat and gas evolution) resulted in a dark brown coloration. Crystalline products were obtained upon addition of DMF and subsequent slow evaporation of the mixture.

[12] The possibility of a second proton on the (Mn_4O_2H) core has been considered; in this case **1** would most likely comprise two Mn^{II} and two Mn^{III} ions. A comparison of bond distances and angles with those of known di- and trinuclear mixed valence complexes indicates that this is very unlikely. Also, two, not three electrons should have been obtained by redox titration. Nevertheless, a neutron diffraction study is planned in order to locate the exact position(s) of the core proton(s).

[13] Bond distances are frequently used to establish the + 3 oxidation state of manganese. See, for example, B. Chiswell, E. D. McKenzie, L. F. Lindoy in G. Wilkinson (Ed): *Comprehensive Coordination Chemistry*, Pergamon Press, New York 1987 Vol. 4, p. 1.

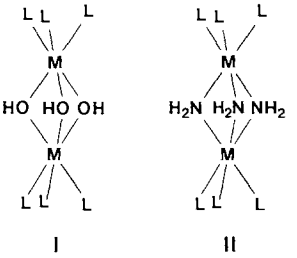
The Tri-μ-amidobis[triamminecobalt(III)] Cation: The First Triply Amido-bridged Complex**

By *Walter Frank,* Klaus Hoffmann*, and *Ludwig Heck**

Shortly after the turn of the century, *A. Werner* succeeded in synthesizing the triply OH-bridged binuclear complexes ("triols") **I** via partial deprotonation of *fac*-triaqua complexes.[1] X-ray studies later confirmed his ideas on their structure. [2]Grimm-isosteric, triply amido-bridged structural units have been discussed by *Schmitz-DuMont* in connection with speculations on the structure of the amides of chromium(III) and cobalt(III).[3] In systematic studies, on the deprotonation of ammine complexes and on complex condensation with the formation of NH_2 bridges ("ammine olation")[4] it has now been possible for the first time to detect a corresponding complex **II** with NH_2 instead of OH.



Upon reaction of hexaamminecobalt(III) perchlorate with one equivalent of potassium amide in liquid ammonia we obtained tri-μ-amidobis[triamminecobalt(III)] perchlorate **1**. From its remarkably stable aqueous solution the bromide **2** can be precipitated with potassium bromide. The crystal structure analysis of **2**,[5] together with the analytical, spectroscopic and crystal data of **1** and **2**, unequivocally confirm the tri-μ-amido structure of the cations in these compounds.

$[(NH_3)_3Co(NH_2)_3Co(NH_3)_3](ClO_4)_3$ **1** $[(NH_3)_3Co(NH_2)_3Co(NH_3)_3]Br_3$ **2**

The cations in the crystal of **2** exhibit a high crystallographic point group symmetry (D_{3h}) (Fig. 1). The amido bridges

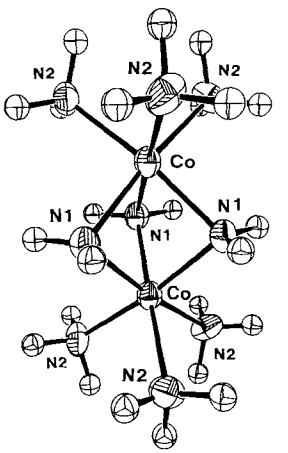


Fig. 1. Structure of the tri-μ-amidobis[triamminecobalt(III)] cation in the crystal of **2**. The ellipsoids of the thermal vibrations are drawn at the 50% probability level; the hydrogen atoms are not labeled, their radius was chosen arbitrarily. Bond lengths [pm] and angles [°]: Co-N1 193.9(5), Co-N2 199.9(5); N1-Co-N1′ 79.8(2), N1-Co-N2 173.1(2), N2-Co-N2′ 89.9(2), Co-N1-Co′ 84.4(3).

force the two cobalt atoms 260 pm apart. The Co–N bonds in the bridges are slightly shorter, the terminal Co–N bonds slightly longer than the mean value of 196.9(3) pm, which agrees with the value in $[Co(NH_3)_6]^{3\oplus}$ (196.6(3) pm).[6] Based on the concept of two face-sharing octahedra the angles observed can be understood as resulting from an elongation along the threefold axis, which only concerns the trigonal bipyramidal core of the cation. The angles between terminally bound N atoms are almost exactly 90°. The observed geometry can thus be understood in terms of a Co–Co

repulsion and restoring force as a result of the angular deformation at the μ-N-atoms.

The crystal structure of **2** can be described in terms of the similarity between the cation substructure and a hexagonal closest packing (hcp): All the cavities in an arrangement of hexagonally packed layers of cations according to the stacking sequence AB,AB...(*h*) are occupied by $Br^{\ominus}$ ions.[7]

Experimental

1: A mixture of hexamminecobalt(III) perchlorate (1.0 g, 2.18 mmol) and potassium amide (0.104 g, 2.61 mmol) in liquid ammonia (15 mL) was heated in a pressure tube for 24 h at 100 °C. After removal of the ammonia by evaporation, all by-products were extracted from the remaining mixture with 10 × 2 mL of water. There remained 0.220 g (35.6% based on $[Co(NH_3)_6](ClO_4)_3$) of rosered **1**.

Correct elemental analysis (Co,N); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3333, 3304, 3252, 3215, 2023, 1615, 1471, 1247, 1142, 1109, 1086, 940, 927, 793, 636, 627, 542, 432, 338; UV/VIS (H_2O): λ_{max} [nm] (ε) = 298 (1740).

2: 100 mL of a saturated solution of **1** (0.188 g, 0.331 mmol) was treated with 25 mL of a saturated potassium bromide solution. A red precipitate of **2** was recrystallized from water (0.129 g, 76.7%).

IR (kBr): $\tilde{\nu}$ [cm^{-1}] = 3333, 3304, 3251, 3215, 1615, 1468, 1245, 927, 793, 542, 432, 338; UV/VIS (H_2O): λ_{max} [nm] (ε) = 298 (1740).

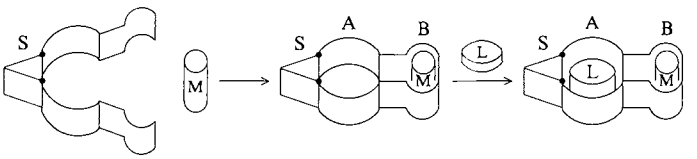
A Synthetic Allosteric System with High Cooperativity between Polar and Hydrophobic Binding Sites**

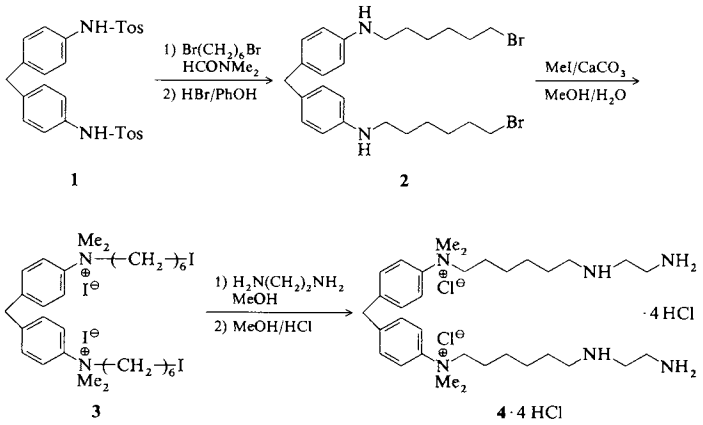
By *Hans-Jörg Schneider** and *Dieter Ruf*

Characteristic of allosteric systems is that the occupation of spatially separated binding sites by different or identical effector molecules leads to a mutual influence of the binding sites. Their role in the regulation of biological processes is long known; it rests on conformational couplings, the molecular mechanism of which can be analyzed only with difficulty because of the complexity of the participating proteins. In the few previously described simple synthetic receptor molecules displaying allosteric behavior this depends on the mutual interaction of two metal ion-binding sites.[1] Artificial systems with significant allosteric effects, e.g., between an ionic and a lipophilic binding site[2] have not yet been reported in the literature. We now present a particularly simple and effective model, in which the occupation of a polar site—e.g. by a metal ion—leads to the closing of a hydrophobic pocket. In aqueous medium a hydrophobic binding site is formed in which a lipophilic guest molecule is complexed (Scheme 1).



Scheme 1. Schematic outline of the cooperative formation of binding sites. S = hinge, M = metal ion, A = hydrophobic binding site, B = polar binding site, L = lipophilic guest molecule.

To synthesize the model complex, the receptor **4** containing an ethylenediamine as metal binding site B was synthesized from the bis(*p*-anilino)methane **1** via **2** and **3**.[3] The



alkane chains in **4** form the lipophilic site A, whose ability to hydrophobically bind aromatic hydrocarbons is enhanced by the ammonium ions on the chains.[4] Furthermore, the presence of doubly charged sites in the receptor **4** makes it sufficiently water soluble to investigate, e.g., the hydrophobic complexation of hydrocarbons. A relatively rigid spacer unit such as diphenylmethane in the hinge S is necessary in order to prevent collapse of the alkane chains and thus also of hydrophobic interaction without substrate intercalation.

At pH 10 in aqueous borate buffer, the receptor **4** shows with copper(II) ions the absorption values λ_{max} = 561 nm, ε_{max} = 112, typical for bidentate ethylenediamine ligands;[5] the UV/VIS titration of **4** with $Cu^{2\oplus}$ indicated formation of a 1:1 complex. Addition of the **4** · $Cu^{2\oplus}$ complex to a solu-

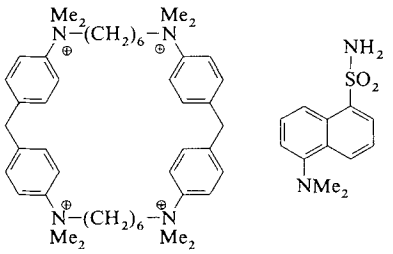
[**] Host-Guest Chemistry, Part 24. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 23: H.-J. Schneider, R. Kramer, I. Theis, M. Zhou, *J. Chem. Soc. Chem. Commun. 1990*, 276.

tion of naphthalene (0.33×10^{-3} M) in D_2O/CD_3OD at pH 10 leads to increased shielding of the naphthalene α-proton in the NMR spectrum (at $[\mathbf{4} \cdot Cu^{2\oplus}] = 6.6 \times 10^{-3}$ M, e.g., by $\Delta\delta = -0.33$); this is not observed upon addition of **4** or $Cu^{2\oplus}$ alone, and affords proof of intracavity inclusion of the hydrocarbon in the $\mathbf{4} \cdot Cu^{2\oplus}$ complex. The incorporation of naphthalene in the analogously built preformed cavity of the azoniacyclophane **5** manifested itself in an upfield shift of



5

6

$\Delta\delta \approx -0.95$ for complete complexation as obtained from computer simulation of the NMR titration curves under the same conditions.[6a] A corresponding titration is not possible in the case of the $\mathbf{4} \cdot Cu^{2\oplus}$ complex because of its sparing solubility; however, if one assumes a CIS value (*C*omplexation *I*nduced *S*hift at 100% complexation) of ca. −0.5 (smaller than in the case of **5**, since $\mathbf{4} \cdot Cu^{2\oplus}$ contains only a half of the shielding arene rings and $N^{\oplus}$ units[6b]), a complex constant of $K \approx 10$ can be estimated.

A further proof of the binding of lipophilic substrates is afforded, for example by a shift in the fluorescence maximum of the fluorscence indicator dansylamide **6** from 520 nm to 510 nm and an increase in intensity of ca. 85% on measuring a solution of **6** (5×10^{-6} M), **4** (10^{-3} M) and a $Zn^{2\oplus}$ salt (6×10^{-4} M) at pH 12 (NaOH/KCl buffer). Here again, the determination of an equilibrium constant is prevented, in this case by too high a self-fluorescence of the acceptor at $[\mathbf{4}] > 10^{-3}$ M; however, by comparison with the fluorescence values of the complete complexation of **6** with **5** a value of $K \approx (0.5 \text{ to } 1) \times 10^3$ can be estimated.

The decrease in the values of the complexation constants K (by a factor of 10–100) of naphthalene and dansylamide (**6**) with $\mathbf{4} \cdot M^{2\oplus}$ (M = Cu, Zn) instead of **5** is consistent with the twofold instead of fourfold $N^{\oplus}$–arene interaction, which is decisive for the binding of aromatic guest molecules.[4] However, the results indicate at least a tenfold to hundredfold stronger complexation of lipophilic substrates by **4** in the presence of metal ions, since NMR or fluorescence control experiments with **4** alone showed no binding of naphthalene or **6**. Thus the allosteric system **4** bears the characteristics of a heterotopic, positive, and especially strong cooperativity.[8] In the case of proteins, systems with a binding constant ratio of ≈10 are already counted as strongly cooperative.[9] Synthetic receptors can be conceived as exhibiting an essentially direct conformational coupling and thus also as being suitable, in principle, as molecular switches.

One of the applications of the systems described here is in the detection of diamagnetic transition metal ions—which, due to their affinity for ethylenediamine units are still bound at concentrations of 10^{-10} to 10^{-20} M—via the fluorescence of suitable dyes in the corresponding ternary complexes. Figure 1 shows the increase in the fluorescence intensity of **6** as a function of the $Zn^{2\oplus}$ concentration. The observed linearity is consistent with the formation of <10% ternary complex $[\mathbf{4} \cdot Zn^{2\oplus} \cdot \mathbf{6}]$. Paramagnetic ions such as $Cu^{2\oplus}$ also bind strongly—also visible by way of NMR line broadening—but lead to quenching of the fluorescence and can therefore be differentiated from diamagnetic ions.

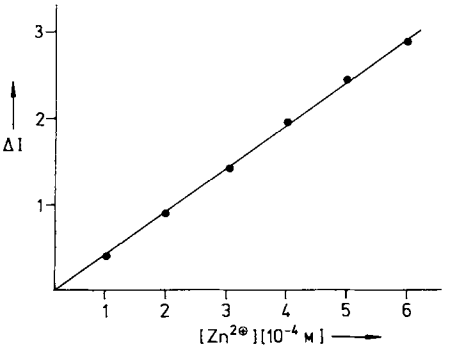


Fig. 1. Increase in fluorescence intensity I of **6** in the presence of **4** as a function of the concentration of added $Zn^{\oplus}$ ions. $[\mathbf{6}] = 5 \times 10^{-6}$ M, $[\mathbf{4}] = 10^{-3}$ M NaOH/KCl buffer, pH 12.

The increase in the binding constants and solubilities of the ternary complexes, as well as the lowering of the self-fluorescence of the receptors should make it possible, with the new principle demonstrated here, to increase the number and variety of known fluorophores.[10]

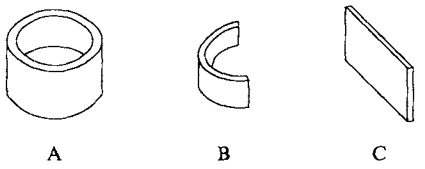
Host-Guest Complexes with Closed, Half-open, and Stretched Receptors: Hydrophobic Cavity Effects and Induced Pole-Dipole Interactions**

By *Hans-Jörg Schneider,* Thomas Blatter,* and *Patrick Zimmermann*

Lipophilic receptor cavities are an essential element for molecular recognition and the binding of unpolar substrates in aqueous solution.[1] We report here on the experimental differentiation of the underlying hydrophobic effects and van-der-Waals interactions by binding studies with closed, half-open, and stretched host compounds (Scheme 1). These studies also emphasize the exceptional properties of water,



Scheme 1. Schematic diagram of closed (A), half-open(B), and stretched host compounds (C).

which can scarcely give rise to entropically determined interactions in complexes with the open structures **2** (≙ B) and **3** (≙ C).[1]

The marked complexation of aromatic hydrocarbons compared to aliphatic substrates by azoniacyclophanes of type **1**[2, 3] and the pronounced decrease in binding upon removal of positively charged nitrogen atoms from the cavity[3b] can be explained both by electrostatic interactions between the $N^{\oplus}$ units and the quadrupoles of aromatic substrates as well as by the induction of a dipole in the complexed arene system.[4] The observation that diiodomethane **8**, in contrast to dichloromethane **9**, forms a complex with **1** (Table 1) now reveals the dominance of the second effect, for iodine has an especially easily polarizable electron cloud. The dependence of the complexation constants of **1** and lipophilic substrates on the water content of the solution gave values which approach those observed in corresponding studies with cyclodextrins:[3a] the hydrophobic effect in the case of the dominating $N^{\oplus}$-arene interactions discussed here is thus due to the fact that the polarizability of water is much lower than that of substrates such as **4**–**8**.[5]

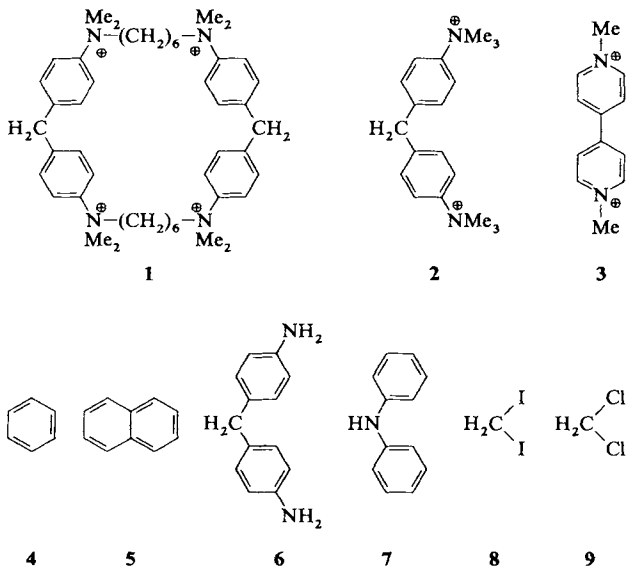


Table 1. Free complexation enthalpies $\Delta G°$ [kJmol^{-1}] at 25 °C for complexes of **1**–**3** with **4**–**9**. Standard deviation ±0.2 kJmol^{-1}.

	4 [a]	**5** [b]	**6** [a]	**7** [c]	**8** [b]	**9** [b]
1	10.0	17.3	14.5	14.5	7.5	<1
2	2.7	–	6.9	6.0	1.7	<1
3	–	4.6	4.7	–	–	–

[a] In CD_3OD/D_2O (5/95, vol/vol). [b] In $CD_3OD:D_2O$ (10/90, vol/vol). [c] In CD_3OD/D_2O (20/80, vol/vol).

With the host compound **2**, a complexation with a half-open receptor is observed—to our knowledge for the first time—which is analogous to that of a macrocyclic host (Table 1). Molecular mechanics simulations demonstrate that the polarizable substrate moieties can, especially in the complexes with **6**, **7** and **8**, assume an almost ideal position with respect to the inducing $N^{\oplus}$-pole (Fig. 1a, b). From the measured complexation enthalpies an average value of $\Delta G_{N^{\oplus}/\pi} \approx 3$ kJmol^{-1} can be calculated for the interaction between a phenyl ring and an $N^{\oplus}$-charge. This value is in satisfactory agreement with previously assumed values.[3] A similar order of magnitude is found for the complexation enthalpy even with the stretched receptor **3** (Table 1). The somewhat lower values can be explained in terms of a rather poor fit (cf. Fig. 1c) (charge transfer contributions to these complexes are relatively small, as shown by a comparison of structurally similar ion-pair complexes[6]).

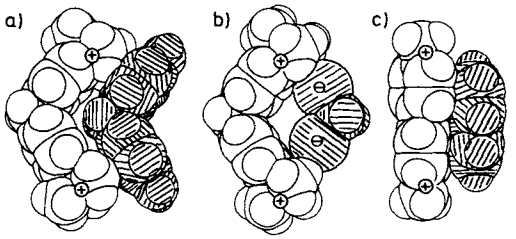

Fig. 1. Space-filling models (from CHARMM/QUANTA simulations) of the complexes **2** · **6** (a), **2** · **8** (b) and **3** · **5** (c). The optimum position of the polarized phenyl ring (a) and iodine atoms (b) with respect to the inducing $N^{\oplus}$ of the receptor **2** is clearly recognizable.

The enthalpies of free binding the substrates **4** and **6**–**8** in the macrocyclic host **1** are in each case about 7 kJmol^{-1} higher than in the half-open analogue **2** (Table 1). The reason for this surprisingly constant difference can be entropic effects, or the unfavorable enthalpy of water molecules, which can form fewer hydrogen bridges inside than outside of the receptor cavity.[7] Molecular mechanics simulations of **1** in a water box using the CHARMM program[8] show that the azoniacyclophane **1** in fact contains about five water molecules in or near the cavity, which altogether participate in only about five hydrogen bridges (Fig. 2); water molecules

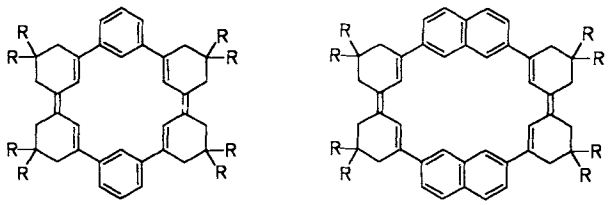
Macrocyclically Fixed Diarylhexatrienes**

By *Fritz Vögtle** and *Carlo Thilgen*

Open-chain and cyclic polyenes have been the subject of intensive research in organic chemistry for many years.[1] 1,6-diphenyl-1,3,5-hexatriene (DPH), for example, is a commonly used fluorescence indicator in investigations concerning the arrangement of molecules in vesicle and cell membranes, in liquid crystal phases, and in polymer films. Our studies in this context are currently directed to the synthesis of novel organic materials with specific properties by incorporating classical structural building blocks into macrocyclic systems, and we now report on the configurationally and conformationally stiffened cyclopolyenes **1** and **2**.

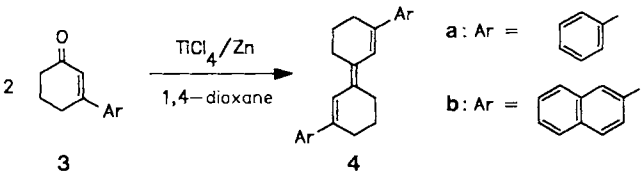


1 **2**

a: R=H; **b**: R=CH_3

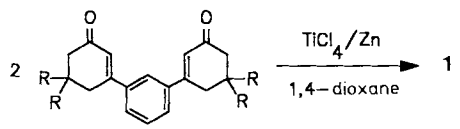
Although the McMurry reaction has found wide application,[2] so far it has rarely been employed for the directed cyclodimerization of dicarbonyl compounds in one step.[3] The one-pot synthesis of the hydrocarbons **1** and **2**, which proceeds in comparatively good yields (**1a**: 36% after optimized coupling of **5a**[4]) makes this method attractive for the synthesis of macrocycles.

In order to work out optimal reaction conditions, but also for comparative purposes, we first prepared the "open chain" triene **4a** from **3a**.



3 **4**

The cyclization to **1** or **2** was best achieved under moderate dilution conditions; we assume that the principle of rigid groups plays a role thereby. The synthetic concept is widely applicable. Thus, in addition to **1a** and **4a**, the macrocycles **1b** (20%), **2a** (20%), and **2b** (4% yield), as well as the triene **4b** could be prepared.



5

The yellowish, sparingly soluble microcrystals of the cycloalkene **1**, which precipitated in analytically pure form on recrystallization from pyridine, melt in an evacuated tube at 385–388 °C (decomp). Besides the peaks for $M^{\oplus}$ [m/z = 468.2817(calcd); 468.2814(obs), base peak] and $M^{2\oplus}$ [m/z = 234], the mass spectrum of **1a** also exhibits peaks of graduated intensity for all the dehydrogenation products down to m/z = 456, which corresponds to the especially stable hexa-*m*-phenylene[6a] (same carbon framework). The ^{1}H-NMR spectrum (200 MHz, $CDBr_3$) shows the following signals: δ = 1.93 (m, 8H; CH_2), 2.51 (m, 8H; CH_2), 2.60 (m, 8H; CH_2), 7.20–7.38 (m, 6H; Ar-CH), 7.57 (s, 4H; vinyl-CH), 8.08 (s, 2H; Ar-CH). A striking feature is the down-

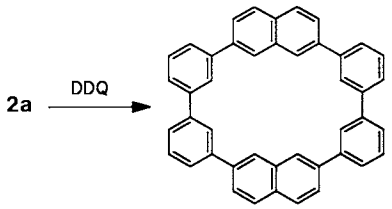
field shift of the olefinic and aromatic protons oriented to the center of the molecule, as has also been observed for hexa-*m*-phenylene[6a] and kekulene.[6b]

The fully aromatized hydrocarbon **6** containing two naphthalene units could be detected for the first time after treatment of the cyclopolyene **2a** with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) [MS: m/z = 556.2185 ($M^{\oplus}$ obs), 556.2191 ($M^{\oplus}$ calcd); 278 ($M^{2\oplus}$)].



6

1a contains two diphenylhexatriene units with a fixed geometry, in which the double bonds are (1*E*, 3*Z*, 5*E*)-configurated, and the free rotation of the benzene rings is suppressed. In the "open-chain" triene **4a**, however, there is still the possibility of (*E*)/(*Z*)-isomerization with regard to the exocyclic double bond.

The diarylhexatrienes **1**, **2** and **4** allow the consequences of configurational and confirmational fixation of the respective chromophore on the electronic excitation to be investigated by UV/VIS spectroscopy. The maxima of the absorption bands of the trienes **4a**, **b** are unstructured, and hypochromic in comparison to those of DPH and DNH (1,6-di[2-naphthyl]-1,3,5-hexatriene), and in each case they exhibit a bathochromic shift of 14–16 nm.[7a, b]

The red shift due to the more extended chromophore in the dinaphthylhexatriene **4b** already manifests itself in its deeper yellow tone when compared to that of the diphenylhexatriene **4a**, whose bright yellow platelet-shaped crystals get a green tinge by the blue fluorescence in incident light (Fig. 1).

Whereas *Zechmeister* et al.[8] found a hypsochromic shift of only 1–2 nm for the longest wavelength absorption maximum of (3*Z*)-DPH in comparison to its all-(*E*)-isomer, the corresponding difference between the "open-chain" all-(*E*)-triene **4a** and its cyclic counterpart **1a** with the fixed double (3*Z*)-configuration amounts to 23 nm.[7a] In the case of (*E*)- and (*Z*)-stilbene the difference of 15.5 nm is attributed to a hindrance of the conjugation in the no longer planar (*Z*)-isomer.[10] In **1a**, a rotation of the benzene rings out of the plane of conjugation may contribute to the observed shift.

The absence of an absorption band at even longer wavelength in the UV/VIS spectra of **1a** and **2a** confirms the assumption that the macrocycles contain two isolated diphenylhexatriene systems instead of a single chromophore extended over the whole ring.[11]

The most outstanding difference between the spectra of **1a**, **2a** and those of the "open chain" analogues **4a**, **b** is the occurrence of an additional band in the former at λ = 273 and 286 nm respectively. From a theoretical viewpoint, this is due to the absence of a symmetry center[12] and has proven to be characteristic of the presence of a (*Z*)-double bond within a polyene chain. The "*cis*-peaks" of the macrocycles **1** and **2** are striking, not only by their high extinction coefficient but also by the sole fact of their occurrence, since **1a** shows an inversion center in the energetically most favorable conformation, as is predicted by calculations.[13] This observation also suggests a division of the molecules into two separate chromophores.

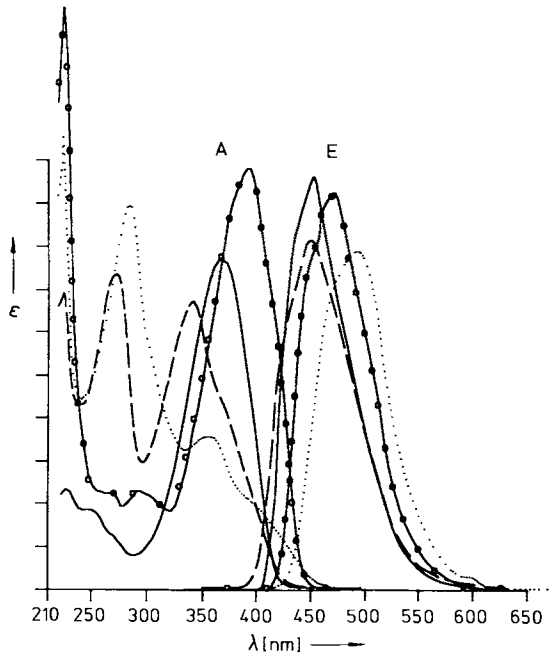


Fig. 1. Absorption (A) and emission (E) spectra (in 1,4-dioxane, T = 292 K, excitation at 380–400 nm) of the diarylhexatrienes **4a** (——) and **4b** (⊖⊖⊖) and of the cyclopolyenes **1a** (– – –) and **2a** (···). ε in relative units.

Whereas the emission maxima[7c] of the diphenylhexatrienes DPH, **4a** and **1a** are located at almost the same λ (blue spectral region), a pronounced bathochromic shift characterizes the transition to the dinaphthylhexatriene **4b** (blue-green) and further to the cyclic dinaphthylpolyene **2a** (green). The difference between absorption and emission maxima is significantly larger in the case of the cyclic compounds **1a** and **2a** than in the case of the "open chain" analogues **4a**, **b**[7a, c] (Fig. 1).

Diphenylpolyenes form cations in sufficiently concentrated sulfuric acid.[15, 16] Those of **4a**, **b**, **1a** and **2a** (in 96% H_2SO_4) are deep-colored, and in each case their absorption spectra exhibit two intense bands.[7b] From the fact that the solutions of the cyclic ions no longer show bands of the hydrocarbons **1a** or **2a** it may be assumed that both chromophoric units of the molecules are protonated.

Deep-blue/violet solutions of anions were obtained on treatment of the diphenylpolyenes **1a** and **4a** with sodium metal in THF. The structural variety observed for the anions of 1,n-diphenylpolyenes[17] should be strongly reduced in the case of the species described here by the additional clamping. Cyclovoltammetric measurements in pyridine afforded the first reduction potentials of the polyenes **1a** and **4a**, which are superimposed to the reduction of the base electrolyte: they have nearly the same value for "open chain" (**4a**) and cyclic triene (**1a**).[18] Unlike **1a**, **4a** displays a quasi-reversible behavior: at potential scanning rates of $\geq$100 mVs^{-1} the reoxidation of its radical anion can be observed, indicating that the chemical stability of $\mathbf{4a}^{\odot\ominus}$ is significantly higher than that of $\mathbf{1a}^{\odot\ominus}$.

Hydrocarbon rings of the type described here—particularly when substituted with eight solubilizing long-chain residues R—provide means for further manipulations of light absorption and emission.

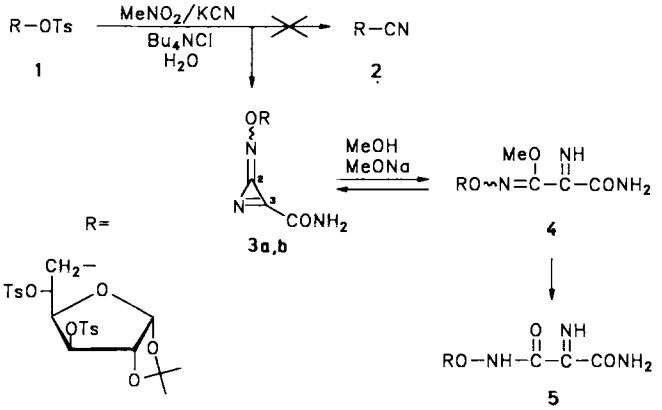
Stable Azirinimines? A Structural Corrigendum**

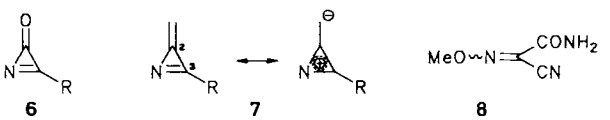
By *Klaus Banert,* Elisabeth Reissaus, Hans-Jörg Deiseroth, Claus Peter Kluge,* and *Eva-Maria Peters*

Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

W. Meyer zu Reckendorf and *N. Schultz* recently reported on abortive attempts to convert the sulfonate **1** (Ts = *p*-toluenesulfonyl) with cyanide ions into the chain-lengthened product **2**.[1] They obtained instead a product with melting point 130–131 °C in 15% yield, which is said to have the surprising structure **3a**. This novel azirinimine was said to be converted into the geometrical isomer **3b** (m.p. 180–182 °C) upon treatment with bases ($NaHCO_3$ in aqueous acetone). As evidence in support of the structures the authors quote spectroscopic data and secondary reactions of **3a**: reaction of **3a** with sodium methoxide in methanol is reported to give mainly **3b** and, in a side reaction, **4**. The product **3b** is likewise described as being formed from **4** under the same reaction conditions, while layer-chromatographic work-up is reported to lead to **5**.



The report[1] on the synthesis and reactions of the first azirinimines[2, 3] is contrary to the hitherto known chemistry of the 2*H*-azirines.[4] The strained heterocycles **3a, b** are said to be surprisingly stable, which is in sharp contrast to the instability which is postulated for the azirinones **6**[5] and has been demonstrated in the case of the methyleneazirines **7**.[6] Usually, 2*H*-azirines show a ^{13}C-NMR signal for C-3 in the range $\delta = 157–173$;[4] in the case of **7** this signal is shifted downfield ($\delta = 185–188$), which points to the participation of a dipolar resonance form.[6] The ^{13}C-NMR spectra[1] of **3a** (C3: $\delta = 133.5$) and **3b** (C3: $\delta = 127.2$) therefore appear to be hardly reconcilable with azirinimine structures. Furthermore, one would also expect the signals for C2 to appear at much lower field (**3a**: $\delta = 112.3$; **3b**: $\delta = 106.8$) if one compares the data quoted in the literature for aziridinimines.[7] In the present communication we present corrected structures for the substances **3a, b, 4** and **5**.



In the case of the model compound **8**[8] it is not a three-membered ring, but the anisotropic effect of the cyano group[9] which gives rise to an upfield shift of the oxime signal in the ^{13}C-NMR spectrum. The ^{13}C-NMR and the ^{15}N-NMR data of **8** resemble those of the reputed azirinimines (Table 1) to which the structures **9** and **11** should accordingly be assigned. In order to confirm this, **11** was synthesized independently from **10**,[10] sodium hydroxide and **1**[11] in dimethyl sulfoxide (DMSO) (16 h, 50 °C, yield 91%).[12] When **1** was allowed to react—as described in the literature[1]—with potassium cyanide and tetrabutylammo-

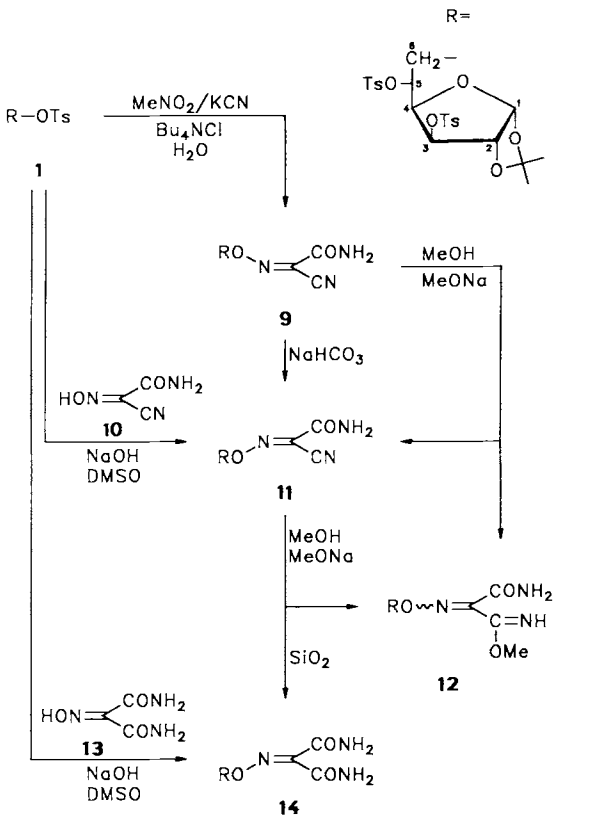
[a] ^{1}H NMR spectra at 80 and 400 MHz, position of the NH signals concentration-dependent; ^{13}C NMR spectra at 100.6 MHz; ^{15}N NMR spectra at 40.5 MHz, CH_3NO_2 as external standard.

nium chloride in nitromethane/water (two-phase system, 2–4 d, 50 °C), after work-up and column chromatographic separation of the starting material (SiO_2, ether/pentane 9:1) a substance (designated **9** in the following) was obtained which was converted into **11** by base-catalyzed isomerization[1] ($NaHCO_3$ in acetone/water 10:1, 3 d, 60 °C). This proves that the reputed azirinimines **3a**, **b** are in fact the substances **9** and **11**.[13] γ-Effects in the ^{13}C-NMR spectroscopy[9, 14] plausibly suggest the *Z*-configuration for **9** and the *E*-configuration for **11**: the signal of the amide C-atom appears at higher field in the case of **9** than in the case of **11**, whereas in the case of the cyanide C-atom the behavior is reversed. In the IR spectrum, **10** shows, just like the model compound **8**, an extremely weak nitrile band. It is not surprising, therefore, that the cyano groups in **9** and **11** cannot be detected IR spectroscopically. Final doubts about the structure of **9** are cleared by a single-crystal X-ray diffraction analysis[15] (Fig. 1).

Reaction of **9** with sodium methoxide in methanol (0.015 M, 4 d, 37 °C) yielded mainly **11** and the carboximide



ester[16] **12** as by-product. After only 24 h reaction time a further by-product could be detected whose amount decreased again on prolonged treatment with the methoxide, and which was completely decomposed upon chromatographic work-up (SiO_2, ether/dichloromethane). ^{1}H-NMR and ^{13}C-NMR spectra of the crude product indicated that it was a geometrical isomer of the carboximide ester **12** listed in Table 1. Very slow reaction of **11** with sodium methoxide (0.015 M, 14 d, 37 °C) furnished the addition product **12**. This could be separated chromatographically (SiO_2, ether/dichloromethane) from unreacted **11**, whereby a further compound was formed which was not contained in the crude product. This new compound was the diamide **14**, which could also be prepared independently from **13**,[17] sodium hydroxide and **1** in DMSO (2 d, 50 °C, yield 88%). The spectroscopic data of **12** and **14** (Table 1) reveal that the

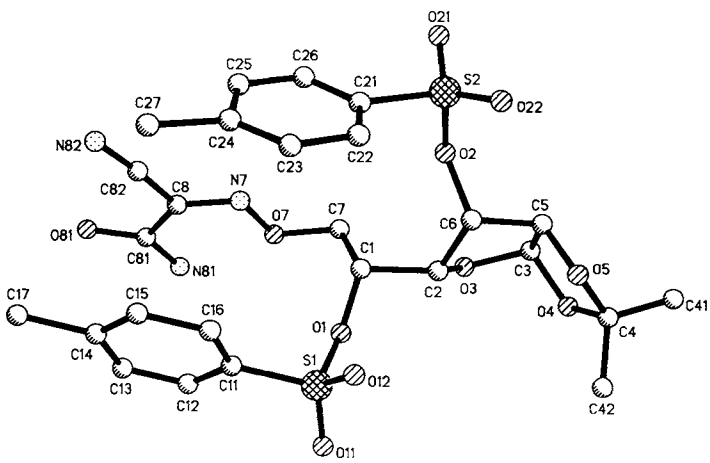


Fig. 1. Structure of **9** in the crystal (H atoms not shown)[15].

structures **4** and **5** were erroneously assigned to the two substances.[1] As the ^{15}N-NMR spectrum shows, **14** has two NH_2 groups and one further nitrogen atom, which is not reconcilable with structure **5**.

$^{\ominus}O-N=CH-CH-NO_2^{\ominus}$ **15**

As has already been suggested,[1] in the reaction of **1** with potassium cyanide and tetrabutylammonium chloride in nitromethane/water the condensation product **15**[18] could be formed initially. Possibly subsequent *O*-alkylation by the sulfonate **1**, nucleophilic attack by cyanide at the neighboring carbon atom and formal double elimination and addition of water (sequence variable) could lead to **9**.

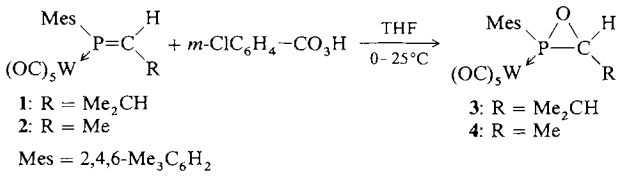
Epoxidation of the P=C Double Bond of Phosphaalkene Complexes: X-Ray Crystal Structure Analysis of a Stable Oxaphosphirane Complex

By *Siegfried Bauer, Angela Marinetti, Louis Ricard*, and *François Mathey**

The oxaphosphirane ring is of special interest because of its analogy to the oxirane ring. However, until now, only one oxaphosphirane, which was obtained by [2 + 1] cycloaddition of hexafluoroacetone to a bulky aminoiminophosphane, has been characterized by spectroscopy.[1] The direct epoxidation of the P=C double bond of phosphaalkenes would provide a far better access to oxaphosphiranes. Unfortunately, however, free phosphaalkenes are preferentially oxidized at the phosphorus.[2] It was thus logical to block the lone pair at phosphorus and to investigate the oxidation of a series of phosphaalkene P-complexes.

Complex **1**, readily obtained from the corresponding aldehyde via the "phospha-Wittig" reaction,[3] was directly oxidized by *m*-chloroperbenzoic acid in THF to give a quantitative yield of the corresponding oxaphosphirane **3**[4] [Eq. (a)].



1: R = Me_2CH
2: R = Me
Mes = 2,4,6-$Me_3C_6H_2$

3: R = Me_2CH
4: R = Me

The X-ray crystal structure analysis of **3**[5] confirmed the presence of a three-membered oxaphosphirane ring. The intracyclic C1–P–O2 angle [50.9(2)°] is close to that found in a phosphirane *P*–$W(CO)_5$ complex,[6] whereas the intracyclic

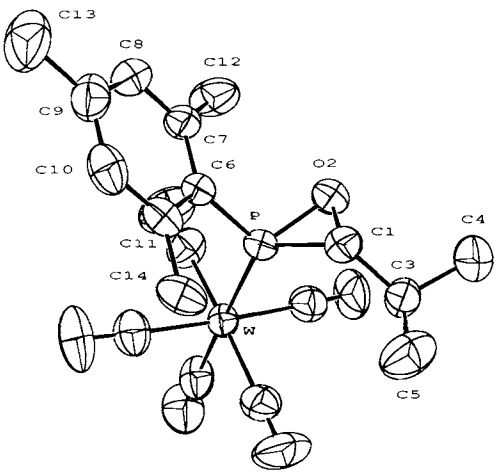


Fig. 1. Structure of **3** in the crystal [5]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances [Å] and angles [°]: W-P 2.443(1), P-O2 1.657(4), P-C1 1.778(6), P-C6 1.819(5), O2-C1 1.480(7), C1-C3 1.505(8); W-P-O2 120.7(2), W-P-C1 128.7(2), W-P-C6 122.1(2), O2-P-C1 50.9(2), O2-P-C6 106.3(2), C1-P-C6 106.5(3), P-O2-C1 68.8(3), P-C1-O2 60.3(3), P-C1-C3 125.7(4), O2-C1-C3 114.9(5).

P–O2–C1 angle is less acute than in epoxides.[7] The most interesting feature of this structure is that it keeps the "memory" of its phosphaalkene precursor. The sum of the W–P–C6, W–P–C1, and C1–P–C6 angles (357.3°) is close to 360°, as in the parent phosphaalkene complex.[3b] The plane of the oxaphosphirane ring is almost orthogonal to the WPC1C6 mean plane [90.3(0.2)°]. The phosphorus atom appears to retain its initial sp^2 hybridization. Even the P–C1 bond [1.778(6) Å] is shorter than expected for a normal P–C single bond. The structure of **3** also shows that the epoxidation of the P=C double bond takes place with retention of the initial *trans* stereochemistry of **1** [C3–P–C1–C6 dihedral angle 161.3(5)°]. However, with the less hindered phosphaalkene complex **2**, this retention is not complete. Indeed, the epoxidation of **2** mainly leads to **4**.[8] The ^{1}H-NMR spectrum of **4**, like that of **3** shows no *H*–C1–*P* coupling.[4] Thus, **4** probably has the same *trans* stereochemistry as **3**. However, besides **4** ($\delta^{31}P = +2.9$ in C_6D_6), another compound **5** ($\delta^{31}P = +6.2$) is produced in minor amounts (ca. 10%). This compound is probably the *cis* isomer corresponding to **4**. Finally, the main decomposition path of the oxaphosphiranes **3** and **4** in the mass spectrometer involves splitting of the ring into the terminal phosphinidene complex [Mes–P=W(CO)$_5$] and the aldehydes RCHO. This process is exactly the reverse of the first described synthesis of this ring.[1]

Experimental

A solution of *m*-chloroperbenzoic acid (1.9 g, 1.1×10^{-2} mol) in THF (10 mL) was added dropwise to a solution of the phosphaalkene complex **1** (5.3 g, 1×10^{-2} mol) in THF (30 mL). The reaction was slightly exothermic. After evaporation of THF, the residue was extracted with hexane. The extract after removal of hexane was recrystallized from pentane/CH_3CN. 5.0 g of **3** (~86%), colorless crystals: m.p. 68–69 °C. The same procedure with **2** gave **4** in 40% yield after recrystallization; m.p. 61–64 °C (along with *ca* 10% of the *cis* isomer).

C*H*); ^{13}C NMR (C_6D_6): $\delta = 19.15$ (s, Me), 19.57 (d, J(CP) = 12.2 Hz, Me), 20.44 (d, J(CP) = 9.4 Hz, Me), 20.87 (d, J(CP) ≃ 8.5 Hz, Me), 20.96 (s, Me), 31.32 (s, *C*H Me_2), 69.78 (d, ^1J(CP) = 28.1 Hz, OCH), 194.96 (d, ^2J(CP) = 7.9 Hz, *cis* CO); The isopropyl substituent displays two nonequivalent diastereotopic methyl groups (^{1}H and ^{13}C NMR). Both show small ^4J(HP) couplings but only the larger one could be measured at 200 MHz. MS (70 eV, ^{184}W): *m/z* 546 ($M^{\oplus}$, 4%), 474 ($M^{\oplus}$ – C_4H_8O, 36%), 446 (474 – CO, 36%), 418 (474 – 2 CO, 19%, 390 (474 – 3 CO, 100%). Correct elemental analysis.

[5] X-ray structure determination of **3**: crystals of **3**, $C_{18}H_{15}O_6PW$ were grown at 4 °C from acetonitrile. Data were collected at 18° ± 1 °C on an Enraf Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf Nonius SDP package. The compound crystallizes in space group $C2/c$, $a = 32.539(3)$ Å, $b = 7.164(1)$ Å, $c = 21.984(2)$ Å, $\beta = 125.79(1)°$; $V = 4156.8(1.9)$ Å^3; $Z = 8$; $\varrho_{calcd} = 1.740$ g/cm^3; $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) graphite monochromator; $\mu = 58.0$ cm^{-1}; $F(000) = 2080$. A total of 6030 unique reflections were recorded in the range $2° \le 2\theta \le 60.0°$, of which 3248 were considered as observed ($F^2 < 3.0\sigma(F^2)$). The structure was solved by Patterson methods. The hydrogen atoms were included as fixed contributions in the final stages of refinement (non-H atoms anisotropic). A non-Poisson weighting scheme was applied with a p factor of 0.05. The final R factors were $R = 0.029$, $R_w = 0.037$, G. O. F. = 1.03. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54755, the names of the authors, and the journal citation.

Nonradioactive Assay of DNA Hybridization by DNA-Template-Mediated Formation of a Ternary Tb^{III} Complex in Pure Liquid Phase

By *Andreas Oser* and *Günther Valet**

The identification of specific nucleic acid sequences by the hybridization technique[1] is usually carried out in a heterogeneous two-phase system. The nucleic acid material being investigated is immobilized on a solid matrix and then incubated in individual steps (prehybridization, hybridization, washings, detection) with various solutions.[2] Homogeneous hybridizations in pure liquid phase exhibit more favorable hybridization kinetics and, moreover, make the prehybridization and washing steps superfluous. This appreciable simplification is of great interest for the development of automated procedures. However, it requires special labeling of the nucleic acid probes, so that a measurable signal—by fluorescence resonance energy transfer (FRET),[3] for example—is only obtained after hybrid formation with the complementary sequence. Here we describe such a system involving suitable pairs of oligonucleotide probes, chemically modified to form a ternary Tb^{III} complex after hybridization with the template nucleic acids. Upon photoexcitation, the salicylate group of one oligonucleotide, serving as a ligand, transfers the excitation energy to the lanthanide ion of the second oligonucleotide[4] and a $Tb^{3\oplus}$-specific, long-lived fluorescence is then emitted.

The chemical modification involved attachment of the energy donor salicylate (pAS) to the 3′ end of one oligonucleotide (3′ON-pas) and a diethylenetriaminepentaacetate (DTPA) ligand bearing the energy acceptor and fluorescence emitter $Tb^{3\oplus}$ to the 5′ end of the other oligonucleotide (5′ON-DTPA-Tb) (Fig. 1). The oligonucleotide sequences were chosen in such a way that, after hybridization to the complementary DNA strand, the energy donor and acceptor were positioned in direct proximity.[5] Compared with ternary complex formation in free solution, the formation of a complex between DTPA-Tb on the one hand and salicylate on the other is strongly favored on the DNA template (Fig. 1).

The 3′-end labeling of 3′ON with 4-aminosalicylic acid (pAS) was accomplished by established methods of 3′-end

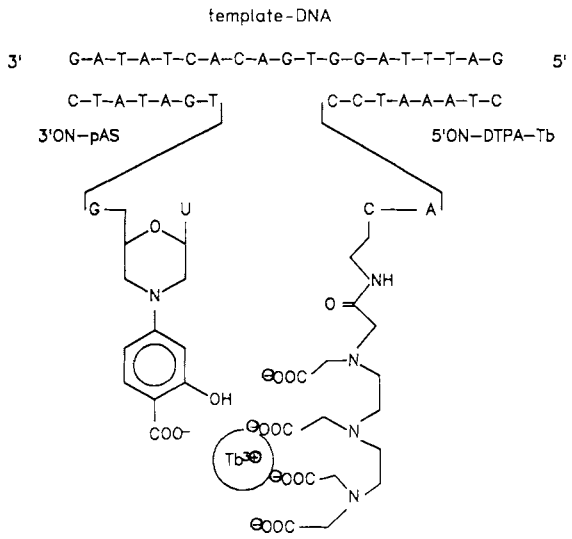

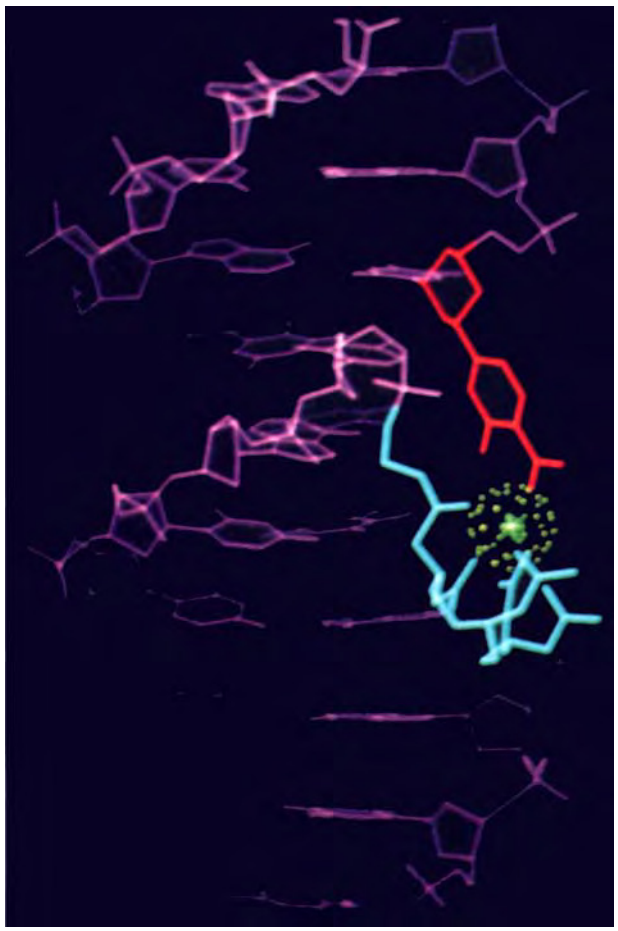

Fig. 1. Schematic (top) and graphic (bottom) drawing of the model system for homogeneous hybridization [6]. The 3'-end label of the 9-mer 3'ON with pAS and the 5'-end label of the 10-mer 5'ON with DTPA-Tb are enlarged. Red, salicylate residue with morpholino moiety; light blue-green, DTPA; yellow, $Tb^{3\oplus}$, magenta, B-DNA helix.

labeling of RNA molecules via periodate oxidation.[7] The extension of this 3' modification to DNA molecules can be performed either enzymatically[8] or—as is the case here—chemically[3b, 9] by the use of a 3'-terminal ribonucleotide moiety. Periodate oxidation affords a dialdehyde group at the 3' ribose moiety. Double reductive amination of this dialdehyde group with pAS in the presence of cyanoborohydride results in conversion of the 3'-terminal ribose moiety to a morpholino moiety containing a salicylate group (Fig. 1, top).

In order to label 5'ON with DTPA-Tb, the oligonucleotide was first synthesized with an aminoethyl linker at the 5' terminus.[10] DTPA dianhydride was then used for covalent coupling of DTPA to the primary amino group of the oligonucleotide[11] and finally made possible the stable complexation of $Tb^{3\oplus}$ ions ($K_a = 10^{23}$[12]).

Figure 2 shows the $Tb^{3\oplus}$-specific fluorescence values after hybridization of the oligonucleotide pair 3'ON-pAS/5'ON-DTPA-Tb, present in constant concentration, with increasing concentrations of the complementary template DNA in solution. The sensitivity of detection is one picomole of template DNA in one milliliter. That the detected ternary complex is indeed formed by binding of the oligonucleotide pair to the complementary DNA was confirmed by the increase in $Tb^{3\oplus}$ fluorescence with increasing concentration of template DNA (Fig. 2). Control measurements showed that the

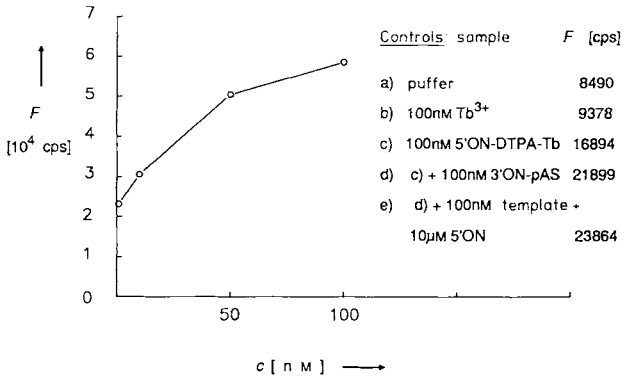

Fig. 2. Delayed $Tb^{3\oplus}$ fluorescence F after hybridization of the oligonucleotide pair with increasing concentrations c of template DNA. The hybridization was carried out for 30 m in 10 mM Tris-HCl/0.5 M NaCl at pH 8.0 in the presence of 100 nM 3'ON-pAS and 100 nM 5'ON-DTPA-Tb at 6 °C. Subsequently, the delayed fluorescence was measured in counts per second (cps) with an Arcus 1230 fluorometer (LKB-Wallac, Turku, Finnland) at 400-μs delay time and 400-μs measuring time (excitation 268–388 nm, emission > 435 nm). Values for the controls are shown on the right-hand side of the figure.

energy transfer can be competitively inhibited by an excess of unlabeled 5' oligonucleotide (control e), thereby demonstrating the specificity of the fluorescence excitation. The control experiments also show that the delayed background fluorescence is not generated by direct excitation of the $Tb^{3\oplus}$ ions (control b) but rather by energy transfer from nucleotide bases of the 5'ON oligonucleotide to the complexed $Tb^{3\oplus}$ ion;[4a] this fluorescence is already measurable before the hybridization (control c).

Further proof for the hybridization-dependent complex formation is provided by the inverse correlation between hypochromicity and increase in the $Tb^{3\oplus}$ fluorescence on cooling of the hybridization solutions—that is, on going from the denatured to the reassociated state of the template/oligonucleotide pair system (Fig. 3). The melting point of the template/3'ON-pAS/5'ON-DTPA-Tb system is about 1 K greater than that of a system containing the same components but without 5'-DTPA-Tb terminal modification. This corresponds to an enthalpy change and therefore a stabilization contribution of about 2.5 kJ mol^{-1}.[13] Accordingly, the positive cooperativity[14] already observed on binding of two directly neighboring oligonucleotides to a complementary template is further increased by the chelate formation.

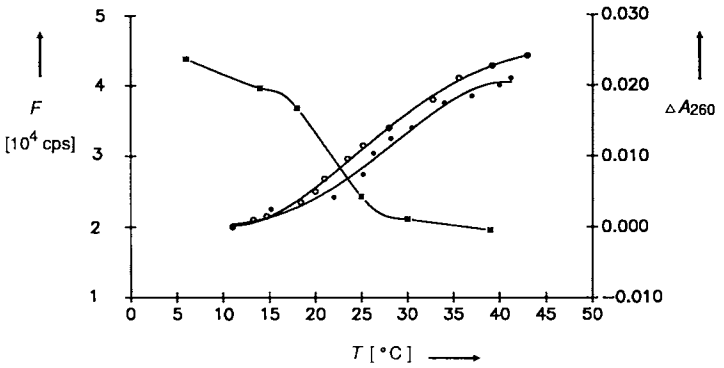

Fig. 3. Time-delayed fluorescence F (■—■) and change of the absorption ΔA_{260} (●—●) for the system template/3'ON-pAS/5'ON-DTPA-Tb (each 100 nM) as a function of temperature T in 10 mM Tris-HCl/0.5 M NaCl at pH 8.0. A T_m value of 27 °C was determined from the variation in hypochromicity; by contrast, the system without 5'-end labeling (template/3'ON-pAS/5'ON, o—o) has a T_m value of 26 °C. The T_m values of 3'ON and 5'ON alone with the template DNA are 19.5 and 20 °C, respectively.

The dependence of the energy-transfer efficiency on the distance of the oligonucleotide pairs was investigated by shortening 5'ON by one nucleotide. The DTPA-Tb label was then located on the adenine residue of 5'ON (see Fig. 1). For the same concentration of template, the hybridization signal thereby decreased by 54%. Lengthening of the spacer between the 5'-phosphate group and the DTPA-Tb chelate from an ethyl to a hexyl arm[15] resulted in restoration of 88% of the original energy-transfer efficiency.

Complex formation between energy donor and acceptor guarantees a more efficient energy transfer in comparison to a system in which energy transfer only occurs owing to spatial proximity of donor and acceptor—as was the case for the earlier described hybridization assays using the FRET principle.[3]

A further advantage of the pAS/Tb donor/acceptor system results from the *long-lived* $Tb^{3\oplus}$ fluorescence with a lifetime of 1.58 ms,[4b] which allows the measurement of delayed fluorescence.[16] The direct donor and acceptor fluorescence emission, which is short-lived and independent of the energy-transfer process, leads to an appreciable, unspecific background fluorescence in the usual FRET systems.[17] Measurement of the delayed fluorescence, however, allows reliable suppression of this background fluorescence. The sensitivity of the DNA-hybridization assay described here might be further increased by a better choice of excitation and emission wavelengths of fluorescence and by the use of other ligand/lanthanide FRET systems.

Besides simplifying the hybridization process compared with two-phase systems, the method described here is of special significance for the rapid identification of mutations, insertions, deletions, chromosome translocations, and splicing sites, since the two oligonucleotide probes must be in direct proximity.

Experimental Procedure

Synthesis of 3'ON-pAS: 16 nmol of 3'ON containing a 3'-ribouridyl residue [3b, 9] was treated for 2 h on ice with $NaIO_4$ (2 μmol) in 0.2 mL of 50 mM sodium acetate buffer at pH 4.75. After addition of ethylene glycol (10 μL, 90 μmol) and Sephadex G-25 chromatography, the oxidized 3'ON was incubated with pAS (4 μmol) and $NaBH_3CN$ (4 μmol) in 0.15 mL of 0.2 M sodium phosphate buffer at pH 8.0 for about 15 h. After Sephadex G-25 purification, 3'ON-pAS was isolated by denaturing polyacrylamide gel electrophoresis (20%, 8 M urea) [18a].

Synthesis of 5'ON-DTPA-pAS: 160 nmol of the 5'-aminolink-functionalized oligonucleotide [10] was treated twice in 50 μL of 0.2 M potassium hydrogen carbonate buffer at pH 8.2 with DTPA dianhydride (4 μmol; 0.2 M solution in anhydrous dimethyl sulfoxide). After Sephadex G-25 purification, the 5'ON-DTPA was isolated by reversed phase HPLC [18b] and then treated with an equimolar amount of $TbCl_3$.

[5] Since we only wanted to show that the FRET detection procedure could work in principle, we chose a model system involving only short oligonucleotides (9- and 10-mers). For practical applications, longer oligonucleotides with higher melting points (T_m) are necessary.

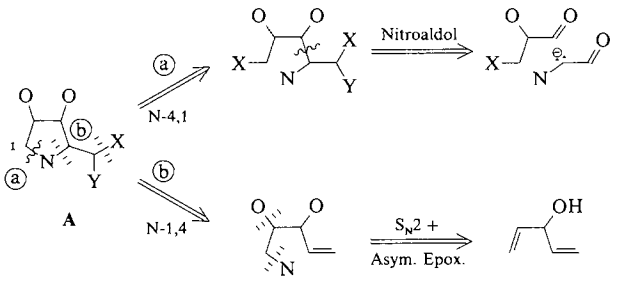
rigid iminosugar derivatives of mono- or bicyclic structure.[1-3] In addition, polyhydroxypyrrolidines such as L- and D-1,4-dideoxy-1,4-iminoarabinitol (LAB and DAB, resp.), polyhydroxypiperidines such as deoxynojirimycin, and indolizidines such as castanospermine have been shown to be (more or less cytotoxic) inhibitors of HIV replication.[2] These findings stimulated syntheses of numerous groups, based, e.g., on the modification of carbohydrates[2]—often involving a sophisticated protecting group strategy—or the use of stereoselective C–C coupling reactions such as the aldolase-catalyzed aldol additions.[3]

We are currently trying to find new and efficient syntheses in this series[4] and report here and in the following communication[5] on various routes to D- and L-*arabino*-configurated dihydroxypyrrolidines of type **A** (Scheme 1). These derivatives are of interest both as target compounds[6] and as intermediates[6b] for syntheses of indolizidines.

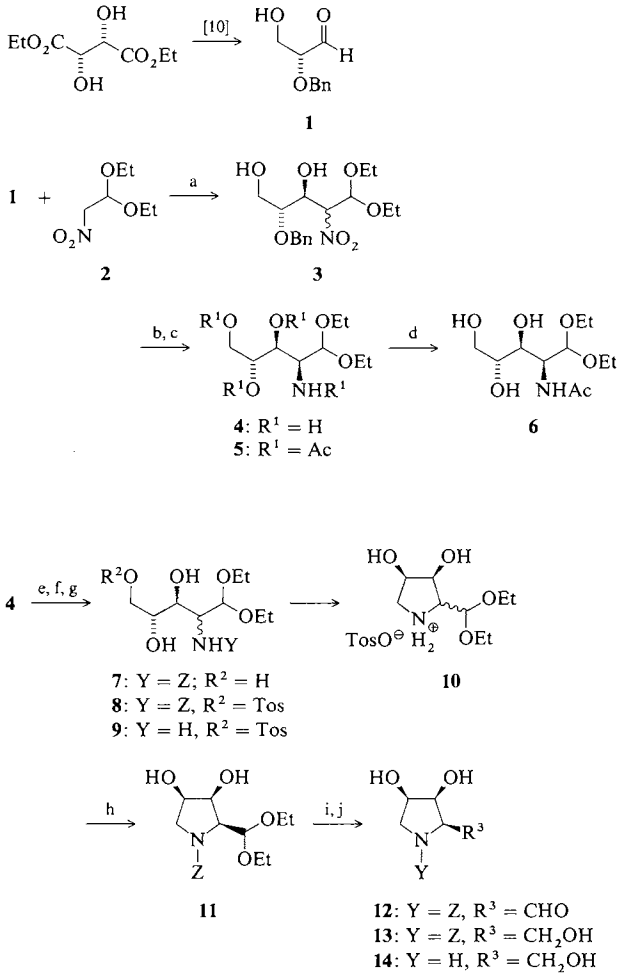


A

Scheme 1. Nitroaldol (this work) and divinylcarbinol route [5] to the dihydroxypyrrolidines **A**.

The key step of the syntheses according to route a presented here is a highly stereoselective case of the often capricious nitroaldol addition (Henry reaction).[7] We have carried out systematic investigations into the conditions and structural variations of more complex components of this reaction.[8, 9] Concerning C_5 products, it emerged that nitroacetaldehyde diethylacetal **2** and 2-*O*-benzylglyceraldehyde, (BGA) **1**[10], developed recently (for that purpose), are best suited. In the presence of tetrabutylammonium fluoride trihydrate at room temperature both combine to afford a mixture of only two of the four possible diastereomers, namely *arabino*- and *ribo*-**3**, in the ratio of 88:12, in 90% yield. Based on cross experiments, this results from a very high 1,2-induction (*erythro*) with regard to the aldehyde **1** (*erythro* configuration referred to C4/C3 in **3**), and subsequent equilibrium epimerization at the nitromethine group (C2) in the adduct **3**. The mixture of the 1,4-protected nitropentoses **3** was reduced[11] and converted into the *N*-acetyl derivative of the acyclic arabinosamine acetal **6** by standard methods[12] (Scheme 2). The epimers could be separated at the stage of the O,N-peracetylation products **5**. L-**6** was obtained in four steps (plus one chromatographic separation) with an overall yield of 51% (D-**6** with 45%).[13] Gratifyingly, **3** survived the reduction to **4** *without* epimerization at C2, and **6** was isolated with an enantiomeric purity of > 99:1 [^{1}H NMR analysis with (+)-Eu(hfc)$_3$]. Once more,[10] this shows that **1** can undergo stereoselective reactions with basic nucleophiles *without* racemization.

The open-chain arabinosamine acetals L- and D-**4** likewise proved suitable intermediates for the synthesis of the iminoarabinitols **13** (*lyxo* configuration when named as 1-deoxysugars). Benzyloxycarbonyl(Z)-protection of the amino group and 5-O-tosylation gave the *N*-Z-protected cyclization precursors **8** which were stable only in basic medium, i.e. in



Scheme 2: Synthesis of 2-arabinosamine acetal **6**, *N*-Z-dihydroxyprolinal **12**, and *N*-Z-1,4-dideoxy-1,4-iminolyxitol **13**. The formulas depict the starting materials and products for the case of (*R*)-**3**; all reactions were carried out in both enantiomeric series. In the case of **3**, **5**–**7**, **11**, **13** the structures and configurations are established by complete analytical and spectroscopic data. a) 0.5 $Bu_4NF \cdot 3H_2O$, THF, $-78 \rightarrow -5$ °C, 4 h, then 13 h at -5 °C; 89–92% **3**, pale-yellow syrup, *arabino*/*ribo* 88:12. b) H_2, Pd/C, MeOH, 25 °C, 24 h; yield of **4** quantitative, pale-yellow, sticky solid. c) Ac_2O, pyridine, 0 °C → 25 °C, 22 h, 97–98% **5** as *arabino*/*ribo* mixture 88:12 (± 2); medium-pressure liquid chromatography (MLPC) (LiChroprep Si60, 25–40 μm, ethyl acetate): D-**5** 61%, m.p. 65–66 °C, after recrystallization, colorless needles, m.p. 67 °C, $[\alpha]_D^{21} = +29.7$ ($c = 0.58$, $CHCl_3$); L-**5** 65%, m.p. 63–65 °C, after recrystallization 67–68 °C, $[\alpha]_D^{21} = -30.0$ ($c = 0.58$, $CHCl_3$). d) 25% NH_3 solution in H_2O, MeOH, 25 °C, 22 h; recrystallization (ethyl acetate), 84% D-**6** and 86% L-**6**, colorless flakes, m.p. 142 and 143 °C; D-**6**: $[\alpha]_D^{20} = -7.1$ ($c = 0.51$, ethanol); L-**6**: $[\alpha]_D^{20} = +7.0$ ($c = 0.51$, ethanol); enantiomeric ratio for both > 99:1 according to ^{1}H NMR analyses with 16 mol-% (+)-Eu(hfc)$_3$ and comparison with 4:96 mixed sample: ^{1}H NMR (200.1 MHz, $CDCl_3$): $\delta = 2.11$ ($COCH_3$) for D- and L-**6**; with 16 mol-% (+)-Eu(hfc)$_3$: $\delta = 2.64$ (D-**6**) and 2.46 (L-**6**). e) Z-Cl, $NaHCO_3$, H_2O, 25 °C, 20 h, filtration through silica gel with petroleum ether/ether 3:7 and ethyl acetate; 63 and 60% of **7**, respectively, as 88:12 mixture, colorless solid, m.p. 73–76 and 73–78 °C resp. f) *p*-TosCl, pyridine/ether, 25 °C, 3 d, 76 and 70% of **8**, resp., pale-yellow syrup. g) H_2, Pd/C, MeOH, 25 °C, 17–18 h; 91 and 88% of **10**, resp., colorless foam, melting range 40–80 °C, *arabino*/*ribo* mixture 88:12. h) Z-Cl, $NaHCO_3$, H_2O, 25 °C, 22 h, silica gel filtration; 70–75% pale-yellow oil; LPLC (Lobar LiChroprep Si60, 40–63 μm, $CHCl_3$/MeOH 95:5), colorless oil; D-**11** 50%, $[\alpha]_D^{21} = -45.6$ ($c = 0.76$, $CHCl_3$); L-**11** 57%, $[\alpha]_D^{21} = +44.7$ ($c = 0.76$, $CHCl_3$). i) 0.1N HCl/THF 4:1, 25 °C, 13 h, TLC control (silica gel/Al foil 60F 254, $CHCl_3$/MeOH 9:1), then addition of $NaBH_4$/EtOH, 25 °C, 6 h, flash chromatography (silica gel, $CHCl_3$/MeOH 9:1); **13**: colorless, analytically pure syrup, 86 and 87% respectively; D-**13**: $[\alpha]_D^{22} = -46.3$ ($c = 0.32$, MeOH); L-**13**: $[\alpha]_D^{22} = +46.1$ ($c = 0.32$, MeOH) ([6c] *Joullié* et al.): $[\alpha]_D^{23} = -47.5$ ($c = 0.32$, MeOH) for D-**13**. ^{13}C NMR: at 20 °C two sets of signals in the ratio of 60:40 (carbamate rotamers), at 60 °C in [D_6] DMSO one set, diastereomeric purity > 94:6. j) **13** → **14** cf. Ref. [6a, c] (*Hashimoto* and *Joullié* et al., resp.). We obtained, e.g., L-**14** with H_2, Pd/C in 99% yield; hydrochloride: m.p. 155.156 °C, $[\alpha]_D^{20} = -18.4$ ($c = 0.22$, H_2O); ([**6a**] (*Fleet* et al.): m.p. 157–159 °C, $[\alpha]_D^{20} = +18.8$ ($c = 0.16$, H_2O) for D-**14** (hydrochloride)).

the presence of pyridine. It should be noted that the selective *O*-terminal tosylation **7** → **8**, for which, inter alia, examples with other acyclic triols,[14] diols and pyranose derivatives[15] are known, opens up further possibilities for the synthesis of imino sugars unexploited so far. The Z-tosylate **8** was converted into a mixture of the diastereomeric dihydroxyprolinal acetals **10** (as hydrotosylates) on catalytic hydrogenation (Pd/C) which liberated the NH_2 group (in **9**), in turn effecting intramolecular OTos substitution. The separation of the diastereomers was accomplished after conversion of **10** into the Z derivatives **11**, by low-pressure liquid chromatography (LPLC). The acetal **11** (prepared in gram amounts) was hydrolyzed (acid-catalysis) to furnish the aldehyde **12**. TLC control and NMR analysis showed the *cis*-aldehyde **12** to be formed first; this then in part epimerized to the *trans*-derivative (*ribo*). When the reaction was stopped after ca. 13 h and the crude product **12** reduced with $NaBH_4$, the all-*cis*-triol **13** (1,4-dideoxy-1,4-imino-D-lyxitol or *cis*-L-dihydroxyprolinol) was secured in analytically pure form. The overall yield for both D- and L-**13** from **1** after eight steps was 17% (from diethyl tartrate 12%/eleven steps).

The synthesis of **13** described here requires only two chromatographic steps and is, in our opinion, more efficient than the previously reported ones starting from D-mannose,[6a] D-glucose[6c] and L-glutaminic acid,[6b] respectively. Several novel acyclic 2-aminoarabinose derivatives with further potential applications are intermediates; in addition, the synthesis is not limited to one enantiomeric series, as is generally the case with carbohydrate educts. The *N,O,O*-tribenzylated aldehyde analogous to **12** was recently converted into (−)-swainsonine in five steps.[6b]

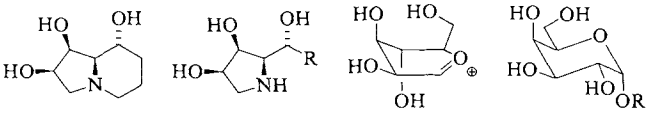
Cyclization of *N*-Protected 1-Amino-4-pentene-2,3-diols to *lyxo*-Configurated Deoxyimino Sugars (*cis*-Dihydroxypyrrolidines); Synthesis of Potential Glycosidase Inhibitors**

By *Volker Jäger** and *Walter Hümmer*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 65th birthday

The inhibition of α-mannosidases[1] by swainsonine **A** and the imino-D-mannitols **B** and **C** (IC_{50} 1.75 to 8,[1a] 0.5,[1b] and 0.6[1c] μM, resp.) is attributed to the topographical equivalence of the respective 1,4-dideoxy-1,4-imino-D-lyxitol fragment **D** with the mannopyranosyl cation **E**.[1a] The individual OH groups are assigned different roles (influence on "binding", "potency", "specificity"); the 4-CHOH group of the mannoside appears to be dispensable.[1a] The iminolyxitol **D**, for which in the preceding communication we present a novel synthesis of both enantiomers via nitroaldol reaction,[2] displays moderate activity as an α-mannosidase inhibitor, but strongly inhibits α-galactosidase [IC_{50} 14 and 0.2 μM, resp].[1b] Compared with the α-D-galactosides **F**, **D** can be regarded as an analogue now lacking the 2-CHOH equivalent.



A **B**: R = CH_2OH **C**: R = CH_3 **D**: R = H **E** **F**

Syntheses of mono- and bicyclic glycosidase inhibitors with modified structure (and configuration) are therefore of particular relevance, and even more attractive when providing novel pathways to this series.[3] The following simple routes to variants of **D** – to the 5-deoxy-5-halo derivatives **3** and **4**, the 2,5-anhydro compound **6**, and the homologue **12**—are based on 1-amino-4-pentenediol **1**. This starting material is equally well accessible in the D- and the L-*erythro* form by Sharpless epoxidation of 1,4-pentadiene-3-ol[4] and

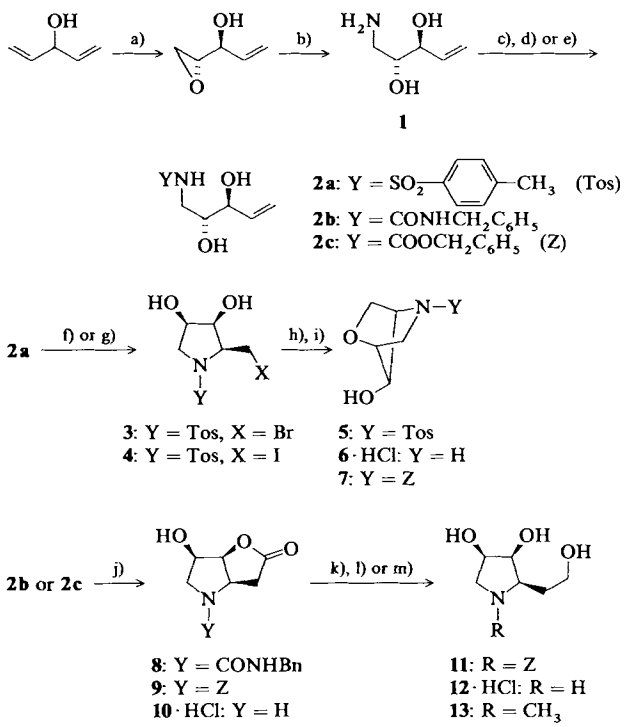
We thank Dr. *D. Häbich* and Dr. *B. Junge*, Bayer AG, for discussions, and Ms. *S. Blumbach* and Mr. *H. Sattler* for experimental assistance. Thanks are also due to Mrs. *E.-M. Peters*, Dr. *K. Peters*, and Prof. Dr. *H. G. von Schnering*, Max-Planck-Institut für Festkörperforschung, Stuttgart, for the crystal structure analysis of **5**.—Presented at the 22nd GdCh-Hauptversammlung, Bonn, September 18–22, 1989, Abstr. OCH 3, p. 345.

subsequent aminolysis[5] (Scheme 1). Following the strategy outlined previously (route b in Ref. [2]), we attempted to extend some of the known cyclizations[6] of unsaturated racemic amines or amino alcohols to *N*-protected derivatives of optically active **1** *bearing two free OH groups*.

Haloamidations[7] were successful with the *p*-toluenesulfonamide **2a** both using *N*-bromosuccinimide (NBS) and iodine/sodium hydrogencarbonate. In each case the crude product contained a mixture (ca. 90:10) of the *cis*/*trans* cyclization products, from which the pure diastereomers **3** and **4**, respectively, could be isolated in ca. 60% yield. Upon reaction with bases such as silver(I) oxide/water or 2N sodium hydroxide the bicyclic species **5** was formed. After reductive detosylation with naphthalene sodium[7b] crude, impure **6** was obtained, which was purified via the Z-derivative **7** and isolated in pure form after subsequent catalytic reduction (Scheme 1). The structure and (relative) configuration of the novel anhydro-iminolyxitol **6** {(1*R*, 4*R*, 7*S*)-7-hydroxy-2-oxa-5-azabicyclo[2.2.1]heptane} are confirmed by a crystal structure analysis of **5**.[8]



Scheme 1. Synthesis of D-*lyxo*-configurated deoxyimino sugars from 1,4-pentadien-3-ol. Structure and configuration of the compounds prepared are confirmed by spectroscopic data and correct elemental analyses. a) Asymmetric Sharpless epoxidation, 60–70% [4]; b) NH_3, quant. For the synthesis of **12** (1,4,5-trideoxy-1,4-imino-D-*lyxo*-hexitol, "*cis*-dihydroxyhomoprolinol"), homologous to **D**, the Pd^{II}-catalyzed bicyclization **2b** → **8** (or **2c** → **9**) proved the key step (an intramolecular amidocarboxylation). This reaction was first performed with unsaturated amines,[9] and recently extended to racemic monohydroxy derivatives. For the latter, urea and methylurethane derivatives were found suitable for optimal adjustment of the *N*-nucleophilicity in order to favor the cyclization step over the competing N-Pd complexation.[10] In the present study we introduced benzyl derivatives, i.e. the *N*-benzylaminocarbonyl and benzyloxycarbonyl compounds **2b** and **2c**: this should guarantee simplified reaction control (by UV detection/TLC analysis) and, in particular, facilitate cleavage of the *N*-protecting group, which is essential for the following transformations. The urea variant (starting compound **2b**) indeed furnished the diastereomerically pure pyrrolidinolactone **8** (58%); with the Z-derivative **2c**, after optimizing the reaction time and work-up, we obtained the desired product **9** chemo-, regio-, and stereoselectively in 83% yield. Thus, a highly selective homologation of an unsaturated aminodiol can be achieved with minimal employment of protecting groups. Moreover, this is the shortest and most efficient synthesis of the pyrrolidinolactone **9**[11,12] (four steps/51% total yield from 1,4-pentadiene-3-ol; previously reported syntheses of **9**, or corresponding derivatives, require 9 to 15 steps to give 1.5–42% overall yields[12]). The diastereomeric purity of the lactones **8** and **10** was found to be > 95:5 (NMR); the enantiomeric purity of **9** proved satisfactory as verified at the stage of the hydrochloride of **10** (obtained rather by accident, see caption to Scheme 1): $[\alpha]_D^{22} = +19.7$ ($c = 0.299$, MeOH), compared to $[\alpha]_D = +20°$ ($c = 0.009$, EtOH) for a product obtained from L-hydroxyproline.[12a]

Upon reduction with $LiBH_4$ the pyrrolidinolactone **9** was converted into the iminotriol **11**, and further, on catalytic hydrogenation, into the previously unknown imino-D-*lyxo*-hexitol (L-dihydroxyhomoprolinol) **12**. Since the *N*-alkylated derivatives of deoxyimino sugars in many cases show increased glycosidase inhibition,[13] the *N*-Z-protected lactone **9** was also reduced to the *N*-methyl derivative **13** using lithium aluminum hydride.[14]

In addition to the novel entries to various dihydroxypyrrolidines as analogues of **D**, these results show that the halogen- as well as the Pd^{II}- induced intramolecular amidation may be extended to substrates with *two (and more?) free hydroxy groups*. Whether the stereochemical course of the addition to the C=C bond to afford *cis* products is solely directed by the α-OH group, should become evident by submitting substrates of the *threo* series to this process. We shall report separately on analogous studies in the C_6 series and related alkoxycarboxylations[9c] with alkene polyols (alkenitols).

Fluorescence "Off–On" Signalling upon Linear Recognition and Binding of α,ω-Alkanediyldiammonium Ions by 9,10-Bis{(1-aza-4,7,10,13,16-pentaoxacyclooctadecyl)methyl}anthracene**

By *A. Prasanna de Silva** and *K. R. A. Samankumara Sandanayake*

In memoriam Sylvia Innocence

We demonstrate the fluorescence 'off-on' signalling of a linear recognition and binding phenomenon.[1] This opens the way to molecular digital devices which display sensitive, fast and remote signalling[2] upon selecting a molecular length with atomic resolution.[3] *Bouas-Laurent, Lehn* et al. have very recently reported an elegant case of 'monomer-excimer' fluorescence switching upon linear recognition.[4] A length-selective absorptiometric sensor was reported recently by *Misumi* et al.,[5] while *Schmidtchen* et al.[6] and *Sutherland* et al.[7] have employed absorptiometric changes in the guest and host respectively to signal the linear recognition by ditopic hosts.[8] The fluorescence of several polytopic polyether hosts have already been examined, though in other contexts.[9] In another case, contrary to expectation the system did not signal the recognition of guest length.[10] Photoswitchable recognition of length is an interesting counterpoint to the phenomenon discussed here.[11] A further impetus to the present work is that α,ω-alkanediammonium ions, the present guests, are important biological species (e.g. putrescine, cadaverine) as also are higher polyammonium ions (e.g. spermine).

The ditopic co-receptor **1**, which is easily synthesized,[12] is designed as a fluorescent PET (Photoinduced Electron Transfer) sensor.[2b, 13] The fluorescence quantum yield of guest-free **1**, $\Phi_{F\,min}$ is 0.0021 in $CHCl_3$:CH_3OH (1:1, v/v). Its fluorescence is 'switched on' only when both nitrogen lone electron pairs are blocked,[14] causing a significant increase in the oxidation potential. Ethyl ammonium ions **2** achieve this via two $[N\cdots H\cdots N]^{\oplus}$ hydrogen bonds.[15] The 2:1 complex of **2** and **1** has a fluorescence quantum yield ($\Phi_{F\,max}$) of 0.13, which is a 62-fold enhancement (Fig. 1). Ammonium ion-azacrown ether binding is known to involve $[N\cdots H\cdots N]^{\oplus}$ bonds.[16–18]

α,ω-Alkanediammonium ions **3** 'switch on' the fluorescence of **1** much more effectively than **2**, since the blocking

$[H_3N(CH_2)_nNH_3]^{2\oplus}$ **3** n = 3–8

of the second nitrogen electron pair is a pseudo-intramolecular cyclization.[19] The effective concentrations for **3**,

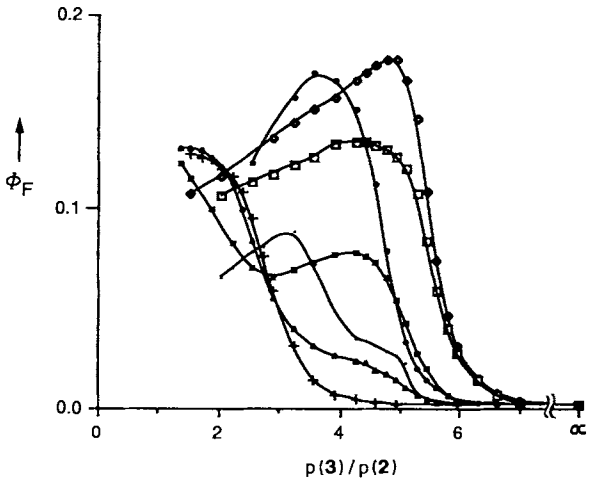

Fig. 1. Fluorescence quantum yield (Φ_F) of **1** (10^{-6} M in $CHCl_3$:CH_3OH (1:1, v/v)) as a function of the concentration of **3**, n = 3–8 or **2** (perchlorate salts). p(**3**) = − lg [**3**]. λ_{em} = 404 (0,0), 427 (0,1), 452 (0,2) ± 2 nm in all cases where measurable. λ_{ex} = 376 nm. λ_{abs} = 396 (0,0), 376 (0,1), 358 (0,2) ± 2 nm in all cases. These constant spectral parameters facilitate the calculation of quantum yields from measured intensities. The quantum yields were calibrated by comparison of spectra with that of 9,10 dimethylanthracene in deaerated C_2H_5OH [25]. The similarity of the spectra obviated the need to correct spectra for instrumental response. Complexed ammonium ion: + = **2**; ▪ = **3**, n = 3; ◇ = **3**, n = 4; □ = **3**, n = 5; ■ = **3**, n = 6; ● = **3**, n = 7; ▲ = **3**, n = 8.

1 **1 · 3** **1 · 3_2**

n = 4,5 are smaller than that for **2** by ca. three orders of magnitude while the fluorescence enhancements are similar (as seen by the $\Phi_{F\,max1}$ values).

Such binding of **1** and **3** is confirmed by NMR paramagnetic shielding effects (Fig. 2) in agreement with previous studies of linear recognition.[7, 18, 20–22] In those cases of **3** (n = 3,6,8) where 1:1 binding results in moderate fluorescence enhancements (indicated by moderate $\Phi_{F\,max1}$ values), higher concentrations of **3** allow the fluorimetric observation of 2:1 interaction via $\Phi_{F\,max2}$ values. The $\Phi_{F\,max1}$ values are so high in **3**, n = 4,5,7 that the 2:1 interaction at higher concentrations of **3** does not result in any further fluorescence increase, i.e., $\Phi_{F\,max2}$ is unobservable.

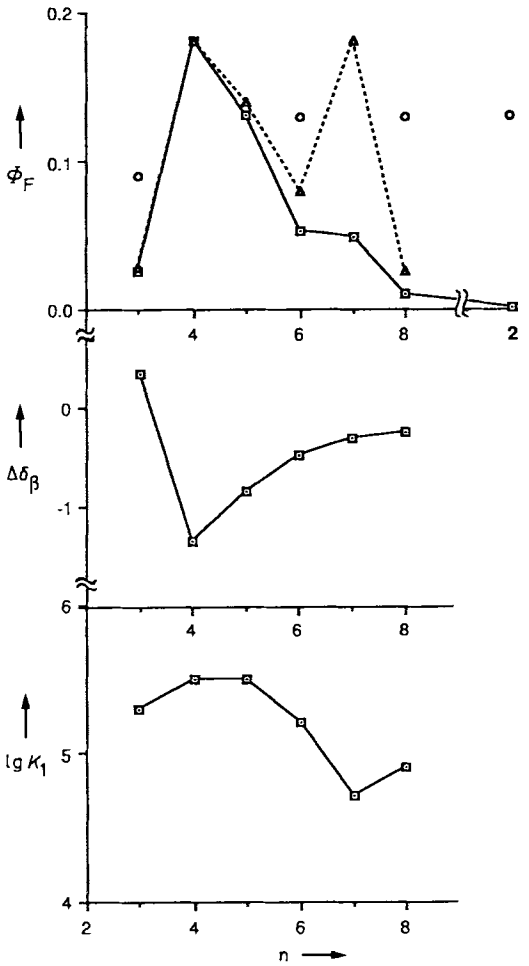

Fig. 2. Fluorescence quantum yield (Φ_F) of **1 · 3** (top), NMR shift displacement, $\Delta\delta$, of the β protons of **3** upon complexation (middle), and binding constant (lg K_1) of **1 · 3** in $CHCl_3$, CH_3OH (1:1, v/v) as a function of carbon chain length of **3**. Three types of Φ_F are shown: Φ_F at p(**3**) = 5 (□), $\Phi_{F\,max1}$ (△) and $\Phi_{F\,max2}$ (○). $\Phi_{F\,max1}$ and $\Phi_{F\,max2}$ values are the first and second maxima or inflexions respectively in the Φ_F/p(**3**) profiles (Fig. 1) as p(**3**) is progressively lowered. Lg K_1 values (bottom) are obtained from the midpoint of the first step in the Φ_F/p(**3**) profiles. A more accurate analysis is deferred since it is hampered by the non-unity activity coefficients of highly-charged species in the rather apolar medium.

From the viewpoint of operational devices, the fluorescence signal (expressed as Φ_F) shows good selectivity in favor of **3**, n = 4 and 5 at p(**3**) = 5 (Fig. 2) due to the presence of the rigid 9,10-dimethylanthracenyl 'spine' in **1**. The sharp fall-off on either side of **3**, n = 4 and 5 in Figure 2 demonstrates that atomic resolution of linear recognition is attainable. It is notable that the electronic emission/absorption spectral parameters of **1** (except Φ_F) are virtually unaffected by **2** or **3**. The more fundamental selectivity patterns are found in the parameters lg K_1 and $\Phi_{F\,max1}$ (Fig. 2). Lg K_1 values are determined by three-point hydrogen bonding of each of the two ammonium groups in **3** to the two azacrown ether units in **1**, among other possible interactions. On the other hand, $\Phi_{F\,max1}$ values are controlled principally by the length and angle of only two of these bonds, i.e. the pair of $[N\cdots H\cdots N]^{\oplus}$ hydrogen bonds. Inspection of molecular models (CPK) of the **1 · 3** complex reveals two points: a) There are repulsions between the methylene hydrogens of **3**, n = 3 and the π-cloud of **1**. However, it is noted that 1:1 complexation is not observed for **3**, n = 3 in the NMR $\Delta\delta$ values (Fig. 2) because the high concentrations (0.05 M **1** and 0.05 M **3**, n = 3) employed encourages alternating copolymerization[23] rather than cyclization.[19] The latter is favored at the lower concentrations (10^{-6} M **1** and 10^{-7}–10^{-2} M **3**, n = 3) used for fluorimetry.

b) There are intrachain repulsions between methylene hydrogens (a type of transannular effect[19]) of **3**, n = 6,8 and (to a lesser extent) 7.

This rationalizes (i) the selectivity of lg K_1 values for **3**, n = 4 and 5, and (ii) the low $\Phi_{F\,max1}$ values for **3**, n = 3,6 and 8, whereas **3**, n = 4,5 and 7 show an essentially constant value (ca. 0.17) produced by linear $[N\cdots H\cdots N]^{\oplus}$ hydrogen bonds of normal length. Such a view is confirmed by the observation in the 2:1 complexes, which are free of conformational constraints by cyclization, of $\Phi_{F\,max2}$ values which approach this same value (ca. 0.12) where observable. The accumulation of light-absorbing impurities at high concentrations of **3** and **2** is responsible for the fact that $\Phi_{F\,max2}$ is somewhat below 0.17.

It is notable that the anthracene unit has been designed to serve a dual role of fluorescent signalling site and rigid spacer between the azacrown ether moieties. The latter is the major contributor to the length selectivity. Selective fluorescent signalling of guest species with various chosen geometries

should be achievable by employing other multisubstitutional patterns as receptor arrays on anthracene and other rigid fluors within the constraints of our design logic.[2b] Related diammonium ion receptors with higher levels of preorganization and other ditopic receptors with rigid and fluorescent spacers are accessible for several laboratories[7, 9, 17, 18, 20, 21, 24] and may be suitable candidates for similar studies.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Metal-DNA Chemistry. (ACS Symp. Ser. 402). Edited by *T. D. Tullius*. American Chemical Society, Washington, DC 1989. x, 213 pp., hardcover, $ 59.95.—ISBN 0-8412-1660-6

The assertion by the editor *Thomas D. Tullius* in his preface to this volume is probably correct: not very long ago a book with a title such as this would have been considered quite exotic, and would probably even have evoked a pitying smile. All that has changed. In fact, transition metal complexes are now important tools of molecular biology and nucleic acids chemistry, whether used directly or as a means of inducing certain chemical behavior. An American Chemical Society symposium was held in Toronto in 1988 with the

objective of improving the understanding of these developments and indicating new directions of research. Some of the papers are collected together in this Volume 402 of the *ACS Symposium Series*, together with several chapters which appear to have been written at the editor's invitation.

The book has been prepared with the degree of care that is usual for ACS symposium volumes, the price is reasonable even without the dollar discount, the literature references are up-to-date and correspond to the current state of knowledge, and the index is helpful. The scientist interested in this subject may well buy the book without seeing it beforehand, only to be a little disappointed, like the present reviewer, with the choice of topis and the treatment. Although the introductory chapter (by *Thomas D. Tullius*) concisely reviews in a few pages the strategies adopted and the potential uses for metal complexes in nucleic acids chemistry, some vitally important details must of necessity be left out here. It would have been desirable to have some more detailed original contributions by authors such as, for example, *P. B. Dervan, J. K. Barton* and *S. J. Lippard*, especially as some of these were participants in the symposium according to the program. The absence of such contributions reduces the overall usefulness of the book as a source of information on the current state of research in this fascinating area. Also the role of OsO_4 as a chemical probe would certainly have merited a chapter. A further criticism is that the treatments of the two highly topical matters "Zinc Fingers" (Chapter 6, *J. M. Berg*) and "Mercury Metalloregulatory Proteins" (Chapter 7, *B. Frantz* and *T. V. O'Halloran*) are inexcusably short. To get a true insight into these topics the interested reader must turn to other monographs (*Prog. Inorg. Chem. 37* (1989); *Met. Ions Biol. Syst. 25* (1989)), where these topics are comprehensively treated by the same authors.

The eleven chapters may be roughly divided into three subject areas: i) applications of metal complexes, especially those with nuclease activity, to studies of nucleic acids, ii) three-component interactions in the protein/metal/nucleic acid system in relation to gene regulatory processes, and iii) fundamental aspects of the interactions of main- and subgroup metals with nucleic acids. The majority of the chapters (1 to 5, 10) are concerned with the first of these areas. Thus in Chapter 1 *T. D. Tullius* describes some elegant studies on the question of the helical periodicity and folding of DNA, based on results from scission reactions using OH radicals generated from the non-coordinating $[Fe^{II}(edta)]^{2\ominus}$ complex and H_2O_2. Chapters 2 (*D. S. Sigman* and *C.-H. B. Chen*) and 3 (*R. Tamilarasan, D. R. McMillin* and *F. Liu*) describe both applications and mechanistic aspects of the activity of Cu(1,10-phenanthroline) complexes, which were the first synthetic metal- containing nucleases discovered. In particular Chapter 2 provides a very good insight into the philosophy underlying the development from agents with little or no selectivity to those that are highly specific. Chapters 4 (*R. F. Pasternack* and *E. J. Gibbs*) and 5 (*G. Raner, J. Goddisman* and *J. C. Dabrowiak*) deal with porphyrins and metalloporphyrins as DNA intercalators and groove-binding species, and with the effect of the metal atom on the bonding behavior and the hierarchy of preferred bonding sites. Finally, in Chapter 10 *J. W. Scuggs, J. D. Higgins III, R. W. Wagner* and *J. T. Millard* report on the nuclease activity of a cyclometallated Pd complex. From the standpoint of an orderly arrangement of subject matter this article would perhaps have fitted in better immediately after Chapter 5.

The slim middle section of the book, consisting of Chapters 6 to 8, is concerned with the role of metals (Zn, Hg, Fe) in gene regulation processes. The shortness of Chapters 6 and 7 has already been mentioned. Chapter 8 (*K. Nakamura, V. de Lorenzo* and *J. B. Neilands*) describes the complex interaction between free Fe^{II}, the siderophore gene and its regulator protein Fur.

The work is completed by two comprehensive and well written chapters (which are the longest in the book) on the fundamentals of metal-nucleic acid interactions. The first (*L. G. Marzilli, T. Page Kline, D. Live* and *G. Zon*) describes ^{31}P NMR studies on the reactions of Pt^{II} coordination compounds with oligonucleotides, and in the second *H. Sigel* discusses the formation of metal-nucleotide complexes. One might well wish that one or two other chapters of the book could have had something of the amount of detail and breadth of these two chapters.

In summary, the book indicates some directions of progress in this topical field of research. In this reviewer's opinion the breadth of the subjects covered leaves something to be desired, but despite this it is recommended that libraries and all chemists and biologists interested in nucleic acids should buy the book.

Chemistry for the Future—State of the Art and Perspectives

By Hans-Jürgen Quadbeck-Seeger*

A particularly close relationship exists between chemistry, the science of the transformation of matter, and developments in human living conditions. Though little more than 150 years old, chemical technology has had a greater influence on our civilization than any other technological discipline. Its roots lie not in the crafts, but in scientific research. Relationships derived from the laws of nature were taken as a basis for the systematic solution of practical problems. It is to this strategy that chemistry owes its success. New opportunities arise from new discoveries. These result from basic research at universities, research institutes, and industrial laboratories. Applied research in turn transforms the discoveries into innovative solutions to problems on an industrial scale. The objectives of applied research are oriented toward the marketplace and to the needs of mankind. Our knowledge of scientific interrelationships has been growing with unabated vigor for decades, but so too has our insight into the enormous complexity of the material world. Many of the problems that civilization faces result from the fact that our knowledge is still inadequate. Intensive research and development offer the only hope for progress. Scientists must of course act responsibly with the knowledge they acquire, and they must provide the information necessary to establish public confidence in their methods and products. This is the prerequisite for broad acceptance of technological progress, and given the extent of the world's population no alternative to progress exists. The shape of that progress is also subject to influences outside the realm of science, however, including social norms and political activities. A country that is not rich in raw materials, like the Federal Republic of Germany, must pay particular attention to these factors as well if it is to maintain its innovative strength.

1. Introduction

"Everything changes except change". *Arthur Schopenhauer* could never have anticipated how well the twentieth century would confirm his formulation of this piece of folk wisdom. The dramatic political, economic, and social changes we are seeing today, especially in Germany, will be recognized by future historians to be just as "revolutionary" as the technological upheavals in the last century that we now describe as the First Industrial Revolution. Most of today's basic industries came into being at that time, among them the chemical industry, which has increasingly evolved into the driving force behind change.

The chemical industry was not a product of the traditional crafts, but arose through the deliberate application of scientific conclusions for industrial purposes. Developments generally followed rapidly in the wake of new scientific discoveries, often by great leaps. Chemistry as the science of the transformation of matter was then, and remains today, particularly closely associated with the conditions of human life. Human beings dependent exclusively on the products of nature were capable of reacting only within very narrow limits

[*] Prof. Dr. H.-J. Quadbeck-Seeger
Member of the Executive Board
BASF Aktiengesellschaft
D-6700 Ludwigshafen

to such threats as food shortages or epidemics. Only with the help of the methods of chemistry did it become possible to create materials lacking in nature, or ones available only to a limited extent, such as fertilizers or effective drugs.

The early successes of the chemical industry were greeted with enthusiasm and wonder, although by today's standards most of the solutions provided were actually inadequate. Today, however, in a period characterized by high standards of living, the chemical industry has been placed in a fundamentally different position with respect to society, and this despite major advances in technology.

The chemical industry with its products has brought lasting improvement to the conditions of human life while at the same time undergoing radical change as the level of understanding has risen. The development of BASF, which this year looks back on 125 years of corporate history, provides a striking example.

2. The Beginnings of Modern Chemistry

The scientific pursuit of chemistry in Germany began with *Justus von Liebig*. His pupils often put their newly acquired knowledge to practical use, thereby giving birth to the chemical industry. The first step was the commercial production of synthetic dyes. A rash of new dye factories quickly sprang into being, though most of them proved short-lived. In fact, Bayer (1863), Hoechst (1863), and BASF (1865) were all latecomers on the scene. Why, then, did these particular companies turn out to be more successful and viable than so many of their contemporary competitors?

The first industrially produced and commercially successful dyes, including mauveine, fuchsin, and methyl violet, had already reached their limits in terms of application, and demand was beginning to lag behind supply. This resulted in the demise of the simplistic but at first highly successful notion of straightforward economic exploitation of a single scientific discovery. A new entrepreneurial strategy was needed, one that emphasized corporate research as the key to increasing scientific knowledge. Companies began to carry out their own research. Two years after the founding of BASF an in-house laboratory began the search for additional dyes and new synthetic routes, a quest that also took into account basic starting materials and intermediates. However, this also entailed an increasing demand for capital, an insight that induced the founder of BASF, *Friedrich Engelhorn*, to choose from the outset the legal form of the joint stock company, a novelty among dye manufacturers in those days. A cooperative relationship involving both scientists and businessmen in management positions proved to be a highly successful formula for developing the innovative powers of the young chemical companies. It also led to an early acceptance of the crucial role of research in ensuring a company's long-term success. From the very beginning there was an awareness of the close interactive role of basic research as well. This early vision on the part of chemical companies proved to be the key to their success and to the overall significance of the chemical industry today.

A research-oriented attitude on the part of chemical companies meant that they were not content with merely improving their existing product lines; they also branched out into new fields based on new discoveries. At BASF, dyes were joined by such diverse product lines as fertilizers, fibers, plastics, pesticides, information systems, vitamins, and pharmaceuticals (Fig. 1). Today it is precisely this breadth of corporate activities, together with extensive integration, that constitutes an important factor in the company's success.

The essential prerequisites for the development of a new field of activity have often emerged from pioneering achievements in basic scientific research. These have then served as the foundation for applied research leading to marketable products and cost-effective processes. Such a division of labor seems at first rather straightforward, but it actually requires some explanation.

3. Basic Research and Applied Research: A Changing Relationship

In all of the sciences, including chemistry, we make a distinction between two types of research: basic research and applied research. How do they differ? The English terms "pure science" and "applied science" actually embody more value judgement than explanation. Among the many possible definitions, the following is particularly incisive, reflecting as it does the Platonic principle of exploring the underlying idea: "The aim of basic research is to understand the world, while the aim of applied research is to improve it."

In *Liebig*'s day, no such distinction was made. The wide range of his personal activities shows him to have been a leading figure in both types of research. *Liebig*'s achievements range from investigating the nutritional requirements of plants (the basis of modern fertilizer theory) to the commercial production of meat extract. When did the distinction first arise between basic and applied research, and what were the reasons for it?

There can be little doubt that applied chemical research first saw the light of day when chemists were hired to study in a scientific way specific problems that were deemed important to companies. Through their involvement with company objectives these researchers soon found themselves confronted with circumstances quite unlike those experienced by their university colleagues. If anything, this trend has become even more marked today.

Basic research, consistent with the precept of scientific freedom, is regulated only by a few fundamental laws and principles, whereas applied research has become entangled in a network of determining factors (Fig. 2). Its principal stimuli come from the demands of the marketplace, which in turn derive from the needs of the populace, both basic and sophisticated. These needs can be subdivided broadly into nutrition, health, shelter, and clothing, as well as communication and leisure. In meeting these needs through new products, industrial research is subjected to regulatory influences of social standards, set down, for example, in laws and ordinances. The competitive situation, including a company's know-how, patent rights, and the strength of its market position, also has an influence on applied research. It is these interrelationships that are evaluated when a decision must be made as to whether research should be undertaken in a specific case, and if so in what directions. With respect to individual research projects, the current state of scientific

1895 Foundation of the company by *Friedrich Engelhorn* of Mannheim.

1867 Two years after the foundation of the company the first plant laboratory for the synthesis of new dyes is erected, and a year later central research is introduced.

1870 Process for the industrial production of the dye alizarin. Further important dyes such as fast red, auramin and eosin follow.

1877 The first German patent application in the field of coal tar dyes is filed for methylene blue. Later, *Robert Koch* succeeds in making bacteria visible in the microscope with the aid of methylene blue.

1888 *Robert Knietsch* develops the process for producing sulfuric acid from roaster gases. The sulfuric acid contact process is the first catalytic process on a large industrial scale.

1897 Under the direction of *Heinrich von Brunck*, indigo is synthesized industrially at BASF after 17 years of development work. Indigo, the "king of dyes", thus becomes available in large quantities and at low price.

1913 After wide-ranging research work in the catalysis and engineering fields, the production of ammonia by the Haber-Bosch process can be started. This provides the raw material base for the production of nitrogenous fertilizers. The further development of high-pressure technology leads to the large-scale synthesis of methanol and urea (1922).

1924 With alkylated naphthalene sulfonic acids BASF establishes a new basis for synthetic detergents and textile auxiliaries (Nekal®).

1928 *Walter Reppe* discovers a process for safely using acetylene in reactions under pressure. Starting in 1938, this chemistry is extended to the reaction of acetylene or olefins and carbon monoxide, using metal carbonyls as catalysts (Reppe chemistry).

1929 With the first industrial synthesis of styrene, the plastics era begins: polymeric acrylic compounds (1929), polystyrene (1930), polyvinyl chloride (1931), polyisobutylene (1931), polyvinyl ether (1928/1934), polyethylene (1937). These are followed by urea/formaldehyde condensation products (e.g. Kaurit® glue) and numerous other polymers with special material properties.

1935 The BASF Magnetophon tape, developed in cooperation with AEG, is presented to the public for the first time at the Radio Exhibition in Berlin.
Start of the production of phthalocyanine dyes: Heliogen® Blue B, followed in 1936 by Heliogen Green G.

1951 Styropor® foam plastic. High-impact polystyrene.

1956 The synthesis of hydroxylamine by catalytic hydrogenation of nitric oxide with hydrogen opens up an economical production route for caprolactam, and thus for the polyamide plastic Perlon®.

1960 New lines of dispersion (Palanil®) and cationic dyes (Basacryl®) extend the range of application for new textile fibers.

1963 New industrial vitamin A syntesis.

The novel, selectively acting pyridazone derivative, chloridazon (Pyramin®), ensures the competitiveness of sugarbeet growing in Europe.

1968 The nyloprint® plate, a photopolymer material developed by BASF for the printing industry, is launched onto the market. Single-stage production of high-purity melamine in a fluidized-bed reactor.

1971 A new foam (Neopolen®) having a wide variety of applications is obtained on the basis of polyethylene. The morpholine derivative tridemorph (Calixin®) has a systemic action on powdery mildew species.

1974 Basagran®, a substituted thiadiazinone dioxide, has a selective action on weeds in the large-scale crops rice, soybean, and cereals.
Kali und Salz AG, a BASF Group company, obtains magnesium sulfate fertilizers for the first time by a dry method by electrostatic separation of raw salts; this is an environmentally friendly and energy-saving production process.

1977 Isotactic polypropylene obtained by a novel BASF gas phase process. Production is started at Rheinische Olefinwerke in Wesseling.

1980 Acrylic acid-based polycarboxylates as additives for detergents allow a reduction in, or replacement of, phosphates.

1982 Citral, a terpene building block for vitamins, carotenoids, and fragrances, is produced by a new process from petrochemical raw materials.

1983 BASF develops the grass herbicide sethoxydim (Poast®) to market maturity for soybean and cotton crops; it allows sowing without plowing in cultivation zones that are susceptible to erosion.
Styrolux®, a glass-clear high-impact polystyrene material for high-grade packaging and medical instruments.

1989 A newly developed, environmentally friendly process for methyl methacrylate, the monomer for plastic glass materials.

1990 Tumor Necrosis Factor (TNF), an endogenous active protein, becomes accessible by a genetic engineering process. It proves to be effective for the treatment of malignant ascites and cancer of the kidneys.

Biotechnological production of vitamin B_2 from renewable raw materials.
The production of the Ultrason® high temperature-resistant thermoplastics with polysulfone and polyethersulfone units widens the range of applications of polymeric materials.

Fig. 1. Milestones in 125 years of BASF research. The development of the chemical industry from its beginnings to its present-day significance has been substantially shaped by chemical research. The history of BASF provides a typical example.

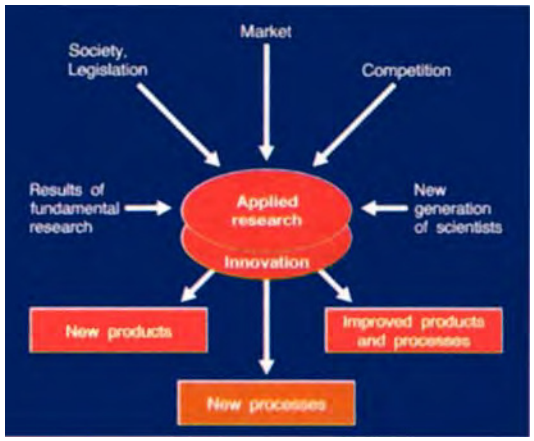

Fig. 2. Environment of applied chemical research. A close interactive relationship exists between applied research and a variety of general parameters that affect not only the selection of research projects but also their course.

knowledge, one's own understanding, and the influx of new methods—particularly through the younger generation of scientists—together with the ideas, skills, and commitment of those associated with the project, all play decisive roles in shaping the way toward innovative problem-solving. Because existing infrastructures and internal know-how are involved, the specific form this path takes can vary greatly from company to company.

Nevertheless, the operating procedures applicable to basic research and applied research are very similar. This is what led *R. B. Woodward* to observe that he recognized no distinction between pure and applied science, only between good and bad research. Changes have occurred, however, particularly in recent decades, and these changes have affected both types of research as well as the relationship between them. In applied research, for example, development has become an increasingly important factor. What is development? Whereas the objective of research, by definition, is to make new discoveries, the objective of development is to use existing knowledge to find new solutions to problems, or to use known methods to answer precisely defined technical questions.

The change in the relationship between basic research and applied research is best depicted with a few outstanding examples. Well over a hundred years ago, *Adolf von Baeyer* determined the constitutional formula of indigo. Proof of the structure was still lacking, however, and this he accomplished through total synthesis. For the basic researcher the problem was thereby solved. But for his friend *Heinrich Caro* at the Badische Anilin- & Soda-Fabrik, the problem had just begun. An industrial synthesis had to be developed, and sixteen years elapsed before the task was completed: the first synthetic indigo came on the market in 1897.

In the case of the ammonia synthesis the step from solving the problem theoretically to implementing the solution in practice was even larger. *Fritz Haber* succeeded in demonstrating at the beginning of this century that atmospheric nitrogen reacts with hydrogen under pressure and in the presence of suitable catalysts to give ammonia. His impressively simple apparatus can be seen today in Munich's Deutsches Museum. But this potential solution to one of mankind's major problems—supplying agriculture with sufficient nitrogenous fertilizer—had been demonstrated only in principle. Building an ammonia factory on the basis of *Haber*'s discoveries called for immense efforts on the part of BASF's applied research team. It became strikingly clear for the first time that additional disciplines were urgently needed for the solution of technical problems; in this specific case above all engineering science. High-pressure technology introduced a completely new approach to the transformation of matter. When the world's first ammonia factory came on stream at Ludwigshafen in 1913 the groundwork had been laid for a fundamental improvement in the world's food supply situation. At the same time this achievement marked the beginning of the development of process engineering, a development that will certainly still continue far into the future, and one whose multi-faceted applications have had an undreamed-of impact on living standards. The ammonia example also points up clearly the difference between invention and innovation. An invention or discovery demonstrates the theoretical potential for solving a problem; innovation, by contrast, constitutes the development of a complete solution to a problem on an industrial scale.

The two examples cited demanded all the strength available to the company at the time, and they consumed many years of development effort. Both represented true pioneering projects. Today the time-span has become significantly longer, even for projects that have more of the character of "further development". The realization of a new product or an industrial-scale process often entails fifteen or more years—and this despite tremendous advances in scientific knowledge. Why is this the case?

As knowledge in every field increases, our understanding of relationships becomes deeper, but so does our insight into their complexity. The result is that research has become increasingly multi-disciplinary. Even problems that appear simple prove on closer analysis to be multi-factorial, and it has become generally accepted that solutions can be reached only through the interaction of several disciplines. In the case of applied research this trend began to be established very early. Scaling up the synthesis of ammonia for industrial application required that chemists and engineers be joined by physical chemists and physicists. And that was only the beginning. Once the synthesis of ammonia had provided access to new "artificial fertilizers" it then became necessary to learn how to handle these synthetic materials. This meant seeking the cooperation of biologists and agronomists. Here we see already a multi-disciplinary team at work, and the trend has continued. The development of modern drugs, for example, requires the joint efforts of natural scientists from virtually every discipline, together with doctors, engineers, and even lawyers and marketing experts.

But it is not only applied research and development that have become more complex; the same applies even to certain areas of basic research. For example, research institutes dealing with the structure of matter or nuclear fusion have long since grown to industrial dimensions. One effective response to increasing complexity has been the growth of international cooperation in research. The "scientific community" represents a model for a true world community. It is therefore only logical that science, and particularly basic research, should take up questions that affect the whole of mankind. Today we are forced to recognize that problems such as

dying forests, the greenhouse effect, or the hole in the ozone layer have their origins in extremely complex cause-and-effect networks. Human concerns such as the assurance of adequate food supplies and the long-term availability of energy are bound to be involved as well. Basic research is confronted by multi-layered challenges that are very similar in their complexity to the problems facing applied research, even though the dimensions are different.

In this context, attention should be drawn to one characteristic of scientific and technological progress that is generally overlooked. As our level of knowledge rises, the tools for recognizing and examining undesirable effects become progressively more efficient. This mechanism of self-monitoring is certainly welcome, yet it has one fatal side effect. The inconceivably low limits of detection associated with modern methods of analysis are being increasingly perceived by some sectors of the public as threats. Politicians in turn often succumb to the temptation to define the ultimate detectable limit as a new *legal* limiting value. This can easily result in the misapplication of resources, or even deflect attention entirely from the real problems. For example, the central problem facing us in the next few decades is the virtually unrestricted increase in world population. From the scientific and medical standpoints this problem has long since been solved. It is now up to individuals, politics, and religion to devise answers.

It has become almost a fad to hold scientific and technological progress responsible for everything. *C. P. Snow* in the 1960s defined the notion of "the two cultures". Now there is an irrepressible demand to recognize the birth of a third, one for which there is no such thing as progress, only difficulties. It finds everything to be "difficult", and might therefore be appropriately designated as the "difficulture". Advances in communication technology have made it easier and easier to influence large numbers of people, so this phenomenon must be taken seriously. It is of particular concern to chemistry (both as an industry and as a science), which is increasingly seen as the cause of problems. By contrast, chemistry's capacity to *identify* problems and find technical solutions to them is virtually ignored.

Regaining public confidence is a challenge confronting both basic and applied research, one that requires cooperation transcending the boundaries of all the subdisciplines. The concept of interdisciplinarity needs to be extended even beyond the various scientific circles, although it also requires further development within them.

4. Interdisciplinary Effort—A Characteristic of Applied Research

Within applied research itself, a division of labor into research and development, each comprising interdisciplinary teams, has become indispensable. Two developments have brought this about. First, the tremendous increase in knowledge means that the individual scientist is no longer able to master and evaluate more than a trickle out of the flood of new information. If the number of papers covered by Chemical Abstracts is a measure of the growth of knowledge, a massive upward trend is apparent, especially since about 1950 (Fig. 3).

This deluge can be dealt with in university research by restricting oneself to an in-depth exploration of some specialized field. In industrial research, however, the current problems are never conveniently tailored to the expertise of a single specialist. Only a team is capable today of approaching the literature and filtering out the essentials for a particular task.

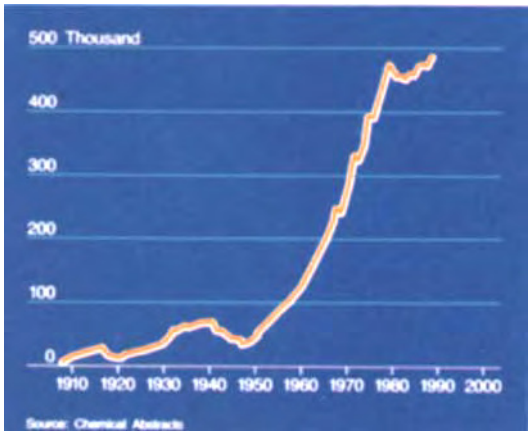

Fig. 3. Papers, patents, and books abstracted in Chemical abstracts. The number of chemical publications, and hence the store of chemical knowledge, is increasing exponentially. Scientists need to specialize more and more while at the same time maintaining contact with other disciplines in order to filter out those advances that are essential for a research project.

