[10] We determined the configuration of **6** by NMR spectroscopy (Table 1) after desilylation of the separated diastereomers to the β-hydroxyethers *syn*- and *anti*-7 (Scheme 2). These should be in the conformations shown in Scheme 2, based on those found for other β-hydroxyethers[11] and γ-hydroxyalcohols[12]. The *syn* isomer of 7 should have the fixed preferred conformation shown, since the substituents of C-1 and C-3 could thus be oriented equatorial; *anti*-7 may be a mixture of two chair conformations in equilibrium (in Scheme 2 only one of these is shown for clarity) with each having one axial and one equatorial substituent. *One* relevant consequence of this relationship for the structural assignments is that the sum $\delta(^{13}C\text{-}1) + \delta(^{13}C\text{-}3)$ of the ^{13}C NMR chemical shifts in *syn*-7, 158.65, is 4.41 greater than that in *anti*-7 [$\delta(^{13}C\text{-}1) + \delta(^{13}C\text{-}3) = 154.24$] [11a]. The coupling constants of the protons in the 2-position with their neighbors in the 3- and 1-positions provide further stereochemical evidence: Especially large ax/ax couplings for one 2-H are observed only for *syn*-7 ($J_{2,1} = 11.9$ Hz, $J_{2,3} = 9.8$ Hz), and especially small eq/ax couplings are observed for the other 2-H ($J_{2,1} = J_{2,3} = 2.2$ Hz). In the diastereomer assigned the *anti* configuration one observes different pairs of J_{vic} values (2-H_A: $J_{2,1} = 6.1$ Hz, $J_{2,3} = 1.6$ Hz; 2-H_B: $J_{2,3} = 9.7$ Hz, $J_{2,1} = 3.9$ Hz).

[11] a) R. W. Hoffmann, U. Weidmann, *Chem. Ber.* **1985**, *118*, 3980–3992; b) H. Priepke, R. Brückner, *ibid.* **1990**, *123*, 153–168.

[12] L. P. Kuhn, R. A. Wires, *J. Am. Chem. Soc.* **1964**, *86*, 2161–2165; S. Kiyooka, H. Kuroda, Y. Shimasaki, *Tetrahedron Lett.* **1986**, *27*, 3009–3012; J.-M. Lancelin, F. Paquet, J.-M. Beau, *ibid.* **1988**, *29*, 2827–2830.

[13] The assignment of *syn*- and *anti*-**9** was possible by NMR spectroscopy (Table 1) in the same manner as that used in the differentiation of *syn*- and *anti*-7. The interpretation of the data is again based on a hydrogen-bonded chairlike structure with a six-membered ring (Scheme 2). The ^{13}C NMR criterion mentioned above (see [10]) could be applied to the oxygen-bearing ^{13}C centers again. According to this, the *syn* diastereomer has a sum, $\delta(^{13}C\text{-}4) + \delta(^{13}C\text{-}6) = 146.64$, 3.69 greater than that of *anti*-**9** [$\delta(^{13}C\text{-}4) + \delta(^{13}C\text{-}6) = 142.95$]. The ^1H NMR spectrum of this last diastereomer supports the *anti* configuration, because the vicinal couplings of the diastereotopic protons in the 5-position (5-H_A: $J_{5,4} = 10.1$ Hz, $J_{5,6} = 3.1$ Hz; 5-H_B: $J_{5,6} = 6.9$ Hz, $J_{5,4} = 2.3$ Hz) are modulated similarly to the J_{vic} values of the analogous protons in the 2-position of *anti*-7 (9.7, 3.9 Hz; 6.1, 3.6 Hz). The $J_{5,4}$ and $J_{5,6}$ coupling constants for *syn*-**9** could not be obtained, because the signal of 5-H_2 is of higher order even in the 600 MHz spectrum, and the resonance frequencies of 4-H and 6-H are the same at this field strength. Desilylation of *syn*-**9** provided a diol, in which the axial 5-H with large diaxial couplings ($J_{5,4} = J_{5,6} = 10.2$ Hz) and the equatorial 5-H with small eq/ax couplings ($J_{5,6} \approx J_{5,4} \approx 1$–2 Hz) are clearly distinguished.

[18] Compounds **13a** and **13b** were isolated as a mixture and were inseparable by flash chromatography[9]. The relative configurations of C-3 and C-1 were deduced from the analysis of the vicinal H,H coupling constants of the protons in the 2-position as was done for **7** [10] and **9** [13]. The configurations of C-4 and C-3 were assigned based on an analogous assignment by Broka et al. [16a].

[19] T. Nakai, unpublished results. We thank Prof. Nakai (Tokyo Institute of Technology) for this information.

[20] Comment during the correction of the manuscript (March 5, 1992): Since this communication was submitted E. J. Verner and T. Cohen (*J. Am. Chem. Soc.* **1992**, *114*, 375–377) have proved the stereoselectivity and inversion of the configuration at the carbanion carbon atom in the ring-expanding [2,3] Wittig rearrangement of *trans*-α-lithio-α'-alkenyltetrahydropyrans to 3-cyclohepten-1-ols. Because the [1,2] Wittig rearrangement competed, a common mechanism leading to both the [2,3] and [1,2] products is not completely ruled out, that is the first may arise from a multistep process.

A Novel Polyoxotungstate Containing a *triangulo* Ni^{II}_3 Cluster with Ferromagnetic Exchange Interactions and an $S = 3$ Ground State**

By *Carlos J. Gómez-García, Eugenio Coronado,** and *Lahcène Ouahab*

Heteropolyoxometalate complexes are proving especially valuable for the study of the magnetic interactions in metallic clusters[1] as well as between delocalized electrons of reduced species ("heteropolyblues") and paramagnetic metal atoms.[2] Many of these molecular metal-oxide clusters have structures that permit the inclusion of magnetic clusters. A good example of this ability is provided by the series of isomorphous complexes $[M_4(H_2O)_2(PW_9O_{34})_2]^{-10}$ ($M = Co^{2+}$, Cu^{2+}, Zn^{2+}, Mn^{2+}). The structural analysis of the Co and Cu compounds[3,4] shows the presence of a rhombus-like tetrameric M_4O_{16} cluster between two $(PW_9O_{34})^{9-}$ units. The magnetic properties of these compounds have shown[5] that the pairwise interactions between the Cu^{2+} ions are antiferromagnetic, but between the Co^{2+} ions ferromagnetic. Despite the different sign of the exchange, in both complexes the ground state is magnetic. The Cu^{2+} cluster has an $S = 1$ ground state resulting from different competing antiferromagnetic exchange windows ("spin frustration") in the rhombus; the Co^{2+} cluster has a doublet ground state (with $M_s = \pm 2$) arising from the splitting of the (effective) $S = 2$ spin state as a consequence of the exchange anisotropy.

We attempted to prepare the Ni^{2+} complex of this series and obtained a novel polyoxotungstate containing a ferromagnetically coupled trinuclear Ni^{2+} cluster. This compound was characterized by elemental analysis, IR spec-

troscopy, magnetic measurements, and X-ray structural analysis[6] and can be formulated as below:

$K_6Na[Ni_3(H_2O)_3PW_{10}O_{39}H_2O]\cdot 12H_2O$ **1**

The anion of this salt has an unexpected structure (Fig. 1): An equilateral triangular Ni_3^{II} unit, formed by three edge-sharing NiO_6 octahedra, is coordinated by the ligand $(PW_9O_{34})^{9-}$ (α-B isomer), which has three vacant coordination sites, and a WO_6 octahedron. The tungsten atom of

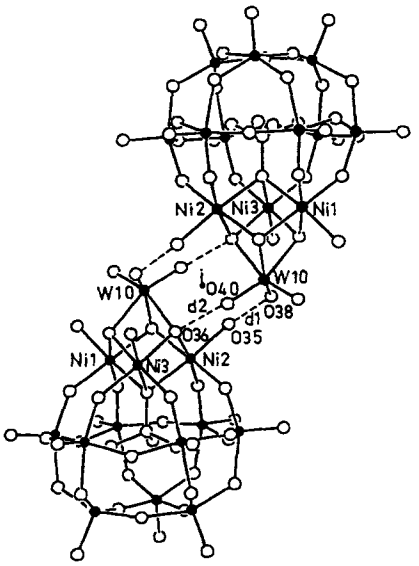

Fig. 1. Structure of the cluster anion $[Ni_3(H_2O)_3PW_{10}O_{39}H_2O]^{7-}$ showing the arrangement of the clusters in centrosymmetrical pairs and the hydrogen bridges (d_1 = 2.68(2) Å, d_2 = 2.73(2) Å). The black circles are the W atoms.

WO_6 forms a distorted $[Ni_3WO_4]$ cubane-type core with the triangular Ni_3^{II} unit. Moreover, these anion clusters are associated pairwise by hydrogen bonds, as sketched in Figure 1, in such a way that the triangular Ni_3^{II} units are parallel and well-isolated magnetically. Figure 1 shows that there are two different hydrogen-bond interactions: One involves O36 (a μ-oxo group) of one cluster and O40 of the neighboring cluster; the other one involves O35 from a water molecule coordinated to Ni2 and O38 of the neighboring cluster. On this basis, one can assign O38 to an oxo anion and O40 to a water molecule. Thus, the coordination around W10 contains a water molecule, in agreement with the Lipscomb's principle.[7]

The results of magnetic measurements on this complex are displayed in Figures 2 and 3. At 1 kG the magnetic moment gradually increases as the temperature is decreased, from 6 $\mu_B mol^{-1}$ at 150 K to a plateau of 8.1 $\mu_B mol^{-1}$ below 5 K (Fig. 2). Such behavior clearly demonstrates that the intracluster Ni–Ni spin coupling is ferromagnetic with negligible intercluster interactions. The magnetic properties of this cluster are largely due to interactions between $^3A_2$ nickel(II) ions as propagated by bridging oxygen atoms. Because this cluster forms a Ni_3 equilateral triangle, these results have been interpreted with an isotropic exchange Hamiltonian operator that assumes that the three pairwise interactions are equal, that is, $\mathcal{H} = -2J(S_1S_2 + S_1S_3 + S_2S_3)$. The susceptibility expression of such a system can be derived from Kambe's treatment.[8] From this expression a close agree-

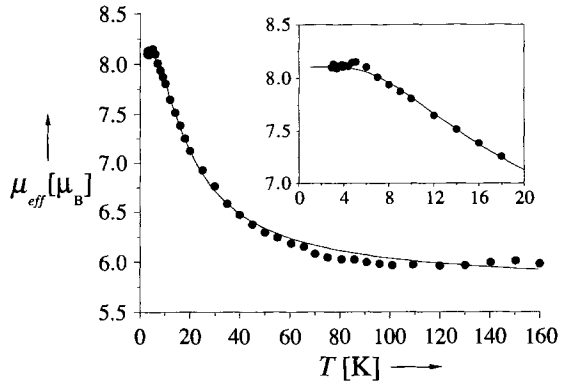

Fig. 2. Plot of μ_{eff} versus T for **1** in a magnetic field of 1.0 kG. The solid line represents the best fit from the Heisenberg exchange model: J = 2.9 cm^{-1}, and g = 2.35.

ment with the experiment in the overall temperature range has been obtained from the following set of parameters: J = 2.9 cm^{-1} and g = 2.35 (solid line in Fig. 2). These parameters lead to an energy diagram in which the ground state has S = 3, and is roughly 17.5 cm^{-1} lower in energy than the lowest lying excited states S = 2. This is the largest spin ground state reported in a heteropolyoxometalate. The existence of very weak intercluster interactions between the S = 3 ground states is detected in the magnetization measurements performed at T = 2 K in magnetic fields between 1 kG and 50 kG (Fig. 3). A typical Brillouin curve is observed which tends to a saturation value of approximately 6 μ_B above 25 kG. As we can see in Figure 3, these data show deviations from the theoretical curve for S = 3 due to intercluster interactions.

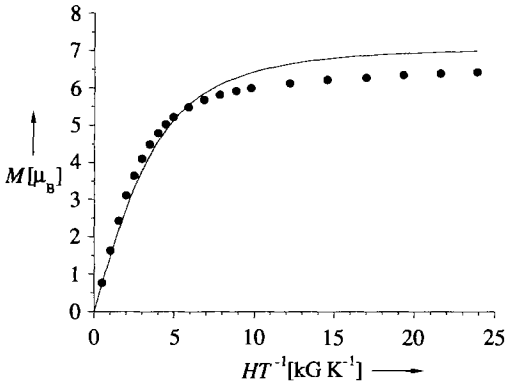

Fig. 3. Magnetization data of the title compound at 2 K. The solid line represents the behavior of a cluster with an S = 3 ground state with a Landé factor g = 2.3.

The unusual ferromagnetic spin coupling of this cluster is related to the Ni-O-Ni angles, which are of two types, those that are close to 90° (92.0(5)°, 92.2(5)°, and 92.1(4)°) involving a common oxygen atom from the PO_4 group, and those that are about 100° (100.5(70°, 100.4(7)°, and 100.7(6)°) corresponding to the three bridging oxygen atoms shared with W10. These angles are in the range in which the Ni–Ni ferromagnetic exchange pathways are dominant (90 ±14°). In this context it should be noted that other nickel ferromagnets are known.[9–11] But in contrast to the title compound, all these complexes show a cubane-type framework and significant intercluster interactions. It is interesting that despite the

structural differences, the *triangulo* cluster has similar exchange couplings to those reported in the cubane clusters ($3-11\ cm^{-1}$).

This kind of heteropolyanionic magnetic cluster could serve in the construction of building blocks for the development of new magnetic molecular materials. In this respect, there is a considerable effort directed to the preparation of molecular magnets based on high-spin molecules.[12] The major difficulty is to interconnect these units in order to build up an extended lattice. Heteropolyoxometalates offer the advantage that they maintain their identity in aqueous and non-aqueous solutions. Thus, these can be associated with suitably chosen cations, for example organic radicals of the type $TTF^{\bullet+}$ and its derivatives, to give extended lattices. This characteristic has been very recently exploited to obtain inorganic/organic charge-transfer salts from diamagnetic heteropolyanions and π-donor organic radicals.[13-15] To our knowledge no studies have been reported with magnetic polyoxoanions.

Experimental Procedure

Compound **1** was prepared following a procedure similar to that reported by Finke [16] for the cobalt derivative of the series $[M_4(H_2O)_2(PW_9O_{34})_2]^{10-}$: $Ni(NO_3)_2 \cdot 6H_2O$ (0.4070 g, 1.4 mmol) was dissolved in distilled water (15 mL). To this light green solution solid $Na_8HPW_9O_{34} \cdot 19H_2O$ (2 g; prepared as described by Finke and dried for 1 h at 140 °C) was added slowly with stirring and gentle warming. KCl (5 g) was then added slowly, and a yellow-green precipitate immediately appeared which was then filtered off. The filtrate was diluted to ca. 50 mL and warmed gently. Slow evaporation of the solvent at room temperature gives after some days a mixture of green needles of **1** and a yellow crystalline powder which were collected and separated carefully. **1** provided a correct elemental analysis. Metal analyses and IR spectra of the yellow powder suggest that this salt contains the anion identified by Knoth et al. [17] as $[Ni_3(H_2O)_2(PW_9O_{34})_2]^{12-}$.

Metallacumulenes: Activation of Diynes and Access to a Novel Bis(Alkenylallenylidene)-ruthenium Complex with the Structural Unit $R_2C{=}C{=}C{=}Ru{=}C{=}C{=}CR_2$**

By *Nadine Pirio, Daniel Touchard, Pierre H. Dixneuf,* Mohammed Fettouhi,* and *Lahcène Ouahab*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Delocalized π-electron systems may endow metal-containing polymers and their organometallic precursors with the properties of electronic conductors, non-linear optical materials, or liquid crystals.[1] It has been shown recently that simple unsymmetrical *trans*-bis(acetylide)platinum complexes display non-linear optical properties[2] and that diynyl–metal polymers behave like liquid crystals.[3] Thus much attention is currently being directed to the preparation of new rod-shaped organometallic compounds containing two unsaturated chains such as the ynyl–metal moities $(RC{\equiv}C)_2M$, $(RC{\equiv}C{-}X{-}C{\equiv}C)_2M$, or $[MC{\equiv}C{-}X{-}C{\equiv}C]_n$[2-5] or acetylide-vinylidene-metal complexes.[6, 7] Our interest in the activation of diynes and the search for new metallacumulenes[8] has led us to discover an interesting synthetic method to new rod-shaped unsaturated ruthenium complexes including a *trans*-bis(diynyl)ruthenium complex and a metallacumulene containing a $>C{=}C{=}C{=}Ru{=}C{=}C{=}C<$ arrangement.

The reaction of the *cis* complex **1**[9] with the diynyltin compound **2** in dichloromethane at room temperature afforded the *trans*-chloro(diynyl)ruthenium compound **3** in 30% yield (Scheme 1). We attempted to generate the metallacumulene intermediate **I** (dppm = bis(diphenyldiphosphino)methane) by displacement of the Me_3SiO^- group.

$[(dppm)_2(Cl)Ru{=}C{=}C{=}C{=}C{=}CPh_2)]PF_6$ **I**

Treatment of **3** in methanol with $HBF_4 \cdot Et_2O$ provided the red (alkenylallenylidene)ruthenium complex **4** in 39% yield.

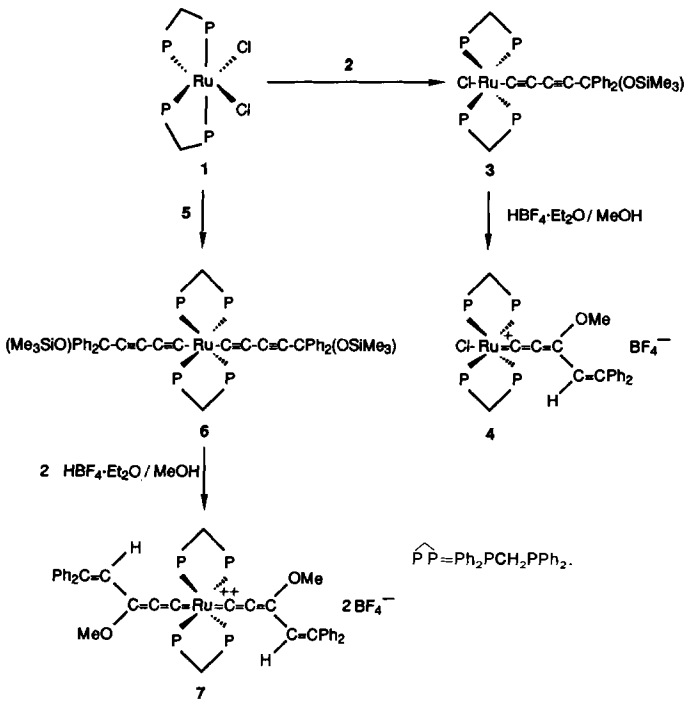
This product most likely resulted from the addition of methoxide to the electrophilic C3 carbon atom of the cation of intermediate **I**.



Scheme 1. **2**: $Bu_3Sn-C\equiv C-C\equiv C-CPh_2(OSiMe_3)$; **5**: $HC\equiv C-C\equiv C-CPh_2(OSiMe_3)$.

The transformation of **3** into **4** suggested that the introduction of two *trans* diynyl groups at the ruthenium center would make a bis(alkenylallenylidene)ruthenium complex accessible. Reaction of complex **1** with an excess of **2** did not lead to the substitution of both chloro ligands. The desired bis(diynyl)ruthenium complex **6** was produced much more simply by the direct reaction of **1** with an excess of diyne **5** (6 equiv) in the presence of $HNiPr_2$ in 24% yield [IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2020 (m, C≡C), 2175 (s, (C≡C)].

The reaction of complex **6** under the same conditions as those required for the conversion of **3** to **4** gave a 76% yield of the novel violet bis(alkenylallenylidene)ruthenium complex **7** [IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1958 (s, C=C=C)]. The symmetric structure of the dication of **7** was evident from the NMR spectra, because of the magnetic equivalence of the PCH_2P protons and the ^{13}C nuclei of the allenylidene group [δ = 233.68 (quint, Ru=*C*, ^2J(P,C)=14.3 Hz), 138.93 (quint, Ru=C=*C*, ^3J(P,C) = 1.6 Hz), 164.96 (s, Ru=C=C=*C*)]. Structural characterization of the dication of **7** revealed that both allenylidene groups and the ruthenium atom are almost in the same plane (Fig. 1).[10] The molecule is centrosymmetric, and the C3′-C2′-C1′-Ru-C1-C2-C3 arrangement is almost linear. Compared to the Ru–C1 and the C1–C2 bond lengths in the cation of the mono(allenylidene)ruthenium complex **8**, (1.884(5) and 1.255(8) Å respectively),[11] the

$[(PMe_3)_2(\eta^5\text{-}C_5H_5)Ru=C=C=CPh_2]PF_6$ **8**

Ru–C1 bond of **7** is long (1.994(7)Å) and the C1-C2 bond short (1.22(1)Å). Apparently the C1–C2 bond has partial triple-bond character, possibly due to conjugation with the methoxy group at C3, which is indicated by a short C3–O

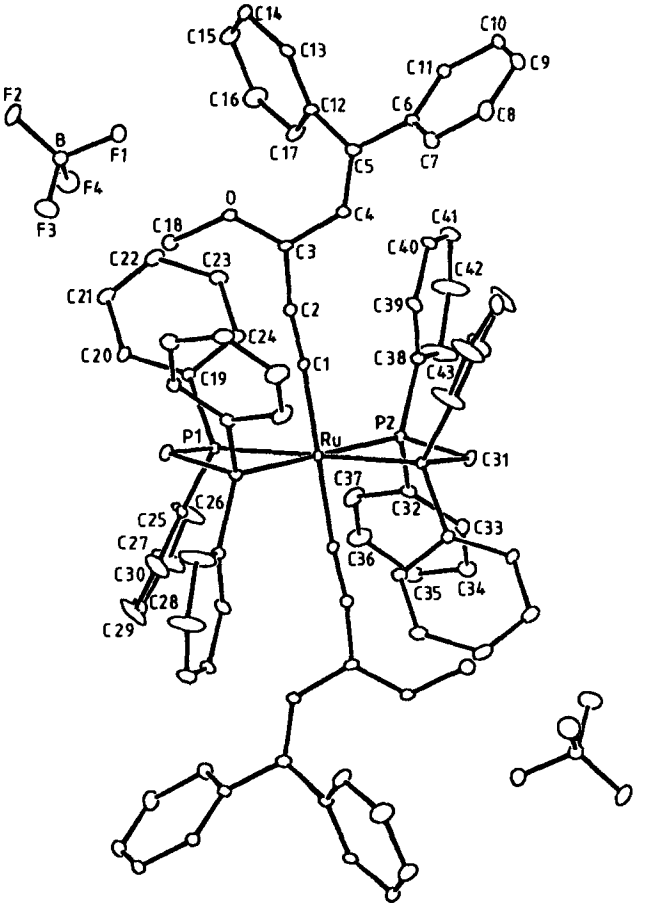


Fig. 1. Crystal structure of **7**. Selected bond lengths [Å] and angles [°]: Ru-C1 1.997(7), O-C3 1.292(9), O-C18 1.46(1), C1-C2 1.22(1), C2-C3 1.39(1), C3-C4 1.45(1), C4-C5 1.36(1); C′1-Ru-C1 180.0, C3-O-C18 121.3(8), Ru-C1-C2 175.0(7), C1-C2-C3 171.4(9), O-C3-C2 122.1(9), O-C3-C4 117.8(7), C2-C3-C4 120.1(7), C3-C4-C5 123.2(8).

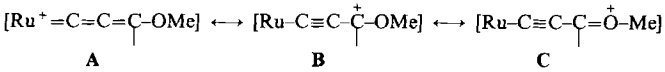
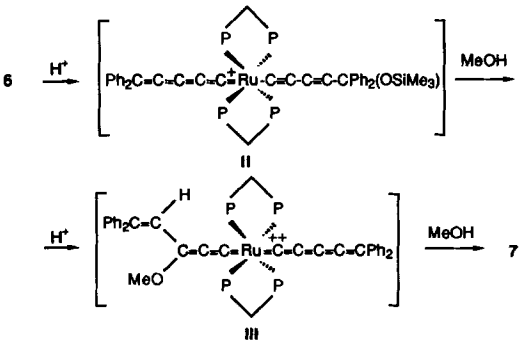
bond (1.292(9) Å). The structural parameters thus indicate a substantial contribution of the mesomeric forms **B** and **C** as shown in Scheme 2. In the transformation of compound **6**



Scheme 2.

into **7** we assume that two consecutive eliminations of Me_3SiO^- and additions of methanol lead to the highly conjugated, rod-shaped metallacumulene intermediates **II** and **III**, and finally to **7** (Scheme 3).



Scheme 3.

Experimental Procedure

All operations were carried out under nitrogen in anhydrous solvent.
3: $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121.50 MHz): $\delta = -6.47$ (s, PPh_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75.47 MHz): $\delta = 125.97$ (quint, Ru-*C*≡C, $^2J(P,C) = 15.2$ Hz), 93.48 (s, Ru-C≡*C*), 80.24, 76.51, 63.79 (s, Ru-C≡C-*C*≡*C*-*C*Ph_2); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2024 (m, C≡C), 2176 (s, C≡C). Correct elemental analysis (C, H, Cl).

4: $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121.50 MHz): $\delta = -11.72$ (s, PPh_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75.47 MHz): $\delta = 252.76$ (quint, Ru=*C*, $^2J(P,C) = 13.5$ Hz), 155.71 (s, =*C*Ph_2), 154,15 (s, Ru=C=C=*C*), 150.18 (quint, Ru=C=*C*, $^3J(P,C) = 2.2$ Hz); ^{13}C NMR (CD_2Cl_2, 75.47 MHz): $\delta = 124.43$ (d, *C*H=, $^1J(C,H) = 163.8$ Hz); IR (KBr): ν[cm^{-1}] = 1955 (s, C=C=C). Correct elemental analysis (C, H).

6: A solution of **5** (0.62 g, 2 mmol) and $NHiPr_2$ (3 mmol) in 60 mL of dichloromethane was added to **1** (0.47 g, 0.5 mmol) and $NaPF_6$ (0.34 g, 2 mmol). The solution was stirred at room temperature for 4 h, and its color changed from orange to brown. The crude product was filtered through 30 g of alumina with ether. Recrystallization from THF/pentane (1:3) gave 0.18 g (24%) of **6** as yellow crystals. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121.50 MHz): $\delta = -4.21$ (s, PPh_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75.47 MHz): $\delta = 131.18$ (quint, Ru-*C*≡C, $^2J(P,C) = 15.2$ Hz), 96.42 (s, Ru-C≡*C*), 80.27, 76.60, 64.96 (s, Ru-C≡C-*C*≡*C*-*C*Ph_2). Correct elemental analysis (C, H, P).

7: To a solution of **6** (90 mg, 0.06 mmol) in 20 mL of methanol was added $HBF_4 \cdot Et_2O$ (0.6 mmol). The yellow solution immediately turned blue and then violet. The reaction mixture was stirred for 2 h, the solvent was removed, and the product was washed with ether. Recrystallization from dichloromethane hexane (1:2) afforded 70 mg (76%) of violet crystals of **7**. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121.50 MHz): $\delta = -9.14$ (s, PPh_2); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75.47 MHz): $\delta = 233.68$ (quint, Ru=*C*, $^2J(P,C) = 14.3$ Hz), 165.58 (s, =*C*Ph_2), 164.96 (s, Ru=C=C=*C*), 138.93 (quint, Ru=C=*C*, $^3J(P,C) = 1.6$ Hz); ^{13}C NMR (CD_2Cl_2, 75.47 MHz): $\delta = 122.01$ (d, *C*H=, $^1J_{CH} = 150.4$ Hz); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1958 (s, C=C=C). Correct elemental analysis (C, H, P).

Ag_5GeO_4, a New Semiconducting Oxide**

By *Martin Jansen** and *Christoph Linke*

The reader of this article may assume a serious printing error in the formulation of the title compound as Ag_5GeO_4; it is correct, however, and the unusual composition of this new oxide has been confirmed beyond doubt by X-ray analysis[1] and energy-dispersive electron beam microanalysis.[2]

We have previously indicated that the characteristic separation of the silver partial structure (by the formation of short silver–silver contacts) and the anionic parts in silver-rich oxides can only be understood if attractive interactions are assumed between the Ag^+ ions despite the closed d^{10} configuration.[3] This assumption is supported by a wealth of structural examples and, particularly, by the connections between this structural feature and characteristic properties of the substances.[4] Also the otherwise inexplicable features in the crystal structures of zinc and cadmium metal are classified here. Since the aggregates of silver(I) cations can be interpreted topographically as sections from the structure of silver metal and as a result an unoccupied 5s orbital should be present as a low-lying acceptor level, we assumed that in this bonding situation silver should tend towards subvalence. Actually, single subvalent silver compounds such as Ag_2F[5] or Ag_3O[6] are known. We believe that the synthesis of Ag_5GeO_4 is an indication that our assumption could be generally valid. The high tendency of formation of Ag_5GeO_4 is shown in that despite the oxidizing conditions during the preparation (high-pressure oxygen) decomposition into Ag (or $1/2\,Ag_2O$) and Ag_4GeO_4 does not occur.

Ag_5GeO_4 is formed by a solid-state reaction (*Experimental Procedure*) from mixtures of Ag_2O, Ag, and GeO_2, or Ag and GeO_2 under the oxidizing conditions of the high-pressure oxygen synthesis. The reaction product is air-stable and consists of yellow-tinged shiny metallic crystals. The decomposition via loss of oxygen begins at 520 °C.

The crystal structure (Fig. 1) contains almost regular tetrahedral orthogermanate ions with dimensions which are in agreement with numerous corresponding examples.[7] Therefore the silver skeleton must be completely responsible for the "anomaly" in the valency. In systems in which we assume bonding d^{10}–d^{10} interactions,[4] the Ag–Ag dis-

tances characteristically lie between 289 pm (atom distance in silver metal) and 340 pm (van der Waals contact distance).[8] By the crystal chemical analysis of the solid-state structure of Ag_5GeO_4, however, distances are encountered which in contrast to the ones given are significantly shortened. The silver atoms of the crystallographically independent positions Ag1 to Ag3 form an octahedral cluster with a center of inversion (site symmetry) with significantly shorter distances (274 to 284 pm).

The other Ag–Ag contacts lie in the normal range for silver-rich oxides above 300 pm (with the exception of 291 pm for Ag2–Ag4). The shortening of the silver-silver distances within the Ag_6 cluster indicates that it includes the excess electrons resulting from a simple count ($10 \times Ag^+$, $2 \times GeO_4^{4-}$). This can be expressed by the formula $[Ag_6]^{4+}[Ag_4(GeO_4)_2]^{4-}$. Precisely two electrons occupy the lowest bonding molecular orbital (A_{1g}) in the Ag_6^{4+} unit, which is thus the most electron-poor octahedral cluster so far.

It is now known that M_6 clusters often are centered by nonmetal atoms. Since furthermore, a $[Ag_6O^{4+}]$ unit with monovalent silver would carry the same overall charge as the previously described cluster, we checked the area of the Ag_6 octahedron for residual electron density and the distances of silver to the center of the octahedron: from both criteria we were able to exclude the presence of nonmetal atoms such as C, N, and O.

Because the formation of a "two-electron six-center bond" alone is probably not sufficient to provide the driving force for the formation of the cluster, once again the not yet completely understood d^{10}–d^{10} interactions come into play as additional bonding components. In agreement with this interpretation, particularly with the assumption of an extensive localization of the excess valence electrons in the Ag_6^{4+} clusters, the substance is diamagnetic (measured range: 4–298 K) and shows an electrical resistance of 5 MΩcm at room temperature. The inclusion of silver in the cluster leads to the characteristically one-sided coordinations of the silver atoms by oxygen. It is either a trigonal threefold coordination with bond angles of around 90° at silver (Ag1 and Ag2), which thus occupies the apex of a trigonal pyramid, or a highly bent twofold coordination (Ag3) with bond angles also of around 90°. The germanate tetrahedra project, each with one edge, into the spaces between two Ag_6 octahedra (Fig. 2). The conditions of formation and the stability of the

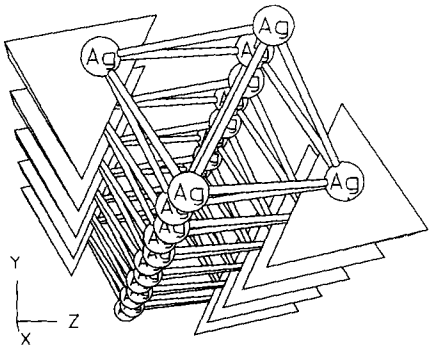

Fig. 2. Relative arrangement of the Ag_6^{4+} clusters and the orthogermanate ions in Ag_5GeO_4.

new compound lead us to expect that other suboxides can also be prepared. Paradoxically, the synthesis of this suboxide can be achieved under increased oxygen pressure. Possible explanations for this are a high thermodynamic stability of the new compound or the fixation of the silver activity by the silver metal always present in the reaction set up, and at the same time a kinetic inhibition of the establishment of an equilibrium between the oxygen activity in the gas phase and in the solid state.

Experimental Procedure

Intimate mixtures of the starting materials Ag_2O and GeO_2 in the molar ratio 5:1 or Ag_2O, Ag, and GeO_2 in the molar ratio 2.5:5:2 were allowed to react in a silver crucible in a high-pressure oxygen autoclave at ($p(O_2) \approx 500$ bar and 320 °C with the addition of a little water as an accelerator (reaction time 10–14 d). GeO_2 (Strem 99.999%); Ag powder was precipitated with hydrazine hydrate as reducing agent at room temperature from a weak ammonia/$AgNO_3$ solution; Ag_2O was obtained by precipitation with potassium hydroxide from a nitric acid/$AgNO_3$ solution. The Ag_2O thus obtained was thoroughly washed and dried in a desiccator over KOH.

Self-Replication by Condensation of 3-Aminobenzamidines and 2-Formylphenoxyacetic Acids**

By *Andreas Terfort* and *Günter von Kiedrowski**

The development of artificial self-replicating systems[1] has been envisioned as an intriguing and challenging task for bioorganic and supramolecular chemistry.[2] The goal is to elaborate the structural, functional, and dynamic principles that played a role in the evolution of the earliest life forms on earth and that might form a framework for the future development of synthetic systems capable of evolution.[3] As originally demonstrated in 1986, the smallest conceivable model of a self-replicating system is the autocatalytic synthesis of a self-complementary template molecule.[4] Attempts to realize this principle[4–9] utilized self-complementary oligodeoxynucleotides,[4] oligonucleotide analogues,[5–7] and hybrid molecules incorporating a nucleotide constituent.[8] In

all these systems the autocatalytic synthesis follows a rate law that is half order with respect to the template concentration (square-root law).[1a-c, 4-8] The growth of autocatalyst concentration is therefore parabolic in the ideal case.[1a-c, 6]

We have attempted to realize self-replication using the simplest possible organic constituents and without any nucleobase for molecular recognition. Our concept is to employ the amidinium–carboxylate salt bridge[10] as a substitute for base pairing. A titration of benzamidinium tetrafluoroborate with cesium acetate monitored by ^{1}H NMR spectroscopy in [D$_6$]dimethyl sulfoxide ([D$_6$]DMSO) confirmed that the amidinium–carboxylate salt bridge is sufficiently stable in the solvent chosen ($K = 350 \pm 50$ M^{-1} at $T = 35$ °C). Condensation of 3-aminobenzamidines **1** with 2-formylphenoxyacetic acids **2** yielded anils of the type **3**,[11] which can exist in conformations in which the recognition sites are aligned roughly parallel to each other according to force-field calculations (MMX). These molecules should act as autocatalysts since they should be able to bind constituents **1** and **2** forming ternary complexes **4** in which the condensation should proceed more easily due to a preorganization effect.

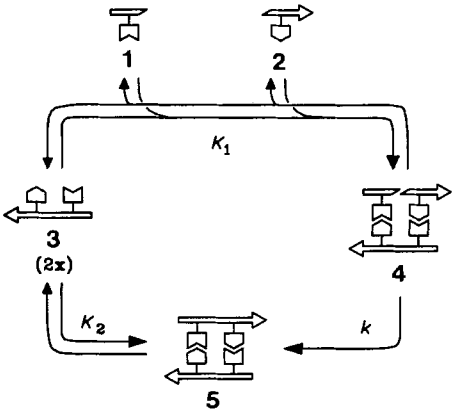
In fact, experimental evidence for an autocatalytic reaction channel was observed for the synthesis of **3a** from **1a** and **2a** when the reaction was monitored by ^{1}H NMR spectroscopy: the higher the initial concentration of **3a** in the reaction mixtures, the faster its formation.[12] The experimental time traces could be satisfactorily approximated by a



square-root model.[13, 14] Under the given reaction conditions ([D$_6$]DMSO, $T = 50$ °C), the autocatalytic synthesis of **3a** is faster than the nonautocatalytic synthesis by a factor of $\varepsilon = 16.4 \pm 4.4$ M$^{-1/2}$. Thus, the autocatalytic efficiency ε[15] may be compared to that of our system of 1986 ($\varepsilon = 24$ M$^{-1/2}$) as well as to that of the Rebek system ($\varepsilon = 22$ M$^{-1/2}$).[6] The reaction of **1b** and **2a** in the presence of the anil **3c**, which is a structural analogue of the reaction product **3b**, yielded an unexpected result, however. The formation of **3b** in [D$_6$]DMSO at $T = 27$ °C was monitored by ^{1}H NMR spectroscopy up to 25% conversion.

Anil **3c** accelerated the synthesis of **3b** by a factor of 370 M^{-1}. Figure 1 provides evidence that the rate increase roughly corresponds to the initial concentration of **3c**. This finding is remarkable because the catalysis by the structurally analogous self-complementary template **3c** is thus no longer described by a square-root law, but for the first time by a first-order relationship. First-order catalysis is expect-

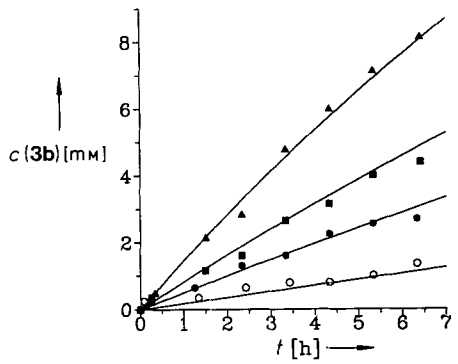


Fig. 1. Reaction rate for the synthesis of anil **3b** in the presence (from bottom to top) of 0, 0.1, 0.2, 0.4 equiv of template **3c** as monitored by ^{1}H NMR spectroscopy. Reaction conditions: 50 mM **1b**, 50 mM **2a**, $T = 27$ °C, solvent [D$_6$]DMSO. ^{1}H NMR frequency: 80 MHz. The set of theoretical curves was calculated using SimFit [14] and the following reaction model: 1) **1b** + **2a** ⇌ **3b** + H_2O. 2) **1b** + **2a** + **3c** → **3b** + **3c** + H_2O. Results: $k_1 = (1.99 \pm 0.15) \times 10^{-5}$ M^{-1}s^{-1}, k_{-1} (no exact solution possible) = $(0.1 \pm 7.3) \times 10^{-5}$ M^{-1}s^{-1}, $k_2 = (7.31 \pm 0.26) \times 10^{-3}$ M^{-2}s^{-1}.

ed, if the concentration of the ternary complex **4b** (formed from **1b**, **2a**, and **3c**) is higher than that of the catalyst duplex **5c**.[16] In this case, the salt bridges in the ternary complex are expected to be more stable than those in the catalyst duplex. Current studies aim to provide experimental support for this hypothesis.

The existence of first-order catalysis by a self-complementary template molecule suggests that self-replication with ex-

ponential autocatalysis should be feasible if the proper model system is used. The strategy might be to search for linking reactions which modulate the molecular recognition process. The linkage must generate a template molecule that forms less stable salt bridges with itself than with its precursors. Current studies aim to couple the modulation of molecular recognition with the generation of chiral template molecules to find an approach towards asymmetric autocatalysis.

[11] Compounds **1** were equipped with alkyl groups to increase the solubility of the corresponding anils sufficiently. Synthesis of compounds **1** will be described elsewhere. 2-Formylphenoxyacetic acids were used instead of the corresponding 2-formylbenzoic acids, since in the latter case it was not possible to prevent an intramolecular attack of the carboxylic group on the anil bond (ring closure).

[12] Compounds **1a** and **2a** (each 50 mM in [D_6]DMSO) were allowed to react in the presence of 0, 0.11, 0.26, and 0.37 mol % of **3a** in NMR tubes sealed by melting. The formation of phenoxyacetic acid **3a** was monitored at a frequency of 500 MHz by observing the following resonances: $\delta = 1.32/1.42$ (*t*Bu **1a**/**3a**), 7.22/7.56 (3′-H **1a**/**3a**), 10.39/8.86 (C*H* = O/C*H* = N). The formation of **3a** is reversible; the equilibrium constant was determined as $K = 5.73 \pm 1$ at $T = 50\,^{\circ}C$. The concentration of the primary adduct is below the limit of detection for the given NMR technique.

[13] The following reaction model based upon the square-root law was chosen for the evaluation of the experimental time courses of NMR integrals with the computer program SimFit [14]: 1) **1a** + **2a** ⇌ **3a** + H_2O. 2) **1a** + **2a** + 0.5 **3a** → 1.5 **3a** + H_2O. The apparent rate constants—as determined by SimFit—are ($T = 50\,^{\circ}C$): $k_1 = (1.50 \pm 0.24) \times 10^{-4}\ M^{-1}s^{-1}$, $k_{-1} = k_1/5.73\ M^{-1}s^{-1}$, $k_2 = (2.46 \pm 0.25) \times 10^{-3}\ M^{-3/2}s^{-1}$.

[14] G. von Kiedrowski, **1991**, unpublished. Program SimFit (Nonlinear *Fit*ting by Dynamic *Sim*ulation) processes the kinetic data of experimental concentration–time traces for any given reaction model. As many as 16 different experiments with varying initial concentrations can by evaluated in a single run. Reaction equations are introduced as input at run-time (i.e. no compiling and linking prior to program start), the program then generates the corresponding set of differential equations and the concentration derivatives (Jacobi matrix). The user may choose either the Runge–Kutta algorithm or a modified Gear algorithm as the method of integration. Nonlinear curve-fitting (by least squares) may be achieved either with the simplex algorithm or with the Newton–Raphson algorithm. The output includes the calculated concentration profiles, the rate constants, and the corresponding variances and covariances. The program supports the input of symbolic assignments of the concentrations of mechanistic species to observable concentrations (expressions with sums and differences). Thus, it is also applicable in those kinetic studies where only the total concentrations can be monitored (e.g. in the case of intermediate complexes which form and dissociate rapidly). In our laboratory, SimFit has proven a valuable tool for a large number of mechanistic studies.

[15] The autocatalytic efficiency ε has been defined as the factor by which the rate of the autocatalytic synthesis exceeds that of the nonautocatalytic synthesis, for a template concentration of 1 M [6].

[16] Normally a square-root law is expected, since a template duplex of type **5** should be more stable than a ternary complex of type **4** for entropic reasons.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Organic Electrochemistry. An Introduction and a Guide. 3rd Edition (revised and enlarged). Edited by *H. Lund* and *M. M. Baizer*. Marcel Dekker, New York, 1991. XXII, 1550 pp., hardcover $ 234.00.—ISBN 0-8247-8154-6

For nearly twenty years now, "Baizer and Lund" has had the status of a proven and highly regarded standard work, which is oriented specifically towards organic chemists, and provides a broad survey of the many wide-ranging applications of organic electrochemistry. This revised and enlarged third edition takes account of the rapid developments occurring in the field, resulting in a book that contains nearly 400 more pages than the second edition. The revision has

been carried out in a responsible and critical way, so that not only have several chapters on recent developments been added, but also some on topics that are now less important have been taken out, transfering those parts that are still relevant into other chapters. The editors have succeeded in enlisting 30 internationally recognized and experienced scientists, all actively engaged in the research and teaching of their specialist areas, to write the 36 chapters.

Compared with the two earlier editions the structure of the book has changed only slightly. It begins with four chapters, totaling 250 pages, in which the basic principles and methods of electrochemistry are described. At several points here a deliberate decision has been made to avoid too detailed a mathematical description. Chapter 5 will certainly be very useful for newcomers to the field, as it offers much practical advice on how to carry out electrochemical experiments. The part of the book that follows is arranged in traditional organic chemistry style, classified according to types of electrodes and electrophoric groups, and consisting of over 350 pages. Reactions at the cathode are dealt with first, for hydrocarbons, halides, nitro compounds and related substances, carbonyl compounds, azomethines, and carboxylic acids and derivatives. This is followed by reactions at the anode, for hydrocarbons, carboxylic acids, nitrogen compounds, oxygen compounds, and sulfur compounds. Four further chapters then deal with the electrochemistry of heterocycles, electrochemical reactions as key steps in the synthesis of natural products and pharmaceuticals, the importance of electrochemistry in the exploitation of biomasses, and electrochemical reactions of organometallic compounds and coordination compounds. This part of the book is followed by detailed discussions of the various types of electrode reactions (reductive coupling, oxidative coupling, detachment and removal of protecting groups, anodic substitution, anodic fluorination). Here, of course, a small degree of overlapping with other chapters is unavoidable. A separate chapter is also devoted to the stereochemical aspects of organic electrode reactions. This is followed by three chapters on indirect electrochemical synthesis. Under the heading "Present and Future Applications" some topical applications-orientated areas are discussed, including industrial electrochemistry, electrochemical polymerization processes, modified electrodes, conducting polymers, and photoelectrochemistry. This section concludes with an assessment of future needs and opportunities.

From the organic chemist's viewpoint this book makes easy reading and is clear and comprehensible. The editors have succeeded in an exemplary way in welding together the individual contributions to make a consistent whole. However, the book does not always live up to its claim of being an introduction to electrochemistry, as the reader is too often referred to other textbooks, especially in the presentation of the fundamental principles. Also many of the methods are only described very briefly. Nevertheless, this only diminishes the book's usefulness very slightly; it impresses through the expert and skillful choice of material, and the wealth of helpful advice that is offered. Access to original publications for more advanced study is facilitated by the inclusion of about 7000 references, backed up by an index of authors, making the book also a valuable source of information for the scientist active in this field. Regrettably, though, the subject index is very scanty for a work of this size, and it is difficult to understand why.

Despite the reservations expressed above, the book can be recommended without hesitation, as the new "Lund and Baizer" is certain to be appreciated as a valuable guide and a mine of information that one cannot afford to be without. Manuel Baizer, who was the prime mover behind this book, sadly died 2½ years before the completion of the third edition; along with Henning Lund he deserves our sincere gratitude. Unfortunately the high price will be an obstacle to the book reaching a wide readership, and regrettably it will, therefore, not be to hand in every laboratory. It is certainly a must for every library.

Biochemical Messengers. Hormones, Neurotransmitters and Growth Factors. By *D. G. Hardie*. Chapman & Hall, London, 1991. X, 311 pp., paperback £ 13.95.—ISBN 0-412-30350-7

The human body consists of over 50 billion cells. Volvox, the simplest multicellular organism, already consists of 50000 cells. An organism only exists when these interact cooperatively. Cooperation implies communication: messages must be sent from cell to cell, and in these the transmitting cell must give specific information which the receiving cell can process and convert into appropriate reactions. In higher animal organisms there are two large communication systems, one consisting of neurones and the other of hormones. Both systems are based on essentially the same principles, which is not surprising since there is no doubt that they have developed in ways that are connected. Both use molecular messengers and depend for their functioning on complicated molecular signal processing systems. Because of their fundamental importance, both are among the most intensively studied fields of current research. This monograph provides an overview of the present state of knowledge in these areas.

Hardie's book encompasses the whole of this very broad subject. It begins with the "first messengers", the messenger molecules of the hormonal and nervous systems, which usually only travel as far as the plasma membrane of the receiver cell. There the information they carry is converted, through receptors and their signal transduction mechanisms, into "second messengers" and their associated intracellular effects. Hardie describes their structures, their biosynthesis, and the cell biology involved in their storage and distribution. After an excursion into the neurobiology of nerve impulse transmission, he then continues, via the biochemical messengers, to the most exciting part of the story, the receptors. Their experimental identification and characterization, their structures, and the way in which they function, form the subject matter of the middle section of the book. The concluding chapters deal with the regulation of cell division, and with gene regulation by steroid hormone receptors that bond directly to the DNA of the cell nucleus.

Is it appropriate to write monographs dealing with areas of research that are still in a state of flux? The publication of books is inevitably a slower and more cumbersome process than that of review articles, and consequently a book may already be partly out of date by the time it appears. In any case, specialists and researchers obtain their information mainly from the primary literature or from relevant review articles. However, monographs such as that reviewed here are not intended for the specialist. Hardie is here writing for advanced students of biochemistry, biology, and pharmacology. From the research scientist's standpoint his book is best regarded as a first point of entry. As a textbook for advanced students it can be recommended unreservedly. It is clearly

written, readable, up-to-date (covering the literature up to 1989), and contains few errors. Above all it identifies features of regulatory mechanisms that are common to widely different fields of molecular biology. This is a useful text for readers with a broad area of interest, written by a competent author with a good overview of the subject; it offers an ideal basis for a course or seminar on regulatory mechanisms.

Iron Oxides in the Laboratory. Preparation and Characterization. By *U. Schwertmann* and *R. M. Cornell*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. XIV, 137 pp., hardcover DM 118.00.—ISBN 3-527-26991-6/0-89573-858-9

Even on first thumbing through this little book, which has a substantial binding and is pleasing to handle, one is impressed by the clear arrangement of its contents. Anyone who has at some time struggled with the study of iron aquoxides will, after reading it for a short time, join this reviewer in exclaiming "If only this had been available then!". Schwertmann and Cornell save the beginner from having to do a lot of tedious literature searching, and they give much valuable advice regarding the "perversity" of the chemistry that can help to prevent failures.

The first few chapters explain the structural relationships between the oxides and hydroxides of iron, and describe the preparative techniques, methods of investigation, and special synthetic methods. These are followed by nine chapters on the various compounds; five of these deal with iron hydroxides, three with iron oxides, and one with basic iron salts, including also doped variants of these in some cases.

Very detailed methods are given for unambiguously preparing each of nine important iron compounds, analyzing them, and storing them for use as reference materials; these are goethite, lepidocrocite, feroxyhyte, ferrihydrite, akaganeite, hematite, magnetite, maghemite, and iron(III)-oxyhydroxy sulfate. In future this will be the standard work always referred to in connection with iron oxides and hydroxides.

According to an old saying, even the most excellent of carpets must have its small defects, so as not to incur the wrath of Allah. Here they include the missing literature citations on pages 29 to 33, and the absence of a cross-reference to the oxalate extraction test for characterizing goethite (page 46). In describing hydrolysis reactions (e.g., on page 57) it would have been desirable to give the formula of the hydrated starting species, and to mention the oligomeric intermediate products. In describing the preparation of goethite a consistent procedure should have been given: on page 64 the caustic solution is added to the solution of the metal salt, whereas a little later (p. 72) the metal salt solution is added to the caustic solution. This fails to take account of the fact that the isoelectric point of the primary precipitate suspension is approached from the acidic side in one case and from the basic side in the other. The nature of the impurities that become incorporated into the primary precipitate, and can affect the properties of the end-product, is quite different in the two cases.

To this reviewer the title of the monograph is a small source of annoyance, which cannot be blamed on the authors. A more suitable title would contain the generic term "iron aquoxides" introduced by Glemser (*Angew. Chem.* **1961**, *73*, 785), although this has, unfortunately, not been generally adopted. Perhaps this different way of looking at things might stimulate an increased interest in the catalytic, magnetic, electronic, electrochemical, and photovoltaic properties of iron aquoxides (including the "iron oxides" extracted from aqueous systems), which are very sensitive to the presence of hydroxide groups, even in sub-trace concentrations.

The list of groups to whom the book is likely to be of interest might well be extended to include the authors of future monographs!

Dieter H. Buß
Institut für Anorganische Chemie
der Universität Göttingen (FRG)

Protective Groups in Organic Synthesis. 2nd Edition. Edited by *T. W. Greene* and *P. G. M. Wuts*. Wiley, Chichester, 1991. XVI, 473 pp., hardcover £ 47.50.—ISBN 0-471-62301-6

Ten years after the publication of the first edition of this very successful book, Theodora W. Green and Peter G. M. Wuts have now prepared a second edition taking into account the latest state of knowledge on the use of protective groups. The division of subject matter is the same as in the first edition. The book starts by describing the functions that protective groups are intended to achieve. The protective groups used for different compound types or groups are then dealt with in turn: those for hydroxy groups, including 1,2- and 1,3-diols, in Chapter 2, for phenols and catechols in Chapter 3, for carbonyl compounds in Chapter 4, for carboxy groups in Chapter 5, for thiol groups in Chapter 6, and for amino groups in Chapter 7. Lastly, Chapter 8 compares the labilities and stabilities of commonly used protective groups under different conditions (basic, acidic, oxidative, etc.), summarizing these in "reactivity charts"; the charts are identical to those in the first edition.

The material in the new edition is impressively up-to-date. The literature has been comprehensively covered up to 1988, with partial coverage up to 1990 for work published in American journals and in Tetrahedron Letters. For each protective group described, methods for its introduction and subsequent detachment are indicated, though often only by giving the reagents together with a literature reference. Generalized reaction equations are given in a few instances, but more usually only the equation for a special case. In this way the authors have achieved a high density of information. The form of presentation adopted inevitably means that the special properties of protective groups, even of some very important ones, are treated too briefly, or sometimes even not at all. This applies, for example, to the stereospecific neighbor group effects of acetates in the synthesis of glycosides. Also there is no mention of the Koenigs-Knorr and related syntheses. However, this was no doubt deliberate on the part of the authors, since it is unmistakably evident that their main area of interest and experience is in the synthesis of the many natural products containing hydroxy and carbonyl groups, which is also reflected in the relative emphasis given to the various protective groups discussed. Consequently, it is essential that the reader interested in using a particular protective group in experimental work should consult the original literature that is cited. A further reason for this is that the authors have deliberately prefered to cite more recent examples of applications, and on grounds of economy they have made the proviso that the citations do not neces-

sarily include the original publication in which the use of a particular protective group was first proposed.

Despite these reservations, the book can be recommended as an excellent and very useful source of information for all chemists concerned with the synthesis of polyfunctional compounds. Its coverage has been extended from that of the first edition to include *N*-protecting groups for five-membered heterocycles and amides, but the latest developments in the use of protective groups that can be removed enzymically were, of course, too recent to be included (H. Waldmann, *Kontakte (Merck)* **1991** (3), 33). The second edition of "Protective Groups in Organic Synthesis" should be available at all times in every organic preparative laboratory.

Horst Kunz
Institut für Organische Chemie
der Universität Mainz (FRG)

Elementary Introduction to Spatial and Temporal Fractals. (Series: Lecture Notes in Chemistry, Vol. 55.) By *L. T. Fan, D. Neogi* and *M. Yashima*. Springer, Berlin, 1991. IX, 168 pp., paperback DM 44.00.—ISBN 3-540-54212-4

The importance of fractals for describing complex structures and complicated phenomena is now generally recognized, and in the last few years quite a number of books explaining the basic concepts of fractals in an easily understandable way have appeared. The book reviewed here is such a one; it gives an introduction to spatial and temporal fractals, and is intended particularly for students and research scientists working in the area of chemistry. The main emphasis is on definitions, methods and applications; detailed mathematical derivations are kept to a minimum. It is roughly 150 pages in length, and is clearly divided into four parts followed by a detailed appendix.

In the first part the concepts and definitions of fractals are explained. Topological and Hausdorff–Besicovitch fractals and Euclidean dimensions are compared. Line, surface, and volume fractals are also explained.

The second part contains examples that the reader can easily understand using the knowledge gained from the first part. The reader progresses via Cantor sets and Koch curves to coastal perimeters. Particular attention is devoted to methods for determining the fractal dimensions of irregular surfaces. The concept of multifractals is also touched on briefly, and it is shown that complex objects cannot always be fully characterized by a single exponent; instead this may require a distribution of exponents. The justification for this procedure in terms of information theory is not gone into here. Almost every book on fractals has to include a discussion of growth models; here the authors confine their attention to the best known of these, namely the Eden model and the diffusion-generated aggregation model. Transport and dynamic processes in fractal structures are not treated, and accordingly only those characteristic exponents that are of importance for structural analysis are discussed.

The third part of the book deals with temporal fractals. These are also taken to include time series arising from measurements as a function of time, for example, data on the prices of commodities as these vary with time. Such price variations often do not show a normal (Gaussian) distribution. Fluctuations of this sort can be analyzed in terms of stable distributions and fractional Brownian motions. Here a distinction is also made between the properties of self-affinity and self-similarity. The Hurst method for determining the characteristic exponents of discrete time series is described. Only in the final section of this part do the authors deal with "real" time fractals. These include stochastic processes in which the intervals between successive events have a distribution characterized by a divergent average interval. However, the fundamental importance of temporal fractals for the interpretation of dispersive transport processes and slow relaxation phenomena is scarcely mentioned.

The last part is devoted to chaos phenomena. The authors clearly explain the role of the strange attractor in characterizing chaos in deterministic nonlinear systems, and that of the Liapunov exponents in predicting trajectories. The relationship between fractals and chaos is made clear by a consideration of the fractal dimensions of the strange attractor.

The appendix should prove useful for readers interested in practical applications. Here the fractal properties for three particular cases are examined, by determining the fractal dimensions for the perimeter of coal particles, for the surface of rice hulls, and for the pressure fluctuations in multiphase flow systems. Each case study begins with a theoretical introduction, which is followed by a description of the experimental arrangement, and finally a discussion of the results with the help of figures and tables.

This book serves very well the needs of the reader who has no previous knowledge of the subject, and wishes to acquire the necessary background for an understanding of fractals, especially for applications to chemistry, in a way that does not make exacting demands. The price of DM 44.00 is appropriate for a book at this level.

Molecular Mechanism for Sensory Signals. By *E. M. Kosower*. Princeton University Press, Princeton NJ (USA), 1991. XVI, 438 pp., hardcover $ 79.50.—ISBN 0-691-08553-6

The elucidation of the molecular mechanisms of sensory perception, signal transduction, and the processing and storage of the information thus obtained is one of the most fascinating research areas of modern biology and biochemistry. Many different approaches are being followed, involving a very wide variety of disciplines ranging from molecular biology to neurobiology, and from molecular structure determination to the study of neuronal networks. E. M. Kosower has performed a valuable service in bringing together in a single publication a survey of the current knowledge on this complex subject.

At the beginning of the book the author defines a hierarchical classification of the world of living organisms, which is made up of levels of organization of varying complexity. A consideration of how these individual levels fit together provides explanations for many apparently unconnected results. This approach from the viewpoint of systems and functions is becoming increasingly important in modern biology. It is a concept to which E. M. Kosower frequently refers back in this book, thereby making many of the relationships easier to understand.

It is only very recently that detailed knowledge has been gained about the mechanism of vision, the olfactory system, the sense of taste, and the transduction of signals. From this a number of common principles and levels of function have been recognized; the receptors, which belong to the lowest level, appear to have similar structures (containing seven

transmembrane helices) in different organisms. This is found not only for bacterial receptors, such as the archaebacterial photoreceptors, but also for eukaryontic receptors such as rhodopsin. At the next level the signal is amplified and converted into a cellular response. A system in which this has been studied especially thoroughly is the G-protein cascade in the mechanism of vision. The transmission, processing and storage of signals is made possible by the communication between neurons. As illustrative examples the author has chosen the nicotinic acetylcholine receptor and the sodium ion channels. The book ends with a discussion of the problems of learning and memory.

A wealth of information is presented in this book, not least through the comprehensive bibliography, which contains 1394 references and provides detailed coverage of results reported up to about 1989. For this reason it could be thoroughly recommended as an introduction to this field, were it not for the author's somewhat individual presentation and interpretation of the results. He gives prominence to his own molecular models of rhodopsin, of the acetylcholine nicotine receptor, and of the sodium ion channel. These ideas regarding their molecular structures are intellectually appealing and are enjoyable to read, and they also allow one to specify some predictions that any theory should satisfy. Nevertheless, one should always bear in mind that these models have not yet been experimentally verified, and that (at least in the case of rhodopsin) some of the details appear to be contradicted by the most recent results.

The data given are often unnecessarily detailed, which is annoying as they are only of interest as examples. Thus, it is not particularly useful to give the structures of so many odor substances and to list the amino acid sequences in such detail as here. Also it is questionable whether secondary structural features such as the α-helix or β-folding need to be described yet again in a book about the molecular mechanisms of sensory perception. Moreover, the quality of the diagrams in these descriptions is very disappointing compared with, for example, those found in textbooks of biochemistry.

To summarize, there are difficulties in the way of recommending this book for a wide readership. However, for those who are interested in an unorthodox treatment of the subject, and who already have at least some relevant knowledge, the book is well worth reading.

Martin Engelhard

Dortmund (FRG)

Electron Deficient Boron and Carbon Clusters. Edited by *G. A. Olah, K. Wade* and *R. E. Williams*. Wiley, Chichester, 1991. xii, 379 pp., hardcover. £ 47.50.—ISBN 0-471-52795-5

For some decades now, we chemists have had access to the theoretical tools needed for the correct quantitative description of bonding in molecules, and nowadays, thanks to developements in computers and programs, they are available for everyone to use. Nevertheless, it still remains true that for the majority of molecules one can, to a good approximation, describe the bonding by assuming the limiting case of localized two-center two-electron bonds. An adequately good approximation often provides qualitative insights that might be obscured by using other, quantitatively more accurate, theoretical methods. In this respect the majority of *classical* molecules can be contrasted to those types of molecules that are still regarded as "exotic" and cannot be described even to a crude approximation in terms of two-center localized bonding; these are the *nonclassical* molecules, to which the Lewis description cannot be applied because they are electron-deficient. Although elements belonging to any part of the Periodic Table can be involved in the formation of nonclassical molecules, it is boron compounds that continue to provide the most striking examples.

The monograph reviewed here, which is dedicated to W. N. Lipscomb on the occasion of his 70th birthday, consists of fourteen articles, eleven of which are on boron cluster compounds. A contribution by T. C. Flood describes some remarkable studies of the oxidative addition of C–H bonds to soluble osmium and iridium complexes, but does not cover electron-deficient boron and carbon compounds. There is only one contribution dealing with carbon clusters, namely that by G. A. Olah on the hypercoordinated nonclassical carbonium ions of which $CH_5^{\oplus}$ is the prototype; this article, a sequel to a recently published monograph on the subject,[*] clearly brings out the relationships between carbon and boron clusters and is well worth reading. These relationships are also emphasized in the editors'short introduction to the book. In their other contributions the editors go beyond their own research in order to explore more general relationships. Olah's article has already been mentioned. R. E. Williams returns to the simple "styx" rules developed by Lipscomb. These state that the bonding skeleton of the boron hydrides and their heteroatom derivatives can be described qualitatively in terms of two-electron bonding between two or three centers, namely between two or three boron atoms or between one hydrogen atom and one (*endo* B–H) or two (B–H–B bridging) boron atoms, provided that where several canonical distributions of these four bond types are possible, resonance is assumed. Williams defines formal charges and derives the structure and the dynamic behavior of the *nido* cluster compounds from the distribution of these charges over the molecule. Boron hydride specialists will benefit from the wealth of knowledge presented here by this doyen of cluster systematics. In a shorter and more general contribution, K. Wade also starts from charge distributions in localized bonding structures according to the styx model to continue with an MO approach to such charge distributions involving more than three centers.

A completely different theoretical approach is described by M. Bühl and P. von R. Schleyer, who report laborious ab initio calculations of the geometries of some boron hydrides and hydroborates. The essential conclusion is that the calculated geometries are better than those determined experimentally, taking as a criterion the ^{11}B NMR signals calculated by the IGLO method; it is well known that these match the observed NMR signals strictly, depending on the correctness of the assumed molecular geometry. A contribution by D. M. P. Mingos and D. J. Wales is concerned with the mechanism of the "diamond-square-diamond" process, in which a polyhedral lattice opens up along one edge of its triangular network to form a square, then closes up again in a direction perpendicular to the original one. (A striking example of this is the Berry pseudorotation.)

The remaining seven articles deal with synthetic, structural, or mechanistic aspects. L G. Sneddon and S. D. Kang describe some new *hypho* clusters and point out that there are regions in these open cluster structures which contain classical bonds. The rest of the contributions are concerned with recent developments, some of the most impressive ones coming from the Fehlner and Greenwood/Kennedy groups in the

[*] G. A. Olah, G. K. S. Prakash, R. E. Williams, L. D. Field, K. Wade, *Hypercarbon Chemistry*, Wiley, New York, **1987**.

field of metalloboranes and from the Greenwood/Greatrex group in the field of borane thermolysis. However, there are also some contributions in which larger portions have already been reported in one or even several previous publications, and even figures have been reproduced unchanged. It is apparent from these articles that the monograph was stimulated by a symposium on electron-deficient clusters held at the Loker Hydrocarbon Research Institute in January 1989.

To summarize, the book contains articles of general importance alongside others of a more specialized nature, representing more or less novel developments. It is a must for the boron chemist and can be recommended for purchase by large libraries.

Chemical Bonding Theory. By *B. Webster*. Blackwell Scientific Publications, Oxford, 1990. x, 276 pp., paperback £ 14.95.—ISBN 0-632-01621-3

This book is an introduction to the theory of the chemical bond, and has deliberately been kept concise. It is intended for undergraduate students and for lecturers teaching at that level. Although the latter will find the breadth and depth of the monograph insufficient, the division of the subject matter and the choice of topics can be recommended as an attractive basis for preparing lectures. It consists of four chapters (1. Electron Pairs and the Formation of Molecules, 2. The Orbital Model of Atomic Structure, 3. Diatomic Molecules, 4. Polyatomic Molecules) which cover both the basic older methods and some quite recent approaches to the description of the chemical bond.

In Chapter 1, after discussing electron pairing according to the Lewis description, an account is given of the VSEPR approach of Nyholm and Gillespie. However, at the end of the chapter, after an example of the so-called hypervalence phenomenon (SF_6), the author fails to point out the important fact that the chemical bonding involved can also be explained by the MO theory without this concept.

In Chapter 2 a description of the principle of building up atomic structures is followed by a short section on spectroscopy, ending with an account of spin-orbit interactions as manifested in the Russell-Saunders coupling. Aspects treated include the ionization energy, electron affinities, the effective nuclear charge, atomic radii and polarizabilities. As is often the case, solid state chemical aspects are treated in a very fragmented way, and in the wrong chapter. However, it is pleasing that here, in contrast to some much more comprehensive treatments such as that by Huheey, at least a general derivation of the Madelung factor is given (not just for AB-type compounds, as is often misleadingly given). With the help of the exercise problems the concept is then developed into a genuinely useful aid even for students. After introducing relationships between atomic radii and explaining their significance, proximity diagrams as developed by W. B. Pearson and fields in the region of the structure are then applied to the discussion of relationships between structure and bonding, including even some that are highly topical.

Diatomic molecules are used as model systems to develop molecular orbitals, followed by considerations of the polarity of the chemical bond and again of radii. Here the arguments could have been treated in more detail and some aspects expanded on, such as the ideas of Drago et al. and Fajans regarding acid–base behavior. On the other hand adequate space is devoted in this monograph to the dynamics of diatomic molecules, including topics such as the analysis of rotational–vibrational spectra and the relevant selection rules. The section ends with a description of Berlin zones, and some modern ideas regarding electron density.

More complex MO bonding schemes and their symmetry properties are then treated, together with ligand field theory, taking some polyatomic molecules as examples. In this context possible distortions are also discussed, including the Jahn–Teller effect and Walsh diagrams. The last section deals with electron number rules for polyhedral molecules, taking borane derivatives as examples.

The book is completed by tables of data, answers to the exercise problems, a bibliography and an index of contents, all of which are again concise but well-chosen. The explanations of the aims that are included with each chapter and the exercise problems are especially welcome and useful. The monograph is very suitable for revision purposes, and is published in the form of a reasonably-priced paperback.

The author has undoubtedly based the book on his own teaching experience, and has tried throughout to combine older basic knowledge with highly topical recent findings—and he has done this in only 270 pages. Consequently in some parts the leaps in the arguments presented are too great, and the student will need to refer to books that treat these matters in more depth. However, brevity is the soul of wit—this book can be well recommended.

Introduction to Zeolite Science and Practice. (Series: Studies in Surface Science and Catalysis, Vol. 58.) Edited by *H. van Bekkum, E. M. Flanigen* and *J. C. Hansen*. Elsevier, Amsterdam, 1991. XVI, 754 pp., hardcover HFl 395.00.—ISBN 0-444-88969-8

This book is based on lectures given at a summer school held in 1989. Zeolites have for many years played a very important role in industry. In particular, the use of zeolites in catalytic cracking has led to enormous savings by increasing the production of gasoline and raising its octane value. Zeolites will become even more important in the future. Because of their stability and capability of regeneration they offer the possibility of developing a new generation of catalysts and processes, which will also take account of environmental acceptability as a high priority. This becomes clearly evident in the book, for example in Chapter 16, in which W. F. Hölderich and H. van Bekkum discuss the use of zeolites in organic synthetic chemistry, and introduce applications as catalysts for isomerizations, rearrangements, alkylations, acylations, etc. Whereas the latter chapter is concerned with the development potential of zeolites as catalysts, in Chapter 15 I. E. Maxwell and H. H. J. Stork give a survey of modern applications in the secondary processing of oil and natural gas that are already carried out on an industrial scale, such as catalytic cracking, the conversion of synthesis gas into gasoline constituents, of methanol into gasoline constituents (MTG) and olefins (MTO), and of light paraffins into arenes (the Cyclar process). In some cases the usefulness of zeolite catalysts is limited by the tendency to coke formation, a problem discussed by H. G. Karge in Chapter 14. He considers, among other aspects, the role of acidic centers and

the localization of coke deposition (within the porous structure of the zeolite, or on the outer surfaces of the crystallites). Chapter 13 (H. W. Kouwenhoven and B. de Kroes) is concerned with the preparation of zeolite catalysts. The main emphasis is on the manufacture of catalysts for the fluidized catalytic cracking (FCC) process, which is the most important method for producing gasoline constituents from higher-boiling products. Many of the reactions used for the conversion of hydrocarbons are acid-catalyzed, and in Chapter 12 P. A. Jacobs and J. A. Martens give an introduction to acid-catalyzed reactions on zeolites. Especially useful here is the section dealing with shape-selective catalysis on acidic zeolites, which is one of the most important areas of application of zeolite catalysts. In (shape-selective) catalytic reactions and selective adsorption/separation processes, the rate of diffusion is a key variable, and this is discussed in Chapter 11 by M. F. M. Post. Chapter 10 by R. P. Townsend is concerned with ion exchange in zeolites; the use of zeolite NaA as an alternative to phosphate in detergents is based on its ion exchange properties. In Chapter 9 R. A. van Santen, D. P. de Bruyn, C. J. J. den Ouden, and B. Smit give an introduction to the theory and modeling of zeolites; they discuss theories of the lattice stability of zeolites and of adsorption and acidity, computer modeling of zeolites, and the simulation of adsorption and diffusion. Chapters 7 and 8 are concerned with methods for characterizing zeolites. In Chapter 7 J. H. C. von Hoff and J. W. Roelefsen discuss methods for determining structure and defects, pore size, chemical composition, acidity, morphology, and particle size. In Chapter 8 G. Engelhardt describes the application of solid state NMR spectroscopy to studies of zeolites. He discusses the capabilities of ^{29}Si and ^{27}Al NMR spectroscopy using the magic-angle-spinning (MAS) technique, and the important question of determining the relative proportions of framework and non-framework aluminum and of "NMR-invisible" aluminum ions. MAS-NMR spectroscopy with ^{17}O, ^{11}B, ^{1}H, ^{13}C, or ^{31}P as the observed species also has potential applications to non-zeolitic molecular sieves.

Chapters 4 to 6 are concerned with the synthesis of molecular sieves. In Chapter 4 J. O. Jansen and S. T. Wilson in turn review the synthesis of zeolites and of molecular sieves, respectively, with $AlPO_4$ as the starting material. The details concerning the synthesis of relatively large single cyrstals of some of the zeolites will undoubtedly arouse much interest. In Chapter 5 on "Modified Zeolites" R. Szostak describes secondary and post-synthesis treatments, such as the various methods for extracting aluminum from the zeolite framework. In Chapter 6 R. A. Schoonheydt discusses the transition from the two-dimensional clay minerals to the pillared clays with three-dimensional structures, which exhibit molecular sieve properties. In these the diameter of the channels is greater than in zeolites, and consequently the critical molecular diameter up to which molecules can undergo conversion in the cavity system is greater.

At the beginning of the book the editors list the special characteristics of zeolites: a uniform pore system, an interior surface that is accessible to reacting molecules, exchangeability of the ions, and the possibility of tailoring the size of the pore entrances and the acidity to suit particular applications. In Chapter 1 these characteristics are discussed in lucid detail by L. Moscou, thereby smoothing the way for newcomers to the subject. In Chapter 2 E. M. Flanigen presents a historical outline of the synthesis and use of zeolites. The structures of zeolites are discussed in Chapter 3 by H. van Koningsveld. Appendix I lists the structural characteristics of some of the most important molecular sieves, and Appendix II contains information on pore sizes and on structural isotypes. Both these appendixes are especially useful for the beginner. The detailed subject index enables one to quickly locate information on desired topics.

Each chapter begins with the fundamentals, then goes on to describe the latest results, citing publications up to 1989. The clear arrangement of the contents makes for easy readability. However, it would have been better to use the Geneva nomenclature throughout for the subject headings. This is a very useful book for beginners as well as specialists, and it can be recommended for everyone with an interest in this field.

Carbonylation. By *H. M. Colquhoun, D. J. Thompson* and *M. V. Twigg*. Plenum Press, New York/London, 1991. XI, 296 pp., hardcover $ 65.00.—ISBN 0-306-43747-3.

This book is devoted to transition metal based carbonylation chemistry leading to the synthesis of carbonyl compounds. Following discussion of concepts and practical aspects, it is organized according to the type of organic compound being synthesized (e.g., aldehydes, amides). The last chapter deals with recipes for catalyst preparation and recovery.

The brief introduction provides a good perspective of carbonylation chemistry, past and present. Why this book is timely is well-reasoned in this chapter.

The second chapter is entitled "Reaction Mechanisms in Carbonylation Chemistry". What an excellent contribution, especially for organic chemists! This chapter deals with the nature of metal–CO bonding, elementary steps in catalytic processes (e.g., oxidative addition), and new mechanistic patterns in carbonylation reactions. The explanation of catalysis is first-class, and the critical analysis which the authors provide here and throughout the text is refreshing. There are a few weak points; for example, while electrophilic attack on carbon monoxide is adequately explained, a more in-depth treatment of nucleophilic attack at carbonyl carbon would have been useful. Nevertheless, this logically organized examination of mechanism and synthesis in carbon monoxide chemistry is the best in the literature.

The third chapter is concerned with the handling of carbon monoxide in the laboratory, and the techniques used in the experiments. This is essential for anyone contemplating research in carbonylation reactions.

The following seven chapters include critical accounts of the synthesis of aldehydes, ketones, carboxylic acids, esters, amides (including anhydrides, aryl halides, urethanes, ureas, and isocyanates), lactones, and lactams. The organizational aspects are excellent, and the authors also highlight areas where further research is desirable. The treatment of the subject in each case is very good, and occasionally includes natural product syntheses. Nevertheless, more details could have been provided in some cases. For instance, the mechanism of the Stille reaction is interesting and merited coverage on pedagogic grounds. Also, no reference is made in the book to the interesting work of Sue Thomas and co-workers on the conversion of α,β-unsaturated ketone complexes to ketenes with carbon monoxide. An inconsistency is the notation of the oxidation state of the metal, which is designated in equations, schemes, etc. in some chapters, but not in others.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0505-0662 $ 3.50+.25/0

A chapter is devoted to a thoughtful analysis of decarbonylation reactions, the reverse of carbonylation processes. This transformation is useful in certain situations, and clearly more work is required in this area.

The final chapter provides experimental procedures for the synthesis of many of the catalysts described in the book. This is a useful contribution, as is the description of methodology for the recovery of metals.

In conclusion, this impressive book is well-written, enjoyable to read, and will be of genuine value to chemists.

Chemometrics. Applications of Mathematics and Statistics to Laboratory Systems. By *R. G. Brereton*. Ellis Horwood, Chichester, 1990. 307 pp., hardcover $ 76.50.—ISBN 0-13-131 350-9

The purpose of this monograph, which is published as an independent volume in the "Ellis Horwood Series in Chemical Computation, Statistics and Information", is to familiarize the experimental chemist with the capabilities and advantages of chemometric methods.

The book proceeds mainly by using simple examples to briefly explain the principle of each of the chemometric methods described, then illustrating how they can be applied to real chemical and analytical problems. This approach has the advantage that the emphasis is on understanding the mathematical and statistical methods used. In describing computer-based methods the author frequently gives details of the wide choice of software that is commercially available, and is in most cases adequate for the purpose. A brief account of the development of chemometrics is followed by an introductory survey of up-to-date literature on chemometrics. The following six chapters describe, in a clearly organized division of subject matter, the most important chemometric methods and their applications.

The chapter on experimental design describes the use of sequential methods such as simplex optimization, factorial plans, multilinear regression methods and variance analysis for the quantitative modeling and optimization of chemical experiments. Next the author describes both well-established methods (control card techniques, the cusum method, autocorrelation analysis) and newer methods (the autoregressive moving average method, the variogram, the Kriging method and the Nyquist frequency) that are used as aids in investigating time series in chemistry and for dealing with the complicated problem of representative sampling. Chapter 4 describes the many different methods for selecting and optimizing the conditions for analyses, such as principal component analysis, information theory, classification procedures, simplex methods, and Fourier and Hadamard transformations. The next two chapters are concerned with the application of univariate and multivariate methods in signal processing. Here there is some overlapping with topics in the previous chapter (e.g. Fourier transformation and principal component analysis), which is an unavoidable consequence of the wide range of uses of chemometric methods. Techniques described under the heading of univariate signal processing include moving average calculations, deconvolution of signals and Kalman filtering. The discussion of factor analysis as a tool for multivariate signal processing omits to give details of the estimation of communalities; however, there is a brief description of the modern method of target transformation factor analysis. In the section on multivariate calibration some important regression methods using latent variables, such as principal component regression and PLS regression, are mentioned but only described very briefly.

The final chapter, which deals with pattern recognition, includes comprehensive descriptions of unsupervised learning methods, especially algorithms for cluster analysis, and the supervised learning methods using either "hard" (linear discrimination analysis, linear learning machine, K nearest neighbors) and "soft" (SIMCA) techniques, as well as "fuzzy" methods.

The user will need to supplement the reading of the short appendix on important mathematical operations by also studying appropriate monographs on mathematical statistics. The appendix does not deal with the use of "robust" statistical methods.

The typography is relatively free of errors, apart from a few exceptions (e.g. Equation 3.5 and Table 5.20), and is very clear. This monograph, with its clear layout of subject matter and the easily understood and well chosen examples of applications in chemistry and analysis, offers a good basic grounding for the experimental chemist who wishes to become involved in chemometrics; also readers who already use mathematical and statistical methods in their area of work will find here new ideas for applying chemometric methods.

Bonding and Structure: Structural Principles in Inorganic and Organic Chemistry. (Series: Inorganic Chemistry. Series editor: *J. Burgess*.) By *N. W. Alcock*. Ellis Horwood, Chichester, 1990. 321 pp., hardcover $ 50.95.—ISBN 0-13-465253-3

The introductory remarks in a book on chemical bonding and structure can provide a very good indication of its underlying philosophy; here, in a chapter entitled "The Evidence", the author clearly states his position: all that we require to know are the positions of the atoms in space and the resulting total energy. In the first forty pages the reader is given a good brief survey of the experimental methods whereby structural information can be obtained (X-ray diffraction, NMR, IR, electron diffraction, neutron diffraction, etc.) and of the sorts of structural phenomena that can appear. Already one becomes aware of two things: 1) crystal structures dominate the discussion from the start, and 2) quantum chemistry, which has now developed into a very reliable method for determining molecular structures and one that can no longer be overlooked, is here ignored. Moreover, the author fails to keep to the promise made in the title, as the book is mainly concerned with inorganic solids.

In a 100-page chapter entitled "Ideal Bonds" the properties of metallic, ionic and covalent bonds are described. The description of the underlying quantum mechanical principles is extremely brief and lacks clarity. The LCAO concept is dismissed in a few lines. In discussing the stationary state wavefunctions of hydrogen the real and complex representations are mixed up. The 1s wave function is given in Equation (1),

$$\psi(r) = 2a_0 - 6.5\exp(-r/a_0) \quad (1)$$

and this is even emphasized by putting it in a frame. One of the d functions, although correctly drawn, is thereafter wrongly described as d_z^2. How could this possibly lead to a conical nodal surface? The molecular cationic form of hydrogen is first written as H_2^+, but then appears for several pages as H_+^2. Also printing errors of all kinds are scattered through the text. We find, again within a frame, the statement: "The probability of finding an electron at a given point is given by ψ^2". Thus no distinction is made between probability and probability density, and as a consequence the significance of the volume element dv is completely ignored. The tetrahedral structure of methane is explained in terms of hybridization, with the remark that "One electron can easily be promoted from the 2s to the 2p level"—no mention is made of the energy needed for this process. Is an energy of 97 kcal mol^{-1} small?—and if so, relative to what standard? Next the molecular orbitals of methane are wrongly shown, and it is stated that the LUMO is threefold degenerate. Space does not allow all the other inconsistencies in this chapter to be listed. After describing several types of double bond and the VSEPR model, Hund's rule is stated in such a confused way that one recognizes it only from the heading above the frame; thus we read: "Electrons occupy separate orbitals rather than being paired up" and "The electrons are aligned parallel rather than antiparallel". What remains here of the precise formulation given by Hund in 1927, which leads directly to unambiguous statements in spectroscopy? Finally it is even claimed that the bent structure of the NO_2 radical is a consequence of the Jahn–Teller effect.

It comes as a relief to find that the second part of the book is entitled "Real Bonds and Real Compounds". Here again metals and alloys occupy a central position, but hydrogen bonds and donor–acceptor bonds are also described. In the second of these the "printer's devil" has ensured total confusion by showing, in contradiction of the text, a double occupancy for the acceptor orbital on the boron atom in the key figure to illustrate the B–N bond. Transition metal complexes are described in detail, but the reader will fail to gain an understanding here of the Jahn–Teller effect, since no distinction is made between the concepts of configurations and states. The reader can skip over a whole section on main-group elements, as it reintroduces antiquated devices that have long since been thrown out (the use of d-functions for main-group elements). The same also applies to the section on aromaticity, which is based on Hückel orbitals and completely ignores the developments of the past ten years.

For which readers can this book be recommended? Certainly not for the chemistry students for whom the author intended it. Instead the last 50 pages, which are the book's saving grace, will provide the advanced specialist in solid state chemistry with some information on complex crystal structures, ceramic materials, ionic conductors, ferroelectric materials, nonlinear optics, magnetic interactions, superconductors and semiconductors.

The Enchanting Alkaloids of Yuzuriha**

By Clayton H. Heathcock*

The oriental plant Yuzuriha (*Daphniphyllum macropodum*) elaborates a fascinating family of polycyclic, squalene-derived alkaloids that provide a test for state-of-the-art methods of organic synthesis. The intriguing structures of these natural products have inspired us to design and explore two rather different approaches for their laboratory synthesis. This article recounts and contrasts these two different syntheses. The first approach was based on a method of synthetic design that emphasizes efficient construction of the polycyclic skeleton of the molecule (Corey's "network analysis"). A strategic bond was identified and the synthesis planned around the late formation of this bond. The synthesis that was designed by this approach proceeded smoothly until the point where it was necessary to remove functional groups that had been incorporated solely for the purpose of forming the strategic bond. Although the problems were eventually overcome, the resulting synthesis was too long and did not control the configuration of one of the stereocenters. The second approach was based on a possible biosynthesis of one of the alkaloids and provided surprisingly easy access to the simpler members of the family. The success of this synthesis led to a concrete proposal about the biosynthesis of the alkaloids and to the discovery of the astonishing transformation depicted in Scheme 27. In this marvelous reaction, an acyclic squalene derivative is converted by successive treatment with ordinary commodity chemicals into a pentacyclic alkaloid. The transformation involves the formation of four carbon–carbon bonds, two carbon–nitrogen bonds, and one carbon–hydrogen bond!

1. Isolation and Structural Elucidation of the Alkaloids

In the Orient there grows a tree that the Japanese call "Yuzuriha," which, loosely translated, means to transfer leaves from hand to hand. The unusual name arose from the uncommon growth habit of Yuzuriha (*Daphniphyllum macropodum* Miquel), which develops an entire new set of leaves each spring before shedding the previous year's leaves later in the summer. Since antiquity, extracts of the bark and leaves of Yuzuriha have been used as a folk remedy for asthma. The first attempt to identify the active principles of the plant was made by the Japanese organic chemist Yagi, who reported in 1909 the isolation of an amorphous material, m.p. 75–84 °C, which he named daphnimacrine.[2] However, with the methods available at the time, no further progress could be made. It now appears that Yagi's daphnimacrine was a mixture of several alkaloids.

It was not until the 1960s that modern methods of structural analysis were equal to the task of deciphering the intricate structures of the alkaloids of Yuzuriha. As in many other cases, it was the group of Yoshimasa Hirata in Nagoya that finally succeeded in isolating two pure substances, daphniphylline (**1**)[3] and yuzurimine (**2**),[4] in 0.01% and 0.015%

[*] Prof. C. H. Heathcock
Department of Chemistry
University of California
Berkeley, CA 94720 (USA)

[**] This review article grew out of a series of lectures presented in Germany in July 1990, as the Merck-Schuchardt Lectureship. The full details of our work on the total synthesis of *Daphniphyllum* alkaloids are reported in a series of articles recently published in the *Journal of Organic Chemistry*: see ref. [1].

yields (based on dry weight of the plant material), respectively.[5] In the following decade, other *Daphniphyllum* alkaloids were identified, including daphmacrine (**3**),[6] macrodaphnine (**4**),[7] methyl homosecodaphniphyllate (**5**),[8] daphnilactone A (**6**),[9] daphnilactone B (**7**),[10] and yuzurine (**8**).[11]

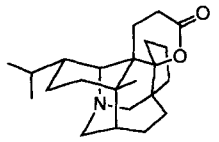
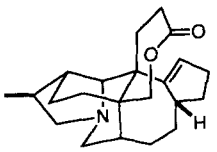
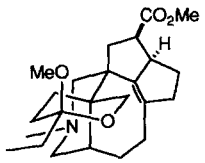
5



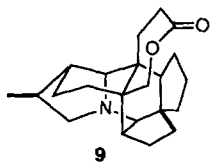
6



7



8



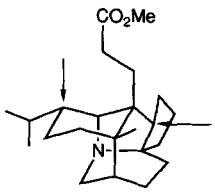
9

A total of 33 alkaloids from Yuzuriha have now been isolated and characterized. In addition, there was a report in 1990 of the isolation of a structurally related alkaloid, bukittinggine (**9**), obtained from the leaves and branches of *Sapium baccatum* collected near the town of Bukittinggi in West Sumatra, Indonesia.[12]

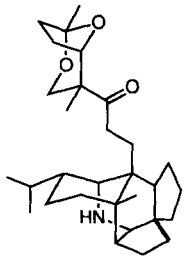
The 34 *Daphniphyllum* alkaloids, including bukittinggine, fall into seven skeletal classes: 1) daphnane (with 7 members), 2) secondaphnane (with 4), 3) daphnilactone A (with 1), 4) daphnilactone B (with 2), 5) yuzurimine (with 10), 6) daphnigracine (with 9), and 7) bukittinggine (with 1). Since the structures of compounds **1**–**9** have all been determined by single-crystal X-ray analysis, the structures, including absolute configuration, of all of the *Daphniphyllum* alkaloids are firmly established.

2. The First Synthetic Approach: Network Analysis

The seductive polycyclic structures of the *Daphniphyllum* alkaloids issue a siren call to the chemist interested in the de novo construction of complex organic molecules.When I first decided to answer this call about twelve years ago, the initial synthetic target that I selected was the C_{22} relative of daphniphylline, methyl homodaphniphyllate (**10**). There were two principal reasons for this choice. First, with only two functional groups and two independent stereocenters (indicated by arrows on its structure),[13] alkaloid **10** appears to be one of the simplest members of the group, its unusual pentacyclic structure notwithstanding. Second, the daphniphylline skeleton was thought to be archetypal of the family because daphniphylline is both wide-spread and abundant.

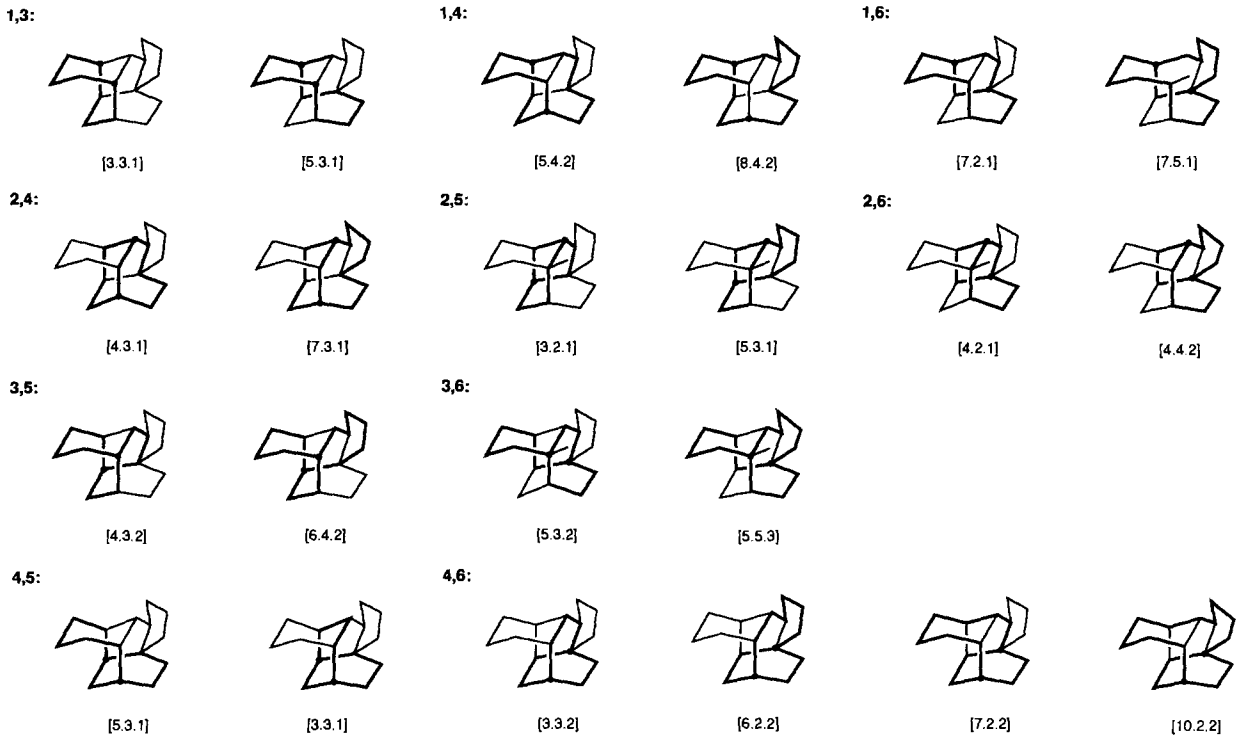


10



11

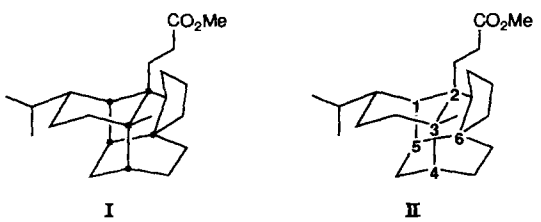
Clayton H. Heathcock was born in 1936 in San Antonio, Texas. After completing his secondary education in San Antonio and his undergraduate education at Abilene Christian College, he joined the Champion Paper and Fibre Company in Pasadena, Texas as Supervisor of the Chemical Tests Group in 1958. In 1960 he left this position and matriculated at the University of Colorado, where he did graduate work on steroidal nitrogen compounds with Alfred Hassner; he obtained his Ph.D. in 1963. He spent 1963–1964 in Gilbert Stork's laboratory at Columbia and joined the University of California at Berkeley as Assistant Professor in 1964. He has remained at Berkeley throughout his entire career and served as Chairman of the Department of Chemistry from 1986 through 1989. Professor Heathcock has also chaired the Organic Chemistry Divison of the American Chemical Society, the National Institutes of Health Medicinal Chemistry Study Section, and the Gordon Conference on Stereochemistry. He has served as Editor of Organic Syntheses and is currently Editor-in-Chief of the Journal of Organic Chemistry. His honors include the Ernest Guenther Award (1986), the American Chemical Society Award for Creative Work in Organic Synthesis (1990), the A. C. Cope Scholar Award (1990), and the Prelog Medal (1991). In 1978 he was a recipient of an Alexander von Humboldt United States Senior Scientist Award and was hosted in Germany by Professors Hans Bestmann and Paul Schleyer at Erlangen. In addition to his interest in natural product synthesis, Professor Heathcock has worked extensively in the area of stereocontrolled synthesis of acyclic compounds, and is particularly known for his work on the aldol and Michael addition reactions.



Scheme 1. For the numbering of the atoms see structure **II** (below).

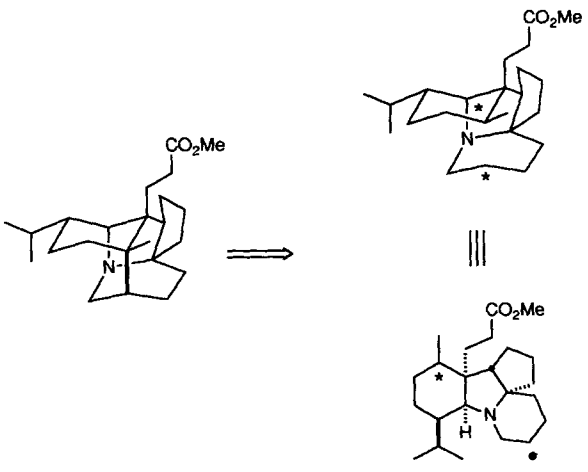
For example, one large-scale extraction of *D. macrododum* leaves yielded 100 g of daphniphylline and only 1.1 g of secodaphniphylline (**11**).[14] It will become clear in the sequel that this reasoning was fallacious and that our identification of **10** as an inaugural goal was unfortunate.

With the target identified, it was neccessary to develop a synthetic plan. Inspection of the structure of alkaloid **10** suggested that the primary obstacle to be overcome is assembly of the intricate pentacyclic skeleton. This is often the case in the synthesis of polycyclic compounds, and Corey has articulated a formal method of analyzing such problems. Corey's formalism, first used in connection with his synthesis of the sesquiterpene longifolene,[15] is called network analysis.[16] A polycyclic molecule will have embedded within its skeleton several bicyclic systems, some fused and some bridged. The basic premise of network analysis is that it is easier to synthesize fused-ring systems than bridged ones.



I **II**

The goal of the analysis is to identify the bond or bonds that are common to the most bridged bicyclic systems (the "maximally bridging" bonds), and to "retrosynthetically" remove these bonds, thereby achieving maximum structural simplification of the synthetic target. To locate the bridged-ring systems within the skeletal network of a polycyclic compound, one must first identify the atoms that can be bridgehead atoms in at least one bridged bicyclic system. The bridgehead atoms for methyl homodaphniphyllate are shown by the bold dots in structure **I**. The next step is to consider the bridgehead atoms in pairs and to identify all of the possible bridged bicyclic systems that exist. For the methyl homodaphniphyllate skeleton, the 22 bridged bicyclic systems shown in Scheme 1 are identified. Close examination of the 22 bridged bicyclic subsystems identified in Scheme 1 reveals that one skeletal bond is common to them all. Accordingly, this skeletal bond is identified as the strategic bond.[14] If this bond is retrosynthetically removed, the problem is simplified to the construction of the tetracyclic skeleton shown in Scheme 2. Although the skeleton of hypothetical target **A** is simpler than that of **10**, our stereochemical problem has become more complex, since **A** has five stereocenters. Nevertheless, the goal of network analysis is to

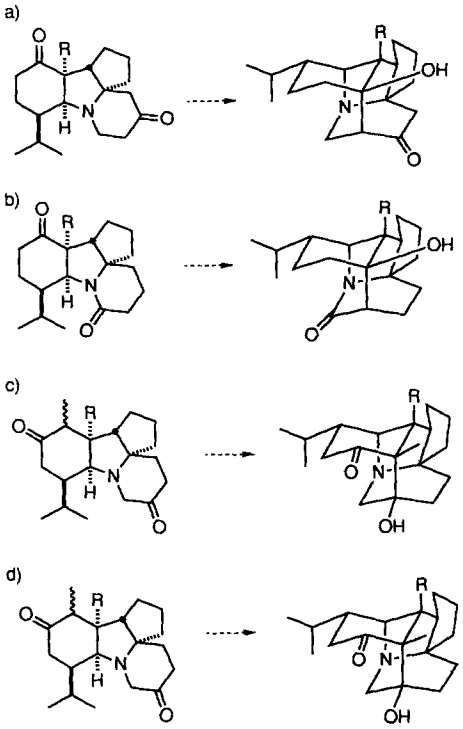


Scheme 2. **A**

identify possible synthetic precursors that have fewer bridged bicyclic systems, and skeleton **A** is clearly indicated as an appropriate target by this approach.

3. Functionality is Necessary to Create the Strategic Bond: "Consonant" and "Dissonant" Relationships

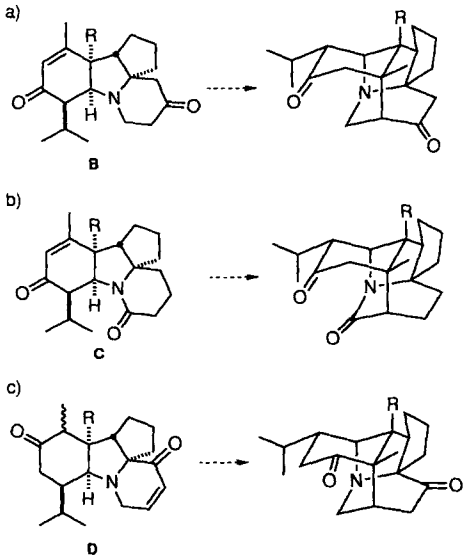
Network analysis only provides a target, not a method of synthesis. There remains the problem of devising a plan to synthesize the target and, equally important, a method of forming the strategic bond. For this purpose, we considered enol/enolate chemistry, namely, intramolecular aldol and intramolecular Michael reactions. For either of these reactions, we need functional groups either at or adjacent to the termini of the strategic bond. Four possible intramolecular aldol reactions are depicted in Scheme 3. A negative aspect



Scheme 3.

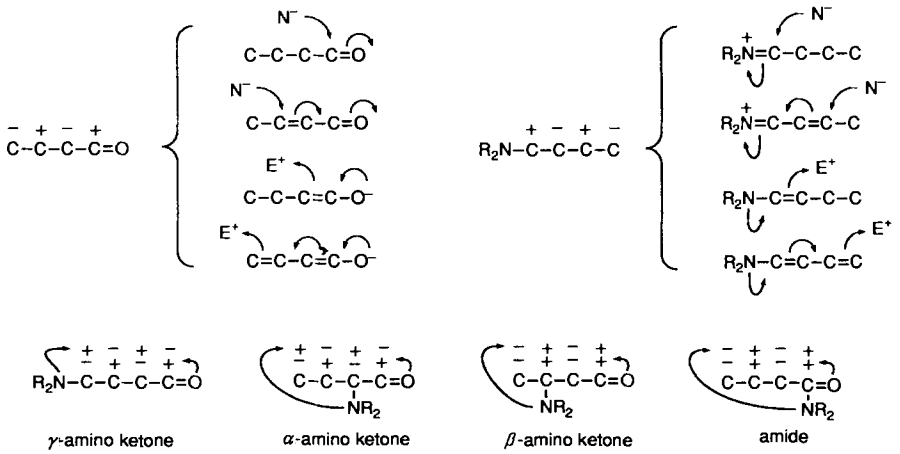
of possibilities a) and b) is the necessity of converting a bridgehead hydroxy group into a methyl group after the strategic bond has been formed. Although possibilities c) and d) are superior in this regard, they still would require a clumsy refunctionalization, replacement of a bridgehead hydroxy group by hydrogen, in addition to removal of the unwanted carbonyl group. Scheme 4 sketches three possible intramolecular Michael reactions that would provide the daphnane skeleton. These routes appear to be superior to the intramolecular aldol routes, because it would only be necessary to remove two carbonyl groups after the strategic bond is formed. Furthermore, there is ample precedent for the formation of six-membered rings by both base- and acid-catalyzed intramolecular Michael reactions.

However, the three possible Michael reaction substrates shown in Scheme 4 are not equally amenable to synthesis. In particular, the tetracyclic amino diketone **D** would be much more difficult to synthesize using standard methods than **B** or **C**. Compound **D** differs from **B** and **C** in its intrinsic functionality pattern. That is, in both **B** and **C** the amino



Scheme 4.

function is either β to a carbonyl group or attached directly to one. In **D**, however, the amino group is α and γ to the two carbonyl groups. The experienced synthetic chemist knows several methods to construct the array N–C–C–C=O (Mannich reaction, conjugate addition of an amino group to an α, β-unsaturated carbonyl function, acylation of an enamine, etc.) or N–C=O (amide formation), but few to construct the structural element N–C–C=O. The difference was recognized long ago by Lapworth, who formulated "the rule of alternating polarities,"[17] and formalized more recently by Evans in terms of "consonant" and "dissonant" bifunctional relationships.[18,19] The basic idea is that the presence of a heteroatom in a molecular skeleton can be viewed as imparting an intrinsic pattern of alternating electrophilicity and nucleophilicity to the atoms making up the skeleton. The situation is illustrated for a carbonyl group and an amino group in Scheme 5. Thus, the oxygen atom of a carbonyl group renders the carbonyl carbon atom itself and the β carbon atoms electrophilic, whereas the α and γ carbon atoms are intrinsically nucleophilic. The inherent difficulty in synthesizing α- and γ-amino ketones, relative to β-amino ketones and amides, is clearly seen from the diagrams at the bottom of Scheme 5. In the former case the two functional groups impart conflicting intrinsic polarities to the skeleton. Therefore, in the synthesis of α and γ-amino ketones it would be necessary to modify inherent polarity when constructing the skeleton. Of course, the reader will be aware that a considerable amount of research over the last two decades has been directed at reversing the innate electrophilicity or nucleophilicity of a given carbon atom through various contrivances. This strategy has been called "charge reversal" or "umpolung."[20] However, the use of



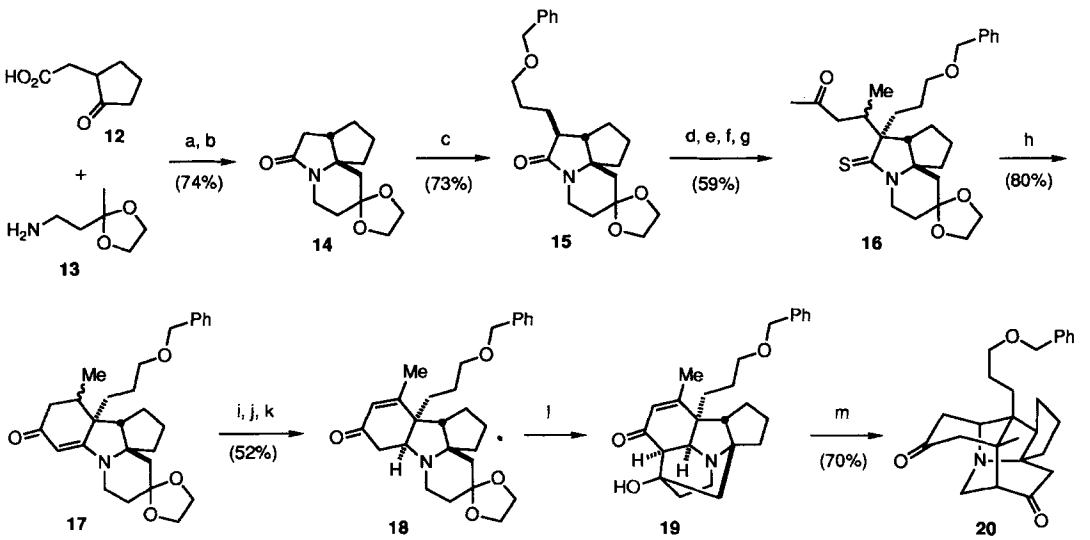
Scheme 5.

umpolung in a synthesis usually requires extra steps, expensive reagents, or esoteric reaction conditions. Since the goal of modern research should be to simplify synthetic routes, umpolung (and the use of protecting groups) must always be regarded as a compromise that is made when a given problem cannot be solved in a more direct manner. In the end, the best solution to a synthetic problem is a well-designed synthesis that takes maximum advantage of the natural functionality of the molecule to be synthesized.[21]

4. The First Synthesis of a *Daphniphyllum* Alkaloid: A Bittersweet Victory

The foregoing analysis directed our attention to the tetracyclic amino diketones **B** and **C** as potential synthetic intermediates for construction of the daphnane skeleton. Of these two possibilities, **B** appeared more attractive because of the great difference in acidity and ease of enolization of a ketone relative to a lactam carbonyl group. Accordingly, this compound became the focus of our attention. The synthesis of a tetracyclic amino diketone with the skeleton of **B** is summarized in Scheme 6. Keto acid **12**[22] and amino ketal **13**[23] were coupled using the mixed anhydride method to obtain a keto amide, which was cyclized by treatment with anhydrous acid. The cyclization reaction involves the reaction of a transient enol ether as the nucleophilic component in an intramolecular Mannich reaction with an acylalkylidenammonium (acylimmonium) ion, a reaction that was first observed by Wenkert et al.[24] The two-step conversion of **12** and **13** to the crystalline tricyclic ketal lactam **14** proceeded in excellent overall yield and was carried readily out on a multigram scale.

Treatment of the lithium enolate of lactam **14** with the benzyl ether of 3-bromopropanol[25] provided **15**, which was treated with the Lawesson reagent[26] to obtain the thiolactam. Surprisingly, thiation of the lactam carbonyl was accompanied by partial replacement of one of the dioxolane oxygen atoms, and it was necessary to remove and reinstall the protecting group before proceeding with the synthesis. In



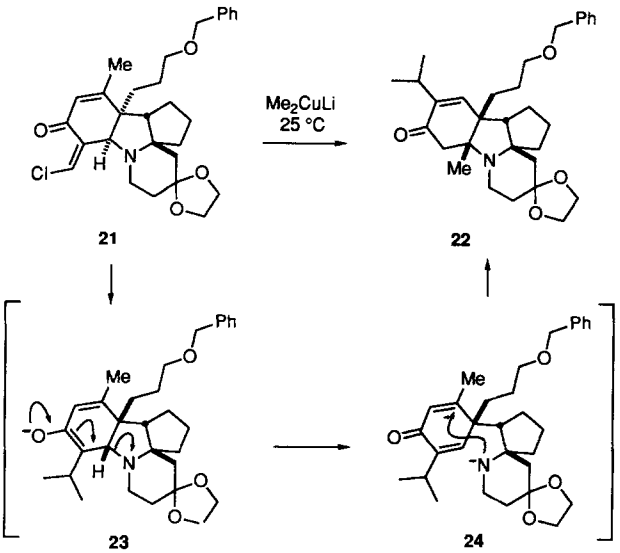
Scheme 6. a: i) **12**, Et_3N,$ClCO_2Et$; ii) **13**. b: *p*-toluenesulfonic acid, toluene, reflux. c: lithium diisopropylamide (LDA), $PhCH_2OCH_2CH_2CH_2Br$. d: Lawesson reagent. e: H_3O^+. f: $(CH_2OH)_2$, H^+. g: LDA, $CH_3COCH{=}CHCH_3$. h: i) $Et_3O^+BF_4^-$; ii) Et_3N. i: i) $Me_3O^+BF_4^-$; ii) $NaBH_4$; iii) H_3O^+. j: i) lithium-2,2,6,6-tetramethylpiperide (LTMP), THF, −78 °C; ii) PhSeCl. k: *m*-chloroperbenzoic acid. l: H_3O^+, acetone. m: MeONa, MeOH.

light of our philosophy with regard to protecting groups articulated at the end of the previous section, this unproductive maneuver constitutes a distinct flaw in the synthesis. However, as will soon be revealed, the entire approach turned out to be flawed for another reason, so there was little incentive to work out more appropriate thiation conditions. Treatment of the lithium enolate of the thiolactam with pent-3-en-2-one afforded **16** as a 6:1 mixture of diastereomers at the methyl-bearing stereocenter in about 80% yield.[27]

The fourth ring was closed by treatment of **16** successively with $Et_3O^+BF_4^-$ and triethylamine to give vinylogous amide **17**. Having reached our first goal of an intermediate with the skeleton of **B** (see Scheme 4), it was necessary to relocate the double bond and set the stage for formation of the strategic bond. This was accomplished by a three-step sequence wherein the double bond of **17** was reduced by successive treatment with $Me_3O^+BF_4^-$, $NaBH_4$, and aqueous acid to obtain a saturated amino ketone. The double bond was then reintroduced by deprotonation with LTMP in THF at $-78\,^\circ C$ and treatment of the resulting enolate with phenylselenyl chloride. Compound **18** was obtained in about 50% overall yield.

With **18** in hand, we could finally test the proposed intramolecular Michael addition and formation of the strategic bond of daphnane. To this end, compound **18** was subjected to aqueous acidic conditions in order to hydrolyze the ketal and thus obtain the enedione corresponding to structure **B** in Scheme 4. The infrared spectrum of the product revealed the presence of a saturated carbonyl group, not the desired α,β-unsaturated carbonyl function. Furthermore, the product clearly contained a hydroxy group. Unexpectedly (but predictably), the initial enedione had undergone an intramolecular aldol reaction under the acidic conditions. Fortunately, this unexpected cyclization was of no real concern, because the aldol cannot dehydrate for geometric reasons, and it is known that aldols are easily reversible under the basic conditions required for the intramolecular Michael reaction. Thus, treatment of aldol **19** with methanolic sodium methoxide smoothly furnished the amino diketone **20**, the first synthetic material having the pentacyclic daphnane skeleton.

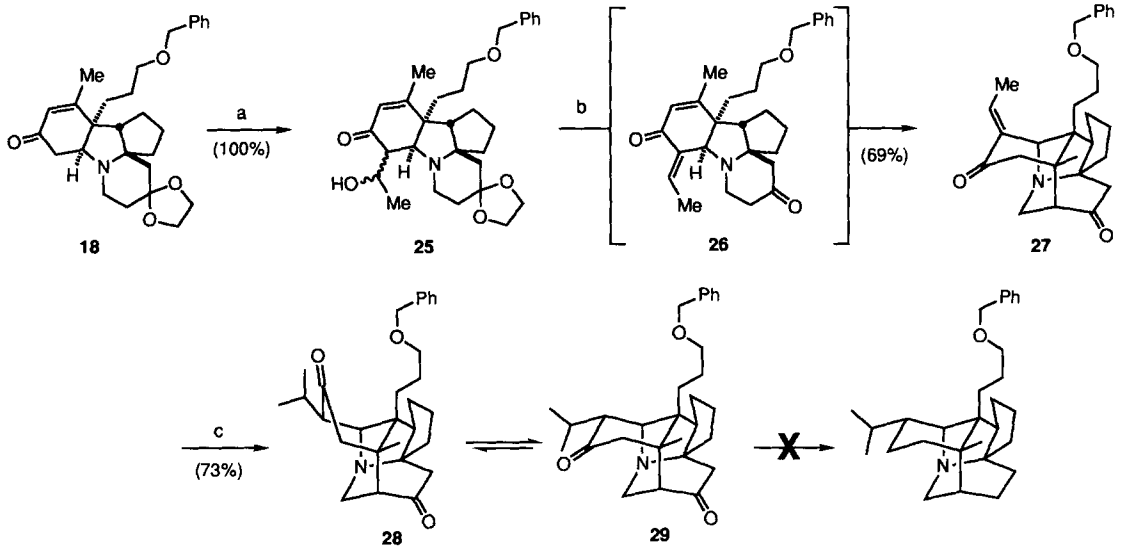
With the path to methyl homodaphniphyllate thus illuminated, three tasks remained before us. The first was installation of the final three carbon atoms, in the form of the isopropyl group. Second, there was the seemingly trivial task of removing the two carbonyl oxygens atoms which, having served their synthetic purpose, were now superfluous. Finally, it was necessary to correctly refunctionalize the three-carbon side chain. At this point, a brief detour was forced upon us. In an attempt to introduce the isopropyl group, compound **18** was formylated, and the resulting keto aldehyde was treated with oxalyl chloride to obtain the β-chloro enone **21**. When this material was treated with lithium dimethylcuprate in ether at room temperature, rearranged enone **22** was the only identifiable product (Scheme 7). At first glance, the transformation of **21** into **22** appears astonishing. Although the product is an enone, as expected, the isopropyl and methyl groups seem to have been miraculously relocated. However, the explanation is ordinary and, in fact, the reaction could have been anticipated. Enolate **23**, formed after reaction with the second equivalent of cuprate, simply undergoes β elimination to give a cyclohexadienone, **24**, which undergoes 1,4-addition at the methyl-bearing double bond. Ironically, the same intrinsic polarization that had made this skeleton easy to assemble also provided the seed of its destruction!



Scheme 7.

The retro-Michael problem was solved in a relatively straightforward fashion. As shown in Scheme 8, the lithium enolate of **18** reacted with acetaldehyde to provide aldol **25**, which was treated with sulfuric acid in aqueous acetone. Careful examination of the reaction intermediates disclosed that the aldol dehydrated rapidly and that the ethylene ketal hydrolyzed more slowly to **26**. This substance, now deprived of the possibility of β elimination or intramolecular aldol reaction by the presence of the ethylidene group, smoothly cyclized to the pentacyclic enedione **27**, which was obtained in about 70% yield.

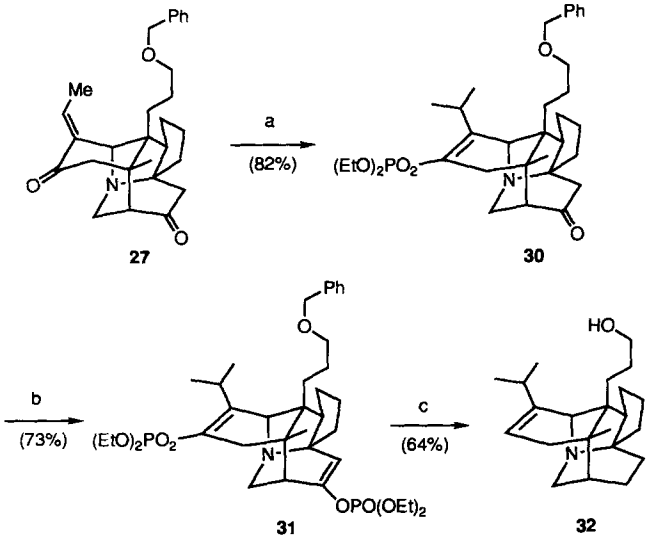
Efforts were next directed toward introduction of the final carbon atom of methyl homodaphniphyllate. We had planned to accomplish this task by conjugate addition of lithium dimethylcuprate to **27** an had anticipated no problems with the maneuver, since the isopropyl group in the natural product occupies an equatorial position. However, our estimation proved to be overly optimistic. Although **27** reacted smoothly with lithium dimethylcuprate, the product was a mixture of diones, epimeric at the isopropyl-bearing stereocenter, in a ratio of 4:1. This development presented us with three problems: First, the isomers equilibrated with great ease, even on attempted separation by column chromatography on silica gel. Second, although molecular modeling suggested that the desired isomer **29** would predominate in the equilibrium, the calculated strain energies of the two isomers were so close that we had no confidence that this isomer was, in fact, the major product. Finally, and most importantly, many attempts to remove the two carbonyl groups utterly failed. Although space does not permit a complete catalog of the methods that were evaluated for deoxygenation of **28** and **29**, it is sufficient to say that a great many reactions were tested, ranging from simple Wolff–Kishner



Scheme 8. a: LDA, CH_3CHO; b: H_2SO_4, acetone; c: Me_2CuLi, Et_2O.

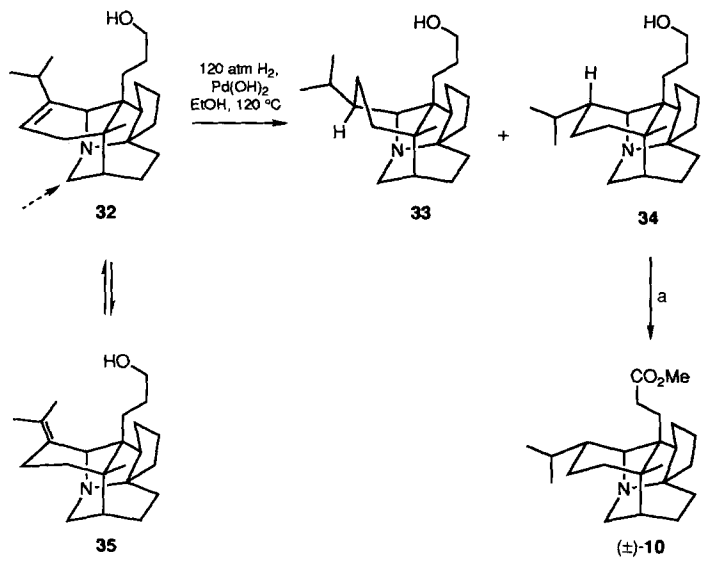
reduction to various strategies designed to proceed through free radical intermediates. The origin of the problem seemed to be the sterically hindered environment of the carbonyl next to the isopropyl-bearing center.

We eventually found a way around the impasse. As summarized in Scheme 9, the initial lithium enolate resulting from reaction of lithium dimethyl cuprate with **27** was phosphorylated to obtain **30**, which itself was deprotonated and phosphorylated to arrive at the bis(enol phosphate) **31**. Ireland reduction[28] of **31** provided the unsaturated amino alcohol **32**. The three-step process accomplished introduction of the final methyl group and removal of the two carbonyl groups, albeit in a rather heavy-handed way; the overall yield was only 38%.



Scheme 9. a: i) Me_2CuLi, ii) $(EtO)_2POCl$. b: i) LDA, THF, hexamethylphosphoric triamide (HMPA); ii) $(EtO)_2POCl$. c: Li, $EtNH_2$.

Having finally dispatched the unwanted carbonyl groups, we had only to adjust the functionality of the three-carbon side chain and reduce the double bond to complete the first synthesis of a *Daphiphyllum* alkaloid. We had not anticipated problems with saturation of the double bond, because molecular models of **32** showed that the same methylene group (indicated with an arrow in Scheme 10) that had impeded removal of the carbonyl oxygen atom now stood squarely in the path of any reagent seeking access to the "bottom face" of the cyclohexene double bond. For this reason, we were rather confident that hydrogenation would occur from the "top face", delivering the daphnane skeleton with the proper configuration at the isopropyl-bearing carbon. However, events proved otherwise. Initial hydrogenations over rhodium did give only one product, but the one having the wrong configuration at the new stereocenter! Subsequent investigations showed that the stereochemical outcome of the reduction was responsive to changes in catalyst and solvent, and we embarked on an extensive program of process development. However, even under the best conditions we could find (Scheme 10), we were able to achieve no better than a 1:1 mixture of the diastereomeric amino



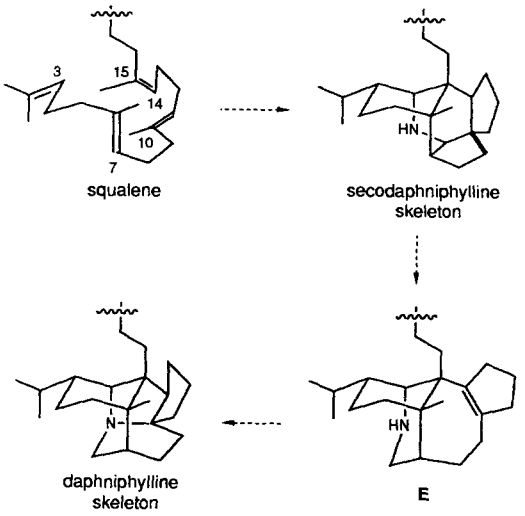
Scheme 10. a: i) Separation; ii) Jones oxidation; iii) 6 M HCl, MeOH.

alcohols **33** and **34** with the respective unnatural and natural configuration at the new stereocenter. Once again, nature had thwarted our simplistic plans. Because hydrogenation of the hindered double bond is slow, it is likely that isomerization occurs to give some isomer, perhaps **35**, in which the bottom face of the double bond is not as hindered as it appears to be in **32**. Nevertheless, amino alcohol diastereomers **33** and **34** were separable by chromatography, and the latter isomer was transformed by succesive oxidation and esterification into racemic methyl homodaphniphyllate, (±)-**10**.

By obtaining a few milligrams of (±)-**10**, we had achieved the first total synthesis of one of the alkaloids of Yuzuriha. However, the problem of finding a truly efficient route to these fascinating natural products had still not been solved. The synthesis just described was not especially long, given the state of synthetic art and the complexity of the target. Only 19 steps were required, starting with keto acid **12** and amino ketal **13**. Although the method of network analysis did identify a facile assembly for the pentacyclic skeleton, the concluding stages of the synthesis, which were occasioned by the need to remove the activating carbonyl groups, were awkward and failed to control one of only two independent stereocenters in the molecule. Thus, the very heuristic that had so simplified the synthetic design had also endowed the synthesis with its Achilles heel.

5. A Fresh Look at the Problem: Dissection of the Target Along Probable Biosynthetic Lines

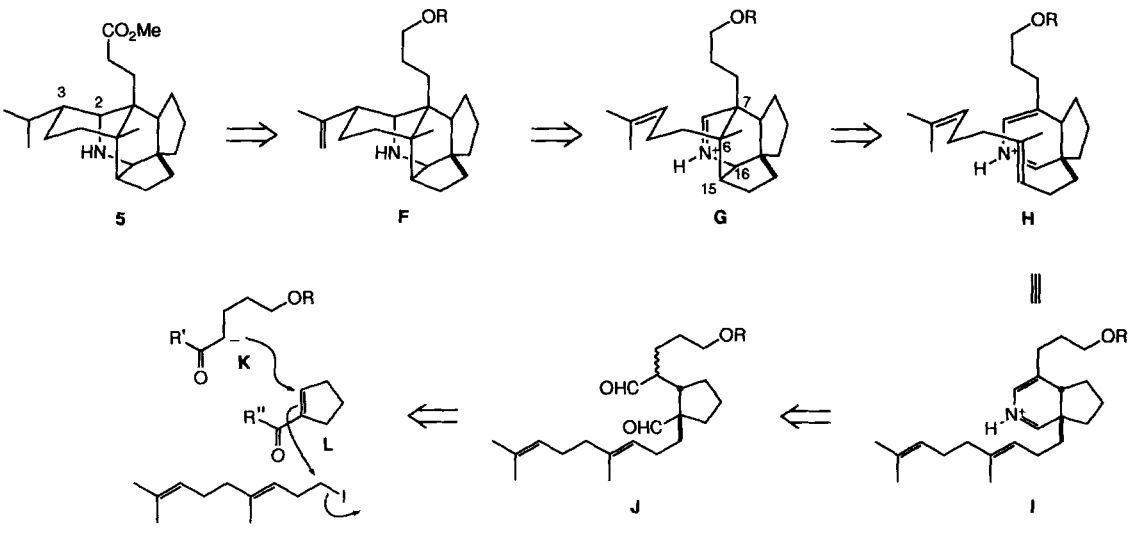
Even while we were struggling with removal of the two carbonyl oxygen atoms and stereocontrolled reduction of the double bond in **32**, we turned our minds back to the original design. Where had we gone wrong? In examining our assumptions, we reconsidered the reasons for selecting methyl homodaphniphyllate as our first target. Because it is widespread and abundant relative to the other *Daphniphyllum* alkaloids, we had made the mistake of bestowing it with singular importance and elected it as our original synthetic goal. However, an examination of the daphnane and seco-



Scheme 11.

daphnane carbon skeletons reveals an important difference. As shown in Scheme 11, the unbroken squalene molecule can be identified in the pentacyclic structural unit of secodaphniphylline but not in that of daphniphylline. That is, in order for squalene to be converted into secodaphniphylline, four C–C bonds must be created: C10 to C14; C6 to C15; C3 to the C15 methyl group; and C7 to the C10 methyl group. The nitrogen atom is inserted between the C10 and C15 methyl groups. In daphniphylline, on the other hand, the nitrogen atom has been inserted between C10 and its methyl group, which has also become bonded to C7. Although circumstantial, the evidence is strong that secodaphniphylline prededes daphniphylline biosynthetically. A reasonable biosynthetic link between secodaphniphylline and daphniphylline is an unsaturated amine with the partial structure **E**.[29]

The perception of this biosynthetic progression was significant, since it suggested the probability of some reasonable chemical path for the conversion of secodaphniphylline to daphniphylline by way of a ring-opened intermediate such as **E**. If we could discover the path, we could use it as a better route to **10**. A natural consequence of this line of thought was a redirection of our attention to the skeleton of seco-



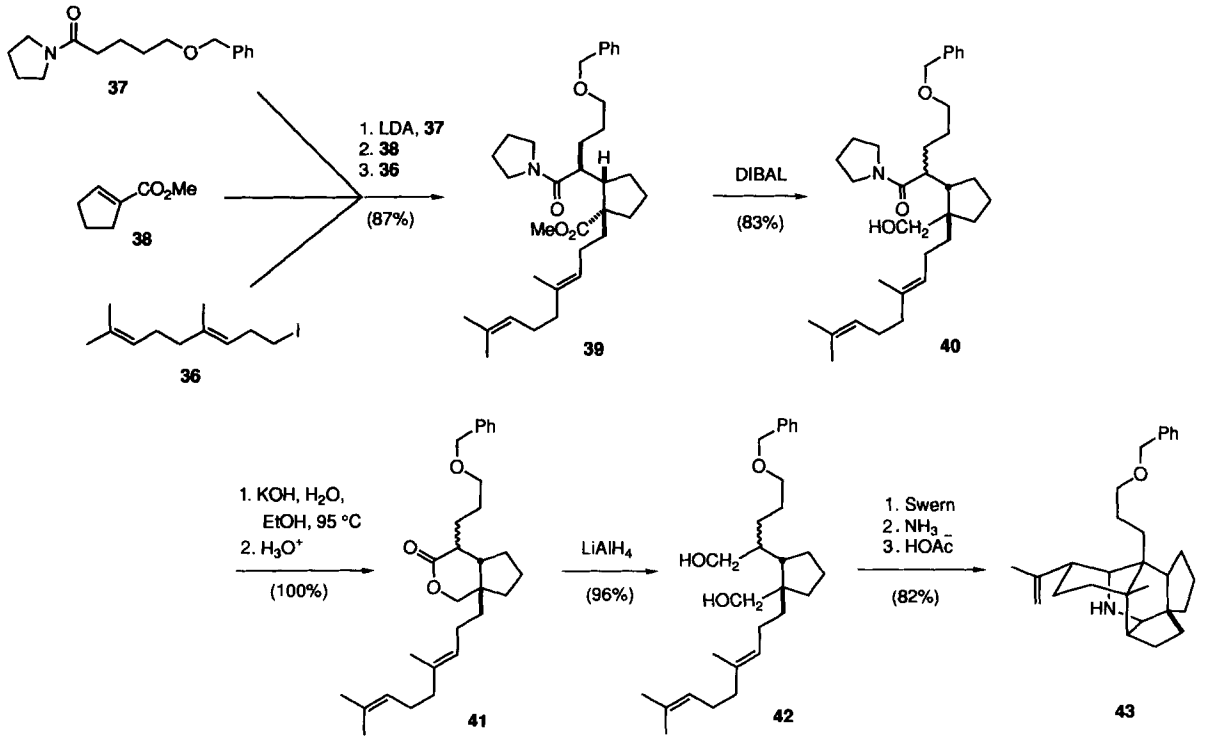
Scheme 12.

daphniphylline, as exemplified by its C_{22} congener, methyl homosecodaphniphyllate (**5**). Although a retrosynthetic analysis centered about the primacy of the pentacyclic network was again possible, we feared that the inevitable end of such a plan would be another struggle to remove necessary but unwanted functional groups. Thus, we abandoned the strategic bond approach in favor of synthetic plans by which the skeleton might be assembled without the wasteful use of auxiliary functional groups. How does nature forge the skeleton of secodaphniphylline from its triterpene raw material? The plan that emerged from these contemplations is summarized in Scheme 12. A key element was the dissection of the skeleton along probable biosynthetic lines. That is, in the retrosynthesis, bond disconnections were made so as to preserve the squalene chain for as long as possible until we recognized an obvious solution based on available materials and methods. This reasoning forced us to consider formation of the C2–C3 bond as the final carbon–carbon bond-forming operation in the formation of secodaphniphylline. Homoallylic amine **F** contains a reasonable retron for the desired transform,[30] which can be viewed as an ene or aza-Prins reaction. Once **G** had been identified as a possible synthetic intermediate, it was natural to take the next step and consider the possible formation of bonds between C6 and C7 and then between C15 and C16. It then became clear that a compound with the part structure of **I** might easily arise from reaction of a monocyclic dialdehyde **J** with ammonia. Up to this point, the plan being developed might even parallel the biosynthesis of the alkaloid. However, with the perception of dialdehyde **J** as an attractive intermediate, a decidedly nonbiosynthetic possibility occurred to us. Compound **J** might be obtained in one grand, triply convergent step by the assembly of an enolate **K**, some α,β-unsaturated carbonyl compound **L**, and homogeranyl iodide (**36**)!

6. Biomimetic Synthesis of Methyl Homosecodaphniphyllate: The Ruggeri Tetracyclization Reaction

The exciting plan was soon put into practice. Successive treatment of the lithium enolate of amide **37** with the α,β-unsaturated ester **38** and homogeranyl iodide (**36**)[31] provided a mixture of three diastereomeric adducts in a total yield of 99%. Compound **39**, the major isomer, was isolated in 87% yield. Two minor isomers were isolated as a 2:1 mixture in a combined yield of 12%. It is not insignificant that the entire carbon skeleton of alkaloid **5** is assembled in this one convergent step. The next task that stood before us was transformation of the ester and amide groups of **39** into aldehyde groups. A good deal of experimentation led to the three-stage protocol summarized in Scheme 13. Treatment of **39** with excess DIBAL gave hydroxy amide **40**, which was hydrolyzed by treatment with KOH in aqueous ethanol. Acidification of the saponification mixture furnished lactone **41** as a 1:1 mixture of diastereomers; epimerization of the benzyloxypropyl center had occurred under the harsh alkaline conditions. However, the configuration at this position is of no consequence because it is destined to have sp^2 hybridization at a later stage in the synthesis. Reduction of **41** with lithium aluminum hydride gave an equimolar mixture of epimeric diols **42** in nearly quantitative yield.

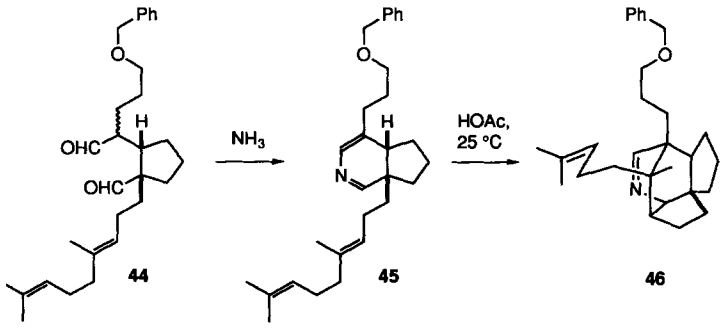
The way was now prepared for the most crucial stage of the plan. Oxidation of diols **42** by the Swern method[32] gave a dialdehyde that turned out to be rather vulnerable to a retro-Michael fragmentation. Consequently, a procedure was developed whereby the material was formed and used in situ. Thus, after the Swern oxidation was complete, gaseous ammonia was passed over the surface of the stirring methylene chloride solution. Concentration of the reaction



Scheme 13. DIBAL = diisobutylaluminum hydride.

solution gave a residue that was taken up in acetic acid containing NH_4OAc. This mixture was heated at 70 °C and worked up in the normal manner to obtain pentacyclic amine **43** in 82% yield. The structure of **43** was eventually proven by its conversion to (±)-methyl homosecodaphniphyllate.

Several intermediates in the conversion of diols **42** into pentacyclic amine **43** have been isolated (Scheme 14). As has already been discussed, the initial Swern oxidation provided the dialdehydes **44**. When the reaction was terminated after

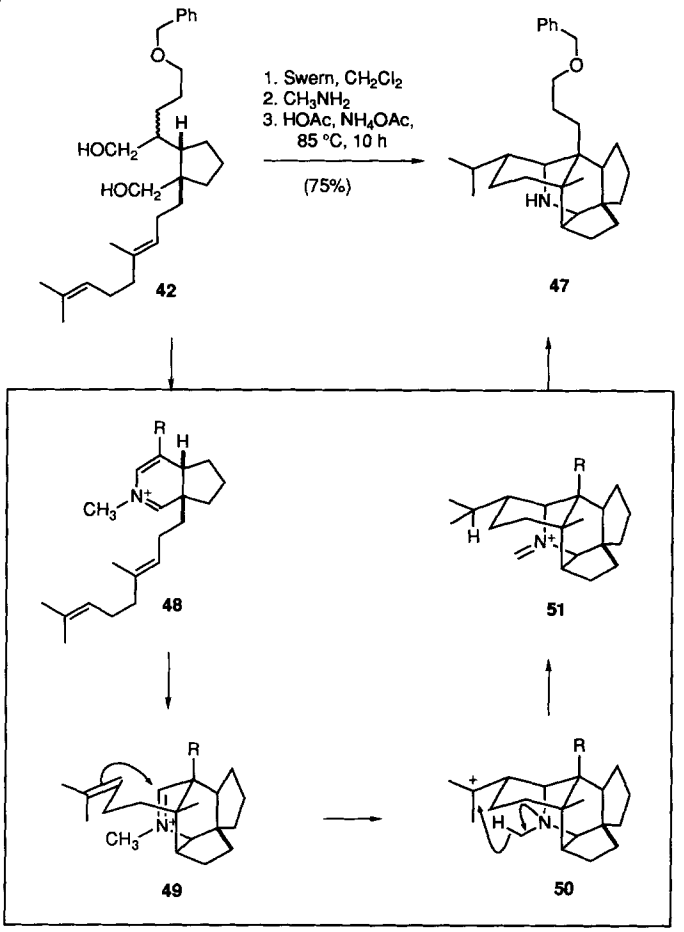


Scheme 14.

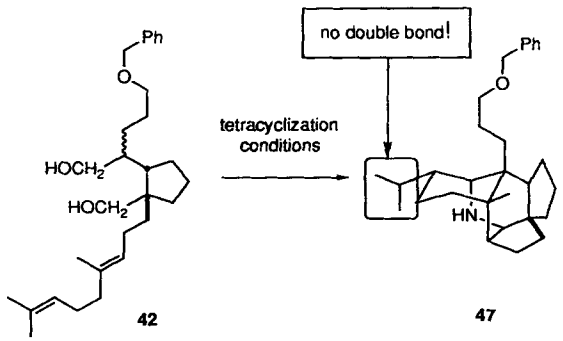
addition of ammonia and before treatment with acetic acid, azadiene **45** was isolated. This material was rapidly transformed into the tetracyclic imine **46** upon being dissolved in acetic acid. Analysis by thin-layer chromatography indicated that the Diels–Alder reaction was complete in less than five minutes. The Diels–Alder step is strongly catalyzed by acid, since the thermal conversion of **45** to **46** has a half-life of about 2 h in refluxing toluene.

7. Serendipity: The "Vollhardt Ammonia" Incident

At this point, a remarkable bit of serendipity will be described. One day, after repeating the tetracyclization process with the goal of obtaining a quantity of pentacyclic amine **43**, one of my co-workers brought me the seemingly impossible news that he had followed the standard protocol that had been developed over a period of about two years and, inexplicably, had obtained the saturated pentacyclic amine **47** instead of the normal product. After having been slandered with various aspersions ranging from amnesia to mixing up his NMR tubes, the co-worker repeated the remarkable transformation and finally succeeded in convincing me that the product of the reaction was, indeed, **47**. Where had the double bond gone? A careful inventory of the materials used revealed one important clue. During the preceding week, our lecture bottle of ammonia had been exhausted and my co-workers had borrowed a new bottle from my colleague, Professor Vollhardt. Mass spectral examination of the "Vollhardt ammonia" revealed it to be methylamine, its label notwithstanding. Initially, this realization brought us no great comfort. The problem was now even more mysterious. Not only were we faced with the quandary of a disappearing double bond, but now we also had to deal with a disappearing methyl group! The explanation was eventually provided by another of my colleagues, Professor Pedersen, who suggested the mechanism shown in Scheme 15. Reaction of di-



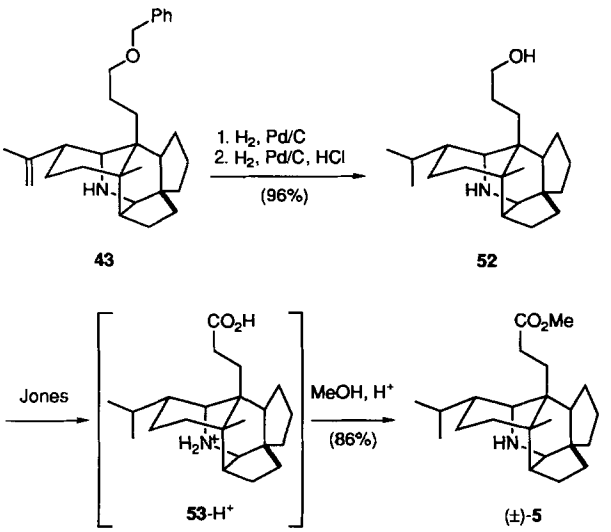
Scheme 15.



aldehyde **44** with the primary amine is postulated to lead to **48**, which reacts with acetic acid at room temperature to give the tetracyclic immonium salt **49**. In fact, an impure intermediate with NMR spectral features consistent with structure **49** has been isolated from the reaction mixture. Further cyclization of **49** is postulated to provide the amino cation **50**, a substance ideally constructed to undergo intramolecular hydride transfer to give **51**,[33] which is hydrolyzed on workup to afford **47**.

After achieving an efficient synthesis of amine **43**, we only had to modify the functionality of the three-carbon side

chain to complete the synthesis of methyl homosecodaphniphyllate. The alkene was readily hydrogenated with Pd/C as catalyst (Scheme 16). Analysis of the reaction mixture by ^{1}H NMR showed that amine **47** was rapidly produced, along with a small amount of amino alcohol **52**. Addition of a



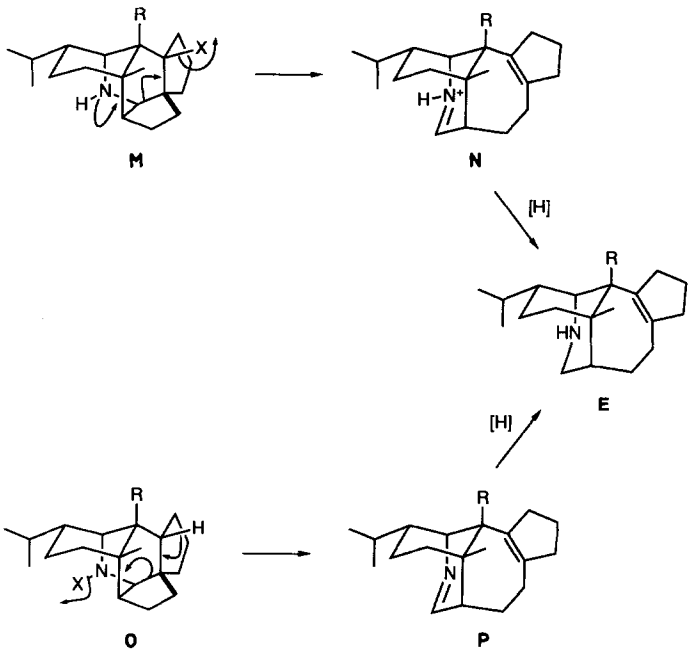
Scheme 16.

small amount of hydrochloric acid increased the rate of hydrogenolysis considerably and permitted complete conversion into **52**, which was isolated as the hydrochloride salt in 96% yield. This material was directly converted to amino acid **53** by oxidation with excess Jones reagent.[34] Finally, compound **53** was converted into racemic methyl homosecodaphniphyllate, (±)-**5**, by Fischer esterification. Comparision of the ^{1}H NMR spectra and R_f values showed the synthetic material to be identical to an authentic sample of the natural alkaloid.[35]

The total synthesis of (±)-methyl homosecodaphniphyllate requires only nine steps and proceeds in 48% overall yield from the simple starting materials **36**, **37**, and **38**. Amide **37** and ester **38** are each made in two steps from commercially available materials. The synthesis of iodide **36** is more complicated, requiring four steps form geraniol. The longest linear sequence requires thirteen steps from geraniol and proceeds in 18% overall yield. The key steps in the synthesis are the tandem Michael addition–alkylation reactions, which assemble all of the carbon atoms necessary for the skeleton, and the tetracyclization reaction, which provides the complete pentacyclic skeleton in one operation. The only disappointing sequence is the conversion of amide **39** to diol **42**; three steps are expended for what would appear to be straightforward functional group manipulations. However, this was the only workable method that we could find for this conversion, and the overall yield for the three steps is quite respectable. All of the steps in the sequence have been carried out on gram scale, and we have used the route to synthesize more than 3.5 g of (±)-methyl homosecodaphniphyllate, several times as much of the alkaloid as has ever been isolated from natural sources. Finally, the synthesis is wholly stereospecific, in contrast to our initial synthesis of methyl homodaphniphyllate.

8. Stealing Another Page from Mother Nature: Conversion of the Secodaphnane Skeleton to the Daphnane Skeleton

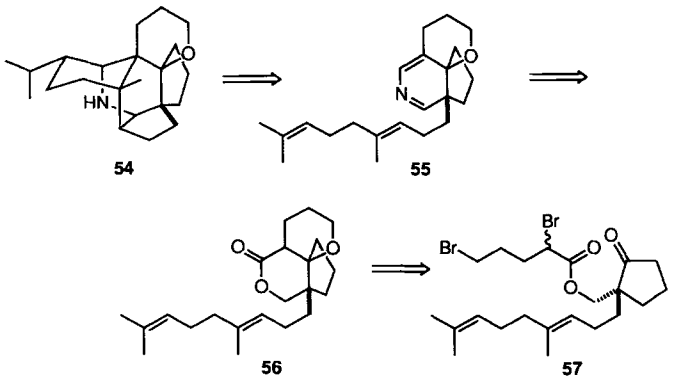
In spite of this success, the original problem that we had set before ourselves was only partially solved; we still had to discover a method to rearrange the secodaphnane skeleton to the daphnane skeleton. It has already been pointed out that the desired rearrangement might be realized in two stages by fragmentation of a secodaphnane to an unsaturated amine with structure **E**, which could undergo transannular addition to the double bond. Two possible fragmentation modes of the secodaphnane skeleton are summarized in Scheme 17. Both of these hypothetical transformations are



Scheme 17.

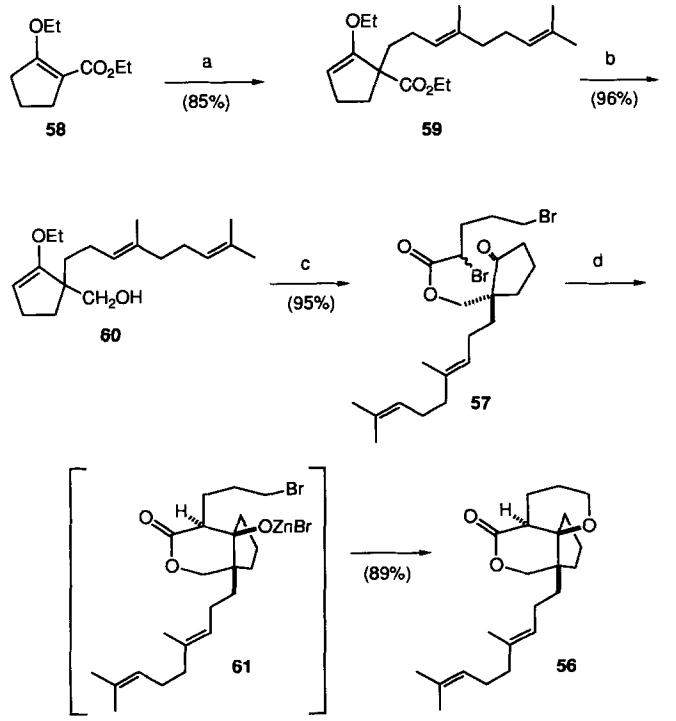
Eschenmoser–Grob fragmentation reactions.[36] The first is more conventional and would convert an angulary functionalized secodaphnane **M** into an immonium ion **N**. The second possibility is less well known and involves movement of electrons in the opposite direction, converting an *N*-functionalized secodaphnane **O** into the imine **P**. In either case, we would have to reduce the carbon–nitrogen double bond of the initial fragmentation intermediate to obtain **E**.

Both of the possibilities in Scheme 17 have been investigated. However, because of the constraints of space, I will only discuss the results of the more traditional fragmentation. Since X must be a heteroatom, and since the three-carbon side chain terminated in a heteroatom, it occurred to us that it would be economical to arrange for the same heteroatom to serve both functions. The substrate for the fragmentation would, therefore, be hexacyclic amino ether **54** (Scheme 18). The necessary cyclization substrate would then be the azadiene **55**. If we followed the same route that was already discussed for the synthesis of methyl homosecodaphniphyllate, we would need tricyclic lactone **56**, which might be available by an intramolecular Reformatsky reaction of **57**, followed by cyclization of the resulting bromo alcohol.



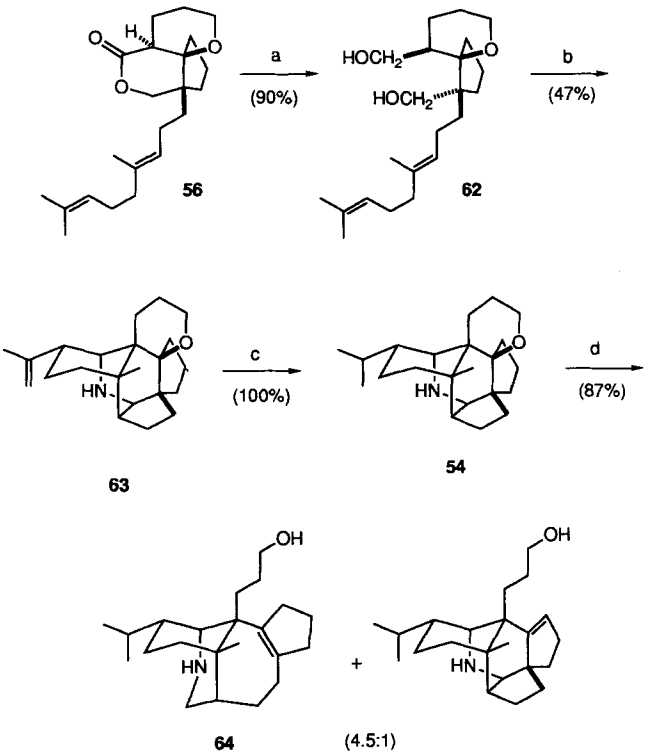
Scheme 18.

To prepare a suitable substrate for the proposed Reformatsky double annulation process, we started with enol ether **58**, which was conveniently prepared from the corresponding β-keto ester. Alkylation of the lithium enolate of **58** with homogeranyl iodide (**36**) provided **59**, which was reduced with lithium aluminum hydride to alcohol **60** (Scheme 19). Esterification with 2,3-dibromopentanoyl bromide[37] provided keto ester **57** after acidic hydrolysis of the enol ether. This material was treated with activated zinc, prepared by treatment of $ZnCl_2$ with sodium naphthalenide in THF,[38] to obtain the tricyclic lactone ether **56**. Although the Reformatsky reaction was rapid, the ensuing cyclization of the zinc alkoxide **61** was slow in pure THF. For this reason, HMPA was added immediately after addition of **57** to the activated zinc suspension. The relative configuration of **56** was assigned on the basis of a single-crystal X-ray structure analysis of a related compound having a methyl group in place of the homogeranyl group.



Scheme 19. a: i) LDA; ii) **36**. b: $LiAlH_4$. c: i) $BrCH_2CH_2CH_2CH_2BrCOBr$; ii) H_3O^+. d: Zn, THF, HMPA.

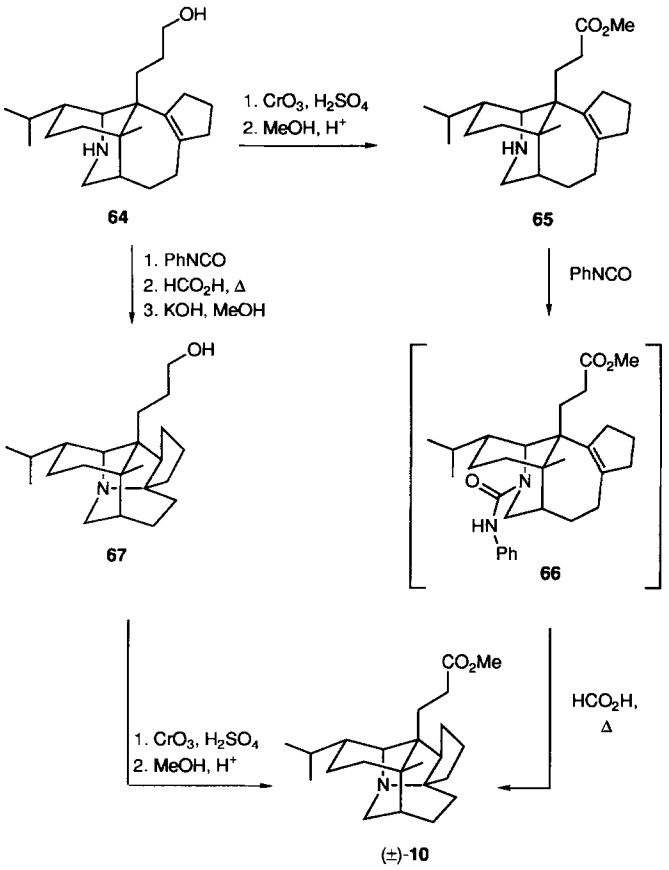
As shown in Scheme 20, reduction of lactone **56** provided diol **62** in high yield. Application of the tetracyclization protocol to this diol was successful, although the yield of the hexacyclic amino ether **63** was lower than that of the cyclization of diol **42**. However, given the fact that **62** has an ether linkage to a tertiary carbon atom that is allylic in some of the tetracyalization intermediates, we were more than pleased with the optimized yield of 47%. Hydrogenation of the double bond over Adams catalyst proceeded in quantitative yield to provide the saturated hexacyclic amino ether **54**. To



Scheme 20. a: $LiAlH_4$. b: i) Swern oxidation; ii) NH_3; iii) HOAc, 55 °C. c: H_2, PtO_2. d: DIBAL, toluene, reflux 36 h.

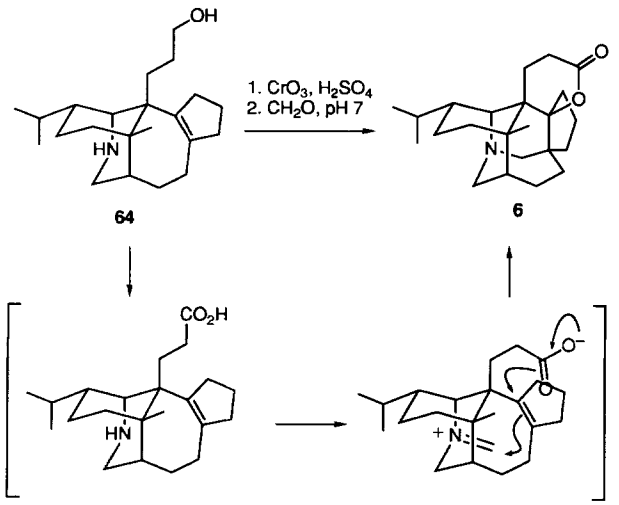
bring about the fragmentation suggested in Scheme 17 we needed a Lewis acid to activate the alkoxy leaving group and a reducing agent to reduce the immonium ion expected to result. We thought that a dialkylaluminium hydride might fulfill both functions and perhaps also activate the nucleofugal group by deprotonation of the secondary amine. To this end, **54** was treated with excess DIBAL in refluxing toluene for 72 hours to obtain the desired unsaturated amino alcohol **64** (71% yield), accompanied by some of the simple elimination product **65** (16% yield).

With unsaturated amino alcohol **64** in hand, we were poised for the second stage of the proposed secodaphnane → daphnane isomerization. To this end, **64** was subjected to Jones oxidation and the resulting amino acid treated with sulfuric acid in refluxing methanol of afford unsaturated amino ester **65** (Scheme 21). We were not surprised when **65** was recovered unchanged from other acidic media (e.g., refluxing formic acid, *p*-toluenesulfonic acid in refluxing benzene). Under these acidic conditions the amine is presumably firmly protonated and therefore not nucleophilic even if the double bond also happens to become protonated.



Scheme 21.

However, the *N*-phenylurea derivative **66**, formed by the reaction of **65** with phenyl isocyanate, cyclized smoothly in refluxing formic acid to provide (±)-methyl homodaphniphyllate (**10**) in 63% overall yield. In an alternative sequence of steps, unsaturated amino alcohol **64** was treated sequentially with phenyl isocyanate, refluxing formic acid, and methanolic potassium hydroxide to furnish (±)-homodaphniphyllol (**67**). Jones oxidation of this material and Fischer esterification of the resulting amino acid provided (±)-**10** in an overall yield of about 70%. These successful



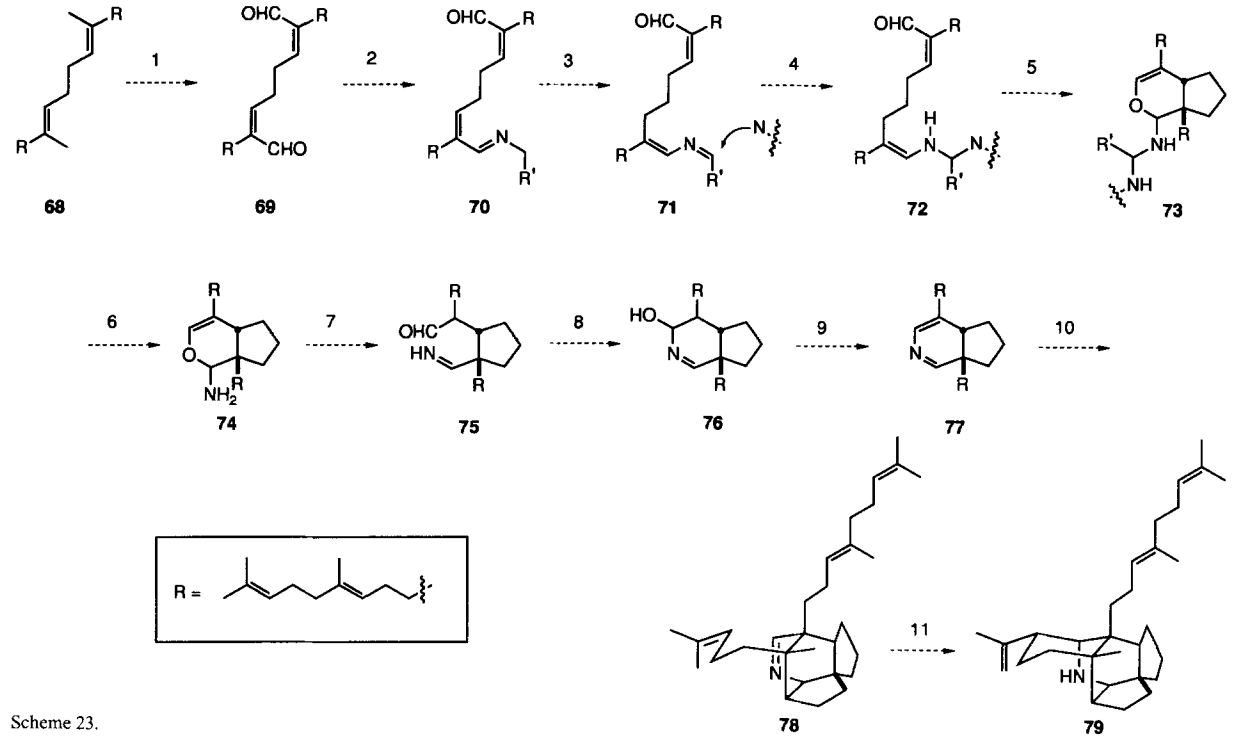
Scheme 22.

cyclizations therefore permitted us finally to solve the problem of a stereocontrolled synthesis of methyl homodaphniphyllate. The synthesis of (±)-**10** by this route required a total of 13 steps from homogeranyl iodide and proceeded in 11% overall yield.

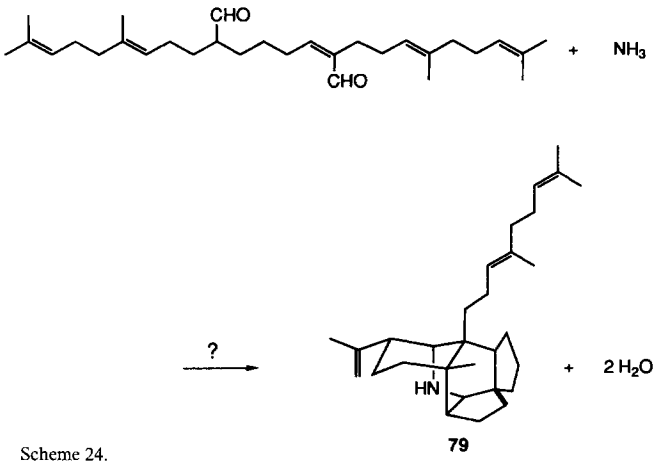
Compound **64** was also converted into racemic daphnilactone A, (±)-**6**, as shown in Scheme 22. Oxidation of **64** delivered the corresponding amino acid, which was treated directly with aqueous formaldehyde at pH 7 to obtain (±)-**6**, whose ^{1}H NMR spectrum and R_f value are identical to those of an authentic sample provided by Professor Yamamura. The complete synthesis of daphnilactone A required 11 steps from homogeranyl iodide and proceeded in 8% overall yield.

9. Transformation of a Squalene Derivative into a Pentacyclic Alkaloid in a Simple One-Pot Transformation

The goal of this project was purely synthetic—we were challenged as molecular architects and engineers by the fascinating structural complexity of the alkaloids of Yuzuriha. Although we applied in our second retrosynthetic analysis a biosynthetic philosophy in performing disconnections that preserved the squalene chain to the extent possible, the resulting synthesis was not truly biomimetic in the sense that it paralleled a known biosynthetic pathway. However, the analysis led us to discover the exceptionally facile tetracyclization process. Could it be that the process actually is biomimetic? A credible biosynthesis is put forth in Scheme 23. The rough outlines of this proposal are as follows: Step 1 is an oxidative transformation of squalene (**68**) into a dialdehyde, **69**.[39] In step 2 it is proposed that some primary amine, perhaps pyridoxamine [40] or an amino acid, condenses with one of the carbonyl groups of **69**, giving imine **70**. Step 3 is the prototopic rearrangement of a 1-azadiene to a 2-azadiene, a process that is well-precedented for the imines formed from α,β-unsaturated carbonyl compounds and benzylamine.[41] Although potassium *tert*-butoxide was used for the prototopic rearrangement of benzylimines, one can imagine that an imine derived from pyridoxamine or an amino acid would rearrange under much milder conditions. Because the 2-azadiene that would result from the foregoing rearrangement is an enimine, its double bond is not especially nucleophilic. However, if some nucleophilic species adds to the imine double bond, as in step 4, the product **72** is a nucleophilic enamine. The subsequent cyclization to give **73** has an exact precedent in vitro in the work of Schreiber, Meyers, and Wiberg.[42] In steps 6–9 the resulting bicyclic dihydropyran derivative **74** is transformed into a dihydropyridine derivative **77** similar to the intermediate in the in vitro conversion of **42** into **43**. Other possible scenarios can be envisioned for the metamorphosis of **74** into **77**. According to our supposition of the biosynthesis **77** would then be converted into **78** by a catalyzed Diels–Alder reaction and the final ring would result from an ene-like cyclization, giving **79**, the putative primordial *Daphniphyllum* alkaloid. Because of the likelihood that **79** is the first pentacyclic substance to occur in the biosynthesis of the al-



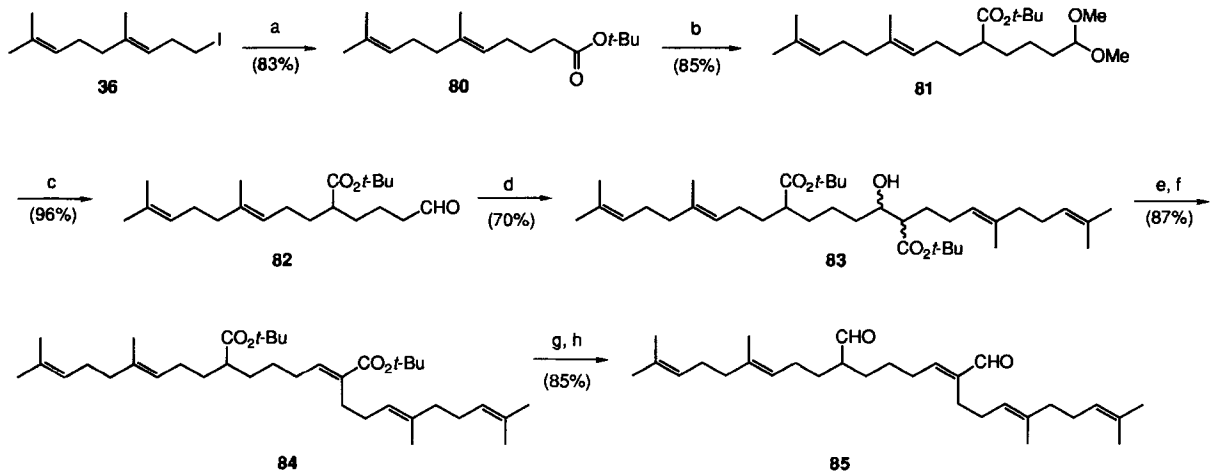
Scheme 23.



Scheme 24.

kaloids of Yuzuriha, we have named it protodaphniphylline.[43]

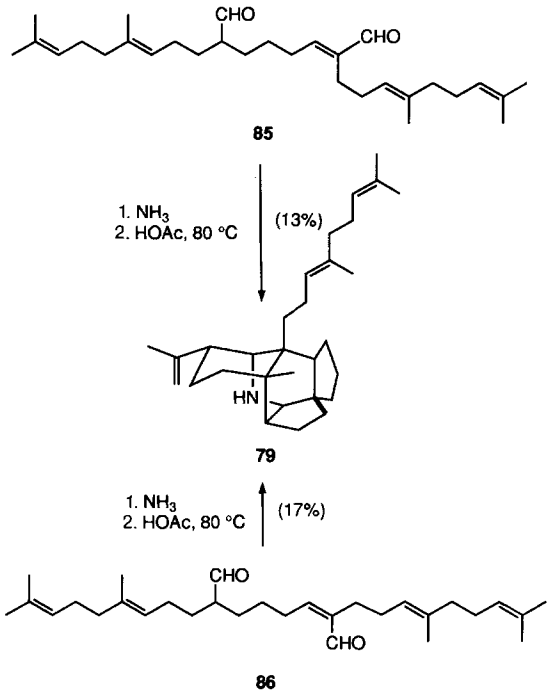
How much of this proposed biosynthesis might we be able to imitate in the laboratory? We thought it possible that we could intercept the proposed scheme at the stage of intermediate **72** or the corresponding dialdehyde (Scheme 24). We therefore set about the relatively simple task of preparing a suitable squalene derivative to put this proposition to the test. The route adopted is summarized in Scheme 25. Alkylation of the lithium enolate of *tert*-butyl acetate with homogeranyl iodide (**36**) afforded ester **80**, which was alkylated with the dimethyl acetal of 4-bromobutanal [44] to provide **81**. Hydrolysis of the acetal gave aldehyde **82**, which was condensed with the lithium enolate of **80** to obtain β-hydroxy esters **83** as a mixture of diastereomers. Elimination



Scheme 25. a: Li enolate of *tert*-butyl acetate. b: i) LDA; ii) $BrCH_2CH_2CH_2CH(OMe)_2$. c: H_3O^+. d: Li enolate of **80**. e: CH_3SO_2Cl, Et_3N. f: 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), toluene, Δ. g: DIBAL. h: Swern oxidation.

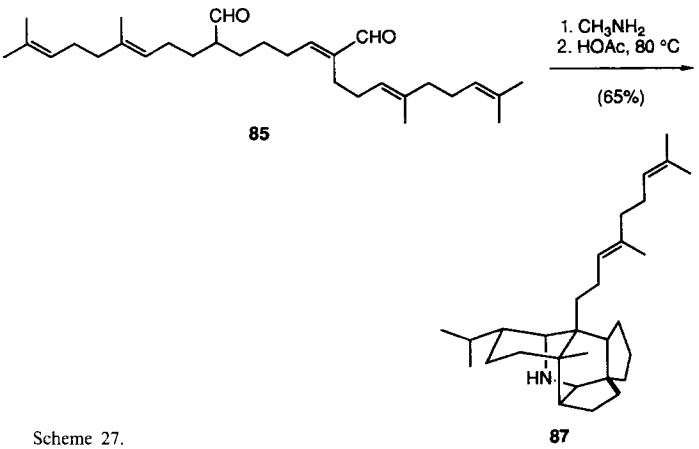
was accomplished by treatment of the methanesulfonate of **83** with DBU in toluene at 80 °C. Diester **84** was obtained in excellent yield, accompanied by approximately 10% of the *Z* isomer. After chromatographic separation to the stereoisomeric diesters, **84** was converted into the *E* dialdehyde **85** as shown in Scheme 25. The pure *Z* isomer **86** was prepared by a slightly different route wherein the C10–C11 double bond was formed by Peterson olefination.

The pentacyclization process was first investigated under the conditions that had served for the teracyclization of **42** to **43** (Scheme 26). Thus, a solution of either **85** or **86** in CH_2Cl_2 was treated with ammonia and triethylamine hydrochloride at room temperature for 16 hours, after which time TLC showed that starting material had been consumed. At this point the solvent was evaporated under vacuum and the resulting residue taken up in acetic acid and heated at 80 °C for 2 hours. Workup gave protodaphniphylline (**79**) in 15 ± 2% yield. Although the yield in this biomimetic synthesis is not high, it must be acknowledged that a profound structural change has occurred—five rings and six σ bonds have been created through the action of the most common of chemical reagents, ammonia and acetic acid.



Scheme 26.

A considerable amount of process development eventually resulted in a somewhat more complicated two-pot protocol wherein **85** or **86** was treated sequentially with KOH under phase-transfer conditions, ammonia in DMSO, and acetic acid, to obtain **79** in obout 50% overall yield. However, it was our unexpected experience with the "Vollhardt ammonia" (methylamine) that eventually provided the best solution to the pentacyclization problem. Because the low yield in the pentacyclization of **85** and **86** with ammonia was presumably due to poor selectivity in the formation of the first carbon–carbon bond, we reasoned that the more nucleophilic *N*-methylenamine derived from methylamine might improve upon the 15% yield observed with ammonia. Indeed, when dialdehyde **85** was treated with methylamine and the crude reaction product heated in acetic acid at 80 °C for 11 hours, dihydro-protodaphniphylline **87** was obtained in 65% yield (Scheme 27).



Scheme 27.

10. Epilogue and Editorial

If progress in important fields such as medicine, biochemistry, and materials science is to continue, it is essential that we be able to synthesize literally any structure that the imagination can conceive. The goal of research in organic synthesis is to reach a level of sophistication where this ability can be taken for granted. Yet, there is abroad an insidious notion that organic chemists have already become so adept at synthesis that further academic exercises such as that described here are no longer necessary, that there is no longer any need for research in multistep synthesis. I believe that, in part, this difficulty stems from a confusion of the adjectives effective ("adequate to accomplish a purpose" [45]) and efficient ("performing or functioning in the best possible and least wasteful manner" [45]). In fact, although chemists *have* over the last half-century become rather adept at constructing small amounts of very complicated molecules, we generally cannot prepare most desired organic compounds in an efficient, practical, and truly cost-effective manner. We *can* synthesize almost any given molecule and demonstrate that we have done it. However, this is due more to the development of high-powered separation and analytical tools (HPLC, capillary GC, TLC, FT-NMR spectroscopy) than to some discontinuous change in our ability to solve synthesis problems. That is, because we can carry out separations and establish structure with minute amounts of material, it is possible to do synthesis on very small scale. Thus, we can carry out multistep synthesis in a much shorter period of time than was possible ten or twenty years ago, since more time can be devoted to the development of new chemistry and less to the time-consuming "bringing up of material". This maturity should be considered a normal step in the development of a productive science, not a sign that all of the problems have been solved and that the field no longer merits investigation. Problems of synthesis still abound, as is known by anyone who practices the art. Our textbooks are

filled with hundreds of synthetic methods, all of which have limitations that will never be discovered unless the methods are tested in the challenging arena of the synthesis of multifunctional compounds. Although our approaches to problems have matured, we need even more mature strategies of synthesis. There is no reason that organic chemists should not be able to surpass nature's virtuosity in the synthesis of complex organic structures. In fact, we are still very far from this goal in most cases.

The cascade of reactions depicted in Scheme 27 represents a significant advance in our ability to orchestrate molecular reorganization. In this magnificent process an acyclic dialdehyde is transformed by ordinary commodity chemicals into a pentacyclic product by the formation of four carbon–carbon bonds, two carbon–nitrogen bonds, and one carbon–hydrogen bond. Furthermore, the process occurs with very high stereoselectivity and in excellent yield. However, it should not be misunderstood that even this highly efficient synthesis is perfect, because compromises have still been made. For example, the synthesis outlined in Scheme 25 still required the use of a protecting group (the dimethyl acetal) and involved the use of ester functions as surrogates for aldehyde groups. The inability to deal more directly with these issues demonstrates that there are still frailties in the science of synthesis, infirmities that will, no doubt, one day be cured through further research in multistep synthesis.

I am indebted to the talented and enthusiastic group of coworkers who performed the difficult experiments upon which this review article is based. The original methyl homodaphniphyllate synthesis was carried out by graduate student Mark Sanner and postdoctoral associates Sander Mills and Steven Davidsen. The tetracyclization reaction was discovered and perfected by graduate student Roger Ruggeri, who also applied it to the total synthesis of daphnilactone A and methyl homodaphniphyllate. Graduate student Marvin Hansen applied the Ruggeri cyclization to the synthesis of methyl homosecodaphniphyllate. The felicitous discovery of the methylamine cyclization was made by graduate student John Kath, who has also completed a total synthesis of the C_{30} alkaloid, (−)-codaphniphylline. The pentacyclization process and synthesis of protodaphniphylline were accomplished by postdoctoral associate Serge Piettre, who also carried out important mechanistic experiments that are described in detail in ref. [1c]. *The marvelous transformation of dihydrosqualene dialdehyde* ***85*** *into dihydroprotodaphniphylline was carried out by postdoctoral associate John Ragan. Not discussed here for lack of space are total syntheses of the C_{30} alkaloid (−)-secodaphniphylline (**11**, ref.* [1d]*) and (±)-bukittinggine (7, ref.* [1e]*), which were carried out by postdoctoral colleague Jeff Stafford. Also not covered here is unpublished research by graduate student Daisy Joe, who has explored the alternative mode of fragmention suggested in Scheme 17 and uncovered some fascinating rearrangements of the secodaphnane skeleton. I am also pleased to acknowledge the financial support of the National Science Foundation for a research grant.*

[13] Of course, alkaloid **10** actually has more than two stereocenters, but stereoisomerism is not possible at several of them for geometric reasons. For example, inversion of configuration at either of the carbons joined by the bold bond in Scheme 2 would lead to diastereomers far too strained for existence. Thus, for practical reasons, the relative configurations of these bridgehead atoms are interdependent.

[29] The traditional nomenclature that has been used by the Nagoya group has been employed in this review and other publications from Berkeley. The reader will note however, that the use of the prefix "seco" in the name of alkaloid **11** is not fully consistent with the structure of the material, which has the same number of rings and skeletal bonds as daphniphylline. Equally mysterious is the origin of "homo" in the common names of **5** and **10**. The Chemical Abstracts Service uses the name daphnane for the C_{22} skeleton of homodaphniphyllic acid and 1,12-secodaphnane for the C_{22} skeleton corresponding to the unknown, but hypothetical biosynthetic link with the structure **E**. In the Chemical Abstracts nomenclature system, the C_{22} skeleton corresponding to methyl homosecodaphniphyllate is 12,16-cyclo-1,12-secodaphnane.

[30] Corey defines a "transform" as the "reverse of a synthetic reaction" and a "retron" of a given transform as "the enabling structural unit for that transform." For example, the basic retron of a Diels–Alder transform is a six-membered ring with one double bond: E. J. Corey, X.-M. Cheng, *The Logic of Chemical Synthesis*, Wiley, New York, **1989**, p. 6. What subscribers and authors have to say about Angewandte Chemie:

Jean-Marie Lehn, Université Louis Pasteur, Strasbourg:

"I consider Angewandte Chemie as one of the top not only chemical but scientific journals... It presents the highly effective combination of well chosen, exciting and thorough review articles, reflecting timely topics that cover a very broad range in science, with short but informative communications reporting specific advances of particular interest for chemistry. It is also carefully produced and nicely presented, which adds to the reading pleasure."

Transition Structures of Hydrocarbon Pericyclic Reactions

By Kendall N. Houk,* Yi Li, and Jeffrey D. Evanseck

Twenty-five years after the discovery of a vast class of organic reactions named "pericyclic reactions" by Woodward and Hoffmann, ab initio quantum mechanics provides a detailed analysis of the geometries, energies, and electronic characteristics of the transition structures of these reactions. Common features are found in all these reactions, and generalizations permit prediction of other transition-structure geometries and energies. At the same time, great diversity is observed—from strongly bonded, rigid, closed-shell entities to weakly interacting, flexible diradical structures.

1. Introduction

1.1. Pericyclic Reactions—Definitions, Examples, and Remaining Questions

In 1965 a series of communications that shook the chemical world appeared.[1] The discoveries reported by R. B. Woodward and Roald Hoffmann culminated in their review, "The Conservation of Orbital Symmetry" which was published in this journal four years later.[2] This work captured the imaginations of chemists by revealing simple theoretical principles that profoundly influence chemical reactions. Since then the properties of molecular orbitals and their interactions have been widely used to predict stereochemistries and mechanisms of organic reactions.

Pericyclic reactions were defined by Woodward and Hoffmann as "reactions in which all first-order changes in bonding relationships take place in concert on a closed curve".[2] An enormous amount has been learned about pericyclic reactions in the last few decades, but there remains intriguing mystery and stimulating controversy about the transition structures of these processes. In this article, we summarize research that defines the nature of pericyclic transition structures as obtained from ab initio quantum mechanical calculations.

Some typical thermally allowed pericyclic reactions and both Woodward–Hoffmann and common names are shown in Figure 1. These reactions all involve six-electron bonding changes. On the right side, rough representations of transition structures for the concerted reactions are sketched. Since this first systematic definition of pericyclic reactions, there has been considerable interest in the nature of the transition structures of such reactions and the theoretical underpinnings of the Woodward–Hoffmann rules.[3] The Woodward–Hoffmann treatment showed that "thermally allowed" reactions could occur by concerted mechanisms, because strong bonding could be maintained throughout the reaction. Other theoretical treatments of these reactions have assumed aromatic transition states,[4] but occasionally very unsymmetrical ("highly asynchronous") transition structures have been advocated.[5]

Pericyclic reactions are widely applicable in synthesis.[6] A few examples are shown in Figure 2. Several masterpieces in synthesis by Woodward, such as that of the steroid hormone,

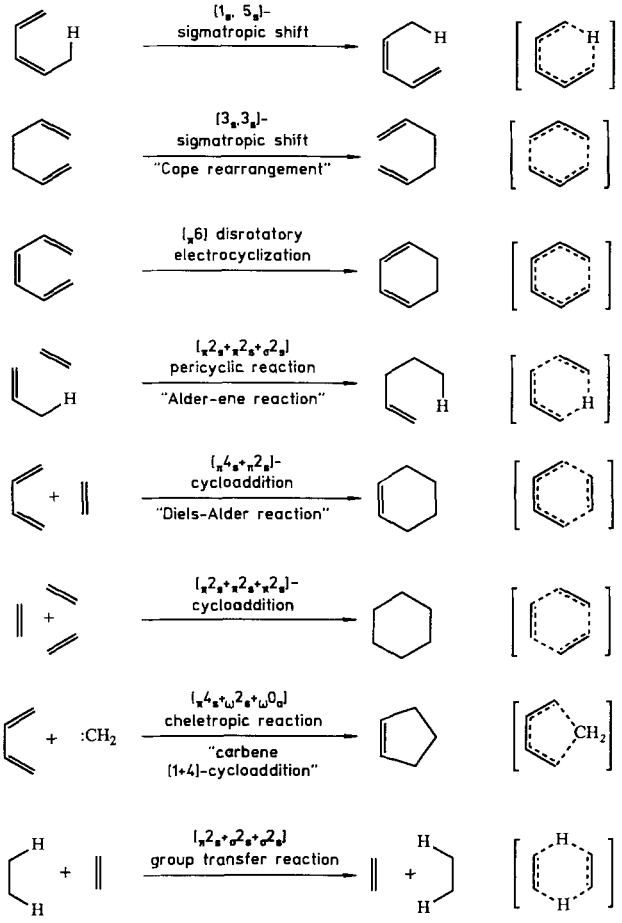

Fig. 1. Examples of common types of pericyclic reactions involving six electrons.

cortisone (Fig. 2a), were based upon the Diels–Alder reaction.[7a] Ireland's group's lasalocid A synthesis (Fig. 2b) used a [3,3] sigmatropic shift, the Ireland version of the Claisen rearrangement,[7b] while electrocyclic openings of benzocyclobutenes and electrocyclization of a hexatriene (Fig. 2c) were important steps in syntheses of xylopinine by Kametani et al.[7c]

There are also pericyclic reactions involved in important biological processes. Ergosterol undergoes a series of photochemical and thermal pericyclic reactions to form Vitamin D_2 (Fig. 3a).[8] The chorismate → prephenate rearrangement, which occurs in the biosynthesis of aromatic amino acids in plants, is a Claisen rearrangement catalyzed (perhaps by altering the mechanism) by the enzyme, choris-

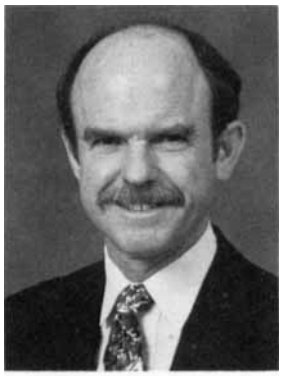
mate mutase (Fig. 3b).[9] The electrocyclic formation of a biradical that reacts with DNA is the origin of activity of the esperamicin and calicheamicin series of antibiotics (Fig. 3c).[10] This biradical mechanism has prompted wide interest in these types of reactions and in the use of thermal rearrangements to generate reactive intermediates for biological action.[11]

The mechanisms of pericyclic reactions have attracted great interest and have frequently generated heated controversy. Thermally allowed pericyclic reactions may also follow stepwise mechanisms with biradical intermediates, rather than concerted mechanisms. Diels–Alder and other cycloadditions, as well as sigmatropic shifts involving two π systems are the pericyclic reactions most often claimed to occur with the intermediacy of biradicals. The first two reactions in Figure 4 involve the addition of one π system to another, and relatively stable biradicals can be written for potential intermediates in such processes. Also shown are the measured activation enthalpies along with the best available estimates of energies to form biradical intermediates. The difference between these energies has been called the "energy of concert" by Doering et al.[12] Diels–Alder and other cycloadditions have small to moderate energies of concert, while reactions such as sigmatropic hydrogen shifts and electrocyclizations usually have large energies of concert. The concerted mechanism through an aromatic transition state is the norm for thermally allowed reactions, although substituents may induce alterations of transition structures and even of reaction mechanisms.

Only calculations can provide information about the geometrical arrangement of constituent atoms for short-lived species like transition structures.[13] It has recently become possible to calculate the details of transition-state geometries and energetics rather than rely upon the approximate descriptions inferred from experimental data. In this article we describe how transition-structure calculations are performed, what type of information can be obtained, and how reliable these data are, depending upon the computational level. We provide a detailed picture of the shapes and bonding present in transition structures of pericyclic reactions. Our major emphasis is on the reactions of the simplest hydrocarbons, but data on substituted cases are also provided for several reactions to show how the energies and geometries are changed by substituents.

We try to give more quantitative meaning to concepts such as "early" and "late" transition states, "synchronicity", and



K. N. Houk is Professor and Chairman of the Department of Chemistry and Biochemistry at the University of California, Los Angeles (UCLA). He was born in Nashville, Tennessee, in 1943, and grew up in Bozeman, Montana, and Chicago. He studied at Harvard University, where he received the Ph.D. with Professor R. B. Woodward in 1968. He then joined the faculty of Louisiana State University, moved to the University of Pittsburgh in 1980, and to UCLA in 1986. He was a 1981 recipient of the Alexander von Humboldt Foundation Senior U.S. Scientist Award and had the opportunity to be a guest professor at Erlangen, Cologne, Darmstadt, and Munich. He is the recipient of the Arthur C. Cope Scholar Award of the American Chemical Society (1989) and the James Flack Norris Award in Physical Organic Chemistry (1991). He was Director of the National Science Foundation Chemistry Division from 1988–1990.

Yi Li is a Research Associate at UCLA. He was an undergraduate at Wuhan University, China, attended the University of Pittsburgh under the Chemistry Graduate Program organized by William von Eggers Doering, and received his Ph.D. in 1988 at UCLA with K. N. Houk.

Jeffrey D. Evanseck was born in 1961 and began studies at Purdue University (1980) with William L. Jorgensen. He received his doctorate under K. N. Houk at the University of California, Los Angeles, in 1990 on the theoretical studies of reactive intermediates. He is presently a postdoctoral fellow with Martin Karplus at Harvard University applying theoretical methods to understand enzymatic catalysis.

"aromatic transition states". Our goal is to paint memorable semiquantifiable images of transition structures and to develop generalizations for quantitative predictions about geometries, energies, and other properties of transition structures for pericyclic reactions.

1.2. Transition Structures and Transition States

A "transition structure" corresponds to a saddle point which separates two energy minima on a theoretical potential energy surface.[14–16] It is closely related, but not identical, to a "transition state", which is the quasi-thermodynamic state defined in Eyring's transition state theory.[17] A transition state is situated at a free energy maximum along the reaction path that connects two energy minima. The free energy, ΔG, differs from the enthalpy, ΔH, by $-T\Delta S$. ΔH is equal to the difference of potential energy E, plus RT, zero-point energy, and the thermal corrections (see Fig. 5a and Section 1.5).

In transition-state theory, the rate of an elementary reaction is determined by the difference between the free energies of the transition state and the reactants, as well as the rate of passage through the region of the transition state.[17, 18] When a reaction has a relatively large barrier and a slowly varying entropy in the region of the potential energy maximum, the transition state corresponds closely to the potential energy maximum of the reaction (Fig. 5b). The transition-state geometry will then be essentially the same as the transition-structure geometry. When the reaction has a low barrier or a rapidly varying entropy in the region of the potential energy maximum, the transition state may be at a

geometry quite different from that of the calculated transition structure (Fig. 5c).