In the second place, projects in applied research become more and more complex as their level of development progresses, because they begin to interact increasingly with various limiting factors (availability of raw materials, market situation, production facilities, approvals, etc.), requiring suitable adaptations. Therefore the path from idea to product no longer leads directly from laboratory to production plant. Instead a wide variety of specialists is required to work in parallel on the project, all at different levels, until it is ripe for a final decision. Once applied research leaves the laboratory stage it is virtually always pursued today by a team. Where a few dominant personalities were formerly in a position to place their stamp on the course of development, today this role is filled by coordinated expertise, which can fully develop only within the framework of a cooperative team spirit.

The increasing complexity of the problems has led to research in the chemical industry demanding not only a growth in the number of active personnel but also full coverage of the entire spectrum of scientific disciplines. If we examine the ranks of scientists and engineers in the German chemical industry since 1964 we find that their numbers have more than doubled over that period (Fig. 4). There has been a constant rise in the number of chemists and engineers, but scientists from other disciplines have been added at a disproportionately high rate. The changing tasks facing applied research are reflected in greatly increased numbers of biologists, physicists, and mathematicians, revealing the growing importance of the life sciences, instrumentation technology, and data processing. Agronomists, on the other hand, have always worked closely with chemists in the agrochemical sector, so the increase in their numbers has been less striking.

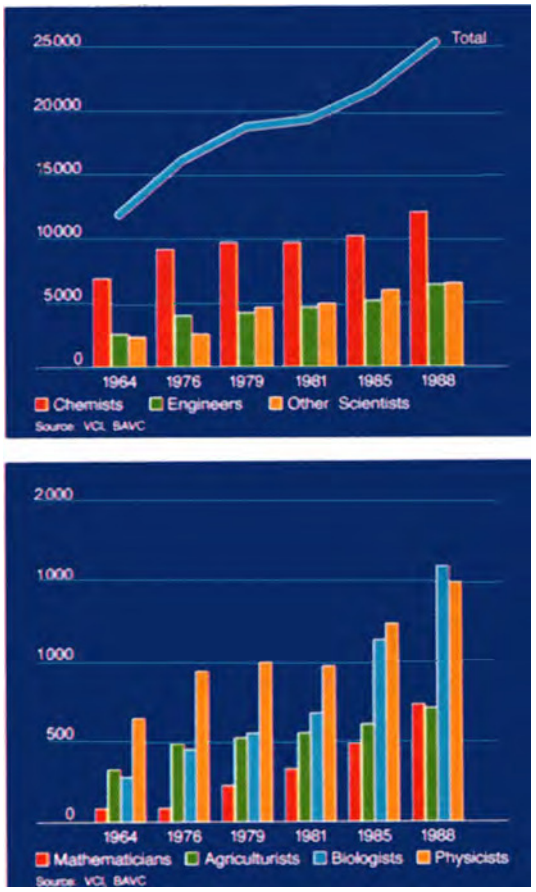

Fig. 4. Scientists and engineers in the German chemical industry. Since 1964, the number of scientists and engineers in the West German chemical industry has more than doubled. The number of chemists and engineers has grown steadily, while there has been a disproportionately large increase in the number of other scientists from other disciplines, in particular biologists, physicists, and mathematicians.

5. Applied Research in a Changing Environment

Apart from changes in the scientific realm, economic, social, and political trends have a critical influence on applied research. In particular, the effort required increases steadily as a result of constantly rising legislative demands. The industrial researcher in Germany is confronted by a rising tide of laws, ordinances, and regulations (Fig. 5). The last 20 years in particular have witnessed a breathtaking escalation. Chemical companies now devote large departments exclusively to the task of ensuring that the right documents reach the right authorities at the right time.

One dubious effect of the numerous statutory requirements, which often start with a justifiable question but end in bureaucratic perfectionism, is a shift in the emphasis of research activity. The innovative content of research—the pursuit of new discoveries—is becoming ever smaller relative to the effort to demonstrate that a problem has been solved responsibly—testing for potential side effects, for example, or confirming environmental compatibility. Innovative research, the quest for new solutions to problems, is today almost matched by "defensive" research aimed at satisfying statutory requirements. In the case of research related to active compounds, this aspect now accounts for well over three-quarters of all expenditures.

Although legal requirements are usually targeted at industrial production, they nevertheless have a direct influence on innovative research as well. Obstacles placed in the path of new products or processes increase the costs, and development times are drastically lengthened. One result is that even advances entailing environment-friendly production and disposal methods, or improved application characteristics, suffer unwarranted delays. Installations aimed directly at improving the state of the environment, such as waste incinerators, waste air filters, exhaust gas scrubbers, or effluent pretreatment units, have become subject to increasingly time-consuming approval procedures. This is a case where environmental legislation often proves to be self-defeating.

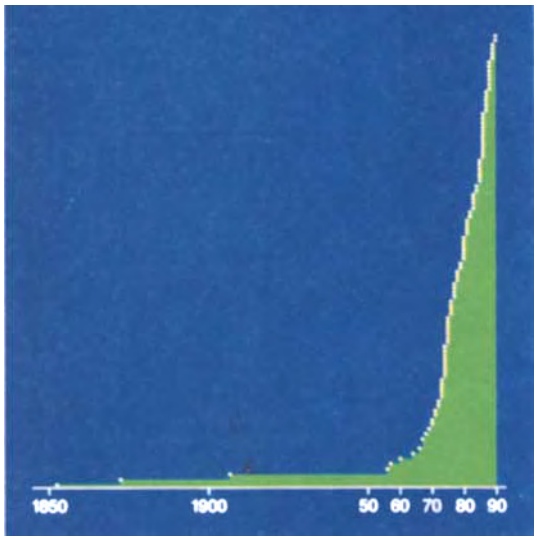

Fig. 5. Changes in environmental legislation (FRG). In the period since about 1960 environmental legislation in the Federal Republic of Germany has escalated to take on crippling proportions. Not a year passes without a further increase in the number of laws, regulations, and amendments. Each dot in the graph represents a newly adopted law or ordinance. In many of these cases, what began as a legitimate question has developed more and more into a bureaucratic obstacle race tying up substantial personnel resources in both industry and government.

In fact, the chemical industry seized the initiative long before the environmental debate began, dramatically tightening the demands for cost-effectiveness and safety in its processes and products, in both research and production. There is a long tradition in the chemical industry of seeking ways to use inexpensive raw materials or previously wasted by-products. The first chemical manufacturers owed their very existence to the utilization of a by-product of energy generation in coking plants: coal tar provided the raw materials for synthetic dyes. Increasing reaction yields, utilizing by-products, and reducing energy consumption have always represented effective responses to the pressure to improve competitiveness. Today, when the emphasis is on environmentally compatible design of our industrial production processes, these same endeavors continue to enjoy top priority. An additional factor is the obligation to ensure proper disposal of those residues that cannot be physically recycled or utilized to generate energy. Alongside continuous im-

provements in landfill technology, the chemical industry has also made notable advances in reducing the amount of waste that needs to be consigned to a landfill. The chemical industry has also expended considerable effort jointly with the recycling industry to develop further the whole concept of recycling.

The energy input required to produce chemical products has undergone a steady decline thanks to advances in process development. In the first ammonia plant of 1913, the production of ammonia still required the introduction of several times the energy content of the NH_3 molecule. Consistent improvement in the process has reduced this today to a factor of 1.3.

The development of crop protection agents provides an impressive illustration of the way in which chemical products have been forced to meet higher and higher standards for safe application and specificity. As recently as the 1960s, the development of one new pesticide entailed the synthesis of about 4 000 new substances. Today the figure has risen to 15–20 000 (Fig. 6). This lower success rate is a consequence

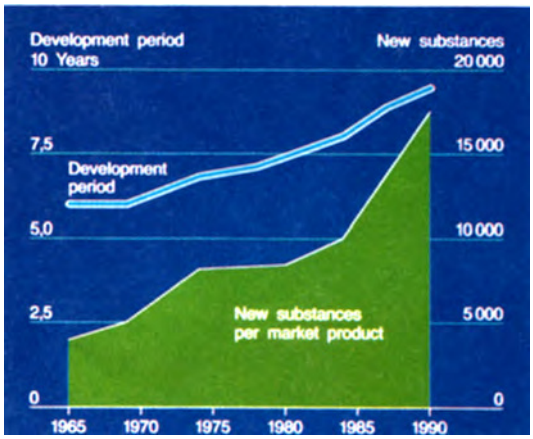

Fig. 6. Development period and success rate in crop protection research. The number of syntheses necessary for the market launch of a single crop protection agent has increased during the past 25 years from 4,000 to more than 15,000. This reduced success rate reflects the requirements products now must meet with respect to efficacy, ecological acceptability, and steadily decreasing dosages. As a consequence, the development period has risen from six years to almost ten.

of searches directed increasingly toward specific activity and minimal dosage. In particular, however, toxicological and ecotoxicological acceptability continue to move into the foreground. Toxicological studies now account for about one third of development costs. As expenditures have risen, so too have development times (Fig. 7), which now stretch out over nearly 10 years in the case of pesticides. In the pharmaceutical sector 12–15 years are already usual. Because of these long development times and the associated high costs, the search for active substances has become a financial risk, which leads to predictable consequences. In addition, the gap is becoming ever narrower between the time required to develop a new market product and the patent term of 20 years, expiration of which means that the product is open to manufacture and marketing by imitators. The latter incur no significant expenses for research and development, so they are able to undercut significantly the prices set for the original products. The German Health Reform Act with its fixed price regulations will make it virtually impossible to recover development costs in the Federal Republic of Germany. This is certain to have medium-term consequences on the Federal Republic as a site for research.

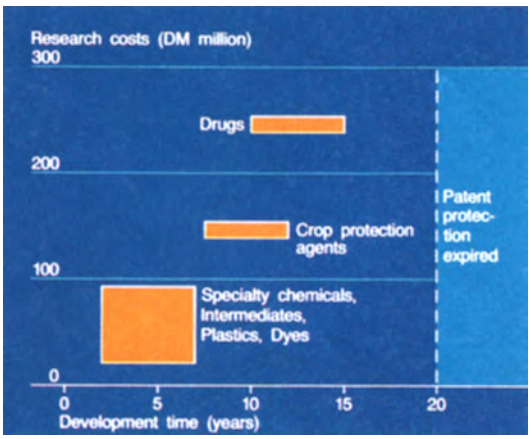

Fig. 7. In general, there has been a substantial rise in both research expenditures and development times for new products or processes. The development of a new drug takes longest of all, and is fast approaching the protection period afforded by a patent. As a result, in precisely those areas with the highest development costs, cost recovery has become virtually impossible. The period of patent protection is soon to be extended, a change that is vital if we are to maintain the power of innovation in these areas.

Applied research is also being influenced more strongly today than in the past by the idiosyncrasies of particular markets. Increasing specificity of customer demands and varying but generally more stringent requirements with respect to the properties and quality of products, together with legislative restrictions, mean that research remains intimately linked with a product or process until well into the production phase. This has always been the case for pharmaceuticals and pesticides, where research is responsible for the so-called "monitoring" of a product throughout its entire life cycle. But in other sectors, such as coatings and paints, specialty plastics, or process chemicals for the paper and leather industries, research is becoming more and more enmeshed in production and marketing.

It is only through intensive cooperation between research, technical services, and production that market stimuli can be rapidly absorbed and transformed into new or improved products. As a result, the local industrial environment generally is becoming more and more important in determining the quality of a research site.

In a country like the Federal Republic of Germany, which is not rich in raw materials, prosperity is essentially a function of innovative skill. The first requirement for innovation is knowledge, and knowledge is acquired through research. We have attained our current standard of living on the basis of convincing research efforts and efficient structures for production. The general environment that prevailed in the past has also played a role. We must be vigilant in the future so that we do not relinquish this high standard. It is certainly nice to enjoy prosperity, but effort is required to maintain it.

6. Applied Research and Technological Change—Reciprocal Influences

Of the most important raw materials used in the chemical industry—oil, natural gas, and rock salt—the Federal Republic of Germany has adequate resources only of the latter. It is for this reason that we are obligated to develop superior technologies and exploit synergies available within our established integrated system of production and our infrastructures, since only in this way can we maintain our competitive edge in the long term over those who do possess raw materials.

These essential raw materials are now the basis worldwide of some 300 important primary products and intermediates, which are in turn converted by a highly diversified chemical processing industry into about 20–30 000 different products that eventually find their way into a wide variety of finished goods (Fig. 8). The chief distinguishing feature of primary

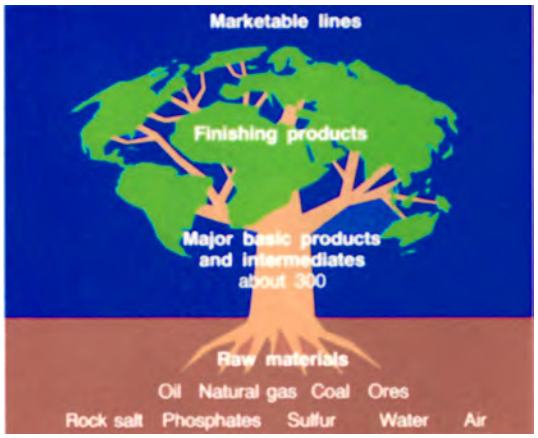

Fig. 8. The spectrum of chemical products begins with a few raw materials and extends through a set of basic products and intermediates up to the wide variety finished products. Only the latter experience a life cycle, and are constantly replaced by better products.

products and intermediates is the diversity of their chemistry. Unlike many end products, which in the course of time are subject to replacement by others, these materials are themselves not subject to the phenomenon known as a "life cycle". The processes involved in their preparation do undergo change, however. Change of this kind is sometimes brought about by new technologies and advances derived from research, but it may also be dictated by the raw materials outlook. At the beginning of this century, most product lines were geared to coal as a raw material, but a shift occurred after about 1940 in the direction of oil. More recently, oil has increasingly been supplemented by natural gas, and the future will witness the growing significance of biomass as a raw material.

Change affects entire areas of operation, not simply isolated product groups or individual products. Products do experience a life cycle, which can be described in terms of an initial phase, a growth phase, and a period of maturity. For this reason, the product portfolio of a single company or of an entire industrial sector will at any given time include operations and products characterized by various stages of development.

Detergents and cleansers provide a particularly interesting example of a change occurring within an essentially mature area of operation, and brought about by an interaction of the conditions of life with consumer demands. Cleansing agents can be regarded as a sensitive indicator of the state of civilization, at the same time reflecting the problems that go hand in hand with a higher standard of living. A few years ago, our rivers and lakes were threatened with eutrophication caused by a high influx of phosphates from detergents. Finding an immediate substitute for sodium polyphosphate proved difficult, however, since this substance is a source of a rich combination of essential characteristics. The replacement of phosphates by zeolites was recognized as a step that would halt the overfertilization of surface waters, but it would also have led to the formation of deposits on textile fibers and on the heating elements of washing machines. Only the development of supplementary polymeric additives (polycarboxylates) by BASF actually made it feasible to effect the replacement of phosphates in detergents without any sacrifice in familiar washing characteristics.

This example clearly illustrates the way demands of the market and of the environment can trigger innovation. Detergents and cleansers also serve as a useful example of a trend currently apparent within applied research generally. Development is moving increasingly from individual substances toward combinations of ingredients. These can then be regarded as *molecular systems*, all the components of which must be carefully matched. Use of such a system permits a set of properties to be varied within rather broad limits by custom-tailoring the blend of components. For example, neutralized polyacrylic acid can be adapted simply by adjusting the molecular weight to such divergent fields of application as dispersion and flocculation, e.g. for water treatment purposes, as a raw material for detergents, or as a thickener for establishing the proper viscosity in cleansing agents (cf. Fig. 9). This principle of optimizing a molecular system has also become extremely important in the finishing of textiles and leather, in electroplating, in the printing sector, and in the design of new polymeric materials, an application with particular significance for the future.

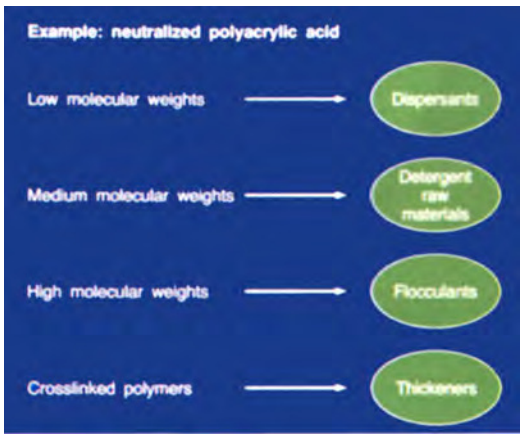

Fig. 9. So far as most consumer products are concerned, individual substances are no longer able to meet today's more demanding standards. Instead, molecular systems are invoked. These are tailored to specific uses, for example by way of special formulations or grades.

One of the distinguishing characteristics of a mature field is the fact that basic innovations result only rarely from fundamentally new discoveries. More often, new products or technical solutions are introduced because of disadvantages associated with the application of conventional market products. By contrast, in an operation passing through its growth phase progress derived from new discoveries and opportunities tends also to shape the market for new applications.

Polymeric materials represent a case in point. Despite more than half a century of development no end is yet in sight. At the same time, various classes of polymers have achieved very different levels of maturity (Fig. 10). The commodity plastics (green) are characterized by a rather high degree of maturity, and their many applications are responsible for a significant market volume. The market segment for engineering plastics (yellow) is smaller, since these are more often restricted to specific applications. During the early stages of product development, markets are generally so limited that development costs outweigh earnings. Thus, a balanced product portfolio is especially important in strengthening the potential for further development.

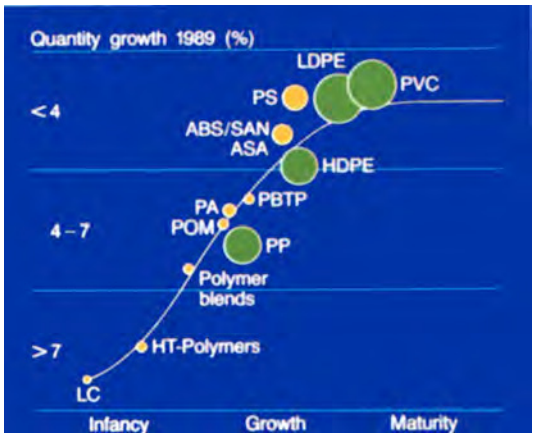

Fig. 10. Levels of maturity of various polymeric materials. The product groups labeled in green are commodity plastics, while those labeled in yellow are engineering plastics. The area of the circle signifies the market volume. LC = liquid crystalline polymers; HT polymers = high-temperature resistant polymers; POM = polyoxymethylene; PA = polyamide; PBTP = polybutylene terephthalate; ASA, SAN, ABS = styrene copolymers; PS = polystyrene; PP = polypropylene; HDPE, LDPE = high density/low density polyethylene.

7. New Opportunities from New Materials

Recent advances in connection with new materials have been made possible by new insights into the relationship between morphology and properties. Use is made here of a characteristic of matter that has given impressive evidence of its value over the course of evolution: the capacity for self-organization under a specific, defined set of molecular circumstances.

The properties of polymeric materials are not only dependent on chemical composition but are also critically related to structure in the molecular and supramolecular ranges, i.e., to morphological factors. In the case of the first-generation plastics there was little recognition of this fact. Today, internal structure can be predetermined to a considerable extent, and it is subject to almost unlimited modification. To this end, polymers are combined in the form of blends, just as metals are combined to produce alloys. The properties of individual components are not simply additive; what instead results is often an entirely new profile of characteristics. Polymer blends are generally not homogeneous single-phase materials, but are made up of microscopically small zones with differing chemical composition and corresponding in some cases even to different physical states. The key to the effectiveness of such a morphology lies in the structures of the individual microphases and in the firm anchoring of the microphases to one another.

A polymer blend consisting of polyamide, polyphenylene ether, and rubber (Fig. 11) displays characteristics that cannot be deduced directly from the property profiles of the components: a very high heat distortion temperature ($> 150\,^{\circ}C$), exceptional impact strength, and, not least, greatly reduced capacity for absorbing water, thereby eliminating a major disadvantage of polyamide as an engineering material.

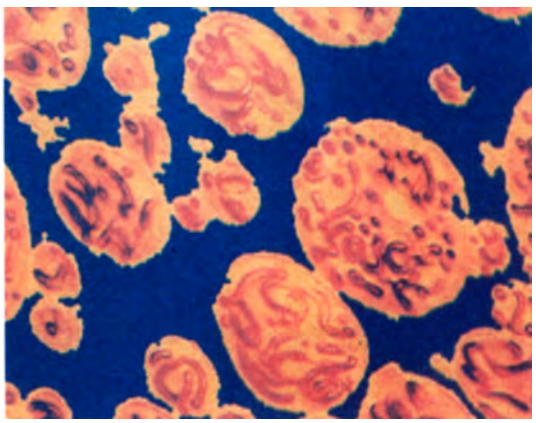

Fig. 11. This electron micrograph shows a blend of polyamide, polyphenylene ether, and rubber. The blue region represents the polyamide matrix. Polyphenylene ether is shown in yellow. The rubber (red areas) is included within the polyphenylene ether particles.

One of the ambitious aims of research into polymeric materials was, and still is, to challenge the supremacy of metals in their ability to absorb energy under conditions of very high stress. The structural principle underlying high-performance composites requires that continuous fibers which can serve as load-bearing elements are embedded within a polymeric resin. This principle is quite familiar from nature. The role assigned to the ribs in leaves or the cellulose fibers in plant stems is assumed in the case of composites by carbon or glass fibers. The fibers must be so oriented in the finished components that they can absorb forces applied along almost any axis. For this reason, components usually consist of several layers, with fibers crossing at specific, precalculated angles. A structure of this type can be achieved, for example, with the aid of computer-controlled winding units (Fig. 12). Particularly when carbon fibers are used, the result is a composite whose ability to absorb stress rivals even that of conventional steel from the standpoint of rigid-

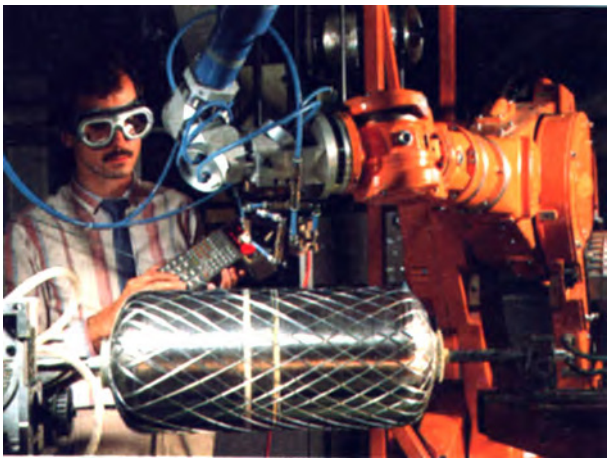

Fig. 12. Winding unit for the manufacture of high-performance composite materials. A robot carries out laser welding of plastic-impregnated glass fibers to form a highly stress-resistant wound article.

ity, tensile strength, and fatigue strength. All these advantages are present in a system that also offers a much lower weight, high corrosion resistance, and absolute dimensional stability. These are properties of considerable value in the aerospace industry, where a reduction in weight is especially critical since it translates into lower fuel consumption or increased payload.

Polymer blends and high-performance composites are just two illustrations of developments in the field of engineering polymers that hold great promise for the future. A whole series of new products has emerged in recent years in this field, offering combinations of unusual properties that cannot be duplicated with conventional materials (Fig. 13). Ex-

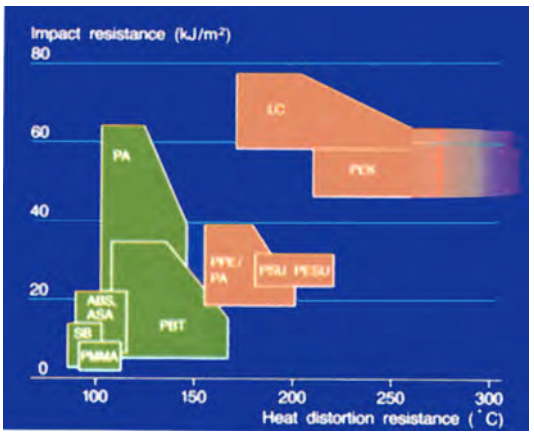

Fig. 13. Novel thermoplastics combine high heat distortion resistance with high mechanical strength. They include, for example, polymer blends of polyphenylene ether and polyamide (PPE/PA), polysulfones (PSU), polyether sulfones (PESU), polyether ketones (PEK), and liquid crystalline polymers (LC). SB = high-impact polystyrene; PMMA = poly(methyl methacrylate); ABS, ASA = styrene copolymers; PA = polyamide; PBT = polybutylene terephthalate.

amples of such properties are increased temperature resistance, toughness, strength, dimensional stability, low flammability, corrosion resistance, specific optical properties, or electrical conductivity. In the case of conventional organic polymers, advantage is taken of only about 5% of the potential to withstand mechanical stress that is actually present in the chemical bonds. Modern developments like carbon fibers already permit more than 50% of this potential to be exploited, and the resistance of such materials to stress is increased correspondingly. Further developments are aimed in two directions. First, it is hoped that improved production techniques will minimize the occurrence of weak spots that reduce product strength. Second, even more advantage is to be taken of the potential residing in chemical bonds, permitting the elimination, for example, of extreme anisotropic behavior with respect to physical properties (e.g., graphite layers in carbon fibers) through chemical cross-linking of adjacent layers.

This trend toward use-oriented specialization in plastics development will, in the future, permit even more rapid progress in electrical engineering, electronics, vehicle and aircraft manufacture, mechanical engineering, and information and communications technology. Because of the leading position Germany has attained in plastics technology—both as a science and in production and application—we expect to play a crucial role in helping to shape the future. The situation looks rather different, however, in another sector currently undergoing dramatic changes and promising to bring substantial improvements in the conditions of life.

8. Genetic Engineering—A Biotechnological Method of the Future

The use of biotechnology is as old as mankind itself. Microorganisms have always played a part in alcoholic fermentation and in the preparation of sour dough or cheese. Specific microorganisms have been selected, now and in the past, on the basis of the effectiveness of their adaptation to the processes in question. A modern example is provided by a new biotechnological process for the production of vitamin B_2 that was commercialized this year by BASF. The process leads directly to vitamin B_2 itself, and it utilizes a renewable raw material, vegetable oil, taking advantage of a microorganism that has been carefully optimized, though not modified by genetic engineering. Alternative chemical processes invariably involve a large number of intermediate steps.

Recently, genetic engineering has provided us with methods for obtaining more rapidly than in the past very high levels of synthetic performance from microorganisms. The secret is discriminate modification of the target organism's genetic information. On the one hand this makes it possible to prepare substances more economically than by the methods of conventional chemistry, but it also opens the way to products obtainable *only* by this route. The advantages of genetic engineering are particularly apparent with respect to a number of new pharmaceutical agents based on endogenous proteins. According to a survey by the World Health Organization (WHO), of about 30 000 discrete diseases only about one third are amenable to cure through drugs. This amply documents the need for further therapeutic advances. Cardiovascular disorders, viral infections, rheumatism, and cancer are widespread diseases with fateful consequences for the victims. There is thus an urgent need for new substances

that might be able to contribute to therapeutic progress. At present, twelve therapeutic agents derived from genetic engineering are commercially available worldwide. These include antibodies, enzymes from the coagulation series such as the tissue plasminogen activator tPA or factor VIII, vaccines (e.g., for hepatitis B), endogenous modulators of the immune system such as interferons, and peptide hormones such as insulin. The number of projects currently at the preclinical and clinical stages of development is about 100, underscoring the dynamic growth of a technology barely 20 years old.

With tumor necrosis factor (TNF), a mediator of the immune system, BASF now possesses a genetic engineering product that is at an advanced stage of clinical trials. TNF was first identified in 1975. The year 1984 witnessed the successful cloning of the TNF gene, the elucidation of its amino acid sequence, and the preparation of the active substance itself by genetic engineering using E. coli bacteria. Since then the protein has also been crystallized and its structure determined in a joint effort with a team of scientists at Oxford (Fig. 14). This means that the active centers can now

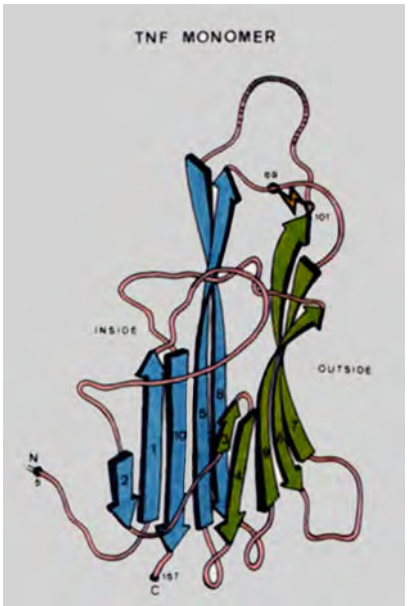

Fig. 14. Structure of tumor necrosis factor (TNF). After BASF had succeeded in obtaining tumor necrosis factor (TNF) in crystalline form, the structure was elucidated in a joint project with Oxford University. In its active form, TNF consists of three identical subunits, each containing 157 amino acids.

be identified and characterized pharmacologically. Clinical trials have demonstrated that TNF is an efficacious agent against malignant ascites. This is a condition that arises in the abdominal cavity as a consequence of cancer, leading to an excessive accumulation of fluid, and it has hitherto not proven amenable to treatment with drugs. A further success has even more recently been recorded: invocation of a combination of TNF and α-interferon as a treatment for metastasizing kidney cell carcinoma led to tumor recession in 50% of the patients tested. Although an industrial-scale synthesis of TNF has already been developed, and the necessary tests—including clinical trials—are well advanced, securing the required approval for production under the German Federal Air Pollution Control Act is proving to be incredibly difficult. The stack of documents prepared to obtain authorization for a TNF production facility with a fermenter volume of 200 L and an annual output of 0.5 kg now exceeds the height of the reactor (Fig. 15). This clearly illustrates the extent of the legal uncertainty at this time in the Federal Republic of Germany in the field of genetic engineering.

Fig. 15. The TNF production plant, now in the approval stage, has a fermentation volume of 200 liters. Annual production is to be 0.5 kg. It is being erected in an existing building and will use existing infrastructures. The picture shows the fermenter and, alongside it, the documents prepared for obtaining official approval for production.

It is therefore a welcome development that the Genetic Engineering Act came into force in July of this year. Binding legal parameters now circumscribe genetic engineering research and the construction and operation of genetic engineering plants. Nevertheless, this act and the regulations associated with it still do not guarantee that approval proceedings will advance smoothly. The mandatory hearings at safety review stages 2–4 are still subject to the influence of "refusal experts". It is to be hoped that practical implementation of the regulations will be governed by an understanding of the subject and not by ideology.

In view of the opportunities opened up by genetic engineering, particularly for medicine but also for food production, one would have anticipated a greater degree of acceptance on the part of the public. Unfortunately such has not been the case in the Federal Republic of Germany, in contrast to the USA or Japan. This may be due in part to the fact that the public and political debates have failed to draw a sufficiently clear distinction between genetic engineering on the one hand and, on the other, reproductive biology with all its ethical, moral, and legal ramifications. The latter falls clearly within the domain of medicine. The chemical and pharmaceutical industries are not active in these areas.

9. The Responsibility of the Chemical Industry for Our Future Society

Growth of knowledge in the field of genetic engineering is occurring at a tremendous rate, and Europe, far from setting the pace, is having trouble keeping up. Extending our understanding of the molecular dimension of life's processes is a challenge to scientists the world over. Practical application of newly acquired knowledge will bring many blessings, but abuse of this knowledge cannot be excluded. We repeatedly see evidence of the fact that although knowledge widens our opportunities it also increases our responsibility. Being aware of this responsibility and behaving accordingly legitimizes the freedom of action to which basic research and applied research lay claim and indeed require. We must continuously demonstrate to the public that we are conscious of our responsibility; only in this way can trust be regained.

The tasks facing applied research grow out of problems that confront our civilization, and these in turn arise from one basic source: unchecked population growth. Indeed, this is the origin not merely of the tasks that face us, but also of our responsibility to continue making technical advances in the interest of mankind. The chemical industry plays the key role, since it alone is able to open up new solutions through the transformation of matter. Its importance relative to other industries will continue to grow, and the fields it encompasses will become ever more complex. This of course has direct consequences for chemical research. Above and beyond areas traditionally associated with chemical operations, interdisciplinary development of new aspects of technology is becoming more and more critical to successful problem-solving. At the same time, the individual scientist will be constantly under obligation to examine the consequences of his actions. For his part, however, he must also insist that his expertise be taken into account in the decision-making process.

The Integrating Effect of the Research Policy of the European Communities

By Karl-Heinz Narjes*

The research and development policy of the European Community (EC) was raised to a more solid legal basis by means of an extension of the treaties—the Single European Act—30 years after the enactment of the treaties of Rome. Today, the EC has succeeded in creating an independent, successful continent-wide research und development community despite rather limited budgetary means. The reasearch activities of the EC were originally restricted to EURATOM, which takes care of problems concerning civil nuclear research. EURATOM brought many experiences in the course of time, and also yielded many successes. We have learned above all how community research and national research are to be coordinated in the most efficient way. After the energy crisis of the seventies, and after many national R & D failures in various fields, high priority was given to the improvement and safeguarding of the technological competitivity of the community and the effective strengthening of its innovation potential. It was more and more generally accepted that all R & D resources had to be concentrated throughout the community in order to enable it to compete successfully, especially with the U.S. and Japan. In order to fulfill this objective a research policy with a strong integrating effect was requested in addition to the national R & D research policies. Cohesion and know-how transfer inside the EC belong therefore to the central issues of the R & D policy of the community, as do special efforts to include small and medium-sized institutes and enterprises (SMEs). Framework programs were introduced in the eighties in order to ensure a medium-term disposability of the budgetary means for R & D and to secure a certain continuity. The third framework program has been agreed upon, and it provides research funding until 1994. In 1987 approximately 1 Bill. Ecu/year were spent for R & D. Today, 1,5 Bill. Ecu/year are available, and this amount will further grow to provide approximately 2 Bill. Ecu/year in 1992/93. Issues like the difference between basic and applied research under inclusion of industry-political viewpoints are also included in this report. Furthermore, cooperation with and delimitation to other countries or communities such as the U.S. and Japan or the EFTA and the Comecon member states will be discussed. Finally, perspectives for R & D policies of the European Community in the nineties will be presented.

1. Introduction

The research and development policy of the European Community is not an isolated function, but an integral part of the overall objectives of the European Union. Since 1950, the Union has been endeavoring to create an irreversible, democratically legitimated European forum with a decision-making procedure anchored in the same manner as a constitution in order to fulfill various tasks and achieve the aims that the six founding states have helped to set in motion when they allocated it appropriate powers. The political circumstances of the 1950s did not enable us to approach all these tasks simultaneously and comprehensively. It was advisable to start with those areas of integration in which the need for union is irrefutable and the consensus needed to bring it about appeared to be solid and lasting. By electing to move toward integration the founding states abandoned the formerly customary systems of national law, and particularly the machinery of cooperation, since these—bilaterally or collectively—had all failed to pass their actual historic test, the preservation of peace in Europe, since the rise of the national state, in other words since the Congress of Vienna. After two terrible world wars, both of which had begun as European civil wars, Europe in 1945 stood on the very brink of the abyss. To assert itself, it needed a radical change of methods and paradigms. This was the origin of the community concept, supranationality, integration, and the endeavor to solve community problems and resolve conflicts jointly, in other words by applying the methods of domestic politics. This actually represents the only real political innovation of the post-war era.

The correctness of this approach has become apparent, not least in the last two years. The successes of the community and its methods have exerted their full effect as a model and catalyst in the historic revolutionary events in Central and Eastern Europe.

2. Research Policy of the European Communities

2.1. Historical Development and the Situation Today

Research and development played only a minor role in the first community founded after 1950, the European Coal and Steel Community (ECSC). Under the influence of the massive American superiority in technology, European public opinion changed very rapidly, so that the European Atomic

B-1040 Brussels (Belgium)

Energy Community came into existence in March 1957, at the same time as the European Economic Community. EURATOM established a communal responsibiity for virtually every function of the peaceful use of nuclear sciences. Its later development, dictated principally by factors associated with power politics, cannot be described here. However, it has brought about many important events and successes, from matters concerned with the efficiency and limitations of community large-scale research installations to sounding out the correct distance between the Community and industry. This task was influenced by the views of the member states regarding economic systems, which originally differed considerably. In particular, there were variations in attitudes toward the functions of the state in the process of innovation and toward the delimitation of those functions from the duties of individual companies. EURATOM also created an "esprit de corps" among the researchers and engineers involved, reestablishing something akin to European self-confidence—the awareness that this continent, once it succeeds in concentrating its resources, is capable of achievements that will guarantee it a seat at the top table in every sphere of world events. Whether the point at issue relates to the high standards of European reactor safety or the development of new types of reactors, the concentration of efforts and of human and economic resources has paid off every time. The same is true today, if we recall for example the important role played throughout the world by the European Community and its effective coordination of European research into thermonuclear fusion, in concert with the United States, Japan, and the Soviet Union.

But the limitations on power and political constraints also became apparent if we think, for example, of the thorny question of the demarcation into nuclear and non-nuclear powers in the European Atomic Energy Community, or the labors that were necessary in order to ensure the autonomy of EURATOM from the Vienna Agency in the world system of the non-proliferation treaty.

Under the influence of the first oil crisis and the substantial technological advances achieved by the United States in the subsequent 15 years, the Community then began, after 1973, to formulate its own research and development policy beyond the spheres of competence of EURATOM and the ECSC. Not only did it progress toward supplying the new demand for research and development in the sector of non-nuclear energy generation and consumption, but it also began to encourage the flagging competitiveness of European industry. Increasingly, the restoration of industry became a political challenge to all member states, as well as to the Community itself. There was no mistaking the loss of the innovative spirit and global competitiveness in key industrial sectors, if one takes as a basis the indices for the Community as a whole rather than restricting oneself to a comparison with the Federal Republic, which in many respects occupies a leading position.

Among the weak points that required action at that time, one important example was the fragmentation of European markets. The almost explosive increase in research and development costs gave rise to an irresistible compulsion to establish a major economic area, one large-scale market, since it was only in an enlarged domestic market that there was any prospect of recovering the high R & D expenditure through the market price, taking full advantage of the scaled-up returns. It immediately became apparent, however, that increasing research projects called for a level of expenditure which exceeded the capabilities of the individual member states. Only by pooling resources was it possible to guarantee that development could keep pace with that in the United States or Japan. Experience with the European Center for Nuclear Research (CERN), the European Space Administration (ESA) and also the European Molecular Biology Organization (EMBO) confirmed this insight, and led the member states to adopt Community initiatives and finance them from the budget.

In 1983, after a great preparatory effort, an initial outline program for research and development was approved, running from 1984 to 1987. In many ways it is in the nature of a compromise, exploiting the experience of the past 30 years and endeavoring, successfully, to initiate a research and development policy with continuity over a number of years and independent of the annual budget disputes. The occurrence of these program compromises in the negotiations of the Council of Ministers made it clear that it was essential to adopt the form of an outline program, which is synonymous with a "negotiation package", in which the various interests are combined. Such an arrangement need not be a political burden if—as in a well-managed company—all those involved cooperate constructively, and if there is the appropriate political will, unity, and mutual trust.

Against this background, it became possible in 1985 to contemplate a first substantive change in the Treaties of Rome and to take advantage of the opportunity presented by the incorporation of the 1992 single-market program to introduce into the amended treaty an express Community responsibility for a number of other policies. This amendment to the treaty took place in 1985 through the Single European Act, which came into force in 1987.

It also lays down that the outline program is to be implemented through specific programs, these specific programs differing from the outline program in that decisions can be taken by means of a qualified majority vote. The effect of this difference is that the member states try insofar as possible to introduce into the outline programs themes and standpoints that reflect their specific interests, since the only way in which they can influence the content of the outline program is by their veto. In addition to this, the Single European Act envisages coordinating the research policy of the member states, though this has hitherto been achieved only to an unsatisfactory extent, principally because the early availability of information necessary for effective ex ante coordination can rarely be anticipated. What is now happening in this area—the comparative assessment of national research and development programs, known as COPOL (*Co*nfrontation de *Pol*itiques nationales)—is nevertheless of considerable interest to some member states, particularly those that have not hitherto developed any procedure for a national R & D policy extending over a number of years.

Experience shows that the other possibility, that of resolving upon additional programs in which only some member states participate, has not been very enthusiastically received. To put it crudely, if there is no money available from Brussels, then neither is there any reason why the Community should be involved at all in cooperation between individu-

al member states—except perhaps for purposes of a joint defense against nuclear attack.

More interesting in the long-term is another possibility, namely involvement in large-scale research installations as a way of ensuring research facilities even for those member states of the Community which, through their own efforts, could neither participate in such an installation nor, as outsiders, negotiate opportunities for jobs and training there for their citizens.

Even today, in the light of our brief experience with research policy since 1986/87, two areas have become apparent in which political efforts should be made to introduce corrections: First, the rigorous nature of the five-year plan should be loosened, preferably by adopting a budgeting procedure based on rolling programming, which would make it possible every 24 or 36 months to change the emphasis and incorporate new themes or abandon obsolete ones. Second, an effort should be made to put an end to the requirement of unanimity for the outline programs. Experience with the single market project has produced highly favorable results as regards decisions taken by means of the qualified majority vote. The mere possibility of being outvoted compels all delegations to formulate their positions from the outset in such a way as to at least achieve a blocking minority and thereby avoid isolation. Since all partners operate in this way, the whole business of negotiation and argument is facilitated and a higher common denominator for constructive decisions is achieved than would be possible if delegations persistied in extreme positions, without perceptiveness or common sense, trusting in the veto option. Since a governmental conference is meeting as early as December of this year to draft institutional improvements to the Treaties of Rome and decisive steps toward European union, I regard it as not inconceivable that such a change in the voting method could be approved before the end of next year.

As regards the budget resources available for Community research and development, I shall confine myself to observing that the actual sum available in the year 1987/88 was about one billion ECUs, that this sum will be increasing to about 2 billion ECUs per year for the years 1989 to 1991/92 (1 ECU currently being equivalent to DM 2.06), and that an annual sum of 3 billion ECUs can be expected by the mid 1990s. This is quite a small budget for a large fraction of a continent. However, it does not include direct payments by the member governments to other European research organizations (especially ESA and CERN), which are not funded from the Community budget. Nor does it include Community military research and development under the *I*ndependent *E*uropean *P*rogramme *G*roup (IEPG), which is now in its early stages.

The present annual expenditure of about 2 billion compares with the Community's gross domestic product of about 4 trillion ECUs. The upper limit of the total Community budget is about 1.2% of this gross domestic product, which means at present about 50 billion ECUs. Of this, the Community's common agricultural policy swallows up more than 50% or, in round figures, at least 15 times the figure for its research and development policy.

This budget situation forces the Community to husband its scarce resources with extreme care if it hopes to make a significant contribution to the Community's research aims.

2.2. Heterogeneous Interests of the Member States

A political, economic, social, and cultural heterogeneity of the member states, to which I have already referred, is also reflected in their relative interests in research policy. Three quarters of the total Community expenditure on research is contributed by the United Kingdom, France, and the Federal Republic of Germany. In addition, there are wide differences in the proportions of the respective total national research expenditures devoted to military research and development. Whereas this percentage was about 50% in the United Kingdom, the figure for military research in the Federal Republic was generally in the vicinity of 10%. The other nine member states did not begin systematic development of a research policy until the 1980s. Also, many of even the larger industrial companies in smaller countries did not have their own research operations (or at most supported a limited development department) with a responsibility to work on innovative products and processes. All of the states recognized, however, that the competitiveness of their national economies, just like that of the Community as a whole, are critically dependent on the efficiency of their research and development potential, and that this in turn is substantially shaped by the quality of university education in the member states, or in those states to which their scientists are sent for training. There was a repeated demand for top performance, "centres d'excellence". In terms of the gross national product, the Federal Republic succeeded some years ago in increasing its R & D expenditure into the range of 2.8–2.9% of the gross national product, thus reaching a level which corresponds to that achieved in Japan. The other member states are also constantly striving, with rates of increase greater than those of their budget and national product, gradually to bring their budgets to a comparable level.

Whatever their individual positions, however, all the countries have an interest in using the route through the Community to expedite the development of their R & D and innovation potentials and bring them to the highest possible qualitative levels, even though focal points and traditions may vary.

In particular, however, great importance is attached to transferring to Community level those research and development projects that call for a greater input of capital expenditures and resources than can be afforded even by the largest of the individual member states. Civil nuclear research within EURATOM was an earlier example, and fusion research is now the most expensive large-scale research sector at nearly 200 billion ECUs per year (JET installation at Oxford).

Similarly, there are no differences of opinion over whether, for example, problems in climatology and broad areas of environmental research should be solved at the national level alone, and whether Community efforts are of universal benefit.

So far as the distinction between military and civil research is concerned, I see fewer problems at Community level than in the member states. Whereas the Community pursues everything for which a civil demand exists, at the national level there often seems to be a concern to find, or even invent, some military use so that the corresponding R & D can be financed from the military research budgets. These budgets offer more generous conditions, exercise less

strict control, and also seem to be more accommodating with respect to deadlines than civil programs, which adopt more stringent yardsticks. The Pentagon's "cost plus" contracts proved almost a guarantee of effortless revenue.

2.3. Research Sectors—Distribution of Budgetary Means

As regards the selection of the specific EC program, this is governed by the distribution of resources and the program description in the framework program. The latter incorporates eight research sectors which, with their sub-sectors and specific allocations of resources for these sub-sectors, are generally defined so extensively and in such detail that little freedom of action remains with respect to specific program decisions and their "quantitative framework". For example, of the approximately 5.4 billion ECUs of the second framework program, 375 million ECUs are allocated to the research sector "Quality of life" (health, radiation protection, environment), 2275 million for the key sector of information and communications technologies, including associated new services, 845 million to the modernization of the industrial sector (not just development of production processes and advanced materials but also prenormative research as part of the preparation of standards, methods, and reference materials), and 280 million for the exploration of biological resources, including agro-industrial technologies and methods of improving competitiveness in rural areas. 1173 million ECUs were provided for energy research, 80 million for science and technology in the field of development aid, and another 80 million for the development of sea bed and marine resources. Finally, for the improvement of European scientific and technological cooperation—which includes basic research—the provision is 288 million ECUs.

In order to understand this allocation of resources, and also in order to follow their use in detail, it is worthwhile pointing out that the Commission can for this purpose call upon a comprehensive consultancy structure, aimed at establishing a consensus, with extensive consultation of the member states and the various research milieus involved. A committee with the acronym CODEST (*Co*mmittee for the *De*velopment of *S*cience and *T*echnology) provides the cooperative link between the Commission and top scientific organizations behind national research policies, such as the Max-Planck Institutes and the German Research Association, to name German examples, or—in other member states—with the personal scientific advisers of the heads of government. This commission, which operates at the highest level, also has a program of its own (SCIENCE) that enables it to refer appropriate short-term assistance to valuable high-level projects provided they involve researchers from a number of member states. Several Nobel prize winners are regular members of CODEST. It exercises a lasting effect on the Community's research activities, and promotes their reputation and standing throughout the world. Another committee, *C*omité de la *re*cherche *s*cientifique et *t*echnique (CREST) was brought into being in order to ensure the closest possible consultation with the basic research departments of the national research ministries or administrations, which in Germany means the current Ministerial Director at the Federal Ministry for Research and Technology who is responsible for these matters. Then there is the very active *I*ndustrial *R*esearch and *D*evelopment *A*dvisory *C*ommittee (IRDAC) committee, currently under the chairmanship of a research manager from Shell. Here leading representatives of industrial research cooperate in order to contribute to the design and implementation of Community research policy. Current German representatives are Prof. Danielmeyer from Siemens and Prof. Dörfel, head of research at BASF until mid 1990. The interaction of these three advisory committees achieves a considerable degree of consensus, and so ensures that the Commission's research initiatives generally arouse interest and approval within the Council of Ministers and the European Parliament—at least so long as purely political motives within the Council or Parliament do not give rise to contradiction, opposition, or even obstruction.

Over and above this, there is a process of "inhouse" agreement within the Commission, because a number of general directorates, as customers for research results, also have a natural interest in exercising an early influence on research. This applies, for example, to environment policy, transport policy, and also fisheries and development policy.

In purely organizational terms, research and development is divided between two general directorates within the Commission, GD XII and XIII. The reasons for this are partly historical, though it is also attributable to the fact that it was expedient to have an independent organizational unit for information and communications technologies, currently the largest key area, which includes the major microelectronic programs ESPRIT and RACE, to which more than DM 800 million are allocated each year. In both general directorates, the officers responsible for project direction and management are recruited primarily from the sciences. The number of appointments falling to lawyers or economists is small. The officers come from all member states and are independently recruited by the Commission either for life or on the basis of 5-year restricted contracts. They are divided in such a way that today, for example, following the expansions, approximetely one officer in 7 holds German citizenship.

The consultancy procedures themselves, largely oriented towards consensus, create what amounts to a special awareness of the Community as the crystallization point of an independent European technological association. The tendency is further underlined by the widespread call for the Community to be given complementary tasks that are as closely dovetailed as possible, and to extend the principle of subsidiarity, an element of constitutional policy, into the field of R & D policy as well. This again is less easy to accomplish in practice than to call for politically; for example, the number of research tasks that Germany can undertake with its own resources is far greater than what would be possible for Portugal, Ireland, Denmark, Greece, or Luxembourg. If German efficiency and capability were to be taken as the yardstick for subsidiarity decisions, all the other 11 states would sooner or later fall out of the running and be deprived of the opportunity for full participation in Community R & D endeavors. Consequently, when it comes to a practical determination of what "subsidiary" means in specific terms, the only choice is to seek compromises. This in turn is accomplished, or at any rate facilitated, by the consensus procedure I have described. However, complementarity and

subsidiarity do not mean that the Community must stand ineffectively aside until all the member states have become aware of the relevance and wealth of opportunity offered by new research areas. On the contrary, the Commission has always endeavored, with considerable assistance from its consultancy structures, to adopt new themes at an early stage, conduct broadly based discussions of new problems, and, above all, pursue new objectives. It is precisely the smaller member states that are grateful for this effort by the Commission, because their own limited conceptual powers means that they are often not in a position to obtain a reliable overview and assessment of the global research landscape in all its ramifications. Interpretive aid and evaluation from Brussels are extremely welcome as they reach their own decisions.

2.4. Precompetitive Research and Shared-Cost-Contracts

In the implementation of the Community's specific programs both direct independent research and contractual research are possible, but there is a clear trend toward the latter. The Joint Research Center (JRC) taken over by EURATOM is in many ways developing into a European edition of the research institute of the American National Bureau of Standards (NBS). In particular, there is an ever-increasing emphasis on environmental and safety research at JRC.

In contractual research, the dominant element is the shared-cost contract, which as a whole has proven very valuable for many reasons. Cost-sharing means first and foremost that neither the Community's research bureaucracy nor technocratic research in Brussels can prescribe what is to be done and what is to be left undone. The process is neither top-down nor bottom-up: mutual agreement is obligatory in the sense of the constructive compromise.

Next, cost-sharing means that research institutes involved must make a high individual contribution: 50%. This prevents any tendency to foist particularly high-risk or less promising projects onto the Community while "hoarding" the supposedly better ones.

Another factor involved in shared-cost contracts is the requirement that projects must be concerned with pre-competitive research; that is to say, with the development of marketable products or processes. To promote direct product development would amount to an inadmissible subsidy of industry. By contrast, pre-competitive research proves successful it should provide sufficient data and "know-how" to finance further development of products and processes through normal commercial channels, relying on the independent responsibility of the company and the researchers involved. Finally, the only projects permitted are those in which at least two partners from different members states participate. The Commission is specifically required to assist international, integrative research.

So far as access to projects is concerned, there is no question of any restriction to industry, universities, or independent research institutes, nor to particular orders of magnitude. The conditions in the Community-wide invitations to tender are decisive, and a system of competitive tendering is in force. There is also a strictly anonymous selection system—peer review—and, consequently no national quotas but only opportunities based on merit. This merit system also means there is no room for the ominous law of the "juste retour", the classical nationalist rule of cooperation whereby each member state must receive from a transnational budget every last cent that it has paid in, if not more.

Another contractual principle is the obligation of all those involved in a project to conduct a mutual exchange of results from prior research that have a bearing on the project at hand. The intention here is to propagate and elevate the level of European achievement, although there is also no mistaking the fact that this obligation also deters one or another highly advanced member from pursuing the route of the European shared-cost contract. If a given member has already acquired precious know-how and valuable knowledge through its own efforts, and it would prefer not to pass these along to others without charge, then it is free to continue going it alone or to find partners on some other basis. Naturally, there are also EC regulations governing the propagation and use of jointly acquired knowledge.

Shared-cost contracts are used primarily in the field of the ESPRIT information technology program and the RACE communications program, as well as in the BRITE and EURAM industrial research programs. Feedback and success rates are very good. Most programs are between six and ten times oversubscribed. The level of projects is also assessed as very high. The quality of researchers assigned to these programs by the participants is described as good to very good. The younger participants in particular very quickly become accustomed to working together with researchers from other countries. The practical effect and range of the joint research efforts in the key areas are very far-reaching despite the limited resources, thanks largely to the shared-cost contracts. Thus the ESPRIT program, for example, embraces and coordinates about 30% of all pre-competitive research and development work done in the Community by all participants, and in this way also exerts an influence on the remaining 70%. Particularly successful and popular are the annual conferences for those involved in these large-scale programs. For example, as many as 1500–2000 researchers, engineers, and assignees of the involved institutions participate in the ESPRIT week. About 1000 pages of working papers are presented, critical masses are formed and synergistic effects discovered, results are discussed, and valuable stimuli are produced for all the institutions and companies involved. Statistics show, incidentally, that these programs are by no means the preserve of large companies or research institutes. Important contributions are noted every year from projects involving small and medium-size enterprises and institutions. Nor are the institutions in the peripheral member states disadvantaged. For example, every Greek university today takes part in at least one ESPRIT project, one of the reasons being that the EC's stimulation of opportunities for research and development in Greece has led to a new research surge there, and even to interesting reimmigration trends, particularly from the United States.

The principle reason why I have described in considerable detail this system of shared-cost programs in the Community's research and development policy is to indicate the high degree to which, in these key areas, integration of the research community is already taking place, leading to an independent European R & D identity. Those familiar with the

American situation have several times assured me that any such development would be inconceivable there. Experience in America, particularly with the Pentagon programs, has apparently demonstrated that shared-cost programs—however they might be individually organized, and whatever the cost-sharing arrangement might be—are rarely staffed by the very best researchers from the institutions and companies involved. The researchers assigned are sufficiently qualified to understand everything in the way of new knowledge that might be contributed by their project partners and competitors, but they are not sufficiently familiar with their own achievements, so they fail to report everything from their home bases that might be relevant to the communal project. It is hardly surprising, then, that the large national laboratories in America retain a lead in quality relative to contractural research.

Naturally, another element of every shared-cost project is the regular check on the performance status. This is paired with a readiness to put a rapid end to projects that prove unpromising for any reason. For example, about 10 to 15% of all ESPRIT projects fail to be carried through to the end.

3. Contribution of the R & D Policy of the European Communities to European Integration

3.1. Complementarity of the Single Market and the European Technological Community

When I referred initially to the encouragement of competitiveness as being one of the essential aims of Community research and development policy, I also observed that the rapidly increasing costs of research and development could no longer be recovered on the basis of safe, accessible foreign markets without a large-scale base or home market. Fragmented markets entail such a competitive disadvantage on the more remote world markets that there is rarely any real chance to win back lost market shares in the high-tech sector. Consequently, the 1992 single-market project, which is likely to be completely implemented on schedule in less than 30 months, is also having a considerable effect on innovation and research policy. It offers European industry a home market which, from the standpoint of its dimensions and buying power, is far superior to the Japanese market and matches the American market. This advantage of magnitude enjoyed by the European single market will become still more pronounced if, as is hoped, it expands economically to embrace the EFTA states in the near future and the former COMECON states at a later stage. A Europe of 400 million consumers is an entirely feasible expectation for the period shortly after the turn of the century. The full opening-up and development of the inherent technological potential of that market is a priority task for the European technological community.

The elements that have opened up an opportunity to Europe's generally successful research and development policy also include a strict refusal to reproduce traditional research policy "dog fights" at European level: basic research versus applied research, university research versus industrial research, research in the humanities and social sciences versus scientific research, large-scale research versus decentralized research, etc. The EC Commission and European Parliament endeavor over the years not only to recognize all cases where there is a justified demand for promising international research and development, but also, in cooperation with the member states, to supply that demand at Community level insofar as possible.

In these efforts, the Commission has had no problem whatsoever in reaching a constructive arrangement and division of labor with other respected European organizations, such as the European Science Foundation or EUREKA. Indeed, all are making every effort to achieve a permanent strengthening of European R & D potential, and to set in motion the scientific renaissance of a continent that has so often been pronounced dead.

3.2. Acceptance of Scientific R & D in Europe

All responsible institutions are conscious of the need to defend the position of the sciences against a public at times unjustifiably inclined to mistrust and reject them, and to wage a common struggle for greater overall acceptance of scientific research and development. The world "struggle" here is no exaggeration. Problems of acceptance are not simply the result of deliberate political interference and repeated attempts to split scientific research in the universities away from that in industry. They are also due to a rapidly widening gap between the accelerating advance of science, and the depth of understanding of public opinion and those who shape that opinion. Particularly in an age like this, in which it has even become possible to drop scientific disciplines before taking one's school leaving examinations, it is hardly surprising if the considerable vacuum in elementary knowledge and understanding of scientific relationships is being filled, and dangerously abused, from another quarter. In such a situation, the precise nature of which varies from one member state to another, a representative European voice of science developed at Community level (perhaps in the form of an academy or a scientific assembly) could make an essential contribution to the restoration, relaxation, and normalization of the necessary public dialog on the progress of science.

One thing, however, does seem to me important: the sciences must recognize that their accountability to the public regarding what they are doing, how much it costs, what they are achieving, and how their results can be put to beneficial use will become more and more urgent and more and more extensive. For example, we will need to consider how the scientist who ventures to portray his field in generally comprehensible terms, without the customary quotable scientific apparatus, is to be protected against professional disadvantages. This may sound banal. Yet my experience suggests that this relationship represents an understandable but avoidable obstacle to acceptance, since every individual career depends on the number and quality of scientific publications. For this very reason, it should be possible to separate without disadvantage publications for non-scientific purposes from those specialist publications that advance a scientist's career. This function cannot be entirely left to the media, since they themselves have enormous personnel prob-

lems in trying to find good writers with appropriate scientific qualifications and available on terms they can offer. Great efforts will be necessary to close the gap in understanding, and the EC should be of assistance here.

Another aspect—or, if you like, a hangover from 1968—also in urgent need of correction seems to me to be a kind of emotional prejudice against scientists, irrespective of whether they work in industry or are involved, for example, in constantly widening the limits of human knowledge in fields such as molecular biology or microbiology. I believe it is intolerable that scientists, collectively and a priori, should be treated as somewhat unstable individuals, believed to be unable and unwilling to take responsibility for their actions, or to regard them as "obsessed" or "infatuated" characters to be closely watched by, for example, sociologists. This is another area where a representative and powerful voice speaking for European scientists generally could make a more balanced contribution to advancing the overdue process of correction.

A comparable benefit to Community development would be a de-emotionalization of environmental policy. The protection of nature and the environment is far too important a task to be left to the vociferous emotions of certain scientists who pursue eclectic lines of argument and selective lines of work. But this task, too, presupposes a great willingness for personal public commitment. It is not only in the media that one rarely encounters individuals who are equally talented in science and in the various forms of communication; the same is true in politics, which ultimately has the last word in any decision regarding the use of public R & D resources. The Community, incidentally, with its nine official languages, is itself under an obligation to produce texts that can be universally read and believed.

3.3. Community Programs for Promoting the Mobility of Scientists and Cooperation with States Outside the Community

Parallel to the various aspects of the common research and development policy, the Community also operates a number of backup programs intended to help integrate young scientists and researchers. The Commission discovered some years ago that only 1% of all students in the Community spend at least one term at university in another member state at some point during their studies. The remaining 99%, then, are ignorant of universities in other states. This situation, alongside the political aim of integrating the Community's citizens, was the essential reason for launching a comprehensive scholarship program which you may already have encountered under the name "Erasmus". The aim of this program is to make increasing use of resources to enable 10% of all the Community's students to benefit from terms abroad by the mid-1990s. The numbers doing so are already increasing sharply, but there are not yet sufficient resources to satisfy the demand immediately. Moreover, the popular universities can only absorb limited numbers of extra students. Even so, we are favorably placed to achieve the ambitious target on time. Another program that serves the same purpose is the *Com*munity action program in *E*ducation and *T*raining for *T*echnology (COMETT) which is more concerned with the exchange of senior colleagues between industries, universities and research institutions from the member states. In some cases, this involves researchers working abroad for periods of several years. Well over 1000 projects have now been accepted, and about 15000 soldiers and civilian workers are now benefiting from these opportunities. Another special program, TEMPUS (*T*rans *E*uropean *M*obility Scheme of *U*niversity *S*tudents), is also to be launched in the near future to assist with the reintegration into the West of academic circles in Poland and Hungary.

Apart from these measures to integrate European human resources, there are other programs whose aim is to use resources from the regional structural fund to enable the basic technological equipment of the more peripheral member states of the Community to be brought rapidly in line with the state of the art (STRIDE and BRIDGE, to cite only the acronyms). In addition, every effort is being made, particularly on the information and communications side, to create a broadly based data infrastructure by extensive networking of the dataflow within the continent.

Up to this point, my remarks have dealt only with the Community. The first necessity was for its formative process and its methods and objectives to be understood. But is also endeavors unceasingly to make its activities available to the other European states that are not members, or not yet members, on a basis of strict mutuality. This applies to the OECD countries (the COST program), the EFTA states (first bilateral cooperative agreement) and all those involved in EUREKA. The most graphic example of this expansion exists in Germany, where the accession of the German Democratic Republic will cause research in that country to be fully integrated with Community research. In addition, R & D relations with the former COMECON states will grow rapidly in intensity and scope. Another effect of these processes will be to bridge political gaps and to restore the integrity of the European cultural and scientific realms. Researchers in all countries are once again to be fully involved in the flow and exchange of information, and they will again be able to take advantage of all the opportunities offered by professional contacts free of frontiers and obstacles, with exchanges and meetings and whatever else benefits the integration of research and researchers, extending to successful joint efforts or unfettered participation in free and undistorted competition. Everyone knows that differences in gross national product do not necessarily reflect similar differences in individual or collective scientific talent.

4. Conclusion

Naturally this EC development has its critics, who focus principally on the way in which it portrays itself, and its organizational proportions, which are not always understood in the broader context. Another adverse factor is that, in contrast to the United States and Japan, nine different languages are spoken within the Community today. Moreover, many protagonists are relatively unfamiliar with EC procedures. The size of the Community necessarily means that a Community authority seems more anonymous than the familiar faces in the R & D Ministry back home in a country of 5 or 10 million inhabitants.

Disappointments, of course, often lead to reproaches. The Commission constantly endeavors to investigate the factual content of such reproaches, and to correct weaknesses. It knows from its own experience, better than others perhaps, that all those involved in the planning of research and development at the European Community level are undergoing a major learning process, a process governed in part by the principle of trial and error.

Despite all this, the inescapable need for communal R & D endeavors must not be forgotten. It is a necessary corollary of the formation of the European home market. Communal endeavors alone make possible the concentration of financial resources needed for the construction of industrial-scale plants of all kinds, now or in the future. Similarly, they permit more effective use to be made of human resources, which are in short supply, and an end to avoidable duplication of effort arising, for example, from unnecessary fragmentation in the pre-competitive R & D sector.

In short, the technological community, too, offers opportunities for the self-assertion and renaissance of a continent that has so often been written off; aims that have ranked second only to the safeguarding of peace as the crucial reasons for integration policies since 1950, and will remain so in future. Their necessity and current relevance has been repeatedly confirmed by the developments of the last 15 months. Our prospects for the 21st Century do not necessarily have to be poor!

Misconceptions on Pollution and the Causes of Cancer**

By Bruce N. Ames* and Lois Swirsky Gold

The public has numerous misconceptions about the relationship between environmental pollution and human cancer. Underlying these misconceptions is an erroneous belief that nature is benign. In this article we highlight eight of these misconceptions and describe the scientific information that undermines each one.

1. Misconception No. 1: Cancer Rates Are Soaring

According to the latest update from the National Cancer Institute (February 1988), "the age adjusted mortality rate for all cancers combined except lung cancer has been declining since 1950 for all individual age groups except 85 and above."[1] That represents a 13-percent decrease overall, 44 000 deaths below expected, and a 0.1-percent increase in the over-85 group (unless otherwise noted, all statistics given in this article refer to the USA.)

The types of cancer deaths that have been decreasing during this period are primarily stomach (by 75 percent, 37 000 deaths below expected), cervical (by 73 percent, 11 000 deaths below expected), uterine (by 60 percent, 9000 deaths below expected), and rectal (by 65 percent, 13 000 deaths below expected). The types of cancer deaths that are increasing are primarily lung cancer (by 247 percent, 91 000 deaths above expected), which is due to smoking (as are 30 percent of all U.S. cancer deaths), and non-Hodgkin's lymphoma (by 100 percent, 8000 deaths above expected).

Changes in incidence rates and effects of treatment are also relevant in interpreting the changes in mortality rates.[1, 2] Incidence rates have been increasing for some types of cancer.

In their definitive study on cancer trends,[2] Sir *Richard Doll* and *Richard Peto* point out that, although incidence rates are of interest, they should not be taken in isolation, because trends in the recorded incidence rates are biased by improvements in the level of registration and diagnosis. Even if particular types of cancer can be shown to be increasing or decreasing, establishing a causal relation among the many changing aspects of our lives is difficult.[3-15] There is no persuasive evidence that life in the modern industrial world has in general contributed to cancer deaths.[2, 10, 13]

Cancer is fundamentally a degenerative disease of old age, although exogenous factors can increase cancer rates (e.g., cigarette smoking in humans) or decrease them (e.g., caloric restriction in rodents).[16-18] For mammalian species, cumulative cancer risk increases with approximately the fourth power of age, both in short-lived species such as rats and mice (about 30% have cancer by the end of their 2-year life span) and in long-lived species such as humans (about 30% have cancer by the end of their 85-year life span).[2, 13, 19-21]

Life expectancy is steadily increasing in the United States and other industrial countries. Infant mortality is decreasing. Although the statistics are less adequate on birth defects, there is no evidence that they are increasing. Conclusion: Americans, Japanese, and Western Europeans are healthier now than they have been in their history.

2. Misconception No. 2: Cancer Risks to Humans Can Be Assessed by Testing Chemicals at High Doses in Rodents

Results from animal cancer tests, which are conducted at near toxic doses of the test chemical, cannot predict the cancer risk to humans at the usually low levels of human exposures. Knowledge of the mechanisms of carcinogenesis is necessary for prediction and is now progressing rapidly. Recent understanding of these mechanisms undermines many of the assumptions of current regulatory policy towards rodent carcinogens and necessitates a rethinking of the utility and meaning of routine animal cancer tests. The following summarizes our current understanding of these mechanisms and how they relate to animal cancer tests.

2.1. Mutagenesis Can Cause Cancer, and Normal Rates of Mutagenesis Are High

Mutagens cause cancer by mutating the DNA of cells in ways that cause cells to proliferate in an uncontrolled manner. It is generally agreed that several mutations are necessary to convert a normal cell into a cancer cell capable of uncontrolled growth.[22, 23] Mutagens are often assumed to be exogenous agents (coming from outside the body), such as synthetic chemicals; however, many endogenous mutagens (coming from inside the body) are formed naturally during normal metabolic processes like oxygen utilization, which produces DNA-damaging oxidants. These oxidants are the same as those produced by radiation, which itself is an oxidative mutagen. Thus, in a sense, breathing oxygen is equivalent to irradiating the body. Normal metabolism causes chronic, oxidative DNA damage: we estimate that the number of oxidative hits to DNA per cell per day is about 100 000 in rats and 10 000 in humans.[21, 24, 25] Endogenous rates of DNA damage are thus so high that it may be difficult for exogenous mutagens to increase this damage significantly at the normal levels of human exposure. All mammals have numerous defenses to counter this damage, such as enzymes

[**] The names of compounds in this article are not always in accordance with IUPAC nomenclature.

that repair damaged DNA.[20, 21, 26] Nevertheless, this damage appears to be a major contributor to aging and to many of the degenerative diseases associated with aging, including cancer.

2.2. Chronic Cell Division Increases Mutagenesis and Carcinogenesis

"Promoters" of carcinogenesis have been recognized for many years, but the concept of "promotion" and its role in carcinogenesis have been fuzzy compared to the concept of mutagenesis and its role in carcinogenesis. This is primarily because the mechanisms of carcinogenesis have in the past not been well understood. Cell division (cell proliferation) promotes carcinogenesis by increasing the vulnerability of the DNA to mutation. A dividing cell is much more at risk from mutagens (either endogenous or exogenous) than is a nondividing, quiescent cell.[26-32] Agents that cause chronic cell division are therefore indirectly mutagenic (and commonly carcinogenic).[28-33] Saccharin, for example, is not itself a mutagen, but high doeses of saccharin given to rodents cause sufficient cell division to be carcinogenic.[32] Low doses, however, would be expected to have no carcinogenic effect. Agents that cause chronic cell division (e.g., by irritation and inflammation of tissues) appear to be important in many of the known causes of human cancer: hepatitis B or C viruses or alcohol in liver cancer, high salt or *Helicobacter* (*Campylobacter*) bacteria in stomach cancer,[34-43] hormones in breast cancer, papilloma virus in cervical cancer,[44] asbestos or tobacco smoke in lung cancer,[45] and excess animal fat and low calcium in colon cancer.[46] For the chemicals associated with occupational cancer, worker exposures usually have been at near-toxic doses that would be likely to cause cell proliferation.

2.3. Animal Cancer Tests Are Primarily Measuring the Effects of Massive Cell Division

Animal cancer tests of chemicals are conducted at near-toxic, chronic doses—the maximum tolerated dose (MTD). (Such high doses are used in order to increase the sensitivity of the test to detect a carcinogenic effect among small numbers of animals, because the tests are very expensive to conduct.) Such high doses often cause chronic cell death and a consequent chronic cell division of neighboring cells that replace the dead cells. Chronic dosing at the MTD can be thought of as chronic wounding, which is known to be both a promoter of carcinogenesis in animals and a risk factor for cancer in humans.[31, 47-49] Thus, by causing chronic cell division, a high percentage of all chemicals might be expected to be carcinogenic at chronic, near-toxic doses. This is exactly what is found (see Section 3). About *half* of all chemicals tested chronically at the MTD are carcinogens.[3, 50-55] The fact that about 40% of rodent carcinogens are not mutagens is consistent with our understanding of the important role of cell division in carcinogenesis.

Although toxicity at or near the MTD often induces cell division, below a certain dose no such effect is observed. Therefore, if animal cancer tests are primarily measuring the effects of cell division, then the dose–response curve would be expected to curve steeply upward rather than be linear.[3, 30-32, 56-58] This means that a tenfold reduction in dose in a rodent experiment would produce much more than a tenfold reduction in cancer risk. This prediction is confirmed by several recent analyses.[32, 59-61]

3. Misconception No. 3: Most Carcinogens and Other Toxins Are Synthetic

About 99.99% of all pesticides in the human diet are natural pesticides from plants.[62] All plants produce toxins to protect themselves against fungi, insects, and animal predators such as man.[62-71] Tens of thousands of these natural pesticides have been discovered, and every species of plant contains its own set of different toxins, usually a few dozen. When plants are stressed or damaged (e.g., during a pest attack), they increase the levels of natural pesticides manyfold, occasionally to levels that are acutely toxic to humans. We estimate that Americans eat about 1500 mg per person

Table 1. Forty-nine natural pesticides (and metabolites) in cabbage. See [a] for remarks on the numbered compounds.

Glucosinolates
prop-2-en-1-yl glucosinolate (sinigrin, **1**)
3-methylthiopropyl glucosinolate
3-methylsulfinylpropyl glucosinolate
but-3-en-1-yl glucosinolate
2-hydroxy-but-3-en-1-yl glucosinolate
4-methylthiobutyl glucosinolate
4-methylsulfinylbutyl glucosinolate
4-methylsulfonylbutyl glucosinolate
benzyl glucosinolate
2-phenylethyl glucosinolate
propyl glucosinolate
butyl glucosinolate

Indole glucosinolates and related indoles
3-indolylmethyl glucosinolate (glucobrassicin)
1-methoxy-3-indolylmethyl glucosinolate (neoglucobrassicin)
indole-3-carbinol (**2**)
indole-3-acetonitrile (**3**)
3,3'-diindolylmethane

Isothiocyanates and goitrin
allyl isothiocyanate (**4**)
3-methylthiopropyl isothiocyanate
3-methylsulfinylpropyl isothiocyanate
3-butenyl isothiocyanate
5-vinyloxazolidine-2-thione (goitrin, **5**)
4-methylthiobutyl isothiocyanate
4-methylsulfinylbutyl isothiocyanate
4-methylsulfonylbutyl isothiocyanate
4-pentenyl isothiocyanate
benzyl isothiocyanate
phenylethyl isothiocyanate

Cyanides
1-cyano-2,3-epithiopropane
1-cyano-3,4-epithiobutane
1-cyano-3,4-epithiopentane
threo-1-cyano-2-hydroxy-3,4-epithiobutane
erythro-1-cyano-2-hydroxy-3,4-epithiobutane
2-phenylpropionitrile
allyl cyanide (**6**)
1-cyano-2-hydroxy-3-butene
1-cyano-3(methylsulfinyl)propane
1-cyano-4(methylsulfinyl)butane

Terpenes
menthol
neomenthol
isomenthol
carvone (**7**)

Phenols
2-methoxyphenol
3-caffoylquinic acid (chlorogenic acid, **8**)
4-caffoylquinic acid (**9**)
5-caffoylquinic acid (neochlorogenic acid, **10**)
4-*p*-coumaroylquinic acid
5-*p*-coumaroylquinic acid
5-feruloylquinic acid

[a] *Clastogenicity:* Chlorogenic acid (**8**) [160] and allyl isothiocyanate (**4**) are positive [75]. Compound **8** and its metabolite caffeic acid are also mutagens [161-163], as is **4** [77]. *Carcinogenicity:* Allyl isothiocyanate (**4**) induced papillomas of the bladder in male rats (a neoplasm that is unusually rare in control rats) and was classified by the National Toxicology Program (NTP) as carcinogenic. There was no evidence of carcinogenicity in mice: however, NTP indicated "the mice probably did not receive the MTD" [164, 165]. Sinigrin (**1**; the glucosinolate, that is, thioglycoside of **4**) is cocarcinogenic for the rat pancreas [166]. Carvone (**7**) is negative in mice [167]. Indoleacetonitrile (**3**) has been shown to form a carcinogen, nitrosoindoleacetonitrile, in the presence of nitrite [168]. Caffeic acid is a carcinogen [169, 170] and clastogen [160] and is a metabolite of its esters **8**–**10**. *Metabolites:* Sinigrin (**1**) gives rise to **4** on eating raw cabbage (e.g., coleslaw); in cooked cabbage it also is metabolized to **6**, which is untested. Indolecarbinol (**2**) forms dimers and trimers on ingestion, which mimic dioxin (TCDD) (see Section 4.2) [71]. *Occurrence* [65, 68, 124, 171], *Toxicology:* The mitogenic effects of **5** (which is goitrogenic) and various organic cyanides from cabbage suggest that they may be potential carcinogens [172, 173]. Aromatic cyanides related to those from cabbage have been shown to be mutagens and are metabolized to hydrogen cyanide and potentially mutagenic aldehydes [174].

per day of natural pesticides, which is 10 000 times more than they eat of synthetic pesticide residues.[62] The concentration of natural pesticides is usually measured in parts per million (ppm), rather than parts per billion (ppb), which is the usual concentration of synthetic pesticide residues or of water pollutants. We also estimate that a person ingests annually about 5000 to 10 000 different natural pesticides and their breakdown products.[62] Table 1 lists 49 natural pesticides (and breakdown products) ingested on eating cabbage and indicates which ones have been tested for carcinogenicity or clastogenicity (the ability to break chromosomes). Lima beans contain a different array of 23 natural toxins that, in stressed plants, range in concentration from 0.2 to 33 parts per thousand fresh weight: none appears to have been tested for carcinogenicity or teratogenicity (the ability to cause birth defects).[66] A large literature has examined the toxicity of many of these compounds to herbivorous animals, such as humans and domestic animals.[63–68]

Surprisingly few plant toxins have been tested in animal cancer tests, but among those tested in at least one species, about half (27/52) are carcinogenic.[62] A search in plant foods for the presence of just these 27 natural-pesticide rodent carcinogens indicates that they occur naturally in the following foods (those at concentrations greater than 10 000 ppb of a single carcinogen are listed in italics): *anise, apple*, banana, *basil*, broccoli, *Brussels sprouts, cabbage*, cantaloupe, *caraway, carrot, cauliflower, celery, cherry*, cinnamon, cloves, cocoa, *coffee (brewed), comfrey tea, dill, eggplant, endive, fennel, grapefruit juice, grape, honey*, honeydew melon, *horseradish*, kale, *lettuce, mace, mango, mushroom, mustard (brown), nutmeg, orange juice, parsley, parsnip*, peach, *pear, pepper (black)*, pineapple, *plum, potato*, radish, raspberry, *rosemary, sage, sesame seeds (heated)*, strawberry, *tarragon, thyme*, and turnip (Table 2).

Thus, it is probable that almost every plant product in the supermarket contains natural carcinogens. The ppm levels of the known natural carcinogens in the above plants are commonly thousands of times higher than the ppb levels of man-made pesticides. The occurrence in the diet of natural pesticides that are rodent carcinogens should be interpreted cautiously. We need not be alarmed by the presence of low doses of synthetic toxins and a plethora of natural toxins in our food. As will be discussed in Section 5.1, humans are well protected against low doses of toxins by many layers of inducible, general defenses that do not distinguish between synthetic and natural toxins.

Dietary exposures to natural toxins are not necessarily of much relevance to human cancer. Indeed, a diet rich in fruit and vegetables is associated with lower cancer rates.[72, 73] This may be because anticarcinogenic vitamins and antioxidants come from plants.[72, 73] What is important in our analysis is that chronic exposures to natural rodent carcinogens may cast doubt on the relevance of far lower levels of exposures to synthetic rodent carcinogens.

Table 2. Concentrations of some natural pesticides that are rodent carcinogens. 1 ppm = 1000 ppb.

Plant food	Rodent carcinogen	Concentration [ppm]
Parsley	5- and 8-methoxypsoralen	14
Parsnip, cooked		32
Celery		0.8
Celery, new cultivar		6.2
Celery, stressed		25
Mushroom, commercial	*p*-hydrazinobenzoate	11
Mushroom, commercial	glutamyl-*p*-hydrazinobenzoate	42
Cabbage	sinigrin **1** (allyl isothiocyanate, **4**) [a]	35–590
Collard greens		250–788
Cauliflower		12–66
Brussels sprouts		110–1560
Mustard (brown)		16 000–72 000
Horseradish		4500
Orange juice	limonene	31
Mango		40
Pepper, black		8000
Basil	*estragole*	3800
Fennel		3000
Nutmeg	safrole	3000
Mace		10 000
Pepper, black		100
Pineapple	ethyl acrylate	0.07
Sesame seeds (heated oil)	sesamol	75
Cocoa	α-methylbenzyl alcohol	1.3
Basil	benzyl acetate	82
Jasmine tea		230
Honey		15
Coffee (roasted beans)	catechol	100
Apple, carrot, celery, cherry, eggplant, endive, grapes, lettuce, pear, plum, potato	caffeic acid	
Absinthe, anise, basil, caraway, dill, marjoram, rosemary, sage, savory, tarragon, thyme		> 1000
Coffee (roasted beans)		1800
Apricot, cherry, peach, plum	chlorogenic acid **8** (caffeic acid) [b]	50–500
Coffee (roasted beans)		21 600
Apple, apricot, broccoli, brussels sprouts, cabbage, cherry, kale, peach, pear, plum	neochlorogenic acid **10** (caffeic acid) [b]	50–500
Coffee (roasted beans)		11 600

[a] Sinigrin (**1**) is a cocarcinogen [166] and is metabolized to the rodent carcinogen **4**, although no adequate test has been done on **1** itself. The proportion of **1** converted into **4** or into allyl cyanide (**6**) depends on food preparation [123, 124, 171]. Chlorogenic acid (**8**) and neochlorogenic acid (**10**) are metabolized to the carcinogens caffeic acid and catechol (a metabolite of quinic acid), but have not been tested for carcinogenicity themselves. The clastogenicity and mutagenicity of the above compounds are discussed in Table 1.

3.1. Teratogens and Clastogens Are Common

It is also reasonable to assume that a sizable percentage of both natural and synthetic chemicals will be reproductive toxins at high doses because a high proportion of positives is reported for rodent teratogenicity tests. One-third of the 2800 chemicals tested in laboratory animals have been shown to cause reproductive damage in the standard, high-dose protocol.[74]

Results from other types of tests also indicate that the natural world should not be ignored and that positive results are commonly observed in high-dose tests. *Ishidate* et al.[75] reviewed experiments on the clastogenicity (chromosome breakage) of 951 chemicals in mammalian cell cultures. Of these 951 chemicals, we identified 72 as natural plant pesticides. Among these, 48% (35/72) were positive for clastogenicity in some or all tests. This is similar to the results of

the remaining chemicals; 53% (467/879) were positive in some or all tests. Thus, about half of the chemicals tested—whether synthetic or natural—have been shown to break chromosomes at high dose. These in vitro experiments do not necessarily simulate in vivo conditions, and chromosome breakage is probably much less extensive in tissues of the body than in laboratory tissue cultures.

Of particular interest are the levels at which some of the carcinogenic plant toxins in Table 2 were clastogenic:[75] (1) Allyl isothiocyanate (**4**) was clastogenic at a concentration of 0.0005 ppm, which is about 200 000 times less than the concentration of its glucosinolate, sinigrin (the parent compound **1**), in cabbage. Allyl isothiocyanate (**4**) was among the most potent chemicals in the compendium[75] and is also effective at unusually low levels in transforming[76] and mutating animal cells.[77] (See also the discussion of cancer tests in the legend to Table 1.) (2) Safrole was clastogenic at a concentration of about 100 ppm, which is 30 times less than the concentration in nutmeg, and roughly equal to the concentration in black pepper. The rodent carcinogens safrole and estragole, and a number of other related dietary natural pesticides that have not been tested in animal cancer tests, have been shown to produce DNA adducts (damaged DNA bases) in mice.[78] (3) Caffeic acid was clastogenic at a concentration of 260 and 500 ppm, which is less than its concentration in roasted coffee beans and close to its concentration in apples, lettuce, endive, and potato skin. Chlorogenic acid (**8**), a precursor of caffeic acid, was clastogenic at a concentration of 150 ppm, which is 100 times less than its concentration in roasted coffee beans and similar to its concentration in apples, pears, plums, peaches, cherries, and apricots. Chlorogenic acid (**8**) and its metabolite caffeic acid are also mutagens (Table 1). The toxicity of coffee to the DNA in mammalian cells has been demonstrated.[79]

3.2. Cooking Food

The cooking of food is also a major dietary source of potential rodent carcinogens. Cooking produces about 2000 mg per person per day of mostly untested burnt material that contains many rodent carcinogens.[3, 69, 70, 80–85] Roasted coffee, for example, is known to contain about 825 volatile chemicals.[69] Only 21 have been tested, and 16 are rodent carcinogens.[51–54] In addition, roasted coffee also contains hundreds of nonvolatile chemicals: caffeic acid has been tested and is a carcinogen. With just these few chemicals tested, the carcinogens total 9 mg per cup of coffee (40 000 ppb). (There is some, but not sufficient evidence to conclude that coffee causes cancer in humans.)[72, 80] When proteins or amino acids are heated, certain mutagens known as heterocyclic amines are sometimes produced. Thus far, ten of these heterocyclic amines have been shown to be carcinogens in rodents, and many others are in the process of being isolated and tested.[86, 87] In addition, cooked food contains a plethora of other mutagens as well as rodent carcinogens (polycyclic hydrocarbons, furfural, and nitrosamines).[3, 69, 70, 80–85]

The total amount of browned and burnt material consumed per person in a typical day is at least several hundred times more than that inhaled in a day

air pollution.[71] Three mutagenic nitropyrenes present in diesel exhaust have now been shown to be rodent carcinogens,[88] but the intake of these carcinogenic nitropyrenes has been estimated to be much higher from grilled chicken than from air pollution.[86, 87, 89] Gas flames generate NO_2, which can form both carcinogenic nitropyrenes[3] and nitrosamines in foods that are cooked in gas ovens. Food cooked in gas ovens may be a major source of dietary nitropyrenes and nitrosamines.

3.3. Residues of Man-made Pesticides

By contrast, human exposures to man-made pesticide residues are minuscule. The Food and Drug Administration (FDA) assayed food for residues of the 200 synthetic compounds thought to be of greatest importance, including most synthetic pesticides and a few industrial chemicals.[90] The FDA estimates that the intake of these residues averages about 0.09 mg per person per day and other analyses are similar.[91] For comparison, we estimate that the intake of natural pesticides averages about 1500 mg per person per day.[62] About half of the intake of synthetic residues is composed of four chemicals (ethylhexyl diphenyl phosphate, dicloran, malathion, and chlorpropham)[90] that were not carcinogenic in rodent tests.[51, 92] Thus, the intake of carcinogens from synthetic residues (0.05 mg a day, if one assumes that all the other residues are carcinogenic, which is unlikely) is extremely tiny relative to the background of natural substances; this 0.05 mg intake is equivalent to about 60 ppb of synthetic residues in plant food consumed daily.

4. Misconception No. 4: Synthetic Toxins Pose Greater Risks than Natural Toxins

The possible carcinogenic hazards from synthetic pesticides (at normal exposures) are minimal compared with the background hazards of nature's pesticides. Even though an overwhelming number of the chemicals that humans eat are natural, the natural world of chemicals has never been tested systematically. Synthetic chemicals account for 350 (82%) of the 427 chemicals tested chronically at high doses in both rats and mice.[3, 50–55] Of the 77 *natural* chemicals tested, the proportion carcinogenic is about *half* (37/77), that is, similar to that of synthetic chemicals (212/350).[3, 50–54] It is unlikely that the high proportion of carcinogens in rodent studies is due simply to selection of suspicious chemical structures: while some synthetic or natural chemicals were selected precisely because of suspect structures, most chemicals were selected because they were widely used industrially; for example they were high-volume chemicals, pesticides, drugs, dyes, or food additives.[50] The natural world of chemicals has never been looked at systematically.

In recent years, we have tried to formulate a method of setting priorities among possible carcinogenic hazards.[3] The potencies of different carcinogens vary more than 10^7-fold in rodent tests, and the comparison of possible hazards

is

Table 3. Ranking possible carcinogenic hazards [a].

Possible hazard HERP [%] [b]	Daily human exposure	Carcinogen dose for a 70-kg human
Environmental pollution		
0.001*	Tap water, 1 liter	Chloroform, 83 μg (U.S. average)
0.004*	Well water, 1 liter contaminated (worst well in Silicon Valley, CA, USA)	Trichloroethylene (TCE), 2800 μg
0.0004*	Well water, 1 liter contaminated (Woburn, MA, USA)	Trichloroethylene, 267 μg
0.0002*		Chloroform, 12 μg
0.0003*		Tetrachloroethylene (perc), 21 μg
0.008*	Swimming pool, 1 hour (for child)	Chloroform, 250 (average pool) μg
0.6	Conventional home air (14 h per day)	Formaldehyde, 598 μg
0.004		Benzene, 155 μg
2.1	Mobile home air (14 h per day)	Formaldehyde, 2.2 mg
Pesticides and other residues [c]		
0.0002*	PCBs: daily dietary intake	PCBs, 0.2 μg (U.S. average)
0.0003*	DDE/DDT: daily dietary intake	DDE, 2.2 μg (U.S. average)
0.0004	1,2-dibromoethane (EDB): daily dietary intake (from grains and grain products)	EDB, 0.42 μg (U.S. average)
Natural pesticides and dietary toxins		
0.003	Bacon, cooked (100 g)	Dimethylnitrosamine 0.3 μg
0.006		Diethylnitrosamine, 0.1 μg
0.003	Sake (250 mL)	Urethane, 43 μg
0.03	Comfrey herb tea, 1 cup	Symphytine, 38 μg (750 μg pyrrolizidine alkaloids)
0.03	Peanut butter (32 g; one sandwich)	Aflatoxin, 64 ng (U.S. average, 2 ppb)
0.06	Dried squid, broiled in gas oven (54 g)	Dimethylnitrosamine, 7.9 μg
0.07	Brown mustard (5 g)	Allyl isothiocyanate (**4**), 4.6 mg
0.1	Basil (1 g of dried leaf)	Estragole, 3.8 mg
0.1	Mushroom, one raw (15 g) (*Agaricus bisporus*)	Mixture of hydrazines, etc.
0.2	Natural root beer (12 oz; 354 mL) (now banned)	Safrole, 6.6 mg
0.008	Beer, before 1979 (12 oz; 354 mL)	Dimethylnitrosamine, 1 μg
2.8*	Beer (12 oz; 254 mL)	Ethanol, 18 mL
4.7*	Wine (250 mL)	Ethanol, 30 mL
6.2	Comfrey-pepsin tablets (nine daily)	Comfrey root, 2700 mg
1.3	Comfrey-pepsin tablets (nine daily)	Symphytine, 1.8 mg
Food additives		
0.0002	AF-2: daily dietary intake before banning	AF-2 (furylfuramide), 4.8 μg
0.06*	Diet cola (12 oz; 354 mL)	Saccharin, 95 mg
Drugs		
[0.3]	Phenacetin pill (average dose)	Phenacetin, 300 mg
[5.6]	Metronidazole (therapeutic dose)	Metronidazole, 2,000 mg
[14]	Isoniazid pill (prophylactic dose)	Isoniazid, 300 mg
16*	Phenobarbital, one sleeping pill	Phenobarbital, 60 mg
17*	Clofibrate (average daily dose)	Clofibrate, 2,000 mg
Occupational exposure		
5.8	Formaldehyde: Workers' average daily intake	Formaldehyde, 6.1 mg
141	EDB: Workers's daily intake (high exposure)	EDB, 150 mg

[a] We have tried to use average or reasonable daily intakes to facilitate comparisons [3]. In several cases, such as contaminated well water or factory exposure to EDB, this is difficult to determine, and we give the value for the worst exposure found. The calculations assume a daily dose for a lifetime; where drugs are normally taken for only a short period, we have bracketed the HERP value. [b] The asterisk means that the HERP value is from carcinogens thought to be nogenotoxic. [c] PCBs = polychlorinated biphenyls, DDE = 1,1-dichloro-2,2-bis(4-chlorphenyl)ethylene, DDT = 1,1,1-trichloro-2,2-bis(4-chlorphenyl)ethane.

into account. We have analyzed animal cancer tests from our Carcinogenic Potency Database[51-54] and, for each chemical, have calculated the TD_{50} (*T*umorigenic *D*ose 50), which is essentially the daily dose of the chemical estimated to give half of the animals tumors. We have constructed an index to rank possible carcinogenic hazards: first, we estimate a reasonable daily lifetime human exposure to each chemical and express that as milligrams (of the chemical) per kilogram of body weight. Then, that mg kg^{-1} human exposure is expressed as a percentage of the rodent TD_{50} dose (mg kg^{-1}) for each carcinogen. We call this percentage the HERP value (*H*uman *E*xposure dose/*R*odent *P*otency dose). Because rodent data are all calculated on the basis of lifetime exposure at the indicated daily dose rates,[8, 51] the human exposure data are similarly expressed as lifelong daily exposure rates, even though the human exposure is likely to be less than daily for a lifetime (Table 3).

The HERP values do not estimate human risk directly, because it is impossible to extrapolate to low doses (see Section 1), but they do offer a way of comparing possible hazards and thus of putting exposures into a relative context so that priorities can be more reasonably set. (Carcinogens clearly do not all work in the same way, and as we learn more about mechanisms, HERP comparisons can be refined, as can risk assessments.) Our results suggest that alcohol at moderate doses should be high on our priority list for epidemiological studies on cancer. The HERP analysis further suggests that the possible carcinogenic hazard of synthetic chemicals that humans ingest from pesticide residues or water pollution appears to be trivial relative to the background of carcinogenic hazards from natural chemicals and chemicals formed by cooking food.[3, 71, 93]

4.1. Water Pollution

The possible hazards from carcinogens in contaminated well water in places like California's Santa Clara ("Silicon")

Valley or Woburn, Massachusetts,[94-99] should be compared with the possible hazards of ordinary tap water.[3] Of the 35 wells that were shut down in Santa Clara Valley because of a supposed carcinogenic hazard to humans (low traces of trichloroethylene), only two were of a possible hazard greater than ordinary tap water. Well water is not usually chlorinated and therefore lacks the 83 ppb of chloroform present in average chlorinated tap water in the U.S.[3] Water from the most polluted well in the Santa Clara Valley had a relative hazard that was orders of magnitude less than that for an equal volume of coffee, beer, or wine.[3] The consumption of tap water is only about one or two liters per day, and animal evidence[3] provides no good reason to expect that either the chloroform produced in water by chlorination or the current levels of synthetic pollutants in water would pose a significant carcinogenic hazard.[3] Natural arsenic appears to be the most significant carcinogen in both well water and tap water and is often present at quite high levels.[100] Arsenic is a known human carcinogen.

The trace amounts of chemicals found in polluted wells are likely to be a negligible cause of birth defects, in comparison to the background level of known teratogens such as alcohol. The important risk factors for birth defects and reproductive damage in humans are the age of the mother, her consumption of alcohol, her smoking habits, and her exposure to the rubella virus.

4.2. TCDD (Dioxin) Compared with Broccoli and Alcohol

Cabbage and broccoli contain a chemical whose breakdown products bind to the body's Ah receptor, induce enzymes, and possibly cause cell division—just as does dioxin (TCDD), one of the most feared industrial contaminants. TCDD is of great public concern because it is carcinogenic and teratogenic in rodents at extremely low doses. The doses humans ingest, however, are far lower than the lowest doses that have been shown to cause cancer and reproductive damage in rodents.

TCDD exerts many or all of its harmful effects in mammalian cells through binding to the Ah receptor.[101] A wide variety of natural substances also bind to the Ah receptor (e.g., tryptophan oxidation products[102]) and, insofar as they have been examined, they have similar properties to TCDD. A cooked steak, for example, contains polycyclic hydrocarbons that bind to the Ah receptor and mimic TCDD. In addition, a variety of other plant substances in the diet also bind to the Ah receptor. Indole carbinol (**2**), for example, is present in large amounts in broccoli (500 ppm), cabbage,[103] cauliflower, and other members of the *Brassica* family. At the pH of the stomach, **2** forms chemical structures (known as dimers and trimers) that induce the same set of detoxifying enzymes as TCDD.[104-106] Like TCDD, **2** protects against carcinogenesis when given *before* aflatoxin or other carcinogens.[106-108] However, when given *after* aflatoxin or other carcinogens, **2**, like TCDD, stimulates carcinogenesis.[105] This stimulation of carcinogenesis has also been shown for cabbage itself.[109] These derivatives of **2** appear to be much more of a potential hazard than TCDD. The Environmental Protection Agency's human "reference dose" (formerly "acceptable dose limit") of TCDD is 6 femtograms per kilogram per day. This should be compared with 50 mg of **2** per 100 g of broccoli (one portion) (see also cabbage).[62, 103] Although the affinity of the indole derivatives in binding to Ah receptors is less than that of TCDD by a factor of about 8000, the effective dose to the Ah receptor from a portion of broccoli would be about 15000 times higher than that of TCDD, taking into account another factor of 1000 for the very long lifetime of TCDD in the body (several years) and assuming that the lifetime of the hydrophobic indole dimers is as short as one day. However, it is not clear whether, at the low doses of human exposure, *either* **2** or TCDD is hazardous. It seems likely that many more of these natural "dioxin simulators" will be discovered in the future.

If TCDD is compared with alcohol, it seems of minor interest as a teratogen or carcinogen. Alcohol is the most important known human chemical teratogen.[72] In contrast, there is no persuasive evidence that TCDD is either carcinogenic or teratogenic in humans, although it is both at near-toxic doses in rodents. If one compares the teratogenic potential of TCDD to that of alcohol for causing birth defects (after adjusting for their respective potency as determined in rodent tests), then a daily consumption of the EPA reference dose of TCDD (6 fg) would be equivalent in teratogenic potential to a daily consumption of alcohol from 1/3000000 of a beer. That is equivalent to drinking a single beer (15 g of ethanol) over a period of 8000 years.

In humans alcoholic beverages are carcinogenic[110] as well as teratogenic. A comparison of the rodent carcinogenic potential of TCDD with that of alcohol (adjusting for the potency in rodents) shows that ingesting the TCDD reference dose of 6 fg per kilogram per day is equivalent to a man ingesting one beer every 345 years. Since the average consumption of alcohol in the United States is equivalent to more than one beer per person per day, and since five drinks a day are a carcinogenic risk in humans, the experimental evidence does not of itself seem to justify the great concern over TCDD at levels in the range of the reference dose.

5. Misconception No. 5: The Toxicology of Man-made Chemicals Is Different from That of Natural Chemicals

It is often assumed that, because plants are part of human evolutionary history, whereas industrial chemicals are not, the mechanisms that animals have evolved to cope with the toxicity of natural chemicals will succeed in protecting them against natural chemicals, yet will fail to protect against synthetic chemicals: "For the first time in the history of the world, every human being is now subjected to contact with dangerous chemicals, from the moment of conception until death" (Rachel Carson: *Silent Spring*, 1962). We find this assumption flawed for several reasons.

5.1. Defenses That Animals Have Evolved Are Mostly of a General Type

Since the number of natural chemicals that might have toxic effects is so large, general defenses offer protection not

only against natural but also against synthetic chemicals, making humans well buffered against toxins.[3, 7, 103, 111] These defenses include the following: (1) The continuous shedding of cells exposed to toxins: the surface layers of the mouth, esophagus, stomach, intestine, colon, skin, and lungs are discarded every few days. (2) The induction of a wide variety of general detoxifying enzymes, such as antioxidant enzymes[20, 21, 112] or the glutathione transferases for detoxifying alkylating agents:[113] human cells that are exposed to small doses of an oxidant, such as radiation or hydrogen peroxide, induce antioxidant defenses and become more resistant to higher doses.[114–118] These defenses can be induced by both synthetic oxidants (e.g., the herbicide paraquat) and natural oxidants and are effective against both. (3) The active excretion of planar hydrophobic molecules (natural or synthetic) out of liver and intestinal cells.[119] (4) DNA repair: this is effective against DNA adducts formed from both synthetic and natural chemicals and is inducible in response to DNA damage.[26] (5) Animals' olfactory and gustatory perception of bitter, acrid, astringent, and pungent chemicals: these defenses warn against a wide range of toxins and could possibly be more effective in warning against some natural toxins that have been important in food toxicity during evolution than against some synthetic toxins. However, it seems likely that these stimuli are also general defenses and are monitoring particular structures correlated with toxicity; some synthetic toxic compounds are also pungent, acrid, or astringent. Even though mustard, pepper, garlic, onions, etc., have some of these attributes, humans often ignore the warnings.

The fact that defenses are usually general, rather than specific for each chemical, makes good evolutionary sense. Predators of plants evolved general defenses against toxins presumably to be prepared to counter a diverse and ever-changing array of plant toxins in an evolving world; if a herbivore had defenses only against a set of specific toxins it would be at a great disadvantage in obtaining new plant foods when favored plant foods became scarce or evolved new toxins.

5.2. Various Natural Toxins, Some of Which Have Been Present throughout Vertebrate Evolutionary History, Nevertheless Cause Cancer in Vertebrates

Mold aflatoxins, for example, have been shown to cause cancer in trout, rats, mice, monkeys, and, possibly, humans.[3, 110] Eleven mold toxins have been reported to be carcinogenic[103] and nineteen mold toxins have been shown to be clastogenic.[75] Many of the common elements are carcinogenic (e.g., salts of lead, cadmium, beryllium, nickel, chromium, selenium, and arsenic) or clastogenic[75] at high doses, despite their presence throughout evolution.

Furthermore, epidemiological studies from various parts of the world show that certain natural chemicals in food may be carcinogenic risks to humans: the chewing of betel nuts with tobacco around the world has been correlated with oral cancer.[110, 120] The phorbol esters present in the Euphorbiacea, some of which are used as folk remedies or herb teas, are potent mitogens (inducers of cell proliferation) that are thought to be a cause of nasopharyngeal cancer in China and esophageal cancer in Curacao.[121, 122] Pyrrolidizine toxins are mutagens that are found in comfrey tea, various herbal medicines, and some foods; they are hepatocarcinogens in rats and may cause liver cirrhosis and other pathologies in humans.[120]

Plants have been evolving and refining their chemical weapons for at least 500 million years and incur large fitness costs in producing these chemicals. If these chemicals were not effective in deterring predators, plants would not have been naturally selected to produce them.

5.3. Humans Have Not Had Time to Evolve into a "Toxic Harmony" with All of the Plants in Their Diet

Indeed, very few of the plants that humans eat would have been present in an African hunter-gatherer's diet. The human diet has changed drastically in the last few thousand years, and people are eating many recently introduced plants that their ancestors did not, for example, coffee, cocoa, tea, potatoes, tomatoes, corn, avocados, mangoes, olives, and kiwi fruit. In addition, cruciferous vegetables such as cabbage, broccoli, kale, cauliflower, and mustard were used in ancient times "primarily for medicinal purposes" and were spread as foods across Europe only in the Middle Ages.[123, 124] Natural selection works far too slowly for humans to have evolved specific resistance to the food toxins in these newly introduced plants.

5.4. Poisoning from Plant Toxins in the Milk of Foraging Animals Was Quite Common in Previous Centuries

In nonindustrial societies, cow or goat milk and other ingested dairy products were contaminated by the natural toxins from plants that were eaten by foraging animals, because toxins that are absorbed through the animal's gut are often secreted in the milk. Since the plants foraged by cows vary from place to place and are usually inedible for human consumption, the plant toxins that are secreted in the milk are, in general, not toxins to which humans could have easily adapted. *Abraham Lincoln*'s mother, for example, died from drinking cow's milk that had been contaminated with toxins from the snakeroot plant.[125] When cows and goats forage on lupine, their offspring may have teratogenic abnormalities, such as "crooked calf" syndrome caused by the anagyrine in lupine.[126–128] Such significant amounts of these teratogens can be transferred to the animals' milk that drinking the milk during pregnancy is teratogenic for humans:[126–128] in one rural California family, a baby boy, a litter of puppies, and goat kids all had a "crooked" bone birth defect. The pregnant woman and the pregnant dog had both been drinking milk obtained from family goats that had been foraging on lupine, the main forage in winter.[126–128]

5.5. Anticarcinogenic Chemicals in the Diet May Help to Protect Humans Equally Well against Synthetic and Natural Carcinogens

Although plants contain anticarcinogenic chemicals (e.g., antioxidants) that may protect against carcinogens,[129, 130]

these anticarcinogens *do not distinguish* whether carcinogens are synthetic or natural in origin.

5.6. Although Synergism between Synthetic Carcinogens Could Multiply Hazards, This Is Also True of Natural Chemicals

Natural chemicals are by far the major source of chemicals in the diet.

5.7. Although the Synthetic Pesticide DDT Bioconcentrates in the Food Chain Due to Its Unusual Fat Solubility, Natural Toxins Can Also Bioconcentrate

DDT is often viewed as the typically dangerous synthetic pesticide because it persists for years; it was representative of a class of chlorinated pesticides. Natural pesticides, however, also bioconcentrate if fat-soluble: the teratogens solanine (and its aglycone solanidine) and chaconine, for example, are found in the tissues of potato eaters.[131-133] Although DDT was unusual with respect to bioconcentration, it was remarkably nontoxic to mammals, saved millions of lives, and has not been shown to cause harm to humans.[134] To a large extent DDT, the first major synthetic insecticide, replaced lead arsenate, a major carcinogenic pesticide used before the modern era; lead arsenate is even more persistent than DDT. When the undesirable bioconcentration and persistence of DDT and its lethal effects on some birds were recognized, it was prudently phased out and less persistent chemicals were developed to replace it. Examples of these newer chemicals are the synthetic pyrethroids that disrupt the same sodium channel in insects as DDT,[135] are degraded rapidly in the environment, and can often be used at a concentration as low as a few grams per acre.

6. Misconception No. 6: Storks Bring Babies and Pollution Causes Cancer and Birth Defects

The number of storks in Europe has been decreasing for decades. At the same time, the European birth rate also has been decreasing. We would be foolish to accept this high correlation[136] as evidence that storks bring babies. The science of epidemiology tries to sort out the meaningful correlations from the numerous chance correlations. That is, epidemiology attempts to determine correlations that may indicate cause and effect. However, it is not easy to obtain persuasive cause-and-effect evidence by epidemiological methods, because of inherent methodological difficulties.[10] There are many sources of bias in observational data, and chance variation is also important. For example, because there are so many different types of cancer and birth defects, by chance alone one might expect some of them to occur at a high frequency in a small community here and there. Toxicology provides evidence that can help us decide whether an observed correlation might be causal or accidental.

There is no persuasive evidence from epidemiology or toxicology that pollution is a significant cause of birth defects or cancer. For example, the epidemiological studies of the Love Canal toxic waste dump in Niagara Falls, New York, or of dioxin in Agent Orange,[137, 138] or of pollutants produced by the refineries in Contra Costa County, California,[139, 140] or of the contaminants in the wells of Silicon Valley[141] or Woburn, Massachusetts,[94-99] or of the now-banned pesticide DDT, provide no persuasive evidence that pollution was the cause of human cancer in any of these well-publicized exposures. At Love Canal, where people were living next to a toxic waste dump. the epidemiological evidence for an effect on public health is equivocal. Analyses of the toxicology data on many of these cases suggest that the amounts of the chemicals involved were much too low relative to the background of naturally occurring carcinogens and carcinogens from cooking food to be credible sources of increased cancer in humans.[3] With respect to birth defects, a comparative analysis of teratogens using a HERP-type index, which would express the human exposure level as a percentage of the dose level known to cause reproductive damage in rodents, would be of interest. Such an analysis has not been done in a systematic way.

Environmental exposures to industrial chemical pollutants are thousands of times lower than some occupational exposures to these same agents.[3, 8] Thus, if ppb levels of these pollutants were causing cancer or birth defects, one might expect to see an effect in the workplace. So far, however, epidemological studies on these chemicals do not suggest an association with cancer.[142]

Historically, for chemicals that have been shown to increase cancer in the workplace, exposures were at high levels. For example, in California the levels of the fumigant ethylene dibromide (EDB) that workers were allowed to breathe in were once shockingly high.[3] We testified in 1981 that our calculations showed that the workers were allowed to breathe in a dose higher than the dose that gave half of the test rats cancer. California lowered the permissible worker exposure more than a hundredfold. Despite the fact that the epidemiology on EDB in highly exposed workers does not show any significant effect, the uncertainties of our knowledge make it important to have strict rules about workers, because they can be exposed chronically to extremely high doses.

7. Misconception No. 7: Trade-offs Are Not Necessary in Eliminating Pesticides

Since no plot of land is immune to attack by insects, plants need chemical defenses—either natural or synthetic—in order to survive pest attack. "It has been suggested that one consequence of crop plant domestication is the deliberate or inadvertent selection for reduced levels of secondary compounds that are distasteful or toxic. Insofar as many of these chemicals are involved in the defense of plants against their enemies, the reduction due to artificial selection in these defenses may account at least in part for the increased susceptibility of crop plants to herbivores and pathogens..."[143] Thus, there is a trade-off between natural pesticides and man-made pesticides.

Cultivated plant foods commonly contain fewer natural toxins than do their wild counterparts. For example, the wild potato, the progenitor of cultivated strains of potato, has a glycoalkaloid content about three times that of cultivated strains and is more toxic.[144, 145] The leaves of the wild cabbage (the progenitor of cabbage, broccoli, and cauliflower) contain about twice as many glucosinolates as cultivated cabbage.[146] The wild bean contains about three times as many cyanogenic glucosides as does the cultivated bean.[147] Similar reductions in toxicity through agriculture have been reported in lettuce, lima bean, mango, and cassava.[65]

One consequence of disproportionate concern about synthetic pesticide residues is that some plant breeders are currently developing plants that are more insect-resistant and, thus, higher in natural toxins. Two recent cases illustrate the potential hazards of this approach to pest control. (1) When a major grower introduced a new variety of highly insect-resistant celery into commerce, a flurry of complaints were made to the Centers for Disease Control from all over the country, because people who handled the celery developed rashes when they were subsequently exposed to sunlight. Some detective work found that the pest-resistant celery contained 6200 ppb of carcinogenic (and mutagenic) psoralens instead of the 800 ppb present in normal celery (Table 2).[64, 103, 148, 149] It is not known whether other natural pesticides in the celery were increased as well. The celery is still on the market. (2) A new potato, developed at a cost of millions of dollars, had to be withdrawn from the market because of its acute toxicity to humans when grown under particular soil conditions—a consequence of higher levels of the natural toxins solanine and chaconine. Solanine and chaconine inhibit cholinesterase, thereby blocking nerve transmission, and are known rodent teratogens. They were widely introduced into the world diet about 400 years ago with the dissemination of the potato from the Andes. Total toxins are present in normal potatoes at a level of 15 mg per 200-g potato (75 ppm), which is less than a tenfold safety margin from the measurably toxic daily dose level for humans.[144] Neither solanine nor chaconine has been tested for carcinogenicity. In contrast, the cholinesterase inhibitor malathion, the main synthetic organophosphate pesticide residue in our diet (0.006 mg per day), has been tested and is not a carcinogen in rats or mice. Common cultivars of plants differ widely in the level of particular natural toxins (Table 2),[103] and other factors in the plant also play a part in pest resistance. Breeding or genetic engineering can be used to increase or decrease specific chemicals or other factors.

Certain cultivated crops have become popular in developing countries because they thrive without costly synthetic pesticides. However, the trade-offs of cultivating some of these naturally pest-resistant crops are that they are highly toxic and require extensive processing to detoxify them. For example, cassava root, a major food crop in Africa and South America, is quite resistant to pests and disease; however, it contains cyanide at such high levels that only a laborious process of washing, grinding, fermenting, and heating can make it edible; ataxia due to chronic cyanide poisoning is endemic in many of the cassava-eating areas of Africa.[150] In one part of India, the pest-resistant grain *Lathyrus sativus* is cultivated to make some types of dahli. Its seeds contain the neurotoxin β-*N*-oxalylaminoalanine, which causes a crippling nervous system disorder, neurolathyrism.[151]

As an alternative to synthetic pesticides, it is legal for "organic farmers" to use the natural pesticides from one plant species against pests that attack a different plant species: for example, rotenone (which Indians used to poison fish) or the pyrethrins from chrysanthemum plants. These naturally derived pesticides have not been tested as extensively for carcinogenicity (rotenone is negative, however), mutagenicity, or teratogenicity as have synthetic pesticides; therefore, their safety compared to synthetically derived pesticides should not be prematurely assumed.

There is a tendency for nonscientists to think of *chemicals* as being only synthetic and to characterize synthetic chemicals as toxic, as if every natural chemical were not also toxic at some dose. Even a recent National Research Council report[152] states: "Advances in classical plant breeding ... offer some promise for nonchemical pest control in the future. Nonchemical approaches will be encouraged by tolerance revocations. ..." The report was concerned with pesticide residues in tomatoes, but ignored the natural pesticides in tomatoes. Tomatine, one of the natural toxins in tomatoes, is a recent chemical, too, since it was introduced to the world diet from Peru 400 years ago. Neither tomatine nor its aglycone, tomatidine, an antifungal steroidlike molecule, has been tested in rodent cancer bioassays. Tomatine is present at 36 mg per 100-g tomato (360 ppm), a concentration that is much closer to the acutely toxic level in humans than are the concentrations of man-made pesticide residues.[144]

Efforts to prevent hypothetical carcinogenic risks of 1 in a million could be counterproductive if the risks of the alternatives are worse. For example, Alar was withdrawn from the market after the EPA proposed cancellation hearings on it and after the Natural Resources Defense Council (NRDC) went to the media to get the process accelerated.[93] However, we incur various risks by withdrawing Alar, and these risks should be addressed. Alar is a growth regulator that delays ripening of apples so that they do not drop prematurely, and it also delays overripening in storage. Alar plays a role in reducing pesticide use on some types of apples, particularly in the Northeast.[153] Without Alar, the danger of fruit fall from the pests known as leafminers is greater, and more pesticides are required to control pests. When fruit falls prematurely, pests on the apples remain in the orchard to attack the crop the next summer, and more pesticides must be used. Since Alar produces healthier apples that stay on the trees, Alar-treated fruit is less susceptible to molds. Therefore, it is likely that the amounts and variety of mold toxins present in apple juice (e.g., patulin[154–157]) will be higher in juice made from untreated apples. The carcinogenicity of patulin has not been adequately examined.[158] Another trade-off of eliminating Alar is decreasing the availability of domestically grown, fresh apples throughout the year and increasing the price of apples, which might lead consumers to substitute less healthy foods.

Synthetic pesticides have markedly lowered the cost of plant food, thus promoting increased consumption. Eating more fruits and vegetables, and less fat, may be the best way to lower risks of cancer and heart disease (other than giving up smoking).

8. Misconception No. 8: Technology Is Harmful to Public Health

Modern technologies are almost always replacing older, more hazardous technologies. Billions of pounds of trichloroethylene (TCE), one of the most important nonflammable, industrial solvents, and perchloroethylene (perc), the main drycleaning solvent in the United States, are used because they are low in toxicity and are not flammable. Chlorinated solvents replaced flammable solvents in industry and in dry cleaning; this was a major advance in fire safety, with a minor trade-off of an occasional ppb contamination in water.

Eliminating a carcinogen may have unwanted effects. For example, 1,2-dibromoethane (ethylene dibromide, EDB), the main fumigant in the United States before it was banned in 1984, was present in trivial amounts (about 0.4 ppb) in our food: the average daily intake was a possible carcinogenic hazard, about one-tenth that of the aflatoxin in the average peanut butter sandwich, itself a minimal possible hazard (Table 3).[3] It is possible that the elimination of EDB fumigation will result in greater insect infestation and contamination of grain by carcinogen-producing molds. This would result in a reduction in public health, not an advance, and would greatly increase costs. Furthermore, alternative fumigants to replace EDB do not appear satisfactory and may be more hazardous and expensive.

Similarly, modern synthetic pesticides replaced more hazardous substances, such as lead arsenate, one of the major pesticides before the modern era. Lead and arsenic are both natural, highly toxic, and carcinogenic. Pesticides have increased crop yields and have brought down the price of foods, a major public health advance. Each new generation of synthetic pesticides is more environmentally and toxicologically benign.

Every living thing and every industry "pollutes" to some extent. The fact that scientists have developed methods to measure part per billion levels of chemicals and are developing methods to measure parts per trillion, makes us more aware of toxicity, but does not mean that exposure to toxins is necessarily increasing or that detected chemicals are causing human disease. Minimizing pollution is clearly desirable for other reasons, but is a separate issue from cancer prevention; getting the most pollution reduction for the lowest economic cost is, of course, important.[159]

Focusing on minor rather than major health risks is counterproductive. If we divert too much of our attention to traces of pollution as a public health concern we do not improve public health—and, in the confusion, the important hazards may be neglected: for example, smoking (400 000 deaths per year), alcohol (100 000 deaths per year), eating unbalanced diets) such as too much saturated fat and cholesterol and too few fruits and vegetables), AIDS, radioactive radon released from the soil into homes, and high-dose occupational exposures to chemicals.

It is the inexorable progress of modern technology and scientific research that is likely to lead to a decrease in cancer death rates, a decrease in the incidence of birth defects, and an increase in the average human life span.

What Will Chemistry Do in the Next Twenty Years?

By George Whitesides*

The path of chemistry in the future will be determined both by its participation in solving large-scale societal problems and by its generation of new ideas through basic research. This article sketches four of the areas of societal "pull" in which chemistry will play a role in solving applied problems—national security, health care, the environment, and energy—and four areas in which basic research will be especially fruitful—materials chemistry, biological chemistry, computational chemistry, and chemistry exploring the limits of size and speed in chemical phenomena.

1. Introduction

Chemistry advances on two feet: one is utility, one curiosity. A prediction of its future path can only be a guess, based on its past progress and its present position. The *most* interesting and important directions to come—those that represent radical departures from the present—I cannot predict. What I *can* identify are societal concerns that seem certain to require solutions that are (at least in part) technical, and scientific ideas that seem equally certain to drive basic research for at least some time. What are these societal problems and scientific ideas?