Quantum mechanical calculations incorporating the Born–Oppenheimer approximation can be used to determine the potential energies of molecules with any arrangement of the nuclei. When a large number of these calculations are performed, a potential energy hypersurface for a vibrationless system is obtained. The regions of greatest interest on this multidimensional surface are those corresponding to stationary points. A stationary point has all zero first derivatives of the energy with respect to the 3N − 6 independent spatial degrees of freedom. Energy minima are those stationary points at which all force constants (second derivatives of the energy with respect to the 3N − 6 coordinates of the atoms) are positive. The saddle points for transition structures have one, and only one, negative second derivative; the remaining 3N − 7 second derivatives are positive. The negative second derivative corresponds to a force constant for the motion along the reaction coordinate. This is also referred to as an "imaginary vibrational frequency", since the vibrational frequency is proportional to the square root of the force constant.[16]

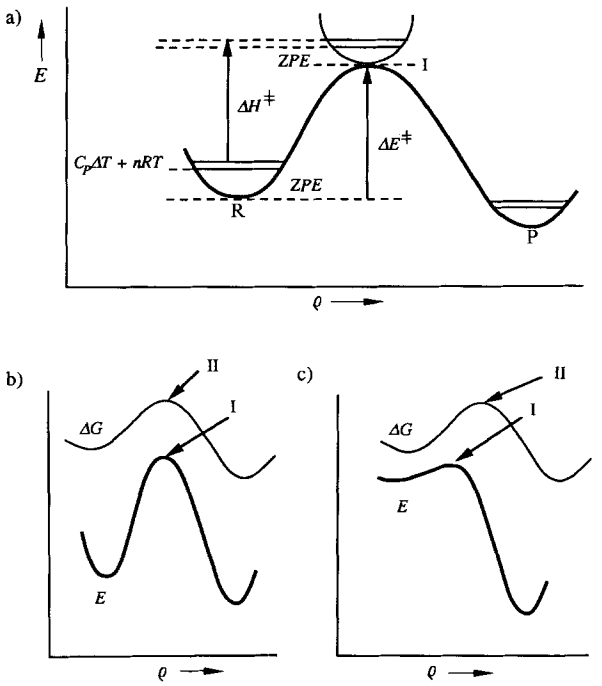

Fig. 5. a) Relationship of ΔH and E along a reaction path ρ. ZPE = zero-point energy, R = reactants, P = products, I = transition structure. The transition structure (I) and transition state (II) coincide in b), but not in (c).

1.3. The Location of Transition Structures with Ab Initio Techniques

It is possible to find both minima and saddle points efficiently, because modern programs such as GAUSSIAN 90 and GAMESS calculate analytically the first and second derivatives of the energy with respect to all geometrical variables.[19, 20] In practice, some explorations of the potential energy surface in the regions of the stationary points are required, and then various programmed procedures can be used to find a point which has all first derivatives as close as desired to zero. In general, it is more difficult to locate transition structures than it is to locate energy minima.[21] In some cases, symmetry restrictions are used to facilitate location of a transition structure, in which case vibrational frequencies are calculated for all 3N − 6 degrees of freedom to verify that the stationary point represent a transition structure. While it is possible to verify that an energy minimum has been found, no procedure exists to ensure that it is the global minimum. Similarly, the authenticity of a transition structure can be proven by a frequency calculation, but only a complete search of the potential energy surface can prove this to be the lowest energy transition structure. In the absence of such complete searches, we generally rely upon limited searches of the potential surface guided by our chemical intuition.

1.4. Ab Initio Computational Methods and Theoretical Levels

Most of the calculations from our group described here use ab initio molecular orbital calculations[16] and the programs developed by Pople and his group over the last two decades.[19] Ab initio calculations are quantum mechanical calculations in which the Schrödinger equation is approximated by using the Hartree–Fock (HF) equations[22] without introduction of arbitrary parameters. The molecular orbitals of a molecule are formed from a linear combination of one-electron functions that describe the atomic orbitals of each atom. This set of functions is the basis set. "Small" basis sets restrict the mathematical description of the atomic orbitals, while "large" basis sets provide a more flexible description, which is also more costly to use in computations. The Hartree–Fock limit, the best approximation that can be achieved with the HF equations, can be approached with the use of large basis sets. We have used the basis sets developed by Pople and co-workers, ranging from the "minimal" STO-3G basis set to the rather large 6-311G** basis set. These are implemented in the GAUSSIAN 82–90 programs[19] and have been described in detail by Hehre et al.[16]

In the HF description of molecules, electron–electron repulsion is calculated as the repulsion between a single electron and the average distribution of all the other electrons obtained iteratively starting form an approximated electron distribution (the *self-consistent field* method, SCF). Such calculations are in error because they neglect the instantaneous correlation of electron motion which reduces the electron repulsion. One of the less expensive methods for estimating the effect of electron correlation is the many-body perturbation expansion method of Møller and Plesset.[23] The perturbation series terminated at n'th order is termed MPn theory. Configuration interaction is another method for calculating "dynamical correlation energy", in which alternative distributions of electrons over the MO's (configurations) are mixed with the lowest energy configuration to form a better wave function.

Multiconfiguration self-consistent field (MCSCF) calculations are used for systems that are poorly represented by a

single configuration of occupied orbitals.[24] Such methods correct for "nondynamical correlation energy". One of the common MCSCF methods is the complete active space (CASSCF) method which mixes together all configurations involving the "active" orbitals. These are defined as those orbitals which undergo significant bonding changes during the reaction.[25a] For example, in a breaking σ bond, there are two electrons in two orbitals, the σ and σ^* orbitals, which constitute the "active space". Pulay et al. described a computational method to choose the active space.[25b] The MCSCF calculations described in this review were performed with GAMESS, a general purpose quantum chemistry program by Dupuis et al.[20]

The choice of a theoretical method is dependent upon the accuracy demanded, the nature of problem to be solved, and the size of molecule. For the calculations of geometries of stable molecules, correlation energy is generally of little consequence. As we shall show, the same is also true for many types of concerted pericyclic transition structures, even though distorted bond lengths and angles are involved, which might be expected to cause the development of biradical character in the wave function. On the other hand, nondynamical correlation does have a dramatic effect upon the geometries of transition structures of forbidden reactions. Correlation energy corrections are always required for the calculation of reasonable activation energies, since correlation energy is larger for transition structures than it is for stable molecules.

1.5. Quantities Obtained from Calculations

The stationary points obtained by the procedures described in the previous section are located on the potential energy surface for vibrationless systems, as shown in Figure 5a. However, a real molecule has vibrational energy, even at 0 K, so that some corrections must be made in order to obtain energies that are directly comparable to experimental quantities. The largest of these is the zero-point energy $1/2\sum h\nu_i$, which is the vibrational energy that a molecule has even at 0 K. This is calculated from vibrational frequencies ν_i, which can be calculated routinely for optimized stationary points, at least in the harmonic approximation. At higher temperatures a molecule will have additional vibrational energy $C_P\Delta T$, which can also be calculated from vibrational frequencies. Addition of $P\Delta V (= \Delta nRT)$ to the internal energy gives the enthalpy of a molecule at a given temperature. Finally, the entropy of a molecule and a transition state at a given temperature can be calculated from the masses, moments of inertia, and vibrational frequencies.[26] Since moments of inertia and vibrational frequencies can be calculated, the former with great accuracy and the latter about 10% too large,[27] the enthalpies, entropies, and free energies of gas-phase stable molecules and transition states can be calculated readily. From the geometry of a transition structure and its vibrational force constants, kinetic isotope effects can be calculated by applying the equation of Bigeleisen and Goeppert-Mayer.[28] The results can then be compared with the experimentally observed values.[29] This method is one of the few means for studying the details of potential surfaces experimentally.[30]

Other properties of transition structures can be obtained from ab initio calculations as well. First of all, calculations provide geometrical details of the transition structure and its electronic structure. The geometry and electron distribution are of great importance for understanding the interactions of the transition structure with its environment, as in the case of reactions in solution or reactions that are catalyzed by enzymes or other catalysts. Calculations also reveal the shapes and energies of the frontier orbitals, which can be used qualitatively to assess the interactions of these orbitals with those of the substituents to predict substituent effects on rates. In addition, bond orders of various partial bonds in the transition structure can also be calculated by various methods,[31] or by Pauling's or other empirical bond length–bond order methods.[32] This type of analysis facilitates the understanding of the nature of partial bonds in the transition structures.[33] Finally, it is conceptually useful to distinguish between a thermodynamic contribution to an activation barrier and an intrinsic barrier. The contributions of intrinsic reaction barriers, defined according to Marcus theory for a reaction $A-B+C\rightarrow A+B-C$ as the mean of the barriers for the reactions $A-B+A\rightarrow A+B-A$ and $C-B+C\rightarrow C+B-C$,[34] can be evaluated systematically to understand the origin of substituent effects.[35]

2. Does Theory Give Reliable Chemical Information about Transition Structures and Energetics? Three Case Studies

There is no general method to determine experimental geometries of transition states.[13] Since exact calculations also are not possible for typical organic reactions, we can only perform calculations at increasingly higher levels of theory until there are no further significant changes in geometries or energies. In Sections 2.1–2.3 we demonstrate how different theoretical levels perform on predictions of geometries and energies for three types of pericyclic reactions. This establishes the validity of the results to be presented later in this paper.

2.1. The [1,5] Sigmatropic Hydrogen Shift in (*Z*)-1,3-Pentadiene

The transition structure corresponding to the $[1_s,5_s]$ hydrogen shift in (*Z*)-1,3-pentadiene is particularly easy to reproduce by a variety of calculations. This is because there are really no alternative mechanisms of similar energy: C–H dissociation followed by recombination would require at least 58 kcal mol^{-1}; a 90° rotation of one terminus, followed by hydrogen transfer would require about 44 kcal mol^{-1};[36] the experimental activation energy is only 36 kcal mol^{-1}.[37] With these additional considerations, the Woodward–Hoffmann rules provide a completely reliable guide to stereochemistries in concerted reactions that have no alternative reaction pathways (sigmatropic hydrogen shifts, electrocyclizations) and a somewhat less firm guide to mechanisms and stereochemistries in cycloadditions, cheletropic reactions, and non-hydrogen sigmatropic shifts, for which several mechanistic paths have rather similar energies.

Transition structures for the degenerate [1,5] hydrogen shift in 1,3-pentadiene calculated at various ab initio levels[38,39] and with several methods of Dewar et al.[40] are shown in Figure 6.[41] At the pictorial level, the geometries

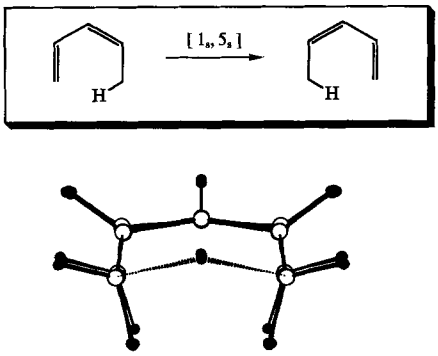

Fig. 6. Superimposed transition structures of the [1,5] sigmatropic hydrogen shift in pentadiene obtained with AM-1, STO-3G, 3-21G, 6-31G, 6-31G*, 6-31G**, MP2/3-21G, and MP2/6-31G* methods.

obtained from all of these calculations are the same! However, on a detailed level, the STO-3G minimal basis set gives results which are quite different from those obtained with better basis sets. The RHF/3-21G geometry is close to that obtained with the 6-31G** basis. The main difference between the RHF and MP2 optimized structures is elongation of bond lengths, but even this is generally limited to only a few hundredths of an Ångstrøm. The MP2 structures are more sensitive to the size of the basis set than the RHF structures. Even so, the overall result is that angles differ by only a few degrees and bond lengths differ by 0.04 Å at most in the various types of calculations. The RHF/3-21G structure is remarkably close to that obtained at the MP2/6-31G* level. For such hydrocarbon reactions with no comparable mechanistic alternatives, the 3-21G transition-structure geometries give bond lengths within several hundredths of an Ångstrøm of the MP2/6-31G* values.[39]

Although the transition structure can be obtained readily, and a reasonable activation energy can be obtained with some additional computational effort (see Section 2.4), the isotope effect calculated for this process is too low, and a tunneling correction must be made to obtain a calculated value near the experimental value.[29c]

2.2. The Cyclobutene → Butadiene Electrocyclization

As shown in Figure 7, the transition-structure geometries for the cyclobutene ring opening are very similar regardless of the level of theory employed.[42-44] The largest deviation in the bond lengths is seen in the elongated cleaving C–C bond which differs by 0.14 Å in the various calculations. The two-configuration (TCSCF) geometry is "latest" (most bond breaking) at 2.238 Å, while the RHF/STO-3G geometry is "earliest" at 2.102 Å. The RHF/3-21G geometries are similar to the MP2/6-31G* optimized geometry. The MP2/3-21G geometry deviates most from the MP2/6-31G* geometry; good MP2 calculations require a reasonably large basis set. In all calculations, the nonplanarity of the carbon skeleton is pronounced, and the C=C–C=C torsional angle ranges from 12° to 16°.

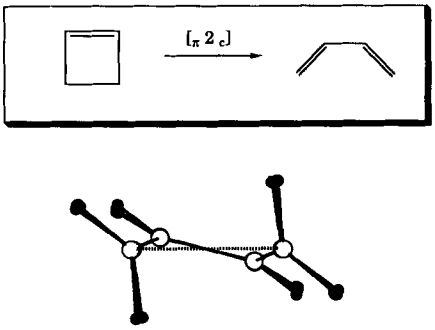

Fig. 7. Superimposed transition structures the electrocyclic ring opening of cyclobutene obtained with AM-1, STO-3G, 3-21G, 4-31G, 6-31G, 6-31G*, 6-31G**, MP2/3-21G, and MP2/6-31G* methods.

The geometries of ground state molecules calculated at either RHF/3-21G or the correlated MP2/6-31G* levels are in excellent agreement with the experimental geometries. For example, the experimental and MP2/6-31G* (value in parentheses) C–C bond lengths of cyclobutene are: C1–C2 1.342 Å (1.345 Å), C2–C3 1.517 Å (1.512 Å), and C3–C4 1.566 Å (1.564 Å). The maximum deviation for cyclobutene is less than 0.005 Å for bond lengths and less than 1.5° for bond angles.

2.3. The Diels–Alder Cycloaddition Reaction

The Diels–Alder reaction between 1,3-butadiene and ethene is exothermic by 40 kcal mol^{-1} and has a reaction barrier of 27 kcal mol^{-1}.[45] There is a reasonable alternative to the concerted mechanism, since thermochemical estimates suggest that the activation barrier for a diradical intermediate is only a few kcal mol^{-1} higher than the experimental activation barrier.[12] Nevertheless, in spite of a long dispute over the reaction mechanism of the Diels–Alder reaction between 1,3-butadiene and ethene, the transition structures located at various levels of theory[46-49] for a concerted mechanism are remarkably similar. Figure 8 shows the geometries of these transition structures obtained by semi-

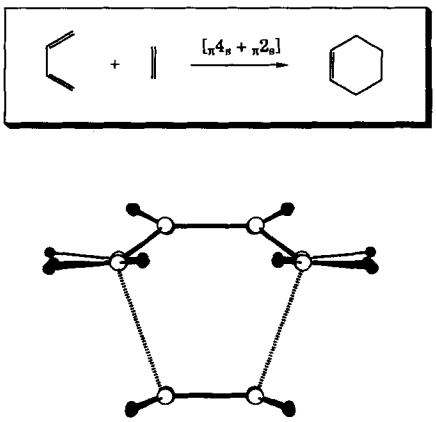

Fig. 8. Superimposed transition structures of the Diels–Alder reaction between butadiene and ethene obtained with AM-1, 3-21G, 6-31G*, MP2/6-31G*, MCSCF/3G, and MCSCF/4-31G methods.

empirical methods,[46] ab initio HF and MP2 calculations,[47,48] and MCSCF techniques.[49] The optimized bond lengths usually agree within a few hundredths of an Ångstrøm in these calculations. The bond lengths of the forming C–C bonds show the largest variation, ranging from 2.20 Å to 2.28 Å. Inclusion of electron correlation tends to lengthen the forming C–C bond. Dewar's early semiempirical methods predicted very asynchronous transition structures, but AM1 and PM3 both predict concerted transition structures similar to the ab initio predictions.[46a]

These three cases provide a sense of the expected accuracy of the calculated transition structures. For the RHF/3-21G or MP2/6-31G* geometries generally described here, the bond lengths are expected to vary at most by a few hundredths of an Ångstrøm from actual ones, while angles will vary by a few degrees at most. The RHF/3-21G geometries are quite good for hydrocarbon transition structures, but MP2/6-31G* optimizations are recommended. For molecules with heteroatoms, calculations with the 6-31G* basis set are necessary to achieve the reliability achieved by the 3-21G basis set for hydrocarbons. Once again, MP2/6-31G* is recommended when feasible. Pople et al. recently described an ab initio method to obtain geometries and bond dissociation energies within a few kcal mol^{-1} of experimental results for much more demanding cases than studied here.[50] This method requires MP2/6-31G* geometry optimizations; these calculations agree well with experimental values, and no significant improvement is achieved at higher levels. However, to obtain accurate energies, much higher levels of theory are required.

2.4. Calculations of Reaction Energetics

In order to compare the experimental activation energies to those calculated for vibrationless systems, the values for the vibrationless cases were calculated from the experimental activation energies by correcting for the thermal vibrational energies and zero-point energies, calculated at the RHF/3-21G level. The experimental activation energies are 36.1 ± 2.2 kcal mol^{-1} for the [1,5] hydrogen shift,[37] 32.9 ± 0.5 kcal mol^{-1} for the conrotatory electrocyclic ring opening of cyclobutene,[51] and 26.5 ± 2 kcal mol^{-1} for the Diels–Alder reaction between butadiene and ethene.[45] The corresponding calculated activation energies (vibrationless) are 39.7 kcal mol^{-1} for the [1,5] shift,[39a] 34.5 kcal mol^{-1} for the conrotatory electrocyclic ring opening of cyclobutene,[44] and 27 kcal mol^{-1} for the Diels–Alder reaction.[47a] The heat of reaction has been adjusted similarly from -11.4 kcal mol^{-1} to -10.9 kcal mol^{-1} for cyclobutene ring opening.[44] The heat of reaction for the Diels–Alder reaction between butadiene and ethene is -34 kcal mol^{-1} when zero-point energies are removed. Table 1 compares experimental and calculated activation energies and heats of reaction for each of these three cases discussed.

A systematic investigation of the effects of the basis set reveals that the minimal STO-3G basis performs exceptionally poorly, but the 3-21G results are in reasonable agreement with higher level RHF calculations. For the [1,5] hydrogen shift, the calculated $\Delta E^{\neq}$ with the 6-31G* basis set approaches the Hartree–Fock limit of 58–59 kcal mol^{-1}, which is about 20 kcal mol^{-1} above the experimental value. For the cyclobutene ring opening, the $\Delta E^{\neq}$ at the RHF level converges to about 46–47 kcal mol^{-1}, which is approximately 12 kcal mol^{-1} larger than the experimental value. The smaller error on correlation of the energies for cyclobutene ring opening is related to the fact that only four electrons are involved in bonding changes, rather than six electrons in the [1,5] hydrogen shift. For the Diels–Alder reaction, the calculated reaction barrier at the RHF level is about 20 kcal mol^{-1} higher than the experimental value. Here, six electrons are involved.

These "correlation energies of activation", that is, the gap between the Hartree–Fock and the experimental activation energies, are different for different reactions. Correlation energy increases as the size of the system—measured by the number of electrons—increases. The correlation energy of the transition structures increases, because partially formed and partially broken bonds have larger correlation errors than fully formed bonds. As demonstrated in the previous examples, the correlation energy is higher when six electrons are involved in bonding changes than when four electrons are involved. The "correlation energy of activation" is 3–4 kcal mol^{-1} per electron in the examples studied here. This quantity provides a rough estimate of activation energies when only RHF quantities are available. A substituent perturbs the energies of the reactants and transition structure, but does not alter the number of electrons involved in bonding processes. Consequently, relative activation energies for the parent and substituted analogs are often reasonable even without inclusion of correlation energy.

At the MP2 level, the calculated reaction barrier with the 6-31G* basis set is in good agreement with experimental

Table 1. Calculated reaction barriers and energies [kcal mol^{-1}] for the [1,5] hydrogen shift of (*Z*)-1,3-pentadiene (I), the electrocyclic ring opening of cyclobutene (II), and the Diels–Alder reaction of butadiene with ethene (III). The subscript rxn means reaction.

[a] With RHF/6-31G* geometries [47b]. [b] TCSCF (DZ) [42b]. [c] CAS2/3G [49]. [d] CISD (DZ) [42b]. [e] CAS1/4-31G [49]. [f] These methods calculate ΔH and not ΔE.

value for the [1,5] hydrogen shift. As more terms in the Møller–Plesset perturbation series are included, the calculated $\Delta E^{\ddagger}$ oscillates, but appears to converge slowly. The activation energy for the [1,5] hydrogen shift estimated with high order MP perturbation theory and the 6-311G** basis set would be approximately 39 kcal mol^{-1}, which is within experimental uncertainty of the observed value of 38.8 $\pm$ 2.2 kcal mol^{-1}.[39]

For the calculations on the cyclobutene ring opening, a quite high level of correlation energy is required in order to reproduce both the experimental activation energy and heat of reaction. The level that is capable of reproducing the heat of reaction may not necessarily be able to reproduce the activation energy. Both $\Delta E^{\ddagger}$ and the ΔE_{rxn} obtained at the MP4(SDTQ)/6-31G*//MP2/6-31G* level are within 2.5 kcal mol^{-1} of the corresponding experimental values.[44]

For the Diels–Alder reaction, the MP2 correlation energy correction overestimates the effect of electron correlation and lowers the $\Delta E^{\ddagger}$ too much. The activation energy at the MP2/6-31G* level is 7 kcal mol^{-1} less than the experimental value; higher level correlation energy corrections are required for the calculation of activation energy. Nevertheless, RHF/3-21G gives a reasonable geometry for the transition structure, as a comparison with the MP2/6-31G* and CASSCF calculations shows.

These results suggest that the geometries of pericyclic transition structures of hydrocarbons can be calculated at the RHF/3-21G level but the MP2/6-31G* level is better when possible, while activation energies must be calculated at least at the MP2/6-31G* level and even this level is often inadequate. Because the correction of correlation energy appears to be characteristic of bond types in the reactant and transition structures, it is possible to make empirical energy corrections based upon the HF limit of activation energy.

3. Classification of Pericyclic Reactions

Woodward and Hoffmann described five categories of pericyclic reactions: cycloaddition reactions, electrocyclic reactions, sigmatropic shifts, cheletropic reactions, and group transfer reactions.[2] There are some, like ene reactions, which do not fit conveniently into this classification scheme—we have named these reactions "miscellaneozations".[52] Another class of reactions was named dyotropic shifts by Reetz.[53]

It is convenient here to classify these reactions further according to the types of bond transformations involved (see also Fig. 1). Molecular reorganizations with no change in the number of π or σ bonds (heats of reaction near zero) include some sigmatropic shifts and group transfers. Transformations of one π bond to one σ bond (1π-to-1σ transformations) include electrocyclic and ene reactions; unstrained reactions of this type are exothermic by about 23 kcal mol^{-1}. The 2π-to-2σ transformations include cycloadditions and cheletropic reactions, and the 3π-to-3σ transformations include three-component cycloadditions such as [2 + 2 + 2] reactions. These two types of reactions are exothermic ($\Delta H \approx -46$ and -69 kcal mol^{-1}, respectively). Based upon the Hammond postulate[54] or Bell–Evans–Polanyi principle,[55] a gradual shift from a central to an earlier transition state is expected along this enthalpy series. This is the order of presentation that we have chosen here, subdivided by the number of electrons involved in the reaction.

4. Transition Structures of Pericyclic Reactions

The best available theoretical transition structures of all types of thermally allowed pericyclic reactions of hydrocarbons will be described in this article, followed by a description of how substituent effects alter transition-structure energies and geometries. In each case, the computational level and the person who performed the calculations are listed if the results have not yet been published. Finally, the features common to all the processes will be summarized.

4.1. Sigmatropic Shifts

A sigmatropic shift involves the migration of a σ bond along one or two π systems. These reactions have been analyzed by Woodward and Hoffmann, who described the electronic structures of transition states in terms of two weakly interacting radicals.[2] Transition structures which have been calculated for sigmatropic reactions do show some resemblance to the geometries of radical fragments. However, the energies of interaction between these fragments are substantial, and diradical intermediates are not generally formed.

4.1.1. [1,2] Sigmatropic Shifts

The dependence of the activation energies of [1,2] shifts upon the number of electrons involved dramatically demonstrates the power of orbital symmetry considerations. The symmetry-allowed two-electron [1,2] shifts in carbocations are facile. In fact, the bridged ("nonclassical") ethyl and vinyl cations that might be thought of as transition structures between classical cations are actually minima on potential energy surfaces obtained by high-level calculations.[56] These ions, like pericyclic transition structures,[4] can be considered to be "aromatic" because of cyclic delocalization of two electrons. Singlet methylcarbene and vinylidene also undergo rapid [1,2] hydrogen shifts to form the much more stable ethene and acetylene, respectively. Transition structures were found to be only slightly higher in energy than the singlet carbenes with inclusion of electron correlation energy corrections.[57] For the [1,2] hydrogen shift of three-electron hydrocarbon radicals[58] and four-electron hydrocarbon anions,[59] transition structures are comparable in energy to the fragments formed in stepwise dissociation–recombination pathways. The barriers for the [1,2] shifts of radicals or of anions are high, because the transition structures are nonaromatic and antiaromatic, respectively.

4.1.2. [1,3] Sigmatropic Shifts

The [1,3] sigmatropic hydrogen shift in propene has been studied extensively.[38, 60–62] The allowed [1_s,3_a] transition structure (Fig. 9) is very contorted and similar in energy to

an allyl radical plus a hydrogen atom which would be formed in a dissociation–recombination mechanism. At the CASSCF/6-31G* level, the partial C···H bond is 1.61 Å long and the C–C bond length is approximately halfway between that of a double and a single bond; the structure thus indeed resembles an allyl radical. The terminal carbons are pyramidalized to maintain partial bonding to the migrating hydrogen.

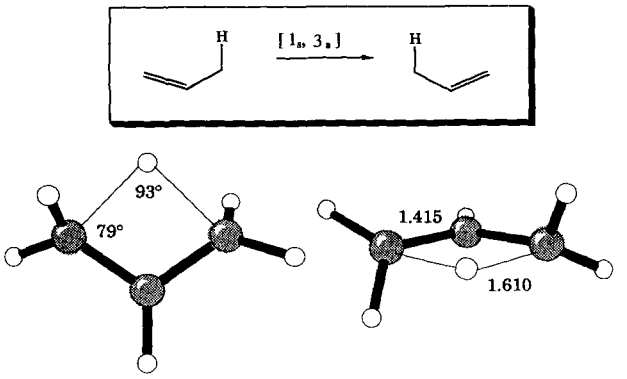

Fig. 9. Two views of the CASSCF/6-31G* transition structure of the $[1_s,3_s]$ sigmatropic hydrogen shift in propene (J. W. Storer).

The symmetry-forbidden suprafacial $[1_s,3_s]$ hydrogen shift is an unfavorable pathway. Both unrestricted Hartree–Fock (UHF) and MCSCF calculations predict a transition structure that resembles a trimethylene diradical.[62] The calculated energy of this species is about 60 kcal mol^{-1} less stable than propene. There is no experimental evidence for a thermal, concerted [1,3] hydrogen shift in simple hydrocarbon systems.

4.1.2.1. [1,3] Sigmatropic Hydrogen Shift of a Radical Cation

The $[1_s,3_s]$ sigmatropic shift in the radical cation of propene has been studied at the MP2 level with UHF/6-31G* geometries.[63] The transition structure has C_s symmetry and resembles the trimethylene radical cation, which corresponds to an energy minimum.[63] The calculated activation energy is 30 kcal mol^{-1}, which is significantly lower than the barrier for this reaction of propene (approximately 60 kcal mol^{-1}). This demonstrates a general principle: forbidden reactions can be made relatively facile by removal of an electron. This is because a forbidden transition state, like the one described above, will always have a very much lower ionization potential than the reactant. This difference in ionization potential is the amount by which the activation energy is lowered by electron detachment. The low ionization potential of the transition state is caused by the avoided HOMO–LUMO crossing that occurs in forbidden reactions.

4.1.2.2. [1,3] Sigmatropic Methyl Shifts

The only geometrically reasonable, thermally allowed methyl shift of 1-butene is the $[1_a,3_s]$ shift (Fig. 10).[64] Steric interactions between the methyl hydrogens and the allyl moiety are indicated by the unusually long forming and breaking C···C bonds (2.5 Å). This distance is about 0.3 Å longer than partial C–C single bonds described earlier for strain-free pericyclic transition structures. Indeed, there is likely to be very little bonding at 2.5 Å, particularly since the p orbital of the migrating center does not point directly at C1 or C3 of the allyl moiety. The calculated activation energy at the MP2/6-31G*//3-21G level is 96 kcal mol^{-1}, which is larger than the required 72 kcal mol^{-1} for the cleavage of the C–C bond.[65] Berson and Salem suggested that a concerted symmetry-forbidden $[1_s,3_s]$ sigmatropic shift would be more favorable than a stepwise process, because subjacent orbital interactions would stabilize the forbidden transition state.[66] However, as in the corresponding hydrogen shift, the transition structure of the $[1_s,3_s]$ methyl shift resembles a 2-methyltrimethylene diradical. Both the allowed and forbidden processes are calculated to have activation energies comparable to, or higher than, the energy required for C–C bond cleavage and recombination. No unequivocal experimental examples of [1,3] sigmatropic alkyl shifts are known in acyclic systems. However, in cyclic or bicyclic systems, where the migrating group is connected to the alkene, examples are plentiful, and some of these are described below.

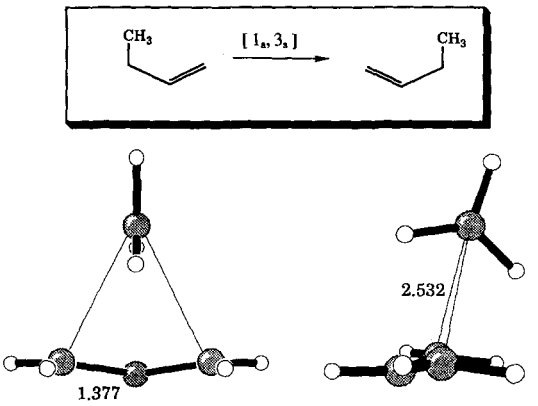

Fig. 10. The RHF/3-21G transition structures of the $[1_a,3_s]$ sigmatropic methyl shift in 1-butene (J. W. Storer).

4.1.2.3. [1,3] Sigmatropic Shifts Involving the Methylene Group

Many [1,3] methylene shifts have been observed experimentally,[67] such as the methylenecyclopropane rearrangement, the vinylcyclopropane to cyclopentene rearrangement, the degenerate analogue—the "walk" rearrangement of bicyclo[2.1.0]pentene—and rearrangements of many bicyclic alkenes such as bicyclo[3.2.0]hept-2-ene to norbornene. These reactions are geometrically constrained to be suprafacial on the allyl system, while the migrating carbon may undergo reaction with either retention or inversion.

Figure 11 shows the transition structure for the allowed $[1_a,3_s]$ vinylcyclopropane → cyclopentene rearrangement.[64] The cyclopropane ring is nearly open, with the breaking C–C bond equal to 2.21 Å, while the formation of the new C–C bond is lagging behind with a bond length of 2.56 Å. The π

system resembles that of an allylic radical (C–C bond lengths of 1.38 Å and 1.39 Å). Inversion of the migrating methylene carbon takes place in the transition structure. The calculated reaction barrier at the RHF level is 84 kcal mol^{-1}. Although MCSCF calculations yield a lower value for the reaction barrier, the transition structure becomes even more diradical in nature, and the stepwise mechanism is likely to be comparable in energy to the concerted path.[68]

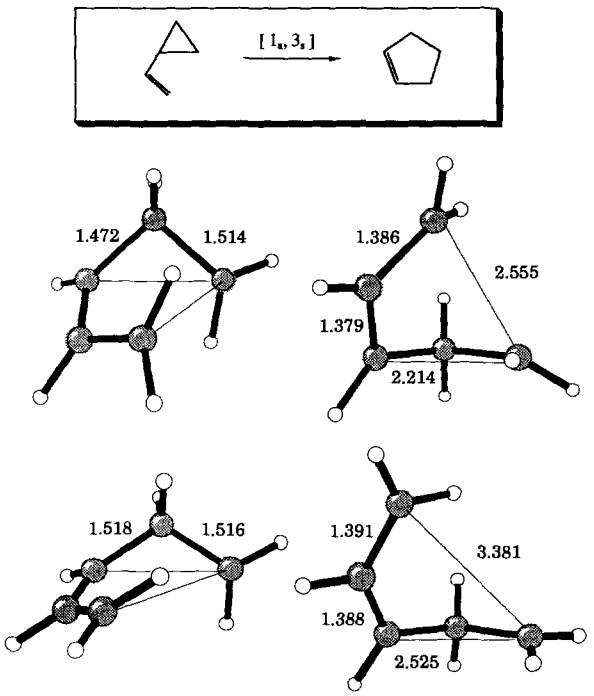

Fig. 11. The RHF/6-31G* (top) and of the CASSCF/3-21G transition structures (bottom) of $[1_a,3_s]$ sigmatropic vinylcyclopropane–cyclopentene shift (J. W. Storer).

The transition structure for the "walk" rearrangement of bicyclo[2.1.0]pentene is shown in Figure 12.[69] The partial C···C single bonds are 2.24 Å long, and the partial double bonds are similar to those of the allyl radical. The cyclobutene ring is planar, a fact which indicates little pyramidalization of the allyl termini or bonding with the migrating group. The calculated activation energy of the concerted

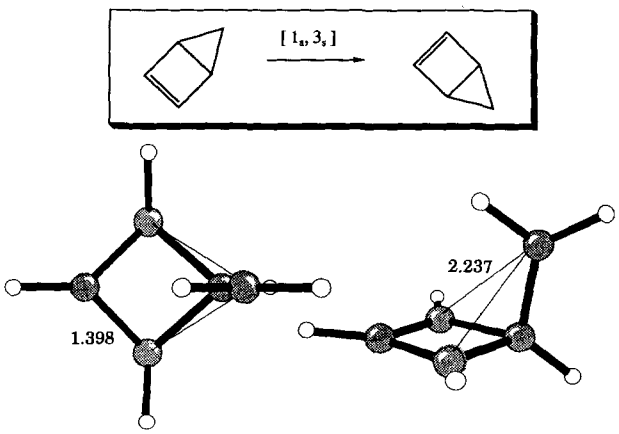

Fig. 12. The RHF/3-21G transition structure of $[1_a,3_s]$ sigmatropic methylene shift in bicyclo[2.1.0]pentene [69a].

[1,3] shift at MP2/6-31G* level is in good accord with the estimated experimental value of 35 kcal mol^{-1}. The forbidden $[1_s,3_s]$ pathway was predicted to be at least 8 kcal mol^{-1} less favorable.[69a]

Better calculations are needed to provide definitive evidence for mechanism, but it appears that [1,3] shift transition structures have much diradical character, and stereochemistries may be controlled by orbital symmetry only when the migrating carbon is forced by the carbon skeleton to interact strongly with the allyl system.

4.1.3. [1,4] Sigmatropic Shifts

The *cis*-1-methylallyl cation may undergo a thermally allowed $[1_s,4_a]$ or a forbidden $[1_s,4_s]$ sigmatropic hydrogen shift. However, attempts to locate transition structures at the RHF/6-31G* level gave instead a bridged C_{2v} minimum (Fig. 13a).[70] This is a hydrogen-bridged nonclassical cation intermediate.

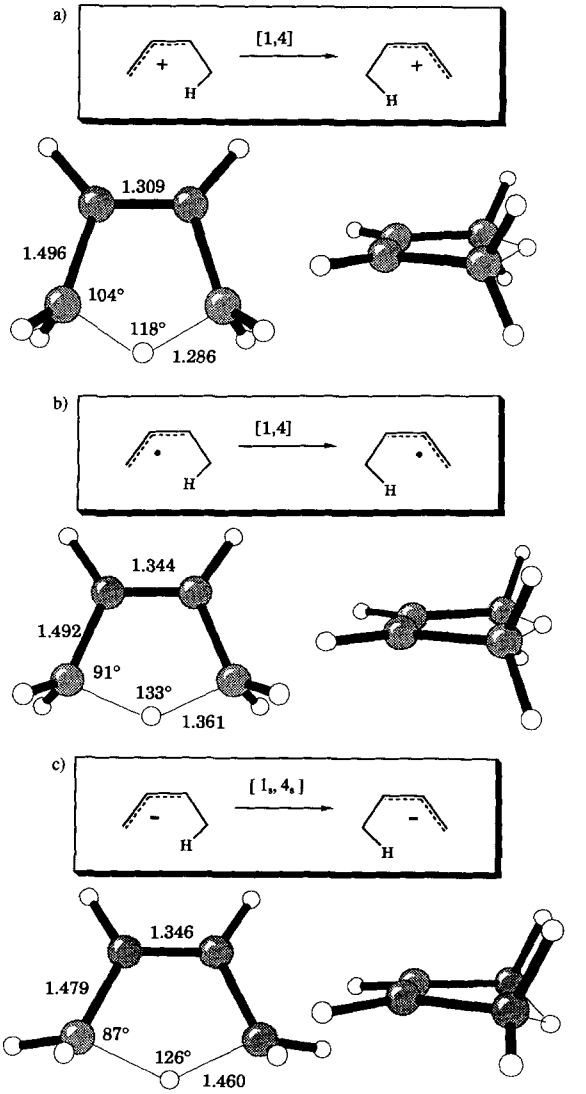

Fig. 13. a) The RHF/6-31G* structure of the hydrogen-bridged butenyl cation (S. M. Ernst). b) The UMP2/6-31G* transition structure of the [1,4] sigmatropic hydrogen shift in the butenyl radical (Y. Li). c) The RHF/6-31G* transition structure of [1,4] hydrogen shift in the butenyl anion (Y. Li).

Transition structures can been located for the [1,4] hydrogen shift in the methylallyl radical and methylallyl anion.[71] The [1,4] hydrogen shift of the methylallyl radical has a transition structure with C_{2v} symmetry (Fig. 13b). The partial C···H bond length is 1.36 Å; the C-C-C bond angle is bent (113°). The central C–C bond is essentially a double bond (1.34 Å), while the terminal C–C bonds are single bonds, 1.49 Å long. This very interesting result shows that the transition structure for this hydrogen shift appears formally like a bridged three-center–three-orbital system, C···H···C. The analogous hydrogen transfer between two methyl radicals has a C···H bond length of 1.3 Å. The double bond in the transition structure only weakly overlap with the C···H···C system, since the H···C-C-C torsional angle is 0°.

Figure 13c shows the transition structure for the allowed $[1_s,4_s]$ hydrogen shift in the 1-methylallyl anion. The migrating hydrogen is only slightly out of the plane defined by the carbons; the H···C-C-C torsional angle is 15°. The terminal methylene groups are rotated in order to maintain bonding with the migrating hydrogen. As with the radical, the terminal C–C bond lengths (1.48 Å) are longer than the central C–C bond (1.35 Å), and the partial H···C bond length is 1.46 Å. The calculated reaction barrier is 30 kcal mol^{-1} at the MP2/6-31G* single-point level, indicating a less favorable process than the [1,4] hydrogen shift in the methylallyl cation.

For the "walk" rearrangement of methylene in the bicyclic cation, a transition structure has been located at the RHF/3-21G level (Fig. 14a).[70] The calculated activation energy for the allowed $[1_a,4_s]$ methylene shift is 18 kcal mol^{-1}, while the experimental value is 15 kcal mol^{-1}.[72] The forbidden process (Fig. 14b) has a very distorted geometry and a predicted activation energy of 33 kcal mol^{-1}.

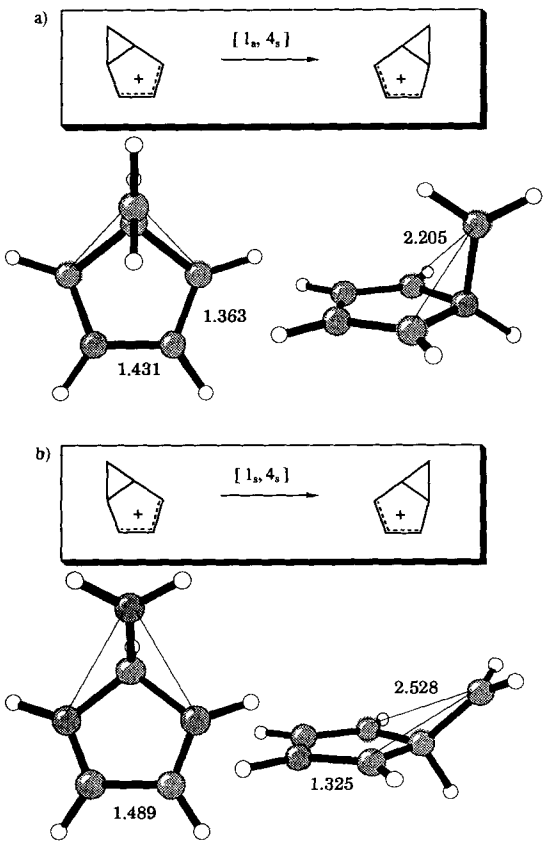

Fig. 14. The RHF/3-21G transition structures of the [1,4] sigmatropic methylene shift in bicyclo[3.1.0]hexenyl cation (S. M. Ernst): a) the $[1_a,4_s]$ pathway; b) the $[1_s,4_s]$ pathway.

4.1.4. *[1,5] Sigmatropic Shifts*

The transition structure for the [1,5] sigmatropic hydrogen shift has been studied extensively, as described earlier.[38–40] For the hydrogen shift in (*Z*)-1,3-pentadiene, the migrating hydrogen projects out of the C1-C2-C4-C5 plane in the transition structure (H···C-C-C torsional angle of 30°, Fig. 15). The partial C···H bond length is 1.41 Å, and the C-H-C angle is 133°. The C–C bonds are 1.40 and 1.42 Å in length; the terminal C–C bonds are the longer bonds. Two hydrogen atoms attached to the terminal carbon atoms are quite near each other. This will cause severe steric interactions when the hydrogens are replaced by larger groups.

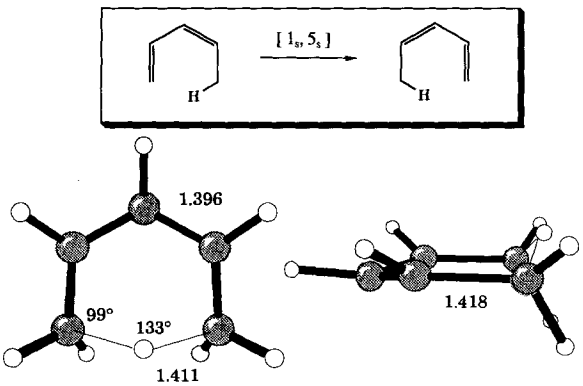

Fig. 15. The MP2/6-31G* transition structure of the $[1_s,5_s]$ sigmatropic hydrogen shift in pentadiene [39a].

Figure 16 shows the transition structure for the [1,5] hydrogen shift in cyclopentadiene. The cyclopentadiene ring and all nonmigrating hydrogen atoms are virtually coplanar. The migrating hydrogen atom is 79° out of the plane. The C–C bond lengths, except that bridged by the migrating hydrogen, correspond to those in aromatic systems, and the

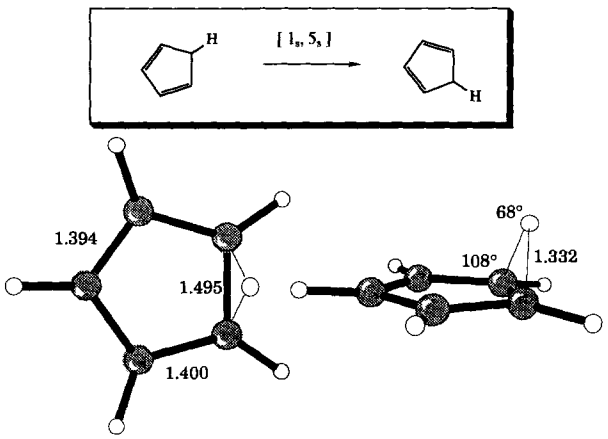

Fig. 16. The RHF/3-21G transition structure of the $[1_s,5_s]$ sigmatropic hydrogen shift in cyclopentadiene [39c].

partial C···H bond lengths are very short. This reaction has a low activation energy of 21 kcal mol^{-1}.[39] It is substantially different from the pentadiene case, because of the close proximity of the migration origin and terminus, which permits good overlap of the hydrogen orbitals with orbitals on both migration origin and terminus.

The transition structure for the thermally allowed [1_s,5_s] sigmatropic methyl shift in *cis*-1,3-hexadiene is shown in Figure 17.[73] The carbon atoms partially bonded to the migrating methyl group are pyramidalized and oriented to maintain interactions with the migrating group. Nevertheless, the degree of bonding is small for the C–C bond length of 2.17 Å, and the predicted activation energy is 73 kcal mol^{-1} at the MP2/6-31G* level. In contrast, the reaction barrier of the corresponding [1,5] hydrogen shift in pentadiene is only 38 kcal mol^{-1}, indicating strong bonding in the transition structure. For the [1,5] methyl shift of 1,3-hexadiene, a stepwise mechanism is comparable in energy to the concerted mechanism. The methyl group cannot take part in multicenter bonding as well as a hydrogen atom can, as described in Section 4.1.5.

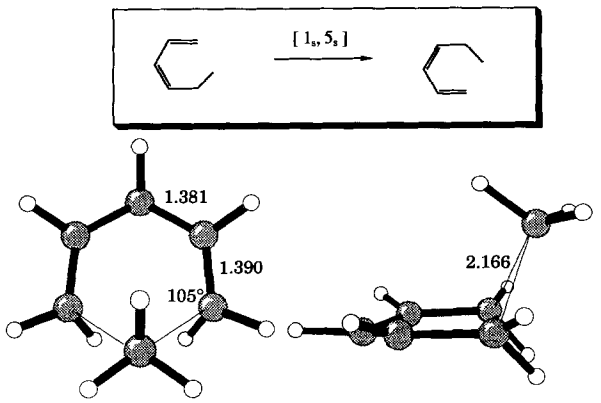

Fig. 17. The RHF/3-21G transition structure of the [1_s,5_s] sigmatropic methyl shift in *cis*-1,3-hexadiene (F. Jensen).

There are many examples of [1,5] methyl shifts in cyclopentadiene systems, and the experimental activation enthalpies are in the range of 40–44 kcal mol^{-1} for simple methyl-substituted cyclopentadienes.[74] Figure 18 shows the transition structure for the allowed [1_s,5_s] methyl shift of 5-methylcyclopentadiene.[73] The partial C···C single bond length is 1.99 Å, while the C···C double partial bonds resemble aromatic double bonds. Little pyramidalization occurs at the carbon centers of the cyclopentadiene ring, even at those two that are formally partially bonded to the migrating methyl group. The calculated reaction barrier at the RHF/3-21G level is 53 kcal mol^{-1}, which should correspond to an actual barrier of about 33 kcal mol^{-1}. The [1,5] shift of a methyl group along a cyclopentadiene is relatively facile, due to the good overlap of a methyl orbital with the orbital on adjacent carbon atoms of a cyclopentadiene ring. This is reflected in the 1.99 Å C···C bond length for the migrating methyl, as compared to 2.17 Å in the hexadiene case. Hydrogen migration is still much more facile.

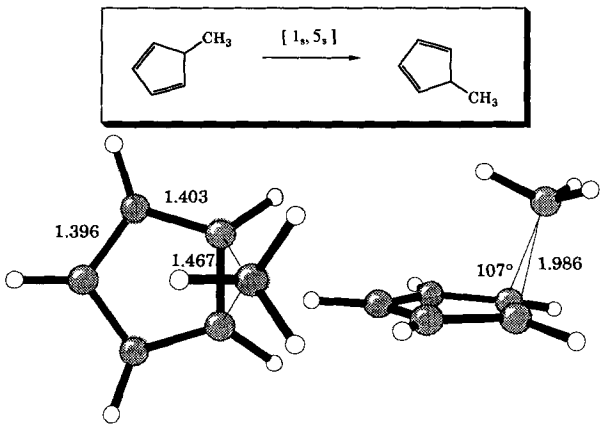

Fig. 18. The RHF/3-21G transition structure of the [1_s,5_s] sigmatropic methyl shift in methylcyclopentadiene (F. Jensen).

The [1,5] sigmatropic methylene shift in bicyclo[4.1.0]-heptadiene (norcaradiene) has been studied at the HF/3-21G level.[73] There are only two possible transition structures for the [1,5] methylene shift: the allowed [1_s,5_s] and the forbidden [1_a,5_s] rearrangements. Figure 19 shows the transition structure located for the allowed process. The activation energy of the [1,5] sigmatropic methylene shift in norcaradiene itself is not known experimentally. The calculated activation energy at the MP2/6-31G* single point level is 53 kcal mol^{-1} for the allowed [1_s,5_s] methylene shift, and 87 kcal mol^{-1} for the forbidden [1_a,5_s] reaction. These results seem to contradict the observed stereochemistry; the reaction is believed to proceed almost exclusively with inversion of the migrating alkyl group in substituted cases.[75] It is likely that the reaction takes place via a diradical mechanism. The calculated activation energy and the geometry of the transition structure (Fig. 19) indicate little or no bonding between the methylene group and the termini of the pentadienyl group. If the rate of recombination of the biradical is much faster than rotation around the C–C bond, the reaction could proceed stereospecifically with inversion of the migrating carbon.

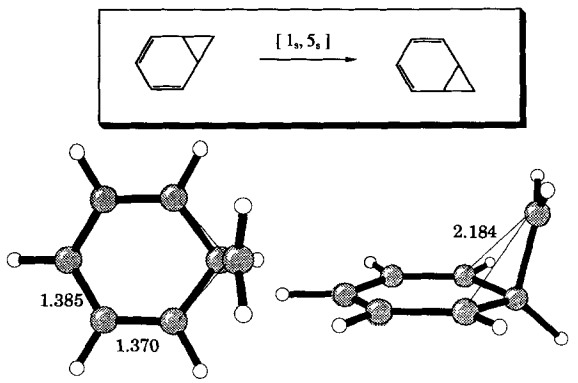

Fig. 19. The RHF/3-21G transition structure of the [1_s,5_s] sigmatropic methylene shift in norcaradiene (S. M. Ernst).

4.1.5. [1,7] Sigmatropic Shifts

Hess, Schaad, and others have reported a transition structure for the allowed [1_s,7_a] hydrogen shift.[38] The RHF/3-21G optimized transition structure of C_2 symmetry is given

in Figure 20.[73] The calculated activation energy is 44 kcal mol^{-1} at the RHF/3-21G level, which is 11 kcal mol^{-1} lower than that for the [1,5] hydrogen shift at the same level of theory. With inclusion of electron correlation, the reaction barrier is estimated to be about 25 kcal mol^{-1}, which is in the range of the experimental estimation.[76] The lower barrier is due to better overlap of the orbitals of the partial C···H bonds and the π system than can occur in the [1,5] shift.[73]

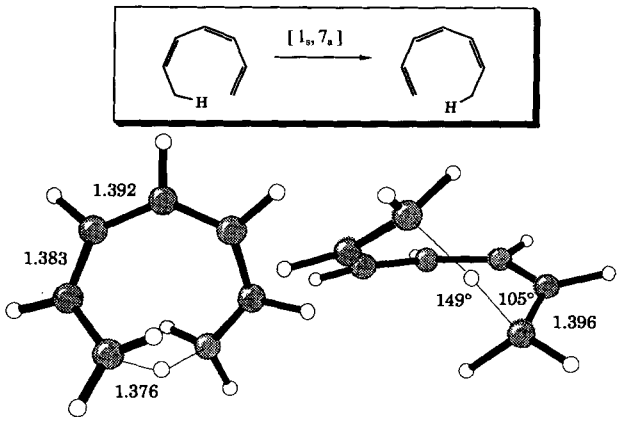

Fig. 20. The RHF/3-21G transition structure of the [1s,7a] sigmatropic hydrogen shift in heptatriene [38].

All of the sigmatropic hydrogen shifts can be considered to involve a C···H···C array, optimally arranged for hydrogen transfer, interacting to a greater or lesser extent with the unsaturated system joining the two carbons involved in the hydrogen transfer. This is further demonstrated by comparisons of the transition structures of sigmatropic hydrogen shifts with those involving intermolecular hydrogen atom transfers (Fig. 21).[77] For the sigmatropic hydrogen shifts, the C···H lengths are 1.33–1.41 Å, about the same as in the transition structure for hydrogen atom transfer between methane and a methyl group. The same comparison holds for methyl shifts. At the UHF/6-31G* level, hydrogen atom transfer from methane to methyl has an activation energy which is 37 kcal mol^{-1} less than that for methyl group transfer.

There are several differences between hydrogen atom and methyl group shifts. The allowed and geometrically feasible hydrogen shifts all have substantial energies of concert. That is, stepwise mechanisms have considerably higher activation energies than observed reactions. On the other hand, there is little or no energy of concert for the alkyl group shifts, which all have transition structures involving very little bonding between radical fragments. The reaction barriers of alkyl shifts are considerably higher than those of the corresponding hydrogen shifts. This arises because hydrogen can readily form reasonably strong bonds simultaneously to two groups. This is difficult for an alkyl group, regardless of whether frontside or backside attack occurs. This is a consequence of the poor overlap achievable between the directional orbital of an alkyl group and two other orbitals simultaneously.

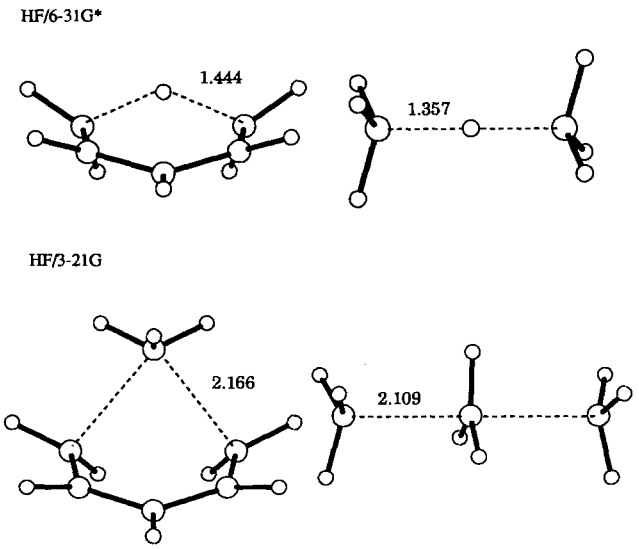

Fig. 21. Comparison of the 6-31G* transition structures of sigmatropic hydrogen shifts with intermolecular hydrogen transfer (top) and the 3-21G transition structures of sigmatropic methyl shifts with intermolecular methyl transfer (bottom).

4.1.6. [3,3] Sigmatropic Shifts

The [3,3] sigmatropic shift, as well as all other higher order sigmatropic shifts, have the possibility of two stepwise mechanisms: fragmentation to two allyl (or other conjugated radical) fragments and recombination, or formation of a diradical by addition of the termini of the two π bonds to each other, followed by cleavage. The concerted pathway may involve transition structures which resemble either one of these extremes. There may even be multiple competing concerted pathways for these processes.[78]

The degenerate Cope rearrangement of 1,5-hexadiene is a case where the precise mechanism is still a matter of uncertainty. A variety of computational techniques have been applied.[79–82] Ab initio CASSCF calculations predict a closed-shell, delocalized, "aromatic" transition state for the Cope rearrangement (Fig. 22).[79] The partial σ bonds are

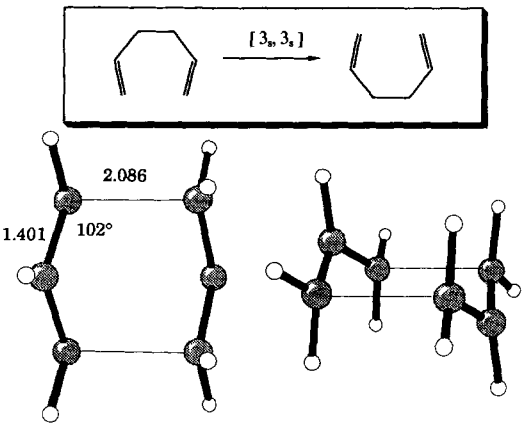

Fig. 22. The CASSCF/3-21G transition structure of [3s,3s] sigmatropic shift (Cope rearrangement) of 1,5-hexadiene [79].

2.09 Å long, which is in the normal range. Transition structures of both chair and boat conformations have been located. The chair is preferred, which is in good agreement with

the experimental observations based upon the stereochemistry of the reaction.[83] The calculated activation entropy for the chair transition structure is in good agreement with the experimental value, but the calculated value is too small for the boat conformation. The experimental isotope effects for Cope rearrangement can be reproduced by the aromatic transition structures from concerted mechanisms,[70] and the 1,4-diyl is estimated to have a significantly higher energy than the observed transition state.[84] Nevertheless, a very high level of calculation will be required to match all available experimental data.[84c]

A variety of other Cope rearrangements of various unsaturated hydrocarbons have also been studied at the RHF/3-21G level.[70] Figure 23 shows the transition structure for the [3,3] sigmatropic rearrangement of 1,5-hexadiyne to form 1,2,4,5-hexatetraene. In the transition structure, the forming

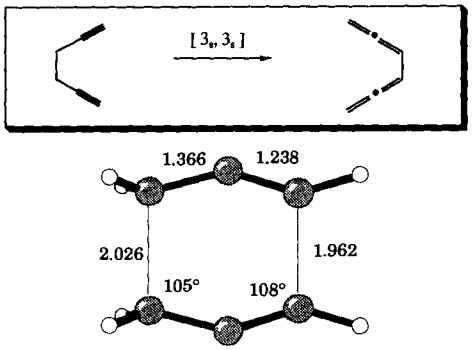

Fig. 23. The RHF/3-21G transition structure of [3s,3s] sigmatropic shift of 1,5-hexadiyne (S. M. Ernst and K. Black).

C···C bond length is 1.96 Å and the breaking C···C bond length is 2.03 Å. The $HC{\equiv}C{-}CH_2{-}$ fragments are bent substantially from linear to a bond angle of 147°. The calculated reaction barrier at the MP2/6-31G* level is 37 kcal mol^{-1}, which is close to the experimental value of 34 kcal mol^{-1}.[85]

Transition structures for the degenerate rearrangement of hexa-1,2-dien-5-yne and the rearrangement of hex-1-en-5-yne to 1,2,5-hexatriene are shown in Figures 24 and 25, respectively.[70, 86] RHF calculations favor the concerted mechanisms for each of these processes, but like the Cope

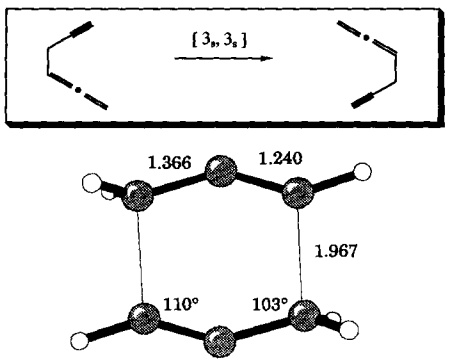

Fig. 24. The RHF/3-21G transition structure of [3s,3s] sigmatropic shift of hexa-1,2-dien-5-yne (S. M. Ernst and K. Black).

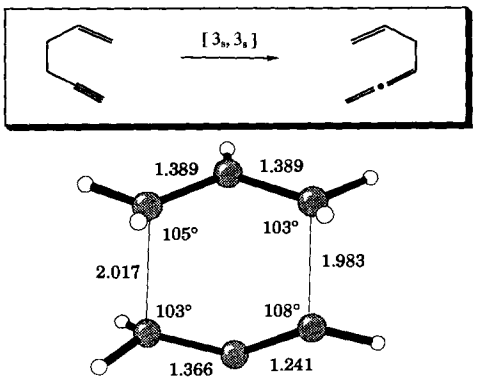

Fig. 25. The RHF/3-21G transition structure of [3s,3s] sigmatropic shift of hex-1-en-5-yne (S. M. Ernst and K. Black).

rearrangement itself, diradical mechanisms are expected to be not too different in energy from concerted mechanisms.[87]

4.2. Group Transfers

Feller, Schmidt, and Ruedenberg reported ab initio studies of the concerted dihydrogen transfer between ethene and ethane.[88] The concerted transition structure has D_{2h} symmetry (Fig. 26).[89] The C···H bonds of the transferring

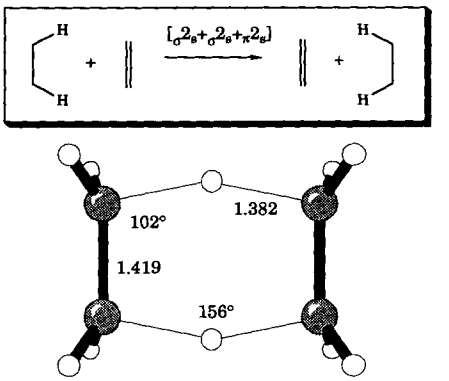

Fig. 26. The CASSCF/3-21G transition structure of hydrogen transfer between ethene and ethane [89].

hydrogens are stretched to 1.38 Å, while the C–C bonds have the usual aromatic-like bond lengths. The partial σ C···H bonds can be described as three-center (C···H···C) three-electron bonds as in sigmatropic hydrogen shifts. The calculated reaction barrier is 71 kcal mol^{-1} at the MCSCF level and 51 kcal mol^{-1} at the MP2/6-31G*//3-21G level.[71] Several molecules have been observed to undergo the concerted dihydrogen transfer reaction.[90]

Figure 27 shows the transition structures for the hydrogen transfer from *cis*-2-butene to 1,3-butadiene.[71] In both *endo* and *exo* transition structures, the partial H···C bond lengths are 1.38 Å, and the butadiene fragments have the usual partial C···C double bond lengths of 1.38–1.40 Å. The *endo* transition structure is predicted to be more stable than the *exo* by 2 kcal mol^{-1}, and the reaction barrier is predicted to be 45 kcal mol^{-1} via the *endo* transition structure at the

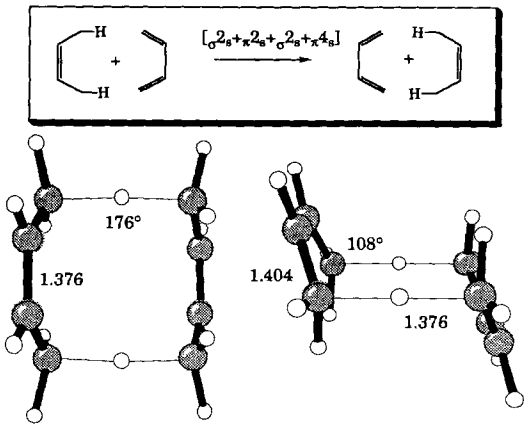

Fig. 27. The RHF/3-21G transition structure of hydrogen transfer between 2-butene and butadiene (Y. Li).

MP2/6-31G*//3-21G level. An example of this reaction is known for a polycyclic case.[91]

4.3. Electrocyclic Reactions

Electrocyclic reactions involve the cyclization of conjugated π systems or the reverse ring-opening process. The reactions may be conrotatory or disrotatory, and generally follow the Woodward–Hoffmann predictions, unless some geometrical constraints such as incorporation into a small ring prevent the allowed process.[92]

4.3.1. Allyl → Cyclopropyl Rearrangements

According to the Woodward–Hoffmann rules, the symmetry-allowed cyclopropyl cation opening to form the allyl cation is disrotatory, while that of the anion is conrotatory. The disrotatory conversion of the cyclopropyl cation to allyl cation is exothermic with a vanishingly small barrier according to MP2 calculations.[93] As shown in Figure 28, the breaking C···C bond length is only 1.56 Å in the transition structure, nearly the same as in the cyclopropyl cation. Indeed, experimental data indicate that the ring opening occurs

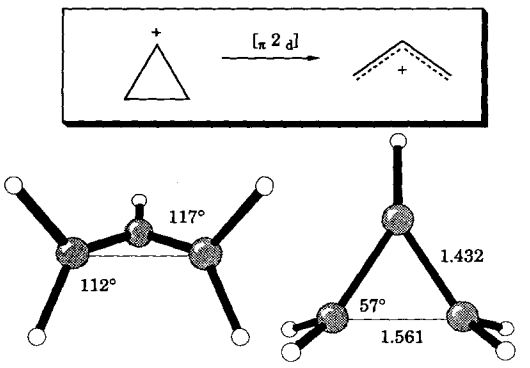

Fig. 28. The MP2/6-31G* transition structure of disrotatory electrocyclic ring opening of the cyclopropyl cation [93]. In this and subsequent drawings of electrocyclic reactions, the angles between the inward and outward rotating hydrogens and the breaking or forming single bond are given.

in concert with ionization in the reactions of cyclopropyl halides and tosylates.[94]

The cyclopropyl radical opens to form the allyl radical with a significant barrier of approximately 20 kcal mol^{-1}.[95] Similarly, the exothermic (-43 kcal mol^{-1}) conrotatory ring opening of the cyclopropyl anion has a reaction barrier of 20 kcal mol^{-1} at the MP2/6-31 + G* level.[96] The breaking C···C bond is stretched to 1.94 Å, and the C–C double bond lengths are 1.45 Å in the transition structure (Fig. 29).

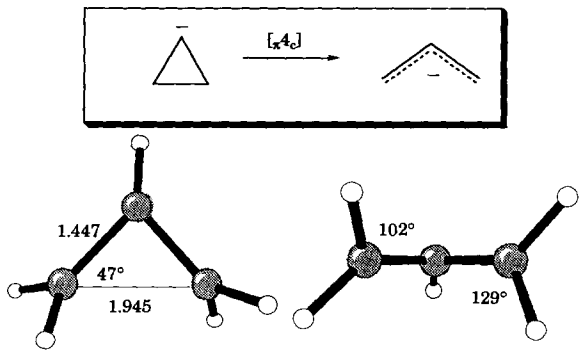

Fig. 29. The MP2/6-31 + G* transition structure of conrotatory electrocyclic ring opening of the cyclopropyl anion (E. A. Kallel).

All carbons are pyramidalized in the transition structure, and the hydrogen atom on the central carbon atom is bent significantly out of the C-C-C plane.

4.3.2. The Butadiene → Cyclobutene Rearrangement

The transition structure for the cyclobutene conrotatory electrocyclic ring opening has been studied extensively.[42–44] Early interest in this reaction focused on the difference in energy between the thermally allowed conrotatory and the thermally forbidden disrotatory processes.[42b,c] There appears to be no concerted C_s transition structure for the forbidden disrotatory process, and experimental and theoretical estimates place the allylmethylene diradical resulting from the rotation of only one of the newly formed methylene and groups of butadiene about 9–11 kcal mol^{-1} above the conrotatory transition structure.[42b]

The concerted conrotatory transition structure obtained at the MP2/6-31G* level is shown in Figure 30. The breaking single bond has stretched from 1.56 Å in cyclobutene to 2.13 Å in the transition structure. The single bond flanking the breaking bond has contracted from 1.51 Å to 1.41 Å; this change of 0.09 Å is about 50% the total change from reactant to product. The conversion of the double bond of cyclobutene to a single bond lags considerably behind the other bond length changes; it has stretched only 0.03 Å in the transition structure, which is only 30% of the total bond extension during the reaction.

These changes are consistent with a description of the reaction in which the major bonding changes occurring to form the transition structure is stretching and twisting of the σ bond, accompanied by the beginnings of interaction of the orbitals at the rotating termini with the π orbitals of the

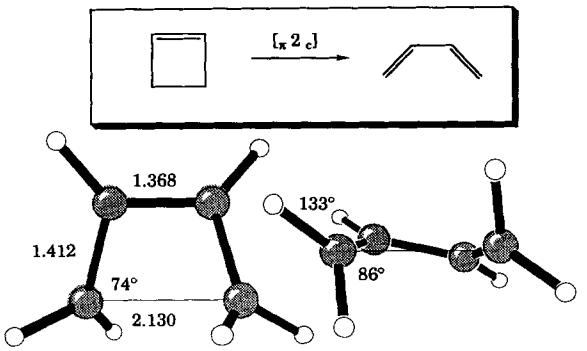

Fig. 30. The MP2/6-31G* transition structure of conrotatory electrocyclic ring opening of cyclobutene [44a].

double bond. Such interaction only becomes substantial when the σ bond is quite long, raising the σ orbital energy, and when rotation has occurred sufficiently to allow σ–π* and σ*–π overlaps. The overlaps are also facilitated by the nonplanarity of the carbon skeleton.[44d] After the transition structure is reached, the energy rapidly decreases toward the s-*cis*-butadiene skew geometry. This analysis helps us understand the substituent effects described in Section 5.1.

The electrocyclic ring opening of benzocyclobutene is analogous, and may be regarded formally as either a 4π- or an 8π-electron process. Figure 31 shows the transition structure for this ring-opening reaction.[97] The cyclobutene motions are very similar to those of the transition structure of the parent cyclobutene ring opening, even though the cyclobutene opening is *exothermic* by 10 kcal mol^{-1}, while the benzocyclobutene opening is *endothermic* by 15 kcal mol^{-1}. The breaking C···C single bond is slightly longer than that in the cyclobutene transition structure, consistent with the fact that the transition structure occurs later in this endothermic reaction.

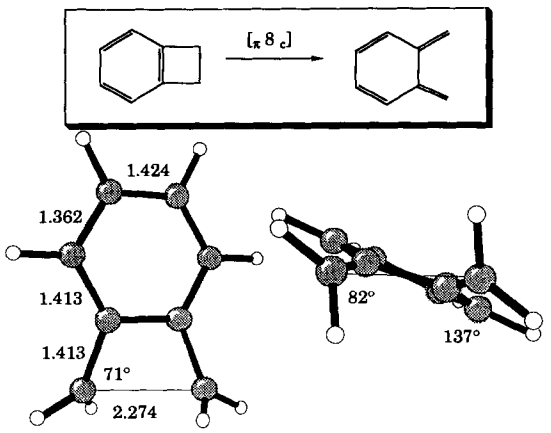

Fig. 31. The RHF/3-21G transition structure of conrotatory electrocyclic ring opening of benzocyclobutene (D. C. Spellmeyer).

4.3.3. The Pentadienyl → Cyclopentenyl Rearrangement

Figure 32a shows the transition structure for the conrotatory electrocyclic conversion of the pentadienyl cation to the cyclopentenyl cation.[96] In the transition structure, the partial C···C single bond is 2.27 Å long, and all partial double bonds have identical bond lengths of 1.39 Å. The activation energy is nearly zero for this highly exothermic process (− 27 kcal mol^{-1}), but the qualitative features are very similar to those for the cyclobutene electrocyclic reaction.

The transition structure for the 6π-electron disrotatory ring opening of cyclopentenyl anion to the more stable pentadienyl anion is shown in Figure 32b.[98] The partial single bond in the transition structure is 2.18 Å in length, while the lengths of the partial double bonds range from 1.39 to 1.44 Å. The calculated reaction barrier is 20 kcal mol^{-1} at the MP2/6-31 + G* single point level.

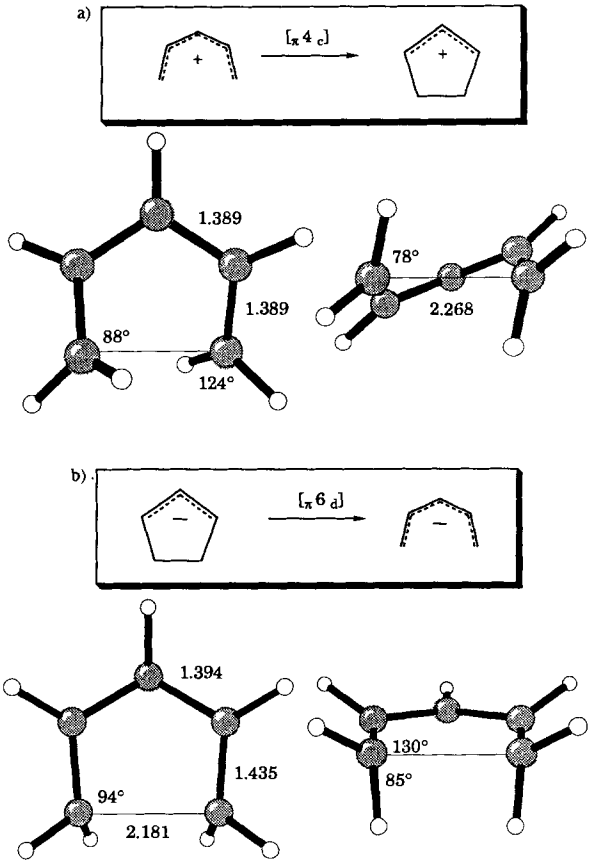

Fig. 32. a) The MP2/6-31G* transition structure of electrocyclization of the pentadienyl cation (E. A. Kallel). b) The RHF/6-31 + G* transition structure of cyclopentenyl anion electrocyclic ring opening (J. D. Evanseck).

4.3.4. The Hexatriene → Cyclohexadiene Electrocyclization

The transition structure for the disrotatory ring closure of *cis*-1,3,5-hexatriene to form 1,3-cyclohexadiene is shown in Figure 33.[97,99] The partial single-bond length is 2.24 Å, and the double-bond lengths are in the range of 1.39 to 1.40 Å. Two hydrogen atoms are in close proximity at the bonding termini, which destabilizes the transition structure to some extent. The boat shape of this transition structure permits the interaction of the π system at carbon atoms 2–4 of the triene with the forming σ bond between carbon atoms

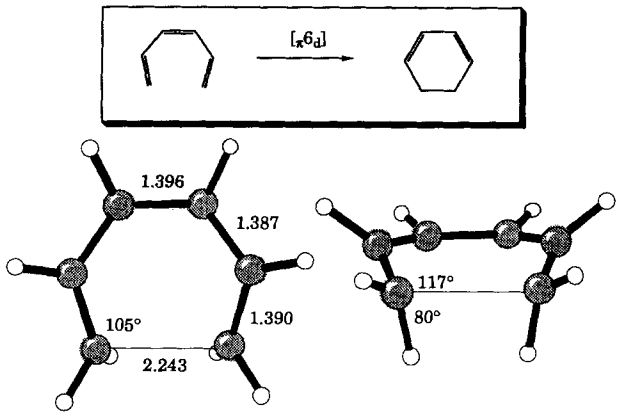

Fig. 33. The RHF/6-31G* transition structure of disrotatory electrocyclization of hexatriene [99].

1 and 6 to be maintained throughout the reaction. The MP2/6-31G* activation energy of 26 kcal mol^{-1} for the ring closure is in good agreement with experimental value of 29 kcal mol^{-1}.[100]

4.3.5. The Hexenediyne → Benzenediyl Electrocyclization

The 6π-electron electrocyclization of hex-3-ene-1,5-diyne gives benzene-1,4-diyl, which opens to form hexenediyne with a rearranged carbon skeleton (Fig. 34).[11e] Bergman et al. studied simple versions of this reaction extensively,[101] but there has been much recent excitement about this process since the discovery that the natural substances, esperamicin and calicheamicin, undergo this type of reaction.[10] In cells, the resulting diradicals abstract hydrogens from DNA to cause double-strand DNA cleavage and cell death.[10]

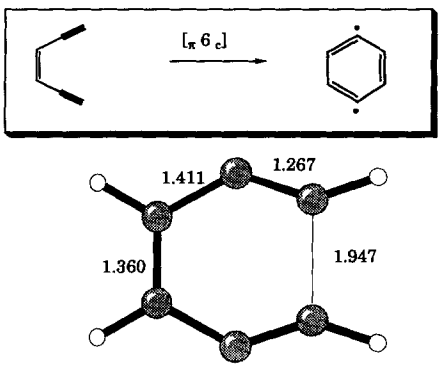

Fig. 34. The CASSCF/MIDI1 transition structure of electrocyclization of hex-3-en-1,5-diyne [11e].

The reaction has also been studied at the semiempirical and MCSCF levels.[11c,d] Generation of the benzene ring compensates for the loss of a bond involved in generation of the diradical, so that the parent system has a relatively ordinary activation barrier for hydrocarbon pericyclic processes. However, ground state strain can lower the barrier so that the cyclization occurs readily at room temperature. Although the reaction might be considered as the addition of two alkynes, it does exhibit geometrical features similar to other pericyclic reaction transition structures.

4.3.6. The Octatetraene → Cyclooctatriene Electrocyclization

The transition structure of this conrotatory eight-electron electrocyclic process is shown in Figure 35.[98] Although the process is clearly conrotatory, the two termini of the partially formed σ bond are aligned nearly perfectly, not twisted as in the conrotatory cyclobutene → butadiene interconversion. The coiled arrangement of the eight carbon atoms permits excellent π overlap throughout the ring in the transition structure. There is also excellent overlap of the π system with the forming C···C bond. The calculated activation energy at the MP2/6-31G* level is 8 kcal mol^{-1}, while Huisgen has found an enthalpy of activation for a substituted tetraene of 22 kcal mol^{-1}.[102]

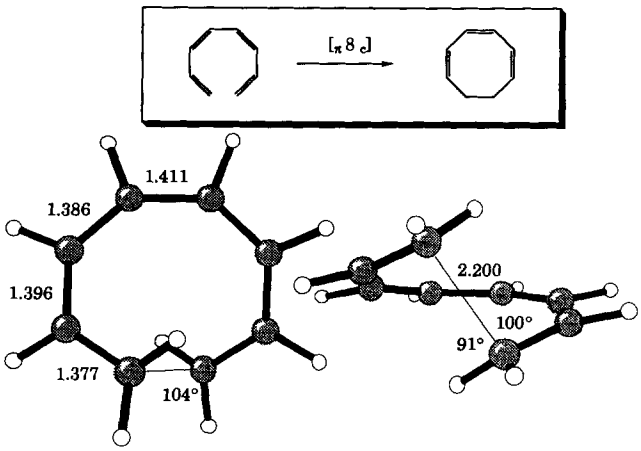

Fig. 35. The RHF/6-31G* transition structure of conrotatory electrocyclic ring opening of cyclooctatriene (J. D. Evanseck).

4.4. The Ene Reaction

The ene reaction is related both to cycloadditions and to sigmatropic hydrogen shifts. One π bond is converted to a σ bond, and a hydrogen atom is transferred at the same time. It has been called a homodienyl [1,5] shift in intramolecular examples.[103] The reaction occurs even with simple unactivated hydrocarbons, although it is best known for the reaction of alkylethylene with electron-deficient molecules such as alkenes, ketones, or azo compounds substituted by electron-withdrawing groups, or singlet oxygen.

The transition structure for the ene reaction of propene with ethene to form 1-pentene is shown in Figure 36.[104] It has an envelope conformation, like that of cyclopentane, but with two long C–C bonds, and the transferring hydrogen atom is placed in one of these long bonds. The forming C···C single bond length is about 2.0 Å, while the two partial C···H bond lengths are 1.22 and 1.52 Å. The calculated reaction barrier at the MP2/6-31G* level is 32 kcal mol^{-1}.

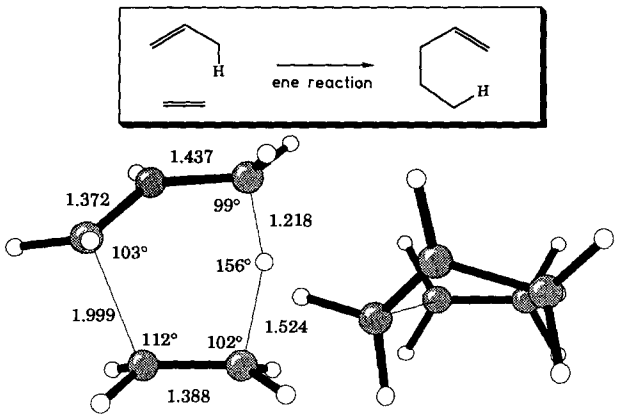

Fig. 36. The RHF/3-21G transition structure of the ene reaction between propene and ethene [104].

The hypothetical diradical, pentane-1,4-diyl, is expected to be close in energy to the concerted transition structure. Nevertheless, the observed stereospecificity of substituted cases implies that the reactions are concerted.[105]

4.5. Hydrogen Additions and Extrusions

The concerted addition of H_2 to ethene is a forbidden four-electron process which will occur in a stepwise fashion. When six electrons are involved, the reaction is thermally allowed. The transition structure for the concerted [1,4] addition of a hydrogen molecule to butadiene is shown in Figure 37.[106] It has forming H···C and breaking H···H bond lengths of 1.60 Å and 0.92 Å, respectively. The H···C-C angle of attack is 96°. The activation energy of the [1,4] addition is predicted to be 36 kcal mol^{-1} at the MP2/6-31G*//HF/3-21G level. The addition of hydrogen to butadiene is exothermic by 36 kcal mol^{-1} at the same level of theory.

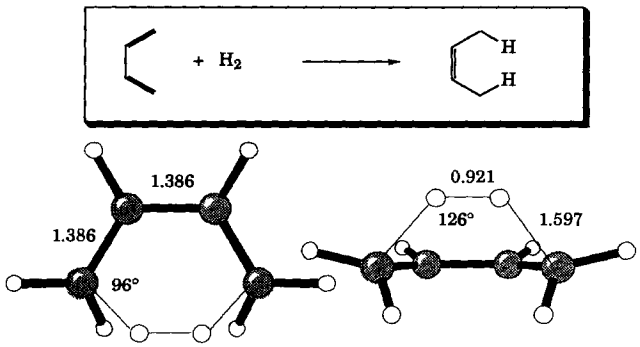

Fig. 37. The RHF/3-21G transition structure of butadiene hydrogenation (A. Dorigo).

Lee and co-workers recently reported experimental studies of the rotational, vibrational, and translational energy distribution of the H_2 formed from elimination from 1,4-cyclohexadiene.[107] They infer from these studies that the transition structure should have a tight H–H distance and that "the H atoms are more likely to move in a plane parallel to the two double bonds rather than perpendicular to it".[107] Thus, the hydrogens are predicted to experience a helicopter-like spinning with respect to the plane of the forming benzene ring. Calculations on this system predict a C_{2v} transition structure (Fig. 38),[71] so that the spinning must be induced by dynamic effects taking place beyond the transition state. The experimental activation energy for the elimination of hydrogen from cyclohexadiene is 44 kcal mol^{-1}, and the reaction is exothermic by 6 kcal mol^{-1}.[108] The calculated quantities at the MP2/6-31G* are 50 and 3 kcal mol^{-1}, respectively.

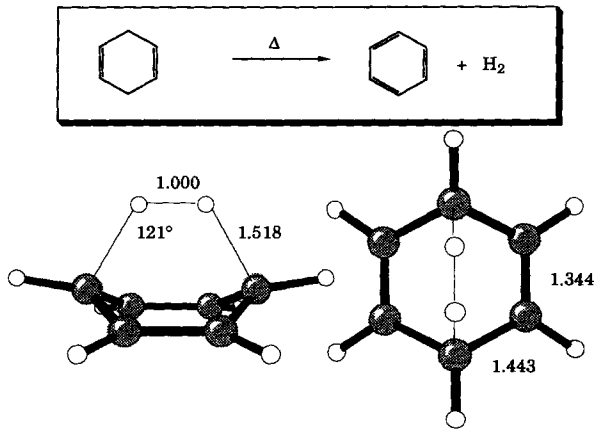

Fig. 38. The RHF/6-31G* transition structure of benzene hydrogenation (Y. Li).

4.6. Cheletropic Reactions

Cheletropic reactions are pericyclic reactions in which two bonds are made or broken to a single atom. This class of reactions includes such common processes as the addition of carbenes to olefins, the loss of CO from cyclopentenones, the loss of N_2 from cyclic *N*-nitrides, and the loss of SO_2 from sulfolene (Fig. 39).

These reactions may be either suprafacial or antarafacial on the olefinic component, and either linear or nonlinear on the chelefuge, the fragment containing the single atom at which the two forming or breaking bonds terminate. This

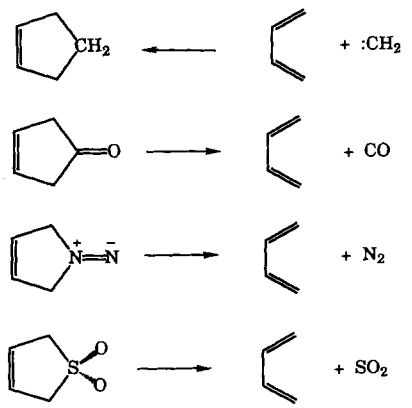

Fig. 39. Examples of cheletropic reactions.

leads to a total of four possible reaction pathways. Direct experimental distinction between all of the mechanistic possibilities cannot be made easily. For three-membered rings (e.g., addition of singlet carbenes to olefins,[109] or loss of SO_2 from thiirane 1,1-dioxides[110]), cheletropic reactions are observed to be suprafacial on the olefin, suggesting that the nonlinear pathway is followed. For five-membered rings, suprafacial reactions are also observed.[111] For seven-membered rings, antarafacial reactions are observed.[112] This suggests that the linear pathways are followed for the larger rings, but calculations have special importance in establishing stereochemistries of such reactions, because of the difficulties of determining them experimentally.

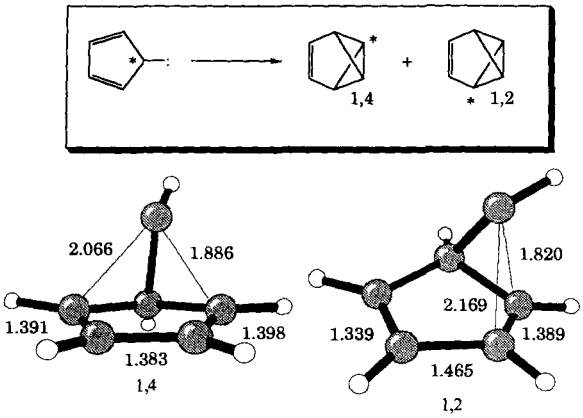

Fig. 40. The HF/3-21G transition structures of 1,4- (left) and 1,2-addition (right) of the carbene in methylene cyclopentadiene [117].

4.6.1. Carbene Additions

Singlet carbene additions to alkenes involve the approach of the vacant π orbital of the singlet carbene to the occupied π orbital of the alkene and subsequent rotation of the methylene fragment to complete cyclopropane formation.[113] This is the classic nonlinear cheletropic mechanism, proposed by Hoffmann twenty-five years ago.[114]

Zurawski and Kutzelnigg studied the ab initio potential energy surface for the addition of singlet methylene to ethene.[115] This study indicates the absence of a barrier, with the energy decreasing monotonically along the entire reaction path. The minimum energy pathway does follow the nonlinear trajectory proposed by Hoffmann. For a variety of substituted carbenes, this nonlinear pathway is followed, but the transition structure varies from a relatively late transition structure for stabilized carbenes (e.g. CF_2) to an early one for unstabilized carbenes (e.g. CCl_2).[116]

4.6.2. Carbene Additions to Dienes

Singlet carbenes may undergo either 1,2- or 1,4-cycloadditions with conjugate dienes. The 1,2-addition is much more favorable than the 1,4-addition. The latter only becomes more favorable in the case of a few intramolecular reactions when the 1,2-addition is made sterically difficult. An example is the singlet cyclopenta-2,4-dienyl carbene to form benzvalene. Transition structures have been located for both 1,2- and 1,4-cycloadditions as shown in Figure 40.[117] The reaction barrier of the 1,4-cycloaddition is 5 kcal mol^{-1} lower than that of the 1,2-addition. In this intramolecular reaction, the ring skeleton constraints prevent the transition structure for the 1,2-addition from achieving the ideal geometry, so that the 1,4-addition becomes more favorable.

4.7. Cycloaddition Reactions

Cycloadditions are reactions involving the addition of two or more unsaturated molecules to each other to form a new ring. Two nomenclature systems are in common use. According to Huisgen's system,[118] a cycloaddition is classified by the number of atoms between the termini involved in ring formation. Thus, Diels–Alder and 1,3-dipolar cycloadditions are (4 + 2) and (3 + 2) cycloadditions, respectively. Parentheses are used to enclose the atom numbers. In the Woodward–Hoffmann system,[2] the number of π electrons involved in bonding changes in the two reactants are used. Thus, Diels–Alder and 1,3-dipolar cycloadditions are both [4 + 2] cycloadditions. Square brackets enclose the numbers of electrons. The latter system will be used here.

4.7.1. [2 + 2] Cycloadditions

According to the Woodward–Hoffmann rules, the $[2_s + 2_s]$ cycloaddition is not a thermally allowed process, while the allowed $[2_a + 2_s]$ process requires a geometrically difficult transition state and should be unfavorable except in unusual circumstances. There have been many theoretical studies of the [2 + 2] reactions involving ethene,[119] acetylene,[120] allene,[121] and ketene.[122] MCSCF calculations on the dimerization of ethene show that there is no symmetrical transition structure for the $[2_s + 2_s]$ process, and the reaction involves two steps with a tetramethylene biradical intermediate.[119] Doubleday et al. has proposed that this intermediate is a free energy minimum because of unfavorable entropy upon cleavage or cyclization.[119c] Figure 41 a shows the *anti* transition structure which leads to the *anti*-butanediyl. The barrier to ring closure includes a contribution from rotation about the central C–C bond. The forming C···C bond length of 1.8–1.9 Å is shorter than those in

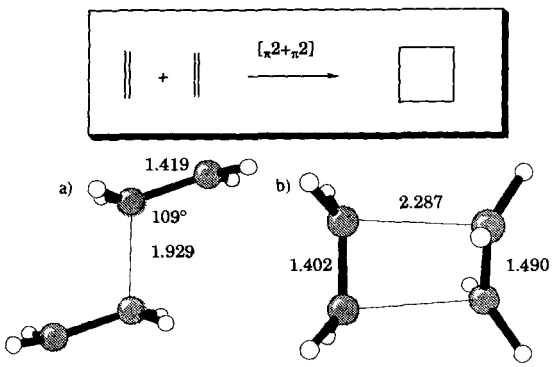

Fig. 41. The MCSCF/3G transition structures of the cyclodimerization of ethene [119b]. a) The nonconcerted $[{}_{\pi}2_s + {}_{\pi}2_s]$ reaction; b) the concerted $[{}_{\pi}2_s + {}_{\pi}2_a]$ reaction.

the concerted reactions discussed in the following sections, while the second bond is not formed at all. All carbon atoms involved in bond formation as well as those at the forming radical are pyramidalized. A transition structure has also been reported for the allowed $[_\pi 2_s + {}_\pi 2_a]$ pathway, but it is very high in energy due to steric repulsions between hydrogens (Fig. 41 b).

By contrast, ketene reacts with ethene via a transition structure that is rather similar to the carbene transition structure.[122b] As shown in Figure 42, the forming bond from ethene to the electrophilic ketene carbonyl carbon is very short while the second bond to the methylene carbon atom is very long. There is zwitterionic character; a charge

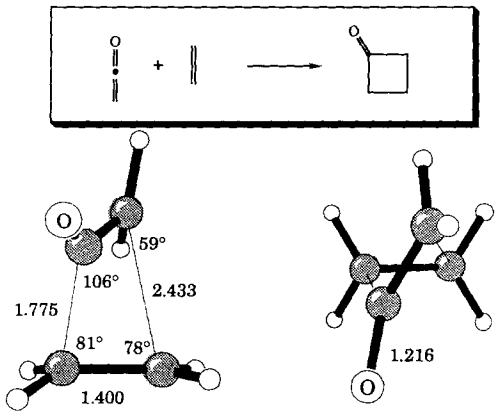

Fig. 42. The MP2/6-31G* transition structure of $[_\pi 2_s + {}_\pi 2_a]$ cycloaddition between ethene and ketene [122].

transfer of 0.2 electrons from ethene to ketene is revealed in this gas-phase calculation.

4.7.2. [4 + 2] Diels–Alder Reactions

The parent Diels–Alder reaction of 1,3-butadiene with ethene to form cyclohexene is the prototype thermally allowed cycloaddition. It has been studied extensively both by semiempirical[46] and ab initio techniques.[47–49] A lively debate over mechanism went on for more than 10 years, because ab initio RHF and MCSCF calculations predict a symmetric transition structure for a route with no intermediates, while semiempirical or ab initio UHF calculations predict a two-step mechanism involving a diradical intermediate. While the concerted, synchronous nature of the prototype reaction is now agreed upon, there is still discussion about the mechanisms of substituted cases.[123]

Figure 43 shows the butadiene–ethene transition structure according to MP2/6-31G* calculations. Several interesting features of the transition structure are summarized here. The angles of attack are approximately tetrahedral, so that the diene and ethene do not approach each other in parallel planes, but instead, the planes are canted with respect to each other. The out-of-plane bending of the hydrogens at C2 and C3 of the diene is quite remarkable, since these hydrogens are nearly coplanar with the attached and germinal carbons in both reactant and product. This pyramidalization of the orbitals on C2 and C3 occurs in order to maximize overlaps

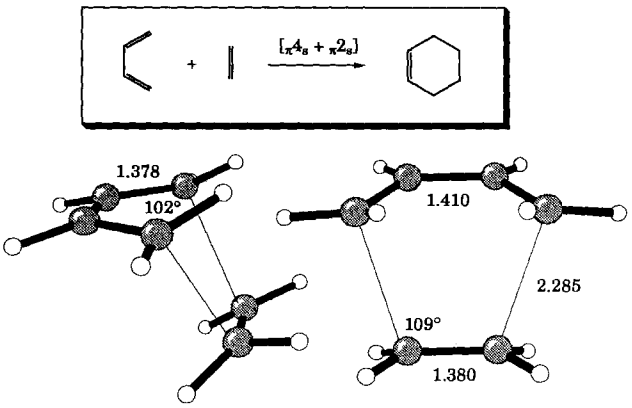

Fig. 43. The MP2/6-31G* transition structure of $[_\pi 4_s + {}_\pi 2_s]$ cycloaddition between butadiene and ethene (R. J. Loncharich).

of the p orbitals at these carbon atoms with the orbitals of forming C···C bonds.[124]

Transition structures have also been located for several other hydrocarbon Diels–Alder reactions. Figure 44 shows the transition structure for the reaction between butadiene and acetylene.[125] The transition structures for the reaction

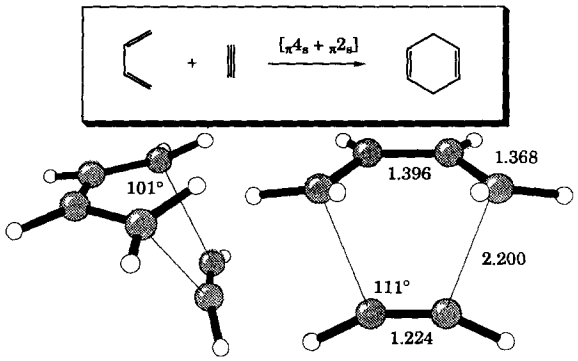

Fig. 44. The RHF/3-21G transition structure of $[_\pi 4_s + {}_\pi 2_s]$ cycloaddition between butadiene and acetylene (M. McCarrick).

between cyclopentadiene and ethene,[126] and cyclobutadiene and ethene[71] are shown in Figure 45 and 46, respectively. Although the reactivity increases from 1,3-butadiene

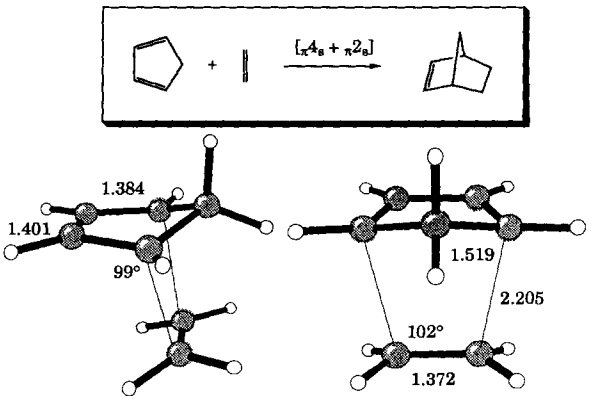

Fig. 45. The RHF/3-21G transition structure of $[_\pi 4_s + {}_\pi 2_s]$ cycloaddition between cyclopentadiene and ethene [126].

over cyclopentadiene to cyclobutadiene, the forming C···C single bond lengths are remarkably constant (2.2 Å) in all of these transition structures. The relative activation energies are related to the reaction exothermicity and to how well the distances between the termini of butadiene and the termini of ethene correspond.

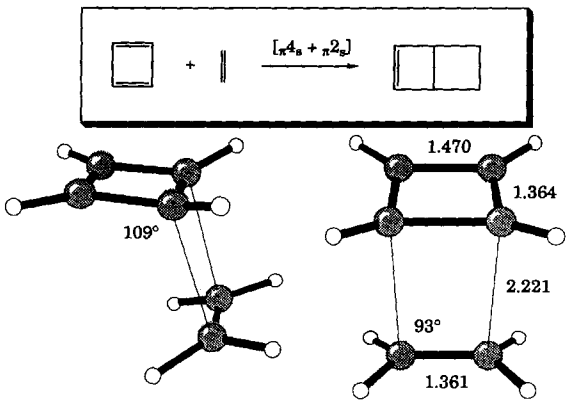

Fig. 46. The RHF/3-21G transition structure of $[\pi 4_s + \pi 2_s]$ cycloaddition between cyclobutadiene and ethene (Y. Li).

The Diels–Alder reaction between benzene and alkenes or alkynes has been suggested to have a strong preference for the concerted pathway and an energy of concert of 23 kcal mol^{-1}.[12] Figure 47 shows the transition structure for the Diels–Alder reaction between benzene and ethene.[71]

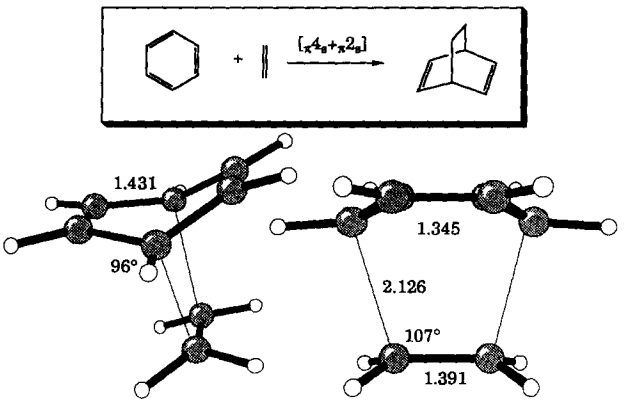

Fig. 47. The RHF/3-21G transition structure of $[\pi 4_s + \pi 2_s]$ cycloaddition between benzene and ethene (Y. Li).

The forming single C···C bond length is 2.13 Å in the transition structure. The benzene moiety is distorted out-of-plane, and the C–C bond lengths of the benzene ring are alternately 1.34 and 1.43 Å. In spite of the distortions, the barrier of this reaction is about the same as that of the prototype Diels–Alder reaction. Thus, the cyclic delocalization of the aromatic ring is maintained in the transition structure. The biradical intermediates which would be formed along nonconcerted path will be very unfavorable due to the significant loss of benzene aromaticity.

Similarly, a concerted transition structure has been located for the Diels–Alder reaction between benzene and acetylene

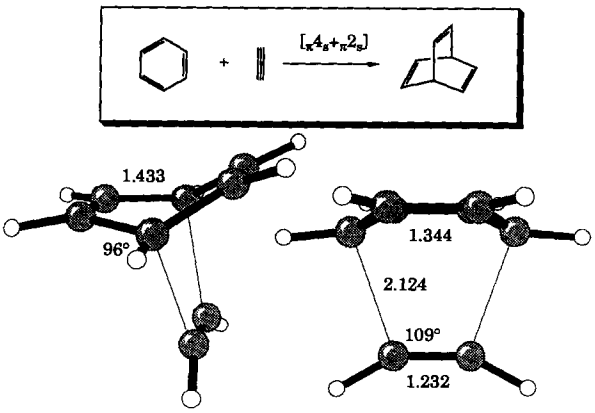

Fig. 48. The RHF/3-21G transition structure of $[\pi 4_s + \pi 2_s]$ cycloaddition between benzene and acetylene (Y. Li).

(Fig. 48).[71] The benzene moiety is almost identical to that in the transition structure of ethene plus benzene, and the forming C···C single bond lengths are 2.12 Å. The calculated reaction barrier at the MP2/6-31G* single point level is 35 kcal mol^{-1}, which is close to the experimental activation energy of 40 kcal mol^{-1}.[127]

4.7.3. [6 + 4] Cycloadditions

Figure 49 shows potential C_s transition structures for the [6 + 4] cycloaddition reaction between *cis*-hexatriene and butadiene.[71] Vibrational frequency calculations indicate two imaginary frequencies for the *endo* stationary point, while the *exo* is an authentic transition structure. The *exo* transition structure is predicted to be 5 kcal mol^{-1} more stable than the *endo* conformation, in full accord with the Woodward–Hoffmann prediction.[2] The forming single-bond lengths are 2.18 Å, and the partial double-bond lengths are in the range of 1.38 Å to 1.40 Å. The patterns of bond alternation resemble those in hexatriene and butadiene, indicating the early nature of these transition structures.

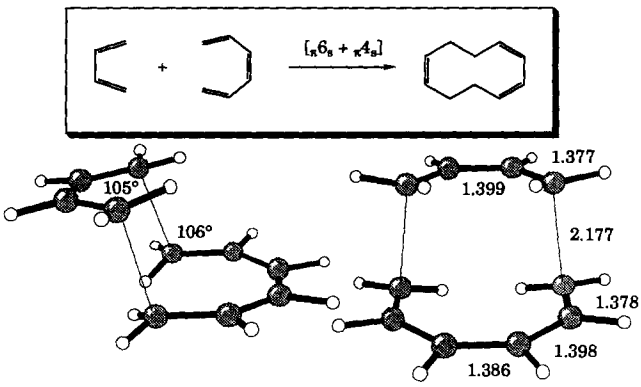

Fig. 49. The RHF/3-21G transition structure of $[\pi 6_s + \pi 4_s]$ cycloaddition between *cis*-hexatriene and butadiene (Y. Li).

For the [6 + 4] cycloaddition between cycloheptatriene and butadiene, both *endo* and *exo* transition structures have also been located (Fig. 50).[71] The *exo* transition structure is

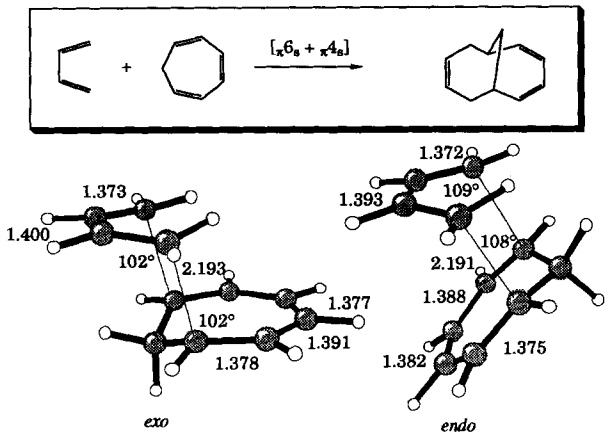

Fig. 50. The RHF/3-21G *exo* and *endo* transition structures of $[_{\pi}6_s + {}_{\pi}4_s]$ cycloaddition between cycloheptatriene and butadiene (Y. Li).

9 kcal mol^{-1} more stable than the *endo*, which may be attributed to the destabilization of the *endo* transition structure by both steric effects and secondary orbital interactions. A similar *exo* preference was found for the [6 + 4] cycloaddition of cyclopentadiene and tropone (Fig. 51).[71] The *exo* transition structure is 10 kcal mol^{-1} more stable than the *endo* stationary point which is, once again, not an authentic transition structure. This reaction has been observed experimentally to give exclusively the *exo* adduct,[128] as predicted by Woodward and Hoffmann.[2] All these transition structures have very similar forming C···C distances of about 2.2 Å.

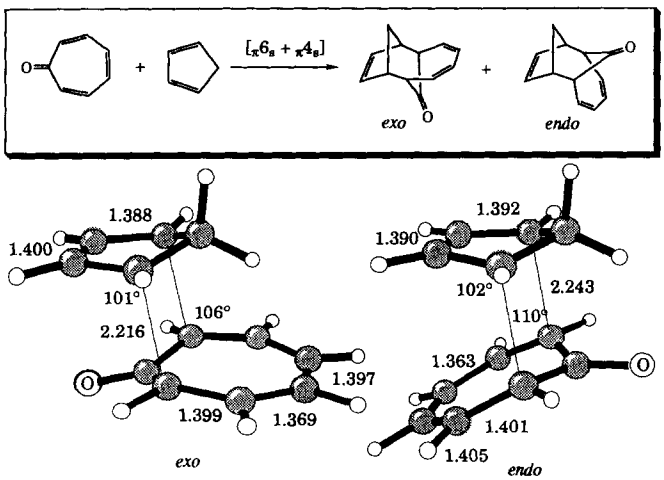

Fig. 51. The RHF/3-21G *exo* and *endo* transition structures of $[_{\pi}6_s + {}_{\pi}4_s]$ cycloaddition between tropone and cyclopentadiene (Y. Li).

4.7.4. [2 + 2 + 2] Cycloadditions

Although cyclotrimerizations are highly exothermic, such reactions are difficult because of unfavorable entropic factors and extremely high reaction barriers. Theoretical studies on the concerted cyclotrimerization of acetylene to benzene have been reported;[129] a very large reaction barrier is predicted. Transition structures have been located for the [2 + 2 + 2] cyclotrimerization of three molecules of acetylene (Fig. 52),[129b] and three molecules of ethene (Fig. 53). For

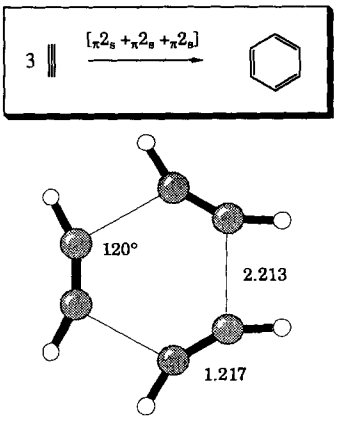

Fig. 52. The RHF/6-31G* transition structure of $[_{\pi}2_s + {}_{\pi}2_s + {}_{\pi}2_s]$ cyclotrimerization of acetylene [129b].

the highly exothermic [2 + 2 + 2] cycloadditions, transition structures are early, and the forming C···C bond lengths are 2.2–2.3 Å. These reactions have high intrinsic reaction barriers because of the necessity of disrupting the closed-shell nature of three molecules in the transition state.

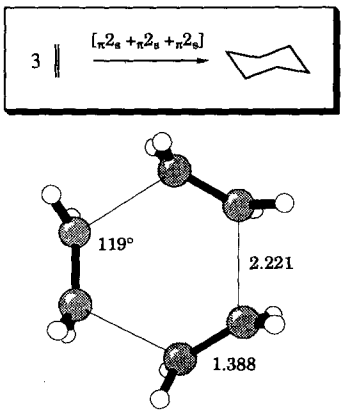

Fig. 53. The MP2/6-31G* transition structure of $[_{\pi}2_s + {}_{\pi}2_s + {}_{\pi}2_s]$ cyclotrimerization of ethene (Y. Li).

5. How Do Substituents Alter Transition Structures?

We have surveyed the hydrocarbon pericyclic reactions and have found a number of features which are common to them all. Substituents may have profound effects on the energies and geometries of the transition structures. In this section, two examples are described. The first case is an example of a reaction for which substituents induce very small changes in geometry, but have large effects of rates and stereoselectivities. This is typical for cases in which diradical alternative mechanisms are much less accessible than the concerted mechanisms, such as electrocyclic reactions and sigmatropic hydrogen shifts. The second example demonstrates a case where substituents alter both the geometry and energy of the transition structure. This will be the case when diradical and concerted mechanisms are close in energy, as in cycloadditions and sigmatropic carbon shifts.

5.1. Cyclobutene Ring Opening

Table 2 summarizes the activation energies of ring openings of a number of substituted cyclobutenes.[44] Also listed are the bond lengths of the breaking C···C bond in each of the transition structures. It is evident that the activation energies of ring openings of substituted cyclobutenes are influenced dramatically by the substituents, but the geometries of the transition structures change very little. Of particular note, a change in activation energy of nearly 20 kcal mol^{-1} is reflected in rather minor changes in geometry. The breaking C···C bond length, the most sensitive measure of geometry alteration, changes by only ± 0.02 Å for substituents at the 3-position rotating outward. Upon inward rotation, larger changes occur.

Table 2. The relative activation energies [kcal mol^{-1}] and lengths of the breaking C···C bond [Å] of transition structures for the substituted cyclobutene ring opening reactions (RHF/3-21G).

Substituent	$\Delta\Delta E^{\ddagger}$ [a]	$\Delta\Delta E^{\ddagger}$ [b]	C3-C4 [a]	C3-C4 [b]
3-NH_2	−11.5	6.0	2.128	2.227
3-OH	−8.8	8.4	2.125	2.181
3-F	−4.2	12.7	2.118	2.154
3-CH_3	−1.7	4.7	2.143	2.175
H	0.0	0.0	2.138	2.138
3-CN	−3.3	1.0	2.140	2.175
3-CHO	−3.6	−8.2	2.143	2.152
3-NO	−4.5	−7.1	2.119	2.129
1-OH	1.9		2.135	
1-F	0.9		2.159	
1-CH_3	1.9		2.145	
1-CHO	−1.1		2.157	

[a] For outward rotation of the substituents on C3 and C4. [b] For inward rotation of these substituents.

Amino and hydroxyl substituents both raise the activation energy substantially upon inward rotation. Repulsive interactions arise between the substituent and the remote terminus of the breaking bond, which cause the length of the breaking bond to increase by almost 0.1 Å and 0.05 Å, for NH_2 and OH, respectively. As shown in Figure 54, the transition structures for the outward and inward electrocyclic opening of 3-aminocyclobutene are nevertheless very similar to each other and to that for the ring opening of cyclobutene. The outward rotating amino group lowers the activation energy by 12 kcal mol^{-1}, while the inward rotating amino group raises the activation energy by 6 kcal mol^{-1}. In spite of the enormous 10^{13} difference in rate constants expected at room temperature for this 18 kcal mol^{-1} difference in activation energy, the geometries are changed very little.

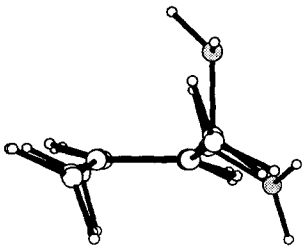

Fig. 54. Transition structures of 3-aminocyclobutene ring openings. The transition structures for the outward and inward rotation of the amino group are superimposed on the transition structure for cyclobutene opening. The nitrogen atom is shaded.

The origin of the stereoselective substituent effects for the ring opening of cyclobutene has been discussed at length.[44] Figure 55 summarizes the theory we have developed. In the

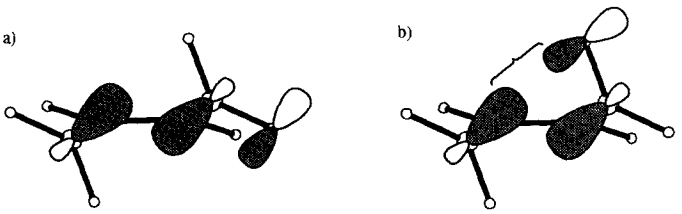

Fig. 55. Orbital interactions in the transition structures for outward (a) and inward (b) rotation of a substituent in cyclobutene ring opening reactions.

transition structure the σ bond is stretched and twisted and interacts weakly with the cyclobutene π bond. A lone pair or π orbital from an outwardly rotating substituent overlaps with the σ and σ* orbitals of the partially broken C···C bond. This overlap results in stabilization. Upon inward rotation, the substituent orbital overlaps not only with the σ and σ* orbitals at the terminus to which the substituent is attached, but also overlaps strongly with the other terminus. If the substituent orbital is doubly occupied, this results in strong destabilization, because a cyclic four-electron antiaromatic interaction occurs.

We have shown that the preference for outward rotation increases as the substituent becomes a more powerful donor. If the substituent is a powerful acceptor, then inward rotation is favored, because a cyclic two-electron interaction occurs. These stereoselective effects of the substituent dictate the direction of the conrotatory opening. Because this is related to the direction of twist, or torque, upon the breaking bond, we have called this type of stereoselectivity, "torquoselectivity".[130]

A substituent on the cyclobutene double bond has a much smaller effect on the activation energy of the reaction (see Table 2), since the π bond for which the substituent is attached interacts only slightly with the breaking σ bond in the transition structure.

5.2. Diels–Alder Reaction

Although the prototype Diels–Alder reaction has been studied extensively, there have been relatively few theoretical investigations of Diels–Alder reactions involving substituents. The transition structures of a series of Diels–Alder reactions have now been investigated.[126, 131, 132] Figure 56 compares the transition structures for the reactions between butadiene and ethene, acrylonitrile, 1,1-dicyanoethene, acrolein, and an adduct of acrolein and a model Lewis acid, BH_3. These were all obtained at the RHF/3-21G level, but many have been studied at higher levels as well.

The activation energies decrease by more than 14 kcal mol^{-1} from the prototype reaction to the acid-catalyzed example. There is a corresponding change from a synchronous reaction towards a diradical or zwitterionic species, where the formation of one bond is far advanced and of the other is in the initial stages. However, these calculations indicate

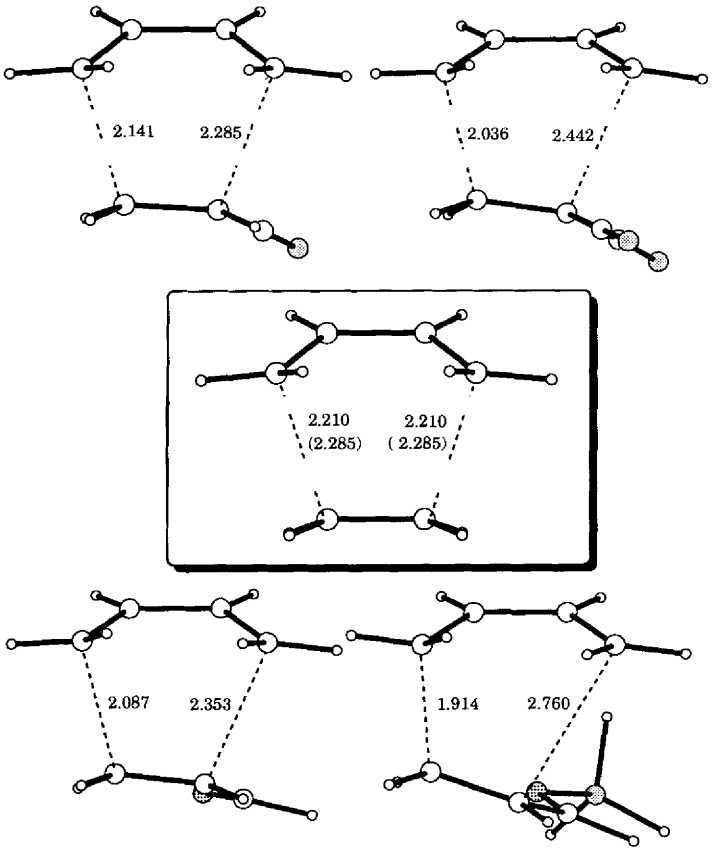

Fig. 56. Transition structures of Diels–Alder reactions between butadiene and acrylonitrile, 1,1-dicyanoethylene, acrolein, and acrolein catalyzed by BH_3. In the center the transition structure for the prototype reaction between butadiene and ethene is shown.

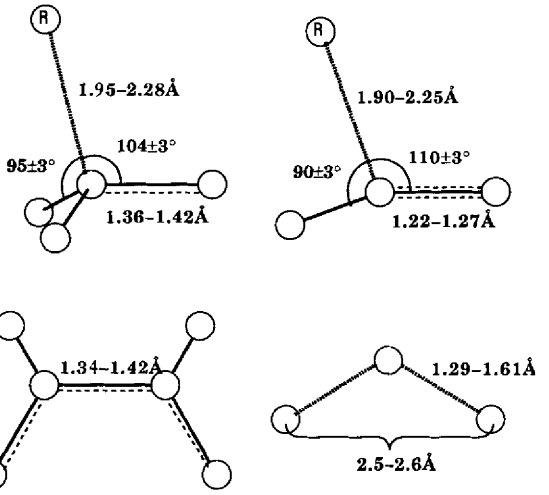

Fig. 57. Summary of geometrical features of transition structures in pericyclic reactions.

that each of these species are transition structures, not intermediates, in the gas phase. When the butadiene → acrolein reaction was studied with MP2/6-31G* geometry optimizations,[132] the asynchronicity of bond formation increased. The difference between the two forming bond lengths was 0.45 Å in this case. However, the species remains a transition structure, if a highly asynchronous one.[132]

In the noncatalyzed reactions the average forming C···C bond length remains nearly constant: the bond to the carbon atom bearing the substituent stretches, while the bond forming to the unsubstituted carbon atom contracts. Only in the Lewis acid catalyzed case, where appreciable charge separation occurs and essentially only one bond is forming in the transition state, is there deviation from this average bond length. The catalyzed reaction might become a stepwise process involving a zwitterion intermediate in solution because of considerable charge separation in the transition structure.

6. Generalizations About Transition Structures in Pericyclic Reactions

The transition structures for pericyclic reactions of hydrocarbons described in this article show remarkable constancy of structure. Figure 57 summarizes the structural fragments found in these reactions. Partially formed or broken C···C single-bond lengths range from 1.95–2.28 Å. This is a value about 50% longer than a normal single bond. This range of 0.3 Å is slightly wider than the range of lengths of single bonds observed experimentally in stable molecules.[133] This is shown graphically in the Figure 58. In transition structures, the partial double bonds range from 1.34–1.42 Å, which is almost double the range observed in aromatic bonds. In the few examples which we have studied theoretically, bonds intermediate between double and triple range in length from 1.22–1.27 Å. The range of partial C···H bond lengths is 1.29–1.61 Å. This is a fairly large range, but more

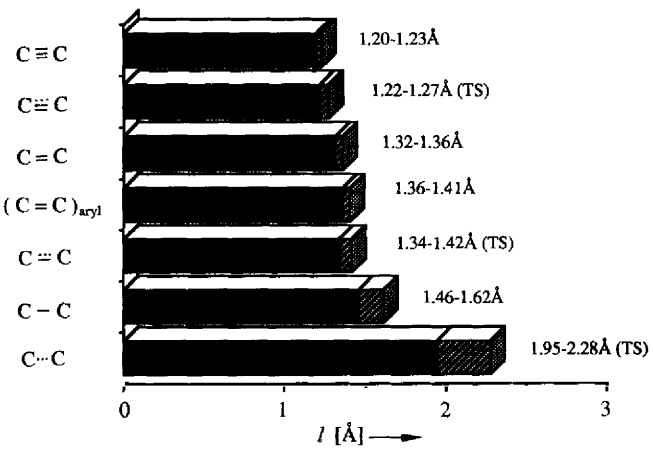

Fig. 58. Carbon–carbon bond-length ranges for normal molecules observed in X-ray structural analyses or calculated for transition structures (TS). Three dots indicate a partial σ bond.

predictable is the distance between the carbon atoms involved in the hydrogen transfer. These distances range from 2.5 to 2.6 Å in a variety of structures we have studied.

The bond angles also follow relatively simple generalizations. The attack on unsaturated linkages for the most part occurs in direction which is expected to lead to bonds in the products of addition—for example, around 109° on an alkene (to give a tetrahedral angle in the product) and in the vicinity of 120° on an alkyne. Since partial bonds are in-

volved, the degree of pyramidalization of sp^2 carbons or bending of sp carbons is intermediate between reactant and product geometries. In general, maximum bonding is maintained in all of these transition structures.

It is also notable that cyclic geometries, substituents, and the "earliness" or "lateness" of these transition structures do not have a large influence on transition-structure geometries. Consequently, we expect the transition structure of a wide variety of substituted molecules to conform to these generalizations.

6.2. Transition State Energies

Because pericyclic reactions include quite a range of reaction types, it might be supposed that the activation energies would vary very widely. While that is indeed the case, particularly for substituted molecules, there is nevertheless a large number of hydrocarbon pericyclic reactions which have experimental activation energies around 32–36 kcal mol^{-1}. A number of these, and a few heterocyclic reactions for comparison, are shown in Figure 59. There are, of course, other reactions that deviate from this generalization. The [2 + 2 + 2] cycloaddition of three ethenes, for which we predict an activation energy of 43 kcal mol^{-1}, and the methylene addition to ethene predicted to have no enthalpic barrier, are examples of large deviations. Substituents also have a large influence on reaction rates either by directly stabilizing or destabilizing the transition structure or by introducing strain into either the reactants or transition state. Nevertheless, many hydrocarbon pericyclic reactions do have activation energies around 32–36 kcal mol^{-1}. This is probably related to the fact that all of these reactions involve the breaking of π or σ bonds and simultaneous formation of partial bonds. The transition states of these reactions are found just at that point on the potential energy surface where the destabilization of the reactants arising from distortion away from the reactant geometries is overcome by stabilization arising from formation of new bonds.

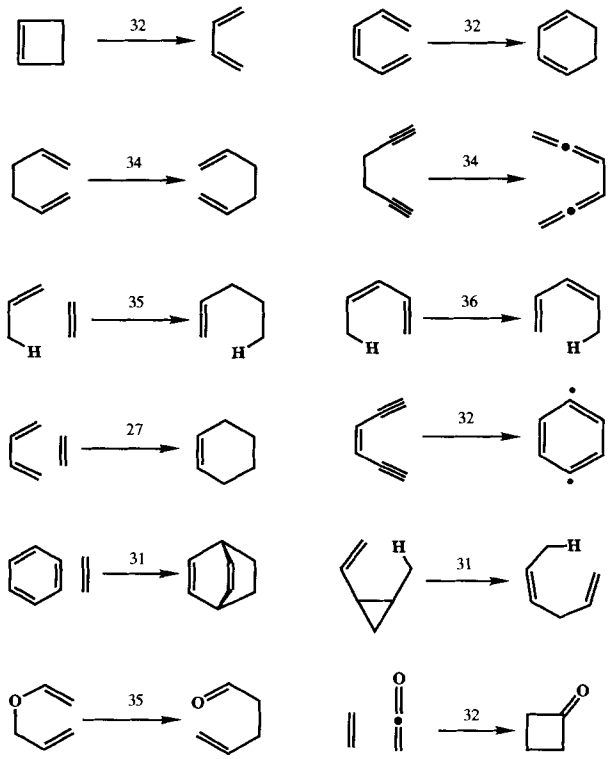

Fig. 59. Examples of pericyclic reactions with activation energies ranging from 31 to 36 kcal mol^{-1} as well as the Diels–Alder reaction prototype (between butadiene and ethene).

We dedicate this review to Professor Roald Hoffmann and to the memory of Robert Burns Woodward, whose brilliant insights created this field. We made the discoveries summarized here during the last decade in our laboratories at Pittsburgh and U.C.L.A. supported by a group of brilliant co-workers. In alphabetical order, they are David M. Birney, Kersey Black, Frank K. Brown, Pierluigi Caramella, Andrea E. Dorigo, Susan M. Ernst, Frank Jensen, E. Adam Kallel, Richard J. Loncharich, Jiri Mareda, Margaret McCarrick, Michael N. Paddon-Row, Nelson G. Rondan, David C. Spellmeyer, Joey W. Storer, Bert Thomas IV, Xuebao Wang, and Yun-dong Wu. Special mention should be made to Dr. Nelson Rondan (Dow Chemical) and Professor Michael Paddon-Row (University of New South Wales) who did the first calculations which inspired this review. We are very indebted to them for their essential contributions. Our thanks are due to the National Science Foundation and the National Institutes of Health for financial support of our research on pericyclic reactions. The calculations reported were made possible by the UCLA Office of Academic Computing and a joint study with the IBM Corporation, which supplied time on the IBM 3090/600J, and the National Science Foundation Supercomputer Centers at San Diego, Pittsburgh, Illinois, and Cornell. We also acknowledge the indispensable contributions of Professor John A. Pople and his group through their development of the GAUSSIAN programs.

Synthetic Bilayer Membranes: Molecular Design, Self-Organization, and Application

By Toyoki Kunitake*

Lipid bilayers are a most central building block of the biological molecular organization. Their two-dimensional self-assembly is essential to the generation of biological shapes and sizes on the molecular level. The observation that a totally synthetic amphiphile in water is spontaneously assembled to a bilayer structure suggested that bilayer formation is a general physicochemical phenomenon that is not restricted to particular structures of biolipid molecules. Bilayer formation is now observed for a large variety of synthetic amphiphiles which contain one, two, three, or four alkyl tails. The flexible alkyl tail may be replaced by perfluoroalkyl chains. The supramolecular structures obtained therefrom can be related to the component's molecular structure in many cases. The structural variety and the ease of molecular design make the synthetic bilayer an attractive vehicle for organizing covalently bound functional units and guest molecules. In addition, stable monolayers on water, planar lipid membranes (BLM), and free-standing cast films are obtainable because of the self-assembling property of bilayer-forming compounds. These molecular organizations display common supramolecular features. The use of the cast film as a molecular template provides exciting potential for the production of novel two-dimensional materials.

1. Introduction

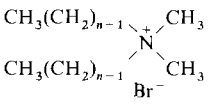
Biomembranes provide one of the most important structural units in the organization of the biological cell. In 1964 Bangham and Horne[1] demonstrated that the bilayer structure forms spontaneously from aqueous lipid dispersions, thus establishing that among the constituents of biomembranes, the lipid bilayer plays a most central role in maintaining biological molecular organization. Their discovery led to extensive research on biomembrane mimics and liposomes.

Attempts to prepare a bilayer assembly from amphiphilic compounds different from the natural lipid were conducted concurrently. For example, Gebicki and Hicks observed formation of globular aggregates ("Ufasome") when they dispersed thin films made of oleic acid and linoleic acid in water.[2] Hargreaves and Deamer[3] obtained vesicles by codispersion of fatty acids and higher alcohols. Vesicular aggregates have also been described for 1:1 mixtures of saturated fatty acids (C_{12} to C_{18}) and lysolecithin. However, these aggregates were not sufficiently stable and provided no definite evidence for the isolated bilayer structure.[**]

Many investigators have discussed reasons why some of the polar lipid molecules can form two-dimensionally aligned assemblies. For example, Brockerhoff interpreted the structural features of membrane lipids in terms of a tripartite structure: hydrophobic aliphatic double chain, hydrophilic head group, and the (hydrogen belt) region linking these two moieties.[4] Tanford proposed that bilayer formation can be accounted for by purely geometrical consideration of the volume of the hydrophobic core and the surface area occupied by the head group in membrane lipids.[5] Israelachvili, Mitchell, and Ninham[6] emphasized the role of molecular geometry in determining the structures of lipidic or amphiphilic assemblies and asserted that the packing constraint of a component molecule decided the surface curvature, that is, the morphology of resulting molecular aggregates.

These theories certainly explain the formation of bilayer membranes from biological lipids; however, they do not provide guiding rules that enable us to design novel bilayer-forming compounds.

When we set out to develop new bilayer-forming compounds in 1976, we assumed that the unique structure of the polar head group of biolipid molecules was determined by the biosynthetic and physiological requirements rather than by the physical chemistry of membrane formation. Our first candidates were, therefore, simple double-chain ammonium salts. Didodecyldimethylammonium bromide (**1**, $n = 12$)



1

gives a clear aqueous dispersion by sonication. When this dispersion was negatively stained by uranyl acetate and observed by electron microscopy, the formation of single- and multiwalled vesicles with a layer thickness of 30–50 Å was recognized (Fig. 1). Their aggregation characteristics such as critical aggregate concentration and molecular weight were consistent with a bilayer vesicle. This result was the first example of a totally synthetic bilayer membrane.[7]

The exceptional behavior of double-chain ammonium salts as aqueous dispersions has been noted many years ago. Ralston, Eggenberger, and DuBrow studied the aggregation behavior of these salts by conductometry and found an unusual dependence of the equivalent conductivities at low concentrations.[8] Kunieda and Shinoda prepared the phase

[**] Spontaneous vesicle formation in aqueous mixtures of cationic and anionic single-chain surfactants was described recently: E. W. Kaler, A. K. Murthy, B. E. Rodringuez, J. A. N. Zasadzinski, *Science* **1989**, *245*, 1371.

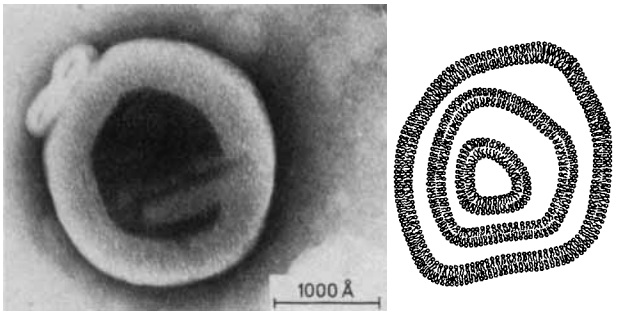

Fig. 1. Electron micrograph (left, negatively stained with UO_2^{2+}) and schematic illustration (right) of the multiwalled vesicle of **1** ($n = 12$).

diagram of these ammonium salts and indicated the transitions between molecular dispersion, liquid crystalline dispersion, and liquid crystal.[9] These dispersions were, however, never referred to as bilayer membranes.

It is important to make a distinction between liquid crystalline dispersions and bilayer membranes. As pointed out by Gray and Winsor,[10] it is the intermicellar forces—that is, the lattice forces—rather than forces from jointing or close packing which determine the viscosities and stabilities of the mesophases. In contrast, a bilayer membrane should be able to exist as an isolated entity without relying on the lattice forces for maintaining its structural integrity. The presence of lamellar multibilayer structures does not warrant the formation of bilayer membranes. We need to show the existence of isolated bilayer structures. The formation of bilayer membranes requires a self-assembling property greater than that of liquid crystalline dispersions.

In the following, we review the molecular design of bilayer-forming molecules, their aggregate morphologies, and some applications. Instead of attempting to prepare an exhaustive catalogue of those compounds, we present the design principle of component amphiphiles and the molecular organization they produce. The molecular design will be discussed in terms of the module concept given in Figure 2. This concept can cover most, if not all, of the types of bilayer-forming compounds. The functional aspects will be discussed only briefly in the last section.

Excellent reviews on various aspects of synthetic bilayer membranes have been published: Fendler prepared an extensive list of amphiphiles that are capable of bilayer formation (up to 1982);[11] routes to functional vesicle membranes have been discussed by Fuhrhop and Mathieu;[12] an extensive review on polymeric bilayer membranes was published by Ringsdorf, Schlarb, and Venzmer[13] in this journal. The last topic is, therefore, not discussed here.

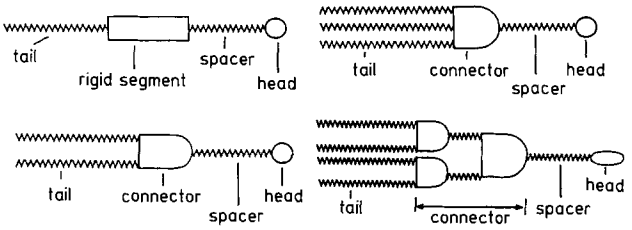

Fig. 2. Structual elements (modules) of bilayer-forming amphiphiles.

2. Bilayer Membranes of Double-Chain Amphiphiles

2.1. Molecular Design and Aggregation Behavior

Many double-chain amphiphiles have been synthesized as analogues of natural lecithin molecules, and their bilayer formation examined. The required molecular modules are tail, connector, spacer, and head groups.

Subsequent to our initial finding,[7] we conducted a systematic survey on the aggregation behavior of dialkylammonium salts with different tail lengths (Table 1).[14] All the

Toyoki Kunitake was born in 1936 in Kurume-shi, Fukuoka-ken, Japan. After completing his M.Sc. in the Faculty of Engineering at Kyushu University in 1960, he studied chemistry under C. C. Price at the University of Pennsylvania, graduating with a Ph.D. degree in 1962. He then spent a year as post-doctorate with C. G. Nieman at the Department of Chemistry, California Institute of Technology, before returning to Kyushu as Associate Professor in 1963. He was promoted to Professor in the Faculty of Engineering in 1974. Besides the field of synthetic bilayer membranes his research interests cover ultrathin films and Langmuir–Blodgett films, surface monolayers, and supramolecular aggregates.

double-chain compounds give colloidal solutions by sonication, and the molecular (aggregate) weights determined by light scattering lie between 10^6 and 10^7. Electron microscopy indicates the presence of vesicles (Fig. 1) and lamellae (Fig. 3), when both alkyl chains are at least ten carbon atoms long. Their layer thicknesses are 30–40 Å, in agreement with

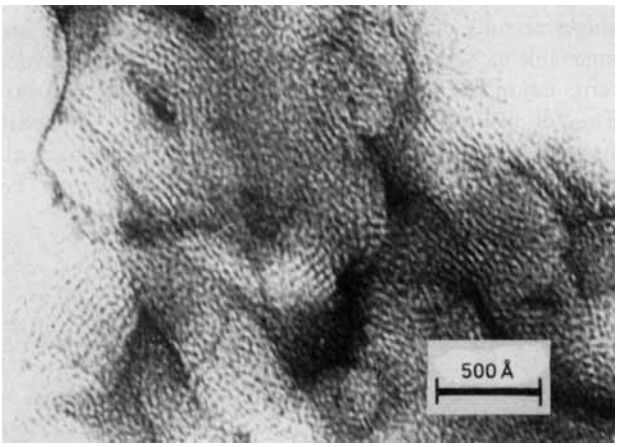

Fig. 3. Electron micrograph (negatively stained with UO_2^{2+}) of lamellar bilayers of **1** ($n = 14$).

the bilayer assemblage. Detection of the gel → liquid crystal phase transition by differential scanning calorimetry (see Section 2.3) strongly suggests the presence of aligned alkyl chains in the aggregate. These ammonium bilayers were extensively characterized.[15–18] The aggregate morphology is naturally affected by the method of dispersion.[17] Carmona-Ribeiro and Chaimovitch reported that large unilamellar vesicles (diameter, 0.5 μm) were obtainable by the solvent vaporization method.[19]

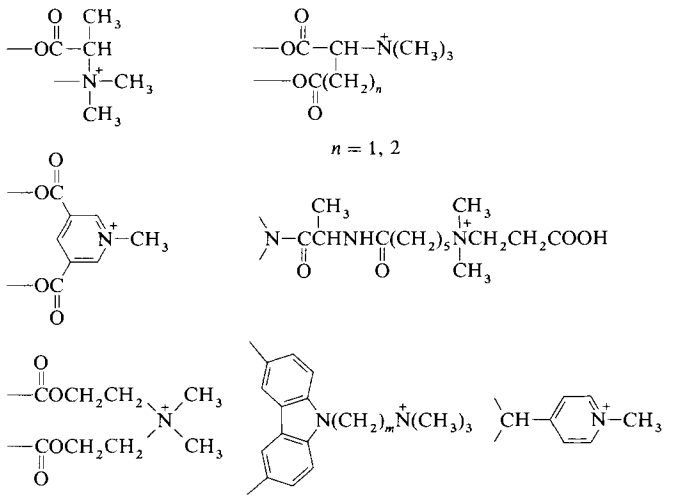

Fig. 4. Connectors of double-chain ammonium amphiphiles [21–25].

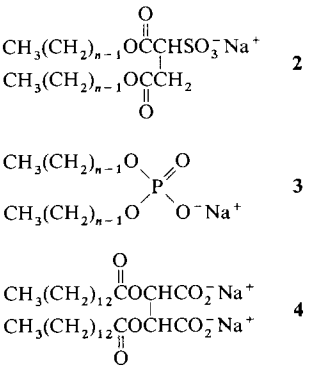
The dimethylammonium head can be modified by other substituents or replaced by the sulfonium group.[20] The connector portion that links the hydrophobic alkyl chains and the hydrophilic head group can be varied (Fig. 4). The major function of this unit is to help promote alignment of the alkyl chains. In the dialkyldimethylammonium salts of Table 1, the ammonium head group is directly bonded to alkyl tails without spacer units. A spacer unit that intervenes between the head group and the connector unit exerts significant influence on the molecular orientation in the bilayer. As discussed in Section 6, the length of the methylene chain functioning as spacer is critical in formation of helical superstructures.

Double-chain amphiphiles with anionic head groups form bilayer membranes. Examples with sulfonate (**2**), phosphate (**3**), and carboxylate (**4**) head groups are given in Table 2.[26]



Stable bilayer membranes are formed again when the alkyl chain contains more than ten carbon atoms. The presence of vesicles and lamellae is confirmed by electron microscopy, and their molecular weights are 10^6–10^7. Mortara et al.[27] similarly noted vesicle formation from dihexadecyl phosphate at an early stage in this research.

Table 2. Aggregation behavior of anionic, dialkyl amphiphiles [26] [a].

Compound	Solution	Electron Micrograph	M	T_c [°C]
2 ($n = 16$)	colloidal	lamella	–	45
2 ($n = 12$)	colloidal	large vesicle	2.2×10^7	28
2 ($n = 10$)	clear	large vesicle	1.9×10^6	
3 ($n = 16$)	colloidal	lamella	1.2×10^7	67
3 ($n = 12$)	colloidal	vesicle	2×10^7	33
3 ($n = 10$)	clear	vesicle	4.4×10^6	
4 ($m = 13$)	slightly turbid	vesicle		

[a] See footnotes to Table 1.

The oxyethylene oligomer is conveniently used for preparing nonionic, bilayer-forming compounds.[28] The aggregation behavior of these compounds is summarized in Table 3 for **5** and **6**. In the case of **5** ($n = 8$), bilayer formation is not detected and the molecular weight of the aggregates (ca. 10^5) is smaller than those for typical bilayer aggregates ($> 10^6$).

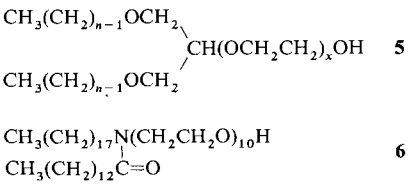


Table 3. Aggregation behavior of nonionic amphiphiles [28] [a].

Compound (n, x)	cmc [b] [μ M]	Electron Micrograph	M	T_c [°C]
5 (8, 6)		unstructured	5×10^5	
5 (8, 10)	50	unstructured	4×10^5

The longer chain analogues **5** (n = 12) and **5** (n = 16) produce bilayer aggregates which exhibit different morphologies. For instance, **5** (12, 15) gives single-compartment vesicles, whereas **5** (16, 15) produces paired bilayers (Fig. 5).

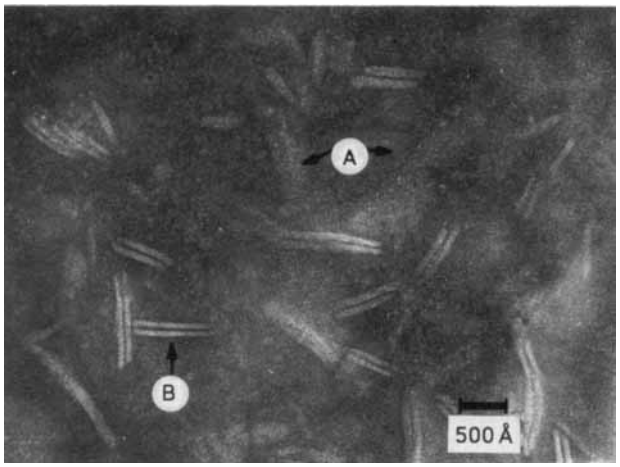

Fig. 5. Electron micrograph of an aqueous dispersion of **5** (16, 15). A top view (arrow A), and a side view (arrow B) of paired bilayers.

Zwitterionic groups such as **7**, **8**, **9**, and **10** were also used as the head group of double-chain amphiphiles.[23, 28]

2.2. Molecular Alignment in Bilayer Assemblage

The detailed molecular arrangement in some of the synthetic bilayers mentioned above has been elucidated by X-ray crystallography. Kajiyama et al.[29] estimated the bilayer thickness of a series of simple double-chain ammonium amphiphiles **1** from widths between dark striations in electron micrographs of negatively stained samples. They also determined the layer thickness of powder samples. Comparisons of these data with the molecular lengths suggested that the component molecules were tilted with respect to the bilayer surface by 32 to 47° depending on the alkyl chain length.

Okuyama et al. succeeded for the first time in preparing single crystals of a synthetic bilayer compound that are amenable to X-ray structural analysis.[30] The structure determination has been conducted for **1** (n = 14, 16, and 18). They all give intrinsically identical structures,[31, 32] apart from the chain length. As an example, the packing structure of the monohydrate of **1** (n = 18) is given in Figure 6. The

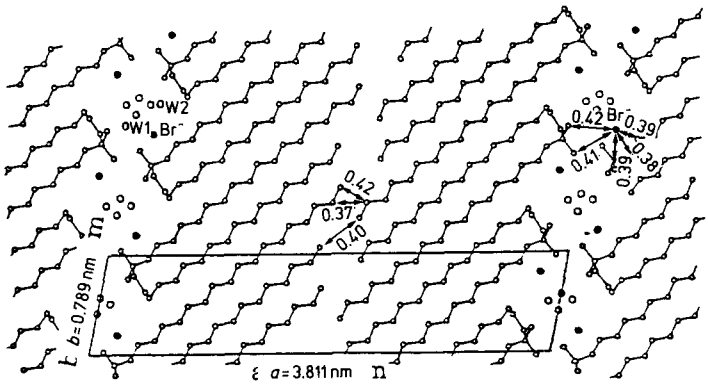

Fig. 6. The packing structure of a single crystal of the monohydrate of **1** (n = 18).

most important aspects in this structure are as follows: a) Br^- and N^+ centers form a hydrophilic plane parallel to the bilayer surface; b) the component molecules are tilted by 45° relative to the bilayer surface; c) one of the octadecyl chains assumes the *trans* zigzag conformation, whereas the other chain shows a folded conformation (*ggtgg*) near the hydrophilic group and the *trans* zigzag conformation towards the alkyl chain end. The chain tilting is caused by the balance between the molecular cross-sections of the hydrophobic portion (40 Å^2 for two methylene chains) and the hydrophilic portion (57 Å^2 for the *bc* plane of the unit lattice). This packing structure is very similar to that found for phosphatidylcholine.[11] The tilt structure was always found for double-chain amphiphiles with the glutamate connector.[33, 114] It is noteworthy that the ammonium amphiphile with two identical chains assumes the unsymmetrical chain packing. This seems to be a common requirement of chain packing among double-chain amphiphiles in order to attain the two-dimensionality.

2.3. Phase Transition and Phase Separation

Phase transition and phase separation are the two, most fundamental properties related to bilayer assemblage. Phase transition is schematically illustrated in Figure 7.

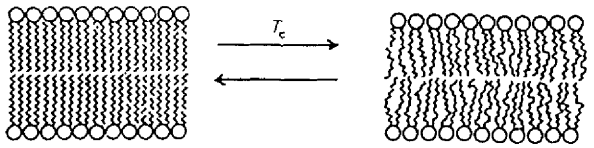

Fig. 7. A schematic illustration of the phase transition, crystalline $\rightleftharpoons$ liquid crystalline at the phase transition temperature T_c.

One of the simplest bilayer-forming amphiphiles, **1** ($n = 18$) shows a remarkably complex phase behavior.[9, 34] We are interested here only in dilute dispersions. The gel→liquid crystal phase transition is commonly observed for dilute aqueous dispersions of double-chain amphiphiles. Figure 8 depicts DSC (differential scanning calorimetry) thermograms for aqueous dispersions of **1** ($n = 12$, 14, 16, 18, and 22). The phase transition temperature, T_c, increases with increasing lengths of the alkyl tail. Many of the bilayer dispersions prepared by sonication give broader DSC peaks. The molecular organization in these well-dispersed samples may not be uniform. In contrast, DSC samples frozen to $-50\,^{\circ}C$ give sharper single peaks, probably because more regular, multilamellar dispersions are formed.

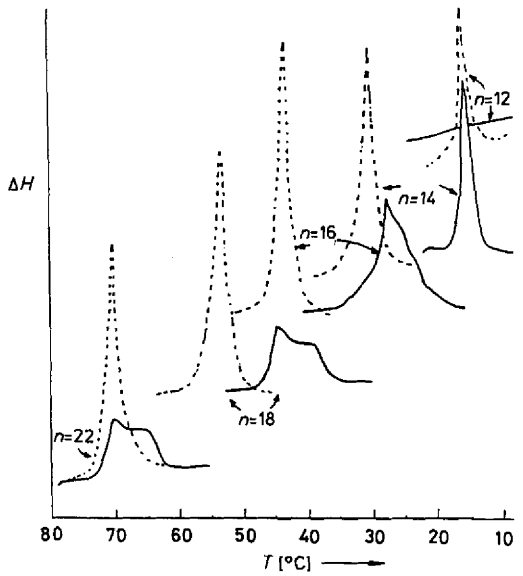

Fig. 8. DSC curves of bilayers of 1–2 wt% of **1** in water. — Samples prepared by the sonication method; - - - samples prepared by the dispersion method or the freezing method.

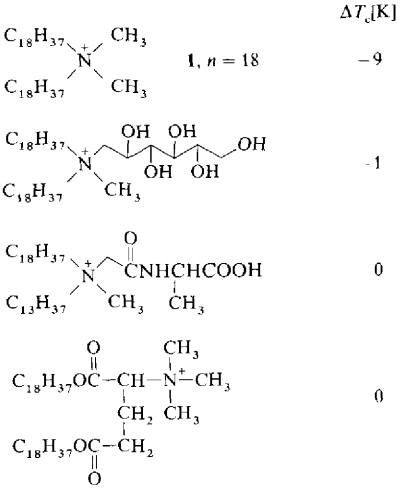
These data are consistent with the phase transition ranges estimated by other methods: reaction rates in the bilayer matrix, NMR line broadening of the crystalline bilayer, fluorescence spectral changes of probe molecules, turbidity changes, and the extent of positron annihilation.[35] The difference in T_c between the sonicated and frozen samples depends on the molecular structure of the component amphiphile, as shown in Scheme 1. In the case of the simple dimethyldioctadecylammonium amphiphile, **1** ($n = 18$), the sonicated sample has a T_c 9 °C lower than the frozen sample. In other dioctadecylammonium amphiphiles, which possess more complex head and/or connector groups, the differences are much smaller. Uniform bilayer organizations appear to be maintained when hydrogen bonding and/or dipolar interaction are expected between component molecules.



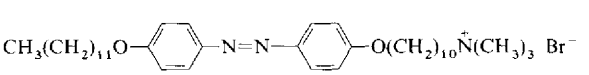
Scheme 1. Difference in T_c of aqueous dispersions of double-chain amphiphiles generated by sonication or freezing.

We compiled DSC date (T_c, enthalpy and entropy change) for the whole family of bilayer-forming, double-chain amphiphiles.[36, 37] The design of a novel bilayer with desired phase transition behavior is now possible. The correlations between this behavior and molecular structure are summarized as follows:

1) The entropy change of the phase transition falls within the range of $60-220\ J\,K^{-1}mol^{-1}$ for stable bilayers of all double-chain amphiphiles including natural lipids. This indicates that all phase transition processes are closely related (chain melting).

2) The variation of the DSC data can be discussed in terms of the structural element of component amphiphiles: a) T_c, ΔH, and ΔS values increase with increasing lengths of tails and spacers, except when diethanolamine is connector; b) enhanced interactions among connectors raise T_c values. However, the corresponding changes in ΔS are not straightforward; c) head-group interactions (electrostatic and/or hydrogen bonding) raise T_c. When the interaction is not very strong, the DSC data (T_c, ΔH and ΔS) for bilayers of different surface charges (cationic, anionic, and neutral) does not vary. Bulky substituents at the head group cause T_c lowering; d) the presence of flexible units (ether and ester) either in the tail or in the spacer leads to T_c lowering. A *cis* double bond (as in the oleoyl group) has the same effect.

Phase separation of synthetic bilayer membranes has been detected by the presence of the component peak in DSC, by λ_{max} shifts in absorption spectroscopy, and by excimer emission in fluorescence spectroscopy. An example of the absorption spectral method is shown in Figure 9.[38] Azobenzene-



11

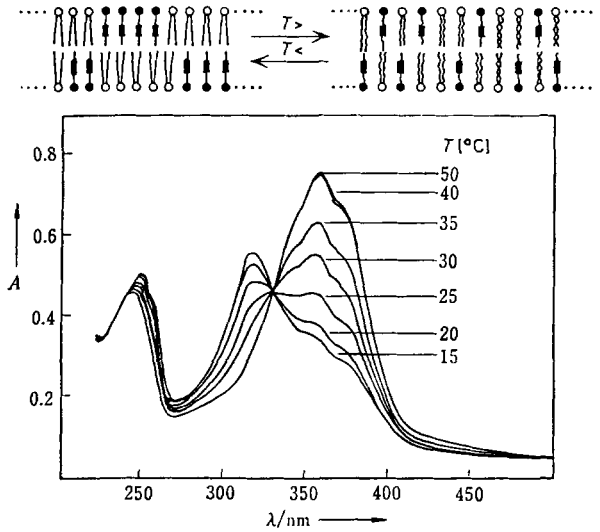


Fig. 9. Spectral changes in the absorption spectrum as a result of phase separation in a 1:10 mixed bilayer of **11** and **1** ($n = 18$).

containing bilayers give large spectral shifts caused by relative orientation and stacking of the azobenzene units (see Section 3.2). A 1:10 mixed dispersion of azobenzene-containing amphiphile **11** and dialkyldimethylammonium amphiphile **1** ($n = 18$) shows λ_{max} at 355 nm in the high-temperature region, indicating the presence of the isolated azobenzene species. By lowering the temperature, a new peak due to formation of the clustered azobenzene component appears at 315 nm. The spectral change corresponds to the phase transition of the matrix bilayer. This property has been exploited in novel applications of bilayers such as detection of chemical signals[39] and control of chemical reactions.[40]

The limited miscibility of hydrocarbons and fluorocarbons is used for controlled formation of separate domains, as will be discussed in Section 5.

2.4. Bilayer Morphology

Bilayer membranes dispersed in water give in many cases vesicular and lamellar morphologies. Unusual morphologies like the paired leaflet of Figure 5 are also noted. Nonbilayer aggregates have been described for phospholipids.[41] Similarly, Murakami et al. reported that there were interconversions between bilayer and nonbilayer morphologies.[42, 43] In contrast to the charged lipids **12** and **13**, which form typical vesicles and lamellae, their nonionic counterpart **14** is dispersed as nonlamellar network aggregates in the neutral pH range (Fig. 10), but is transformed into multilamellar vesicles in the deprotonated form. Addition of cationic **12** also transforms the nonlamellar aggregate into vesicles. An equimolar mixture of the cationic and anionic amphiphiles leads to nonlamellar networks with repeating distances of 70 and 130 Å in the liquid crystalline temperature region. Small-angle X-ray diffraction suggested the formation of a face-centered cubic lattice.[44]

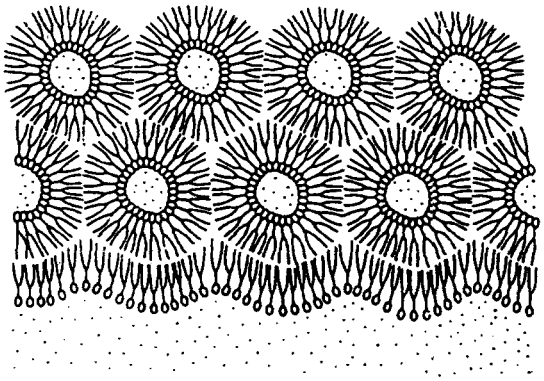

Fig. 10. Nonlamellar network aggregates of the neutral form of **14** [43].

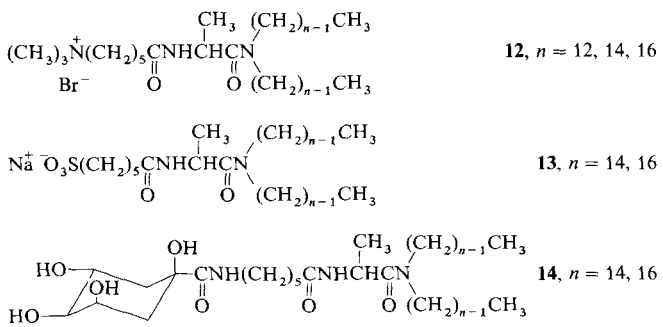
Dynamic morphological changes are intrinsic to many physiological functions of the biological cell. The corresponding study on synthetic bilayer membranes is limited. Rupert et al. examined the ability of vesicles of **1** ($n = 12$) to undergo fusion.[45, 46] They found that dianions such as dipicolinate promoted fusion of vesicles with a diameter of at least 3000 Å, whereas smaller vesicles did not readily fuse despite their aggregation. The fusion was facile when the vesicles were in an overall fluid state. This research group also showed that the lamellar to hexagonal II phase transition proceeded by Ca^{2+}-induced fusion of didodecyl phosphate vesicles.[47] Salt-induced aggregation of dimethyldioctadecylammonium chloride and sodium dihexadecyl phosphate vesicles has been discussed by Carmina-Ribeiro and Chaimovitch.[48]

Optical microscopy is convenient for real-time observation of the morphology change. Evans et al. used video-enhanced contrast-differential interference contrast microscopy to observe dynamic changes of aggregate morphologies of simple double-chain ammonium amphiphiles (**1**, $n = 12$).[49] H. Hotani showed a few years ago that dark-field optical microscopy was particularly advantageous for studying the finer details of biological structures.[50] These investigations confirmed that several transformation pathways existed for various morphologies of liposomes: biconcave, elliptical, regular polygonal, etc.

We applied this technique to examine the morphology of **1** ($n = 12$).[51] The dynamic changes observed are remarkably similar to those of the phospholipids mentioned above. For example, a tubule attached to a vesicle is elongated with time while the vesicle shrinks (Fig. 11 a). A vesicle with protuberance, is converted into a spherical vesicle via an irregular intermediate (Fig. 11 b), and a tadpole and a tripod interconvert (Fig. 11 c). Electron microscopy of freeze-fracture replicas of this dispersion shows that elongated tubules branch



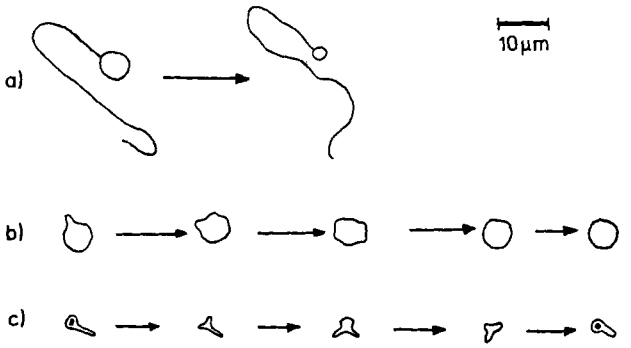


Fig. 11. Schematic illustration of morphological transformation of an aqueous dispersion of **1** ($n = 12$).

into smaller tubules and fibers, which, in turn, are transformed into trains of very small vesicles (diameter, 300–400 Å). The dark-field optical microscopy was further em-

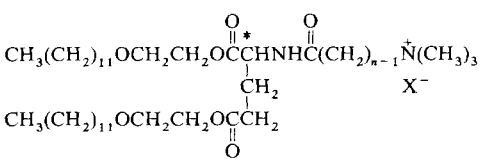
ployed for observation of Myelin figures and double-helical fibers of bilayers of double-chain ammonium amphiphile **15** (Fig. 12)[52] The latter morphology was observed for egg-yolk lecithin.



15, $n = 2$ (X = Cl), 11 (X = Br)

3. Bilayer Membranes of Single-Chain Amphiphiles

3.1. Molecular Design

Attachment of two alkyl chains, instead of one, to a single head group should enhance molcular orientation in aggregates because their conformational mobility is restricted. The larger liquid crystalline region in the phase diagram of double-chain amphiphiles compared with that of single-chain counterparts is consistent with this view. If this were the case, stable bilayer membranes would be produced even from single-chain amphiphiles whose conformations are restricted by incorporation of rigid segments or by intermolecular interactions.

Figure 13 illustrates a design principle of a bilayer-forming, single-chain amphiphile. A conventional liquid crys-

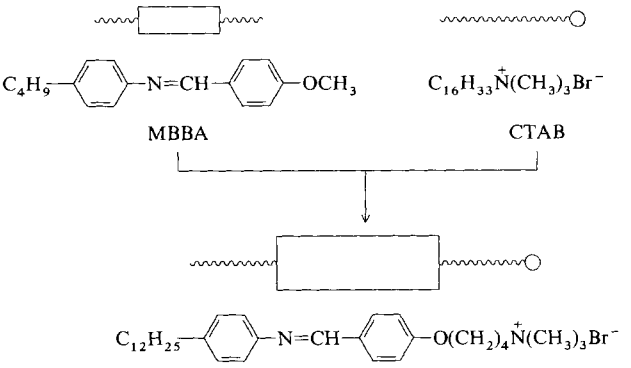


Fig. 13. Design of a single-chain bilayer component by combining the structural features of a compound capable of a liquid crystal transition (MBBA) and a tenside (CTAB).

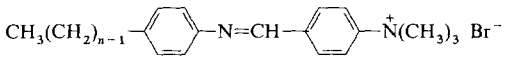
talline material, MBBA, contains a rigid Schiff base unit connected to a flexible alkyl chain. A micelle-forming surfactant, CTAB, contains a trimethylammonium head group and a hexadecyl chain. The combination of the structural features of these two compounds results in a novel amphiphile that should form aqueous aggregates with a molecular orientation better than that of the conventional micelle. It contains a hydrophilic head, a spacer, a rigid segment, and a flexible tail as structural modules.

Within this structural framework (as in **16** and **17**), the lengths of the methylene chain of the spacer and of the hydrocarbon tails were varied, and their aggregation behavior examined (Table 4).[53] Molecular aggregation detected by



16, $n = 0, 4, 7, 12$

17, $n = 0, 4, 7, 12$, $m = 4, 10$

surface tension measurements occurs at concentrations of 10^{-4}–10^{-5} M except for **16** ($n = 0$) and **17**(0, 10), which did not show any appreciable lowering of surface tension. The critical aggregate concentration is lowered by lengthening of the hydrocarbon tail (C_n portion), but is affected little by the length of the intervening methylene group (C_m portion). The critical aggregate concentrations for **16** ($n = 4$) and **17** (4, 10) lie in the common range of $(2-3) \times 10^{-4}$ M. The critical

aggregate concentration for **16** ($n = 12$) contrasts sharply with that of **17** (0, 10) or **17** (4, 10). In terms of the hydrophile–lipophile balance, these compounds should show similar results. Since this is not so, the location of the rigid segment must determine, to a large extent, the tendency of these amphiphiles to align at the air–water interface.

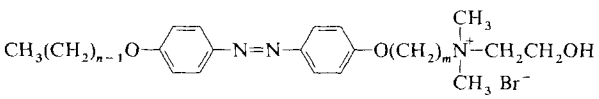
Table 4. Aggregate behavior of single-chain amphiphiles.

Amphiphile	n	m	cmc [a] [mM]	M [b]	Electron Micrograph
	0		>10	$<10^4$	unstructured
16	4		0.22	1×10^5	unstructured
	7		0.06	8×10^6	lamella
	12		0.01	4×10^6	vesicle and lamella
	4,	4	0.16	8×10^6	unstructured
	7,	4	0.01	2×10^7	lamella
	12,	4	0.01	4×10^6	vesicle
17	0,	10	>10	4×10^6	unstructured
	4,	10	0.33	6×10^6	unstructured
	7,	10	0.02	2×10^7	vesicle
	12,	10	0.01	1×10^7	lamella

[a] Critical aggregate concentration. [b] Molecular weight determined by light scattering.

The average molecular weight of most of the aggregates is 10^6–10^7. Therefore, the average aggregation numbers are in the range of 10^3–10^5. The electron microscopic observation establishes the structural requirement for the formation of a stable bilayer. The development of the bilayer structure is improved with increasing chain lengths of the flexible tail (C_n portion), the minimal chain length being probably between $n = 7$ and $n = 4$. It is worthy of emphasis that **16** ($n = 4$) and **17** (4, 10) fail to form well-organized assemblies in spite of their formation of very large aggregates. A certain tail length is required for an amphiphile to align in aqueous aggregates as well as at the air-water interface.

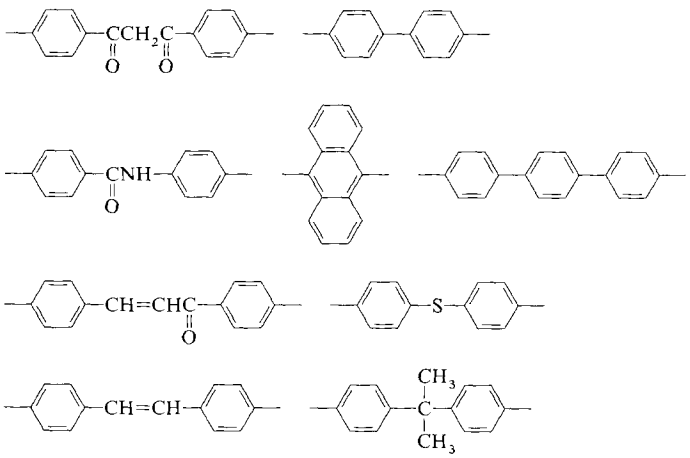
A systematic variation of lengths of flexible tail and spacer was also conducted for azobenzene-containing, single-chain amphiphiles **18**.[54] Among the total of 21 compounds, the



18

formation of stable bilayer membranes as judged by three criteria was concluded for the following combinations of tail length n and spacer length m: $n = 12/m = 2$–$12/n = 10$, $m = 5$–$10/n = 8$, $m = 10$. These results indicate that the tail length is more critical than the spacer length in bilayer formation.

The subsequent studies on molecular design of the single-chain amphiphile established that the kind of head group could be varied as much as those of the double-chain counterpart (cationic, anionic, nonionic, and zwitterionic)[55, 56] and that the rigid segment is extensively variable[57, 58] (Scheme 2). An extensive list of this class of single-chain compounds was compiled.[59] Cho et al. recently reported that an ammonium derivative of cholesterol formed bilayer



Scheme 2. Examples of rigid segments for single-chain bilayer-forming amphiphiles. For more examples see Scheme 3.

vesicles.[60] It has to be noted that „the rigid segment" implies the structural unit which promotes molecular alignment by intermolecular stacking and other intermolecular interactions. The aromatic „rigid segment" of Scheme 2 promotes intermolecular stacking. The molecular alignment can be improved in single-chain ammonium amphiphiles by strong hydrogen-bonding capability.[61]

3.2. Molecular Orientation within the Bilayer

A systematic structural variation of single-chain amphiphiles indicated that a certain length of the flexible tail was required for bilayer formation. The role of the spacer methylene chain, in contrast, was not clear. The crucial influence of the spacer length on bilayer assembly was first clarified in relation to absorption spectra of the azobenzene bilayer of **18**. Figure 14 shows representative spectral variations which depend on the molecular structure. All the bi-

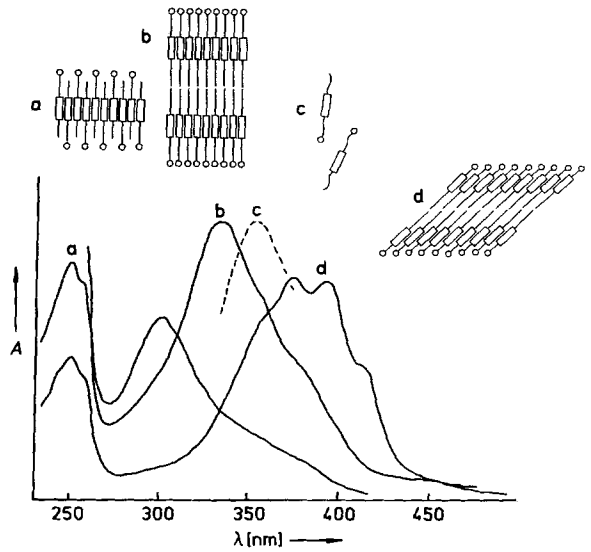


Fig. 14. Absorption spectra and the packing modes of bilayers of **18** (n, m). a) $n = 8$, $m = 10$; H-aggregate; b) $n = 12$, $m = 10$; c) absorption of monomeric azobenzene derivatives; d) $n = 12$, $m = 5$, J-aggregate.

layer components contain the identical azobenzene chromophore, yet their spectral patterns are quite different. λ_{max} covers a wide range from 300 nm for **18** (8, 10) to 390 nm for **18** (12, 5). The observed λ_{max} variation needs to be explained in terms of the chromophore interaction (orientation and aggregation) in the aggregate. According to the molecular exciton model of Kasha,[62] the blue shift for the bilayer of **18** (8, 10) relative to the absorption of the isolated chromophore (λ_{max} 355 nm) results from a parallel orientation of the neighboring transition dipoles (the H-aggregate, Fig. 14a), and a red shift for the bilayer of **18** (12, 5) is attributable to the tilted chromophore orientation (the *J*-like aggregate, Fig. 14d). The other bilayers of **18** (10, 4), **18** (12, 10), and **18** (12, 6) apparently have intermediate orientations (Fig. 14b).

The interdigitated bilayer structure was first proposed for the bilayer of **18** (8, 10) on inspection of the X-ray diffraction of its cast multibilayer film.[63] More recently, Okuyama and co-workers determined its structure from a single crystal (Fig.15).[64] The parallel azobenzene packing is appropriate

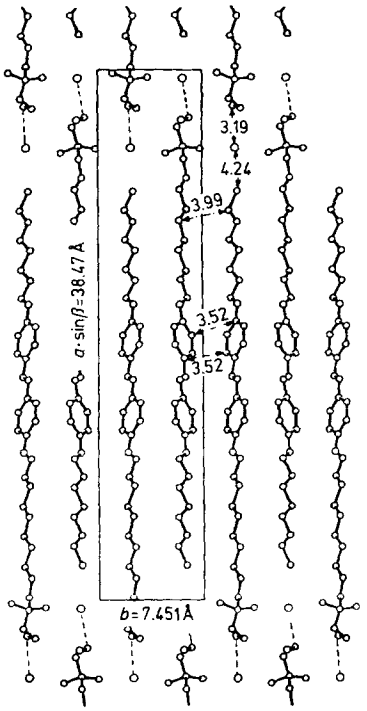

Fig. 15. The packing structure of a single crystal of **18** (8, 10).

for its particular molecular structure, since the cross section of the ammonium head group is about twice the cross section of the hydrophobic portion and the lengths of spacer and tail are very similar.

The crystal structure of the bilayer of **18** (12, 5) is shown in Figure 16.[65] A typical bilayer structure is formed. The tilt angle of the molecular axis from the layer normal amounts to 62°. This inclination is required in the bilayer assemblage in order to match the cross sections of the head group and the hydrophobic chain. The J-aggregate formation inferred from the spectroscopic data is consistent with the crystal structure. The spacer length of $m = 5$ appears essential for the tilted packing, because analogous tilted arrangements are observed for the bilayers with the common $m = 5$ spacer and different tail lengths of $n = 6$, 8, and 10.[66, 67]

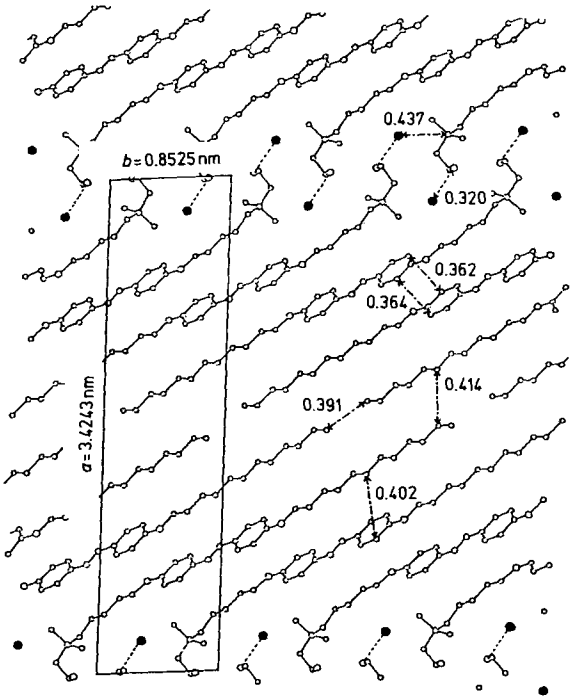

Fig. 16. The packing structure of a single crystal of **18** (12, 5).

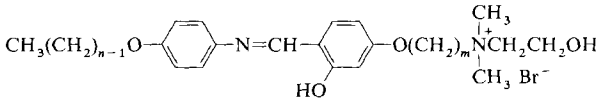
X-ray photoelectron spectroscopy (XPS) is also useful for estimation of the molecular packing in single crystals. Nakayama et al.[68] examined the N_{1S} spectrum of a single crystal of **18** (12, 5). The calculated intensity ratio of the azobenzene nitrogen center to the ammonium nitrogen center agreed with the experimental pattern if the molecular axis was assumed to incline ca. 60° to the bilayer normal at the outermost surface of the crystal. This inclination is in close agreement with that determined by X-ray diffraction.

The variation of the molecular alignment with methylene chain lengths is not restricted to bilayers of azobenzene derivatives. Partially interdigitated structures were proposed for **16** ($n = 10$, 12, 14).[69] We very recently prepared a series of single-chain amphiphiles **19** which contain the σ-hydroxydiphenylazomethine unit as rigid segment.[70] The spectral shifts in the absorption spectrum and the layer thickness



19:(n, m) = (8, 10), (12, 5), (12, 10)

determined by X-ray diffraction of cast films indicated that the effect of alkyl chain lengths on the molecular packing is virtually identical with those of the azobenzene-containing bilayer.

3.3. Morphology of Bilayers

Single-chain amphiphiles form bilayer vesicles and lamellae, similar to those of double-chain amphiphiles. The rigid segment in these amphiphiles promotes regular molecular orientation. The effect of the chemical structure of the rigid segment on aggregate morphologies has been studied systematically for a series of single-chain ammonium amphiphiles.[57] Electron microscopy indicates the formation of aqueous aggregates with various morphologies: the representative cases are globule, vesicle, lamella, rod, tube, and disk (Fig. 17). These morphologies can be explained as arising from different characteristics of the rigid segment, as summarized in Scheme 3. When the rigid segment is biphenyl or azobenzene, globular aggregates (probably collections of small bilayer fragments) are formed. The diphenylazomethine group is structurally similar to the azobenzene group, but their behavior as rigid segment is quite different. The amphiphile with a diphenylazomethine rigid segment produces much better developed bilayer membranes as a result of the dipolar interaction between the diphenylazomethine groups. In the case of the symmetrical rigid segments (biphenyl and azobenzene), the extensive organization appears less favored.

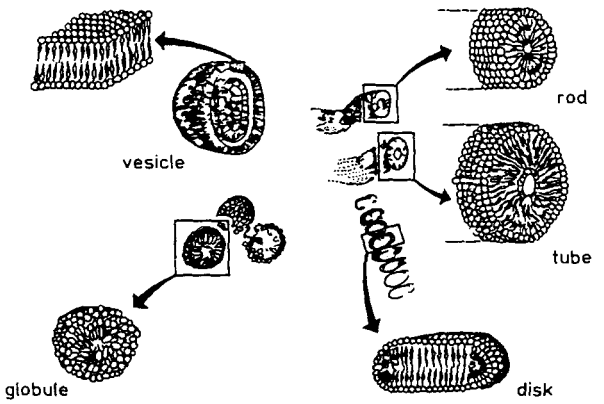


Fig. 17. Aggregate morphologies of single-chain amphiphiles.

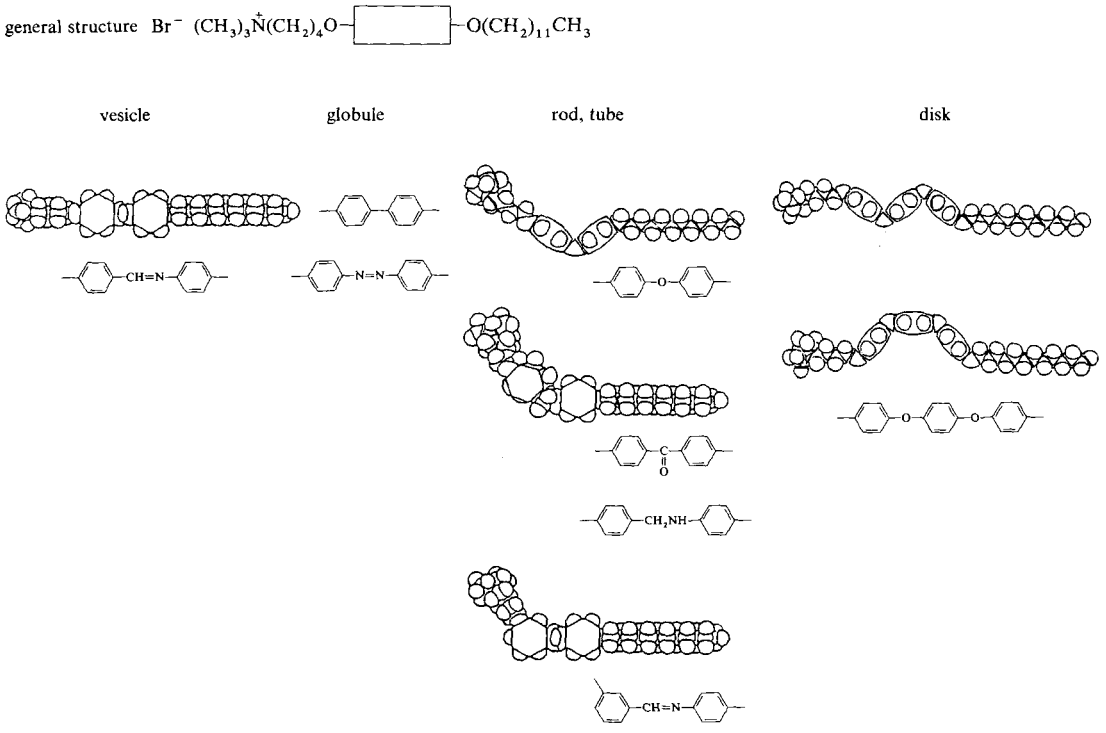
A structural feature common to the third group of single-chain ammonium amphiphiles is that they contain bent rigid segments. The bending is either due to single-atom connection of two benzene rings, to rotation of the single bond, or to *meta* substitution. The contrasting behavior of the straight and bent ammonium amphiphiles is interesting. The straight molecules tend to assemble in a neat, two-dimensional arrangement (membrane), but the bent molecules give rise to curvatures which result in a radial molecular arrangement (rodlike and tubular structures). Double *meta* substitution at the rigid segment produces less organized aggregates.

The disk structure contains two kinds of molecular arrangement. One is the two-dimensional arrangement (flat portion) as in the typical bilayer membrane, and the other is a highly curved arrangement (side of the disk) as in the rodlike structure. The fourth group of amphiphiles can assume both the extended and bent conformations, which may be used advantageously to produce the two kinds of molecular packing involved in a disk.

These morphological correlations suggest that the surface curvature of an aggregate is controlled by appropriate mixing of different classes of amphiphiles. Amphiphile **17** (12, 4) gives well-developed, multilamellar vesicles (Fig. 18a). Replacement of this rigid segment with the diphenyl ether unit results in a tubular morphology (Fig. 18b). A 1:1 mixture of



Scheme 3. Schematic representation of the morphology of aggregates and the rigid segments which gives rise to them.

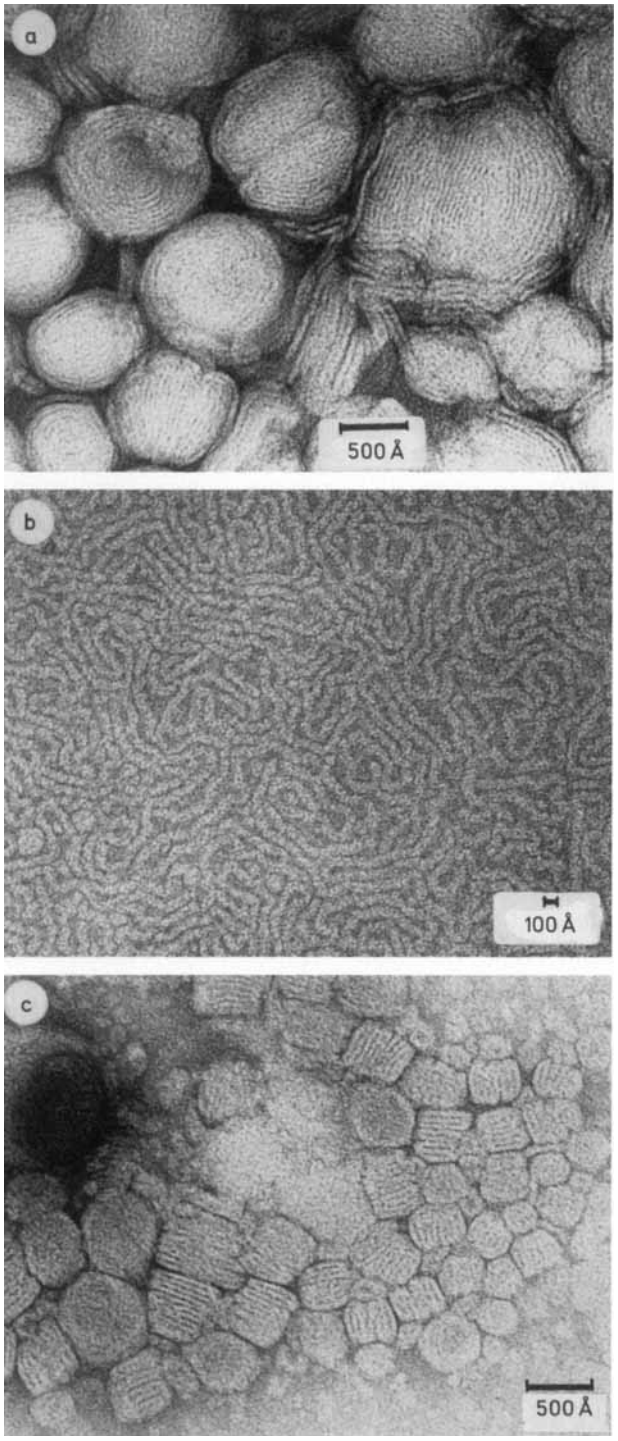


Fig. 18. Electron micrographs of aqueous bilayer dispersions of single-chain ammonium amphiphiles (negatively stained by UO_2^{2+}). a) **17** (12, 4); b) **20**; c) a 9:1 mixture of **17** (12, 4) and **20**.

these amphiphiles gives tubular aggregates very similar to Figure 18b. When the molar ratio is 7:3, an obscure mixture of tubes and lamellae is found. A 9:1 mixture produces stacked disks (or stacked patches of bilayers) with a layer thickness of 40–50 Å (Fig. 18c). It is conceivable that the flat portion of the disk is mainly composed of **17** (12, 4), and that **20** is concentrated along the side of the disk where large curvature is required.

A related morphology control is found for a mixture of **17** (12, 4), and **21**. Cosonication of multiwalled vesicles of **17** (12, 4) and globular **21** gives single-walled vesicles.

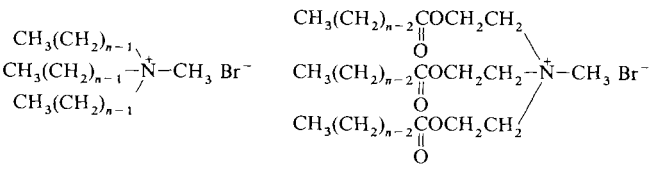
20

21

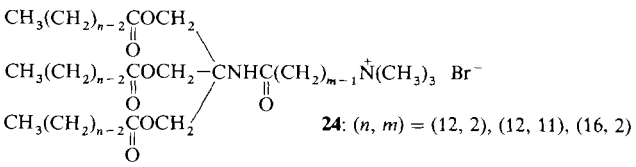
4. Molecular Membranes of Multichain and Two-Headed Amphiphiles

4.1. Triple-Chain Amphiphiles

As discussed in Section 1, the hydrophile–lipophile balance is not the most crucial factor that determines bilayer formation. Certain degrees of imbalance will be accommodated by the stabilization gained by molecular alignment. Compounds **22**–**24** are examples of triple-chain ammonium amphiphiles that were tested for bilayer formation.[71]

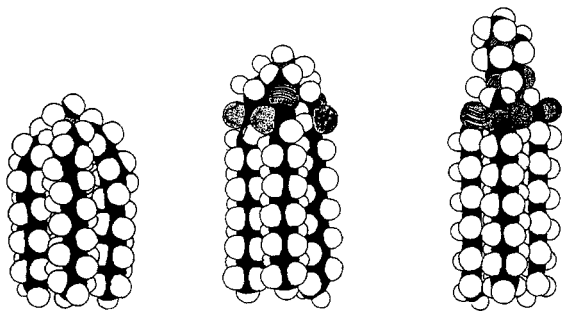


22, $n = 12, 16$ **23**, $n = 12, 16$



24: $(n, m) = (12, 2), (12, 11), (16, 2)$

Simple triple-chain compounds **22** do not seem to give well-developed bilayer structures. Amphiphiles **23** and **24** form stable bilayer membranes in water, as inferred from their huge molecular weights, the presence of a phase transition, and electron microscopic observation. The CPK molecular



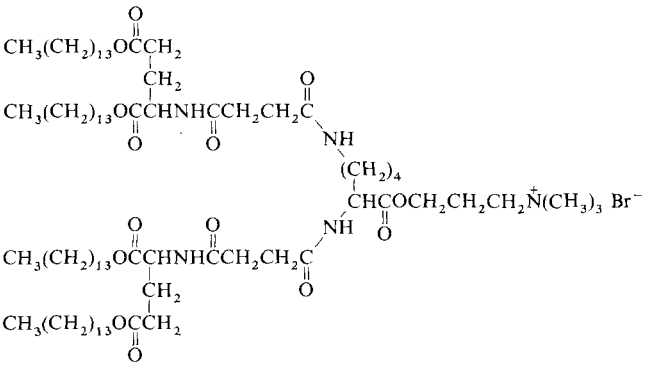
22, n=12 **23**, n=12 **24** (12, 2)

Fig. 19. CPK model of triple-chain amphiphiles with different connectors. The parallel alignment of the alkyl chains in **22** is inferior to that in **23** and **24**.

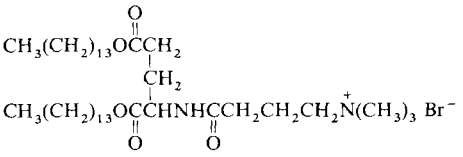
models of these amphiphiles with different connector structures (Fig. 19) endorse these experimental observations. In the case of **22** ($n = 12$), the long alkyl chains cannot be aligned at locations close to the ammonium group because of its tetrahedral configuration. In contrast, the alkyl chains of **23** ($n = 12$) can be well aligned. The compact chain packing is produced by the presence of the ester unit, and the ammonium head can protrude without conformational constraint. The same situation is found for **24** (12, 2), again due to the presence of the ester linkage.

4.2. Quadruple-Chain Amphiphiles

Very recently, we discovered that even quadruple-chain ammonium amphiphiles such as **25** are suitable for two-dimensional molecular alignment.[72] These compounds give



25



26

transparent aqueous dispersions at 20 mM, and display typical bilayer characteristics. Electron microscopy indicates the formation of vesicles and tapelike aggregates. A DSC experiment showed the presence of the phase transition peak. The transition behavior of **25** is not very different from that of the corresponding double-chain amphiphile **26**. The chain alignment is strongly dependent on the kind of the connector. The chiral unit in **25** and **26** should produce different chiral binding sites at the membrane surface.

The native counterpart of these amphiphiles is four-chained cardiolipin. It is interesting to note, however, that cardiolipin cannot form a stable bilayer assembly by itself.

4.3. Two-Headed Ammonium Amphiphiles

Some archeobacteria contain another class of membrane lipids. One of those lipid components is a macrocyclic amphiphile that spans the bilayer thickness.[73] Covalent bonding of alkyl chain ends of synthetic bilayer components would produce two-headed amphiphiles which may form monolayer membranes in water.