I propose to organize this discussion in terms of the "pull" of societal concerns and the "push" of science and technology. I suggest four topics in each category (Table 1). A fifth topic under "pull"—globalization— is probably equally important as a determinant of societal concerns. The technical aspects of globalization (as opposed to its political or commercial aspects) are, however, largely subsumed in the other topics. I start with a discussion of the four current societal issues, not because they are more important than the four scientific themes driving basic research, but because they provide the context for discussions of applications of the basic research.

Table 1. The "pull" of societal concerns and the "push" of basic research set the direction of chemistry.

Pull	Push
National Security	*Materials Chemistry*
Economic competition as the equivalent of war	Polymers
	Surfaces and interfaces
	Functional and "smart" materials
Health Care	Materials for manufacturing
An aging population	Environmentally compatible materials
Global epidemics	
Cost containment	*Biological Chemistry*
Drugs	Molecular recognition
	Evolution and self-assembly
The Environment	Bioenergetics
Global change	
Waste management	*Computational Chemistry*
Toxicology	Increasing power
	New architectures: massively parallel machines and neural nets
Energy	
Alternatives to fossil fuels	
Electricity	*Small Basic Science*
	Exploring the limits: very small; very fast; very large
Globalization	

2. Societal Concerns That Will "Pull" Chemistry

2.1. National Security

Concern for national security is a major determinant of the allocation of resources. ("National" will, undoubtedly, be replaced by "regional" as globalization proceeds, but the concern remains the same.) National security concerns (largely meaning, in the past, military concerns) have been a major source of motivation, developmental capital, and markets for new technology. Development of nuclear power, high-octane gasoline, penicillin, computers, the jet airplane, and satellite communications, for example, all had roots in military problems.

For an interval (and perhaps permanently), we can hope that the probability of large-scale war between major powers will be small. What, if anything, will take the place of war as the ultimate expression of national and regional competition? As concerns with military technology decline, what will the consequences be for the development of new technology?

One form of competition that seems certain to intensify is economic. The future success or failure of nations—as judged by their ability to pay for essential public services for their citizens—may be based largely on their ability to compete in global markets. This competition will, I believe, emphasize an ability to produce and sell products with very high quality and acceptable cost for consumer markets. Chemistry will certainly play a key role in manufacturing and economic competitiveness, because it supplies key materials to virtually all manufacturing sectors of the economy.[1] Further, as the manufacturing process becomes more highly integrated—with, for example, designers of plastic automobile body parts ultimately specifying the detailed molecular weight distribution of the polymers from which these parts are made, to ensure the quality and reproducibility of their injection-molding processes—chemistry will necessarily be more heavily involved in materials, design, and manufacturing issues. *Simply making chemical compounds will not suffice for economic success.*

The shift in focus of national security from national defense to economic competitiveness will probably foster a

[*] Prof. G. M. Whitesides
Department of Chemistry, Harvard University
12 Oxford Street, Cambridge, MA 02138 (USA)

shift in emphasis from very high performance materials to materials for manufacturing. At the same time, national subsidies for materials-related research will decline, and an increasing share of these research and development expenses will fall upon corporations. In effect, until or unless there are changes in national policies that will make manufacturing a government priority (unlikely, in most countries, in a world in which capitalism has emerged triumphant), the shift from military to economic defense will represent a form of privatization of national security.

One other, smaller, area of national competition (and, perhaps, cooperation) seems likely to influence the allocation of resources in technology and science—namely, "big science" projects. The motivations for these projects are complex, but a decision to pursue the manned exploration of the planets, the superconducting supercollider (SSC), or the human genome project would represent a major choice in setting national priorities in science and technology. Each of these projects has a specific molecular component, but this component can range from moderately large (for the genome project) to insignificantly small (for the SSC).

2.2. Health Care

Health care remains a central societal concern (Table 2). Four issues in health care will be important in the next years: all have implications for chemistry.

Table 2. Prevalence in USA of selected conditions [prevalence in millions]. The list of human infirmities is, depending on one's viewpoint, a sorrow or a shopping list of opportunities for biomedical research. (Adapted from *In Vivo*, January 1990; Source: Mattson Jack).

Condition	Prevalence	Condition	Prevalence
Periodontal disease	45.0	Polyps (colon/rectum)	7.0
Obesity	34.0	Diabetes sequelae	6.0
Chronic sinusitis	28.1	Insomnia	6.0
Arthritis	25.9	Cancer	4.8
Hypertension	23.7	Congestive heart failure	4.0
Osteoporosis	18.0	Ulcers	3.8
High cholesterol	17.8	Stroke	2.2
Heart conditions	16.4	Alzheimer's disease	2.0
Allergy	15.6	Emphysema	2.0
Lower back pain	15.0	Psoriasis	2.0
Depression	11.1	Benign prostatic hypertrophy	1.0
Migraine	7.7	AIDS and AIDS-related conditions (ARC)	0.7

One is an aging population. The great majority of health care costs pay for treatment of the diseases of old age—heart disease, cancer, stroke, diabetes, arthritis, and others. As the population ages, the number of individuals subject to and concerned with these diseases increases. In addition, new concerns arise—most recently, Alzheimer's disease and related neurological conditions. The importance of chemistry in developing drugs to treat these conditions, and the importance for chemistry (and for society) of forming effective interactions with biology and medicine in order to solve these medical problems, increases. The majority of drugs will continue to be chemical entities, made by chemical syntheses.

A second health-care issue is the emergence of global epidemics. Rapid, large-scale movement of people and materials between countries makes it likely that new diseases will emerge and spread rapidly: AIDS, antibiotic-resistant bacterial disease, and new strains of influenza represent current examples. There will be an increased need to respond rapidly to these epidemics with analytical and clinical tests, drugs, and vaccines.

A third health-care issue is cost. Although no one will argue that health care is not an essential component of a high standard of living, many will argue that even now health care costs too much. There will be intense pressure from both government and insurers, and as a result of competition among companies, to decrease the cost of developing and producing new drugs. The fact that many of these costs are mandated by regulatory requirements will not decrease these pressures and will, in fact, provide competitive advantage to the companies able to meet them. To meet these challenges will require the fusion of chemical and biological sciences to improve all phases of the process of drug development: screening, targeted drug design, optimization, demonstration of safety and efficacity, manufacturing, formulation, and distribution.

A fourth issue related to health care is drug abuse. The direct impact of drug use on the standard of living, especially in large cities, is large and increasing. The indirect impact—through spread of disease, damage to children born to women using drugs, loss of individuals from the work force—is perhaps even larger. Curiously, chemistry has, so far, played a relatively modest part in dealing with drug abuse: it has contributed primarily through development of clinical assays and a small number of drugs used in treating addiction. As neuropharmacology advances, chemistry may have a more active role in this area.

2.3. The Environment

The environment promises to be a major societal concern for many years (Table 3). It is based simultaneously on heartfelt popular concern and interest, inadequate scientific evidence, and exceptionally difficult matters of public policy requiring international cooperation and agreement.[2, 3] Both analysis of the problem and the technical component of its solution will require essential contributions from chemistry and active cooperation between chemistry and other fields.

Global warming is of intense current interest and will remain so until the implications of large-scale climatic change caused by human activities—especially combustion of fossil fuels and farming—have been resolved (Fig. 1). If, in fact, it is possible to establish that human activities are responsible for global warming and that this warming is undesirable, it may then be possible (or necessary) to ameliorate the climatic change by modifying these activities or by supplying corrective solutions. The role of chemistry in these activities will be crucial. The analytical methods necessary to establish the stable and reactive chemical entities in oceans and atmospheres are still incomplete; understanding the kinetics of the reactions of these chemical entities is a necessary part of global modeling; development of alternative methods of

Table 3. Public concern with environmental problems corresponds only approximately to the seriousness of these problems, as characterized by the US Environmental Protection Agency (EPA). (From L. Roberts, *Science (Washington, D.C.) 249* (1990) 616.)

EPA's top environmental problems (not in rank order)	Public concerns (in rank order)
Ecological risks	1. Active hazardous waste sites (67%)
Global climate change	2. Abandoned hazardous waste sites (65%)
Stratospheric ozone depletion	3. Water pollution from industrial wastes (63%)
Habitat alteration	4. Occupational exposure to toxic chemicals (63%)
Species extinction and biodiversity loss	5. Oil spills (60%)
	6. Destruction of the ozone layer (60%)
Health risks	7. Nuclear power plant accidents (60%)
Criteria air pollutants (e.g., smog, O_3, SO_2, NO_x)	8. Industrial accidents releasing pollutants (58%)
	9. Radiation from radioactive wastes (58%)
Toxic air pollutants (e.g., benzene)	10. Air pollution from factories (56%)
Radon	11. Leaking underground storage tanks (55%)
Indoor air pollution	12. Coastal water contamination (54%)
Drinking water contamination	13. Solid waste and litter (53%)
Occupational exposure to chemicals	14. Pesticide risks to farm workers (52%)
Application of pesticides	15. Water pollution from agricultural runoff (51%)
Stratospheric ozone depletion	16. Water pollution from sewage plants (50%)
	17. Air pollution from vehicles (50%)
	18. Pesticide residues in foods (49%)
	19. Greenhouse effect (48%)
	20. Drinking water contamination (46%)
	21. Destruction of wetlands (42%)
	22. Acid rain (40%)
	23. Water pollution from city runoff (35%)
	24. Nonhazardous waste sites (31%)
	25. Biotechnology (30%)
	26. Indoor air pollution (22%)
	27. Radiation from X-rays (21%)
	28. Radon in homes (17%)
	29. Radiation from microwave ovens (13%)

producing energy or fuels that do not generate CO_2—electricity from nuclear-, solar-, or wind-powered generators, dihydrogen from nuclear thermal cycles—will require the development of relevant materials technologies. The biochemistry of CO_2 consumption and methane generation is incompletely understood. Dramatic large-scale ideas—promoting CO_2 fixation by marine algae by adding iron to the polar seas—would require detailed modeling. We may yet be called on to produce a chemical consumer of CO_2 that is the equivalent of the Amazonian rain forest!

The management of industrial and urban waste is a second economically and technically demanding environmental problem. Cleanup of existing waste will require innovative technology, particularly if some value is to be recovered from this waste by the separation of its components. Minimization of future industrial waste will be a key part of the development of new processes, of redesigning or replacing old ones, and of integrating production of basic starting materials with manufactured products. The cost of waste management will make "yield" an increasingly important parameter and may require the large-scale modification of catalysts and processes for the largest-volume chemicals. The minimization of the quantity, environmental impact, and unfavorable public reception of industrial waste (including byproducts of chemical production such as scrap and solvents/materials used in manufacturing, packaging, use, and disposal—that is, overall production and life-cycle waste) will increasingly determine the cost of products. Minimization of costs—especially costs of waste management—is not as exciting as generating new materials and products, but will be an essential (and probably heavily regulated) part of any business that uses chemicals or materials.

The impact of requirements for waste management will, in due course, probably also strongly influence the course of basic research. University laboratories are even less well equipped to handle the costs of disposal of chemicals and treatment of effluents than are industrial laboratories—there are no customers to whom to pass on the cost! The environmental costs of a university laboratory involved in biochemistry, for example, are intrinsically less than those of a laboratory doing exploratory synthesis in organoselenium chemistry. The difference will inevitably encourage some types of research relative to others, influence the rates at which new ideas are generated in different fields, and determine the numbers of trained professionals that are produced in these fields.

A final, constant theme in concern about the environment is understanding the toxicology of chemicals and materials, both products and waste (Fig. 2). Developing truly rational

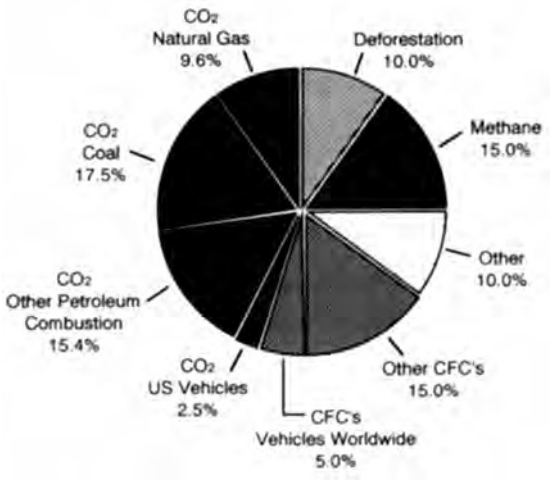

Fig. 1. Currently identified, major worldwide contributors to global warming include combustion of fossil fuels, agricultural practices, and release of chlorofluorocarbons. The contribution associated with each is uncertain.

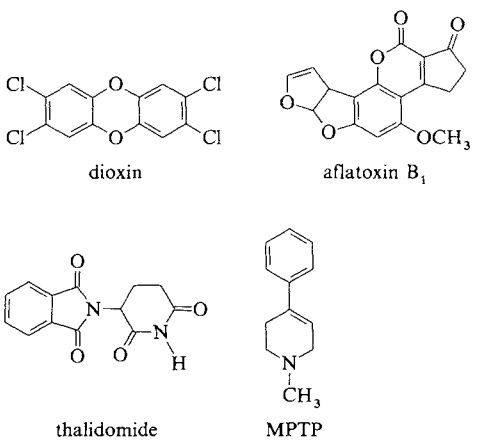

Fig. 2. The hazard associated with many prominent chemical substances (dioxin, aflatoxin, thalidomide, MPTP) was discovered only retrospectively: in most cases, this hazard could not have been predicted based on knowledge of metabolism. Accurate *prediction* of toxicity for new compounds requires much deeper understanding of metabolism and molecular biology.

bases for regulating release of chemicals into the environment or the workplace during manufacture, use, disposal, or accident may be too much to hope for, but wildly *irrational* bases for regulation are guaranteed unless we acquire a firm understanding of metabolism and toxicology of chemicals and materials and of their transformations during processing and in the environment.

2.4. Energy

The fourth major societal concern will continue to be energy. In the next 20 years the cost of energy will rise as the most readily available of the world's petroleum reserves are depleted. Whether significant new opportunities will arise for application of chemistry in enhanced oil production and exploitation of other fossil fuels, in developing technologies that promote conservation or increase fuel efficiency, or in rationally or irrationally mandated alternative fuels such as methanol and ethanol, remains to be seen.

The only technology capable of replacing fossil fuel combustion in very large-scale power generation is, of course, nuclear. If nuclear generation does reemerge as a politically acceptable source of power, the replacement of liquid hydrocarbons by electricity as an energy source for vehicles will create a myriad of opportunities in batteries and electrically functional materials (such as conductors, insulators, and dielectrics) (Fig. 3). Even if the transition from fossil-fuel-based to nuclear power is slow, regulations designed to control urban air pollution now seem certain to force the development of electric and hybrid-combustion electric automobiles. This process of regulation is most clear and most advanced in southern California. In this matter, with high probability, "As goes Los Angeles, so goes the world!"

Fig. 3. The General Motors "Impact" prototype electric vehicle. Environmental issues and a declining availability of petroleum are forcing serious consideration of electric and hybrid automobiles. These vehicles will require new materials and technologies for electrical storage and use, for lightweight, aerodynamic construction, and for safe operation.

The development of small, safe nuclear reactors might, in the longer term, make electrochemistry and high-temperature chemistry attractive for new chemical processes.

3. Four Scientific Themes That Will Push Chemistry

One reason for pursuing scientific research is to solve problems; another is to understand how nature functions. Three scientific themes in chemistry—materials chemistry, biochemistry, and computational chemistry—have captured the interest and imagination of many chemists, because these areas offer important problems in basic science, rapidly advancing analytical technology to use in addressing these problems, and opportunities for applications. Each of these three themes will remain strong for years to come.

A broad range of other areas in basic research are also being explored on smaller scale. From these many exploratory efforts, I have arbitrarily selected one representative theme that seems certain to produce important new science: research involving phenomena occurring at scales of size, time, or intensity that have historically defined the limits or boundaries of interest of chemistry—that is, phenomena occurring at scales of fractions of atomic dimensions, or faster than bond vibrations.

3.1. The Chemistry of Materials

The chemistry of materials is the first of the major scientific themes that will unite broad areas of research in the future.[4] Chemistry has moved from the study of atoms and small molecules to the study of large molecules and collections of molecules. One focus of this study is the chemistry of materials (an area of ill-defined boundaries, sharing many concerns with polymer and solid-state chemistry, condensed matter physics, and materials science and engineering). Two of the broad objectives of this area are understanding the macroscopic properties of matter based on a knowledge of its microscopic (atomic-scale) structure, and preparing new materials having new properties. Questions representing these objectives would be: "How can one predict the structure and moduli of a organic polymer knowing only the structure of its monomeric units?" and "How can one synthesize a solid that is superconducting at 400 K?" The chemistry of materials is an exceptionally broad field, and I will only touch on a few themes here.

3.1.1. Man-made Polymers

Man-made polymers have historically been the most important of the contributions of chemistry to materials science. It seems unlikely that there will be many new commodity polymers introduced in the future. A new polymer would have to provide fundamentally new properties or significantly lowered cost for existing properties to justify its introduction; neither possibility seems likely. New *processes* for existing monomers and polymers will, however, be important, to minimize byproduct streams and environmental costs and to adapt to changing raw materials. These process improvements for manufacture of large-volume chemicals (and production of hydrocarbon fuels), and development of new processes to produce specialty polymers, will continue to provide important and deeply challenging problems in catalysis.

Heterogeneous systems based on polymers—phase-separated copolymers, alloys, fiber-reinforced composites—provide a field of great interest and utility.[5] The development of fundamental understanding of all aspects of these systems is still at an early stage. Fiber-reinforced composites represent a particularly interesting example. In principle, these systems offer very attractive properties; in practice, their application has been limited by incomplete fundamental understanding of almost every aspect of their behavior: What is the atomic basis of fracture in composites? How are composite properties related to the bulk properties of the matrix, the fiber, and the matrix–fiber interface? How is energy dissipated in the solid at the molecular level? Answering these questions will require a deep understanding of the atomic/molecular behavior of solids under stress.

3.1.2. *Surfaces and Interfaces*

Surfaces and interfaces are ubiquitous in systems from microelectronic devices through heterogeneous catalysts to living tissue.[6] One trend in materials is toward the use of nanostructured materials—that is, materials having components with dimensions of 0.2–100 nm. In nanostructured materials, interfaces may be major determinants of properties and may constitute a significant fraction of the total volume of the system. The interface can be considered, in a certain sense, as a separate phase of matter. Interfaces are regions where gradients in properties can be very steep, and where structure, properties, and reactivity can be very different from those in bulk matter (Fig. 4).

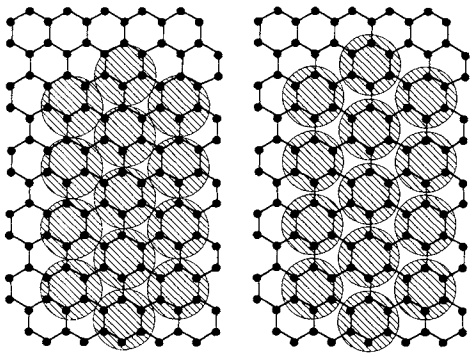

Fig. 4. Monolayers of matter can show behavior distinct from that of bulk matter. For example, krypton on graphite shows two distinct crystalline phases, one commensurate with the underlying graphite lattice, one incommensurate. (Adapted from work of R. Birgenau, *Science (Washington D.C.) 232* (1986) 329.)

New analytical techniques—from X-ray photoelectron spectroscopy (XPS) to scanning tunneling microscopy (STM)—have revolutionized the study of interfaces.[7] Synthetic techniques such as chemical vapor deposition (CVD)[8] and molecular self-assembly make possible a high level of control over the structures of interfaces. Combination of these analytical and synthetic techniques makes interfacial chemistry as tractable now as solution chemistry has been in the past.

Developing structure–property relationships for interfaces will be an extremely rewarding area of condensed matter science and invaluable in the design and applications of materials whose properties are based on phase-separated systems.

3.1.3. *Functional and "Smart" Materials*

A current challenge to materials synthesis is the design and preparation of materials with exceptional properties. Three recent examples are metal oxide high-temperature superconductors,[9] polyaniline-derived organic conductors,[10] and vapor-deposited diamond thin films.[11] The list of candidates for new ideas in design is enough to engage the creativity of those interested in the solid state for the foreseeable future: examples include "room temperature" ($T_c \approx 400$ K) superconductors, materials with very large nonlinear optical coefficients,[12] organic ferromagnets,[13] solids having negative Poisson's ratios,[14] thermally conducting organic solids, and high-temperature elastomers.

The availability of materials with unusual properties leads naturally to what promises to be a major area of materials science in the next years: namely, the development of so-called smart materials and structures—materials and structures that respond to their environment with large changes in one or several of their properties. Examples of smart materials are photochromic glasses (which change color in response to light),[15] ferromagnetic fluids (which change shape in response to magnetic field gradients),[16] and electrorheological fluids (which change viscosity in response to electric fields).[17] These materials often exhibit their interesting properties as reflections of cooperative behaviors—phase changes and aggregation—of central interest in pure chemistry. They offer the basis for new classes of devices (in the examples given, sunglasses, rotary magnetic seals, and clutches).

3.1.4. *Materials for Manufacturing*

The increased emphasis on understanding and controlling manufacturing has highlighted a broad series of problems offering both basic and applied components. For example, understanding the wetting of solids by polymers and the flow of polymers in high shear is central to understanding the manufacturing of composites, injection molding of polymers, and a host of other technologies. These areas have also provided a stimulus to try to rationalize the motion of fluids (especially polymeric fluids) near interfaces.[18] Designing packages for integrated circuits has focused attention on understanding the influence of strain on thin films and on controlling adhesion and the coefficient of thermal expansion in these systems.

Virtually every manufacturing process—molding, machining, welding, coating—contains elements of basic science that have seemed in the past too complicated and too applied to address at the level of basic science (Fig. 5). The combination of new analytical techniques, advanced computational techniques, and practical necessity now makes many of these problems tractable. In the same way that much of the basic research in biochemistry has been supported under the banner of "health care," "manufacturing" (as opposed

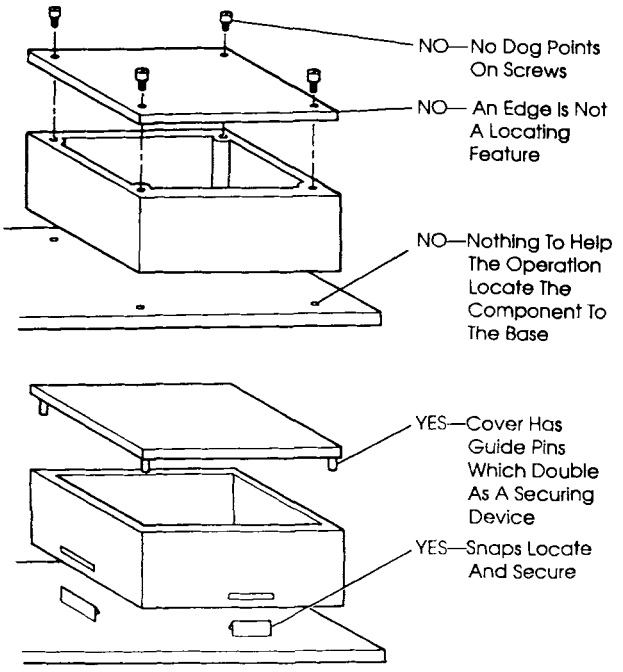

Fig. 5. Design for manufacturing (DFM) introduces complex shapes into molded parts. Successful application of DFM requires close control over materials and process variables. (Adapted with permission from a drawing by Munro and Associates, Inc.)

to "high-performance materials for defense") may provide both the justification and the focus for a broad group of neglected but very interesting problems in the chemistry of materials.

3.1.5. Environmentally Compatible Materials and Processes

The concern of society for the environment has been slow to sink into the chemical consciousness and slower still to be converted into programs leading to new classes of materials *designed* for compatibility with the environment. At least two themes have, however, emerged from this concern to receive increased (although still small) effort in materials science: materials that can be recycled[19] and materials that will biodegrade.[20] Both of these themes are, of course, well recognized, but their ultimate impact in terms of new materials and processes in not yet defined.

3.2. Biological Chemistry

The second major scientific theme dominating current basic chemistry and certain to push chemistry in the future is the study of the substances and reactions relevant to life. Biology has been the center of one of the great intellectual revolutions of the century, and its excitement will continue for many years. Reducing the broad descriptions provided by biology to molecular detail, exploiting the knowledge from these molecular descriptions in pharmacological and agricultural chemistry, and extracting new principles of organization and reaction for development in nonbiological systems are a central occupation of chemistry.

The scope and speed of development of biology and biological chemistry are so broad as to make any short description trivial, but some of the areas of opportunitiy for chemistry are already well established.

3.2.1. Molecular Recognition

A very large number of biological processes share a common event: the selective recognition of one molecule or molecular fragment by another in the very complex mixture present in the cell or organism, as well as the association of these two entities.[21] Although this sort of recognition—of an enzyme for its substrate (and perhaps transition state) or of a receptor for its ligand—is ubiquitous, understanding the basis for molecular recognition in sufficient detail to make successful predictions has proved astonishingly difficult.[22, 23] Chemistry has been very successful in dealing with systems involving single strong bonds—the covalent bond, the hydrogen bond. Biological systems seem to utilize large numbers of relatively weak interactions, occurring over large areas of molecular surface, together with poorly understood contributions from solvent, to achieve selectivity in recognition. A range of techniques—from site-specific mutagenesis through two-dimensional NMR spectroscopy and X-ray analysis to computation—is now being focused on understanding molecular recognition in biological systems. There is every reason to expect rapid progress in this area, but no reason to expect that there will be a single solution to it, or that molecular recognition will ultimately prove to be simple.

An application and extension of molecular recognition is the problem of "rational drug design".[24] The process of drug development is presently slow and expensive, with much time spent in random trial and error. In principle, it should be possible to make this process much more efficient by taking advantage of techniques from molecular biology. The proposed paradigm (much oversimplified) would have three steps: first, through studies of biology, identify a key enzyme or receptor involved in a disease; second, clone the gene for this protein, obtain substantial quantities of it, and determine its structure by X-ray crystallography; third, design and synthesize molecules that bind tightly to its active site (Fig. 6). This process would, of course, only generate tight-binding inhibitors of key target proteins and would

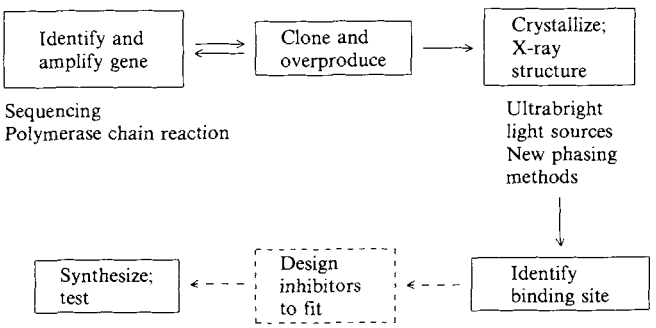

Fig. 6. All phases of the paradigm for rational design of candidate drugs work well, except for that part requiring the design of organic molecules to fit specific sites on proteins.

leave the other parts of the cycle of drug discovery—testing for safety and efficacity, manufacturing—unchanged. It would, nonetheless, shorten and simplify the overall process.

All elements of this process work well except that of designing molecules to fit an active site. This problem in molecular recognition has proved difficult, and, although certain specific systems have yielded impressive results, the difficulty and labor involved in achieving these successes have remained large.[25]

A third aspect of studies of molecular recognition that has increasingly attracted attention focuses on "biodiversity". Nature, so the teleological argument goes, achieves tight binding by randomly generating many structures (for example, polypeptides) and selects from among these, using various strategies, those having biological activity. Can chemistry use the same strategy? Can it generate compounds randomly, and efficiently select desirable activities from this random collection?

It is clear that this approach can sometimes work brilliantly, especially when chemical and biological approaches are coupled. One example is the development of catalytic monoclonal antibodies, by raising antibodies to analogues of transition states.[26] There are, so far, no purely chemical analogues to this type of process, since it is difficult to achieve the type of selection and amplification that characterizes life in nonbiological systems. The challenge of developing practical tactics for generating large numbers of compounds, and for selecting desirable activities from them is, however, being actively studied.

A final theme in molecular recognition is that of binding "simple" molecules to one another[22, 23] and to relatively ordered biological targets such as nucleic acids.[27] Starting from the discovery of crown ethers and proceeding to recognition based on hydrogen-bonding networks, it has been possible to generate satisfyingly specific interactions, often by incorporating and adapting naturally occurring recognition elements. The extension of these systems to self-replicating structures, complex self-assembled molecules, and related topics promises to offer substantial understanding of recognition, to provide guidelines for synthesizing structures based on noncovalent interactions, and to generate new reagents for biochemistry.

3.2.2. *Evolution and Self-assembly*

The origin of life and the nature of evolution are among the great questions in natural science. Early studies showed that it was possible to form simple molecules under plausible prebiotic conditions, but gave no hint of the route from these simple species to complex ones, or to living organisms.[28] Demonstrations of plausible pathways from α-amino nitriles to porphyrins and from glycolaldehyde phosphate to ribose have established a new paradigm for examining this type of problem and offer evidence that the path from simple to complex molecules may be remarkably direct.[29] These studies suggest that a broad range of processes in the early molecular stages of evolution should be reconsidered and perhaps used as the basis for new types of chemical reactions.

These studies open one new door along the corridor leading (perhaps) from an undifferentiated, primordial soup to life; they leave others still closed, or only slightly ajar. The spontaneous assembly of certain classes of molecules into assemblies or structures held together by noncovalent bonds is also central to understanding the procession from molecules to life. "Self-assembly" is clearly relevant to the formation of lipid membranes, to the folding of polypeptides into globular proteins, and to a wide variety of other processes leading to organized assemblies in biological systems.[30 - 32] Self-assembly has also stimulated interest in uncovering the rules for these systems and in using them in nonbiological or quasi-biological systems to form new types of structures (such as ordered monolayer films, liquid crystals, and liposomes).

These advances in a number of separate areas have suggested sections of a pathway from molecules to life. A key part of the path—that dealing with self-replication of the organized ensemble representing a primitive cell—still remains hidden.[33] A major step in understanding self-replicating systems might enable chemistry to begin to make serious proposals concerning the origin of life.

3.2.3. *Bioenergetics*

One of the most interesting unresolved puzzles in biological systems is that surrounding "vectorial" chemistry (Fig. 7). Energy is stored in all organisms (to some extent) in

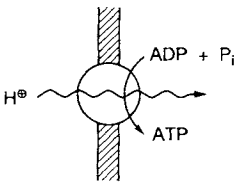

Fig. 7. In biological systems, energy is stored, in part, in concentration gradients across membranes. The discharge of a concentration gradient coupled with the formation of a chemical bond is a ubiquitous process in biology, but poorly understood at the molecular level.

the form of concentration gradients of ions across membranes.[34] Despite its enormous importance, this idea—*Mitchell*'s famous chemiosmotic hypothesis—has virtually no nonbiological model. How is the discharge of the concentration gradient coupled to the formation of ATP from ADP?[35]

The structures of the proteins involved in these vectorial processes are now emerging and will help to solve the puzzle.[36] As with molecular recognition, however, until good models that have predictive power have been developed, the puzzle of how energy is stored in and regenerated from concentration gradients across cell membranes remains unsolved.

3.3. Computation

The use of computation is the third major scientific theme that will push chemistry in the future. Computational power is one of the few items in chemistry that is rapidly becoming more available. Large-scale computation has traditionally

been the province of the "quantum mechanician". Computation (especially in semiempirical forms such as molecular mechanics,[37] molecular dynamics,[38] and large-scale simulation) is now rapidly becoming an indispensable component of experimental programs as well, particularly those concerned with complex systems. The power of computation is such that calculated results may exceed experimental results in their ability to identify trends and to distinguish contributions of individual factors. It is, for example, straightforward by simulation to "mutate" an NH group in a protein into a CH_2 group while leaving other elements of the structure unchanged, or to change the dielectric constant of water.[39, 40] Accomplishing these transformations experimentally is, obviously, more difficult (or impossible!).

Identifying some of the pending changes in the technology of computation is relatively straightforward: chemistry is, in general, a follower rather than a leader in applying computers, and one has only to look at computationally more advanced areas—electrical engineering, fluid dynamics, or computer science—to see what will be available. In addition to an ever lower "price per bit" and "price per flop", the next years will see exploration and application to chemistry of two important new architectures in computers: massively parallel machines and neural networks (Fig. 8). The former

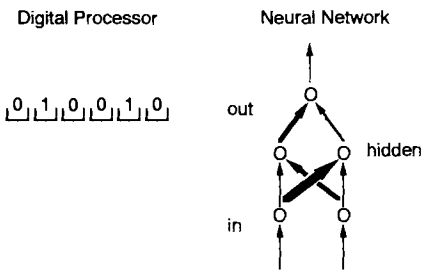

Fig. 8. The information in a digital processor (a conventional computer) is stored in bits (0 or 1) in specified locations. The information in a neural network is stored in connections of different strengths between nodes. Neural networks are particularly useful for analyzing complex nonlinear problems where high numerical precision is not required and for problems in pattern recognition. The fact that chemistry has many such problems suggests that neural networks may be useful here.

should make it possible to handle problems involving very large numbers of atoms (or other components); the latter is presently poor for problems requiring high numerical precision, but may be excellent for certain types of problems involving pattern recognition, highly nonlinear relationships, or relationships in which the functional form connecting input and output is unknown.[41, 42]

To what problems will these new methods of computation be applied? To calculations in molecular and supramolecular structure and reactivity, of course, but also to a range of problems that have historically been outside the realm of chemistry: fracture, complex coupled systems of many reactions in the atmosphere or in a cell, flow of a non-Newtonian polymer, and protein folding. The routine incorporation of large-scale computation into experimental programs has as much potential as any other technique to change the way in which chemistry is practiced.

3.4. Exploring the Limits: Very Small, Very Fast, Very Large

This fourth theme that will push chemistry is one of many that could be identified in basic research. The new capabilities and ideas emerging constantly in chemistry and in related areas of physics and biology are an astonishing testimonial to the vitality of these fields. Chemistry has begun, in certain areas, to push to the limits of what is usually defined as "chemistry". It is, for example, now possible to visualize atoms directly and to study processes occurring more rapidly than a bond vibrates. There is an enormous amount to be learned now, and in the future, by studying phenomena occurring at these boundaries of the intellectual territory named chemistry. Whether chemistry will respond to reaching these boundaries by pushing further (for example, to studies of inner-shell electrons) or whether, more probably, it will turn toward other frontiers (for example, very complex systems and the chemistry of cognition, perception, and memory[43]) remains to be seen. Some of the activities in basic research at the present limits are discussed below.

3.4.1. Very Small

The scanning tunneling microscope (STM) and its many progeny have started a revolution in the visualization of structure.[44] Subatomic-scale resolution—the limit of interest in almost all chemical problems—of nonperiodic structures is routine in many systems, although interpretation of STM images remains a challenge. STM will clearly be a key instrument for high-resolution structure determination in conducting materials; atomic force microscopy provides complementary information, including information concerning insulators.

The phrase "very small" applies to quantity as well as size. The polymerase chain reaction (PCR) has made routine the manipulation of very small numbers of copies of a gene.[45] As chemistry incorporates techniques from biology, the PCR and yet-to-be-discovered techniques for gene identification, amplification, and modification will be indispensable.

3.4.2. Very Fast

Femtosecond IR spectroscopy also reaches the practical limit of interest in chemistry.[46] The ability to follow a characteristic infrared chromophore on scales of time short compared to vibrations is clearly not a general technique, but it makes possible the analysis of bond-forming and bond-breaking processes and of energy transfer with exquisite detail (Fig. 9).

Femtosecond spectroscopy depends on the laser to generate very short pulses of light. A related application of intense photon sources is flash X-ray diffraction—using a synchrotron as a source of X-rays and an array detector to collect diffraction data, it is possible to obtain the information needed to solve the structure of a protein (in favorable cases) in very short intervals.[47]

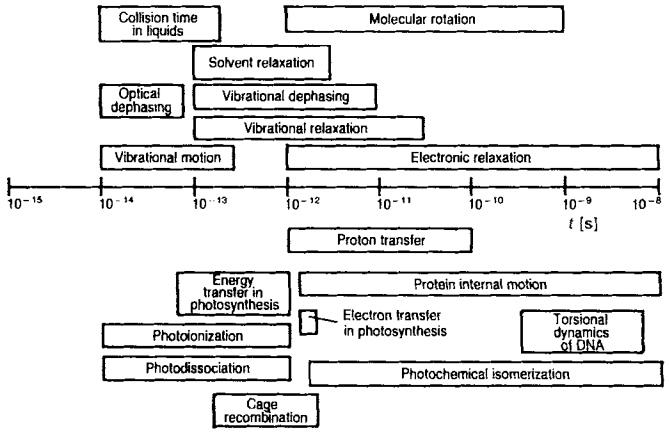

Fig. 9. Fast forms of spectroscopy have opened for investigation areas that encompass the fastest processes that concern chemistry. (From G. R. Fleming, P. G. Wolynes, *Phys. Today 43* (1990) No. 5, p. 36.)

3.4.3. Very Large

The very large electromagnetic fields generated by focused lasers make possible the ordering of particles in new ways ("light matter")[48] and even the trapping and observation of single atoms (in light traps).[49] The synthesis of isotopically pure ^{12}C diamond[50] has confirmed the theoretical prediction that this material has the largest thermal conductivity known and illustrates the coupling of theory and synthesis in materials science.

4. Conclusion

Although the subjects of interest in chemistry have changed dramatically in the last 20 years and will probably change even more in the next 20, its fundamental character remains the same. *Chemistry is the most fundamental of the sciences concerned with perceptible reality*. The affairs of nucleons and of galaxies are extraordinarily interesting, but are removed from everyday experience. Biology ultimately reduces to chemistry. Chemistry combines understanding of the molecules and processes that underlie reality as we experience it directly—from inanimate structures and fire through life—with tools to shape this reality—polymers, fuels, and drugs. It combines curiosity and utility in the direct service of man.

The details of recent changes in chemistry suggest its future. In the commercial sphere, the era of large-scale "simple" chemistry is over as an area of innovation. Discovering processes to new compounds has largely been replaced by the effort to discover sophisticated processes to existing compounds, while meeting increasingly complex boundary conditions: low cost, low capital cost, safety, environmental acceptability. Although new reactions or new catalysts always offer the opportunity to develop new processes, the emphasis has shifted to strategies for adding value to bulk chemicals—by blending or compounding them or by moving downstream to production of complex systems (coatings, multilayer films, components of composites) to meet complex needs. More carefully specified raw materials compatible with high-quality manufacturing will either be offered by chemical producers in the future or be demanded of them by users.

The chemical industry seems determined to move to materials to increase its margins and perhaps to the manufacture of engineered components. Catalysis will remain centrally important in providing economical routes to the precursors and to the final materials (Fig. 10). Although materials and components offer great opportunities, they also require a degree of sophistication in design, manufacturing, and contact with customers that is unfamiliar to many chemical companies.

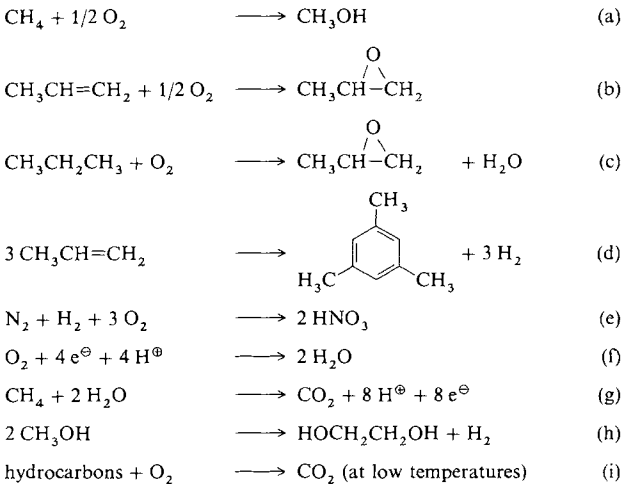

Fig. 10. Catalysis, one of the central disciplines in chemistry, offers a continuing range of challenges. All of these reactions are presently unknown or impractical, and the development of efficient reactions and catalysts to accomplish them would be useful in areas such as commodity synthesis (b, c, d, e, h), fuel transportation (a), fuel cell operation (f, g), and automobile emissions control (i).

The pharmaceutical companies expect, doubtless correctly, a stream of opportunities from biochemistry, biology, and research medicine. Organic synthesis will remain the most important technology in manufacturing drugs.

In basic science also, the focus has shifted from simple chemistry—synthesis of new organic and inorganic compounds (albeit of very great structural complexity), study of the dynamics of basic reactions—to studies of much more complex molecules, molecular ensembles, and processes. The physical-organic chemistry of 20 years ago (solvolysis of norbornyl tosylate) has become the study of factors influencing binding of oligopeptides to proteins using site-specific mutagenesis. Studies of intermolecular potentials using molecular-beam scattering has evolved into studies of two-dimensional phase separation of lipids in supported bilayers.

The problems posed by biology and by the behavior of condensed phases—solids and solutions—offer a host of opportunities for those attracted by complexity. Computers, advanced light sources, and new classes of analytical instruments capable of dealing with very small objects and very fast processes provide new tools for studying these problems. The first hints of answers to certain big questions—the origin of life, the molecular basis of memory—are beginning to appear.

What the unexpected developments will be in the next years is, of course, impossible to predict. The rate of change in chemistry and in the fields surrounding it is, however, sufficiently rapid that there is, fortunately, no doubt but that there *will* be unexpected developments. I will be lucky if the

predictions I have offered here are good for ten years; beyond that, all is conjecture.

Elementary Steps in Heterogeneous Catalysis**

By Gerhard Ertl*

Despite the great importance of heterogeneous catalysis, research in this field has long been characterized by its empiricism. Now, however, thanks to the rapid development of methods in surface physics, the elementary steps can be identified at the atomic level and the underlying principles understood. Defined single crystal surfaces are employed as models, based on the analysis of the surfaces of 'real' catalysts. Direct images, with atomic resolution, can be obtained using scanning tunneling microscopy, while electron spectroscopic methods yield detailed information on the bonding state of adsorbed species and the influence of catalyst additives (promotors) upon them. The successful application of this approach is illustrated with reference to the elucidation of the mechanism of ammonia synthesis. The catalyst surface is usually transformed under reaction conditions, and, as the processes involved are far-removed from equilibrium, such transformations can lead to intrinsic spatial and temporal self-organization phenomena. In this case, the reaction rate may not remain constant under otherwise invariant conditions but will change periodically or exhibit chaotic behavior, with the formation of spatial patterns on the catalyst surface.

1. Introduction

The term 'catalysis,' originally coined by *Berzelius* in 1835 was itself occasionally the subject of considerable controversy up to the end of the 19th century, until *W. Ostwald* was finally able to clarify its relationship to the rate of chemical reaction. How exactly a catalyst works remains, however, something of a mystery to this day. It is for this reason that the strategy of extensive catalyst screening for technical applications, introduced by *A. Mittasch* around 1909, still finds widespread use today. Between 1909 and 1912 *Mittasch* carried out about 6500 activity determinations on around 2500 different catalysts, as part of the development of the Haber-Bosch process.[1] His endeavors met with striking success—the catalyst composition he developed is still being used industrially today, in largely unaltered form. For *Fritz Haber* the catalyst question had been solved with the discovery of the catalytic activity of osmium and uranium. It soon became evident, however, that the large-scale application of such materials was hardly a realistic proposition.

Mittasch was inspired by the idea "in the catalytic production of ammonia some kind of intermediate nitrides are formed, even if of very labile nature."[2] Following the discovery of the increased activity of mixed catalysts (promotor effect), first described in a patent dated January 9, 1910,[3] he speculated, "that the nitrogen is taken up by one component and the hydrogen by another in a labile form and activated. As a result of the intimate association of both components, the strongly reactive nitrogen then unites with the similar form of the hydrogen, thus readily forming ammonia, which is then emitted". He admitted, somewhat meekly, however, "that this is just a rough model, which in theoretical terms leaves us somewhat out on a limb."[4]

Apart from the intellectual curiosity expressed in this statement, *Mittasch* had recognized that, despite the success achieved, the situation would remain unsatisfactory in practical terms as long as a better comprehension of the fundamental atomic processes was lacking. Only such an approach would one day enable an optimal catalyst to be 'tailored' for a desired application.

Nevertheless, one should always bear in mind that, for practical purposes, not only the intrinsic chemical activity but also other properties, such as the diffusive behavior, the strength, mechanical stability etc., can be decisive factors. This further complicates the situation and ensures that for a given reaction *the* catalyst is usually a pipe dream.

Thanks to the development of powerful techniques in the area of surface physics and the accompanying theoretical advances, considerable progress has been made in the last few years towards answering the major questions concerning the characterization of the elementary processes underlying a catalytic reaction. This paper will report some aspects of the advances which have been achieved as examples.

Since industrial reactions proceed on complex catalysts and under conditions, e.g. high pressure, that rule out the direct in-situ application of most of the experimental methods mentioned, the following stepwise approach has proved both expedient and successful:

1. The surface properties, especially chemical composition and the distribution of various elements, may deviate considerably from those of the bulk. It is thus first necessary to characterize the surface, and in particular the 'active centers' of a catalyst, in as much detail as possible. The so-called 'pressure gap' mentioned before can present special difficulties, as an examination under actual reaction conditions is problematical. Simplified model systems for the structure and chemical composition are therefore enlisted, above all to permit the systematic variation of these parameters. The most convenient systems for this purpose are well-defined, single crystal surfaces. Their use naturally introduces a 'materials gap', meaning one subsequently has to check, in each case, the extent to which the properties of the 'real' catalyst agree with those of the model system.

2. The essence of the surface science approach is the study of the energetics and dynamics of the interactions between the molecules participating in the reaction and the model

[**] From a paper presented at the awarding of the A.-Mittasch Medal during a colloquium celebrating the 125th. anniversary of the founding of BASF on September 24, 1990 in Ludwigshafen (FRG).

surfaces mentioned and structures of the chemisorbed phases formed thereby. On this basis, one determines the microscopic reaction mechanism and the kinetics of the elementary steps.

3. Information on the reaction mechanism, which should be as complete as possible, enables one, in principle, to develop a kinetic scheme for calculating the steady state reaction rate as a function of external parameters, such as temperature, partial pressure, etc. When translating the results to industrial conditions, the agreement between the calculated (i.e. predicted) and experimental conversions is the yardstick for success.

Although the strategy outlined has up to now only been realized thoroughly and successfully in two instances (CO oxidation and ammonia synthesis), these have demonstrated its basic soundness. Quite apart from this, even clarification of individual aspects can provide a rich vein of important data relevant to practical applications.

2. From "Real" Catalysts to Single Crystal Surfaces

Industrial catalysts are, as a rule, very complex systems in terms of the structure and chemical composition of their surfaces. This is evident in Figure 1, which depicts a scanning

Fig. 1. Scanning electron microscope image of the surface topography of a commercial ammonia synthesis catalyst [5].

electron microscope image of the BASF ammonia synthesis catalyst S6-10.[5] The topography exhibits a labyrinth of catalyst material and pores with a diameter of typically several hundred angstroms, which is reflected in the relatively high specific area of around 15 $m^2 g^{-1}$. The source material, magnetite (Fe_3O_4), which is reduced to metallic iron during the activation process, contains low concentrations of Al_2O_3 (+ CaO) and K_2O as additives. As *Mittasch* discovered,[3] these 'promotors' make an important contribution toward raising the activity. During the course of complex solid-state chemical reactions associated with catalyst activation,[6] aluminum, in the form of its ternary oxides fabricates a kind of framework, which prevents the Fe particles from sintering together, and thus plays the role of a 'structural' promotor.

The rather inhomogeneous distribution of the various elements over the catalyst surface can be seen from Figure 2 in the series of Auger electron spectra taken at different locations. In the case of No. 1, a catalytically active site with

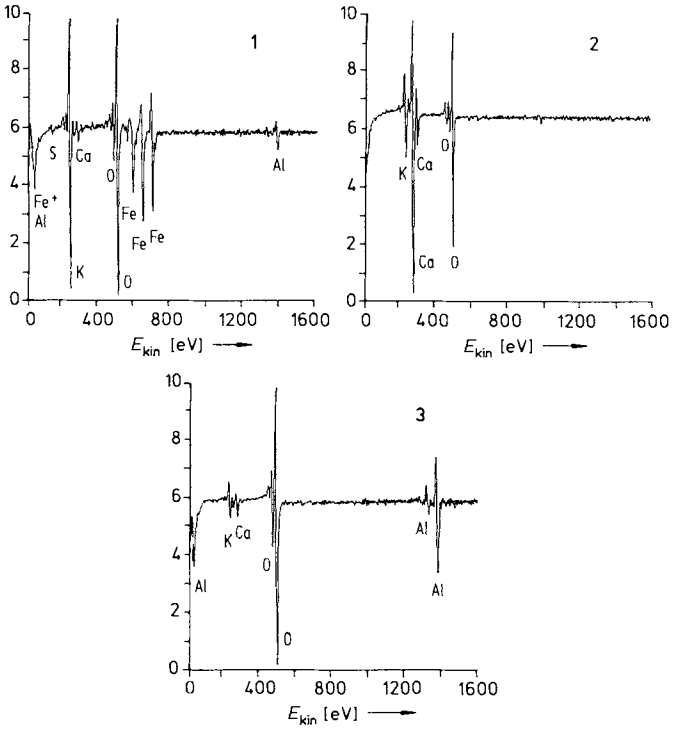

Fig. 2. Auger electron spectra from various locations on the surface of an ammonia synthesis catalyst [5]. E_{kin} = kinetic energy of the electrons.

considerable concentrations of Fe and K (+ O) is analyzed, while No. 2 largely consists of CaO, and No. 3 of Al_2O_3. The laterally resolved chemical composition of the surface is illustrated in 'Auger maps' in Figure 3. Remarkably, potassi-

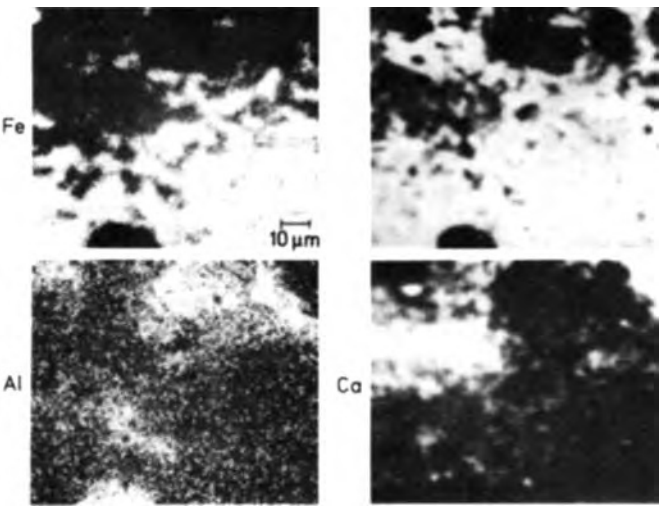

Fig. 3. 'Auger maps' showing the lateral distribution of the elements Fe, K, Al and Ca on the surface of an ammonia catalyst [5].

um is always found at locations where iron is also present. Although the total potassium concentration is only around 0.5%, its strong tendency to segregate out of the bulk leads to it covering about 30% of the metallic iron surface, where it serves as an 'electronic' promotor. More precisely, the catalytically active surface consists of metallic iron onto which a sub-monolayer amount of a two-dimensional K + O

phase (with a stoichiometry of about 1:1) is chemisorbed. This is certainly not one of the known bulk compounds of potassium, since these would be unstable under the reaction conditions.

Figure 4 depicts a high resolution transmission electron microscope (TEM) image of an activated catalyst particle, together with an electron diffraction pattern, at a selected location. The latter illustrates the single crystal character,

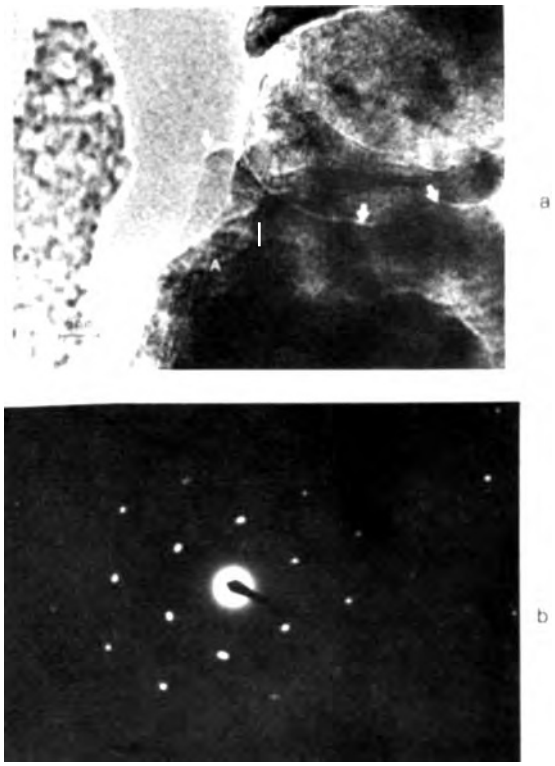

Fig. 4. a) Transmission electron microscope (TEM) image of an ammonia catalyst. Region A shows the lattice planes of a α-Fe lamella with (111) orientation. The arrows indicate the boundaries of this lamella within a stack of others having different orientations. The region on the left-hand side is amorphous carbon from the mounting support. b) Corresponding electron diffraction image, which can be identified as an iron single crystal (111) orientation [6].

which can be identified unambiguously as the (111) plane of α iron.[6] Closer inspection of the TEM image reveals the individual network layers and indicates that the catalyst primarily consists of small single crystallite particles of iron, the external surface of which, as we have previously seen, is partially covered with a K + O adsorption layer.

It therefore makes sense to use clean single crystal surfaces of iron with different orientations as a suitable model system for studying the influence of the atomic structure of the surface. The effect of electronic promotors can then be investigated via deliberate dosing with potassium.

Such samples have areas of at most 1 cm^2, so that measuring the conversion of a catalytic reaction represents a considerable experimental challenge. Despite this, *Somorjai* et al. were able to conduct such measurements successfully for a stoichiometric N_2:H_2 mixture at a pressure of 20 bar and a temperature of 500 °C.[8] They found that the activity varied between the various surface orientations by two orders of magnitude in the sequence (111) > (100) > (110), that is to say it was strongly influenced by the surface structure. However, even the Fe(111) surface exhibits only relatively low activity: the probability that a nitrogen molecule arriving at the surface will leave it as ammonia is only of the order of magnitude of one in a million.

The direct determination of chemisorbed complexes bound on the surface using the techniques of surface physics, requires, as mentioned above, a shift to much lower pressures ($\leq 10^{-3}$ mbar). Whether or not the surface species formed at high pressures remain stable under high vacuum depends on the temperature and the strength of the chemisorption bonding, and this has to be checked for each case individually. Provided one proceeds with adequate caution, however, surmounting the 'pressure gap' presents no problems in principle.

3. Elementary Processes in the Interaction between Molecules and Surfaces

Conceptually, a chemical reaction can be envisaged in its general form as the motion of a system of atoms along a 'reaction coordinate', in the course of which the energy changes in the manner shown in Figure 5. The local minima

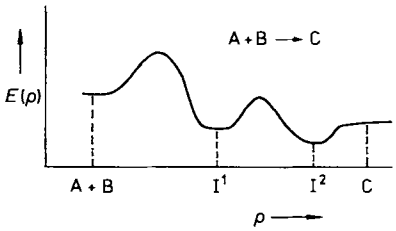

Fig. 5. Schematic diagram of the energy changes along the reaction coordinate ϱ for a chemical reaction (A + B → C). I = intermediate.

denote the nuclear configurations of intermediate compounds, while the maxima, representing the transition states, have to be overcome by summoning up the associated activation energy. Knowledge of the intermediates' properties and the rates of the respective transformations furnishes the reaction mechanism and, moreover, enables one to predict the total rate of the reaction. With the exception of the simplest gas phase reactions, a complete a priori theoretical evaluation is, however, still a long way off and one still has to rely on detailed experimental data.

The elementary processes in heterogeneously catalyzed reactions are as shown schematically in Figure 6: a molecule arriving at the surface can be bound (chemisorbed) there; the

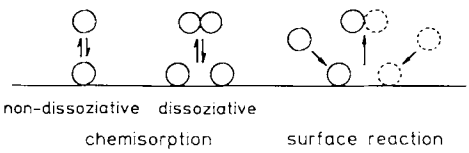

Fig. 6. Elementary processes in the interaction between molecules and a solid surface.

bonding process can be reversed and the molecule desorbed as a result of thermal activation. The surface bonding can also lead to bond rupture within the molecule (dissociative chemisorption), in which case desorption occurs via recombination of the fragments on the surface. Finally, the formation of new bonds can take place on the surface and, as a consequence of this, different molecules will then be desorbed.

It is obvious that the determination of the chemisorption complexes, together with the dynamics of their formation and transformation, is the key to understanding the elementary processes in a heterogeneously catalyzed reaction. Nowadays there is a whole variety of experimental methods available for such work.[9] These have recently been augmented in a spectacular fashion by the invention of scanning tunneling microscopy (STM) by *Binnig* and *Rohrer*.[10] Figure 7 illustrates the direct imaging of an Al(111) surface with

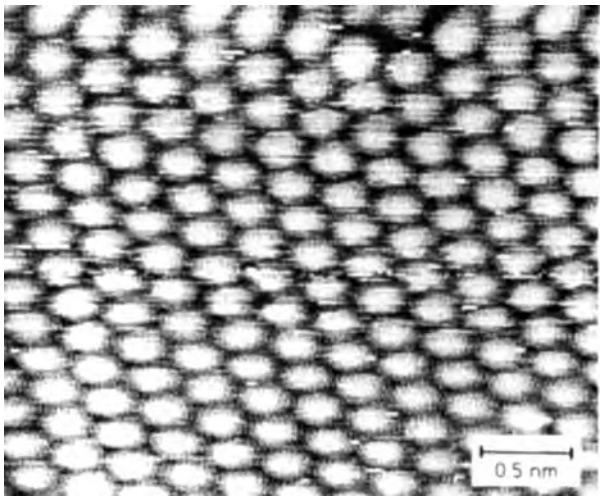

Fig. 7. Image of an Al(111) surface with atomic resolution obtained with the help of scanning tunneling microscopy [11].

atomic resolution as obtained by this technique.[11] Figure 8 shows the same surface with three chemisorbed C atoms.[12] One can see that these favor a coordination with three neighboring substrate atoms, i.e. they occupy defined adsorption sites.

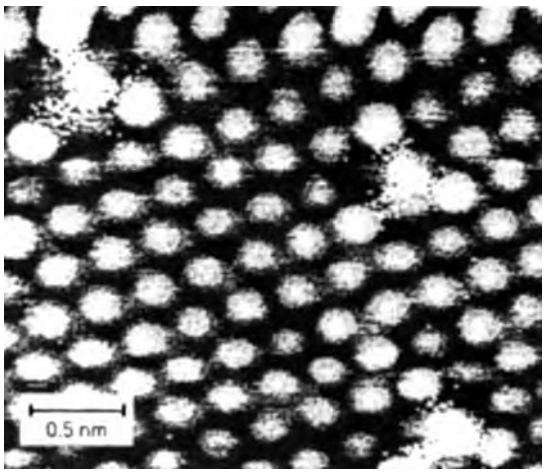

Fig. 8. Scanning tunneling microscope image of an Al(111) surface with three chemisorbed C atoms, which are discernible as diffuse light spots over a triangle of neighboring substrate atoms [12].

Generally, neighboring chemisorbed particles interact with each other, and this commonly gives rise to the formation of ordered two-dimensional phases. As an example, a sequence of STM images of a Cu(110) surface with increasing coverage of chemisorbed oxygen atoms is shown in Figure 9.[13] At low surface concentrations, small islands of a

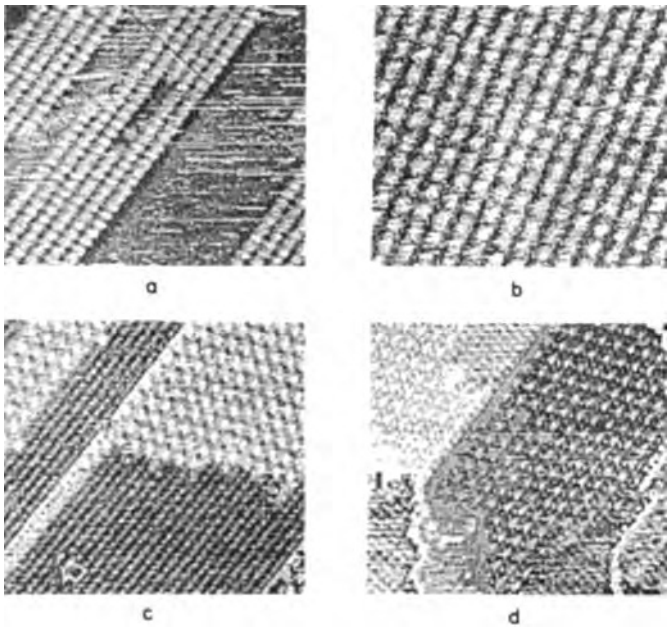

Fig. 9. Series of scanning tunneling microscope images of a Cu(110) surface with increasing O coverage [13]. a) Coverage $\theta < 1/2$: domains of a 2×1 phase together with patches of surface free from adsorbate. b) Fully developed 2×1 structure at $\theta = 1/2$. c) For $\theta > 1/2$: domains of a $c(6 \times 2)$ phase are formed in addition to the 2×1 phase (depicted as parallel streaks). d) Fully developed $c(6 \times 2)$ phase on terraces whose levels are separated by monatomic steps as differentiated by the gray scale.

2×1 phase are formed (a), which at higher concentrations cover the entire surface (b). Further increasing the degree of coverage leads to the formation of domains of an additional $c(6 \times 2)$ phase (c), rich in oxygen, which ultimately marks the saturation of the chemisorption phase (d) before the transition to three-dimensional oxide formation.

The actual structure of ordered surface phases can be determined by low-energy electron diffraction (LEED), a method which is analogous to X-ray diffraction for the determination of three-dimensional crystal structures. As an example, Figure 10 shows the structure of a 2×1 phase of chemisorbed oxygen atoms on a Ni(110) surface ascertained in this way[14] (this represents the counterpart to the previously depicted tunneling microscope image of the O-(2×1)/Cu(110) phase). The formation of chemisorption bonds has a profound influence on the substrate surface: every second row of atoms in the [001] direction is removed ('missing row' structure), that is to say the surface is reconstructed, and there is also an effect on the positions of atoms in deeper layers. Since the strength of the chemisorption bond is usually comparable to that between substrate atoms, it is entirely plausible that the most favorable overall atomic configuration may deviate considerably from that of the clean, i.e.

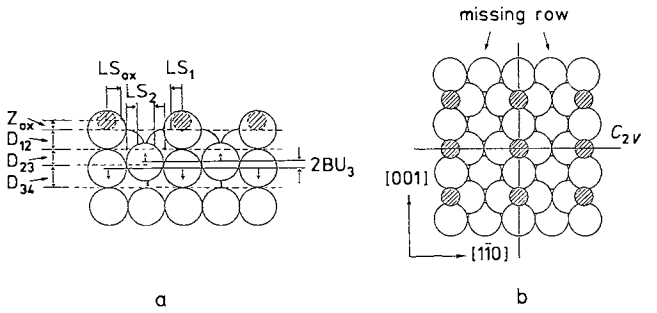

Fig. 10. Structural model of the 2×1 phase formed upon chemisorption of O atoms (shaded circles) on a Ni(110) surface [14]. Structural parameters: $Z_{ox} = 0.2$, $LS_{ox} = 0.1$, $LS_1 = 0.0$, $LS_2 = 0.0$, $D_{12} = 1.30$, $D_{23} = 1.23$, $D_{34} = 1.25$, $2BU_3 = \pm 0.05$ Å. a) Profile. b) Bird's-eye view.

adsorbate-free, surface. Conversely, there are a number of cases in which already the structure of clean surfaces deviates from the ideal bulk termination.[15]

In the above examples, the chemisorption phase was produced via the dissociative chemisorption of oxygen molecules, rather than by the action of oxygen atoms on the surface. This process is of decisive importance for catalysis, and can be rationalized with the aid of the schematic potential diagram shown in Figure 11. A molecule approaching

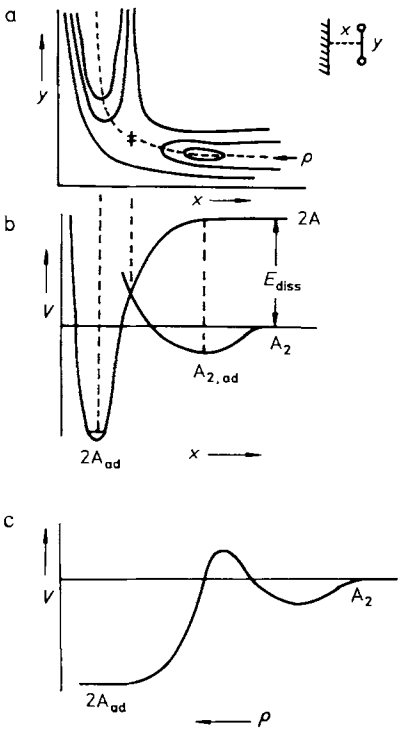

Fig. 11. Schematic potential diagram for dissociative chemisorption of a diatomic molecule A_2. a) Contour plot as a function of the distances x from surface and y between the two atoms. b) One-dimensional Lennard-Jones potential. c) Variation of potential along the reaction coordinate.

the surface experiences an initial decrease in its energy, can be weakly bound to the surface in the form of a molecular 'precursor', and will subsequently undergo dissociation when the activation barrier is surmounted. Since the formation of two bonds between the surface and the resultant two atoms more than compensates for the dissociation energy, the overall process involves a net energy gain. The course of the potential along the reaction coordinate and, in particular, the height of the activation barrier, determine the sticking coefficient, i.e. the probability that a molecule arriving at the surface will be chemisorbed dissociatively rather than bouncing back into the gas phase. Surface structure and coadsorbed particles, acting either as promotors or poisons, exert an appreciable influence at this juncture. As the rate constants of chemical reactions exhibit an exponential dependence on the activation energy, even slight energetic changes have a substantial effect on the kinetics.

4. Mechanism of Ammonia Synthesis

Let us now return to the problem of catalytic ammonia synthesis for a while. Figure 12 illustrates the increase in the surface concentration of atomically adsorbed nitrogen as a function of the nitrogen supply in the gas phase for the three low-index single-crystal surfaces of iron.[16] 1 L =

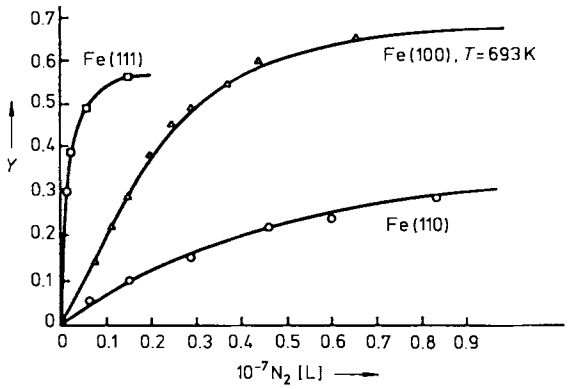

Fig. 12. Increase in surface concentration of chemisorbed N atoms (Y, in relative units) on Fe(111), (100), and (110) surfaces at 420 °C as a function of the exposure to N_2 molecules from the gas phase [16].

10^{-6} mbar s is a convenient unit for the gas exposure, because it suffices for the saturation of a surface with adsorbed particles if the sticking coefficient equals unity. Two features can be recognized from Figure 12: 1) the rate of dissociative nitrogen chemisorption depends strongly on the surface structure according to the sequence (111) > (100) > (110); 2) since typically not 1 L but $> 10^6$ L N_2 are necessary to achieve saturation, the sticking coefficient must be very low, i.e. of the order of 10^{-6}. Both findings are in full agreement with the results mentioned above concerning the catalytic activity of iron single crystal surfaces in ammonia formation, and demonstrate that the rate of ammonia synthesis is limited by the dissociative chemisorption of nitrogen. The agreement is all the more remarkable when one considers that the reaction conversions were measured at 20 bar and the chemisorption at 10^{-7} bar—the 'pressure gap' thus presents no serious hurdle in this case.

As the Fe(111) surface exhibits the highest activity, the interaction of nitrogen on this surface has been examined in

greatest detail. It has been shown that three different forms of adsorbed nitrogen can arise in this case, which may be characterized using the differing 'fingerprints' in the N_{1s}-photoelectron spectrum[17] (Fig. 13a): 1) a very weakly bound molecular state (γ), with terminal coupling[18] and a N-N stretching vibration at 2100 cm^{-1}, close to the value for the free molecule;[19] 2) under mild thermal activation, the γ-state is transformed into another molecular form (α), which is also directly populated from the gas phase and represents the actual 'precursor' for dissociative chemisorption.[20] The frequency of N-N stretching is much reduced (ca. 1500 cm^{-1}) signaling a pronounced weakening of the N–N bond.[17, 19, 21] The molecular axis is tilted with respect to the surface, so that an interaction with both nitrogen atoms occurs;[17, 18] 3) from the above state, the final dissociation ensues upon surmounting a modest activation barrier, yielding the strongly bound, atomic β form, as illustrated schematically in the potential diagram in Figure 13b.

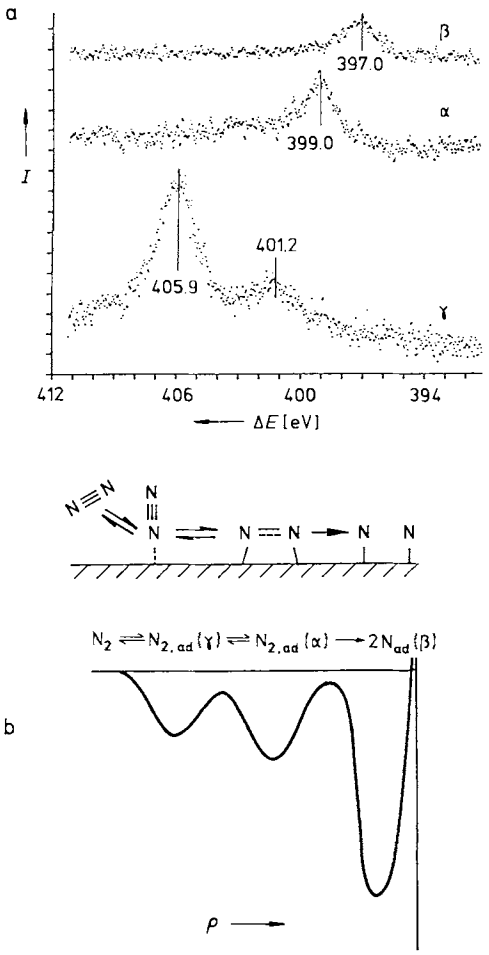

Fig. 13. N-1s photoelectron spectra of the various adsorbed N species on a Fe(111) surface (a) and the corresponding schematic potential (b) [17]. I = intensity; α,γ = molecular states; β = atomic state; $\Delta E = E - E_{Fermi}$; ϱ = reaction coordinate.

An example of a structure formed by chemisorbed N atoms on a Fe(100) surface is illustrated in Figure 14.[22] The nitrogen atoms occupy sites with fourfold coordination and, additionally, exhibit a strong interaction with the Fe atoms of the second layer. In other cases, the formation of the chemisorbed nitrogen phase is associated with considerable reconstruction of the substrate (see Section 3). Such phases can generally be denoted as 'surface nitrides' (the familiar bulk nitrides are thermodynamically unstable under the conditions of the ammonia synthesis!). *Mittasch*'s speculation that "in the catalytic formation of ammonia some kind of intermediate nitrides" arise, is thus entirely vindicated in its essence.

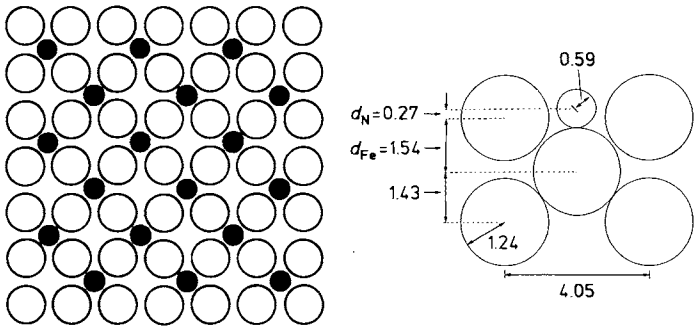

Fig. 14. Structural model of the c(2 × 2) phase formed by chemisorbed N atoms on an Fe(100) surface [22]. d = layer separation.

The role played by 'electronic' promotors can be studied by application of sub-monolayer amounts of potassium to pure iron surfaces. In this manner, it was shown that the sticking coefficient for dissociative nitrogen chemisorption could be raised dramatically.[23] This is essentially due to the increased substrate electron density in the vicinity of an adsorbed $K^{\delta\oplus}$ atom, which leads to a stabilization of the molecular α-state through increased π-back donation. This state (α_2) has a higher adsorption energy and the frequency of the N-N vibration is further lowered, thus facilitating dissociation.[21, 23–25]

The occurrence of various binding states for nitrogen on a potassium doped Fe(111) surface is manifested also in the thermal desorption spectrum, which exhibits maxima at the respective desorption temperatures (Fig. 15, curve a).[19] For

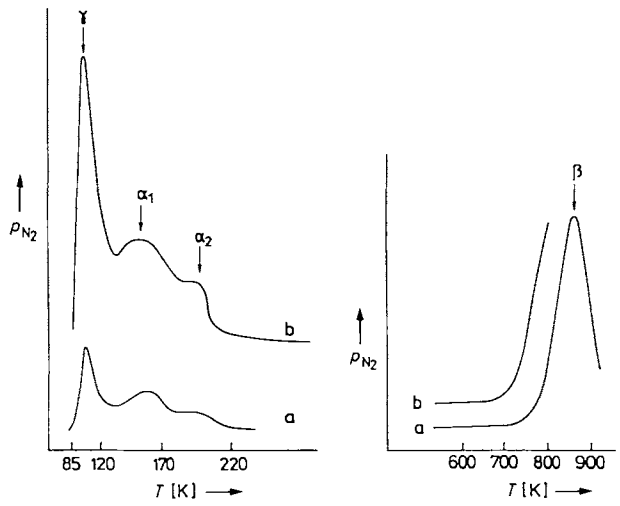

Fig. 15. Thermal desorption of N_2 from a K covered Fe(111) surface (curve a) and from a commercial ammonia catalyst (curve b) [19]. Left: desorption from the molecular states γ,α_1 and α_2. Right: Desorption following recombination of the atomic state β.

comparison, this figure depicts (curve b) data determined upon heating a nitrogen covered industrial catalyst.[26] It is notable that the temperature maxima, i.e. the respective bond energies, are in full agreement with one another. This demonstrates that the adsorption behavior of the commercial catalyst is simulated really well by the model system (Fe(111) surface, covered with around 1.2×10^{14} K atoms/cm^2). It further shows that the 'materials gap' mentioned above can be overcome in this case, and thus that the information obtained from surface science studies can form a basis for the *quantitative* modeling of 'real' catalysis in its own right.

The quintessential features of the results obtained from a large number of detailed studies on the individual steps of the catalytic ammonia synthesis are summarized in the energy diagram shown in Figure 16:[7, 27] the homogeneous reac-

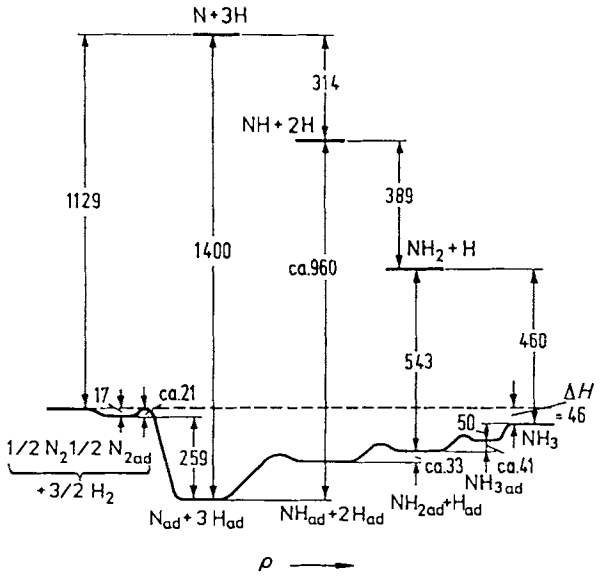

Fig. 16. Schematic potential diagram for the course of catalytic ammonia synthesis along the reaction coordinate in comparison to the energy differences for the corresponding non-catalytic steps (energy in kJ mol^{-1}) [7, 27].

tion in the gas phase would require a prohibitive amount of energy for the dissociation of the H_2 and N_2 molecules. In the presence of the catalyst, on the other hand, this process may be achieved by overcoming only relatively low energy barriers, the formation of chemisorbed nitrogen and hydrogen atoms actually even producing surplus energy. The further reaction steps comprise the successive recombination of N_{ad} and H_{ad}, ending with the desorption of NH_3. The corresponding energy demands of these elementary processes are easily met by virtue of the high reaction temperature ($\geq 400\,^{\circ}C$).

The attempt to predict the conversion in high-pressure industrial reactors using commercial catalysts on the basis of detailed information about the kinetic parameters for the individual steps, as obtained from the single-crystal model systems under the high vacuum conditions described, has been tackled by several research groups employing differing approaches.[28-29] As is evident from Figure 17, the agreement, e.g. in the analysis by *Stoltze* and *Nørskov*,[28] is really surprisingly good. This example illustrates that catalysis is

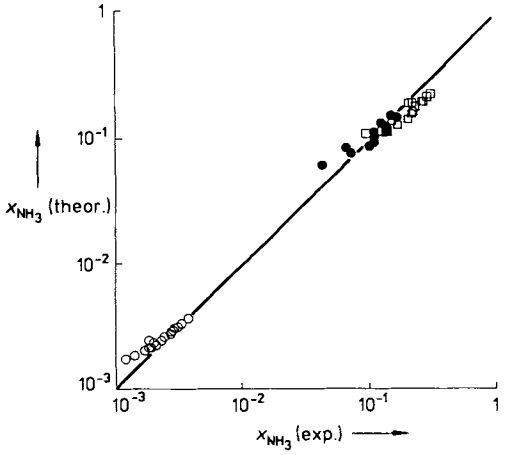

Fig. 17. Comparison of the ammonia yields determined experimentally under industrial conditions with theoretical values calculated with the help of model studies on a single surface. Taken from *Stoltze* and *Norskov* [28]. x = mol fraction. ○ = 1 atm, ● = 150 atm, □ = 300 atm.

by no means a 'black art', and that even complex technical systems can be described quantitatively via an analysis of the underlying elementary processes.

5. Nonlinear Dynamics: Temporal and Spatial Intrinsic Organization

The possibility of being able to calculate exactly the rate of a chemical reaction from a detailed knowledge of the kinetic parameters (i.e. reaction order and rate constants) for the individual steps, can admittedly, in certain cases, come up against fundamental limitations having their origins in the mathematical structure of the underlying equations.

For a catalytic reaction taking place in a continuous flow reactor, an open system well-removed from equilibrium is involved, the temporal behavior of which can be described by a series of coupled, nonlinear differential equations for the individual concentration variables (in our case the coverages by the various species), hence the expression 'nonlinear dynamics'. Systems of this kind need not behave in a stationary (i.e. time-independent) manner, even when external parameters (temperature, pressure) are maintained at constant levels, but can undergo transitions to temporal and spatial self-organization. Such phenomena were classified as 'dissipative structures' by *Prigogine* et al.[30] and were later incorporated into the general area of synergetics by *Haken*.[31]

Temporally oscillating reaction rates were observed early on in detail, e.g. with the Belousov-Zhabotinsky (BZ) reaction in homogeneous solution[32] and with electrochemical systems.[33] Such effects were first described for a heterogeneously catalyzed reaction, CO oxidation on supported Pt catalysts, by *Wicke* et al. about twenty years ago.[34] Here too, the reaction mechanism could be clarified using the strategy described.

For Pt(100) and Pt(110) single crystal surfaces at low partial pressures and under strictly isothermal conditions, the presence of CO triggers a structural transformation of the surface, with an associated increase in the sticking coefficient

for oxygen. In this way, the adsorbed CO is removed by reaction with a high probability and the surface reverts to its original structural modification. Under certain conditions, the surface can thus alternate between two states with high and low activities, giving rise to corresponding oscillations in the reaction rate. As an example, Figure 18 shows for a Pt(110) surface the development of regular oscillations following a rapid change of the O_2 partial pressure to a new value at the point marked by the arrow.[37]

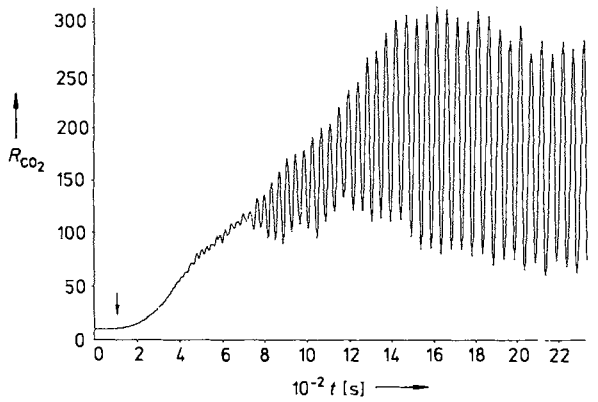

Fig. 18. Rate R_{CO_2} of catalytic CO_2 formation on a Pt(110) surface (in arbitrary units) as a function of time under steady-state flow conditions [37]. $T = 470$ K, $p_{CO} = 3.0 \times 10^{-5}$ mbar, at the point indicated by the arrow, p_{O_2} was raised from 2.0×10^{-4} to 2.6×10^{-4} mbar.

The occurrence of such oscillations is usually restricted to a certain range of values for the external parameters. In the example shown in Figure 19, small amplitude oscillations commence upon adopting a particular value of the CO partial pressure ($p_{CO} = 5.6 \times 10^{-5}$ mbar) (a). The amplitude initially grows upon further reduction of p_{CO}, while the frequency remains unchanged (b); this signals the occurrence of a so-called Hopf bifurcation. Reducing the CO partial pressure still further leads to a doubling of the period (i.e. with alternating large and small amplitudes) (c), which is then itself superseded by a further doubling (not shown here). Finally, at $p_{CO} = 5.2 \times 10^{-5}$ mbar, irregular dynamic behavior is observed. A detailed analysis[38] indicated that this reflects a transition to deterministic chaos via the so-called Feigenbaum route.[39] In contrast to the regular oscillations, the dynamic behavior is no longer predictable, hence the term 'chaos'. This effect occurs *despite the fact* that the external conditions, and thus also the mathematical formulation, are well defined (apart from small stochastic fluctuations, which can never be eliminated entirely), hence the adjective 'deterministic'.

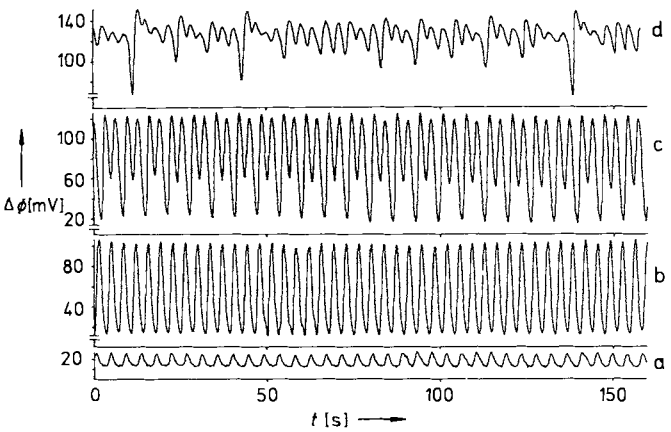

Fig. 19. Various forms of oscillation encountered during the catalytic oxidation of CO on a Pt(110) surface under steady state conditions. $T = 530$ K, $p_{O_2} = 1.1 \times 10^{-4}$ mbar, p_{CO} was varied between 5.6×10^{-5} (a) and 5.2×10^{-5} mbar (d) [37].

Chaotic phenomena occur in totally different areas and have shaken the scientific credo of being able, in principle anyway, to predict the temporal behavior of *macroscopic* systems.

The system under consideration exhibits a further peculiarity: the manifestation of temporal variations in the reaction rate integrated over the entire surface of 30 mm^2 necessitates some form of communication between different locations, i.e. an additional, spatial self-organization. For the Belousov-Zhabotinsky reaction mentioned earlier, local variations in concentration can be rendered visible by means of color differences, and manifest themselves, for example, as expanding concentric rings or spirals[40]. With the system just described, corresponding differences in CO and O coverages can be visualized using a recently developed photoemission electron microscope for which the contrast is determined by variations in the (local) work function associated with the dipole moments of the adsorbates. Two examples of the numerous different patterns formed (the phenomenology of which is dictated uniquely by temperature and partial pressure) are shown in Figure 20, corresponding to the rings and spirals of the BZ reaction mentioned earlier. It should once again be stressed that these patterns are truly two-dimensional. The contrast is created only by local differences in the coverage on an initially homogeneous surface (dark: O_{ad} coverage; bright CO_{ad} coverage). The patterns change on a time scale of about 1 s (sometimes much more rapidly too); when conditions are no longer suitable (e.g. one of the gases is cut off) the patterns disappear immediately and the surface once again assumes a fully uniform appearance.

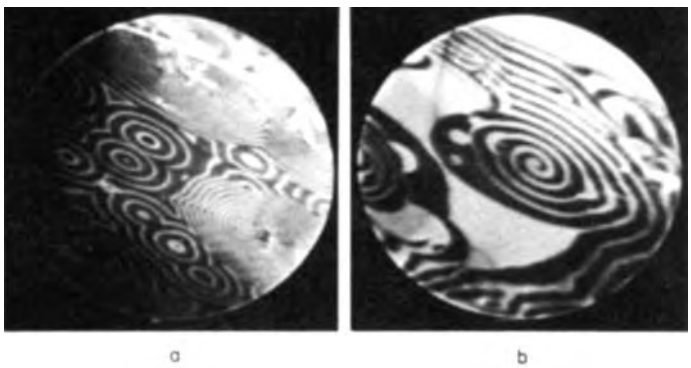

Fig. 20. Spatio-temporal pattern formation on a Pt(110) surface during the oscillatory CO oxidation. Both figures depict a section of the surface with a diameter of approximately 0.5 mm as imaged by photoemission electronmicroscopy [41]. a) $T = 430$ K, $p_{O_2} = 3.2 \times 10^{-4}$ mbar, $p_{CO} = 3.0 \times 10^{-5}$ mbar. b) $T = 435$ K, $p_{O_2} = 3.0 \times 10^{-4}$ mbar, $p_{CO} = 2.8 \times 10^{-5}$ mbar.

6. Conclusion

In this paper, an attempt has been made to show how, even for a phenomenon as complex as heterogeneous catalysis, basic research can enable one to proceed to underlying fundamental principles. This route and its likely future relevance for practical applications was formulated by *Mittasch* several decades ago as follows:[41]

"When one considers that catalysis is truly a 'land of unlimited possibilities', one cannot exclude the likelihood that continued experimental research will not only provide complete theoretical explanations, but could also become of importance in the further refinement of commercial processes."

What Does the Chemical Industry Expect from Physical and Industrial Chemistry?

By Wolfgang Jentzsch*

Process innovation—the systematic optimization of raw materials, energy consumption and product yields—is a constant challenge for those operating plants producing vital basic and intermediate chemicals. The production processes, rather than the products themselves, exhibit life cycles and determine the profitability of downstream manufacturing. The ongoing task of interdisciplinary teams of experts is not just to develop new process routes, but, more commonly, to improve individual process steps. The impulse for this innovation arises from changes in the price and availability of raw materials, economic and environmental considerations and, last but not least, scientific and technological progress. This paper illustrates the opportunities available using examples which have already been put into practice as well as problems not yet resolved. Questions such as the use of alternative feedstocks and the switch to catalytic processes are addressed and used to suggest novel ideals for basic research. Worthwhile projects are identified in the area of industrial oxidation, both catalytic and non-catalytic. A highly developed, systematic, computer-based method for optimizing the integration of energy flows within a plant is presented and novel measurement techniques for efficient production control and product quality are discussed. The successful realization of such concepts requires the ability and the willingness to think in terms of new approaches to problem solving, making this an important objective for university education geared to future needs.

1. Innovation as a Basic Corporate Element

From the very beginning, the basic entrepreneurial idea behind the chemical industry was to commercialize innovations in chemical technology. Scientific advances have always provided the basis for strategic planning.

We always have to ask ourselves which factors are responsible for success, and so ascertain the future importance of innovation and the possible contribution of basic research.

Even in the early days, the chemical industry was involved not only in the synthesis of the desired final products, but also in the necessary preliminary processing. For example, BASF manufactured not only fuchsin and Hofmann-violet, but also the aniline, sulfuric acid and soda from which they were produced. Then as now, the aim was to ensure that production costs were kept below the added value by means of extensive vertical integration, as opposed to operating just a couple of synthesis steps. In this manner, the well-known "family trees" of products arose. These are synonymous with intelligent integration of production, often yielding synergies which are decisive for success (Fig. 1).

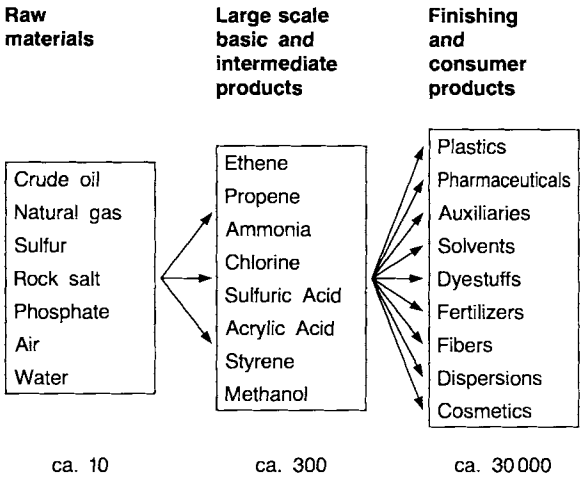

Fig. 1. From raw material to finishing and consumer products.

2. Product and Process Innovation

The various "family trees" demand different types of innovation. The relatively few commercial products marketed by the chemical industry in its infancy have since been supplanted and supplemented by several generations and many thousands of new products. In this evolutionary process, product innovation has played the dominant role, supported by progress in synthesis development. The basic stimulus has been provided by man's need for nutrition and health, clothing and housing, communication, leisure and, last but not least, mobility.

Nevertheless, the basic products have remained the same, and their total number has only increased to several hundred individual chemicals in the course of time. New final products are almost always based, for whatever reason, on existing precursors. As each precursor is converted into hundreds of commercial derivatives, one is concerned exclusively with the large-scale inorganic and organic basic chemicals, produced worldwide in thousands to millions of tons annually. There are, in all, little more than 300 such key products, and they are largely independent of changes in the range of mar-

[*] Dr. W. Jentzsch
Deputy Chairman of the Board of Executive Directors
BASF Aktiengesellschaft, E100
D-6700 Ludwigshafen

ket products. It therefore makes no sense to categorize such products as "fledgling" or "mature". The production process rather than the chemical itself exhibits a life cycle curve, as illustrated for acrylic acid in Fig. 2.

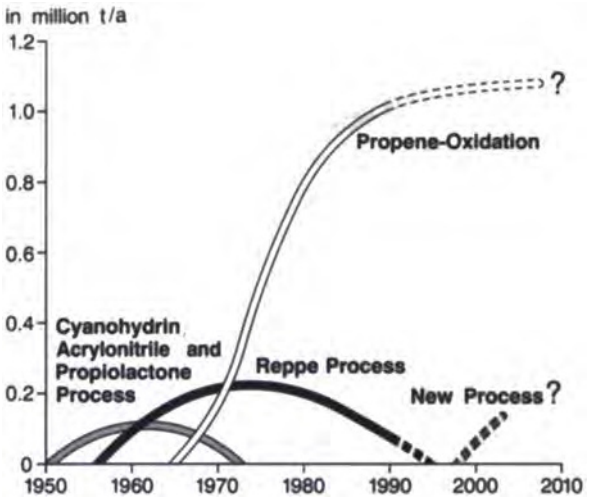

Fig. 2. Life cycles of processes for manufacturing acrylic acid.

The first three processes have already passed through their life cycles. Their demise was ushered in by the emergence of the Reppe process. This acetylene-based process too, however, has long passed its zenith and been superseded by propene oxidation. The question whether this synthesis will pass the baton on to a new process is presently unresolved. A fundamental principle in the production of such basic chemicals is evident: each innovative impulse improves the production economics, thus expanding the spectrum of applications and increasing demand. The resultant capacities, expressed in tons per annum, are almost always considerably higher than those for the preceding generation of plants.

There is virtually no room for product innovation in this area; instead, process innovation becomes the decisive factor for success. Every material, energetic, technological, or ecological advantage achieved in the large-scale synthesis propagates itself via an intricate network of chemical processing steps through to the products sold.

There is a series of entrepreneurial questions which needs to be answered in connection with every process innovation: the efficient integration of the individual process into the production network of a site and thus into the entire global strategy of production locations; whether a large-scale product should be processed internally or sold externally, and the extent to which one might profit from the success of the customer, who could also be a competitor, in the market. The detailed treatment of such questions is beyond the scope of this paper.

3. Interplay between Industrial and Academic Research

Research and development for the systematic, innovative optimization of production processes and production integration is usually carried out entirely in industry. It is here that one has access to the nucleus of know-how and where the processes are actually operated. Economic necessity thus determines both the underlying nature and methods of technical chemistry, compelling one to use simple cheap molecules as feedstocks and to exploit the most effective process parameters: catalysts, temperature, and pressure. On the other hand, the results from research in the many specialist disciplines at universities are indispensable tools for industry, and often serve to trigger innovation. Nowadays, an exceptional degree of broadly based, interdisciplinary work is the prerequisite for successful process research.

The demand for such scientific contributions is clearly increasing. If I were to attempt to illustrate this with concrete examples, I would have to anticipate future research results. Not being in a position to do this, I will try to demonstrate, using topical examples, that older process can also possess considerable potential for improvement and thus still profit from innovation. By means of some historical examples, I wish to show just how enormous the actual repercussions of an innovative impulse can be.

3.1. An Example: The Synthesis of Ammonia

I would like to use the historical development of the ammonia synthesis as an example of the interdisciplinary interplay and the contribution of fundamental research (Fig. 3). More than 80 years ago, in Karlsruhe, *Haber* managed to synthesize ammonia from its elements. The work was prompted by basic research on the law of mass action and chemical equilibrium. The technical realization of the process, however, only became possible thanks to the systematic catalyst development pursued by *Mittasch* and the elegant solution of the materials problems devised by *Bosch*—both success stories of BASF development work.

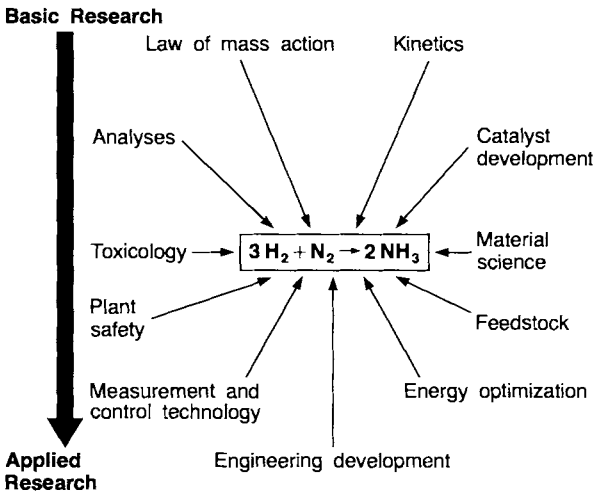

Fig. 3. Development of a basic process, using as an example the synthesis of ammonia.

The constant technological development of this process in industry and engineering firms is a model example of process innovation for a large-scale basic product: the switch from coal, via naphtha, to natural gas feedstocks and the transfor-

mation from purely thermal processing of raw materials to the present day synthesis-gas manufacture in seven catalytic stages. One should also mention the advances in mechanical and equipment technologies that have led to giant single-train plants, the development of hydrogen-resistant steels, progress in measurement, control, and process control techniques, and the systematic integration of energy flows. All these measures have brought energy consumption in the present process down very close to the theoretical level (Fig. 4).

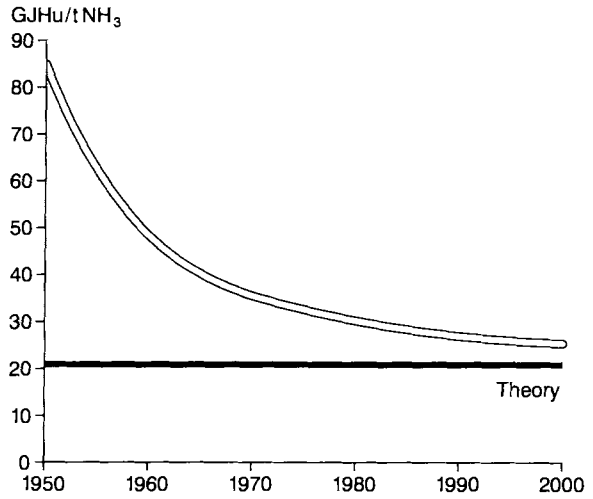

Fig. 4. Specific energy consumption of ammonia synthesis plants.

The extent of technological change is evident from a comparison of the resources required for the old and the new synthesis routes (Table 1). In contrast to the modern single-train plants, restrictions on the size of equipment and mechanical units meant that earlier plants comprised parallel batteries of production lines. Even though such plants had less than half the capacity of today's "worldscale" plants, they required twice as much area and materials. Moreover, manning was at several times present levels to cope with the time-consuming maintenance and manual plant operation and control.

Table 1. Comparison of ammonia synthesis on the basis of coke and methane.

	Multi-train plant 1940	Single-train plant 1990
Capacity [t/d]	800	1800
Plant area [m^2]	35000	18000
Steel [t]	30000	13000
Personnel	1800	50
Investment [a] [10^6 DM]	1000	300
Energy consumption [GJ/t/NH_3]	88	28

[a] Price basis 1990

Dyestuffs, fertilizers, synthetic fibers, plastics, pharmaceuticals, and plant protection agents were all beneficiaries of this gigantic improvement. It was brought about by technological and scientific progress just in the peripheral areas of process technology and by a switch in feedstocks without, however, a change in the product or chemistry of the underlying synthesis step.

4. Raw Materials as the Driving Force behind Technological Change

This leads us to another stimulus for technological change, namely variation in the price and/or availability of raw materials. The transition from coal to petrochemicals following the Second World War, in conjunction with fundamental advances in process technology, resulted in an unprecedented impulse for innovation; the era of plastics would not have been possible without this switch. The key technology involved, steam cracking, still suffers from a basic flaw, despite its technological maturity (Fig. 5). While it has proved possible to attain feedstock flexibility on the input side, an important factor for profitability, the product mix can at most be varied within narrow limits. One is thus confronted with the awkward problem of large-scale coupled production. Ethene is always the major product, and even a change of feedstock only alters the product spectrum to a slight extent. A constellation in which propene, for example, constitutes the primary product has so far proved elusive. Theoretical solutions, such as a flexible-output cracker and the functionalization of alkanes in order to produce individual products independent of the cracker mix are still hampered by lack of suitable techniques for their realization.

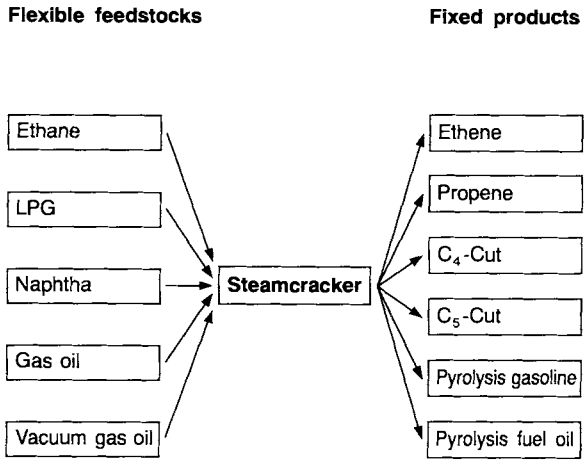

Fig. 5. Production of basic petrochemical products by steam cracking.

A topical example of a new, industrially feasible, synthesis route for an intermediate which has been important for decades is that for methacrylic acid, the monomer building block for perspex and a component of many other plastics and polymer dispersions. The conventional process (Fig. 6) is characterized by the use of chemical "auxiliaries", such as sulfuric and prussic acids, and the unavoidable formation of 2 tons of ammonium sulfate by-product for every ton of methyl methacrylate. Although not previously active in this sector, BASF developed a process (Fig. 7) based on C_1 buildung blocks in the form of synthesis gas, methanol, and formaldehyde and the C_2 component ethene. Our expertise in oxo-chemistry and with oxidation reactions proved especially valuable with the compact, purely catalytic, reaction scheme.

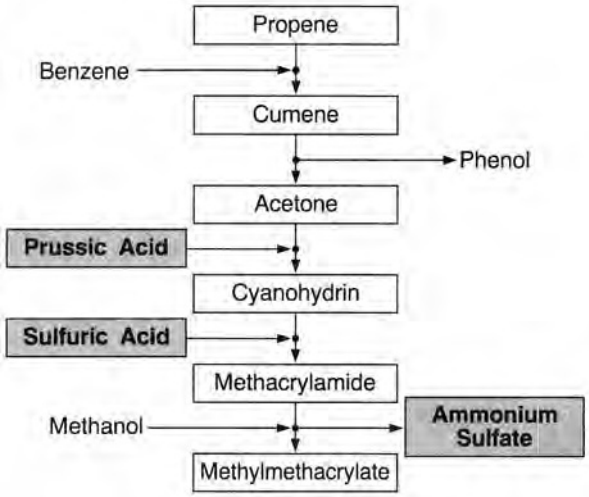

Fig. 6. Methyl methacrylate synthesis: the cyanohydrin process.

This example demonstrates the entrepreneurial and economic importance of process innovation: existing supplier structures could be broken up to the advantage of the innovator. The new process offers market benefits, providing fresh quantitative and qualitative impulses for the derived product lines. As with every new process, it contains the

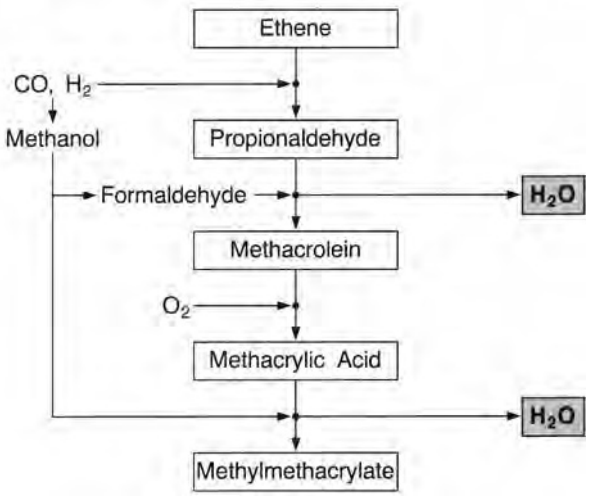

Fig. 7. Methyl methacrylate synthesis: the BASF process.

potential for further improvements. The spectrum of BASF intermediates was complemented by three important monomers: methacrolein, methacrylic acid and methyl methacrylate, thus opening new avenues for the creative synthesis chemist. Bifunctional methacrolein became available on a large scale for the first time.

5. The Potential for Improvements in Long-Established Processes

The rationalization of existing processes is of the greatest importance, and there are plenty of starting points even for well-established processes. Experts know just how difficult it is to raise the yield in the oxidation of *o*-xylene to phthalic acid anhydride even by tenths of a percent. Nobody, however, would dispute that a yield of 78% leaves considerable room for improvement. Further examples are ethene oxide, with a conversion of around 80%, and acrylic acid with 85%, all of which, it can be seen, involve oxidation reactions.

Hydrogenations, even those with exacting demands on structural selectivity and where methanization can occur, generally yield good results. In the final analysis, this could be due to the fact that with catalytic hydrogenations one can fall back on a much greater accumulation of know-how than with catalytic oxidations. Chemists were already carrying out hydrogenations with the most diverse catalyst systems at a time when they were still carrying out oxidations with chromic and nitric acids. Selective catalytic oxidations remain a challenge for the practitioner and basic science alike. The molecular processes are every bit as complex as the structure and composition of the catalysts themselves.

The material optimization of a process is always the highest priority, closely followed by the energetic aspects. Increases in yield and selectivity correlate directly to higher feedstock utilizations and lower by-product formation levels. The economic advantage of an increase in selectivity of just 1% is not just a matter of small change, but involves annual savings of millions, owing to the scale of production.

The economic advantage of an improvement in the process always goes hand in hand with environmental benefits. Higher selectivities minimize the environmental impact by saving raw materials and cutting by-products and residues for disposal.

6. The Great Importance of Catalyst Research

Catalyst optimization usually necessitates a simultaneous adaptation of process parameters in the broadest sense. The chemical reaction controlled by the catalyst, which is being studied at ever deeper levels, must be correlated with the chemistry and physics of the catalyst itself. In many cases, our knowledge of the function and the influence of promotors on the reaction is incomplete, as is the information on the structure of active and deactivated phases.

A purely empirical approach to the fine optimization of catalysts is no longer sufficient. The deeper insight into the structure of the catalytically active centers afforded by various surface analysis techniques is now indispensable. In this area, a whole new field is opening up for finding out more about the relational interaction between the nature and function of a catalyst. The characterization of a catalyst is often carried out on oxidized precursors in atypical operating atmospheres. Setting up experimental possibilities for studying the idealized situation with simulation of the operating conditions, including the material environment, would dramatically expand the horizons of our knowledge.

An oxidation process urgently in need of improvement is the air oxidation of cyclohexane to so-called anolone, a mixture of cyclohexanol and cyclohexanone (Fig. 8). Around 4 million tons of anolone are produced annually worldwide via this route. Although the yield has been increased considerably over the years, the conversion is still less than 4%. As

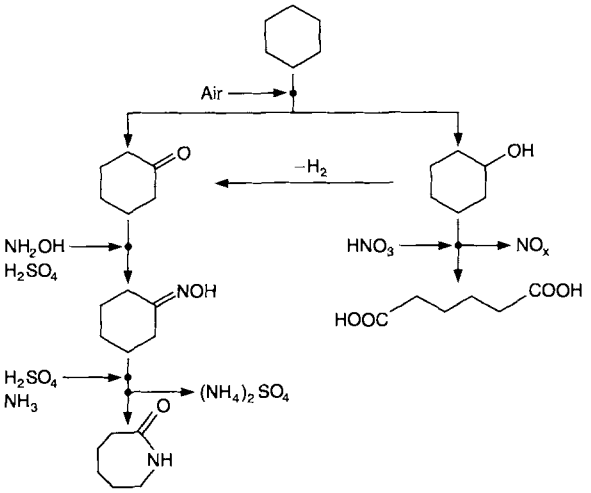

Fig. 8. Manufacture of caprolactam and adipic acid starting with cyclohexane.

a consequence, a huge amount of cyclohexane has to be recycled—a safety problem as well as one of economics.

Anolone is either oxidized to adipic acid by mixing with nitric acid, (i.e., a conventional chemical oxidation with ring cleavage) or converted to caprolactam via cyclohexanone oxime following catalytic dehydrogenation of the cyclohexanol present. New synthesis routes were developed, above all to avoid the unsatisfactory two-stage oxidation synthesis for the adipic acid fraction.

Rhone-Poulenc has patented a process whereby diacetoxybutene, which can be obtained on a large scale via the acetoxylation of butadiene, is carbonylated to the 3-hexene dicarbonic acid diester. Subsequent hydrogenation and saponification yields adipic acid. The successful technical realization of this process would offer a synthesis route for adipic acid based on butadiene.

BASF has also developed a novel synthesis for adipic acid (Fig. 9). The direct carbonylation of butadiene means that

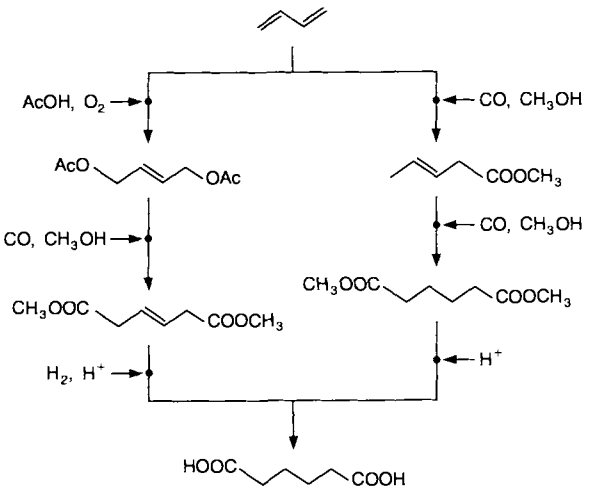

Fig. 9. Manufacture of adipic acid from butadiene.

one pays the price of a two-stage synthesis for adipic acid diester, the isomers formed being recycled after cleavage, but the process has the advantage that the C_4 cut can be drawn directly from the steam cracker. Chemical extraction of the butadiene is thus carried out concurrently with its further processing.

This provides two basic insights:

- even for large-scale products of more than 40 years standing, competition between innovations can arise, the outcome of which is by no means certain
- the raw material source for the new competitive process is a by-product from the C_4 fraction in olefin synthesis, one that has not previously been fully exploited.

The intrinsic possibilities for butadiene are by no means exhausted, and the C_5 fraction from the steam cracker is similarly not being optimally exploited. These are just a few of the many conceivable indications of the treasures which remain to be unearthed sooner or later.

7. Reduction of Energy Input

While the material rationalization remains an ongoing objective, something of an end-point has been reached in the area of energy integration down to temperatures of about 100 °C. In the 1980s, BASF made great efforts in this direction and was able to achieve considerable energy savings by the systematic application of heat integration methods in individual plants and processes. Investment in measures for saving energy by means of more intensive use of process heat not only obviated the need for a new power station, it also saved 700 tons per hour of steam. This success was reflected in a significant reduction in specific energy expenditure (Fig. 10). Despite an increase of 60% in production from

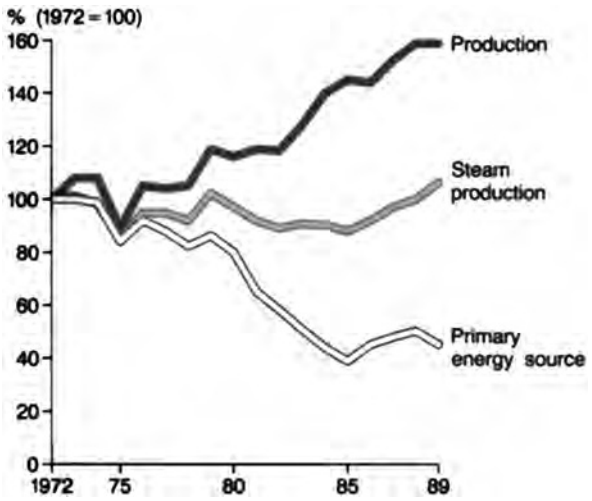

Fig. 10. Changes in production and energy consumption between 1972 and 1989.

1972, the consumption of primary energy sources was cut to 40% of its previous value. The substantial reduction in the past decade is due to the systematic implementation of the program for saving energy.

Since a reduction in the energy inputs always entails lower CO_2 and pollutant discharges, such measures have a considerable positive impact on the environment (Table 2). BASF

Table 2. Environmental advantages of energy savings.

Energy Savings	
Fuel Oil	600000 t/a
Reduction in emissions	
Carbon dioxide	1900000 t/a
Sulfur dioxide	12000 t/a
Nitrogen oxides	6000 t/a
Ash	180 t/a

has thus already made a major contribution towards cutting CO_2 emissions. This is an exceptionally successful, recent example of how innovation can be initiated by theoretical work at universities, in this case by Professor *Linnhoff* at Manchester University. The collective expertise and specific technical knowledge available in industry then enable such methods to be put into practice in production plants.

8. Further Development of Process Analysis and Control: Fascinating Opportunities

We see further innovation shortfall in electrical, measurement, and control technologies. Detailed knowledge of the individual process steps through to modelling and simulation of the entire process are a sine qua non for the further expansion of process control using advanced control systems. The increasing computer-supported application of these techniques will benefit above all those large-scale processes with varying raw materials and feedstock quality due to the resultant minimizing of energy and material inputs. Minimization of the off-specification production between charges is a further plus.

For many applications, however, a more thorough realization is impeded by a principal shortcoming: electronic data processing can combine manifold and diverse measurement data for process control; the main problem, however, lies in the determination of these data. Although the in-situ determination of temperature, pressure, flows, and certain material properties presents no real problems, sensors for on-line, or better still, in-line measurement of concentrations are, as a rule, missing. In particular, low concentrations of chemically similar substances are still elusive in terms of direct, exact determinations. This is especially true for heavy or non-volatile compounds, which cannot be monitored using gas chromatography. Even seemingly trivial questions, such as the concentration of nitric acid in sulfuric acid, of metal or salt ions in various oxidation states, or traces of metal in gas streams, can still not be resolved by direct and continuous analysis. This state-of-the-art clamors for the development of suitable sensors and measurement techniques.

Above all in solids processing, the rapid and direct determination of product state and measures to alter it are of vital importance for control and quality assurance. An important characteristic of solids processing is that the product properties depend not only on the chemical compositon but also, to a large extent, on the dispersive properties of the product. The fineness and crystallinity of a product, for example, influence the filtration process and its results to a considerable degree.

The color effect of automobile varnish paint is dictated by both the size of the pigment particles and, for example, the rheological properties of the varnish paint and its treatment. Figure 11 shows the dependency of the desired objective parameters on the measured values. Since both properties depend on particle size in differing ways, and because the color intensity should be strong and the flow limit small, there is only a narrow optimal range (gray in Fig. 11). Matters are complicated by the fact that this characteristic parameter is influenced not only by the synthesis of the pigment, but also by its subsequent treatment, such as drying, confection, or dispersion in the varnish paint resin.

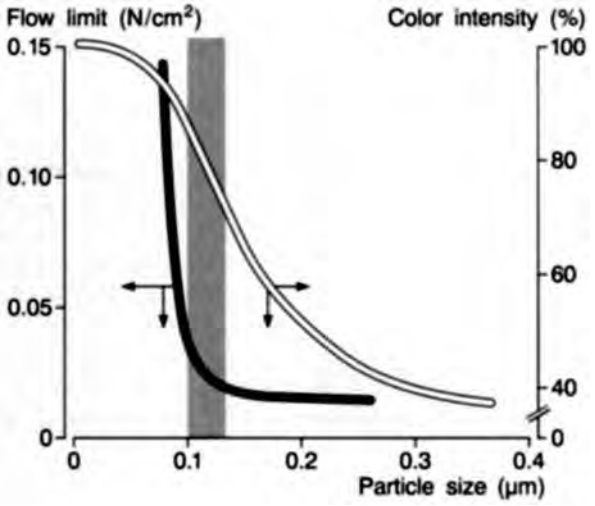

Fig. 11. Influence of particle size on the flow limits of paint dispersions and on the color intensity of pigmented paints.

To control the production process exactly and ensure an appropriate quality, it is necessary to establish which key parameters are suitable indicators for the final quality. Furthermore, one should also be aware of how these quantities depend on the process conditions in the various stages, and be able to monitor changes in them clearly when conditions in the plant are altered. Commonly, however, such objective parameters cannot be established by direct physical measurements. Phenomenological properties of materials, such

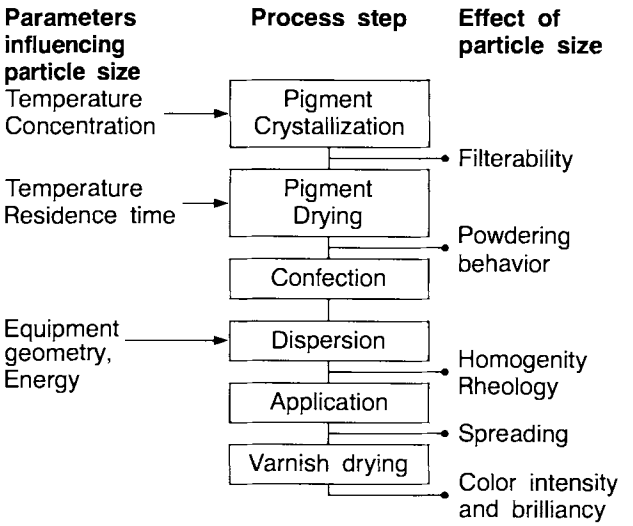

Fig. 12. Manufacture of varnish paint and lacquering.

as cohesive behavior of crystallizates during drying, the brilliance of pigments, or the dust formation of powders, simply cannot be determined using standardized physical measurement techniques. The control of such production processes using analytical data, only possible after time-consuming sample preparation, is empirical and extremely difficult. There is thus a great need here to progress from heuristic models to generally applicable measurement processes, and to correlate the results with the desired product properties and the process operating and equipment parameters.

9. Perspectives

The chemical industry will remain a dynamic growth industry. Modern standards of living and the performance of many other sectors of the economy would be inconceivable without the chemical industry. The innovative momentum of our industry is relentless. Finally, we still need the economic muscle of our traditional activities, to provide the resources for expansion into new areas, be it biotechnology or novel, high performance materials.