Structural extention of single-chain, bilayer-forming amphiphiles to two-headed amphiphiles results in molecular structures such as **27**–**29**.[74] Two ammonium groups at the ends of a molecule are connected by a single chain that is composed of methylene chains and aromatic unit. They are all dispersed in water as stable aggregates with molecular weights of 10^6–10^7. Electron microscopy shows that lamellae and rodlike structures are formed. As shown in Figure 20, **27** (10 mM) gives highly developed lamellae with layer thickness of 30–40 Å. This figure corresponds to the extended molecular length; therefore, the bisammonium molecule is aligned normal to the layer plane. Molecular elongation and increase in the flexible hydrocarbon chain as in **28** (molecular length, 67 Å) leads to the appearance of tubular structures (diameter 70–100 Å), with dark striations (deposits of uranyl acetate) in the middle. The flexible methylene chain in the center of the molecule would allow the bent molecular packing required for the tubular morphology (Fig. 20b).

The rigid lamella of Figure 20a can be transformed into single-walled vesicles as in Figure 20c by cosonication with cholesterol in the ratio 3:1. The vesicles are 1000–3000 Å in diameter and 60–70 Å in layer thickness. We propose that cholesterol molecules are preferentially located in the outer half of the membrane, thus creating surface curvature suitable for vesicle formation (see Fig. 21a). Remarkable transformations of morphology of lecithin vesicles by addition of lysolecithin and cholesterol were reported in a landmark paper of Bangham and Horne in 1964.[1]

Another way of creating curvature is the use of unsymmetrical bisammonium compounds. Attachment of a decyl chain to one of the ammonium heads of **27** changes the aggregate morphology from lamella to multiwalled ves-

icles.[75] The decyl-substituted ammonium head in **30** seems to be more populous in the outer surface (Fig. 21 b).

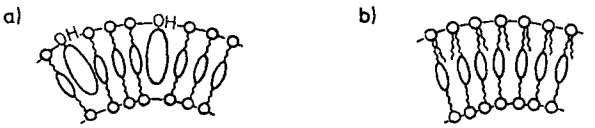

Fig. 21. Creation of surface curvatures in monolayer membranes. a) **27** + 1/3 cholesterol; b) **30**.

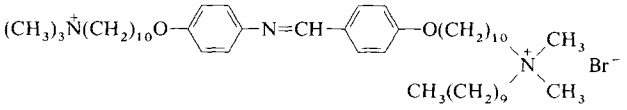
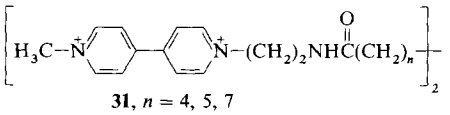


30

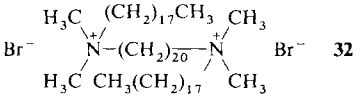
Formation of monolayer vesicles was reported by Fuhrhop and co-workers from single-chain amphiphiles with two viologen head groups (**31**).[76] They subsequently



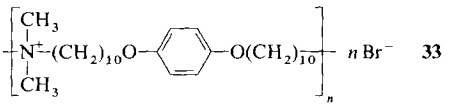
31, $n = 4, 5, 7$

conducted extensive research on this type of compounds, the bolaamphiphiles. For example, they prepared a series of macrocyclic compounds with two polar head groups and studied their vesicle formation.[77]

Amphiphiles related to **27**–**31** can be designed by combining only one end of the alkyl chain in double-chain amphiphiles.[78] Bisammonium compound **32** and related ionene oligomers **33** can form monolayer membranes.



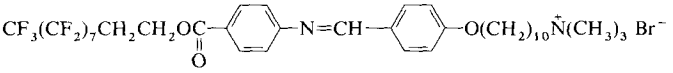
32



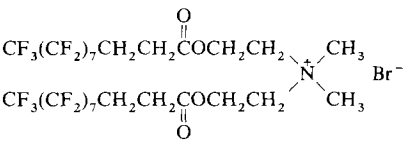
33

5. Bilayer Membranes of Fluorocarbon Amphiphiles

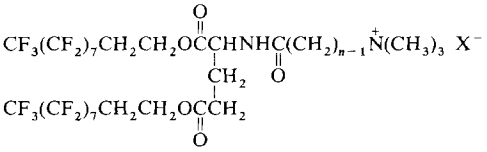
A new class of bilayer membranes are derived by replacement of hydrocarbon chains with fluorocarbon chains. They are single-, double-, and triple-chain compounds; for example, **34**–**38**.[79–82]



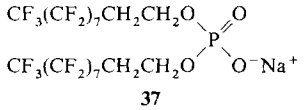
34



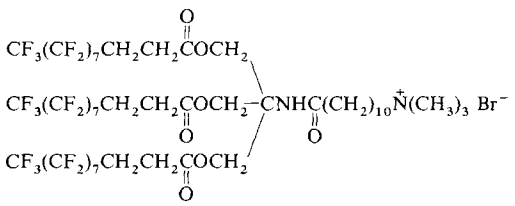
35



36, $n = 2-11$, X = Cl, Br

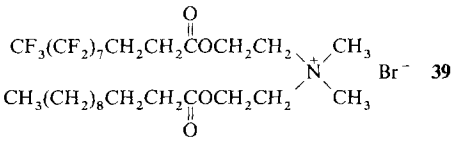


37



38

Sonication of these amphiphiles in water produces clear to translucent dispersions. Electron microscopic observation after the negative staining reveals the existence of the bilayer structure (vesicles and/or lamellae). For instance, **35** gives well-dispersed, single-walled vesicles. A related hydrocarbon (dodecanoate) amphiphile produces multi-walled vesicles. Double-chain **39**, which possesses both fluorocarbon and hydrocarbon tails gives even better developed single-



39

walled vesicles. Those amphiphiles which differ only in the tail portion (fluorocarbon vs. hydrocarbon) show aggregation morphologies that are fairly similar. Single-chain amphiphile **34** and triple-chain amphiphiles like **38** also produce bilayer aggregates.

Fluorocarbon bilayers exhibit small endothermic peaks in DSC thermograms. The phase transition temperature (T_c) of the fluorocarbon bilayers is detected at temperatures 20–30 °C higher and have smaller enthalpy changes than those of hydrocarbon bilayers. The smaller enthalpy changes to be an inherent property of bilayers made from fluorocarbon amphiphiles.

Figure 22 illustrates, as an example, the variation of fluorescence depolarization P of diphenylhexatriene embedded in bilayer membranes of the triple-chain amphiphiles.[82] At low temperatures, the P values are large irrespective of the number of fluorocarbon chains, but they decrease sharply near T_c, leading to large P differences. These data indicate that 1) the membranes are equally rigid at low temperatures, 2) the fluidity increases (decrease in P) at the temperature regions which correspond to the respective DSC peaks, and 3) the membrane fluidity of the liquid crystalline bilayer (at $T > T_c$) decreases with increasing number of fluorocarbon chains.

Fluorocarbons are not readily miscible with the corresponding hydrocarbon compounds. This is exemplified by the formation of heterogeneous micelles from fluorocarbon and hydrocarbon surfactants.[83] In the same vein, fluorocarbon and hydrocarbon bilayers show limited miscibilities. This situation can be improved by adding unsymmetrical components such as **39**. The improved miscibility is also

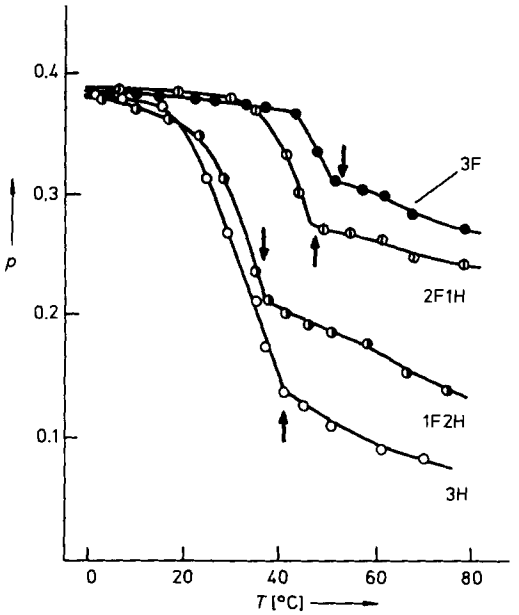


Fig. 22. Fluidity of fluorocarbon bilayers, measured by fluorescence depolarization P of diphenylhexatriene embedded in them. The arrows indicate the T_c values determined by DSC. 3F = **38**, 3H = **24** (12, 11); in 2F1H one and in 1F2H two fluorohydrocarbon chains of **38** are replaced by hydrocarbon chains of **24** (12, 11).

demonstrated in the case of triple-chain bilayer components. As shown schematically in Figure 23, the hydrocarbon component (3H) and the fluorocarbon component (3F) are hardly miscible. Upon addition of a partially fluorocarbon-

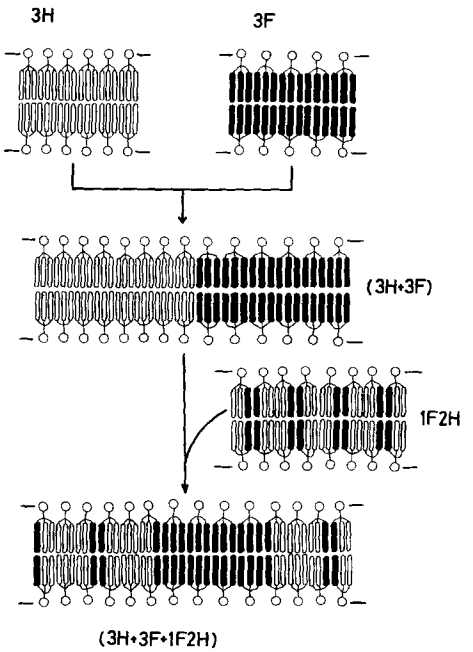

Fig. 23. Miscibility of bilayer membranes of triple-chain amphiphiles containing fluorohydrocarbon and hydrocarbon chains, before and after addition of a mixed amphiphile.

tailed amphiphile 1F2H, the original two components become more miscible.

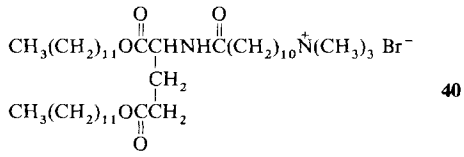
General aggregation behavior of the fluorocarbon amphiphiles is closely related to that of the corresponding hy-

drocarbon compounds. However, the bilayer properties are very different for the two systems: First, fluorocarbon bilayers are much less permeable than hydrocarbon bilayers toward ions and small molecules. Second, these two membrane components tend to form separate domains, and the phase separation has been effectively used for controlled permeation and catalysis.[81]

6. Chiral Bilayer Membranes

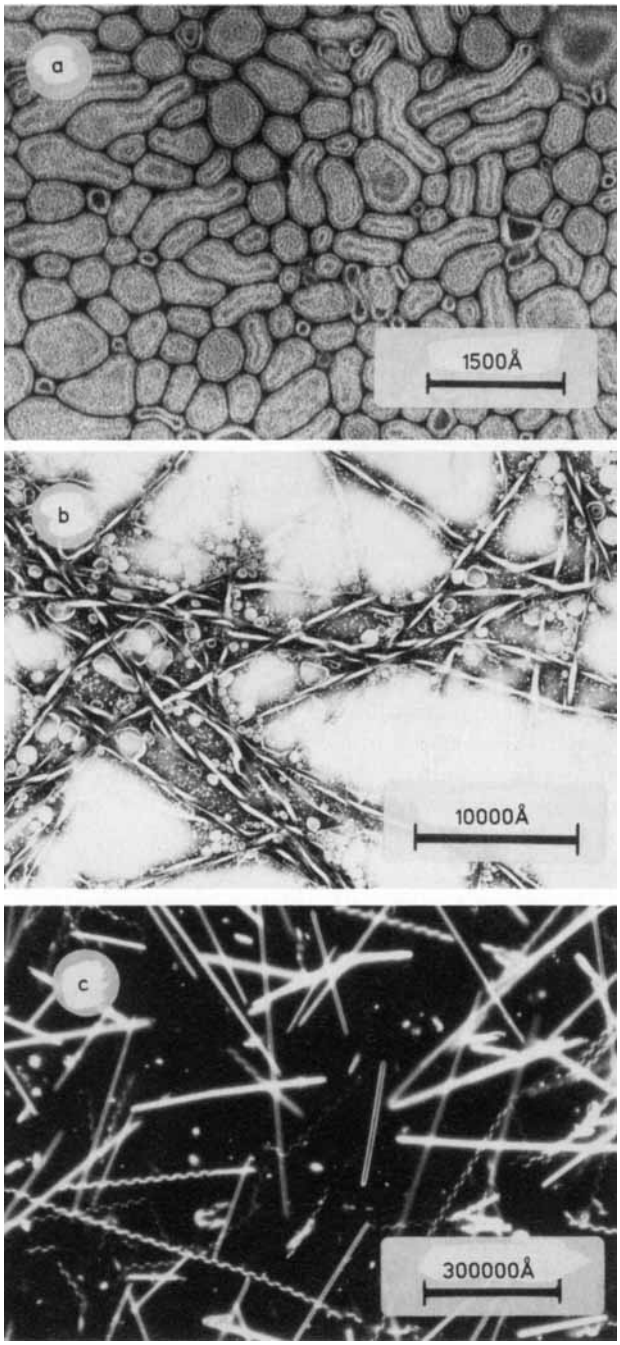
As discussed in Section 2, the amino acid unit acts as a useful module in the design of bilayer-forming compounds. Some of the resulting chiral bilayers of single-chain and double-chain amphiphiles display much enhanced circular dichroism (CD).[84, 85] These data suggested that the chiral components were arranged asymmetrically in fixed spatial dispositions as a result of the formation of higher order structures.

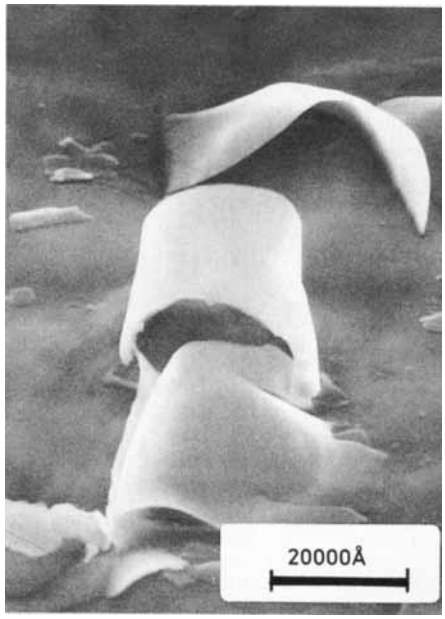
A fairly simple, double-chain amphiphile, L-**40** forms single- and double-walled vesicles with diameters of 300–1000 Å, when dispersed in water by sonication (Fig. 24a).[86]



40

These vesicles are slowly transformed into the helical morphology which is made of twisted tapes, as shown in Fig. 24b). Further ageing gives tubes with helical streaks. These helices and tubes are better observed by dark-field optical microscopy (Fig. 24c)[87] and by high-resolution scanning electron microscopy (Fig. 24d).[88] An advantage





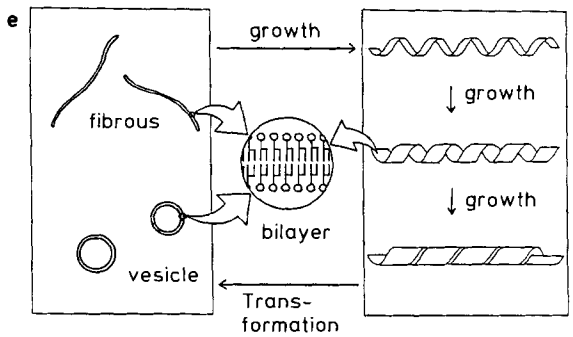


Fig. 24. Formation of helical superstructures from bilayer membranes of chiral ammonium amphiphiles. a) Electron micrograph of aqueous vesicles of L-**40**; no ageing, stained with UO_2^{2+}. b) Electron micrograph of the helical superstructure of L-**40**; stained by UO_2^{2+}. c) Dark-field optical micrograph of the helical superstructure of L-**40**. d) Electron micrograph (high resolution scanning electron microscopy) of the helical superstructure of L-**40**. e) A schematic illustration of helix formation.

of the latter two microscopic methods is that direct images are obtainable. The growth and degradation processes of the helices in water is observable by optical microscopy at a resolution of 1 μm, and the three-dimensional structure of the molecular aggregate can be determined by the scanning electron microscope at a theoretical resolution of less than 10 Å.

The helical superstructure is maintained only in the crystalline state. When the aqueous dispersion of L-**40** (T_c of the bilayer, 33 °C) is warmed to 35 °C, the helices and tubes are all converted into large flexible vesicles. The melting process can be observed directly by optical microscopy.

Enantiomeric amphiphile D-**40** similarly showed a slow growth of helices. These are left-handed, in contrast to the right-handed helices of the L enantiomer. In the case of its racemic bilayer, initially formed vesicles are converted into rodlike aggregates without formation of helices.

Helix formation is sensitive to the molecular structure. It is not observed for a closely related amphiphile with a shorter spacer length: CH_2 instead of $(CH_2)_{10}$. The shorter spacer may interfere with the regular molecular arrangement, since this amphiphile instead forms smooth single-walled vesicles.

The helical superstructure has been obtained for other bilayer-forming amphiphiles. Single-chain ammonium amphiphile **41** gives helical superstructures accompanied by CD enhancement.[89] Cho and Park reported helical superstructures formed by cationic cholesterol-containing polymers.[60] Yamada et al.,[90] concurrently with our initial finding, observed that dialkyl amphiphiles with the oligoglutamate head group **42** produced helical superstructures (twisted ribbons with a layer thickness of 30–40 Å). Single- and double-chain phosphate amphiphiles can form helical superstructures as well.[91] Tubular aggregates, which are products of helical growth, are found in a dispersion of a diacetylenic phosphocholine lipid.[92] Related helical fibers of lipid bilayers were obtained from *N*-octylaldonamides.[93, 94]

7. Applications and Further Developments

In the preceding sections we described molecular design and basic physicochemical properties of synthetic bilayer membranes. Since a multitude of physiological functions involve biomembranes, functional applications of synthetic bilayers should be numerous. They are briefly described in the following.

7.1. Models and Substitutes of the Biomembrane

The basic structural and physicochemical features of synthetic bilayer membranes are common to those of bilayer membranes of natural lipids. Therefore, lipid components of biological membranes may be replaced with their synthetic counterpart. For example, Ringsdorf and co-workers[95] reconstituted ATPase in a polymerized bilayer membrane of a diacetylenic amphiphile. O'Brien et al.[96] used partially polymerized vesicles of a dienoyl phosphatidylcholine to incorporate rhodopsin without denaturation. We have shown recently that myoglobin, the water-soluble heme protein, can be embedded in the interbilayer region of cast films of synthetic amphiphiles without denaturation.[97] The spatial orientation of myoglobin is fixed apparently by electrostatic attraction between the positively charged residue of the protein surface and the negative phosphate unit of the bilayer membrane. Interestingly, the membrane-bound myoglobin displayed redox reactivity.[98] This functional conversion opens an exciting future for composite molecular systems that are composed of natural and artificial molecules.

Murakami and co-workers recently carried out an extensive investigation on the use of functionalized synthetic bilayers as enzyme-like reaction sites for vitamin B_6-dependent transamination and β-replacement reactions,[99] and vitamin B_{12}-dependent carbon-skeleton rearrangements.[100]

7.2. Substrate Trapping and Reaction Control

Synthetic bilayer vesicles can retain ions and molecules in the inner aqueous phase, just like liposomes of biolipids. In addition, a large number of polymerized synthetic vesicles have been investigated to obtain stabilized drug carriers.[11] The trapping capability leads to separation of chemical species inside and outside the vesicles. This has been studied by many research groups in order to mimic the conversion of solar energy in the photosynthetic reaction center.[101] Other organic reactions were also affected by reactant separation by bilayers and by flip-flop exchanges of reaction bilayer components.[102]

The molecular organization and the physical state (phase separation and phase transition) of bilayers can be used as effective means to control reactions. For instance, phase separation (domain formation) of two reacting species produce a unique feature of reactivity.[40] It is possible to construct a surface receptor which performs discrimination, transduction, and amplification of chemical signals by inducing phase separation.[39]

7.3. Designed Organization of Functional Units

The two-dimensional feature of bilayer membranes is particularly advantageous for designed alignment of photonic, electronic, and magnetic functional units. A correlation be-

tween the chemical structure and the component alignment as discussed in Section 3.2 is useful in this respect. A bilayer of an azobenzene derivative, which possesses a tilted (J-like) molecular packing (see Fig. 14), shows highly efficient electron transfer and energy transfer within the bilayer and to a membrane-bound cyanine dye. These efficient transfers are not observed for analogous bilayers with parallel chromophore stacking.[103]

Some oppositely charged dye molecules are bound to the bilayer surface in a specific manner. For example, anionic cyanine dyes are bound to ammonium bilayer membranes in water either as the monomeric species, as H-aggregates, or as J-like aggregates.[104]

When the polar head of bilayers is a chelating group that binds transition metal ions, electron spins are aligned at the membrane surface. A single-chain amphiphile with the cyclam head group forms a bilayer Cu^{II} chelate, which displays a strong antiparamagnetic interaction.[105] Modifications of the metal complex organization should give rise to interesting magnetic and optical properties.

7.4. Surface Monolayers, Langmuir–Blodgett (LB) Films, and Planar Lipid Membranes (BLM)

Most of the bilayer-forming amphiphiles can form stable monolayers at the air-water interface. That the molecular orientations in monolayers and in the corresponding LB films are closely related to those in aqueous bilayers was demonstrated by absorption spectroscopy.[106] The self-assembling property of these amphiphiles is particularly suitable for enhancing the monolayer stability and the subsequent deposition as LB films. Stable BLMs are also formed from many double-chain ammonium amphiphiles.[107] The extent of alkyl chain alignment critically affects the life time. Common structural features exist for the aggregation behavior of aqueous bilayers, surface monolayers, and BLMs (planar bilayers). Therefore, the molecular design discussed in this article is useful for developing new LB films and BLMs.

7.5. Cast Films and Their Use as Molecular Templates

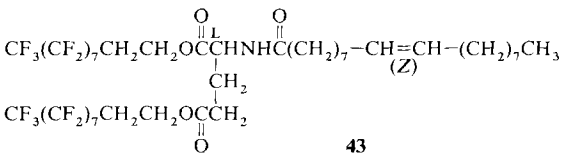
The outstanding self-assembling property of bilayer membranes is fully demonstrated by the formation of free-standing cast films. Transparent films with regular, multilayer structures are readily obtained when aqueous dispersions of synthetic bilayer membranes are spread on solid supports,[63, 108] as is the case with some phospholipids.[109] It is remarkable that flexible, self-supporting films are obtainable from non-covalent molecular aggregates. Unique molecular sensors and permeation control have been realized by application of these cast films.[110]

The macroscopic anisotropy of the cast film has been used to incorporate planar metal complexes into designed spatial arrangements.[111] More recently, Ishikawa and Kunitake[112] demonstrated that anionic porphyrins are incorporated into cast films of ammonium bilayer membranes in specific spatial orientations, depending on the optimized electrostatic attraction of the negative charge on the porphyrin ring and the positively charged bilayer surface. This methodology should lead to designed molecular systems.

Because of the stability of synthetic bilayers as independent entities, the regular bilayer organization is maintained even when guest molecules are introduced in the interbilayer space of a cast film. Cross-linking of a polymerizable guest and the subsequent removal of the bilayer matrix by solvent extraction produces multilayers of two-dimensional molecular networks.[113, 114] This approach is also applicable to synthesis of molecularly controlled siloxane networks[115, 116] and to the hydrolysis of $FeCl_2$ in a cast film to obtain oriented iron oxide particles.[117] It is clear that cast multibilayer films serve as superb templates for preparation of two-dimensional organic and inorganic materials. Sol–gel condensation of inorganic starting materials in the multibilayer matrix results in novel ceramics with molecular precision.

7.6. Bilayer Assembly in Organic Media

The major driving force of self-assembly of biomembranes and synthetic molecular membranes is the hydrophobic interaction. It is lost in organic solvents with which alkyl tails of the membrane component are miscible. We recently took advantage of the immiscibility of fluoroalkyl chains with conventional organic solvents, in order to prepare bilayer assemblies in organic media.[118, 119] The principle of their molecular design is common to that of aqueous bilayer membranes, although the hydrophilic head group has to be replaced with flexible hydrocarbon groups such as in **43**. Compartmentalization of the molecular space and novel organization of functional molecules are just two examples of the versatile possibilities we can envisage for this system.



43

Our research described in this review was made possible only through dedication of our co-workers. The author wishes to express his gratitude to these people. He also appreciates the help of Ms. R. Ando, Ms. C. Tsuda, and Mr. T. Nishimi in the preparation of the manuscript.

Are Denser Packings of Spheres than Closest Packings Possible? How Many Closest Packings of Spheres Exist?

By *Ulrich Müller**

In 1611 Johannes Kepler wrote a humorous 24-page epistle which was a New Year's present to his benefactor in Prague, the Imperial Councilor Wackher von Wackenfels.[1] Here he proposed an explanation of the hexagonal shape of snowflakes: Water vapor, once it feels the penetrating coldness, freezes into little spheres with some definite size which he calls vapor spheres (*sphaere vapidae*). The vapor spheres in contact with one another adopt the arrangement that we nowadays call cubic closest packing of spheres and which we know to be the structural principle of many metals and of the solid noble gases. For this packing Kepler asserted, "It is the tightest possible; in no other arrangement can more spheres be accommodated in the same vessel."[2] The term closest packing of spheres shows that chemists, physicists, and crystallographers have long intuitively accepted Kepler's assertion; however, it was not proven mathematically until 1991 by W. Y. Hsiang.[3]

For periodically ordered packings of spheres, i.e. lattice packings, Gauss furnished the proof of the highest packing density, although he did not mention packings of spheres at all.[4] However, he introduced the concept of a lattice, and by relating it to the Seeber's theorems[5] on number theory he stated: the volume V of the (primitive) unit cell of a lattice will always satisfy the condition $V\sqrt{2} \geq abc$ if the face and body diagonals of the cell are not shorter than the lattice parameters a, b, and c. The upper limit of the space filling of a lattice packing of equal spheres follows from this condition as was shown by Minkowski.[6] The primitive unit cell of the cubic closest packing of spheres fulfilling Gauss's condition is a rhombohedral cell with the cell edges $a = b = c = 2r$ and the volume $V = \frac{1}{2}a^3\sqrt{2}$ ($r =$ radius of a sphere). This volume is exactly equal to the limiting value of the Gauss condition: $V\sqrt{2} = (\frac{1}{2}a^3\sqrt{2})\sqrt{2} \geq a^3$ (it also is identical for any other closest packing of spheres). A crystal lattice having a smaller unit cell volume, i.e. with greater packing density, is therefore not possible for a packing of equal spheres. This statement, however, is valid only when there is a crystal lattice.

Just as chemists presently have caught the buckyball fever, crystallographers are fiercely discussing the topic of quasi crystals. Quasi crystals have symmetry (e.g. fivefold rotation axes or icosahedral symmetry), and there is a near order around the atoms, but they have no three-dimensional periodical order. Could a quasi-crystalline packing of spheres exist having a higher degree of space filling than a cubic closest packing of spheres? Since the twelve spheres surrounding a central sphere of the same size in an icosahedral arrangement are not in contact with each other, a larger space filling seems possible at first (the coordination number in a closest packing of spheres is 12). Mathematicians have repeatedly furnished proofs with upper limits for the space filling, with values that have been decreasing over the years in the third or fourth decimal place, e.g. 0.77964 (1958), 0.77844 (1986), and finally 0.77836 (1988). There have also been repeated attempts to design nonperiodical packings of spheres, for instance with fivefold symmetry[7] or consisting of shells with icosahedral symmetry,[8] but not even the space filling of a closest packing of spheres was ever achieved.

The central idea of Hsiang's proof concerns the domains of influence of the spheres (also called the Wirkungsbereich, Voronoi domain, Dirichlet domain, or Wigner–Seitz cell). The domain of influence of a sphere is the polyheron made up of the set of planes perpendicular to the lines that connect the sphere under consideration to the surrounding spheres and passing through the midpoints of these lines. (For spheres in contact with each other these are the tangent planes between the spheres.) Kepler described the domain of influence of a sphere in the cubic closest packing by considering the seeds in a pomegranate. Initially the seeds are round, but later as the rind hardens and the seeds continue to grow, they become tightly packed and squeezed together, filling the remaining space and finally taking the shape of rhombic dodecahedra (Fig. 1). In an arbitrary packing of spheres the domains of influence fill the space completely, so that the space filling results from the ratio of the sphere volume to the mean volume of all domains of influence. The domain of influence of the cubic closest packing of spheres, the rhombic dodecahedron, has a volume of $4\sqrt{2}$ when the sphere radius is $r = 1$. With the sphere volume $\frac{4}{3}\pi$ we thus calculate the well-known degree of space filling of the cubic closest packing of spheres to be $\frac{4}{3}\pi/(4\sqrt{2}) = \frac{1}{6}\pi\sqrt{2} = 0.7404805$.

The smallest possible local domain of influence of a single sphere results when it is coordinated icosahedrally;[9] this domain of influence is a pentagonal dodecahedron (Fig. 1). It has a volume of $10\sqrt{2(65 - 29\sqrt{5})}$, which yields a local space filling of 0.7546974. This value had been suspected to be the upper limit for sphere packings but was never proven.[9] Since space cannot be completely filled by pentagonal dodecahedra, other spheres must have different domains of influence. What is the minimum mean volume of all domains of influence?

[a] Hexagonal closest packing. [b] Cubic closest packing, space group $Fm\bar{3}m$.

In addressing this question Hsiang considered a second shell of spheres, consisting of 42 to 44 spheres around the 12 spheres of the first shell; including the central sphere this amounts to a total of 55 to 57 spheres. His impressive goal was to analyze all possible configurations and to derive the domains of influence of the spheres of the first shell. Most configurations could be eliminated because the volumes are too large; for other configurations it had to be shown that they are close to certain key configurations. The distinction of these cases makes up the greater part of the proof which extends over more than 150 pages. First a new method for estimating the volume of local domains of influence was used to prove that the global space filling cannot exceed the local space filling in a pentagonal dodecahedron. Then after introducing the concept of semiglobal space-filling, he derived the maximum global space-filling; it is 0.7404805.

Hsiang first circulated his proof among mathematicians who now have the opportunity to check its correctness. In other circles his work became known by two communications.[10, 11]

Another problem that had never been solved was the question of the possible number of different closest packings of spheres that all have the same space filling as cubic closest packing. For stacks of hexagonal layers of spheres, any stacking sequence of layers with the positions A, B, and C is possible as long as no two layers of the same position are adjacent; therefore, the number of stacking variants is infinite. But how many arrangements are possible for periodical stackings in which a packet of a given number of layers is repeated? First of all, we have to make a clarifying statement: if we take the cubic closest packing of spheres and consider a stacking direction inclined towards the layer plane $A \rightarrow B \rightarrow C \rightarrow A$..., then we have a translationary equivalent layer after one layer (one layer per packet). However, if we only consider a stacking direction perpendicular to the layers, the packet is repeated only after three layers, $(ABC) \rightarrow (ABC)$... An inclined stacking of a packet having N layers will always result in a rhombohedral structure which can be described in a hexagonal setting with packets consisting of $3N$ layers. In the following we will only consider the perpendicular stacking direction.

For a small number of layers per packet the possible stacking sequences can be written down and counted.[12–14] The method for calculating the number of possibilities for an arbitrary number of layers per packet was first demonstrated in 1981 by McLarnan.[15] This approach is based on Pólya's theorem,[16] (which can also be used to calculate the number of isomers of organic compounds). If, in addition, some group theory and White's extension of Pólya's theorem are included,[17, 18] the number of stacking variants with a given symmetry (space group) can also be calculated. Table 1 lists some of the numbers calculated by McLarnan. The table illustrates why it is a significant progress to be able to calculate the numbers with dependence on symmetry: The largest numbers result for low symmetries, whereas in the higher symmetry space group types $P6_3/mmc$ and $R\bar{3}m$ the numbers are relatively small. Chemically reasonable crystal structures are usually only those with higher symmetry. The method described by McLarnan[18] can also be adapted for the calculation of the number of crystal structure types possible with particular space groups for any kind of compound, provided that some definite packing principle can be stated.[19]

I thank Prof. Dr. E. Krafft for helping me locate Kepler's papers.

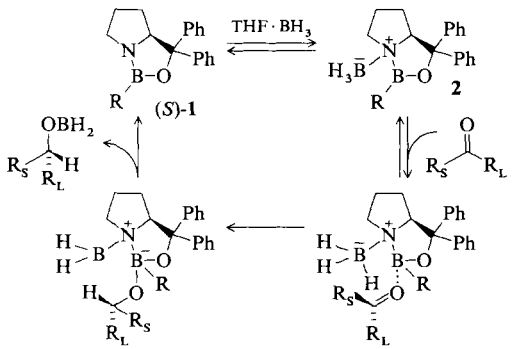
Oxazaborolidines and Dioxaborolidines in Enantioselective Catalysis**

By *Braj B. Lohray**, and *Vidya Bhushan*

The success of enantioselective catalysts depends on the nature of the metal and the structure and electronic properties of the chiral ligands. A number of highly efficient and useful catalysts are now available for various reactions.[1] Boranes serve as chiral reagents for a number of asymmetric reactions. One of the earliest examples of borane catalysts for the reduction of ketones (or ketoxime ethers) to secondary alcohols (or amines) was reported by Itsuno et al.,[2] in which (*S*)-valinol was used as chiral ligand. Simultaneously, Corey et al.[3a] investigated the enantioselective reduction of ketones with THF · BH_3 and (*S*)-diphenylprolinol borane adduct as catalyst. Later they also employed other oxazaboroles, for example, **1**, R = Me, *n*Bu, as catalysts and used other boranes as reducing agents.[3b,c] (The catalysts **1**, which are easily accessible in both the *R* and the *S* form, are termed CBS reagents.) These afforded excellent yields and enantioselectivities (80–99% *ee*) under very mild reaction conditions (0–25 °C). The reaction (Scheme 1) requires both



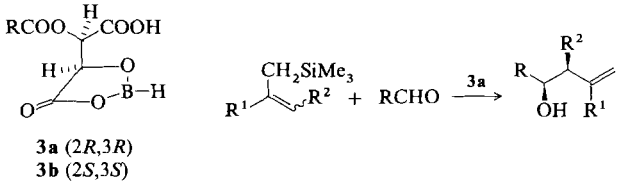
Scheme 1. Possible mechanism of the borane-catalyzed enantioselective reduction of ketones with THF · BH_3.

reagents: neither the catalyst (*S*)-**1** nor THF · BH_3 alone are able to reduce the ketone in considerable yield. Thus, the active reducing species, the "chemzyme" has been postulated to be an intermediate complex **2**, which is formed from (*S*)-**1** and BH_3. Mathre et al. from industry[4a] have modified the preparation of (*S*)-**1** and used it for the synthesis of MK-0471, a carboanhydrase inhibitor.[4b] Martens et al.[4c] reported the use of oxazaborolidines derived from (*S*)-indole-2-carboxylic acid for asymmetric reduction of aromatic ketones, though in lower selectivity.

Two particularly recent examples of borane-catalyzed reductions will now be described: Corey and Link[5] have reported a general method for the synthesis of α-amino acids using (*S*)-**1** (R = *n*Bu) as the chiral catalyst for the enantioselective reduction of alkyl (trichloromethyl) ketones by catecholborane. The (2*R*)-1,1,1-trichloroalkan-2-ol thus obtained was treated with NaOH (4 equiv) and NaN_3 (2 equiv) at 23 °C affording (*S*)-α-azido acids, which were subsequently reduced to α-amino acids. Bringmann and Hartung[6] have synthesized substituted chiral biaryls by the reduction of substituted 2-pyranones with THF · BH_3 in the presence of oxazaborolidines.

Brown et al.[7] achieved the enantioselective addition of diethylzinc to several aldehydes in high yield and optical purity (up to 96% *ee*) by using (4*S*,5*R*)-3,4-dimethyl-5-phenyl-1,3,2-oxazaborolidine. Because B–O and B–N bonds are shorter than metal-oxygen and -nitrogen bonds, there is a better chance that the boron catalysts will be more effective.

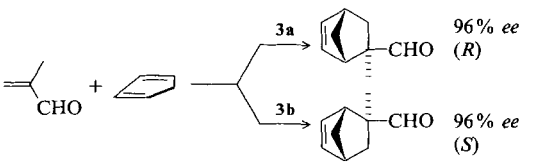
Yamamoto et al.[8] suggested that acyloxyboranes might behave as mixed anhydrides because of the electronegative trivalent boron atom and could serve as effective catalysts for various reactions. The chiral acyloxyborane (CAB) **3** prepared by the reaction of monoacylated tartaric acid with one equivalent of THF · BH_3 in dichloromethane at 0 °C is an excellent catalyst for the asymmetric allylation of aldehydes by allylsilanes (Scheme 2).[8] The reaction proceeds at



3a (2*R*,3*R*)
3b (2*S*,3*S*)

Scheme 2. Asymmetric allylation with allylsilanes in the presence of 20 mol % **3a**. R = 2,6-dimethoxyphenyl.

−78 °C to furnish predominantly *erythro* homoallylic alcohols (*erythro*:*threo* = 80:20 to 97:3) regardless of the configuration of the allylsilanes. CAB is an equally effective catalyst for the Diels–Alder reactions[9] of a variety of dienes with several dienophiles (α,β-unsaturated acids and aldehydes) under very mild reaction conditions (−78 °C) (Scheme 3). Good to excellent diastereo- (99:1 to 88:12) and



Scheme 3. Diels–Alder reactions enantioselectively catalyzed with 10 mol % **3**.

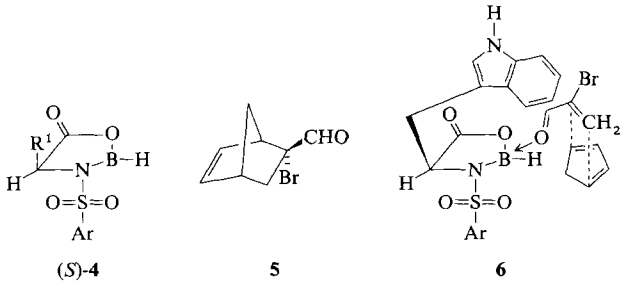
enantioselectivities (80–97% *ee*) have been observed in most of the cases. The reactive species is assumed to be 1,3,2-dioxaborolidine **3** and the dienophile.

Yamamoto et al.[10] have extended these studies to Diels–Alder reactions catalyzed by *N*-arylsulfonyl 1,3,2-oxazaborolidine **4**. The stereoselectivity with these catalysts is relatively inferior to that observed with **3**. Similar observations have been reported by Helmchen et al.[11] for the Diels–Alder reaction of cyclopentadiene and methacrolein (*exo*:*endo* = 99:1, 64% *ee* for the *exo* isomer) or crotonaldehyde (*exo*:*endo* = 3:97; 72% *ee* for the *endo* isomer). Use of bulkier aryl substituents such as 2,4,6-triisopropyl- and 2,4,6-tri-*t*-butylphenyl in **4** had little influence on the diastereoselectivity of the cycloaddition.

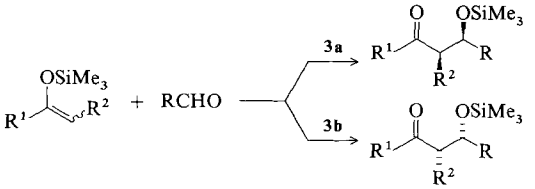
[*] Dr. B. B. Lohray, Dr. V. Bhushan
Division of Organic Chemistry
National Chemical Laboratory
Pune 411008 (India)

[**] N.C.L. communication no. 5394.

Corey and Loh[12] have reported that the Diels–Alder reaction of cyclopentadiene and 2-bromoacrolein, which is catalyzed by oxazaborolidines **4** derived from *N*-tosyl-(*S*)-tryptophan, in dichloromethane at −78 °C gives (*R*)-bromoaldehyde **5** (*exo*:*endo* = 97:3, 96% *ee*) in 1 h. The observed stereoselectivity in this case is opposite to that normally observed for oxazaborolidines **4** generated from *N*-tosyl derivatives of (*S*)-valine or (*S*)-hexahydrophenylalanine. These results suggest a transition state **6** for the synthesis of **5**,[12] in which the dienophile assumes an orientation parallel to the indole ring because of the π–π donor–acceptor interactions. The CAB **3** not only catalyzes allyl transformations (Scheme 2) but also asymmetric aldol reactions between silylenol ethers and aldehydes (Scheme 4).



(*S*)-**4** **5** **6**

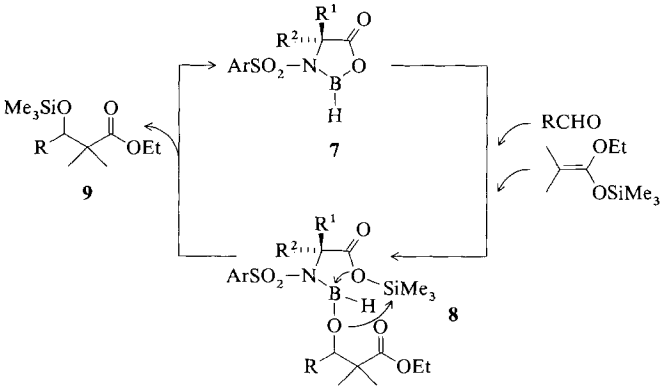


Scheme 4. Aldol reactions enantioselectively catalyzed with 20 mol % **3**.

Yamamoto et al.[13] used 20 mol % of CAB **3** in propionitrile at −78 °C as a highly efficient catalyst for the condensation of several *E* and *Z* silylenol ethers and ketene acetals with a variety of aldehydes (yields 49–97%, 80–97% *ee*). Interestingly, regardless of the configuration of the enol ethers, the *erythro* isomer always predominated (*erythro*:*threo* = 80/20 to >95/<5).

Aromatic and α,β-unsaturated aldehydes always provided higher diastereo- (*erythro*:*threo* ≥ 94:6) and enantioselectivities (92–97% *ee*) than saturated aldehydes. Polar solvents improved the selectivity by decreasing the association of the catalyst with the formation of oligomers as observed by Helmchen.[11]

Kiyooka et al.[14] and Masamune et al.[15] used oxazaborolidine **7** under stoichiometric and substoichiometric (ie, as chiral catalysts) conditions, respectively, as the catalyst for aldol reactions. Masamune suggested that the initial aldol adduct **8** must undergo ring closure (as indicated by arrow in Scheme 5 to release the final product **9** and to regenerate the catalyst. In many cases, slow addition of the aldehyde to the reaction mixture proved beneficial (permits enough time for **8** to undergo ring closure) for improving the enantioselectivity of the reaction. Thus, α,α-disubstituted *N*-arylsulfonylglycines were used for the preparation of the oxazaborolidine **7**, which resulted in catalytic asymmetric aldol processes providing β-hydroxy esters of >97% *ee* from α-unbranched aldehydes (RCH_2CHO) and 84–96% *ee* with α-branched aldehydes (R_2CHCHO). The reaction proceeds smoothly in propionitrile at −78 °C if the aldehydes are added slowly over 3.5 h affording high yields (68–89%) of the adduct.



Scheme 5. Oxazaborolidine in aldol reactions.

In summary, oxaza- or dioxaborolidines have been found to be effective catalysts for several reaction types and probably in the future other applications will be discovered for such catalysts.

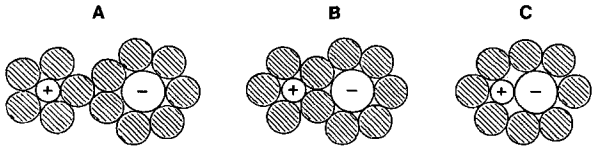
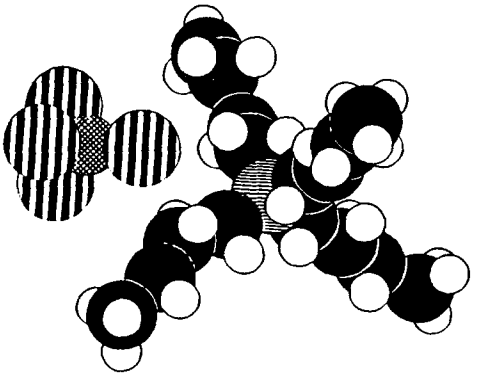
Penetrated Ion Pairs: a New Form of Ion Pair

By *Gernot Boche**

Since the pioneering work of Grunwald[1], Winstein et al.,[2] and Fuoss et al.[3] the terms *contact*, *tight*, or *intimate ion pair* and *solvent-separated* or *loose ion pair* have become well known in the chemical world.[4] More recently, Marcus coined another phrase, the *solvent-shared ion pair*.[5] The simplest representations of these ion pairs are shown in Scheme 1.



Scheme 1. Schematic representation of a solvent-separated ion pair **A**, a solvent-shared ion pair **B**, and a contact ion pair **C**.



Scheme 2. Penetration of a BF_4^- ion into the empty spaces between the alkyl chains of a tetrabutyl ammonium ion. C atoms are represented by black, H atoms by white, N atoms by fine-hatched, F atoms by coarse-hatched, and B atoms by cross-hatched spheres.

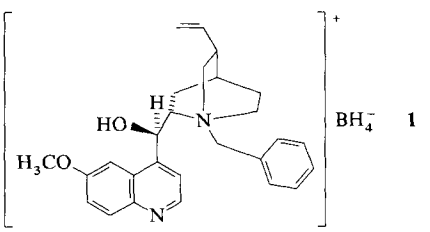
In solvent-separated ion pairs the solvation shells of the cation and the anion touch each other, in solvent-bridged ion pairs the ions share solvent molecules, and in contact ion pairs cation and anion are directly bound to each other and are surrounded by a common solvation shell. There are very few cases in which all three forms have been structurally confirmed; one example is fluorenyllithium, by crystal structure investigations. The cation in fluorenyllithium·2quinuclidine is bound to two C atoms of the fluorenyl anion, an example of a contact ion pair.[6] The ethylenediamine molecules in [fluorenyllithium·2ethylenediamine]$_\infty$ form a three-dimensional network with the Li^+ ions fourfold coordinated to the NH_2 groups. The N-H bridged fluorenyl anions are embedded in this network; thus, cation and anion share the ethylenediamine "solvent" molecules. Models for solvent-separated ion pairs are 1,ω-bis(9-lithio-fluoren-9-yl)ethane and -hexane, each of which crystallizes with eight tetrahydrofuran molecules; each Li^+ ion is tetrahedrally surrounded by four "solvent" molecules. The THF molecules have no bonding contact with the anion.

Recently, greater emphasis has been placed on structural details of the interaction of cation and anion for more complex ion pairs in solution. $^6Li,^1H$ HOESY measurements on fluorenyllithium in different solvents have provided the most accurate information so far concerning this compound,[9] which has been intensively studied. The structure of the ion pair from *N*-allyl-*N*-ethyl-*N*-methylanilinium-*p*-toluenesulfonate, in which the *p*-toluenesulfonate anion can be bound to four different sides of the chiral ammonium ion, was investigated by dipole moment measurements in various solvents.[10]

The interpenetration of the ions is the most recent discovery, which was originally deduced from conductivity measurements on tetraalkylammonium salts with alkyl chains of varying length, and with different anions.[11] The empty spaces between the alkyl chains can be occupied to a certain degree by smaller ions as shown in Scheme 2. Thus, ion pairs are formed whose van der Waals volume is smaller than the sum of the volumes of the single ions.

More precise information on the position of an "anion in the cation" was provided by $^1H,^1H$ and $^{11}B,^1H$ NOE investigations on tetra-*n*-butyl ammonium borohydride:[12] the BH_4 anion and the quaternary nitrogen atom of the cation must be in close contact, since each of three of the BH_4^- hydrogen atoms is in van der Waals contact with two α-CH_2 protons and one β-CH_2 proton of the alkyl chain.

Investigations concerning the interactions of the two ions in ion pairs such as 1-benzyl-15-methoxycinchonanium hydroborate (**1**) are of practical signifiance for the stereoselective synthesis.[13] Cations such as that of **1** are applied in



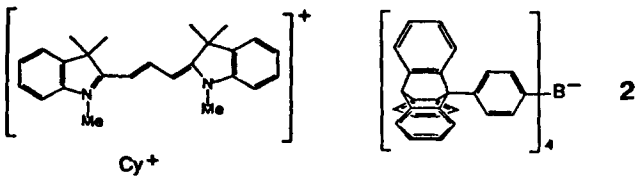
1

phase transfer catalyzed reactions, in which the cation transports the anion into the organic phase. In this phase the chirality of the cation can lead to induction of the BH_4^- reaction. Hence, it is important to know which structure(s) the ion pair forms so that the cause of the chiral induction can be traced and more effective chiral catalysts can be applied. The complete assignment of the protons in the ^1H NMR spectrum of the chiral ion pair **1** and the investigation of the interionic contacts was achieved with a combination of COSY and ROESY NMR spectroscopy. The investigation showed that BH_4^- can penetrate the cationic center at two of the four faces of the trigonal pyramidal coordination polyhedron of the quaternary nitrogen. If this result is compared with the model representations of ion pairs shown in Scheme 1, it is clear which details of the structure of ion pairs are nowadays

[*] Prof. Dr. G. Boche
Fachbereich Chemie der Universität Marburg
Hans-Meerwein-Strasse, D-W-3550 Marburg (FRG)

accessible by NMR spectroscopy. It seems appropriate at this point to mention the term molecular recognition.

A recent publication about a photochemical investigation[14] also provides inside information into important aspects of a structure with penetrated ion pairs. Whereas trimethinecyanine borates in which the borate possesses different substituents than the 4-(1-triptycyl)phenyl groups in **2**, form *trans* → *cis* isomerizations of a double bond on irradiation, this does not happen for **2**.



2

Model calculations showed that there is sufficient space in **2** for the penetration of the trimethinecyanine cation (Cy^+) between the 4-(1-triptycyl)phenyl substituents of the borate. However, as soon as the anion has been penetrated by the Cy^+ ion, the cation cannot start the rotation that would lead to the *trans* → *cis* isomerization without cooperative movements in the borate. Figure 1 shows the difference in the ion pair character depending on the borate substituents: the trimethinecyanine cation (red) can penetrate the borate with 4-(1-triptycyl)phenyl groups (Fig. 1, top), whereas a contact ion pair occurs for the $(C_6F_5)_4B$ anion (Fig. 1, bottom).

In summary, the realization that there are *penetrated ion pairs* is a result of recent structure investigations of ion pairs. The importance of this new form of ion pair is already shown by the few examples known.

German version: *Angew. Chem.* **1992**, *104*, 742

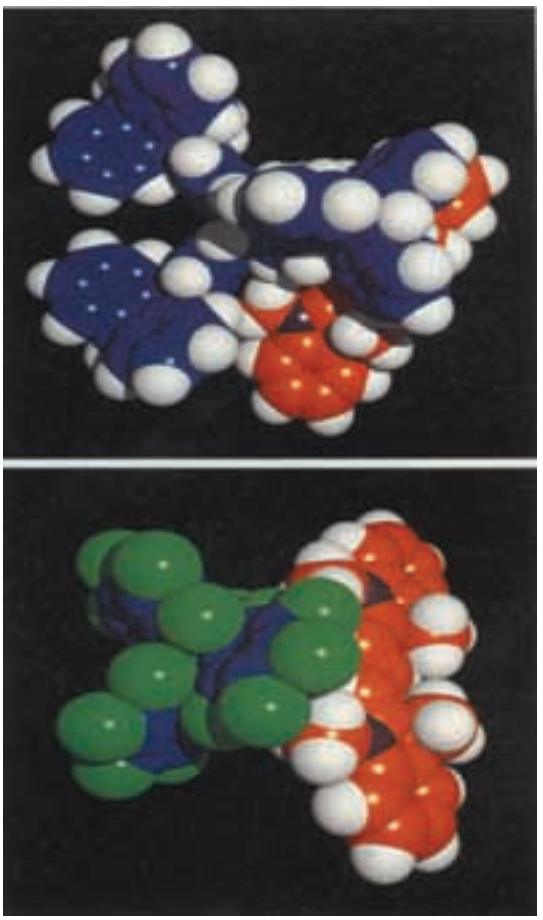


Fig. 1. Top: **2** occurs as a penetrated ion pair. Bottom: If $(C_6F_5)_4B^-$ is used as anion then a contact ion pair is formed.

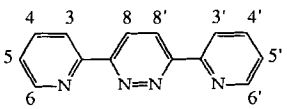
Self-Assembly of a Cu_4 Complex with Coplanar Copper(I) Ions: Synthesis, Structure, and Electrochemical Properties**

By *Marie-Thérèse Youinou,* Noureddine Rahmouni, Jean Fischer*, and *John A. Osborn*

Ligands containing multiple binding sites are of interest for the construction of structural and reactivity models of certain metallobiomolecules as well as polyelectronic systems.[1] The ligand 3,6-bis(2'-pyridyl)pyridazine (dppn)[2] complexes a variety of metal ions,[3] and given our interest in dicopper-containing proteins, the binuclear copper(II) complexes of dppn attracted our attention.[4] Therefore, we studied the interaction of copper(I) ions with this ligand and report here the structure and some properties of the resultant complexes.



Scheme 1. Structure of the dppn ligand. The numbering is based on the interpretation of its NMR spectra.

When 2 equivalents of dppn were added to 1 equivalent of $[Cu(CF_3SO_3)]_2 \cdot C_6H_6$[5] in benzene, a brown precipitate was isolated (85% yield) and recrystallized as brown crystals from acetone and ether. Microanalytical results combined with the FAB^+ mass spectrum (FAB = Fast Atom Bombardment) indicate that the isolated product is the tetrameric complex **1**.

$[Cu_4(dppn)_4](CF_3SO_3)_4$ **1**

The ^1H and ^{13}C NMR spectra of **1** reveal the molecule to be highly symmetric, with a pattern of resonances similar to that of the free ligand. Additionally, the IR spectrum of **1** indicates that dppn binds in a tetradentate fashion.[4a] X-ray quality crystals of $\mathbf{1} \cdot 2CH_3OH$ were obtained from a 1:1:1 mixture of methanol/acetone/ethanol.

The structure determination[6] shows that the complex consists of discrete $[Cu_4(dppn)_4]^{4+}$ ions and uncoordinated triflate ions with two methanol molecules of crystallization. The structure of the complex cation (Fig. 1), which has crystallographically imposed C_2 symmetry about the Cu1–Cu2 diagonal, is best described as a planar arrangement of four copper atoms lying at the vertices of a slightly distorted rhombus, with sides of length 3.566(1) and 3.582(1) Å and interior angles of 78.72(4) and 101.28(3)°. The four copper atoms are spanned by four dppn ligands, two lying above the Cu_4 mean plane and two below. The distorted tetrahedral environment about each copper(I) ion is provided by two different dppn ligands, each of which supply a pyridine and a pyridazine nitrogen donor atom. Each of the individual

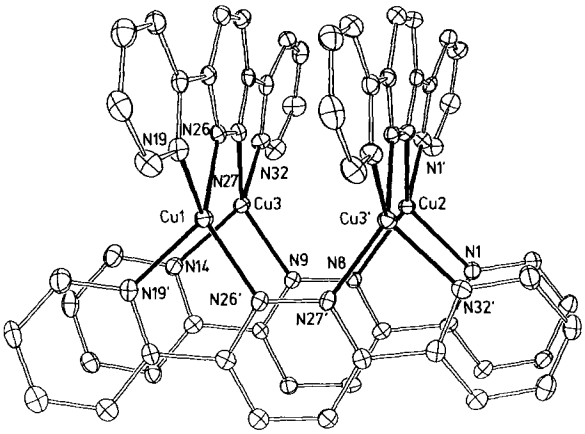


Fig. 1. Top: ORTEP drawing of the crystal structure of $\mathbf{1} \cdot 2CH_3OH$, showing the 50% probability thermal ellipsoids. The hydrogen atoms are omitted for clarity. Selected bond distances [Å] and angles [°] are as follows: Cu1-Cu3 3.566(1), Cu2-Cu3 3.582(1), Cu1-N19 and Cu1-N19' 2.022(5), Cu1-N26 and Cu1-N26' 1.979(5), Cu2-N1 and Cu2-N1' 2.041(5), Cu2-N8 and Cu2-N8' 1.990(5), Cu3-N9 1.991(5), Cu3-N14 1.999(6), Cu3-N27 1.974(5), Cu3-N32 2.005(6); Cu3-Cu1-Cu3' 78.72(4), Cu1-Cu3-Cu2 101.28(3), N19-Cu1-N19' 107.2(3), N19-Cu1-N26 and N19'-Cu1-N26' 80.2(2), N19-Cu1-N26' and N19'-Cu1-N26 134.2(2), N26-Cu1-N26' 127.4(3), N1-Cu2-N1'105.5(3), N1-Cu2-N8 and N1'-Cu2-N8' 79.9(2), N1-Cu2-N8' and N1'-Cu2-N8 132.0(2), N8-Cu2-N8' 131.8(3), N9-Cu3-N27 132.5(2), N9-Cu3-N32 117.5(2), N14-Cu3-N27 119.3(2), N14-Cu3-N32 131.1(2), N9-Cu3-N14 81.8(2), N27-Cu3-N32 81.7(2). Bottom: Representation of $\mathbf{1} \cdot 2CH_3OH$ using the Chem-Ray program.

rings involved in the chelation is planar, but within each dppn ligand the pyridine and pyridazine rings are slightly twisted about the exocyclic C–C bond with dihedral angles of 9(1)°, which are larger than those previously observed in other dinuclear complexes.[4a] Thus the dppn ligand is sufficiently flexible to adjust to the stereochemical requirements of the Cu_4 unit. A striking feature is the almost parallel orientation of the pairs of dppn ligands which are separated by a distance of 3.47 Å, leading to significant π-stacking interactions most likely responsible for the distorsion from the ideal Cu_4 square to the observed rhombus. Distorted tetrahedral Cu_4 units such as the Cu_4X_4 cubane structures are well known,[7] but **1** appears to be a rare example of a planar arrangement of four copper atoms each possessing a tetrahedral geometry.[8] Interestingly, the symmetry evident in the NMR spectra (^1H, ^{13}C) would indicate that, in solution, the Cu_4 framework is either square or oscillating between rhombic structures.

The electrochemical properties of **1** were studied by cyclic voltammetry in DMF.[9] A first series of four successive waves of equal height was observed with $E_{1/2}$ at −0.88, −1.01, −1.16, and −1.32 V (vs. SCE). Peak separations (Δi_p) of between 60 to 70 mV, independent of scan rates (50–250 mVs^{-1}), indicate that **1** undergoes four reversible one-electron processes. In contrast, the reduction of the free ligand begins at −2.07 V and is irreversible. The observed sequence can be interpreted tentatively as a stepwise reduction of each dppn ligand in the tetrameric complex. A second set of reversible waves, presumably due to a second reduction of the ligands, was detected at significantly more negative potentials, −1.74, −1.99, and −2.21 V. The eighth expected reduction step could not be observed, most likely due to its proximity to the reduction potential of the solvent. The remarkable stability of complex **1** during these multielectronic processes would appear to result from reduction taking place mainly on the ligand, as already observed in some ruthenium complexes with bipyridine ligands[10] or copper(I) complexes with catenands;[11] the metal and its stereochemistry would then be largely unchanged.[12] One also may suggest that the reduced states may further be stabilized by interligand π interactions. The metal thus serves not only to lower the reduction potential of the dppn ligand, but also to hold the dppn ligands in parallel proximity.

The formation of **1** appears to result from a spontaneous self-assembly process. When, however, $[Cu(CF_3SO_3)]_2 \cdot C_6H_6$ in acetone was added to an approximatively threefold excess of dppn (per copper atom), a dark green precipitate formed that analyzed as **2**. As expected **2** shows no significant EPR signal and is probably polymeric.[13] Complex **2** is not soluble in most common solvents but can be dissolved in a donor solvent such as CD_3CN. Upon dissolution of **2** the ^1H NMR spectrum reveals immediate formation of **1** and the concomitant liberation of four equivalents of dppn [Eq. (a)]. In solution, the formation of **1** thus appears to be under thermodynamic control. Self-assemblage does not inevitably follow a direct path to **1**; detours such as the formation of **2** can occur if they are rapid and reversible.

$$4\ \underset{\mathbf{2}}{[Cu(dppn)_2(CF_3SO_3)]} \rightleftharpoons \underset{\mathbf{1}}{[Cu_4(dppn)_4](CF_3SO_3)_4} + 4\ dppn \qquad (a)$$

$[Cu(dppn)_2(CF_3SO_3)]$ **2**

In summary, this system involves a ligand which provides two chelating sites and possesses a quasi-rigid, planar structure. Such preorganization, coupled with the stereochemical and coordination demands of the metal ion, predictably leads to the formation of the tetranuclear structure **1**, as long as solvation and anion interactions are minimized. The π-stacking interactions of the dppn ligands may also play an important role in causing closure to the tetranuclear form rather than yielding a polymeric chain structure. The potential of such an electron reservoir to serve as a relay in multielectronic reduction processes is being pursued.

Experimental Procedure

dppn: The ligand 3,6-bis(2'-pyridyl)pyridazine was prepared [2] and characterized. ^1H NMR (200.1 MHz, $(CD_3)_2CO$, 25 °C): δ = 8.75 and 8.73 (m and s, 6H, 8 + 8'; 3 + 3' and 6 + 6'), 8.04, (dt, 2H, 4 + 4'), 7.54 (ddd, 2H, 5 + 5'). ^{13}C NMR (50.3 MHz, $(CD_3)_2CO$, 25 °C): δ = 158.83 (2 + 2'); 154.15 (7 + 7'); 150.28 (6 + 6'); 137.81 (4 + 4'); 125.48 and 125.24 (3 + 3', 8 + 8'); 121.68 (5 + 5').

The syntheses of complexes **1** and **2** were carried out under inert atmosphere with dried and degassed solvents.

1: To a stirred solution of $[Cu(CF_3SO_3)]_2 \cdot C_6H_6$ [5] (0.125 g, 0.25 mmol) in warm benzene (10 mL) was added dropwise under nitrogen a solution of dppn (0.117 g, 0.5 mmol) in warm benzene (10 mL). The reaction mixture was allowed to stir for 15 min. The brown precipitate which formed immediately was filtered, washed with benzene, and recrystallized by diffusion of Et_2O into an acetone solution of the complex (yield 85%). – Correct C,H,N-analysis. MS (FAB^+, NBA): *m/z* 1488.4 ($[M - 2CF_3SO_3]^+$, 8%), 1402.8 ($[M - CF_3SO_3 - dppn]^+$, 68%), 1253.9 ($[M - 2CF_3SO_3 - dppn]^+$, 33%), 956.9 ($[M - 2CF_3SO_3 - 2dppn - Cu]^+$, 15%), 508.9 ($[M - 3CF_3SO_3 - 3dppn - 2Cu]^+$, 75%), 297.0 ($[M - 4CF_3SO_3 - 3dppn - 3Cu]^+$, 100%); ^1H NMR (200.1 MHz, $(CD_3)_2CO$, 25 °C): δ = 9.15 (s, 2H, 8 + 8'), 8.57 (br. d, 2H, 3 + 3', J_{3-4} = 7 Hz), 8.37 (m, 2H, 6 + 6', J_{5-6} = 4.2 Hz), 8.10 (dt, 2H, 4 + 4', $J_{4-5} = J_{4-3}$ = 7 Hz, J_{4-6} = 1.4 Hz), 7.48 (ddd, 2H, 5 + 5', J_{3-5} = 1.1 Hz); ^{13}C NMR (50.3 MHz, $(CD_3)_2CO$, 25 °C): δ = 155.20 (2 + 2'), 150.22 (6 + 6', 148.46 (7 + 7'), 139.90 (4 + 4'), 129.23 and 128.72 (3 + 3', 8 + 8'), 124.68 (5 + 5'). UV/VIS (PC): λ_{max} [nm] (ε) = 441 (31 500); 294 (134 000); IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1600 (s), (pyridazine); 1265 (br. s), $(S\text{-}O)_{asym}$; 1030 (s), $(S\text{-}O)_{asym}$; 1015 (w, sh.) 1005 (w), (pyridine).

The analogous BF_4^- or ClO_4^- salts can be prepared by adding dppn to $[Cu(CH_3CN)_4]X$ ($X = BF_4^-, ClO_4^-$) in CH_3CN (ratio 1:1) followed by addition of C_6H_6. In the preparation of the PF_6^- derivative, CH_2Cl_2 was preferred as solvent, since the complex then precipitated directly.

2: To a stirred solution of dppn (0.070 g, 0.3 mmol) in acetone (10 mL) was added dropwise under nitrogen a solution of $[Cu(CF_3SO_3)]_2 \cdot C_6H_6$ (0.030 g, 0.060 mmol) in acetone (5 mL) (after elimination of the copper(0) traces due to some decomposition of $[Cu(CF_3SO_3)]_2 \cdot C_6H_6$ in acetone). Stirring for 15 minutes resulted in the complete precipitation of the dark green solid (yield 50% with respect to copper).—Correct C,H,N-analysis. MS (FAB^+, NBA): *m/z* 531.0 ($[M-CF_3SO_3]^+$, 30%); 297.0 ($[M-CF_3SO_3-dppn]^+$, 100%); minor peaks (< 5%) typical of **1** indicate some transformation of **2** into **1** by dissolution in the matrix and prevent the detection of higher peaks if a polymeric nature of **2** was to be confirmed. IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1600(s), 1575(w), 1567(w), (pyridazine); 1287(s) and 1255(s), $(S\text{-}O)_{asym}$; 1035(s), $(S\text{-}O)_s$; 1050(w), 1007(w), 995(w), (pyridine). EPR (solid state, RT): 0.1% Cu(II) impurities.

[12] In contrast, the electrochemical oxidation of **1** was ill-defined and irreversible, undoubtedly because of the instability of Cu^{II} in a tetrahedral environment.

[13] The IR spectrum of **2** shows, besides a monochelating behavior for the dppn ligands, that the triflate anion is coordinated in a bridged fashion.

Alkoxyalkyl-Substituted β-Diketonate Complexes of Barium and Copper: Evidence for Inter- and Intramolecular Stabilization**

By *William S. Rees, Jr.,* Celia R. Caballero,* and *Werner Hesse*

In memorium Manfred L. Ziegler

There is much current interest in the development of new methods for the preparation of electronic materials.[1] Such explorations include sol–gel processing for powder or bulk samples[2] and chemical vapor deposition (CVD) for thin film coatings.[3] Several barium-containing materials systems are of interest because of their demonstrated properties.[4] In an exploration aimed at increasing the vapor pressure of barium-containing compounds while retaining vapor-phase thermal stability—two key features of a useful CVD source compound[3]—we recently examined the intermolecular stabilization of barium-bis-β-diketonates,[5] intramolecular stabilization of barium-bis-η^5-cyclopentadienide compounds,[6] and intramolecular stabilization of barium-bis(oligoalkoxyalkoxides).[7] Whereas each of these new types of compounds offers significant advantages over existing CVD sources,[8] each also suffers some limitation which prohibited broad application in the preparation of thin films.

The limitation of the class of compounds $[Ba\{C_5H_4(CH_2)_nER_m\}_2]$ ($n = 2, 3$; ER_m = OMe, OEt, NMe_2) is their pyrophoric nature;[6] $[\{Ba(tmhd)_2 \cdot 2NH_3\}_2]$ (tmhd = 2,2,6,6-tetramethylheptane-3,5-dionate) is not stable over extended times at the temperatures required for CVD;[5] and the class of compounds $[Ba\{O(CH_2CH_2O)_nR\}_2]$ ($n = 2, 3$; R = Me, Et) is unstable in the vapor phase.[7] We now report the preparation of a new class of ligands, namely the alkoxyalkyl-substituted β-diketones, and their application in the preparation of novel families of both main-group and transition element complexes.

Following our investigation of the decrease in the degree of association of $[\{Ba(tmhd)_2\}_{3,4}]$ by intermolecular addition of Lewis bases[5] and the isolation of monomeric clamshell type oligoalkoxyalkoxides,[7] we now report the successful extension of these discoveries to include intramolecular stabilization of compounds based on the well-known β-diketonate ligand framework by incorporation of an ethereal "scorpion tail". The synthesis of the ligand 2,2-dimethyl-8-methoxyoctane-3,5-dione (**1**) utilizes the Claisen condensation [Eq. (a)]. This synthesis currently is unoptimized; nevertheless, the yield of **1** (66%) is sufficient to permit useful exploration of its properties as a ligand after deprotonation at the acidic methylene position between the two carbonyl groups.

$$Me_3CCOMe + MeO_2C(CH_2)_3OMe \xrightarrow[2.\ HCl(aq)]{1.\ NaH,\ \Delta;\ DME,\ 18\,h} MeOH + \underset{\mathbf{1}}{Me_3CCOCH_2CO(CH_2)_3OMe} \quad \text{(a)}$$

DME = dimethoxyethane

Following Equation (b) CuL_2 (HL = **1**) was prepared from deprotonated **1** and a Cu^{+2} salt.[9] The structure of the

$$2\,HL + Cu(NO_3)_2 \xrightarrow[NH_4OH]{EtOH/H_2O} \underset{\mathbf{2}}{[CuL_2]} + 2\,NH_4NO_3 + H_2O \quad \text{(b)}$$

product $[CuL_2]$ (**2**) was determined by X-ray diffraction (Fig. 1).[9] The ligands are packed on top of each other in the unit cell (Fig. 1b), and an intermolecular, weakly coordinating fifth oxygen atom is 2.987 Å from the copper center. The in-plane Cu–O distances are all 1.90 ± 0.02 Å, and the observed geometry is almost perfectly square-planar (deviation < 0.02 Å). The wavelength of the most intense absorption in the UV spectrum (λ_{max} = 298 nm) does not indicate any significant amount of a five-coordinate complex (square-based pyramid) in solution, since for $[Cu(acac)_2]$, which is known to have a four-coordinate square-planar central atom, λ_{max} is 295 nm (both spectra obtained in THF). Thus, we explain

[**] This project was supported by the United States Defense Advanced Research Projects Agency contract number MDA 972-88-J-1006 and the Deutsche Forschungsgemeinschaft (postdoctoral fellowship for W. H.). We also thank D. A. Moreno for collecting the UV/VIS data for compound **2**, and CAChe for permitting a trial calculation on the hypothesized geometry of compound **3**.

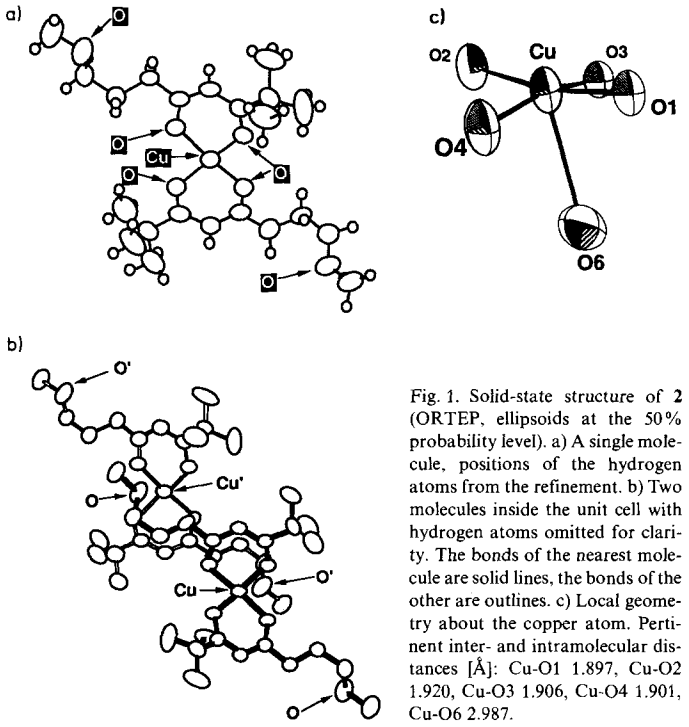

Fig. 1. Solid-state structure of **2** (ORTEP, ellipsoids at the 50% probability level). a) A single molecule, positions of the hydrogen atoms from the refinement. b) Two molecules inside the unit cell with hydrogen atoms omitted for clarity. The bonds of the nearest molecule are solid lines, the bonds of the other are outlines. c) Local geometry about the copper atom. Pertinent inter- and intramolecular distances [Å]: Cu-O1 1.897, Cu-O2 1.920, Cu-O3 1.906, Cu-O4 1.901, Cu-O6 2.987.

this very weak interaction between each copper atom and a fifth oxygen atom in the solid state as more the consequence of molecular packing and not strong domination by tight-binding intermolecular interactions.

Following Equation (c) $[BaL_2]$ (**3**) was prepared by a redox reaction of elemental barium and HL (**1**) accompanied by evolution of $H_{2(g)}$. This new barium compound was purified by distilling off the excess HL, and its composition was confirmed by elemental analysis. It is a monomer in benzene. To our knowledge, this is the first barium compound with β-diketonato ligands which is a liquid at room temperature.[10] Based on the data currently available, it would appear that the metal center is six-coordinate. Examination of space-filling molecular models lends some credence to this suggestion (Fig. 2). Recent publications have appeared describing intermolecular Lewis-base stabilization of monomeric barium-bis-β-diketonates either by crown ethers,[11] or by linear oligoethers.[12] However, to our knowledge compound **3** is the first example of a base-free monomeric barium(II) β-diketonato complex. Current work is aimed at expanding this newly discovered class of ligands.

$$HL_{excess} + Ba \longrightarrow \underset{\mathbf{3}}{[BaL_2]} + H_2 \qquad (c)$$

Experimental Procedure

1 (HL): Under dry, pure N_2, 44.0 g (0.50 mol) of pinacolone were added dropwise at room temperature to a rapidly stirred suspension of 49.4 g (0.37 mol) of $MeO(CH_2)_3COOMe$ and 15.5 g (0.67 mol) of NaH in 190 mL of freshly distilled DME. After the addition was complete, the mixture was heated at reflux with vigorous stirring for 18 h. After the reaction mixture was cooled to room temperature, 70 mL of concentrated aqueous HCl were added to the orange-brown suspension. A small amount of a white, water-soluble residue remained. The aqueous fraction was extracted with Et_2O (5 × 200 mL), and the combined organic fractions were dried over anhydrous $MgSO_4$, filtered, and concentrated on a rotary evaporator. Distillation of the residue gave pure **1** (b.p. 45 °C at 0.01 mm Hg) in 65.5% yield (49.0 g).

Spectroscopic data of **1**: ^1H NMR (300 MHz, $CDCl_3$): $\delta = 1.10$ [s; $C(CH_3)_3$], 1.85 (m; $CH_2CH_2CH_2$), 2.35 (t; CH_2CO), 3.30 (s; CH_3-O), 3.35 (t; O-CH_2), 5.50 (s; $COCH_2CO$); $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta = 25.13$ ($C(CH_3)_3$), 26.83 ($CH_2CH_2CH_2$), 35.02 ($COC(CH_3)_3$), 58.17 (O-CH_2CH_2), 71.35 (CH_3-O), 94.98 ($COCH_2CO$), 195.50 ($COC(CH_3)_3$), 200.10 (CH_2COCH_2). IR (KBr, neat $\tilde{\nu}$[cm^{-1}]): 2960 s, 2920 m, 2860 w, 1720 w, 1700 w, 1600 s, 1480 w, 1460 w, 1360 w, 1270 w, 1120 m, 1020 w.

2: In an open beaker were combined 1.21 g (6.45 mmol) of $Cu(NO_3)_2$, 20 mL of distilled H_2O, 1.53 g (7.64 mmol) of **1**, 20 mL of 95% EtOH, and sufficient $NH_4OH_{(aq)}$ to create a homogeneous, dark blue solution (ca. 6 mL). The solution was extracted with Et_2O (3 × 50 mL). The organic fractions were combined, dried over anhydrous $MgSO_4$, filtered, concentrated to 20 mL, layered with 60 mL of hexane, cooled to −20 °C, and allowed to stand for 48 h. Crystals were collected by filtration and air-dried (m.p. 55–56 °C). Crystals of **2** suitable for X-ray diffraction were obtained by cooling a hexane solution of the compound (− 20 °C, 20 h).

3: Under dry, pure N_2, 3.41 g (17.0 mmol) **1** were added all at once at room temperature to a flask containing a magnetic stirring bar and 0.87 g (6.30 mmol) of freshly cut cubes of elemental Ba. The reaction mixture was stirred until no visible metal fragments remained (5–6 h). Excess **1** was removed by distillation (10^{-2} mm Hg, 45 °C) leaving a clear viscous liquid identified as **3** in almost quantitative yield.

Analytical data of **3**: Satisfactory C,H-analysis; molecular weight (cryoscopic in benzene): calcd. 535, found 600 g mol^{-1}; TGA (N_2, 1 atm): 85% to 270 °C, 46% to 460 °C, 39% to 600 °C; ^1H NMR ($CDCl_3$): $\delta = 1.00$ (s), 1.10 (s), 1.85 (br, m), 2.10 (br, m), 2.40 (s), 3.20 (s), 3.40 (br, m), 5.30 (s).

[9] A crystal of **2** (0.8 × 0.6 × 0.3 mm) was affixed to a glass fiber with two-component epoxy cement. Data collection was carried out at room temperature in the $\omega/2\theta$ scan mode in the range $2° < 2\theta < 55°$, employing an

automated Enraf-Nonius CAD 4 diffractometer with $Mo_{K\alpha}$ (0.71073 Å) radiation. The space group was $P\bar{1}$ (No. 2), with $a = 9.444(2)$ Å, $b = 10.773(2)$ Å, $c = 13.220(2)$ Å, $\alpha = 68.72(1)°$, $\beta = 81.49(1)°$, $\gamma = 84.32(1)°$, $V = 1238$ Å^3, $Z = 2$, and $\rho_{calc} = 1.240$ g cm^{-3}. Two standard reflections (0$\bar{2}$5, 312), measured every hour, gave <2% intensity deviation over the duration of data collection. Of 6010 measured reflections, 4356 were observed and 3616 with $I > 2\sigma(I)$ were used for structure solution and refinement employing the SDP computer programs by Enraf-Nonius. The final cycle of least-squares refinement of 262 parameters gave residuals of $R = 0.058$ and $R_w = 0.064$ and greatest unassigned electron density of $0.880\ e^- \cdot Å^{-3}$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-56191, the names of the authors, and the journal citation.

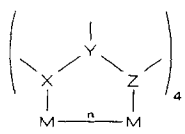
The First Complex with a $\sigma^2\pi^4$ Triple Bond between Vanadium Atoms in a Ligand Framework of Fourfold Symmetry—$[V_2\{(p\text{-}CH_3C_6H_4)NC(H)N(p\text{-}C_6H_4CH_3)\}_4]$**

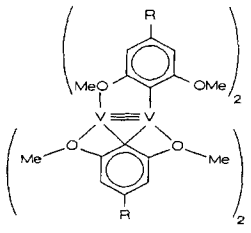
By *F. Albert Cotton*,* *Lee M. Daniels*, and *Carlos A. Murillo**

In memoriam Rosa Víquez de Murillo

The chemistry of compounds containing metal-to-metal multiple bonds has been widely developed in the last two decades. Many of the compounds structurally characterized possess frameworks of structure type **1** (*n* refers to the bond order between the metal atoms). However, progress in the related chemistry of metals in the 3d transition series, with the exception of chromium, has been slow.[1] Only one other complex with a first-row metal with this structure is known, $[Co_2\{(p\text{-}CH_3C_6H_4)NNN(p\text{-}C_6H_4CH_3)\}_4]$.[2] A triple bond between vanadium atoms has been claimed for two compounds **2**,[3] in which the coordination number of the metal atom is greater than in a structure of type **1**. The latter structure is probably best described as an edge-sharing bioctahedron. We now report the structural characterization of the first dinuclear vanadium(II) compound of this type, tetrakis(*N*,*N*′-di-*p*-tolylformamidato)divanadium(II).



1



2 R = H, OMe

Theoretical calculations have clearly indicated the possible existence of molecules of type **1**, with vanadium-to-vanadium triple bonds between 2.0 and 2.1 Å in length.[4] This presented a challenge for the synthetic chemist. Unfortunately, the chemistry of vanadium(II) had not been widely investigated until recent years.[5] We thus decided to undertake a comprehensive study of the chemistry of V^{II} with the goal of eventually characterizing a compound of the type **1**.[6]

In addition to the high instability towards air of most of the V^{II} compounds, one of the major difficulties in their preparation is the lack of good starting materials.[7] Early work indicated that *N*-donors such as amines bind to vanadium(II) quite strongly.[7, 8] However, reactions of vanadium complexes containing monocoordinated amines, such as pyridine, or chelating amines, such as tetramethylendiamine (TMEDA), led mainly to mononuclear vanadium(II) compounds. In no single instance did such starting materials provide any of the type **1** compounds, even when suitable ligands were used.[8d]

It became clear that an amine-free starting material was needed. A potentially bridging ligand with only *N*-donor groups was very appealing, but we did not want to generate a complex with a forced configuration that could raise a question as to the presence of a metal-to-metal bond. We decided that the *N*,*N*′-di-*p*-tolylformamidato (dfm) ligand was a good candidate. It has two potential *N*-donor centers and is able to adopt various configurations depending on the requirements of the metal atoms.

Compounds in which dfm (or a closely related ligand) bridges a metal-to-metal bond have been structurally characterized for M = Cr,[9] Mo,[10] W,[9] Re,[11] Ru,[12] Os,[13] Co,[2] Rh,[14] and Ir.[15] Compounds with a similar framework but without metal-to-metal bonds are also known for M = Ni and Pd.[16] The dfm ligand is also capable of forming a bridge between Cu^I or Ag^I ions, although in this case the stoichiometry is different, namely $[M_2(dfm)_2]$.[17] The metal-to-metal distances vary from 1.930(2) Å in $[Cr_2(dfm)_4]$ to 2.705(6) Å in $[Ag_2(dfm_2)]$. The torsion angle (N-M-M-N) also changes from a very few degrees to about 27° in the cation $[Ni_2(dfm)_4]^+$.[16]

Dfm can also act as a chelating ligand, the most relevant example of which is found in the mononuclear vanadium(II) compound $[V(dfm)_2(py)_2]$ formed by the reaction of $[VCl_2(py)_4]$ (py = pyridine) with Li(dfm) in toluene.[7d]

The title compound, $[V_2(dfm)_4] \cdot$ toluene has been fully characterized by various physical and chemical techniques including X-ray crystallography.[18] It is of the same type as other dinuclear formamidato complexes having four bridging ligands. Its structure, depicted in Figure 1, is homologous to that of the dimolybdenum[10] and ditungsten[9] complexes.

The vanadium(II)-to-vanadium(II) separation of 1.978(2) Å is the second shortest bond length found for the $[M_2(dfm)_4]$ species. Only the Cr_2 unit of $[Cr_2(dfm)_4]$ has a shorter M–M distance (1.930(2) Å). This bond is roughly 0.3 Å shorter than the vanadium-to-vanadium distance found in the complexes of type **2** and 0.47 Å shorter that the V–V bond in $[\{PhNC(Me)O\}_4V_2(tmeda)]$.[8d] The vanadium-to-nitrogen separations of 2.092(4) Å and 2.120(4) Å are also much shorter than the typical distance of 2.2 Å found in a host of mononuclear vanadium(II) compounds in which there is pyridine or tmeda.[7, 8] This is probably an indication of the higher basicity of the dfm ligand. The M–N bond is only slightly longer than that found in $[Cr_2(dfm)_4]$ (average 2.047 Å). The vanadium-to-vanadium distance and the small

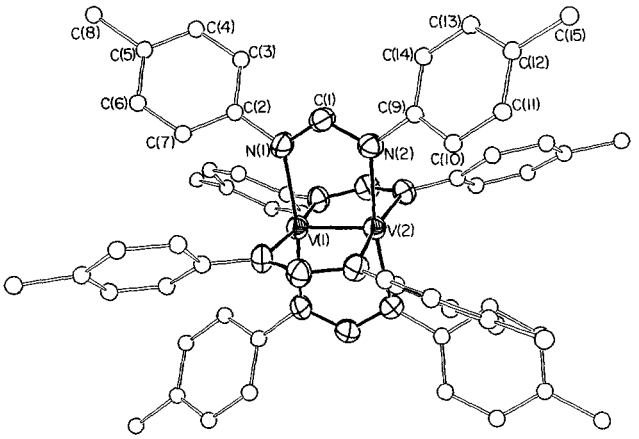

Fig. 1. ORTEP perspective drawing of the molecular structure of $[V_2(dfm)_4]\cdot$ toluene with ellipsoids at the 30% probability level. The carbon atoms of the tolyl groups are drawn as arbitrarily sized spheres.

"formal shortness ratio"[11] (FSR) supports the presence of a fairly strong bond. The FSR of 0.808 is very similar to those of the homologous series with metal–metal quadruple bonds: 0.814 (Cr), 0.840 (Mo), and 0.838 (W). However, a striking difference is found in the magnetic anisotropy, $\Delta\chi$ of the M–M bond. The change in the chemical shift of the methine proton is very large. Relative to the nickel analogue $\Delta\delta$ for the title complex is 4.08. The calculated $\Delta\chi$ value of 7300×10^{-36} m^3 molecule^{-1} is the highest known for any of the dinuclear $[M_2(dfm)_4]$ compounds.[19]

The electronic absorption spectrum (toluene solution) shows two bands (24700, 21300 cm^{-1}) and a shoulder (18200 cm^{-1}) which following some preliminary SCF-Xα-SW calculations[20] can probably be assigned to the N $\rightarrow\delta$, $\pi\rightarrow\delta^*$, and $\pi\rightarrow\delta$ transitions, respectively. These are on the edge of a rapidly rising absorption into the UV which probably arises from one or more L $\rightarrow$ M charge-transfer transitions.

Experimental Procedure

All syntheses were carried out under an inert atmosphere (argon) and with dry and deoxygenated solvents. $[V_2(dfm)_4]\cdot$ toluene was prepared by the reduction of $VCl_3(thf)_3$ [21] (0.80 g, 2.14 mmol) with one equivalent of $NaHBEt_3$ in 20 mL of THF at -70 °C and further addition of a cold suspension of Li(dfm) (4.28 mmol) in 20 mL of THF. After the temperature of the bath reached 20 °C, the red solution was stirred for 30 min. The solvent was then removed under vacuum. The dried solid was extracted with 35 mL of toluene and the solution was kept at -70 °C overnight. The long fiberlike, copper-colored crystals formed were filtered and quickly washed with small amounts of hexane (0.55 g, 52% yield). Upon recrystallization from toluene and layering with hexane, red block-shaped crystals of $[V_2(dfm)_4]\cdot$ toluene formed. Both crystalline forms gave the same NMR spectrum; that of the copper-colored crystals showed only a negligible amount of toluene. The compound is diamagnetic (by NMR). ^{1}H NMR (200 MHz, C_6D_6, 25 °C): $\delta = 1.99$ (s, $-CH_3$), 6.00 and 6.63 (d, $-C_6H_4-$), 10.24 (s, -NCHN-). UV/VIS(toluene): λ_{max} [nm] = 550 (b. sh), 470, 405.

[18] Crystal data for $V_2N_8C_{60}H_{60}\cdot C_7H_8$, $T = 298$ K: $M_r = 1087.2$, space group $P4/n$, $a = 13.214(6)$, $c = 17.427(5)$ Å, $V = 3043(3)$ Å^3, $Z = 2$, $\varrho_{calcd} = 1.19$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 29.4$ cm^{-1}, Rigaku AFC5R, $4° \le 2\theta \le 120°$. 4971 reflections were collected; 2282 unique, 1179 having $I > 3\sigma(I)$. The data were corrected for absorption (ψ-scans) and an overall decay of 14.4%. Initial positions were taken from the homologous structure of $[W_2(dfm)]\cdot$ toluene [9]. The coordinates and isotropic temperature factor for the methine H atom were included in the refinement. Positions for other hydrogen atoms in the complex were calculated. Disordered solvent molecules reside on the fourfold axis between the metal complexes. The toluene molecules were modeled as two rigid groups with the methyl groups pointing in opposite directions along the fourfold axis. The final cycles of refinement led to $R = 0.049$ and $R_w = 0.068$. Further details of the crystal structure investigation may be obtained from the Cambridge Crystallographie Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK) on quoting the names of the authors and the journal citation.
[19] The magnetic anisotropy was calculated using the McConnell equation $\Delta\delta = \Delta\chi\,[(1 - 3\cos^2\theta)/12\pi r^3]$, where $\Delta\delta = 4.08$, $\theta = 90°$, $r = 3.62$ Å. See ref. [9] for further discussion.
[20] The SCF-Xα-SW calculations were carried out for the model system $[V_2(HNCHNH)_4]$ and will be reported elsewhere. Also see the work on $[Mo_2(HPO_4)_4]^{2-}$ in M. D. Hopkins, V. M. Miskowski, H. B. Gray, *J. Am. Chem. Soc.* **1986**, *108*, 959–963.

How High is the Barrier for the Valence Isomerization of Cyclobutadiene?**

By *Günther Maier,* Reinhard Wolf,* and *Hans-Otto Kalinowski*

"Our current knowledge about cyclobutadiene[1] allows this chapter to be terminated. It is now secured textbook material," wrote one of us (G.M.) three years ago.[1d] This statement did not remain unchallenged,[2] although even at the time two existing gaps were indicated. The first concerns the UV spectrum of cyclobutadiene that still is not clearly established. The spectrum must show an absorption maximum

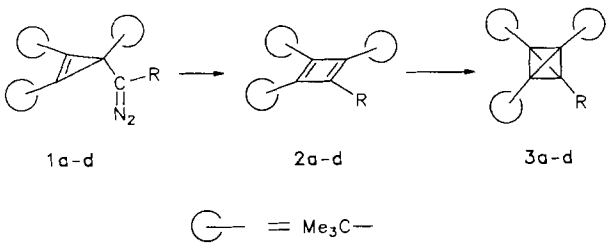
above 254 nm, because irradiation of cyclobutadiene with longer wavelengths causes its rapid cleavage into two molecules of acetylene.[1d] The extinction of this band is so small that experimental determination has failed so far. The second question still open concerns the activation energy of the valence isomerization of cyclobutadiene. We report here on the first reliable experimental determination of this barrier.

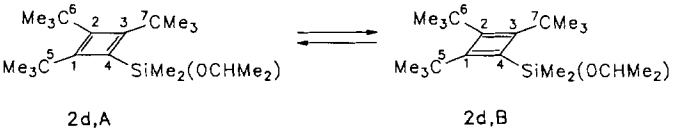
The "Masamune Route"[3a, b] for the synthesis of sterically hindered cyclobutadienes can be applied to cyclopropenyldiazomethane derivatives **1a–d**. Irradiation of cyclobutadienes **2a** and **2b**, available from **1a** and **1b**, respectively, led to tetra-*tert*-butyl- (**3a**)[4a] and tri-*tert*-butyl(trimethylsilyl)-tetrahedrane (**3b**).[4b] The analogous deazotization of the



1-3	a	b	c	d
R	CMe_3	$SiMe_3$	$SiMe_2Ph$	$SiMe_2(OCHMe_2)$

diazo compound **1c** (yellow crystals, m.p. 33 °C) and **1d** (orange oil) in the presence of CuCl provided cyclobutadiene–CuCl complexes which were treated with 1,2-bis(diphenylphosphino)ethane to furnish the free cyclobutadienes **2c** (dark red crystals, m.p. 55 °C, 40%) and **2d** (dark red crystals, m.p. 45 °C, 50%). Photoisomerization of **2c** and **2d** yielded the corresponding tetrahedranes **3c** (colorless plates, m.p. 58 °C) and **3d** (colorless, waxy crystals, m.p. 77 °C) (**2c** → **3c**: $\lambda > 300$ nm, 10%; **2d** → **3d**: $\lambda = 254$ nm, 40%). The structures of the two new stable tetrahedranes **3c** and **3d**[5] and their precursors were assigned on the basis of the spectroscopic data given in Table 1. Tetrahedrane **3c** was also characterized by X-ray structure analysis.[6]

The ^{13}C NMR spectra of the silyl-substituted cyclobutadienes **2b–d** are temperature dependent. This is especially interesting since the constitution of these cyclobutadienes offers the possibility of observing the valence isomerization of the two rectangular forms with dynamic NMR spectroscopy. If in cyclobutadiene **2d**, for example, the rectangular structures **A** or **B** are frozen, then the two diagonal atoms C-1 and C-3 and their substituents are magnetically nonequivalent; in a square structure they would be equivalent. However, a single signal would also be found if a fast equilibrium **A** ⇄ **B** existed, feigning a square structure. Until now it has never been possible to observe separate NMR signals for C-1 and C-3, not even for tri-*tert*-butylcyclobutadiene (**2**, R = H).[7a] Application of Saunders' isotopic per-



turbation method to the same cyclobutadiene derivative with a perdeutero *tert*-butyl group in the 1 position proved that this system has a double minimum.[7b]

If a solution of **2d** in propane/[D_{10}]diethyl ether (ca. 80:20) is cooled to −60 °C, a single ^{13}C NMR signal at $\delta = 167.7$ is found for C-1/C-3 and at $\delta = 35.3$ for C-5/C-7. As the temperature is lowered these signals become broader and each gradually resolves into two separate signals, which at −158 °C again have the usual half width. The downfield signal ($\delta = 167.7$) is split into two signals at $\delta = 178.4$ and 157.3; the second signal ($\delta = 35.3$) now appears as two signals at $\delta = 36.0$ and 34.6. The coalescence temperature T_c for C-1/C-3 is −123 °C (150 ± 5 K), for C-5/C-7, the T_c is −145 °C (128 ± 3 K; this determination for C-5/C-7 is somewhat more precise than that for C-1/C-3). Thus there are two independent probes for the determination of the free energy of activation for the valence isomerization of **2d**. The values provided are 5.8 ± 0.2 (C-5/C-7, $\Delta\nu = 134$ Hz) and 6.0 ± 0.2 (C-1/C-3, $\Delta\nu = 2120$ Hz) kcal mol^{-1}. The line-shape analysis in the region of the intermediate exchange of the C atoms 5 and 7 furnished the following activation parameters: $\Delta H^{\neq} = 5.3 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\neq} = -4.8 \pm 0.1$ cal K^{-1} mol^{-1}, $\Delta G^{\neq} = 5.9 \pm 0.3$ kcal mol^{-1}, $E_a = 6.6 \pm 0.3$ kcal mol^{-1}.

What does the experimentally determined barrier $\Delta G^{\neq} = 5.8$ kcal mol^{-1} (24.4 kJ mol^{-1}) imply? This value is less than that calculated for the parent compound ($\Delta E^{\neq} = 8.1$–13.4 kcal mol^{-1}),[1d, 8] but agrees remarkably well with the latest results of CI calculations (CI = *C*onfiguration *I*nteraction). Multiconfigurational reference wave functions form the basis of this calculational method, and the zero-point vibration is also taken into account in the determination of $\Delta H^{\neq}$. The CAS(4,4)-CEPA calculational method provides, according to Janoschek,[8b, c] an activation enthalpy of $\Delta H^{\neq} = 6.2$ kcal mol^{-1}. If one considers that the bond alternance in the cyclobutadiene ring system depends very little on the substitution pattern,[1d, 9] then the good agreement between the value determined for **2d** and the calculated activation barrier for the parent compound is not surprising.

Low-temperature ^{13}C NMR measurements with a highest field NMR spectrometer[10] confirmed the barrier of 5.8 kcal mol^{-1} for **2d**. In addition, an analogous coalescence phenomenon was observed for C-1 and C-3 of **2c** under these measurement conditions. At temperatures above −150 °C

Table 1. NMR spectroscopic data (^1H NMR: 400 MHz, ^{13}C NMR: 100.6 MHz, δ values relative to TMS) for compounds **1c,d**, **2c,d** and **3c,d**. All compounds provided correct elemental analyses.

1c: ^1H NMR: $\delta = 7.6$–7.3 (m, 5H; Ph), 1.1 (s, 18H; 2*t*Bu), 1.0 (s, 9H; *t*Bu), 0.5 (s, 6H; $SiMe_2$); ^{13}C NMR: $\delta = 138.7$, 134.1, 129.1, 127.7 (Ph), 128.1 (C = C), 42.4 (CN_2), 40.1 (quart. C), 36.8 (CMe_3), 31.1 ($2CMe_3$), 30.9 ($2CMe_3$), 30.4 (CMe_3), −0.9 ($SiMe_2$)[a]

1d: ^1H NMR: $\delta = 4.0$ (sept, 1H, $J = 6.0$ Hz; $CHMe_2$), 1.2 (s, 18H; 2*t*Bu), 1.1 (d, 6H, $J = 6.0$ Hz; $CHMe_2$), 0.9 (s, 9H; *t*Bu), 0.3 (s, 6H; $SiMe_2$); ^{13}C NMR: $\delta = 128.0$ (C=C), 65.5 ($CHMe_2$), 42.3 (CN_2), 39.9 (quart. C), 36.2 (CMe_3), 31.6 ($2CMe_3$), 31.4 ($2CMe_3$), 30.4 (CMe_3), 25.7 ($CHMe_2$), 0.0 ($SiMe_2$)[a]

2c: ^1H NMR: $\delta = 7.8$–7.2 (m, 5H; Ph), 1.3 (s, 9H; *t*Bu), 1.2 (s, 18H; 2*t*Bu), 0.5 (s, 6H; $SiMe_2$); ^{13}C NMR: $\delta = 168.4$ (C-1/C-3), 149.1 (C-2), 142.3 (Ph), 140.4 (C-4), 134.4, 128.9, 128.1 (Ph), 34.0 ($2CMe_3$), 32.5 (CMe_3), 31.0 (CMe_3), 30.1 ($2CMe_3$), 2.6 ($SiMe_2$)[b]

2d: ^1H NMR: $\delta = 3.9$ (sept, 1H, $J = 6.0$ Hz; $CHMe_2$), 1.4 (s, 18H; 2*t*Bu), 1.3 (s, 9H; *t*Bu), 1.2 (d, 6H, $J = 6.0$ Hz; $CHMe_2$), 0.4 (s, 6H; $SiMe_2$); ^{13}C NMR: $\delta = 168.1$(C-1/C-3), 148.4 (C-2), 141.9 (C-4), 64.9 ($CHMe_2$), 35.5 ($2CMe_3$), 33.3 (CMe_3), 32.6 (CMe_3), 31.1 ($2CMe_3$), 27.0 ($CHMe_2$), 3.0 ($SiMe_2$)[b]

3c: ^1H NMR: $\delta = 7.8$–7.2 (m, 5H; Ph), 1.2 (s, 27H; 3*t*Bu), 0.6 (s, 6H; $SiMe_2$) ^{13}C NMR: $\delta = 140.6$, 134.1, 129.0, 127.8 (Ph), 31.3 ($3CMe_3$), 27.1 ($3CMe_3$), 13.9 (3C-*t*Bu), 0.3 ($SiMe_2$), −22.1 (C-$SiMe_2$)[b]

3d: ^1H NMR: $\delta = 4.1$ (sept, 1H, $J = 6.0$ Hz; $CHMe_2$), 1.2 (s, 27H; 3*t*Bu), 1.15 (d, 6H, $J = 6.0$ Hz; $CHMe_2$), 0.4 (s, 6H; $SiMe_2$); ^{13}C NMR: $\delta = 64.7$ ($CHMe_2$), 31.2 ($3CMe_3$), 27.1 ($3CMe_3$), 26.2 ($CHMe_2$), 14.0 (3C-*t*Bu), 2.1 ($SiMe_2$), −22.4 (C-$SiMe_2$)[b]

[a] In $CDCl_3$. [b] In C_6D_6.

only a single broad signal is observed; at $-168\,^{\circ}C$ the resolution into two separate signals is recognizable. The coalescence temperature $T_c = -158\,^{\circ}C$ ($115 \pm 5\,K$) and the shift difference $\Delta\delta = 17.1$ furnish a free energy of activation of $4.5 \pm 0.2\ kcal\,mol^{-1}$ for **2c**. In the case of **2b**, coalescence cannot be observed even with the highest field NMR spectrometer. It is estimated that the coalescence temperature of **2b** is probably another 35 K lower, that is, at about 80 K. If the shift difference is similar to that of **2c**, this would correspond to a barrier of $\Delta G^{\ddagger} \approx 3.5\ kcal\,mol^{-1}$. The activation barriers determined for **2d** and **2c** have an important consequence. Carpenter's kinetic study[11] of the automerization of 1,2-dideuteriocyclobutadiene ($\Delta H^{\ddagger}$ between 1.6 and 10 $kcal\,mol^{-1}$, $\Delta S^{\ddagger}$ between -17 and $-32\ cal\,K^{-1}mol^{-1}$) kindled a discussion[12] on the extent of the effect of heavy-atom tunneling in this process. According to most calculations[12] the tunneling rate is so high that the "thermal" barrier is practically inconsequential.

This prognosis certainly does not hold for the valence isomerization of cyclobutadienes **2**, whose ring C atoms must be moved along with their large substituents. In this context, one should recall that heavy-atom tunneling has not been proved experimentally by means of dynamic NMR spectroscopy, not even for the migration of unsubstituted C atoms.[13]

The upshot is that the valence isomerization of cyclobutadiene **2d** proceeds with an energy barrier of $\Delta G^{\ddagger} = 5.8\ kcal\,mol^{-1}$. For **2c** the free energy of activation is even lower ($4.5\ kcal\,mol^{-1}$), and for **2b** a further decrease of about 1 $kcal\,mol^{-1}$ is estimated. These reactions are faster than earlier calculations had predicted. Nevertheless, we rule out the participation of heavy-atom tunneling.[14]

[13] M. Saunders, C. S. Johnson, Jr., *J. Am. Chem. Soc.* **1987**, *109*, 4401-4402. According to these authors there is no need to discuss a heavy-atom tunneling effect (M. J. S. Dewar, K. M. Merz, Jr. *ibid.* **1986**, *108*, 5634-5635) for the norbornyl cation (C. S. Yannoni, V. Macho, P. C. Myhre, *ibid.* **1982**, *104*, 907-909, 7380–7381).

[14] For the unsubstituted cyclobutadiene a value of $\Delta G^{\ddagger} = 5.8\ kcal\,mol^{-1}$ would already require a rate constant that is consistent with the fast automerization at $-50\,^{\circ}C$ as measured by Carpenter, but not with the results of Michl (A. M. Orendt, B. R. Arnold, J. G. Radziszewski, J. C. Facelli, K.-D. Malsch, H. Strub, D. M. Grant, J. Michl, *J. Am. Chem. Soc.* **1988**, *110*, 2648-2650) based on the estimated exchange rates [$k(25\,K) \geq 10^3\ sec^{-1}$] from the solid-state ^{13}C NMR spectrum of doubly ^{13}C-labeled cyclobutadiene. The influence of the substituents on the exchange rate is difficult to estimate. The reduction of the barrier in the series **2d** to **2c** to **2b** supports the notion that the rate of valence isomerization increases with increasing steric hindrance. This could be explained by the fact that the substitution raises the energy of the rectangular ground-state more than that of the transition state: a) W. T. Borden, E. R. Davidson, *J. Am. Chem. Origin of the Stabilization of Vinyldiazonium Ions by β-Substitution; First Crystal Structure of an Aliphatic Diazonium Ion: β,β-Diethoxyethenediazonium Hexachloroantimonate**

By *Rainer Glaser,* Grace Shiahuy Chen,* and *Charles L. Barnes*

Dedicated to Professor Andrew Streitwieser on the occasion of his 65th birthday

In contrast to aromatic diazonium ions, most aliphatic diazonium ions are highly reactive intermediates that spontaneously lose N_2,[1,2] making the characterization of these important intermediates quite difficult. Aliphatic diazonium

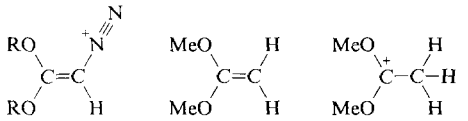
[**] This research was supported by the Petroleum Research Fund of the American Chemical Society and the Research Council of the University of Missouri (92-RC-023-BR). The X-ray diffractometer and the Bruker 500 MHz NMR spectrometer were partially funded by the National Science Foundation (CHE 90-11804 and CHE 89-08304, respectively). This research is part of the projected Ph.D. dissertation of G. S. Chen.

ions have been observed in superacid media[3] and in the gas phase.[4] Alkanediazonium ions have been stabilized by transition metals, but in these complexes the diazonium ions are bent and differ greatly from the free ions.[5] Bott discovered that various β,β-disubstituted ethenediazonium ions[6] are rather stable while the parent system is not.[2] This was attributed to the resonance stabilization of the β substituents. Bertrand et al. recently reported on the alkylation of a diazomethylenephosphorane which gives rise to stable C_β P-analogues of ethenediazonium ions, best described as phosphonio-substituted diazoalkanes.[7]

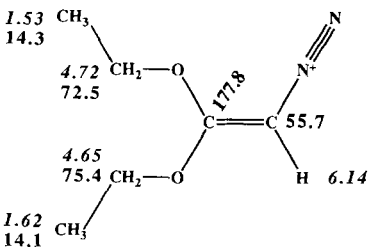
In this article, we report the first crystal structure analysis of an aliphatic diazonium ion, β,β-diethoxyethylenediazonium ion (**1**) in **1**-$SbCl_6$. With this crystal structure, we provide for the first time experimental information with which theoretical structural studies can be judged. The ab initio structures of **1** and its dimethoxy analogue **2**, 1,1-dimethoxyethene (**3**), and 1,1-dimethoxyethenium ion (**4**) also have been determined for the examination of the importance of individual mesomeric resonance forms.



1, R = Et
2, R = Me

3 **4**

1-$SbCl_6$ was prepared by direct alkylation of diazoacetic ester with triethyloxonium hexachloroantimonate in 1,2-dichloroethane as described by Bott.[6] The white needles of **1**-$SbCl_6$ obtained after recrystallization from 1,2-dichloroethane were characterized by elemental analysis and by infrared and ^1H and ^{13}C NMR spectroscopy. IR spectra of **1**-$SbCl_6$ were recorded in CH_2Cl_2 and in the solid state (KBr). In the solution spectrum, the characteristic N–N stretching vibration appears at 2193 cm^{-1} while two bands[6] arise for this N–N stretching mode in the solid-state spectrum at 2192 and 2161 cm^{-1}. The ^1H (italics) and ^{13}C NMR chemical shifts are summarized in Scheme 1. The ^1H



Scheme 1. ^{13}C and ^1H (italics) NMR chemical shifts of **1**.

signals were assigned based on the observed NOE between the vinylic H and the *trans*-CH_2 hydrogen atoms and the two-dimensional ^1H–^1H and ^1H–^{13}C COSY spectra. The signal for the vinylic H at $\delta = 6.14$ is most diagnostic. Unexpectedly, the ^{13}C NMR signal of the α C atom shows a lower intensity than that of the quaternary β C atom, but a DEPT experiment[8] clarified the assignment of these signals.

Single crystals suitable for X-ray crystallography were obtained from a solution of **1**-$SbCl_6$ in 1,2-dichloroethane which was covered with a layer of dry hexane and left standing in a dry box under N_2. Colorless single crystals formed at the interface after three days.[9]

The asymmetric unit of the orthorhombic unit cell of **1**-$SbCl_6$ contains two symmetry-independent cations **A** and **B** (Fig. 1) as suggested by the solid-state IR spectrum. **A** and **B** are surrounded by $SbCl_6^-$ ions, and all chlorine atoms are more than 3.35 Å away from the cations. The β N atoms are

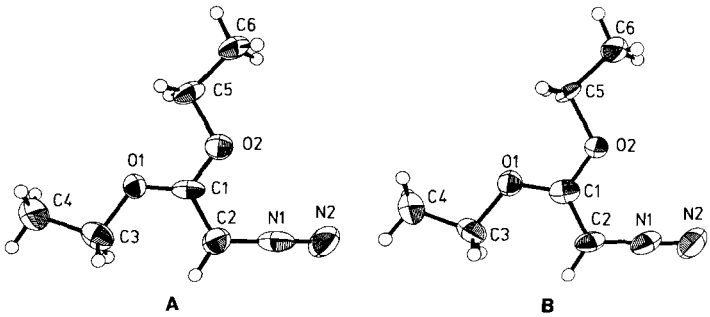


Fig. 1. Crystal structures of the two symmetry-independent β,β-diethoxyethenediazonium ions **A** and **B**. For bond lengths and angles see text.

coordinated by four chlorine atoms, and some of these chlorine atoms occupy bridging positions between the β N and α C atoms. The β C atoms in **A** and **B** are relatively close to two chlorine atoms (>3.4 Å). The ions **A** and **B** have the same conformation, and deviate from local C_s symmetry only slightly. C–O s-*trans* and s-*cis* conformations are preferred for the C_β–O bonds that are *cis* and *trans* with regard to the N_2 group, respectively, and all conformations are s-*trans* about both the Et–O and C–C bonds. Significant structural differences are evident for **A** and **B** (Table 1). The C–N bond in **A** is about 0.05 Å longer than in **B** while both of the C_β–O bonds, and the *cis* C1–O2 bond in particular, are shorter. Angular differences are small except for the *trans* ethyl group. **A** and **B** both exhibit C1–C2 bond lengths of 1.37–1.38 Å and N–N bond lengths of 1.10 Å. The bond angles involving the C1–C2 bond indicate attractive interactions between the N_2 group and the proximate ethoxy group. The C1-C2-N1 and C2-C1-O2 angles are less than 120°, whereas the corresponding angles C1-C2-H and C2-C1-O1 are larger. Importantly, the Et-O-C_β angles indicate approximately sp^2-hybridized O atoms, and the C_β–O distances are comparatively short.

The C_s structure of the diethoxyethenediazonium ion with the conformation of **1** was optimized with the 3-21G and 6-31G* basis sets (Fig.2). Conformational analysis of **2** suggests than this conformation is the most stable one.[11] The ab initio structures agree well with the average experimental values. Bond lengths generally are over- and underestimated at the lower and higher levels of calculation, respectively, but these differences are of about the same magnitude as the experimental uncertainties. The most significant deviations between the calculated and the solid-state structure occur for the Et-O-C_β angles (larger by 3.6–5.8°) and for the N–N bond length (underestimated by 0.01–0.02 Å).[12] Note that both the C_β–O and the Et–O bonds are consistently longer for the *cis* ethoxy group. The C1-C2-H angle is predicted to be significantly larger than the sp^2 hybridization angle.

The structural parameters of the CNN units in diazo compounds and diazonium ions are similar,[13] and thus provide little information regarding contributions of the mesomeric resonance forms of **I**–**IV** (Scheme 2). The C–C and the O–C bond lengths probably are the parameters best suited for this

Table 1. Selected important structural parameters of the crystal and ab initio structures of β,β diethoxyethenediazonium ion [a].

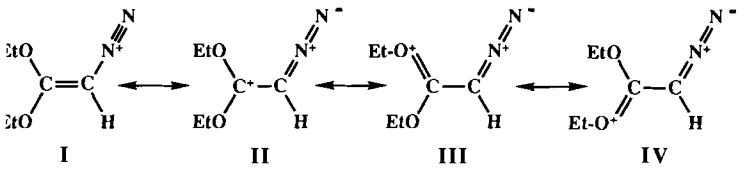
analysis. The short C_β–O bonds and the large Et-O-C_β angles indicate that the Lewis structures of types **III** and **IV** contribute significantly. This importance of **III** and **IV** can be



Scheme 2. Resonance forms I–IV of 1.

demonstrated convincingly by comparison[14] of **2** with **3** and **4** (Fig. 2). Note the structural similarities of **1** and **2**. The C_β–O bond lengths in the carbenium ion **4** are only moderately shorter than in **2** (0.015–0.026 Å) while the O–CH_3 bonds are slightly longer (0.008–0.012 Å). In contrast, the C_β–O bonds in **3** are significantly longer (>0.074 Å), and the H_3C–O bonds are shorter (>0.035 Å) than in both **2** and **4**. Thus, the characteristic shortening of the C_β–O bonds and the concomitant lengthening of the H_3C–O bonds in the carbenium ion **4** are also clearly evident in **2**. This finding stresses the importance of resonance forms **III** and **IV**. The longer C–C bonds in **1** and **2** compared to **3** provides evidence for the importance of all of the resonance forms **II**–**IV**. Oxosubstituted carbenium ("oxenium") ions[15] as well as dioxo derivatives[16] ("dioxenium" ions) are known, and a few crystal structures of the former have been reported. Childs et al.[15a] determined the crystal structure of two hydroxycarbenium ions; their short C–OH bond lengths (1.288–1.302 Å) indicate significant contributions of the oxenium ion resonance form.[17]

These results point out the crucial importance of the O-stabilized carbenium-type resonance forms **II**–**IV** in understanding the stability of the β-substituted alkenediazononium ion. Our conclusions are in agreement with topological electron density analysis of other β-substituted ethenediazonium ions[2d] as well as of the unsubstituted system[2a] which suggest electronic structures with overall *neutral* dinitrogen

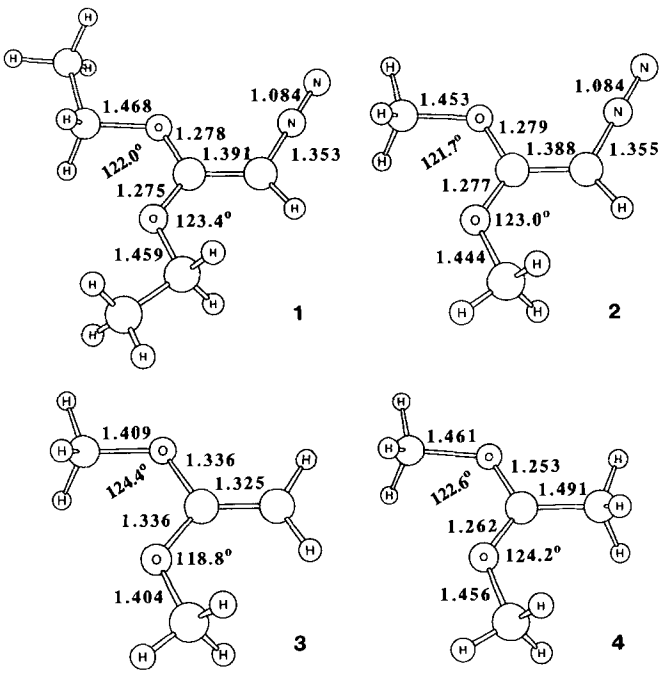


Fig. 2. RHF/6-31G*-optimized C_s structures of **1**–**4**.

fragments. Moreover, the ^{13}C NMR chemical shifts of **1** are indicative of electron depletion at C_β which is also in agreement with the additions of nucleophiles to the β carbon atom in the chemistry of β,β-disubstituted ethenediazonium ions.[18]

Experimental Procedure

Caution: Oxonium salts are toxic and carcinogenic. All experimental work was carried out in a glove box under dry N_2. Solvents were dried over P_4O_{10}; hexane was dried over molecular sieves.

1: To a stirred solution of diazoacetic ester (2.08 g, 18 mmol) in 15 mL of 1,2-dichloroethane was added triethyloxonium hexachloroantimonate (2.6 g, 6 mmol). The resulting mixture was allowed to react 24 h at room temperature. Upon addition of 40 mL of CCl_4 **1** precipitated. The crude product was purified by recrystallization. A saturated solution of **1** in dichloroethane at room tem-

perature was treated with CCl_4 until the crystallization of **1** was observed. Recrystallization at 5 °C furnished 2.08 g of the pure salt **1** as white needles; m.p. 110–112 °C; yield 24%.

^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 1.53$ (t, $J = 7$ Hz, 3H), 1.62 (t, $J = 7$ Hz, 3H), 4.65 (q, $J = 7$ Hz, 2H), 4.72 (q, $J = 7$ Hz, 2H), 6.14 (s, 1H); ^{13}C NMR (CD_2Cl_2): $\delta = 14.14$ (CH_3), 14.28 (CH_3), 55.75 (CH), 72.47 (CH_2), 75.41 (CH_2), 177.8 (C1). – Correct elemental analyses (C,H,N,Cl).

[9] X-ray data of **1**: were collected at −100 °C on an Enraf-Nonius CAD4 diffractometer with $Mo_{K\alpha}$ radiation. The needle-shaped crystal was mounted on a glass fiber approximately along the long axis of the needle. The data was corrected for Lorentz and polarization effects. An empirical absorption correction was applied using ψ scans, giving relative transmittance factors between 0.90 and 0.99. The structure was solved by Patterson techniques and refined in the space group $Pca2_1$ with $Z = 8$. Though the antimonate ions are related by a pseudo center of symmetry, the organic cations do not agree with this symmetry element. The acentric space group reported is therefore correct. The polarity of the crystal could not be determined, probably as a result of the pseudocentrosymmetrically related antimonates. Refinement included anisotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were included in the model at calculated positions; the orientation of the methyl hydrogen atoms were established in a difference Fourier map. Full-matrix least-square refinements gave final $R = 0.032$, $R_w = 0.044$ and $S = 1.20$ for 2203 reflections with $I > 2.5\,\sigma(I)$. The final Fourier map includes four peaks of about 0.8 $e^-Å^{-3}$ near the antimony atoms, but no other features above 0.5 $e^-Å^{-3}$. All calculations were performed with the NRCVAX suite of programs.[10] Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

[11] It is certainly reasonable to assume that the methyl and the methylene groups in the ethoxy fragments are staggered and in the *s-trans* conformation with respect to the C3–C4 and C5–C6 bonds. The dimethyl compound therefore serves well in the investigation of the conformational preferences about the four C–O bonds. R. Glaser, G. S. Chen, unpublished results.

[12] The former is likely to be a crystal-packing effect requiring relatively little energy (bending modes), and the latter reflects the importance of electron correlation in predictions of the N–N bond length as discussed in ref. [2c].

Cyclohexadienyl-Type Cationic Intermediates in the Friedel–Crafts Alkylation of Benzene Derivatives with the 9-Fluorenyl Cation—Observation by Laser Flash Photolysis**

By *Frances Cozens, Jianhui Li, Robert A. McClelland,** and *Steen Steenken**

There have been a number of recent reports of the use of laser flash photolysis to directly study carbocations under conditions where they are actually found as intermediates in organic reactions.[1] This approach allows the measurement of absolute rate constants for the further reactions of the cation. Previously, reactivities of short-lived cations had been examined only in terms of *relative* rate constants, obtained, for example, from competition experiments in which an intermediate not observed directly partitions between two nucleophiles. One fundamental reaction that has seen considerable investigation in the latter regard is electrophilic aromatic substitution. In this paper we demonstrate that flash photolysis can be employed to *directly* study the key steps in such a reaction. In particular, *both* cationic intermediates of a Friedel–Crafts alkylation can be observed, the initial electrophile *and* the cyclohexadienyl cation, the "σ complex" formed by addition to the arene.

The experiments employed the 9-fluorenyl cation (Fl^+), generated photochemically from 9-fluorenol (Fl-OH) in 1,1,1,3,3,3-hexafluoroisopropyl alcohol (HFIP)[2] (Scheme 1). This system has several features that make it useful for studying reactions with arenes: 1) The photoheterolysis of 9-fluorenol is very clean in this solvent with no competing reactions such as photohomolysis. 2) The solvent itself is relatively unreactive to cations, so that the added arenes can compete for the cation. 3) 9-Fluorenol has sufficient absorbance to be excited at 300–310 nm, a range in which simple aromatic compounds have essentially *no* absorbance.

Indeed, the rates (k_{obsd}) for the exponential decrease of Fl^+ (due to reaction with solvent[2]) increase in the presence of alkenes and arenes, with the expected linear dependence on the concentration of the additive. The second-order rate con-

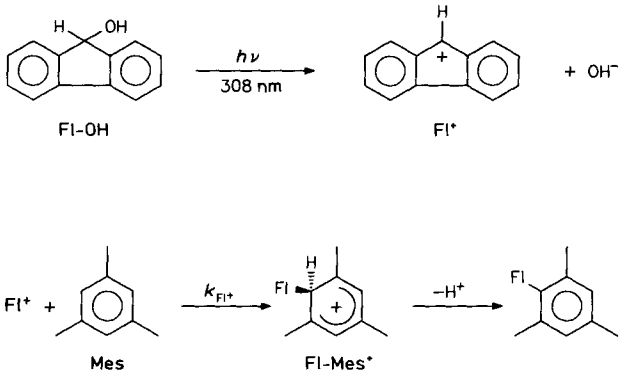

Scheme 1.

stants k_{Fl^+}, determined from the slope of the plot of k_{obsd} versus the concentration of the additive are given in Table 1. For benzene and the monosubstituted benzenes **1**–**5** the rate constants are strongly dependent on the substituents; a plot of log k_{Fl^+} versus σ_p^+ is linear with a slope ϱ of -5.0 ($r = 0.999$). The rate constants, however, approach a plateau at anisole. This "saturation effect" can also be seen in the data for the methylated benzenes, in which additional methyl substituents have little effect after *m*-xylene (compare **5**–**9**). Styrene and its derivatives **10a–e** and 1-methylcyclohexene (**11**) react with the same rate constant, 3×10^9 M^{-1}s^{-1}. This value is probably close to the diffusion limit, at least as based on the observation that there is *no* dependence on substituent in this series.

Table 1. Rate constants for the reaction of π nucleophiles with the 9-fluorenyl cation Fl^+ (k_{Fl^+}) [a] and for the reaction of *n*-nucleophiles with $FlMes^+$ (k_{FlMes^+}) [b].

Reaction with Fl^+		Reaction with Fl-Mes$^+$	
Nucleophile	k_{Fl^+} [M^{-1}s^{-1}]	Nucleophile	k_{FlMes^+} [M^{-1}s^{-1}]
benzene (**1**)	3.3×10^5	$(CF_3)_2CHOH$	5×10^4 s^{-1} [c]
fluorobenzene (**2**)	7.9×10^5	MeOH	3.3×10^6
biphenyl (**3**)	2.8×10^6	EtOH	3.0×10^6
toluene (**4**)	1.1×10^7	iPrOH	1.9×10^6
anisole (**5**)	1.7×10^9	tBuOH	1.3×10^6
m-xylene (**6**)	1.1×10^9	Br^-	2.8×10^9
mesitylene (**7**)	1.9×10^9		
1,2,3,5-$(Me)_4C_6H_2$ (**8**)	1.7×10^9		
pentamethylbenzene (**9**)	1.5×10^9		
$ArCH{=}CH_2$ **10a–e** [d]	$(3.0 \pm 0.2) \times 10^9$		
1-methylcyclohexene (**11**)	2.9×10^9		
$(CF_3)_2CHOH$	$(2-5) \times 10^4$ s^{-1} [c]		

[a] Experiments were carried out at 20 ± 1 °C with solutions of 0.1–0.2 mM 9-fluorenol in HFIP, and excitation at 308 nm. The decay of the cation was monitored at 515 nm, and five to seven concentrations of nucleophile were employed. k_{Fl^+} was obtained as the slope of k_{decay} versus [nucleophile]. [b] Determined by monitoring the rate of decay of Fl-Mes$^+$ at 370 nm as a function of [nucleophile] in a solution of 1 mM 9-fluorenol and 2 mM mesitylene in HFIP. [c] Pseudeo-first-order rate constant for the decay in solvent alone. Number varies depending on water content [2]. [d] Ar = 4-$MeOC_6H_4$ (**a**), 4-MeC_6H_4 (**b**), C_6H_5 (**c**), 4-BrC_6H_4 (**d**), 3-BrC_6H_4 (**e**).

For the photolysis in the presence of selected arenes, experiments were conducted with excitation at 300 nm in a Rayonet reactor, followed by GC analysis of the products. The expected products of electrophilic substitution were observed (Table 2). Authentic samples of these adducts were prepared by the reaction of the appropriate aryl Grignard compounds and fluorenone followed by reduction.[3–5] The product of the capture of Fl^+ by HFIP, 9-(1′,1′,1′,3′,3′,3′-hexafluoroisopropoxy)fluorene,[2] was also present, and together with the substituted arenes quantitatively accounted for all the photolyzed 9-fluorenol. The solvolysis of 9-bromofluorene in HFIP in the presence of toluene, a thermal reaction proceeding via Fl^+, gave a product distribution identical to that of the photochemical reaction (of 9-fluorenol), establishing that the latter also proceeds by way of the free, ground state, 9-fluorenyl cation.

Table 2. Products from the photolysis of 9-fluorenol in the presence of arenes.

Arene	Product(s)
benzene	9-phenylfluorene
toluene	(9-fluorenyl)toluenes, *o*:*m*:*p* = 5:5:90
anisole	(9-fluorenyl)anisoles *o*:*p* = 55:45, *m* < 0.1
m-xylene	(9-fluorenyl)-1,3-dimethylbenzenes 2:4:5 = 0.1:98:2
mesitylene	1-(9-fluorenyl)-2,4,6-trimethylbenzene

As determined from product analysis following photolysis in the presence of both benzene and toluene, the statistically corrected ratio of the rate constants for *para* substitution of toluene compared to reaction with benzene is 200. This quantity can also be calculated from the directly measured rate constants as $[6 \times 0.90 \times k_{Fl^+}\text{(toluene)}]/[k_{Fl^+}\text{(benzene)}] = 180$; the factors 6 and 0.9 represent the statistical correction for benzene and the fraction of *para* product with toluene, respectively. A similar competition between toluene and mesitylene also results in product ratios predictable from the ratio in absolute rate constants (observed mesitylene: *p*-toluene product ratio (statistically corrected) = 70, calculated $[\frac{1}{3} \times k_{Fl^+}\text{(mesitylene)}]/[0.9 \times k_{Fl^+}\text{(toluene)}] = 63$). There has been some discussion as to the consistency of kinetic data based on competition experiments,[6] but in the present case there is clearly excellent agreement with the time-resolved data.

As illustrated for mesitylene in Figure 1, the cyclohexadienyl cation of "σ complex" that results from the reaction of Fl^+ with the arene can be directly observed. In the *absence* of mesitylene, the 9-fluorenyl cation Fl^+ produced by the 308 nm photolysis of 1 mM 9-fluorenol in HFIP decays to zero with $k = (2-5) \times 10^4$ s^{-1}.[2] In the *presence* of mesitylene, however, the disappearance of Fl^+ is much

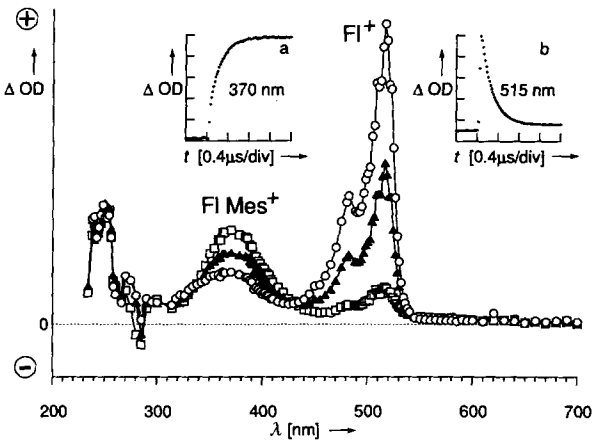

Fig. 1. Absorption spectra of transient species observed upon 308 nm excitation of a solution of 1 mM 9-fluorenol in HFIP (air-saturated) in the presence of 2 mM mesitylene. Spectra were recorded 100 ns (circles), 250 ns (triangles), and 800 ns (squares) after the laser flash. Inset b shows the decrease of the concentration of Fl^+ due to reaction with mesitylene (Mes), inset a the concomitant buildup of the resulting cation Fl-Mes$^+$ (timescale 0.4 μs per division; OD = optical density).

faster, and a new absorbance centered at 365 nm grows in at the same rate as the absorbance of the cation at 515 nm decays (see insets a) and b) in Fig. 1). The 1:1 transformation is also documented by the isosbestic points at 335 and 430 nm.

After reaching a maximum the absorbance at 365 nm eventually decreases again and decays to zero with a rate constant of $5 \times 10^4\ s^{-1}$. This new transient is identified as the 1-(9′-fluorenyl)-2,4,6-trimethylbenzenium ion, Fl-Mes$^+$ (Scheme 1).[7] In support of the assignment of the transient species absorbing at 365 nm to a cyclohexadienyl cation is the fact that the 2,4,6-trimethylbenzenium ion, which is obtained by photoprotonation of mesitylene in HFIP,[8] decays in HFIP with a rate constant of $1 \times 10^5\ s^{-1}$ and has λ_{max} at 355 nm, in agreement with the spectrum of the cation in strong acids.[9–11] The 2,4,6-trimethylbenzenium ion has an additional absorption band at 250–260 nm.[8–11] A band in this spectral region is also apparent in Figure 1, although there is overlap with absorbance[2] due to Fl$^+$.

As a further characterization of the species absorbing at 355 and 260 nm, its reactivity with O_2 (none) and with *n*-nucleophiles was determined. The results (Table 1) show the species to be highly electrophilic, as expected for cyclohexadienyl cations.[8, 12] It is interesting that the rate constants are of a factor 2–6 smaller than those[12] of the corresponding cyclohexadienyl cations produced by addition of *para*-substituted phenyl cations to mesitylene.

Transient σ complexes (cyclohexadienyl cations) were also observed in the reaction of Fl$^+$ with *m*-xylene, anisole, and the tetra- and pentamethylbenzenes, but not with toluene or the less reactive arenes. The latter observation is explained by assuming that the rate of disappearance of the cyclohexadienyl cation is larger than its rate of formation.

There have been suggestions that, depending on the reactivity of the electrophile, transition states in arene substitutions resemble either the σ complex or a π complex.[13] Very fast reactions have been assumed to occur via the latter and to lead to low intramolecular selectivity, such as, with toluene, *ortho*:*para* ratios near 2:1. However, we have found that this concept is not necessarily correct: The reactions of Fl$^+$ with aromatic compounds are very fast, and yet there is significant intra- as well as intermolecular selectivity. The former is reflected by the low yield of *ortho* product from toluene, the latter in the large ratio of rate constants for the reactions of Fl$^+$ with toluene and benzene.

In summary, although the rate constants for the reaction of the 9-fluorenyl cation with arenes measured by laser flash photolysis are large, the system exhibits selectivity patterns indicative of a transition state that has characteristics of the intermediate cyclohexadienyl cation. Such a species has been observed with the more reactive arenes, so that in the same experiment both cationic intermediates of a Friedel–Crafts reaction could be studied directly.

Selective Binding of Sugar to β-Cyclodextrin: A Prototype for Sugar–Sugar Interactions in Water**

By *Yasuhiro Aoyama,** *Yoshiro Nagai, Jun-ichi Otsuki, Kenji Kobayashi*, and *Hiroo Toi*

Oligosaccharides play important roles in biological information transfer, especially in the intercellular recognition.[1] Selective complexation of sugars in apolar organic media is a rapidly growing area of research in the field of molecular recognition.[2] The object of the present work is to shed light on the oligosugar–sugar interactions *in water*; we report here on the first example: β-cyclodextrin (β-CD)[3] selectively binds aldopentoses.

8-Anilinonaphthalene-1-sulfonate (ANS, in this study as Mg^{2+} salt) is known to form a 1:1 complex with β-CD in water [Eq. (a)], thereby undergoing a significant enhancement of its fluorescence intensity *I* (from 25 arbitrary units for free ANS to 400 for the complex). A binding constant

$$\beta\text{-CD-ANS} \underset{K_{ANS}}{\overset{ANS}{\rightleftharpoons}} \beta\text{-CD} \underset{K}{\overset{guest}{\rightleftharpoons}} \beta\text{-CD-guest} \qquad (a)$$

K_{ANS} of $95\ M^{-1}$ was obtained by fluorimetric titration (pH 6.8 at 25 °C; literature values: 77, 64, 110, and 65[4]). The fluorescence intensity of ANS (1.0×10^{-4} M) at a fixed β-CD concentration (1.2×10^{-2} M) was reduced in the presence of aldopentoses and their derivatives [D-ribose (D-**1**), D- and L-arabinose (D- and L-**2**), D-xylose (D-**3**), D-lyxose (D-**4**), D-2-deoxyribose (D-**5**), and methyl β-D-ribopyranoside (D-**6**)], as well as of aliphatic alcohols [*tert*-butanol (**7**), cyclohexanol (**8**), and *cis*- and *trans*-1,2-cyclohexanediol (**9c** and **9t**)]. In marked contrast, aldohexoses and their derivatives

[D-glucose (D-**10**), D-galactose (D-**11**), D-mannose (D-**12**), D- and L-fucose (D- and L-**13**; fucose = 6-deoxygalactose), and methyl α-D-fucopyranoside (D-**14**)] showed almost no effect. Typical correlations between the difference in intensity ΔI ($I - I_0$) and the concentration of the guest are shown in Figure 1 for selected guests (D-**1**, L-**2**, D-**5**, D-**6**, **9t**, and D- and L-**13**.

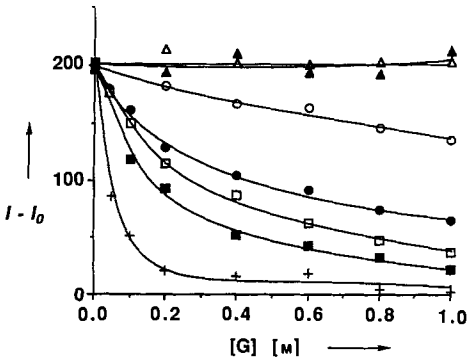

Fig. 1. Correlations between ΔI ($I - I_0$) and the concentration of the guest [G] (excitation at 348 nm and emission at 520 nm) for D-**1** (●), L-**2** (○), D-**5** (□), D-**6** (■), **9t** (+), D-**13** (▲), and L-**13** (△) under conditions of $[ANS]_0 = 1.0 \times 10^{-4}$ M and $[\beta\text{-CD}]_0 = 1.2 \times 10^{-2}$ M at pH 6.8 and 25 °C. I_0 = fluorescence intensity for ANS without guest.

The reduction in fluorescence intensity can be interpreted in terms of competitive inhibition of the ANS binding as a result of β-CD–guest complexation [Eq. (a), guest is **1**–**14**]. More direct evidence for the selective guest binding came from the ^{13}C NMR results. Sugars **1**–**6** and alcohols **7**–**9** (1.0×10^{-1} M) caused characteristic site-specific changes in the ^{13}C chemical shifts δ_C of β-CD (1.0×10^{-2} M). Sugars **10**–**14**, on the other hand, gave practically no effect. Some typical examples are shown in Table 1.

Table 1. Shifts ($\Delta\delta_C$) in ^{13}C NMR signals for β-CD (1.0×10^{-2} M) in the presence of guests (1.0×10^{-1} M) in D_2O.

L-**13**	ca. 0	ca. 0	ca. 0	ca. 0	ca. 0	ca. 0	ca. 0

[a] The chemical shifts (relative to external TMS) of β-CD in the absence of any guest are δ_C = 102.9 (C1), 82.2 (C2), 74.1 (C3), 73.1 (C4), 72.9 (C5), 61.4 (C6): P. Colson, H. J. Jennings, I. C. P. Smith, *J. Am. Chem. Soc.* **1974**, *96*, 8081–8087. A positive sign for $\Delta\delta_C$ indicates a downfield shift. [b] Binding constants for the β-CD–guest complexation determined by fluorimetric analysis (cf. Table 2).

Analysis of the competitive inhibition data[5, 6] gave the binding constants [K, Eq. (a)] shown in Table 2. The trend in the constants for guests **5**, **6**, **7**, **10**, **11**, and **13** parallels the complexation-induced shifts in δ_C ($\Delta\delta_C$, Table 1). They decrease in the general order **8** > **9c** ≈ **9t** ≈ **7** > **1**–**6**. The decreasing order in the aldopentose series (**6** > **5** > **1** > **4** > **3** > **2**) is essentially the decreasing order of hydrophobicities.[7] These results suggest that hydrophobic interactions make an important contribution to the present oligosugar–sugar complexation, but it can not be the sole governing factor. First, the correlation between K and P (lipophilicity)[8] established for the β-CD-alcohol complexation[5] suggests that even the lipophilicity of **6** is not enough to allow its binding to β-CD. Second, fucose (**13**) is more hydrophobic than aldopentoses **1**–**4**, and its methyl glycoside **14** is the most hydrophobic among sugars investigated here; nevertheless, they are not bound by β-CD. There is, however, a rather surprising selectivity between aldopentoses **1**–**6** and aldohexoses **10**–**14**. This selectivity can hardly be due to favorable furanose binding, since the furanose contents for xylose (**3**) and lyxose (**4**) in water are approximately 0[9] and *pyranoside* **6** is in fact best bound. Thus, the absence (aldopentoses) or the presence (aldohexoses) of a substituent X on C5 of a pyranose ring must be the crucial factor.

Table 2. Binding constants K for the β-CD–guest complexation [a].

guest	K [M^{-1}]	guest	K [M^{-1}]	guest	K [M^{-1}]
D-**1**	5.3	D-**6**	14	D-**11**	ca. 0

D-**4**	4.3	**9t**	61	D-**14**	ca. 0
D-**5**	9.4	D-**10**	ca. 0		

[a] The binding constants are average values obtained from fluorescence measurements for at least three different guest concentrations at pH 6.8 and 25 °C. Estimated errors are ≤20%. [b] Literature value [5]: 47. [c] Literature value [4]: $(2.0 \times 10^{-3})^{-1} = 500$.

The inhibitory effect of both hydrophilic 5-CH_2OH (for **10**–**12**) and hydrophobic 5-CH_3 groups (for **13**–**14**) suggests that the inhibition is steric in origin. This may rule out an *axial* binding mode, in which the substituent X exerts a minimal steric effect but some hydrophilic ring-OH groups of a bound sugar are exposed to the hydrophobic wall of β-CD. If, on the other hand, the polar cluster composed of 1-, 2-, 3-, and 4-OH groups of a bound pyranose stays in a relatively polar region in the vicinity of the rim of β-CD, the remaining ring oxygen atom and C5 bearing substituent X can for steric reasons be accommodated in the cavity when X is H, but not when X is CH_2OH or CH_3.

In summary, hydrophobic contributions to the present β-CD–sugar complexation are evident. However, polar interactions of the OH groups of bound sugar with bulk water and/or the OH groups of β-CD are also extremely important in determining the structure of the complex and hence the selectivity of the sugar binding.

Assistance by Electrophiles in Photoinduced Alkylidyne–Carbonyl Coupling**

By *Andreas Mayr,** *Cecilia M. Bastos, Richard T. Chang, John X. Haberman, Katrina S. Robinson,* and *Deirdre A. Belle-Oudry*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

The coupling of alkylidyne and carbonyl ligands may be induced in different ways.[1] In most reactions, including the first example discovered by Kreissl et al.,[2] alkylidyne–carbonyl coupling is induced by the addition of a strongly nucleophilic ligand to the metal center. There is some indication that the coupling of alkylidyne and carbonyl ligands may also be induced by electrophiles. Schrock et al.[3] reported that the reaction of $[W(CH)Cl(PMe_3)_4]$ with CO in the presence of aluminum reagents such as $(AlCl_3)_2$ gives $[W(\eta^2\text{-}HCCOAlCl_3)Cl(CO)(PMe_3)_3]$. Lippard et al.[4] demonstrated the formation of disiloxyalkyne ligands upon reaction of the siloxymethylidyne complex $[Ta\{COSi(iPr)_3\}(CO)(dmpe)_2]$ [dmpe = bis(dimethylphosphinoethane)] with silylating agents. Related alkyne ligands of the type RCCOE (E = electrophile) are easily accessible by the addition of electrophiles to η^2-ketenyl ligands obtained by nucleophile-induced alkylidyne–carbonyl coupling.[5] Geoffroy et al.[6] were able to demonstrate that ketenyl complexes may also be generated by irradiation of alkylidyne carbonylmetal complexes in the presence of nucleophiles. It was proposed that the role of the nucleophile was that of trapping a photochemically generated ketenyl metal complex. The possibility that some alkylidyne–carbonyl coupling reactions may be induced by electrophiles, and the well-established reactivity of η^2-ketenyl ligands towards electrophiles, suggested that electrophiles may also be effective in assisting the photoinduced process. Here we report that in photoinduced alkylidyne-carbonyl coupling reactions electrophiles are effective reagents for trapping the coupling products.

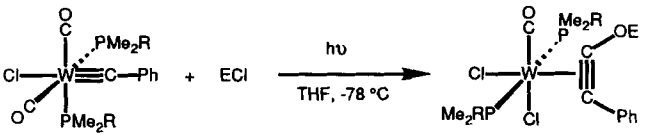
Irradiation of the alkylidyne carbonyltungsten complexes *cis*-**1a**, **b** with visible light in the presence of electrophiles ECl affords the alkyne complexes *trans*-**2a**–**e**.[7, 8] The reactions are accompanied by the photochemical *cis–trans* isomerization of complexes **1**.[9] Thus, the same results are obtained when the *trans* isomers of complexes **1** are used as the starting materials. In the absence of light, either no reaction or a different outcome is observed under otherwise similar conditions. The reaction of *trans*-**1a** with HCl was previously reported to give the alkylidene complex *trans*-$[W(CHPh)Cl_2(CO)(PMe_3)_2]$[9].



1a: R = Me
1b: R = Ph

2a: R = Me, E = H
2b: R = Me, E = $C(O)CMe_3$
2c: R = Me, E = $C(O)C_6H_4$-4-OMe
2d: R = Ph, E = $C(O)CMe_3$
2e: R = Me, E = $Si(CMe_3)_2Ph$

Complexes **2a**–**e** belong to a well-established group of metal complexes with four-electron-donor alkyne ligands[10] and were characterized by spectroscopic methods.[11] In the ^1H NMR spectra the virtual triplets for the phosphine methyl groups indicate the mutual *trans* arrangement of the phosphine ligands.[12] In the ^{13}C NMR spectra the alkyne ligands give rise to two resonances between $\delta = 190$ and 230, chemical shifts characteristic of four-electron-donor alkyne ligands.[10] The carbonyl ligand of complexes **2b**–**e** gives rise to a single absorption in the IR spectrum. In dichloromethane solution complex **2a** exhibits two IR absorptions at 1925 and 1940 cm^{-1} indicating the presence of two isomers; however, in the solid-state spectrum (KBr) only one CO absorption is found.

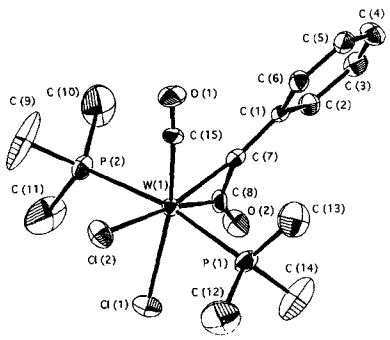


Fig. 1. Crystal structure of **2a**. Selected bond lengths [Å] and angles [°]: W1-C7 2.05(1), W1-C8 1.97(1), W1-C15 2.01(1), W1-P1 2.511(3), W1-P2 2.512(3), W1-Cl1 2.528(3), W1-Cl2 2.454(3), C7-C8 1.32(1); C1-C7-C8 135(1), C7-C8-O2 136(1).

The solid-state structures of the ynol complex **2a** (Fig. 1) and of the alkynyl ester complex **2c** (Fig. 2) were determined by X-ray crystallography.[13] The structural parameters (Table 1) are not unusual, but the orientation of the ynol ligand in complex **2a** is opposite to that expected. In complexes of the type $[WX_2(alkyne)(CO)L_2]$ the alkyne ligands

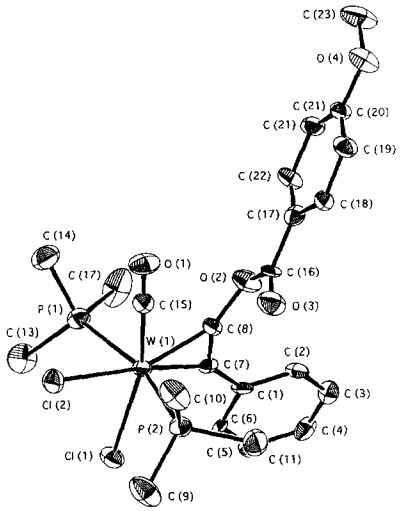

Fig. 2. Crystal structure of **2c**. Selected bond lengths [Å] and angles [°]: W1-C7 2.03(1), W1-C8 1.99(1), W1-C15 1.96(1), W1-P1 2.507(4), W1-P2 2.522(4), W1-Cl1 2.518(3), W1-Cl2 2.479(3), C7-C8 1.28(1); C1-C7-C8 137(1), C7-C8-O2 135(1).

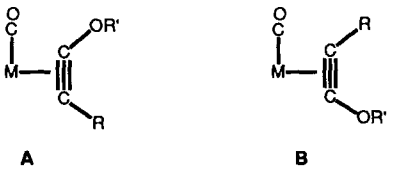
prefer the orientation parallel to the W–CO axis for electronic reasons.[10] Alkyne ligands of the type RCCOR′ are expected to prefer the orientation with the oxygen-substituted carbon atom proximal to the carbonyl ligand (**A**).[14] This situation is found in the solid-state structure of the alkynylester complex **2c**. In the ynol complex **2a** the oxygen-substituted end of the alkyne ligand is oriented distal to the carbonyl ligand (**B**). This electronically less stable orientation is presumably stabilized by a hydrogen bond between the OH group of the ynol ligand and the chloro ligand Cl 1. Even though the OH hydrogen atom was not found in the X-ray structure analysis, the O2-Cl1 distance of 3.022(9) Å is suitable for a hydrogen bond.[15] The presence of two ν(CO) frequencies in the IR spectrum of **2a** in solution indicates that the hydrogen bond between the OH group and the chloro ligand stabilizes the electronically less favorable orientation **B** to such an extent that both conformers **A** and **B** are present in comparable amounts in solution.



In two other structurally characterized ynol tungsten complexes **3**[16] and **4**[17] the OH group is stabilized by hydrogen bonding to cocrystallized donor solvent molecules, whereby the ynol ligand in **4** also adopts the electronically less favorable orientation. The synthesis of **3** by irradiation of **5** in

$[W(acac)Cl(PhCCOH)(CO)_2] \cdot OEt_2$ **3**

$[W(CPh)Cl(CO)_4]$ **5**

the presence of acetylacetone was reported by Fischer and Friedrich.[16] It is now recognized as the first example of photoinduced alkylidyne–carbonyl coupling.[6] Based on the results reported here it appears that this reaction may also represent the first example of an electrophile-assisted photoinduced alkylidyne–carbonyl coupling.[11] Formation of **3** could involve initial substitution of the chloro ligand and one carbonyl ligand in **5** by acetylacetone, accompanied by elimination of hydrogen chloride. The liberated HCl could then trap a photochemically generated ketenyl complex to give the final product.

The reaction of photochemically generated ketenyl ligands with electrophiles is an efficient method for the assembly of metal-coordinated ynols and alkyne derivatives, such as alkynyl esters and alkynyl silylethers, from three components: alkylidyne ligand, carbonyl ligand, and electrophile. This method may prove useful in the synthesis of such compounds. The reactions of organic alkynyl esters has been investigated only in recent years,[18] and very little is known about their coordination chemistry. Several complexes of alkynyl esters were previously prepared by acylation of stable ketenyl metal complexes.[19]

Experimental Procedure:

In a typical procedure, one equivalent of the electrophile was added to a solution of **1a, b** in THF at −78 °C. (For the synthesis of **2a**, slightly moist $AlCl_3$ was used as the source of HCl.) The mixture was irradiated from a distance of 10–20 cm with a regular 300 W projector lamp for approximately 2–3 h. During this time the color of the solution changed from light yellow to blue. Compounds **2a–e** were purified by chromatography on silica gel at −30 °C (10% THF/CH_2Cl_2 for **2a**, CH_2Cl_2 for **2b**, and 2% THF/CH_2Cl_2 for **2c–e**) and recrystallization from CH_2Cl_2/hexane (isolated yields: 80% for **2a**, 68% for **2b**, 77% for **2c**, and 51% for **2d**). Complex **2e** is obtained in 20% yield in only about 80% purity.

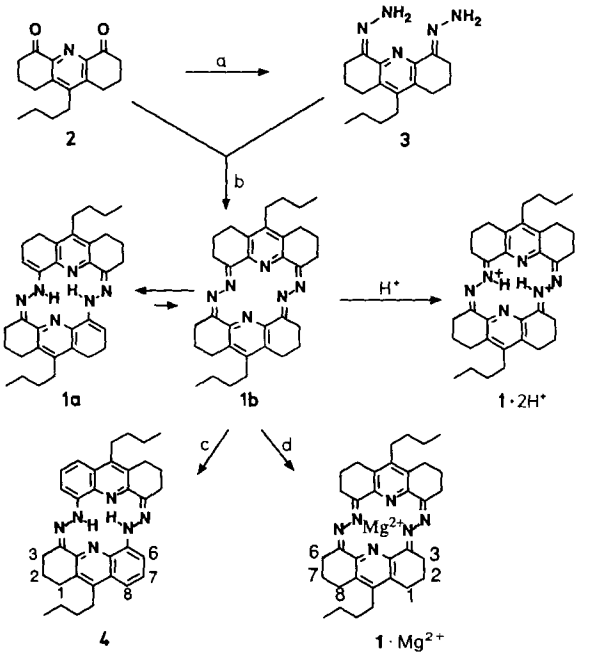
Ion-Selective Hydrazone–Azine Tautomerism of a 14-Membered Macrocylic Ligand**

By *Thomas W. Bell** and *Andrew T. Papoulis*

Bridged pyridine ligands,[1] including torands,[2] are versatile complexing agents for metal ions. In the course of current efforts to incorporate pyrrole rings into torands using the Piloty rearrangement of azines,[3] we have discovered a novel 14-membered azamacrocycle **1**. The binding of lithium and the smaller alkaline-earth metal ions by this ligand is accompanied by pronounced changes in its UV/VIS absorption characteristics. Ion-selective optical sensors based on metal complexation are of current interest for analytical applications.[4]

Macrocyclic ligand **1** was synthesized in two steps from 9-*n*-butyl-2,3,7,8-tetrahydro-1*H*,6*H*-acridine-4,5-dione **2**[5] (Scheme 1). Slow addition of **2** to a large excess of hot methanolic hydrazine gave (*E*,*Z*)-dihydrazone **3** as a yellow precipitate. Condensation of diketone **2** with dihydrazone **3** in hot methanol gave macrocycle **1** as a yellow-orange solid in 38–47% yield with most methods of addition of the reactants. However, when higher dilution was achieved by simultaneous, slow addition of **2** and **3** to hot methanol, **1** was produced in 82% yield. The ^{1}H NMR spectrum of **1** in $CDCl_3$ is consistent with the apparently unique bis(vinylhydrazone) structure shown in **1a** rather than the expected bis(azine) tautomer **1b**. The resonance of the vinyl protons is observed at $\delta = 6.0$, and the downfield shift of the internal NH protons ($\delta = 14.3$) is consistent with their intramolecular hydrogen bonding to the transannular pyridine nitrogen atoms. Addition of trifluoroacetic acid to the $CDCl_3$ solution apparently gives **1** · 2H$^+$ since the vinyl proton resonances are no longer observed and the acidic protons give a broad resonance centered at $\delta = 19$. As suggested by the presence of enamine moieties in structure **1a**, DDQ selectively aromatizes two rings of **1** to give bis(arylhydrazone) macrocycle **4**, which still possesses two internal hydrogens ($\delta = 17.6$).



Scheme 1. a: Hydrazine, MeOH (55%); b: MeOH (82%); c: Dichlorodicyanobenzoquinone (DDQ), toluene (63%); d: $Mg(NO_3)_2 \cdot 6H_2O$, CH_3CN (33%).

Macrocycles **1** and **4** both contain 14-membered rings with four of the six nitrogen atoms in the correct positions to coordinate metal ions. To do this **4** must either lose the internal protons or tautomerize to the bis(azo) form, whereas **1** should readily form metal complexes by tautomerization to the bis(azine) form **1b**. Thus **1** reacts with $Mg(NO_3)_2$ in CH_3CN to form **1** · $Mg(NO_3)_2$, which was isolated as a yellow solid. FAB-MS, ^{1}H NMR, ^{13}C NMR, and FT-IR data are in keeping with the C_2 symmetric structure. Apparently **1** · $Mg(NO_3)_2$ does not possess a horizontal mirror plane, since two-proton multiplets are observed in the ^{1}H NMR spectrum at $\delta = 2.8$ and 3.3 displaying geminal coupling ($J = 17$ Hz). This feature suggests that **1** exists in a puckered conformation in the complex, possibly due to axial coordination of Mg^{2+} by NO_3^- on only one face. Ring methylene

protons of **1** thus serve as stereochemical probes which are absent in reported complexes of bis(azine) macrocycle **5**.[6, 7]

Tautomerism of **1a** to **1b** during complexation produces dramatic changes in the UV-VIS absorption spectrum of the ligand. Figure 1 shows that the largest change is the disappearance of the absorption band at $\lambda_{max} = 380$ nm upon complexation of Mg^{2+}. The spectra shown in Figure 1 were

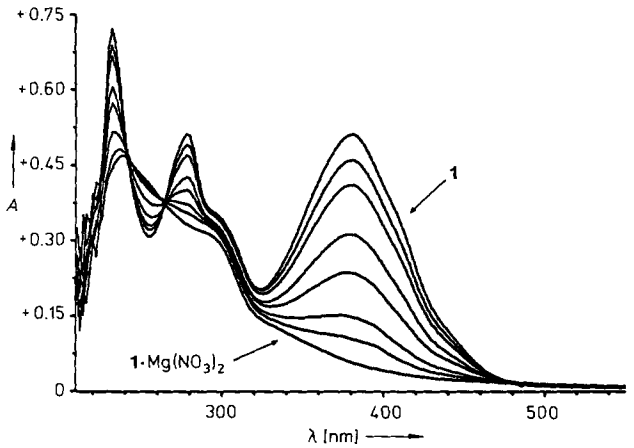

Fig. 1. Overlayed plots of the UV/VIS spectra of **1** and **1** · $Mg(NO_3)_2$ in CH_2Cl_2 (1.9×10^{-5} M). Wavelengths in nm; A = absorbance.

obtained from dissolved samples of **1** and **1** · $Mg(NO_3)_2$ in CH_2Cl_2. The same spectroscopic changes were observed when solid $Mg(NO_3)_2 \cdot 6\,H_2O$ was added to a solution of **1** in CH_2Cl_2. To test the selectivity of **1** in extractions, solutions of **1** in CH_2Cl_2 were exposed to alkali-metal and alkaline-earth nitrates and chlorides. We followed the complexation by measuring changes in the ratio of absorbances at $\lambda = 380$ and 265 nm (the isosbestic point). The results of this study (Fig. 2) show that the optical response is selective for small cations of high charge density such as Li^+, Mg^{2+}, and Ca^{2+}. It is not clear why the nitrate and chloride salts of individual cations respond differently, but this effect may be related to solubility differences in CH_2Cl_2. Anion effects on the stability of crown ether complexes and on the extractability of salts from aqueous into organic solution have been observed.[8]

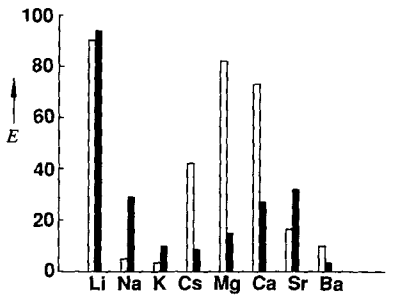

Fig. 2. Spectroscopic changes observed for solutions of **1** in CH_2Cl_2 (2.1×10^{-5} M) exposed for one day to metal salts. Extraction efficiency $E = [R(\mathbf{1}) - R(obs)]/[R(\mathbf{1}) - R(\mathbf{1} \cdot Mg(NO_3)_2)]$, where $R = A_{380}/A_{265}$. ■: Cl^- anion, □: NO_3^- anion.

Ion-selective optical response has also been reported for the bis(bipyridyl) macrocycle **6**, which solubilizes lithium chloride in CH_2Cl_2 with decolorization.[9]. In nonpolar solvents this ligand exists in the intramolecularly hydrogen-bonded form shown in **6**, as indicated by the presence of NH resonances in the ^1H NMR spectrum at $\delta = 15.0$. Although **1**, **4**, **5**, and **6** all contain 14-membered, fully unsaturated rings, the presence of cross-conjugated pyridine rings reduces the diamagnetic ring current expected in (4n + 2) annulenes, an effect observed in *meta*-fused benzannulenes.[10]. Thus, the NH resonances of **1**, **4**, and **6** all appear at relatively low field. It is noteworthy that the macrocyclization leading to **1** proceeds in higher yields than that providing **5**. The latter was prepared in 7% yield by cyclization of the bis(diacetylpyridine) azine and could not be isolated from reaction of 2,6-diacetylpyridine with 2,6-diacetylpyridine(dihydrazone).[7] As was recently pointed out by Thilgen and Vögtle,[11] metal-free macrocyclic bis(azines) are rarely reported, apparently because azines are produced under equilibrium control. The yield of the macrocyclization furnishing **1** appears to be influenced partly by precipitation of the product and partly by kinetic product distribution. Relative to 2,6-diacetylpyridine, **2** is apparently preorganized for macrocyclization by the acridine framework. A predetermined conformation can produce unusual and useful effects.

Experimental Procedure

3: A solution of 1.0 g (3.7 mmol) of diketone **2** [5] in 50 mL of methanol was added dropwise over 3.5 h to a rapidly stirred, boiling solution of 3.5 mL (3.6 g, 110 mmol) of anhydrous hydrazine in 50 mL of methanol. The resulting yellow solution was heated at reflux under N_2 for 30 min, then cooled to room temperature. Methanol was removed under vacuum, and 100 mL of water was added to the residue. The resulting mixture was extracted with $CHCl_3$ (3 × 50 mL), and the combined extracts were dried over Na_2SO_4 and concentrated. Ethyl acetate was added, producing a yellow precipitate, which was allowed to stand at 5 °C for several hours and was then collected by vacuum filtration. Drying in vacuo gave 0.61 g (55%) of **3** as a light yellow solid. M.p. 175–192 °C (decomp.). ^1H NMR (300 MHz, $CDCl_3$): $\delta = 0.96$ (t, $^3J(H,H) = 6.6$ Hz, 3H; CH_3), 1.42 (m, 4H; $CH_2CH_2CH_3$), 1.96 (m, 4H; H2, H7), 2.53–2.64 (m, 6H; H1, H8, $ArCH_2nPr$), 2.77 (m, 4H; H3, H6), 5.5 (s, 2H; (*E*)C = NNH_2), 8.7 (br s, 2H; (*Z*)C = NNH_2); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 149.0$, 147.5, 145.9, 145.3, 135.8, 131.5, 130.4, 33.7, 30.7, 28.2, 26.5, 24.9, 23.6, 23.0, 22.9, 20.9, 13.7. FT-IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3355 s (NH_2), 3273 m (NH_2), 3192 m (NH_2), 2935 s (CH), 2912 s (CH), 2842 s (CH), 1634 m (C = N). MS (70 eV): *m/z* 299 (M^+, 13), 211 (100%). – Correct C,H,N-analysis.

1: Separate solutions of 50 mg (0.18 mmol) of **2** and 55 mg (0.18 mmol) of **3** in 30 mL of methanol were added dropwise over 5 h to 20 mL of rapidly stirred, boiling methanol. The resulting mixture was heated at reflux under N_2 for 14 h, then cooled to room temperature. The precipitate was collected by filtration, washed several times with methanol, and dried in air to give 80 mg (82%) of **1** as a yellow solid. M.p. 190 °C (decomp.). ^1H NMR (300 MHz, $CDCl_3$): $\delta = 0.98$ (t, $^3J(H,H) = 6.6$ Hz, 6H; CH_3), 1.47 (m, 8H; $CH_2CH_2CH_3$), 2.01 (m, 4H; H2), 2.50 (m, 4H, H7), 2.67 (t, $^3J(H,H) = 7.2$ Hz, 4H; $ArCH_2nPr$), 2.78 (t, $^3J(H,H) = 6.3$ Hz, 4H; H1), 2.82–2.91 (m, 8H; H3, H8), 5.99 (t, $^3J(H,H) = 4.8$ Hz, 2H; H6), 14.28 (s, 2H; NH). ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 147.2$, 147.0, 144.8, 137.1, 135.6, 132.6, 129.6, 99.0, 34.3, 31.1, 28.6, 26.9, 24.3, 23.2, 22.9, 21.7, 13.7. FT-IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3178 s (NH), 2943 s (CH), 2849 s (CH), 1637 s (C = N). UV/VIS (CH_2Cl_2): λ_{max}[nm](ε) = 380 (27000), 296 (19000), 278 (27000). FAB-MS (Xe^+, 6–8 kV): *m/z* 535 ($M + 1$, 100%). Correct C,H,N-analysis for $C_{34}H_{42}N_6 \cdot (H_2O)_{0.5}$.

4: To a solution of 200 mg (0.37 mmol) of **1** in 300 mL of toluene was added 170 mg (0.75 mmol) of DDQ. The reaction mixture was stirred at room temperature under N_2 for one day and then filtered. The filtered solid was rinsed thoroughly with toluene, and the filtrates were combined and concentrated under vacuum. Recrystallization from toluene gave 125 mg (63%) of **4** as a brownish-red solid. M.p. 244–254 °C (decomp.). ^1H NMR (300 MHz, $CDCl_3$): $\delta = 1.00$ (t, $^3J(H,H) = 6.6$ Hz, 6H; CH_3), 1.55 (m, 8H; $CH_2CH_2CH_3$), 2.03 (m, 4H; H2), 2.79 (t, $^3J(H,H) = 6$ Hz, 4H; $ArCH_2nPr$), 2.94 (m, 8H; H1, H3), 7.17 (d, $^3J(H,H) = 8.4$ Hz, 2H; H6), 7.30 (m, 2H; H7), 7.47 (d, $^3J(H,H) = 7.8$ Hz, 2H; H8), 17.61 (s, 2H; NH). FT-IR: (KBr): $\tilde{\nu}$ [cm^{-1}] = 3429 br (NH), 3060 s (ArH), 2952 s (CH), 2854 s (CH), 1603 s (C = N). FAB-MS (Xe^+, 6–8 KV): *m/z* 530 (M^+, 100%). UV/VIS (CH_2Cl_2): λ_{max}[nm] (ε) = 266 (33000), 302 (16000), 358 (20000), 374 (22000), 404 (25000), 438 (13000), 464 (18000). Correct C,H,N-analysis for $C_{34}H_{38}N_6(H_2O)$.

1 · $Mg(NO_3)_2$: To a mixture of 96 mg (0.37 mmol) of $Mg(NO_3)_2 \cdot 6\,H_2O$ and 50 mL of acetonitrile was added 200 mg (0.37 mmol) of **1**. The mixture was heated at reflux under N_2 for 15 min. until all of **1** dissolved. The resulting dark yellow solution was cooled to room temperature and concentrated with a rotary evaporator. Drying in vacuo gave 277 mg of a dark amber glass. Recrystallization from ethanol gave 85 mg (33%) of a yellow solid. M.p. 170 °C (decomp.).

^{1}H NMR (600 MHz, $CDCl_3$): [12] δ = 0.96 (t, ^3J(H,H) = 6.9 Hz, 6H; CH_3), 1.40 (m, 4H; $CH_2CH_2CH_3$), 1.45 (m, 4H; $CH_2CH_2CH_3$), 1.94 (m, 2H; H7), 2.05 (m, 4H; H2), 2.26 (m, 4H; H3, H7), 2.63 (m, 4H; $ArCH_2nPr$), 2.79 (ddd, ^2J(H,H) = 17.2 Hz, ^3J(H,H) = 9.8 Hz, ^3J(H,H) = 4.9 Hz, 2H; H1), 2.94 (m, 10H; H1, H6, H8), 3.34 (ddd, ^2J(H,H) = 17.5 Hz, ^3J(H,H) = 4.8 Hz, ^3J(H,H) = 4.8 Hz, 2H, H3); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 159.1, 157.6, 153.0, 144.6, 144.3, 139.1, 136.3, 33.6, 29.8, 28.5, 26.3, 25.2, 25.0, 23.1, 22.4, 20.3, 13.6. FT-IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3370 br (H_2O), 2942 s (CH), 2860 s (CH), 1619 m (C = N). FAB-MS (Xe$^+$, 6–8 kV): *m/z* 620 ($M-NO_3$, 100), 557 ($M-HN_2O_6$, 21.2%). UV/VIS (CH_2Cl_2): λ_{max}[nm] (ε) = 238 (25000), 296 (16000). Correct C,H,N-analysis for $C_{34}H_{42}N_8O_6Mg(H_2O)_{0.5}$.

Synthesis, Structure, and Thermolysis of an Unusual Azaphosphasiliridine**

By *Matthias Driess** and *Hans Pritzkow*

Dedicated to Professor Friedrich Bickelhaupt on the occasion of his 60th birthday

The reactivity of disilenes, phosphaalkenes, and diphosphenes towards organoazides and diorganodiazomethanes leads to new five- and three-membered heterocycles, in which the bonding is of particular interest.[1] It was observed that disilenes can react with organoazides and diazomethanes by a [2 + 3] or [2 + 1] cycloaddition depending on electronic and steric factors. In contrast, phosphaalkenes only react by [3 + 2] cycloaddition, and diphosphenes react with diazoalkanes to give stable diphosphiranes. Of particular interest is the [2 + 1] cycloaddition of disilenes, which for the reaction with alkylazides and aryldiazomethane derivatives leads to **A** and **B**, respectively; however, for the reaction with alkenes there are no examples.

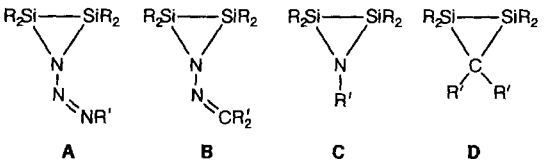
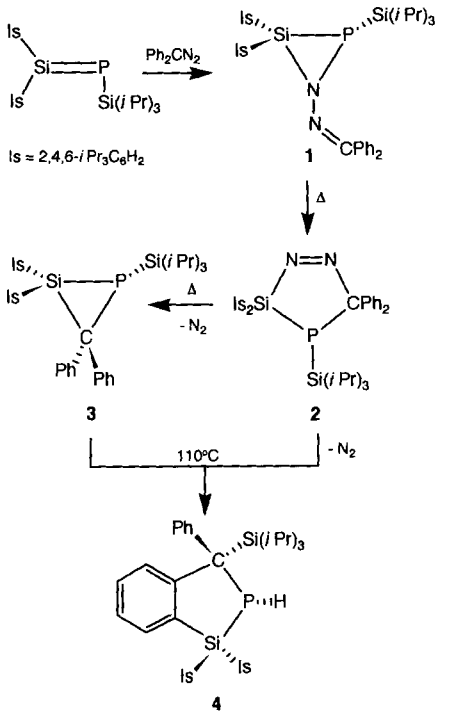
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247). We also thank Prof. Dr. W. Siebert (Heidelberg) for his support.

Whereas beginning from **A**, compounds of the type **C** are readily accessible by N_2 elimination, starting from **B** (R' = aryl) the analogous formation of **D** is not observed.[1] However, a disilirane **D** (R' = H) is accessible from the reaction of CH_2N_2 with tetrakis(2,6-dimethylphenyl)disilene,[2] although an intermediate could not be observed. Recently we described a simple, high-yield access to stable phosphanylidensilanes (phosphasilenes),[3] so that it is now possible to investigate the reaction pathways of such compounds with diazoalkanes and other cycloaddition partners. Herein we report the synthesis and structure of the first azaphosphasiliridine **1** and its stepwise conversion to the thermolysis products **2**–**4**.



The reaction of the phosphasilene $Is_2Si{=}P{-}Si(iPr)_3$ (Is = 2,4,6-$iPr_3C_6H_2$) with diphenyldiazomethane led to the [2 + 1] cycloadduct **1**[4] in 87% yield, which was isolated in the form of yellow crystals (Scheme 1). The composition of



Scheme 1. Synthesis of the heterocycles **1**–**4**.

1 was deduced from the mass spectrum[4] and a correct elemental analysis. The ^{31}P NMR spectrum shows a singlet at δ = – 25.6. In the ^{29}Si spectrum a ^{14}N/^{15}N relaxation-broadened doublet is observed for the Si atom in the three-membered ring at extremely high field (δ = – 86.0) and with an unusually small $^1J_{Si,P}$ coupling constant (J = 3.9 Hz). In contrast, the corresponding coupling constant for the ^{29}Si nucleus of the $Si(iPr)_3$ group (99.5 Hz) is very large. In cyclic, three-membered phosphasilanes the ^{29}Si chemical shifts of the ring atoms lie between δ = – 31.3 and δ = –75.3 and show values of 72.5 to 121.7 Hz for the $^1J_{P,Si}$ coupling constants.[5]

The ^{29}Si chemical shifts for compounds of the type **A**–**C** are typically found at around $\delta = -53$.[1] Since the constitution of **1** could not be unequivocally proved from the NMR data, an X-ray structure determination was carried out (Fig. 1).[6]

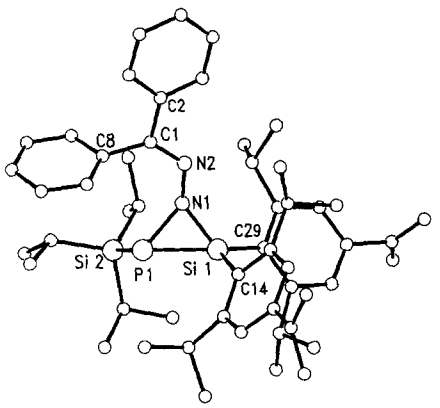


Fig. 1. Crystal structure of **1**. Selected distances [Å] and angles [°]: P1-Si1 2.237(2), P1-Si2 2.298(2), P1-N1 1.817(3), Si1-N1 1.729(3), N1-N2 1.375(4), N2-C1 1.287(5); Si1-P1-Si2 112.9(1), Si1-P1-N1 49.2(1), Si2-P1-N1 109.2(1), P1-Si1-N1 52.7(1), P1-N1-Si1 78.2(1), P1-N1-N2 136.3(3), Si1-N1-N2 133.2(2), N2-C1-C2 114.6(4), N2-C1-C8 129.3(4).

The endocyclic P1–Si1 distance (2.237(2) Å) is significantly shorter than the exocyclic P1–Si2 (2.298(2) Å) distance; however, it is typical for Si–P distances in three-membered cyclophosphasilanes.[5] Notable differences were also found for the N1–P1 and N1–Si1 distances. In comparison to azadiphosphiridines,[7] in which N–P distances of 1.698 and 1.710 Å were observed, the N1–P1 distance (1.817(3) Å) in **1** is extremely long. In contrast to azadiphosphiridines (sum of angles 359.9°), the N1 atom is not coordinated in a planar fashion (347°). Obviously, an ideal, planar conformation at the N1 atom in **1** is prevented as a result of the bulky substituents. Thus, no N–P bond strengthening is possible as was previously discussed for azadiphosphiridines and 1,3,2,4-diazadiphosphetidines.[7] The endocyclic angles at the phosphorus (49.2°) and nitrogen atom (78.2°) in **1** correspond approximately to the values in the azadiphosphiridine derivatives. The sum of the exocyclic, basal bond angles at the Si1 atom (359°) is similar to that in three-membered rings with two Si atoms and one heteroatom,[8] in which the coordination geometry at the silicon and phosphorus atom could be interpreted with the Dewar–Chatt–Duncanson model when described as a π complex. The two planes Si2–P1–Si1/Si1–C29–C14 are twisted into one another by 24°, which would be consistent with a description of **1** as a π complex from phosphasilene and the nitrene form of diphenyldiazomethane.

Thermolysis experiments have shown that **1**, despite its bulky substituents, can undergo rearrangement reactions which can be controlled. After a yellow solution of **1** in toluene was heated for 12h at 95°C, a deep orange solution was obtained whose ^{31}P NMR spectrum showed that **1** had completely rearranged into a mixture consisting of **2** ($\delta = -101.9$), **3** ($\delta = -197.4$), and a small quantity of **4** ($\delta = -100.7$) in the ratio of approximately 3:1:0.5. Although so far the isolation of **2** and **3** has not been successful, an unequivocal characterization is possible on the basis of the ^{31}P and ^{29}Si NMR data. In the ^{29}Si NMR spectrum (INEPT pulse sequence) a relaxation-broadened doublet (as for **1**) at $\delta = -6.1$ ($^1J_{P,Si} = 3.6$ Hz) is detected for the Si atom present in the ring of **2**, whereas the analogous ^{29}Si nucleus in **3** shows a sharp doublet at $\delta = -54.4$ ($^1J_{P,Si} = 49.7$ Hz). The ^{29}Si NMR data assigned to compound **3** are identical with that of comparable cyclophosphasilanes and other three-membered rings containing Si atoms.[5, 8] The NMR spectroscopic assignment for **2** and **3** is also proved by the fact that after the 3:1 mixture was heated for two days at 80°C, the concentration of **3** significantly increases at the expense of that of **2** (ca. 1:1, ^{31}P NMR control), without the appearance of new signals or an increase in the small amount of **4**.

If the thermolysis is now carried out at 110°C for 48h, the ^{31}P NMR spectrum shows that compound **4**[10] is the only product. Compound **4** could be isolated in the form of analytically pure, colorless crystals by crystallization from hexane. The constitution of **4** was also completely established by an X-ray crystal structure analysis (Fig. 2).[11]

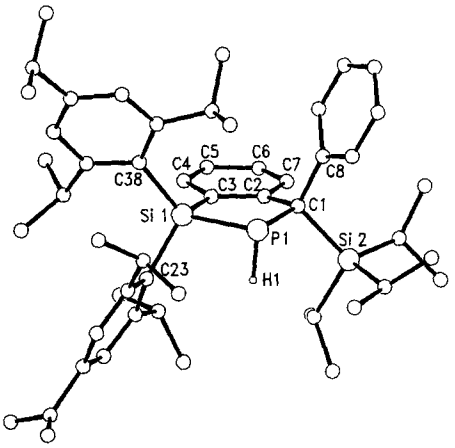

Fig. 2. Crystal structure of **4**. Selected distances [Å] and angles [°]: P1-C1 1.912(2), Si1-P1 2.267(1), Si2-C1 1.973(2), Si1-C3 1.879(2), C1-C2 1.544(3), C2-C3 1.409(3); Si1-P1-C1 95.8(1), P1-Si1-C3 93.6(1), P1-C1-C2 110.5(1), C1-C2-C3 122.0(2), C2-C3-Si1 117.1(1).

The $SiPC_3$ five-membered ring is almost planar. The long P1–C1 distance of 1.912(2) Å is surely a result of the steric hindrance of the substituents at the chiral C1 atom. In the crystal, as in solution (25°C), only one of the two possible diastereomers is found, that in which the H atom at the phosphorus atom occupies a position *trans* to the phenyl group at the C1 atom. Although only tentative statements can be made so far concerning the mechanism of the rearrangement of **3** into **4**, the formation of **4** is worth consideration regarding two aspects. On the one hand, the ring strain of **3** affects the cleavage of a C_{sp2}–H bond at the phenyl ring under simultaneous loss of the Si1–C1 bond and a 1,2-silyl shift of the $Si(iPr)_3$ group from the phosphorus to the saturated C1 atom, whereby the H atom, which was originally attached to the C3 atom, becomes attached to the phosphorus atom. On the other hand, it should be noted that these processes probably occurring in a radical fashion, obviously proceed so effectively that only **4** is obtained (^{31}P NMR control).

Experimental Procedure

1: Ph_2CN_2 (311 mg, 1.60 mmol) in hexane (2 mL) was added to a solution of $Is_2Si{=}P{-}Si(iPr)_3$ (1 g, 1.60 mmol) in toluene (30 mL) at 0°C. The reaction solution immediately changed color from red-orange to bright yellow. After removal of the solvent at 10^{-2} Torr, the residue was taken up in hexane (ca. 2 mL) and left to stand for 12h at room temperature. Compound **1** was isolated in the form of air-stable, bright yellow crystals. More of **1** could be obtained by

concentration of the mother liquor. Yield: 1.13 g (1.38 mmol, 87%); m.p. 150–153 C (decomp.).

4: **1** (435 mg, 0.53 mmol) was dissolved in toluene (1 mL) and heated at 110 °C for ca. 2.5 d (^{31}P NMR control). Following the thermolysis only the presence of **4** could be proven. The volatiles were removed at 25 °C and 10^{-2} Torr, and the residue was crystallized from hexane (ca. 1 mL). Yield: 372 mg (0.47 mmol, 89%) colorless crystals; m.p. 205–206 °C.

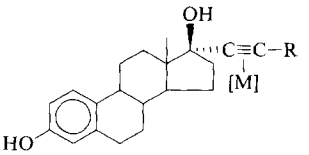
Estradiols Modified by Metal Carbonyl Clusters as Suicide Substrates for the Study of Receptor Proteins: Application to the Estradiol Receptor**

By *Anne Vessières, Siden Top, Colette Vaillant, Domenico Osella, Jean-Paul Mornon*, and *Gérard Jaouen**

The intimate association of a hormone with its receptor is known to be implicit in the triggering of hormone action; however, mechanistic detail is largely unknown.[1] One approach to identifying the specific amino acids in the receptor implicated in the binding of the hormone is affinity labeling, that is, the use of molecules that will recognize the site of association and bind irreversibly.[1] It is well known that complexation by an organometallic moiety may dramatically alter the properties and reactivity of an organic substrate, and make possible reactions that are difficult or impossible by conventional procedures.[2] Extrapolation of this concept to the biological domain suggests that organometallic complexation of a bioligand may also alter its properties allowing access to information on the nature of recognition.

In studies of the estradiol–receptor complex, it has been postulated that the association site is acidic in nature and may contain an SH group.[3] It also has been demonstrated that the hydroxyl groups at C-3 and C-17 of estradiol are necessary for effective recognition.[1] In addition, substitution studies show that the 17α position can tolerate fairly large substituents without severely diminishing recognition.[4] We thus set about synthesizing the organometallic hormone derivatives **1**–**5** with the aim of binding estradiol



1, R = Me, [M] = $[Co_2(CO)_6]$
2, R = Me, [M] = $[Mo_2Cp_2(CO)_4]$
3, R = H , [M] = $[Os_3(CO)_{10}]$
4, R = H , [M] = $[Ru_3(CO)_{10}]$
5, no R, [M] = $[Ru_3(CO)_9H]$

covalently to its receptor. We hoped to make use of the fact that the transformation of alcohols to their corresponding carbenium ions is facile when the C atom with the hydroxyl group is stabilized by an organometallic moiety. These species may in turn demonstrate strong alkylating properties.[5]

The preparation of **1** and **2** has been described previously.[6] The trimetallic Os and Ru complexes **3** and **4** were synthesized by reaction of ethynylestradiol with the activated clusters $[M_3(CO)_{10}](MeCN)_2$ (M = Os, Ru) and display characteristic chemical shifts in the ^{1}H NMR spectra for the

coordinated acetylenic proton at $\delta = 8.98$ and 8.33, respectively. Direct heating of $[Ru_3(CO)_{12}]$ with ethynylestradiol in benzene yields the hydrido complex **5**, in which migration of the acetylenic proton to the cluster framework is evidenced by the upfield shift of the ^1H NMR signal at $\delta = -20.45$.

The Relative Binding Affinities (RBA) of these compounds for the estradiol receptor have been determined and are reported in Table 1. The molybdenum complex **2** displays a strong affinity for the estradiol receptor (RBA 33%), while the dinuclear cobalt complex **1** has a good though weaker affinity (RBA 18%). The trinuclear ruthenium complex **4** maintains an acceptable affinity (RBA 8%); however, the other trimetallic complexes studied display a markedly weaker interaction (RBA $\approx$ 2%). A comparison of the RBA values of these complexes reveals a steady decrease in affinity, which may be roughly correlated to the increasing steric hindrance in the 17α position.

Table 1. RBA of the estradiol receptor and the inactivation of the receptor in the presence of the organometallic hormone derivatives **1**–**5**.

Compound	RBA [%] [a]	Inactivation [%] [b]
1	18	80
2	33	22
3	2.5	65
4	8	68
5	2.6	62

[a] The affinity to the estradiol receptor was determined in a competition radioreceptor binding assay with lamb uterine cell extracts (prepared as described in [14]) and [^{3}H]estradiol as a tracer [7]. [b] The inactivation of the estradiol receptor by **1**–**5** was determined by the incubation of the lamb uterine cell extracts (0.3 nmol) with 10 nmol of the hormone derivative. The fraction of the hormone derivative not bound was removed by treatment with charcoal/dextran. The remaining amount of reversibly bound hormone derivative was measured by protamine sulfate precipitation assay after exchange with 10 nm [^{3}H]estradiol (16–20 h, 20 °C).

Following this initial study we set out to investigate the possible existence of a covalent bond between the hormone derivatives and the receptor by receptor inactivation studies. The results shown in Table 1 indicate that these complexes may be separated into three categories: The first contains the cobalt complex **1** which causes a strong inactivation of the estradiol receptor (80%), the second consists of the trinuclear osmium and ruthenium complexes **3**, **4**, and **5**, capable of moderate inactivation (65%), and the third consists of the molybdenum complex **2** which produces only weak inactivation of the receptor (22%). These preliminary experiments with uterine preparations suggest that the 17β OH function of the hormone labeled with an organometallic fragment may be selectively activated at the association site of the estradiol receptor. This may occur by reaction with an acidic species to generate a carbenium ion-like reactive intermediate. Ideally a nucleophile should be located very close to this suggested acidic group to react instantly with the transient electrophile.

The carbenium ion analogues of these hormone complexes may be generated in the presence of acids. Measurement of their pK_{R^+} values was performed with H_2SO_4 according to the method of Deno et al., in a 1:1 mixture of MeCN and H_2O using the appropriate coefficients.[8] Due to the limited stability of the trinuclear hormone complexes in solution, and the additional complication of an equilibrium between the alcohol, carbenium ion, and elimination products,[9] measurements were made on the model compounds **6**–**9** (Table 2).

Table 2. pK_{R^+} Values for the model compounds **6**–**9** [a].

Compound	**6**	**8**	**9**	**7**
pK_{R^+}	−5.5 [b]	−3.4	−1.4	+3 [b]

[a] The pK_{R^+} values for the alcohols in aqueous H_2SO_4/MeCN solution was determined spectroscopically according to the method of Deno et al. [15]. The model compound corresponding to **5** could not be synthesized. [b] Value from ref. [9c].

Complexes **6**, **8**, and **9** all display a negative values of pK_{R^+}, indicative of highly reactive carbocations. The dimolybdenum species is again the anomaly with a positive pK_{R^+} and is expected to be weakly reactive towards nucleophiles. This behavior corresponds to the relative deactivating effect of the labeled hormones (Table 1).

$HC{\equiv}C{-}CH_2OH$

6, [M] = $[Co_2(CO)_6]$, **7**, [M] = $[Mo_2Cp_2(CO)_4]$
8, [M] = $[Os_3(CO)_{10}]$, **9**, [M] = $[Ru_3(CO)_{10}]$

The postulated acidic character at the association site of the receptor necessary for the generation of the carbenium ion, may be due to Brønsted or Lewis acids, or in this case the doubly charged, positive metal ions.[10] Preliminary results showed that the model compound 2-ferrocenylethanol couples with methylcysteinate not only in the presence of CF_3COOH, but also Zn^{2+} and Mg^{2+}.[11] The reaction occurs exclusively at the sulfur atom leaving the nitrogen atom untouched. Interestingly, recent work has suggested the presence of metal dications in the estradiol-binding domain.[12] Furthermore, deactivation studies with MMTS (methyl methane thiosulfate), a highly specific reagent for the SH group,[13] shows a 90% efficiency in deactivating the estradiol receptor.[14] This result suggests that the organometallic hormone derivatives are cysteine-specific reagents.

To ascertain the formation of a covalent bond between the organometallic hormone derivatives and the estradiol receptor, compound **1** was prepared in two radioactive forms: [^{3}H]**1** is tritiated at the 2 and 4 positions with a specific activity of 1.26 TBq mmol^{-1} (34.2Ci/mmole), and [^{14}C]**1** is labeled with ^{14}CO on the cluster unit (specific activity 500 GBq mmol^{-1}, 135 mCi mmol^{-1}). Under conditions suitable for the displacement of the tritiated estradiol from its specific receptor (e.g. treatment with Dextran-coated charcoal at 37 °C for 30 min), [^{3}H]**1** and [^{14}C]**1** remained bound indicating the establishment of an irreversible association between the estradiol receptor and the organometallic hormone. Moreover, the results obtained with [^{14}C]**1** indicated that no decomplexation occurs during the irreversible binding of the organometallic hormone derivatives to the receptor. Further investigations are needed to pinpoint the location of this particular cysteine residue in the receptor and clarify the effect of even bulkier cluster units in affinity labeling.