Innovation is by no means a unidimensional process, but rather comparable to the intermeshing gears of a clock. Advances are generally the sum total of numerous creative ideas and interdisciplinary cooperation. Figuratively speaking, our diverse operational integration of products and energy flows must have its counterpart in an overlapping "brain trust". Universities should be an active component in this intellectual integration.

Research in process technology will remain the domain of the chemical industry, as it is here—and not in the universities—that one must confront rigorous competition and comply with the demands of economics and environmental compatibility. Such constraints should not apply to the university researcher, for whom the acquisition of knowledge should have precedence. Where their interests coincide, industry and universities have to adopt differing basic positions corresponding to the fundamental differences in their functions within society. Even so, I consider both an intensive dialogue and close cooperation between the two to be indispensable, and not just in the early phase of evolution. The same holds true for other branches of industry, such as mechanical and electrical engineering. Here too, innovative synergies between universities and the corresponding sectors of the economy are vital factors for success, in final analysis for both the economy as a whole and the prosperity and health of the population.

Mathematical Modeling of Chemical Reactors—Development and Implementation of Novel Technologies

By Yuri Shaevich Matros*

Mathematical modeling is an important tool for rapid and reliable reactor development and design. The models are built up from basic studies of the reaction mechanism and kinetics, the transfer processes, and the interactions within the system. A detailed understanding of the elementary processes enables the construction of powerful and complex models for dynamic and steady-state simulation. With the aid of experimentally determined parameter values one can develop new processes or improve existing ones. Excellent results obtained in experimental work under idealized laboratory conditions can seldom be fully realized in practice. This is due to factors such as transfer resistances, local gradients, fluctuating conditions, and constructional and other limitations which lead to unsatisfactory parameter values and higher costs to compensate for these shortcomings. Some recommendations are made for circumventing these deficiencies.

1. Introduction

This review is mainly concerned with the problems involved in applying the results of mathematical modeling to the design of highly efficient chemical reactors. These will be briefly outlined with the aid of examples. The plethora of excellent books and reviews devoted to chemical reactors[1–8] bears witness to the breadth of the subject matter. It is no easy task to condense a topic of this scope into the limited space available, and for this reason I will concentrate primarily on scale-up discrepancies between small-scale experimental and production plant results. Despite the huge variety of chemical reactors, it is tempting to suggest that there is a certain "something" that thwarts extrapolation of laboratory data and mathematical models to industrial units. The emphasis on catalytic reactors as examples reflects both their complex nature and the research and industrial activities of the author.

2. Mathematical Models

2.1. Application of Mathematical Models

The practical value of mathematical modeling can be best illustrated by two examples: the oxidation of methanol to formaldehyde, and the industrial application of the reverse flow reactor.

2.1.1. Reactor for the Partial Oxidation of Methanol

Mathematical modeling of the oxidation of methanol to formaldehyde has established that reactor productivity can be improved by using tubes with internal diameters of 20–21 mm in conjunction with 3–4 mm pellets of an iron-molybdenum catalyst.[9, 11] To meet industrial demands for further productivity increases, the development of a reactor with a series of adiabatic beds and intermediate removal of the heat of reaction was proposed,[11]—an unworkable solution according to contemporary opinion.[10] A further complication was the presence of spatial inhomogeneities in the system. Initial calculations indeed indicated a high parametric sensitivity (PS), i.e. the outlet temperature was extremely sensitive to inlet parameters, such as temperature, flow rate, and composition. By further mathematical modeling and experimental investigations it was possible: a) to understand why the PS is so high and what can be done to decrease it; b) to significantly reduce the spatial inhomogeneities and their influence; c) to elucidate the formation of and to suppress "hot-spots"; d) to develop an appropriate reactor control system.

An industrial reactor with multiple adiabatic beds of oxide catalyst for the production of 60 000 tons/year of formalin was constructed on the basis of these results and has been operated successfully over the last few years in the Soviet Union (Fig. 1).[11] This was probably the first industrial realization of a partial oxidation process based on such a reactor configuration.

2.1.2. *Reverse Flow Reactors*

The second example concerns the development and industrial implementation of fixed-bed, reverse flow reactors. Mathematical modeling of unsteady state reactor processes taught us how to set up and control optimal temperature and concentration profiles in a catalyst bed operating under forced periodic conditions induced by reversal of the flow regime. We have since proposed reverse flow, catalytic reactors for a variety of industrial problems, such as the oxidation of SO_2 to SO_3 in the production of sulfuric acid,[12] the removal of CO, nitrogen oxides[14] and organic impurities[13] from waste gases, the methanol and ammonia syntheses,[15, 16] the recovery of sulfur by the Claus process,[17] and the production of synthesis gas.[18] The advantages that a reverse flow reactor offers over a traditional one in terms of constructional simplicity are illustrated in Figure 2. The reverse flow reactor (Fig. 2a) has no heat exchangers, fewer valves, and a single catalyst bed.

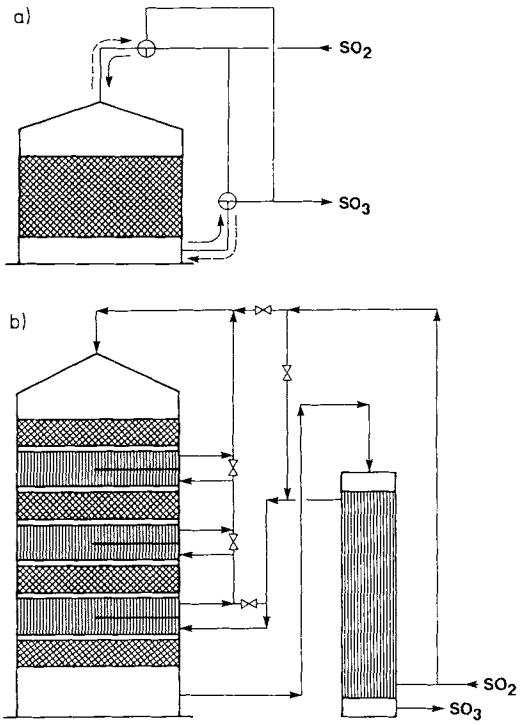

Fig. 2. Catalytic reactors for SO_2 oxidation under a) steady-state and b) unsteady-state conditions.

2.2. Formulation of Mathematical Models

We should first note that scale-up procedures based on similarity theory belong to the past. For many years the development and improvement of chemical processes mostly depended on a hit-and-miss approach to theoretical and experimental studies. Assuming that sufficient data are available to formulate a kinetic model of the process which quantitatively describes the rate of chemical transformation as a function of concentration, temperature, and pressure in the system with adequate precision, one can derive the reactor's present state from its past history. The generalized representation of a kinetic model for an unsteady state chemical process is shown in Equations (1)–(5), where $\boldsymbol{W}$ = reaction rate, $\boldsymbol{f}$ = vector of underlying kinetic functions, $\boldsymbol{\varphi}$ = vector characterizing the effect of reaction mixture on catalyst properties, $\boldsymbol{c}$ = vector of gas phase concentrations, $\boldsymbol{\theta}$ = vector of reactant concentrations on the catalyst surface, $\boldsymbol{\alpha}$ = vector of catalyst parameters influenced by reaction medium, T = temperature.

$$\boldsymbol{W} = \boldsymbol{F}(\boldsymbol{f}, \boldsymbol{\varphi}) \tag{1}$$

$$\boldsymbol{f} \equiv \boldsymbol{f}(\boldsymbol{c}, \boldsymbol{\theta}, \boldsymbol{\alpha}, T) \tag{2}$$

$$\boldsymbol{\varphi} \equiv \boldsymbol{\varphi}(\boldsymbol{c}, \boldsymbol{\theta}, \boldsymbol{\alpha}, T) \tag{3}$$

$$\frac{d\boldsymbol{\theta}}{dt} \equiv \boldsymbol{F}_1(\boldsymbol{c}, \boldsymbol{\theta}, \boldsymbol{\alpha}, T) \tag{4}$$

$$\frac{d\boldsymbol{\alpha}}{dt} \equiv \boldsymbol{F}_2(\boldsymbol{c}, \boldsymbol{\theta}, \boldsymbol{\alpha}, T) \tag{5}$$

Modern kinetic studies are characterized by a trend toward models extending right down to the molecular level. They thus enable one to predict the rules governing the formation of compounds with the required properties and structural features.

The model is a means to an end, but not a solution in its own right. The suitability of the model is thus primarily dictated by the extent to which it solves the problem under consideration. The more we know about a process, the easier it becomes to describe it. On the other hand, as Einstein put it, "everything should be made as simple as possible but no simpler".

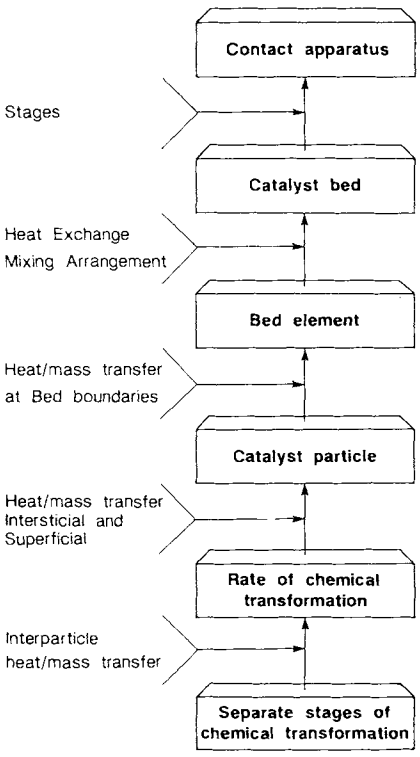

Fig. 3. Structure of a mathematical model for a fixed-bed catalytic reactor.

Reactors are complex systems but generally have a repetitive, multistage structure. Mathematical models are thus often assembled from and embody several constituent submodels derived from a preliminary analysis, a procedure illustrated in Figure 3. The fundamental principles of model formulation depend on the uniform scale of reactor elements and their invariance with time.[11] This basis permits the prediction of dynamic reactor performance for reactors of all shapes and sizes.

2.3. Limitations of Mathematical Models

The satisfactory agreement of experimental data with model calculations is a necessary, but not sufficient, condition for model acceptability. It is easy to envisage a situation in which two different models describe the same set of data equally well. Under conditions deviating from the experimental ones, however, models selected according to empirical or intuitive criteria can lead to serious errors.

An example of this is the model of a porous catalyst particle covered by a liquid film of uniform thickness, used for a long time to simulate gas–liquid–solid systems with low heat evolution. For systems such as the hydrogenation of benzene, β-methylacrolein, α-methylstyrene, cyclohexene etc., this model proved to be totally inadequate. The particle surface was actually found to be only partially wetted with the liquid.[19] Shortly thereafter, data were obtained showing a "strong" dependence of the chemical reaction rate on the wetted surface area fraction and "weak" dependence on gas and liquid velocities.[20] A model which took into account the presence of liquid velocity pulsations in the vicinity of the wetted surface was able to explain these "anomalies". Further investigations showed that, in the case of strongly exothermic reactions, it was also necessary to consider the partial wetting of the pore network within the particle.[21] This detailed model was ultimately able to account for the significant gradients across the particle radius and multiple steady state behavior.

The imperfect mixing often encountered in reactors offers a further example. The traditional solution is to develop ever more detailed models, e.g. cell models with stagnant zones and by-pass routes. Sooner or later, one derives a model which reasonably matches the experimental residence time distribution function for the reaction mixture in the reactor. Due to the non-linear dependence of the kinetics and other properties on composition, temperature, and pressure, however, it is almost always impossible to use such models to calculate reactor processes with any degree of precision.

Consider a mathematical model describing unsteady state reactor processes in an adiabatic catalyst bed [Eqs. (6)–(15)].

$$(C_g + \varepsilon_g C_p)\frac{\partial T_g}{\partial t} = \lambda \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial T_g}{\partial r}\right) + QW(T_g, y) \qquad 0 \leqq r \leqq R_g,\ 0 \leqq \tau \leqq \tau_L \quad (6)$$

$$\varepsilon_g \frac{\partial y}{\partial t} = D\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 \frac{\partial y}{\partial r}\right) + W(T_g, y)\frac{1}{c_0} \qquad 0 \leqq r \leqq R_g,\ 0 \leqq \tau \leqq \tau_L \quad (7)$$

$$\varepsilon \frac{\partial T}{\partial t} = \frac{\lambda_M + \lambda_B}{C_p u^2}\frac{\partial^2 T}{\partial \tau^2} - \frac{\partial T}{\partial \tau} + \frac{\alpha S}{C_p}(T_g - T) \qquad r = R_g,\ 0 \leqq \tau \leqq \tau_L \quad (8)$$

$$\varepsilon \frac{\partial x}{\partial t} = \frac{D_M + D_B}{u^2}\frac{\partial^2 x}{\partial \tau^2} - \frac{\partial x}{\partial \tau} + \beta S(y - x) \qquad r = R_g,\ 0 \leqq \tau \leqq \tau_L \quad (9)$$

$$-S\lambda \frac{\partial T_g}{\partial r} = S\alpha(T_g - T) - \frac{\lambda_r}{u^2}\frac{\partial^2 T_g}{\partial \tau^2} \qquad r = R_g,\ 0 \leqq \tau \leqq \tau_L \quad (10)$$

$$SD\frac{\partial y}{\partial r} = S\beta(y - x) \qquad r = R_g,\ 0 \leqq \tau \leqq \tau_L \quad (11)$$

$$\frac{\partial T_g}{\partial \tau} = 0;\ \frac{\lambda_M + \lambda_B}{C_p u^2}\ \frac{\partial T}{\partial \tau} = T - T_0;\ \frac{D_M + D_B}{u^2}\ \frac{\partial x}{\partial \tau} = x - x_0 \qquad r = R_g,\ \tau = 0 \quad (12)$$

$$\frac{\partial T_g}{\partial \tau} = \frac{\partial T}{\partial \tau} = \frac{\partial x}{\partial \tau} = 0 \qquad r = R_g,\ \tau = \tau_L \quad (13)$$

$$\frac{\partial T_g}{\partial r} = \frac{\partial y}{\partial r} = 0 \qquad r = 0,\ 0 \leqq \tau \leqq \tau_L \quad (14)$$

$$t = 0;\ x = y = 1;\ T_g = T = T_{in} \quad (15)$$

The model incorporates: mass and heat transfer within the particle, between the catalyst particles and the gas phase, and the axial transfer processes within the gas phase; T = gas temperature; T_0 = initial bed temperature; T_{in} = inlet temperature; T_g = catalyst temperature; x = conversion in gas phase; y = conversion in catalyst; c_0 = reactant inlet concentration; S = specific external surface area of the catalyst per unit bed volume (e.g. for spherical particles: $S = 3(1 - \xi)/R_g$); L = length of the catalyst bed; l = axial bed coordinate; $\tau = l/u$, the gas residence time; $\tau_L = L/u$; u = gas velocity; r = radial catalyst coordinate; R_g = pellet radius; λ = effective radial conductivity of pellet; D = effective diffusivity within the pellet; C_g = heat capacity of pellet; C_p = heat capacity of gas; λ_M and λ_B are the coefficients of molecular and eddy heat transfer in the gas; D_M and D_B are the coefficients of molecular and eddy diffusion in the gas; α and β are the coefficients for heat and mass transfer at the pellet surface; Q = heat of reaction. Prior to formulating the detailed equations, the optimal regime should be established theoretically, using only the kinetic model, regardless of whether it can be realized technically or not. This regime defines theoretical limits for such factors as productivity and selectivity. Simulation work based on mathematical models then makes it possible to determine the main technological parameters of the process and design data for the details of the one or more reactor configurations which could be expected to operate near the theoretical optimum. In most cases, however, the process characteristics observed in this optimal reactor are inferior to those obtained at the theoretical optimum and often in comparison to those obtained in laboratory units too. What can be done about this? Unfortunately we live in an imperfect world!

The deterioration in performance is caused by numerous factors: the balances relating composition and temperature, diffusion limitations, heat exchange in the bed, transfer resistances at phase interfaces, temperature and concentration gradients at various reactor levels, micromixing and microflow regimes within the reactor, instability or autooscillatory behavior, variation in inlet parameters etc. etc.

2.4. Influence of Inhomogeneity on Reactor Operation

Although the results of mathematical modeling may be intrinsically reliable, the pilot or industrial equipment constructed on the basis of them usually exhibits inferior operational indices. A significant reason for this deviation from

ideal behavior is the presence of spatial inhomogeneity in the temperature, concentration, and pressure distributions. Such inhomogeneity in the reactors may arise owing to both external and internal generic factors. Irregular temperature, concentration, velocity and pressure profiles in the reactor inlet belong to the first class. The usual response to non-uniform inputs in practice is to try and compensate for them by changing the reaction mixture residence time in the reactor (MRTR), a mostly unsuccessful approach. For example, due to the thermodynamic equilibrium in a reversible exothermic system, it is impossible to counteract the negative influence of a non-uniform temperature profile in the inlet simply by increasing the MRTR.

2.4.1. Non-Uniform Flow

Internal inhomogeneities are caused, for instance, by irregularities in the distribution of flow permeability within the reactor. In Figure 4 the experimentally measured temperature values in the outlet section of an adiabatic reactor with exothermic reaction are presented by way of an example. The catalyst was charged via hoses at two locations, giving two piles. These were subsequently leveled off carefully, to

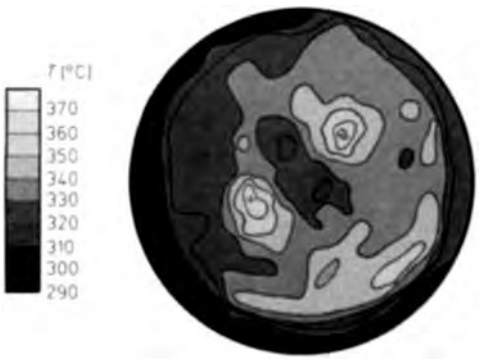

Fig. 4. Isotherms in the outlet of an adiabatic catalyst bed, in which the catalyst was loaded by "piling" from a hose. The crosses indicate the centers of the catalyst piles formed during charging.

yield a bed of uniform depth. Tomographic measurements, however, showed that the bed density at the charging locations was higher than elsewhere, and the "hot-spots" were also found in these zones.[22] It should be noted that variations in MRTR across a reactor can yield unexpected results, with superadiabatic or superequilibrium temperatures. The charging of catalyst by a "rain" technique[23] yielded pratically uniform permeability over the bed section.

Developing suitable, detailed methods for installing catalysts, internals, heat exchangers and intermediate inlets and outlets so as to ensure uniform permeability and heat and mass transfer conditions in the reactor is one of the major challenges facing chemical engineers.

The empty regions before and after the reaction zones function as distinctive collecting points with practically homogeneous static pressure values. The pressure drop between them drives the reaction mixture through the reaction zone. Mathematical modeling commonly asumes that the velocity of the reaction mixture, u, is constant. The correct formulation of the problem, however, is to assume a constant value for Δp over the reactor and treat the u as the unknown parameter.[24–28] This approach describes the effects of positive feedback (for exothermic reactions): decreasing values of u lead to increasing residence times, conversions, and reaction temperatures, the last of which further decreases the value of u and so on. This phenomenon, only recently fully appreciated, explains why a high PS is often observed in practice and how various parts of the reactor can operate under significantly different conditions—a feature demonstrated by the large scatter in some experimental data. Assuming a constant value of Δp allows for the possibility of several steady states under similar inlet conditions (Fig. 5), even for those reactors operating in or around the plug flow regime.

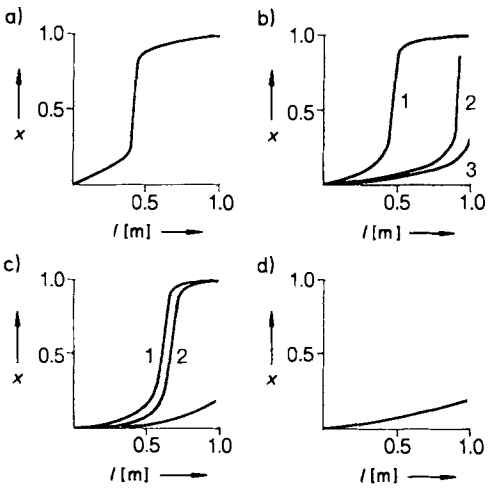

Fig. 5. Profiles of the degree of conversion (X, or temperature, given by $T = \Delta T_{ad} X$) as a function of normalized catalyst bed length (l) in a plug flow, adiabatic reactor. For a single irreversible reaction, the system can exhibit either unique high (a) or a low (d) temperature regimes, or three steady states (1,3 stable, 2 unstable).

The possibility of high- and low-temperature regimes occurring simultaneously was finally able to explain how adiabatic beds can give rise to "hot-spots". This phenomenon is most pronounced for temperature-sensitive reaction rates, for large heats of reaction, and in cases where viscosity is a strong function of temperature and composition. The last criterion is especially important for thermonuclear reactions.

2.4.2. Non-Uniform Inlet Conditions

Two main parameters determine the extent to which the non-uniform inlet conditions influence the hydrodynamic situation within the reactor: the ratio of the distance between inlet and bed to bed diameter, h, and the ratio of bed cross-section to that of the inlet duct divided by the square root of the bed pressure drop coefficient, $A = F_b/[F_{in}\sqrt{\xi}]$, where ξ is the coefficient of the drop in pressure in the bed. The velocity field may be assumed to be uniform prior to entering the bed if $A < 0.2–0.5$.

Novel reactor configurations providing improved hydrodynamic homogeneity are of great practical interest. An example in this context is the concentric spherical flow reactor

in which the feed is introduced via an inner perforated spherical surface and the products are removed through a similar outer shell.

Modern, high-speed computers permit the simultaneous calculation of pressure, velocity, concentration, and temperature profiles in reactors, even for multidimensional problems. Generally, however, the solutions are restricted to idealized geometrical structures. It is still difficult to calculate global and especially local hydrodynamic conditions when the stochastic nature of parameters has to be taken into account.

We should at this juncture perhaps consider the equations that enable us to estimate the effect of spatial inhomogeneities on reactor performance. Let the distribution of a nonuniform parameter P be described by the differential distribution function $\alpha(P)$ [Eq. (16)] with moments given by Equation (18) and assume that a unique outlet parameter

$$\int_{P_{min}}^{P_{max}} \alpha(P)\,dP = 1 \tag{16}$$

$$\bar{P} = P_{average} = \int_{P_{min}}^{P_{max}} P\alpha(P)\,dP \tag{17}$$

$$M_i = \int_{P_{min}}^{P_{max}} (P - \bar{P})^i \alpha(P)\,dP \tag{18}$$

function exists $A(P)$, the derivatives of which with respect to P can be obtained from the mathematical model. The average value of this parameter is then given by Equation (19).

$$\bar{A} \cong A(\bar{P}) + \sum_i \frac{1}{i!} M_i \frac{\partial^i A(P)}{\partial P^i}\bigg|_{P=\bar{P}} \tag{19}$$

3. Optimal Reactor Design

3.1. Economic Factors

Assume that a reactor has been selected with the help of mathematical modeling and that an optimal operating regime has been determined for this configuration (line "e" in Fig. 6). The economics of converting reactants into products in this reactor may still be unfavorable, however. As a rule, simplifications in reactor construction diminish the depreciation while increasing the operating costs. One thus has to balance off the amortization (B_1) and operating costs (B_2) to achieve an economic optimum for production. The optimal point "B_3" can be established using mathematical modeling.

3.2. Technical Factors

The precision with which an optimal regime can be realized depends on the intrinsic reactor properties and the unavoidable external perturbations. The intrinsic reactor behavior is characterized by the values of PS, the number and stability of the various steady states, the margin of stability, the dynamic properties, by the laws governing the variation of certain parameters with time, spatial inhomogeneity etc. The efficiency and stability of the process are determined by intrinsic reactor properties and the nature of the external perturbations. Reactor stability is dictated by the insensitivity to external disturbances and the extent to which one can achieve a given narrow optimal operating regime under varying inlet conditions.

As a rule, increasing efficiency leads to diminishing stability. The problem in mathematical modeling is to provide the maximum efficiency for the process under the constraints imposed by its stability criteria.

The efficiency is given by the specific productivity of the reactor, the selectivity, and the costs of constructing, controlling and operating the reactor.

3.3. Optimization of Tubular Reactor Diameter

Let us now consider a few examples of this, starting with a multitubular reactor in which the reaction takes place within tubes surrounded by a circulating heat transfer medium. The stability of such reactors is determined primarily by the value of the inner tube diameter (IDT). The capacity of the reactor may be increased by enlarging the tubes, but this results in a reduction in heat exchange area, a corresponding drop in cooling-agent temperature, increased PS, and greater dynamic overshoot (Fig. 7).

For an exothermic process, the decisive factors controlling IDT are: PS, the dynamic characteristics, the pressure drop,

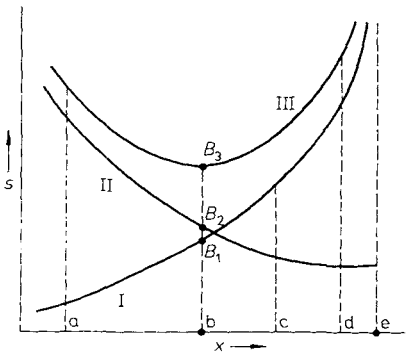

Fig. 6. Dependence of amortization (I), operating (II) costs and total costs (III) on the product yield (X). a) CSTR; b) practical optimum; c) best laboratory results; d) PFR; e) theoretically obtainable maximum yield in an ideal reactor. S = costs.

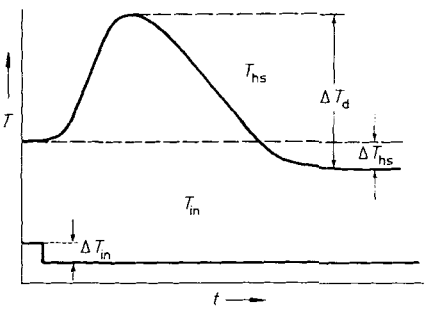

Fig. 7. Variation in "hot-spot" temperature (T_{hs}) in a tubular reactor following a step reduction in inlet temperature (T_{in}) of ΔT_{in}. $\Delta T_{hs}/\Delta T_{in}$ is the parametric sensitivity of "hot-spot" to inlet temperature and $\Delta T_d/\Delta T_{in}$ the dynamic overshoot.

the selectivity, and the potential fluctuation in all inlet parameters when the control system is working satisfactorily. IDT is chosen on the basis of an analysis of the temperature and concentration profiles calculated for a range of tube diameters. The operating conditions—residence time, temperature range, coolant temperature, initial composition, etc.—are chosen so as to achieve conditions close to the optimum, to obtain the desired productivity etc.. The maximum IDT is selected from the variants calculated to fulfill two main criteria:

1) so as to ensure that permissable deviations in the critical sections of the tube are not exceeded for the fluctuation in inlet parameter values which can be expected from the operational precision of the automatic control system, and

2) so that the hydraulic pressure drop Δp does not exceed a given value.

For endothermic processes operating near equilibrium, the parameters determining the choice of IDT are generally the specific capacity of the equipment and the magnitude of the pressure drop Δp. The maximum IDT for the oxidation of methanol to formaldehyde over oxide catalysts is around 25 mm; for the synthesis of vinyl chloride from acetylene 55 mm for concentrated and about 80 mm for dilute streams. For a periodic process manufacturing cyanogen chloride via the trimerization of chlorine cyanide, the IDT is approximately 80 mm.

It should be mentioned that the main reserve for increasing efficiency in tubular reactors lies in raising the effective radial conductivity λ_r, which permits larger IDT values and thus greater specific reactor capacities. To achieve the necessary increase in λ_r one can install special packing elements in the reactor to intensify turbulence. For heterogeneous catalytic processes, one increases λ_r by employing pellets with high voidage, e.g. Raschig rings with internals. Suitable preparation and charging of these pellets decreases both pressure drop and pore diffusion resistance, thus reducing the amount of catalyst needed and often yielding improved selectivity. A very promising area in catalyst design is the development of special catalysts using the tube wall as a catalyst carrier. We have calculated that this technique could permit a reduction in the amount of catalyst by a factor of ten and substantially improve selectivity.

4. Conventional Reactors

4.1. Adiabatic Reactors

High conversion levels or values close to equilibrium lead to very stable reactor operation. For multiphase processes with spatial distribution, the main danger is the possible formation of non-monotonic (see Fig. 7) transient regimes with dramatic dynamic overshoot. If the degree of conversion in the reactor outlet is far from equilibrium, then the PS of the outlet parameters compared to the inlet ones is approximately proportional to $\exp[(T_{out} - T_{in})\ E/RT_{in}]$, with T_{in} and T_{out} being the inlet and outlet temperatures respectively, R the universal gas constant and E the observed activation energy for the reaction. In the case of catalytic processes, for example, the value of E is halved upon going from kinetic to internal diffusive control. This essentially results in lower PS and improves stability. The quality of the automatic control system and the permissible drop in selectivity with increasing pore diffusion resistance were the factors which finally determined the main technological and constructional features of the reactor design for the production of formaldehyde from methanol in adiabatic oxide catalyst beds (see Fig. 1).

Recently, there has been an increasing tendency to employ monolithic (honeycomb) catalysts to carry out large-scale catalytic processes, for instance the catalytic reduction of nitrogen oxides with ammonia. This trend is a consequence of the lower pressure drop characteristics, the feasibility of treating dusty gases, the relative insignificance of pore diffusion resistances, and a number of other advantages inherent in the use of monolithic catalysts.

4.2. Fluidized Bed Reactors

4.2.1. Advantages

This reactor type has several very attractive practical features: 1) very high specific productivity; 2) large and adjustable axial bed conductivity, which, together with suitable distribution of heat exchange surface and partitioning within the reactor, permits near-optimal temperature profiles; 3) simple exchange of fluidized material during operation; 4) quasi-ideal plug flow in the gas phase by structuring the bed with packing elements, partitioning, and other methods; 5) very low external and internal diffusive resistance for the small fluidized particles; 6) the possibility of carrying out unsteady state processes on the internal pore surfaces of the catalyst particles; 7) easy heat removal and temperature control for strongly exothermic systems.

In organic syntheses alone, fluidized bed reactors are employed in the manufacture of vinyl acetate, pthalic anhydride, vinyl chloride, and maleic anhydride.

4.2.2. Shortcomings

In the last ten to fifteen years, however, the initial optimism accompanying the use of fluidized beds has waned somewhat. This can be explained both by the significant advantages often offered by alternative reactor configurations and by the shortcomings of fluidized bed reactors. These include the presence of large bubbles and their detrimental effect on interphase mass transfer, and large-scale particle circulation, often avoided by resorting to partitioning, rotating internals, special geometries or arranging spillover between separate bed sections. The countermeasures, however, result in decreased particle mobility and therefore reduce radial heat transfer, which can lead to hot-spot formation. A further consequence is the increased clogging and sintering of particles, all of which can lead to blockages on the walls or at other locations in the fluidized bed. Some more "generic" disadvantages should be added to those listed above: the high pressure drop, the mechanical erosion of metallic reactor internals, the large reactor volume, reaction in the gas space over the bed and connecting

lines, rapid particle attrition, and the need for dust removal in the product stream. All these factors usually mean that selectivity of the reaction is relatively low.

5. Novel Reactors

Up to now, only the problems involved in the detailed design of optimal reactors have been dealt with. It is, however, probably also worthwhile mentioning several fundamentally new techniques for carrying out chemical reactions, for example plasmochemical and unsteady state processes.

5.1. Plasma Chemistry

This is a new area in chemical technology developed in the 60's and 70's.[29] An essential prerequisite for its application was the availability of plasma generators producing low-temperature, chemically active plasma in either arc, glow, high-frequency or super-high-frequency discharges. Plasma entering the reactor serves both as a heating medium and the initiator for chemical reaction. The main characteristics of such reactors are the extremely low reaction times (10^{-3}–10^{-4} s), the high temperatures (1000–1300 °C), and the need for thorough mixing of streams within the plasma. The mathematical modeling of the process requires the study of simultaneous heat, mass, and momentum transfer. This means that the form and solution of the mathematical model are more complex. Gas mixing is carried out by co-current injection, and utilizes the kinetic energy of both component streams. Perhaps the most efficient mixing technique is to introduce one component into the flow so as to provide jet impact, leading to the formation of a turbulent zone. Examples of plasmochemical processes being developed include the pyrolysis of hydrocarbons (methane, benzene) in a hydrogen plasma for the production of acetylene and ethylene; the pyrolysis of chlorine- and fluorine-containing hydrocarbons, the synthesis of hydrogen cyanide, cyanogen and dicyanogen from hydrocarbons and nitrogen, and the fixation of atmospheric nitrogen. Plasmochemical processes obviously entail a high specific energy consumption.

5.2. Reactor Operation under Forced Unsteady-State Conditions (FUSC)

Under unsteady state conditions it is possible to enhance transfer, sorption, rectification, extraction, separation, grinding, and crystallization processes. Forced pulsing in the combustion of solid fuels improves both oxidation and heat exchange, cuts energy consumption for draught, and permits operation with less surplus air and oxygen. Furthermore, nitrogen oxide levels are lower and the heat exchange surface stays cleaner. Interphase transfer can often be promoted significantly by means of hydrodynamic instability or forced velocity pulsations close to the natural turbulence frequency. Pulsed mixing in the reaction zone by periodic variation of the pressure has been found to be very effective.[30]

FUSC in polymerization systems leads to shifts in the molecular weight distribution function for the resultant polymer and increased reactor productivity.[31, 32] Such an operation can be realized, for example, by periodically changing the hydrogen concentration in the reactor inlet for a free-radical and polycondensation polymerization of olefins. In complex biological systems, it is possible to stabilize two competitive populations dynamically, when under similar steady state conditions one of them would be suppressed.[33]

The effectiveness of FUSC in CSTR reactors can be observed clearly where a chemical reaction of an order greater than unity is occurring.[34] For reactions of second order, for example, the productivity of the reactor increases in proportion to the square of the amplitude of inlet concentration pulsations and attains a maximum value at low frequencies.[35, 36] The productivity can be raised still further if the flow rate and composition are both changed periodically, especially if the pulsations are of large amplitude and out of phase with each other. FUSC has been found to be very efficient in cases where the rate of chemical reaction exhibits extreme sensitivity to process parameters. One of the most effective ways to "excite" a reactor is to use the temperature of the heating medium. For example, a switch to FUSC in gas–solid systems permits one to intensify ore roasting, or some other interaction between the gaseous and solid phases and can improve the efficiency of heterogeneous catalytic processes.[36 - 38]

The application of pulsed voltages in electrochemical reactors used for electroorganic syntheses (amplitude, impulse duration, magnitude of reverse voltage) can give rise to changes in selectivity, producing different products simultaneously from the same feedstocks,[39] or to superior reproducibility in the electrochemical machining of metals.[40] Changing the direction and value of the applied voltage can be used to vary the color of anodic oxide films on metals and the composition and properties of alloys manufactured by electrodeposition.

The examples presented above illustrate that efficiency is improved by exploiting the wider range of concentration, temperature, and pressure profile conditions which can be achieved at unsteady state and which are often unattainable under steady state conditions. In particular, much steeper concentration and temperature gradients are feasible with FUSC. Temporal and spatial shifts in concentration and temperature profiles, non-linear dependence of reaction rates on concentration and temperature, and other factors lead to dynamic overshoots, superadiabatic behavior, oscillating transient regimes, stable limit cycles, and even chaos. Under optimal FUSC conditions, one cannot achieve worse results than at steady state.

The impact of the transition from steady to unsteady state heterogeneous catalysis can be judged according to two major criteria: the influence on catalyst structure and composition and the dynamic properties of the reactor as a whole.

Experimental data presented in the literature confirm that it is possible, in principle, to improve the performance of a variety of catalytic processes by this means: ammonia synthesis on iron or ruthenium catalysts,[41, 42] SO_2 oxidation on vanadium catalysts[43, 44] oxidative dehydrogenation of ethylbenzene to styrene on active carbon,[45] the oxidation of ethylene on silver,[46] the hydrogenation of butadiene on nickel,[47] the Fischer-Tropsch synthesis on supported ruthe-

nium catalyst,[48] CO oxidation on platinum and vanadium catalysts,[49-51] the synthesis of ethyl acetate,[52] etc.

Let us now consider the periodic variation in the inlet conditions of a fixed catalyst bed as a means of increasing the efficiency of reactor performance, using temperature cycling as an example.[53]

In Figure 8, it can be seen that in an unsteady state regime, an almost total conversion can be attained at an average temperature of 160 °C, while steady state operation would require 250 °C. For a reversible, exothermic process a temperature drop of 90 °C over the reactor could result in considerable improvement in conversion. An optimization of ammonia synthesis over iron catalyst, for example, showed that the productivity of the reactor can be increased by a factor of 1.5 by using suitable periodic temperature control in the inlet.[54]

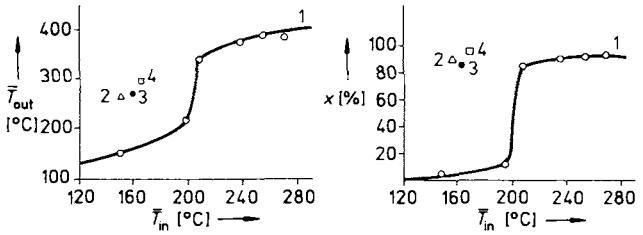

Fig. 8. Influence of average inlet temperature (T_{in}) on the cycle-averaged outlet temperature (T_{out}) and the overall degreee of conversion (x). Oxidation of 0.12% butane under (1) steady- and (2–4) unsteady-state conditions. Steady-state residence time is ca. 4.5 s. Unsteady-state cycles are characterized by t_c, the cycle duration, t_c^{max}, the duration of the maximum temperature phase, and Δ_{in}, the amplitude of the forced temperature pulsing in the inlet, T_{max}-T_{min}. 2: $\Delta_{in} = 200$, $t_c = 3600$ s, $t_c^{max} = 1800$ s; 3: $\Delta_{in} = 230$, $t_c = 2400$ s, $t_c^{max} = 1200$ s; 4: $\Delta_{in} = 255$, $t_c = 3000$ s, $t_c^{max} = 1500$ s.

5.2.1. *Reverse Flow Reactor*

A reverse flow system (Fig. 9) for heterogeneous catalytic processes was proposed in the mid 70's[38,55-57] and has since found widespread industrial application. The basic concept, as described earlier in this paper, comprises the periodic reversal of the cold feed gas being fed to a preheated catalyst bed. The theoretical basis of the reverse flow process is founded on fundamental studies of unsteady state behavior in fixed bed reactors.[11,38] The main advantages of the reverse flow process have been formulated as follows:[57]

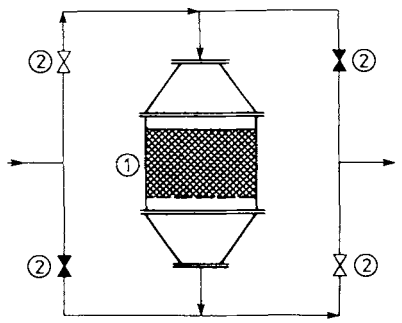

Fig. 9. Basic flowsheet of a reverse flow process in which the flow direction of the reaction mixture through the adiabatic catalytic reactor ① is alternated by appropriate operation of the valves ②.

1. The catalyst fixed bed serves firstly to accelerate the chemical reaction and secondly as a regenerative heat exchanger. It enables one to do without heat exchangers prior to the reactor and additional heat to maintain the reaction.
2. Autothermal operation is feasible even when the reaction mixture is so dilute that the adiabatic temperature rise for complete conversion is only 10–15 °C.
3. Feedstocks with considerable fluctuations in inlet characteristics can be treated.
4. The conditions created in the catalyst bed approach the optimum. Productivity and/or selectivity are often improved and reactor construction simplified. Thus, for a reversible exothermic process it is necessary to decrease the temperature to achieve higher conversions, the exact opposite of what occurs in the normal steady-state arrangement. In the reverse flow process on the other hand, a much more favorable temperature profile is obtained (Fig. 10).

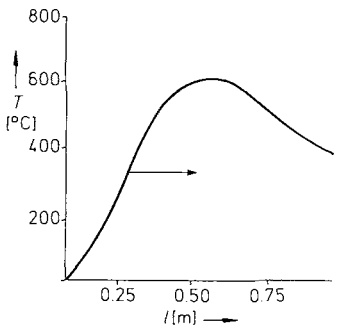

Fig. 10. Typical temperature (T) profiles along the bed length (l) in an exothermic reverse flow process prior to switching the flow direction. The arrow indicates the motion of the temperature wave.

5. The average temperature in the catalyst bed and connecting lines is reduced significantly, which, together with the simplified reactor design, leads to a large decrease in the energy consumption needed to counteract the pressure losses (20–50%).
6. The unsteady state of the catalyst surface may also be beneficial for catalyst performance in comparison to the steady state.
7. Decreasing the average temperatures and sizes of the reactors and the simplified construction combine to cut heat losses.
8. The catalytic oxidation of low energy content reaction mixtures or fuels in a reverse flow process permits the removal of high grade heat at high temperature from the central reaction zone (Fig. 11).[57]

Let us now take stock of some of the industrial applications of the reverse flow process.

Decontamination of Industrial Exhaust Gases: The decontamination of industrial exhaust gases by removing various organic compounds, CO, and nitrogen oxides[13,56-59] (Fig. 12) is one increaslingly important application of the reverse flow reactor. Experience has shown that the new method of operation reduces the capital cost of a detoxifica-

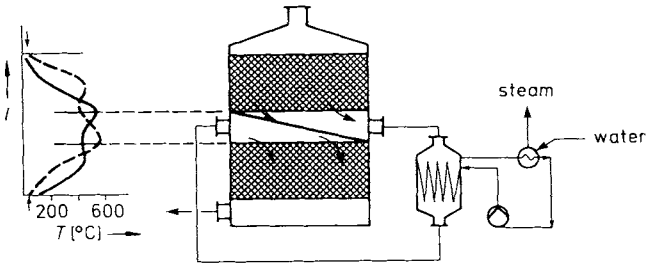

Fig. 11. Basic flowsheet for high-grade heat recovery in a reverse flow process for waste-gas treatment. The temperature profiles prior to flow reversal are shown on the left-hand side.

tion plant by a factor of 1.5 to 3 and cuts operating costs by a factor of 1.5 to 2. The process is able to purify gases with low and varying contents of pollutants, at average concentrations around 0.5 g/m^3 or higher, autothermally. At concentrations above 3 g/m^3, high-grade heat may be extracted. The numerous reverse flow processes that have been developed for waste-gas purification applications are characterized by high levels of removal (99%) for pollutants and for other odoriferous or toxic impurities and by the use of cheap oxide catalysts.

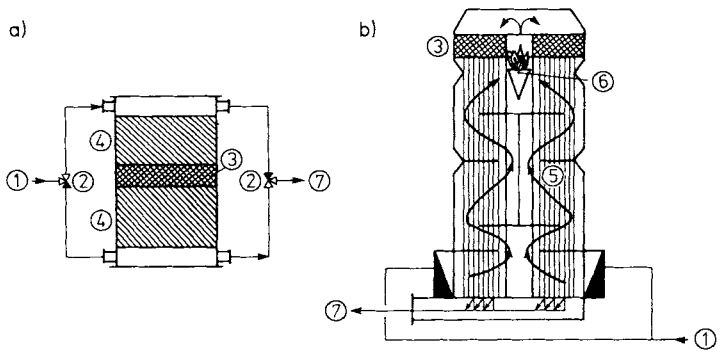

Fig. 12. Technical flowsheet of reactor units for waste gas treatment in a) unsteady-state (cf. Fig. 11) and b) conventional steady-state operation. ① feed to be decontaminated; ② valves; ③ catalyst bed; ④ inert bed; ⑤ recuperative heat exchanger; ⑥ jet burner; ⑦ purified gas.

Sulfur Dioxide Oxidation: Sulfur dioxide oxidation on vanadium oxide catalysts for sulfuric acid production using a reverse flow process[12, 60] has attracted considerable industrial interest. The reverse flow process does not require multiple catalyst beds (Fig. 2). For start-up at low SO_2 concentrations, small quantities of additional energy must be supplied. Depending on the actual conditions encountered in practice, unsteady state operation permits reductions of 50–70% in reactor size (metal weight), 30–50% in pressure drop, 30–80% in total capital cost, 5–20% in the sulfuric acid production costs, as well as simplifying construction. The operating principles of the reverse flow process make it possible to treat "dilute" roasting gases containing 0.5–3% SO_2 or to convert the gases following intermediate absorption with 0.5–1% SO_2 in a double catalyst–double absorption plant, in a simple single stage reactor with no external heat exchangers.

Claus Process: In the Claus process for sulfur production, estimates for reverse flow operation indicate that capital costs could be reduced by 20–30% and the amount of catalyst by 20–35%. Furthermore, it would not be necessary to expend external energy to heat up the feed prior to reaction.

The theoretical principles for the unsteady Claus reactor were developed using an original mathematical model,[62] which took into account sulfur condensation in the low-temperature reactor inlet zone. It could be shown that, with heat removal from the central portion of the bed in combination with sulfur condensation and separation (Fig. 13), sulfur removal rates around 98% were feasible.[61]

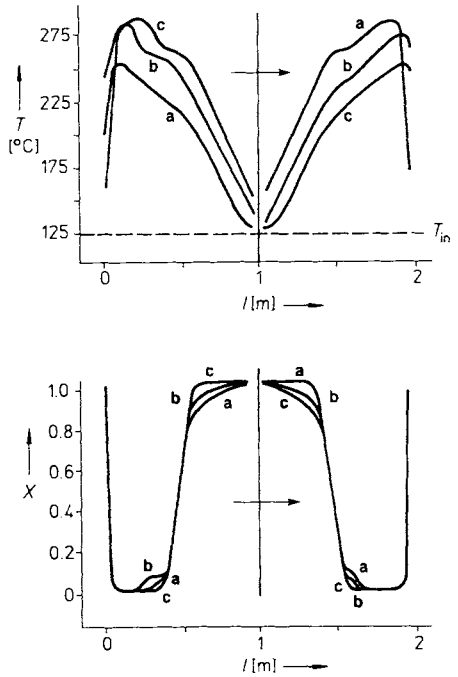

Fig. 13. Calculated profiles of temperature (T) and sulfur content (X) along catalyst bed length (l) in a reverse flow reactor with intermediate gas cooling and sulfur condensation. Curves a, b and c correspond to the beginning, middle, and end of the cycle, respectively. The arrow indicates the flow direction and T_{in} is the inlet temperature of the feed gas.

Recently, a so-called "double" reverse flow Claus process has been proposed,[63] comprising a primary catalytic stage and a subsequent purification step (Fig. 14). In this arrangement, high-temperature gas is fed to the first reactor (1), in

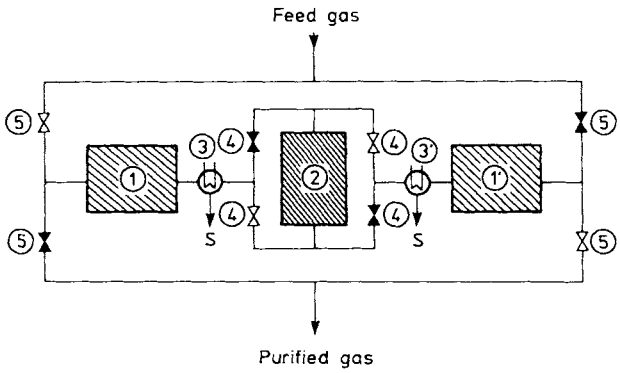

Fig. 14. Three stage, unsteady state Claus process. ①, ①', ② reactors; ③, ③' sulfur condensation; ④ valves for switching flow in intermediate, periodic reactor; ⑤ valves for switching flow through entire system.

which the Claus reaction together with COS and CS_2 hydrolysis take place under steady-state conditions. Following sulfur separation in a condenser (3), the gas, at a temperature of 120–160 °C, is passed into the second reactor (2) which operates in a periodic mode with alternating flow. Sulfur is then once again condensed out (3') and the gas fed to the third reactor (1'), which is operated so as to adsorb the sulfur formed on the catalyst. When this reactor becomes saturated with sulfur, the gas flow in the system is reversed. This configuration is predicted to be capable of achieving average sulfur removal rates of 99.5–99.9% over one cycle.

Due to the limited space available, this review is unable to deal with further fascinating features of reverse flow reactors, such as the development of other processes, the influence of the chemical dynamics of the catalyst on operational efficiency, the formulation of dynamic models, optimization, qualitative and quantitative analyses, control systems, etc.

6. Ideal Reactors—Pitfalls and Perspectives

Despite the availability of reliable experimental data, promising model calculations, and the convincing arguments of experienced engineers, the efficient chemical reactor usually remains an unrealized ideal. Why is this so? In the remainder of the review, we will try to elucidate the difficulties responsible for this shortfall.

1. The absence of unambiguous, reliable kinetic data for chemical processes. Despite the availability of good equipment, kinetic measurements are often either falsified by undesirable transport effects or restricted to too narrow a range of temperature and concentration. It is pointless to try and cut corners and save money in kinetic studies. It is well known that the greedy end up paying twice over!
2. The presence of spatial inhomogeneities due to external factors and internal characteristics. Achieving homogeneous operation within the reactor volume is both complex and costly, but nevertheless worth it. A major problem is the scale-up from pilot plant to industrial level. Adequate theory and reliable mathematical models are a weak link in this chain.
3. Inferior mathematical models and large errors in model parameters leading to poor modeling and design. To circumvent this, engineers who repeat serious mistakes should move on to less demanding jobs!
4. High parametric sensitivity of the system to inlet fluctuations or system parameters, instability or narrow stability margin. All these difficulties can be solved if enough time, care, and qualified personal are invested in the development of the automatic control system. A well-developed theory for automatic control permits one to provide a control system which ensures that the reactor parameters remain within admissible limits. Mathematical modeling methods are a *sine qua non* for the design of optimal chemical reactors operating in the vicinity of an unstable steady state or within a tight stability margin.
5. Explosion and fire hazards. The potential must be evaluated and, if possible, eliminated. In fluidized-bed processes at risk from explosions, the adoption of passive measures, e.g. designing ducts and particle separations so as to extinguish conflagration and hinder flame propagation, are to be recommended. Such conditions need only be fulfilled at the reactor inlet and outlet as these then isolate the reactor system.
6. Poor choice of construction materials. Such problems can almost always be eliminated if cost is no object. But nowadays, who can afford not to think cost-effectively?

General shortcomings, such as poor facilities, inadequately qualified staff, and low quality feedstocks are, naturally, problems confined to the competition!

It is important to notice that the gravity of the problems listed increases with increasing reactor size. Above all, this is a consequence of spatial inhomogeneity, in particular of the generic variety. In addition, difficulties arising with construction, transport, installation, and maintenance become greater. The negative influence of dynamic behavior, especially during start-up and shutdown, and the costs of ensuring a reliable and environmentally acceptable operation are also exacerbated in the case of larger reactors.

For the mathematical modeler there is no greater satisfaction than being able to behold and touch a reactor created with the help of his work. It is a pleasure to record that the expanding potential of modern scientific and engineering disciplines and techniques should enable us to experience such elation more frequently.

Molecular Thermodynamics for Chemical Process Design

By John M. Prausnitz*

Thermodynamic properties are essential for quantitative process design to produce chemical products. Caloric properties are required for heat balances, but these properties are usually available or estimated easily. More important—and often much more difficult to estimate—are the chemical potentials of components in mixtures; it is these potentials which determine phase equilibria, as required for separation operations, and chemical equilibria, as required for chemical reactors and for separation operations based on chemical reactions. Molecular thermodynamics is an engineering-oriented science for calculating the desired chemical potentials from a minimum of experimental data. This applied science, based on classical and statistical thermodynamics, yields chemical potentials through models that are based on molecular physics and physical chemistry. Selected examples are cited to illustrate the applicability of molecular thermodynamics: group-contribution methods for obtaining chemical potentials in highly nonideal mixtures as required for distillation-column and process-safety design; equation of state for precipitation of uniform-sized crystals from supercritical fluids; molecular-orbital calculations to guide process development for alternatives to environmentally dangerous chlorofluorohydrocarbons; molecular-simulation calculations for separation of gas mixtures with porous adsorbents; equilibria in two-phase aqueous systems for separation of protein mixtures; and, finally, extended polymer-solution thermodynamics to guide synthesis of hydrogels suitable for protein recovery from soybeans and for novel drug-delivery devices.

1. Introduction

One generation ago, the goal of chemical engineering was stated easily: to establish efficient and economic methods for producing on a large scale what the chemist or material scientist produces in small quantities. Today, that statement is incomplete. Today's chemical engineer does not start where the chemist stops. Increasingly, chemists and chemical engineers work together on product conception and development. Twenty-five years ago, chemists and chemical engineers worked in series: first the chemist, then the chemical engineer. Today they must work in parallel.

If the idea for a new product is to become a reality, then its early development must soon be linked to a process for its production. That process must be concerned not only with production capacity and product quality but, increasingly, with consideration for safety and for environmental protection.

Chemical process design is based on several scientific disciplines, whose relative importance depends on the nature of the product. Only a few of these disciplines are always essential; they are the cornerstones of chemical engineering. One of these is chemical thermodynamics. This article presents some applications of chemical thermodynamics for chemical engineering.

For process design, the first law of thermodynamics gives energy balances which require primarily caloric properties of materials; these properties are usually available from published experimental data or from semiempirical correlations.

The second law of thermodynamics gives a quantitative framework for calculating phase equilibria and chemical equilibria. These equilibria are essential for the design of separation operations such as distillation and extraction and they are often required for design of chemical reactors and for separation operations based on chemical reactions.

2. The Chemical Potential

For calculation of equilibria in mixtures, the most important thermodynamic property is the chemical potential μ for every component in the mixture, as a function of temperature, pressure, and composition. These chemical potentials are often not readily available.

The essential relations for phase equilibria and chemical equilibria were given by *Gibbs* 115 years ago; they are remarkably simple. When two phases (′ and ″) are in equilibrium, Equation (1) holds for every component i that exists in these phases.

$$\mu_i' = \mu_i'' \tag{1}$$

When a reversible chemical reaction, $A + B \rightleftharpoons C$, attains equilibrium, Equation (2) holds.

$$\mu_C = \mu_A + \mu_B \tag{2}$$

While the Gibbs equations are deceptively simple, it is their reduction to practice which is difficult, especially for multicomponent systems containing complex molecules. For such systems, experimental data are scarce or, as often happens, totally absent.

To apply chemical thermodynamics to chemical process design, it is necessary to relate the abstract, essentially mathematical, chemical potential μ to the physical, measurable

quantities pressure P, temperature T, and composition x. Classical thermodynamics gives only formal relations between the chemical potential and other macroscopic properties. To establish relations between the chemical potential and molecular properties, we must go beyond classical thermodynamics to statistical thermodynamics. But for most realistic situations, present knowledge in statistical thermodynamics is not sufficient. To reduce the Gibbs equations to practice, it is necessary to establish approximate models based on molecular physics or physical chemistry. The parameters that appear in these models are obtained from only a few experimental measurements. These models serve as a bridge between the Gibbs equations and the quantities needed for chemical process design. It is the development and application of these approximate but useful models which we call molecular thermodynamics.[1] Molecular thermodynamics provides essential information for the manufacture of a large variety of chemical products, as illustrated by the examples below.

3. Nonideal Liquid Mixtures: Activity Coefficients from Group Contributions

In the chemical industries many (indeed most) separation methods are based on phase-contacting: at equilibrium, when two phases are in contact, the composition of one phase is not the same as that of the other; well-known examples are distillation, absorption, extraction, crystallization, and adsorption. In chemical technology, separation operations are essential. In the manufacture of numerous chemical products, separation costs are often dominant; it is therefore of direct economic interest to conceive and design efficient separation operations. To achieve that efficiency, it is necessary to know the thermodynamic properties of mixtures, especially liquid mixtures.

Thermodynamic properties are conveniently expressed through models based on the ideal-solution concept; the large advantage of the ideal solution is that properties of mixtures can often be predicted using only experimental data for the pure components. For real solutions, the ideal-solution equations serve as a useful point of departure for constructing a systematic theory; to represent the properties of real solutions, we require activity coefficients γ. For every component i in a liquid mixture, we require its activity coefficient, which, typically, depends strongly on composition, moderately on temperature, and (except for high pressures or critical conditions) weakly on pressure.

There are numerous methods for measuring activity coefficients and the literature is rich with experimental results, especially for binary systems at temperatures near ambient. But the possible number of mixtures (especially multicomponent mixtures) and the extensive variety of conditions (composition, temperature) are so large, that experimental determination of all desired activity coefficients is prohibitive. One task of molecular thermodynamics is to provide a procedure for estimating coefficients for a wide variety of mixtures, using minimum experimental information.

For liquid mixtures containing typical nonelectrolytes (e.g., hydrocarbons, ketones, alcohols, nitriles, ethers, weak organic acids, esters, water), activity coefficients can often be estimated from group contributions.

To illustrate, consider a mixture of toluene and acetone. For each component, there are two contributions to the activity coefficient: the first comes from the difference in molecular size, the second from attractive forces between molecular pairs. In this binary mixture there are three possible pairs: toluene–toluene, acetone–acetone, and toluene–acetone. To characterize these pair interactions, it is useful to introduce the group-contribution concept: each molecule is divided into groups as indicated in Figure 1. The interaction between one molecule and another is given as the sum of the group–group interactions, where each group in the first molecule interacts with each group in the second.

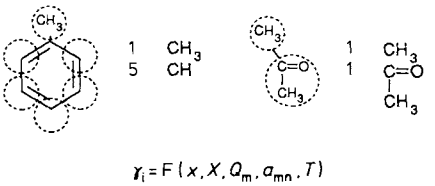

Fig. 1. Activity coefficients γ from group contributions, as exemplified by a mixture of toluene and acetone. γ_i = activity coefficient of toluene or acetone; x = molecular mole fraction; X = group mole fraction; Q_m = size of group m; a_{mn} = energy of interaction between group m and group n.

Contributions to γ_i from differences in molecular size depend on the composition through the usual mole fractions x. But contributions to γ_i from differences in attractive intermolecular forces depend on composition through the *group* mole fractions X. A semiempirical framework for calculating γ_i is provided by a model called UNIFAC.[2–4]

UNIFAC provides a group-contribution method for characterizing molecule–molecule interactions by summing suitably weighted group–group parameters for each group–group interaction. This procedure has a significant advantage: while the number of different molecules of interest in chemical technology is very large, these molecules are composed of a much smaller number of groups that appear over and over again. Nearly all organic molecules of current interest can be characterized by perhaps 40 to 60 groups, depending on how much distinction one allows for steric effects or for the influence of neighboring groups. In the group-contribution method, we replace molecule–molecule interaction parameters by group–group interaction parameters. For a wide variety of fluid mixtures, the number of different group–group interaction parameters is much smaller than the number of different molecule–molecule interaction parameters. Using group–group interaction parameters obtained from published activity-coefficient data, it is possible to predict activity coefficients for mixtures that have not been studied experimentally.

During the last 15 years, there has been a concerted effort to evaluate group–group interaction parameters from experimental data. Thanks to numerous contributors, primarily Prof. *Fredenslund* and Dr. *Rasmussen* and their co-workers at the Technical University of Denmark and Prof. *Gmehling* and his co-workers at the University of Dortmund (now at the University of Oldenburg), we now have a substantial

data bank of group–group interaction parameters; we also have computer programs for calculating activity coefficients based on UNIFAC.

To illustrate applicability, Figure 2 shows a freezing-point diagram for the system benzene–phenol. The lines are predictions; the points show experimental results. With some modifications, UNIFAC has also been applied to polymer solutions.[5–7] Some illustrative results are shown in Figure 3.

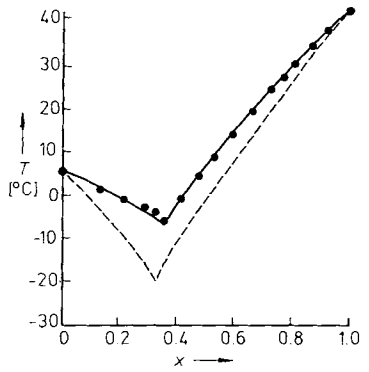

Fig. 2. Solid–liquid equilibria for the system benzene–phenol x = mole fraction of phenol in liquid phase; • = experimental; —— = predicted by UNIFAC; – – – = predicted for an ideal solution.

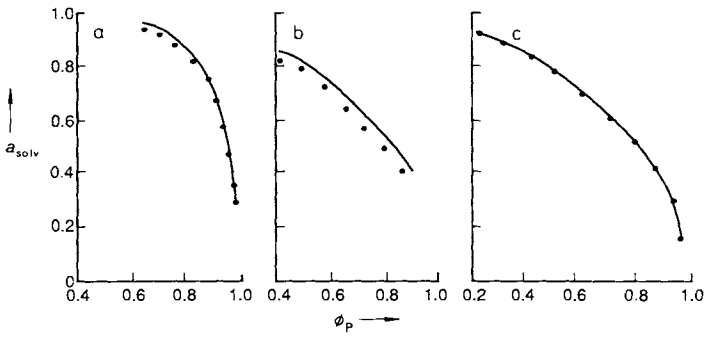

Fig. 3. Activities a of solvents in polymer solutions calculated from group contributions. Φ_p = volume fraction polymer; $\bar{M}$ = number-average molecular weight; • = experimental;—predicted by UNIFAP (UNIFAC for polymers). a) Benzene in polyisobutylene, 25 °C, $\bar{M}$ = 40000; b) ethyl acetate in polyvinyl acetate, 30 °C, $\bar{M}$ = 110000; c) benzene in polyethylene oxide, 70 °C, $\bar{M}$ = 5700.

Flaningham and *Hand*[8] have recently described an application of UNIFAC concerning the manufacture of silicones for specialty polymers, wetting agents, anti-foaming formulations, and numerous other uses in electronics and packaging. A key step in the manufacture of silicones is the synthesis of chlorosilanes, that is, compounds of silicon, hydrogen, and chlorine. In the chemical reactor, where silicon is allowed to react with methyl chloride, many different chlorosilanes are produced. Following synthesis, it is necessary to separate those chlorosilanes desired for a particular silicone from numerous side products. By studying experimentally a few selected binary mixtures of chlorosilanes, *Flaningham* and *Hand* obtained a set of pertinent group–group parameters; using UNIFAC, they are then able to predict activity coefficients in multicomponent mixtures containing many different chlorosilanes.

UNIFAC (or any other group-contribution method) does not eliminate the need for experimental data, but it very much reduces the amount of experimental work that is needed to estimate activity coefficients in multicomponent mixtures. The accuracy of prediction is not very high, but it is often sufficient for preliminary design purposes.

Two additional examples indicate the versatility of the group-contribution method. These examples are not concerned with the usual distillation or extraction applications found in textbooks. Instead, they are concerned with a subject that has always been important but that in recent years has become a major focus of industrial chemistry: safety.

In chemical process design, serious attention must be given to prevention of fires and explosions. Toward that end, a useful design parameter is the flash temperature (also called flashpoint), that is, the temperature where a flame can be propagated when the equilibrium vapor of a liquid is mixed with air at atmospheric pressure, as illustrated in Figure 4. L_i

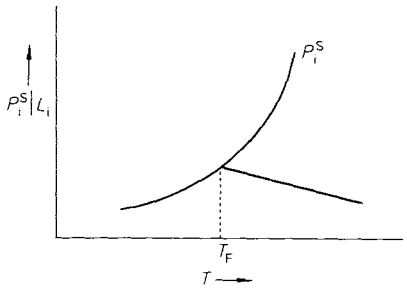

Fig. 4. Flash temperature T_F for a pure substance. P_i^s = partial pressure (vapor pressure) of liquid i; L_i = partial pressure of i at lower flammability limit.

has been obtained experimentally for many liquids using standardized procedures. Figure 4 is for a pure liquid. To calculate the flash temperature for a liquid mixture, we must find the temperature which satisfies relation (3), where p_i is the partial pressure of component i in the liquid mixture.

$$\sum_i p_i/L_i = 1 \tag{3}$$

(Equation (3) is not exact but provides a good approximation.) For finding the flash temperature of a mixture, the essential problem is the calculation of p_i given by Equation (4),

$$p_i = \gamma_i x_i P_i^s \tag{4}$$

where x_i is the mole fraction of component i in the liquid mixture and γ_i is its activity coefficient.

A group-contribution method such as UNIFAC can be used to estimate γ_i. To illustrate, Figure 5 compares UNIFAC predictions with experimental results for the flash temperatures of water–ethanol mixtures.[9] Similarly, Figure 6 shows calculated and experimental flash temperatures for the partially immiscible binary system methanol–heptane.[10] Also shown are predicted results assuming ideal-solution behavior ($\gamma_i = 1$). Figure 6 shows that flash tempera-

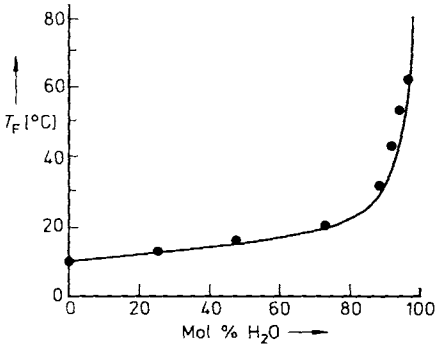

Fig. 5. Predicted and observed flash temperatures T_F for mixtures of ethanol and water. • = experimental (*M. Choe, H. G. Schecker*, 1981); — = predicted using UNIFAC [9].

tures based on ideal-solution behavior are dangerously high because they indicate that the mixtures are safe under conditions where, in fact, they are not safe.

Activity coefficients may also find application in monitoring air quality in chemical plants where solvent mixtures are used. Vapors from these mixtures may be harmful to plant personnel. To monitor air quality, it is often possible to use a chemical sensor which continuously measures the concentration of one key component, but it is not practical to use sensors for every component that may exist in the multicomponent solvent mixture.

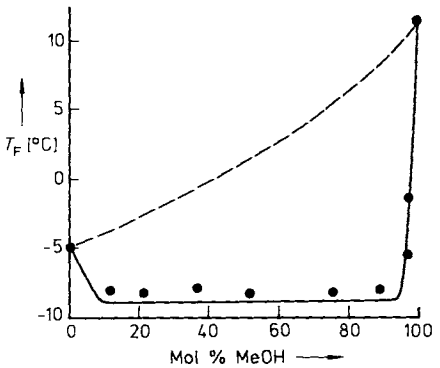

Fig. 6. Predicted and observed flash temperatures for mixtures of methanol and heptane, including the partial-miscibility region. • = experimental (*M. Choe*, 1982); — = predicted using UNIFAC [10]; - - - = predicted for an ideal solution.

In a chemical plant, the composition of the air depends not only on the equilibrium partial pressures of the components in the solvent mixture but also on the extent of ventilation. Suppose the chemical sensor measures Y_j, the moles of component j per liter of air. For typical solvent mixtures, the ratio of Y_i to Y_j can be estimated to a good approximation by Equation (5), where x is the liquid-phase mole fraction,

$$\frac{Y_i}{Y_j} = \frac{\gamma_i x_i P_i^s}{\gamma_j x_j P_j^s}\left(\frac{D_i}{D_j}\right)^k \tag{5}$$

P^s the pure-liquid vapor pressure, γ the activity coefficient, and D the diffusivity in air. Under stagnant conditions (negligible flow of air), $k = 1$. As air velocity rises, k falls. For typical normal ventilation conditions, $k = 0.5$.[11]

Equation (5) provides a simple method for continuous chemical analysis of air pollutants arising from solvent mixtures. Analytical measurement is required for the concentration of only one key component (j); the concentrations of the others (i) are calculated. The estimate provided by Equation (5) requires the liquid-phase composition of the solvent mixture, as well as pure-component vapor pressures and diffusivities in air, which depend only on temperature. But in addition, Equation 5 requires activity coefficients, which often depend strongly on composition; for components at high dilution, γ_i may be of the order of 10 or 100. These activity coefficients can be obtained from a group-contribution method. While the accuracy is not very high, it is often sufficient for maintenance of industrial hygiene. In a chemical production facility where solvent mixtures may present a potential health hazard, a single chemical sensor, coupled with a microprocessor, can produce continuous surveillance of air quality.

4. Crystallization of Uniform Particles from a Supercritical Solvent

For describing the thermodynamic properties of fluids, the classical procedure (dating back more than 100 years to *van der Waals*) is to construct an equation of state, that is, an equation relating the pressure of a system to its temperature, density, and composition. From a equation of state, we can calculate many of the thermodynamic properties required for chemical process design.

A well-known application of equations of state is for calculation of vapor–liquid equilibria as required for design of distillation columns, especially at high pressure.[1] Since that application is well described, we need not discuss it here. Instead, we call attention to a recent application, which is directed at design of a crystallization process for obtaining very small crystals with a narrow size distribution, as required, for example, for pharmaceutical products.

Normally, crystallization is achieved by cooling a solution of the desired solid in a liquid solvent. Since bulk cooling cannot be achieved rapidly, thermal gradients in the solution tend to produce a broad distribution of particle sizes. By contrast, if the liquid solvent is replaced by a dense gas near its critical state, a small, sudden decrease in pressure can precipitate particles of uniform size. The essential advantage is that the solvent power of a dense gas falls very quickly in response to a drop in pressure. To design a pressure-induced crystallization process, we need to know the solubility of the solid component in the dense gas as a function of temperature and pressure; that solubility can be obtained from an equation of state. Further, the rate of crystallization is described by theories which require information on the chemical potential of the dissolved solid in a supersaturated solvent; that chemical potential is also obtained from the same equation of state.

Chang and *Randolph*[12] designed a process for recrystallizing β-carotene from supercritical ethylene; β-carotene is a potentially useful medication for lowering blood cholesterol and for cancer prevention. For optimum pharmaceutical effect, β-carotene particles should be small with a narrow size distribution.

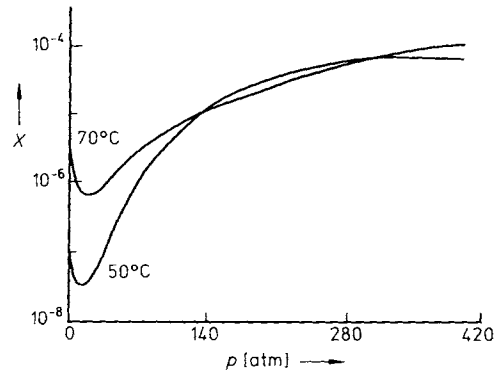

Fig. 7. Solubility of β-carotene in supercritical ethylene. The calculations are based on a modified Peng–Robinson equation of state, using only a few experimental measurements [12]. x = mole faction of β-carotene.

Figure 7 shows the solubility of β-carotene in ethylene, whose critical temperature and pressure are 9 °C and 50 atm. Near critical conditions, a small change in pressure can produce a large change in solubility. The results were obtained using an equation of state coupled with only a few experimental data. Figure 8 shows two size distributions for solid β-carotene particles. The broad distribution is for the feed material, the narrow distribution for the product crystallized from supercritical ethylene.

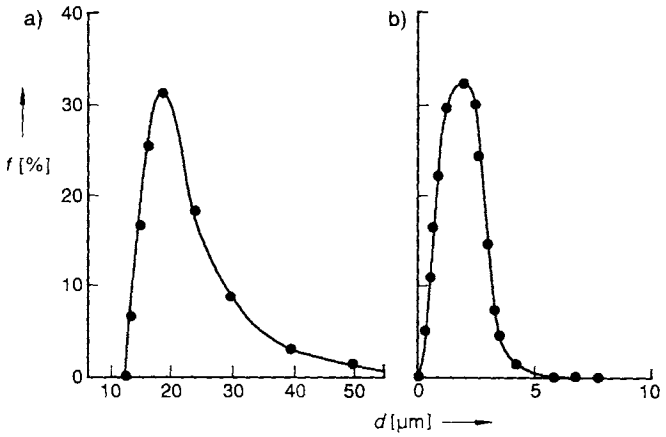

Fig. 8. Crystallization of β-carotene from supercritical ethylene. The product has a much smaller average particle size and a more narrow size distribution. f = differential fraction expressed as per cent; d = particle diameter. a) Experimental data for feed; b) experimental data for product.

Design of a supercritical-fluid crystallization process requires transport data (heat and mass transfer) in addition to thermodynamic information. But the thermodynamic information is primary because, prior to any rate calculations, it addresses the question of feasibility: what conditions are needed to make a process possible? An equation of state, coupled with a few experimental measurements, can quickly answer that question.

5. Thermodynamic Properties from Molecular (Computer) Simulations

The range of thermodynamic applications in industry has been significantly extended by supercomputers which enable calculation of thermodynamic properties by molecular simulations. In such simulations, intra- and intermolecular forces are given by quantum-mechanical or semiempirical equations. The properties of individual molecules or of assemblies of molecules are then obtained by numerical methods which require vast computing power. To illustrate such applications, we briefly discuss two examples.

5.1. Chemical Stabilities of Chlorofluorohydrocarbons (Freons)

Chlorofluorohydrocarbons are used extensively throughout the world as coolants in refrigerators and air conditioners, as blowing agents, and as solvents. But, unfortunately, many commonly used freons destroy ozone in the stratosphere and therefore, to protect the environment, there has been a search for new refrigerants that are useful for technology but that do not decompose ozone.

Ironically, presently used freons are environmentally unacceptable because of their remarkable chemical stability. A typical conventional freon passes through the troposphere without decomposing and then has a long lifetime in the stratosphere, where, ultimately, ultraviolet radiation causes cleavage of C–Cl bonds; the released chlorine atoms catalyze ozone decomposition.

For a compound i, chemical stability is measured by an equilibrium constant K_i given by $K_i = \exp - G_i^f/(RT)$, where R is the gas constant and G_i^f the Gibbs energy of formation of compound i from its stable elements; for example, for CF_2Cl_2, G^f is the change in Gibbs energy for reaction (6). For high stability (large K_i), $G^f/(RT)$ is negative and much larger than unity.

$$C + F_2 + Cl_2 \rightarrow CF_2Cl_2 \qquad (6)$$

The stabilities of conventional freons are so high that they reach the stratosphere where, eventually, they contribute to ozone decomposition; such freons must be rejected. On the other hand, chlorofluorohydrocarbons with very low stability constants are also unsatisfactory because they decompose too easily. To provide guidance in searching for an environmentally acceptable refrigerant, it is desirable to have G^f values for numerous chlorofluorohydrocarbons so that those with very high or very low stability constants can be eliminated from further consideration.

The Gibbs energy of formation is obtained from H^f, the enthalpy of formation, and S^f, the entropy of formation [Eq. (7)].

$$G^f = H^f - T S^f \qquad (7)$$

While H^f can be measured directly using calorimetry, S^f is obtained from the third law of thermodynamics through integration of heat-capacity measurements at low temperatures. The required experimental measurements are tedious and require much patience. Therefore, experimental G^f results are available for only a limited number of chlorofluorohydrocarbons.

Molecular simulation provides an alternative to experimental measurements. The enthalpy of formation can be

...ated using molecular-orbital theory and, for molecules of moderate size at reasonable temperatures, the entropy of formation can be calculated using statistical mechanics with parameters obtained from spectroscopic correlations.[13]

It is therefore possible to use large computers to generate stability constants for a substantial number of refrigerants that *may* be useful for technical application. The stability constant can immediately tell us whether a given chlorofluorohydrocarbon can exist under ordinary conditions and whether it is likely to decompose before it reaches the stratosphere.

In the troposphere, the most common reactive species is the hydroxyl radical ·OH. To estimate if a chlorofluorohydrocarbon is likely to decompose, it is therefore helpful to calculate the equilibrium constant for reaction (8). For that calculation we again require the Gibbs energy of formation of the chlorofluorohydrocarbon in the reaction.

$$\text{chlorofluorohydrocarbon} + {}^{\cdot}\text{OH} \rightarrow \text{products} \qquad (8)$$

While kinetic and other nonthermodynamic properties are also important for assessing a chlorofluorohydrocarbon, molecular-simulation calculations provide a helpful screening procedure; these calculations give guidance concerning which refrigerants are most likely to satisfy requirements for technical applicability as well as for meeting environmental concerns.

5.2. Adsorption of Gas Mixtures

Another industrially oriented example is provided by molecular-simulation calculations for adsorption of gas mixtures in porous media. For a given system of gases and adsorbent at fixed temperature, these calculations give the individual amounts of fluid adsorbed per gram of adsorbent as a function not only of partial pressure, but also of pore size.

Consider adsorption of methane on solid carbon as shown schematically in Figure 9. Because there is a strong energy of

	Small pores	Large pores
Surface area per gram of carbon	High (ΔH is strongly favorable)	Low (ΔH is only weakly favorable)
Accessibility of pores to methane molecules	Low (ΔS is strongly unfavorable)	High (ΔS is only weakly unfavorable)

Fig. 9. Effect of particle size on adsorption of methane on carbon.

attraction between a methane molecule and the carbon atoms of the solid, methane "likes" to adsorb on the carbon surface. To maximize adsorption per gram of carbon, it is desirable to increase the surface area per gram; this increase is achieved by using porous carbon. But now a problem arises: to maximize surface area, we want very small pores; however, if the pores are too small, the methane molecules are not able to move easily into and within the pore. We have here a classical optimization problem directly related to thermodynamics [Eq. (9)].

$$\Delta G(\text{adsorption}) = \Delta H(\text{adsorption}) - T\Delta S(\text{adsorption}) \qquad (9)$$

For strong adsorption, we want ΔG(adsorption) to be large and negative. Because methane is attracted to carbon, ΔH(adsorption) is negative and that is good; we want a large surface area, because ΔH(adsorption) is directly proportional to the accessible surface area. But ΔS(adsorption) is also negative and—because of the minus sign in Equation (9)—that is not good. As pores become smaller, the magnitude of ΔS(adsorption) becomes increasingly larger due to geometrical interference of the methane molecules in the pore; this interference is called the excluded-volume effect. As pore size becomes very small, the total surface area rises but the accessible surface area declines.

For a fixed temperature and partial pressure of methane, there is an optimum pore diameter where methane adsorption is maximized. This optimum can be calculated using molecular simulations.

Instead of methane, consider ethane adsorbing on the same carbon surface. Again, we can use molecular simulation to calculate an optimum pore diameter. The optimum pore diameter for ethane will not be the same as that for methane, because ethane molecules are larger than methane molecules and because the attractive energy for ethane-carbon is not the same as that for methane-carbon.

But now, finally, consider a mixture of methane and ethane. We want to separate the mixture by adsorption using a carbon adsorbent; what is the best pore diameter for achieving this separation? In other words, what pore diameter will give the maximum selectivity β?

The selectivity of component 2 (ethane) relative to component 1 (methane) is defined by Equation (10), where ζ is the mole fraction in the adsorbed phase and y is the mole fraction in the bulk (gas) phase. For efficient separation, we want β_{21} to be as large as possible.

$$\beta_{21} = \frac{y_1(1-\zeta_1)}{\zeta_1(1-y_1)} \qquad (10)$$

Consider a gaseous mixture at 200 K containing 90 mol% methane and 10 mol% ethane; at 18.6 bar, this mixture is near its dew point. We want to remove ethane by selective adsorption on porous carbon. For this mixture, Figure 10 shows selectivities calculated by *Tan* and *Gubbins*[14] as a function of pore diameter. For small pores, the selectivity oscillates as pore size rises, as we might expect since the diameter of methane is about 3.8 Å while that for ethane is only a little larger. For small pores, wall effects are extremely important. As pore size increases, wall effects begin to disappear and eventually the selectivity reaches an asymptotic value where pore size no longer matters.

An economic adsorbent must possess not only good selectivity but also high capacity. The model used by *Tan* and *Gubbins* necessarily gives only an idealized representation of a real porous carbon. A model should never be confused with reality. Nevertheless, computer-generated calculations

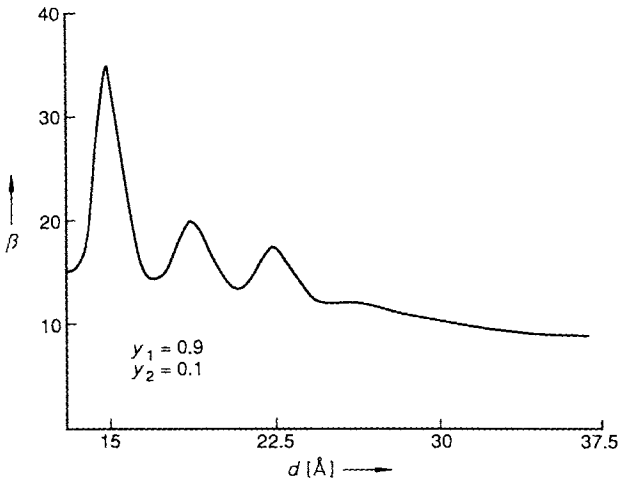

Fig. 10. Molecular simulation of the effect of pore diameter on selectivity in adsorption of a mixture of methane (1) and ethane (2) on carbon [14]. β = selectivity; d = pore diameter; y = mole fraction in the gas phase; $T = 200$ K; $p = 18.6$ bar.

similar to those outlined here can provide guidance for selecting the best absorbent for a desired separation.

6. Separation of a Protein Mixture

The rising importance of biotechnology presents a new challenge: Can molecular thermodynamics be extended to apply also to biotechnical processes? Efforts toward that end are now in progress in many laboratories. An example is provided by applying molecular thermodynamics toward design of an aqueous two-phase extraction process for separation of mixtures containing proteins.

Figure 11 presents a schematic of the extraction system. When two water-soluble polymers are dissolved in an excess

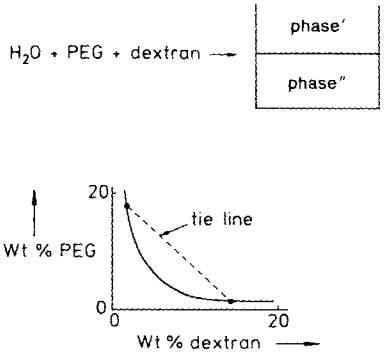

Fig. 11. Formation of a two-phase aqueous mixture for extraction. Phase' = PEG containing a small amount of dextran; phase" = dextran containing a small amount of PEG. Below: Calculated phase diagram.

of water, we obtain two separate phases. Figure 12 indicates the extraction process; when a mixture of proteins is added to the two-phase aqueous system, some proteins prefer to go to the upper phase, others to the lower phase. Therefore, separation can be achieved.

Typical phase-forming polymers are polyethylene glycol (PEG) and dextran. To prevent denaturation and to maintain pH control, small amounts of (buffer) salts may be added. The desired contribution of molecular thermodynamics is to provide a model for predicting the partition coefficient of a protein.

Fig. 12. Separation of a mixture of proteins i, j, k, ... by extraction. For the definition of the partition coefficient K, see Equation (13).

The first task is to calculate the liquid–liquid phase diagram formed by water and the two water-soluble polymers. This calculation is achieved by expressing the chemical potentials of all three components through an osmotic virial expansion in the polymer concentrations; the coefficients in that expansion are obtained from low-angle light-scattering data.[15]

For equilibrium between liquid 1 and liquid 2, Equation (11) holds; μ is the chemical potential; subscript 1 refers to

$$\mu_1' = \mu_1''; \; \mu_2' = \mu_2''; \; \mu_3' = \mu_3'' \tag{11}$$

water and subscripts 2 and 3 refer to the water-soluble polymers. For i = 1, 2 or 3, μ_i is given by Equation (12),

$$\mu_i = \mathscr{J}_i \text{ [concentrations of 2 and 3; } B_{22}; B_{33}; B_{23}] \tag{12}$$

where B_{jk}, the osmotic second virial coefficient, reflects the interaction of solute molecule j with solute molecule k in the aqueous solvent. $\mathscr{J}_i$ is a known function, obtained from the osmotic virial expansion.

With virial coefficients obtained from low-angle laser light-scattering measurements, it is possible to generate a reliable phase diagram, as shown schematically at the bottom of Figure 11.

Consider now a protein component (4) which is distributed between the two aqueous phases. The partition coefficient K is defined by Equation (13).

$$K_4 = \frac{\text{concentration of protein in phase'}}{\text{concentration of protein in phase"}} \tag{13}$$

Depending on pH, the protein may be electrically charged and therefore the presence of ions (salts) must be taken into account. When all proteins in the system are dilute, Equation (14) holds. Here, F is Faraday's constant, Φ the electric

$$\ln K_4 = \ln \frac{\gamma_4''}{\gamma_4'} + \frac{F z_4 (\Phi'' - \Phi')}{RT} \tag{14}$$

potential, z the electric charge (vector), and γ the chemical activity coefficient.

Activity coefficients are found from the osmotic virial expansion with coefficients B_{22}, B_{33}, B_{23}, B_{24}, and B_{34}; addi-

tional terms for protein–salt and polymer–salt interactions are obtained from osmometric data.[16]

The electric-potential difference between the two phases arises because the salt does not partition equally between the two phases. This difference is given by a relation [Eq. (15)] similar to the Nernst equation,

$$\Delta\Phi = \Phi'' - \Phi' = \left(\frac{RT}{F}\right)(z_+ + z_-)^{-1} \ln\left(\frac{\gamma''_-}{\gamma''_+}\right)\left(\frac{\gamma'_+}{\gamma'_-}\right) \qquad (15)$$

where z is the absolute value of the ion's electric charge. Activity coefficients γ_+ and γ_- are again found from the osmotic virial expansion.

In typical cases, the potential difference is small, perhaps a few millivolts. But that small potential difference can have a large effect. In some cases, the effect of the potential difference on K_4 is dominant, much more important than that of the activity coefficients.

Figure 13 compares calculated and experimental partition coefficients for albumin, chymotrypsin, and lysozyme. The horizontal axis of Figure 13 is the tie-line length (Fig. 11, bottom), which provides a measure of how different phase′ is from phase″; when the tie-line length is zero, the two phases are identical.

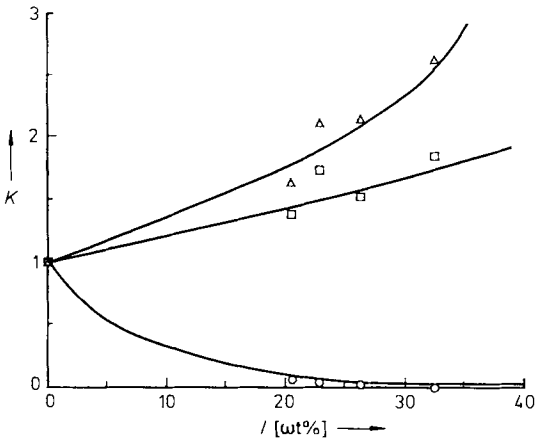

Fig. 13. Predicted and experimental partition coefficients for a protein mixture in an aqueous two-phase system containing PEG 3350, dextran T-70, and 50 mM KCl (overall). l = tie-line length; d = diameter [Å]; z = electric charge; pH = 7.5; 25 °C. ○ = albumin (d = 78; z = −8); □ = chymotrypsin (d = 34; z = 2); △ = lysozyme (d = 22; z = 7).

The molecular-thermodynamic analysis shows that when the protein is charged, the influence of the electric potential is often decisive. This molecular-thermodynamic analysis, therefore, suggests that enhanced partition coefficients for a protein could be obtained by raising the asymmetry of partition of the salt. One method for doing so is provided by adding to the two-phase system a very small amount of α-cyclodextrin and a salt whose cation is strongly adsorbed by that cyclodextrin. Figure 14 shows the effect on the partition coefficient for chymotrypsin when the salt is KI.

We have here a particularly happy example to indicate how molecular thermodynamics can benefit process design. Thermodynamic analysis showed the unexpectedly large influence of salt partitioning on the partition coefficient of a charged protein. Once that influence was identified, the sharpness of separation could be significantly improved by enhancing the electric potential difference between phases′ and ″ through the addition of a suitably chosen entrainer.

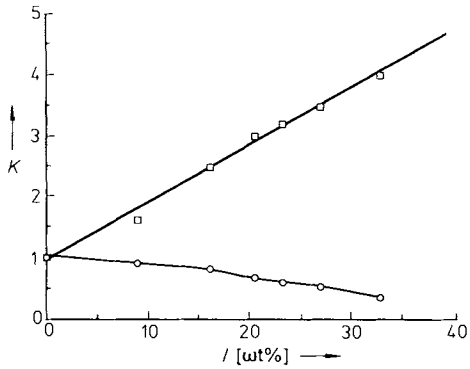

Fig. 14. Effect of electric potential $\Delta\Phi$ on the partition coefficient for chymotrypsin in PEG 3350/dextran T-70/water. z = 5; pH = 7.3; 25 °C. ○ = 1 mM KI; □ = 1 mM KI + 1 mM α-cyclodextrin.

7. Molecular Thermodynamics of Hydrophilic Gels

The traditional domain of chemical thermodynamics has been confined to gases, liquids, and solids. However, especially in recent years, physical chemists and chemical engineers have also applied thermodynamics to partially ordered media such as liquid crystals, micelles, and gels. These partially ordered materials are likely to have numerous applications in different areas of technology including packaging, insulation, extractive metallurgy, and agriculture, as well as medicine and pharmaceutics.

Here we present briefly a few results of recent studies on temperature-sensitive phase transitions in hydrophilic gels made from cross-linked poly(*N*-isopropylacrylamide). When this gel is in contact with water (or with aqueous solutions), it can experience a tremendous increase in volume. That increase depends strongly on temperature.

Figure 15 shows some experimental results by *Hirotsu* et al.[17] where the gel volume is plotted against temperature for different compositions of the aqueous phase. For some temperatures we see large first-order phase transitions; a very small change in temperature can produce either a large

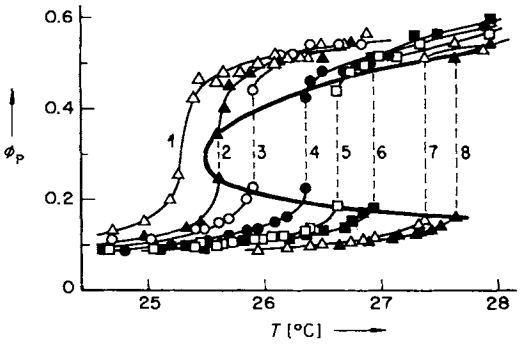

Fig. 15. Swelling of *N*-isopropylacrylamide gels in water–methanol mixtures [17]. Vol% methanol: 18.5 (curve 1), 18.0(2), 17.5(3), 17.0(4), 16.5(6), 15.5(7), 15.0(8). Φ_p = volume fraction of polymer.

swelling of the gel (similar to vaporization of a liquid) or a collapse (similar to condensation). These volumetric properties, including first-order phase transitions, can be described quantitatively using molecular-thermodynamic methods.

Hirotsu's results are for gels in contact with aqueous mixtures. For simplicity, we consider here a gel that is in contact with pure water. For such a gel, the equation of equilibrium is (16), where μ_w is the chemical potential of water. We know the chemical potential of pure water as a function of temperature. However, for the chemical potential of water in the gel phase we must develop an appropriate model.

$$\mu_w(\text{pure liquid}) = \mu_w(\text{gel}) \tag{16}$$

To obtain μ_w (in gel), we need an expression for the Gibbs energy G of the gel phase because μ_w (in gel) is related to G by Equation (17), where n_w = moles of water.

$$\mu_w(\text{in gel}) = \left(\frac{\partial G(\text{gel phase})}{\partial n_w}\right)_{T,p} \tag{17}$$

When water enters a gel phase, there is a contribution to G from mixing; in addition, there is a contribution to G from elastic deformation, because the gel stretches (swells). To calculate the chemical potential of water in the gel, we need one model for mixing water and gel and another for elastic deformation. Fortunately, such models are now available.[18-20] Calculations at two characteristic temperatures are shown schematically in Figure 16. At some unique temperature, when a plot of the second type meets the equal-area criterion (Maxwell construction), we have a first-order phase transition; at that unique temperature, we have three coexisting phases: water, swollen gel, and collapsed gel. Thus, classical thermodynamic methods, coupled with molecular-thermodynamic models, can be used to calculate swelling properties of hydrophilic gels, including phase transitions.

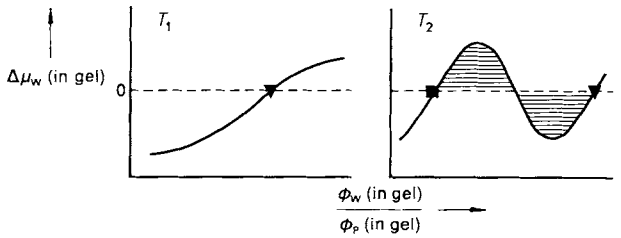

Fig. 16. Phase transition in a temperature-sensitive hydrogel. Φ_w = volume fraction of water. At T_1, water is in equilibrium with swollen gel (▼). At T_2, water is equilibrium with swollen gel (▼) and collapsed gel (■). The shaded areas are equal (Maxwell construction).

Figure 17 shows an application: a continuous extraction process for separating proteins from soybeans, where the extracting agent is a temperature-sensitive gel. By controlling the extent of cross-linking in the gel, water is readily absorbed while protein is not; in effect, the gel acts as a filter. The temperature-sensitive properties of the gel make regeneration possible as required for a continuous process.[21]

Pharmaceutical companies are now giving attention to collapsible gels as devices for drug delivery, shown schematically in Figure 18. For some gels, the collapse can be produced by a small change of temperature; for others, it can be produced by changing the composition or pH of the surrounding liquid. The drug is placed in the fluid-filled gel, which acts as a holding matrix. When the gel collapses, the drug rapidly flows out of the gel by convection. Molecular thermodynamics provides a useful method for correlating and predicting the properties of a gel in response to changing external conditions.[22]

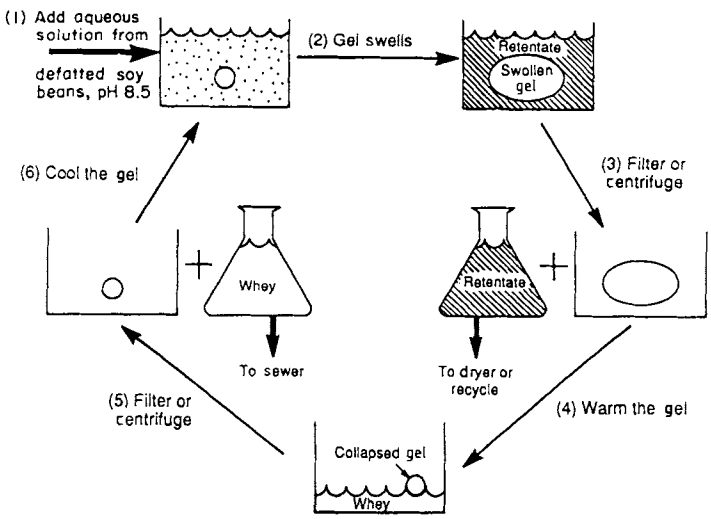

Fig. 17. Purification and concentration of a protein extract (from *Cussler* et al. [21]). Upon swelling, the gel rejects solutes with a molecular weight of about 10^4 or more ("retentate").

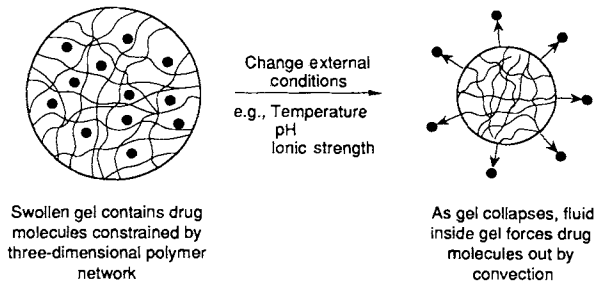

Fig. 18. Gels for controlled drug delivery.

8. Conclusion

The examples presented here show how molecular thermodynamics can contribute toward the development of chemical products and processes. Although the examples indicate a broad variety of applications, they all contain some common characteristics: in every case, there is a combination, a synthesis, of concepts from classical thermodynamics and from molecular physics or physical chemistry. This combination, this synthesis, is expressed through an approximate model that retains the essential physics of the phenomenon but that is also sufficiently simplified so that it can

be used for engineering purposes with a minimum of experimental data.

During the last generation, we have seen two related trends: first, unprecedented advances in science as shown in the exploding scientific literature; second, extensive advances in the quantity and variety of chemical products as shown in the prosperity of our material standard of living. All evidence indicates that these trends will continue and accelerate, subject only to the limits of raw materials and environmental concerns. These trends clearly indicate that there is an ever-growing need for effective communication between fundamental chemical sciences and chemical engineering. This needed communication is one form of what economists call technology transfer, that is, the challenge of bringing new scientific knowledge to the market place. Numerous tools are required to meet that challenge. One of these tools is molecular thermodynamics.

Advanced Materials: Trends and Possibilities in Liquid Crystalline Polymers

By James Economy*

During the past ten years there has been a sharp increase in interest in the opportunities afforded by R & D in the field of specialty polymers. Interest is mainly being shown in two distinct categories of polymers, namely, a) polymers which are used in very small quantities to fulfill critical needs as a part of device system, and b) high-performance engineering polymers which significantly extend their mechanical and thermal properties for structural applications. The first category ranges from advanced resists and insulating layers for microelectronic devices to membranes for filtration systems. The second category encompasses improved matrices for advanced composites as well as liquid crystalline polymers. In the present paper an overview is first given of the emerging opportunities for advanced materials and particularly specialty polymers. The status of work on liquid crystalline copolyesters is then discussed with special emphasis on one of the major problems confronting this field, namely interpreting the microstructure of the copolyesters.

1. Advanced Materials with a Future

As we look to the future technological possibilities of the 21st century it is generally accepted that the areas of advanced materials, biotechnology and information will represent the cornerstones of the high-technology industries of the future. It is noteworthy that the fields of biotechnology and information will also depend on the development of new materials. And, it quickly becomes apparent that scientific and technological advances in most of the technologies critical to the future (e.g. transportation, infrastructure, environmental control, energy, microelectronics, aerospace, defense) will depend on advanced materials.

One might justifiably question the potential for designing new and improved materials to address the myriad of needs that exist across these fields. In fact, one might also question the feasibility of even educating and training scientists and technologists to undertake R & D which encompasses the field of metals, ceramics and polymers, let alone composites, electronic materials, and biomaterials.

Regarding the first question one has only to look at the discoveries of the past two decades in the area of advanced materials to sense the tremendous opportunities in designing and tailoring new and improved systems for use by the high-tech industries of the future. The field of ceramics is particularly noteworthy when one recounts recent achievements concerning phase transformation toughened ceramics, high-temperature superconductors, ceramic composites, diamond films, and new kinds of ferroelectrics. In the case of polymers one might note recent developments in the areas of liquid crystalline polymers, molecular composites, membranes, thermoplastic matrices, radiation sensitive polymers, and thermally stable polymers.

With respect to the second question concerning the education and training of scientists and technologists in materials science and engineering (MSE) this is clearly a major challenge. We can see some glimmerings of the future from the attempts of educators in MSE who are trying to design a curriculum which will permit the scientists of the future to effectively work at the interfaces of this field. A closer scrutiny of the six major areas of materials science (Table 1) suggests that the field can be described as a matrix in which the fields of metals, ceramics and polymers, and electronic materials, composites and biomaterials are clearly interdependent and share many points in common. Then what remains is to structure a curriculum which provides the student with the skills in synthesis and processing, structure and property relationships and characterization without in any way sacrificing the basics in mathematics, physics and chemistry—a tremendous challenge for the universities!

Table 1. Materials science and engineering. A: There is a critical interdependency. B: There are some areas of overlap.

	Composites	Electronic Materials	Biomaterials
Ceramics	A	A	B
Metals	A	A	B
Polymers	A	A	A

This responsibility cannot be deferred to industry with the expectation that the young scientist will master the key elements of MSE during his first few years in industry. The logical place, in fact the only place where this process can occur is in a university environment. I tend to be very optimistic about the prospect of achieving this goal based on my personal experience in beginning to implement a completely new, integrated curriculum in MSE at the University of Illinois.

2. Possibilities for New Types of Polymers

Let me turn more specifically to the field of polymers, since this represents an area where the BASF Corporation has made many major contributions over the past 50 years.

[*] Prof. Dr. J. Economy
Department of Materials Science and Engineering
1304 West Green Street, Urbana, IL 61801 (USA)

From the period 1930–60 we witnessed the birth and maturation of the field of commodity synthetic plastics. This plastics revolution dramatically changed the field of materials providing far more versatile materials to replace the natural fibers, cellulosic film, phenolic molding compounds and even structural metals. However, by the mid 1960's it became apparent that there were no new commodity polymers left to be discovered and the emphasis began to shift to speciality polymers. Today one could easily argue that the opportunities that exist for research in polymers is greater than ever before (Table 2). These opportunities will be discussed in somewhat more detail in the following sections.

Table 2. Scope of application of specialty polymers.

Structural polymers
● Thermoplastic matrices for advanced composites
● Molecular composites
● Melt processible liquid crystalline polymers
Polymers for electronic applications
● Ultrasensitive resists for submicron lithography
● Thermally stable dielectric insulators
● Substrates and encapsulants
Polymers for pollution control
● Selective adsorption of CO_2, Freons, SO_x
● Removal of trace pollutants from ground water
Membranes
● Biopolymers

In the area of structural polymers significant progress has been achieved in the design of improved matrices for high performance composites. Thus, we have witnessed development of both rubber toughened thermosets as well as thermoplastic matrices. Today both areas are being pursued aggressively in order to further optimize the damage resistance of fiber reinforced composites. These approaches are indicated schematically in Figure 1 along with other related con-

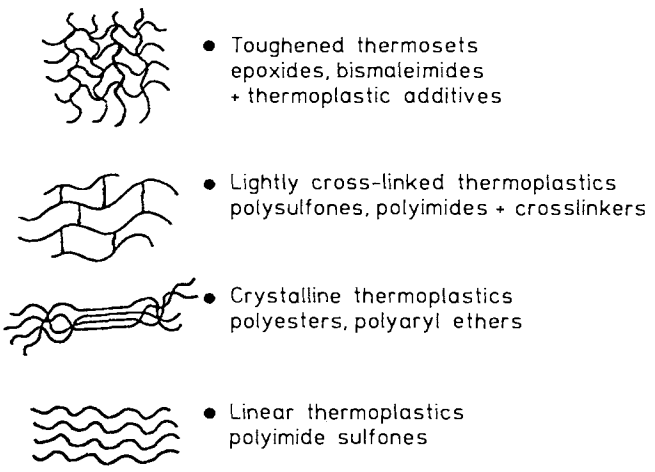

Fig. 1. Molecular approaches to improved matrices for advanced composites

cepts. The concept of molecular composites in which high strength/modulus microfibrils such as polybenzoxazole are dispersed in a high-temperature polymer matrix has also received considerable attention. One should mention however that these microfibrils may have diameters in the range of 1000 Å, hence the teminology "molecular composites" may be somewhat inappropriate. Work on liquid crystalline polymers based on aromatic polyesters has been pursued intensively since the late 1960's; this will be discussed in more detail later.

Turning to electronic materials there is little doubt that the need for new kinds of polymers such as resists, substrates and insulating layers is greater today than at any time in the past 20 years. Thus, progress in going to higher density D-RAM chips and packages requires ultrasensitive resists for use in far-UV, X-Ray and E-Beam lithography. New kinds of photosensitive, high-temperature polymers with very low dielectric constants are required as insulating layers in both the advanced chips and packages. Figure 2 shows the

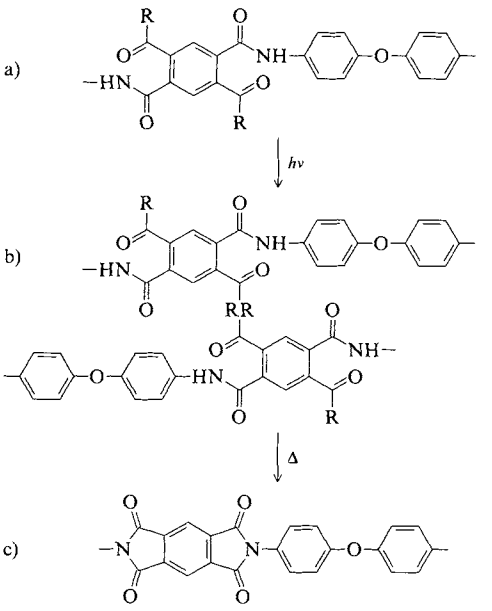

Fig. 2. Chemical steps in the processing of a photosensitive polyimides; R = $-OCH_2CH_2OC(O)C(CH_3)=CH_2$. a) Soluble, photoreactive precursor, b) insoluble photo-crosslinked intermediate, c) heat-resistant final product.

well known chemistry of the photosensitive polyimides developed in the 1970's at Siemens. A more recent approach involves the use of photosensitive diacetylenic oligomers which, on exposure to light and heat, yield a cross-linked structure (Fig. 3). Such systems are inert to moisture and can display significantly lower dielectric constants of less that 3.[1] The increased numbers of interconnects between the chip and substrate result in fatigue problems that can only be resolved by development of substrates that better match the thermal expansion coefficient of silicon. These are some of the needs facing the microelectronics industry which promise to challenge polymer scientists through the next decade.

In the area of pollution control, opportunities for advanced materials have hardly been addressed. In fact, most of the research on the problems of global warming, ozone depletion, acid rain, and urban air pollution have focussed on attempts to quantify the seriousness of the problem. Attempts to design materials for solving these problems have not been pursued in any substantive manner. Undoubtedly, one of the reasons is that many of the government funding agencies have not, as yet, been made aware of the opportuni-

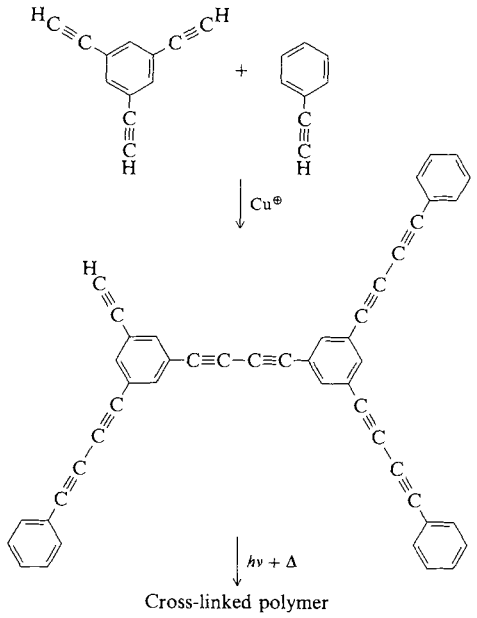

Fig. 3. Design of a photosensitive diacetylene polymer with a low dielectric constant.

ties afforded by the design of advanced materials to quantitatively remove atmospheric impurities from the environment. It would seem that during the next decade we will witness a greatly increased effort in the design of advanced polymers to control both air and water pollutants. One interesting approach to the design of activated carbons uniquely tailored to adsorb specific trace contaminants has been reported recently.[2] In this method the activated carbon surface is locally chemically converted into a range of different surfaces (Fig. 4). Some of the characteristics of these new materials are collected in Table 3.

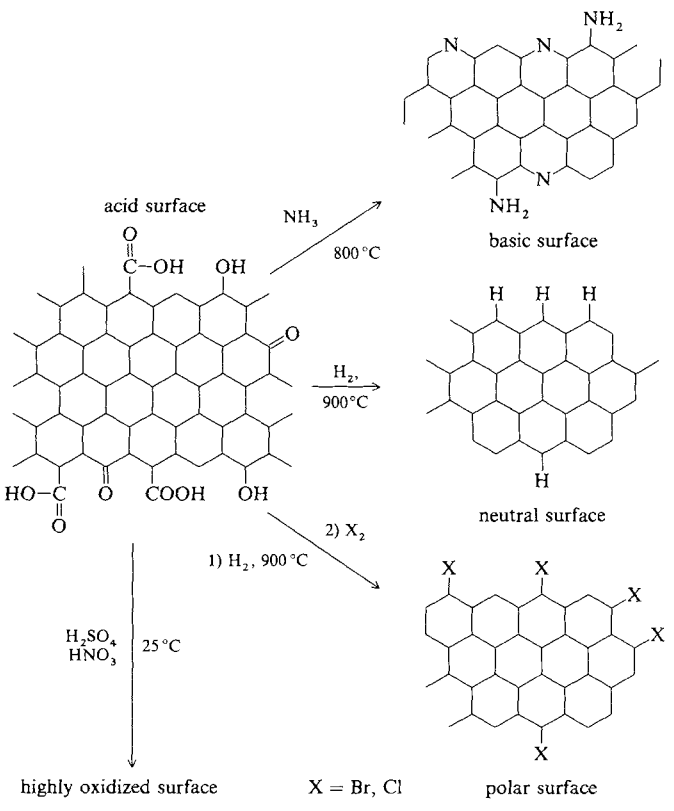

Fig. 4. Preparation of chemically tailored carbon surfaces.

Table 3. Characteristic data of chemically tailored carbon surfaces.

Chemical treatment	T [°C]	Elemental analysis	Surface area [m^2/g]	Weight change [%]
Steam [a]	900	4.1% O	1658	−40
NH_3(gas)	800	6.3% N	2274	−32
H_2(gas)	900	0.5% H	1276	−6.8
Cl_2(gas)	450	25% Cl	891	+8.5
Br_2	25	13% Br	890	+23
H_2SO_4/HNO_3	25	40% O	574	+25

[a] Used as precursor for the preparation of the surface.

For sake of brevity, the opportunities in biopolymers and advanced membranes will not be considered in this paper. However, it should be noted that both of these fields provide tremendous opportunities for basic and applied research, and this is clearly evident from the intense efforts currently underway in the USA, Germany, and Japan. Considerable effort is also being expended on improving the processes and properties of many of the commodity polymers developed in an earlier era. Such efforts continue to pay off handsomely, as with the recent improvements in the manufacture of polypropylene.

One might summarize that the field of materials and especially of polymers afford many opportunities for research. One point that cannot be overemphasized is the importance of carrying out fundamental research associated with the more directed developments in advanced materials. In fact, the discussion which follows on liquid crystalline polymers provides an excellent example of the problems that may arise when technologists get too far ahead of the scientists.

3. Liquid Crystalline Polymers

3.1. Background

The phrase "liquid crystalline polymers" encompasses both lyotropic as well as thermotropic systems. Since many of the questions concerning lyotropics such as the Aramids have been addressed since the early 1970's emphasis here will be placed on the thermotropics and particularly the aromatic copolyesters of *p*-hydroxybenzoic acid (HBA).

This class of polymers was discovered in the Spring of 1963, and in 1970 began the commercialization of homo- and copolymers of HBA.[3] During this early period practically all of the R & D was of a developmental nature and directed at the goals enumerated in Table 4. The significance of these early efforts is illustrated by the fact that the materials which were introduced in 1970 and 1972 are still commercially available today, some 20 years after their original introduction. In the meantime, starting in the late 1970's and continu-

Table 4. Early developmental thrusts on the aromatic polyesters.

Synthesis –	low cost, scaleability, reproducibility

Patent protection –	composition, processing, end-use
Customer applicatons –	tailored compositions

ing to the present, a number of companies have introduced their own versions of the liquid crystalline copolyesters of HBA.[4, 5] However, today it appears that further commercial development is gated by our lack of understanding of 1) the microstructure of these copolyesters and 2) the rheological features which control the tendency for these materials to form skin-core and microfibrillar structures (Fig. 5). The

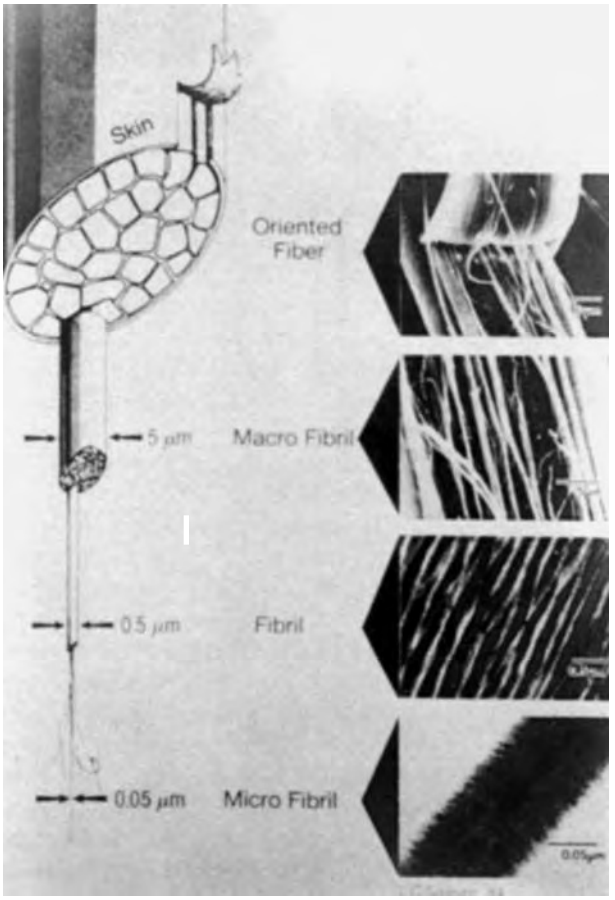

Fig. 5. Structure of liquid crystalline polyesters.

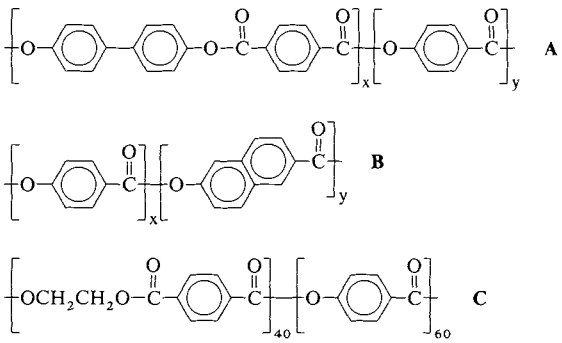
first problem has been identified as the single most important fundamental problem deterring progress in this field, while the second problem has greatly hindered efforts to take advantage of the unique directional properties inherent to thermotropic polymers, both in molded shapes and in films.

In the following, our work on elucidating the nature of the microstructure of the aromatic copolyesters is described, which demonstrates the profound role of chemical processes in influencing and controlling the microstructure of these copolymers. In a more global sense, by taking into account the subtle chemical and physical processes that occur at elevated temperatures one is now able to predict both the nature of the microstructure as well as many of the morphological features of the commercially available liquid crystalline copolyesters of HBA.

3.2. Factors Which Influence the Microstructure of Liquid Crystalline Copolyesters

Undoubtedly, much of the confusion surrounding the nature of the microstructure of the copolyesters of HBA arises from the relative intractability of the copolymers, which greatly reduces the number of analytical techniques which can be used in the characterizations of these systems. Interestingly, there are almost an equal number of publications which describe the respective copolymers of Scheme 1 as being either random or blocklike with respect to their microstructure.[6–10] In considering the behavior of these systems in the nematic melt there is also consideable confusion. Thus, some workers describe these sytems as undergoing a



Scheme 1. Commercially available liquid crystalline copolyesters. **A** Amoco (Carborundum), **B** Celanese, **C** Tennessee Eastman.

crystallization-induced ordering[11] or a physical ordering,[12] while others indicate that mixtures of different copolyesters are stable in the nematic melt.[13] In contrast, we point out in a recent publication that, in the nematic melt, mixtures of polyesters will undergo very rapid transesterification reactions to a random microstructure.[14] Clearly, a systematic study was required to examine not only the possible changes that might occur in the microstructure during high-temperature processing, but also to establish the influence of the original synthetic route on the microstructure. The factors that would appear important concerning the microstructure are enumerated in Table 5. In the following the role of the synthetic route on microstructure is considered briefly, followed by a more detailed discussion of the

Table 5. Origin of the microstructure of the liquid crystalline aromatic polyesters.

- Role of the synthetic route
  - Reactivity ratios
  - Interchain transesterification
  - Homogenous vs heterogenous conditions (isotropic or nematic)
- Role of temperature on ordering and randomizing
  - Annealing below $T_{c\rightarrow N}$
  - Heating near $T_{c\rightarrow N}$
  - Processing in the nematic melt

effects of high-temperature processing. Finally, the role of trace impurities, nucleating agents, and the nature of the end groups are briefly mentioned.

With respect to the synthetic route, obviously the reactivity ratios of the monomers as well as the conditions of polymerization will determine the initial microstructure. We decided to focus on the 50/50 HBA/HNA copolymer (HNA = 6-hydroxy-2-naphthoic acid) because of its relative tractability. On stopping the polymerization at a M_n of 2000 we found that the composition was identical to that of the ratio of the starting reactants, indicating that reactivity ratios for the HBA and HNA were identical. To characterize the possible role of a very rapid interchain transesterification we also examined the reaction of ^{13}C enriched HBA* with the dimer of HBA-HNA at the reaction temperature of 245 °C. By use of ^{13}C-NMR techniques we were able to identify 14% of HBA*-HNA in the oligomer with 2000 M_n, indicating interchain transesterification did occur but was not a dominant factor in this process. The temperature dependence of this reaction was also examined and it was found that at 225° and 275 °C the concentration of HBA*-HNA remained the same. This ought not to be surprising, since the concentration of COOH end groups was the same in all three cases and the degree of polymerization was carried out to the same M_n.