Recently the complete complementary DNA of the estradiol receptor was cloned and sequenced for the human,[15] chicken, mouse, rat, xenopus (a type of African aquatic frog), and rainbow trout, and their homologues were discussed.[1] In the human estradiol receptor (hER)[15] the hormone-binding domain contains only four cysteine residues (Cys) at positions 381, 417, 447, and 530. The sequence after Cys 447 is conserved in all the receptors (consensus domain

451–471),[16] and the sequence before Cys 530 is highly preserved in all the estradiol receptors sequenced so far.[1] This specific region has recently been identified by point mutations as the key steroid-binding domain of the estrogen receptor.[17]

Furthermore, according to Hydrophobic Cluster Analysis (HCA),[18] the lysine-cysteine-lysine sequence (529–531) appears to be situated at the threshold of the suggested hormone-binding site.[19] This relatively peripheral location of the strong sulfur nucleophile of Cys 530 explains the deactivating effect of the bulky alkynylestradiol clusters **1**–**5**. Finally two independent studies based on the radiosequencing of peptide fragments and truncation experiments have also implicated the region of Cys 530 in the binding of estradiol.[20]

Experimental Procedure

4: To a solution of $[Ru_3(CO)_{12}]$ (100 mg, 0.16 mmol) in 10 mL CH_2Cl_2 and 3 mL CH_3CN at 0 °C was added a solution of Me_3NO (26 mg, 0.35 mmol) in 7 mL CH_2Cl_2 dropwise over 15 min. The solution was allowed to stir for 1 h, then filtered through silica gel, and concentrated to dryness. The orange $[Ru_3(CO)_{10}](MeCN)_2$ was redissolved in 20 mL THF, and ethynylestradiol (46 mg, 0.16 mmol) was added as a solid. The resulting deep orange solution allowed to stir for 1 h. Removal of the solvent and purification by thin-layer chromatography on silica gel eluting with CH_2Cl_2/CH_3CN/pentane (3:1:6) provided a bright orange product, $[Ru_3(CO)_{10}$(ethynylestradiol)], in 47% yield.

^1H NMR (250 MHZ, CD_3COCD_3, 20 °C): $\delta = 7.24$ (d, H1), 6.71 (dd, H2), 6.68 (d, H4), 8.03 (s, O-H3), 4.30 (s, O-H17), 1.15 (s, Me-13), 8.33 (s, ≡CH); ^{13}C NMR (62.87 MHz, $CDCl_3$, 20 °C): $\delta = 153.4$ (C3), 138.1 (C5), 132.2 (C10), 126.5 (C1), 115.2 (C4), 112.7 (C2), 85.5 (C17), 48.6 (C13), 15.1 (C18), 192.8 (C19), 136.7 (C20), 197.7 (CO); IR (pentane): $\tilde{\nu}$ [cm^{-1}] = 2096vw, 2059s, 2052w, 2029m, 2011m, 1884w (CO).

3 was prepared in a similar manner from $[Os_3(CO)_{10}]$ in 63% yield.

^1H NMR (250 MHz, $CDCl_3$, 20 °C): $\delta = 7.18$ (d, H1), 6.65 (dd, H2), 6.56 (d, H4), 6.67 (s, O-H3), 4.47 (s, O-H17), 0.92 (s, Me-13), 8.98 (s, ≡CH); ^{13}C NMR (62.87 MHz, $CDCl_3$, 20 °C): $\delta = 153.5$ (C3), 138.1 (C5), 132.4 (C10), 126.5 (C1), 115.3 (C4), 112.8 (C2), 92.5 (C17), 47.8 (C13), 15.1 (C18), 169.3 (C19), 115.4 (C20), 174.5 (m, CO); IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2098w, 2059m, 2050m, 2022s, 2014s, 1845vw (CO).

Spectroscopic data of **5**: ^1H NMR (250 MHz, CD_3COCD_3, 20 °C): $\delta = 7.22$ (d, H1), 6.73 (dd, H2), 6.62 (d, H4), 8.10 (s, O-H3), 4.80 (s, O-H17), 1.01 (s, Me-13), −20.45 (s, Ru-H); ^{13}C NMR (62.87 MHz, $CDCl_3$, 20 °C): $\delta = 153.9$ (C3), 138.1 (C5), 132.4 (C10), 126.5 (C1), 115.2 (C4), 112.7 (C2), 90.7 (C17), 48.6 (C13), 15.0 (C18), 103.8 (C19), 162.9 (C20), 197.1 and 188.5 (s, s, CO, 1:2). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2096w, 2070s, 2050s, 2017s, 1986w (CO).

"Kinetically Enhanced Metalation"—How Substituents Direct *ortho* Lithiation**

By *Nicolaas J. R. van Eikema Hommes* and *Paul von Ragué Schleyer**

Many organic molecules with functional groups are lithiated by RLi selectively in the vicinity of these functional groups. Roberts and Curtin[1] were the first to suggest the now commonly accepted rationalization of this phenomenon: Complexation of the lithium atom to the substituent, for example in benzene derivatives, facilitates the removal of an *ortho* hydrogen atom by the anion R^-. "Directed *ortho* metalation"[2] and "complex-induced proximity effects"[3] have become designations to describe a large class of highly important synthetic reactions.[2–5] However, there is only circumstantial evidence that complex formation between the lithiating reagent and the substrate is really essential. We now propose a new explanation which emphasizes that the directing and activating effects of electronegative substituents are transition-state phenomena.[5, 6]

If strong complexation were responsible for the high regioselectivity, the reactions should proceed more slowly since the complexation energy would have to be overcome in going to the transition state. However, if the energy of the transition state is lowered more than that of the initial complex, the reactions will be accelerated, as is observed experimentally.

Although a complex of *n*-butyllithium and anisole in [D_8]toluene has actually been identified[7] (e.g. by means of HOESY NMR spectroscopy, a method which also reveals agostic interactions,[8, 9] i.e. small distances between lithium and the *ortho* hydrogen atoms), no reaction occurs in this

[a] Absolute energies (MP2/6-31 + G*//6-31G*) are given in Hartree, energies (E_{rel}) relative to those of the separated reactants are corrected for zero-point vibrational energy differences and are given in kcal mol^{-1}. [b] T.S. = transition state.

hydrocarbon solvent even at room temperature. When *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) is added, lithiation takes place even though the anisole–butyllithium complex is no longer present! Furthermore, no complex between fluorobenzene and *n*-butyllithium can be detected in toluene, even though F is known to be a better *ortho*-directing group than OMe.[10]

In the present ab initio study[11] of the mechanism of the lithiation of aromatic compounds, we consider the reactions of lithium hydride (as a model for organolithium reagents[12]) with benzene, phenol (as a model for anisole), and fluorobenzene. Calculated structures are shown in Figures 1–3. Total and relative energies [MP2/6-31 + G*//6-31G* with zero-point energy corrections (ZPE)] and selected Natural charges[13] are given in Table 1.

The π complex **1** of lithium hydride and benzene is computed to be 15.8 kcal mol^{-1} more stable than the separated species. The complexation of LiH with phenol and with fluorobenzene is quite exothermic; for **4** the complexation energy (17.6 kcal mol^{-1}) is somewhat more than for **10**

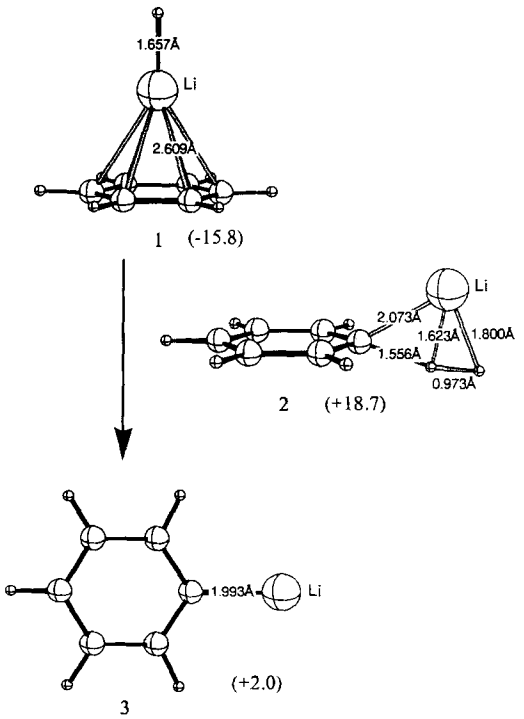

Fig. 1. Calculated structures for the lithiation of benzene with lithium hydride.

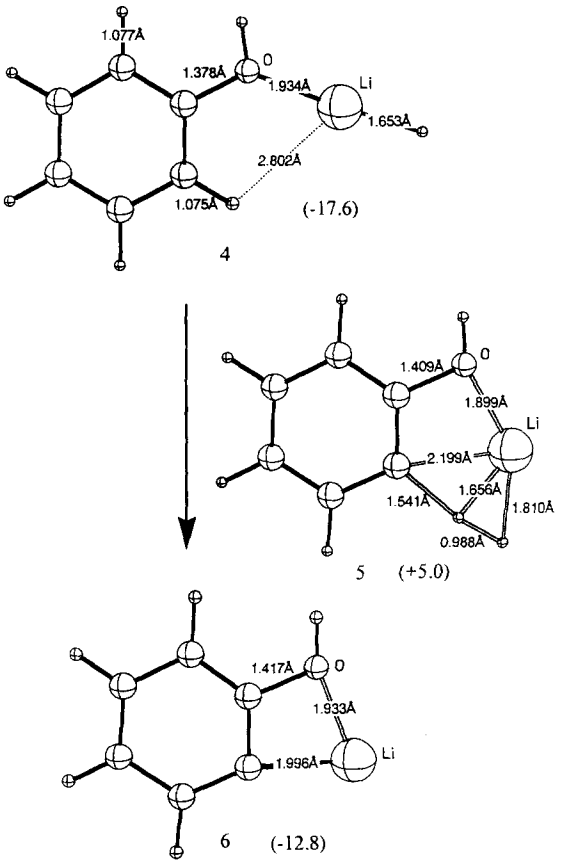

Fig. 2. Calculated structures for the lithiation of phenol with lithium hydride.

(12.8 kcal mol^{-1}). These values are in line with the results of the aforementioned NMR experiments in which anisole but not fluorobenzene forms a detectable complex with the lithium reagent in [D_8]toluene.[7]

Interestingly, in the most stable complex of C_6H_5F and LiH, **10**, the lithium atom is coordinated to the aromatic ring (with the shortest distance to C(4)) rather than to the fluorine. The complexation to fluorine in **7** is computed to be 0.4 kcal mol^{-1} less favorable. Hence, one might expect fluorobenzene to be less reactive than benzene and to be metalated in the *para* position, provided that complex formation is the determining factor for reactivity and regioselectivity. Experimentally, the opposite is observed: Fluorobenzene is metalated in the *ortho* position rapidly at $-50\,^{\circ}C$ in THF, while benzene is unreactive under the same conditions.[10, 14]

(30.6 kcal mol^{-1} relative to the precursor complex). The overall reaction energies show a similar trend: The calculated reaction energies for the *ortho* lithiation of phenol and fluorobenzene are -12.8 and -13.2 kcal mol^{-1}, respectively, while values of $+2.0$ and $+0.3$ kcal mol^{-1} are computed for lithiation of benzene and *para* lithiation of fluorobenzene. As expected from the calculated complex structures the *para*-metalation of fluorobenzene is similar to that of benzene in this respect as well.[15]

The transition structures (**2**, **5**, **8**, and **11**) are also strongly influenced by the substituents. In **2** (Fig. 1) and **11** (Fig. 3) the C-Li-H-H groupings lie in the plane of symmetry perpendicular to the aromatic ring. In contrast, the transition structures **5** (Fig. 2) and **8** (Fig. 3) are planar, with the lithium atoms coordinated intramolecularly by oxygen and by fluorine, respectively. However, the geometries of the C-Li-H-H moieties are very similar in all the transition structures (e.g. H–H = 0.985 ± 0.015 Å, see Figs. 1–3).

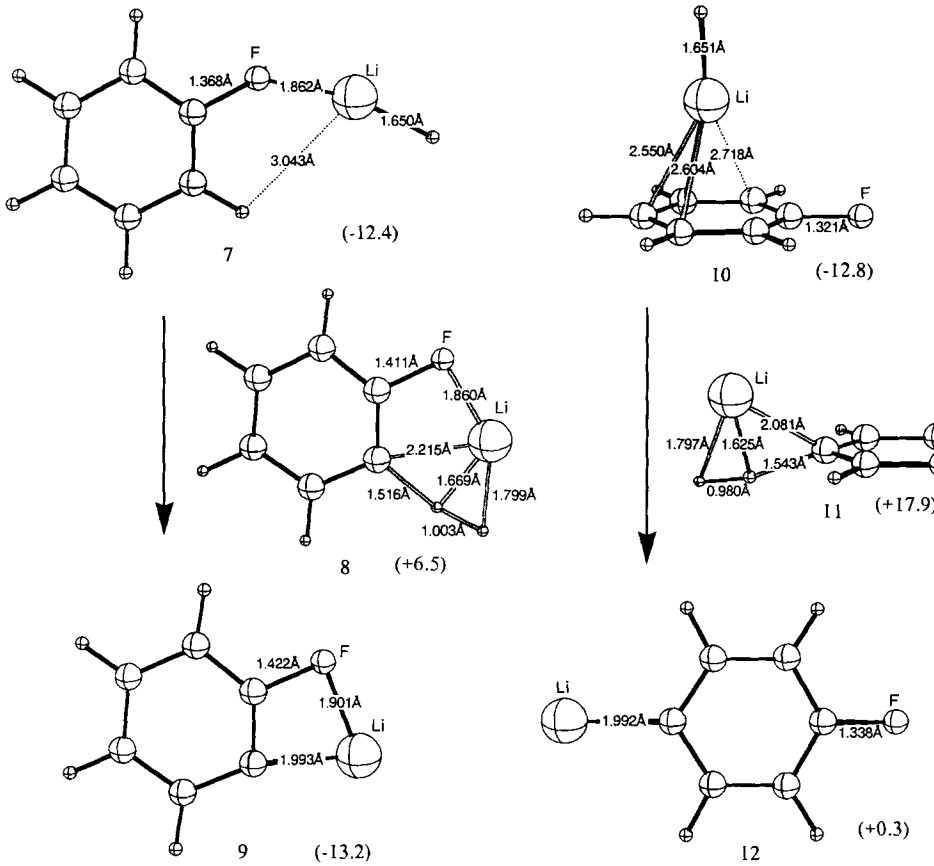

Fig. 3. Calculated structures for the lithiation of fluorobenzene with lithium hydride. Left: Complexation by the fluorine substituent. Right: Complexation by the aromatic ring.

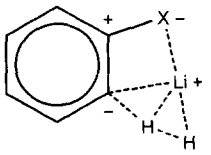
In the complex between phenol and lithium hydride, **4**, *no* signs of agostic activation[8, 9] of the *ortho* hydrogen atom by lithium are evident. The C2–H bond (1.075 Å) is actually shorter than the C6–H bond (1.077 Å). Furthermore, the Li–H2 separation of 2.8 Å is far too large to allow any significant interaction.

In contrast, the effect of electronegative substituents on lowering the activation energies is dramatic. The calculated activation barrier for the lithiation of benzene is 18.7 kcal mol^{-1} relative to the separated reactants and thus 34.5 kcal mol^{-1} relative to the precursor complex. For phenol, these values are 5.0 and 22.6 kcal mol^{-1}, respectively, while those for the *ortho* lithiation of fluorobenzene are 6.5 and 18.9 kcal mol^{-1}. For the *para* lithiation of fluorobenzene, a reaction which is not observed experimentally, we compute a much higher activation barrier of 17.9 kcal mol^{-1}

The Natural charges on Lithium, the *ipso* carbon C1, the migrating hydrogen atom, and the hydride ion (Table 1) are also very similar in all the transition structures. The charge on the migrating hydrogen atom is very low, that is, metalation should be considered in this sense to be a transfer of a hydrogen atom, rather than a proton.[16]

Electronegative *ortho* substituents stabilize the transition states for aromatic lithiation in two ways. First, an electrostatically favorable arrangement of charges is provided (Scheme 1): lithium (positive), *ipso* carbon (negative), *ortho* carbon (positive), and the substituent (negative). Second, the strong coordination of Li–O and Li–F (apparent from their separations which are shorter in the transition structures

than in both the precursor complexes and products, see Figs. 2 and 3) compensates for the effective decrease in the coordination of lithium resulting from the partial bonding in the transition structure. The combination of these effects



Scheme 1. Charge distribution in the transition state of the *ortho* lithiation of aromatic compounds.

leads to a substantial decrease of the activation energy, and is the cause of the strong preference for *ortho* metalations and other regioselective metalations.[3] This conclusion can be expected to be general. We propose "kinetically enhanced metalation" as a more appropriate designation for the accelerating effects of *ortho* substituents.

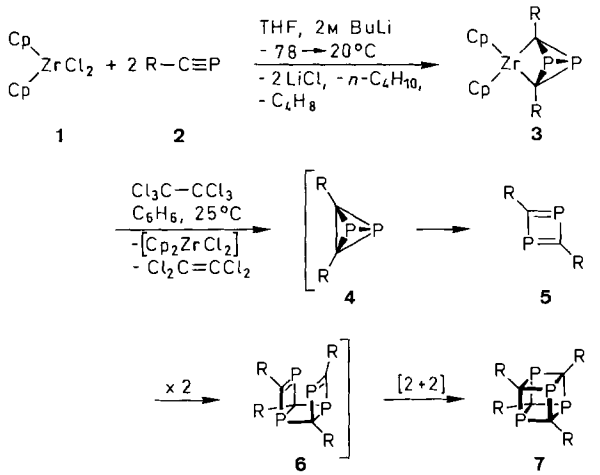
A New, High-Yield Synthesis of Tetraphosphacubanes**

By *Thomas Wettling, Bernhard Geissler, Ronald Schneider, Stefan Barth, Paul Binger,* and *Manfred Regitz**

Dedicated to Professor H.-G. Kuball on the occasion of his 60th birthday

Recently we reported that *tert*-butylphosphaacetylene **2a**[1] can be cyclooligomerized, although only in 8% yield, to the tetraphosphacubane **7a** by heating without solvent to 130 °C.[2] Among known cyclooligomers of **2a**,[3,4] as well as cubanes with P/Si[5] and P/Al[6] combinations of atoms, **7a** is special: strong participation of the "lone pair" on phosphorus in the σ bond between the phosphorus and the framework carbon atoms[7] leads to the NMR resonance signals occurring at extreme positions for the two nuclei (^{31}P NMR: $\delta = +257.4$, ^{13}C NMR: $\delta = -29.1$).[2] To establish whether this effect also influences the reactivity at phosphorus and also whether the phosphorus atoms can now be functionalized, a selective, high-yield access to the pentacycle **7a** was necessary. The pentacycle is the result of two separate cyclodimerization steps; the first is known in principle [8] and the second is basis of this article.



1 2 3 4 5 6 7

2-7a: R = *t*Bu
b: R = CMe_2Et
c: R = 1-adamantyl

The dimeric complex **3a** is the starting material,[8] accessible from bis(cyclopentadienyl)zirconium dichloride (**1**) and 2 mol of the phosphaalkyne **2a** in the presence of magnesium in 53% yield. However, it was obtained reproducibly in 70% yield if the magnesium was replaced by 2 equivalents of *n*-butyllithium and the reaction was carried out at −78 °C.[9]

From previous investigations it is known that reactions of **3a** with halogens and metal or nonmetal halides lead to the

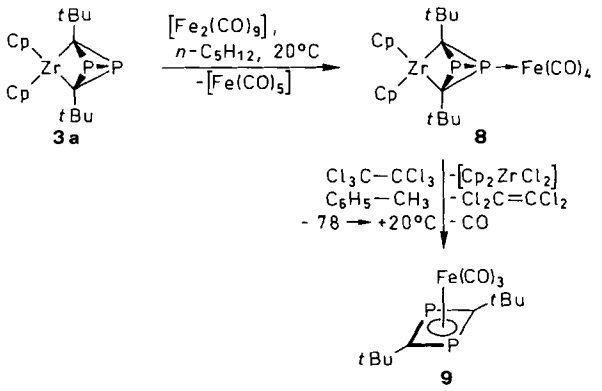
[**] Phosphorus compounds, Part 55. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. Part 54: U. Bergsträsser, J. Hoffmann, M. Regitz, *Tetrahedron Lett.* **1992**, *33*, 1049–1052.

exchange or elimination of the [Cp_2Zr] fragment as well as the incorporation of halogen into the reaction products.[10] We report herein the removal of the metal residue with a mild halogenation reagent which is followed by the second dimerization step.

The reagent of choice is hexachloroethane,[11] whose reaction with **3a** in benzene at room temperature leads smoothly to the pentacycle **7a** (70%); to our knowledge there are no comparable reactions known. The cyclotetramerization **2a** → **7a** can therefore be achieved in an overall yield of 50%. If the same reaction sequence is applied to the *tert*-pentylphosphaacetylene **2b**, then **3b** [red crystals, 70%, m.p. ≥ 300 °C (decomp.), ^{31}P NMR: $\delta = -247.3$, ^{13}C NMR: $\delta = 133.1$ (t, $^1J_{P,C} = 70.5$ Hz, framework C)] and **7b** [pale-yellow crystals, 75%, m.p. 264 °C, ^{31}P NMR: $\delta = +248.3$, ^{13}C NMR: $\delta = -25.8$ (framework C)][12] are accessible in an analogous way. 1-adamantylphosphaacetylene **2c**, can be converted smoothly into the zirconium complex **3c** [orange-red crystals, 65%, m.p. ≥ 300 °C (decomp.), ^{31}P NMR: $\delta = -257.4$, ^{13}C NMR: $\delta = 131.0$ (t, $^1J_{P,C} = 62.6$ Hz, framework C)]; however, the subsequent yield of **7c** [30%, ^{31}P NMR: $\delta = +245.3$, ^{13}C NMR: $\delta = -21.6$ (framework C)] is reduced by the formation of an isomer whose structure has so far not been confirmed.[13]

A reasonable explanation for the reaction **3** → **7** involves the intermediates **4**–**6**, which could not be proved directly; **5** and **6** are probably also intermediates in the thermal cyclotrimerization of **2a** to **7a**.[2] The thermal isomerization of tetra-*tert*-butyltetrahedrane to the corresponding cyclobutadiene is known in carbon chemistry.[14]

That the zirconium complex **3a** can be converted into the 2,4-di-*tert*-butyl-1,3-diphosphet (**5a**) with hexachloroethane by the elimination of the [Cp_2Zr] fragment is considered plausible from the following experiment: If **3a** is complexed with nonacarbonyldiiron, then **8** is formed [red-brown crystals, 63%, ^{31}P NMR: $\delta = -134.4$, -272.5 (for each d, $^1J_{P,P} = 106.8$ Hz), ^{13}C NMR $\delta = 125.5$ (dd, $^1J_{P,C} = 70.9$ and 64.8 Hz, framework C)]. If this iron complex is treated with



the halogenation reagent, then the complex stabilized diphosphet **9** is formed.[15] However, we do not see the possibility of proving the free diphosphet **5a** under similar conditions.

Experimental Procedure

3a: To a stirred solution of the zirconium compound **1** (2.9 g, 10.2 mmol) in THF (40 mL) at −78 °C (exclusion of air and moisture), 1.6 M *n*-butyllithium in *n*-hexane (12.5 mL, 20.4 mmol) was added dropwise. After 1 h the phosphaalkyne **2a** [1] (2.0 g, 20.0 mmol) was added to this solution at the same temperature. The mixture was allowed to warm up and the solvent was removed at 30 °C/10^{-3} mbar. The residue was dissolved in ether (20 mL) and filtered over a D3 frit. The filtrate was concentrated and cooled to −78 °C which afforded **3a**. Yield: 3.0 g (70%) orange-red crystals; m.p. ≥ 300 °C (decomp.). IR, ^{13}C and ^{31}P NMR spectra are identical with those of an authentic sample. [8]

7a: A solution of the zirconium complex **3a** (1.4 g, 3.3 mmol) in benzene (10 mL) was treated with hexachloroethane (0.79 g, 3.3 mmol) and stirred for 5 d at 25 °C. The solution was pipetted from the precipitated [Cp_2ZrCl_2], concentrated at 25 °C/10^{-2} mbar and the residue was subjected to kugelrohr distillation [155 °C (oven temperature)/10^{-2} mbar]. Yield: 0.47 g (70%) pale yellow crystals; m.p. 241 °C (from *n*-pentane). IR, ^{13}C and ^{31}P NMR spectra are identical to those of an authentic sample. [2]

croscopy[1] to the generation of receptor arrays for biosensors and parallel ligand-binding assays.[2] Photolithography has been extensively used to spatially direct the formation of electrical circuits and, more recently, the synthesis of peptides and oligonucleotides.[3] We now report the use of photolithographic techniques to spatially direct the covalent attachment of biomolecules to a functionalized glass surface. Antibodies have been crosslinked to a benzophenone-derivatized glass surface in a 500×500 μm checkerboard pattern and subsequently detected by means of epifluorescence microscopy.

Benzophenone was chosen as the crosslinking agent by virtue of its chemical stability, relatively low-energy absorption ($\lambda_{max} \approx 350$ nm), and high efficiency in photochemical crosslinking.[4, 5] Moreover, because the n,π* triplet state of benzophenone reacts with a wide variety of C–H bonds, it should be generally useful for immobilizing many different biomolecules with a wide range of functional groups (including both proteins and nucleic acids).[5] Silica substrates were first derivatized with *t*-butyloxycarbonyl (Boc)-protected 3-aminopropyltriethoxysilane, then deprotected by treatment with 50% trifluoroacetic acid/CH_2Cl_2, and washed with ethyldiisopropylamine/CH_2Cl_2 followed by dimethylformamide (DMF), CH_2Cl_2, and EtOH.[3] The *N*-hydroxysuccinimide (NHS) ester[6] of 3-benzoylbenzoic acid (100 mM in DMF) was then coupled to the aminopropylated glass substrate (Fig. 1). The derivatized substrate was washed with DMF, CH_2Cl_2, and EtOH, and the free NH_2 groups were capped by treatment with acetic anhydride/dimethylaminopyridine. The coupling efficiency of benzoylbenzoic acid was estimated to be approximately 80%.[7]

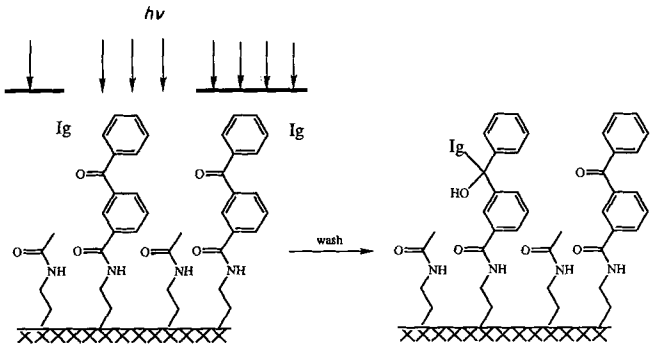

Fig. 1. Light-directed spatially defined immobilization of protein on a solid support.

In order to determine whether spatially addressable crosslinking could be achieved, we attempted to generate a 500×500 μm checkerboard array of photoimmobilized immunoglobulin (Ig) molecules. A 5 μM solution of rabbit IgG (Ig**1**) (in 150 mM NaCl, 10 mM Na_2HPO_4, pH 7.4 (PBS buffer), and 0.05% tween 20) was applied to the benzophenone-derivatized surface and irradiated through a 500×500 μm checkerboard mask (Fig. 1).[3] After a 30 minute irradiation with the 300–400 nm output of a high-pressure mercury arc lamp (12 mW cm^{-2}), the surface was washed with PBS, 1% bovine serum albumin (BSA), and 0.05% tween buffer. Photoimmobilized Ig**1** was labeled by incubating the substrate with fluorescently tagged goat anti-rabbit IgG (Ig**2**). The fluorescent regions of the silica substrate were detected by scanning the substrate in an epifluorescence microscope ($\lambda_{ex} = 488$ nm; $\lambda_{em} > 520$ nm).[8]

The presence of a fluorescent checkerboard pattern (Fig. 2) demonstrates that antibody Ig**1** is bound covalently to the support in specific regions by spatially localized photocrosslinking. Unexposed areas of the checkerboard image appear dark, whereas irradiated regions appear light, due to to the presence of the fluorescent Ig**2** · Ig**1** complex. A photocrosslinking experiment carried out under the same conditions, but with acetylated silica substrate lacking benzophenone, did not yield a checkerboard pattern, and the fluorescence intensities were similar to underivatized substrate. These experiments demonstrate that light-directed immobilization of protein occurs by a photochemical reaction with benzophenone.

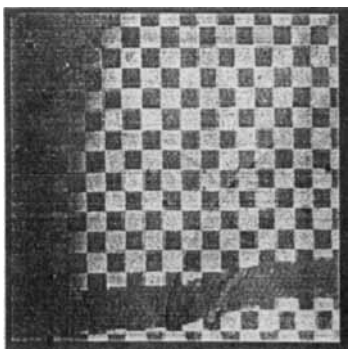

Fig. 2. Spatially localized crosslinked and fluorescence labeling. Light areas correspond to areas of increased fluorescence intensity.

A quantitative comparison between the fluorescence intensity of the checkerboard glass substrate and standardized fluorescent beads (Flow Cytometry Standards) yields an approximate density of one crosslinked antibody per 5000 nm^2. For comparison, the average end-to-end distance of the two ends of the Fab arms of the antibody is approximately 200 Å.[9] The contrast of the fluorescent checkerboard image in this case is 5:1 (after subtracting the background fluorescence of derivatized substrate not exposed to Ig**1** or Ig**2**), representing the ratio of covalently bound antibody (Ig**1**) to noncovalently bound antibody (Ig**1** and/or Ig**2**). However, in other cases lower fluorescence contrast ratios were obtained, presumably due to nonspecific antibody binding.[10] The degree of nonspecific binding is likely to vary as a function of the biomolecule and detection method used in each experiment.

We have demonstrated that proteins can be immobilized on surfaces in spatially defined arrays by the use of photoaffinity labels and photolithography. This method should be generally applicable to a wide range of biopolymers with a variety of functional groups. An important next step is the development of site-selective photoactive or photocaged crosslinking reagents.[11] In addition, it should be possible to construct spatially defined arrays of biomolecules for general use in developing novel biosensors or ligand-binding assays.

[7] A section of a silica substrate bearing nitroveratryloxycarbonyl (NVOC)-protected amino groups was photodeprotected [3] and then derivatized with the NHS ester of 3-benzoylbenzoic acid. A second section of the substrate was then deprotected and derivatized with the NHS ester of biotin. Any unreacted sites in the first section (due to incomplete coupling of benzophenone) will also react with the biotin NHS ester. The entire surface was then treated with fluorescein-streptavidin (Molecular Probes Inc., Eugene, OR (USA)). The coupling efficiency of benzophenone was then determined by comparison of the fluorescence intensities of the two sections.

First Atropo-Enantioselective Ring Opening of Achiral Biaryls Containing Lactone Bridges with Chiral Hydride-Transfer Reagents Derived from Borane**

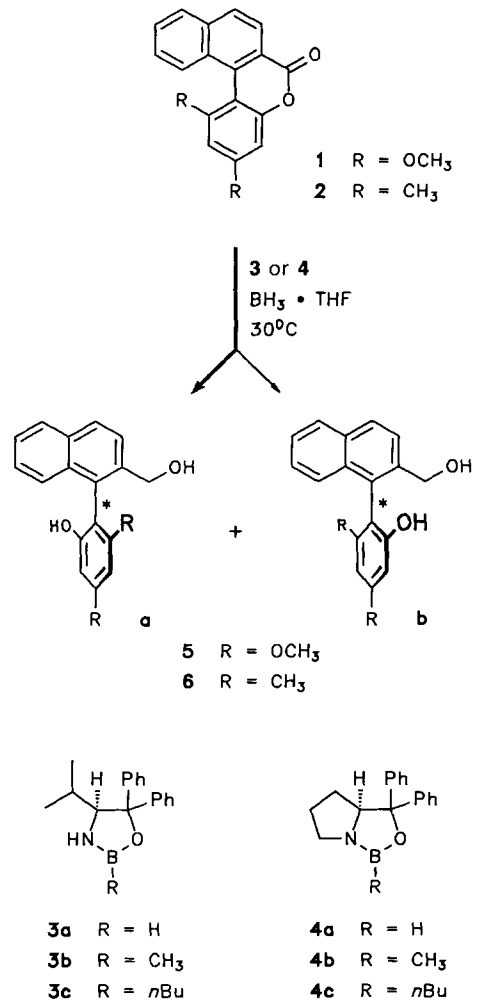
By *Gerhard Bringmann** and *Thomas Hartung*

Dedicated to Professor Gerhard Quinkert on the occasion of his 65th birthday

Rotationally restricted biaryl compounds from natural and synthetic sources have attracted ever more attention because of their biological activity but also as chiral auxiliaries. For the regio- and stereocontrolled construction of even extremely sterically congested biaryl systems, the lactone-bridged biaryls have proved to be very useful intermediates.[1, 2] They are easily accessible through Pd-catalyzed intramolecular aryl coupling of the molecular halves, which are joined by an ester linkage.[3, 4] Most of these bridged biaryls (if containing *ortho* substituents of "normal" size) are not differentiated into stable atropisomers, since at room temperature they undergo a rapid "helimerization".[5, 6]

This suggests the possibility of cleaving the lactone bridge atropisomer-selectively to form the configuratively stable ring-opened products. By utilizing achiral *H*- or *O*-nucleophiles for chiral substrates (i.e., under internal asymmetric induction) or chiral *O*- and *N*-nucleophiles for achiral substrates (i.e., under external asymmetric induction),[7] we performed this reaction atropodiastereoselectively and demonstrated its application in natural product synthesis. Recently we extended this principle to the atropo-enantioselective ring opening of achiral lactones with chiral *H*-nucleophiles using chirally modified aluminum hydrides.[8] The major problems were the lack of chemical reactivity of the reagents, which had in most cases been developed for chemoselective reduction, for example, of ketones, their tendency to function simultaneously as *N*-nucleophiles, and the mediocre selectivities (in the most favorable case, 88:12 and not attainable for all substrates), as well as the laborious workup. We now report atropo-enantioselective biaryl syntheses by stereoselective reduction of achiral biaryl lactones with modified boranes.

For this purpose, we selected the oxazaborolidines developed by Itsuno et al.[9] and Corey et al.[10] of the type $\mathbf{3}\cdot BH_3$ and $\mathbf{4}\cdot BH_3$, which had already been extremely successfully applied for the enantioselective reduction of ketones, where they gave excellent optical and chemical yields, and required very short reaction times;[9, 10] even a catalytic reaction procedure ("CBS" procedure,[10] "molecular robot"[11]) was possible. The *B*-alkylated compounds **3b** and **3c** were first prepared,[12] analogously to the synthesis of **4b** and **4c**.[10, 13, 14]



As substrates we used the configuratively labile, axially prostereogenic bridged biaryls **1** and **2**, which can easily be synthesized by esterification and intramolecular aryl coupling[4] from 1-bromo-2-naphthoic acid and 3,5-dimethoxy- or -dimethylphenol. The results of the ring-opening experiments are summarized in Table 1.

The efficiency of the process can be seen in the good results already obtained for the monocyclic derivatives **3a–c**, but in particular for the excellent atropisomeric ratios attained with the bicyclic reagents **4a–4c**, which are at least 90:10 for prac-

tically quantitative yields in all cases. By far the highest asymmetric induction is obtained with the *B*-methyl and *B*-*n*-butyl derivatives **4b** and **4c**, independent of the lactone used.

Table 1. Ratios for the atropisomers on reduction of **1** and **2** with the chirally modified boranes **3**·BH_3 and **4**·BH_3 in THF at 30 °C [a].

Lactone	Oxazaborolidine	Alcohol	Ratio [b] **5a**:**5b** or **6a**:**6b**
1	**3a**	**5**	93:7
1	**3b**	**5**	89:11
1	**3c**	**5**	85:15
1	**4a**	**5**	91:9
1	**4b**	**5**	97:3
1	**4c**	**5**	95:5
2	**3a**	**6**	84:16
2	**3b**	**6**	88:12
2	**3c**	**6**	84:16
2	**4a**	**6**	90:10
2	**4b**	**6**	98.5:1.5
2	**4c**	**6**	97:3

[a] All transformations were conducted on an analytic scale (0.03 mmol lactone) in the lactone/oxazaborolidine/BH_3·THF ratio of 1/3/4. [b] The ratio of atropisomers was determined by analytic HPLC on a chiral stationary phase. **5a**/**b**:[8] Chiralcel OF (Daicel), petroleum ether (b.p. 56–64 °C)/*i*PrOH/HCO_2H = 85/15/0.05; the alcohol eluted first is **5b**. **6a**/**b**:[12] Chiralcel OD (Daicel), petroleum ether (b.p. 56–64 °C)/*i*PrOH = 90/10; the alcohol eluted first is **6a**.

The practicality of this stereoselective synthesis is increased by the discovery that when the reaction is performed on a preparative scale, the atropisomeric ratios achieved (e.g., 98.5:1.5 for the reduction of **2** with **4b**) can be improved still further by a simple crystallization step that effortlessly yields enantiomerically pure material (**6a**:**6b** > 99.9:0.1).

Experimental Procedure

3b: A solution of (*S*)-(−)-2-amino-3-methyl-1,1-diphenylbutan-1-ol (510 mg, 2.0 mmol) [9] in dry toluene (10 mL) was treated with trimethylboroxine (190 μL, 171 mg, 1.36 mmol) and stirred for 0.5 h at 20 °C. Thereafter the solution was concentrated to 2 mL, and twice treated with 5 mL of toluene and destilled. After removal of the solvent, colorless crystals of **3b**[12] were obtained in quantitative yield. M.p. 99.5–101 °C, $[\alpha]^{20}_D$ −221.8 (*c* = 1.66, THF).

3c: A solution of (*S*)-(−)-2-amino-3-methyl-1,1-diphenylbutan-1-ol (510 mg, 2.0 mmol) and *n*-butylboronic acid (205 mg, 2.01 mmol) in toluene (30 mL) was heated for 24 h under reflux; water was removed with a Dean–Stark trap. Workup analogous to that of **3b** gave a quantitative yield of **3c**[12] as colorless oil; $[\alpha]^{20}_D$ −185.7 (*c* = 1.89, THF).

6a (*preparative* atropo-enantioselective ring opening of **2** with **4b**): A solution of BH_3·THF (0.80 mmol in 4 mL, 0.2 M) was treated with a 0.2 M solution of oxazaborolidine **4b** (3 mL, 0.60 mmol) in THF at 0 °C under argon. After the addition the mixture was warmed to 30 °C, and a solution of the lactone **2** in THF (0.20 mmol, 55 mg in 6 mL) was added dropwise over 10 min. The reaction solution was stirred for a further 30 min at 30 °C, upon which it was hydrolyzed by addition of water (5 ml) and HCl (2 M, 2 mL). After extraction into ether, the organic phase was dried over $MgSO_4$, and the solvent destilled off in vacuum. Chromatography of the residue on a short silica gel column (CH_2Cl_2) afforded the alcohol **6a** [12] (**6a**:**6b** = 98.5:1.5); yield 52.5 mg (94%), m.p. 141–142 °C, $[\alpha]_D^{20}$ −31.6 (*c* = 0.51, CH_3OH). A subsequent crystallization from dichloromethane/petroleum ether furnished enantiomerically pure material (**6a**:**6b** > 99.9:0.1).

Matrix-Assisted Laser Desorption Mass Spectrometry of Lignins**

By *Jürgen O. Metzger,* Christine Bicke, Oskar Faix, Wilfried Tuszynski, Raimond Angermann, Michael Karas,* and *Kerstin Strupat*

As component of the lignocelluloses, the skeletal substance of terrestrial plants, lignin is the most common biopolymer besides the polysaccharides cellulose and hemicelluloses. As side product of the cellulose recovery over 50 million tons of technical lignins is produced yearly worldwide, and its use as renewable raw material with a view to protecting the environment is a challenge for chemists. Knowledge about lignins is still fragmentary.[1–3] It is certain that its monomeric precursor in conifers is predominantly coniferyl alcohol (**1a**); in deciduous trees sinapyl alcohol (**1b**) is an additional precursor, as is *p*-cumaryl alcohol (**1c**) in grasses and herblike dicotyledons.[1] According to Freudenberg,[4] these alcohols polymerize to give lignin, by a radical mechanism. However, the biosynthesis path from the monomers to the macromolecule has not yet been unambiguously elucidated.[2] At any rate lignin is fundamentally different from other biopolymers like proteins, nucleic acids, and polysaccharides, in

which the type of linkage and order of the units is stipulated; in lignin at least ten types of binding are found to different extents linking the phenylpropane units into a completely irregular three-dimensional polymer.[5]

To determine the constitutional makeup of lignin by chemical degradation methods is extremely labor-intensive and time-consuming and nevertheless gives no clear answers. In the ^{13}C NMR spectrum, about forty different carbon atoms can be assigned.[5] The molecular weight determination is problematic, because lignins tend strongly toward molecular aggregation in solution.[2] Mass spectrometry has hitherto been used as analytical method for the study and characterization of lignins only in the form of pyrolysis mass spectrometry, in which only monomeric, and to a small extent dimeric, pyrolysis products are detected.[6]

The study of polymers in general, and biopolymers in particular, by mass spectrometry has, however, made enormous advances in recent years with the development of new "soft" ionization techniques such as secondary ion (SI),[7] fast atom bombardment (FAB),[8] and ^{252}Cf plasma desorption (PD) mass spectrometry,[9] as well as various spray processes like ion spray,[10] and in particular, matrix-assisted laser desorption (MALD).[11] The accessible mass range has been steadily extended. Thus MALD mass spectrometry has provided proof of proteins of at least 250000 Da.[12] The protonated quasi-molecular ion was detected, but fragmentation was not observed with this method. MALD-MS was also used successfully for oligosaccharides like maltodextrins and dextrans. The mass spectrum showed peaks for the individual oligomers at well-defined spacings corresponding to the monomeric units, and enabled the determination of the molecular weight distribution up to about 10000 Da.[13] A series of linear polymers like polystyrene and polyethyleneglycol of average molecular weight $\bar{M}_n < 10000$ Da were studied mainly with SIMS.[14]

The lack of a rapid, sensitive, and powerful method for characterizing small amounts of lignins prompted us to investigate the potential of the soft ionization techniques for lignins. Although FAB-MS and PDMS brought no success, MALD-MS provided the breakthrough in the application of mass spectrometry to lignins.

Milled-wood lignin from birch (*Betula alba*), which was well-characterized by classical methods of lignin chemistry,[15] was mixed in the mass ratio 1:15 without further purification with 2,5-dihydroxybenzoic acid as matrix in acetone/water (9:1). A little of the solution (1 μL corresponding to 50 ng of lignin) was placed onto a silver support, dried, and mounted in a time of flight mass spectrometer, as described in reference [12]. A nitrogen laser with a wavelength of 337 nm and an impulse duration of less than 5 ns was used for desorption. The resolution is relatively low ($m/\Delta m = 50$), and the signals thus relatively broad. The peak centroids can, however, be determined with quite good precision (standard deviation $\pm 0.1\,\%$).[12]

The obtained mass spectrum (Fig. 1) shows a wide molecular weight distribution of several hundred to larger than 16000 Da. The center of gravity of the distribution lies around 2600 ± 100 Da, which agrees quite well with the number average of the molecular weight $\bar{M}_n$ of birch lignin determined by gel chromatography.[15] The broad distribution curve (Fig. 1) has a pronounced fine structure up to about 2000 Da (Fig. 2), which may be assigned to oligomeric lignin molecules. These oligomers are not all the same, but themselves show a broad molecular weight distribution. Clear groups of oligomers—from trimers of ca. 600 Da to nonamers of ca. 1800 Da—can be distinguished. The center of gravity of the peaks of oligomeric groups yields the number average of

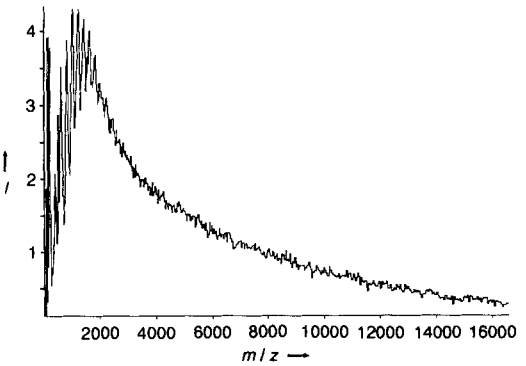

Fig. 1. MALD mass spectrum of birch lignin. Sum of twenty single spectra. I = relative intensity in arbitrary units, molecular weight M_r in Da (m/z).

their molecular weight $\bar{M}_n$. This number average divided by the degree of oligomerization gives an average formula weight of between 214 and 204 Da for one phenylpropane unit of these oligomers, which agrees well with the chemically determined average formula weight of birch lignin (209 Da). The conclusion is that the ionized lignin molecules are probably protonated, since a cationization with Na^+, as observed for sugars,[13] would lead to distinctly higher average molecular weights.

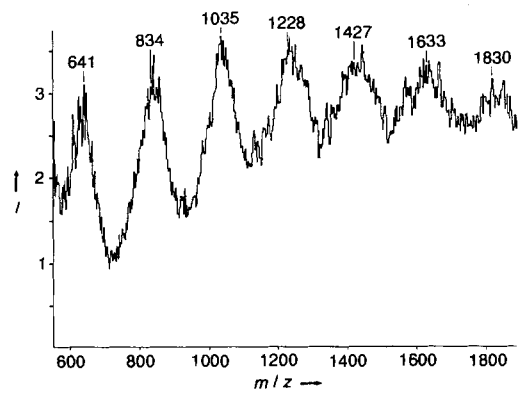

Fig. 2. Fine structure of the MALD mass spectrum in the range 600–1800 Da for birch lignin (section of Fig. 1). The numbers over the peak maxima give the center of gravity of the distribution of the oligolignol signals. I in arbitrary units, M_r in Da.

Figure 2 shows that superimposed on the fine structure of the oligomers (Fig. 1) is a hyperfine structure, which is depicted, expanded, for tetramers in Figure 3. Many tetramers with different molecular weights can be recognized. Two sequences with $\Delta m = 30$ Da (826, 856, 886; and 776, 805, 834, 866) confirm the existence of guaiacyl and syringyl propane building blocks in birch lignin, which differ only by the mass of a methoxy group ($\Delta m = 30$), and indicate that tetramers with four guaiacyl units, three guaiacyl and one syringyl unit, etc. to four syringyl units are present. The center of gravity of the molecular weight distribution of the tetramers lies between m/z 826 (two syringyl and two guaiacyl units) and m/z 856 (three syringyl and one guaiacyl units), which shows that the statistical distribution of the monomers in lignin (syringyl:guaiacyl ≈ 1.4) is already present in the low oligomers. The distribution of the different linkages in lignin identified by chemical degradation[5] also seems to correspond in the low oligomers and in the polymer, as a molecu-

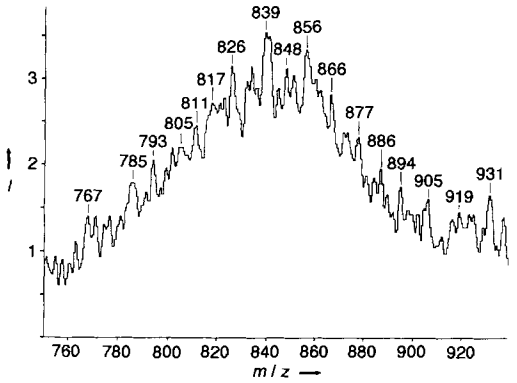

Fig. 3. Hyperfine structure of the MALD mass spectrum in the range for tetramers of birch lignin (section of Fig. 2).

lar mass analysis of the many different tetramers shows. The hyperfine structure of the MALD mass spectrum contains the coded information that enables an increasingly detailed analysis of the complex construction of lignin.

Apart from birch lignin the lignin from a conifer (Chinese redwood, *Metasequoia glyptostroboides*)[17] was studied. The MALD mass spectrum revealed a broad distribution of several hundred to larger than 12000 Da and again directly yielded the number average molecular weight $\bar{M}_n = 2300 \pm 100$. The fine structure of the peaks up to 2000 Da is assigned to oligomers from trimers to decamers (Fig. 4). In contrast to

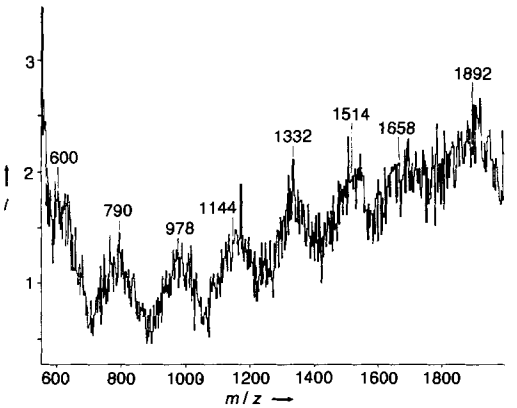

Fig. 4. Fine structure of the MALD spectrum of a conifer lignin (Chinese redwood) from 600 to 2000 Da. Section of the complete spectrum. The numbers above the peak maxima give the center of gravity of the molecular weight distribution for each oligomer range.

birch lignin (Fig. 2), the chemically determined average formula weight of a phenylpropane unit is 190 Da, because conifer lignin consists almost exclusively of guaiacyl propane units. This value is also confirmed by the MALD mass spectrum. As for birch lignin, the hyperfine structure reveals several different oligolignols of the same degree of oligomerization in which the monomers are linked by various binding types.

The results presented here show that MALD mass spectrometry is a fast, sensitive, and extremely powerful micromethod for the characterization of lignins, which yields the molecular weight distribution directly. Up to nonamers (birch lignin) or decamers (conifer lignin) were detected and their average molecular weights determined. In addition, the technique revealed that many different oligomers with the same degree of oligomerization are present in lignin, which reflect the variety and statistical distribution of binding types. It can be expected that the development of MALD mass spectrometry will extend the accessible mass range to lignins of substantially higher molecular weight. An improvement in the spectrometric resolution will enable the fine structure of even the high polymers and the hyperfine structure of the middle range polymers to be analyzed. It remains to be seen whether a subsequent collision-induced fragmentation and application of MS/MS techniques will allow sequencing. Furthermore our results show that mass spectrometry can be used on cross-linked and irregular polymers, which is of significance for many technically important polymers.

Transition Metal in a Cube—A Discrete Eight-Coordinate $[Mn^{2+} \subset [2.2.2]$cryptand$]$ as a Body-Centered Cube with an N_2O_6 Donor Set**

By *Karl S. Hagen**

Discrete eight-coordinate complexes of the actinides, lanthanides, and early transition metals are fairly common. However, only two high-symmetry, idealized, polyhedrons are generally observed; the dodecahedron (DD, D_{2d} point group) and the square antiprism (SAP, D_{4d}).[1-3] Various calculations based on interligand repulsion[3,4] or Hückel methods[5] obtain higher energy surfaces for other geometries, such as the hexagonal bipyramid (HB, D_{6h}), bicapped trigonal antiprism (BTAP, D_{3d}), end-bicapped trig-

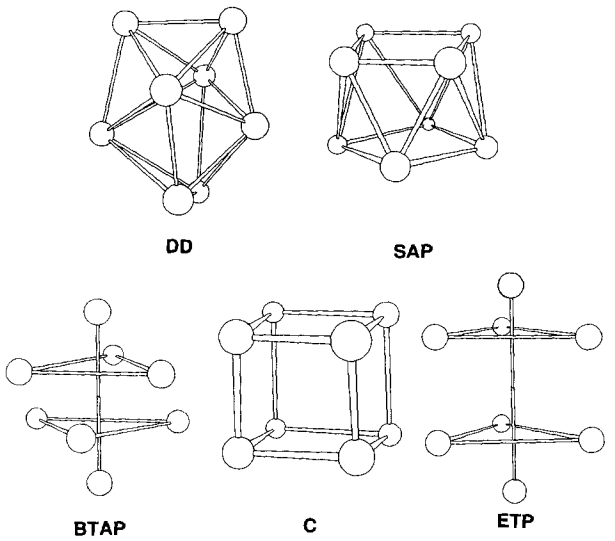
onal prism (ETP, D_{3h}), bicapped trigonal prism (BTP, C_{2v}) square prism (SP, D_{4h}), and the cube (C, O_h) (Scheme 1). The rare eight-coordinate complexes of the middle to late transition elements are generally coordinated by bidentate ligands with a small bite such as NO_3^- (51.8–53.7°).[6] However, sandwich complexes with tetradentate crown ethers are known for Mn^{II}[7] and Fe^{II},[8] as well as Ag^{I},[9] and we have recently utilized tetraaza macrocyclic ligands to prepare analogous SAP sandwich complexes of the small divalent first row transition metals, Fe^{II} and Mn^{II}.[10]



Scheme 1.

Since macrobicyclic ligands have been used to impart unusual kinetic, thermodynamic, or stereochemical properties to six-coordinate metal complexes,[11] one might expect uncommon eight-coordinate structures with ligands such as Lehn's macrobicyclic, diazapolyoxa cryptand ligands.[12] Such is the case for the [2.2.2]cryptates[13] of the large cations Cs^+[14] and K^+,[15] which exhibit a small trigonal distortion from the rare ETP geometry. The Na^+ [2.2.2]cryptates[15] have a trigonal twist closer to BTAP geometry. One might expect a further twist to BTAP or C geometries with smaller spherical cations such as high-spin d^5 Mn^{2+}. No transition-metal [2.2.2]cryptates have yet been isolated, although studies indicate weak binding in protic solution,[17] but this should not preclude their isolation from aprotic media.

Indeed, we have isolated the $CF_3SO_3^-$ salt of [$Mn^{2+} \subset$ [2.2.2]cryptand] (**1**), the first discrete eight-coordinate complex of a transition metal having idealized cubic symmetry, and the first transition-metal complex with this ligand. Although numerous structural studies of cryptates of alkali metals, alkaline earth metals, and of some lanthanides are available,[18] only two structures of transition-metal cryptates have been reported. These are the seven-coordinate Co^{II}[19] and six-coordinate Ni^{II}[20] cryptates with the smaller [2.2.1]cryptand.[13]

The complex **1** (Fig. 1) consists of the Mn^{II} ion encapsulated within the cryptand and located at a crystallographic D_3 site, well separated from the $CF_3SO_3^-$ anions. The triad passes through the Mn atom and the two nitrogen atoms and the three diads pass through the Mn center and bisect each C3–C3′ bond. Eightfold coordination for Mn in **1** (with crystallographically imposed BTAP symmetry) is established by the six O atoms (equivalent by symmetry) and the two symmetry-related N atoms. As emphasized in Figure 2, these atoms are disposed at the eight vertices of the cube about the Mn atom, which gives the Mn^{II} cryptate idealized cubic geometry (O_h point group). Deviations of the MnN_2O_6 atoms from the best fit to a perfect body-centered cube with edge length 2.777 Å (Fig. 2) are only 0.007 Å for N and 0.073 Å for O.

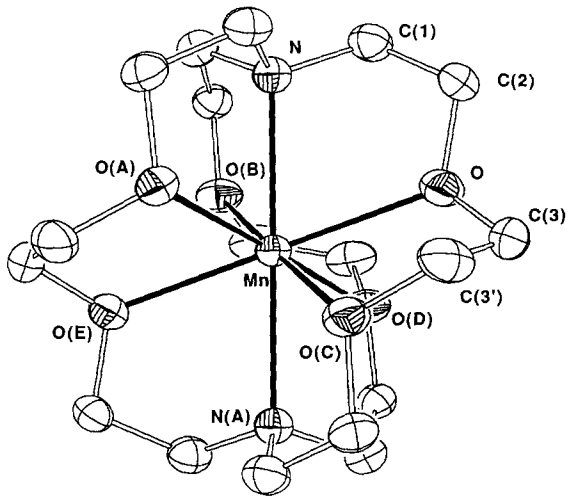


Fig. 1. ORTEP structure of **1** showing the 50% probability thermal ellipsoids and atomic labeling scheme. Selected interatomic distances [Å] and angles [°] are as follows: Mn-N 2.406(4), Mn-O 2.393(2), N···N(A) 4.81, O···O(E) 4.79; N-Mn-O 69.4(1), N-Mn-O(C) 110.6(1), O-Mn-O(A) 108.3(1), O-Mn-O(C) 69.4(1), O-Mn-O(D) 74.0(1), O-Mn-O(E) 177.3(1), N(1)-Mn-N(1′) 111.4(2), N(1)-Mn-N(3) 144.2(2).

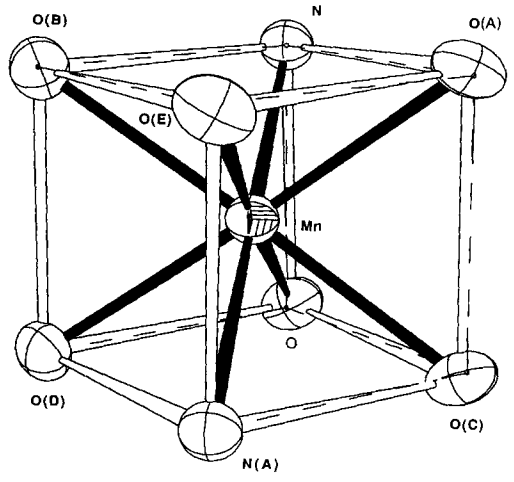

Fig. 2. Structure of **1** showing the body-centered cubic arrangement of oxygen and nitrogen donor atoms about Mn^{2+} as a best fit to a perfect cube having edge length 2.777 Å (dashed lines). Angles [°] and lengths [Å] for the cube: all O-N-O(A) 90.5, N-O-O(C) 92.6, N-O-O-(D) 89.3, O(C)-O-O(D) 87.6; N···O 2.733, O···O(C) 2.724, O···O(D) 2.881 Å.

The edge lengths of the cube are N···O 2.733 Å, O···O 2.724 Å for donor atoms which make up five-membered rings (with the Mn and two CH_2 units), and O···O 2.881 Å between O donor atoms of separate sectors of the cryptand. The L-Mn-L bite angles within five-membered rings are 69.4(1)°, but 74.0(1)° when the two O atoms are not part of the same ring. The mean deviation from the ideal of any one of the four atoms which define a face of the cube is 0.017 Å, and the distance of the Mn ion to each of the six faces is 1.383 Å. The Mn–O bond lengths (2.393(2) Å) are identical by symmetry and within experimental error the same as the

Mn–N bond lengths (2.406(4) Å). As expected with a higher coordination number, Mn to ligand bonds are considerable longer than those of six-coordinate Mn^{II} complexes, but are similar to those found in the square-antiprismatic complex, $[Mn(cyclen)_2]^{2+}$ (2.384–2.435 Å)[10] (cyclen = 1,4,7,10-tetraazacyclododecane). The only other examples of discrete cubic complexes are $[La(bpyO_2)_4]^{3+}$[21] ($bpyO_2$ = 2,2′-bipyridine-*N*,*N*′-dioxide) and $(Et_4N)_4[U(NCS)_8]$.[22]

The great flexibility of the [2.2.2]cryptand is manifested in the cube's N ··· N diagonal distance of 4.462 Å, which is the smallest yet observed for [2.2.2]cryptates[18] and is considerably less than the 6.1 Å for [$Cs^+ \subset$ [2.2.2]cryptand],[14] and 6.872 Å in the empty cryptand.[23] The metal has induced a twisting of the ligand about the triad resulting in an oblique (*ob*) arrangement of the C3–C3′ groups compared to the parallel (*lel*) configuration of the cryptand and cryptates of larger cations. This creates a chiral dication which is isolated as a racemic mixture in a centrosymmetric space group. The large change in ligand conformation compared to the uncomplexed cryptand and lack of crystal field stabilization energy for a high-spin d^5 Mn^{II} ion[24] suggests that there is little kinetic stability to this complex. Yet the complex is stable in anhydrous acetonitrile where its solution EPR spectrum is distinct from that of $Mn(CF_3SO_3)_2$.[24b] A pure powder of **1** exhibits a broad signal at $g = 2.03$, although powder and orientated single-crystal samples of **1** in a diamagnetic matrix (1% in [Cd ⊂ [2.2.2]cryptand] $(CF_3SO_3)_2$)[25] exhibit well-resolved multiline axial spectra with a small zero-field splitting, $D = 220$ gauss (Fig. 3).

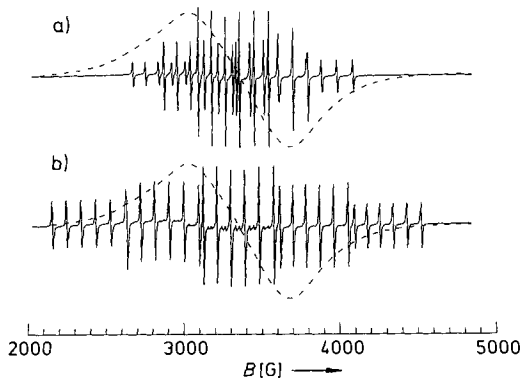

Fig. 3. EPR spectra (X-band) of **1** in a [Cd ⊂ [2.2.2]cryptand]$(CF_3SO_3)_2$ matrix (1%) at 21 °C. The spectrum of a single crystal with the field a) perpendicular to the unique axis and b) parallel to it. The dashed lines represent the signal of an undiluted, powdered sample of **1**.

Experimental Procedure

The triflate salt of **1** is isolated as colorless, analytically pure,[26] crystallographic quality,[27] hexagonal plates in 80% yield, by diffusing diethyl ether into an anhydrous acetonitrile solution of an equimolar mixture of $Mn(CF_3SO_3)_2 \cdot 2CH_3CN$ and the ligand under a dry, dinitrogen atmosphere.

Titration of C_{60}: A Method for the Synthesis of Organofullerenes**

By *Andreas Hirsch,** *Antonio Soi,* and *Heinrich R. Karfunkel*

The synthesis of well-defined organofullerenes is still very challenging. There are only few reports on the preparation of isomerically pure single compounds.[1–4] The possible organic reactions of C_{60} are: 1) the addition of nucleophiles,[5, 6] 2) the addition of dienes and 1,3-dipoles,[3, 6] and

Ciba Geigy AG, Basel (Switzerland)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

3) the addition of radicals.[7] Because C_{60} is a polyfunctional molecule, a myriad of products is formed after treatment with an excess of a reagent, for example a nucleophile.[6] It is impossible to isolate isomerically pure single compounds from such reaction mixtures.

To control nucleophilic additions to only one double bond in C_{60} and to maximize the yield of the monoadducts, we titrated dilute solutions of C_{60} in toluene with *tert*-butyllithium and ethylmagnesium bromide. The concentrations of C_{60}, the monoaddition product, and higher addition products upon addition of the nucleophile was determined quantitatively by high-pressure liquid chromatography (HPLC). For this purpose the initially formed fullerides were protonated with methanolic HCl to give $C_{60}HtBu$ **1** and $C_{60}HEt$ **2** (Scheme 1). In this way the formation of products and the

$$C_{60} + t\text{BuLi} \longrightarrow C_{60}t\text{BuLi} \xrightarrow{H^+} \underset{\mathbf{1}}{C_{60}HtBu}$$

$$C_{60} + \text{EtMgBr} \longrightarrow C_{60}\text{EtMgBr} \xrightarrow{H^+} \underset{\mathbf{2}}{C_{60}HEt}$$

Scheme 1. Synthesis of the organofullerenes **1** and **2**.

consumption of C_{60} could be followed very closely from the calculated peak areas (Fig. 1). The UV/VIS spectrum of each peak was simultaneously recorded by means of diode array scans (200–500 nm) allowing the unambiguous assignment of the HPLC peaks to the compounds based on their optical spectra. Because other anionic nucleophiles like amides, hydrides, alkoxides, and thiolates react similarly with C_{60},[6] this synthetic method should allow access to a large variety of monofunctionalized fullerenes as isomerically pure single compounds.

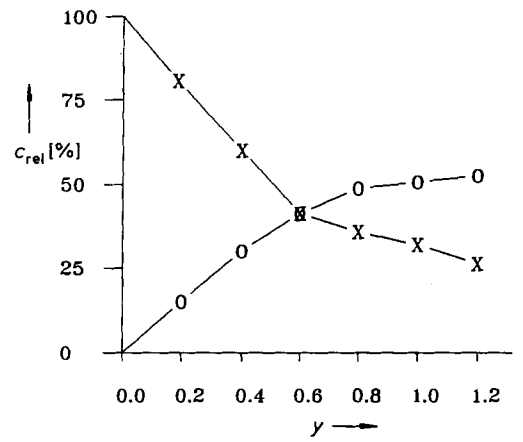

Fig. 1. Results of the titration of the reaction of C_{60} with *tert*-butyllithium. X = amount of C_{60} in % relative to the starting concentration c_A ($c_A = 1.66 \times 10^{-5}$ mol L^{-1}), o = concentration of **1** relative to that of C_{60}; y = equivalents of *t*BuLi. For details see *Experimental Procedure*.

The maximum yield of **1** was about 50%. If the concentration of remaining C_{60} becomes too low, side reactions like $C_{60}t\text{BuLi} + t\text{BuLi} \rightarrow C_{60}t\text{Bu}_2\text{Li}_2$, though heterogeneous, become increasingly important (Fig. 2). In a control experiment an overtitration was carried out: After the addition of about 1.2 equivalents of *t*BuLi the concentration of **1** decreased again, and the concentration of higher addition products increased markedly. The titration with the less reactive ethylmagnesium bromide provided **2** in a maximum yield of about 80%. In this case the formation of higher addition products takes place to a much smaller extent. The chromatograms in Figure 2 show the appearance of five smaller peaks at higher retention times attributed to higher addition products (bis- to hexaadducts). Whereas the UV/

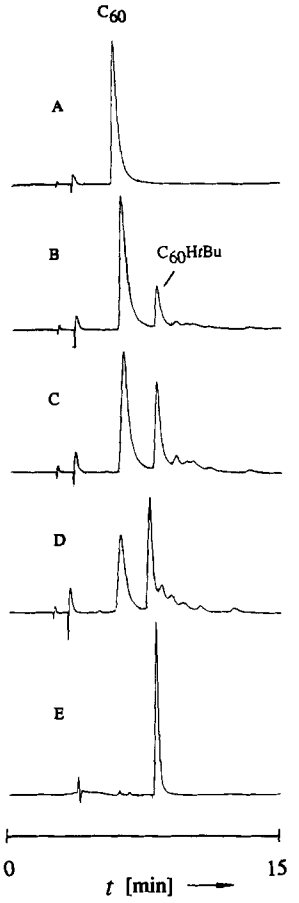

Fig. 2. HPLC control of the reaction of C_{60} with *t*BuLi (also see *Experimental Procedure*). C_{60} before the addition of *t*BuLi (A) as well as after the addition of 0.4 equiv (B), 0.8 equiv (C), and 1.2 equiv *t*BuLi (D). The chromatogram of purified **1** is shown in E. Experimental conditions: Beckman silica gel column (25 × 0.4 cm); particle size 5 μm; eluent *n*-hexane; pressure 4700 kPa; flow rate 0.8 mL min^{-1}; detection at 340 nm.

VIS features of **1** and **2** are very similar to those of C_{60}, the spectra of the higher homologues (diode array scans) are more and more structureless, resulting in a broad tailing from 200 nm into the visible region. Almost the same behavior was observed in the fulleroid series $C_{61}Ph_2$–$C_{66}Ph_{12}$.[3]

Compounds **1** and **2** were purified by preparative reverse-phase HPLC.[8] Here, the higher addition products eluted first and were collected together. The mass spectrum of the mixture of *tert*-butyl adducts shows the peaks of the bis-, tris-, and tetraadducts (*m/z* 836, 894, and 952, respectively).[9] Compounds **1** and **2** were characterized by mass spectrometry, and UV/VIS and ^1H NMR spectroscopy (Table 1). The ^1H NMR spectra exhibit only one signal for the fullerene protons at low field and only one type of ethyl or *tert*-butyl group. Thus only one isomer of either **1** or **2** were formed, namely the product formed by the addition to a six-ring/six-ring double bond (a 6–6 bond). The presence of low-field signals gives evidence of the strong electron-withdrawing influence of the fullerene core. ^1H NMR spectra of mixtures of the higher addition products show two characteristic trends: 1) As the number of substituents increases, the electron-withdrawing influence of the fullerene core decreases (smaller downfield shifts) and 2) higher addition products consist of different regioisomers which produce many signals, finally leading to very broad NMR signals.[6, 10]

Table 1. Selected physical data for the monoadducts **1** and **2**.

1: $M = 778.78$; MS(FAB): m/z 779 (M^+, 15%), 720 ($M^+ - C_4H_9 - H$, 100%); UV/VIS(*n*-hexane): λ_{max}[nm] = 213, 248 (sh), 257, 308 (sh), 326, 408 (sh), 435, 464, 484, 640; IR(KBr): $\tilde{\nu}$[cm^{-1}] = 2959 (s), 2922 (s), 2866 (w), 1462 (s), 1427 (m), 1396 (w), 1369 (s), 1188 (m), 1094 (m), 902 (m), 763 (w), 730 (s), 582 (w), 572 (w), 567 (w), 553 (w), 542 (w), 526 (s) und 513 (w); ^{1}H NMR(400 MHz, CS_2/$CDCl_3$, 25 °C): δ = 6.67 (s, 1H; CH), 2.09 (s, 9H; CH_3). Analysis calculated for $C_{64}H_{10}$: C 98.71, H 1.29%; found C 98.82, H 0.97%.

2: $M = 750.73$; MS(FAB): m/z 750 (M^+, 20%), 748 ($M^+ - 2H$, 25%), 721 ($M^+ - C_2H_5$, 100%); UV/VIS(*n*-hexane): λ_{max}[nm] = 214, 248 (sh), 258, 308 (sh), 326, 408 (sh), 436, 465, 484, 640; IR(KBr): $\tilde{\nu}$[cm^{-1}]: 2959 (m), 2922 (s), 2866 (m), 1452 (s), 1427 (m), 1380 (m), 1261 (m), 1184 (m), 1101 (w), 580 (w), 572 (w), 563 (w), 553 (w), 542 (w), 526 (s), 523 (w); ^{1}H NMR(250 MHz, CS_2/$CDCl_3$, 25 °C): δ = 6.45 (s, 1H; CH), 3.52 (q, ^3J(H,H) = 7.4 Hz, 2H; CH_2), 2.09 (t, ^3J(H,H) = 7.4 Hz, 3H; CH_3).

The experimental findings for **1** and **2** are confirmed by the results of AM1 calculations (MOPAC 6.0)[11]. Calculations were performed on $C_{60}H_2$, $C_{60}HCH_3$, and $C_{60}HtBu$ as 5–6 as well as 6–6 adducts. The 6–6 adducts were shown to be considerably more stable (Table 2); their heats of formation are about 20 kcal mol^{-1} lower than those of the 5–6 adducts. The carbons atoms with the substituents are sp^3-hybridized. The calculated bond length between these carbon atoms is about 1.57 Å and the bond order 0.93. The fullerene protons are deshielded (Mulliken charge in **1** is +0.16), which is in agreement with the downfield shift of the ^{1}H NMR signal (δ = 6.67). Calculations on the intermediate $C_{60}tBu^-$ show that the negative charge is not delocalized (Fig. 3).[12] The highest electron density is found on the C atom next to the sp^3 carbon atom across the 6–6 bond.

Table 2. Calculated energies (AM1 heats of formation) [kcal mol^{-1}] of $C_{60}HtBu$, $C_{60}HCH_3$, and $C_{60}H_2$ as 5–6 and 6–6 adducts.

	$C_{60}HtBu$	$C_{60}HCH_3$	$C_{60}H_2$

6–6	922.1	929.2	931.2

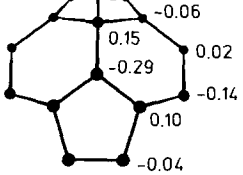

Fig. 3. Electron densities (Mulliken charges) of the affected pyracylene unit of the intermediate $C_{60}tBu^-$ obtained from AM1 calculations.

The titration method described allows the quantitative control of nucleophilic additions to C_{60} necessary for the synthesis and separation of specific addition products in reasonable yields. The attack of one 6–6 bond leads to the formation of single isomers. This method allows access to the organofullerenes C_s-$C_{60}RR'$ and D_{2d}-$C_{60}R_2$ in which R and R′ can be C, H, N, P, O, or S substituents.

Experimental Procedure

For a typical experiment, 30 mg of C_{60} was dissolved in 50 mL of toluene. From this solution 200 µL was used to prepare a dilution series in *n*-hexane (1.66, 0.83, 0.42, and 0.17 [10^{-5} mol L^{-1}] in 10 mL) for HPLC calibration. This allows the subsequent determination of all concentrations of C_{60} and the monoadduct within this range. The nucleophile *tert*-butyllithium (1.7 M in pentane) or ethylmagnesium bromide (0.4 M in THF) was added in portions of 0.2 equivalents relative to C_{60}. To minimize the formation of higher addition products care was taken (rapid stirring and slow addition) to avoid high local concentrations of the nucleophiles in the reaction mixture. A dark precipitate of the lithium or magnesium fullerides formed immediately, which was suspended homogeneously with stirring. After each addition of the nucleophile, 200 µL of the suspension was removed, quenched with 200 µL of 0.01 M HCl, and diluted with *n*-hexane to 10 mL for quantitative HPLC analysis. For the comparison of the concentrations of C_{60} to those of **1** or **2**, the extinction coefficients at the HPLC detection wavelength (340 nm) were determined. After the titration was over, the reaction mixture was quenched with 4 mL of 0.01 M HCl in methanol causing all of the precipitate to dissolve immediately. After evaporation of the solvent **1** and **2** were isolated by preparative HPLC.

A New Reaction Type in the Conversion of Enamines with 1,4-Diphenyl-2-butene-1,4-dione to Give Cage Compounds**

By *Gerd Kaupp,* Uwe Pogodda, Adnan Atfah,* Herbert Meier,** and *Anita Vierengel*

Complex addition, elimination, and substitution reactions in organic chemistry can be classified systematically if not more than four bonds are formed and broken, and when up to two rearrangements are involved.[1] For more complicated cases, at most only individual steps can be interpreted; such

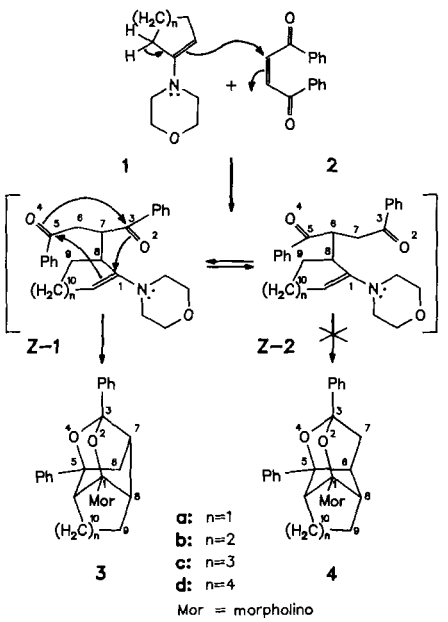
[**] This work was supported by the Deutsche Akademische Austauschdienst (Stipend for A. A.) and the Fonds der Chemischen Industrie.

considerations must, of course, be mechanistically plausible. We report here on fertile preparative reactions of 1,4-diphenyl-2-butene-1,4-dione ("dibenzoylethylene") with enamines in which six bonds are formed or broken and which also involve a rearrangement. The cage compounds **3** are formed selectively from **1** and **2**.

The reaction of **1a–1d** with **2** gives useful yields in spite of its complexity. The reaction can be interpreted most simply as the result of an ene addition followed by a [2+2+2] cycloaddition of two carbonyl groups to the enamine double bond (tandem reaction). In the conversion **1a** → **3a** it was possible to identify the intermediate **Za**: workup by column chromatography gave the hydrolysis product of the intermediate enamine, 2-(1,2-dibenzoylethyl)cyclopentan-1-one. Elucidation of the structure of the products **3a–d** and their differentiation from the possible alternatives **4** was achieved with the usual spectral data. Definitive proof was provided by ^{1}H,^{1}H(COSY)-, and ^{1}H,^{13}C-correlated 2D NMR spectra together with NOE difference spectra. The vicinal couplings 11-H/10-H,H′/9-H,H′/8-H/7-H/6-H,H′ were demonstrated unequivocally in the COSY 45 recording. This coupling route is, however, in agreement with both structures **3a** and **4a**. Differentiation was made possible by NOE difference spectra: the spatial proximity of the three CH_2 groups is only given in **3a**. Accordingly, positive nuclear Overhauser effects could be measured for the interactions 9-H′/6-H and 10-H′/6-H together with an INDOR effect for the coupled protons 9-H′ and 10-H′.



The heteropolycycle in **3a–d** was hitherto unknown. Moreover, the type of reaction is unusual, and its thermal realization has been observed here for the first time. Previously, only two distantly related photochemical examples of the second of the formulated reaction steps were known, i.e. the [2+2+2] cycloaddition of a 1,4-diketone to an alkene.[2]

The usefulness of this type of reaction is increased considerably by the observed regiospecificity. This specificity can be understood on the basis of semiempirical PM3 calculations:[3] the enthalpy of formation of **3a** (−185.07 kJ mol^{-1}) is 3.5 kJ mol^{-1} more negative than that of **4a** (−181.59 kJ mol^{-1}). Moreover, compound **3a** is both thermodynamically and kinetically favored. As added confirmation, therefore, the reactive conformers **Z-1** and **Z-2** were sought as energy minima, with the least possible distance between the reactive centers, and completely optimized. According to these calculations **Z-1** is 25.6 kJ mol^{-1} more stable than **Z-2**. This result is a satisfactory argument for the regioselectivity (formation of **3** but not of **4**), as the distances relevant for reaction of these completely geometrically optimized conformers are comparable (Table 1): for energetic reasons **Z-2** is not involved.

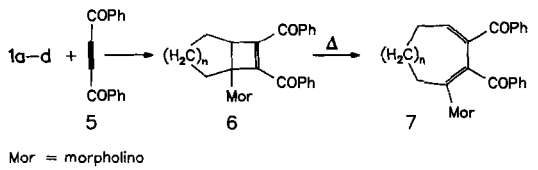
The most obvious mechanistic explanation for the reaction of **Z-1** can be assumed as follows: The C5–C11 bond is formed first, leading to a relatively stable zwitterion (enamine + ketone), followed by formation of the bonds C3–O4 and C1–O2. The difference in charge density (Table 1) between the centers C5 and C11 is considerable (larger in **Z-1a** than **Z-2a**). The difference in charge density between C3 and O4 in the zwitterion is larger than in the educt; the same is also true for the centers C1 and O2, as the C3–O4 bond is formed.

Table 1. Relevant distances (from PM3 calculations) d and total charge density differences ΔQ for **Z-1a**, **Z-2a**, **3a**, and **4a**.

Compound	d [Å] (ΔQ) C5–C11 [a]	C3–O4	C1–O2	Σd [Å]
Z-1a	3.731 (0.567)	3.060 (0.607)	3.476 (0.177)	10.267
3a	1.438	1.433	1.577	
Z-2a	3.409 (0.545)	2.970 (0.625)	4.001 (0.187)	10.380
4a	1.438	1.435	1.564	

[a] Numbering as in structure **3a** and analogously in **4a**.

The selectivity of the reaction of **2** with **1a–d** is surprising, because other unsaturated 1,4-diketones, such as 1,4-diphenyl-2-butyne-1,4-dione ("dibenzoylacetylene") (**5**), react with **1** in a known fashion by [2+2] cycloaddition to give the bicyclic cyclobutenes **6**, which—with the exception of **6a**—undergo immediate isomerization to the monocyclic 1,3-dienes **7**[4].



Of critical importance for this new type of reaction is the high preference of compound **2** to undergo ene addition, which presumably proceeds by way of an iminium/enolate zwitterion and which is completed by a protonation/deprotonation step. This allows the fertile synthesis, in a single step, of new oxygenated heteropolycycles with stable acetal- and N,O-acetal groups.[5] Easily available derivatives of **2** or **1** should permit access to a variety of new spherical oxygenated heterocycles; at the same time the regioselectivity is of particular interest because the products could be biologically active on account of the acetal function.[6]

Experimental Procedures

To a solution of **2** (470 mg, 2.0 mmol) in 10 mL of hot methanol was added 2.4 mmol of enamine **1a–d** and the resulting mixture allowed to stand at room temperature for 2–3 d. The product crystallized out and was recrystallized from methanol. **3a**: Yield 30%, m.p. 133–135 °C; **3b**: 22%, m.p. 196–198 °C; **3c**: 84%, m.p. 202–204 °C; **3d**: 80%, m.p. 153–155 °C. The mother liquor still contains some **3**, but no **4** could be detected by ^{1}H NMR spectroscopy. 2-(1,2-

Dibenzoylethyl)cyclopentan-1-one was isolated from the first mother liquor of **3a** by column chromatography on SiO_2 using CH_2Cl_2 as eluent [16% in the crude product from **3a**; ^1H NMR: ^3J(2-H, 1-H') = 4.0 Hz, ^3J(1-H',2-H') = 8.6 and 4.8 Hz; ^{13}C NMR (100 MHz, $CDCl_3$): δ = 218.7, 201.1, 197.7, 136.5, 135.9, 133.2, 133.1, 128.8 (2C), 128.5 (4C), 128.1 (2C), 49.7 (d), 41.0 (d), 38.3, 36.9, 26.1, 20.6; MS (70 eV): *m/z* 320 ($M^{\oplus}$, 1.5%), 215(2), 105(100). **3a**: ^1H NMR (400 MHz, $CDCl_3$): δ = 2.75 [7-H, dd, ^3J(7-H, 6-H') = 5.6 Hz, ^3J(7-H, 8-H) = 8.3 Hz], 2.60 (8-H, m), 2.59 (6-H, d, ^2J = 11.6 Hz), 2.34 [11-H, d, ^3J(11-H, 10-H) = 5.3 Hz], 2.00 [6-H, dd, ^2J = 11.6 Hz, ^3J(6-H', 7-H) = 5.6 Hz], 1.88 (10-H, m), 1.85 (9-H, m), 1.67 (9-H, m), 1.44 (10-H, m); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 110.1 (C-3), 105.5 (C-1), 88.7 (C-5), 52.8 (C-7), 44.2 (C-11), 43.7 (C-8), 36.4 (C-6), 25.0 (C-10), 22.6 (C-9); MS (70 eV): *m/z* 389 (10%), 302 (7), 284 (27), 159 (24), 151 (39), 105 (100), 77 (48). The homologs (**3b–d**) gave similar ^1H and ^{13}C NMR spectra which are completely in accordance with their structure.

Addition of 5 mmol of enamine **1a–d** to a boiling solution of **5** (936 mg, 4.0 mmol) in 15 mL of toluene gave **6** or **7**, which crystallized out after standing for 1–3 d at room temperature. The product was recrystallized from toluene/petroleum ether.

6a: Yield 79%, m.p. 125–127 °C, ^{13}C NMR (75 MHz, $CDCl_3$): δ = 192.2, 190.6, 150.1, 145.3, 137.0, 136.3, 133.2, 133.1, 128.6 (2C), 128.5 (2C), 128.4 (2C), 128.3 (2C), 80.5, 67.1, 49.9, 49.6, 29.8, 25.3, 24.2; **7b**: 80%, m.p. 179–181 °C, ^{13}C NMR (75 MHz, $CDCl_3$): δ = 198.1, 194.8, 164.7, 143.4, 141.5 (2C), 138.6, 131.4, 131.0, 129.6 (2C), 129.0 (2C), 127.9 (2C), 127.7 (2C), 110.4 (C-2), 66.4, 51.5, 29.5, 28.4, 22.9, 22.6; **7c**: 95%, m.p. 151–153 °C, δ(C-2) = 108.4; **7d**: 97%, m.p. 202–204 °C, δ(C-2) = 110.5.

$[(CO)_3(PPh_3)_2OsAg(O_2CCF_3)]$: A Model for an Intermediate on the Reaction Coordinate in Electron Transfer**

By *Lin Song* and *William C. Trogler**

Electron-transfer reactions have been investigated extensively in recent years; however, there is little information available on X-ray structures of precursor complexes because they are short lived and unstable. The Marcus theory of electron transfer between a donor D and acceptor A postulates association between the reactants to form a metastable D–A complex, as a precursor to electron transfer.[1] This mechanism has possible relevance to electron-transfer reactions in living organisms.[2, 3]

Silver(I) salts have been widely used as one-electron oxidants to generate organic and organometallic radicals; they form the basis for the photographic industry. In previous work the formation of an intermediate was observed spectroscopically on oxidation of *trans*-$[Fe(CO)_3(PPh_3)_2]$ with $AgPF_6$, but isolation and further characterization of the short-lived species was not possible.[4] The decay of the intermediate involved in this redox reaction yielded the $[Fe(CO)_3(PPh_3)_2]^+$ radical and metallic silver. Spectroscopic data also suggest that the one-electron oxidation of $[Ru_2(\mu\text{-}CO)(CO)_4\{\mu\text{-}(MeO)_2PN(Et)P(OMe)_2\}_2]$ by silver(I) salts occurs by an inner-sphere intermediate, but attempts to obtain single crystals of the intermediate proved unsuccessful.[5] Here we report the molecular structure of a metal–metal bonded intermediate in one such reaction, which serves as a structural model for a precursor complex in electron-transfer reactions between organometallic species and silver(I) salts.

The heavy metal complex **1** adopts the same trigonal-bipyramidal structure as the analogous Fe complex,[6, 7] and it is more prone to one-electron oxidation.[8] Although the

trans-$[Os(CO)_3(PPh_3)_2]$ **1**

oxidation of **1** with $Ag(O_2CCF_3)$ is thermodynamically favorable in CH_2Cl_2, it becomes less exoergic in THF (Table 1). By performing the reaction in THF, followed by extraction with benzene, we have been able to crystallize the Os–Ag complex **2**, an apparent precursor to the Os(0) → Ag(I) electron-transfer reaction. This 1:1 complex provides

$[(CO)_3(Ph_3P)_2OsAg(O_2CCF_3)]$ **2**

astructural evidence for a metal–metal bonded intermediate in the Ag^+ oxidation of an organometallic compound. This complex also differs from the majority of 1:2 adducts known to form between Ag^+ and transition-metal complexes.[9]

Table 1. Redox properties of $Ag(O_2CCF_3)$ and $[Os(CO)_3(PPh_3)_2]$ obtained from cyclic voltammetry measurements [a].

Solvent	$(E_P)_{red}(Ag^+)$ [V]	$(E_P)_{ox}(Os^0)$ [V]	ΔE_P [V] [b]
THF	0.17	0.13	+0.04
CH_2Cl_2	0.41	0.04 [c]	+0.37
CH_3CN	−0.20 [d]	0.08	−0.28

[a] Experimental conditions: $[AgO_2CCF_3] = 2 \times 10^{-3}$ M, $[Os(CO)_3(PPh_3)_2] = 1 \times 10^{-3}$ M, (in CH_3CN limited by solubility to less than 0.5×10^{-3} M, supporting electrolyte $[Bu_4NPF_6] = 0.1$ M, $T = 23 \pm 2$ °C, scan rate = 200 mVs^{-1}, platinum working electrode, platinum auxiliary electrode, $Ag/AgNO_3$ (0.1 M in CH_3CN) reference electrode, no IR compensation. [b] $\Delta E_P = (E_P)_{red}(Ag^+) - (E_P)_{ox}(Os^0)$. [c] $(E_P)_{ox}$ of **2** is 0.55 V under the same experimental conditions. [d] Ag^+ is stabilized in CH_3CN because $[Ag(CH_3CN)_4]^+$ forms.

An X-ray structural analysis of **2** reveals that it has a distorted trigonal-bipyramidal geometry about Os, and Ag^+ approaches Os in the equatorial plane (Fig. 1). The Ag–Os bond forms 69.0° and 73.5° angles with the neighboring CO

[**] This work was supported by a National Science Foundation Grant (CHE-88-15958).

groups, which can be regarded as semibridging.[10] This type of slight structural rearrangement about the metal center was also reported for the 1:2 adduct $[Ag\{Rh(CO)(PPh_3)(\eta\text{-}C_5H_5)\}_2](PF_6)$, which can be viewed as a silver-stabilized radical cation.[11] The linear geometry of the two semibridging CO groups in **2** suggests a net repulsive Ag–CO interaction.[12] The Lewis-base nature of 18-electron osmium complexes containing CO and phosphane ligands has been previously demonstrated by the formation of metal–metal bonded adducts,[13] although the structure about Os in those complexes is nearly octahedral. The coordination environment about Ag^+ in **2** is nearly linear, as often occurs for silver(I). The Ag–Os separation of 2.712(1) Å is consistent with a Os $\rightarrow Ag^+$ dative metal–metal bonding interaction.

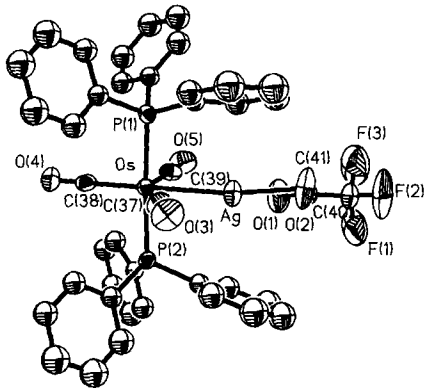

Fig. 1. Structure of **2** (ORTEP, thermal ellipsoids at 50% probability). Selected bond lengths [Å] and angles [°]: Os-Ag 2.712(1), Os-P(1) 2.386(2), Os-P(2) 2.396(2), Os-C(37) 1.936(11), Os-C(38) 1.904(12), Os-C(39) 1.912(10), Ag-O(2) 2.287(12), C(37)-O(3) 1.142(14), C(38)-O(4) 1.145(15), C(39)-O(5) 1.165(12), C(41)-O(1) 1.223(19), C(41)-O(2) 1.233(15), P(1)-Os-P(2) 174.5(1), P(1)-Os-Ag 91.8(1), P(2)-Os-Ag 85.4(1), Ag-Os-C(37) 73.5(4), Ag-Os-C(39) 69.0(3), C(37)-Os-C(38) 113.7(5), C(38)-Os-C(39) 103.8(4), Os-Ag-O(2) 170.8(2).

IR spectra of **2** measured in solution show that its carbonyl stretching frequency shifts more than 30 cm^{-1} to higher energy than that of **1**.[14] The oxidation potential of **2** in CH_2Cl_2 is also 0.51 V more positive than that of **1** according to cyclic voltammetry measurements (Table 1). When **2** is dissolved in THF a weak triplet signal appears in the EPR spectrum ($g = 2.006$, $A_P = 16.3$ G (THF); $g = 2.005$, $A_P = 15.0$ G (toluene)) with hyperfine coupling to the two phosphane ligands. The intensity of the triplet signal decreases and eventually disappears, as metallic silver and other species are observed. We attribute the EPR signal to the short-lived $[Os(CO)_3(PPh_3)_2]^+$ radical, which forms slowly from **2** in solution. For comparison, the solution EPR spectrum of $[(Fe(CO)_3(PPh_3)_2]^+$ in CH_2Cl_2 exhibits a triplet signal at $g = 2.053$ and $A_P = 18.7$ G.[15]

Complex **2** remains stable in CH_3CN for several hours, but it yields metallic silver and other oxidation products in CH_2Cl_2 and THF. The electron-transfer process occurs faster in CH_2Cl_2 than in THF. These stabilities parallel the estimated driving potential (ΔE_P) shown in Table 1. The final products of the Os(0)–Ag(I) electron transfer in THF are $[Os(CO)_2(PPh_3)_2(\eta^2\text{-}O_2CCF_3)](O_2CCF_3)$ and **1**, from disproportionation of the 17-electron $[Os(CO)_3(PPh_3)_2](O_2CCF_3)$ radical.[16] In CH_2Cl_2 the known complex *trans*-$[OsCl_2(CO)_2(PPh_3)_2]$ forms.[17]

Both Xα calculations and qualitative crystal-field considerations predict that the HOMO in trigonal-bipyramidal **2** should be a degenerate d_{xy}, $d_{x^2-y^2}$ derived orbital in the equatorial plane (z axis taken as axial).[15] The X-ray structure of **2** suggests that the Lewis acid $Ag(O_2CCF_3)$ binds to this frontier orbital from which the electron is ultimately removed. The ability of Ag^+ to oxidize organometallics by an inner-sphere metal–metal bonded intermediate may explain its high effectiveness in such oxidations. The strength of the metal–metal bond and the further geometric reorganization necessary in the Os and Ag coordination spheres apparently provides sufficient activation energy for electron transfer, which permits isolation of **2**. Nucleation effects may also be important. We have observed an induction period (followed by zero-order kinetics) in the further electron-transfer reaction of **2** in CH_2Cl_2 that appears to correlate with the formation of metallic silver. The measured redox potential for Ag^+ refers to its reduction to the bulk metal. In **2** electron transfer would produce initially a solvated silver atom, which might be a higher energy intermediate.