Turning now to possible high-temperature processes that might influence the microstructure, it is appropriate to start with those that might occur during annealing (typically 20 h at 50–70 °C below the $T_{C\leftrightarrow N}$). What was found was that the degree of crystallinity of the 50/50 HBA/HNA copolymer increased from ca. 10% to 25–30% based on Differential Scanning Calorimetry (DSC) measurements of transition enthalpies. Analysis of the microstructure by ^{13}C-NMR spectroscopy indicated that there was essentially no change in the dyad sequence. On the other hand, the M_n increased from 10000 to well over 20000 indicating significant mobility of the end groups leading to further polymerization by ester interchange at the end groups. Examination of the DSC curves indicated no shift in the position of the peak of an endothermic reaction of the 50/50 copolymer. These results can only be interpreted on the basis that annealing leads to a higher incidence of the like-ordered units in the defective three-dimensional crystallites. There does not seem to be any tendency for further ordering of the like-ordered sequences via interchain transesterification otherwise one would observe a shift in the DSC peak to a higher C↔N transition temperature. On the other hand, the increased M_n indicates that transesterification processes can occur in the solid state.

Turning to the use of annealing conditions just above or below the $T_{C\leftrightarrow N}$ of the HBA/HNA copolyesters, one observes a completely different behavior. In this case we examined both the 73/27 and 50/50 HBA/HNA polyesters. For the 73/27 polyester the peak at 280 °C corresponding to the crystalline → nematic transition disappears and is replaced by two new peaks for endothermic reactions occurring at 240 and 330 °C; in the case of the 50/50 system the endothermic transformation at 250 °C is replaced by two transformations at 240° and 330 °C and one at 380 °C. In both cases the total increase in transition enthalpy was modest and nowhere near that observed in annealing at 50–70 °C below $T_{C\leftrightarrow N}$. In addition, the annealed samples were almost insoluble in pentafluorophenol, suggesting either a more highly ordered structure, a sharply increased M_n, or both. By use of capping agents such as 2-naphthoic acid it was possible to control the M_n of both compositions down to well under 10000; however, the solubility was still very low. Consequently, these results could only be interpreted as arising from the emergence of a new kind of a more highly ordered sequence distribution. Fortunately, we had available to us DSC scans of the homopolymers of HBA and HNA[15] (both showing strong endothermic transitions at ca. 330–340 °C) and one of the alternating copolyester of (HBA-HNA)$_x$ with endothermic transitions at 240° and 380 °C. Thus, one obvious interpretation of the changes associated with heating near $T_{C\leftrightarrow N}$ is that, within the poorly formed three-dimensional crystallites of the "as-prepared" copolesters, interchain transesterification occurs leading to highly ordered domains of the homopolymers and alternating copolymer. The relative concentrations of these domains is determined by the composition of the original copolyester as well as the approximate starting sequence of the poorly formed crystallites. The driving forces are kinetic and arise from the improved packing and dipole interactions that are obtained. Since it is reasonable to expect a higher concentration of carboxylic acid end groups at the interfaces between the crystalline and nematic phases, there is more than sufficient concentration of end groups to effect the necessary ordering through intermolecular transesterification. Additional evidence in support of such a transformation is obtained from X-ray diffraction analysis of the two materials. Thus, the low-temperature annealed material displays a hexagonal symmetry, while the more ordered system shows an orthorhombic structure consistent with the structures of the homopolymers of HBA and HNA.

The final question that remains is the nature of the processes that may occur well above $T_{C\leftrightarrow N}$. A unique experiment was designed to eliminate the presence of any possible ordering just above $T_{C\leftrightarrow N}$.[14] A 50/50 mixture of the two homopolymers of HBA and HNA was compression molded above 450 °C, ensuring the absence of any three-dimensional order in the melt. It was found that by using relatively low M_n homopolymers the mixture reacted extremely rapidly to form the random 50/50 copolyester. The structure of the copolyester was confirmed by DSC and ^{13}C-NMR measurements showing a high concentration of HBA-HNA dyads. Thus, entropic effects seem to dominate in driving the system toward randomization. The extremely rapid rate of the reaction (completed in less than one minute) is consistent with what one would extrapolate from similar processes carried out at ca. 280 °C[16] and assuming that the Arrhenius process holds.

4. Conclusions

The picture that emerges from the results of this work indicates that both the microstructure and resultant morphology are controlled by subtle chemical and physical processes that very much depend on the thermal history of the materials. As illustrated in Table 6, one can clearly distinguish the chemical and physical processes which are operative in these systems. Thus, at temperatures well above $T_{C\leftrightarrow N}$

Table 6. Chemical and physical processes in liquid crystalline polyesters

Temperature	Dominant processes	Changes in microstructure or morphology
$\gg T_{C\leftrightarrow N}$	Chemical	Randomization
$\sim T_{C\leftrightarrow N}$	Physical	Crystallization
Annealing (near $T_{C\leftrightarrow N}$)	Chemical	Crystal/Ordering
Annealing (below $T_{C\leftrightarrow N}$)	Physical	Further crystallization
T_{NG}	Physical	Nematic glass

chemical processes dominate. The calculated number of interchain transesterification reactions at 450 °C is extremely rapid, i.e. ca. 100 interchanges/chain/second. At the same time M_n increases rapidly, resulting in a sharp reduction in end-group concentration and thus reducing the potential for further reaction. The propensity of randomization in the nematic phase (below $T_{C\leftrightarrow N}$) continues with decreasing temperature, but with correspondingly slower rates until the nematic phase freezes into a glass (e.g., in the HBA-HNA system the nematic glass transitions range from 80–130 °C depending on composition).

As one goes from the nematic melt through the crystal-nematic transition, physical processes dominate and the rod-like random chains match up to produce relatively small concentrations of defective three-dimensional crystallites. If one continues to anneal in this temperature range, chemical processes dominate and within the ordered regions interchain transesterification occurs to yield bimodal crystalline domains of highly ordered sequences. Further polymerization is observed during these annealing experiments.

Finally, if one anneals at 50–70 °C below the $T_{C\leftrightarrow N}$ diffusion processes dominate, resulting in a significant increase in concentration of the defective crystallites. Some chemistry also occurs at the end groups, as shown by the increase in M_n.

From the outline in Table 6 we appear to have a reasonably self-consistent interpretation of the microstructure of the liquid crystalline copolyesters. Most of the earlier confusion can be explained from this model. However, it is important to note that capping of the copolymers will eliminate the ability of the carboxylic acid to effect the randomization, ordering or polymerization reactions. Furthermore, presence of trace impurities and nucleating agents can profoundly influence the course of these processes. Hence, when one is confronted by apparently inexplicable behavior in these copolyesters, one of the first items that should be checked is the possible role of trace impurities.

Perspectives in the Development of High-Temperature Polymers

By Paul M. Hergenrother*

Research on high-temperature organic polymers was initiated in the late 1950s primarily to meet the needs of the aerospace and electronics industry. Since then, many different heat-resistant polymer systems have been reported, of which several are now commercially available. These polymers are used in many diverse applications such as circuitry in microelectronic components, coatings on cookware, binders in brake systems, sealants for fuel tanks in high-speed aircraft, gears in copying machines, structural components in high-speed aircraft, and space vehicles, films and wire coatings for electrical insulation. Worldwide use for high-temperature polymers in 1988 was estimated at 90 million kilograms with a value of $ 2.3 billion. This market is expected to double by the end of this decade. The major polymer classes discussed in the present paper are polyimides and poly(aryl ethers).

1. Introduction

High-temperature organic polymers are often described as polymers that retain useful properties after thousands of hours of exposure at 200 °C in air under static conditions. This definition is misleading and varies considerably depending upon the supplier and user. In many instances, temperature is reported without regard to other important factors that influence the performance of a polymer such as time, thermal cycling, stress, and environmental factors like moisture, or chemical and electrical action. In addition, polymers that can survive high-temperature processing cycles such as high-temperature soldering steps in the fabrication of microelectronic components but are otherwise not exposed to high temperatures are also referred to as high-temperature polymers.

The quest for high-temperature organic polymers began in the late 1950s primarily to meet the demands of the aerospace and electronics industries. Since then, many different high-temperature polymer systems have been reported. Several of these polymers are now commercially available as adhesives, coatings, composite matrices, fibers, films, foams, membranes, and moldings. They are currently already in use or are being considered for use in the following representative applications:

- Electronic and microelectronic components (circuit boards, moldings, flexible cables, insulators, coatings, wire wraps, etc.)
- Gaskets, sealants and tubing
- Binding systems in brake shoes, abrasive wheels and cutting disks
- Structural resins (adhesives, composite matrices, foams) for aircraft, space vehicles, and military items
- Jet engine components (fan blades, flaps, ducting, bushings, cowlings, races, etc.)
- Nuclear reactor components (coolants, insulation, structural parts)
- Conveyor belts for treating and drying materials
- Pipes for chemical processing and energy generators
- Fire-resistant materials (protective clothing)
- Reinforcements (high-modulus and high-strength fibers and ribbons)
- Ablators (thermal protection systems)
- Automotive components (connecting rods, wrist pins, pistons, switches, electrical components)
- Household items (nonstick interior and decorative exterior surfaces on cookware, irons)
- Medical devices (prostheses, circuitry in bio-implants, dental instruments)
- Copying machines (gears and picks)

Unknown to the vast majority of people, these polymers affect our lives in many different ways. For example, commercial airplanes and large traction motors that drive locomotives use high-temperature polymers as insulation for electrical wiring. Their excellent chemical resistance, mechanical properties and ability to survive sterilization cycles have opened applications in the medical field. Household items such as lightweight electric irons, microwave cookware, and other non-stick decorative cookware use high-temperature polymers. These polymers are used in protective, flame-resistant suits for firemen, energy conversion systems, space probes such as communication satellites, and complex computer systems. High-temperature polymers have had and will continue to have a significant impact on mankind. The worldwide market for high-temperature polymers in 1988 was estimated at 90 million kilograms with a value of $ 2.3 billion[1] (Fig. 1). This market is expected to double by the end of this decade.

2. Historical Review

Early work uncovered the many factors that contribute to the thermal stability of polymers. Some of these are primary bond strength, resonance stabilization, secondary bonding forces, rigid intra-chain structure, molecular weight and molecular weight distribution, and stable end-groups on the molecules. Most high-temperature polymers are composed predominantly of aromatic or heteroaromatic units (excluding systems like fluoropolymers and silicones). The chemical structure that makes a polymer thermally stable also makes it difficult to form into useful items because of limited solubility and moldability. Since most of the early high-temperature polymers were virtually intractable, stable flexibilizing groups such as carbonyl, oxygen, sulfone and hexafluoroisopropylidene were incorporated between aromatic rings to improve solubility and moldability. In addition, pendant groups such as phenyl rings and *meta* catenation within the polymer backbone were introduced which further improved the fabricability. These modifications had only minor effects upon the thermal stability of the polymer although the actual utilization temperature was generally compromised (lowering of the glass transition temperature T_g). This work, coupled with control of molecular weight and end-capping, opened the way for the synthesis of many soluble, readily moldable, high-temperature polymers with excellent mechanical properties. Some of these materials are now commercially available. The evolution of the major high-temperature polymers is outlined in Table 1. As is evident from the table, polyimides are of special importance and have received considerable attention. A large number of other important high-temperature polymers have intentionally been omitted from Table 1 to avoid confusion. Information on these polymers can be found in many review articles and books.[26-28]

Table 1. Major high-temperature organic polymers.

Polymers	Year Reported or Introduced	Commercial Availability	Ref.
Poly(phenylene sulfide)	1948	yes	[2]
Polyimide solution (Pyre-ML)	1959	yes	–
Polybenzimidazole	1961	yes	[3]
Polyimide binder (Skygard®)	1962	yes	–
Polyimide	1963	yes	[4,5,6]
Polyquinoxalines	1964	no	[7,8]
Polyimide film (Kapton®, wire coatings, moldings)	1965	yes	–
Polyamideimides	1965	yes	[9]
Polyaryl sulfone (Astrel® 360)	1967	no	[10]
Polyphenylquinoxalines	1967	yes	[11]
Polyimides containing hexafluoroisopropylidene groups (NR 150)	1967	yes	[12]

Aromatic polyamides (PRD-49, Kevlar®)	1970	yes	–
Bismaleimide resins	1970	yes	[14]
Norbornene-terminated polyimides (PMR-15)	1972	yes	[15]
Ethynyl-terminated polyimides (Thermid® 600)	1974	yes	[16]
Poly(ether imides) (Ultem®)	1974	yes	[17]
Polyimide-containing indane (Matrimid® 218)	1975	yes	[18]
Liquid crystalline polyester [poly(4-benzoate), Ekonol®]	1976	yes	[19]
Polyketoimide (LARC-TPI)	1976	yes	[20,21]
Rigid rod polybenzazoles (PBT, PBI, PBO)	1981	no	[22,23]
Polyimide film (Upilex® R and S)	1985	yes	–
Semicrystalline polyimides (LARC-CPI, New TPI)	1987	yes	[24]
Poly(aryl sulfone) (Radel® C)	1989	yes	–
Polyimides via Friedel-Crafts reaction	1989	no	[25]

Polyimides and poly(aryl ethers) including poly(aryl ether ketones), more so than other high-temperature polymer systems, have captured the attention of scientists and engineers alike as materials that offer outstanding properties for high-performance applications. Their versatile synthesis permits tailoring of these polymers for specific applications. With this in mind, the remaining discussion in this paper will concentrate on these two polymer systems.

3. Polyimides

Polyimides are generally divided into two types, addition and condensation polymers. Addition polyimides are exemplified by bismaleimides, norbornene-terminated imide oligomers such as PMR-15 and ethynyl-terminated imide oligomers such as the Thermid® series.[29] These cure upon heating to yield brittle resins. In spite of their brittleness, these materials are used as composite matrices in applications such as printed circuit boards and structural composites. Composites are receiving considerable attention for several diverse applications, particularly in airplanes, automobiles, trains, and off-shore oil-drilling platforms. For these applications, composites offer the following benefits over metals:

- better design flexibility
- corrosion resistance
- higher specific strength and stiffness
- lower thermal expansion
- better fatigue resistance

High specific strength and stiffness is extremely important, particularly for commercial airplanes, because this translates into lower weight and thus means better fuel economy and the ability to carry a higher payload. As the cost of fuel increases and the supply decreases, composites will be used more extensively on commercial airplanes. In addition, as the overall cost of composites becomes more competitive with that of a metallic component, more extensive use of composites, particularly in commercial airplanes, will be realized. The high cost of large composite structures today is due primarily to the labor intensive fabrication processes. New ways of fabricating large composite structures such as resin-transfer molding show excellent promise to reduce the manufacturing cost and provide a structure with excellent mechanical performance.

During the last few years, new bismaleimide formulations have evolved which offer good toughness and accordingly damage tolerance [composites that exhibit useable *c*ompression strength *a*fter *i*mpact (CAI) at a stress level of 6.67 $kJ\,m^{-1}$ (1500 pounds per inch)]. Damage tolerance is described as the ability of a structure to sustain damage but still carry a load. Table 2 summarizes the properties of three leading bismaleimide-based composite systems. Although significant improvements, particularly in impact resistance, have been made in bismaleimide-based composites over the last few years, the users desire further improvements. Some of these are better performance at 200 °C wet, higher CAI

(comparable to the new toughened epoxy system), no microcracking upon thermal cycling (influenced by prepreg layup) and better tack. One of the better materials that has been developed to meet these new goals is the BASF Structural Materials/Narmco X5260 system.[33] The CAI ranges from 331 to 348 MPa, the highest value reported for a bismaleimide-based system.

Another addition polyimide composite matrix offering higher temperature performance than bismaleimides is PMR-15, a norbornene-terminated imide oligomer formed by the *p*olymerization of *m*onomeric *r*eactants at a calculated molecular weight of 1500 g/mol. The synthetic route is shown in Scheme 1.

PMR-15 cures via a complex thermally induced retro-Diels-Alder reaction to yield a brittle resin. As a result, even unidirectional composites of PMR-15 undergo pronounced microcracking upon thermal cycling. This is accompanied by substantial loss of mechanical properties. Microcracking is significantly more severe in crossply composites. Since PMR-15 is one of the few high-temperature composite matrices with an engineering data base, work has been directed towards toughening PMR-15 to alleviate the microcracking problem. Unidirectional laminates from a blend of a tough, high T_g, polyimide (NR150B2) with PMR-15 showed no microcracking after thermal cycling and mechanical properties equivalent to PMR-15 at 316 °C.[34] No results were reported on crossply composites.

The current interest in PMR-15 composites is primarily due to their anticipated use in jet engines. This market could be quite substantial. As a result, several companies are actively involved in PMR-15 work. For example, BASF Structural Materials has obtained promising results on neat resins from a blend of PMR-15 powder and a high-T_g thermoplastic polyimide powder. Powder impregnation to form prepreg offers certain attractive features such as a means of applying insoluble but fusible polymer, no organic solvents, and drape in the prepreg.

Condensation polyimides can be prepared from a variety of relatively inexpensive monomers by the following synthetic methods. By judicious choice of starting materials, polyimides can be tailor-made for specific applications:

- Aromatic dianhydrides and aromatic diamines (formation of polyamidic acid in solution and subsequent chemical or thermal cyclodehydration.[35]
- Aromatic dianhydrides and aromatic diamines (melt polymerization).[36]
- Aromatic dianhydrides and aromatic diisocyanates.[37]
- Aromatic dianhydrides or tetracarboxylic acids and aromatic or aliphatic diamines in high-boiling solvents, e.g. *N*-methylpyrrolidinone or *m*-cresol (direct to polyimide).[38]
- Esters of aromatic tetracarboxylic acids with aromatic diamines.[39]
- Aromatic tetracarboxylic acid ester chlorides with aromatic diamines.[40]
- Displacement of an activated nitro group by a phenoxide anion, e.g., bis(nitrophthalimide) and bisphenolates.[41]
- Transimidization (amine–imide interchange).[42]
- Friedel-Crafts reaction (dicarboxylic acid chloride and imide monomer)[25]

For example, the glass transition or crystalline melt temperature, toughness, dielectric constant, coefficient of thermal expansion, modulus, melt viscosity, and other properties can be controlled within certain boundaries. This versatility has permitted the development of various commercial products from condensation polyimides. These include adhesives, composite matrices, coatings, films, fibers, foams, moldings, and membranes. The chemistry, physical and mechanical properties, and uses of polyimides have been reviewed recently in a book.[43]

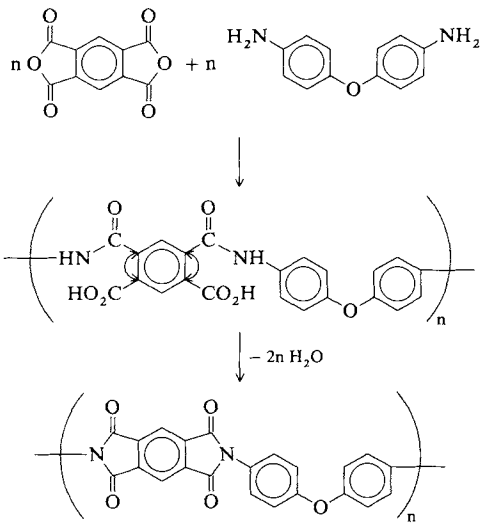
The most popular condensation polyimide, which is available in various forms (e.g. coatings, binders, films, and moldings), is that obtained by reaction of pyromellitic dianhydride with 4,4'-diaminodiphenyl ether (Scheme 2). In film



Scheme 2. Reaction route to a polyimide.

form, this material is known as Kapton®[44] and Apical®.[45] The market for polyimide films in 1988 was about $ 150 M with Kapton® comprising about 75%. This market is expected to grow substantially, and to double by 1995. As a result, a few new polyimide films have been introduced within the last few years. The properties of several commercial and experimental polyimide films are presented in Table 3. Although the polyimide film market is relatively large, the market for polyimide compression and injection molded parts is significantly larger.

The material called LARC-CPI (*La*ngley *R*esearch *C*enter-*C*rystalline *P*oly*i*mide) is a relatively new polyimide. The synthetic route is shown in Scheme 3. It exhibits many attractive features such as excellent chemical resistance, fracture energy [critical strain energy release rate (G_{Ic})] of 6600 Jm^{-2} (37.8 psi),[46] adhesive titanium tensile shear strength at 232 °C of 25.9 MPa (3670 psi [*]),[46] AS-4 unidirectional laminate flexural strength and modulus[47] at 232 °C of 1441 MPa (209 Ksi[*]) and 91.7 GPa (13.3 Msi) respectively and high thermooxidative stability at 316 °C in air. Work is underway to develop an optimized, end-capped, controlled molecular weight form that can be more readily compression molded for adhesive and composite components.

Another relatively new polyimide is New-TPI,[48] whose neat resin properties are presented in Table 4. Composites from this material have shown good properties. A drawback, however, is the temperature of about 427 °C necessary for the fabrication of these composites.

Several polyimides have been reported which contain the hexafluoroisopropylidene group located between aromatic rings in the dianhydride and/or diamine portion of the molecule. This group imparts several advantageous features to the polymers such as lower dielectric constant, better solubil-

[*] psi = pounds per square inch; Ksi = thousand pounds per square inch.

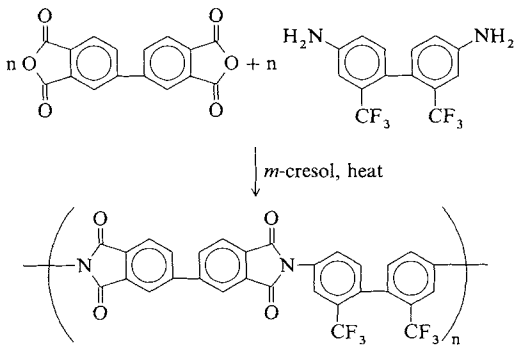
Heat Deflection Temp. [°C]	236	250

ity, lower pickup of moisture and less color. Some of these properties of a polymer are particularly important in integrated devices in microelectronic applications. More recent work in Japan[49, 50] and the United States[51–54] has involved strategically locating trifluoromethyl groups on the aromatic rings of the dianhydride and/or diamine portion of the polyimide molecule. The trifluoromethyl group imparts properties to the polymer similar to that imparted by the hexafluoroisopropylidene group, but with one notable advantage: In some polyimides, the tensile properties of drawn films and fibers were exceptional. For example, fibers[53] of the polyimide obtained by reaction of 3,3′,4,4′-biphenyltetracarboxylic dianhydride with 2,2′-bis(trifluoromethyl)-benzidine as shown in Scheme 4 which were spun from an



Scheme 4. Reaction route to a polyimide with good fiber properties.

isotropic solution in *m*-cresol and subsequently drawn, gave properties better than that of Kevlar®.[55] Crystalline ordering was observed to occur in this polymer when it was in a gelled state in *m*-cresol at ambient temperature. In addition, this particular polyimide exhibited outstanding stability at 371 °C under 4 atm air pressure, conditions present in some parts in jet engines.

4. Poly(aryl ethers)

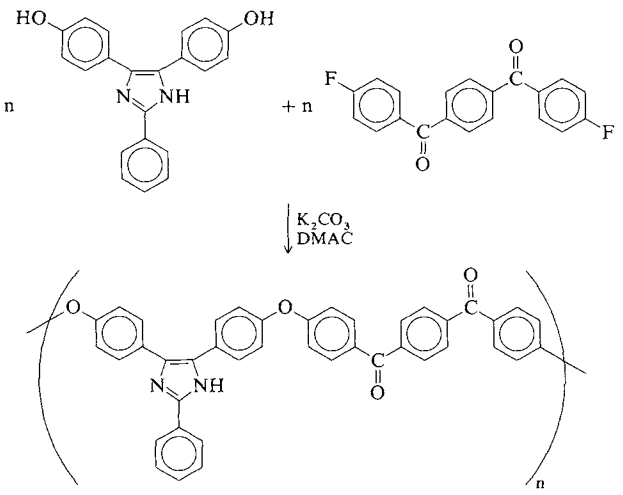
Poly(aryl ethers), like polyimides, offer an attractive combination of properties. Many of these polymers are commercially available and find use in diverse applications. Poly(aryl ethers) can be synthesized by the following methods:

- Nucleophilic substitution[56]
- Electrophilic substitution[10, 57]
- Oxidative coupling[58]
- Ullmann ether synthesis[59]

Nucleophilic and electrophilic substitution reactions are the methods commonly used in the preparation of high-performance poly(aryl ethers). In general, amorphous and semicrystalline poly(aryl ethers) are less expensive than polyimides and some display high optical transparency, making them potentially useful in windows and canopies for aerospace vehicles. Poly(aryl ethers) find use in a wide variety of applications primarily in the form of adhesives, coatings, composite matrices, membranes, and moldings. Because of their excellent chemical inertness and mechanical properties, these polymers are under evaluation for use in different medical applications such as prostheses.

Some of the most recent synthetic work on poly(aryl ethers) has involved the incorporation of fluorinated groups[60, 61] and heterocyclic units within the polymer backbone. Poly(aryl ethers) containing quinoxaline,[62–64] imidazole,[65, 66] 1,3,4-oxadiazole,[67] 1,2,4-triazole,[67] and benzoxazole[68] have been prepared. The heterocyclic unit generally brings about an increase in the cohesive energy density which is reflected in an increase of the strength, of the modulus, and of the glass temperature T_g. Polymers can be designed for specific applications and can be readily prepared because of the versatility offered in the polymer synthesis. Properties such as hydrophilicity, T_g, and solubility can be altered considerably by incorporation of pendent groups on the heterocyclic ring. These polymers show promise for use in a variety of applications including membranes for separating gases (e.g. carbon dioxide/methane) and enzymes.

An example of the reaction route to a poly(aryl ether) containing heterocyclic units is shown in Scheme 5. 4,5-



Scheme 5. Reaction route to a poly(aryl ether) containing phenylimidazole units.

Bis(4-hydroxyphenyl)-2-phenylimidazole reacts with 1,4-bis(4-fluorobenzoyl)benzene in the presence of potassium carbonate in *N,N*-dimethylacetamide (DMAC) to yield a high molecular weight polymer. The polymer exhibits an inherent viscosity of 0.89 dL g^{-1}, and an apparent T_g of 248 °C. Thin films showed a tensile strength and modulus of 97.9 MPa (14.2 Ksi) and 2.81 GPa (407 Ksi) respectively at 25 °C, and excellent adhesive properties.[66]

Various poly(aryl ethers) such as poly(ether ketone ketone) (PEKK)[69] are being evaluated as matrices for high-

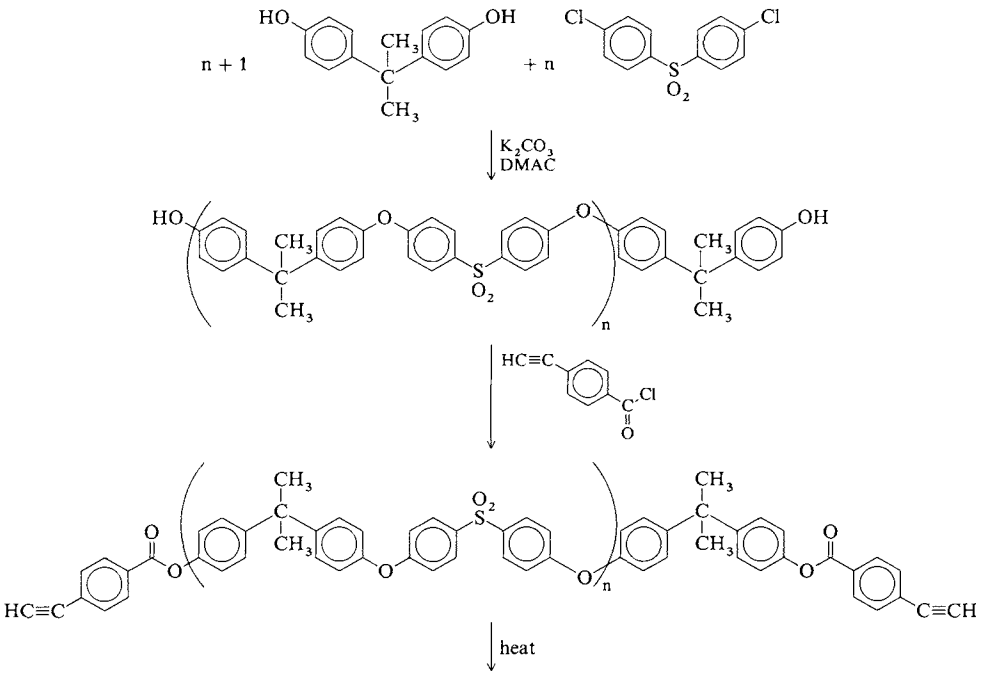
performance, graphite-filament, reinforced composites. These thermoplastic composites exhibit good flexural, tensile, and CAI properties, but the compressive and interlaminar shear strengths are lower than those of epoxy- and bismaleimide-based systems. Although thermoplastics have been suggested to offer certain advantages over thermosets such as the potential of low-cost composite manufacturing, this has not been fully realized. The fabrication of thermoplastic composites requires higher temperatures and pressures than that of most thermosets. Conventional autoclave fabrication of composites is not cost-effective for thermoplastics. Matched-metal tooling, although expensive initially, can offer lower cost if many of the same composite parts are made. A potential advantage of thermoplastics over thermosets is the thermoforming of flat panels. Although the future of thermoplastic composites is unclear, new innovative prepreg forms and composite fabrication processes will resolve certain problems and make them more competitive with thermosets as composite matrices.

Aryl ether oligomers and polymers have been modified with various reactive groups such as ethynyl, allyl, amino, cyanato, epoxy, maleimido, and norbornenyl. The molecular weight of the oligomer and polymer can easily be controlled stoichiometrically. Several of these end-group-modified oligomers and polymers have been subjected to further thermal treatment to provide cured materials whose properties are governed primarily by the chemical structure, molecular weight of the oligomer or polymer, and curing conditions. This route opens up a method for controlling properties such as solubility, toughness, modulus and T_g of the cured material. An example is a study reported on ethynyl-terminated sulfone oligomers[70] (Scheme 6) where the molecular weight was varied from 4000 to 12000 g mol^{-1}. Upon thermal curing, the ethynyl group undergoes a complex reaction leading to some linear chain extension, branching and cross-linking.[71] Cured resins from low molecular weight oligomers exhibited higher modulus and higher T_g, lower toughness, and less solvent sensitivity than cured resins from high molecular weight oligomers due to increased cross-link density.

Because of their low cost, compatibility with thermosets, high toughness, and other properties, aryl ether oligomers terminated with groups such as amino, epoxy and maleimido have been used as toughening agents with thermosets. Several epoxy-[72, 73] and maleimide-based[30-32] systems presumably modified with functionalized aryl ether oligomers are available in prepreg form. Composites therefrom have provided outstanding properties including high CAI. Although these systems are not classified as true high-temperature materials, it is important to note that this technology is being extended as a means of toughening high-temperature thermosets (e.g. PMR-15 and ethynyl-terminated imide oligomers).

5. Imide/Aryl Ether Copolymers

Since polyimides and poly(aryl ethers) each offer specific attractive properties, it seemed only reasonable to combine these two families of polymers into one via blends or copolymers. The latter approach has been successfully used to obtain the excellent features of each polymer family in one material. For example, by synthesizing block copolymers[74] the high fracture energy and good compression moldability of a specific poly(aryl ether) and the high modulus and excellent solvent resistance of a particular polyimide were incorporated within one material, based upon rule of mixture. This approach has been successfully used with many other polymer families and offers an attractive route for tailoring polymer properties.



Scheme 6. Reaction route to ethynyl-terminated sulfone oligomers.

6. Concluding Remarks

The thermal performance of high-temperature polymers today and that projected for the year 2000 are presented in Table 5. Only marginal improvements in the thermal stability of organic polymers are anticipated. We are approaching the thermal capability offered by these materials. Advances will be made primarily in developing lower cost, more processable materials with better properties. As a result, the market for high-temperature polymers will grow significantly over the next decade as new and improved materials evolve with a more favorable combination of *price, processability and performance.*

Specific Interactions of Proteins with Functional Lipid Monolayers – Ways of Simulating Biomembrane Processes

By Michael Ahlers, Wolfgang Müller, Anke Reichert, Helmut Ringsdorf* and Joachim Venzmer

The interplay between molecular self-organization and molecular recognition leads to the construction of functional supramolecular systems in which order and mobility are combined and whose function is based on their organization. These fascinating phenomena, for which the living cell is a perfect example, can be understood only if a wide range of scientific disciplines work together. For this purpose, synthetic supramolecular systems can be used to simulate natural biomembrane processes. One example of this is the specific recognition and interaction between membrane-bound ligands and receptor proteins. Thus, the specific interaction of vitamin H (biotin) with the tetrafunctional protein streptavidin in the monolayer leads to 2D crystallization of the protein. Structural analysis shows that the protein is attached to the lipid membrane by two biotin-binding sites, leaving two still free. The opportunity this allows for biotinylated molecules to dock to the protein leads to interesting possibilities for constructing protein-containing functional multilayers. Another example for the simulation of biomembrane processes is the function of enzymes which is coupled to the recognition process. In the interaction of phospholipase A_2 with lecithin monolayers, specific recognition between enzyme and substrate is followed by an active phase of lipid cleavage and then by aggregation of the enzyme to give domains of regular morphology. Fluorescence microscopy can be used to follow this process directly: an enzyme caught in action.

Der Witz ist der Finder und der Verstand der Beobachter.
Georg Christoph Lichtenberg**

1. Steps across Borders?

1.1. There are Many Ways of Solving a Scientific Problem

Steps across borders? Is it going too far to choose such a title for the introduction to a presentation of scientific results? Without a question mark it would be ridiculous. Nevertheless, the question involves one of the essential problems of modern scientific development: the almost worrying one-sidedness of scientific thought. The pressures are great, and specialization has become indispensable. This is why it is necessary to make steps across borders. Can we learn how to do this?

There are various theories relating to the acquisition of scientific knowledge.[2] The emphasis now is on the discursive method, which entails reasoning and drawing causal conclusions, at the expense of the intuitive approach to solving problems. Intuition has been devalued because of the lack of absolute certainty, and it is treated badly in our education system.[3] Part of the reason for this is historical, derived from the predominant aim of epistemology (theory of cognition): the securing of knowledge. *Descartes* and *Kant* made certainty virtually the criterion of truth: only really certain knowledge can be true, which does not leave much room for intuition. Many scientific and technical discoveries demonstrate the increasing success of conclusions drawn by the discursive method from facts and unambiguous concepts. This has led to an overestimation of scientific thinking and to a fundamental devaluation of what is less certain and, especially, of intuition in science. Positivists do not even accept that knowledge which is uncertain actually is cognition and regard it as no more than a leisure time occupation. However, it is demonstrably true that certain knowledge is far from sufficient for breakthroughs in science, to say nothing of coping with existence.[4]

Georg Christoph Lichtenberg, who was an eighteenth century physicist and philosopher in Göttingen, posed the question about steps across borders, and the answer he gave was:[1b] "A really serious examination is necessary of why most inventions come about by chance. The main reason is probably that people view everything in the same way as their teachers and colleagues do. This is why it would undoubtedly be useful to suggest certain rules for departing from the rules." The development of macromolecular chemistry is a good example of this. It arose from steps across borders, preferring intuitive concepts to accepted doctrines. It is of historical interest to see how *Hermann Staudinger*, at the height of his creativity in organic chemistry, dared to leave this "classical" area and go into macromolecular chemistry.[5] There is no doubt that the time was ripe, but he still had to overcome established concepts. This is also an interesting example of what *Leonardo da Vinci* said so long ago: "In a difference of opinion, the person who quotes authorities is using his memory and not his intellect."

1.2. Functionalized Supramolecular Systems

One of the areas of organic chemistry now being intensively studied, on an interdisciplinary basis in many laboratories,

Dipl.-Chem. J. Venzmer
Institut für Organische Chemie der Universität
J.-J.-Becherweg 18–20, 6500 Mainz (FRG)

[**] "Wit is the finder and intelligence the observer" [1a].

is that of supramolecular systems. Since classical organic chemistry is now able to construct highly complicated molecules and provide biologists and biochemists with detailed insights into natural processes, the chemists are becoming interested in investigating organic chemistry beyond the covalent bond, as *J. M. Lehn* called it.[6]

In nature, system functioning is achieved by interplay between different functional units. The smallest unit which demonstrates this perfectly is the cell:[7] it is the interplay between molecular self-organization and molecular recognition of its individual constituents (lipids, proteins, nucleic acids...) which leads to the construction of this natural supramolecular system. It combines order and mobility, and its functioning is based on its organization. This fascinating phenomenon can be understood only if a wide range of modern scientific disciplines work together. The special tasks of organic and macromolecular chemistry in this connection involve finding new syntheses and solving structural problems. One of the interesting questions which arises is whether it is possible to develop new materials which simulate natural supramolecular systems in that their functioning is determined by their organization. This will not be possible without going beyond the limits of classical thinking in the individual disciplines.

Where are examples of connecting links between apparently separated disciplines of science? Figure 1 describes common perspectives of life science and materials science relating to functional supramolecular systems.

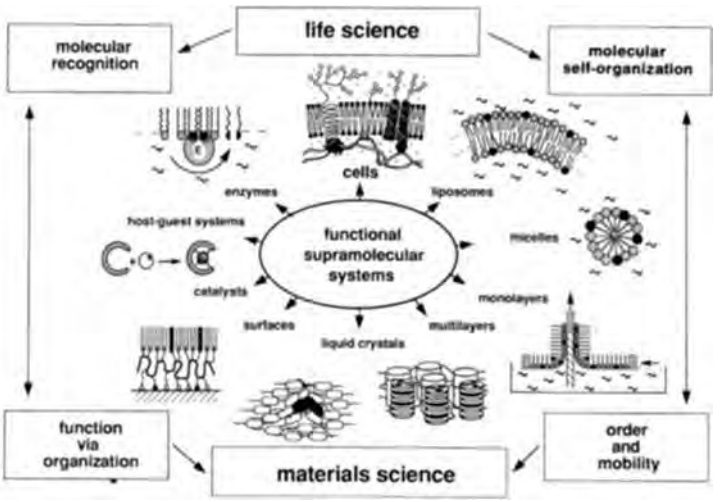

Fig. 1. Functional supramolecular systems—connecting link between life science and materials science.

The cell with its recognition structures on the surface is structured by the lipid membrane and dominantly functionalized by proteins. Its stability is determined both by proteins or lipids which extend through the membrane and by polymer networks, for example the cytoskeleton. Descending in complexity from this perfect natural pattern one finds liposomes[8] with their relatively simple bilayers and finally micelles[9] with their various lyotropic structures.[10] They have long been important in studies of synthetic and natural systems and, in colloid science, determined the course of physical chemistry in the 1920s. Recent developments in monolayers and multilayers (Langmuir and Langmuir-Blodgett systems)[11] have resulted in ultrathin films in which order and mobility can be combined. Of more interest to materials science are liquid crystals[12] which are already of industrial importance, in both low molecular weight and macromolecular forms. Their order is based on their form-anisotropy, and it is possible for rods,[13] disks[14] or boards[15] to self-organize. Too often, it is forgotten that liquid crystals have always been essential in nature. Many of the natural polymers, and cell membranes themselves should be regarded as liquid-crystal systems, although lyotropic not thermotropic.[16]

Besides molecular self-organization, another crucial property of natural supramolecular systems is their capability of molecular recognition, which leads to specific interactions. Many processes on the cell membrane start with recognition and lead on to enzymatic reactions, such as cleavage of lipids by the various phospholipases.[17] The problem of molecular recognition has for some time been an important part of organic chemistry owing to the variety of studies on guest-host systems[18] and their importance for synthetic supramolecular systems. This area also includes the alteration of surfaces and the structuring of ultrathin layers, which are of particular interest in catalyst research, sensor technology and tribology. As Figure 1 indicates, it is also possible to functionalize liquid crystals. The function of such addressable liquid crystals is, in principle, based on their organization, and the molecular recognition is introduced by reactive groups, for example photosensitive groups.[19] Intensive study of this is now in progress in the area of non-linear optics[20] and optical storage.[21]

In this contribution it is not intended to review the field of functional supramolecular systems. Only three examples showing the interplay between molecular self-organization and molecular recognition will be presented in this paper. The techniques employed combine the self-organization of lipids in the monolayer, which can represent half a cell membrane, with the specificity of molecular recognition of proteins and enzymes. This is briefly discussed in the next section.

1.3. Attempts to Simulate Recognition Processes and Protein Functions on Model Membranes

The self-organization of lipids to form the plasma membrane[7] was a crucial step in the evolution of the earliest forms of life—cellular life is impossible without the protection provided by the lipid membrane. However, it is more than just a passive barrier between the cytosol and the surroundings. On the contrary, it is a highly selective, active filter. Moreover, the cell surface plays an essential part in intercellular communication (for example in immune reactions). Whereas the lipid bilayer determines the basic structure of biological membranes, most of their functions, for example specific receptors, enzymes or transport systems, are provided by proteins embedded in the lipid bilayer. However, the structure of the cell membrane is so complex that it is difficult to study specific individual processes in biological systems. This is why it is an advantage to choose model membranes for investigating biomembrane processes be-

cause they can be limited to a few variable factors (see Section 2). Figure 2 outlines various membrane processes whose simulation in monolayers is to be discussed.

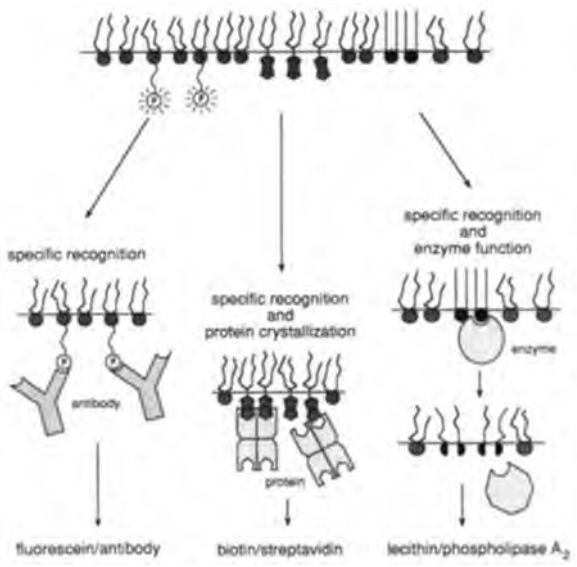

Fig. 2. Examples of the simulation of specific recognition reactions at model membranes: recognition (fluorescein/anti-fluorescein antibody), recognition and protein crystallization (biotin/streptavidin), recognition and enzyme function (lecithin/phospholipase A_2).

The first important step in many surface reactions is the specific recognition taking place between a ligand on the membrane and a receptor protein (for example an antibody). An interaction of this type will be exemplified by fluorescein-lipids and the anti-fluorescein antibody (Section 3). As a consequence of specific recognition different processes can take place on the membrane. One example of this is the 2D crystallization of streptavidin after binding to biotin-lipid monolayers which is described in Section 4. This process is also of interest with a view to potential use in biosensors. If the protein is an enzyme, the specific recognition can be followed by an enzymatic function being carried out. This will be illustrated by the example of phospholipid-monolayer hydrolysis by phospholipase A_2 (Section 5).

Before these membrane processes are discussed in detail, the next section will briefly describe the various model membrane systems and especially the characterization methods for monolayers used in this article.

2. Lipid Monolayers as Simple Models of Biomembranes

2.1. Model Membranes

Single membrane processes are preferably investigated on the four model systems depicted in Figure 3. These model membranes are, like their natural prototype, the cell, composed of lipids which, since they are amphiphilic molecules which are insoluble in water, undergo spontaneous self-organization on contact with water. The force behind this self-organization is the hydrophobic effect.[22] Depending on the

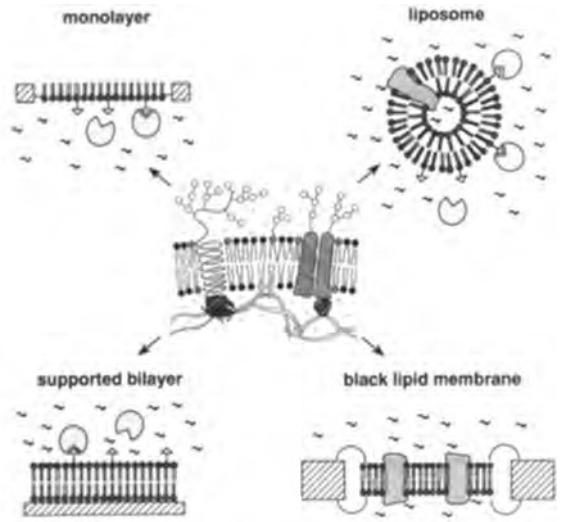

Fig. 3. Simple models for biological membranes: model membranes for studying surface recognition reactions, protein reconstitution and protein functions.

preparation technique, different supramolecular structures are formed, which can be used as model membrane systems.

Liposomes (vesicles)[8] are lipid bilayers which form a closed sphere containing an aqueous compartment in a similar way to the cell membrane. They are used, inter alia, for reconstituting membrane proteins and studying surface recognition reactions.

Black lipid membranes (BLMs)[23] are planar lipid bilayers, which, by covering a hole in a teflon wall, separate two aqueous compartments from one another. It is possible in this way, for example, to study the transport of ions through lipid membranes – passively or actively assisted by incorporated proteins – by conductivity measurements.

Preparation of lipid bilayers on a solid substrate (*supported bilayers*)[24] results in membranes which are considerably more stable than BLMs and can easily be manipulated on the exposed side not facing the substrate. They are therefore particularly suitable for studying surface recognition reactions.

Monolayers[25] are formed when a lipid is spread on a water surface and they correspond formally to one half of the lipid bilayer of a cell membrane. The hydrophilic headgroups of the lipids face towards the water and the hydrophobic alkyl chains face towards the air. There are a number of methods for investigating lipid monolayers and their interaction with substances (for example proteins) dissolved in the water, and those which will be dealt with are the characterization by pressure/area diagrams and fluorescence microscopy.

2.2. Pressure Area Diagrams of Lipid Monolayers[25a]

When the solution of a lipid is spread on the water surface in a Langmuir balance, the tendency of the molecules to self-organization results in spontaneous formation of a two-dimensional lipid phase. This monolayer can be gas-, liquid- or solid-analogous depending on the lipid concentration (molecules/area). Use of a movable barrier to reduce the area available to the lipid allows a two-dimensional phase

diagram (surface pressure/area diagram) to be measured at constant temperature. The packing of the molecules in a monolayer as a function of the surface pressure is shown schematically in Figure 4.

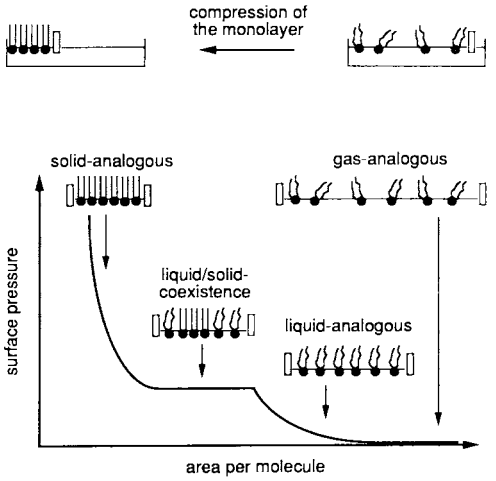

Fig. 4. Pressure/area diagram of a lipid monolayer: representation of the compression behavior and packing in the gas-, liquid-, and solid-analogous phase.

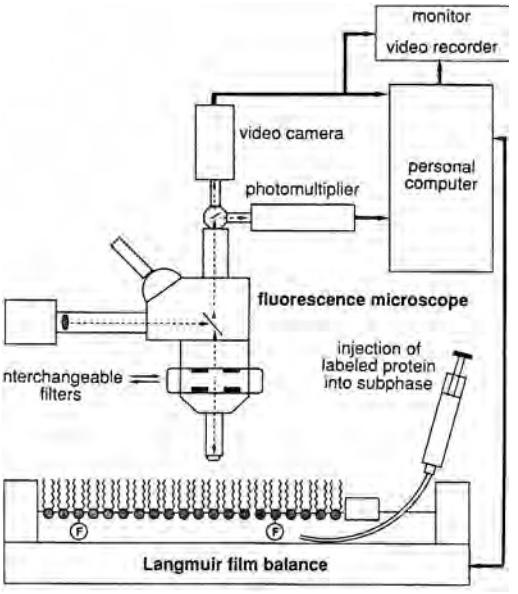

Fig. 5. Schematic representation of a fluorescence film balance (combination of a Langmuir film balance with a fluorescence microscope): the fluorescence microscope is used to observe a monolayer at the gas/water interface. The processes taking place can be recorded by a video system. The fluorescence can be quantified by means of a photomultiplier. The interchangeable filter system can be used for selective observation of the monolayer and the protein by using different fluorescence dyes.

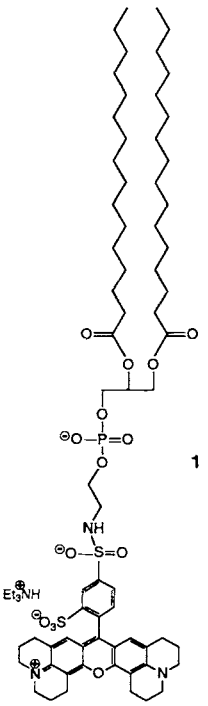
In the gas-analogous phase, there is extensive disorder of the lipid molecules. A reduction in the area leads to the formation of a liquid-analogous phase, and the closer-packing of the amphiphiles becomes evident from an increase in the surface pressure. Further compression results in the monolayer entering the region of solid/liquid coexistence. At this transition, the alkyl chains of the lipids start to form two-dimensional crystals which are solid-analogous in a liquid-analogous lipid matrix. Further compression results in crystallization of the complete monolayer so that its compressibility is now low and there is a steep rise in the isotherm. The shape of the isotherms depends greatly on the structure of the lipids.[27] The pressure/area diagrams allow statements to be made about their orientation, mobility and interactions with compounds dissolved in the subphase.

2.3. Fluorescence Microscopy of Lipid Monolayers

Combination of a Langmuir balance with a fluorescence microscope (Fig. 5) allows processes in or at the monolayer to be observed by using fluorescent dyes as probes.[26] For this, the lipid to be investigated is doped with 0.5 mol% of a fluorescence-labeled lipid (for example the sulforhodamine lipid **1**).

Such a small amount of fluorescent marker does not influence the phase behavior of the monolayer so that direct observation of the lipid phases is possible under the fluorescence microscope. A video camera is used for continuous recording of the processes taking place in the monolayer. A photomultiplier allows the fluorescence emitted by the monolayer to be quantified, which permits the measurement of quenching effects (see also Section 3).

The appearance of a monolayer doped with a fluorescence dye (for example **1**) during measurement of a pressure/area diagram is shown by the images taken at different surface pressures (Fig. 6).



In the liquid-analogous phase, the fluorescence is homogeneous throughout the field of observation. Compression of the lipid film into the phase transition region produces dark, non-fluorescent domains (solid-analogous lipid) in a bright matrix with homogeneous fluorescence (liquid-analogous lipid mixed with a fluorescence dye). The solid-analogous

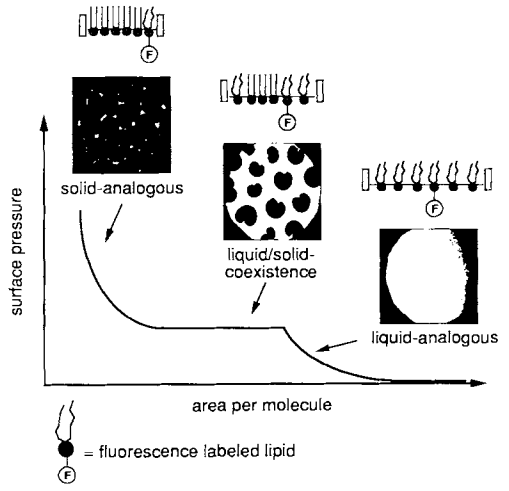


Fig. 6. Phase behavior of a lipid monolayer doped with a fluorescence lipid: diagram and appearance under the fluorescence microscope: in the liquid-analogous phase, the fluorescence dye is homogeneously distributed in the monolayer; in the phase transition region there are solid-analogous lipid domains, which appear dark because the fluorescence dye is not incorporated, in a bright liquid-analogous matrix; the solid-analogous phase is almost completely dark.

domains are dark because the fluorescence dye is not incorporated in the crystalline regions. The morphology of the lipid domains depends greatly on the lipid used. Thus, chiral lipids may form domains with a chiral structure. Finally, in the solid-analogous phase, the lipid has undergone almost complete 2D crystallization and phase separation from the fluorescence dye. Now there are only small fluorescing areas (pure fluorescence dye) in a dark matrix of solid-analogous lipid.

It is advantageous when investigating the interaction of the lipid monolayer with a protein dissolved in the subphase to be able to observe the lipid layer and the protein selectively. This can be achieved by using a suitable filter system and two fluorescence dyes whose absorption and emission spectra do not overlap (for example sulforhodamine: $\lambda_{Ex} = 584$ nm, $\lambda_{Em} = 607$ nm and fluorescein: $\lambda_{Ex} = 497$ nm, $\lambda_{Em} = 521$ nm). One of the two dyes is mixed with the lipid monolayer as described above, while the other is covalently bound to the protein. Thus, for example, it is possible by using a rhodamine filter to excite fluorescence only from the monolayer doped with sulforhodamine in order to follow the changes in the morphology of the lipid layer. On the other hand, with the fluorescein filter fluorescence is excited only from the fluorescein which is attached to the protein, and the lipid layer becomes virtually transparent.

Application of these methods to the investigation of the specific interactions between proteins and monolayers (see Fig. 2) is described in the following sections.

3. Hapten Antibody Interactions on Monolayers: Specific Recognition of Fluorescein by the Anti-Fluorescein Antibody

Intercellular communication in assemblages of cells is based on specific recognition and binding at the molecular level. Recognition reactions of this type are also extremely important for immune processes: the specific interaction between receptor and ligand for binding antibodies to cellular antigens represents a key element in histocompatibility and immunogenicity,[7] Specific recognition reactions also form the basis for developing new drug delivery strategies[27] and for constructing new immunoassays.

The study of such antigen/antibody interactions on model membranes has to date mainly used dinitrophenyl (DNP)-lipid conjugates as haptens.[24, 28] Here, the fluorescein/anti-fluorescein antibody system will be discussed. Their interaction can easily be followed spectroscopically because binding of the antibody causes fluorescence quenching.

3.1. Properties of Fluorescein and Its Antibody

Fluorescein is very suitable as an antigenic determinant because of its aromatic, dianionic nature and space-filling structure.[29] The monoclonal anti-fluorescein antibody used in these studies has the highest known binding constant (3.4×10^{10} M^{-1}) for a synthetic antigen.[30, 31]

Binding leads to almost complete quenching of the fluorescence of fluorescein. This means that fluorescence spectroscopy can be used to monitor and quantify the specific recognition and binding of the antigen by the antibody.[29a]

Figure 7 shows the fluorescence spectra of a fluorescein solution titrated with an antibody solution. The decrease in

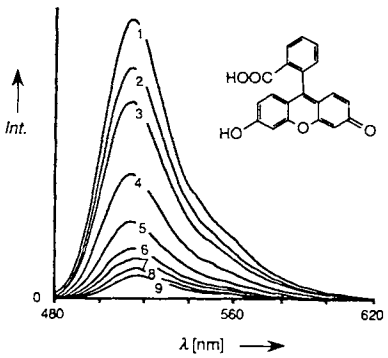

Fig. 7. Fluorescence spectra of fluorescein (2.7×10^{-12} M) before (1) and after (2–9) incubation with the anti-fluorescein antibody: increasing the antibody concentration increases the quenching of the fluorescein fluorescence; antibody concentrations: (2) 8.5×10^{-13} M; (3) 1.7×10^{-12} M; (4) 3.4×10^{-12} M; (5) 5.1×10^{-12} M; (6) 6.8×10^{-12} M; (7) 8.5×10^{-12} M; (8) 1.1×10^{-11} M; (9) 1.5×10^{-11} M.

fluorescence intensity as the antibody concentration increases is evident. F_{AB} fragments of the antibody complexed to fluorescein can be crystallized, which made it possible to determine the spatial structure of the antibody binding site.[32] In the antibody/hapten complex the fluorescein molecule is anchored deep (about 15 Å) in the binding site on the antibody by van der Waals interactions, hydrogen bonding, and charge neutralization (Fig. 8).

On these grounds, it is to be expected that fluorescein attached to a membrane will be available for such binding only if the attachment is via a sufficiently long spacer. This is why the investigations on monolayers were carried out

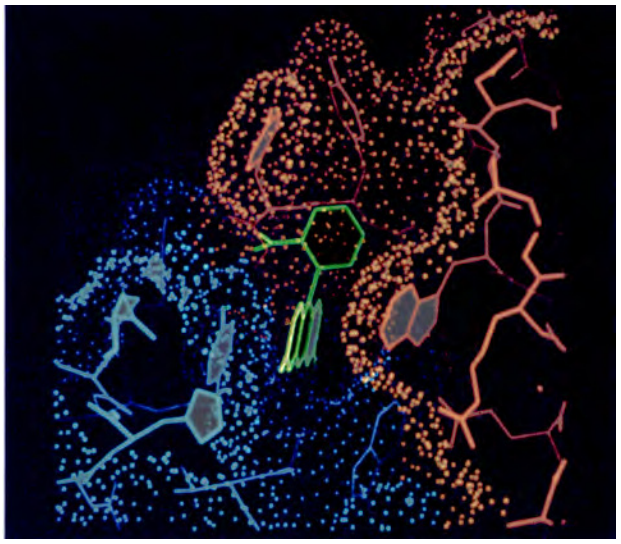

Fig. 8. 3D model of the binding region of the antifluorescein antibody (orange, blue); its hapten fluorescein (green) is anchored deeply in the binding pocket which is accessible only through a narrow channel [32].

with the spacer-containing lipid **2** and lipid **3** which has no spacer.[33a]

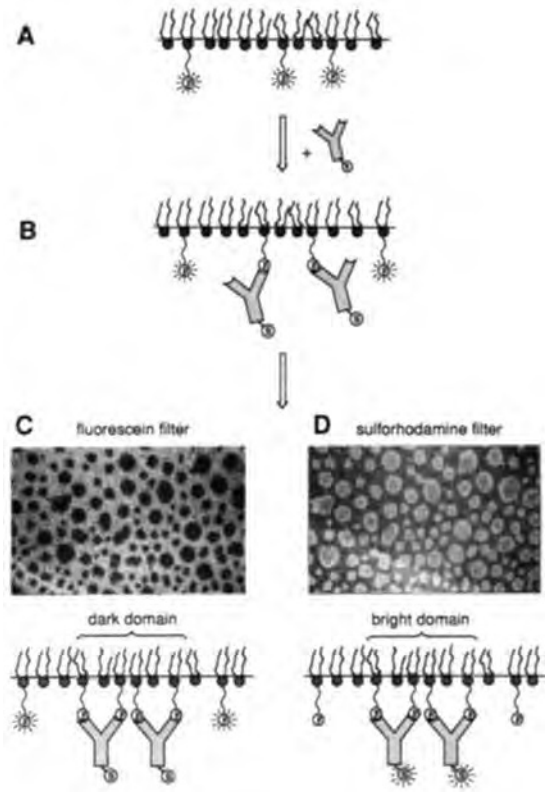

Fig. 10. Schematic representation of the binding of the anti-fluorescein antibody to monolayers doped with fluorescein-lipid: the sulforhodamine-labeled antibody dissolved in the subphase binds specifically to the hapten on the membrane and quenches its fluorescence (A,B); domain formation of the antibody can then be observed under the fluorescence microscope (C,D). These domains appear dark through the fluorescein filter (C) because of the fluorescence quenching, and appear bright through the sulforhodamine filter owing to the labeling of the antibody with sulforhodamine (D); 1% fluorescein-lipid **2** in POPC; $\pi = 5$ mN/m; 5 mm $\triangleq$ 20 μm.

The fluorescence quenching shows that the antibody binds considerably better to the fluorescein-lipid **2** with a spacer than to the lipid **3** without a spacer. A long hydrophilic spacer between the functional group (fluorescein) and the alkyl chains which form the membrane in the case of lipid **2** makes it possible for the antibody to bind to the fluorescein without hindrance from the lipid monolayer. However, the antibody binding is influenced not only by the nature of the lipid but also by the state of the monolayer. Thus, although the extent of quenching is approximately independent of the pressure between 2 mN/m and 30 mN/m, the domain formation as shown in Figure 10 only occurs at low pressure. In this case, the low packing density allows high lateral mobility of the antibody-fluorescein-lipid complexes, which makes the formation of the protein aggregates possible.

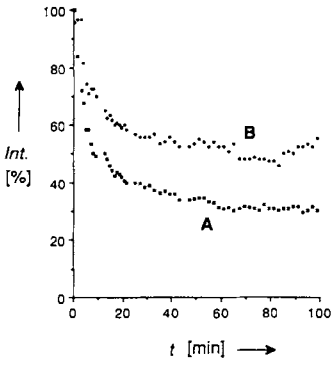

Fig. 11. Quantification of the fluorescence quenching when the antibody binds to fluorescein-lipids in monolayers: (A) the fluorescence of the spacer-containing lipid **2** is quenched by 70%; (B) the fluorescence quenching is only 50% with the lipid **3** without a spacer; 1% fluorescein-lipid in POPC, $\pi = 30$ mN/m.

4. Biotin-Lipid/Streptavidin Interaction in Monolayers: Specific Recognition and 2D Crystallization of Streptavidin

One example of specific protein-lipid interactions in monolayers is the recognition of the fluorescein-lipids **2** and **3** by their antibody which has been discussed in the previous section. Studies by *R. Kornberg* et al. have shown that this type of interaction can lead to 2D crystallization of the protein under certain conditions.[34] The example of the specific recognition between the tetrafunctional protein streptavidin and biotin attached to lipids[35] will be used to show how such processes in monolayers can be studied and possibly utilized in biosensors.

4.1. Importance of the Biotin/Avidin System

Avidin ($M = 68$ kDa) and streptavidin ($M = 60$ kDa) are two homologous water-soluble proteins which differ in molecular weight due to additional oligosaccharide units in the avidin.[36] Each is composed of four identical subunits and each of these four subunits has a specific binding site for biotin **4** (vitamin H) (Fig. 12).[37]

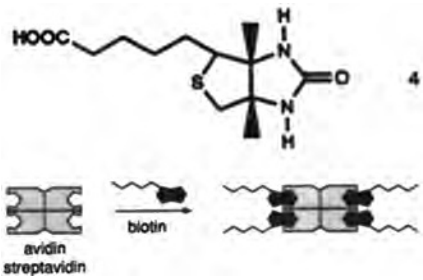

Fig. 12. Schematic representation of the binding of biotin **4** (vitamin H) to the tetrameric proteins avidin and streptavidin.

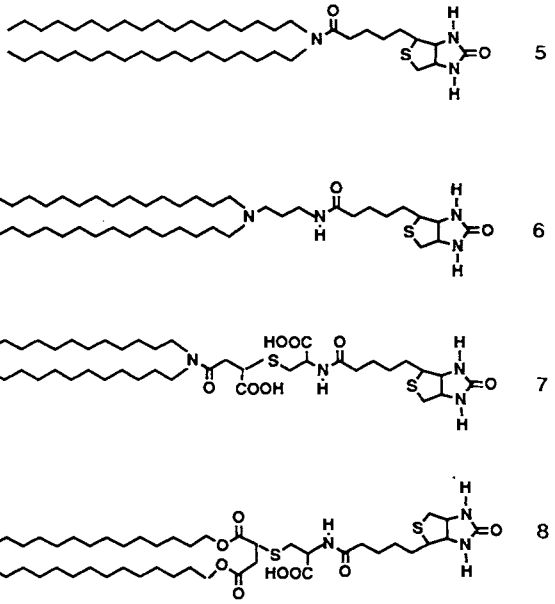
This recognition reaction has the exceptionally high binding constant of 10^{15} M^{-1}, which corresponds to a binding energy of 20 kcal mol^{-1}. This is only about one order of magnitude less than the energy of a covalent bond.[38] Binding of biotin to avidin/streptavidin is thus virtually irreversible.

The significance of this interaction in nature is not yet clearly known. On the other hand, the function of biotin itself is known in considerably more detail. It is found in all higher organisms and acts as a coenzyme in the fixation of CO_2 by various carboxylases.[39] This function is inhibited by avidin and streptavidin, which bind biotin so strongly so that it is no longer available for the enzymatic carboxylation.

Knowledge of the specific biotin/avidin binding has led to wide use in bioanalytics,[40] molecular biology[41] and immunology.[42] Other advantages of this system are that the protein is very stable and that biotin can be functionalized on its free carboxyl group without impairing its binding properties. This makes it possible to incorporate biotin into lipid head groups and thus to investigate the recognition between biotin and avidin or streptavidin in model membrane systems.

4.2. Specific and Non-specific Interactions between Streptavidin and Biotin-Lipid Monolayers[43]

A number of biotin lipids have been synthesized (**5**–**8**) to study the interaction between biotin and avidin or streptavidin in monolayers. They differ in the length of the hydrophilic spacer between the membrane-forming alkyl chains and the biotin head group which is to be recognized.



Account has to be taken of the fact that streptavidin and avidin not only interact specifically with membrane-bound biotin but also undergo non-specific adsorption on interfaces. This non-specific adsorption is considerably stronger for the glycoprotein avidin than for streptavidin. Thus, streptavidin was always used for the experiments to be described, since the specific recognition was the reaction of interest.

Specific and non-specific interactions of streptavidin with biotin-lipid monolayers are distinguished by measuring pressure/area diagrams on various protein-containing subphases. The protein used was either active, with four free biotin binding sites, or inactivated, that is saturated with biotin. There were significant differences in the isotherms (Figs. 13 and 14). In the case of spacer lipid **8**, there was a large shift to bigger areas when the subphase contained active protein (Fig. 13). This is explained by strong interaction between the streptavidin and the biotin-lipid monolayer. When inactivated streptavidin was used there was only a small shift in the isotherms. This derives from a non-specific interaction between the protein and the lipids because the protein has no free binding sites for specific recognition of

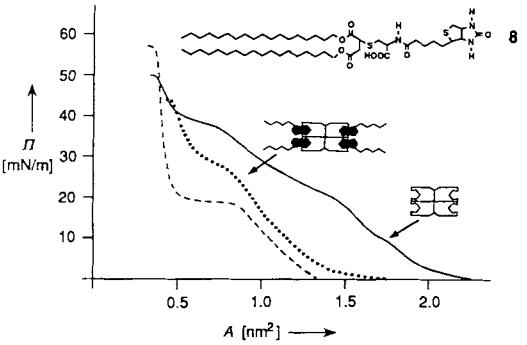


Fig. 13. Distinction between specific and non-specific binding of streptavidin to monolayers of spacer-containing biotin-lipids: specific interaction of the protein with the biotin-lipids (subphase containing active streptavidin) leads to a large expansion of the monolayer, unlike the non-specific interaction (subphase containing inactive, biotin-saturated protein); pressure/area diagram for biotin-lipid **8**: (– – –) subphase without protein; (——) subphase containing active streptavidin; (····) subphase containing inactivated (biotin-saturated) streptavidin.

biotin. Thus there is no doubt that the strong interaction found between the active protein and the biotin-lipid monolayers is an effect deriving from specific recognition.

The effect of the spacer between the biotin head group and the membrane-forming alkyl chains is evident from Figure 14. In this case, the pressure/area diagrams for the

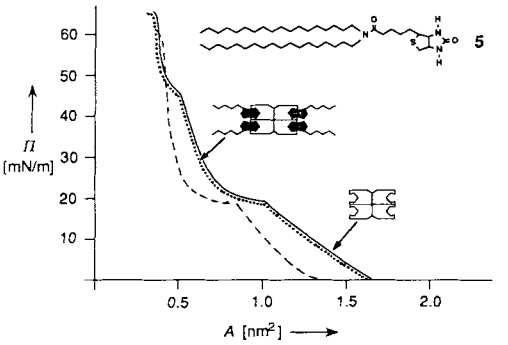

Fig. 14. Interaction of streptavidin with monolayers of spacer-free biotin-lipids: pressure/area diagrams for biotin-lipid **5** show only non-specific adsorption of the protein because the distance of the biotin from the membrane is too short for efficient binding: (– – –) subphase without protein; (——) subphase containing active streptavidin, (····) subphase containing inactivated (biotin-saturated) streptavidin.

spacer-free lipid **5** are identical after addition of streptavidin and of biotin-saturated streptavidin. The biotin thus appears to be too close to the membrane for efficient binding, and the only interaction possible is the non-specific one between the streptavidin and the biotin-lipid monolayer.

4.3. 2D Crystallization of Streptavidin as a Consequence of the Specific Recognition

4.3.1. Observation of Domain Formation by Fluorescence Microscopy

The specific recognition process between biotin and streptavidin was examined using the fluorescence microscopy method described in Section 2.3. A solution of fluorescein-labeled streptavidin was injected under a monolayer of biotin-lipid **8** in the gas-analogous state. Streptavidin domains of a regular shape are formed after a certain time. The explanation of this is that the protein molecules, which are initially homogeneously distributed in the subphase, recognize the ligands presented on the lipid layer (Fig. 15A, B). The protein molecules bind to the monolayer and undergo preliminary orientation and finally aggregate because of the high mobility in the plane of the monolayer (Fig. 15C).

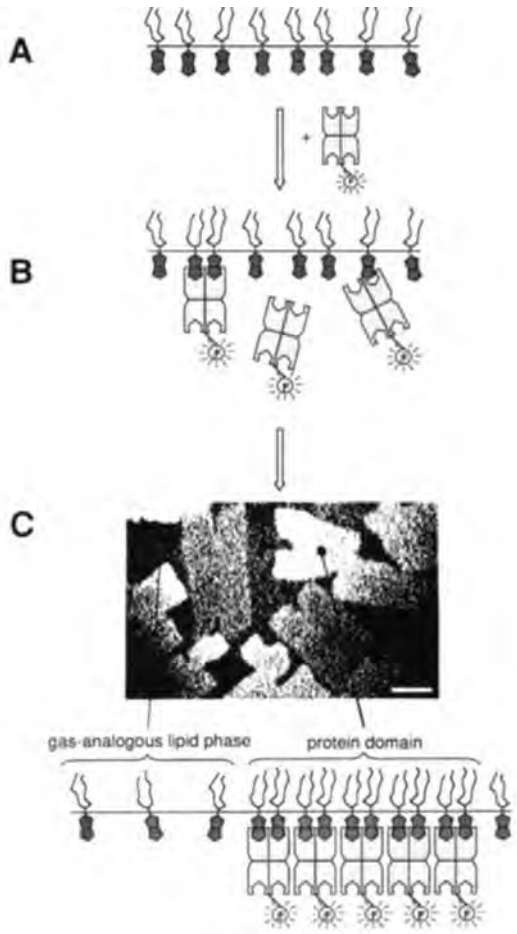

Fig. 15. Diagram representing the binding of streptavidin to monolayers of biotin-lipid **8**: the fluorescein-labeled streptavidin dissolved in the subphase binds specifically to biotin on the membrane (A,B); formation of streptavidin domains can then be observed under the fluorescence microscope (bright areas through the fluorescein filter; C); $\pi = 0$ mN/m; bar $\triangleq$ 20 μm.

The shape of the domains depends greatly on the conditions of preparation. The various morphologies can be described as dendritic, H-shaped, or butterfly-shaped.

Excitation of fluorescence using linearly polarized light results in the relation shown in Figure 16 between the fluorescence intensity of the streptavidin domains and the polarizer setting. The two photos are of an identical area of the monolayer, with the polarizer having been turned through 90° from Figure 16A to Figure 16B. Protein domains which appear light in Figure A are dark in Figure B and vice versa. This optical anisotropy suggests a high degree of order and low mobility of the protein molecules in the domains.

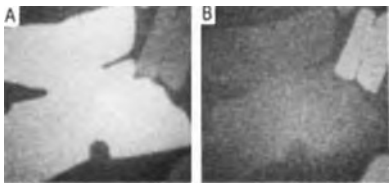

Fig. 16. Optical anisotropy of the streptavidin domains under the fluorescence microscope: the plane of polarization of the exciting light differs by 90° in A and B; domains which appear bright in A are dark in B because of the optical anisotropy, and vice versa; biotin-lipid **8**, 5 mm $\triangleq$ 30 μm.

Control experiments with biotin-saturated streptavidin and with lipid layers incapable of binding, that is biotin-free (for example DPPC) produced no protein domains in any instance. Thus the formation of these domains is a consequence of the specific recognition of biotin by streptavidin.

4.3.2. Structure Determination by Electron Microscopy

The optical anisotropy of the streptavidin domains suggests that they are two-dimensional protein crystals. This prompted detailed investigation of the protein domains by electron microscopy in cooperation with *R. D. Kornberg* et al. (Fig. 17).[33]

Figure 17A shows several protein domains under low magnification, some of which are disrupted by the preparation. Increasing the magnification (Fig. 17B, C) reveals a

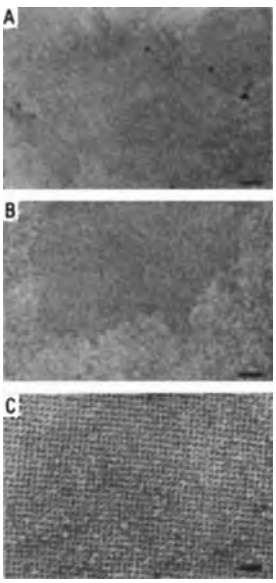

Fig. 17. Electron micrographs of streptavidin crystals with increasing magnification; bar $\triangleq$ (A) 0.5 μm, (B) 125 nm, (C) 25 nm; negative staining with uranyl acetate.

regular pattern with tetragonal ordering. Electron diffraction of these ordered regions showed that they really are two-dimensional streptavidin single crystals. These 2-D crystals could be used to determine the 3-D structure of the streptavidin bound to the biotin-lipid layer with a resolution of 15 Å. At the same time, *Hendrickson* determined the three-dimensional structure of the protein, including the position of the biotin binding sites by X-ray structural analysis with a resolution of 3 Å.[44] When the structure found by *Hendrickson* and that obtained from the 2D crystals are superimposed there is found to be very good agreement. This permits the position of the biotin binding sites to be transferred to the reconstruction of the protein obtained from the 2D crystals (Fig. 18).

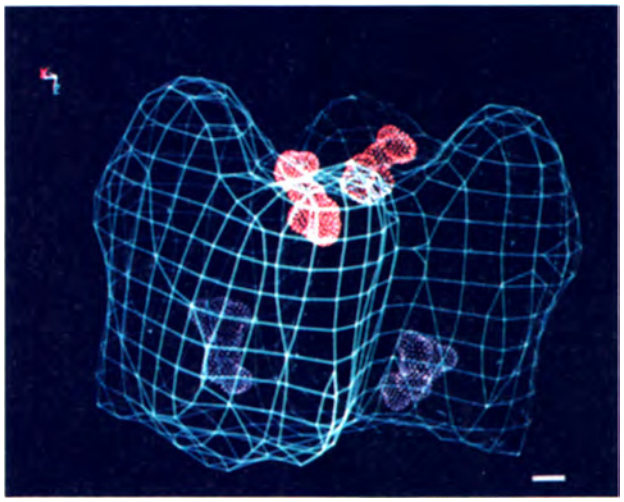

Fig. 18. 3D model of streptavidin (blue contour lines); the four biotin binding sites are indicated (after *Hendrickson* [44]); bar ≙ 4 Å.

These results allow the orientation of the streptavidin bound to the biotin-containing monolayer to be visualized for the first time (Fig. 19).

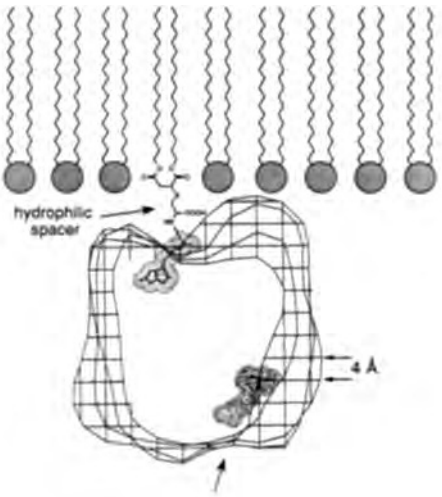

Fig. 19. Section through a monolayer containing biotin-lipids with bound streptavidin: the distance of the upper biotin binding site from the monolayer approximately corresponds to the length of the spacer in the biotin-lipid **8**; the lower free binding site is accessible from the subphase (arrow).

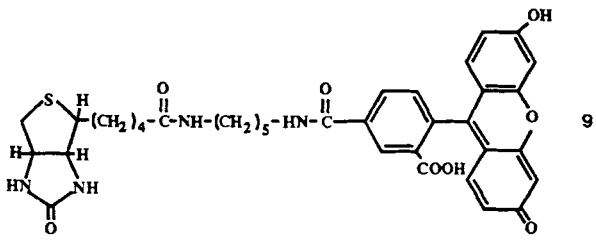
There are two points worthy of note here: the distance between the binding site and the lipid monolayer approximately corresponds to the length of the spacer in the biotin-lipid **8** used. This explains the rapid interaction of the protein with this biotin-lipid and its 2D crystallization. In addition, each streptavidin molecule contains two other free binding sites for biotin which point into the aqueous phase. As will be seen, these are available for further reactions of biotinylated molecules with the protein layer.

4.4. Docking of Biotinylated Molecules to 2D Streptavidin Crystals

Docking of an easily detectable biotinylated molecule can be used to demonstrate that there really are free binding sites for biotin available on the crystallized streptavidin layer. An example of such a molecule is the fluorescein-biotin **9** (Fig. 20).[45]



9

The experiment was carried out with streptavidin labeled with sulforhodamine. The protein domains formed as described under a biotin-lipid monolayer appear bright in the sulforhodamine filter. Injection of fluoroscein-labeled biotin under a protein monolayer of this type (**9**), as shown in the

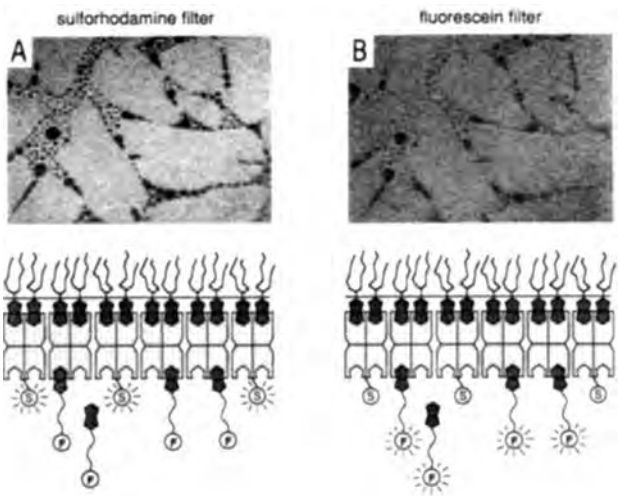


Fig. 20. Docking of biotin-fluorescein **9** to 2D crystals of sulforhodamine-labeled streptavidin: under the fluorescence microscope the streptavidin domains appear bright through both the sulforhodamine filter (marker on protein, A) and the fluorescein filter (fluorescein-biotin, B); 5 mm ≙ 20 μm.

above diagram, results in docking of the biotin to the free binding sites on the streptavidin. This becomes evident from the fact that, after a short incubation time, the protein do-

mains appear bright not only in the sulforhodamine filter but also in the fluorescein filter.

Biotinylated ferritin was chosen as model macromolecule for the docking.[33] The molecular weight of this protein is 600 kDa, which is about ten times that of streptavidin. In addition, it contains iron and thus is easy to detect with the electron microscope. Streptavidin domains were transferred to a solid substrate and incubated with a solution of biotinylated ferritin and then thoroughly washed. Under the electron microscope there are seen to be isolated ferritin molecules bound to the regular crystal structure of the streptavidin layer (Fig. 21). The fact that this is based on the biotin/streptavidin interaction is shown by the comparison experiment with non-biotinylated ferritin, where the 2D streptavidin layer can be washed free of ferritin.

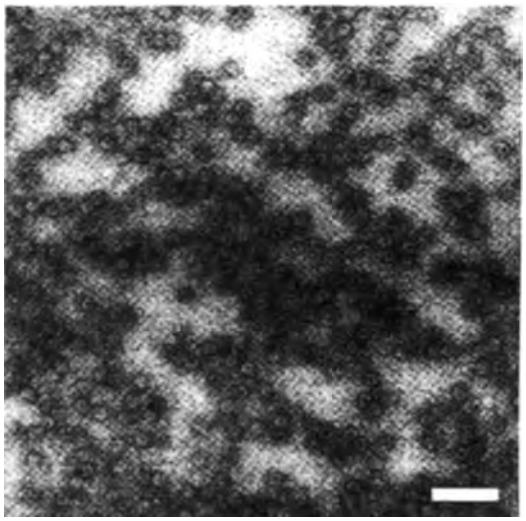

Fig. 21. Electron micrograph of a 2D streptavidin crystal with bound biotinylated ferritin; bar ≙ 50 nm; negative staining with uranyl acetate.

These two examples show unambiguously that the 2D streptavidin crystals represent a matrix which can be further functionalized with biotin.

4.5. Protein-Containing Monolayers in Biosensors?

The highly specific and extremely strong binding of biotin to avidin/streptavidin has found application in affinity chromatography for some time now.[40] There are also a number of immunoassays which utilize this protein/ligand interaction. However, no use has yet been made of the properties of highly ordered monomolecular layers which can be prepared with streptavidin at biotin-lipid layers.

The possibility of functionalizing 2D streptavidin crystals which has been mentioned in the previous section has resulted in a number of ideas which may lead to applications of protein-containing monolayers (Figure 22).

Bifunctional biotin derivatives could conceivably be used to construct very thin well-defined streptavidin multilayer structures. In addition, since the crystalline protein layer is a highly ordered matrix which is compatible with proteins, it might be used for docking of other biotinylated proteins

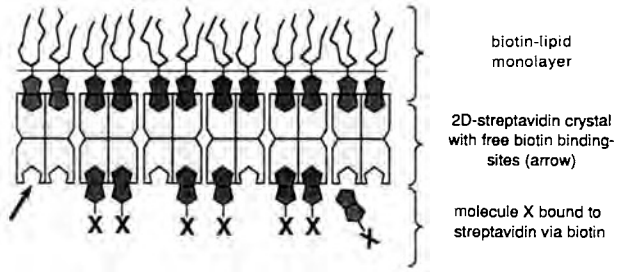

Fig. 22. 2D crystalline streptavidin layer functionalized by binding of biotinylated molecules X to free biotin binding sites: X = protein, functional group, polymer, biotin (bis-biotin compound).

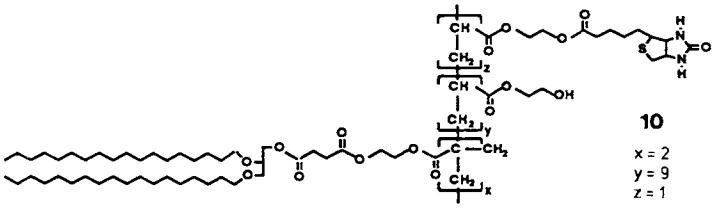
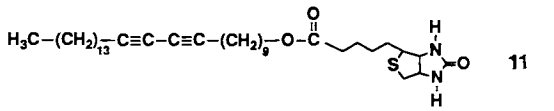
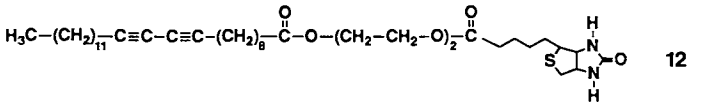
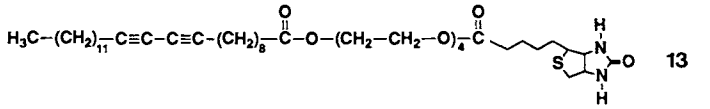
(for example enzymes, antibodies) or nucleic acids (for example RNA, DNA). In these cases, both the function of the coupled proteins and their tendency to crystallize may be of interest.

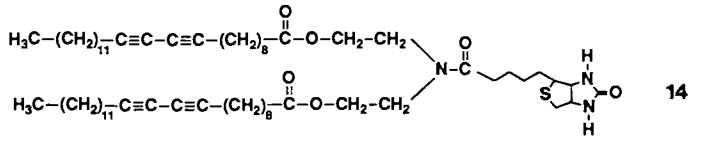
A stabilized lipid layer to which the streptavidin can bind would be advantageous for such applications. Suitable examples are biotin-containing polymers (for example **10**) or polymerizable biotin-containing amphiphiles such as the diacetylene-biotin-lipids **11**–**14**. Besides high stability, the











biotin-containing polydiacetylenes have other interesting properties. Thus, tiny changes in the conformation of the polymer backbone can be detected very sensitively by changes in the spectroscopic properties of the polymer (for example UV, Raman[46, 47] and CD[48]) or the conductivity after doping. This might form the basis for the development of a sensitive sensor for the binding of streptavidin to the polymeric lipid layer. Coupling of streptavidin to a molecule to be detected is a conceivable basis for a large number of biosensors.

5. Enzyme Substrate Interaction: Specific Recognition, Function and Domain Formation of Phospholipase A_2 at Lecithin Monolayers

Most of the chemical reactions taking place in an organism and regulating metabolism are enzymatic.[49] The first step in these is, just as it is in the examples discussed in Sections 3 and 4, the specific recognition between a protein and its substrate. The particular feature of an enzyme is that it not only recognizes the bound substrate but also brings about a chemical change in it (formation or breaking of bonds). One example of such a reaction taking place on a membrane is the hydrolytic function of phospholipase A_2. Its interaction with lecithin monolayers will be dealt with in this section.

5.1. Function and Properties of Phospholipase A_2

Phospholipases comprise an important class of enzymes.[17, 50] They catalyze the hydrolysis of ester bonds in membrane-forming phospholipids. The enzyme from this class which has been investigated most thoroughly is phospholipase A_2, which is very widespread.[51] One of its most important functions is to rebuild and modify cell membranes. However, the mechanism for regulating this enzyme is still unknown. The reason why cell membranes are not all destroyed remains to be found. Phospholipase A_2 also induces the release of arachidonic acid which leads to the formation of substances which produce inflammation (prostaglandins, leukotrienes, thromboxanes).[52] Thus, a way of regulating their activity would provide a good method for controlling inflammatory processes.

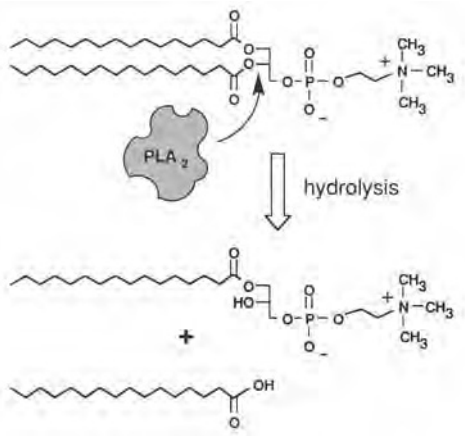


Fig. 23. Cleavage reaction catalyzed by phospholipase A_2 (schematic): the enzyme hydrolyses of the ester bond in C-2 position of a lecithin, resulting in the corresponding lysolecithin and the free fatty acid.

Phospholipase A_2 is relatively small, with a molecular weight of 12–14 kDA, is soluble in water, and is very stable, having a large number of disulfide linkages. It catalyzes ester cleavage at the C-2 position in naturally occurring glycerophospholipids to give the corresponding lysolecithin and the free fatty acid (Fig. 23).

The reaction takes place both regioselectively, that is, only the ester linkage in the C-2 position is cleaved, and stereospecifically, that is only the naturally occurring L form of the lipid can be hydrolyzed – the D form is inert.[53] Phospholipase A_2 activity depends very strongly on the physical state of the substrate.[17, 50, 51, 54] It increases many times over in going from a homogeneous solution to organized substrates such as micelles, liposomes or monolayers. The highest activity in liposomes is found when the lipid is in the phase-transition region.[54g, 55] This property of phospholipase A_2 makes it especially interesting for investigations in monolayers because it is easy to bring about large changes in both the composition and the physical state of the membrane (compare lipid domain formation in Fig. 6 in Section 2.3).

5.2. Hydrolysis of Substrate Lipids of Phospholipase A_2 in Monolayers

The fluorescence film balance described in Section 2.3 was used to investigate the hydrolytic activity of phospholi-

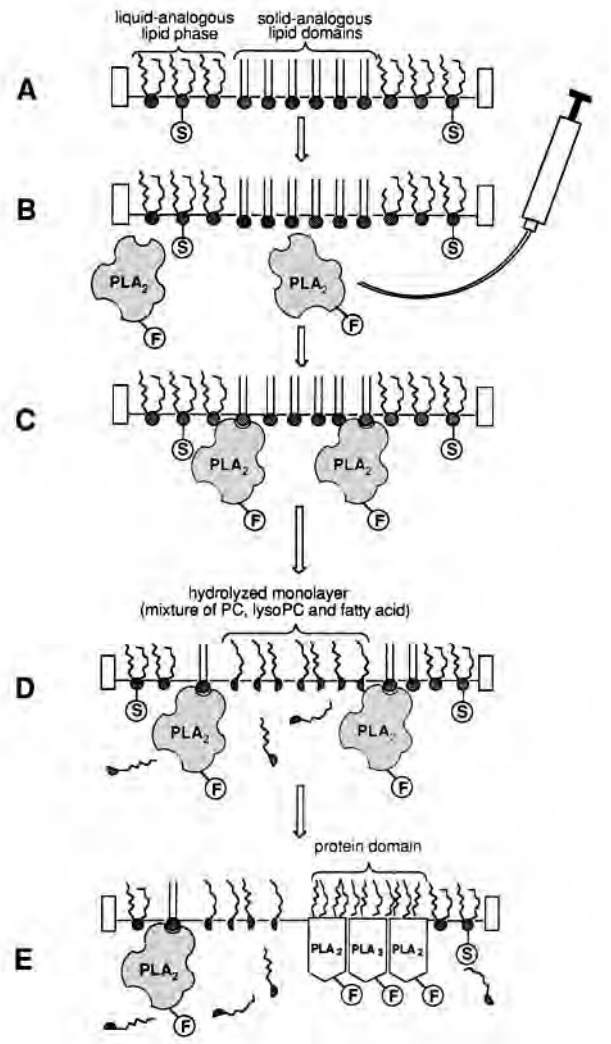

Fig. 24. Hydrolysis of a lipid monolayer by phospholipase A_2 (schematic): (A) monolayer in the phase transition region with solid-analogous lipid domains in a liquid-analogous lipid matrix mixed with a sulforhodamine marker; (B) injection of the FITC-labeled phospholipase A_2; (C) specific recognition of the substrate lipids by the enzyme and preferential attack at the boundaries between liquid- and solid-analogous phase; (D) hydrolysis of the solid-analogous lipid domains and accumulation of the hydrolysis products in the monolayer; (E) aggregation of the enzyme. PC = phosphatidylcholine.

pase A_2. In these experiments the monolayer was doped with a sulforhodamine-lipid, and the phospholipase was labeled with fluorescein isothiocyanate (FITC). These two labels made it possible to observe processes in the lipid monolayer and the behavior of the enzyme separately. An experiment of this type is outlined in Figure 24.

The lipid monolayer is compressed until it is in the phase transition region. This leads to the formation of solid-analogous lipid domains in a liquid-analogous matrix (Fig. 24A; see also Section 2.3). Injection of the labeled phospholipase A_2 into the subphase (Fig. 24B) is followed by specific recognition between the enzyme and its substrate. The attack by the protein takes place preferentially at the boundary between the solid-analogous and the liquid-analogous phase (Fig. 24C).[56] As hydrolysis progresses, the solid-analogous lipid domains are broken down and the hydrolysis products accumulate in the monolayer (Fig. 24D). After a certain time, the phospholipase A_2 starts to aggregate to form domains of its own which have a specific shape (Fig. 24E). This may indicate a change in the conformation of the protein due to interaction with the hydrolyzed monolayer. These processes can be observed directly under the fluorescence microscope,[57] as will be illustrated by the examples of L-α-dipalmitoylphosphatidylcholine (DPPC) and L-α-dimyristoylphosphatidylcholine (DMPC) monolayers.

5.2.1. *Hydrolysis of Solid-Analogous* L-α-*DPPC Domains*[57]

As mentioned above, the enzyme is injected under a monolayer which is in the phase transition region. Viewed through the sulforhodamine filter, dark solid-analogous lipid do-

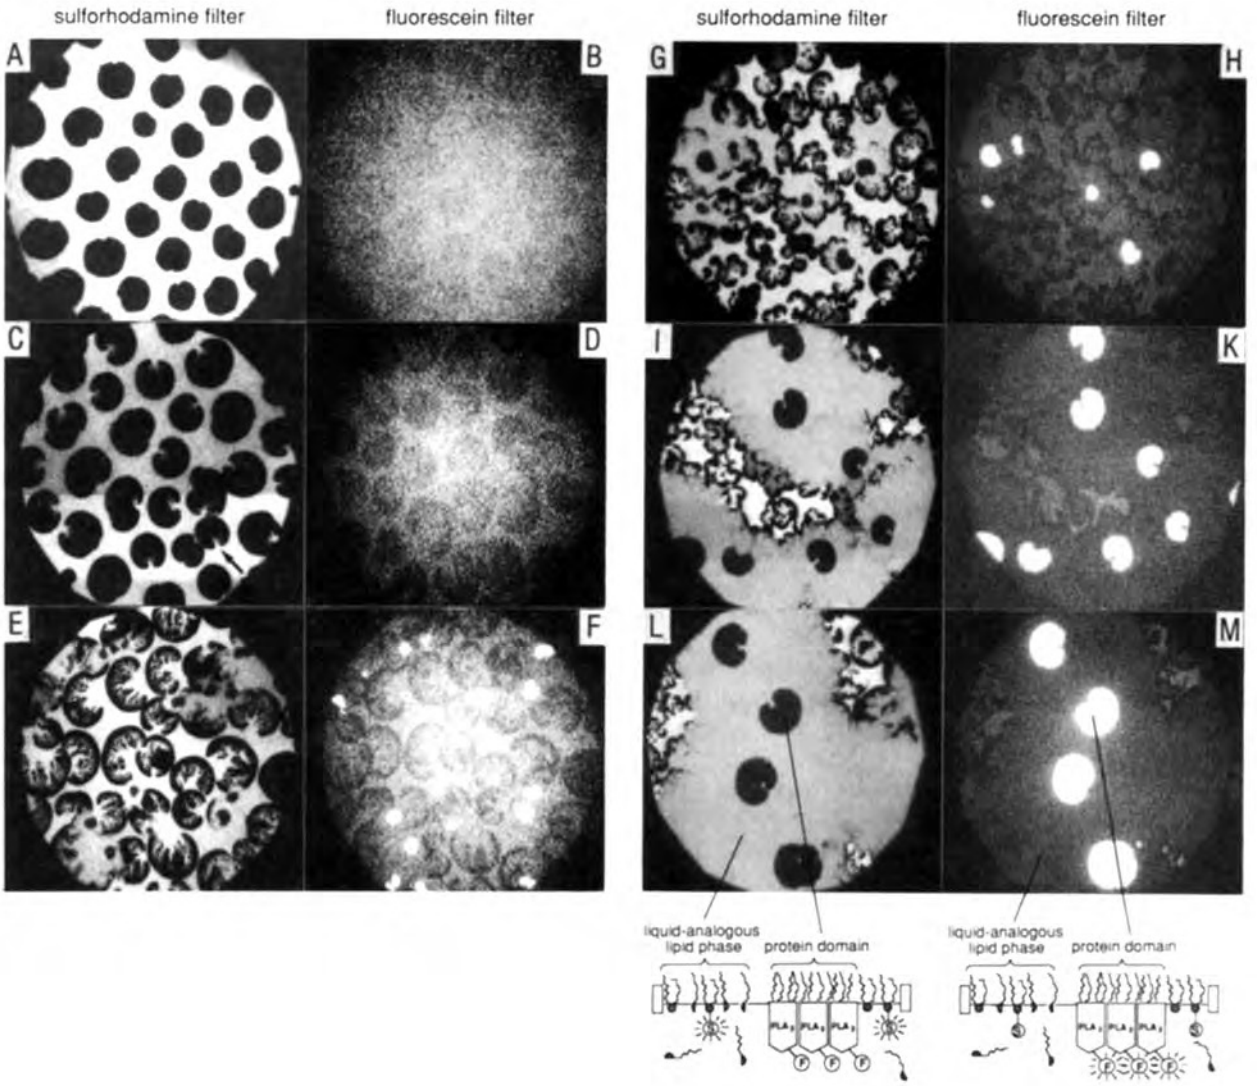

Fig. 25. Hydrolysis of an L-α-DPPC monolayer by phospholipase A_2 observed by fluorescence microscopy; the monolayer is seen through the sulforhodamine filter (on the left) and the enzyme is seen through the fluorescein filter (on the right): (A) dark solid-analogous lipid domains in a bright liquid-analogous matrix; (B) homogeneous fluorescence of the enzyme in the subphase; (C) first signs of hydrolysis of the lipid domains (arrow); (D) homogeneous fluorescence of the enzyme in the subphase; (E), (F) progressive degradation of the lipid domains and first signs of the formation of enzyme aggregates below the monolayer (bright spots through the fluorescein filter) (E), dark spots through the sulforhodamine filter (F)); (G)–(K) further hydrolysis of the lipid domains (G,I) with simultaneous growth of the protein domains (H,K); (L), (M) after almost complete degradation of the lipid domains there are now only protein domains in a fluid matrix composed of the hydrolysis products and DPPC; these enzyme domains have a specific shape and appear dark through the sulforhodamine filter (L) and bright through the fluorescein filter (M); (A), (B) $t = 0$ min (immediately after enzyme injection); (C), (D) $t = 10$ min; (E), (F) $t = 30$ min; (G), (H) $t = 40$ min; (I), (K) $t = 50$ min; (L), (M) $t = 60$ min; $\pi = 22$ mN/m; $T = 30\,^{\circ}C$; 5 mm $\triangleq$ 20 μm.

mains which are typical of L-α-DPPC[58] are seen in the bright matrix of liquid-analogous lipid and sulforhodamine marker (see Fig. 25A and scheme in Figs. 24A, B). With the fluorescein filter, the homogeneous fluorescence of the protein is seen under the monolayer (see Fig. 25B). The first signs that the enzyme has recognized its substrate in the monolayer and started to hydrolyze it appear after 10 minutes. Firstly, areas of erosion form, specifically at the concavities previously present in the lipid domains (see Fig. 25C and scheme in Fig. 24C). The enzyme then starts to degrade the domains inwards from these points (Fig. 25C, E). Once the enzyme has bound to the phase boundary and started to hydrolyze the lipid, there is local accumulation of the acid and lysolecithin, which may lead to autocatalytic activation of the phospholipase A_2 at this point.[59] This would explain why further hydrolysis from an initial point of attack is preferred. After about 60 minutes, only slight remains of the lipid domains are left (Fig. 25E, G, I, L).

Observation through the fluorescein filter reveals small bright dots after 30 minutes (Fig. 25F), which appear dark through the sulforhodamine filter: the protein is starting to aggregate underneath the monolayer.[57, 59a, 60] These bright dots increase in number and size as the reaction progresses (Fig. 25F, H, K) until, at its end (after about 60 minutes), they have a typical kidney shape (see Fig. 25L). The monolayer now consists only of almost completely destroyed solid-analogous lipid domains and the protein domains in a matrix of liquid-analogous lipid (see Fig. 25L, M).

It is noticeable that the domains of phospholipase A_2 are similar in shape to some of the lipid domains present at the start of the reaction (see Fig. 25L, M and Fig. 24A). To examine whether there is a template effect, the hydrolysis experiment was repeated with L-α-DMPC which forms solid-analogous domains of different morphology.

5.2.2. *Hydrolysis of Solid-Analogous L-α-Domains*[57b]

The lipid domains in the phase transition region of a DMPC monolayer differ from those of DPPC in being small and star-shaped (see Fig. 26A and Fig. 25A). 5 minutes after the injection of the FITC-labeled phospholipase A_2, small concavities are evident in these domains in the sulforhodamine filter. With the fluorescein filter, bright dots are seen at the corresponding points, which are the first signs that protein aggregation is starting (see arrows in Fig. 26B and 26C).[57, 59a, 60] These protein aggregates grow as the reaction progresses (Fig. 26D–I), and finally the enzyme domains have the same morphology as in the hydrolysis of an L-α-DPPC monolayer (see Fig. 25L, M). This shows that the shape of the protein domains does not depend on the original shape of the solid-analogous lipid domains.

However, observation of the progress of hydrolysis reveals some differences. Whereas individual domains of L-α-DPPC are specifically attacked and degraded, in the case of L-α-DMPC the enzyme produces large areas containing no solid-analogous lipid. The protein domains then appear in the middle of these areas (Fig. 26D–G). It is not yet clear how this different degradation behavior relates to the mechanism of hydrolysis.

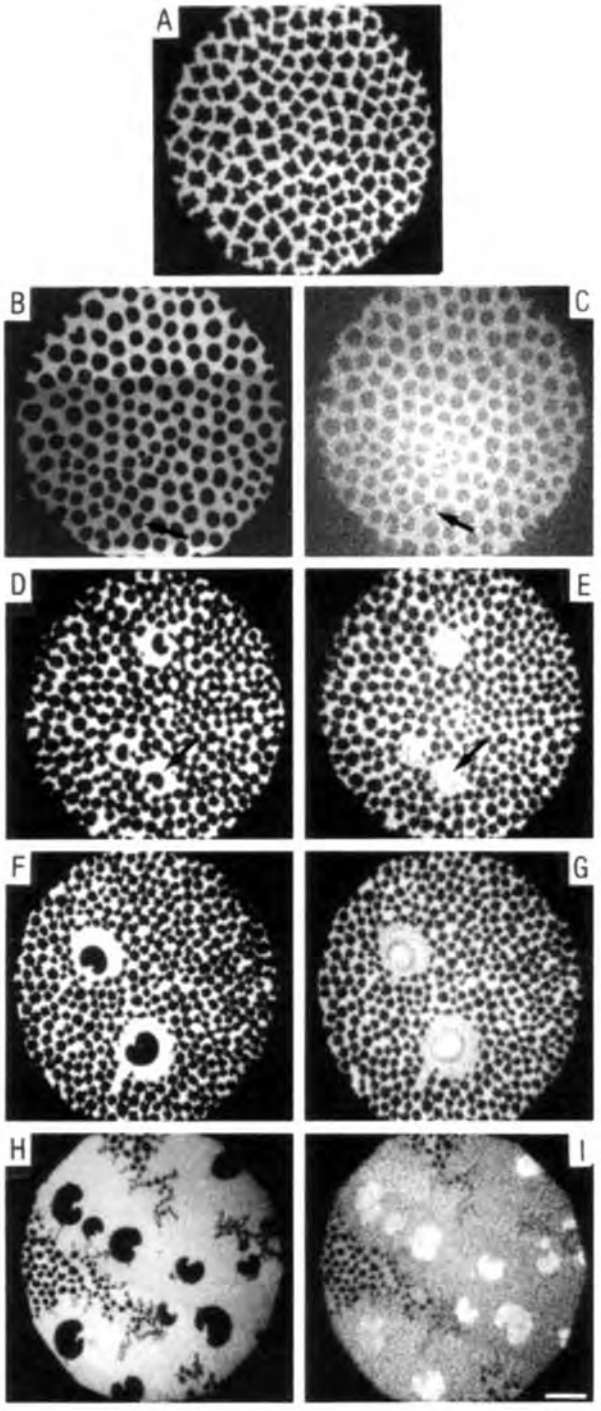

Fig. 26. Hydrolysis of an L-α-DMPC monolayer by phospholipase A_2 observed by fluorescence microscopy; the monolayer is seen through the sulforhodamine filter and the enzyme is seen through the fluorescein filter: (A) dark solid-analogous lipid domains in a bright liquid-analogous matrix; (B), (C) first signs of hydrolysis of the lipid domains; small bright dots are seen at the corresponding sites through the fluorescein filter – these are signs that protein aggregation is starting (arrows in B and C); (D)–(G) progressive hydrolysis leads to circular areas without solid-analogous lipid, in the centers of which the protein domains (arrow) are growing; (H), (I) after almost complete degradation of the lipid domains; there are now only the protein domains in a fluid matrix composed of the hydrolysis products and DMPC; these enzyme domains have specific shapes and appear dark through the sulforhodamine filter (H) and bright through the fluorescein filter (I); (A) $t = 0$ min (immediately after enzyme injection); (B), (C) $t = 10$ min; (D), (E) $t = 20$ min; (F), (G) $t = 30$ min; (H), (I) $t = 50$ min; $\pi = 22$ mN/m; $T = 10$ °C; bar ≙ 20 μm.

5.2.3. *Compression of a Hydrolyzed* L-α-DPPC Monolayer

More information about the nature of the protein in the domains was obtained by changing the surface pressure in a hydrolyzed L-α-DPPC monolayer.[57b] Expansion to the gas-analogous state ($\pi = 0$ mN/m) has no effect on the shape of the protein domains, which indicates that they are very stable. Figure 27 shows the processes observed during compression, both schematically and as they appear under the fluorescence microscope. New solid-analogous lipid domains are formed in the fluid matrix (Fig. 27B). This shows

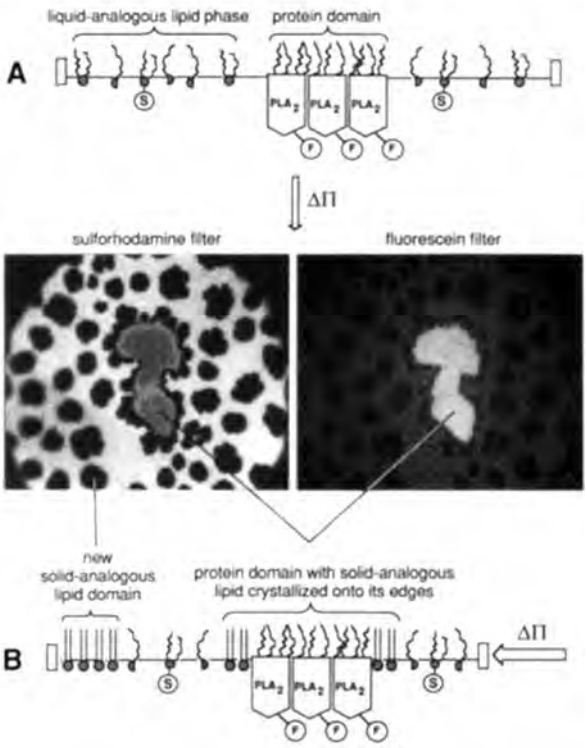

Fig. 27. Compression of an L-α-DPPC monolayer after hydrolysis by phospholipase A_2; (A) schematic representation of a protein domain in a fluid matrix composed of hydrolysis products and DPPC; (B) compression leads to formation of new solid-analogous lipid domains both in the fluid matrix and directly on the edges of the protein domains (appearance under the fluorescence microscope and schematic representation); 5 mm ≙ 20 μm.

that even after complete hydrolysis of the original lipid domains there is still uncleaved lecithin present in the monolayer. However, it is noteworthy that new lipid domains are produced not only in the fluid phase but also directly on the edges of the protein domains (bright through the fluorescein filter). This lipid crystallized onto the protein domains is not attacked and degraded by the enzyme organized in them, which indicates that the aggregated phospholipase A_2 is no longer active.

The first evidence that the lysolecithin and fatty acid produced in the hydrolysis play an important part in the formation of the protein domains was gained from analogous experiments with D-α-DPPC: although the enzyme is able to recognize this lipid it cannot cleave it.[53] Unlike the hydrolysis of an L-α-DPPC monolayer, even after 2 hours there is neither degradation of the solid-analogous lipid domains nor formation of protein domains. Thus, because the existence of the hydrolysis products in the monolayer appears to be a necessary precondition for the formation of protein domains, investigations were carried out using mixed monolayers.

5.3. Phase Behavior of Mixed Lecithin, Lysolecithin and Fatty Acid Monolayers and Their Interaction with Phospholipase A_2

In order to confirm that the existence of the hydrolysis products in the monolayer is crucial for the observed aggregation and inhibition of phospholipase A_2, the effect of the hydrolysis products was investigated separately from the hydrolysis process. This can be achieved by using mixed monolayers composed of lecithin, lysolecithin and fatty acid in various ratios (1:x:x, x = 1–5); such mixtures simulate the situation after a hydrolysis reaction. Assuming that only the cleavage products and not reactions during the hydrolysis (for example acylation[61]) induce domain formation and inhibition of phospholipase A_2, there should be spontaneous development of protein domains when the composition of these mixed monolayers is suitable. The following example shows this.

After spreading of a 1:5:5 mixture of L-α-DPPC, L-α-LysoPPC and palmitic acid, the liquid-analogous monolayer appears homogeneously bright under the fluorescence microscope (Fig. 28A). However, compression leads to phase separation and thus formation of domains of unknown composition[62] (Fig. 28B).

These mixed domains are gray, unlike the black solid-analogous lipid domains described above; thus these domains do not completely exclude the fluorescent dye.

Injection of the FITC-labeled phospholipase A_2 under a mixed monolayer containing these gray domains results in binding of the protein to the domains within two minutes without visible evidence of hydrolysis (Fig. 28C). This is even more noteworthy when it is compared with the relatively slow formation of the protein domains during hydrolysis with phospholipase A_2 (about 60 minutes, see Fig. 25L, M). The mixed domains therefore represent a preferred environment for protein binding. They act directly as templates for the rapidly forming protein domains: the shape of the mixed domains (sulforhodamine filter) is identical to the shape of the protein domains (fluorescein filter). The results are the same when the D form of DPPC is used in the mixing experiments. This is clear evidence that recognition of the headgroup of the lecithin, but not its cleavage, is necessary for rapid aggregation of the protein.

A 1:1 mixture of lysolecithin and fatty acid, without DPPC, shows no domain formation by these hydrolysis products nor protein aggregation. Uncleaved lecithin is thus necessary for inducing protein aggregation.

The results of these monolayer investigations do not yet make a direct contribution to the vigorous discussion in the literature about the mechanism of hydrolysis by phospholipase A_2.[17, 50, 51] Whereas many studies have discussed inhibition of phospholipase A_2,[17, 50, 51, 52] no domain formation of the protein has been observed. The straightforwardness of the described method might not only provide

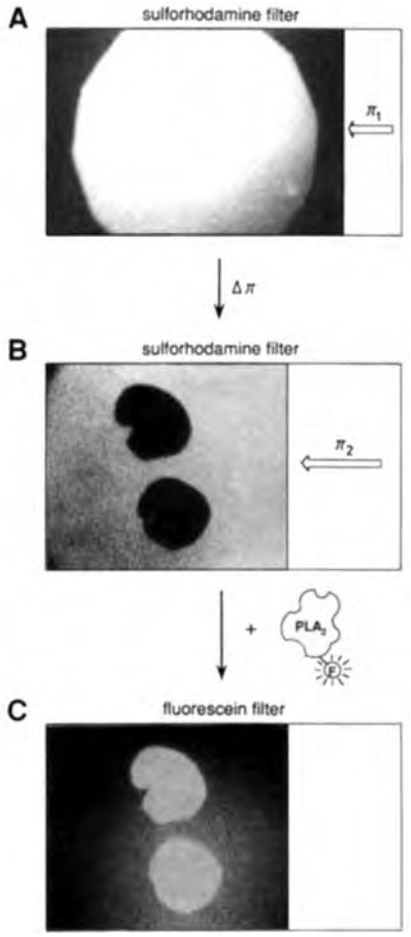

Fig. 28. Interaction of phospholipase A_2 with monolayers composed of a 1:5:5 mixture of lecithin, lysolecithin and fatty acid: (A) homogeneous fluorescence of the liquid-analogous mixed monolayer doped with sulforhodamine-lipid **1**; (B) compression leads to the formation of gray mixed domains of unknown composition; (C) fluorescein-labeled phospholipase A_2 injected under this monolayer binds very quickly to these mixed domains which thus appear bright through the fluorescein filter. 5 mm ≙ 20 μm

new ways of testing inhibitors for phospholipase A_2 but also contribute to providing detailed information on the mechanism of the catalysis by this essential class of enzymes.

6. Conclusion

The experiments with fluorescein/anti-fluorescein antibody and biotin/streptavidin were attempts to use monolayers as systems to model specific recognition reactions at cell membranes. It was possible, by using the relatively new method of fluorescence microscopy on monolayers, to observe other phenomena apart from the expected specific interaction. In both cases there was spontaneous formation of protein domains at the monolayer. In the case of streptavidin, the protein domains proved to be 2D crystals. However, a far more interesting fact is that the highly ordered streptavidin layer provides a matrix which has two further highly active binding sites per protein molecule. This suggests possible uses in biosensors, as already discussed in Section 4.5.

The example of the enzymatic activity at the monolayer, that is the interaction of phospholipase A_2 with lecithin domains, was originally based on ideas about the breaking down ("uncorking") of liposomes by phospholipase A_2.[6c] In the monolayer experiments it was possible for the first time to follow the progress of enzymatic reactions on organized substrates, the lipid domains, by direct visual observation. Once again, enzyme domains with a regular morphology were formed, which indicates inhibition of phospholipase A_2 by the hydrolysis products. This might help to explain why the phospholipases which are widespread in the body do not destroy all cell membranes.

There remains the interesting question of how functional supramolecular systems can be used as a basis for materials science to learn from life science. There are no doubt very many biochemical processes which can be transferred to model membrane systems. Increasing numbers of examples are being provided by affinity chromatography and the new area of biosensors.

Organic Synthesis in the Age of Computers

By James B. Hendrickson*

The computer affords four areas of interest to synthetic chemists: (1) storage and retrieval of information; (2) complex calculations of shape and reaction dynamics; (3) artificial intelligence (AI) to solve synthetic and analytical problems; (4) overall direction of multiple laboratory experiments. Our work began 30 years ago initiating molecular geometry calculations to match experimental results. The explosive growth of computer power since will be illustrated. Synthesis design (as AI) requires an efficient protocol to search huge trees. The SYNGEN program is based on simplification and systematization, first of skeletal dissection, then of structure and reaction characterization, for generation of optimal synthesis routes. The program will be be described and its future development outlined. Finally, a perspective on the future of all four areas will be sketched, noting the necessary attendant growth in systematic use by chemists and in sympathetic interfaces by software designers.

1. Introduction

The overlap of organic synthesis with understanding of computers has traditionally been small. As we stand back to view our science on this celebration of the 125th anniversary of BASF, it may be useful to explore how this has happened and what we may look for in the future for their codevelopment. The impact of computers on science has certainly been dramatic and organic synthesis has a lot to gain by intimate collaboration. Here is a perspective on what computers can do.

1. Complex calculations: molecular properties, reaction dynamics, and molecular modeling.
2. Information storage and retrieval: very large amounts of data stored, with retrieval completely dependent on efficient search systems.
3. Artificial intelligence for intellectual problem solving: synthesis design and structure elucidation.
4. Automation of laboratory experiments: robotics to explore reaction optimization.

The order is roughly historical. Thirty years ago as a natural products chemist at UCLA, I introduced myself to computers because I needed to know the conformations of rings larger than six-membered in order to understand the possibilities for stereocontrol in sesquiterpene synthesis. The problem involves calculating the molecular geometry and may be appreciated by considering the cycloheptane molecule, for which seven bond and seven dihedral angles must be set and then all of the 189 interatomic distances between nonbonded atoms calculated from these, each by a complex formula involving functions of the angles along the connecting bond path. The strain energy corresponding to the overall geometry is calculated from these angles and interatomic distances using individual parameters for each of these three kinds of geometrical measure. The problem then becomes one of closing in on the minimum energy and its corresponding geometry as established experimentally. This requires, in turn, calculating a sequence of these molecular geometries and their energies to establish the correct minimum-energy conformation with the correct energy. Another dimension is added, however, since the whole set must be done with various estimates of the energy parameters, which were only to be extracted from other kinds of physical measurements.

Here is a typical problem involving a huge set of iterative complex calculations. I set out to explore this for the cycloalkanes of ring size 6–10, having available at that time a slide rule, the sine/cosine tables, and pencil and paper! It quickly became clear that this was a problem which could be systematically solved only with a computer, and so I enrolled for an early one-day course in FORTRAN programming and access to the only computer at UCLA—an IBM 709 in the Engineering Department. The procedure was to punch out each line of program on an IBM card with a noisy card-punch typewriter, submit the stack of instructions so obtained to the computer operator, and come back the next day for printed output. The problem would never have been solved without a computer. With it I was able to publish the first paper[1] in an area which has since grown enormously and been designated as molecular mechanics, a full collaboration of computers and organic chemistry.

With the development of great calculation speed and computer graphics presentation, these calculations of molecular shape are now routine and vividly presented in three dimensions on the screen, with energy minimization in real time as you watch. Such calculations are widely used for comparing the shape of a molecule with some model. Pictorially, the presentation is so convincing that it is sometimes hard to remember that the intrinsic weakness of these calculations remains the still-empirical assignment of the parameters in the equations that produce the molecular energy and so direct the conformational preferences. Furthermore, in modeling we are usually really asking for the nature of the interaction of a molecule with some other (e.g., a receptor). By calculating shape we learn something of the molecule as a kind of neutral sponge, increasingly resistant to penetration, but nothing of its electrical "color"—the intermolecular effects of local partial charges and their fields, π electrons, and orbital interactions. In short, we focus in these calculations on steric interactions but not electronic ones.

The problem of molecular nature was approached in the same period from a more secure physical basis with ab initio and semiempirical molecular orbital calculations. Before

[*] Prof. J. B. Hendrickson

computers, the solution to the problem of the hydrogen molecule was a proud achievement in the 1930s. Owing to thirty years of rapid growth in computer speed for iterative calculations, this field has also expanded enormously. Not only are larger molecules accessible to more or less full physical description, but also it is possible to assess the reliability of a number of simplifying assumptions and so make possible the solution of much larger molecules to a rougher accuracy which is still usefully predictive. This is the same kind of approach as with the molecular geometry above in altering parameters and calculational details, through numerous individual cases, in order to match experimental fact. It is the huge capacity of computers for this iterative work that makes these developments possible at all.

2. Logical Basis for Synthesis Design

Twenty years ago the area of artificial intelligence, or problem solving, was opened with the Corey–Wipke publication[2] of the OCSS program for synthesis design. They began with the problem of establishing facile communication between man and machine and created the molecular graphics which allow the presentation of material on the terminal screen in familiar structural formulas. This is not a trivial problem, and some detail on its implementation will be shown below, but without structural formulas the synthetic chemist would probably never have paid much attention to computers, since organic chemistry is very little dependent on mathematical calculations.

Corey's approach to synthesis design for the computer was straightforward.[3] The net structural change of a reaction is seen in reverse as a transform, from product to substrate. Thus, all possible transforms can be applied to the target to create the intermediates one step back, and these as subtargets further transformed a second step back to the next level of intermediates, and so forth. The process was called "computer-assisted" and so was set up as interactive with the operator, who pruned the tree down to a few intermediates at each level as he went along. This procedure depended on the presence of a library of general transforms, kept as a database in the computer and keyed to be applied wherever the functionality of the target under consideration matched that of a transform in the library. This was said to be the process by which synthetic chemists designed their syntheses, but curiously the chemical literature was mute on the subject of this design process.

The problem of synthesis design is simply that the number of possible synthetic routes to any target molecule of interest is enormous, much larger than generally appreciated. A view of the synthesis tree in Figure 1 is meant to emphasize this. The points are compounds: target at right, intermediates in the midst, and available starting materials as heavy dots at the left, all more or less diminishing in size to single-carbon materials at the far left. The lines are reactions, directed to the right (or transforms to the left), so that particular synthesis routes may be picked out, as shown in red, from the whole. The intermediates stand in levels, or steps, back from the target, with diminishing overall yields for the routes shown below, assuming 80% per step.

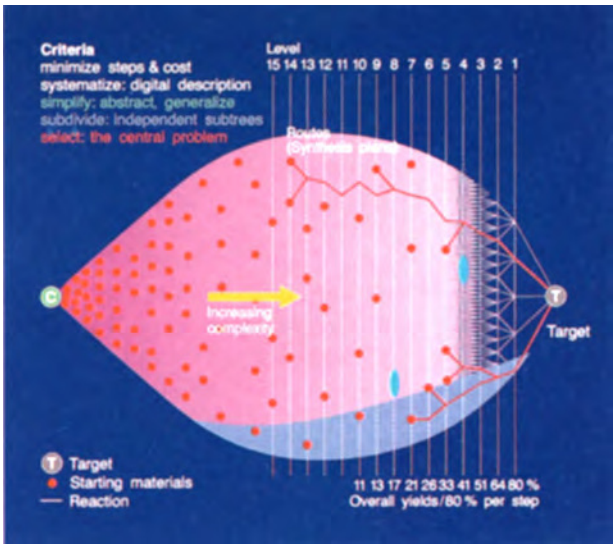

Fig. 1. Synthesis tree.

For the computer it is simple in principle to generate a whole tree; the real problem is one of selecting the optimal routes. It would not be unreasonable to expect 30 reactions which might convert intermediates at the first level into the target. Since each of these 30 intermediates will still be of comparable complexity, each will also have some 30 reactions from level-2 intermediates. To proceed back five levels will therefore produce 30^5, or 24 million, possible routes, and many syntheses are much longer. Now the question is, which is the one route to take in the laboratory?

To create an approach for the computer to this problem,[4] we can apply some principles from large tree searches in other fields. The data in the search space—here, it is structures and reactions—must be *systematically* described in digital format, not only for rapid computer manipulation but also to assure that all possibilities can be derived as simple mathematical combinations, and so none will be missed. The tree is so large that *simplification* is imperative and consists of generalizing the entries by coalescing trivial detail. This makes a much smaller tree, with fewer entries abstracting all the original ones. The digital system used can be designed to facilitate this reduction. This simplification is analogous to maps in that a map of a small area shows far more detail than that of a large area. In practice, we use the latter to find our way to the desired locale and the former to refine the detail as we approach it. The same principle of generalize first and refine later to practical detail is used here to seek optimal routes from the synthesis tree. The simplified, generalized tree is still enormous, but it can be made more manageable by *subdividing* it into subtrees, which are independent and so may be explored separately and sequentially.

The problem remaining is that of *selecting* the few best routes. This requires defining criteria for "optimality", stringent enough to select only a few routes. In our approach to synthesis design we opted for a criterion of economy—the shortest routes with the most efficient assembly from the cheapest starting materials. We also wanted all these best routes to be found by the computer via consistent application of the criteria, rather than leaving the process interactive, at the whim of the operator.

To seek these, we first consider any structure as divisible into two parts: (1) the carbon *skeleton* or backbone (later to include some skeletal heteroatoms as well) and (2) the *functionality*, that is the placement of double bonds and attached heteroatom functional groups on the skeleton. This dichotomy then divides reactions similarly into *constructions*, which create C–C σ bonds and so assemble the skeleton and *refunctionalizations*, which alter functional groups without affecting the skeleton. In this view the assembly of the skeleton is primary and considered first. This leads to an initial and drastic simplification of the tree—by considering only the skeletons. Thus, while there are perhaps 50 000 available starting materials, there are only 13 acyclic starting skeletons of six carbons or less. A survey of published syntheses shows that the average-size starting material for nonaromatic targets is only *three carbons* incorporated into the target skeleton.

3. Focus on Skeleton

The primary importance of the skeleton and its assembly in synthesis is philosophical: *synthesis itself is a skeletal concept*. Synthesis consists of joining small starting molecules to make a large target. Therefore, the central, obligatory reactions are the skeletal constructions, which join those small pieces. In principle, refunctionalizations are not needed at all, despite the observation that the average synthesis has twice as many refunctionalizations as constructions. This leads to a stringent criterion for economy: to seek only *ideal syntheses*, those consisting only of construction reactions, since these—though rare—must be the shortest routes. In an ideal synthesis, the chosen starting materials have the correct functional groups to initiate the constructions joining them, and the subsequent constructions, in direct sequence, lead to the target skeleton with all its correct functional groups in place, as a natural consequence of the chemistry of the construction reaction sequence.

These considerations imply that we need to systematize the structures in the synthesis tree to deal efficiently but separately with the skeleton and the functionality on the skeleton. We need to determine which skeleton bonds of the target will the the best ones to construct, and then what functional groups are required to construct those bonds so as to result in the final target functionality directly.

Even though the focus on skeleton greatly simplifies the tree, there remains an enormous number of possible ways just to assemble a target skeleton. This arises from a combinatorial monster of what pieces to use and what order to join them. We may designate a *bondset* in a target skeleton as a set of λ bonds which are the ones to construct, as in Figure 2 for the estrone skeleton. If we remove all the bondset bonds from the skeleton, we are left with the several smaller skeletons of the starting materials. The bondset defines a family of syntheses which all make just those skeletal bonds. For any bondset, the order, or sequence, in which the bonds are made defines a generalized route, that is, a plan of assembly of the starting skeletons into the target skeleton. The assembly plan in Figure 2 is just a route from the synthesis tree (Fig. 1), but composed only of the construction reactions. Indeed, the simplest gross description of any synthetic route—of its essentials—is this *ordered bondset*, which shows the starting material skeletons and the sequence of target bonds which are constructed to link them.

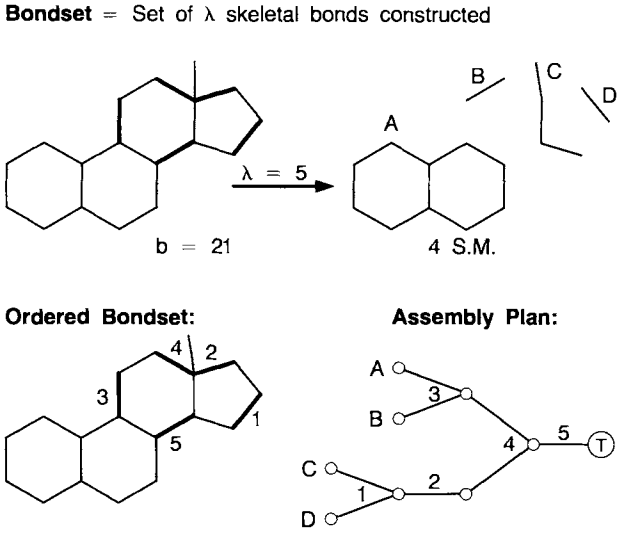

Fig. 2. Skeletal dissection and assembly. λ = number strategic bonds; b = number of CC bonds; S.M. = number of starting materials.

The number of possible ordered bondsets is the number of ways to dissect the skeleton: for a target of b bonds this is $b!/(b-\lambda)!$ Thus, an assembly of the estrone skeleton ($b = 21$ bonds) from pieces averaging three carbons would require a bondset of $\lambda = 9$ bonds and affords 10^{11} assembly plans (ordered bondsets), that is, 100 billion routes, even without considering the detailed chemistry involved. A dramatic realization of these combinatorics may be seen in the total synthesis of cortical steroids from one-carbon units, for which there are 6×10^{23} assembly plans: this means that to make a mole of cortisone one can make every molecule by a different route!

There are two powerful criteria which allow a severe reduction in these numbers. The first is the choice of a *convergent* assembly, which can be shown[5] to be significantly more efficient than a linear plan, in terms of the total weight of starting materials required. The convergent plans can very simply be created by cutting the target skeleton into two pieces and cutting each of these again into two more. The second choice is merely to require that the four starting skeletons so derived each time must be found in a catalog of actual, available starting materials. This implies that a target of twenty carbons will result in starting materials averaging five skeletal carbons each, and our experience with such catalogs shows a sharp drop-off in functional group variety in starting materials above five carbons. This suggests that by applying these criteria we should be able to find real chemistry for at least some of these plans. Not only are these convergent plans the shortest and most efficient syntheses, they are also quite rare and so afford the needed severe reduction in the total bondsets that must be examined.[6]

Here we may pause to look at the problem for the computer in storing these skeletons and comparing them with those in a catalog to find matches.[7] Figure 3A shows a skeleton

of eight atoms, arbitrarily numbered, and an adjacency matrix of its connectivity, which fully defines the structure. This matrix may be strung out to form a linear binary string; this is now just a binary number which can be used as an identification number for this skeleton. However, there are 8! ways to number this skeleton, that is, 40 320 numberings, of which we must pick one which will always be unique. This can be done by finding the one for which its binary string will be the *maximum binary number*. Such a maximal numbering is shown in Figure 3B. The catalog is then a list of maximal

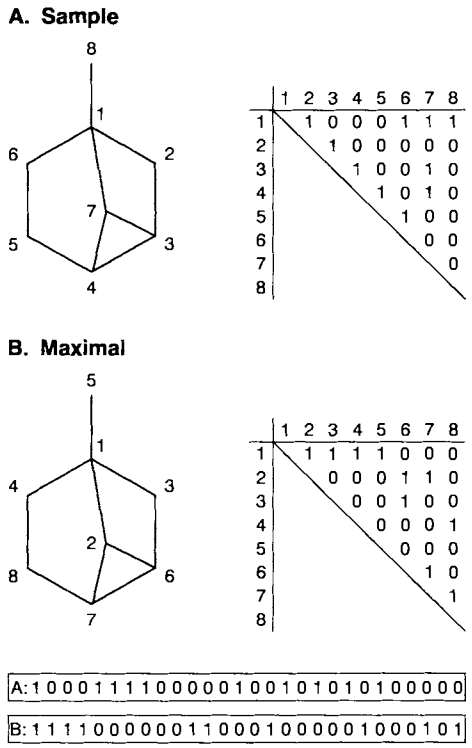

Fig. 3. Maximal canonical numbering. A) Arbitrary canonical numbering; B) maximal canonical numbering. Below: Binary numbers corresponding to the numberings in A and B.

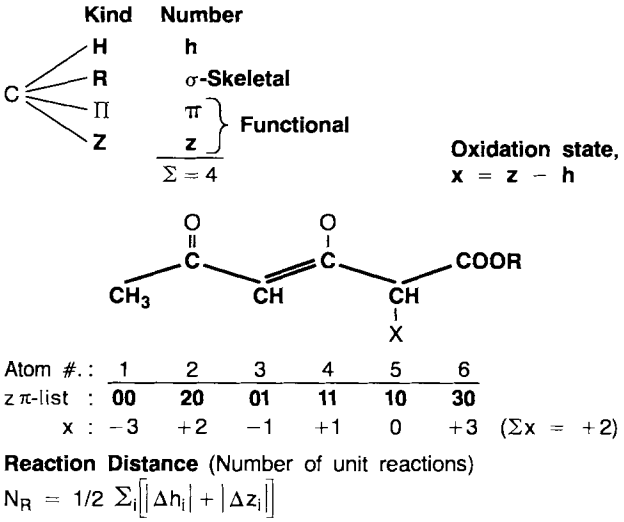
binary numbers of its contained skeletons, arranged in numerical order so that any search for a match with some generated skeleton becomes a simple binary search, very fast in the computer. Also, we created a program to draw the structural formula from its maximal binary number.

4. Systematizing Reactions

To proceed now to the chemistry for synthesis routes, we must first create a system to describe the functional groups on the skeletons and the net structural change they undergo in reactions. Such a system must be digital for the computer, simple but rigorous in its description of chemistry and capable of generalizing and simplifiying by coalescing trivial structural detail. The system[8] summarized in Figure 4 assigns four synthetically important kinds of attachment which any skeletal carbon may have: H for bond to hydrogen, electron pair, or electropositive atom; R for a σ bond to carbon—its skeletal connectivity,[9] Π for a π bond to another skeletal carbon; Z for bond (σ or π) to electronegative atom (O,N,X,S,P). The *number* of bonds to the carbon for each kind of attachment is then given by h,σ,π or z, respectively, with a sum of 4. The oxidation state of any carbon is given by x = z − h, and the change in oxidation state in any reaction is found by summing all the changes in x.



16 Units Reactions (one carbon)

Oxidation	ZH	
Reduction	HZ	
Substitution	HH, ZZ	
Addition	HΠ, ZΠ, RΠ	ΠΠ
Elimination	ΠH, ΠZ, ΠR	ΠΠ
Construction	RH, RZ, RΠ	RR
Fragmentation	HR, ZR, ΠR	RR

Fig. 4. Digital characterization of structures and reactions.

The functionality of a carbon may now be abstracted as its zπ value, contained in the computer with only two bits each for z (= 0–3) and π (0–2). Computer description of a compound then consists first of its skeleton as a maximal binary number followed by the zπ list of the functionality on its numbered carbons in numerical order. The σ value of each carbon comes from the row sums of the adjacency matrix (Fig. 3) and the h value by subtraction of (σ + z + π) from 4. This compound binary list for the skeleton and functionality of any structure may then be compared with any starting material in the catalog for a match, either by skeleton separately or by the whole abstracted structure. The coalescence of detail may be appreciated by noting in the example in

Figure 4 that all carboxylic derivatives are denoted by a $z\pi$ value of 30.

Reactions may also be described using the system presented in Figure 4. Ignoring its mechanism, any reaction may be described by its *net structural change* from substrate to product at each changing skeletal carbon. A unit reaction at any one carbon is just a unit exchange of attachments, for which $4 \times 4 = 16$ unit exchanges are possible. These we denote with a two-letter symbol, the first letter for the bond made, the second for that broken. The possible unit reactions at one carbon fall into familiar chemical categories as shown below in Figure 4. Reactions like elimination, addition, and construction require more than one (adjacent) carbon changing; each carbon will have a symbol.

The value of such a system is that it affords an abstract description of every possible change a carbon may undergo. Hence, it forms a basis for a rigorous organization of all organic reactions.[10] Like the Beilstein system for organic structures, this can create a catalog of organic reactions in which every possible reaction will have a place. Such an organization of all the unit reactions on one to three carbons is presented in Figure 5 and will be seen to include all common reactions.[11]

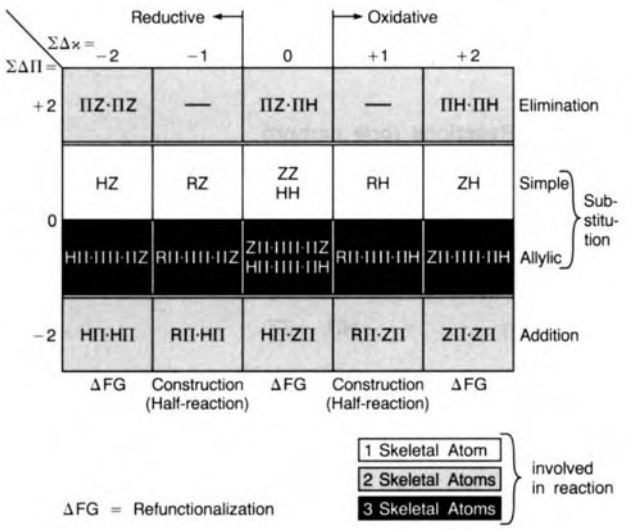


Fig. 5. Reaction characterization for one to three skeletal atoms.

The construction reactions are those with which synthesis design is specially concerned and are the only reactions in an ideal synthesis. A construction may be seen as the combination of two half-reactions, usually one oxidative (nucleophilic) and one reductive (electrophilic); the three possible unit half-reactions of each kind are included in Figure 5. On inspection of the net structural changes depicted, one can see that these represent the common familiar construction half-reactions: for example, formation of carbanions or allylic carbanions, enolates and enamines, alkylations and allylic alkylations, carbonyl addition, acylation, and conjugate addition. With the systems described above, we can see how the computer can quickly generate the substrates from the products (or vice versa) for any given construction, illustrated with an example in Figure 6. Here the bond to construct (heavy line) is dictated by the ordered bondset, and up to

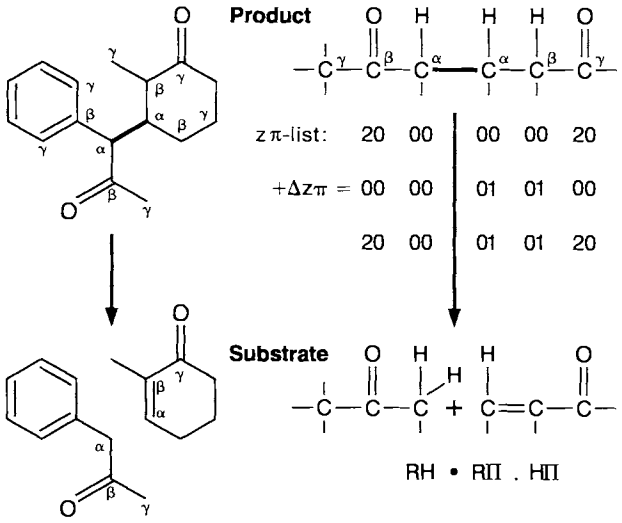

Fig. 6. Rapid generation of reactions in SYNGEN.

three atoms out from each end (labeled α, β, γ) will bear the functionality of a construction product. A combined $z\pi$ list of each αβγ strand across the bond made is called and to it is added a *$\Delta z\pi$-list generator* characteristic of any combination of nucleophilic and electrophilic half-reactions. This directly generates the $z\pi$ list for the possible substrates, shown for one example on the right side of Figure 6. The process is very fast for the computer.

5. The SYNGEN Program

The foregoing exposition of a synthesis design logic for the computer is realized in the SYNGEN program developed in our laboratories over the last ten years.[12] The program is designed to locate and generate all the possible shortest synthetic routes—convergent ideal syntheses—for any target. The program is not interactive and so is independent of the user's preconceptions. An overview of its operation is presented in Figure 7 and has two phases.

First, only the target skeleton is examined; it is cut through two levels to find all the most efficient, convergent modes for its assembly from four (or less) available starting material skeletons found in the catalog (the present catalog contains over 6000 compounds). These modes are the possible ordered bondsets, each of which is an independent subtree of the whole synthesis tree. In Figure 7, one such bondset, consisting of three bonds, is shown for an estrone derivative and leads through two levels to starting skeletons B,C,D (Fig. 7, left).

Second, the program then generates the functionality changes, as in Figure 6, back from the target functionality through the successive bonds of each bondset. When all the bonds in each bondset have been constructed (in the retrosynthetic direction), the functionality required on each starting material is revealed and these structures are then sought in the catalog. Only routes with all of the starting materials found in the catalog are accepted. The three starting materials for Figure 7 are B-2,C-3,D-5, generating the commercial (and ideal) synthesis of estrone, after reduction

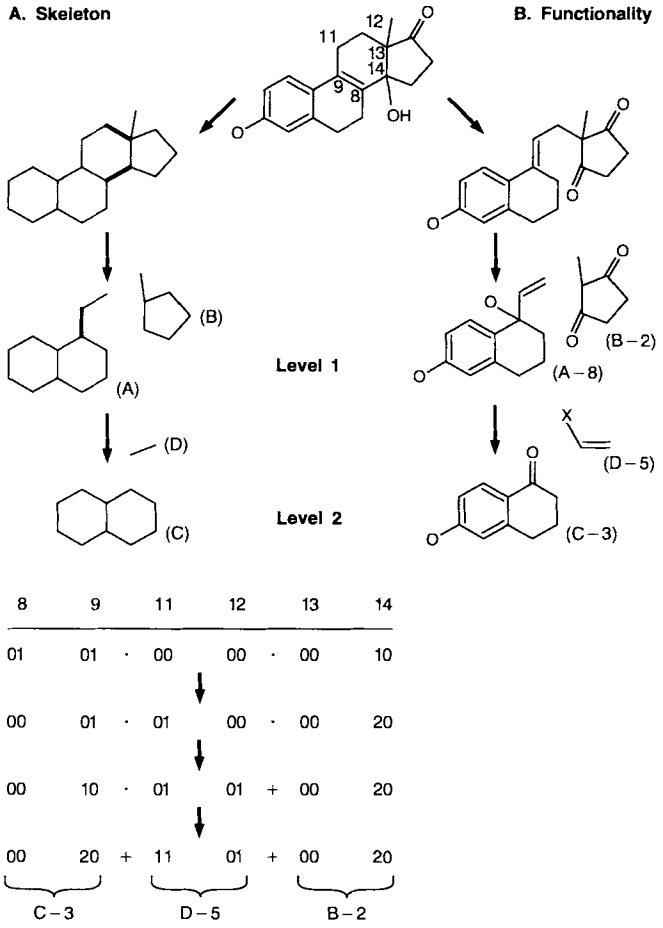

Fig. 7. Overview of SYNGEN protocol (see also Section 6).

of the target shown. At the bottom of Figure 7 are the successive $z\pi$ lists of the changing carbons through the three successive constructions.

In practice the SYNGEN program is very easy. In a facile drawing routine the user enters a crude structure of the target, which the program normalizes; the synthesis routes are then generated without operator interaction in 1–3 minutes. The output is stored in a directory and may be called up at any time for inspection of the results, summarized first on a screen like that of Figure 8 for synthesis of the AIDS drug AZT (3'-azidothymidine). The number of entries for each of four categories is appended for each level below.[13] At the top may be seen the four categories which may be separately accessed for examination: *bondsets, starting materials, intermediates*, and *reactions*. Any entry in any of the categories may be individually retained or deleted, along with its related entries in each other category; for example, if unwanted bondsets are deleted, all related reactions and compounds are also deleted. The totals at the top of the screen automatically adjust for each selection so that the operator may see the scope of his choice.

A sample listing of starting materials (Fig. 9) shows that some starting materials can be made by refunctionalization

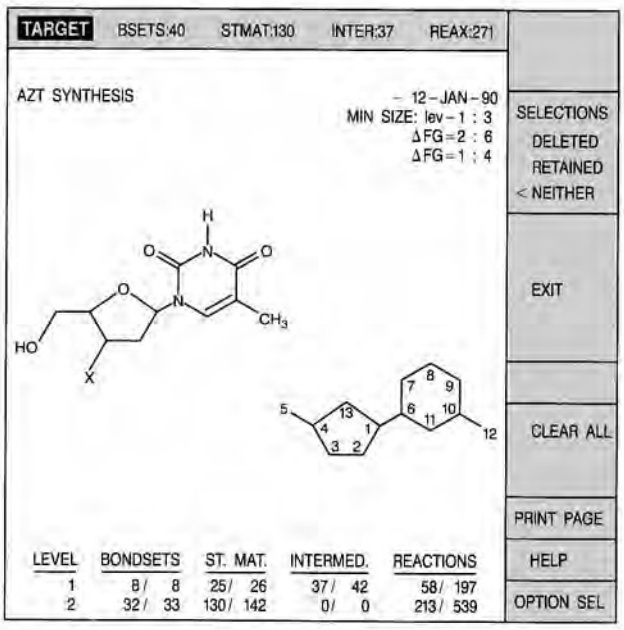

Fig. 8. Application of SYNGEN program to AZT synthesis (x = N_3).

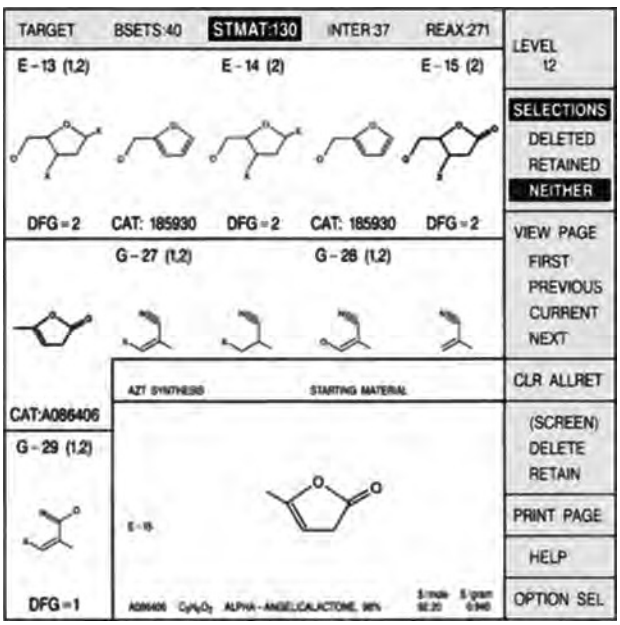

Fig. 9. Sample screen showing starting materials for the synthesis of AZT.

of others if they are not found in the catalog, indicated by DFG and followed by a real starting material with an Aldrich number. The DFG signifies a "reaction-distance"—the number of steps for refunctionalization between the generated material and the nearest one in the catalog. This may be calculated with the formula for N_R (Fig. 4). The insert in Figure 9 shows how an expansion of the listing can be called if desired, here of compound E-15.

A sample listing of reactions (Fig. 10) shows the structure being made at upper left (the target at level 1, intermediates at level 2) and they reactions for it in abstracted form with abbreviated notations of the involved half-reactions for each construction. Again, an expansion of any entry appears, as in the insert for reaction 3-34 of bondset 3, and expands on the abbreviated reaction notations as well.

Even when large numbers of routes are found, there are powerful pruning tools to allow one to focus in quickly on desirable pathways,[14] such as the individual delete/retain

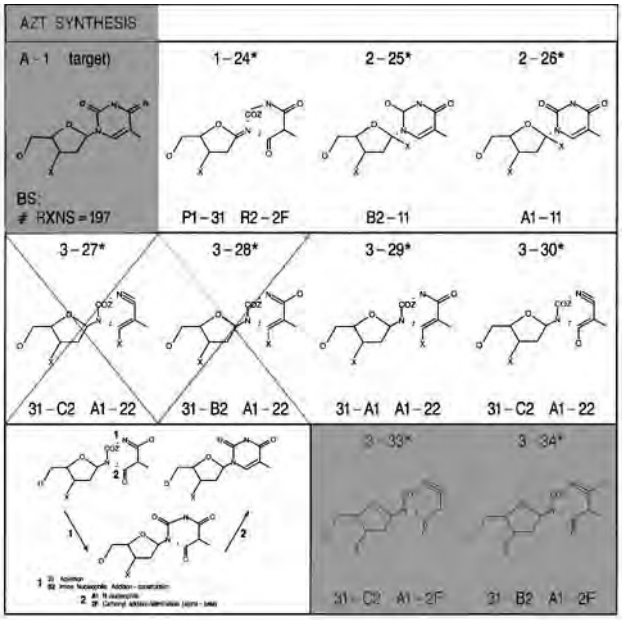

Fig. 10. Sample screen showing reactions for the synthesis of AZT.

options for entries in each category, or the possibility of tracing all reactions involving any single chosen bondset, starting material, or intermediate. Another tool is a set of broad conditions about either compounds or reactions, as in Figure 11. These include starting material cost or the necessity of repairing its functional groups, and regiochemical or other uncertainties or incompatibilities which may be present in the reactions. Selections among these broad options can dramatically reduce the total number of allowed routes; the deletions made on the options screen of Figure 11 have reduced the total reactions from 736 in Figure 8 to only 34.

Fig. 11. Reaction/selections option screen.

The operation of this program has shown it to be a very facile way of finding all the possible shortest syntheses for many targets. It finds known syntheses and suggests many other interesting routes. It has the particular advantage of assuring the operator that he has not missed some short pathways to the synthesis of his choice target.

6. Current Developments

In extension of the SYNGEN program we have now developed an interface to the large commercial databases of organic reactions, REACCS and SYNLIB. This allows close literature precedents to be found for the reactions that are generated by SYNGEN. The databases must first be annotated as in the SYNGEN system to recognize not compound structures but rather just the *net structural change* in the reaction. To do this, we probed the reactant and product structures in the database entries to find C–C bonds made and then listed the $z\pi$-list changes occurring on the $\alpha\beta\gamma$ strands for each half-reaction. These were then ordered into a (nucleophile × electrophile) matrix for rapid retrieval. This allows us to locate all matches for the reactions that are generated by SYNGEN. When there are too many examples of one reaction type, a closer match of the atom types and the σ,z,π values at the construction site is made until the best matches are found. Organizing the reactions this way creates a subset of some 26000 construction reactions accessible from REACCS and SYNLIB. This now constitutes a powerful library of literature precedents of the closest structural matches for any particular reaction generated by SYNGEN and provides the chemist with the practical laboratory details that he needs to execute a chosen synthetic route.

In other variations on the theme of efficient synthesis, we have created two ancillary programs to seek special opportunities for multiple constructions of targets to make their syntheses even shorter.[15] In another area we have built a program to proceed in the forward instead of retrosynthetic direction, from available starting materials to close derivatives of the target. This aims at locating routes which will involve some refunctionalization reactions in the path as well as just constructions of the skeleton and so expands the variety of routes found.

This FORWARD program begins like SYNGEN in first defining the best convergent bondsets and their derived starting skeletons. It then proceeds by pairwise combinations of all the catalog starting materials so designated, accepting only those for which the functional groups converge toward the target. This is possible through calculation of the "reaction distance" (see Fig. 4) of intermediates from target and then massively prunes what would otherwise be an unmanageable combinatorial explosion. This FORWARD program produces not only the target molecule but also all close derivatives which may easily be transformed into it and so offers a much larger selection of short, practical synthetic routes. Thus, the synthesis in Figure 7 is for a derivative of

estrone, not estrone itself (which produces only few and rather poor routes in SYNGEN). In the FORWARD program, however, routes to various close derivatives of estrone are all found when estrone is entered, including that of Figure 7; others are shown in Figure 12, but the program excludes those which are more than two steps from the target.

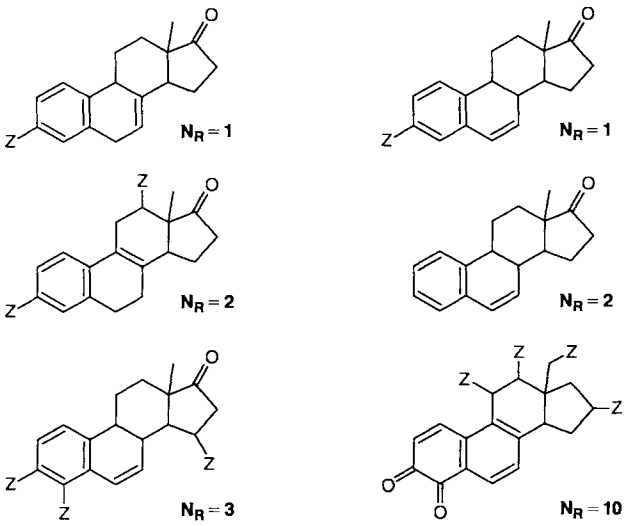

Fig. 12. Estrone derivatives from FORWARD program. N_R = reaction distance (cf. Fig. 4).

These programs are based on a developing logic for synthesis design. In a further search for design logic embedded in published syntheses, we are creating a database of published routes, especially to popular targets which have been synthesized in many ways. These now can be manipulated in the computer to create a number of numerical measures of complexity and similarity which are submitted to multivariate analysis in an effort to see if threads of general logic can be discerned in these routes and so to define some measure of synthesis "optimality".

7. Perspectives on the Future

Looking now to the future prospects for interaction between synthesis and computers, we may address the original four areas of collaboration (see Section 1). In the area of complex calculations the ultimate need is real-time calculation of reaction rates. In generating reactions, SYNGEN uses generalized abstract descriptions. These must be reduced to real prediction for the particular case, specifying rate preferences for solvent, bases, counterions, etc., and comparing them to those of possible competing reactions. At a qualitative mechanistic level, the prediction of possible competing reactions is already well underway in the CAMEO program of *Jorgensen*.[16] Meaningful rate calculations will require more powerful computers.

Here we may look at some hopeful projections from the historical growth of computer capability. In Figure 13, we see the remarkable increase with time of computer speed, measured in floating point operations per second (FLOPS). This certainly implies that the desired rate calculations may be accessible in real time in the very near future. Furthermore, Figure 13 shows that the cost of such capability is coming down at the same logarithmic rate (MIPS = million instructions per second), to become available to practicing chemists.

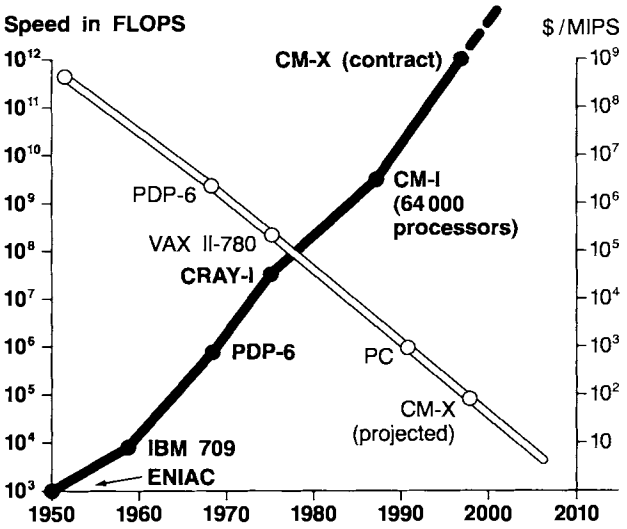

Fig. 13. Speed and cost of computing since 1950. FLOPS = floating point operations per second. MIPS = 1×10^6 instructions per second.

But practicing chemists are also involving themselves in the other direction, developing instead of using the computer. One way to speed up a computer is to make it smaller, and the size of transistors has been inexorably decreasing in proportion to the speed increase. The smallest commercial transistor now is about a micron and the present technology is limited to about 0.1 μm by quantum tunneling. *Wrighton* and *Whitesides* have projected work aimed at making a molecular switch.[17] These molecules are to be covalently attached to vapor-deposited metal conductor strips, and the molecular gap can now be on the order of 0.01 μm. An even greater potential is on the horizon when one considers that such a "switch" molecule may have more than two accessible molecular states and thus be adaptable for a more complex computer logic than one simply based on "on/off" choices.

In the area of information storage we are desperate to reduce the accelerating consumption of paper and library space for journals and books. We use the computer now for searches of references by author, keyword, or structure, but we still require the library of bound volumes to read the primary source. What we want is to be able to dial up a reference on our office terminal and read it from the screen, then to be able to call up all subsequent articles which refer to it as well, to obtain a quick update on the subject.

This source material can be stored as well as searched on a computer as long as a single storage unit could accommodate everything for searching all at once. Like the growth of computing capability (Fig. 13), the evolution of disk storage capacity for digital information continues, more or less doubling every year in the last decade. An optical disk can now store 2×10^{10} bits. Our library at Brandeis contains 1000 meters of chemical and biological journals for the last 15

meters of chemical and biological journals for the last 15 years. If this were all text, it would amount to 10^{12} bits of information. The annual journal input could then be accommodated on four present disks, and a 20-fold increase (perhaps 5 years) in storage capacity would store the whole library on one disk! An even smaller storage unit has been explored[18] with a three-dimensional molecular matrix for optical reading and writing, theoretically capable of storing 10^{12} bits per cubic inch.

The problem of pictures in the text can be confronted by a compression program, operating in reverse on retrieval to decompress for display. At present an hour of television pictures (216000 pictures) can be compressed by such a program onto a single CD. Indeed chemical structures are much less dense than text, since our program for storing structures (Fig. 3) requires only 400 bits to store the AZT structure, while the same journal space in the form of printed text requires 3200 bits.

Accordingly, we can envision a system (Fig. 14) in which the contents of journals are beamed up by the publisher to a satellite which then sends them continuously to library receivers, to be sifted automatically for those subscribed and stored on the library disk (the same sifter can pass on copies to individual subscribers). This would make possible a system in which one could call up on an office terminal any journal article, read it, and make a copy if desired; no paper need be kept except that which is actually read.

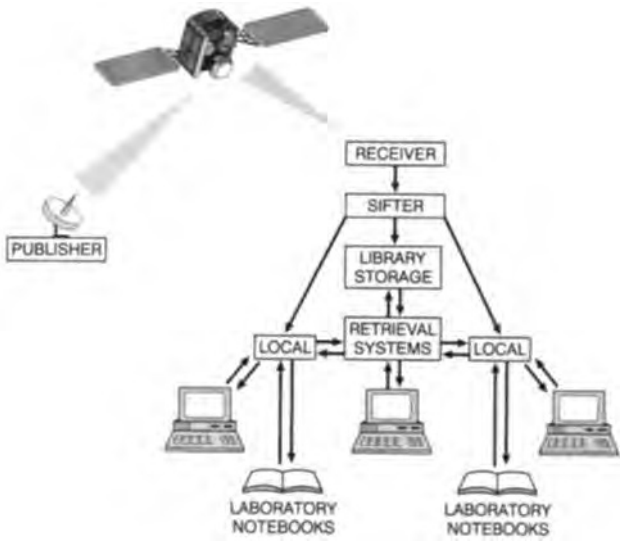

Fig. 14. The computerized library.

The problem of retrieval raises the issue of documentation for retrieval. While we have reasonable means for retrieving authors, references, keywords, and structures, we need a good system for the retrieval of reactions, nested from the general to the particular as in the Beilstein system for structures, to provide a place for every conceivable reaction, whether currently realized or not. Our approach (Fig. 5) from unit reactions is offered in this vein and we are currently exploring reaction databases to locate refunctionalizations as well as constructions in this way, with considerable success. Chemists will have to take a more lively interest in creating these documentation systems if they wish to have really efficient means of finding information.

The third area of artificial intelligence can be applied both to synthesis and to analysis. In synthesis design the SYNGEN program can offer all the shortest generalized reactions; it needs a stereochemical component as well. Linking it to CAMEO would reveal what other reactions might interfere, and a link to a substantive rate prediction program could quantify these. In analysis the chemist needs a master "black box" program to collect data from various analytical instruments and interpret it in structural terms, showing the chemist what he actually obtained in a reaction.

Finally, the computer can be instructed to run the experiments. Utilizing a Zymark computer-directed robotic apparatus, *Fuchs*[19] has demonstrated an integrated system for running series of parallel experiments intended to optimize conditions for a reaction on a scale of 0.1 mmol mL^{-1}. The system centers on an arm programed to move vertically and radially to syringe substrates and solvent into a reactor (and to wash it afterwards!) and, after a programed time and temperature, to filter, extract, and analyze them by chromatography, with analytical spectra taken on the effluents. With eight reactors and two gas chromatographs, he can program the system to perform 400 reactions a day, and he has shown a complex reaction optimized from almost nothing to a yield of over 70%.

These rosy (if dangerous) predictions of the future seem to suggest that synthetic chemists themselves will have little to do except to man their computer terminals! While this is certainly not at all likely, it is clear that they will have to be much more familiar with computers than they are now and use them more intensively. More than that, they will need more appreciation of the importance and nature of the logical systems used to describe and retrieve chemical information, and they must actively assist in the development of clear, useful software for chemical purposes. In short, they will become much more involved with computers than they are at present.

I wish to acknowledge the wonderful spirit, devoted diligence, and remarkable computer skills of my colleagues who have made possible the work I have described here: Glenn Toczko, with me since the inception of SYNGEN ten years ago, David Grier, Zmira Bernstein, Ping Huang, Todd Miller, and Camden Parks.

Catalytic Antibodies: A New Class of Transition-State Analogues Used to Elicit Hydrolytic Antibodies

By Kevan M. Shokat, Marcia K. Ko, Thomas S. Scanlan, Lynn Kochersperger, Shirlee Yonkovich, Suvit Thaisrivongs, and Peter G. Schultz*

The design and generation of selective catalysts is an important aim of chemists and biologists. A number of successful strategies have emerged, including the synthesis and derivatization of synthetic hosts, the chemical modification and site-directed mutagenesis of enzymes, and the attenuation of natural enzyme activities in organic solvents. Since 1986 several laboratories have exploited the immune system to generate selective catalysts capable of catalyzing a wide range of chemical transformations. These include acyl transfer, β-elimination, carbon–carbon bond-forming, carbon–carbon bond-cleaving, porphyrin metalation, peroxidation, and redox reactions. The variety and number of transformations catalyzed by antibodies in this short period of time is testament to the versatility and power of the method in generating selective catalysts for applications in chemistry, biology, and medicine. Here we report the use of a new class of uncharged transition-state analogues for generating antibodies capable of catalyzing ester and carbonate hydrolysis. These antibodies are compared to those raised against tetrahedral phosphate and phosphonate transition-state analogues.

1. Introduction

The immune system has the potential to generate more than 10^{11} unique antibodies.[1] The ability to generate this degree of diversity and to select molecules with the desired biological properties from this enormous pool is unique to biological systems. The mechanism by which the immune system generates and screens this huge collection of antibodies is clonal selection. Each antibody molecule of the primary immunological repertoire is stored on the surface of cells called lymphocytes. When a cell with a unique antibody expressed on its surface encounters an antigen, it undergoes division and differentiation and starts to produce soluble antibody molecules. At the same time, the genes encoding the binding site of the antibody undergo mutation, leading to an increase in affinity for the hapten. Antibodies can be selectively generated against virtually any biopolymer, small synthetic molecule, or natural product of interest. With the ability to generate a binding site for virtually any potential substrate, the challenge becomes one of designing chemical strategies to introduce catalytic activity into these macromolecules. Enzymes utilize a variety of strategies simultaneously, including transition-state stabilization, general acid–general base catalysis, cofactors, and proximity effects to catalyze reactions. Each of these strategies has been successfully applied to the generation of antibody catalysts. Several comprehensive reviews on the design and characterization of catalytic antibodies have been written.[2–5]

The first examples of antibody-catalyzed reactions were based on the notion of transition-state stabilization. *Jenck*'s first proposed over twenty years ago that antibodies raised against a transition-state analogue should bind the transition state of a reaction selectively over the substrate and thereby catalyze the reaction (Fig. 1).[6] In fact, many enzymes have evolved to provide an active site that is sterically and electronically complementary to the rate-determining transition state.[7,8] Hydrolytic enzymes such as the zinc peptidase thermolysin function in part by selectively stabilizing the negatively charged tetrahedral intermediate in peptide hydrolysis.[9] Analogues of the transition-state configuration have been shown to be potent enzyme inhibitors. Such transition-state analogues seek to take advantage of the complementarity of the enzyme to the transition-state configuration to achieve high binding affinities. One of the best inhibitors of thermolysin is phosphonamidate **1**, where a tetrahedral phosphorus is substituted for the scissile carbonyl

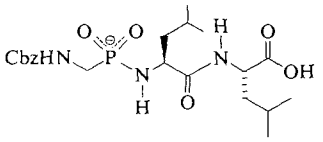
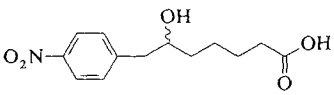
carbon in the substrate.[9] Because a typical P–O single bond is 10–15% longer than a C–O single bond, these analogues are quite similar to the tetrahedral transition-state structure which has longer, partially formed bonds.



1

Phosphonamidate **1** was shown to be a transition-state analogue inhibitor by the synthesis of a series of analogues of inhibitor **1** and the corresponding substrates with substitutions at the carboxy-terminal amino acid and measurement of K_I and K_M/k_{cat} values, respectively. The K_I values correlated not with K_M values but with K_M/k_{cat} values, suggesting that the factors that influenced binding of inhibitors similarly affected binding of the transition state relative to the substrate.

Another important class of peptidase inhibitors consists of uncharged tetrahedral mimics of the transition state, including hydrated ketones,[10] fluoroketones,[11] and secondary alcohols.[12] One such molecule is pepstatin, an inhibitor of the aspartic protease pepsin.[13] The key feature of this inhibitor is the novel amino acid statine, which contains an uncharged secondary alcohol substituted for the carbonyl of the scissile amide bond in the substrate. An analysis similar to that performed in the case of thermolysin compared a series of inhibitor K_I values and substrate K_M/k_{cat} values for pepsin, but yielded inconclusive results due to the fact that two distinct rate constants contribute to the measured k_{cat} values for this enzyme.[10] The fact that pepstatin K_I values do not correlate with K_M or with K_M/k_{cat} values suggests that these inhibitors do not function exclusively as either transition-state analogue inhibitors or as multisubstrate inhibitors. Since statine-like compounds at least in part resemble the tetrahedral transition state for hydrolysis of an amide bond, we reasoned that antibodies raised against a statine-based inhibitor might catalyze the hydrolysis of the corresponding ester or amide substrates. Antibodies elicited against alcohol **2** do indeed catalyze the hydrolysis of *para*-nitrophenyl acetate and *para*-nitrophenyl methyl carbonate.



2

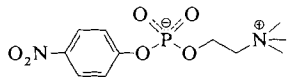
This study extends the transition-state stabilization strategy for generating catalytic antibodies to a new class of peptidase inhibitors. The kinetic properties of antibodies elicited toward statine-like inhibitor **2** are comparable with those of the more numerous phosphonate-specific antibodies.

2. Phosphate- and Phosphonate-Specific Antibodies

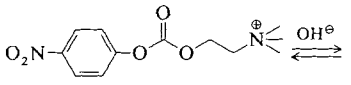
A large number of antibodies elicited against compounds that contain charged tetrahedral phosphorus and function as analogues of the transition states in hydrolytic reactions have been characterized and several examples are reviewed below.

2.1. Phosphorylcholine-Binding Antibodies MOPC 167 and T15

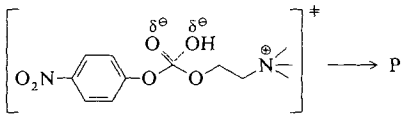
Two of the first catalytic antibodies characterized, MOPC 167 and T15, were not elicited against a synthetic immunogen but were members of a well-studied class of antibodies binding phosphorylcholine (PC). These antibodies had been previously characterized with regard to ligand-binding specificity,[14, 15] kinetics, and biomolecular structure.[16] Both are specific for *para*-nitrophenyl phosphorylcholine (**3**), which is an analogue of the transition-state **5** in the hydrolysis of *para*-nitrophenyl phosphorylcholine carbonate (**4**). Indeed, MOPC 167 and T15 catalyze the hydrolysis of **4** with kinetics obeying the Michaelis–Menten rate expression.[17, 18] The Michaelis constant K_M is equal to the



3



4



5

concentration of substrate, [S], that produces one-half the maximal catalyzed rate, $k_{cat}[E_T]$, where $[E_T]$ is the total enzyme concentration and k_{cat} is the unimolecular rate constant for the catalytic step. The k_{cat} and K_M values for MOPC 167 and T15 are $k_{cat} = 0.4\ min^{-1}$, $K_M = 208\ \mu M$ and $k_{cat} = 0.32\ min^{-1}$, $K_M = 708\ \mu M$, respectively. The highly specific nature of antibody–antigen recognition leads to highly specific catalysts. For example, *para*-nitrophenyl ethyl carbonate is not hydrolyzed to any appreciable extent by MOPC 167. The inhibition constants measured for MOPC 167 and T15 were 5 μM and 55 μM, respectively. Between pH 6.25 and 8.0, both antibody-catalyzed reactions were shown to be first order with respect to hydroxide ion. Comparison of the $OH^{\ominus}$-catalyzed rate $k_{OH}[OH^{\ominus}]$ (corrected for intramolecular assistance by the tetraalkylammonium ion) with the antibody-catalyzed rate k_{cat} affords rate accelerations of 11 500 for MOPC 167 and 9200 for T15. However, the observed differential binding energy of the transition-state analogue over the substrate (K_M/K_I) does not account for the entire rate acceleration, indicating that other factors must be contributing to the observed rate acceleration.

2.2. X-Ray Crystal Structure of the Phosphorylcholine-Specific Antibody McPC603

The X-ray crystal structure of McPC603, which is an antibody highly homologous to T15, has been solved.[16] This

crystal structure makes possible direct identification of the combining-site residues responsible for catalysis (Fig. 2).[19] Phosphorylcholine is bound in the cavity of McPC603 with the choline group deep in the interior and the phosphate toward the exterior, in contact with aqueous solvent. The heavy-chain residues, Tyr 33H and Arg 52H, which are invariant in all of the phosphorylcholine binding antibodies sequenced to date, bind the phosphate via hydrogen bonding and electrostatic interactions with the phosphoryl oxygen atoms. The X-ray structure demonstrates that the combining

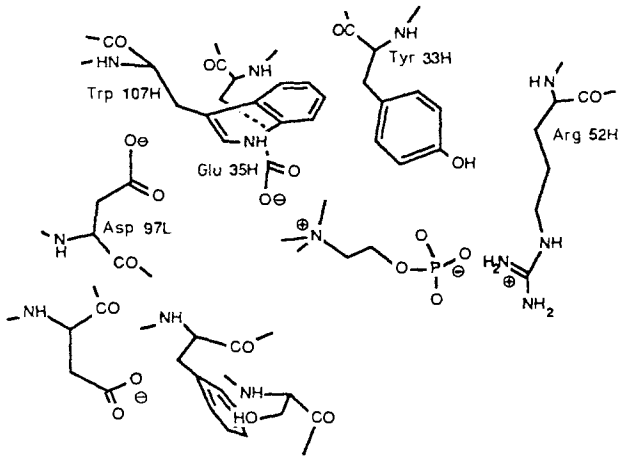


Fig. 2. Schematic representation of binding interactions between phosphorylcholine and amino acid side chains in the combining site of McPC603.

site of McPC603 is both sterically and electronically complementary to the tetrahedral, negatively charged phosphate moiety of phosphorylcholine. Inasmuch as this tetrahedral phosphate mimics the transition state for $OH^{\ominus}$-catalyzed hydrolysis of **4**, the phosphorylcholine antibodies should be capable of polarizing the bound carbonate for attack of hydroxide ion in the rate-determining step. Because the ground-state structure of **4** differs substantially from the transition-state configuration for hydrolysis, **5**, the differential binding affinity of the antibody to these two species is reflected in a lowered free energy of activation for the reaction.

2.3. Site-Directed Mutagenesis of the Phosphorylcholine-Specific Antibody S107

A site-directed mutagenesis study of the PC-specific antibody S107, which has the same heavy-chain variable sequence as T15, has further delineated the catalytic roles of residues Arg 52H and Tyr 33H.[20] Both residues were substituted with a variety of amino acids with no charge, with opposite charge, or with side chains designed to serve specific catalytic functions such as general acid or general base catalysis. One mutant (Tyr→His 33H) displayed increased catalytic activity over the wild-type antibody. The increase in activity is attributed to His 33H functioning as a general base.

The mutant S107 antibodies were expressed in myeloma cells not expressing endogenous antibody. The mutant DNA was introduced into the myeloma cells by electroporation using an azaserine/hypoxanthine selection. Large quantities of the mutants (1–50 mg) were isolated from ascites of immunosuppressed mice injected with the transfected cells.

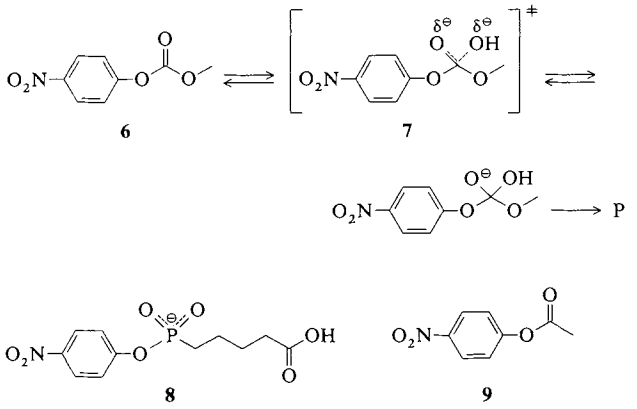
Tyrosine 33H was mutated to Phe, Glu, Asp, and His in the study. Without exception, all mutants exhibited only slight increases in K_M for **4** compared to wild-type S107. With the exception of the His mutant, the effect of the Tyr mutations on the catalytic activity was small. These results suggest that Tyr 33H is not involved in binding or catalysis of the reaction being studied. By substituting His for Tyr at position 33H, a general base is placed in close proximity to the bound carbonyl carbon of **4** as shown by molecular modeling using the McPC603 crystal structure. Indeed, the His 33H mutant was shown to accelerate the hydrolysis of **4** by a factor of 6700 compared to methylimidazole free in solution. Alternatively, it might have been expected that placement of a general acid in the combining site, such as the β or γ carboxyl group of Asp or Glu, might also lead to enhanced catalysis relative to the wild type. The failure of these substitutions suggests that the formation of the negatively charged transition state in the hydrolysis of **4** is disfavored in the presence of the negatively charged carboxylates, at neutral pH.

Arginine 52H was mutated to Lys, Gln, and Cys. The Lys 52H mutant showed only slightly lowered catalytic efficiency compared to wild type S107. In contrast, the Gln 52H and Cys 52H mutants showed considerably lowered catalytic efficiencies, presumably due to the loss of positive charge necessary for stabilization of the negatively charged oxyanion in the transition state of the reaction. Consistent with this notion, the Gln 52H and Cys 52H mutants bound **3** much more weakly than wild-type S107, whereas the mutants showed little change in binding to the uncharged substrate **4**. The Cys mutation was introduced as a chemical handle to enable derivatization with cofactors or reporter molecules to generate semisynthetic catalytic antibodies.[21, 22] The mutagenesis study of S107 demonstrates the importance of electrostatic interactions in transition-state stabilization and also shows that the catalytic efficiency of a catalytic antibody can be enhanced by rational design.

2.4. Generation of Antibodies to Phosphonate and Phosphonamidate Transition-State Analogues

Besides antibodies that fortuitously bind transition-state analogues for carbonate hydrolysis, catalytic antibodies have been rationally designed to bind transition-state analogues for specific reactions. The hydrolysis of *para*-nitrophenyl methyl carbonate (**6**) proceeds through the tetrahedral negatively charged transition state **7**. The corresponding phosphonate transition-state analogue **8** was synthesized and coupled to protein carrier keyhole limpet hemocyanin (KLH).[23] Small molecules are not immunogenic by themselves and must be covalently attached to a protein in order to elicit an antibody response. Fourteen distinct monoclonal antibodies specific for **8** were isolated in this way and assayed for catalysis of the hydrolysis of *para*-nitrophenyl methyl carbonate (**6**) and *para*-nitrophenyl acetate (**9**). Two of these antibodies catalyzed the reaction and were inhibited

by free hapten **8**. Inhibition by free hapten strongly suggests that the catalysis observed is taking place in the antibody combining site. Antibody 48G7-4A1 catalyzed hydrolysis of ester **9** with $k_{cat} = 7.4\ min^{-1}$ and $K_M = 430\ \mu M$. The kinetic constants for the hydrolysis of the related carbonate **6** were $k_{cat} = 26.2\ min^{-1}$ and $K_M = 360\ \mu M$. The rate enhancements over the uncatalyzed rate are 1600 and 7300 for **9** and **6**, respectively. Inhibition studies demonstrated competitive inhibition by the free hapten **8** with $K_I = 330$ nM.



Several possible mechanisms could account for the catalysis observed: direct hydroxide attack, general base catalysis, or acyl-antibody formation followed by hydrolysis (Fig. 3).

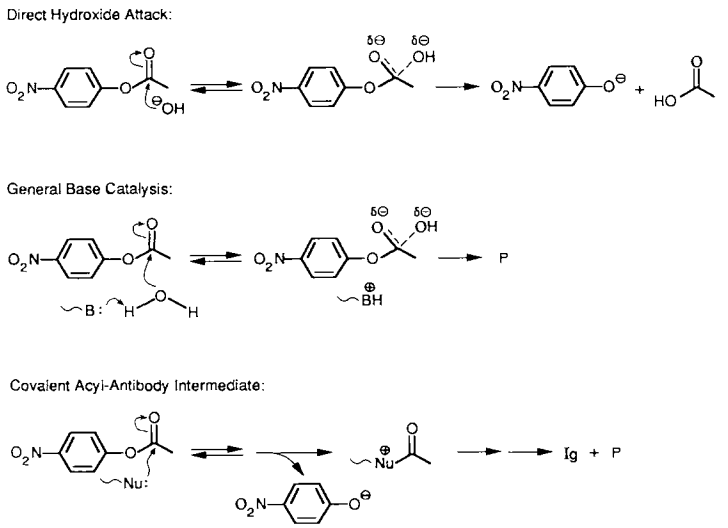


Fig. 3. Possible mechanisms for hydrolysis of **9** by antibody 48G7-4A1. Ig = immunoglobulin, p = product.

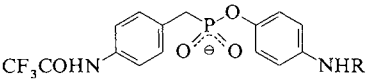
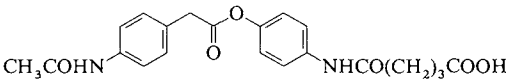
The pH dependence of antibody catalysis was shown to be first order with respect to hydroxide between pH 7.5 and 9.4, arguing for direct attack by hydroxide ion in this pH range. If the general base mechanism were responsible for the catalysis observed, the pH dependence of k_{cat} would reflect a dependence on the pK_a of a specific residue in the combining site. Note, however, that a general base could be present but its pK_a cannot lie in the range of 7.5–9.4. Kinetic analyses using high antibody concentrations were not consistent with a pre-steady-state burst of *para*-nitrophenolate and thus ruled out the third mechanism involving acyl-enzyme formation. Chemical modification studies revealed the presence of tyrosine, arginine, and histidine in the combining site of this antibody.[24] Interestingly, antibody S107, which catalyzes the hydrolysis of *para*-nitrophenyl choline carbonate (**4**) also has an arginine and a tyrosine, which were identified by chemical modification studies. Perhaps in analogy to S107, arginine serves to stabilize the oxyanion formed in the transition state for ester or carbonate hydrolysis.

The largest rate acceleration by an esterolytic antibody was achieved using a phosphonate transition-state analogue. *Lerner, Tramontano* et al. isolated twenty antibodies specific for compound **10** and found five which catalyzed the hydrolysis of ester **12**.[25] The kinetic constants measured for the most active antibody were $k_{cat} = 20\ s^{-1}$ and $K_M = 1.5$ mM. The free hapten **11** binds extremely tightly with $K_I = 50$ nM. The large difference in affinity of the antibody for the substrate versus the inhibitor accounts for most of the large rate acceleration achieved by this antibody, $k_{cat}/k_{uncat} = 6.25 \times 10^5$.

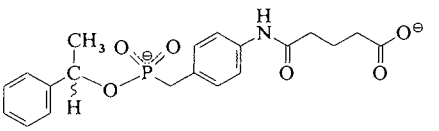


10, R = $(CH_2)_4COON(COCH_2)_2$
11, R = CH_3

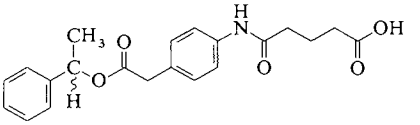


12

Antibodies have been shown to catalyze the stereospecific hydrolysis of unactivated esters. Antibodies elicited toward phosphonates **13** and **15** were shown to catalyze the hydrolysis of **15** and **16**, respectively, in a stereospecific manner. In both cases, antibodies were elicited against a racemic mixture of the hapten. Of eighteen antibodies specific for **13**, nine catalyzed the hydrolysis of (*R*)-**14** and two catalyzed the hydrolysis of (*S*)-**14**.[26] Two antibodies, one of each specificity, were further characterized. The rate acceleration for the hydrolysis of (*R*)-**14** by antibody 2H6 was 80 000, whereas the (*S*)-**14**-specific antibody 21H3 only showed a modest 1600-fold rate acceleration over the uncatalyzed reaction. The *R*/*S* selectivity is greater than 98%.

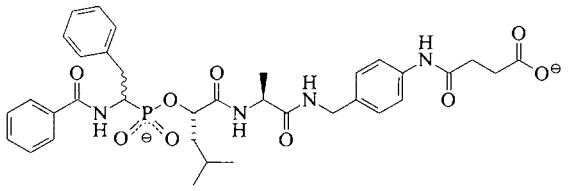


13

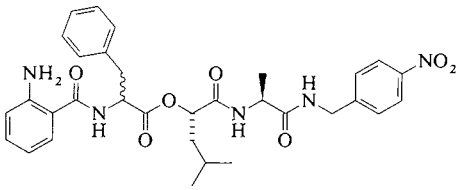


14

Of 25 antibodies isolated that were specific for the tripeptide phosphonate **15**, 18 accelerated the hydrolysis of the



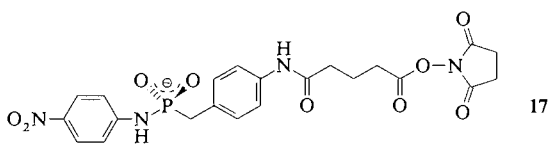
15



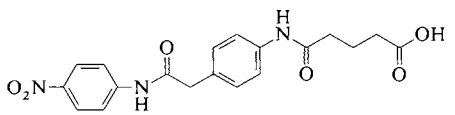
16

corresponding ester substrates.[27] It is interesting that an exclusive preference for antibodies of one specificity was observed. All 18 antibodies were selective for the D-phenylalanyl isomer of **16**. The selectivity for D- over L-phenylalanine at this position was greater than 99.5% for three of the five antibodies characterized. The modest rate accelerations of 50–300-fold may be a result of the size of the immunogen. The tetrahedral phosphonate contributes proportionally less to the overall binding energy of hapten to antibody than it does in smaller haptens. Note that substrate **16** also contains fluorogenic and quenching groups at the amino and carboxy termini, respectively. These groups allow hydrolysis of the substrate to be monitored by observing the fluorescence increase which occurs when the fluorescent 2-aminobenzoyl group is separated from the quenching 4-nitrobenzylamide group in the reaction. This sensitive assay may allow direct screening of ELISA[28] plates or of λ libraries expressing up to 10^6 different F_{ab} fragments,[29] greatly facilitating the production of catalytic antibodies. These two examples suggest that excellent stereoselectivities can be achieved by antibodies with large or small substrates and chiral centers in the alcohol portion or the acyl group portion of the substrate.

An antibody, NPN43C9, elicited against phosphonamidate **17** was shown to catalyze the hydrolysis of the activated amide bond in **18**.[30] A rate acceleration of 2.5×10^5 over



17



18

the uncatalyzed rate was reported. This rate acceleration is again much higher than the differential binding of the transition state over the substrate for the reaction, $\Delta\Delta G = -2.2$ kcal mol^{-1}. This difference in binding energy only accounts for a 100-fold rate acceleration. Again other factors such as acid/base catalysis must be responsible for the observed rate acceleration. In this context it was found that 150 mM NaCl completely inhibited antibody catalysis. The structural feature of this hapten responsible for induction of such acid/base catalysis is not apparent because the phosphonamidate NH group is not charged in the immunogen.

3. Statine-based Peptidase Inhibitors

In addition to negatively charged phosphonates, a number of uncharged transition-state analogues exist for hydrolytic enzymes. The most well characterized of these is the potent pepsin inhibitor pepstatin, which contains the novel amino acid analogue statine (Fig. 4). The measured K_I of pepstatin

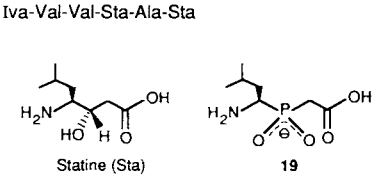


Fig. 4. Structures of pepstatin and the phosphinate analogue **19** of the novel amino acid statine.

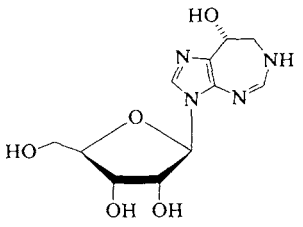
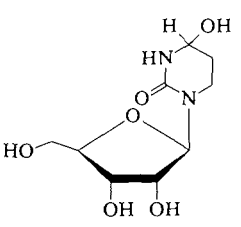
for pepsin is 46 pM, making it one of the most potent enzyme inhibitors known. Statine is considered a dipeptide analogue which contains a hydroxyl group substituted for the carbonyl group of the scissile amide bond in pepsin substrates. The hydroxyl group is thought to displace an enzyme-bound water molecule which is contacted by the two catalytically important aspartate residues in pepsin. In the X-ray crystal structure of the complex formed between pepstatin and *Rhizopus chinensis* aspartic protease, the hydroxyl group is within hydrogen-bonding distance of the two aspartate residues.[30] Based on this structure, statine is considered to be a "collected" substrate analogue possessing binding determinants of both the peptide substrate and the enzyme-bound water responsible for addition to the scissile amide bond. The sp^3-hybridized carbon attached to the hydroxyl group mimics the tetrahedral transition state for amide bond hydrolysis.

A comparison between the two classes of inhibitors, phosphorus-based versus statine-based, can be made directly because the phosphinate analogue of statine, **19**, has been synthesized.[31] The K_I of the pepstatin-like peptide, where statine is substituted with the phosphinate analogue **19** is < 70 pM. Thus, the two classes of inhibitors display roughly the same inhibitory potency.

In addition to peptidase inhibitors, uncharged transition-state-analogue inhibitors of enzymes in nucleotide biosynthesis pathways have been isolated. Coformycin (**20**) inhibits the enzyme adenosine deaminase and is one of the most potent inhibitors known for any enzyme ($K_I = 2.5$ pM).[32] The enzyme converts adenosine into inosine, which involves the hydrolysis of the amidine moiety of adenine. Tetrahydrouridine (**21**) is another member of this class of inhibitors.[13] One interesting common feature of this class of inhibitors, which is not understood, is the slow binding nature of the inhibition observed. The rate constant for formation of the tight enzyme–inhibitor complex is exceedingly slow, the half-time for dissociation of coformycin from



20

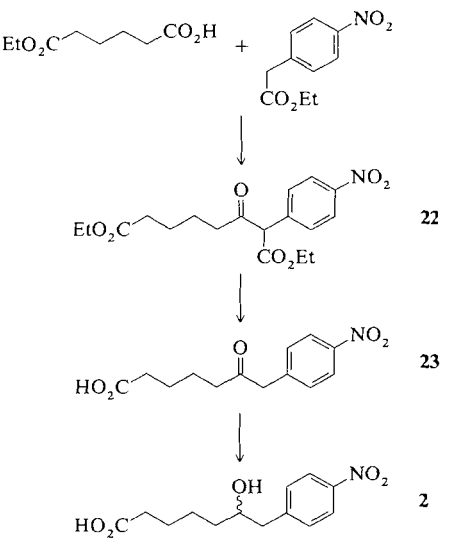


21

adenosine deaminase is 24 h. Based on the tight binding constants of these transition-state analogues, haptens with similar structural features might be expected to elicit catalytic antibodies.

4. Hydrolytic Antibodies Elicited toward an Uncharged Hapten

In this study we have generated five antibodies toward racemic 6-hydroxy-7-(4-nitrophenyl)heptanoic acid (**2**), which is a "statine-like" transition-state-analogue inhibitor for the hydrolysis of *para*-nitrophenyl acetate (**9**) and *para*-nitrophenyl methyl carbonate (**6**). This hapten was chosen because it is an uncharged hydroxyl-containing analogue of hapten **8**.[23] Direct comparison of the catalytic properties of antibodies elicited toward these different haptens is straightforward since they are designed to catalyze the same reactions. Indeed, one antibody, 7K16.2, was isolated which catalyzed the hydrolysis of **6** and **9**. This is the first example of the use of an uncharged hapten to elicit an esterolytic antibody. This is a surprising result considering the importance of charge–charge complementarity between the antibody combining site and the transition state as demonstrated by the mutagenesis study of the PC-binding antibody S107.[20] The hydroxy carboxylic acid **2** was prepared from adipic acid monoethyl ester and ethyl *para*-nitrophenylacetate via **22** and **23** (Scheme 1).



Scheme 1.

Experimental Procedure

22: To a stirred solution of adipic acid monoethyl ester (102.3 mg, 0.59 mmol) in 0.6 mL of tetrahydrofuran was added carbonyldiimidazole (100 mg, 0.62 mmol). The resulting mixture was allowed to stir at room temperature for 45 min. To a stirred solution of 0.62 mL (0.62 mmol) of 1 M sodium hexamethyldisilazide in tetrahydrofuran at −78 °C under argon was slowly added a solution of ethyl 4-nitrophenylacetate (123.3 mg, 0.59 mmol) in 0.5 mL of tetrahydrofuran to give a purple reaction mixture. After 5 min, the above solution of the imidazolide was slowly added. The resulting mixture was allowed to warm to 0 °C. After 30 min, it was allowed to warm to room temperature. After an additional 30 min, the reaction mixture was partitioned between dichloromethane and aqueous NH_4Cl. The organic phase was dried over $MgSO_4$ and then concentrated. The resulting residue was chromatographed on silica gel with 20% ethyl acetate in hexane to give 182 mg (0.5 mmol, 85%) of **22**. IR (thin film): $\tilde{\nu}$ [cm^{-1}] = 3000, 1730, 1650, 1600, 1520, 1350. ^{1}H NMR (250 MHZ, $CDCl_3$) (equilibrium mixture of keto and enol tautomers): δ = 1.20 (m, 6H), 2.2 (m, 4H), 2.55 (m, 3H), 4.15 (m, 4H), 4.81 (s, 1H), 7.33, 7.55 (d, 2H, J = 9 Hz), 8.21, 8.24 (d, 2H, J = 9 Hz). High-resolution FAB MS: m/z 366.1546 (M + H$^{\oplus}$).

23: A solution of **22** (145 mg, 0.4 mmol) in 2 mL of 40% aqueous H_2SO_4 was heated in an oil bath at 100 °C for 15 h. The cooled reaction mixture was diluted with water and then extracted with dichloromethane. The organic phase was washed with saturated aqueous NaCl, dried over $MgSO_4$, and then concentrated. The residue was chromatographed on silica gel with 5% methanol in ethyl acetate to give 44 mg (0.16 mmol, 42%) of **23**. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2950, 1710, 1605, 1520, 1340. M.p. 103–105 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.63 (m, 4H), 2.36 (t, 2H, J = 7 Hz), 2.55 (t, 2H, J = 7 Hz), 3.83 (s, 2H), 7.36 (d, 2H, J = 9 Hz), 8.19 (d, 2H, J = 9 Hz). High-resolution FAB MS: m/z 266.1021 (M + H$^{\oplus}$).

2: To a stirred solution of **23** (44 mg, 0.16 mmol) in 1 mL of methanol at 0 °C was added sodium borohydride (13 mg, 0.34 mmol). After stirring at 0 °C for 1 h, the reaction mixture was allowed to warm to room temperature and then partitioned between dichloromethane and aqueous $KHSO_4$. The organic phase was dried over $MgSO_4$ and then concentrated to give 44 mg (0.16 mmol, 100%) of **2**. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3000, 1710, 1700, 1600, 1510, 1320. M.p. 81–84 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.6 (m, 6H), 2.37 (t, 2H, J = 7 Hz), 2.79 (dd, 1H, J = 8, 14 Hz), 2.91 (dd, 1H, J = 4, 14 Hz), 3.90 (m, 1H), 7.38 (d, 2H, J = 9 Hz), 8.16 (d, 2H, J = 9 Hz). High-resolution FAB MS: m/z 268.1195 (M + H$^{\oplus}$).

4.1. Generation and Characterization of Antibody 7K16.2

The racemic hapten **2** was coupled to carrier proteins KLH and bovine serum albumin (BSA) by treatment of the *N*-hydroxysuccinimide-activated ester of **2** with the individual proteins at pH 9.0 in order to derivatize surface ε-amino groups of surface lysine residues.[33] The ratio of hapten to protein carrier, calculated by using UV difference spectroscopy (**2**: ε_{400} = 9100), was 7 per KLH monomer and 3 per BSA monomer.

Five monoclonal antibodies were isolated from the fusion of KLH–**2** conjugate-immunized Swiss Webster mouse spleenocytes with P3X63 myeloma cells.[34] Monoclonal antibodies were produced in vivo and isolated by affinity chromatography on Protein-A-coupled Sepharose 4B.[35] Following Protein A affinity chromatography, the antibodies were further purified by Pharmacia FPLC Mono S 10/10 cation-exchange column chromatography. Antibody was determined to be > 95% pure by 12.5% SDS polyacrylamide gel electrophoresis with Coomasie blue staining.[37] Of these five antibodies one (7K16.2) accelerated the hydrolysis of *para*-nitrophenyl acetate (**9**) and *para*-nitrophenyl methyl carbonate (**6**) and was inhibited by free hapten.

The 7K16.2-catalyzed reactions obeyed classical Michaelis–Menten kinetics. Lineweaver–Burke plots obtained at pH 7.5 were linear with kinetic constants k_{cat}(**9**) = 0.72 min^{-1} K_M(**9**) = 3.65 mM and k_{cat}(**6**) = 0.31 min^{-1}, K_M(**6**) = 3.33 mM (Fig. 5). The uncatalyzed rate constants under the same conditions are k_{uncat}(**9**) = 3.33×10^{-4} min^{-1} and k_{uncat}(**6**) = 3.2×10^{-4} min^{-1}. The antibody is competi-

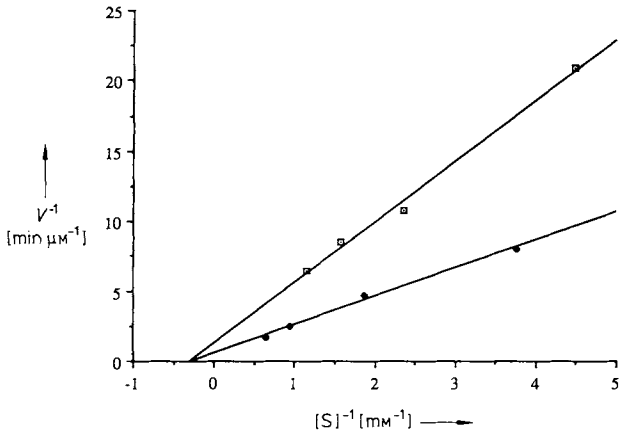


Fig. 5. Lineweaver–Burke plot for the hydrolysis of **6** (□) and **9** (◆) catalyzed by antibody 7K16.2. Velocities were determined spectrophotometrically by measuring the initial absorbance increase at 400 nm (*para*-nitrophenol λ_{max} = 400 nm (ε = 4.05)). The concentration of 7K16.2 was 2.5 μM as determined by absorbance at 280 nm using E(1 cm, 0.1%) = 1.37 and M_r = 150000 for IgG. Antibody 7K16.2 was preincubated at 30 °C in 10 mM sodium phosphate, 100 mM NaCl, pH 7.5. The reaction was initiated by adding 10 μL of a stock solution of **6** or **9** in tetrahydrofuran (THF) to give a final THF concentration of 2%. The uncatalyzed rate was measured under the same conditions, affording k_{uncat} (**6**) = 3.2×10^{-4} min^{-1}, k_{uncat} (**9**) = 3.3×10^{-4} min^{-1}.

tively inhibited by free hapten **2** with a K_I of 140 μM (Fig. 6).[38] As in other examples of hydrolytic catalytic antibodies, the differential binding energy between the substrate and inhibitor, $K_M(\mathbf{6})/K_I = 24$, $K_M(\mathbf{9})/K_I = 26$, found with antibody 7K16.2 does not account for the full rate acceleration observed, $k_{cat}(\mathbf{6})/k_{uncat}(\mathbf{6}) = 930$; $k_{cat}(\mathbf{9})/k_{uncat}(\mathbf{9}) =$

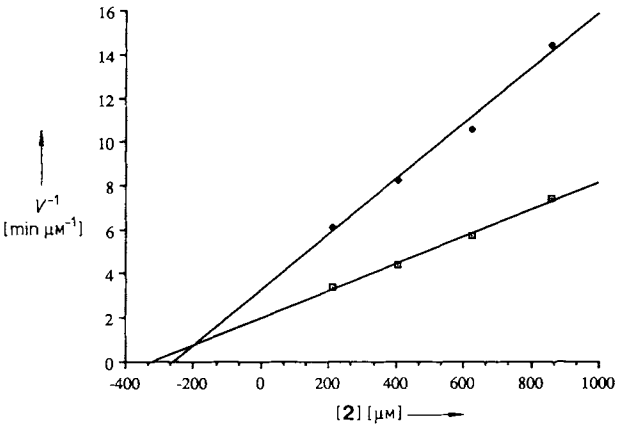

Fig. 6. Dixon plot of inhibition of antibody 7K16.2 by **2**. Antibody concentration was 2.5 μM. Data were obtained at two concentrations of substrate **9**: 500 μM (◆) and 1 mM (□). Buffer conditions are as described in Figure 5.

2250. For the identical reaction catalyzed by antibody 48G7-4A1 raised against phosphonate **8**, the differential binding energy is $K_M(\mathbf{6})/K_I(\mathbf{8}) = 1300$, compared to the observed rate accelerations of $k_{cat}(\mathbf{6})/k_{uncat}(\mathbf{6}) = 7300$. However, the disparity between the two values is much more pronounced in the case of antibody 7K16.2, suggesting that other factors (such as immunological diversity) contributing to the catalysis besides transition-state stabilization are of greater relative importance than was the case for antibody 48G7-4A1. In order to more definitively determine the differences between catalysts elicited toward different classes of inhibitors, large numbers of antibodies must be analyzed. With recent λ-library technology these statistically significant numbers of different antibodies may be accessible.[29]

Catalysis by 7K16.2 of a more energetically demanding hydrolytic reaction was also explored. The rate of hydrolysis of *para*-nitrophenylacetanilide at pH 9.0 was not accelerated by this antibody as determined by an HPLC assay, using *para*-nitrobenzamide as an internal standard. In a separate study, antibodies were elicited against a KLH–coformycin conjugate. None of the eight coformycin-specific antibodies accelerated the conversion of adenosine to inosine ($k_{uncat} = 1.8 \times 10^{-10}$ s^{-1}) as measured by an ammonia release assay.[39] It is possible that further screening of antibodies specific for these haptens will yield catalytic antibodies.

5. Outlook

In the past five years the diversity of the immune system has been exploited to generate catalysts capable of carrying out many different transformations. Moreover, a number of successful strategies have been developed to produce catalytic antibodies. Several strategies have yet to be demonstrated such as the use of strain to destabilize substrates as well as genetic screens and selections to identify more active catalysts generated by random and directed mutagenesis. The efficient and selective hydrolysis of peptides, nucleic acids, and carbohydrates continue to be major targets for catalysis by antibodies. Clearly, the antibody molecule will play an increasingly important role in chemistry. In addition, exciting new approaches for tapping the diversity of biological systems are being developed.[36,40–41] These advances will no doubt lead to new molecules with novel biological properties in much the same fashion as the development of antibody catalysts.

Perspectives in Supramolecular Chemistry—From Molecular Recognition towards Molecular Information Processing and Self-Organization

By Jean-Marie Lehn*

The selective binding of a substrate by a molecular receptor to form a supramolecular species involves molecular recognition which rests on the molecular information stored in the interacting species. The functions of supermolecules cover recognition, as well as catalysis and transport. In combination with polymolecular organization, they open ways towards molecular and supramolecular devices for information processing and signal generation. The development of such devices requires the design of molecular components performing a given function (e.g., photoactive, electroactive, ionoactive, thermoactive, or chemoactive) and suitable for assembly into an organized array. Light-conversion devices and charge-separation centers have been realized with photoactive cryptates formed by receptors containing photosensitive groups. Electroactive and ionoactive devices are required for carrying information via electronic and ionic signals. Redox-active polyolefinic chains, like the "caroviologens", represent molecular wires for electron transfer through membranes. Push-pull polyolefins possess marked nonlinear optical properties. Tubular mesophases, formed by organized stacking of suitable macrocyclic components, as well as "chundle"-type structures, based on bundles of chains grafted onto a macrocyclic support, represent approaches to ion channels. Lipophilic macrocyclic units form Langmuir–Blodgett films that may display molecular recognition at the air–water interface. Supramolecular chemistry has relied on more or less preorganized molecular receptors for effecting molecular recognition, catalysis, and transport processes. A step beyond preorganization consists in the design of systems undergoing self-organization, that is, systems capable of spontaneously generating a well-defined supramolecular architecture by self-assembling from their components under a given set of conditions. Several approaches to self-assembling systems have been pursued: the formation of helical metal complexes, the double-stranded helicates, which result from the spontaneous organization of two linear polybipyridine ligands into a double helix by binding of specific metal ions; the generation of mesophases and liquid crystalline polymers of supramolecular nature from complementary components, amounting to macroscopic expression of molecular recognition; the molecular-recognition-directed formation of ordered solid-state structures. Endowing photo-, electro-, and ionoactive components with recognition elements opens perspectives towards the design of programmed molecular and supramolecular systems capable of self-assembly into organized and functional supramolecular devices. Such systems may be able to perform highly selective operations of recognition, reaction, transfer, and structure generation for signal and information processing at the molecular and supramolecular levels.

1. Introduction

Supramolecular chemistry, the chemistry beyond the molecule, is the *designed* chemistry of the intermolecular bond, just as molecular chemistry is that of the covalent bond.[1–3] It is a highly interdisciplinary field of science covering the chemical, physical, and biological features of chemical species held together and organized by means of intermolecular (noncovalent) binding interactions. This relatively young area has been defined, conceptualized, and structured into a coherent system. Its roots extend into organic chemistry and the synthetic procedures for receptor construction, into coordination chemistry and metal-ion–ligand complexes, into physical chemistry and the experimental and theoretical studies of interactions, and into biochemistry and the biological processes that all start with substrate binding and recognition. A major feature is the range of perspectives offered by the cross-fertilization of supramolecular chemical research due to its location at the intersection of chemistry, biology, and physics. Such wide horizons are a challenge and a stimulus to the creative imagination of the chemist.

Earlier research has been thoroughly reported and discussed in numerous books, chapters, reviews (see, for instance, Refs. [1–12]), and publications devoted to the basic aspects of supramolecular chemistry, molecular recognition, reactivity and catalysis, and transport processes. Our own work has been reviewed in recent papers[1–3] which contain references to earlier publications.

Based on the chemical, physical, and biological features of supramolecular systems, novel lines of investigation have developed, concerned with the design of molecular devices and of systems displaying higher forms of molecular and supramolecular behavior such as self-organization, regula-

tion, cooperativity, communication, and replication. One may note that a common thread of all areas of supramolecular chemistry is the *information*[3, 4] stored in the structural (and eventually temporal) features of molecules and supermolecules. Thus, it is a kind of *molecular information science* or *molecular "informatics"* that is progessively shaping up.

The present article will build on the most recent of the previous reviews,[3] focusing on the lines of development that lead from molecular recognition to the various aspects of handling information and signals at the molecular and supramolecular levels.

2. Molecular Recognition, Information, and Signals: Semiochemistry

The selective binding of a substrate by a molecular receptor to form a supermolecule involves *molecular recognition*, which rests on the *molecular information*[4, 13] stored in the interacting partners. It requires the design of receptors possessing steric and electronic features complementary to those of the substrate to be bound and a balance between rigidity and flexibility suitable for the function to be performed. Such organization of molecular structural and dynamical features has been at the origin of the development of the cryptands[4] and other types[5 - 11] of more or less rigidly built ligand molecules.

Molecular recognition events represent the basis of information processing at the supramolecular level. They may give rise to changes in electronic, ionic, optical, and conformational properties and thus translate themselves into the generation of a signal. A great variety of receptor molecules has been designed for effecting the recognition of numerous and very diverse types of substrates (spherical, tetrahedral, linear or branched, charged or neutral, organic, inorganic or biological, etc.). Structural units have been incorporated that may respond to or be perturbed by external factors. Most investigations have focused on *endo-receptors* in which the binding (information) sites are oriented into a molecular concavity; *exo-receptors*, with outward-directed sites, present "informed" surfaces on which recognition may occur.[3] By making use of the three-dimensional information storage/readout operating in molecular (endo- or exo-) recognition, in combination with substrate transformation and translocation, one may design components for *molecular devices* that would be capable of processing information and signals at the molecular and supramolecular levels. The resulting area of investigation may be termed *semiochemistry* (from the greek σημεῖον: sign, signal), the chemistry of molecular signal generation, processing, transfer, conversion, and detection.[14]

3. Molecular and Supramolecular Devices

Molecular devices have been defined as structurally organized and functionally integrated chemical systems built into supramolecular architectures.[3] They are based on specific components arranged in a suitable manner. The *function* performed by a device results from the integration of the *elementary acts* performed by the components. The components may, for instance, be photoactive, electroactive or ionoactive, depending on whether they operate with photons, electrons, or ions.

Molecular recognition processes may play a role at several key levels: (1) the building up of the device from its components; (2) its incorporation into supramolecular arrays; (3) the selective operation on given species (e.g., ions); (4) the response to external physical or chemical stimuli (light, electrons, ions, molecules, etc.) that may regulate the operation of the device and switch it on or off; (5) the nature of the signals generated and signal conversion effected (photon/photon, photon/electron, electron/electron, electron/ion, ion/ion, etc.)

Recognition-dependent devices, which one may term *informed molecular devices*, represent the molecular and supramolecular entities by which molecular recognition events may be transduced into information and signals. This requires the design of receptor components responding to external stimuli and suitable for incorporation into devices.

Our work has been concerned with various aspects of device chemistry, related in particular to basic device design and to recognition-dependent processes. The present description extends an earlier article in *Angewandte Chemie*.[3]

3.1. Molecular Photonic Devices

Compared to the isolated components, supramolecular entities containing photoactive components may display novel properties, thus defining a *supramolecular photochemistry*.[15 - 17] Various processes may take place within these *photochemical molecular devices*, modulated by the arrangement of the bound units as determined by the organizing receptor: photoinduced energy migration, charge separation by electron or proton transfer, perturbation of optical transitions and polarizabilities, modification of redox potentials in ground or excited states, photoregulation of binding properties, selective photochemical reactions, etc. These processes may depend on recognition events and occur only if the correct selective binding of the complementary active components takes place, as illustrated for a two-component case in Figure 1 (see also Fig. 10 in Ref. [3]).

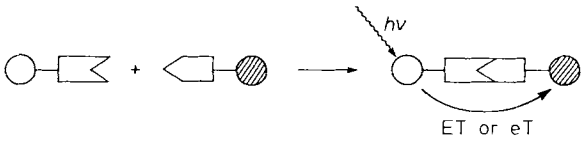

Fig. 1. Molecular-recognition-dependent photochemical molecular devices. Photochemical processes such as energy transfer (ET) or photoinduced electron transfer (eT) may be induced via association of two (or more) complementary units, each bearing a component of the device; the complementary units may be as small as heterocyclic bases or as large as antigen–antibody conjugates.

In principle, molecular photonic devices require a complex organization and adaptation of the components in space, energy, and time, leading to the generation of optical, electronic, protonic, or ionic photosignals.

3.1.1. Light Conversion by Energy Transfer

Conversion of absorbed light into emitted light of another wavelength occurs in any luminescent species. One would like, however, to perform *separately* the various steps of the overall process by means of different components that may be optimized for a given purpose (wavelength of absorbed or emitted light; lifetime of emission, etc.). This is the case for a *light-conversion molecular device* consisting of two components, a *light collector* (or *antenna*) formed by an array of absorbing units and an *emitter*, which allow separate optimization of absorption and emission. In order to function, intercomponent *energy transfer* must occur (as efficiently as possible). Thus, such a device operates in a three-step mode: absorption–energy transfer–emission (A–ET–E, Fig. 2).

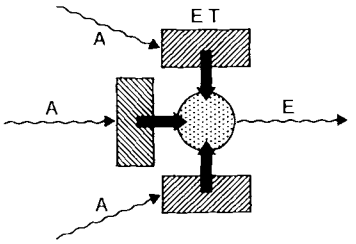

Fig. 2. Light-conversion photochemical molecular device, consisting of two components, a light collector (or antenna, light-absorbing groups A) and a light emitter E, and performing a three-step process: absorption (A), energy transfer (ET), and emission (E).

This has been realized in europium(III) and terbium(III) cryptates of macrobicyclic ligands that incorporate various heterobiaryl groups (2,2'-bipyridine, phenanthroline,[18, 19] bithiazole, biimidazole, bipyrimidine,[20] biisoquinoline,[21] and their *N,N'*-dioxides[21, 22]) serving as light-collecting antenna components. These complexes present a unique combination of features arising from both their cryptate structure and the nature of the emitting species: protection of the included ion from deactivation due to interaction with solvent (water) molecules; very high thermodynamic stability and kinetic inertness; multiple absorbing groups suitable for ET; characteristic long wavelength (for Eu^{III}) and long lifetime of the emission. They display a bright luminescence that results from UV light absorption by the organic groups followed by energy transfer to the included lanthanoid cation which then emits its characteristic visible radiation.[16, 20–24] The corresponding A-ET-E process is shown for the cryptate **1**.

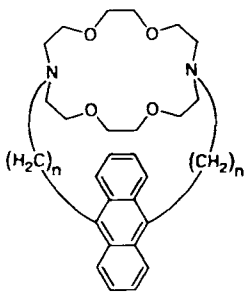
Higher conversion efficiency and stronger luminescence are found for europium cryptates such as **2**[21] containing *N*-oxide ligands.[22] In the solid state, complex **1** exhibits especially high energy-conversion efficiency (about 60%).[25] This is also the case for the corresponding Tb^{III} cryptate up to about 100 K; at higher temperature, energy migration and back-transfer from the ion to the cryptand decreases the emission intensity.[26] Since the nature of the ligand groups strongly influences the photophysical properties, it may be possible to tune them to the desired purposes by suitable structural variations.

Such photoactive cryptates are of interest as novel luminescent materials (in solution or in the solid state) and as labels for biological applications subject to very stringent constraints (labeling of monoclonal antibodies, oligonucleotides, membrane components; cytofluorimetry, etc.). Linked, cascade systems performing very long range energy transfer (VLRET) may be imagined.

3.1.2. Ion-Binding Luminophores

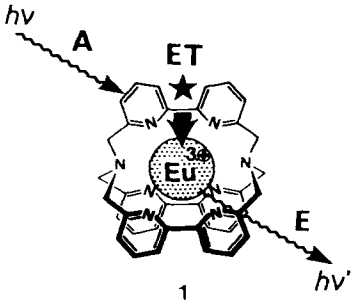
Photosensitive receptor molecules may display marked modifications in their photophysical properties on binding of substrate species, allowing their detection by absorption or emission measurements.[27] They represent molecular devices for *substrate-selective optical signal generation.*

Cryptands such as **3** combine the strong complexing ability of cryptands and the intense fluorescence emission of the anthracene group. They display dramatic changes in fluorescence emission upon complexation of alkali-metal cations and protonation.[28]

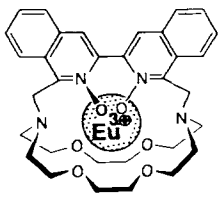


3 (n = 2, 3)

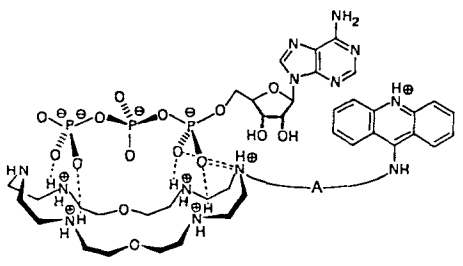
Of special interest is the strong enhancement of the acridine fluorescence observed when adenosine triphosphate binds to a receptor molecule formed by a $[24]N_6O_2$ macrocycle bearing a lateral acridine group.[29] Double recognition



1



2



4, A = CH_2-CH_2-CH_2

occurs via binding of the triphosphate group to the protonated macrocycle and stacking of the adenine unit with the dye residue, as shown in **4**. Furthermore, guanosine triphosphate slightly decreases the emission. Thus, this receptor is a *sensitive* and *selective ATP probe* that generates a fluorescence signal on ATP binding.

3.1.3. Photoinduced Electron Transfer in Photosensitive Cryptates

Irradiation of a device containing a photosensitizer (PS) as well as suitable donor (D) and acceptor (A) groups may induce electron transfer, generating the charge-separated state $D^{\oplus}$-PS-$A^{\ominus}$. Such processes are being investigated very actively in view of their interest in photosynthesis and in photocatalysis.[15a]

Our own work has been concerned with photoinduced charge separation in macropolycyclic coreceptors containing both a photosensitive porphyrin group and binding sites for silver(I) ions as acceptor centers. Irradiation leads to transfer of an electron from the porphyrin to Ag^{I}, generating a porphyrinium cation of long lifetime. The efficiency of the charge separation is much higher in these coreceptor species than in the nonlinked model compounds.[16, 30]

Systems undergoing photoinduced electron-transfer processes represent components for *light-to-electron conversion devices*. Of special interest is the design of systems capable of performing long-range electron transfer (see Section 3.2.3), for instance, to generate transmembrane photoelectric signals or to serve as the basis of an electronic shift register memory at the molecular level.[41c]

3.1.4. Photoinduced Reactions in Supramolecular Species

Receptor molecules that contain suitable light-sensitive groups may undergo structural and conformational changes that affect their binding properties.[31a] As a consequence, substrate uptake or release occurs, representing a way to generate protonic or ionic photosignals in *light-to-ion conversion devices* (see also Section 3.3).

Receptor-substrate binding may affect their photochemical reactivity. The recognition process could thus modify the course of a reaction, affecting its rate or the nature of the products. For instance, the binding of cobalt(III) hexacyanide by macrocyclic polyammonium receptors markedly affects their photoaquation quantum yield in a structure-dependent manner.[32] One may imagine a number of other photoreactions whose course could be altered by selective binding.

In this way, recognition is expressed via a chemical transformation, in the nature or the rate of formation of the products, amounting to the generation of a specific molecular signal.

3.1.5. Nonlinear Optical Effects in Supramolecular Species

Highly polarizable molecules may be expected to present marked optical nonlinearities.[33] Novel effects should arise on going from the molecular to the supramolecular level.[34] Incorporation into supramolecular arrangements may influence the properties of the individual molecules by orientation and/or perturbation of their electronic properties.

Of special interest are push-pull polyenes, composed of a polyolefinic chain bearing a donor group on one end and an acceptor on the other end. In the course of our studies on molecular wires of caroviologen type (see below), a number of push-pull carotenoid derivatives were also synthesized in order to investigate their nonlinear optical properties. These are highly polarizable conjugated polyenes that also represent polarized molecular wires (Fig. 3). They have been found to display marked second harmonic generation as powdered samples.[35] The determination of the hyperpolarizabilities in solution gave exceptionally large values for the longer of these compounds.[36] Incorporation of such a compound into Langmuir–Blodgett films yields oriented arrangements of interest for nonlinear optical studies.[37]

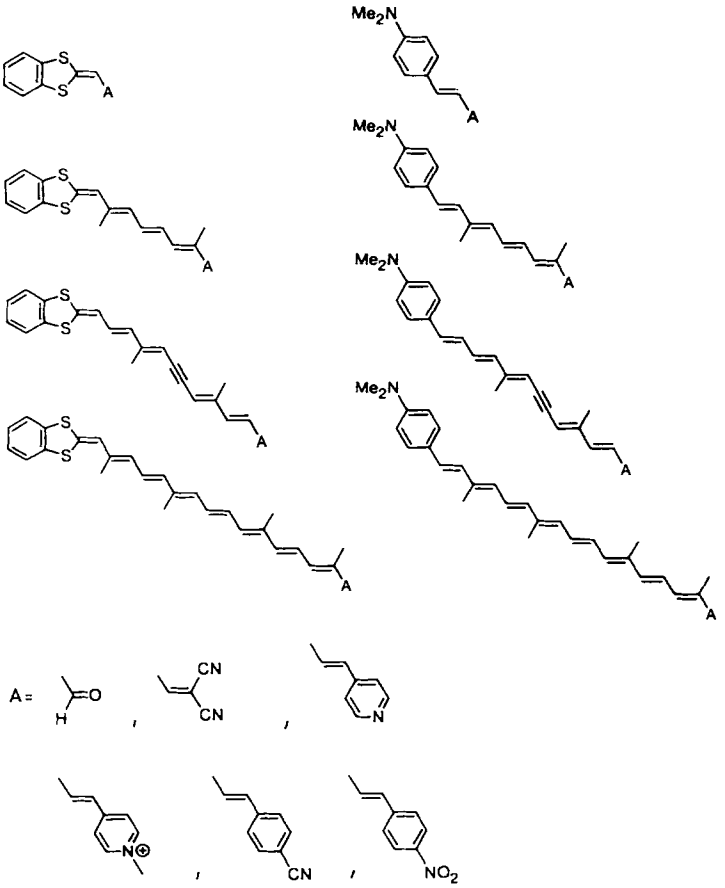


Fig. 3. Structures of a series of donor–acceptor carotenoid (D-C-A) derivatives.

If a highly polarizable group is introduced into a receptor molecule, substrate binding may cause substantial perturbations, so that the recognition event will be converted into a nonlinear optical signal. Such recognition-dependent nonlinear optical probes may be derived from polyenes such as those shown in Figure 3.

All the photochemical and photophysical processes discussed above may be coupled to recognition processes, as already pointed out. Thus emerges the area of recognition-dependent molecular photonics, the transduction of molecular information into photosignals.

3.2. Molecular Electronic Devices

Molecular devices operating on electrons are basic elements for converting molecular recognition events into electronic signals. For example, redox properties may be affected by binding in a structure-dependent manner. This is the case for the complexation of metal hexacyanides by polyammonium macrocycles where the shift in redox potential depends on the binding constant.[38] Such perturbations by complexation lead to an electrochemical characterization of recognition. Electrochemical effects resulting from receptor–substrate binding define a domain of *supramolecular electrochemistry*.

Much interest has been shown in the possibility of designing electronic devices that would operate at the molecular level (for recent discussions see, for instance, Refs. [39–41]). This involves several steps. It is first necessary to imagine a molecule that may possess the desired features, synthesize it, and study its properties. The second step is to incorporate it into supramolecular architectures, such as membranes or other organized structures, and to investigate whether the resulting entity possesses the required properties. The third step requires the connection of the basic unit to other components, in order to address it via relay molecules or with an external physical signal. Of course, the goal of designing molecular electronic circuitry may have many spin-offs along the way, in addition to raising novel questions about the handling of molecules. It is probably premature to try to define clearly the routes to the goal; indeed, the definition of the goal itself may change under the influence of progress made along a given path.

The possibility of designing devices such as molecular rectifiers, transistors, switches, and photodiodes has been envisaged and some of the required features are present in compounds such as metal complexes or D-PS-A systems (see above) that lead to photoinduced charge separation at the level of the isolated molecule.[15a]

3.2.1. Caroviologens as Molecular Wires

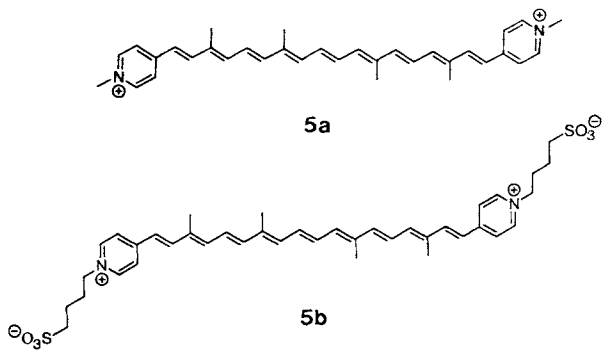
Among the various devices and components performing molecular-scale electronic functions that may be imagined, a crucial one is a *molecular wire*, which might operate as a connector permitting electron flow to occur between the different elements of a molecular electronic system.

Our first approach towards the design of molecular wires was based on the *caroviologens* ($CV^{2\oplus}$), long, conjugated polyolefinic chains bearing pyridinium groups at each end, which combine the structural features of carotenoids with the redox properties of methylviologen. Such compounds (e.g., **5a**) were synthesized and shown to be incorporated in a transmembrane fashion into dihexadecyl phosphate (DHDP) vesicles.[42]

The orientation of caroviologens in model lipid membranes was studied by linear dichroism measurements. Dichroic ratios were determined on caroviologens of different lengths solubilized in lyotropic lamellar phases of different thicknesses and macroscopically aligned between quartz plates. The orientation parameters obtained indicated transmembrane arrangement for caroviologens of length compatible with the bilayer thickness of the membrane.[43]

Electron-transfer experiments employing the initial $CV^{2\oplus}$/DHDP vesicle system did not give positive results, perhaps because of the high negative charge of the membrane surfaces, which might reduce interfacial electron transfer rates and modify the redox potential of incorporated $CV^{2\oplus}$.

Zwitterionic caroviologens $CV^{2\oplus}$ such as **5b** were therefore prepared[44] and incorporated into phospholipid vesi-



cles.[45] Electron-transfer experiments were performed between an external reducing phase and an internal oxidizing phase, as shown in Figure 4; only a small amount of incorporated $CV^{2\oplus}$ was used in order to be able to study the effect of a few molecules per vesicle.[45] The rate of reduction of the internal oxidant ferricyanide to ferrocyanide was accelerated by a factor of about 4, which, although small, nevertheless clearly indicated that electron conduction did occur. No measurable rate acceleration was produced by lipophilic viologens under the same conditions.

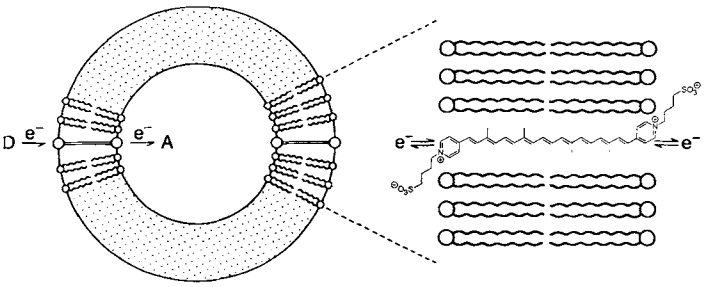


Fig. 4. Schematic representation of transmembrane electron transfer from a reducing agent (such as sodium dithionite) to an oxidizing agent (such as potassium ferricyanide) by a zwitterionic caroviologen such as **5b**, incorporated in the bilayer membrane of a phospholipid vesicle.

Thus, the caroviologen approach does produce *functional molecular wires* that effect electron conduction in a supramolecular-scale system. Incorporation into black lipid bilayer membranes (BLMs) should allow further investigations of the electron-transfer properties of these caroviologens.[46] Other approaches to molecular wires may also be envisaged (see below).

3.2.2. Polarized Molecular Wires

Conjugated polyolefinic chains bearing an electron-acceptor group on one end and a donor on the other end represent

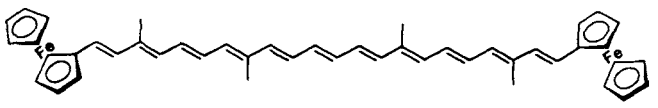
polarized molecular wires that should display preferential *one-way electron transfer* and act as a *rectifying component*.

Such molecules, donor–acceptor carotenoids (cf. Fig. 3), were prepared and shown to possess very pronounced *nonlinear optical properties* in powder form,[35] in solution,[36] or in Langmuir–Blodgett films[37] (see above). Oriented incorporation into vesicles and electron-transfer experiments might reveal one-way conduction by polarized molecules of this or similar type.

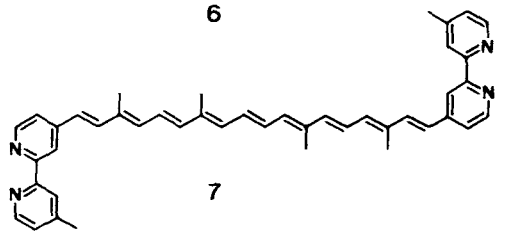
3.2.3. *Modified and Switchable Molecular Wires*

Modifications on the original $CV^{2\oplus}$ type of molecular wire may be made on the terminal groups or on the conjugated chain or on both. The carotenoid chain might be replaced, for instance, by extended dye systems, oligopyrroles, or oligothiophenes or strings of redox centers allowing electron "hopping". We first performed variations on the terminal groups.

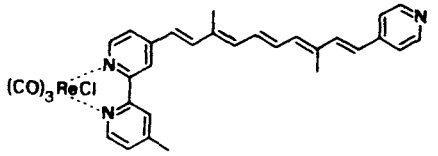
Carotenoid chains bearing ferrocene, 2,2'-bipyridine, and pyridine as terminal groups have been prepared (see **6** and **7**). Metal complex derivatives, such as **8**, were also obtained.[47a] These *metallocarotenate* type of molecular wires combine the rich electrochemical and photochemical activities of metal complexes with the long-range conjugation properties of carotenoid chains, thus leading the way towards systems capable of performing electro- or photoinduced very long range electron transfer (VLReT).[48] The redox-active ferrocene unit has also been introduced into donor–acceptor type conjugated systems (as in **9a** and **9b** or its metal complexes) to serve as donor center or redox switch.[47b]



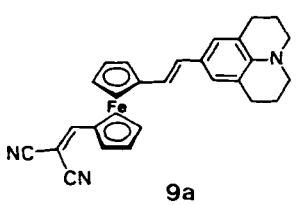
6



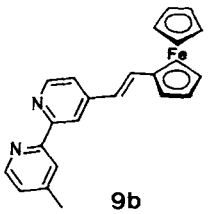
7



8



9a



9b

These types of compounds incorporate electro- and photosensitive switches at the end of or inside the conjugated chain and thus represent switchable molecular wires responding to external stimuli.

3.3. Molecular Ionic Devices

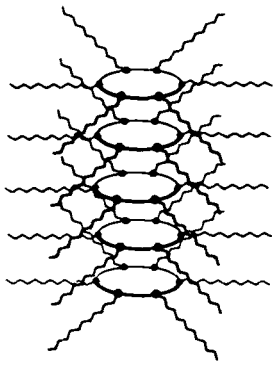
The vast amount of data available on selective ion binding and transport by a great variety of ligands and carrier molecules provides the basis for the design of molecular devices handling ionic species. The molecular recognition events involved may be directly related to information and signal processing by means of ions, as is the case in biology. Receptors containing light- or redox-sensitive groups[31] represent photo- or electro-switchable components responding to external physical stimuli and capable, for instance, of generating photoionic pulses.[49] Analytical devices based on ion binding and transport have been developed.[50]

On the basis of our work on ion binding, we have studied extensively ion transport by mobile carriers, together with its regulation by coupling to symport or antiport processes and to physical or chemical gradients.[51]

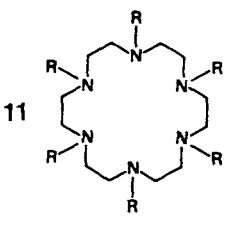
In addition to transport by mobile carriers, ion transfer may also be performed by selective ion channels. The design of such transmembrane channels has been much less explored, probably because of the inherently larger molecular structures involved, despite the fact that biological transport is thought to occur mainly via channel-type species. We have investigated various approaches to the design of ion channels and ion-responsive membrane systems.

3.3.1. *Tubular Mesophases*

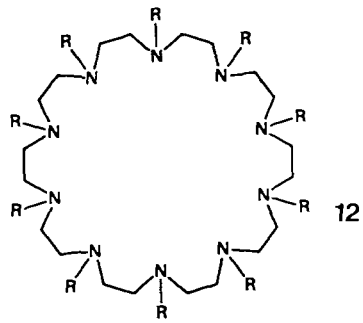
A stack of macrocyclic rings represents a molecular tube through which ions might flow, as illustrated by a solid-state model of such an ion channel.[52] Since in discotic liquid crystals, the spontaneous axial stacking of molecular discs



10



11



12

R = *p*-*n*-$C_{12}H_{25}O$-C_6H_4-CO

yields columnar mesophases, it appeared that if such phases could be obtained with ring elements, their arrangement in an axial stack would yield a hollow column, that is, a molecular tube (**10**). Macrocyclic polyamines bearing suitable side chains, such as **11** and **12**, indeed give *tubular mesophases* that contain stacks of macrocycles forming tubes.[53] Although the macrocyclic elements used at present are not well suited for ion binding, further elaboration could lead to ion channels that are phase (temperature) dependent.

3.3.2. *Ion-Responsive Monolayers*

Deposition of macrocycles bearing lipophilic side chains at the air–water interface could form Langmuir monolayers, thus yielding ion-responsive molecular films.

Indeed, macrocycles **11** and **12** form such monolayers.[53b, 54] Comparison of measured surface areas with molecular models indicated that the macrocycles were lying flat on the water surface while the aliphatic chains were tilted upright in the compressed film, as shown in Figure 5.[54]

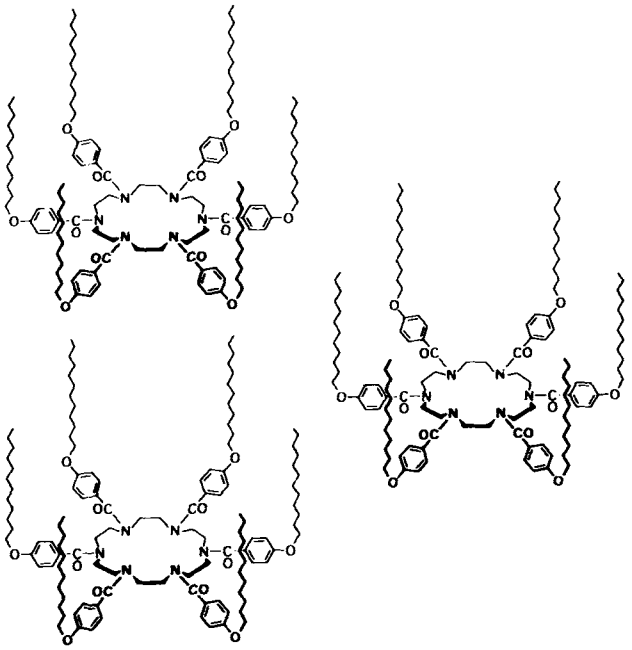


Fig. 5. Schematic representation of the arrangement of macrocycle **11** in a compressed film at the air–water interface; the aliphatic chains are represented in their fully extended form, but some curling may occur.

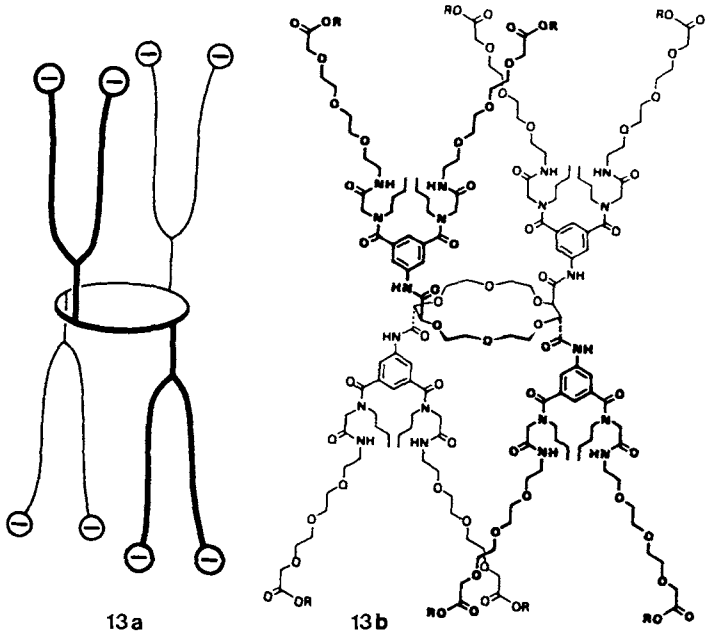
Such monolayers should be able to interact selectively with ions present in the subphase; this has been shown to be the case for monolayers formed of calixarene derivatives.[55]

Various developments may be envisaged, such as monolayers effecting molecular recognition at an interface (of interest, for instance, for selective detection) or ion-binding, electro- or photoactive films.

3.3.3. *The "Chundle" Approach to Molecular Channels*

A channel may also be defined by a bundle of transmembrane chains, formed either by the spontaneous association of individual molecules (e.g., the polymolecular channel formed by the peptide alamethicin[56–58]) or by grafting several chains onto a supporting unit such as a polyfunctional macrocycle that constitutes the organizing core, as represented by **13a**. This may be termed the *chundle* (or

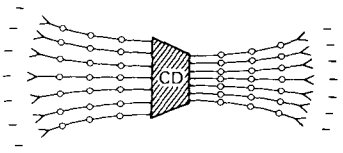


"bouquet") approach to a transmembrane *ch*annel based on a b*undle* of chains. Such an entity should present three main features: (1) two bundles of chains long enough to span half a membrane bilayer, (2) a central annulus serving both as support to maintain the two bundles of chains and as substrate-selection component, and (3) terminal polar groups for anchoring the molecule to each interface in a transmembrane fashion.

The synthesis of a chundle molecule, **13b**, has been realized.[59] Its structural features correspond to those desired for studies of chundle-type molecular channels: (1) the functionalized macrocyclic annulus possesses selective metal-cation binding properties; (2) it bears two axially oriented bundles of four oxygen-containing chains, which provide binding sites for metal cations and are long enough for the molecule to span a typical lipid membrane (the overall length with the chains in an extended state may be estimated to lie in the 45–50-Å range); (3) the eight terminal carboxylate groups allow for anchorage at water–membrane interfaces and transmembrane orientation, as well as for eventual coupling to proton gradients.

The octacarboxylate **13b** has been incorporated into model bilayer membranes.[60] The synthesis and properties of a related molecule based on a similar macrocyclic core have been reported.[61] Whether molecule **13b** is a functional cation channel is being investigated. Structural modifications may be required. In particular, the nature of the central annulus should be critical for rapid and selective ion flow. The alamethicin bundle contains a central annulus of hydrogen-bonded glutamine residues[57] which is much wider than the macrocyclic unit in **13b**, suggesting that a larger macrocycle may be required.

For this reason, a much bigger core was chosen for a second chundle-type molecule: β-cyclodextrin (β-CD), whose cavity diameter is about 6 Å. Selective derivatization by oligooxyethylene units (terminated, for instance, by a carboxylic group) should lead to a species such as that represented schematically by **14**.[62] Such a very large molecule bearing seven chains on each side of the rigid β-CD core has been obtained.[63] It is in itself of interest since, by its size, its internal space, and its chains, it represents a sort of *molecular vesicle*.



14

Because it is dissymetric, this β-CD chundle could act as an oriented transmembrane device. Its transfer selectivities might have analogies with those of the channel of the acetylcholine receptor. Physical, chemical, membrane-incorporation, and substrate-transfer properties of this and other β-CD derivatives will provide basic information about the handling and the behavior of very large functional molecular species. Whether or not the present or other chundle-type molecules do indeed act as ion channels, they should nevertheless allow the testing of approaches to channel design and to the handling of selective ionic conduction.

Incorporation of the molecular ionic devices described above into supporting structures (such as membranes, layers, and films) will allow the exploration of their functional properties and of their ability to produce ionic signals. Regulation of flow, switching, and coupling to other components will require further structural modifications.

4. Molecular Recognition and Self-Organization. Programmed Molecular Systems

Supramolecular chemistry has relied on more or less rigidly organized,[4, 10] synthetically built up, molecular receptors for effecting molecular recognition, catalysis, and transport processes. Beyond *pre*organization lies the design of systems undergoing *self-organization*, that is, systems capable of *spontaneously* generating a well-defined (functional) supramolecular architecture by *self-assembly* from their components under a well-defined set of conditions.[13b] It is *designed* assembly into a well-defined discrete supramolecular species, as compared to the spontaneous formation of molecular layers, films, membranes, etc. (see, for instance, Sections 3.3.1 and 3.3.2).[64 - 66] Self-assembly requires binding; self-organization additionally implies information. The *information* necessary for the process to take place and the *algorithm* (the "Aufbau" rules) that the process follows must be stored in the components and operate via selective molecular interactions. Thus, these systems may be termed *programmed molecular and supramolecular systems*[67] that generate organized entities following a defined plan based on molecular recognition events.[68] Self-organization represents a basic feature of supramolecular chemistry, since it rests on intermolecular interactions, whereas preorganization makes use of covalent bonding. Note also that it amounts to a (noncovalent) replication process at the supramolecular level.

Self-organization may occur in solution, in liquid crystalline phase, or in the solid state and make use of hydrogen bonding, electrostatic and donor–acceptor effects, or metal-ion coordination as basic interactions between the components, as well as of medium (solvophobic) effects. Multiple binding subunits are required, as present in polytopic coreceptors. The process may display positive cooperativity and lead to *molecular amplification devices*, if, once initiated, the subsequent steps of the assembly are facilitated. This can be the case for polytopic coreceptor molecules in which interaction between the multiple subunits, or substrate binding to them, occurs in such a way that each association step sets the stage for the following one.[3] Cooperativity may also be considered to present features of an *error filter* device.

Numerous biological supramolecular structures result from self-assembly, such as the spontaneous formation of the double helix of nucleic acids,[69] the viral protein coat,[70] and multiprotein complexes.[71]

We have pursued several approaches to self-organizing systems: (1) the formation of double-helical metal complexes, the *helicates*, from two oligobipyridine strands and suitable metal ions; (2) the generation of mesophases and liquid crystalline polymers of supramolecular nature from complementary components; (3) the molecular-recognition-directed formation of ordered solid-state structures.

4.1. Self-Organization of Double-Helical Metal Complexes: Helicates and Deoxyribonucleohelicates (DNH)

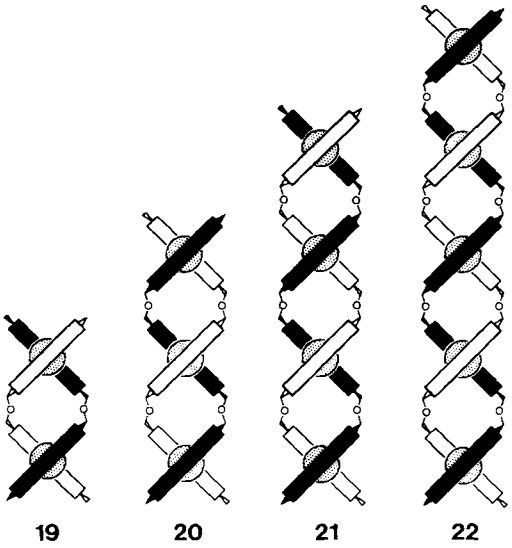
Self-organization may occur in repetitive chain ligands, acyclic coreceptors containing several identical binding subunits arranged linearly, if substrate binding to a given site is connected to binding to the other sites so that full site occupation is only compatible with a defined final architecture.

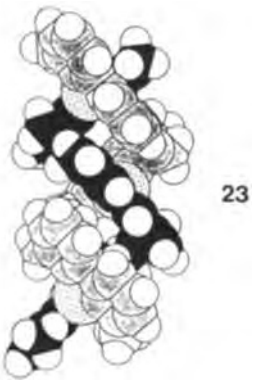
This is the case for the ligands **15**–**18** containing two to five bipyridine (bpy) groups. In the presence of Cu^{I} ions,

	X = H	X = COOR or $CONR_2$
n = 0	**15**	**24**
n = 1	**16**	**25**
n = 2	**17**	**26**
n = 3	**18**	**27**

spontaneous assembly takes place giving *double-stranded helicates*, ds-$\mathscr{H}$, in which two ligand strands are wrapped around each other in a double-helical fashion with Cu^{I} ions holding them together.[72 - 74] The di- to pentahelicates **19**–

22 have thus been obtained. Their *double-helix* structure rests on the determination of the crystal structures of **19**[75] and **20**[73] and on spectroscopic data. It results from the tetrahedral-like coordination imposed by each $Cu(bpy)_2^{\oplus}$ site and from the design of the ligands, which disfavors binding to only a single strand. These two features make up, respectively, the recognition process (the algorithm) and the molecular steric "program" that leads to preferential formation of the double-helical structures. In other words, helicate formation amounts to a tetrahedral reading of the molecular information stored in the bpy strands. Thus, only metal ions presenting the appropriate coordination features with bpy will yield double helicates. This has also been shown to be the case for Ag^I, which yields the tri-, tetra-, and pentahelicates, as confirmed by determination of the crystal structure of the silver trihelicate **23**.[76] On the other hand, the analogous





oligobipyridines containing two or three bpy units separated by a CH_2CH_2 group also yield the corresponding Cu^I helicates.[77] The formation of double helicates may be expected to occur only in a narrow range of coordination and structural parameters. Figure 6 shows a molecular model of the pentahelicate **22**.

Of particular interest is the finding that the helicate formation process appears to take place with *positive cooperativity*[73, 78] and with *self-recognition*,[73] a given ligand forming a double helix preferentially with an identical strand if a mixture of ligands is used.

Fig. 6. Molecular model of the pentahelicate **22** formed by self-assembly of two oligobipyridine ligands **18** and five Cu^I cations.

A major feature of this spontaneous generation of a double-helical structure is that it can be employed as an *organization framework*, allowing the arrangement in space in a double-helical fashion of substituents attached to the bpy units. To this end, the oligo-bpy strands **24**–**27**, containing substituents in 4,4′ position on the bpy groups, were synthesized.[79]

Especially attractive was the possibility to connect nucleosides, as has been realized, for instance, with the hexathymidine **28** and with the elongated and alternating strands **29** and **30**.[80] These compounds represent *artificial oligonucleosides*, which may interact with natural polynucleotides or nucleic acids. On treatment with Cu^I, **29** and **30** gave the double-helical complexes **31** and **32**, respectively, inside-out analogues of double-stranded nucleic acids which may be termed *deoxyribonucleohelicates* (DNH).[80] Since these species are positively charged and present the hydrogen-bonding base on the periphery, one may expect them to bind to both single-stranded and double-stranded nucleic acids with formation of mixed natural-artificial triple- and quadruple-stranded species.[81] Such interactions may present selectivities resulting both from the overall shape of the DNHs and from the thymidine groups. The DNH molecules **31** and **32**, which bear outward-oriented recognition sites, represent polytopic variants of exo-receptors of the metallonucleate type.[3] Figure 7 shows molecular models of the deoxyribonucleotrihelicate **31** (left) and its pentahelicate analogue **32** (right).

Of course, it is possible to organize numerous other units by means of the helicate framework, thus bringing together groups capable of conferring, for instance, energy-transfer, electron-transfer, or specific ion-binding features.

Finally, one may note that the dihelicate **19** has features reminiscent of the two homochiral components obtained in the "Coupe du Roi" (Fig. 8, left)[82] rendered in a sculpture by *Max Bill* (Fig. 8, right). The aesthetic features of the double helix have also been widely recognized (Fig. 9)!

4.2. Molecular-Recognition-Directed Assembly of Organized Phases

Molecular processes occurring in a material may induce marked changes in its properties. For instance, the interaction between molecular units that by themselves would not be mesogenic could lead to the formation of a supramolecular species presenting liquid crystalline behavior. If so, it might be possible to take advantage of selective interactions so that the mesogenic supermolecule would form only from complementary components. This would amount to *macroscopic expression of molecular recognition*, since recognition processes occurring at the molecular level would be displayed at the macroscopic level of the material by the induction of a mesomorphic phase that may be termed supramolecular and "in-formed", since it is conditioned by the molecular information present in its components. This has been accomplished in the generation of supramolecular mesophases and liquid crystalline polymers from complementary molecular units.

4.2.1. Mesophases Induced by Association of Complementary Molecular Components

The most common type of molecular species that form thermotropic liquid crystals possess an axial rigid core fitted with flexible chains at each end. One may then imagine a splitting of the central core into two complementary halves $\in$ and $\ni$, whose association would generate the mesogenic supermolecule, as schematically represented in Figure 10.

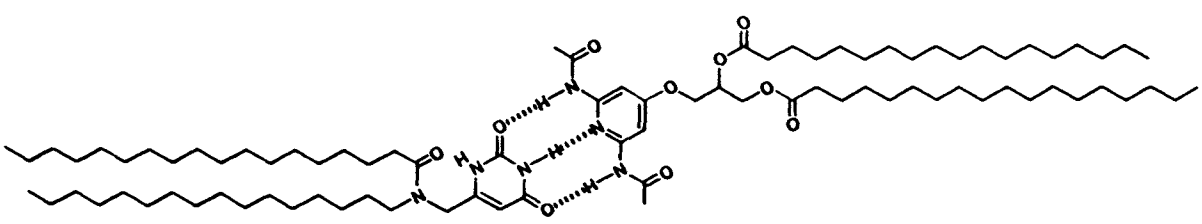
Fig. 10. Formation of a mesogenic supermolecule from two complementary components.

This was realized with derivatives of the complementary heterocyclic groups 2,6-diaminopyridine and uracil bearing long aliphatic chains.[83] Whereas the pure compounds did not show liquid crystalline behavior, 1:1 mixtures gave a metastable mesophase of columnar hexagonal type. Its existence may be attributed to the formation of a mesomorphic supermolecule **33** via molecular-recognition-directed association of the complementary components.

Numerous extensions may be envisaged, such as the introduction of various central cores, in particular those already known to yield molecular liquid crystals, the incorporation of light-sensitive or electrosensitive units, the potential use for detection devices, and the extension to various recognition components of biological nature.

4.2.2. Self-Organization of Supramolecular Liquid Crystalline "Polymers" from Complementary Components

If two (or more) complementary units $\in$ or $\ni$ are grafted on a template T, mixing $T\in_m$ with the complementary $T\ni_m$ may lead to the self-assembling of a linear or cross-linked polymeric supramolecular species ($T\in_m$, $T\ni_m$), whose existence is conditioned by the molecular-recognition-directed association between the $\in$ and $\ni$ groups. Figure 11 represents schematically such a process in the case of two-site (ditopic) complementary components $T\in_2$ and $T\ni_2$. The resulting supramolecular polymeric material, $(T\in_2, T\ni_2)_n$, may present liquid crystalline properties if suitable chains are introduced on the components.



33

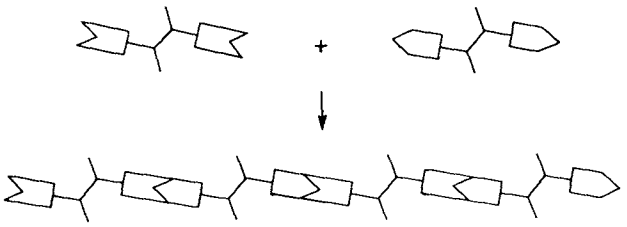


Fig. 11. Formation of a polymeric supramolecular species by association of two complementary ditopic components.

Condensation of the complementary heterocyclic groups 2,6-diaminopyridine (P) and uracil (U) with long-chain derivatives of L-, D-, or *meso*-tartaric acid gave substances LP_2, LU_2, MP_2, MU_2, etc., each containing two identical units capable of undergoing association via triple hydrogen bonding.[84] The pure compounds are solids exhibiting a more or less complex melting behavior due to solid-state polymorphism. In contrast, the 1:1 mixtures (LP_2 + LU_2) and (MP_2 + MU_2) display a *thermotropic mesophase* from below room temperature to above 200 °C. The material has the aspect of a highly birefringent glue that forms fibers under spreading.

It is reasonable to assume that the complementary units will form the expected triply hydrogen-bonded pairs, so that the entirely different behavior of the pure compounds and of the 1:1 mixtures may be attributed to the spontaneous association of the complementary components into a polymolecular entity based on hydrogen bonding. The overall process may then be described as the *self-assembling of a supramolecular liquid crystalline polymer* based on molecular recognition. The resulting species, $(LP_2 + LU_2)_n$, is represented schematically by structure **34**.

The X-ray patterns show that the two materials obtained from the configurational isomers of tartaric acid have different structures. Both are hexagonal columnar mesophases, but, whereas the data for $(LP_2, LU_2)_n$ are consistent with columns formed by three polymeric strands having a triple-helix superstructure (Fig. 12), those for the $(MP_2, MU_2)_n$ mixture fit a model built on three strands in a zigzag conformation. One may note that these species also represent self-assembled molecular tubes. The LD mixture has yet another arrangement. These three materials make clear the profound influence of chirality on the superstructure formed.

The results above show that it is possible to engineer molecular-recognition-dependent liquid crystals based on mesogenic supermolecules formed by association of complementary components.[85] Furthermore, molecular species that may form liquid crystalline *polymers* of *supramolecular* nature (or mesomorphic polymolecular associations)[86] may be obtained by the *self-assembly* of complementary subunits, thus expressing the recognition process occurring on the molecular level via the formation of a macroscopic mesophase.

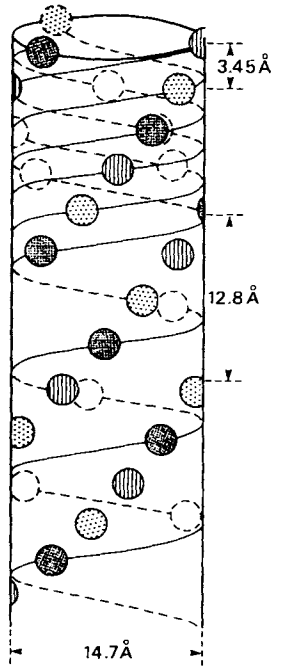

Fig. 12. Schematic representation of the columnar triple-helical superstructure derived from the X-ray data for $(LP_2, LU_2)_n$; each spot represents a PU or UP base pair; spots of the same type belong to the same helical strand of the triple helix; the dimensions are compatible with an arrangement of the PTP and UTU components along the strands indicated (see also **34**); the aliphatic chains stick out of the cylinder, more or less perpendicularly to its axis; a single helical strand and the full triple helix are represented, respectively, on the bottom and at the top of the column.

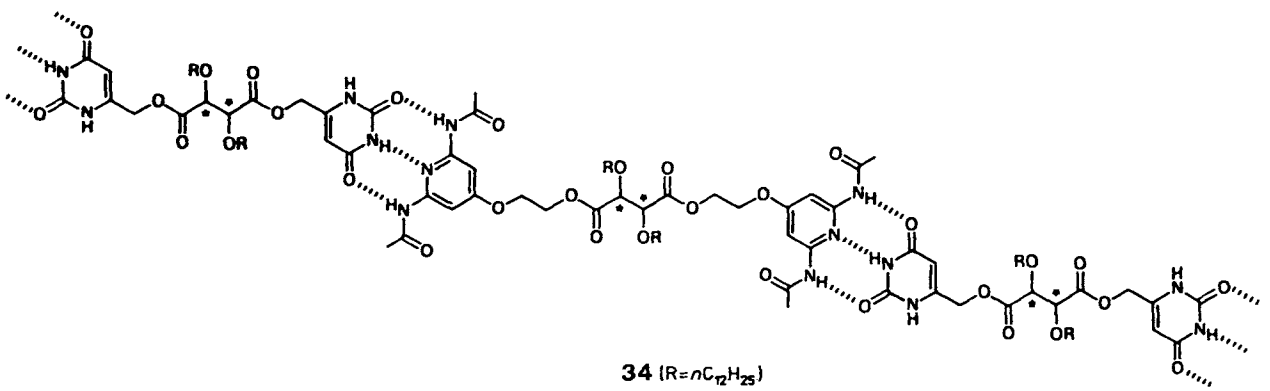
These effects amount to a macroscopic reading of molecular information via a phase change which, being a highly cooperative process, also corresponds to an *amplification* of molecular recognition and information from the microscopic to the macroscopic level.

4.2.3. Supramolecular Automorphogenesis

Control over the generation of molecular shapes and architectures may rely on covalent bond formation (covalent



34 (R=$nC_{12}H_{25}$)

or molecular morphogenesis).[3] This is the case for polymeric oriented systems derived from molecular assemblies[87] and for branched structures formed via cascade processes growing from a central core, as realized in "starburst dendrimers"[88] and "arborols".[89]

On the other hand, it may be possible to achieve the spontaneous generation of supramolecular shapes by self-assembly of complementary molecular components. This represents a recognition-dependent *automorphogenesis* of supramolecular nature, based on noncovalent, intermolecular bonding. It should open paths to the controlled self-organization of polymolecular shapes, architectures, and patterns (for instance, in molecular layers).

4.3. Molecular-Recognition-Directed Self-Assembly of Ordered Solid-State Structures

The architectural and functional features of organized supramolecular structures result from the molecular information stored in the components and from the active groups which they bear.

A simple and general concept for generating molecular order is based on the recognition-directed spontaneous assembly of a supramolecular strand from complementary molecular components, each of which presents two identical recognition sites (Fig. 13). The interaction of two such units

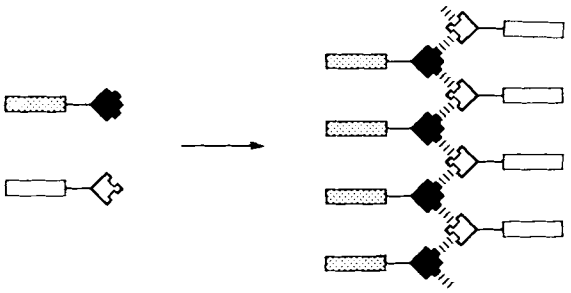


Fig. 13. Schematic representation of the formation of an ordered supramolecular strand by the molecular-recognition-induced association of two different molecular units. Each unit contains a group that possesses two identical binding sites complementary to those of the other unit.

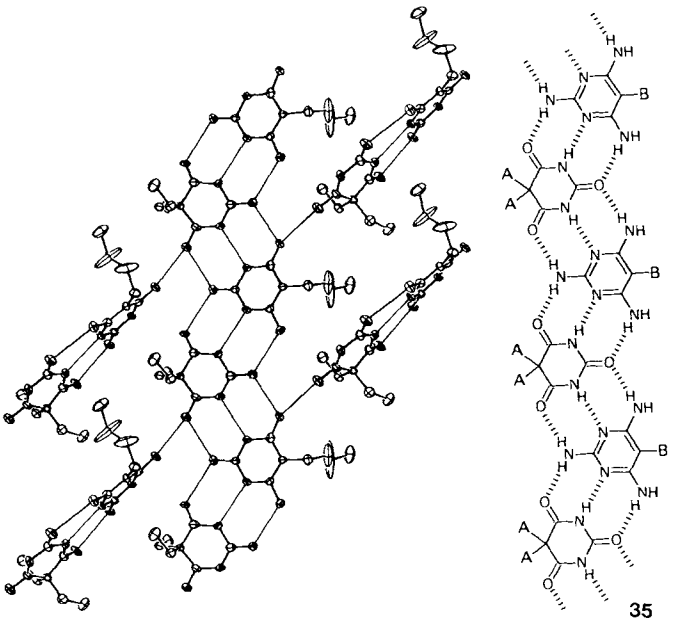
may generate organized polymolecular strands in solution, in a mesomorphic phase, or in the solid state by cocrystallization. In the latter case, recognition-based crystal engineering may allow the structural design of organic solids.[90, 91] All residues of the same type are expected to be located on the same side of the strand (Fig. 13), thus providing spontaneous like/unlike *sorting* (into two substrands) and *orientation* of the molecular components in the supramolecular arrangement.

2,4,6-Triaminopyrimidine and barbituric acid derivatives are complementary components presenting the required features, since they should be able to form *two* arrays of three hydrogen bonds with each other. Mixtures of the two species gave indications for association in solution and formed 1:1 mixed crystals by cocrystallization.

The crystal structure of such a compound showed that the components are arranged in mixed supramolecular strands in which each unit forms six hydrogen bonds with its two complementary neighbors, as schematically represented by structure **35** (Fig. 14). As a consequence of molecular recognition, expressed by the hydrogen-bonding pattern between the two components, *all like residues* A and B are indeed located on the same side of the strand.[92]



35

Fig. 14. X-ray structure (left) of the cocrystal of the 1:1 species (right) formed by two complementary components derived from barbituric acid (A = ethyl) and 2, 4, 6-triaminopyrimidine (B = butyl).

Thus, the recognition interaction between the present complementary components spontaneously induces molecular sorting of like/unlike species and generates long-range order, orientation, and left/right differentiation at the molecular level. The process may be considered as the operation of a programmed molecular system that contains the information required for the self-organization of precisely this supramolecular architecture. The species formed represents a kind of self-assembled "ladder" polymer of supramolecular nature. The solid is thus a supermolecule, a very large supermolecule indeed (this applies to molecular solids in general).

The arrangement produced may impart specific properties to the material at the macroscopic level. If the barbituric unit is regarded as the "assembler" component, mixing it with a triaminopyrimidine derivative should automatically lead to the generation of an *oriented* arrangement of functional B groups along a strand, thus offering the opportunity of inducing novel properties (optical, electronic, ionic, magnetic, etc.). For instance, such a process may allow the designed engineering of cocrystals of organic molecules exhibiting nonlinear optical, electron-transfer, or energy-transfer properties.

Other basic recognition units could give rise to numerous patterns (ribbons, rings, cylinders, strips, belts, friezes, etc.), leading to a recognition-based "molecular patterning". It is of particular interest that the self-assembly of such supra-

molecular species also occurs in solution, thus providing self-organization in the fluid state.[93]

Molecular-recognition-directed processes thus provide a powerful entry into *solid-state engineering*.[90, 91] Modification of surfaces with recognition units leads to extended exo-receptors that could display selective surface binding on the microscopic level and to *recognition-controlled adhesion* on the macroscopic scale.

The design of molecular-information-dependent, *informed*, and functional self-organizing systems reveals new horizons in supramolecular chemistry. The possibility of *"intelligent"*, functional supramolecular materials, network engineering, and polymolecular patterning makes such systems the subject of increasing activity in chemical research.[3, 94]

5. Chemionics. Outlook

The chemistry of molecular components and devices that operate on photons, electrons, and ions defines areas—molecular photonics, electronics, and ionics—of a broad field which may be termed chemionics.[3]

Substances such as the caroviologens **5**, the chundle **14**, and the helicate **22** are of rather large size, entering the nanometric domain. They are members of the class of *organized and functional nanostructures*, synthetically constructed or self-assembled species possessing features suitable for the design of molecular and supramolecular devices.[95] The increasing size of such molecules and supermolecules leads to species of nanometric dimensions defining a *nanochemistry* that works its way upward towards microlithography and microphysical engineering, which, by further and further miniaturization, strive to produce ever smaller elements.

The processing of molecular information via molecular recognition events implies the passage from the molecular to the supramolecular level. Recognition-directed processes may be expressed at the macroscopic level by the formation of mesophases or of ordered solid-state structures, or by the generation of an optical, electronic, or ionic signal.

The reading of molecular information as well as the operation of molecular devices requires ways and means of *addressing* molecular and supramolecular species. Despite the problems and difficulties that one may apprehend, encouraging perspectives are offered, for instance, by the recent demonstration of tunnel diode effects on an atomic scale,[96] of optical absorption spectroscopy on nanometer dimensions,[97] and of single-atom positioning[98] using scanning tunneling microscopy, or the display of a light source smaller than the optical wavelength.[99]

Endowing photo-, electro-, or ionoactive components with recognition elements leads to programmed molecular systems capable of molecular-recognition-directed self-assembly into organized and functional (photonic, electronic, ionic) supramolecular devices. Cooperative processes display amplification and represent error filters. Thus, *chemionics* is the chemistry of recognition-directed, self-organized, and functional entities of supramolecular nature (Fig. 15), which may eventually be capable of replication. It points to a *molecular information science*, molecular *informatics* and *semiochemistry* involving information and signal processing and communication at the molecular and supramolecular levels.

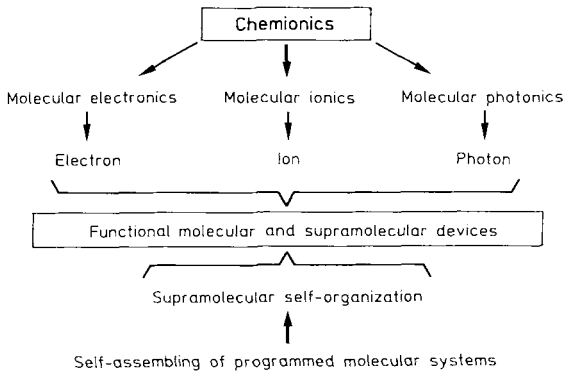


Fig. 15. Chemionics as the chemistry of recognition-directed and self-organized photonic, electronic, and ionic molecular and supramolecular devices.

6. Conclusion

The development of supramolecular chemistry involves a more and more complete control over molecules, supermolecules, and materials. Although many studies are concerned with substances of biological or biomimetic type, the emphasis is definitely on abiotic, non-natural species, figments of the imagination of the chemist, which possess a desired chemical, biological, or physical property.

Such an evolution rests on a definite outlook: the elaboration of *strategies towards properties and functions*[4] rather than towards structures, the goal being to express a desired property in a molecule or a material, whatever the composition and structure of the substance.

This opens wide the door to the creative imagination of the chemist at the meeting point of chemistry with biology and physics, in order not only to discover but above all to *invent*, to *create*: the score of chemistry is not just to be played but to be composed!

The essence of chemical science thus finds its full expression in the words of *Leonardo da Vinci*: "Where nature finishes producing its own species, man begins, using natural things and in harmony with this very nature, to create an infinity of species."

I wish to express my warmest thanks to my collaborators at the Université Louis Pasteur in Strasbourg and the Collège de France in Paris who have performed the work described above.

Organic Synthesis—Where now?

By Dieter Seebach*

This review article is an attempt to sketch the important developments in organic synthesis during the past 25 years, and to project them into the future.—The primary motivations that once induced chemists to undertake natural product syntheses no longer exist. Instead of target structures themselves, molecular function and activity now occupy center stage. Thus, inhibitors with an affinity for all the important natural enzymes and receptors have moved to the fore as potential synthetic targets.—New synthetic *methods* are most likely to be encountered in the fields of biological and organometallic chemistry. Enzymes, whole organisms, and cell cultures for enantioselective synthesis of specific substances have already been incorporated into the synthetic arsenals of both research laboratories and industry. In addition, designing appropriate analogues to transition states and intermediates should soon make it possible, with the aid of the mammalian immune system and gene technology, to prepare catalytically active monoclonal antibodies for almost any reaction; perhaps more important, such processes will increasingly come to be applied on an industrial scale.—The discovery of truly *new* reactions is likely to be limited to the realm of transition-metal organic chemistry, which will almost certainly provide us with additional "miracle reagents" in the years to come. As regards main group elements ("organoelemental chemistry"), we can surely anticipate further stepwise improvements in experimental procedures and the broader application of special techniques, leading to undreamed of efficiency and selectivity with respect to known procedures. The primary center of attention for all synthetic methods will continue to shift toward catalytic and enantioselective variants; indeed, it will not be long before such modifications will be available with every standard reaction for converting achiral educts into chiral products.—Analysis, spectroscopy, structure determination, theory, and electronic data processing have all become indispensable in organic synthesis. Only with the aid of these "tools" will the methods of organic chemistry permit selective syntheses of ever larger and more complex systems on both the molecular and supramolecular levels.—Examples have been introduced throughout this discourse to illustrate its many themes, and a very comprehensive bibliography should help the interested reader become more familiar with important keywords and authors.[**] This article will have served its intended purpose if it changes the minds of some of those who claim organic chemistry is a *mature science*, and if it causes students to discover the vitality and forcefulness with which organic synthesis is meeting new challenges and attempting to fulfill old dreams.

Er zeigt uns so in seinem wissenschaftlichen Leben, daß die Chemie nicht von einer *Theorie, nicht von* einer *Methode aus zu erschöpfen ist, und daß Erkenntnis und Nutzen in ihr untrennbar verwoben sind.*[***]
R. Koch, writing about Louis Pasteur

1. Introduction—a Difficult Subject!

1.1. On the Problems Associated with Prognostication

One can certainly plan research,
but not the results!
(Addressed to all those engaged in the distribution of research grants!)

The task I have set myself, ten years before the end of the present century, is to take inventory of the field of organic chemistry and attempt to discern the nature of some of the developments that lie ahead.

It is obviously impossible to review such a broad topic in the space available without imposing certain limits. To begin with, all my prognostication is subject to the bounds imposed by one general consideration that arises out of the very nature of scientific progress, which results from a combination of discovery, invention, development, and explanation. By definition, a *discovery* is something totally unexpected—even to the discoverer. Thus, Columbus set out in search of a route to India, but instead *discovered* America. If one accepts the premise that organic chemistry entails discoveries, then one is also compelled to be somewhat wary of predictions. On the other hand, impending inventions, explanations, and especially developments often *can* be foreseen through careful analysis of current trends and application of the time-tested scientific principle of extrapolation.

One additional imponderable is the effect of outside influences on the development of the discipline. No one in the mid-1960s would have anticipated the impending precipi-

[**] The list of references is also available upon request in the form of a Microsoft Word* file on diskette.

[***] "He showed us through his scientific life that chemistry cannot be exploited fully with the aid of a *single* theory or a *single* methodology, and that it is a field in which knowledge and application are inextricably linked." G. Bugge: *Das Buch der großen Chemiker, Vol. 2*, 4th reprint, Verlag Chemie, Weinheim 1974.

tous decline in United States dominance of the field of mechanistic physical organic chemistry, which was in part a consequence of research-political decisions by the National Institutes of Health at the end of the decade to limit funding more strictly to health-related projects. Japan illustrates how quickly a new nation can come onto the playing field and completely change the course of the game. Thus it is tempting to hope that the forthcoming steps toward European unification will eventually produce a system of elite universities like those in the USA, which would be in a position to attract the most talented minds in a population reservoir of nearly 300 million.

There is one other limitation that must be recognized with respect to the present endeavor, and it relates directly to the author himself. I have necessarily treated the subject from my own personal vantage point, which reflects my particular range of experiences. This in turn implies an emphasis on organic *synthesis*, and a time span of direct observation encompassing only 25 years. Nevertheless, a quarter of a century should more than suffice, and synthesis is certainly at the center of the discipline. No matter what the narrow goal of any particular project, whether the work involved is groundbreaking or of a more routine nature, synthesis and analysis are crucial to every chemist's activities.

1.2. Organic Chemistry in Crisis?

The biologists usually pick out the raisins, while the chemists are left to do the foot-work.
(The observation of a young researcher immediately after a postdoctoral experience in a research group concerned with the chemistry of DNA)

We are all very much aware of the fact—and also partly responsible for it!—that chemistry has a rather poor reputation in the media and within the public generally.[1] Even so, it is somewhat surprising to see an educated layman like the editor of *Nature*, *John Maddox*, declaring[2] that chemistry as a discipline has lost its identity, and citing as evidence the fact that the 1985 Nobel Prize for chemistry was actually awarded to two mathematicians.[3] It is also sad to find respected colleagues referring to organic chemistry, and specifically to organic synthesis, as a "mature" science.[4] There is no way this remark can be regarded as anything but an expression of resignation, of self-pitying nostalgia—indeed, as evidence of a "drop-out" mentality. A more accurate diagnosis would focus on the fact that discrete boundaries no longer exist between the various natural sciences (mathematics, physics, chemistry, biology, medicine) and especially between related subdisciplines (in this case inorganic, biological, organic, and physical chemistry). This has been the case for a long time in the world of applications, and it is just as true along the frontlines of research. Chemistry has not lost its identity: it has instead gained important footholds within the domains of other disciplines—albeit rarely at the initiative of chemists. Most of the real advances in the field of biochemistry, and increasingly in medicine as well, result directly from a deeper understanding of the processes of life at the molecular and supramolecular levels, and they must clearly be numbered among the accomplishments of chemistry. What is DNA sequencing[5] if not the structural analysis of a macromolecule? Is a DNA-[6, 7] or peptide-synthesizing machine[8] anything more than an automaton for repetitively carrying out a particular series of high-yield synthetic steps, always relying on the same reagents and very similar subunits? In the field of polymers, block polymerization via O-silyl ketene acetals (intermediates that were developed originally for organic synthetic purposes) has led to materials with very remarkable properties,[9] and careful introduction of "functional groups" has made it possible to use chemical reactions and the resulting covalent bonds as a way of binding surfaces together.[10] It is also appropriate to point to the recent synthesis of palitoxin,[11] a substance with 68 stereogenic units; organic synthesis has been responsible for a number of monumental breakthroughs in the pharmaceutical industry, contributing daily to the saving of countless lives.

In summary, the crass contradiction between the accomplishments and the reputation of chemistry, of which organic synthesis and its industrial applications constitute a significant part, can only be characterized as remarkable.[12, 13]

That which follows is a descriptive look at the current goals of organic synthesis; recently developed approaches to the purification, isolation, and identification of organic substances; key considerations in the development of improved techniques and in research into synthetic methodology; new insights gained through further investigation of classic reactions; and a few industrial applications drawn from the field of pharmaceutical synthesis. The selection is a *very* personal one, based on a much larger pool of potential examples, but it should nevertheless demonstrate quite clearly the vitality and ferment that characterize organic chemistry and organic synthesis in our day.[14]

2. Old and New Target Structures in Organic Synthesis—Not Simply a Matter of Fashionable Trends!

La chimie crée son objet. Cette faculté créatrice, semblable à celle de l'art lui même, la distingue essentiellement des sciences naturelles et historiques.[*]
M. Berthelot (1860)

2.1. From Natural Products to Supramolecular Structures

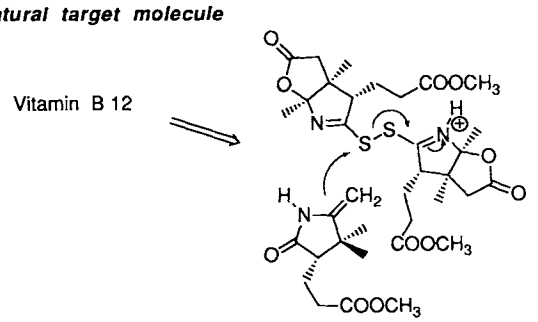
New synthetic methods have traditionally emerged from one of two sources: a) the deliberate attempt to perfect a known reaction or invent a new one in order to permit the preparation of a specific target molecule, which may be either a natural product or some structure that so far exists only in the imagination, or b) studies of the reactivity of some new class of carbon derivatives (organo*metallic* compounds, perhaps, or the more classical "organo*elemental*" substances). To these traditional sources of innovation we

[*] "Chemistry creates its own object. This creative power, similar to that of the arts, distinguishes it fundamentally from the natural and historical sciences."

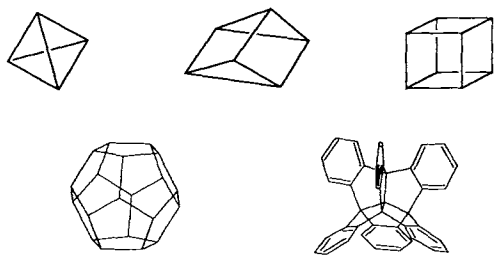
must add, thanks to the initiative of *E. J. Corey*,[15, 16] c) the directed search for reactivity, including attempts to realize specific desirable synthetic transformations (an approach that gave birth to the terms *synthon*,[17] *retron*, and *transform*[16]), as well as systematic *umpolung* of known modes of reactivity.[18] A few examples taken from these three distinct breeding grounds are presented in Scheme 1.

The most celebrated aspect of synthesis has been the preparation of ever larger and more complex natural products, an endeavor in which creativity, intelligence, and endurance are prerequisites to success. The masters of the art have been immortalized in classic achievements, and their names can be found not only in the annals of chemistry but also among the ranks of Nobel Prize winners.[36–45] Through their efforts, we have come to believe (like them) that virtually any molecule is amenable to synthesis. Together with non-natural products chemists as well as the pioneers of synthetic methodology and elemental (i.e., "main group") organic chemists generally, they managed to discover almost every reaction there was to find; indeed, only transition-metal organic chemistry can still be regarded as a fertile field for synthetic surprises (see Sec. 6 below). Moreover, almost everything the study of unusual molecules could teach us about the nature of the chemical bond has probably already been learned. In other words, all the most important traditional reasons for undertaking a synthesis—proof of structure, the search for new reactions or new structural effects, and the intellectual challenge and pride associated with demonstrating that "it can be done"—have lost their validity. Exceptions[46–51] only prove the rule (cf. Scheme 2).

Natural target molecule

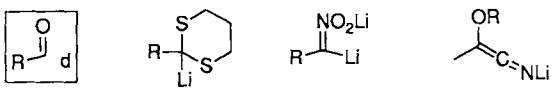


Non-natural target molecules

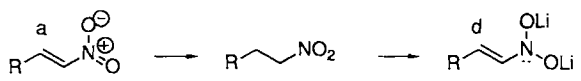


Olefination of a carbonyl compound

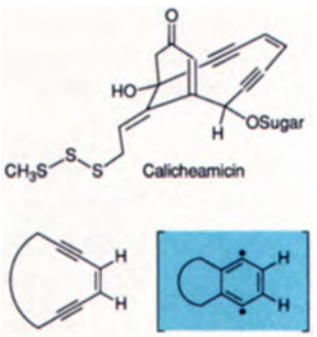
Synthetically equivalent reagents



Umpolung of nitroolefin reactivity



Scheme 1. New synthetic methods have arisen as "by-products" of natural product syntheses (sulfide contraction [19, 20]), as well as in the course of preparing such unusual, non-natural substances as tetrahedrane [21], prismane [22], cubane [23], dodecahedrane [24], and centrohexaindane [25]. Olefinations have resulted from a preoccupation with heteroatom-substituted organometallic reagents [26–30]. Nucleophilic acylation via dithianes [31], doubly metallated nitroalkanes [32] or cyanohydrin derivatives [33, 34], and umpolung of a nitroalkene to a super-enamine [35] all owe their discovery to systematic searches.



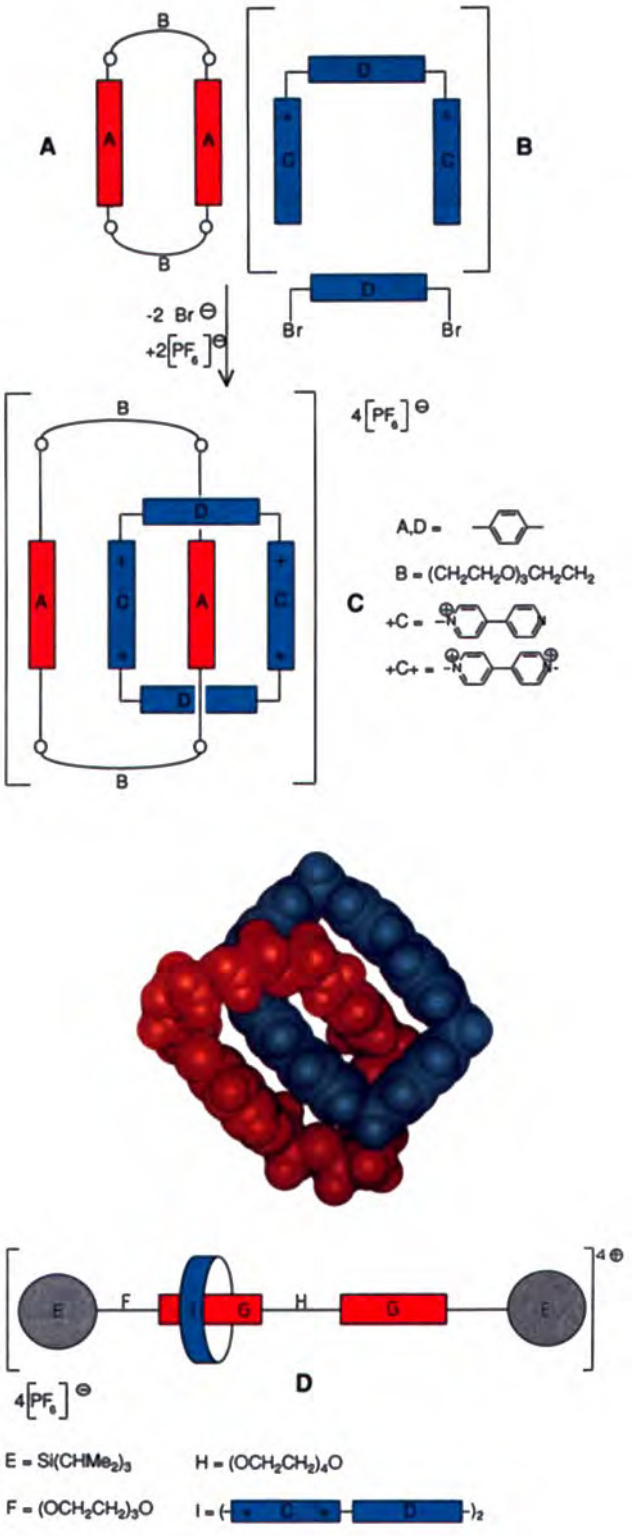
Scheme 2. A novel natural product system containing the *cis*-en-diyne moiety. Several derivatives with this characteristic skeleton have now been isolated (neocarcinostatin [46], esperamycin [47a], calicheamicin [47b], dynemicin A [47c]). The high antitumor activity of these compounds is based [48] on an elegant initiation of the illustrated ring-closure reaction to give an aromatic diradical (1,4-dehydrobenzene [49]), which reacts with a nucleotide unit of DNA to cause chain cleavage. Numerous synthesis-oriented research groups in the USA are busy trying to develop a synthesis of this natural system, and especially of simpler analogues [50].

Attempts are often still made to synthesize natural products with interesting biological properties or pharmacological activity, compounds unavailable from natural sources in quantities sufficient for thorough biological testing, but here there is an important financial motivation: such an effort stands a good chance of attracting research funds, either from government or industry. Multistep syntheses could also be said to provide the broadest possible training for graduate students in organic chemistry, and they certainly represent ideal preparation for jobs in the pharmaceutical industry, but sponsoring a project for this reason amounts to the fulfillment of a teaching responsibility rather than a commitment to the conduct of basic research within a university environment.[52a] In short, it really should come as no surprise that someone not prepared to adapt to new kinds of goals might refer to organic chemistry as a *mature* science.[52b]

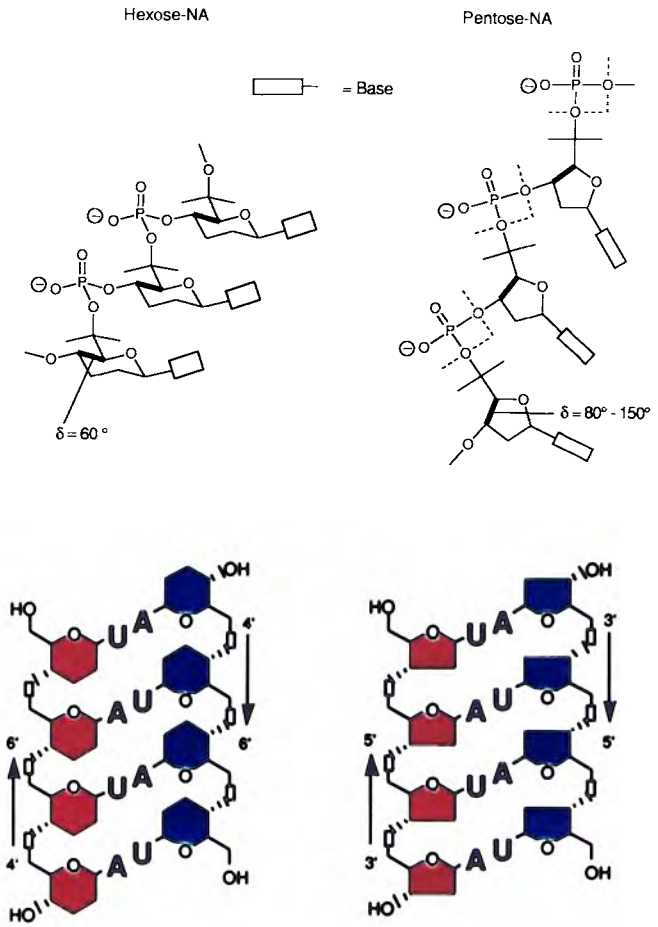
How can we characterize the new generation of appropriate target structures for organic synthesis? In answering this

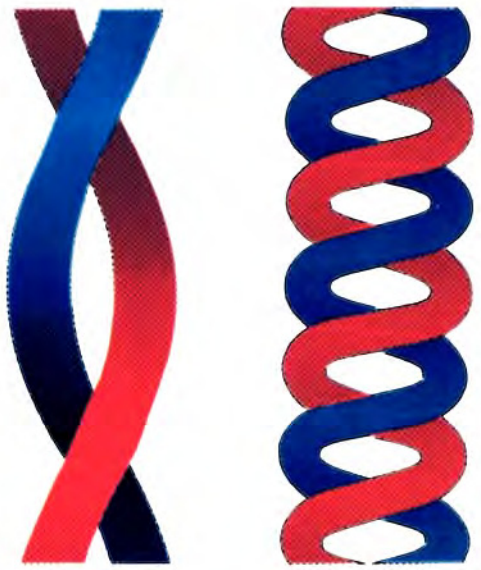
question it is useful to consider an observation of one of my colleagues in Zürich, a theoretical physical chemist who remarked during a 1982 lecture to the local chemical society: "Nowadays, the molecular program of chemistry has arrived at its successful termination" (*H. Primas*). What he meant is that research should no longer be directed primarily toward areas that lend themselves to treatment by simple molecular models. Instead, we should take the risk of attacking more complicated systems, ones whose structures and properties are determined by non-covalent interactions. This is precisely the shift in emphasis that has occurred in organic chemistry. In all aspects of the discipline—target structures, analysis, synthetic methodology, mechanistic investigations—discussions now tend to revolve around topics such as molecular recognition; supramolecular chemistry (or "supermolecules", to use *Lehn*'s terminology);[53] inclusion compounds (clathrates);[54] self-assembly, self-organization,[53, 55] even the self-reproduction or self-replication[56] of structures. Titles of lectures and publications now regularly include expressions like host–guest,[57] intertwining molecular threads,[58] information storage and processing,[53] molecular architecture,[59] molecular hole burning,[60] molecular computers,[60] molecular devices,[53] molecular cybernetics,[61] molecular cavities and clefts,[62] molecular Lego,[60] molecular mechanisms of biomineralization,[63] molecular robots,[12b, 64] molecular slits,[56] molecules within molecules,[57] nanochemistry,[53] programmed molecular systems,[53] spontaneous structure generation,[53] starburst dendrimers (control over size, form, and surface),[65] synzymes,[62, 66] template-associated synthetic proteins,[67] triple-helix formation in the non-enzymatic cleavage of DNA,[68] and van der Waals molecules.[57] The names of some of the key players on this new stage can be identified with the aid of the cited notes and literature references. An impressive example illustrative of the modern approach, particularly from the standpoint of "classical" catenane and rotaxane syntheses,[69] is summarized in Scheme 3. Scheme 4 compares the structure of the recently synthesized homo-DNA with that of normal DNA. Scheme 5 shows two self-orienting double helices in which bipyridyl–metal complex formation assumes the role of the familiar base-pairing interactions in DNA.

The exciting synthetic targets today are no longer molecules to be prepared "for their own sake"; instead, they are systems associated with particular functions or properties (cf. Scheme 6). Organic chemists are busy designing new materials,[10, 73, 74] and not only within the context of polymer chemistry,[9, 75] which—except in the case of certain biopolymers—is concerned largely with the preparation and investigation of products that show a Gaussian distribution in molecular weight. The molecular "design" of a (super)-structure[76] now captures the spotlight, while the synthetic process itself may withdraw into the background. The very simple organic reactions often turn out to be appropriate for the purpose of synthesizing such structures: acetal formation, alkylation, etherification, esterification, the formation of amides and sulfamides, or electrophilic aromatic substitution. Nevertheless, it will still be the chemists skilled in synthesis who will succeed in preparing the most interesting targets and exploring the most challenging themes, also in this area!

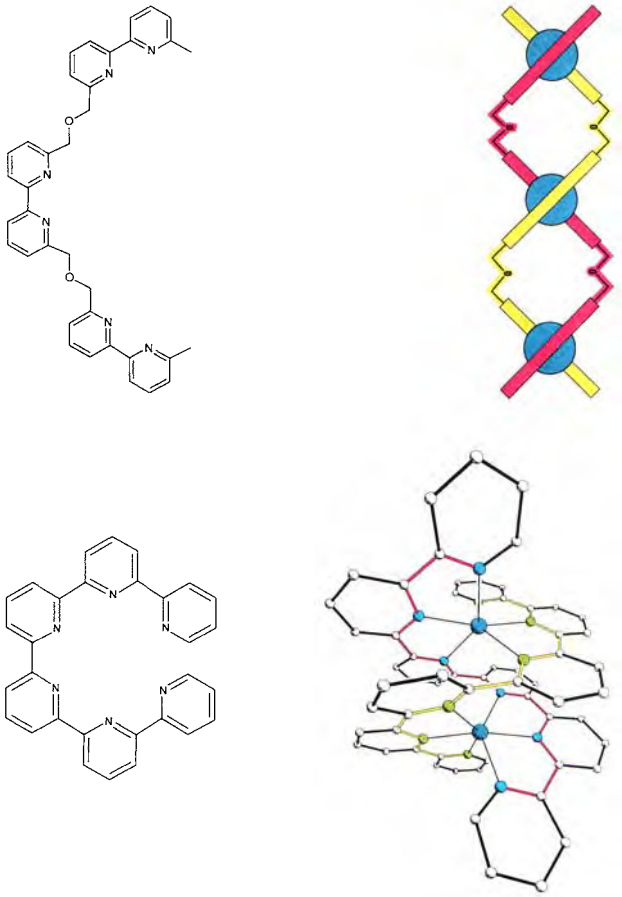


Scheme 3. "Self-assembly" of a catenane and a rotaxane (the authors employ the term *fabrication*) [60]. The O–*p*-phenylene–O units (O–A–O) of the macrocyclic ether **A** "bind" the two *p*-bis(pyridinium) units (+ C) of **B**, one inside the ring and the other outside. This causes the two pyridine nitrogen atoms to be kept in close proximity, so they can be joined using dibromo-*p*-xylene to provide, in 70% yield, the catenane **C**. The crystal structure of **C** displays not only a layer-like packing of donor and acceptor aromatic units but also "edge-to-face" interactions [70] between benzene rings A and benzene rings D. A similar synthesis of a simple catenane was accomplished starting with components held together by metal complexation [58]. Rotaxane **D** [60] was constructed using the same principle that was applied to catenane **C**. Back-and-forth motion of ring **I** [a bis(pyridinium) dication unit] between the *p*-phenylene units **G** has been verified by NMR spectroscopy ($\Delta G^{\neq} = 54.3$ kJ mol^{-1} in [D_6]acetone). The authors [60] call the system a "molecular shuttle".





Scheme 4. An oligonucleotide that contains bis(desoxy)glucose (left) in place of the usual desoxyribose (right) carbohydrate units [55]. Perfect staggering about *all* the single bonds in the hexose derivative results in an inherently linear chain, along which the bases are arranged in parallel array. The tetrahydrofuran ring of DNA is characterized by incomplete staggering, leading to an intrinsically helical chain and greater conformational flexibility ("pseudorotation"). The most distinctive features of homo-DNA relative to normal DNA include stronger complexation between the strands, a much longer helix pitch, and pairing rules that differ from the Watson–Crick rules.



Scheme 5. "Inorganic" double helices constructed from doubly methylated, CH_2–O–CH_2-bridged bipyridine ligands and copper(I) ions (top) [53] or sexipyridine and cadmium(II) ions (bottom) [71]. In the first case it has been shown that (a) complex formation is attributable to positive cooperativity, (b) the mixing of bipyridine ligands with differing numbers of bpy units leads to "self-recognition" (i.e., complexes containing two ligands of the same length are favored), and (c) introduction of chiral substituents into one pyridine ring of a bpy unit causes preferential formation of one of the two possible enantiomeric helices (diastereoselectively!). In the second case, the double helix is probably stabilized by stacking interactions between superimposed pyridine rings. One of the ligands (top) was prepared by etherification, the other (bottom) through a Kröhnke reaction [72].

Molecules with the following

Form:		Function:	
- ball bearings	- knots	- abacuses	- nuts and bolts
- beads and threads	- ladders	- capacitors	- resistors
- belts	- nets	- catalysts	- screws
- cages	- springs	- circuits	- semiconductors
- chains	- stacks	- clocks	- sensors
- chimneys	- strips	- conductors	- shuttles
- clefts	- washers	- dynamos	- superconductors
- coils	- wires	- membranes	- switches
- collars		- motors	

Scheme 6. *Stoddart*'s list of objects and functions that are familiar from everyday life and for which he has proposed equivalents at the molecular level. (Taken from a lecture delivered by Prof. *Stoddart* at the ETH Zürich, 5 February 1990) [60].

2.2. Concerning Inhibitors, Suicidal Substrates, and Flustrates

Für die Biochemie braucht man mindestens so viel organische Chemie wie für die organische Chemie.[*]
L. Ruzicka (1964)

Another important new type of synthetic target is related to the active centers of biological catalysts (enzymes, receptors, transport and channel proteins, ribosomes). Recently there has been an explosive increase in the number of proteins whose structures have been characterized, proteins taken from throughout the realm of nature, beginning with viruses and proceeding through microorganisms, plants, and animals, all the way to man. This development can be attributed primarily to advances in gene technology and to modern methods of structure determination. Sequencing of the human genome is expected to be the key to all the proteins in our bodies, which should then become more readily available through expression in other organisms. Many proteins are already available on short notice and in substantial quantity, and this means that prospects are greatly improved for success in the crystallization experiments that of necessity precede X-ray structural analysis (see below).[77] At the same time, NMR spectroscopy is being used to carry out protein studies in solution, an approach supported by powerful computer modelling and computer dynamics (see Sec. 3). Characterization of an active center, or perhaps a substrate–enzyme complex, is the step that opens the way to further study through organic synthesis. Once the interaction between enzyme and substrate has been clarified, the likelihood is increased that an effective inhibitor can be designed. Medicinal chemistry is on the way to targeted preparation of inhibitors for all the crucial enzymes in the mammalian organism. Even agricultural chemistry is turning increasingly to selective intervention in the cellular chemistry of plants and pests.

Success in these areas demands a great deal of fantasy, considerable knowledge of structure–reactivity relationships, and experience in the efficient assembly of complex molecules—but it also requires a willingness to learn the "languages" of biochemistry, biology, and medicine.[78, 79] The importance of biological chemistry can easily be inferred from what has already been said in this section and from Sections 2.3 and 7.2.1 below. It is also apparent, however, from the number of relevant articles published in the new review journal *Chemtracts (Organic Chemistry)*:[80] in 1988 such articles accounted for 90 of the 500 pages, and by 1989 the proportion had grown to 130 out of 400! Other representative examples can be drawn from recent Nobel Prize lectures.[81, 82] Effects of all this activity on the methodology of organic synthesis are evident, for example, in a series of innovative investigations of compactin and its analogues[83] (useful for reducing cholesterol levels) as well as in syntheses of statin[84] and other rhenin inhibitors (which act to lower the blood pressure).[85] Interest in the latter has resulted in an active demand for novel approaches to non-proteinogenic amino acids,[86] peptides, and their analogues (cf. Sec. 7).[87]

[*] "Biochemistry requires at least as much organic chemistry as does organic chemistry."

Organofluorine compounds frequently play a role in the synthesis of inhibitors, substrate analogues, so-called enzymatic or metabolic probes, antimetabolites, "transition state analogues",[88a] and suicide substrates or inhibitors.[88b] Indeed, there has recently been a real "boom" in this field,[89, 90] producing considerable research activity in both academia and industry. This will certainly lead to improved methods for the synthesis of organofluorine compounds,[91, 92] but it will also provide a deeper understanding

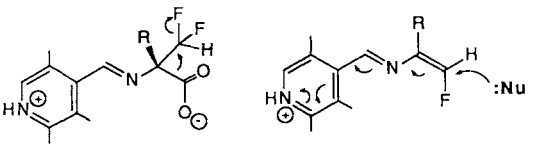
Suicide inhibition

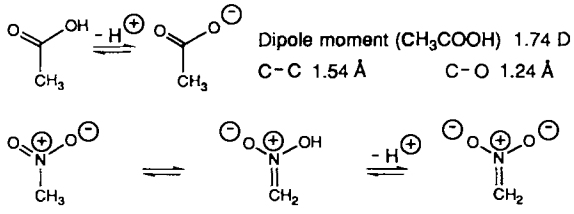


Scheme 7. Characteristic features of organofluorine compounds [91, 92]. The C–F bond is particularly strong; of all the bonds involving carbon, the C–F bond is the shortest apart from C–H; despite the fact that a CF_3 group has nearly twice the van der Waals volume of a CH_3 group, it is still capable of replacing the latter statistically in crystals (solid solutions [94a]); the C–F bond is extremely polar, but is nevertheless stable under most conditions; fluorine has a very high electronegativity, but fluorine compounds are very volatile; and substitution of CH, CH_2, or CH_3 by CF, CF_2, or CF_3 increases the lipophilicity of a compound (low polarizability of the fluorine electrons). On the other hand, fluorine substitution has enormous effects on the characteristics of functional groups: pK_a (C_2H_5OH) 16, (CF_3CH_2OH) 12.4; i.e., the trifluoro alcoholate is stabilized by 21 kJ mol^{-1} [92]; the introduction of F-substituted aromatic rings into pharmaceutical agents usually causes little change in general characteristics, but it leads to inhibition of oxidative metabolism (increased bioaccessibility, reduced dosage, patent "jumping"; the first fluorine-containing drugs were *Fried*'s fluorosteroids [98]); α-CF_2 ketones exist as hydrates in aqueous solution (cf. the similarity between the resulting hydrate and the tetrahedral intermediate of a peptide serinase-cleavage [92, 99]); α-difluoromethyl amino acids [91d] act as irreversible inhibitors ("suicide inhibitors") in that they lead to formation of a Michael acceptor at the active site of the enzyme responsible for pyridoxal phosphate metabolism (by nucleophilic addition to a neighboring group in the protein [100]). The magnetic properties of the ^{19}F nucleus facilitate the investigation of receptors and metabolic phenomena without interference from other magnetic nuclei [101]. (For sources of the data on fluorine compounds generally see [102].)

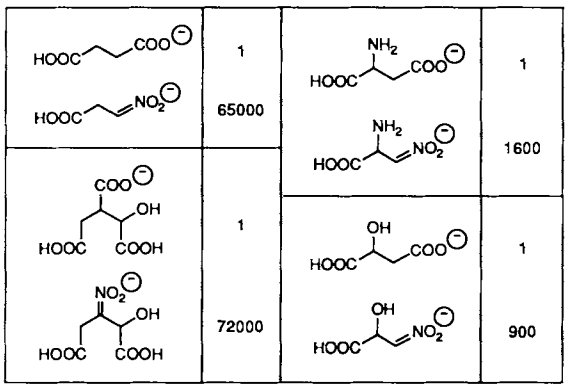
of the effects of fluorine on physical properties and of the frequently unexpected reactivity of this class of compounds.[91-97] A few aspects of the subject are illustrated in Scheme 7. The hectic state of activity in this field and the surprises that often emerge from what should be the simplest transformations of fluorine derivatives make it hard for me to resist coining a new term: *flustrates* (≡fluorine-containing substrates).

Not quite so well developed, but still subject to similar types of investigation, are nitro- and sila-analogues of physiologically active compounds, a few examples of which are shown in Schemes 8 and 9.

Properties of carboxyl and nitro groups



Relative binding constants of carboxylate enzyme substrates and their nitronate analogues



Scheme 8. A comparison of the nitronate group with the carboxylate group. According to [103], nitronate effectively mimics the characteristics of carboxylate with respect to geometry, polarity, and charge. Despite the great polarity of the nitro group [102], nitroaliphatics behave as non-polar compounds—in chromatography over silica gel, for example (NO_2 is a poor candidate for hydrogen bonding; cf. the fluorine derivatives in Scheme 7); references [95, 96, 104, 105] provide access to some of the author's preparative work and recent reviews of the literature. The greatly increased enzyme affinity of nitronate anion analogues compared with carboxylate anion substrates results in (apparently very successful) competitive inhibition [103].

Sila-isosteres of carbon compounds in particular may someday become very important, but within an entirely different context. Although sila derivatives have the same geometries as their carbon counterparts, their van der Waals dimensions are somewhat greater. In certain cases they might therefore serve as transition-state analogues for the preparation of catalytic antibodies, which would then accelerate reactions leading to the corresponding carbon systems. The same principle should apply to other heteroatom deriva-

***Bond lengths** [Å] CX vs. SiX*

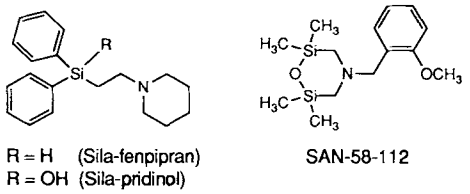
***Bioisosteric relationship** between C/Si analogues*

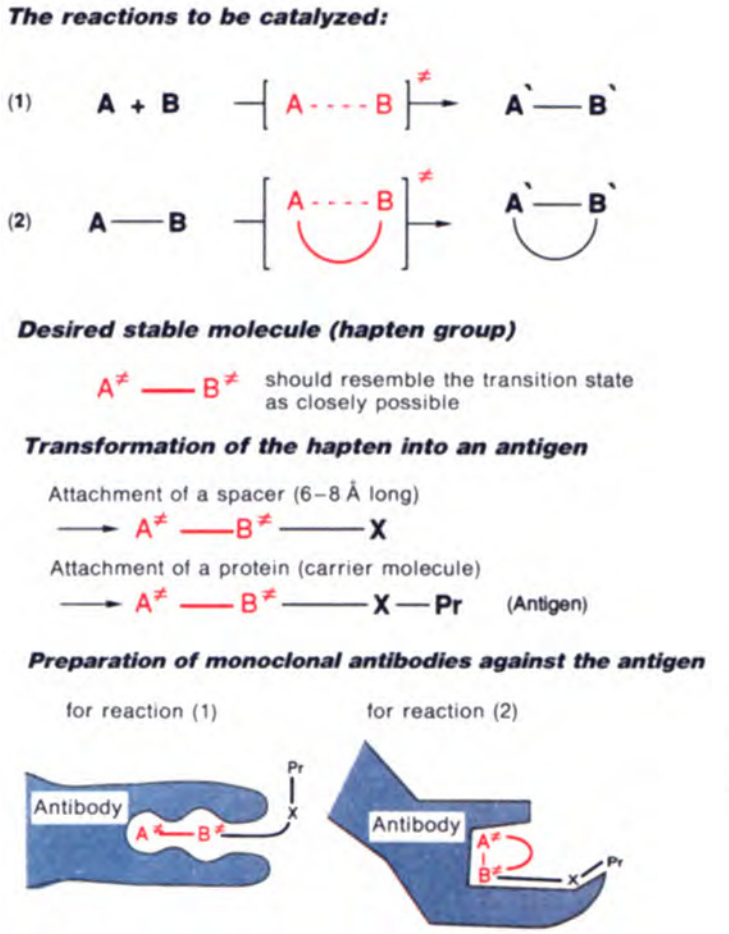


Scheme 9. Comparison of isosteric C and Si compounds. The illustrated Si isosteres of active substances [106] differ in interesting ways from the parent compounds; once again, the spatial arrangements [102, 107b] of the compounds are almost unaffected by incorporation of Si, but the reactivities (metabolizabilities) change considerably, as do electronic properties (possible formation of hypervalent species [107], σ-donor characteristics of the Si–C bond [108, 109]).—Deuterated derivatives have so far not been utilized, although the somewhat reduced size of CD_3 relative to CH_3 [110], for example, should have significant consequences, as should kinetic isotope effects [111] in interactions with receptors and in rates of metabolism (particularly on the physiological time scale).

tives as well, "organoelemental" compounds in which bonds to elements in the first row of the periodic table (such as C–H, C–N, C–C, C–O, R_3N, and R_2O bonds) are replaced by ones to elements displaying similar bonding geometries but greater bond lengths (bonds such as Si–H, Sn–H, C–P, C–Si, C–S, R_3P, R_3As, R_2S, R_2Se, etc.); the point is elaborated in the section that follows and in Schemes 10 and 11.

2.3. Antibodies as Catalysts in Synthetic Reactions: from Abzymes to Diels–Alder-ases

The intended targets of the molecular probes discussed in the preceding section were active centers of enzymes and receptors. Four years ago, two groups[112, 113] in the USA showed that with the aid of the immune system[79] chemists can also prepare selective catalysts that have antibody-type structures (i.e., immunoglobulins, giant protein molecules with molecular weights of ca. 150 000 daltons), substances that have been referred to as "abzymes" (*antibody enzymes*).[112] Work in this area is particularly dependent on the chemist's imagination and knowledge. In *one* of the reported variants, the preparative procedure is essentially[114] as follows (Schemes 10 and 11): first, a molecule is synthesized with a shape resembling as closely as possible either a transition state or a short-lived intermediate in the reaction to be catalyzed. This substance is treated as a hapten and coupled with a carrier molecule (e.g., a protein) to produce a combination with immunogenic properties (an antigen). The antigen is then introduced into the circulatory system of



Prerequisites for an antibody effective as an enzyme-like catalyst

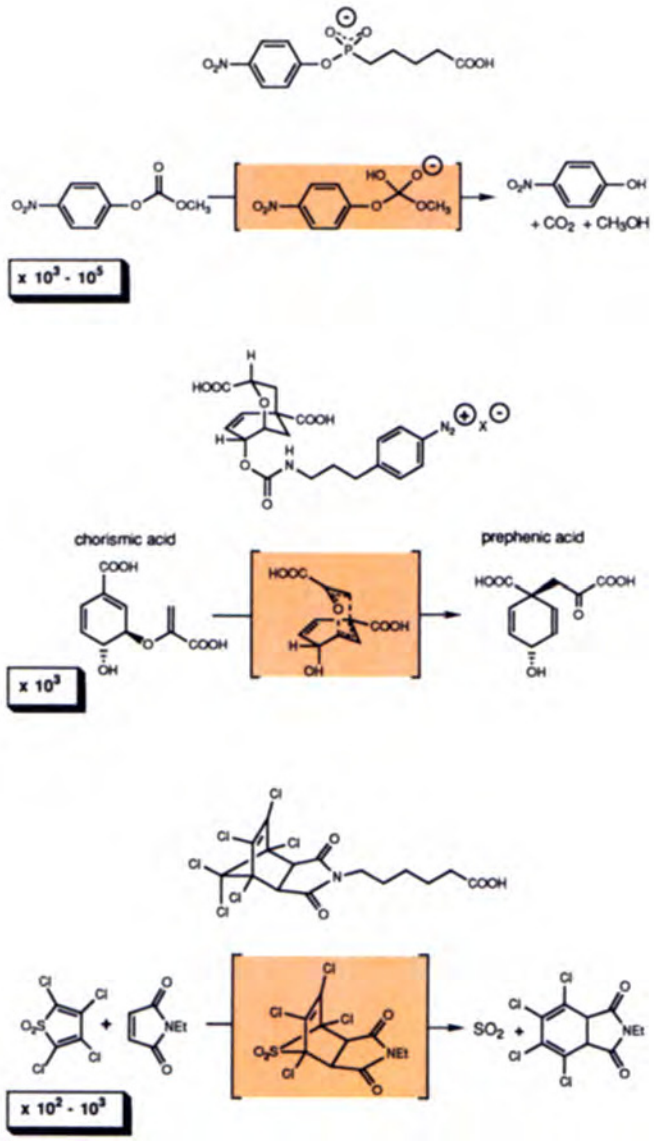
The "active center" must have a greater affinity for the transition state or intermediate than for the educt or product

Scheme 10. Preparation of monoclonal antibodies with "recognition potential" for the arrangement of transition states or intermediates; there also exist other methods by which catalytically active antibodies (abzymes) can be prepared [114b].

a mammal,[119] which responds with an immune reaction leading to antibodies. The antibodies are isolated, and those with the highest affinity are separated and replicated monoclonally.[120] Finally, a test is performed for catalytic effectiveness in accelerating the target reaction. Abzymes prepared in this way[114] have been shown to accelerate by factors as great as 10^5 such reactions as ester-,[115, 121] amide-,[114b] and peptide-bond cleavages;[122] lactonizations;[123] and even Claisen rearrangements,[116] Diels–Alder reactions (catalysis by "Diels–Alder-ase"),[118] and redox reactions.[124] All such reactions of course display enantioselectivity.

It would be unreasonable to suggest that synthetic chemists will soon be trying to make an abzyme for "the next step" in a multistep laboratory-scale synthesis. On the other hand, industrial chemists interested in the production of larger amounts of fine chemicals or pharmaceuticals are not likely to shy away from the effort required to prepare such custom-designed catalysts. Indeed, the day may come when attempts will be made to develop entire reaction cascades mediated by multi-abzyme systems, with a final, irreversible step ensuring the smooth operation of a complex sequence of abzyme-catalyzed reactions. Just as has happened with enzymatic transformations,[125] abzyme procedures are likely soon to be extended beyond the constraints of aqueous media, and some abzyme-catalyzed processes will probably prove to be essentially substrate-independent (as in the case, for example, of lipase- and esterase-catalyzed enzymatic reactions;[126] cf. also Section 7.2.1).

We have so far been dealing with considerations that impinge directly on the synthetic organic chemist, but recent developments also have the potential for deepening our over-



Scheme 11. Three examples of abzyme-catalyzed reactions. The observed rate enhancements in ester hydrolysis [114b, 115] and in the rearrangement of chorismic to prephenic acid [116] are significantly less than those produced by natural enzymes (esterases and chorismate mutase [117]). In the case of the Diels–Alder reaction [118], the antibody—generated in response to the hapten, and replicated monoclonally—must be methylated with $CH_2O/NaCNBH_3$ in order to keep it from reacting with tetrachlorothiophene dioxide (cf. suicide substrates). In each of the three examples, the hapten and the spacer are shown at the top, and directly below is the corresponding catalyzed reaction, including the transition state or intermediate and an indication of the observed extent of rate enhancement.

all understanding of molecular interactions. Examples have already been reported[114b] of structural investigations based on the use of catalytic antibodies and their complexes with transition-state analogues, permitting identification of the interactions that are at the root of hapten affinities. In the future, investigations of this type may compete successfully with the point-mutation methodology in protein studies ("site-specific mutagenesis"), especially since they offer the prospect of a much wider choice of potential substrates ("the whole of organic chemistry"). This potential may soon be further enhanced as a result of recent successes in the biosynthetic, targeted introduction of *non-proteinogenic* amino acids into proteins.[127–131]

3. Analysis, Computers, and Theory—No Progress without Help

—citius, altius, fortius[*]
Pierre de Coubertin, father of the modern Olympic Games

Dramatic progress in organic chemistry has always been closely linked to the introduction of new methods in analytical chemistry generally. The pace of advances increases as a direct function of the speed, sensitivity, and precision of the methods available for following a reaction, for establishing a reaction's outcome, or for determining the constitution of

[*] "Swifter, higher, stronger."

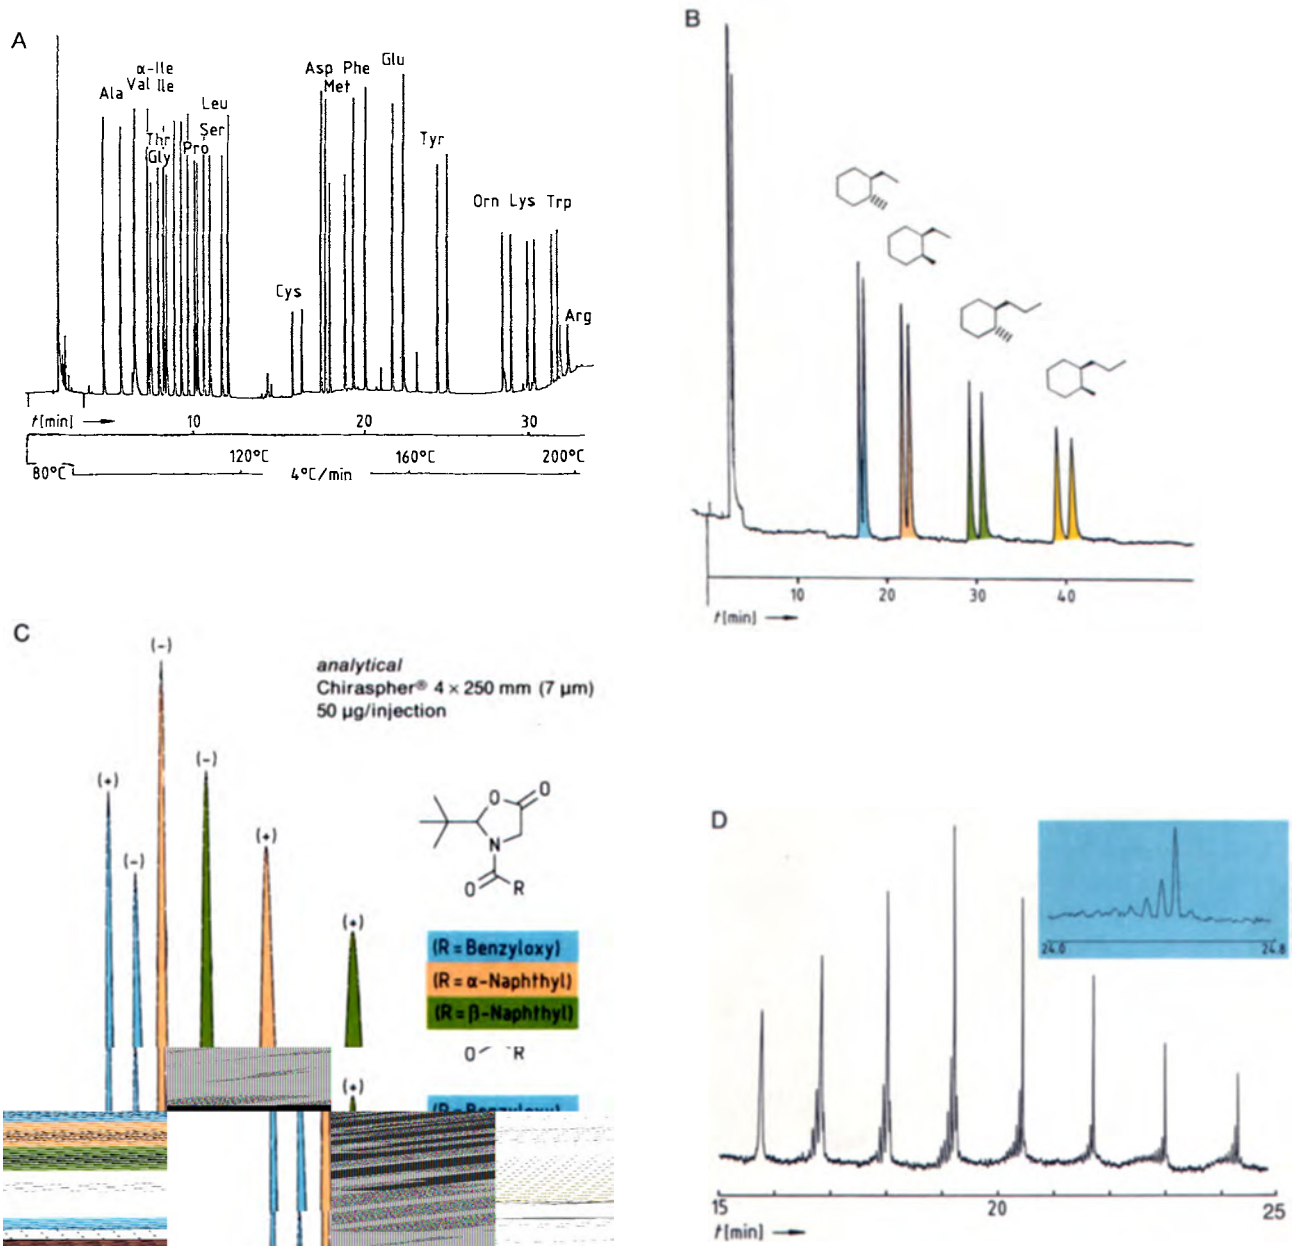


Fig. 1. Selected examples of separations accomplished with the aid of modern analytical methods. A) Gas chromatogram from a mixture of all the proteinogenic amino acids (racemic mixtures, in the form of *N*-pentafluoropropionyl isopropyl esters); Chirasil®-L-Val column containing 5% Kóvats phase [135]. B) Gas chromatogram from a preparation containing racemic *cis*- and *trans*-1-ethyl-2-methyl- and *cis*- and *trans*-1-methyl-2-propylcyclohexane; cyclodextrin column [136]. C) HPLC separation of a mixture of three racemic oxazolidinones for amino acid synthesis; Chiraspher® column [137]. D) HPCE separation of a poly(desoxy)thymidylic acid mixture, with an enlargement of the region near 160 nucleotide units; polyacrylamide gel, 3×10^7 plates [138].

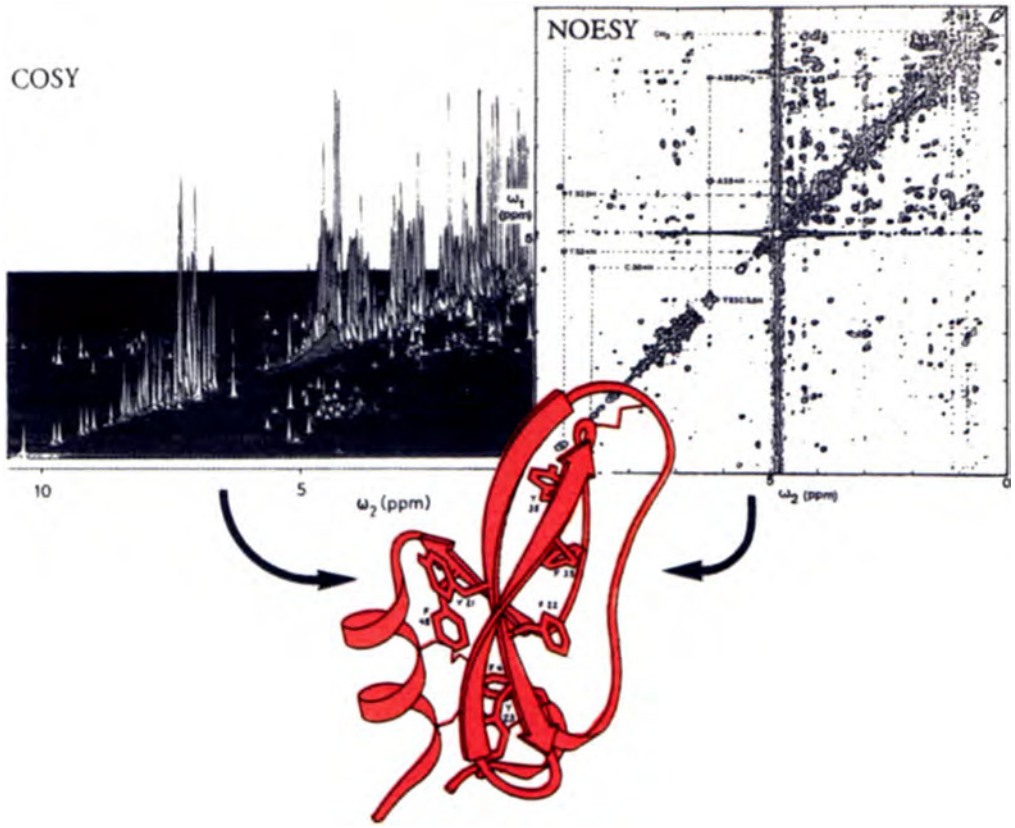

Fig. 2. 2D-NMR spectrum of the basic trypsin inhibitor from the pancreas [143]. A combination of X-ray structure analysis, NMR spectroscopy, and computer-assisted modeling/dynamic calculation on proteins results in detailed information about both their structure and their enzymatic function (see Sec. 3.3 and Fig. 8).

a mixture or the structure of a complex molecule—up to and including antibodies, DNA, or supermolecules held together by non-covalent forces. It would be wrong in a presentation such as this not to acknowledge, at least, the dependency of organic chemistry upon analytical chemistry. Unfortunately, limits of time and space preclude my doing much more than "name-dropping", although I will provide a few key citations and introduce a handful of impressive examples.

3.1. Chromatography, NMR, and Mass Spectroscopy

The last 35 years have witnessed the advent of remarkable new analytical techniques. These can be conveniently separated into three categories: chromatography, spectroscopy, and miscellaneous methods. With respect to the first, thin-layer and gas chromatography[132] appeared in the vanguard, then came HPLC, and finally chiral stationary phases for determining enantiomeric ratios[133, 134] (Fig. 1). Very recent additions include HPCE ("high-performance capillary electrophoresis")[138] and FFF[139] ("field flow fractionation", which actually involves a different principle altogether). Now there is even talk of *neochromatographic* techniques.[139, 140]

The earliest of these developments in chromatography coincided with the introduction of NMR spectroscopy, a technique whose triumphal march through chemistry is far from exhausted. Accustomed originally to small instruments based on permanent magnets and applicable only to ^{1}H measurements, we now take for granted sophisticated high-field spectrometers with magnetic coils fabricated from superconducting materials. Various pulse techniques and Fourier transform capability have been incorporated into versatile devices suitable for routine multi-element analysis. 2D-[141] and 3D-spectroscopy[142] (Fig. 2) as well as the study of

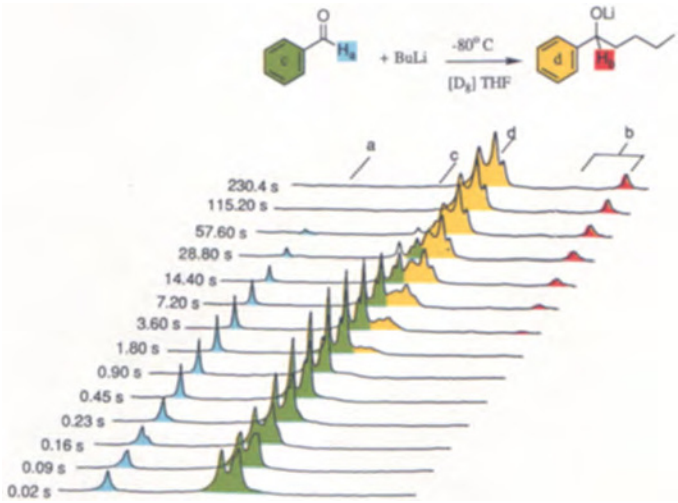

Fig. 3. Rapid-injection ^{1}H-NMR measurement (RI-NMR) [145] during the reaction of butyllithium with benzaldehyde at $-80\,^{\circ}C$ in perdeuteriotetrahydrofuran. A benzaldehyde solution of the substrate (2.3 mg in 250 μL [D_8]THF) and butyllithium (15 μL, 2 M in hexane) were injected into a 5 mm NMR tube (rotation frequency 10 Hz). Pulses and Fourier transforms were applied after the indicated time intervals (Bruker model WH-360) [146]. Further applications of this method involve studies of reactions of other organolithium systems and of organomagnesium compounds [147, 148], and investigations of short-lived cations [149].

dynamic processes have all become possible through the introduction of extremely clever pulse sequences,[144] and accessories have been made available for automatic sampling and for low-temperature analysis of fast chemical processes [RI ("rapid injection") NMR methods, cf. Fig. 3].[145, 147]

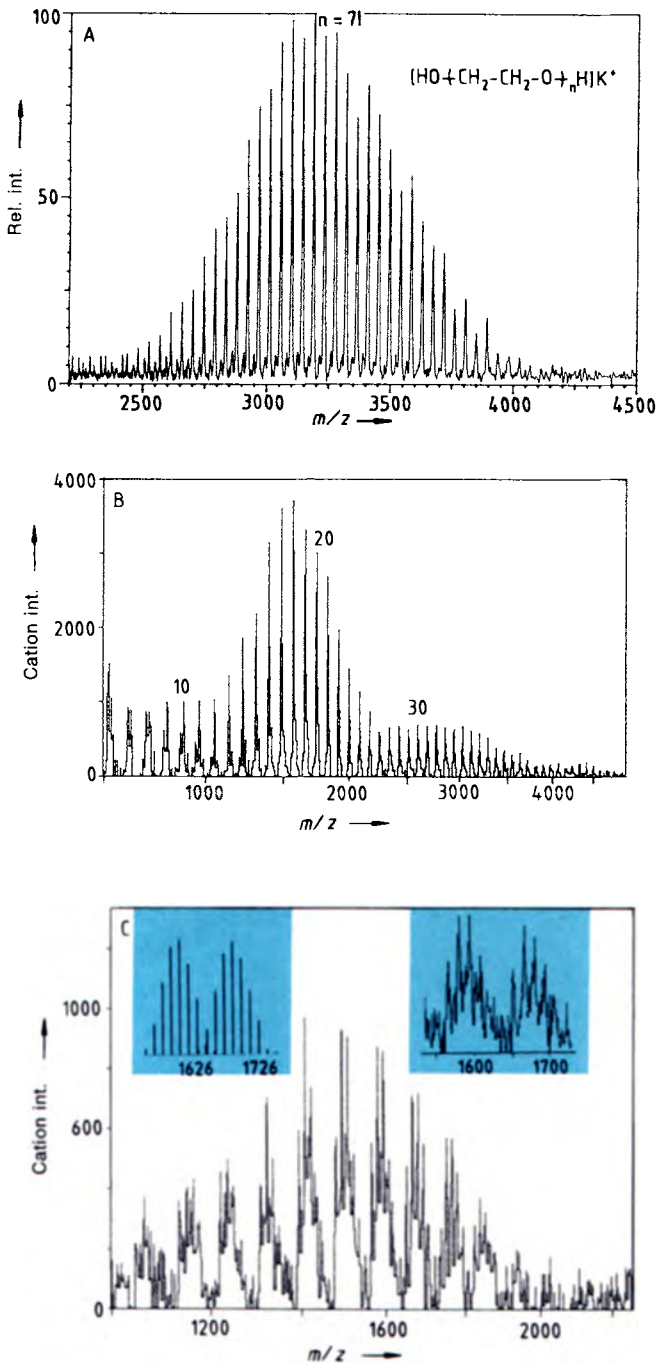

Fig. 4. Analysis of the molecular weight distribution of polymers by mass spectroscopy. A) Laser-desorption Fourier-transform mass spectrum (LD-FTMS) of a poly(ethylene glycol) sample (mean molecular weight 3550 dalton) [155]. B) Plasma-desorption mass spectra (PDMS) of poly[(*R*)-3-hydroxybutyric ester] [PHB, mean molecular weight 2740 dalton (osmometric)] and C) of a copolymer consisting of 78% PHB and 22% poly[(*R*)-3-hydroxyvaleric ester] (BIOPOL®). The inserts show observed intensities and intensities calculated for a statistical distribution of HB and HV [156]. Recently, a special laser-desorption mass-spectroscopic method was used to detect the molecular ion of the protein bovine albumin (67 000 dalton) [157]. Coupled capillary-zone electrophoresis/ion-spray mass spectroscopy permitted the detection of (multiply charged) molecular ions from proteins with molecular weights as high as 150 000 dalton [154c].

Chiral shift reagents now permit the direct determination by NMR spectroscopy of enantiomer ratios,[134] and difference-nuclear Overhauser effect measurements are used routinely as a source of information about configuration, once determined almost exclusively by "wet chemical" methods (i.e., chemical correlations). It seems quite likely that NMR will soon be providing structural resolution at the level of one C–C bond length (1.5 Å) with proteins containing over 100 amino acid residues. Indeed, bets have been placed on the question of whether NMR spectroscopists or X-ray crystallographers will be the first to establish a protein structure with a given degree of precision. The principal differences between the two methods are that NMR deals with structures as they exist in solution rather than in the crystalline phase, and only NMR is capable of probing dynamic processes.[141–152] Solid-state NMR spectroscopy is also well on the way to becoming a routine technique.[153]

Mass spectroscopy has undergone developments comparable in importance to those of NMR. For example, FAB ionization has finally made it possible to apply this technique to the detection and study of molecules of ever-increasing size. Radically new ionization techniques[154] have been introduced very recently, and these are currently undergoing tests (cf. Fig. 4). The combinations GC/MS, HPLC/MS, and HPCE/MS have facilitated analysis of the most complicated mixtures as well as high molecular mass materials—a major advance for chemistry, but one subject to serious abuse by those who ignore *Paracelsus'* still valid definition of a "poison".[158]

The fact that organic synthesis is now preoccupied with increasingly complex systems has effectively brought an end to the days when a synthetic chemist could hope to identify a product with a "quick glance" at a set of IR, NMR, and mass spectra. Today, and even more in the future, such problems warrant the involvement of teams of specialists. The methods available for structural analysis are now so diverse that one can no longer aspire to be both an imaginative chemist who studies a wide range of reactions and an expert at analyzing the resulting products. On the other hand, a "super-spectroscopist" runs the risk of becoming little more than a sterile technician in the absence of contact and collaborative interaction with those in a position to recognize and investigate important chemical problems and isolate species with intriguing new structures.[159]

3.2. X-Ray Structure Analysis—Also Valuable for Probing Reactivity!

The difference between a chemist and a crystallographer can be compared to two people who try to ascertain what furniture is present in a darkened room; one probes around in the dark breaking the china, while the other stays by the door and switches on the light!
J. D. Dunitz (1977)

Among the remaining analytical methods, X-ray structure analysis surely deserves to be mentioned first.[160] It has

become impossible for a synthetic organic chemist to remain competitive without access to this technique. Tears well up in crystallographers' eyes when they hear synthetic chemists assert that X-ray structure analysis is on the verge of becoming a type of spectroscopy. Instruments are indeed being developed that use more powerful X-ray tubes and incorporate faster mechanical devices for more rapid collection of reflections, and increasingly efficient computers and better software[161] are being incorporated for the solution of structures. It is now possible to carry out routine X-ray structural analyses of moderately complex molecules in the same amount of time that used to be set aside for NMR analysis. State-of-the-art technology for the solution of very large structures is soon likely to feature a synchrotron as the source of short-wavelength radiation, and to invoke non-monochromatic radiation (as in the original Laue method, cf. Fig. 5).[162-164] The ability to grow perfect single crystals of pure compounds—one of the most ancient of chemical arts—will once again command respect in the laboratory. Chemists who display a combination of dexterity and devotion as they manipulate their products will stand the greatest chance of success in this endeavor. The foregoing generalization is equally applicable to small and large structures;[165, 166] compounds that are stable and those that are extremely air-sensitive;[167a] and materials subject to decomposition[167b] well below room temperature,[168] loss of solvent,[169] melting,[170] or the development of plastic crystallinity.[171]

It has recently become apparent that X-ray diffraction can be important to the chemist not only for establishing the structures of isolated products, but also as a means of learning something about the structures of reactive intermediates—and therefore about reactivity in general. Many of the idiosyncrasies and imponderables associated with the chemistry of polar organometallic compounds have become better understood, or have even been circumvented entirely, once the corresponding crystal structures were "seen";[167, 171-174] four recent examples are presented in Fig. 6. Other cases show how structural data can be correlated with the reactivity of compounds (the principle of structure–reactivity correlation)[179-181] or with force constants.[182] Three examples are presented in Fig. 7 in which pyramidalization of trigonal carbon atoms, determined in the crystalline phase, has been used to explain reactivities in solution. It is to be hoped that the future will bring more such non-routine applications of structure determination, and it is almost certain that X-ray results will continue to "open the eyes" of synthetic chemists. The crystallographic data bank in Cambridge (CSD)[189] already contains a wealth of uninterpreted information, a veritable treasure trove waiting to be exploited by the initiated!

It is difficult to predict which other analytical techniques will provide valuable information for synthetic chemists in the future.[190] We look with envy, for example, at tunneling electron microscopy,[191] which permits one to probe surfaces with a resolution sufficient to cause pyrrole and benzene rings—even individual xenon atoms—to become "visible",[192a] and capable of revealing a piece of double-stranded DNA as a kind of "molecular braid".[192b]

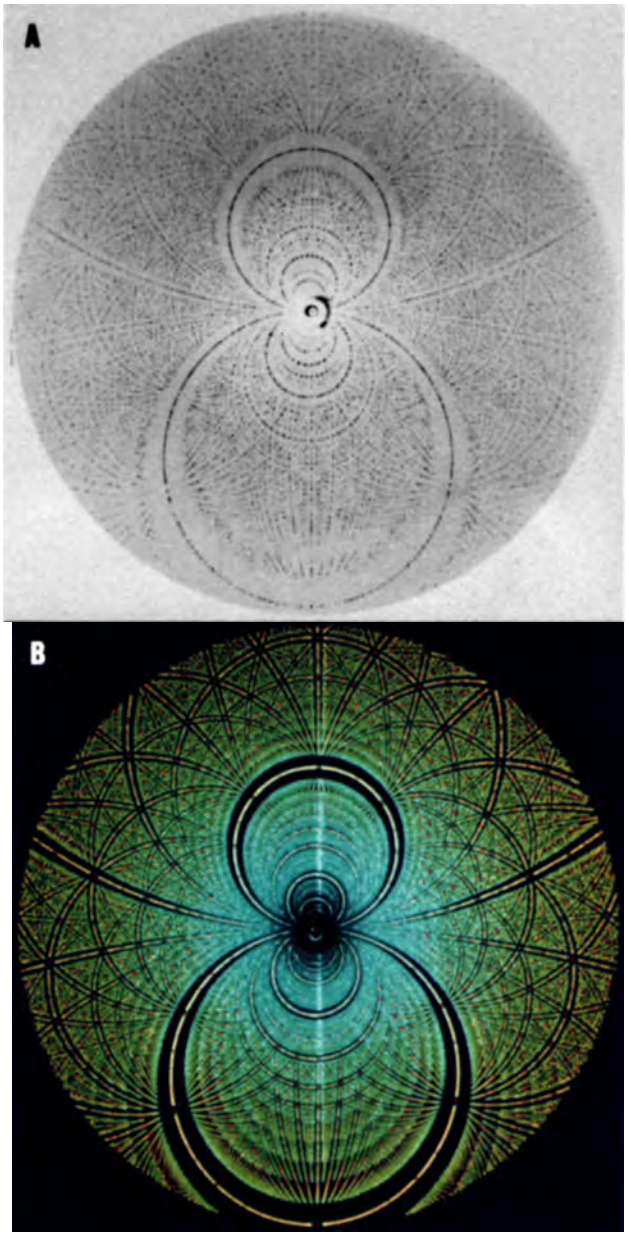

Fig. 5. Laue diffraction pattern of glycogen phosphorylase B. The use of high intensity, non-monochromatic synchrotron irradiation permits the collection within minutes of the data associated with a large protein or nucleic acid molecule—even an entire crystalline virus [162, 163]. Polychromatic irradiation permits a great many planes to fulfill the conditions of reflection, so that a single 100 μs "shot" can produce 150 000 measurable reflections. Employing a video camera as the recording device makes it possible to record the reflections generated by several pulses directed in rapid succession at a rotating crystal. This method is of course equally applicable to crystals of smaller molecules or even typical inorganic solids, although it requires crystals of higher quality than those typically used for monochromatic irradiation. *J. Hajdu* [164] has visions of employing pulse lengths of 10–40 ps, intervals of a few ns, and intensities equivalent to those produced by the highest energy synchrotrons to investigate on the ps time scale reactions occurring in the crystalline state. Nevertheless, enormous problems remain to be overcome (computer programs for the corresponding structural calculations, radiation damage, etc.). A: Laue photograph of glycogen phosphorylase B (space group $P4_32_12$, $a=b=128.8$, $c=116.2$ Å), taken at station 9.7 of the Daresbury synchrotron radiation source. The crystal was rotated 33.75° from the position with a^* antiparallel to the beam and c^* coinciding with the spindle of a one circle camera. Wavelength range: 0.20–2.10 Å; crystal to film distance: 133.8 mm; film radius: 59 mm; exposure time: 1 s; predicted total number of reflections: 49 570.—B: Computer-generated Laue pattern of glycogen phosphorylase B (parameters as above) at 2.4 Å resolution. Reflections were color-coded to their wavelengths: blue signifies 0.20 Å and red is 2.10 Å (other wavelengths shown correspondingly in relation to the visible spectrum; computer program written by *I. J. Clifton*, Laboratory of Molecular Biophysics, Oxford University); total number of reflections: 49 570.

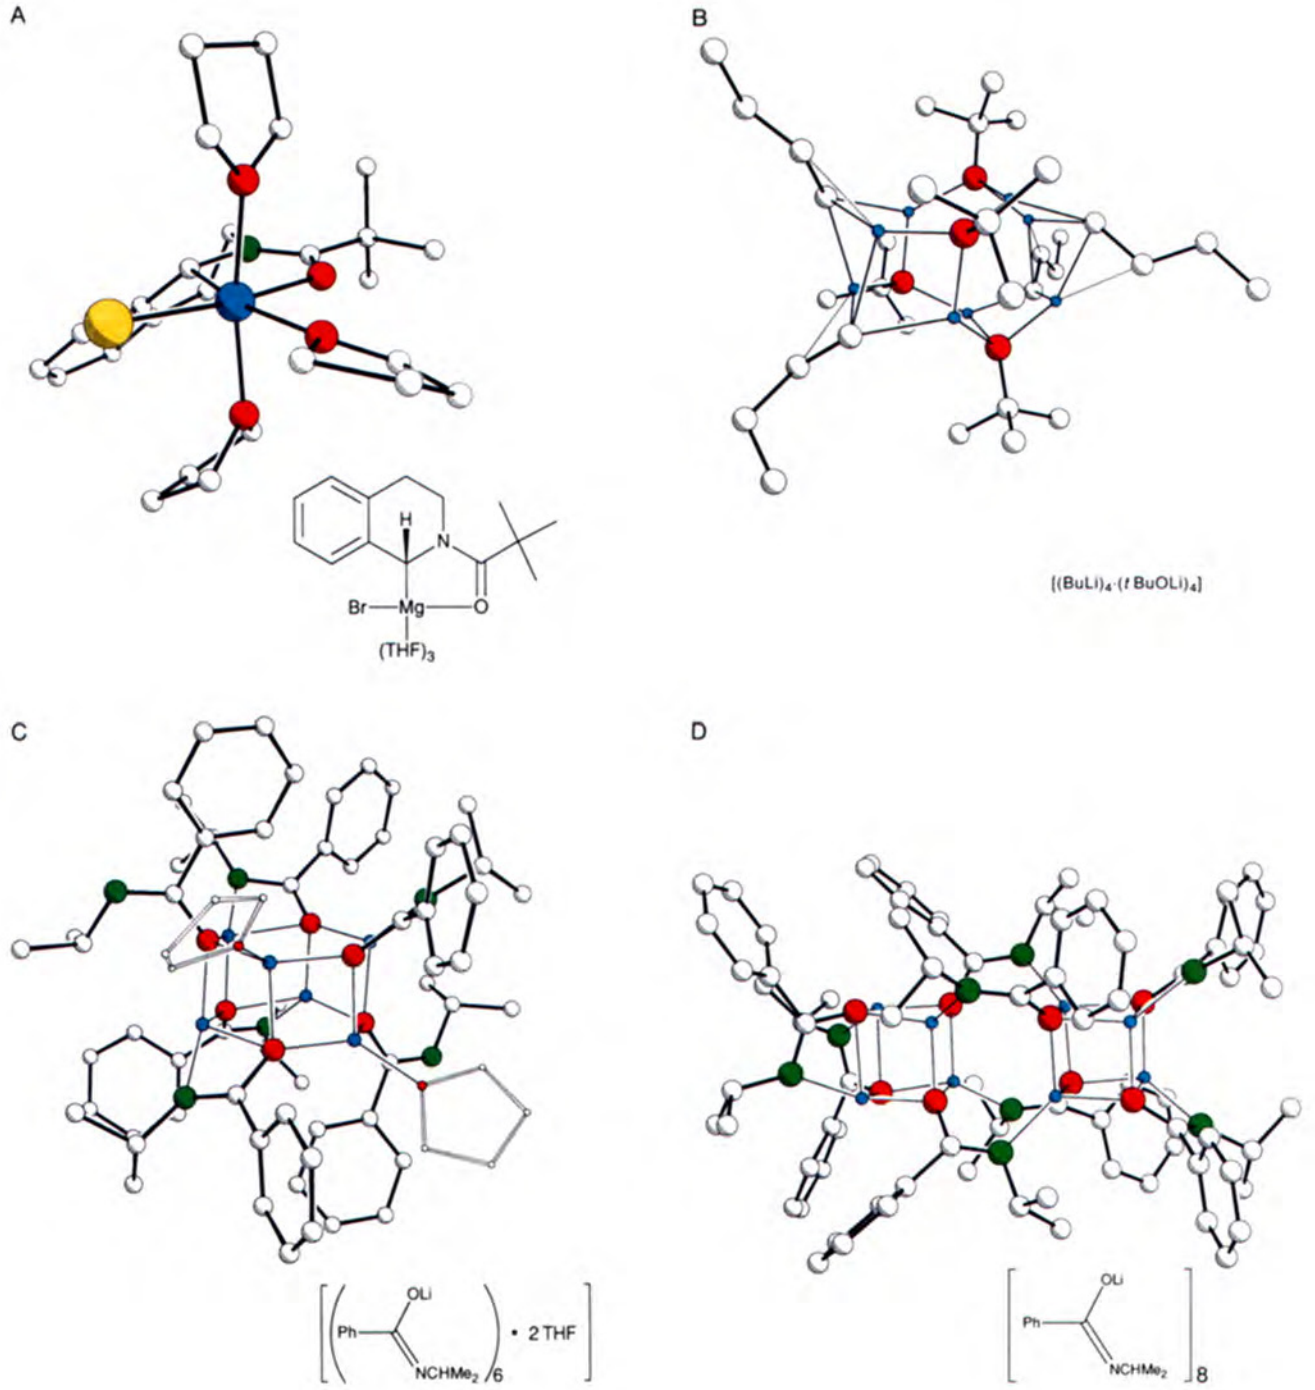

Fig. 6. Four structures of polar organometallic compounds of preparative significance. A) A tetrahydroisoquinoline derivative metallated in the 1-position; in contrast to the Li analogue, the Mg derivative whose crystal structure is shown here [174] adds with high diastereoselectivity to aldehydes [175]; structural data (Mg octahedral, Li tetrahedral; one of the THF solvent molecules is considerably further removed from the metal than the other two) were used in the development of a mechanistic model. B) Crystal structure [176] of an octameroid complex with the composition $[(BuLi)_4 \cdot (t\text{-}BuOLi)_4]$. Complex bases derived from butyllithium and potassium *tert*-butyl alcoholate (Lochmann–Schlosser bases [177]) prove to be much more efficient deprotonating agents than their components; it has been suggested that the uniqueness of such bases is a consequence of their complex structure. C) and D) Hexamer and octamer of lithiated benzoic acid isopropylamide [178]; the existence of such complex structures may be responsible for the remarkably selective reactions of polylithiated oligopeptides [172].

3.3. Quantum Mechanics and Force Fields: Ever Larger Pictures, Increasingly Reliable (a Contribution to Chemistry from Microchips)

Electronic data processing has played an important part in all the dramatic advances in instrumental analysis described above[193]—a contribution of microelectronics to chemistry. The same applies to other areas of considerable interest to the synthetic chemist: literature searching, the organization of information about reactions, retrosynthetic analysis, structural data banks, structural and dynamic modelling of molecules and transition state geometries, and ab initio cal-

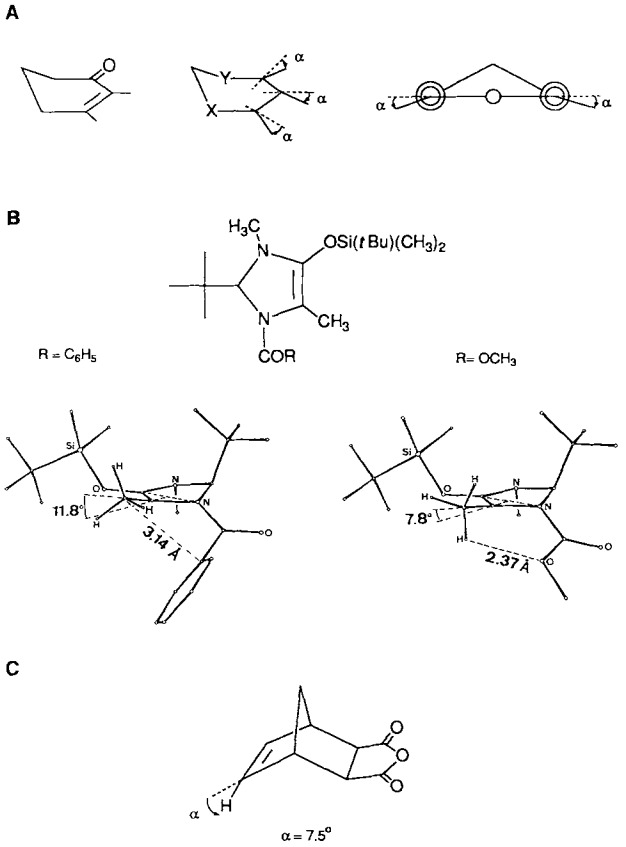

Fig. 7. Pyramidalization and reactivity at trigonal centers. A) In the crystalline state, cyclohexenones and similar derivatives with five atoms nearly in a plane and a sixth atom outside this plane ("sofa" conformation) often display pyramidalization of the trigonal centers in precisely that direction from which attack occurs during reactions transforming the trigonal centers into tetragonal centers [183]. B) Crystal structures of silylenol ethers from imidazolidinones, where $R = C_6H_5$ or OCH_3; the trigonal, methyl-substituted C atoms are displaced by 7.8 or 11.8° ($\Delta = 0.07$, 0.11 Å) from the plane of the five-membered ring, and pyramidalization is in the direction from which reaction occurs with electrophiles for both the Si enol ethers and the corresponding Li enolates [184] (see also Scheme 12). C) The crystal structure of a norbornene derivative (determined using neutron diffraction) displays pyramidalization in the *exo* direction for the trigonal carbon atoms of the C–C double bond [185] (cf. the suggestion made in 1967 that the unexpectedly high *exo* selectivity in reactions of norbornenes might be due to torsional effects [186, 187], as well as *Huisgen*'s "Factor X" [188]).

culations, to name but a few. Computer technology and the advent of instantaneous worldwide data transfer have transformed the everyday life of the chemist, and their importance will certainly continue to grow. Table 1 contains a list of computer programs we have assembled for use in our research group. Most are for the Apple Macintosh computers that are running day and night in our laboratories and offices, serving also as terminals that can be used for tapping the extensive resources of the ETH computer center.

Product and transition-state geometries of increasingly large molecules and even supermolecules can be simulated effectively with the aid of computer programs that are also constantly increasing in their power. The demonstrated reliability of such predictions—judged on the basis of comparisons with structural parameters obtained through spectroscopy or diffraction—has caused even novices to trust computed results for systems that are not (or not yet!) susceptible to experimental verification (cf. the examples in Scheme 12). Virtually all the fundamental reactions of or-

Table 1. Sources of computer information, and computer-based tools useful to the synthetic chemist [194]. Most of the programs and databases listed here are currently available in the organic chemical laboratories of the ETH Zürich. (To be fully effective, the programs must be immediately accessible within the laboratory itself.)

ganic synthesis[218]—including nucleophilic addition to carbonyl groups,[219] the Michael addition,[220] the aldol addition,[221] 1,3-dipolar cycloaddition,[222] the Diels–Alder reaction,[223] hydroboration,[224] and addition to double bonds with stereogenic centers at their allyl positions[219, 220–224]—have been subjected to more or less elaborate calculations based on force field and/or ab initio methods. "Theoretical Chemistry en route to a Theory of Chemistry" is a proclamation[225] that pertains not only to very simple systems, and not just to reactants; it even embraces solvents (in modeling,[226] as well as in the context of proteins and nucleic acids;[227] cf. Fig. 8).

4. Experimental Design, Experimental Procedures, Types of Reactions, and Reaction Techniques—a Question of More Than Just the Scale of the Reaction

Necessity is the mother of invention!

Many of the modern techniques for carrying out reactions or purifying products still have a reputation for being somewhat exotic, and certainly inapplicable to large-scale work, but it is easy to foresee the day when these same methods will begin to play a significant role in the manufacture of organic compounds, opening the way to the synthetic reactions that depend on them. Meanwhile, other industrial processes that are now wide-spread will need to be abandoned because they are associated with indefensible levels of risk and the cost of retaining them will prove too high [e.g., reactions in hexamethylphosphortriamide (HMPT), which has mutagenic properties].[228] When I speak here of industry I am really referring to the preparation (usually in several steps) of specialty chemicals—particularly pharmaceutical agents, perfumes, vitamins, and agricultural products—not the bulk manufacture of petrochemicals, solvents, or polymer precur-

Scheme 12. A comparison of several structures obtained by crystal structure analysis with predictions based on ab initio calculations. A) Observed and computed (3-21G for the unsubstituted dioxinone $R^1=R^2=R^3=R^4=H$) pyramidalization of the trigonal C atoms of dioxinones (cf. Fig. 7); bond lengths in Å, angles in degrees [183]. B) Pyramidalization at the trigonal centers of norbornene; comparison of observed parameters (Fig. 7) [185] with predictions (STO-3G) made many years earlier [215]. C) The acyliminium ion is found experimentally to be more stable than the oxonium ion, and it is also predicted to be more favorable by ab initio calculations (3-21G) [216]. Perhaps the most ambitious calculations to date (MP3/6-311++G**//6-31G*) are due to *Wiberg* [217], and they have shaken the foundations of our qualitative models of resonance stabilization.

sors. In this context, many methods have already been introduced into large-scale practice that only a few years ago would have classed as truly bizarre ("the stuff of academia"). Consider the following examples, arranged al-

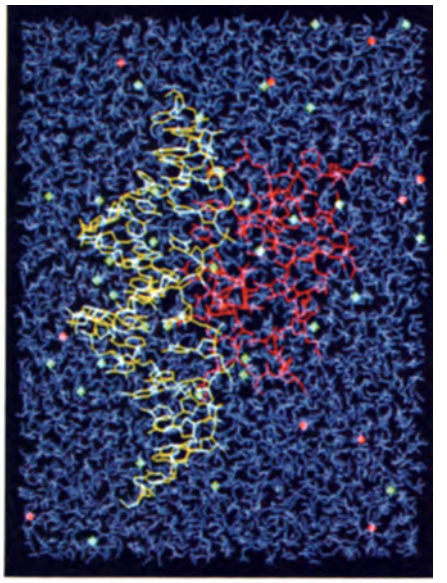

Fig. 8. Modelling in chemistry from the early days to the present. A) Calculations by *van Gunsteren* et al. (a complex of a DNA containing 14 base pairs with the lac-repressor protein from *Escherichia coli* in the presence of 34 $Na^{\oplus}$ ions, 10 $Cl^{\ominus}$ ions, and 3906 H_2O molecules; support provided by NMR data) [227]. B) "Match box" models of *van t'Hoff* (from the chemistry museum in the *Maison de chimie* of the French Chemical Society in Paris).

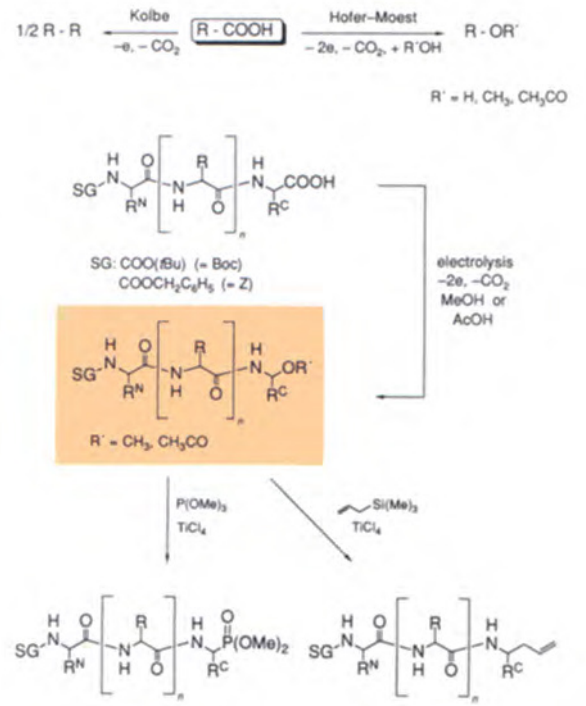
phabetically and supplemented with illustrations (or at least key literature references).

- *B*iological-chemical reactions (i.e., processes involving microorganisms and enzymes) are a good place to start, although some have actually been in limited use for years (cf. *Reichstein*'s vitamin C synthesis).[229] BASF now prepares (*R*)-lactic acid and various fragrances by fermentative routes; ICI makes tons of poly[(*R*)-3-hydroxybutanoate] by fermentation,[230] and the company has recently developed a process for the production of polyphenylene starting with *cis*-cyclohexa-3,5-dien-1,2-diol, an enzymatic oxidation product of benzene;[231] amino acids are prepared in Japan with immobilized enzymes and microorganisms that display unbelievably long catalytic lifetimes; and enantioselective esterification and saponification with lipases are accepted as standard procedures in both large- and small-scale applications (cf. also "abzymes" and the EPC synthesis, Sections 2.3 and 7.2).
- *C*hromatography over aluminum oxide, silica gel, or ion exchangers has apparently proven to be economically feasible in the purification of products like cyclosporin[232]

and in the bulk isolation of amino acids from protein hydrolyzates.[233] About ten years ago, a synthetic chemist in the pharmaceutical industry reacted to a management directive stating that active ingredients were no longer to be developed as enantiomeric mixtures by exclaiming "Then from now on we'll only study achiral compounds!" A decade later, chromatographic separation (by preparative HPLC) of a kilogram of an enantiomeric mixture is thought to be possible for less than 1000 DM (ca. $600).[133d]

- *C*lays, zeolites, and aluminum oxide have been recommended as catalysts or carriers for synthetic reagents.[234]
- *E*lectrolysis is seeing increasing use both in industry[235, 236] and in the laboratory[237, 238] (cf. Scheme 13).



Scheme 13. Electrolysis of carboxylic acids and its application to the modification of peptides [239]. The great advantage of carboxylic acid electrolysis in particular is the fact that no electrolyte is required, and it is not necessary to employ divided cells. Addition of an amine causes the solution to become conductive; CO_2 is formed at the anode, and H_2 at the cathode. Equipment demands are minimal. "Normal" carboxylic acids afford Kolbe coupling products, while α-heterosubstituted acids undergo oxidative decarboxylation [237, 238]. In the case of oligopeptides (with up to six amino acid residues), electrolysis permits straightforward modification of the acid end of the molecule [239]; cf. the formation of phosphonic acid and allyl derivatives (polar vs. lipophilic end groups).

Indirect electrolysis[240] has proven particularly attractive, since it can be regarded as a catalytic process (e.g., an electrochemically generated oxidizing agent undergoes reduction in the course of a "perfectly normal" substrate oxidation, and is then regenerated at an electrode).[241]

- *F*luorination with elemental fluorine is now a subject of active investigation even in industrial laboratories.[92]
- *H*igh- and very-high-pressure conditions (up to 20 kbar) permit the realization of reactions with negative activation volumes ($\Delta V^{\neq}$).[242] For example, Diels–Alder reactions between sterically hindered components become feasible under such conditions, whereas equilibrium considerations preclude the usual approach of simply heating the mixture of starting materials to a high temperature.
- *L*ow and very low temperatures[243] under inert atmosphere have become commonplace even in large reactors—a source of some satisfaction for those who 20 years ago were telling industrial chemists about the remarkable selectivity of reactions with organometallic reagents at −100°C under argon, often to be greeted with smiles reflecting pity for the naiveté of "academic eggheads". To-

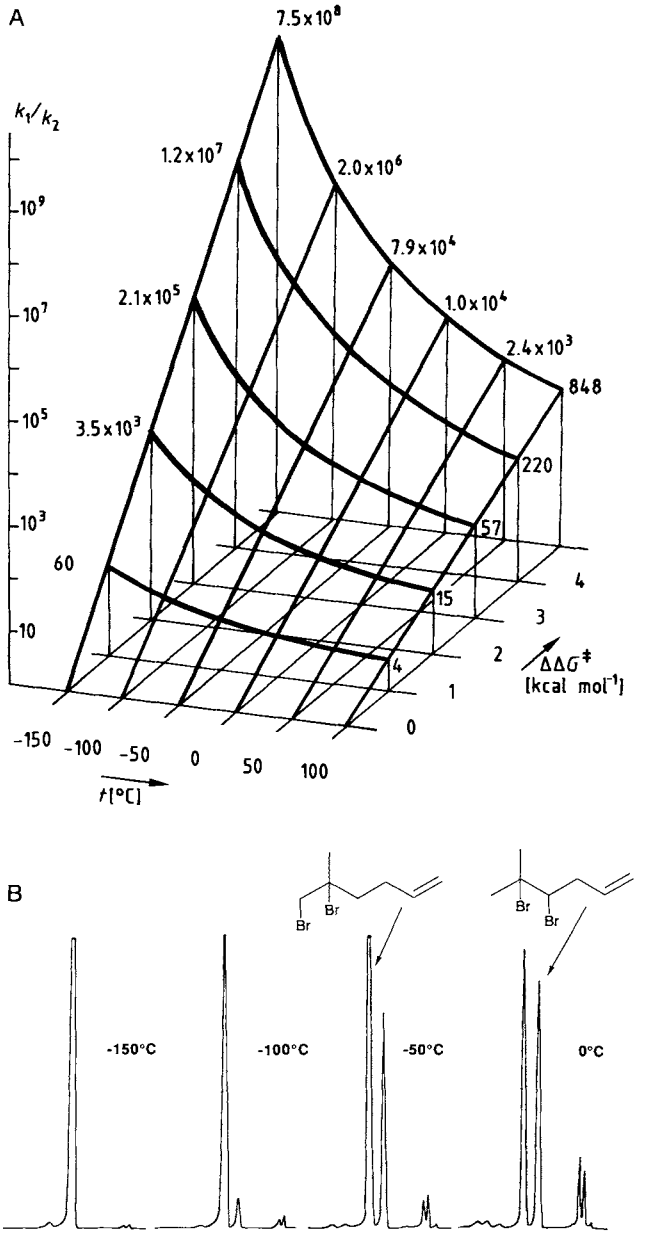


Fig. 9. Increase in the selectivity of reactions at extremely low temperature [243a]. A) 3D diagram showing the relationship between the yields of two products (from competing reactions, both first-order) as a function of difference in enthalpies of activation ($\Delta\Delta G^{\neq}$) and temperature. B) Gas chromatogram of the reaction mixture obtained on treatment of 2-methyl-1,5-hexadiene with bromine; ratios of the principal components at 0°C (in $CH_2Cl_2/CHCl_3$), −50°C (in CHF_2Cl), −100°C (in $CH_2Cl_2/CHCl_3$), and −150°C (in CHF_2Cl) 1:1, 2:1, 200:1, > 500:1. Of course, lower temperatures do not always result in greater selectivity [243b], since selectivity is a function of the relative temperature dependencies of competing reactions, which intersect at the isoselective temperature [243c]. Complex reactions (sequential reactions, pre-equilibria, systems with feedback) also lead to situations much more complicated than that depicted in diagram A [172, 243d–f, 253].

day, when these same "deranged prophets" are invited to tour the "holiest-of-holies", they are likely to encounter a perfectly ordinary-looking 1500 L reaction vessel—cooled by liquid nitrogen!—to which is being added 150 L of butyl lithium solution. The result of such efforts is often a considerable increase in selectivity, achieved despite free energy of activation differences smaller than one kcal mol^{-1}[243] (cf. Fig. 9). An example of a continuous low-temperature process is outlined in Fig. 10.[247] Even C–C bond formation with the aid of lithiated 1,3-dithianes,[18i] now a standard laboratory method but one that requires low temperatures,[31, 248] has been adapted for large-scale application.

- *M*icrowaves are the answer!—or so it would appear from the increasing number of papers in which this approach to introducing energy is described as the "method of choice".[249]
- *O*zonolyses are being used in the manufacture of specialty chemicals.[250] No one would have believed that possible in the days when I was working on my dissertation with *Criegee*!
- *P*hotoreactions (progeny of a venerable family of chemical transformations)[251] now are employed not only for initiating chain reactions, but also under circumstances in which the quantum yield is smaller than 1, especially if they lead in a single step to structural changes that cannot be realized in other ways[252–254] (cf. Table 4G and Scheme 20B).
- *R*adical reactions were viewed with considerable suspicion by synthetic chemists as recently as 10 years ago, attracting favor only among those interested in the study of mechanisms.[255] Today they are securely embedded in the methodology of synthesis,[256–258] and it is likely they will become still more important, especially as tin derivatives relinquish their roles as chain initiators and synthetic reagents generally.[259]
- *S*alt effects are as old as organic chemistry itself. It has recently been discovered, however, that alkali metal and alkaline earth salts in particular have extraordinary solubilizing effects with respect to compounds otherwise insoluble in organic solvents (e.g., polylithiated derivatives[172] and oligopeptides;[260] cf. Table 2 and Fig. 11).
- *S*olid-phase syntheses have been achieved on a wide variety of carriers.[8, 263] Combination of the Merrifield peptide synthesis with modern separation methods has even made it possible to prepare relatively large peptide segments useful in the pharmaceutical industry for the *production* of active ingredients.[264]
- *S*olid–solid reactions are not likely to evoke images that are especially appealing. Nevertheless, close inspection of the abstracts from a conference[265] on the subject[54, 266] reveals astonishing possibilities. A few examples are presented in Scheme 14.
- *S*olvents are more and more becoming the "problem children" in applied organic chemistry. For instance, it is absolutely necessary that new and safer techniques be developed for the use of dichloromethane in those cases where it cannot be avoided, techniques that will guarantee the recycling of over 95% of the solvent. The urgency of finding replacements for the equally unique HMPT has already been noted.[228] Easily recoverable chiral solvents, especially ones available in both enantiomeric forms,[276] would be useful for enhancing stereoselectivity.[277, 278]
- *U*ltrasound has been found to work wonders in many heterogeneous reactions—sometimes in homogeneous systems as well.[249, 279, 280] It is especially effective for activating surfaces (e.g., in virtually any reaction that involves a dissolving metal) and has become a standard

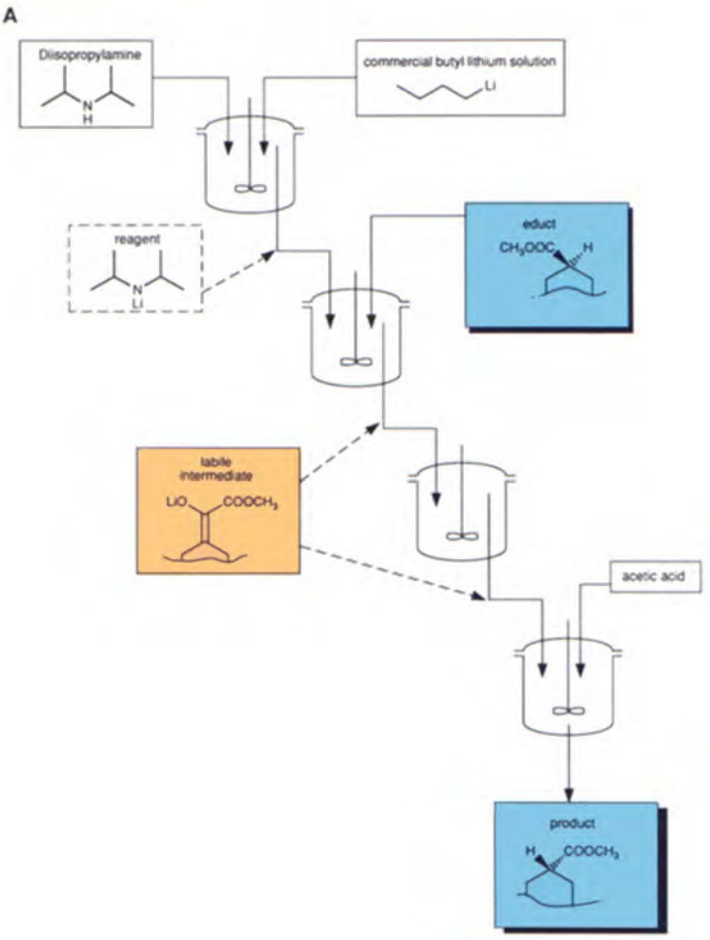

Fig. 10. Example of a low-temperature reaction carried out as a continuous process. Dihydrolysergic acid methyl ester is deprotonated to the Li enolate using lithium diisopropylamide (LDA) generated in situ. Subsequent protonation results in iso-9,10-dihydrolysergic acid methyl ester [245, 246]. A) Schematic representation of the process, and B) photograph of the pilot facility [244]. 1–4 correspond to the stirred reactors in A.

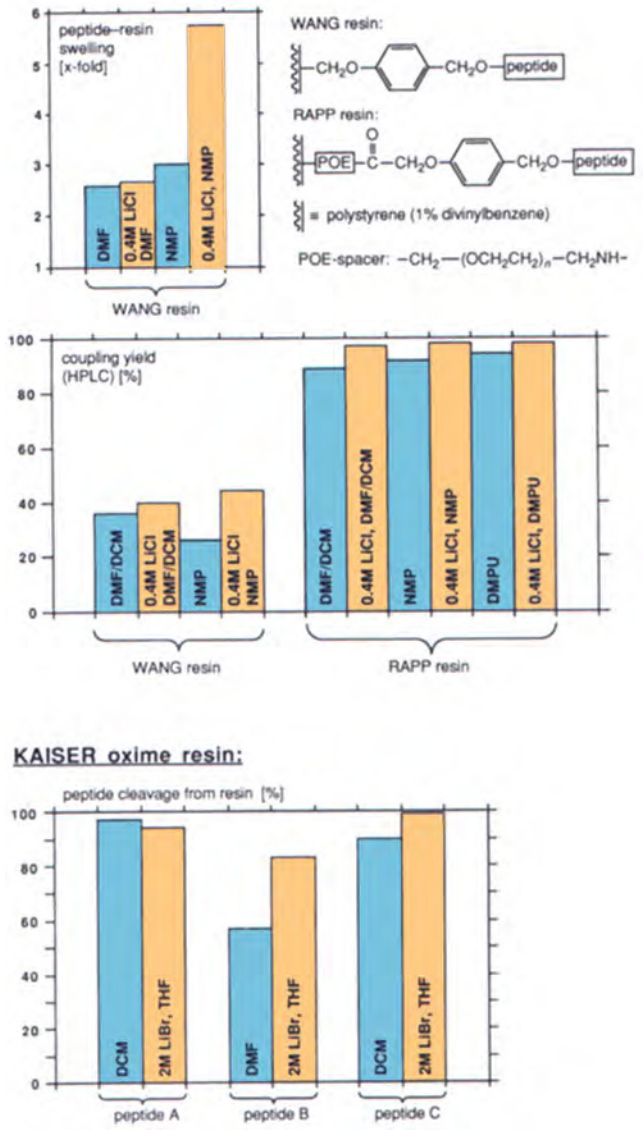

Fig. 11. Use of LiX-containing solvents [260] in Merrifield peptide syntheses involving various anchoring groups and coupling methodologies. The peptides chosen were notorious for a tendency to undergo aggregation (β-pleated sheet!), which normally implies a decrease in yield after a certain chain length has been attained. Experiments with Rapp and Wang resins [261] as well as with Kaiser oxime resin [262]. Polystyrene/1% divinylbenzene was the basis resin in each case. DCM = dichloromethane; NMP = *N*-methylpyrrolidone.

Table 2. Solubilization of oligopeptides in tetrahydrofuran and other organic solvents through the addition of salts and titanates. The reported maximum solubility is often achieved only after redissolving the residue from a much more dilute solution [260]. This method made it possible to obtain solutions of peptides soluble in *no* other solvent (example at the bottom of the table) [262]. For an application involving solid-state synthesis see Fig. 11.

These examples have been selected to call attention to a number of unusual or at least (until recently) atypical ways of carrying out reactions. At the same time, they illustrate the principle that the feasibility of extreme conditions is limited in practice only by the value of the product to be synthesized.

5. Reactivity: the Age-Old and Uniquely Chemical Fascination. New reactions—Are Any More Waiting to Be Discovered?

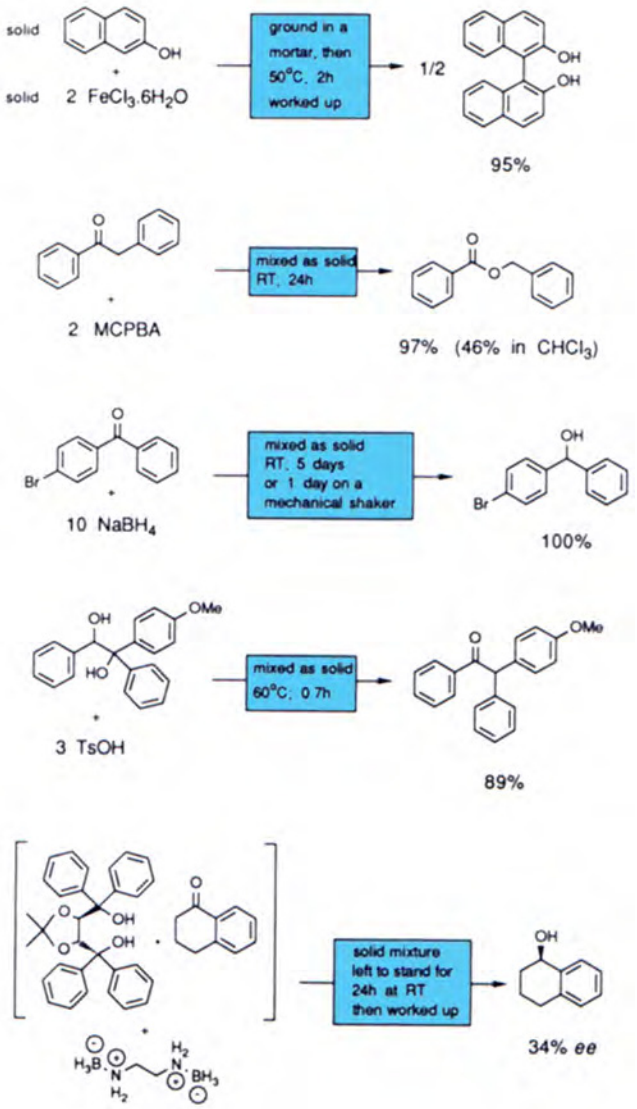
For the great things are not done by impulse, but by a series of small things brought together.
Vincent van Gogh (1888, in a letter to his brother Theo)[*]

A great many synthetic chemists, whether devotees of natural products synthesis or simply interested in synthesis gen-

method in the research laboratory, where an ultrasonic cleaning bath will usually do the job. To the best of my knowledge, however, no technological solution has so far been found to the problem of adapting ultrasound techniques to a large reaction vessel.

- Water has been recommended[281–284] as a medium for organic reactions, even ones involving organometallic intermediates. The advantages of water as a solvent are self-evident.

[*] Quoted from Irving Stone (ed.): *Dear Theo*, Doubleday, New York 1969, p. 164.



Scheme 14. In certain cases, solid–solid reactions are superior to the corresponding transformations in solution with respect to yield and selectivity. The examples shown come from the laboratory of *Toda* [267], and illustrate a phenol coupling reaction [268a], a Baeyer–Villiger oxidation (MCPBA = *m*-chloroperbenzoic acid) [268b], a $NaBH_4$ reduction [269], a pinacol rearrangement [270], and an enantioselective reduction [271] [by mixing a crystalline clathrate from an achiral ketone and a chiral host [272–275] with the solid complex $(H_3B)_2 \cdot (CH_2NH_2)_2$].—To the best of my knowledge it is not yet known to what extent such reactions represent a safety risk in terms of large-scale adaptation. Nevertheless, it is reasonable to anticipate that a technical solution might be found if the approach proves its superiority in other ways (absence of solvent, high volume-efficiency!).

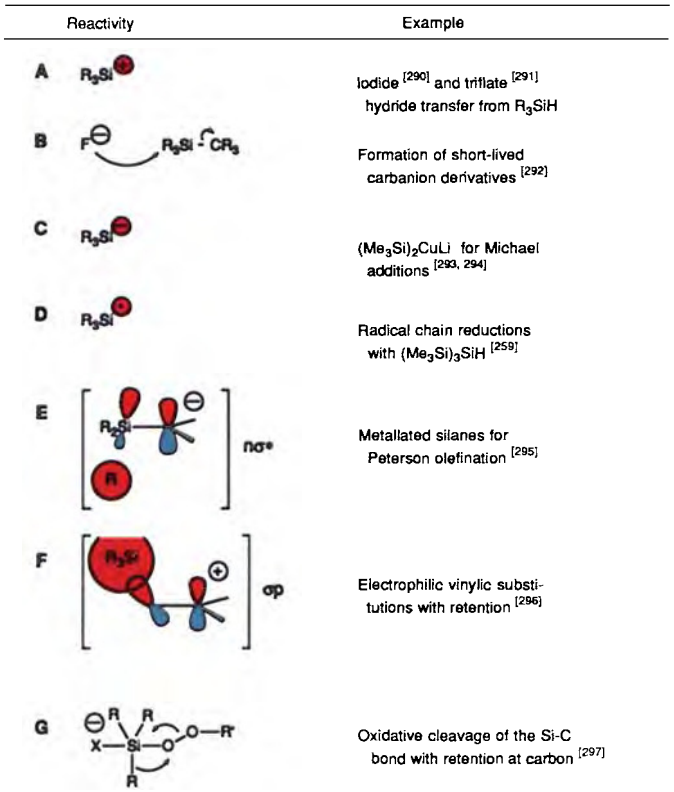
erally,[285, 286] list one of their areas of specialization as "new synthetic methods". It would be difficult, though, to develop a general consensus on the issue of what a "new" synthetic method really is. It has also become common to find words like *principle*, *strategy*, or even *protocol* linked with the adjectives "new" or "novel" (even "new *and* novel"!). But when one examines the piece of work to which such a description has been applied it often turns out to contain only a minor improvement on a well-known reaction, or a new *application* of an old technique. (Such observations tend to become more frequent as one grows older and wiser!) Years ago, a bet was made between one of my colleagues in Zürich and a chemist in Munich[287] about whether it is possible to find a truly new reaction with the help of a computer program[288] rooted in general principles of reactivity. The challenge is still open! For my part, I am convinced that only in the area of transition-metal organic chemistry are there new reactions waiting to be discovered (see Sections 6 and 7.2.2). In terms of main-group elements, whether metallic (Li through Ca, Be through Ba, Al through Tl, Ge through Pb, or Bi), metalloid (B, Si, As, Sb, Se, Te), or non-metallic (N, P, O, S, the halogens, or the noble gases), carbon derivatives have been examined for so long and with such intensity that no fundamentally new types of reactivity can reasonably be anticipated (see the applications associated with silicon and a few elements from higher periods outlined in Table 3 and

Table 3. Examples for Si-modified reactions from A to U. Most of the cases offer more or less significant advantages relative to the corresponding "normal" procedures. The Si variants can also be implemented at reasonable cost provided commercial silylating agents are utilized. (Numerous silyl compounds are manufactured in bulk for use in the preparation of silicones [314].)

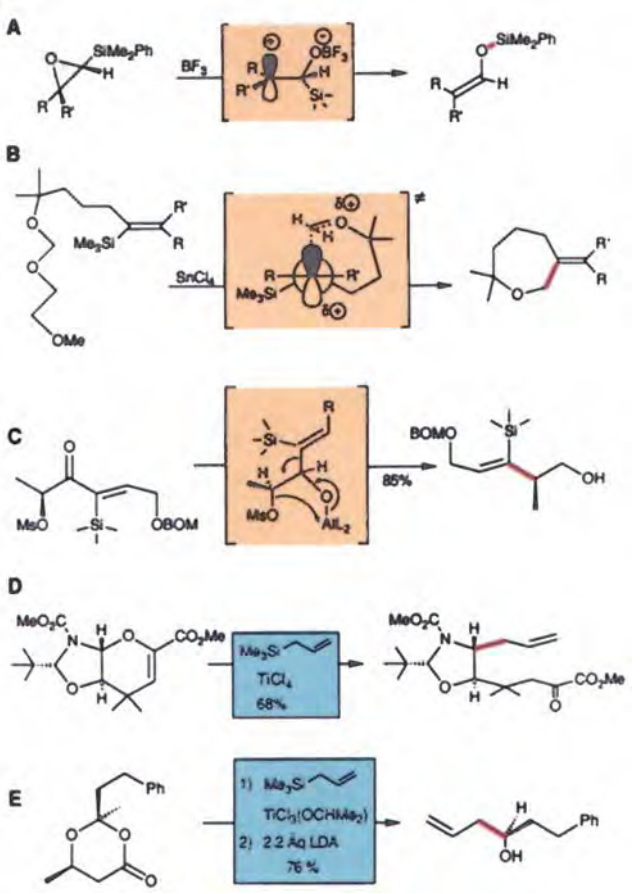
Si-acetalization	of aldehydes and ketones, Si-triflate catalysis (based on *Noyori*) [298–300]
Si-acyloin condensation	Rühlmann variant of the acyloin reaction [301,302]
Si-aldol additions	see Schemes 19 and 26
Si-azide	"the versatile reagent" [303]
Si-Birch reduction	and other Si-modified reactions of dissolving metals [304]
Si-cyanohydrin reaction	see below, Si-umpolung
Si-diazomethane	safer variant of the standard diazomethane reactions [305]
Si-Friedel–Crafts-type acylations	at aromatic, vinylic, and acetylenic C-atoms [109,289]
Si-Mannich	see below, Mannich reactions [336]
Si-Nazarov reaction	five-membered ring annelation [306], cf. also the Si-variant of the Robinson annelation [307]
Si-nitroaldol additions	diastereoselective to give products of *l* or *u* configuration [18f,308]
Si-olefination	Peterson olefination [108,295,309]
Si-ozonolysis	with triethylsilyl-hydrotrioxide [310]
Si-pinacol rearrangements	migrating α-Si-vinyl group [311], see also Scheme 16 and [322] therein
Si-Pummerer rearrangement	from sulfoxides to α-Si-thioethers [312]
Si-radical chain reductions	see above, Scheme 15 **D**, ref. [259]
Si-umpolung	with trimethylsilylcyanide [34] or with Me_3Si-thiazole [313]

Schemes 15–17). This obviously does not mean that in the areas we have long regarded as the true domain of classical organic chemistry there will be no more progress. On the contrary! The achievements of the past 30 years,[330] indeed the past 10 years, have been quite remarkable. To a greater extent than in the past, however, progress has been not the product of solitary, revolutionary discoveries, but rather the cumulative effect of innumerable small steps taken by increasing numbers of researchers throughout the world.

Thus, we have not witnessed the discovery of new aldol,[331] Beckmann,[332] Claisen,[333] Cope,[334] Diels–Alder,[335] Mannich,[336] Michael,[331a, 337] or Wittig[26, 27, 338]



Scheme 15. R_3Si: more than just a "big, fat proton". In most of the organic synthetic applications of R_3Si derivatives, the Si group plays a role identical to that of the proton in analogous classical reactions (cf. A and B, as well as the aldol reactions in Scheme 19) [289]. The Si group can be introduced nucleophilically by way of Li or Cu derivatives (cf. C). Radical hydrogen transfer can be accomplished with SiH compounds in the presence of chain initiators such as AIBN (D). Stabilization by Si of α-anionic charges (E), as well as β-cationic charges (F, cf. Scheme 16) also leads to useful applications of Si derivatives in synthesis. The oxidative cleavage of SiC bonds indicated in G establishes synthetic equivalence between silyl groups and OH.



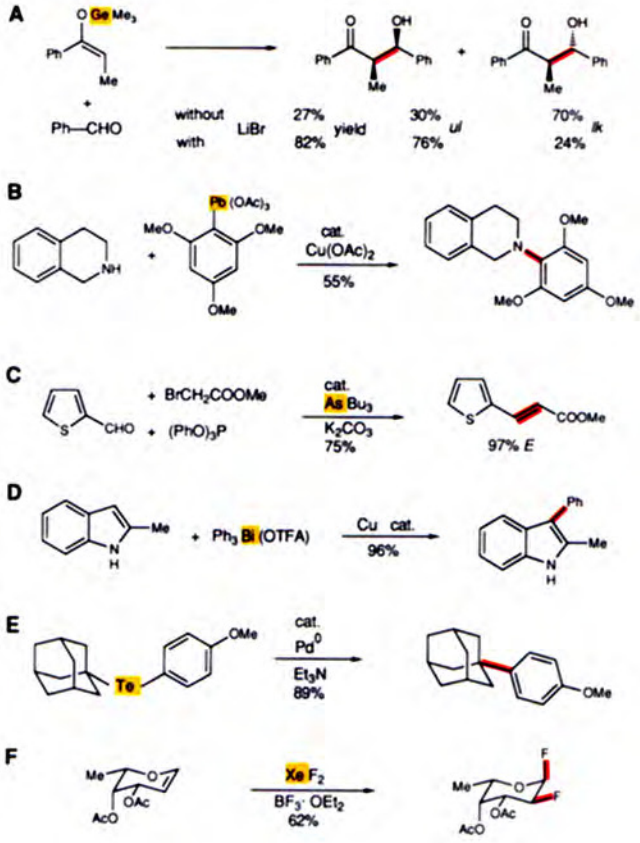
Scheme 16. Transformations facilitated by the stability of β-Si carbocations. The amount of stabilization associated with the β-Si effect has been estimated to be as great as 159 kJ mol^{-1} [315]. Vinyl- [109] and allylsilanes [107, 316] have acquired considerable significance in organic synthesis. Thus, Si groups activate double bonds, control regioselectivity in electrophilic attack, ensure stereoselectivity during reaction (cf. the preference for retention in substitution of vinylic silyl groups [109, 296] and S_E-*anti*-substitution of allylic silyl groups [109, 317, 318]), and function—formally speaking—as leaving groups of the type $R_3Si^{\oplus}$. A) Stereoselective (*cis* → *Z*, *trans* → *E*, ca. 95% *ds*) rearrangement of silyloxiranes to Si enol ethers [319, 320]. B) Attack of an oxonium ion on a vinyl silane, leading to an oxepane via substitution with retention (R = Bu, R′ = H and R = H, R′ = Bu, > 98% *ds*) [321]. C) Migration of an α-silylvinyl group in what amounts to a pinacol rearrangement (retention at the migrating carbon, inversion at the migration terminus; this process may involve a β-Si stabilized cyclopropylmethyl carbocation) [311, 322] (BOM = benzyloxymethyl). D) Allylation with allyltrimethylsilane via an acyliminium ion, accompanied by retention of configuration [323]. E) Allylsilane/$TiCl_3(OCHMe_2)$ used to effect S_N2 ring opening of a dioxanone with the (1*R*,6*R*) configuration, a process that entails subsequent elimination to provide a homoallylic alcohol (overall yield 76%, enantiomeric excess 94% *ee*) [299, 324].

reactions; even the exploitation of strain effects in small rings[339] and the broader application of 1,3-dipolar cycloadditions,[340] dithiane methodology,[18i] ortho metallation ("new arene chemistry"),[341] the acyloin[342a] and pinacol condensations,[274, 342b–d], photochemical[251–254, 343] and radical reactions,[255–259, 344–346] nucleophilic substitution,[347] and "umpolung" of reactivity[18, 31–35, 313, 348] took place without the discovery of new modes of reactivity. Nevertheless, each of the transformations cited[349] has, in a sense, been raised to a much higher level of sophistication. Major thrusts of recent activity have centered around catalytic modifications, diastereoselectivity,[350] enantioselectivity, and the linking together of series of reactions into multistep in situ sequences.[351]

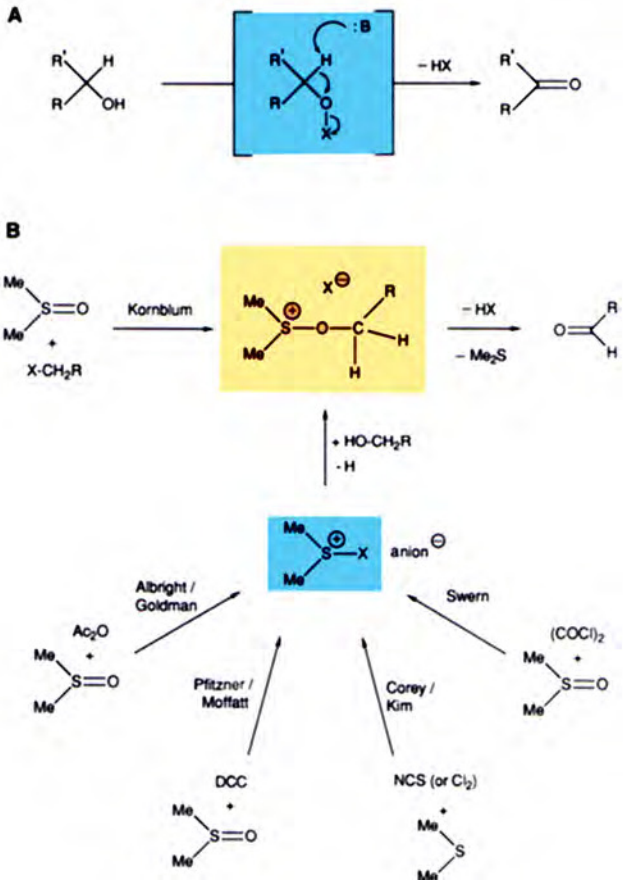
It is obviously quite impossible within the confines of this paper to present an account that even begins to describe the true extent of the efforts and accomplishments of the research groups responsible for these many developments. Instead, I have chosen the following course: First, two Schemes (18 and 19) present selected examples of stepwise improvements to certain standard reactions, and Table 4 highlights some diastereoselective reaction sequences in which a few steps suffice to generate surprisingly complex molecules. These representative samplings are followed by two chapters more directly related to my own interests,[273, 274, 342d, 352–354] illustrating the application of transition-metal derivatives in organic synthesis and the preparation of enantiomerically pure compounds, with an emphasis on catalytic methods. It is my conviction that precisely these two areas will become increasingly important over the next few years.

6. Transition-Metal Derivatives—Always Good for a Discovery

Anyone who has attended one of the biennial conferences on *o*rgano*m*etallic *c*hemistry directed toward *o*rganic *s*ynthesis (OMCOS), and sensed there the atmosphere of excite-



Scheme 17. Synthetic transformations involving organometallic compounds containing main-group elements from higher periods. A) The Li enolate of propiophenone, prepared with the aid of LDA, was transmetallated to give the indicated Ge enolate, which in turn leads preferentially, depending on the reaction conditions, to either an *lk*- or a *ul*-aldol [325]. B) Cu-catalyzed reaction of tetrahydroisoquinoline with aromatic Pb(IV) compounds, resulting in *N*-arylation [326]. C) A first catalytic olefination following the scheme of the Wittig reaction proceeds via an arsenic ylid [327a]. D) Phenylation of an indole with triphenylbismuth trifluoroacetate [327b]. E) A type of mixed Wurtz coupling between adamantyl and *p*-methoxyphenyl, accomplished via a telluride [328]. F) Use of XeF_2 as reagent for the addition of fluorine to a double bond [329] (cf. also Scheme 7). It is worth noting that three of the six reactions shown are catalyzed by transition metals! (cf. also Sections 6 and 7.2).



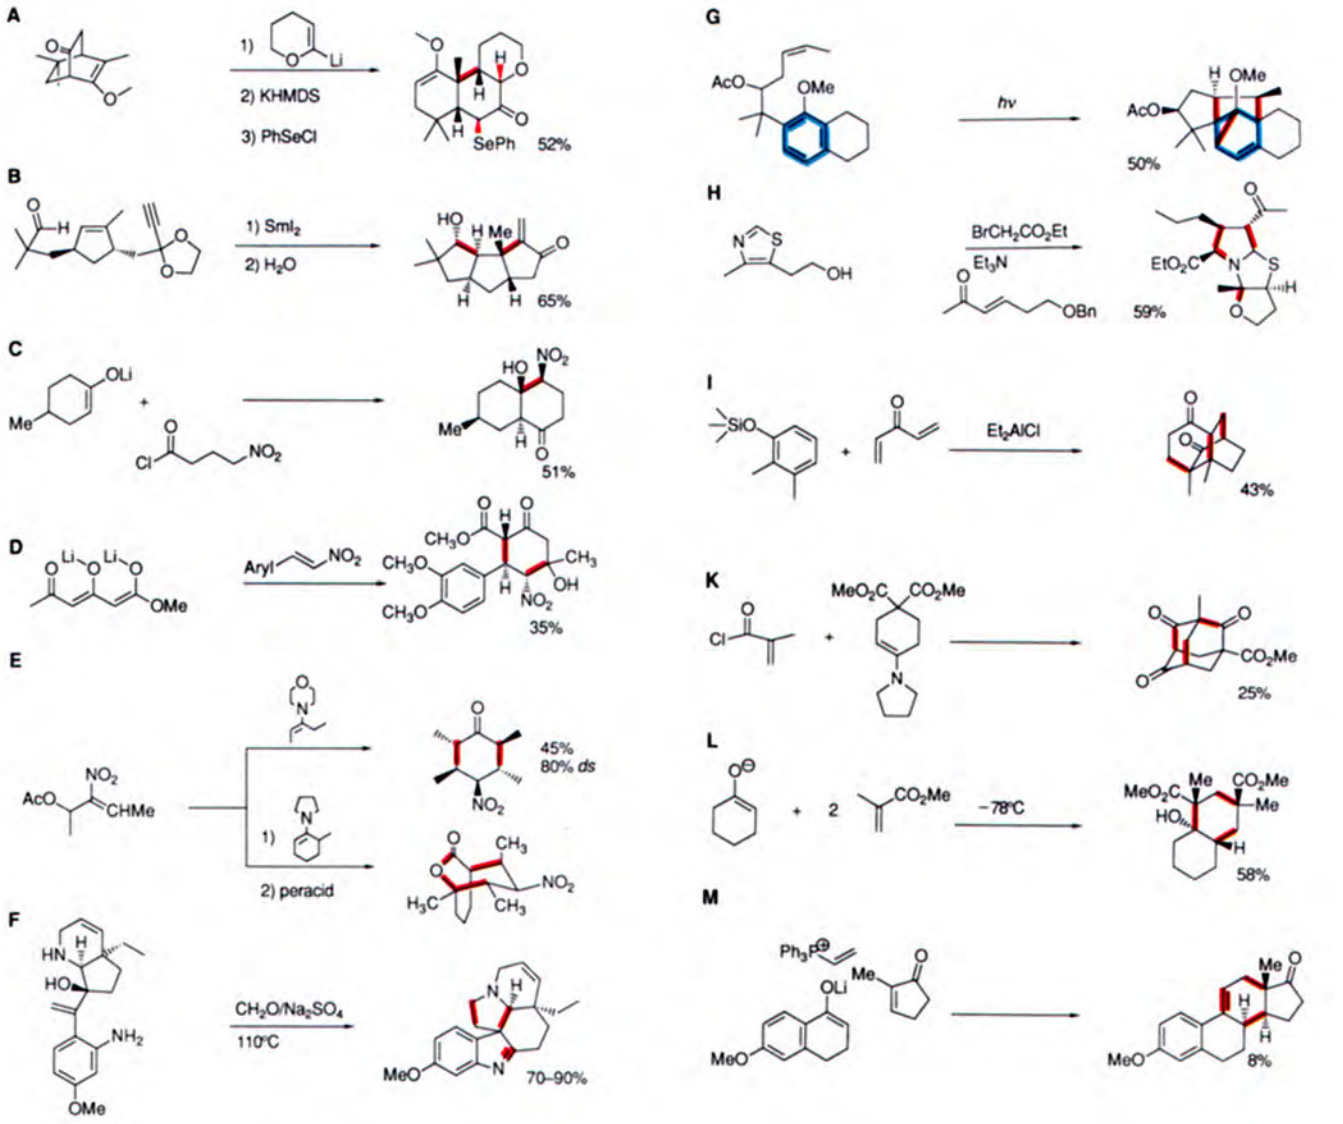
Scheme 18. "Evolution" in the oxidation of an alcohol to a carbonyl derivative [355]. A) A leaving group is first introduced, after which the actual oxidation at carbon takes place by HX elimination. This scheme characterizes, for example, chromic acid oxidation [355], the reaction with hypochlorite [356], corresponding reactions of peroxides [357]—in principle, even the oxidation of amines to carbonyl compounds with the aid of an *o*-quinone [358]. B) Reaction by way of sulfoxonium salts can occur starting with educts of widely varying type [359–363], with the Kornblum oxidation itself [359] serving to convert an alkyl halide into an aldehyde. The currently most popular variant is the Swern oxidation [362], favored because of its mild conditions. There are numerous other possibilities for activating DMSO in the oxidation of alcohols to aldehydes and ketones (cf. the review articles cited under [362, 363]). DCC = dicyclohexylcarbodiimide, NCS = *N*-chlorosuccinimide.

ment enveloping both speakers and audience, will surely find it inconceivable that organic chemistry could be described as a "mature" science. At the last of these OMCOS conferences (in Florence) the air was full of the way "we OMCOS people" would tackle something—and do it better! Many general treatises[388] and reviews, of which only two will be cited here,[389, 390] as well as the even more numerous monographs and articles dealing with specific reactions of the derivatives of particular metals,[391] demonstrate the increasing role of transition metals in the field of organometallic synthesis. Relevant papers may appear in general, inorganic, organic, organometallic, or even more specialized chemical journals, and it is difficult to maintain a satisfactory overview.[392] Furthermore, the reactions themselves are often not easy to classify, and despite great progress in both theory and formalism[393] they do not always lend themselves to detailed formulation, frequently leaving the reader to puzzle over the marvelous transformation of educt into product. One indication of activity in the field is the fact that most of the new organic name reactions of the last decades trace their origins to transition-metal chemistry;[394, 395] a few examples are presented in Table 5. (The author accepts full responsibility for incorrect classifications and missing names!) Scheme 20 illustrates several cyclizations that proceed via carbonyl complexes and are without precedent in classical organic chemistry.

Here, too, there have been significant developments with respect to well-known reaction types;[408–411] for the practitioner, some of them amount to genuine quantum leaps. Thus, by using transmetallation to go from classical Grignard or organolithium reagents to the easily prepared titanium,[273–275, 299, 412] zirconium,[273, 274, 413] or lanthanide derivatives,[414–416] it is possible to experience selectivity increases during carbonyl addition that raise the yield of the desired product from less than 10% to over 90%. Examples of differentiation among several functional groups, preparation of specific diastereoisomers, and the realization of enantioselective transformations are provided in Scheme 21, Fig. 12, and Scheme 22, respectively.

Reductive coupling[301, 342] of carbonyl derivatives and their thio and imino analogues has been greatly facilitated by the advent of low-valent derivatives of titanium, vanadium,

Table 4. In situ sequences [373] of classical reactions leading to the formation of up to five new stereogenic centers. Enthusiasm over successful "complexity-enhancement" has resulted in several dazzling descriptions [351, 374–376]. A) Carbonyl addition, oxy-Cope rearrangement [334b], proton transfer, and selenization leads to a tricyclic product with five stereogenic centers (where the educt contained only two); KHMDS = potassium hexamethyldisilazanide [343c]. B) Two bonds, two rings, and three stereogenic centers are formed in this sequence of radical reactions [377]. C) A C-acylation of 4-methylcyclohexanone enolate with 4-nitrobutyryl chloride, followed by an intramolecular nitroaldol addition, results in a *trans*-decalin derivative [378]. D) Michael addition of the di-enolate of 3,5-dioxohexanoic acid ester to a nitrostyrene, followed by nitroaldol addition, gives a cyclohexanone with four adjacent stereogenic centers [337d]. E) Intermolecular Michael addition (or S_N substitution?), intramolecular Michael addition, and proton transfer accomplishes diastereoselective generation of a total of five stereogenic centers [337e]. F) Iminium salt formation, aza-Cope rearrangement, a Mannich reaction, and condensation between the *ortho* amino group and the newly formed carbonyl function all occur in situ during synthesis of the alkaloid methoxytabersonine [336a, 379]. G) Light truly works wonders in this intramolecular cycloaddition between an olefinic double bond and a benzene ring [380] (Kaplan–Bryce–Smith reaction [254, 381, 382]). H) Ethoxycarbonylmethylation at the nitrogen of a thiazole, ylid formation, cycloaddition to the C–C double bond of an enone, and tetrahydrofuran formation are the steps leading from two achiral educts to a tricyclic system with five centers of chirality [383]. I) Three-fold Michael addition produces four stereogenic centers [384]. K) Enamine acylation, followed by intramolecular Michael and Dieckmann reactions, transforms methacrylyl chloride and a cyclohexanone derivative directly into the adamantane skeleton [385]. L) A 1:2 intermediate trapped along the way toward polymerization [9] in the reaction of cyclohexanone enolate with methacrylic ester [386]. M) Michael addition to methylcyclopentanone, trapping of the resulting enolate with a vinylphosphonium salt, and an intramolecular Wittig reaction—carried out as a one-pot sequence leading to the estrone skeleton, albeit in low yield [387].



and niobium, and the scope of the reaction has been broadened (e.g., to include nitriles), as shown in Scheme 23.

An application of allyl protective groups in DNA synthesis[430–434] provides a particularly impressive example of what can be achieved with organometallic methodology: Nitrogen atoms in the constituent bases were subjected to allyloxycarbonyl (AOC) protection, and *O*-allyl groups were incorporated into the added phosphoramidite units. In a dramatic final step, with the substrate still attached to the polymeric carrier, all the protective groups were removed at once by treatment with Pd^0/Ph_3P/butyl amine/formic acid in THF. Oligonucleotides resulting from this "Nagoya method" are of unprecedented purity; this is illustrated in Fig. 13, which compares samples of nucleotides containing up to 60 nucleoside units prepared by the conventional method and by the new method.

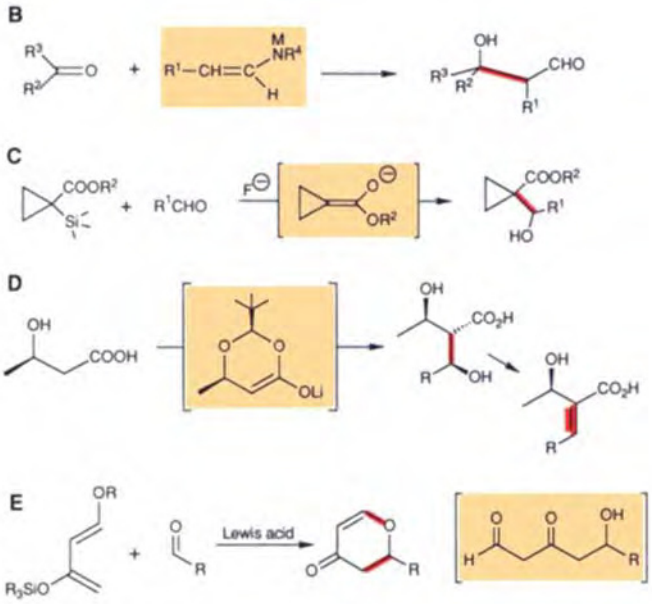
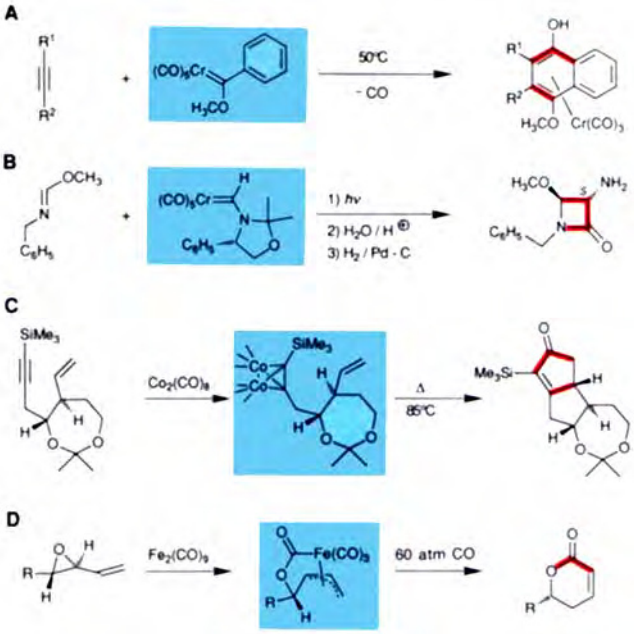
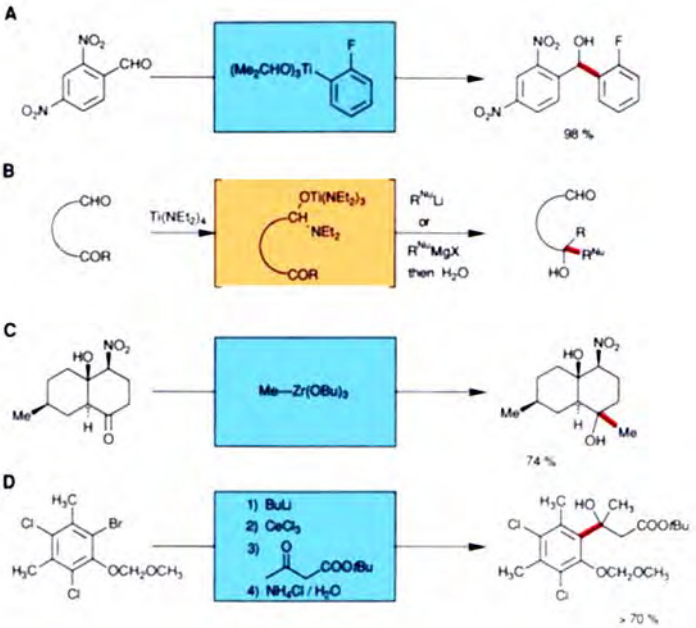


Scheme 19. Aldol addition—from humble origins to undreamed of heights (the enantioselective variant is included in Sec. 7, Scheme 26). A) Development of the aldol reaction from an unselective process in protic solvents to a diastereoselective variant in non-polar medium at low temperature. B) Directed aldol addition (and increased enolate nucleophilicity) with enamides and enhydrazides [369]. C) In situ generation of unstable or highly reactive enolates via α-Si carbonyl compounds, exemplified by a cyclopropanecarboxylic acid derivative [292, 370]. D) Aldol adducts and condensation products from aldols via enolates of (2*R*,6*R*)-dioxanones [371]. E) Aldol addition (or is it a hetero-Diels–Alder reaction?), cyclization, elimination, and desilylation leads to dihydropyran units with synthetic utility. The Lewis acid-induced addition (LACDAC = "*L*ewis *a*cid-catalyzed *d*iene–*a*ldehyde *c*yclocondensation") of a "double enol ether" to an aldehyde (stereoselectively in the case of a 1-substituted diene or a chiral aldehyde) has proven to be a veritable gold mine in the hands of *Danishefsky* and his group [372].



Scheme 20. Four cases of cyclization accompanied by CO insertion and made possible by transition-metal derivatives. A) [3+2+1]-Carbocyclization in the Dötz reaction [397–399]. B) β-Lactam formation through photochemical addition of an aminocarbene complex to an imine (*Hegedus* [390, 394]). C) [2+2+1]-Carbocyclization via a cobalt carbonyl–acetylene complex (*Magnus* [390, 401, 403]). D) Lactone formation by CO insertion into a vinyloxirane (*Ley* [390]).



Scheme 21. Highly selective nucleophilic addition of Ti, Zr, and Ce reagents to carbonyl groups (cf. also Fig. 12). A) *o*-Fluorophenyl triisopropoxytitanium, stable at room temperature, adds nearly quantitatively to a dinitrobenzaldehyde [417] (cf. case A in Fig. 12). B) The non-basic reagent tetrakis(diethylamino)titanium (synthesis described in [274]) adds selectively to the aldehyde group in a formyl ketone, leaving only the keto group accessible to attack by a polar nucleophile [412]. C) Neither electron transfer nor base-induced retro-nitroaldol addition interferes with diastereoselective (> 98% *ds*) addition of the methylzirconium reagent (74% yield) [413]. D) If all else fails, or if an absolutely foolproof method is required, then the answer today is transmetallation of a Li or Mg derivative with $CeCl_3$ prior to introduction of a carbonyl compound! [414].

The high price and/or toxicity of many transition metals adds urgency to the ongoing quest for catalytic approaches to such transformations, even on the laboratory scale; this particular problem has recently been addressed in a review article.[435]

Table 5. A few examples of transition-metal *name* reagents or reactions that in the last 20 years have come to be regarded as standard procedures. Excluded from consideration here are primarily industrial methods, such as hydroformylation or the Ziegler–Natta polymerization. Some of the reactions shown require stoichiometric amounts of the organometallic reagents, whereas others are catalytic (in some cases involving polymer-bound catalysts). Enantioselective transformations are discussed further in Sec. 7. The book [394] by *Collman, Hegedus, Norton,* and *Finke* includes pertinent references to all the examples shown.

7. The Preparation of Enantiomerically Pure Compounds (EPC)

There is nothing faster than the years.
Ovid (43 B. C.–17 A. D.)

At the present time, almost no aspect of organic synthesis is generating as many publications as the preparation of enantiomerically pure compounds.[436–438] It is easy to predict that by the year 2000 this flurry of activity will have provided us with all of the following: a) simple approaches to the synthesis of enantiomerically pure chiral compounds

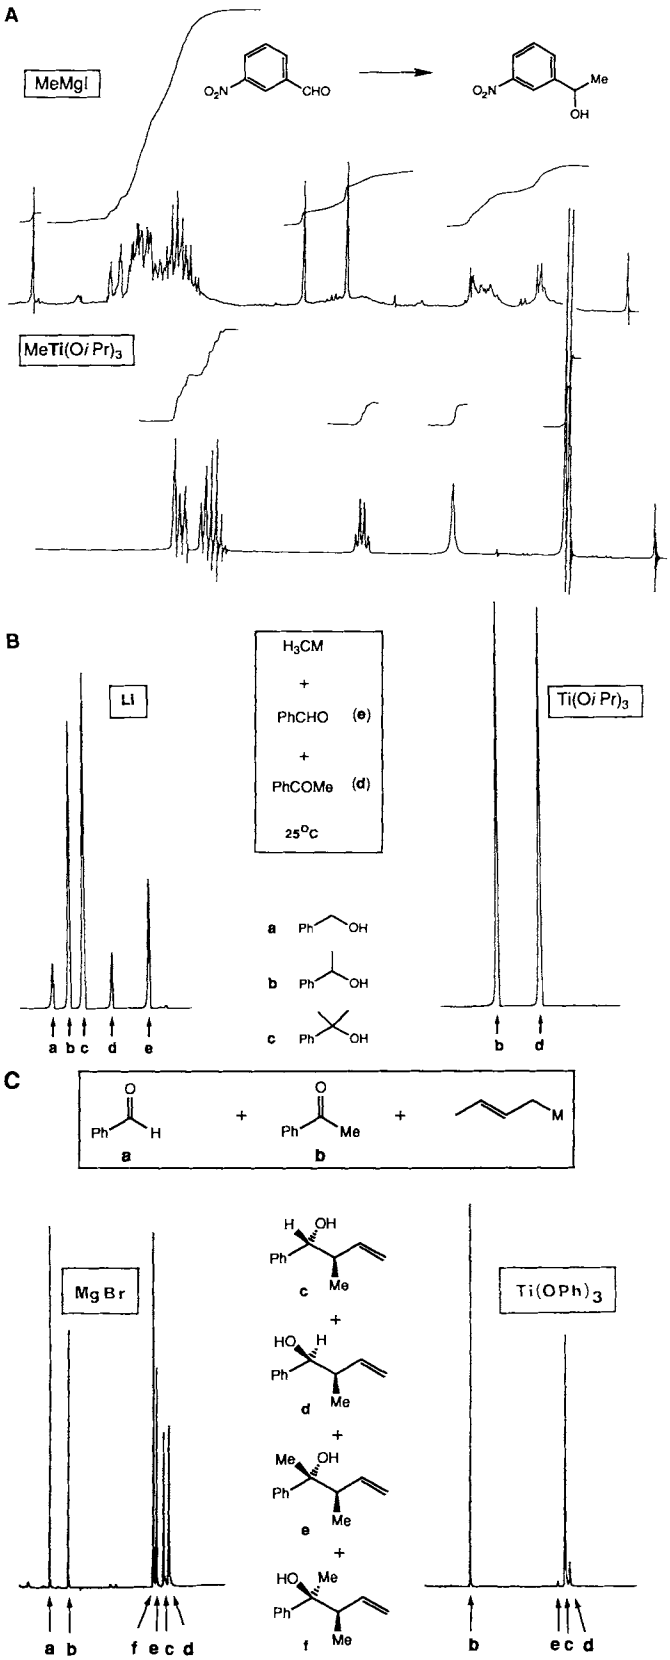

Fig. 12. Three examples of yield and selectivity increases that can be achieved by transmetallation of Li and Mg reagents to Ti derivatives. A) A glance at the NMR spectrum of the crude product betrays the high yield obtained upon addition of the methyltitanium reagent to *m*-nitrobenzaldehyde [418] relative to addition of a Grignard reagent. B) A comparison of crude product gas chromatograms reveals the perfect selectivity of MeTi vs. MeLi with respect to aldehyde/ketone addition. With the Li reagent, the rate of addition at the ketone is comparable to that at the aldehyde [274]. C) Crotyltitanium adds more selectively than the crotyl Grignard reagent to a mixture of benzaldehyde and acetophenone [273a].

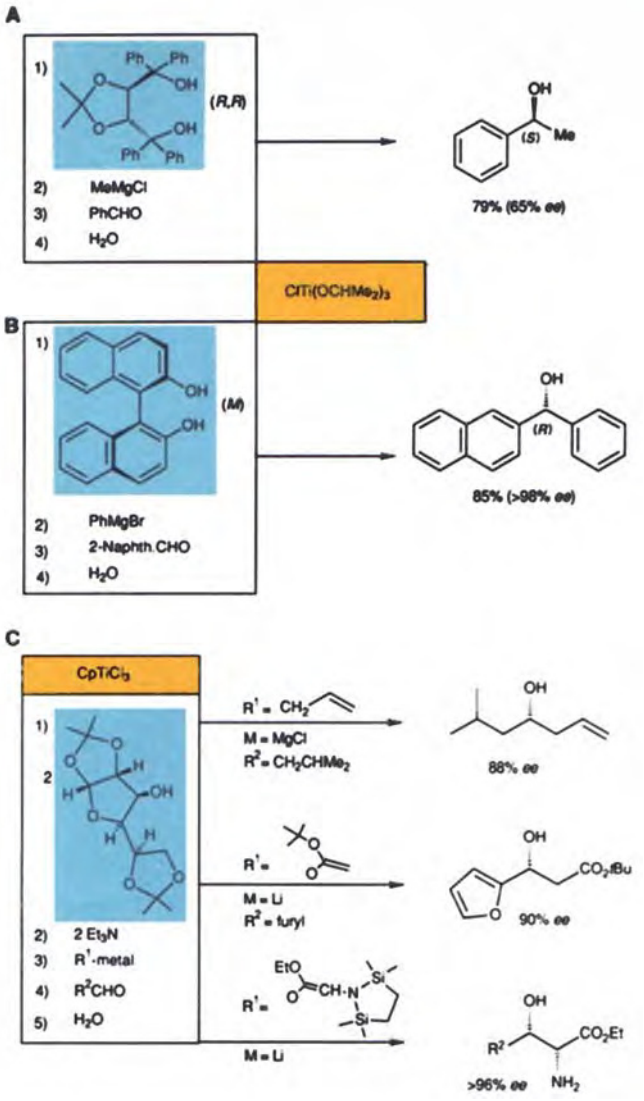
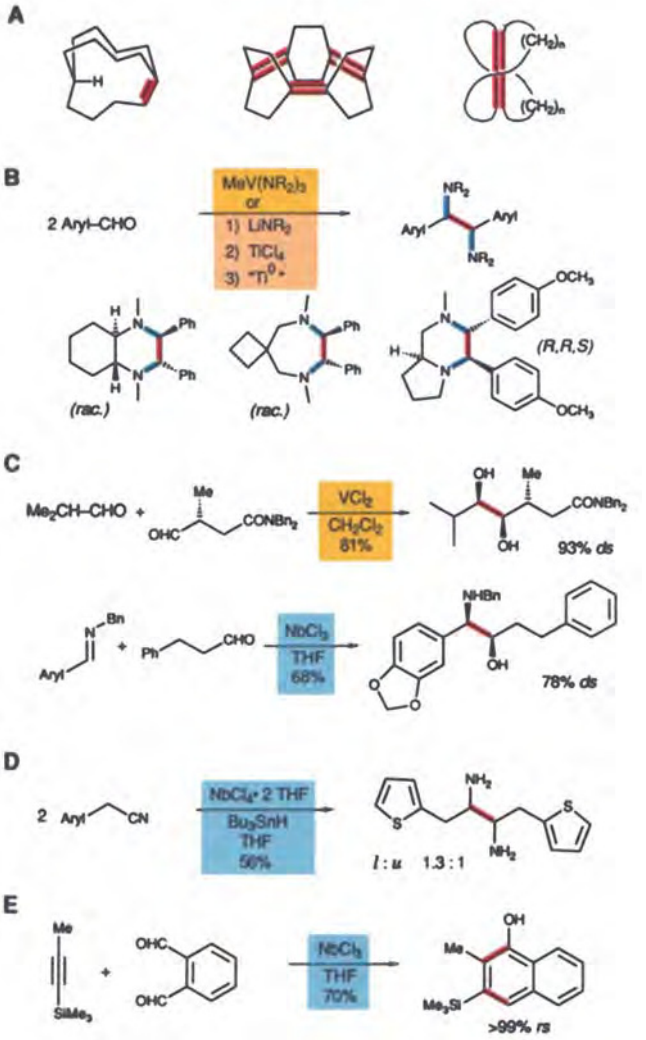


Scheme 22. The in situ generation of chiral alkyl, allyl, aryl, and vinyloxytitanium derivatives bearing $(R^*O)_2$ ligands, followed by addition to aldehydes. A) The chiral diol derived from tartaric acid [272–274] ensures fair-to-good enantiomeric excesses in the addition of alkyl groups to aldehydes (in this example, 79% yield, 65% *ee*) [273a, 275]. B) Particularly useful for the preparation of enantiomerically pure benzhydrol derivatives [419, 420] is the binaphthol ligand (here providing an 85% yield, > 98% *ee*) [402]. C) The use of CpTi derivatives in which the R*O group is derived from glucose offers distinct advantages (recoverability of $CpTiCl_3$; inexpensive, commercially available auxiliary; reproducible results); this method has been successfully utilized for allyl transfer (*lk* combination, cf. Fig. 12c) and aldol additions [421]. The diol shown in A has also been allowed to react with $CpTiCl_3$, providing access to both enantiomers of products of the type illustrated in C [422].



Scheme 23. Reductive coupling of carbonyl compounds and their analogues using derivatives of low-valent metals from the fourth and fifth subgroups. A) Three (attractive!) unsaturated hydrocarbons prepared from the corresponding diketones and a ketoaldehyde via the McMurry reaction (reviews: [342b–d]). B) Reductively aminating one-pot coupling of aromatic aldehydes to 1,2-diarylethan-1,2-diamines using either a vanadium(IV) derivative [423] or "titanium(0)" [342d, 424]. C) Diastereoselective crossed coupling with VCl_2 of two different aldehydes [425], and of an imine and an aldehyde using $NbCl_3$ [426] (cf. also the *like*-selective coupling of aromatic aldehydes with $TiCl_4$/BuLi [427]). D) 1,2-Diamines from nitriles and $NbCl_4$/Bu_3SnH [428]. E) Regioselective reductive [4 + 2]-carbocyclization of *o*-phthalaldehyde with an alkyne to give a naphthol [429] (rs = regioselectivity).

representing all the known classes of substances; b) catalytic variants for every reaction in which achiral precursors lead to at least one element of chirality; c) corresponding methods suitable for industrial use on any desired scale; and d) much wider understanding of intermolecular interactions and the detailed course of reactions.

Why is it that enantiomeric compounds have moved so decisively toward the center of attention? One important factor is certainly the *general* recognition that living systems, which are themselves made up of chiral components,[439] interact with enantiomers in different ways (as a result of diastereomeric relationships). This awareness has led to increasingly restrictive guidelines with respect to the registration of racemic mixtures of active substances (by the FDA, for example),[440] which has in turn forced industry to amend its ways.[435, 441, 442] Anyone who has had the occasion to sniff samples of both enantiomers of certain fragrances will not be surprised to learn that the fragrance industry has been one of the leaders in this development.

Ever since stereochemistry was in its infancy, experts—or perhaps one should say "the educated"—have understood the profound difference between enantiomers and racemates; *Pasteur* himself was able to show that microorganisms have no trouble distinguishing between (*R*,*R*)- and (*S*,*S*)-tartaric acid (Scheme 24).

Actually, there has been nothing fundamentally new discovered in this area during the 140 years since *Pasteur* took the first steps along the three basic paths to pure enan-

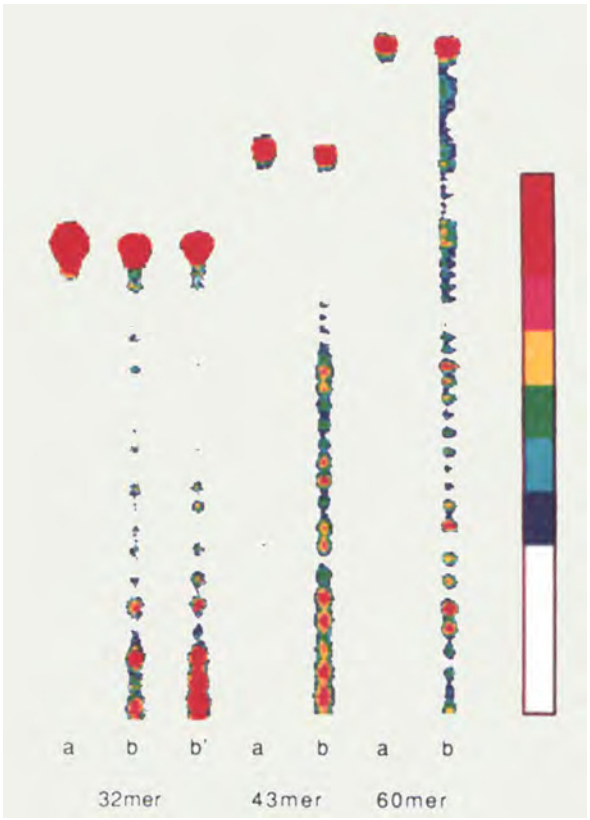


Fig. 13. "Bio-image" chromatogram of oligo-DNA crude products [430–433]. Track a: products prepared via the new (allyl–allyloxycarbonyl) protective group method. Track b: products obtained by what are now the standard routes. Color scale: red (high intensity) to blue (lower intensity) [434].

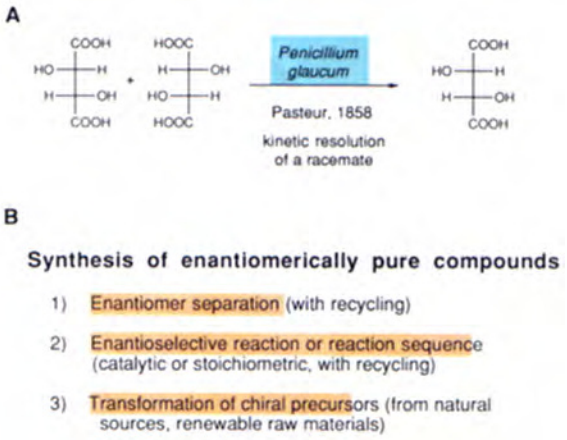


Scheme 24. *Pasteur*'s kinetic separation of the tartaric acid enantiomers with the aid of a microorganism (an enantioselective biological-chemical reaction!), and the three techniques for synthesis of enantiomerically pure compounds. A) If *Penicillium glaucum* is permitted to grow on racemic tartaric acid (*acidum racemicum*), fermentation ceases as soon as the (*R*,*R*)-(+)-tartaric acid has been consumed; *Pasteur* succeeded in isolating residual (−)-enantiomer from the growth medium. B) The following review articles on the three methods of preparing enantiomerically pure compounds (EPCs) have already been cited in Sections 2–5: separation of racemates [133–137, 343a], enantioselective reaction [125, 126, 331a, c, 353, 354, 402, 435], incorporation of chiral building blocks [199, 352–354] (the author of the present article accepts responsibility for the widespread use of the term "chiral pool" [443]—a sin from the days of his youth, of which he first became fully aware in *Vlado Prelog*'s circle [444, 445]; a "readily available supply" cannot be chiral! See the remarks in [436]).

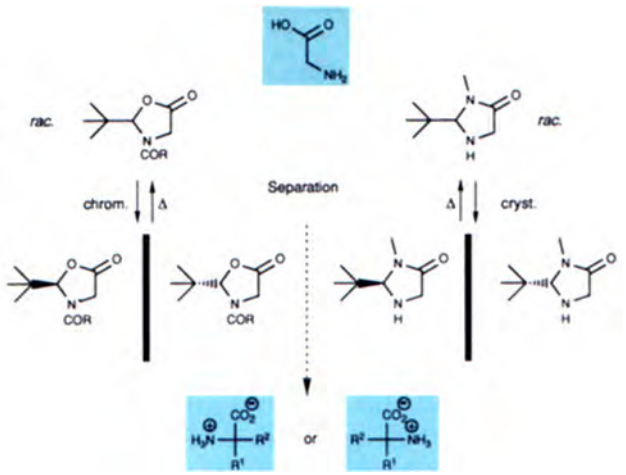
tiomers: separation of a racemic mixture, enantioselective reaction, and synthesis based on chiral starting materials isolated from natural sources. Quite properly, synthetic chemists devoted themselves first to the subject of reactivity in general, and natural products chemists nearly always synthesized their targets in racemic form. After all, a complex synthesis must be seen basically as the struggle to arrive at a correct constitution containing many stereogenic units; enantioselective generation of the first center of chirality, or separation of some intermediate into its enantiomers ("resolution"), represented the least of the worries! Times have changed, however, and interest in this subject has now become so intense that entire conferences have been devoted to it.[442, 446] Some have hailed enantioselective synthesis as *the* challenge,[447] and new publications have been established with titles like *Asymmetry* and *Chirality*.[448] In the present context it will be possible to touch upon only a few highlights.[449] Moreover, the subject itself is such that it precludes the offering of general prescriptions or advice regarding, for example, which of the three general approaches to enantiomerically pure compounds is "the best".

7.1. Separation, Selectivity, or Incorporation—That is the (Gretchen) Question![*]

Which of the three routes one chooses to prepare an enantiomerically pure compound depends essentially upon the task at hand. The substance in question may be required on a tons-per-annum basis (as in the case of phenylalanine, lactic acid, or menthol). On the other hand, a few hundred kilograms per year might suffice for an expensive pharmaceutical agent, and pharmacological screening can be carried out with much smaller amounts. A research laboratory is more likely to need a few grams of one enantiomerically pure substance today and a different one tomorrow. If the problem is one of developing a new stereoselective application, or of completing a mechanistic investigation, a few hundred milligrams of a pure substance will probably serve the purpose. The greater the quantity of material required, the more important it becomes to recycle the unwanted enantiomer after a resolution, to recover an auxiliary introduced in stoichiometric quantities, to choose natural (renewable) chiral building blocks, or to develop efficient catalytic methods. The more limited and diverse the needs, the more flexible must be the methods with respect to product structure and to the chemistry involved; cost is not then an issue, as exemplified by the extreme case of a radioactively labeled material for use in metabolic studies.

The examples shown in Schemes 25–27 have been selected to demonstrate all three of the basic methodologies. Thus, heterocyclic glycine derivatives obtained through separation of enantiomeric mixtures (Scheme 25) facilitate the synthesis of non-proteinogenic amino acids, and this method of preparation is quite competitive with other approaches.[86] By the way, the *tert*-butyl group responsible here for selectivity came from BASF, which supported our work with a gener-

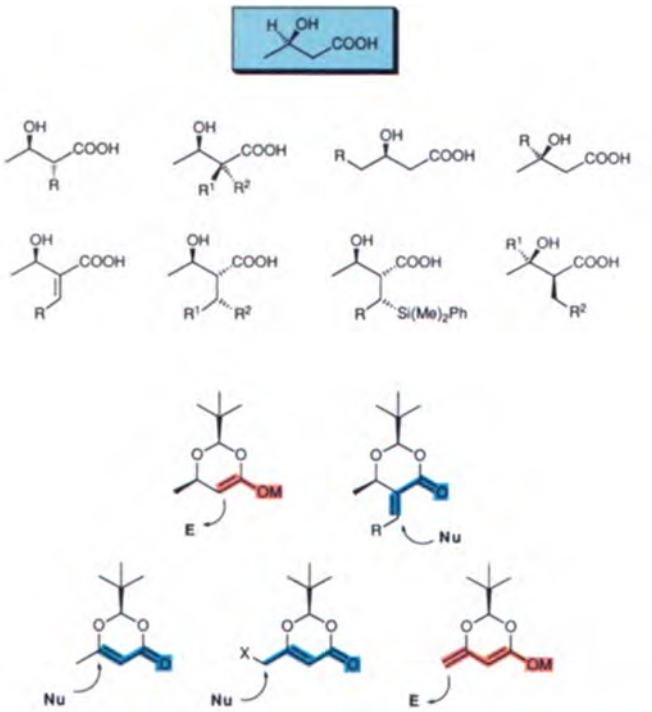
[*] An allusion to Margaret's (Gretchen's) famous query of Faust: "How do you feel about religion?" (Goethe).



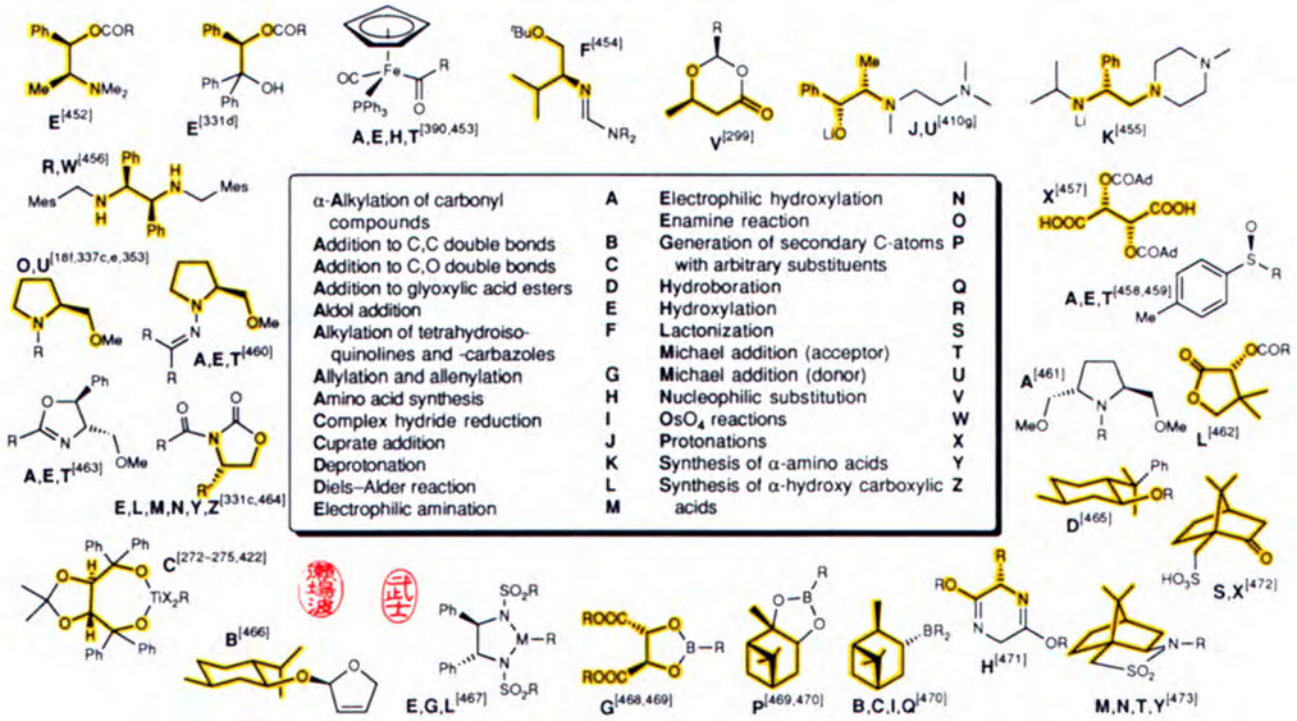
Scheme 25. Glycine derivatives that are readily accessible by the separation of racemates and are useful in the synthesis of (*R*) or (*S*) amino acids. The oxazolidinones (R = OBn, aryl) are obtained by the chromatographic separation of enantiomers [137] (Fig. 1), and the imidazolidinones by crystallization of their mandelic acid salts [450] (recycling by heating). A versatile series of transformations [137, 353, 450, 451] leads ultimately to branched and unbranched nonproteinogenic amino acids with a wide "structural bandwidth".

ous gift of pivalaldehyde (a byproduct in the hydroformylation of isobutylene, previously disposed of by burning!).

The collage of auxiliary groups for stereoselective synthesis shown in Scheme 26 is only a small sample, representing a few of the most successful reagents; most were prepared from inexpensive chiral precursors such as amino acids, ephedrine, 3-amino-3-phenylpropan-1,3-diol, β-hydroxybutyric acid, mandelic acid, tartaric acid, pantolactone, men-



Scheme 27. Products obtained through transformations of (*R*)-3-hydroxybutyric acid derived from the biopolymer PHB. In a formal sense, the β-hydroxy acids shown at the top constitute aldol adducts of aldehydes or ketones with acetic acid, higher acids, or α-branched acids. Directly below these are the nucleophilic and electrophilic intermediates utilized for CC bond formation [183, 294, 353, 354, 371, 474–476]. It is clearly apparent that substituents can also be introduced at C-3 and C-4 of the hydroxybutyric acid without the occurrence of racemization (principle of self-regeneration of a stereogenic center [353, 477, 478]).



Scheme 26. A selection of chiral auxiliaries for multistep enantioselective syntheses. The chiral auxiliaries included in this collage are attached to the reactive center of an achiral molecule by way of a covalent bond in order to carry out the various transformations A–Z. The point is to ensure that a diastereoselective reaction, followed by removal of the auxiliary, will lead to the isolation of product enriched in a single enantiomer. No attempt has been made to provide a comprehensive list of such auxiliaries. Color has been used to emphasize the sources of the various auxiliary reagents. To the best of my knowledge, those auxiliaries not depicted in color result from the separation of racemic mixtures.

thol, pinene, or camphor. The long list of suggested applications for *Evans*' acyloxazolidinone is testimony to the profound significance of this particular reagent (cf., for example, the total synthesis of fujimycin).[51]

Finally, Scheme 27 illustrates a few transformation products derived from poly[(*R*)-3-hydroxybutyrate], which is prepared on a commercial scale by fermentation. Some of the compounds even contain quaternary centers, rendering them inaccessible in enantiomerically pure form by alternative methods.[479] Other applications of the incorporation method can be mentioned here only in passing.[480–482]

7.2. Catalytic Enantioselective Reactions: from Enzymes to Chemzymes

Even after casting off the phlogiston theory, chemists were (and remain today) fascinated by the synthetic achievements of nature, many of which can now be appreciated at the molecular level. The synthetic organic chemist typically regards nature's achievements not only as a standard to be emulated, but also as a formidable challenge, especially from the standpoint of selectivity (above all enantioselectivity). A single enzyme molecule is capable of supervising the transformation of millions and billions of substrate molecules before it loses its own activity. When an achiral educt is converted enzymatically into a chiral product, the enantiomeric yield is of the order of 10^6–10^9%, at least according to the way some chemists prefer to make calculations of this type!

Lurking between the lines of the following three more or less prosaic utterances is a subtle mixture of anxiety and fascination:

"Lord, I fall upon my knees
And pray that all my syntheses,
May no longer be inferior,
To those conducted by bacteria."[483]

"These new catalysts will be better than enzymes in that they will work under more flexible conditions than biological systems. Also, they don't need to work in water and don't have complicated cofactors and all this other garbage around that has to be gotten rid of when the product is purified."[484]

"Chemzymes are small, soluble organic molecules that can catalyze certain reactions in much the same way that natural enzymes catalyze biochemical reactions. ... Think of a submicroscopic production-line worker: over and over again, the chemzyme grabs a pair of reactant molecules out of the surrounding solution, twists them into position, welds them together into a precise three-dimensional structure, and then tosses the product molecule away to free itself for the next pair of reactants."[64b, 485]

It is no wonder that synthetic chemists have frequently tried to make direct use of biochemical catalysts,[486] and countless standard laboratory methods[487–489] have been perfected for the biological-chemical synthesis of simple compounds. Increasingly, however, various research groups are turning their attention to non-biochemical catalysis.[490] In fact, there is a real atmosphere of discovery surrounding the subject of catalysis in organic synthesis, as evidenced by the recently released collection of essays *Catalysis of Organic Reactions*.[491, 492] It would appear that most of the true sorcerers in this field are located in Japan. The following sections constitute brief discussions of enantioselective catalysis—first with enzymes, and then without.

7.2.1. *Biological-chemical Transformations*

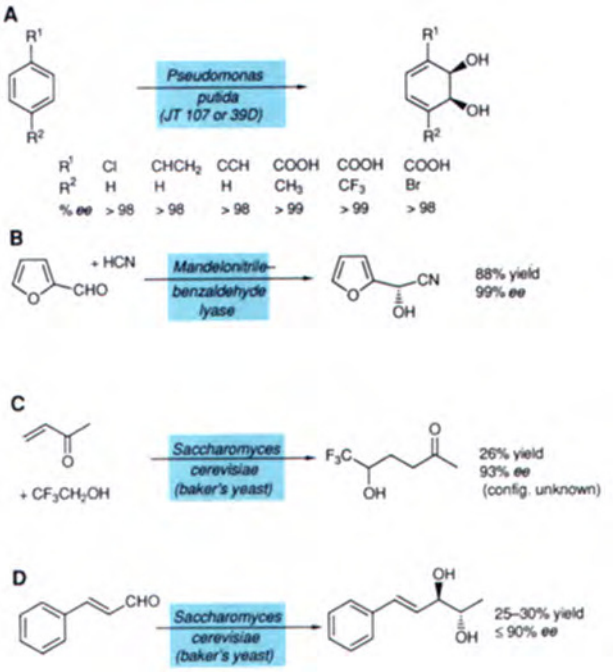
Biological-chemical transformations on both an industrial scale and in the laboratory can be carried out using either whole cells or isolated enzymes. In certain industrial applications it has even proven feasible to "optimize" the required organisms or enzymes, sometimes carrying it to the point of preparing abzymes (Sec. 2.3).[114] Unusual types of reactions or conditions may be invoked (again, after extensive optimization) in the effort to prepare specific products. All the following substances are currently being synthesized on a more or less large scale by fermentation techniques:[493] alkaloids and dyes (in plant cell cultures),[494, 495] *cis*-3,5-cyclohexadien-1,2-diol (using a dioxygenase),[231, 496] cyclosporin (with *Tolypocladium inflatum* Gans),[232] a copolymer based on (*R*)-3-hydroxybutyric and valeric acids (PHB/PHV, Biopol®, with *Hydrogenomonas eutropha*),[230] 2-hydroxypropionic acid (by lactic acid fermentation; used by BASF in the production of an agricultural product), penicillin (and other antibiotics), proteins (such as insulin and interferon, using *Escherichiia coli* modified with the aid of gene technology), hydroxysteroids (using oxygenases),[497] vitamin C (L-sorbose, from D-sorbitol, with *Acetobacter suboxydans*),[229] and tartaric acid.[352] A recently conducted analysis[498] of publications and patents dealing with preparative applications and included in the 1987/1988 "Warwick Biotransformation Abstracts" demonstrated on the one hand that 40% of the reported transformations involved syntheses or reactions of esters, 25% were dehydrogenase-related procedures, and 24% had to do with peptide or oligosaccharide syntheses. Of the ester-cleaving enzymes employed (proteases, esterases, and lipases, enzymes that are available commercially), by far the most prevalent was pig liver esterase. Almost all the applications related to reduction involved whole cells; according to this source, half were carried out[488b] with baker's yeast (*Saccharomyces cerevisiae*). Enzymatic enantioselective esterifications, transesterifications, and saponifications can clearly be regarded today as standard laboratory procedures. The reduction of carbonyl groups requires the presence of NADPH as a hydride donor, and in this case it is more common to take advantage of the metabolic capabilities of whole cells. Yeast for this purpose can be managed successfully without a bioreactor,[499–501] at least with small preparations.[487]

There are, of course, a great many tricks and variations applicable to biological-chemical reaction steps, but this is true for the "classical" methods of organic synthesis as well.[502] For example, simple reductions with yeast alone sometimes fail to produce adequate enantioselectivity, usually because of competition between a number of oxidoreductases.[503] The situation can often be improved by carrying out the reaction in the presence of additives, or by an expedient such as pretreatment of the yeast (e.g., "starving"),[504a]

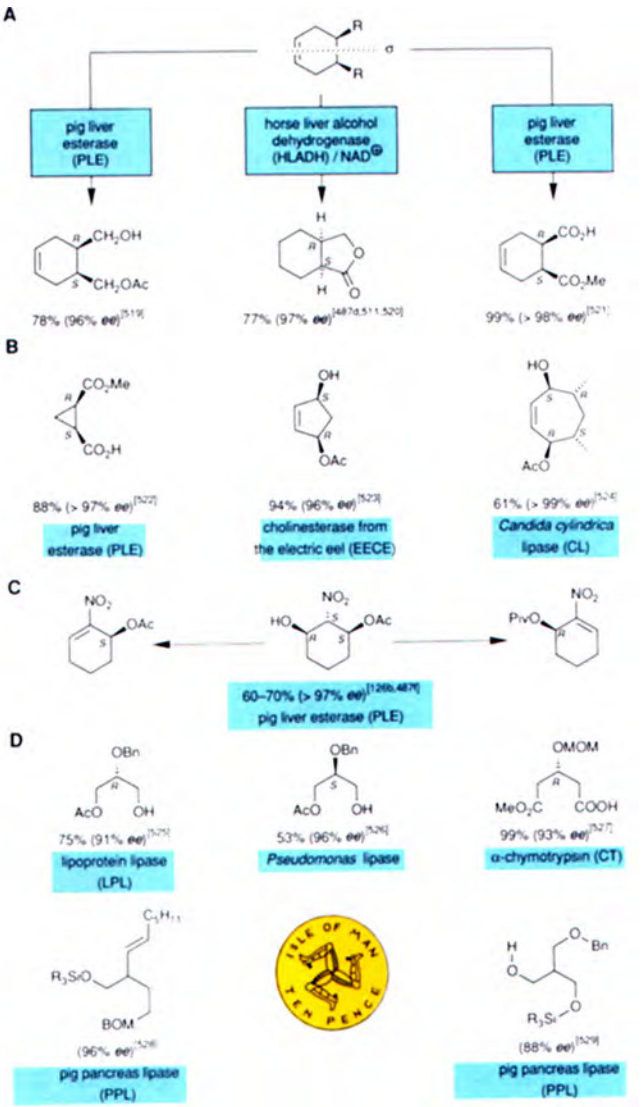
temporary modification of the substrate (cf. protective group techniques),[503] or switching to an organic medium (e.g., the "microemulsion"[504b] method).[505] Use of the easily cultured thermophilic microorganism *Thermoanaerobium brockii*, which is most comfortable at 70–80 °C, may lead to advantages in both selectivity and convenience (sterilization of the apparatus is not required).[506, 507] Methods have also been devised for improving the yield, selectivity, and isolability of the product in applications involving isolated enzymes or enzyme concentrates (pig liver esterase is often employed as a concentrate[126]); examples appear under the first two entries in the alphabetical list in Chapter 4. Biological-chemical methods are currently used for synthesizing amino acids both on a large[508–510] and a small[511] scale. Here the enzymes themselves are immobilized on a solid phase or trapped within a membrane[509–511] (dialysis tubing or a bag—permeable, for example, to molecules with a molecular weight less than 1000 daltons, i.e., to educts and products). Aqueous medium is not a disadvantage with amino acids—indeed, it is essential—but in other applications of biological-chemical methods insufficient polarity or lack of water solubility on the part of educt and/or product can often be a serious limiting factor. Organic solvents sometimes help, especially in transformations involving isolated enzymes,[125, 512, 513] but this alternative is usually associated with a significant retardation in the reaction rate.

The biological-chemical reactions with the strongest appeal for synthetic chemists are those capable of converting achiral educts (or chiral educts that rapidly equilibrate through achiral intermediates) into a *single* enantiomerically pure product containing as many stereogenic centers and functional groups as possible. It is therefore appropriate to conclude the discussion with a few examples that fall in this category (Schemes 28–30). The easiest to carry out are based on enzymes that require no cofactors (other than metal ions).

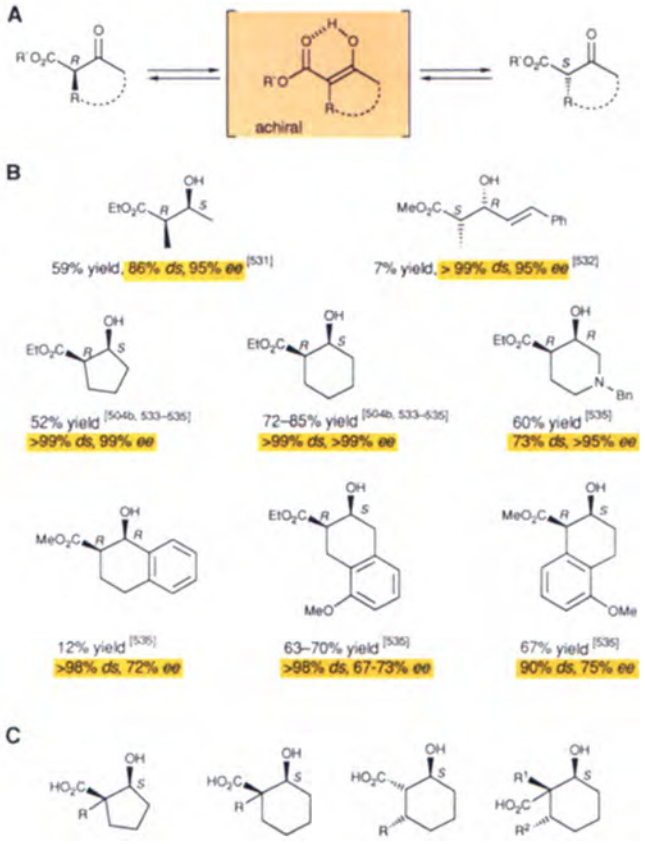
Even a cursory examination of the many "unnatural" compounds that have been successfully subjected to biological-chemical transformations[486–489, 496, 512] reveals a remarkable degree of diversity, and one is forced to conclude that enzymes are amazingly "tolerant".[536] Perhaps it is no accident that the most frequently utilized biological reagents have assignments in nature that also demand flexibility.



Scheme 28. Biological-chemical reactions involving enantioselective hydroxylation or C–C bond formation. A) The microorganisms capable of hydroxylating arenes to cyclohexadiendiols were discovered in a landfill in which aromatic compounds had been deposited [231, 496, 514]. B) MBL, extracted from almond flour, catalyzes the cyanohydrin reaction to give the nitriles of (*R*)-2-hydroxycarboxylic acids, a procedure that is effective with both aliphatic and aromatic aldehydes [513]. C) Formally speaking, this is a Michael addition of trifluoroethanol (d^1 reactivity [18g]) to methyl vinyl ketone (oxidation of trifluoroethanol to an aldehyde and thiamine pyrophosphate umpolung !?) [515]. D) Analogous reaction involving 1,2-addition of acetaldehyde to cinnamaldehyde [516].



Scheme 29. Compounds with the *meso* configuration [517] and other achiral educts containing enantiotopic groups [518] can be ideal substrates for biological-chemical transformations. Subsequent to the enzymatic reaction it is almost always possible to invoke straightforward synthetic manipulations in order to prepare either enantiomer of the desired product (e.g., C). A) Products derived ultimately from the Diels–Alder adduct of butadiene with maleic ester; in the first case, R = CH_2OAc; in the second, CH_2OH (hydrogenation of the double bond!); in the third, CO_2Me. B) Three-, five-, and seven-membered ring derivatives containing up to four stereogenic centers and prepared from *meso* precursors. C) Three adjacent functional groups and stereogenic centers in a cyclohexane and enantiomeric nitrocyclohexenyl esters. D) Chiral derivatives of compounds with C_s and C_{3v} symmetry—versatile educts!

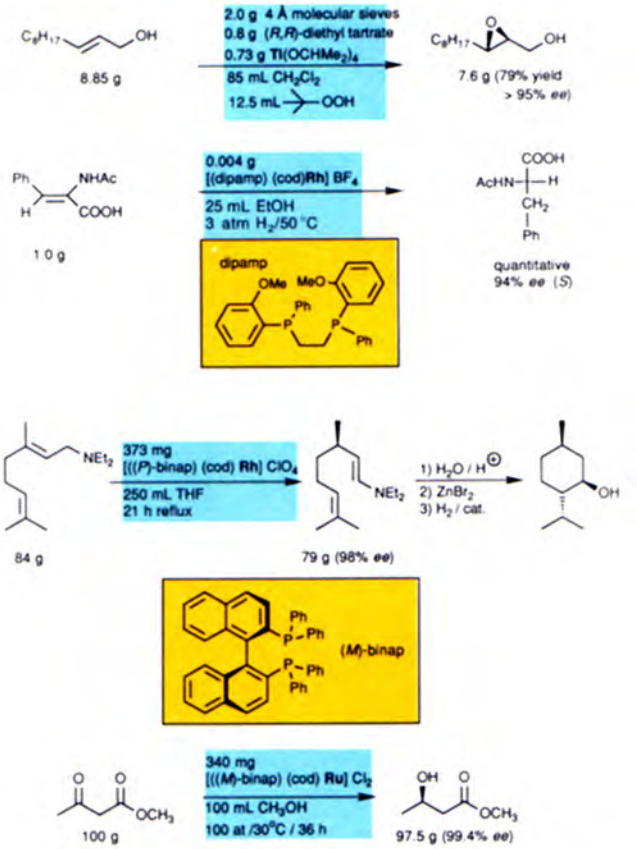


Scheme 30. Baker's yeast will do it [530]! Yeast reduction of 3-oxo esters with stereogenic centers at the 2-position is preceded by keto–enol tautomerization. Yeast reduces the (*R*) enantiomer, thereby removing it from the equilibrium; the process can thus be described as a kinetic resolution of enantiomers with in situ recycling, followed by diastereoselective reduction. The relative topicity [444] of the carbonyl reduction is consistent with the Prelog rule; that is, hydride is transferred from the *Re* side of the trigonal center in $R_L COR_S$ (with the priority $R_L > R_S$; in the case of styryl derivatives the styryl group assumes priority—although with a yield this low it is questionable whether any such consideration is permissible!). A) Equilibrium between enantiomeric 3-oxo esters. B) Yeast reduction products of the corresponding 3-oxo esters. C) Enantiomerically pure hydroxycyclopentane- and hydroxycyclohexanecarboxylic acid derivatives from the corresponding yeast reduction products [534].

Thus, liver esterases come from the mammalian organ most responsible for detoxification, and they have been shown to consist of isoenzyme mixtures; monooxygenases ("hydroxylases") owe their existence in part to the need for making hydrocarbons "metabolizable"; lipases promote cleavage of all types of fatty acid esters; and yeasts have "evolved" in such a way that they grow on a wide variety of culture media and under diverse sets of conditions.

7.2.2. Enantioselective Catalysis: Bases, Phase Transfer, and the Ligand Spheres of Metals

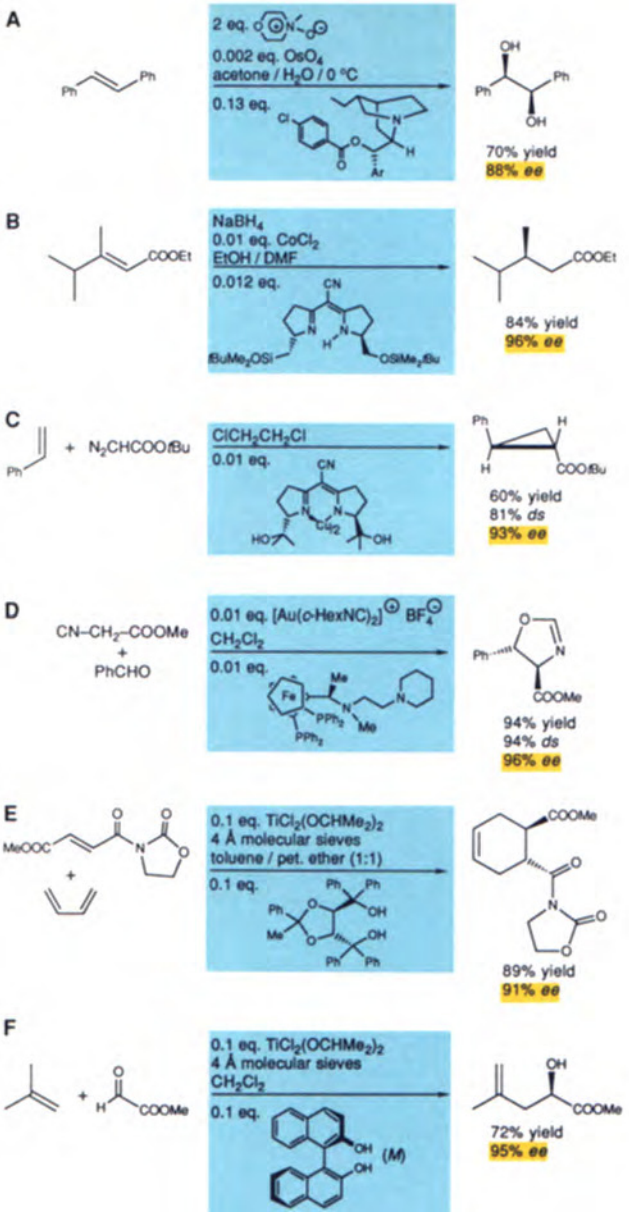
So far, the only popular, standard laboratory reaction that is both enantioselective and catalytic in nature is the Sharpless epoxidation.[537] Not only does it employ inexpensive reagents (*tert*-butylhydroperoxide, titanate, and ethyl tartrate) and involve educts (allyl alcohols) and products (epoxides) that are ubiquitous in organic synthesis, but it also enjoys an unusually wide range of applicability because of insensitivity to many aspects of substrate structure (constitution, configuration, chirality). Selection of the proper chiral form of the starting tartrate ester allows one to establish both the chirality of the product and/or its relative configuration.[538] An example of a simple enantioselective epoxidation is presented in Scheme 31.



Scheme 31. Four examples of enantioselective transformations catalyzed by transition metals: Sharpless epoxidation of 2-undecen-1-ol [537d], Knowles hydrogenation to phenylalanine [435, 539], the Otsuka synthesis of menthol [540], and Noyori reduction of acetoacetic ester [402a].

Enantioselective hydrogenations and hydrogen shifts catalyzed by phosphane complexes of rhodium and ruthenium[402, 539–541] (Scheme 31) are not quite so straightforward on a laboratory scale, nor are they as easy to reproduce, but they do have broad applicability. Looking at the conditions[402a] required for the reduction of acetoacetic ester to (*R*)-3-hydroxybutyrate (Scheme 31) one cannot help but wonder what process will triumph for large-scale preparation of this important hydroxy acid (useful, for example, in the synthesis of thienamycin): the catalytic transition-metal approach or one of the fermentative methods mentioned previously.[230] The "volume yield" criterion (i.e., mass of product obtained per unit volume of reactor) argues for the non-biological procedure.

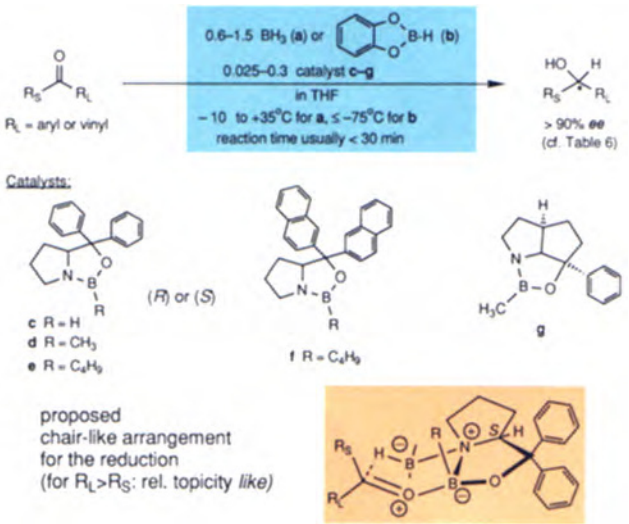
Scheme 32 illustrates a few other standard organic reactions[542] that can be induced to proceed in a catalytic and enantioselective way by the addition of transition-metal complexes. Brief mention should also be made of two catalytic processes that do not involve the ligand spheres of metals: a phase-transfer route to enantioselective amino acid synthesis[543a] and the cycloaddition reaction of ketene with α-halogenated aldehydes to give β-lactones, catalyzed by cinchona alkaloids.[543b]



Scheme 32. Some examples of enantioselective reactions catalyzed by transition metals. A) Hydroxylation with osmium tetroxide, accelerated and made enantioselective by the presence of a cinchona alkaloid [544]. B) Hydrogenation of an α,β-unsaturated ester with $NaBH_4$/chiral-Co catalyst (ligand based on pyroglutamic acid) [490e]. C) Cyclopropanation with diazoacetic ester [copper(II)/chiral-semicorrin ligand] [490e]. D) The gold complex of a complicated chiral-ferrocene ligand catalyzes the addition of isocyanoacetic ester to benzaldehyde, leading to a *threo*-phenylserine derivative [545]. E) A ligand derived from tartaric acid [272–275] provides a Ti complex capable of catalyzing the Diels–Alder reaction in an enantioselective way [546, 547]. F) A derivative prepared from binaphthol/$TiCl_2(OCHMe_2)_2$ causes differentiation between the enantiotopic faces of the aldehyde in the ene reaction of isobutylene with glyoxylic ester [548].

It is interesting to note that many reactions called "catalytic" in the literature actually require the addition of rather large amounts of the alleged catalyst. For example, consider a benzylated or benzoylated quinine derivative with a molecular weight of over 400 daltons. If 0.1 mole-equivalent of such a material were to be utilized in a transformation leading to a product with a molecular weight of 120, then the substrate/catalyst relationship would be such that few *true* catalysis chemists would be willing to regard the reaction as belonging to their discipline.[549] It is also remarkable that precisely those enantioselective catalytic reactions that are most successful were either discovered accidentally or resulted from years of effort devoted to optimization. Even though it has sometimes been possible to discern the mechanism of a catalytic reaction[550]—the recently proposed mechanism for the Sharpless epoxidation is a case in point[537f]—the rational design of a structurally defined chiral catalyst is still in its infancy.[551] A noteworthy example of such an effort is mentioned near the end of this discussion.

One group of enantioselective reactions has been the subject of special attention in recent years. I am referring to reactions in which organometallic compounds that are normally unreactive toward aldehydes and ketones can be activated by catalytic amounts of a chiral amino alcohol so that they undergo enantioselective carbonyl addition. Organometallic agents of this type include alkyl zinc[552] and alkyl lead[553] derivatives, but most interesting perhaps are the boranes and borates.[554] The latter have the advantage that their reactions seem to lend themselves best—before or after the fact—to rationalization on the basis of mechanistic models. Alkyl, alkoxy, aryloxy, and dialkylamino groups are kinetically more tightly bound to boron than to other metallic centers, inhibiting dynamic processes that might otherwise result in ligand-exchange reactions. More important, however, one can rely on the fact (thanks to the octet rule!) that boron will never associate with more than four ligands, and that the ligands will be arranged tetrahedrally. With the single exception[555] of beryllium, whose toxicity has so far prevented its application in organic chemistry, all other metals are capable of supporting as many as six (or more!) ligand sites, characterized (depending upon valence and placement in the periodic table) by tetragonal planar, tetrahedral, trigonal bipyramidal, tetragonal pyramidal, or octa-



Scheme 33. The catalytic enantioselective reduction due to *Corey* et al. [559]. Several examples and references are collected in Table 6. As suggested by the analogy to an assembly line worker (see text), the authors believe that the bi- or tricyclic boron derivative functions at the boron atom as a Lewis acid, which is capable of activating the ketone that is to be reduced. The neighboring bridgehead nitrogen atom in turn binds to borane, activating it for the hydride transfer. The two achiral reaction partners are brought together in a chiral environment such that one of the enantiotopic sides of the carbonyl group is preferentially directed toward the hydride-transferring boron atom. Nevertheless, it is also important for the catalytic course of the reaction that the product alcoholate group is transferred from the boron atom in the ring to another boron atom, thereby removing it from the catalyst.

Table 6. Reductions of ketones with the boranes **a** and **b** of Scheme 33 and the chiral catalysts **c**–**g** [567]. Even the purely aliphatic substrate cyclohexyl methyl ketone undergoes reduction with an enantioselectivity as high as 95:5. In the last case the borane in question (**b**) contained D in place of H.

Product from the corresponding ketone (or aldehyde)			Borane		Catalyst		Ref.
formula	yield	*ee*		equiv.		equiv.	
	> 99%	97%	**a**	1.2	(*S*)-**c**	0.1	[559]
	quant.	97%	**a**	0.6	(*S*)-**d**	0.1	[560]
	> 90%	95%	**a**	0.6	**g**	0.1	[561]
	96%	97%	**a**	0.6	(*R*)-**f**	0.1	[562]
	> 95%	93%	**b**	1.5–2.0	(*S*)-**e**	0.1	[563]
	91%	90%	**a**	0.6	(*R*)-**d**	0.2	[564]
	88%	93%	**a**	0.6	(*S*)-**d**	0.1	[565]
	90%	91%	**b**	1.5	(*S*)-**f**	0.3	[566]

hedral geometries. Finally, BC, BO, and BN bonds are shorter than the corresponding bonds to carbon,[556] so that the groups bonded to boron approach each other more closely than in the case of boron-free systems, and considerably more closely than in compounds with other metals, permitting steric (van der Waals repulsion) and polar interactions (Coulomb forces) to play a more effective role.[557] The currently favored mechanistic model for enantioselective borane reduction of aromatic and α,β-unsaturated ketones with various chiral catalysts has been proven so reliable in explaining all the observed experimental results that *Corey* allowed himself to be seduced into inventing the word "chemzyme", a term already alluded to several times in this contribution.[12b, 64, 485, 558] Scheme 33 and Table 6 provide several examples of this type of borane reduction along with the proposed mechanism.

8. Concluding Remarks

Teach me the glorious lesson
that occasionally it is possible
that I may be mistaken
"Prayer of an ageing woman",
ascribed to Teresa of Ávila (1515–1582)

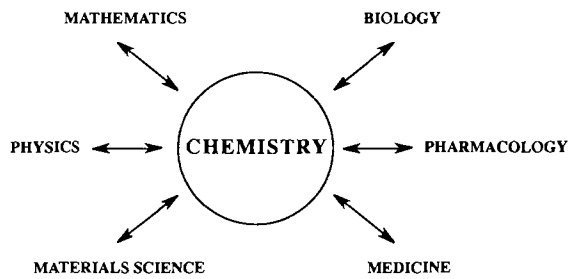
In presenting a paper or a talk, nothing is worse than beginning with a bad title, and the worst titles are ones that promise too much! I hope my contribution does not fit in this category, though I confess that the last part of the title ("Where now?") caused me to lose a certain amount of sleep and suffer several crises of conscience.

The effort will not have been wasted if I have convincingly swept away the one-sided but prevalent notion that organic chemistry and organic synthesis are mature sciences. On the contrary: they are neither stagnating, nor are they on the decline! The general directions I expect our disciplines to take in the future are apparent in the structure of the presentation itself and in the summary at the beginning. The topic treated last—preparing enantiomerically pure compounds, in particular with the aid of enantioselective catalysis—is one I would especially like to have discussed in more detail, but time and space constraints have made this impossible.

My time will also have been well spent if the roughly 1000 literature references prove to be stimulating, especially for my younger colleagues. I hope those readers who find the limited and very personal selection of topics unbalanced, or who regard the mode of presentation as awkward or somewhat "gauche" (Fig. 14), will nevertheless take to heart what

Fig. 14. Color plate based on an ancient Egyptian pattern [and distributed by the Franklin Mint AG, Zug (Switzerland)]. Hunter and huntress are shown with homochiral pairs of left hands, despite which they achieve their goal. The author hopes–despite taking controversial positions, passing judgments, and making difficult decisions regarding the research areas and research groups to be mentioned–that no friendships or feelings have been hurt, and that (unlike the archer in this picture) he has not put his neck into the "noose".

I consider the most important message: that organic synthesis continues to react forcefully and with vitality to new challenges, still ready to pursue old dreams. Considering the



Scheme 34. Chemistry—including organic synthesis—at the center of the natural and technical sciences.

extent of chemical methodology's contributions to other disciplines it is tempting to take the charge that chemistry is in danger of losing its identity[2] and turn it around, proclaiming instead that chemistry—today more than ever before—is "the central science" (Scheme 34).[568] What a change from the days when *Albertus Magnus* (1193–1280) in his tract "De Alchemia" placed at the head of the list of essential characteristics for an alchemist:

He must be taciturn and circumspect,
and should communicate to no one
the results of his operations.

This article could not have been written without the help of a great many coworkers: Albert K. Beck (bibliography); Silvia Sigrist (preparation of the manuscript); Linda Behrendt (figures, schemes, tables); Josef Meienberger (departmental librarian) and Christoph von den Bussche Hünnefeld (literature searches); Bernd Lamatsch and Dietmar Plattner (strucural data); Stefan Blank, Denis Blaser, Richard Breitschuh, Urs Gysel, André Jeanguenat, Axel Neidlein, Christof Schickli, and Adrian Thaler (preparation of drawings and figures); as well as the rest of the group for checking in the library all the names and numbers in the bibliography. I offer all of you my heartfelt thanks; it is a real privilege to be surrounded by such a host of talented and motivated young people.

I also wish to thank those colleagues who have supplied me with information, data, drawings, or figures for use in this article (see also the acknowledgements in the legends and the list of references): E. Bayer (Tübingen), G. Boche (Marburg), Z. Brich (Sandoz, Basel), E. C. Constable (Cambridge, U. K.), R. R. Ernst (Zürich), A. Eschenmoser (Zürich), E. Galantay (Sandoz, Basel), J. Hajdu (Oxford), D. Hilvert (La Jolla), B. L. Karger (Boston), P. T. Lansbury (Boston), R. Noyori (Nagoya), L. E. Overman (Irvine), Sir D. Phillips (Oxford), J. F. Stoddart (Sheffield), W. F. van Gunsteren (Groningen), E. Vedejs (Madison), E. Zass (Zürich).

[12] a) A complete description of the situation as seen through American eyes is the so-called *Pimentel Report: Opportunities in Chemistry*, National Academic Press, Washington, D.C. 1985 (ISBN 0-309-03594-5); b) "Something Valuable from Almost Nothing: A Personal View of Synthetic Chemistry", E. J. Corey, *Chemist (Washington, D. C.) July/August 1989*, 3–5.

[13] A recently published book that illustrates how the products of chemistry have transformed everyday life in the past 135 years: E. Bäumler: *Farben Formeln Forscher. Hoechst und die Geschichte der industriellen Chemie in Deutschland*, Piper Verlag, München 1990.

[14] In 1985 the *Pimentel Report* [12a] came to the conclusion that five priorities should be established within the areas of chemistry. The first two are related to synthesis: A) *Understanding Chemical Reactivity* ("We propose an initiative to apply the full power of modern instrumental techniques and chemical theory to the clarification of factors that control the rates of reactions and to the development of new synthetic pathways for chemical change"). B) *Chemical Catalysis* ("We propose an initiative to apply the techniques of chemistry to obtain a molecular-level and coherent understanding of catalysis that encompasses heterogeneous, homogeneous, photo-, electro-, and artificial enzyme catalysis").

[15] "General Methods for the Construction of Complex Molecules": E. J. Corey, *Pure Appl. Chem. 14* (1967) 19–37.

[16] E. J. Corey, X.-M. Cheng: *The Logic of Chemical Synthesis*, Wiley, New York 1989.

[17] a) *Corey*'s original definition of *synthon* [15] was very useful in the context of retrosynthetic analysis, but the expression has now degenerated into one that is applied to synthetic intermediates. As a result, Corey himself no longer employs it at all—in the book cited previously [16], for example, which deals with all of his work to date! b) "Retrosynthetic Thinking—Essentials and Examples" (Robert Robinson Lecture): E. J. Corey, *Chem. Soc. Rev. 17* (1988) 111–133.

[18] Review articles: a) "Methods and Possibilities of Nucleophilic Acylation": D. Seebach, *Angew. Chem. 81* (1969) 690–700; *Angew. Chem. Int. Ed. Engl. 8* (1969) 639–649; b) "Nucleophile Acylierung mit 2-Lithium-1,3-dithianen bzw. 1,3,5-trithianen": D. Seebach, *Synthesis 1969*,17–36; c) "Umpolung (dipole inversion) of carbonyl reactivity": D. [36] The "Habilitationsschrift" of *R. Neier*, Universität Freiburg (Switzerland) 1989, contains an interesting discussion (with extensive bibliography) of the history of natural product synthesis and the role it has played in the discovery of new synthetic methods. I wish to thank Dr. *Neier* for providing me with a copy of this work.

[37] All of *E. J. Corey*'s natural product syntheses are collected in [16].

[38] "Synthesis in Biochemistry": R. Robinson, *J. Chem. Soc. 1936*, 1079.

[39] "Synthesis": R. B. Woodward in A. R. Todd (Ed.): *Perspectives in Organic Chemistry*, Interscience, New York 1956, pp. 155–184. *Woodward* says here: "We do not propose to examine this vast domain in detail, or to *prognosticate* the direction of its advance, in response to the need, desire, and fancy of man. We shall leave it that the evidence is overwhelming that the creative function of organic chemistry will continue to augment nature, with great rewards, for mankind and the chemist in equal measure."

[40] "The Total Synthesis of Strychnine": R. B. Woodward, M. P. Cava, W. D. Ollis, A. Hunger, H. V. Daeniker, K. Scheuber, *Tetrahedron 19* (1963) 247–288.

[41] "Über organische Naturstoffsynthese: von der Synthese des Vitamin B_{12} zur Frage nach dem Ursprung der Corrinstruktur": A. Eschenmoser, *Nova Acta Leopoldina*, Neue Folge, Issue 247, Vol. *55* (1982) pp. 5–47; see also [20].

[42] "Vitamin B_{12}: Experiments Concerning the Origin of Its Molecular Structure": A. Eschenmoser, *Angew. Chem. 100* (1988) 5–40; *Angew. Chem. Int. Ed. Engl. 27* (1988) 5–39.

[43] An important document in this context is an interview with *A. Eschenmoser* and *R. B. Woodward* about Vitamin B_{12} and the situation in organic chemistry, bearing the title "Herr Woodward bedauert, daß die Sache fertig ist": *Nachr. Chem. Techn. 20* (1972) 147–150.

[44] "Organische Synthese—Zukunft und Gegenwart" is the title of an interview with *G. Stork* in *Nachr. Chem. Tech. Lab. 35* (1987) 349–353.

[45] *Kishi*'s palitoxin synthesis [11] must also be mentioned again here.

[52] a) It is no wonder that one often leaves a lecture or a symposium in which "something else has just been synthesized" with a feeling of boredom coupled with a sense that the same lectures could just as well have been delivered 20 years ago! b) Nowadays the synthetic portion of a lecture is sometimes delivered almost in an apologetic tone: "it has to be done, but it's not exciting, so let's get it over with". Not long ago a well-known young synthetic (organic) chemist observed as part of the introduction to a lecture that people like himself now represent "a dying beast".

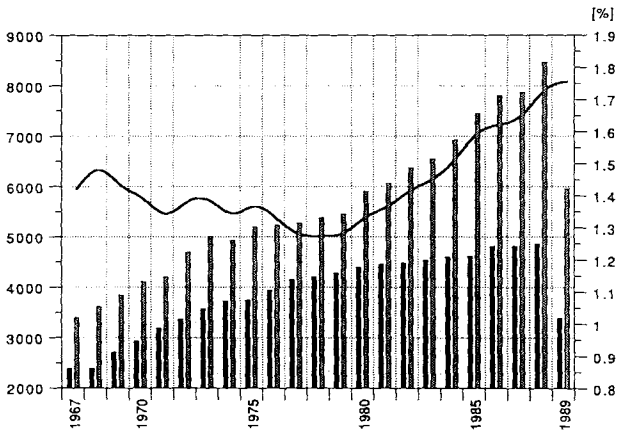
[86] R. M. Williams: *Synthesis of Optically Active α-Amino Acids*, Pergamon Press, Oxford 1989.

[87] The design of building blocks that mimic the turns in peptides and lead to conformational fixation ("turn mimetics") is subject to a great deal of phantasy; a few recent examples are described in the following publications: M. Kahn, B. Chen, *Tetrahedron Lett. 28* (1987) 1623; D. S. Kemp, W. E. Stites, *ibid. 29* (1988) 5057; M. G. Hinds, N. G. J. Richards, J. A. Robinson, *J. Chem. Soc. Chem. Commun. 1988*, 1447; amino acid isosteres for incorporation into peptides are intended to mimic the geometry and/or functionality of amino acids, but inhibit cleavage by peptidases: "Peptide Backbone Modifications: A Structure–Activity Analysis of Peptides Containing Amide Bond Surrogates, Conformational Constraints, and Related Backbone Replacements": A. F. Spatola in B. Weinstein (Ed.): *Chemistry and Biochemistry of Amino Acids, Peptides, and Proteins, Vol. 7*, Marcel Dekker, New York 1983, pp. 267–357; "The Synthesis of Peptide Analogues with a Modified Peptide Bond": D. Tourwé, *Janssen Chim. Acta 3* (1985) No. 1, pp. 3–18.

[88] a) W. P. Jencks: *Catalysis in Chemistry and Enzymology*, McGraw-Hill, New York 1969; "Analog Approaches to the Structure of the Transition State in Enzyme Reactions": R. Wolfenden, *Acc. Chem. Res. 5* (1972) 10–18; b) S. Ghisla, H. Ogata, V. Massey, A. Schonbrunn, R. H. Abeles, C. T. Walsh, *Biochemistry 15* (1976) 1791.

[89] At the Chemical Congress of Pacific Basin Countries in Honolulu (17–22 Dec. 1989), 12% of all the contributions (lectures and posters) in the Organic Chemistry Section contained the five letters *fluor* in their titles; there were two symposia on organofluorine compounds, with the titles "Symposium on Modern Synthetic Methods in Fluorine Chemistry" and "Symposium on Biologically Active Organofluorine Compounds" (The 1989 International Chemical Congress of Pacific Basin Societies, Book of Abstracts II). The following fluorine symposia were arranged in the course of 1990 ACS conventions: 199th National ACS Meeting, 22–27 April 1990, Boston, MA: Symposium on the Effects of Selective Fluorination on Reactivity, Symposium on Fluorine Containing Polymeric Materials; 200th National ACS Meeting, 21–31 Aug. 1990, Washington, D.C.: Symposium on Mass Spectrometry of Fluorinated Compounds, Symposium on Fluorine Chemistry for Organic Chemists.

[90] The growing interest in fluorine chemistry is documented by the steadily increasing number of publications in the area. The following diagram was constructed on the basis of publications covered by *Chemical Abstracts* in the period from Jan. 1967 to March 1990 (solid bars: total number, in units of 100; dotted bars: publications indexed under "fluorine"; black line: contribution of "fluorine" publications in terms of percent).



[91] Monographs: a) M. Hudlicky: *Chemistry of Organic Fluorine Compounds, 2nd Edition*, Ellis Horwood, Chichester 1976; b) R. D. Chambers: *Fluorine in Organic Chemistry*, Wiley-Interscience, New York 1973; c) "Fluorinated Organic Molecules": B. E. Smart in J. F. Liebman, A. Greenberg (Eds.): *Molecular Structure and Energetics, Vol. 3*, VCH Publishers, Deerfield Beach 1986, pp. 141–191; d) J. F. Liebman, A. Greenberg, W. R. Dolbier, Jr.: *Fluorine-Containing Molecules—Structure, Reactivity, Synthesis and Applications*, VCH Publishers, New York 1988; e) J. T. Welch, S. Eswarakrishnan: *Fluorine in Bioorganic Chemistry*, Wiley, New York 1990.

[92] Recent review articles with an emphasis on synthetic aspects of the chemistry of organofluorine compounds: a) "Modern Synthetic Procedures for the Fluorination of Organic Molecules": A. Haas, M. Lieb, *Chimia 39* (1985) 134–140; b) "Präparative Fluorierung mit molekularem Fluor": H. Vyplel, *ibid. 39* (1985) 305–311; c) "Fluorination with Diethylaminosulfur Trifluoride and Related Aminofluorosulfuranes": M. Hudlicky, *Org. React. (N. Y.) 35* (1988) 513–637; d) "A Guide to Modern Organofluorine Chemistry": R. E. Banks, J. C. Tatlow, *J. A few reviews that have appeared since 1987 and which focus on the biological activity of F-derivatives: h) "Modern Methods for the Introduction of Fluorine into Organic Molecules: An Approach to Compounds with Altered Chemical and Biological Activities": J. Mann, *Chem. Soc. Rev. 16* (1987) 381–436; i) "A New Approach to Synthetic Pyrethroids Having a Trifluoromethyl Group": M. Fujita, T. Hiyama, *Yuki Gosei Kagaku Kyokaishi (J. Synth. Org. Chem. Jpn.) 45* (1987) 664–671; j) "New Catalytic Reactions of the Hydrolytic Enzymes in Fluorine Chemistry": T. Kitazume, T. Yamazaki, *ibid. 45* (1987) 888–897; k) "Advances in the Preparation of Biologically Active Organofluorine Compounds": J. T. Welch, *Tetrahedron 43* (1987) 3123–3197; l) "Synthetic Fluoropeptides as Pharmacologically Useful Compounds": B. Imperiali, *Adv. Biotechnol. Processes 10* (1988) 97–129.

[93] As an outsider one has the impression that specialists take it for granted that reactions of "normal" compounds *won't* work with fluorine derivatives; if they do succeed, the astonishing news warrants immediate publication! A few personal experiences would suggest that one should be prepared for anything with even the simplest reactions—a thrilling prospect; see [94–97] (cf. also Chapter 4, "Aliphatic Fluoronitro Compounds", in [105a]).