Experimental Procedure

All experiments were performed under a nitrogen atmosphere and with dried solvents. Complex **1** was prepared by the method of Collman and Roper [6].

Complex **2**: 10 mL of THF was added into a mixture of **1** (40 mg, 0.050 mmol) and $Ag(O_2CCF_3)$ (11 mg, 0.050 mmol) with stirring in the dark. THF was removed under vacuum after 10 min, and the pale brown residue was extracted with 15 mL of benzene and filtered. The benzene solution was concentrated to about 5 mL and 30 mL of pentane was added to yield 14 mg of **2** (27%). Crystals of **2** · 0.5 C_6H_6 suitable for an X-ray diffraction study were obtained by storing the benzene/pentane mixture at 5 °C for several days.

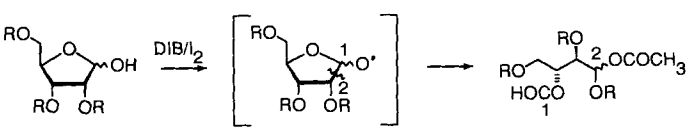
[14] IR of **1**: ν(CO) 1890 cm^{-1} (CH_2Cl_2); 1892 cm^{-1} (THF); IR of **2**: ν(CO): 1925(s), 1946(s), 2006(w) cm^{-1}, $\nu(O_2CCF_3^-)$: 1674 cm^{-1} (CH_2Cl_2); ν(CO): 1927(s), 1946(s), 2010(w) cm^{-1}, $\nu(O_2CCF_3^-)$: 1676 cm^{-1} (THF).
[15] M. J. Therien, W. C. Trogler, *J. Am. Chem. Soc.* **1986**, *108*, 3697.
[16] The intensities of the absorbances of ν(CO) at 1975 and 2045 cm^{-1} and $\nu(O_2CCF_3^-)$ at 1694 and 1644 cm^{-1} increase in a constant ratio. Compared with $\nu(O_2CCF_3^-)$ of 1676 cm^{-1} in **2** and 1692 cm^{-1} in $[Bu_4N](O_2CCF_3)$, the hypsochromic shift of one $O_2CCF_3^-$ group (1694 cm^{-1}) corresponds to an ionic $O_2CCF_3^-$ unit and the bathochromic shift of a second $O_2CCF_3^-$ group (1644 cm^{-1}) is typical for the formation of a bidentate complex. Therefore the absorbances are assigned to $[Os(CO)_2(PPh_3)_2(\eta^2\text{-}O_2CCF_3)](O_2CCF_3)$ The other absorbance at 1892 cm^{-1} is identical to that of **1**.
[17] IR spectrum of the final product from thermal reation of **2** in CH_2Cl_2: ν(CO): 1977(s) and 2046(s) cm^{-1}, $\nu(O_2CCF_3^-)$: 1691 cm^{-1}. For comparison the known $[OsCl_2(CO)_2(PPh_3)_2]$, prepared by the method of Collman and Roper [6], caused these absorptions to increase when added to the same solution. The uncoordinated $O_2CCF_3^-$ group in $[Bu_4N](O_2CCF_3)$ has an absorbance at 1691 cm^{-1} in CH_2Cl_2.

Reagents with Hypervalent Iodine: Formation of Convenient Chiral Synthetic Intermediates by Fragmentation of Carbohydrate Anomeric Alkoxy Radicals**

By *Pedro de Armas*, *Cosme G. Francisco*, and *Ernesto Suárez**

Carbohydrates owe their present importance in part to their use as chiral template precursors for a variety of complex non-carbohydrate substances.[1] In this context many efforts have been made in recent years to develop a new and efficient methodology to create or destroy asymmetric centers by chemical manipulation. The proposed reactions must be compatible with the temporary protective groups that might be employed in this type of synthesis. Special attention has been devoted to the preparation of four-carbon chiral building blocks of the threose and erythrose series,[2] which have been used in the synthesis of several polyhydroxylated natural products.[3]

During the past few years, we have examined several compounds with hypervalent iodine that can generate alkoxy radicals, in order to promote β-fragmentation reactions.[4] A new synthesis of medium-sized lactones and spirolactones was developed by use of these reagents on appropriate oxabicyclic hemiacetals.[5] We now report a new method for the synthesis of four-carbon chiral building blocks of the D- and L-erythrose types by β-fragmentation of the C1–C2 carbon bond of suitably protected D- and L-arabinose, D-ribose, and 2-deoxy-D-ribose (Scheme 1). The reaction has also been extended to the synthesis of five-carbon chiral building blocks of the arabinose type by β-fragmentation of D-mannose and D-glucose derivatives.



Scheme 1. DIB =(diacetoxyiodo)benzene.

Cleavage of the C1–C2 carbon bond in carbohydrate chemistry can be performed by several methods such as those of Ruff, Wohl, Weerman etc., but they suffer from several drawbacks, for instance, the number of steps required, low yields, and inconveniently strong reaction conditions.[6] Although sodium periodate and lead tetraacetate are routinely used to test for the presence of vicinal diols,[7] they have hardly been used in synthesis to cleave the C1–C2 carbon bond.[8]

The carbohydrate derivative was treated with (diacetoxyiodo)benzene (DIB) and iodine in cyclohexane under the con-

ditions specified in Table 1. The reaction conditions were determined with the readily available 5-*O*-(*tert*-butyldimethylsilyl)-2,3-*O*-isopropylidene-D-ribofuranose (**1**),[9] which gave a major stereoisomer at C1 (ca. 95:5) of the erythrose derivative **2** (entry 1). The proposed stereochemistry at C1 is based on the observed *trans* coupling constant between H1 and H2 ($J_{H1,H2} = 1.96$ Hz). The presence of iodine was necessary for the reaction to take place (entry 3), and lower yields were observed when catalytic amounts were used (entry 2). The reaction mechanism seems to involve the initial formation of the anomeric alkoxy radical followed by β-fragmentation and subsequent trapping of the carbon radical formed at C1 by an acetoxy radical from the reagent. At this point the anomeric carbon is a part of a formate group that forms an ester with the alcohol at C3 (Scheme 1).

A differently protected erythrose building block **4** was obtained from 2,3,5-tri-*O*-benzyl-D-ribofuranose (**3**)[10] (entry 4). Substrate **3**, which lacks the steric bias of the previous example, was found to give a mixture (ca. 1:1) of stereoisomers at C1.

The reaction course does not seem to be dependent on the configuration of the alcohol at C2, since D- and L-2,3,5-tri-*O*-benzylarabinofuranose (**5** and **6**, respectively) were fragmented analogously to substrate **3** to give D- and L-erythrose building blocks **4** and **7**, respectively, in similar yields (compare entry 4 with entries 5 or 6).

β-Fragmentation of 2-deoxy-D-ribofuranose (**8**) and -pyranose derivatives (**10**)[11] gave rise to two potentially interesting synthetic intermediates, the 1-iodo-2,3,4-trihydroxybutane derivatives **9** and **11**, respectively; although yields were lower (entries 7–9), the generation of the formyl group allows subsequent selective modifications of these building blocks to be carried out.

The reaction was also extended to hexoses (entries 10 and 11); thus the 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (**12**) and 2,3:5,6-di-*O*-isopropylidene-D-mannofuranose (**14**) were transformed into the D-arabinose derivatives **13** and **15**. In the glucopyranose a mixture (ca. 1:1) of C1 stereoisomers of **13** is observed, where the formyl group forms an ester with the hydroxyl group at C4, whereas in the mannofuranose a single stereoisomer is obtained, the formate group being at C3 (the observed *trans* coupling constant between H_1 and H_2 was $J_{H1,H2} = 2.1$ Hz). The spectroscopic data of compounds **2**, **9**, **11**, and **15** are summarized in Table 2.

The fragmentation reaction is independent of ring size; thus, similar yields were obtained for furanose and pyranose derivatives (compare entries 7–8 with 9, and 10 with 11).

We consider that some features of the reported procedure are remarkable: for example, the mild reaction conditions, compatible with the protective groups most widely used in carbohydrate chemistry; the regioselectivity observed during the fragmentation; and also the fact that the reaction outcome does not depend on C2 configuration, the protective groups, or ring size. The generation of the formate group and of the masked aldehyde that permits a flexible use of the resulting building blocks is very valuable. This reaction can also be considered a convenient method to descend the aldose series of carbohydrates and compares well with those reported.[6]

Experimental Procedure

A solution of 5-*O*-(*tert*-butyldimethylsilyl)-2,3-*O*-isopropylidene-D-ribofuranose (**1**) [9] (100 mg, 0.33 mmol) in dry cyclohexane (10 mL) containing (diacetoxyiodo)benzene (127 mg, 0.39 mmol) and iodine (84 mg, 0.33 mmol) was stirred at room temperature (20 °C) for 3 h. The reaction mixture was then poured into water and extracted with ether. The organic layer was washed with aqueous sodium thiosulfate and water. Chromatography of the residue (Chromatotron, Merck silica gel 60 PF 254, *n*-hexane/ethyl acetate 9:1 v/v) gave **2** (99 mg, 84%).

Table 1. Formation of heteroaromatic carboxylic acids from methylated heterocycles with cells of *Pseudomonas putida* ATCC 33015 grown on *p*-xylene

Starting material	Product	Yield [%]
2,5-dimethylpyrrole	5-methylpyrrole-2-carboxylic acid	40
3,5-dimethylpyrazole	5-methylpyrazole-3-carboxylic acid	80
2,5-dimethylfuran	5-methylfuran-2-carboxylic acid	40
3-methylthiophene	thiophene-3-carboxylic acid	70
4-methylthiazole	thiazole-4-carboxylic acid	80
3-methylpyridine	pyridine-3-carboxylic acid	50
2-chloro-6-methylpyridine	6-chloropyridine-2-carboxylic acid	90
2-chloro-3-ethyl-6-methylpyridine	6-chloro-5-ethylpyridine-2-carboxylic acid	10
2,4-dimethylpyridine	2-methylpyridine-4-carboxylic acid (90%) 4-methylpyridine-2-carboxylic acid (10%)	40
2,5-dimethylpyrazine	5-methylpyrazine-2-carboxylic acid	90
2,3,6-trimethylpyrazine	5,6-dimethylpyrazine-2-carboxylic acid	90
3-chloro-2,5-dimethylpyrazine	6-chloro-5-methylpyrazine-2-carboxylic acid	90

Enzymatic Oxidation of Methyl Groups on Aromatic Heterocycles: A Versatile Method for the Preparation of Heteroaromatic Carboxylic Acids**

By *Andreas Kiener**

Chemical oxidation reactions used for the industrial scale preparation of heteroaromatic monocarboxylic acids from heteroaromatic compounds bearing one or more methyl groups are often nonspecific and lead to the formation of undesired by-products. To overcome this problem we have been interested in developing a biological oxidation method for this type of reaction. Although enzymatic oxidations of alkyl side chains on heteroarenes by bacteria and fungi have been described,[1] none of these biotransformations have been used for the preparation of aromatic heterocyclic carboxylic acids or their hydroxymethyl derivatives. This communication describes a versatile enzymatic method capable of selectively oxidizing a single methyl group on heteroarenes on a pilot plant scale.

The wild-type strain *Pseudomonas putida* ATCC 33015 was used as the biocatalyst in our investigations. This microorganism can grow on toluene, *m*-xylene, or *p*-xylene as sole carbon and energy source.[2] Both the biochemistry[3, 4] and genetics[5, 6] of the xylene degradative pathway have been extensively studied. *p*-Xylene, for example, is oxidized by xylene monooxygenase to 4-methylbenzylalcohol, which is then further oxidized by benzylalcohol and benzylaldehyde dehydrogenase to 4-methylbenzoic acid. The aromatic carboxylic acid is converted by toluate dioxygenase and dihydroxycyclohexadienecarboxylate dehydrogenase into 4-methylcatechol prior to the cleavage of the aromatic ring by catechol dioxygenase. The cleavage product is then transformed into Krebs-cycle intermediates. Investigations on the substrate specificity of key enzymes in the xylene degradative pathway have focused mainly on substituted aromatic carbocycles.[7] Only a few publications concerning heterocycle oxidation have appeared. One example is the bacterial formation of indigo initiated by hydroxylation of indole by xylene monooxygenase.[8]

We have now demonstrated that *P. putida* grown on *p*-xylene as sole carbon and energy source was capable of oxidizing many methylated heteroaromatic five- and six-membered rings to the corresponding monocarboxylic acids (Table 1). The carboxylic acids accumulated in the fermentation broth and were isolated for analysis. In most cases the generated heteroaromatic carboxylic acids were not further degraded, which indicates that aromatic heterocycles are poor substrates for toluate dioxygenase (none of the heterocycles supported the growth of *P. putida*). As shown in Table 1, biotransformations of 2,3,6-trimethylpyrazine and 3-chloro-2,5-dimethylpyrazine were also regiospecific; this was expected since substituents *ortho* to a methyl group prevent hydroxylation by xylene monooxygenase.[6] The oxidation product of 2,4-dimethylpyridine, however, contained a mixture of 2-methylpyridine-4- and 4-methylpyridine-2-carboxylic acid. The formation of 6-chloro-5-ethylpyridine-2-carboxylic acid from 2-chloro-3-ethyl-6-methylpyridine showed that the enzymatic oxidation was specific for the methyl group. In no experiment did we detect the formation of dicarboxylic acids or the direct hydroxylation of the heteroaromatic ring.

The performance of this biocatalyst system was studied in more detail on 2,5-dimethylpyrazine (DMP). The oxidation product, 5-methylpyrazine-2-carboxylic acid (MPCA), is an intermediate for the production of 5-methylpyrazine-2-carboxylic acid 4-oxide, a drug with antilipolytic activity.[9] The chemical oxidation of DMP to MPCA along any routes still remains inefficient.[10] Resting cell suspensions furnished with more than 30 mM (3.2 $g L^{-1}$) DMP showed a strong accumulation of 2-hydroxymethyl-5-methylpyrazine, which was only partially oxidized to MPCA. However, high product concentrations and high yields were achieved by performing the biotransformation with growing cells. For this reason a mixture of 75% (v/v) *p*-xylene and 25% (v/v) DMP was supplied as growth substrate in large-scale fermentations. Figure 1 shows the accumulation of up to 20 g MPCA L^{-1} during 54 h bacterial growth on a 20 L scale. 2-Hydroxymethyl-5-methylpyrazine was detected in the medium during early stages of fermentation. The biotransformation was terminated when bacterial growth entered the stationary phase (MPCA concentrations $>15 g L^{-1}$ inhibited the growth of *P. putida*). At the end of the fermentation, MPCA was the only oxidation product of DMP detected in the fermentation broth by HPLC analysis.

Biotransformations up to a volume of 1000 L following a slightly modified fermentation procedure were performed to assess the potential of this biological oxidation method for industrial application: The maximal product concentration was 24 g MPCA L^{-1} (at a yield >95%); the concentration of DMP at the end of the biotransformation was below

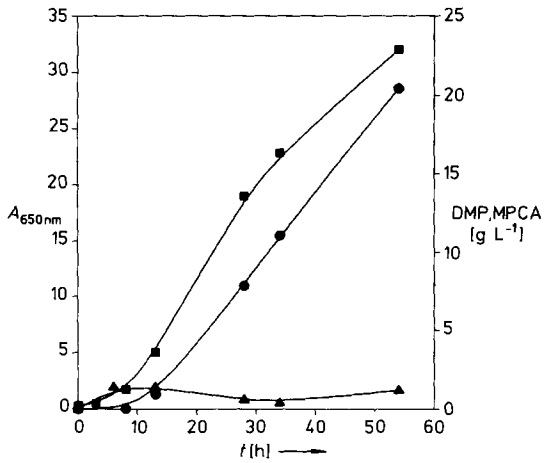

Fig. 1. Microbial oxidation of 2,5-dimethylpyrazine (DMP) to 5-methylpyrazine-2-carboxylic acid (MPCA). Absorption of the cell suspension at 650 nm (■); concentration of DMP (▲) and MPCA (●). After 52 h of fermentation the growth substrate was changed to 100% *p*-xylene.

0.1 g L^{-1}. No bacterial metabolites from *p*-xylene which could hamper product purification were detected in the broth.

In summary, our experiments showed that *P. putida* is a useful biocatalyst for the selective oxidation of a methyl group on aromatic heterocycles to the corresponding monocarboxylic acid. The yield and conditions of the oxidation reactions described here have been optimized only for 2,5-dimethylpyrazine. Nevertheless, in order to develop a general method for the biological oxidation of a methyl group on aromatic heterocycles, we will now focus on the isolation of various mutants defective in the xylene-degradative pathway so that further degradation of certain heteroaromatic carboxylic acids can be prevented or benzylalcohol dehydrogenase inactivated to permit the production of hydroxymethylated compounds.

Experimental Procedure

Starter cultures of *P. putida* were grown in 300 mL Erlenmeyer flasks containing 100 mL of a mineral salt medium (H. G. Kulla, F. Klausener, U. Meyer, B. Lüdeke, T. Leisinger, *Arch. Microbiol.* **1983**, *135*, 1–7) at pH 7. A 10 mL polypropylene tube containing 1 mL *p*-xylene as carbon source was inserted into the Erlenmeyer flask. The xylene vapor formed during incubation at 30 °C on a rotatory shaker was sufficient for cell growth. For large-scale fermentations (20–1000 L) xylene was added directly to the growth medium. The xylene concentration in the fermenter was regulated by measuring the absorbance of fermenter exhaust air at 214 nm with an ISCO UA-5 absorbance detector (ISCO, P.O. Box 5347, Lincoln, NE 68505, USA). The electronic signal of the detector was coupled with a dosage pump for xylene in such a way that the concentration of the growth substrate was about 0.1 mM. Best transformation rates were obtained under substrate-limited growth.

For small-scale biotransformations, methylated heterocycles (10 mM were added to 20 mL suspensions of cells grown on *p*-xylene ($A_{650nm} = 10$) in mineral salt medium in 300 mL sealed flasks to prevent the loss of volatile compounds and incubated for 16 h at 30 °C on a rotatory shaker. Xylene was omitted during biotransformation. The concentrations of oxidation products in cell-free solution were analyzed by thin-layer chromatography. For incomplete conversions the balance of the yield was, in most cases, unoxidized starting material.

One-Pot Syntheses of Novel Arene Tricarbonyl Chromium Macrocycles and Macrobicycle: Structure of a Pentanuclear Trichromium(0)-Dicopper(I) Cryptate**

By *Marie-Thérèse Youinou,** *Jean Suffert,** and *Raymond Ziessel**

Polyaza receptor molecules with large cavities have recently received a great deal of attention as hosts for metal ions which form binuclear or polynuclear complexes,[1,2] in view of their potential as supramolecular catalysts.[3] Schiff-base condensation of the tris(2-aminoethyl)amine (tren) with suitable dicarbonyl compounds provides N_8 cryptands in good yield.[4] Although macrocycles synthesized from difunctional metal complexes were reported previously,[5,6] such macrobicycles have not yet been prepared. The use of such subunits may provide new photoactive, electroactive, and chiral cryptates. We have recently reported new molecular tweezer ligands based on chiral arene tricarbonyl chromium subunits. Their complexation properties with rhodium(I)[7] and copper(I)[8] as well as their photochemical[9] and electrochemical[10] behavior were studied.

Pursuing this work, we now report a very efficient route, through condensation of various amines with a terephthalaldehyde tricarbonyl chromium complex, to macrocyclic ligands **1** and **2**, macrobicyclic ligands **3**, and a novel trichromium(0)-dicopper(I) cryptate **4**.

The reaction of equimolecular amounts of 1,3-bis(aminomethyl)benzene and chromium(0) complex **6** (synthesized from its precursor **5**[11]) in chloroform gave pure macrocycle

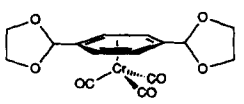
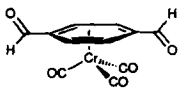
1 in 75% yield after recrystallization. If the reaction is carried out in anhydrous tetrahydrofuran, macrocycle **1** is also formed (55% yield); then the ^{1}H NMR spectrum shows an additional singlet at $\delta = 10.92$ ppm, corresponding to four protons. The rapid H–D exchange detected for these protons in D_2O suggests that two water molecules are present, which interact weakly with the macrocycle through hydrogen bonding with alkylidenamine units. The significant deshielding of the water protons probably indicates the formation of an inclusion complex containing two water molecules in the intramolecular cavity of the receptor;[12] the water protons are then expected to be in the deshielding cone of the arene–chromium subunit. To our knowledge, the strength of this effect is very unusual although a similar behavior was observed in the diprotonated form of a spheroidal macrotricycle ligand but the chemical shift for the water protons was much lower ($\delta = 7.32$[12c]). It is also worth noting that condensation of 1,3-bis(aminomethyl)benzene with terephthalaldehyde in anhydrous tetrahydrofuran gave the expected macrocycle, which polymerized after a few hours even at low temperature (−30 °C). It therefore demonstrates that the coordination of the tricarbonyl chromium subunits leads to a stabilization of the alkylidenamine bonds, probably as a result of both electronic[13a] and steric effects. Surprisingly, the use of flexible diamines such as 1,6-diaminohexane also gave macrocycle **2** in an excellent yield (75%).



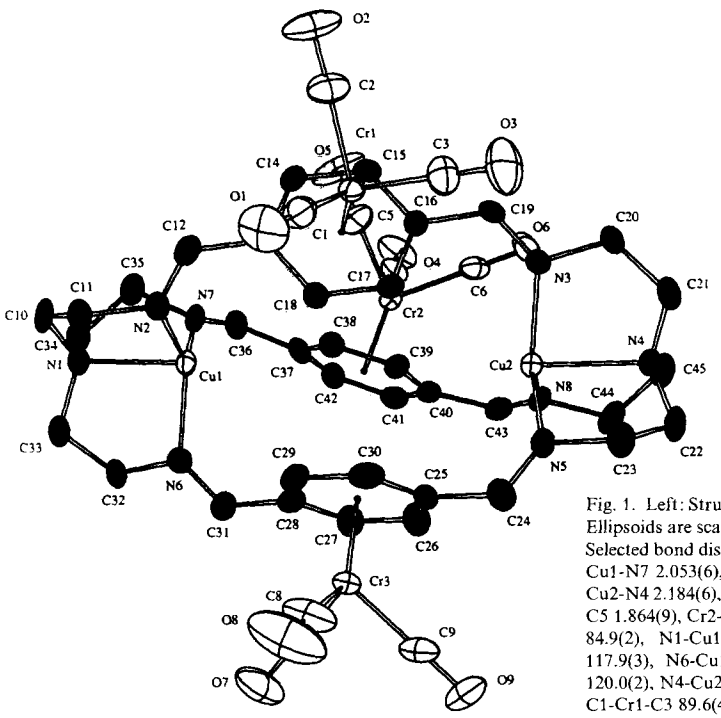
5



6

Macrobicycle **3** was prepared by addition of dialdehyde **6** (3 equiv) to a solution of tren (2 equiv) in acetonitrile at room temperature. Precipitation of the corresponding macrobicycle hexaimine from the reaction mixture yielded a yellow solid (95% yield, $\lambda_{max} = 430.4$ nm, $\varepsilon = 6600$). Interestingly, this one-pot cyclization which leads to the creation of six bonds does not require high dilution conditions since the expected product precipitates readily from the reaction mixture.

Treatment of cryptand **3** with $[Cu(CH_3CN)_4]ClO_4$[14] in a 1:2 ratio gave the orange-red complex **4** (yield 85%, $\lambda_{max} = 448.4$ nm, $\varepsilon = 12000$), which was fully characterized. In particular, its ^{1}H NMR spectrum was markedly different from that of the macrobicycle **3**: the signals of the alkylidenamine, the complexed aromatic, and the methylene protons α to the alkylidenamine bonds were shifted downfield,



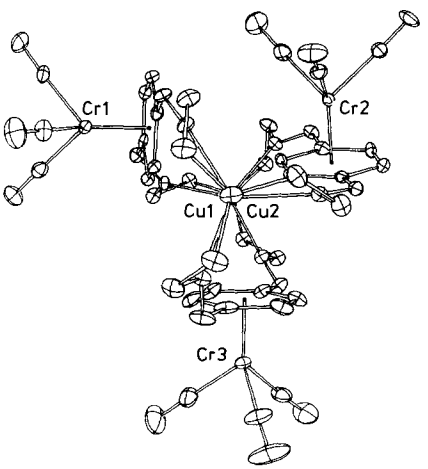


Fig. 1. Left: Structure (ORTEP plot) of **4** · 0.5 CH_2Cl_2 showing the numbering scheme used. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted. Selected bond distances [Å] and angles [°] are as follows: Cu1-N2 1.949(6), Cu1-N6 1.983(6), Cu1-N7 2.053(6), Cu1-N1 2.207(6), Cu2-N5 1.985(6), Cu2-N3 1.995(6), Cu2-N8 2.020(6), Cu2-N4 2.184(6), Cr1-C1 1.846(9), Cr1-C2 1.849(9), Cr1-C3 1.847(9), Cr2-C4 1.860(9), Cr2-C5 1.864(9), Cr2-C6 1.862(9), Cr3-C7 1.83(1), Cr3-C8 1.82(1), Cr3-C9 1.82(1); N1-Cu1-N2 84.9(2), N1-Cu1-N6 85.6(2), N1-Cu1-N7 82.4(2), N2-Cu1-N6 128.9(3), N2-Cu1-N7 117.9(3), N6-Cu1-N7 110.4(3), N3-Cu2-N4 85.6(2), N3-Cu2-N5 126.3(3), N3-Cu2-N8 120.0(2), N4-Cu2-N5 85.7(2), N4-Cu2-N8 84.9(2), N5-Cu2-N 111.7(3), C1-Cr1-C2 86.7(4), C1-Cr1-C3 89.6(4), C2-Cr1-C3 89.0(4). Right: Viewed along the bridgehead N-N axis.

whereas the methylene protons α to the bridgehead nitrogens were not affected. The most significant shift ($\Delta\delta = 0.42$) observed for the alkylidenamine protons was due to coordination of the copper(I) cations. In addition, the IR stretching band ν(C=N) was shifted 30 cm^{-1} by the copper complexation, as previously observed for other related compounds[8] and for copper(I) Schiff's base complexes.[15] Additionally, the crystal structure of cryptate **4** was determined[16] (Fig. 1). The hexaimine cavity has an elongated ellipsoidal shape (with a separation of 11.041(9) Å between the bridgehead nitrogens N1 and N4). The two copper atoms are 6.655(1) Å apart and inside the molecular cavity, whereas the three chromium atoms span a triangle outside the cavity (Cr1 ··· Cr2 6.349(2), Cr1 ··· Cr3 7.415(2), Cr2 ··· Cr3 7.217(2) Å). Each copper(I) ion is similarly coordinated in a distorded tetrahedral fashion to three alkylidenamine nitrogens (Cu1-N2 1.949(6), Cu1-N6 1.983(6), Cu1-N7 2.053(6), Cu2-N5 1.985(6), Cu2-N3 1.995(6), Cu2-N8 2.020(6) Å) and to one bridgehead nitrogen at a longer distance (Cu1-N1 2.207(6) and Cu2-N4 2.184(6) Å). As expected, the geometry about the three chromium atoms is very similar to that of the closely related complex $[C_6H_6Cr(CO)_3]$,[17] which has comparable distances and angles. Furthermore, the mean plane of the phenyl ring containing C13 through C18 is roughly perpendicular to those containing C25 through C30 (89.4(3)°) and C37 through C42 (82.3(3)°). More interestingly, the angle of 165.5(2)° between the mean planes of the phenyl rings involved in coordination with Cr3 and Cr2 (C25 through C30 and C37 through C42 respectively) illustrates the distorsion of the core complex, leading to the absence of a threefold axis of symmetry. When comparing the structure of the same hexaimine macrobicyclic ligand coordinated to two Ag^+ ions (approximate D_3 symmetry[4c]) one may suggest the specific role of the tricarbonylchromium entity in the overall conformation of the core.

Cryptand **3** is the first cage constructed from a difunctional metal complex and cryptate **4** represents a novel pentanuclear entity, containing two encapsulated Cu(I) ions and three photo- and/or electroactive complex fragments in the periphery of the molecular cavity. The synthesis of optically pure receptors from chiral arene tricarbonyl chromium building blocks for use in enantioselective recognition of chiral molecules now seems feasible.

Experimental Procedure

All syntheses were carried out under inert atmosphere with dried and degassed solvents.

1: To a solution of freshly distilled 1,3-bis(aminomethyl)benzene (0.25 g, 1.85 mmol) in anhydrous $CHCl_3$ (40 mL) under argon at room temperature was added a solution of **6** (0.5 g, 1.85 mmol) in $CHCl_3$ (40 mL) within 30 min. After 96 h the solvent was removed under vacuum, the residue dissolved in hot THF, and the mixture cooled and kept at −30 °C overnight. The orange-yellow solid was filtered, washed with Et_2O, and dried under vacuum: Yield 75%.

UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 428.6 (2500), 326.4 (11000), 229.2 (36000). ^1H NMR (for numbering see the structural formula of **1**): (200.1 MHz, [D$_8$]THF, 25 °C): δ = 4.90 (s, 8H; H4), 6.21 (s, 8H; H1), 7.17 (d, 4H, ^3J(H,H) = 6.8 Hz; H6), 7.30 (t 2H, ^3J(H,H) = 6.8 Hz, H7), 7.59 (s, 2H; H8), 8.11 (s, 4H; H3); ^{13}C NMR (100.6 MHz, [D$_8$]THF, 25 °C): δ = 65.25 (C4), 94.64 (C1), 104.47 (C2), 127.18 (C6), 127.57 and 129.76 (C7 or C8), 142.41 (C5), 160.79 (C3), 234.06 (CO). MS (FAB$^+$, *m*-nitrobenzyl alcohol matrix): *m/z* 741.3 (M^+ + H), 656.3 (M^+ − 3CO), 572.3 (M^+ − 6CO), 519.2 (M^+ − 6CO − Cr − H). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2960 (CH_2), 1980, 1915 (C=O), 1610 (C=N). Correct C,H,N analyses.

2: A solution of **6** (250 mg, 0.926 mmole) in THF (15 mL) was added slowly to a stirred solution of 1.6-diaminohexane (108 mg, 0.926 mmol) in anhydrous THF (20 mL). After 24 h, the solvent was removed under vacuum, and the residue recrystallized in THF/Et_2O. The deep orange solid was filtered, washed with Et_2O and dried under vacuum: Yield 95%.

UV/VIS (CH_2Cl_2) λ_{max} [nm] (ε) = 423.8 (4100), 327.4 (14900), 232.0 (47200). ^1H NMR (for numbering see structural formula of **2**) (200.1 MHz, $CDCl_3$, 25 °C): δ = 1.39 (m, 8H; H6), 1.67 (m, 8H, H5), 3.58 (t, 8H, ^3J(H,H) = 6.6 Hz, H4), 5.85 (s, 8H; H1), 7.84 (s, 4H; H3); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C): δ = 27.72 (C6), 31.46 (C5), 61.83 (C4), 92.24 (C1), 102.13 (C2), 157.32 (C3), 232.08 (CO). MS (FAB$^+$, *m*-nitrobenzyl alcohol matrix): *m/z* 701.0 (M^+ + H), 565.1 (M^+ − 3CO). IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 2930 (CH_2), 1980, 1915 (C=O), 1610 (C=N). Correct C,H,N analyses.

3: To a stirred solution of tris(2-aminoaethyl)amine (0.105 g, 0.715 mmol) in anhydrous CH_3CN (30 mL) under argon was added at room temperature, a solution of **6** (0.290 g, 1.07 mmol) in CH_3CN (15 mL) within 2 hours. During the addition the color of the solution turned orange, and a yellow precipitate formed rapidly. After 15 h the solid was filtered, washed with Et_2O, and recrystallized in CH_2Cl_2/hexane at −20 °C: Yield: 95%.

UV/VIS (CH_2Cl_2) λ_{max} [nm] (ε) = 430.4 (6600), 331.4 (26000), 229.6 (75000). ^1H NMR (200.1 MHz, $CDCl_3$, 25 °C): δ = 2.68 (m, 12H; CH_2), 3.72 (m, 12H; CH_2), 5.55 (s, 12H; complexed arene H), 7.77 (s, 6H, N=CH). ^{13}C NMR (50.3 MHz, [D$_6$]DMSO, 25 °C): δ = 51.67, 57.11, 93.51, 103.50, 157.38, 233.15. MS (FAB$^+$, *m*-nitrobenzyl alcohol matrix): *m/z* 995.1 (M^+ + H), 911.2 (M^+ − 3CO + H), 859.2 (M^+ − Cr − 3CO + H), 827.2 (M^+ − 6CO + H). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2965 (CH_2), 1968, 1905 (C=O), 1655 (C=N). Correct C,H,N analyses.

4: To a stirred solution of **3** (50 mg, 0.05 mmol) in anhydrous CH_2Cl_2 (5 mL) under argon was added at room temperature a colorless solution of $[Cu(CH_3CN)_4]ClO_4$ (33 mg, 0.1 mmol) in anhydrous CH_3CN (5 mL). The color of the solution turned deep red instantaneously, showing rapid Cu(I) complexation. After 48 h the solution was filtered over celite. Slow diffusion of pentane produced complex **4** as crystals suitable for X-ray analysis. Yield 86%.

UV/VIS (CH_3CN) λ_{max} [nm] (ε) = 448.4 (12000), 332.2 (34000), 217.2 (11800). ^1H NMR (200.1 MHz, CD_3CN, 25 °C): δ = 3.08 (m, 12H, CH_2), 3.79 (m, 12H; CH_2), 5.98 (s, 12H; complexed arene H), 8.19 (s, 6H; N=CH): ^{13}C NMR (50.3 MHz, CD_3CN, 25 °C): δ = 51.68, 60.77, 91.37, 101.66, 161.81, 238.83. MS (FAB$^+$, *m*-nitrobenzyl alcohol matrix): *m/z* 1220.6 (M^+ − ClO_4), 1084.7 (M^+ − ClO_4 − $Cr(CO)_3$), 948.8 (M^+ − ClO_4 − 2Cr(CO)$_3$), 812.9 (M^+ − ClO_4 − 3Cr(CO)$_3$), 713.0 (M^+ − 2ClO_4 − 3Cr(CO)$_3$), 649.1 (M^+ − 2ClO_4 − 3Cr(CO)$_3$ − Cu). IR (CH_3CN): $\tilde{\nu}$ [cm^{-1}] = 1970, 1920 (C=O), 1625 (C=N). Correct C,H,N analyses for $[C_{45}H_{42}Cr_3N_8O_9Cu_2](ClO_4)_2$.

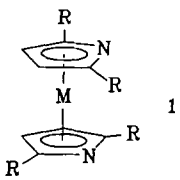
2,2′,5,5′-Tetra-*tert*-butyl-1,1′-diazaplumbocene—a Stable Azacyclopentadienyl Compound of Lead**

By *Norbert Kuhn,* Gerald Henkel,* and *Stefan Stubenrauch*

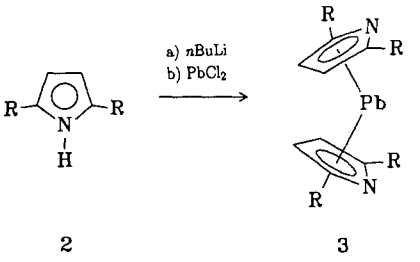
Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Azacyclopentadienides[1] and other π ligands[2, 3] formally derived from the cyclopentadienide ion by the exchange of CH fragments for heteroatoms are applied successfully in the complex chemistry of the transition metals; however, attempts at the coordination on main group element centers analogous to the rapidly developing chemistry of the cyclopentadienyl complexes[4] have so far not been very successful. Heterometallocenes of divalent group 14 elements, which have been the focus of attention since the discovery of the decamethylsilicocene,[5] are unknown apart from a small number of tin complexes with boron-containing ligands.[6] With the recently demonstrated stabilization of the diazametallocene structure by steric shielding of the nitrogen atoms in complexes of the type **1**, M=Fe,[7a] Co,[7b] now also the coordination of two azacyclopentadienyl ligands to divalent main group element centers is possible as is shown for example for lead. By the lithiation of 2,5-di-*tert*-butylpyrrole



1

2 and subsequent reaction with $PbCl_2$, the stable diazaplumbocene **3** is accessible in good yields (Scheme 1). Compound **3** is the first heteroplumbocene and at the same time also the first azacyclopentadienyl compound of a main group element with classical π coordination.[8]



2 3

Scheme 1. R = *tert*-butyl.

Unlike the well-known plumbocene itself,[9, 10] **3** is monomeric in the solid state (Fig. 1.). The crystal structure analysis[11] shows the tilting of the ring planes (Pyr_z–Pb–Pyr'_z 142.7°) also observed for the decamethylplumbocene.[12] This occurs as a result of the stereochemically active lone pair at the metal center,[13] which only allows a parallel arrangement of the ring ligands for strong and uniform steric loading such as in $[(C_5Me_5)_2Si]$[5] and $[(C_5Ph_5)_2Sn]$.[14] The shift of the central atom ("slip") in the direction of the nitrogen atoms N1 and N2 lying opposite to the carbon atoms C2 and C3 and C14 and C15 is identifiable from the Pb–C bond lengths. This is contrary to the geometry of the diazametallocenes **1** and can be seen as the result of the tilted structure; a similar "slip" occurs in the decamethylplumbocene.[12]

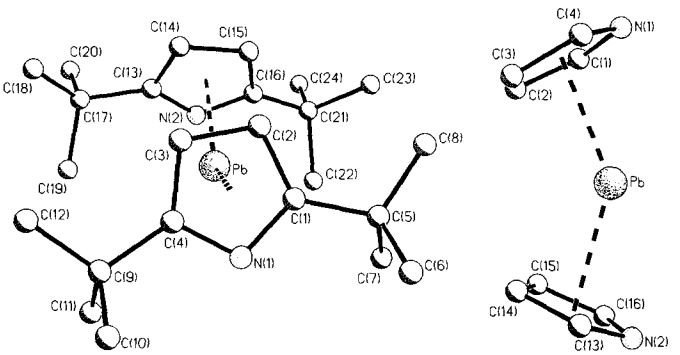


Fig. 1. Plan view and side view of the crystal structure of **3** (without hydrogen atoms, in the side view also without *tert*-butyl groups). Selected bond distances [Å] and valence angles [°] with standard deviations: Pb-N(1) 2.878(12), Pb-C(1) 2.752(14), Pb-C(2) 2.628(11), Pb-C(3) 2.672(11), Pb-C(4) 2.814(12), Pb-N(2) 2.854(12), Pb-C(13) 2.719(19), Pb-C(14) 2.604(18), Pb-C(15) 2.625(14), Pb-C(16) 2.832(13), N(1)-C(1) 1.389(14), N(1)-C(4) 1.373(20), C(1)-C(2) 1.420(25), C(2)-C(3) 1.415(19), C(3)-C(4) 1.426(20), N(2)-C(13) 1.341(21), N(2)-C(16) 1.350(16), C(13)-C(14) 1.398(16), C(14)-C(15) 1.425(22), C(15)-C(16) 1.433(17); N(1)-C(1)-C(2) 111.9(13), N(1)-C(4)-C(3) 111.9(10), C(1)-N(1)-C(4) 104.7(12), C(1)-C(2)-C(3) 105.6(12), C(2)-C(3)-C(4) 105.9(14), N(2)-C(13)-C(14) 111.3(13), N(2)-C(16)-C(15) 109.0(13), C(13)-N(2)-C(16) 108.5(11), C(13)-C(14)-C(15) 105.3(13), C(14)-C(15)-C(16) 105.7(11).

The steric relief in **3** also caused by the tilting of the ring ligands enables a reduction of the torsion angle N1–Pyr_z–Pyr'_z–N2 to 17.2° in contrast to ca. 85° in **1**.[7] An eclipsed conformation with heteroatoms in the *syn* position can be forced in derivatives of the coplanar diazaferrocene by fixing the nitrogen atoms to the bridging metal centers.[15] In contrast to **3**, the significantly extended distance between the central atom and the ring planes (Pyr_z–Pb 2.477, Pyr'_z 2.459 Å) in decamethylplumbocene can be interpreted as a result of repulsive steric interactions between the tilted C_5Me_5 ligands. For the carbocyclic plumbocene this cannot even be balanced by a staggered arrangement of the ligands.

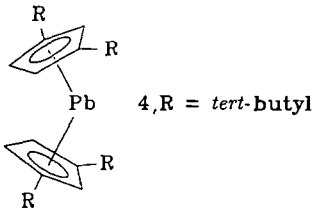
[**] Heterocycles as ligands, part 14. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 13: [7b].

Compound **3** can be compared with its carbocyclic analogue **4**[16] only in solution, since **4** was not structurally characterized. The ^{207}Pb–^{1}H and ^{207}Pb–^{13}C coupling constants of **3** ($^{2}J_{Pb,H} = 33.6$, $^{1}J_{Pb,C2} = 5.8$, $^{1}J_{Pb,C3} = 31.8$ Hz) are smaller than those of **4**, which might indicate a larger percentage of ionic bonding in **3**. The significant deshielding of the carbon atoms contained in the ring in **3** (δ C2,C5 = 161.71, C3,C4 = 105.19) in comparison with the pyrrole **2** (δ C2,C5 = 139.51, C3,C4 = 102.70) is contrary to the coordination shift in the azacyclopentadienyl compounds of the transition metals.[1, 7, 17] The exchange of two



4, R = *tert*-butyl

CH fragments contained in the ring of **4** for nitrogen atoms leads to a significant deshielding of the Pb atom [δ(^{207}Pb) = −4142 in **3** in contrast to −4756 in **4**]. The mass spectrum (EI) shows, probably as a result of the low thermal capacity of **3** (decomposition above 104 °C), the molecular peak only in low intensity.

The synthesis of the diazoplumbocene **3** shows that the azacyclopentadienyl ligand is also suitable for the formation of low molecular weight main group element π complexes. This opens up new possibilities in the coordination chemistry of pyrrole and its derivatives.

Experimental Procedure

To a suspension of $PbCl_2$ (1.39 g, 5.2 mmol) and 2,5-$C_4R_2H_2NLi$ (R = *tert*-butyl) (1.94 g, 10.5 mmol) in toluene (50 mL), THF (2 mL) was added, and the mixture was stirred for 2 h. After the removal of the volatiles the residue was extracted with *n*-pentane (40 mL). After recrystallization yellow crystals of **3** were obtained. Yield 2.50 g, (85%). M.p. 104 °C (decomp).

^{1}H NMR (60 MHz, C_6F_6, TMS int.): δ = 5.51 (4H; C(3,4)-H; ^{2}J (^{207}Pb, ^{1}H) = 33.6 Hz), 1.39 (s, 36H; Me); ^{13}C NMR (75.43 MHz, C_6H_6, TMS int.): δ = 161.71 (C2,C5; ^{1}J(^{207}Pb, ^{13}C) = 5.8 Hz), 105.19 (C3,C4; ^{1}J(^{207}Pb, ^{13}C) = 31.4 Hz), 33.31 (qC), 32.69 (Me); ^{207}Pb NMR (62.7 MHz, C_6H_6, $PbMe_4$ ext.): δ = −4142. – MS (70 eV, EI): *m/z* 564 (M^+, 1%), 386 (M^+ − pyr, 20), 164 (pyr − H^+ − Me, 100), and further fragments.

Benzo-1,2,3-triselenolium Trifluoromethanesulfonate—a C_2Se_3 Radical Cationic Salt with Unusual Solid-State Structure**

By *Gotthelf Wolmershäuser** and *Gert Heckmann*

Ring compounds containing S atoms with a 7π electron framework are often unusually stable.[1, 2] In contrast, there are hardly any of the homologous Se compounds known. However, we recently proved the existence of such an unstable compound with the radical **1**. Compound **1** was formed by the reduction of the corresponding cationic 6π electron species.[3] If the N atom in **1** is replaced by Se^+, then the benzo-1,2,3-triselenolium radical cation **2** is obtained, which contains a new 7π-electron heterocycle.

1

2

To our knowledge **2** is the first selenium-centered radical cation with a cyclic C_2Se_3 unit. There are two possible synthetic routes for the preparation of **2**. A reaction step which occurs in both cases is the addition of Se to a Se–halogen bond (Scheme 1). Compound **2**-Cl is formed at room temperature by the reaction of *o*-$C_6H_4Se_2Cl_2$[3] (**3**) with two equivalents of gray selenium in 72% yield. Alternatively, $(C_6H_4Se_2)_x$[4]

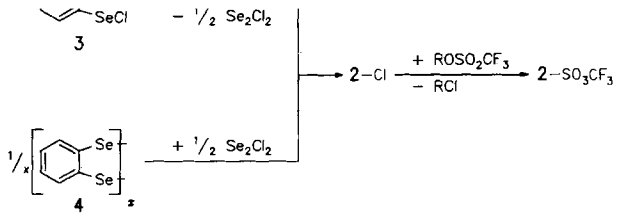

Scheme 1. R = $SiMe_3$

(**4**) can be allowed to react with Se_2Cl_2 under the same reaction conditions. Compound **2**-Cl is a dark blue solid, which is almost insoluble in organic solvents. Readily soluble salts are obtained if the Cl^- is exchanged for complex anions such as $SO_3CF_3^-$. Thus, from the reaction of **2**-Cl with trimethylsilyl trifluoromethanesulfonate and subsequent extraction with acetonitrile a deep violet solution of **2**-SO_3CF_3 is formed, from which gold-colored, metallic shiny crystals precipitate on removal of the solvent.

The X-ray crystal structure[5] shows that **2**-SO_3CF_3 is dimeric in the solid state[6, 7] (Fig. 1). The five-membered heterocycle is almost planar (maximum deviation of the atoms from the plane is 0.09 Å) and coplanar to the C_6 ring. The dimers are formed by two rings which are superimposed and are arranged almost parallel to one another. This conformation allows almost identical interactions for all Se atoms and thus, despite the Coulombic repulsion, an effective spin pairing between the two cations. The average Se–Se distance between the monomeric units in the rings is 3.2 Å, significantly longer than a Se–Se single bond (2.35 Å); however, it is also considerably shorter than the van der Waals distance (4 Å). Somewhat weaker Se···Se interactions between the monomeric units (3.57 Å and 3.76 Å in the direction of the *a* axis, and 3.72 Å along the *c* axis) additionally cause a cross linkage of the planes (Fig. 2). Cation–anion interactions (Se···O = 2.7–3.0 Å), in which two oxygen atoms of two trifluoromethanesulfonate anions bridge the four Se–Se bonds of a dimer, contribute to the reduction of the coulombic repulsion of the cations.

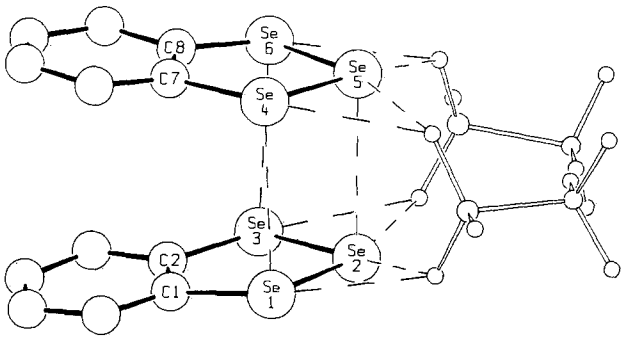

Fig. 1. Crystal structure of **2**-SO_3CF_3. Selected bond distances [Å] and angles [°]: Se1-Se2 2.298(5), Se2-Se3 2.293(5), Se1-C1 1.91(4), Se3-C2 1.88(3), C1-C2 1.41(4), Se4-Se5 2.280(5), Se5-Se6 2.276(5), Se4-C7 1.89(3), Se6-C8 1.85(3), C7-C8 1.38(3), Se1-Se4 3.278(4), Se2-Se5 3.153(4), Se3-Se6 3.246(4); C1-Se1-Se2 99(1), Se3-Se2-Se1 97.2(2), C2-Se3-Se2 98(1), C7-Se4-Se5 98.9(8), Se6-Se5-Se4 97.6(2), C8-Se6-Se5 96.9(9).

The ESR spectrum of **2**-SO_3CF_3 in acetonitrile shows a singlet of low intensity (g = 2.0758 G) with a half-intensity width of about 26.5 G. However, the use of trifluoroacetic acid as the solvent increases the signal intensity considerably, which is an indication of a solvent-dependent dissociation equilibrium. The ion pairs observed in the solid state are probably more strongly dissociated in polar protic solvents so that the coulombic repulsion between the radical cations can become effective. Quite obviously the dimeric structure of **2** is also favored in solution.

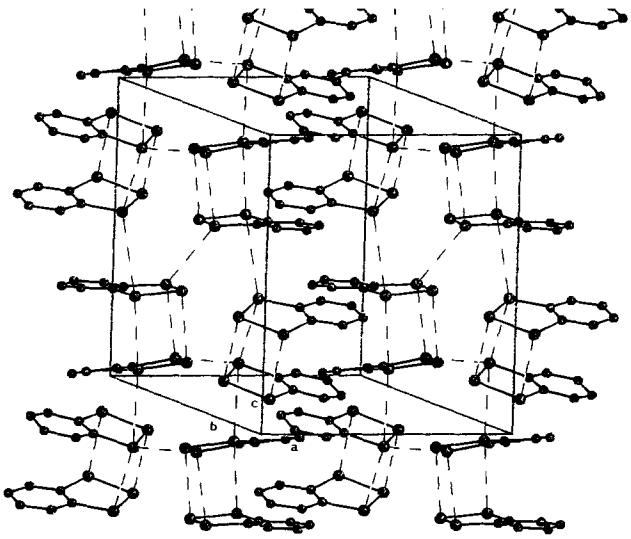

Fig. 2. Arrangement of **2**-SO_3CF_3 in the solid state.

Experimental Procedure

2-SO_3CF_3: A solution of Se_2Cl_2 (0.70 g, 3 mmol) in dichloromethane (5 mL) was added dropwise to a yellow suspension of "[3,4][7,8]dibenzotetraselenocin"(0.72 g, 1.5 mmol)[4] in dichloromethane (30 mL) at room temperature. After 3h the gray-black reaction mixture was allowed to react with trimethylsilyl trifluromethansulfonate (0.5 mL, 3 mmol). The gold, shiny microcrystalline solid was separated after 1h, washed several times with dichloromethane, and dried under vacuum; Yield 0.91 g (64%), m.p. 208 °C.

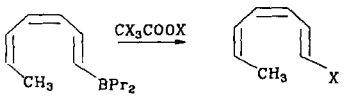
[6] Also the results of magnetic measurements are consistent with this. The surprisingly small Curie constant of $C = 1.24 \times 10^{-3}$ emu mol^{-1} K^{-1} indicates an antiferromagnetic spin pairing.
[7] However, stacks of monomers with a layer distance of 4.1 Å occur in crystals of 4,5-bis(trifluoromethyl)-1,2,3-trithiolium hexafluoroarsenate [2].

Hydrogen Shift in a Parent Compound *Z,Z*-1,3,5-Heptatriene and Its Monodeuterium Analogue

By *Mikhail E. Gurskii, Ilya D. Gridnev, Yuri V. Il'ichev, Anatoly V. Ignatenko,* and *Yuri N. Bubnov**

The [1,7] sigmatropic shift of hydrogen was observed for the first time by Havinga and Schlatmann in the interconversion of vitamin D and precalciferol.[1] The facile antarafacial [1,7] hydrogen shift predicted by Woodward and Hoffmann[2] stimulated a wider study of the phenomenon. Since then the kinetics of [1,7] hydrogen shifts in analogues of the provitamin D_3 system and related compounds[3] have been reported often. There are also some investigations of [1,7] hydrogen shifts in aromatic[4] and open-chain hydrocarbons.[5]

Nevertheless the shift for the parent compound *Z,Z*-1,3,5-heptatriene (**1**) has not been reported. The kinetics of its [1,7] hydrogen shift is important for comparison with quantum mechanics calculations, which have been performed only for **1**.[6] We have now found an easy route to **1** and its deutero-analogue **2**.

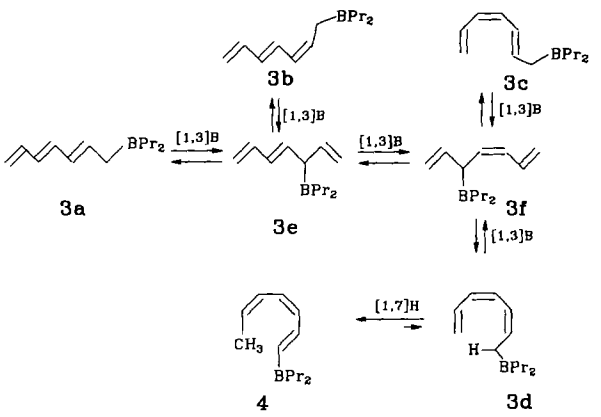


1: X=H
2: X=D

Scheme 1. Synthesis of **1** and **2** from **4**.

During our study on the [1,3] sigmatropic shifts of boron in the allylic type organoboranes we synthesized 2,4,6-heptatrienylborane (**3**), which possesses unusual dynamic properties: besides the [1,3] boron shifts which easily interconvert isomers **3a**–**d**, a [1,7] hydrogen shift occurs in the *Z,Z* isomer **3d** (Scheme 2).

The vinylic borane **4**, the product of the [1,7] H shift, is thermodynamically more stable than the initial heptatrienyl-



Scheme 2. Dynamic properties of **3**.

treatment of **4** with acetic acid or [D_4] acetic acid gives **1** or **2** (Scheme 1).

The [1,7] hydrogen shift in **1** is too slow to measure accurately from the NMR spectra (Fig. 1) by line shape analysis. Moreover **1** dimerizes and polymerizes readily, except when dissolved in a nonpolar solvent. Nevertheless we have man-

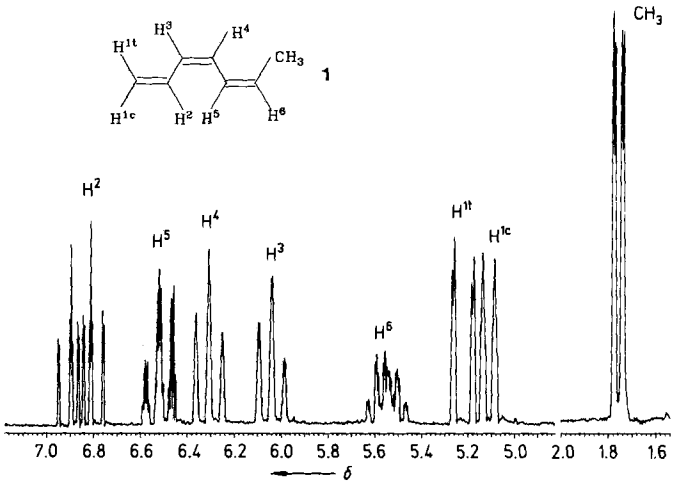

Fig. 1. ^{1}H NMR spectrum of **1** (200 MHz, C_6D_6, 25 °C, TMS).

aged to observe the degenerate [1,7] hydrogen shift in **1** directly by two-dimensional chemical exchange NMR spectroscopy; the results are presented in Figure 2.

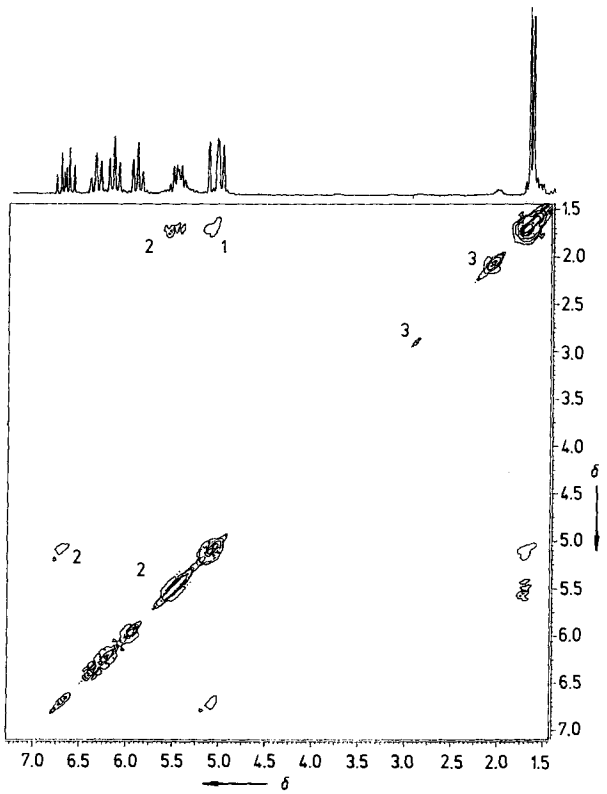

Fig. 2. Direct observation of the degenerate [1,7] hydrogen shift in **1**. Contour plot of ^{1}H NOESY spectrum for **1** (200 MHz, neat liquid, 140 °C, mixing time 0.5 s). 1: Cross-peak caused by the exchange between positions 1 and 7; 2: NOE cross-peaks for the protons adjacent to the exchanging hydrogen; 3: the signals of the dimer of **1** formed during the acquisition of the spectra.

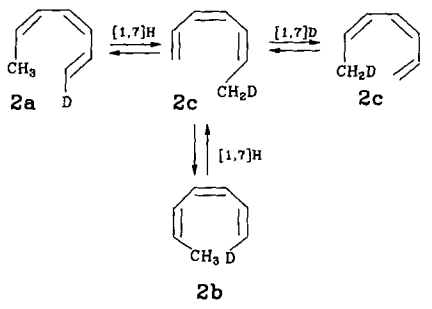
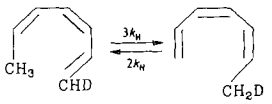
We used the [1,7] hydrogen shift in the labeled compound **2** for the kinetic measurements. As shown in Scheme 3, the [1,7] shift in **2** leads to the exchange of deuterium between positions 1 and 7. The [1,7] deuterium shift in **2c** is degenerate and does not affect the distribution of deuterium between positions 1 and 7. Therefore, deuterium substitution only should affect the rate of [1,7] hydrogen shift slightly, and the reaction can be described as in Scheme 4, where k_H is the rate constant of the [1,7] hydrogen shift for a single hydrogen atom. Therefore the equilibrium ratio of **2c** and the sum of **2a** and **2b** should be 3:2. This agrees well with the experimental findings (see Fig. 3).



Scheme 3. Dynamic properties of **2**.



Scheme 4. Kinetic description of the nondegenerate [1,7] hydrogen shift in **2**.

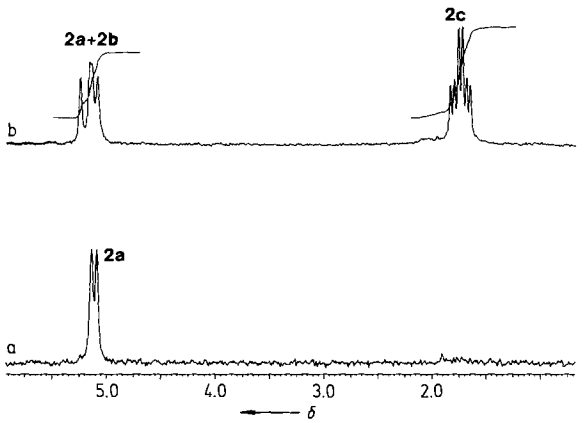


Fig. 3. ^{2}H NMR spectra of the compounds **2a–c** (31 MHz, decane, 25 °C). a) Initial spectrum of **2a**. b) The spectrum of the same sample after 2 h heating at 130 °C. The signals of **2a**, **2b**, and **2c** are clearly visible; the ratio of the intensities for the signals **2c** and **2a** + **2b** is 7:5.

The [1,7]-shift kinetics of **2**, linearized according to Scheme 4, are given in Figure 4a. The concentrations of **2c** and sum of the concentrations of **2a** and **2b** were obtained from the ^{2}H NMR spectra by the integration of the signals at δ = 5.1–5.2 and at 1.7.

The Arrhenius plot presented in the Figure 4b shows a good linear correlation and gives expression (a) for the rate constant k_H of the [1,7] hydrogen shift in the parent compound **1**.

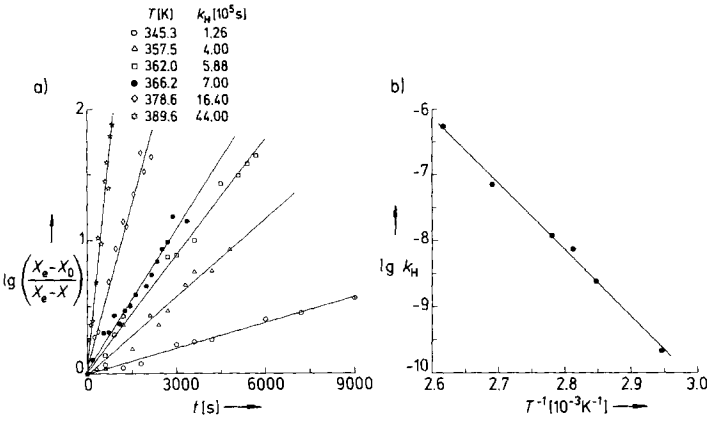

Fig. 4. a) Plots of **2c** concentrations X vs time, linearized according to the Scheme 4. X_0 are the initial concentrations, X_e the equilibrium concentrations of **2c** at each temperature. b) Plot of lg k_H vs T^{-1}.

$$k_H = 1.6 \times 10^8 \, e^{-\frac{87 \pm 3 \text{ kJ mol}^{-1}}{RT}} \, s^{-1} \quad (a)$$

A comparison of the activation parameters in (a) with those reported earlier for the [1,5] hydrogen shift in *Z*-1,3-pentadiene[7] (E_A = 152 kJ mol^{-1}, $A = 2.8 \times 10^{11}$ s^{-1}) shows that our experimental results support the theoretical prediction that [1,7] hydrogen shifts have a lower activation energy but a more negative entropy of activation than [1,5] hydrogen shifts.[6, 8]

Experimental Procedure

The spectral data (see Table 1) were obtained on the Brucker AC-200P, Bruker AM-300 (NMR), UR-20 (IR), and Varian MAT-311A (HRMS) spectrometers.

3a–d was obtained from heptatrienyllithium in hexane/THF [9] and chlorodipropylborane with the yield 70%; b.p. 75 °C (2 Torr), n_D^{20} 1.5115. IR: $\tilde{\nu}$ [cm^{-1}] = 1584, 1629, 3010, 3023, 3091; ^{11}B NMR (64 MHz, neat, 25 °C, $BF_3 \cdot Et_2O$): δ = 85.1. Satisfactory C,H,B analyses.

4: **3** was heated neat in a sealed tube for 1 h at 100 °C (water bath). The equilibrium mixture of **4** (92%) and **3** (8%) was obtained: n_D^{20} 1.5029. IR: $\tilde{\nu}$ [cm^{-1}] = 1556, 1598, 1729, 3017, 3045. ^{11}B NMR (64 MHz, neat, 25 °C, $BF_3 \cdot Et_2O$): δ = 76.6 (**4**), 85.1 (**3**).

1 was obtained from acetic acid and **4** (yield 65%); n_D^{20} 1.5199. IR: $\tilde{\nu}$ [cm^{-1}] = 1570, 1620, 3034, 3050, 3090. ^{13}C NMR (50 MHz, neat, 25 °C, TMS): δ = 131.55 (C2), 128.65 (C3), 126.77 (C6), 123.90 (C4), 123.80 (C5), 116.93 (C1), 12.99 (C7). High-resolution MS (M^+) *m/z* 94.0763, calcd for C_7H_{10} 94.0782.

Table 1. Chemical shifts δ and coupling constants J [Hz] for the compounds **1** [a], **3**, and **4** (without BPr_2 ligands).

Compound	δH1 ($J_{1,2}$)	δH2 ($J_{2,3}$)	δH3 ($J_{3,4}$)	δH4 ($J_{4,5}$)	δH5 ($J_{5,6}$)	δH6 ($J_{6,7c}$)	δH7c (^2J)	δH7t ($J_{6,7t}$)
1 [b]	1.70 (7.2)	5.55 (10.6)	6.52 (10.6)	6.31 (10.6)	6.03 (10.6)	6.85 (10.6)	5.11 (2.2)	5.21 (16.9)
3a	2.19 (8.4)	5.85 (14.9)	6.08 (9.8)	6.28 (14.7)	6.17 (9.8)	6.43 (9.8)	5.08 (1.9)	5.21 (17.0)
3b	2.29 (8.5)	5.70 (10.3)	[c] (11.5)	6.61 (15.3)	[c] (10.1)	6.92 (10.1)	[c]	(16.8)
4	1.81 (7.2)	5.63 (10.3)	6.81 (10.8)	6.55 (11.8)	6.31 (10.6)	7.87 ($J_{6,7}$ = 16.6)	6.68	

[a] The spectral characteristics for the compounds **2** are the same as for the compound **1**, except for: **2a**: 6.85 (ddt, ^3J(H,D) = 1.7 Hz), the signal of H7c is absent; **2b**: 6.85 (ddt, ^3J(H,D) = 2.6 Hz), the signal of H7*t* is absent; **2c**: 1.68 (dt, ^2J(H,D) = 2.2 Hz). [b] The numbering of the atoms for compound **1** in this table is reversed to make it the same as for the compounds **3** and **4**. [c] The signals overlap with the signals of the major isomer.

2 was obtained from **4** and [D_4] acetic acid (yield 68%); n_D^{20} 1.5211. IR: $\tilde{\nu}$ [cm^{-1}] = 1710, 1712, 2200. High-resolution MS (M^+) m/z 95.0853, calcd for C_7H_9D 95.0845.

Kinetic measurements were performed in the probe of the AC-200P NMR spectrometer for the 10% solutions of **2** in *n*-nonane; temperature control was carried out by a VT-1000 variable temperature unit (Bruker).

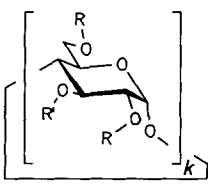
Synthesis of a Lipophilic Cyclodextrin–[2]-Rotaxane**

By *Gerhard Wenz,* Eva von der Bey,* and *Lothar Schmidt*

For a long time cyclodextrins **1** have been known to include smaller guest molecules in aqueous solution.[1] Several attempts have been made to exploit their well-defined topology in the construction of "interlocking" molecules like catenanes,[2] rotaxanes,[3] and polyrotaxanes.[4] In aqueous solution, however, the preparative possibilites are limited because of side reactions. In order to provide cyclodextrins for use as host molecules in inert organic solvents, we synthesized a series of lipophilic cyclodextrin derivatives.[5] As a result we discovered that per(3-*O*-acyl-2,6-di-*O*-alkyl)cyclodextrins



1 k=6,7,8, R=R'=H

1a k = 7, R = *n*-butyl, R' = acetyl

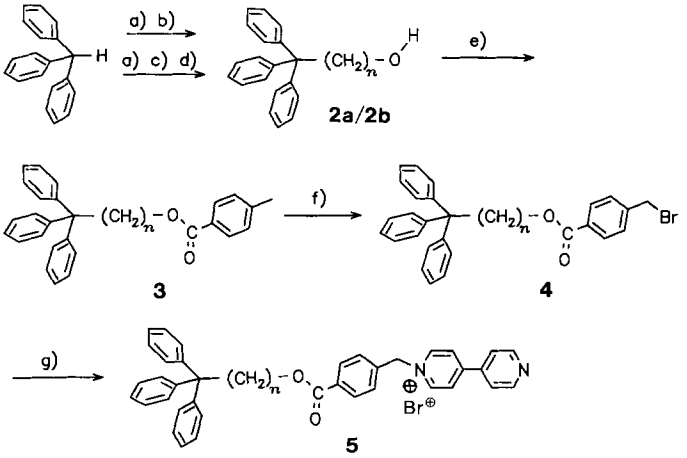
[+] ^{252}Cf-PD mass spectrum

[**] This research was supported by the Bundesministerium für Forschung und Technologie (BEO/22/0319055A), Henkel KGaA, and Wacker-Chemie GmBH. We thank C. Lepilleur and J. Thiel for optimizing the synthesis and Prof. H. Jungclas, Universität Marburg, and Prof. G. Wegner for discussions.

complex cationic guest molecules and neutral ones as well.[6] Here we describe how the complexation of a guest molecule can be employed in the construction of a [2]-rotaxane.

We chose heptakis(3-*O*-acetyl-2,6-di-*O*-butyl)-β-cyclodextrin (**1a**) as the host and a substituted pyridinium ion as the guest. Compounds **5a** and **5b**, 4,4'-bipyridyl derivatives blocked on one side, were synthesized for the construction of the rotaxane according to Scheme 1. Alcohols **2a** and **2b** were prepared from triphenylmethane and esterified with *p*-toluyl chloride. The methyl groups of esters **3** were brominated, and the bromomethyl compounds **4** were treated with excess 4,4'-bipyridyl providing pyridinium bromides **5**.



Scheme 1. Synthesis of the rotaxane building blocks **5** from triphenylmethane. **a**, n = 1; **b**, n = 6. Reagents: a) *n*BuLi, b) paraformaldehyde, c) 6-(*tert*-butyldimethylsilyloxy)hexylbromide, d) Bu_4NF, e) *n*BuLi, *p*-toluyl chloride, f) NBS, AIBN, g) 4,4'-bipyridyl.

^{1}H NMR experiments show that the region around the pyridinium group of **5** is indeed complexed by **1a**. For example, the signals of the benzylic protons of **5a** and **5b** shift markedly downfield upon addition of **1a**, whereas the signals of the trityl group remain unchanged. The dependence of the chemical shift of the benzylic protons on the concentration of the host **1a** (Fig. 1) allows the calculation of a stability constant K_s of 150 M^{-1} for the complex **1a** · **5a**, and 450 M^{-1} for **1a** · **5b**.[5a]

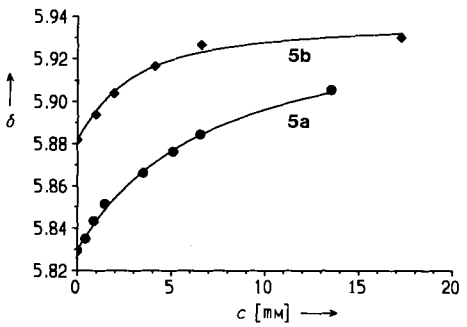


Fig. 1. Chemical shift δ of the benzylic protons of 0.58 M **5a** and 1.25 mM **5b** in CD_3CN at 20 °C as a function of the concentration c of the host **1a**.

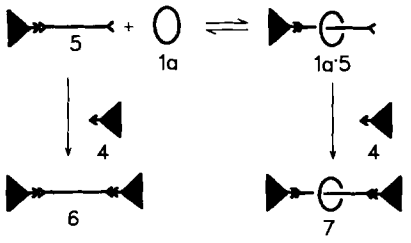
The attempt to synthesize a rotaxane by quaternizing the pyridine unit in **1a** · **5a** with the bromide **4a** led only to the dumbbell-shaped **6a** (Scheme 2). Thus the alkylation only



Scheme 2. Construction of rotaxane 7 from the complex **1a** · **5b**.

occurs outside the complex. In contrast, rotaxane **7** was detected in the reaction of **1a** · **5b** with **4b**. The ^{252}Cf-PD mass spectrum[7] of the reaction mixture (Fig. 2a) shows a pronounced signal at *m/z* 3293, the molecular mass of **7**.

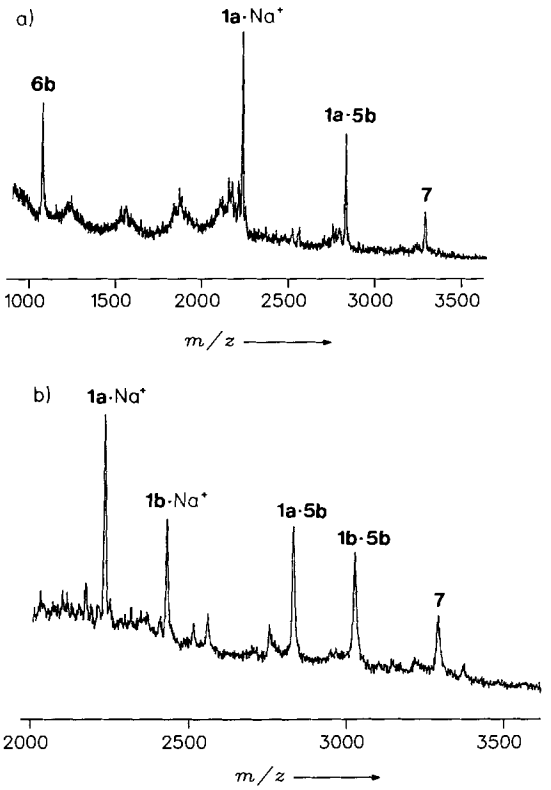


Fig. 2. Mass spectra [7] of the reaction mixture of rotaxane 7 a) before and b) after equilibration with host **1b**.

Because ^{252}Cf-plasma desorption mass spectrometry is very "soft", signals of host–guest complexes were also evident in the mass spectrum. For example, the signal at *m/z* 2833 arose from **1a** · **5b**, and that at *m/z* 2236 from **1a** · Na^+. Thus the signal at *m/z* 3293 could also be due to a loose association of **1a** and **6b** rather than rotaxane **7**. In a control experiment the reaction mixture of **1a**, **5b**, and **4b** was equilibrated with a second host, heptakis(3-*O*-acetyl-2,6-di-*O*-pentyl)-*β*-cyclodextrin (**1b**), whose molecular weight is *m/z* 196 higher than that of **1a**. All associations of **1a** should be recognizable in the mass spectrum because of the exchange of the host. The signal of the rotaxane, on the other hand, should remain unchanged. This is indeed the case (Fig. 2b): In the mass spectra of the aforementioned mixture after the equilibration with **1b** two new signals at *m/z* 2432 and *m/z* 3028 are observed and assigned to **1b** · Na^+ and **1b** · **5b**, respectively. Since no signal at *m/z* 3489 is found, the presence of rotaxane **7** is assured.

Compound **7** was isolated from the reaction mixture in 20% yield.[18] According to the ^{1}H NMR spectrum the C_7 symmetry of the host is retained and the mirror symmetry of the dumbbell is broken by the permanent complexation of the asymmetric host compound (Fig. 3). It is especially noticeable that the signals of the benzylic protons are split into an AB system γ and a singlet γ'. This strong splitting is probably related to the preferred complexation of one half of the dumbbell. The AB system results from the diastereotopic interaction of the benzylic protons with the host.

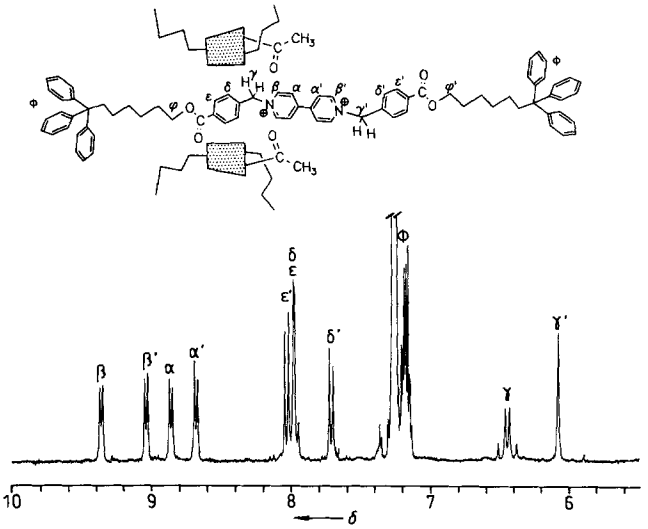

Fig. 3. Structural formula and part of the ^{1}H NMR spectrum of 7. The signals were assigned based on homonuclear decoupling experiments; the low-field signals were assigned to the complexed side.

These first results show that the outcome of a rotaxane synthesis critically depends on the length *n* of the spacer. This is most likely caused by steric interactions between the host and the blocking group. Which of the two triphenylmethyl blocking groups causes the most steric hindrance in the transition state is open for further investigations.

Experimental Procedure

Silica gel Si-60 (40–65 μm) was used for the chromatography. All compounds provided correct elemental analyses. The IR spectra support the assigned structures; ^{1}H NMR: 300 MHz, 20 °C, TMS; ^{13}C NMR: 75.46 MHz, 20 °C, TMS.

1a: Heptakis(2,6-di-*O*-butyl)-*β*-cyclodextrin[5d] (1.92 g, 1 mmol) was allowed to react with acetic anhydride (0.61 g, 6 mmol) and 4-dimethylaminopyridine (0.043 g, 0.35 mmol) in 10 mL CH_2Cl_2 at 40 °C for 3d. The reagents were replenished every day. After workup and chromatography with CH_2Cl_2/*tert*-butyl methyl ether (1/1) **1a** (1.5 g, 68%) was obtained as a colorless oil. ^{1}H NMR($CDCl_3$): δ=0.89 (t, J = 7.3 Hz, 3H), 0.92 (t, J = 7.3 Hz, 3H) 1.26–1.43 (m, 4H), 1.43–1.62 (m, 40H), 2.05 (s, 3H), 3.29 (dd, J = 3.2, 10.1 Hz, 1H), 3.35–3.58 (m, 5H), 3.81 (t, J = 9.1 Hz, 1H), 3.94 (m, 2H), 5.03 (d, J = 3.3 Hz, 1H), 5.18 (t, J = 9.3 Hz, 1H); ^{13}C NMR($CDCl_3$): δ = 13.9, 13.95, 19.0, 19.4, 21.0, 31.8, 69.3, 70.8, 71.2, 73.0, 77.2, 78.4, 98.6, 169.5.

1b: Synthesis (from heptakis(2,6-di-*O*-pentyl)-*β*-cyclodextrin [5d]; yield 76%) and characterization analogous to that of **1a**.

2a: Triphenylmethyllithium was converted to **2a**[9].

2b: A solution of triphenylmethyllithium (8.3 g, 34 mmol) in 100 mL THF under Ar was cooled to −78 °C, and *n*BuLi (1.6 M, 32 mL, 51 mmol) was added dropwise. The reaction mixture was stirred at 20 °C for 24h, then 6-(*tert*-butyldimethylsilyloxy)hexylbromide[10] (10 g, 36 mmol) was added. After being stirred at 20 °C for another 24h, the reaction mixture was treated with Bu_4NF (1.1 M in THF, 50 mL, 55 mmol) and heated at reflux for 2d. Workup with water/chloroform, chromatography with CH_2Cl_2, and recrystallization from petroleum ether/cyclohexane (3/1) provided 6.08 g **2b** (53%). M.p. 74.5 °C; ^{1}H NMR($CDCl_3$): δ = 1.08 (m, 2H), 1.32 (m, 5H), 1.47 (J = 7.0 Hz,

2H), 2.56 (m, 2H), 3.56 (t, J = 6.6 Hz, 2H), 7.16 (m, 3H), 7.26 (m, 12H); ^{13}C NMR($CDCl_3$): δ = 25.6, 25.7, 30.1, 32.7, 40.5, 56.6, 62.9, 125.7, 127.7, 129.2, 147.6.

3a: To a solution of **2a** (1 g, 3.6 mmol) in THF under Ar cooled to −78 °C was added *n*BuLi (1.6 M, 2.25 mL, 3.6 mmol). After 15 min *p*-toluyl chloride (0.5 mL, 3.8 mmol) was added, and the reaction mixture was stirred at 20 °C for 1 d. After workup and recrystallization from cyclohexane/CH_2Cl_2 (9/1) 0.97 g **3a** (65%) were obtained. M.p. 154 °C, ^{1}H NMR($CDCl_3$): δ = 2.35 (s, 3H), 5.31 (s, 2H), 7.12 (d, J = 8.1 Hz, 2H), 7.20–7.32 (m, 15H), 7.58 (d, J = 8.1 Hz, 2H); ^{13}C NMR($CDCl_3$): δ = 21.5, 56.8, 70.9, 126.5, 127.3, 128.0, 129.0, 129.2, 129.5, 143.5, 145.0 166.3.

3b: In analogy to the above procedure, **2a** (1.5 g, 4 mmol) was allowed to react with *p*-toluyl chloride (0.68 mL, 4.4 mmol). Purification by chromatography (eluent CH_2Cl_2/petroleum ether (3/2)) furnished 1.25 g **3b** (62%) as a yellow oil. ^{1}H NMR($CDCl_3$): δ = 1.15 (m, 2H), 1.41 (m, 4H), 1.71 (m, 2H), 2.43 (s, 3H), 2.61 (m, 2H), 4.28 (t, J = 8.6 Hz, 2H), 7.17–7.31 (m, 17H), 7.95 (d, J = 8.0 Hz, 2H); ^{13}C NMR($CDCl_3$): δ = 21.6, 25.6, 25.9, 28.7, 30.0, 40.4, 56.4, 64.7, 125.7, 125.6, 127.7, 129.0, 129.2, 129.5, 142.6, 147.4, 166.3.

4a: A mixture of **3a** (1.04 g, 2.65 mmol), *N*-bromosuccinimide (NBS) (0.52 g, 2.9 mmol), and 2,2′-azodiisobutyronitrile (AIBN; 20 mg) was dissolved in 5 mL CCl_4 and 10 mL $CHCl_3$ and heated at reflux for 3 d. Each day the same amounts of NBS and AIBN were added again. Finally the reaction mixture was filtered at 20 °C. The filtrate was concentrated and dissolved in $CHCl_3$. Precipitation of the product with petroleum ether provided 0.75 g **4a** (60%). ^{1}H NMR($CDCl_3$): δ = 4.42 (s, 2H), 5.31 (s, 2H), 7.17–7.29 (m, 15H), 7.33 (d, J = 8.5 Hz, 2H), 7.63 (d, J = 8.5 Hz, 2H); ^{13}C NMR($CDCl_3$): δ = 32.1, 56.9, 71.2, 126.6, 126.5, 127.3, 128.0, 129.0, 129.3, 129.5, 143.5, 145.0, 166.3.

4b: Analogous to the above reaction, the bromination of **4a** furnished compound **4b** as a yellow oil, yield 80%. ^{1}H NMR($CDCl_3$): δ = 1.15 (m, 2H), 1.45 (m, 4H), 1.65 (m, 2H), 2.55 (m, 2H), 4.25 (t, J = 8.6 Hz, 2H), 4.50 (s, 2H), 7.08 7.28 (m, 15H), 7.62 (d, J = 8.0 Hz, 2H), 8.03 (d, J = 8.0 Hz, 2H); ^{13}C NMR($CDCl_3$): δ = 25.6, 25.8, 28.7, 30.0, 40.4, 32.1, 56.6, 65.1, 125.7, 126.6, 127.7, 128.9, 129.2, 130.0, 142.5, 147.5, 166.0.

5a: Solutions of **4a** (235 mg, 0.5 mmol) in 3 mL CH_3CN and 4,4′-bipyridyl (78 mg, 0.5 mol) in 1 mL $CHCl_3$ were mixed and stirred at 20 °C for 24 h. Then *tert*-butyl methyl ether was added, and **5a** was removed by filtration. Yield 98 mg (31%). ^{1}H NMR(CD_3CN): δ = 5.34 (s, 2H), 5.86 (s, 2H), 7.20–7.33 (m, 15H), 7.46 (d, J = 8.2 Hz, 2H), 7.72 (d, J = 8.2 Hz, 2H), 8.35 (m, 4H), 8.98 (m, 4H); ^{13}C NMR([D_6]DMSO): δ = 56.4, 62.5, 70.2, 121.9, 125.9, 126.5, 128.0, 128.8, 129.4, 130,0, 139.2, 140.7, 144.6, 145.5, 150.9, 152.9, 164.6.

5b: A procedure analogous to that for **5a**, starting with **4b** (220 mg, 0.41 mmol) and 4,4′-bipyridyl (130 mg, 0.82 mol), provided 140 mg **5b** (49%). ^{1}H NMR (CD_3CN): δ = 1.05 (m, 2H), 1.40 (m, 4H), 1.63 (m, 2H), 2.56 (m, 2H), 4.23 (t, J = 8.5 Hz, 2H) 5.91 (s, 2H), 7.15–7.25 (m, 15 H), 7.59 (d, J = 8.0 Hz, 2H), 7.92 (d, J = 8.0 Hz, 2H), 8.05 (d, J = 8.5 Hz, 2H), 8.32 (d, J = 7.0 Hz, 2H), 8.86 (d, J = 8.5 Hz, 2H), 8.99 (d, J = 7.0 Hz, 2H); ^{13}C NMR([D_6]DMSO): δ = 30.3, 30.4, 33.2, 34.3, 44.6, 61.4, 67.5, 70.0, 127.3, 130.9, 131.2, 133.0, 134.0, 134.3, 135.0, 135.8, 144.3, 146.3, 150.8, 152.4, 155.8, 158.0, 170.4.

6a: 4,4′-Bipyridyl (64 mg, 0.4 mmol) in 4 mL CH_3CN and **4a** (571 mg, 1 mmol) in 2 mL $CHCl_3$ were mixed and stirred at 20 °C for 24 h. The resulting yellow precipitate was filtered, washed with $CHCl_3$, and redissolved in hot CH_3CN/$CHCl_3$ (3/1). The slow addition of petroleum ether caused the precipitation of 168 mg **6a** (38%). Yellow solid, m.p. 171 °C. ^{1}H NMR(CD_3CN): δ = 5.35 (s, 4H), 5.86 (s, 4H), 7.21–7.31 (m, 30H), 7.45 (d, J = 8.2 Hz, 4H), 7.72 (d, J = 8.2 Hz, 4H), 8.39 (d, J = 7.1 Hz, 4H), 8.99 (d, J = 7.1 Hz, 4H); ^{13}C NMR([D_6]DMSO): δ = 56.4, 62.7, 70.3, 126.5, 127.2, 128.0, 128.8, 12.0, 129.4, 130.2, 139.0, 144.4, 145.9, 149.3, 164.5.

7: To a solution of **5b** (100 mg, 0.14 mmol) and **1a** (620 mg, 0.28 mmol) in 3 mL CH_3CN was added a solution of **4b** (152 mg, 0.28 mmol) in 0.5 mL $CHCl_3$. The reaction mixture was stirred at 20 °C for 3 d before being separated in four portions by middle-pressure chromatography (column size 30 × 1.5 cm, packed with Si-60 (18–32 μm) from ICN Biomedicals, deactivated with CH_2Cl_2/CH_3OH (7/1)). Elution first with *tert*-butyl methyl ether gave **1a** and **4b**, then with CH_2Cl_2/CH_3OH (7/1) provided **7**: Yield 92 mg (20%), yellow oil. ^{1}H NMR (CD_3CN): δ = 0.81 (t, J = 7.3 Hz, 21H), 0.88 (t, J = 7.3 Hz, 21H), 1.03 (m, 4H), 1.21 (m, 14H), 1.28–1.42 (m, 32H), 1.43–1.54 (m, 14H), 1.61 (m, 4H), 1.88 (s, 21H), 2.57 (m, 4H), 3.12 (dd, J = 3.2, 10.3 Hz, 7H), 3.26–3.56 (m, 42H), 3.69 (t, J = 9.5 Hz, 14H), 4.21 (t, J = 6.4 Hz, 2H), 4.28 (t, J = 10.3 Hz, 7H), 4.93 (d, J = 2.6 Hz, 7H), 4.96 (t, J = 10.1 Hz, 7H), 6.09 (s, 2H), 6.42 (d, J = 14.6 Hz, 1H), 6.46 (d, J = 14.6 Hz, 1H), 7.13–7.30 (m, 30H), 7.72 (d, J = 8.4 Hz, 2H), 7.98 (m, 4H), 8.03 (d, J = 8.4 Hz, 2H), 8.68 (d, J = 6.8 Hz 2H), 8.85 (d, J = 6.8 Hz, 2H), 9.03 (d, J = 6.8 Hz, 2H), 9.38 (d, J = 6.8 Hz, 2H).

Retro-Inverso Amide Bonds between Trifunctional Amino Acids**

By *Hansjörg Dürr, Murray Goodman*, and *Günther Jung**

Dedicated to Professor Ralph Hirschmann on the occasion of his 70th birthday

During the last decade numerous modifications of the peptide backbone[1] were introduced mainly to increase proteolytic stability of peptide-derived drugs. Among these variations the retro-inverso amide bond[2] is outstanding in preserving the essence of the primary structure. The synthesis requires a substituted malonic acid and a 1,1-diaminoalkyl moiety. Most of the retro-inverso peptides reported so far contain no functionalized side chains at the inverted residues.[1] However, for their intended use in drug development the trifunctional amino acids are even more important. We report here the synthesis of the first partially modified retro-inverso analogue of a T-cell epitope of the influenza nucleoprotein designed to fit into the groove of the major histocompatibility complex (MHC) class I molecule.[3] For the first time, the amide bond between the more complex amino acids glutamine and arginine was inverted by combination of solution and solid-phase synthesis.

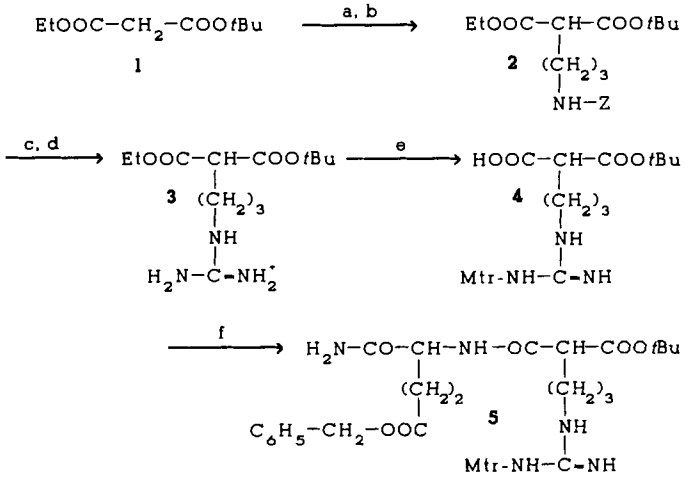
[**] This work was been supported by the Fonds der Chemischen Industrie. H. Dürr is recipient of a doctorate stipend from the Studienstiftung des Deutschen Volkes.

We used [*I,I*-bis(trifluoroacetoxy)iodo]benzene (TIB), also named iodobenzene bistrifluoroacetate (IBTFA), for the synthesis of optically pure *N*-acyl-1,1-diaminoalkanes directly from their peptide amide precursors.[2a] The mild reaction conditions and the one-step procedure made this approach the most favorable for generating the 1,1-diaminoalkyl moiety of retro-inverso peptides, with the exception of sulfur-containing amino acid side chains sensitive to oxidation, and the indole and phenol rings. Applying TIB to glutamine and asparagine causes rearrangement of their amide groups to 2,4-diaminobutyric acid and 2,3-diaminopropionic acid, respectively. Hofmann rearrangement with TIB can also be carried out with peptide amides covalently linked to a polymer support.[4] The malonic acid derivatives are usually synthesized by alkylation of malonic acid diesters with an alkyl halide containing the corresponding side chain.

The synthesis of the glutamyl–arginine pre-retro-inverso dipeptide is summarized in Scheme 1. Alkylation of ethyl *tert*-butylmalonate (**1**) with (*N*-benzyloxycarbonyl)-3-chloropropylamine yields the malonyl ornithine derivative **2**. After hydrogenolysis of the benzyloxycarbonyl protecting group, the guanidino group is introduced with amino-iminomethanesulfonic acid.[5] The crude derivative **3** is allowed to react with 4-methoxy-2,3,6-trimethylbenzenesulfonylchloride (Mtr-Cl) in order to obtain the malonate–arginine derivative **4** with a protected side chain.[6] Simultaneously, the basic medium necessary to deprotonate the guanidino group saponifies the ethyl ester and m(*R,S*)Arg(Mtr)-O*t*Bu **4**[7] is obtained in 30% overall yield after column chromatography on silica gel with chloroform/methanol/acetic acid (85:15:2) as eluent.

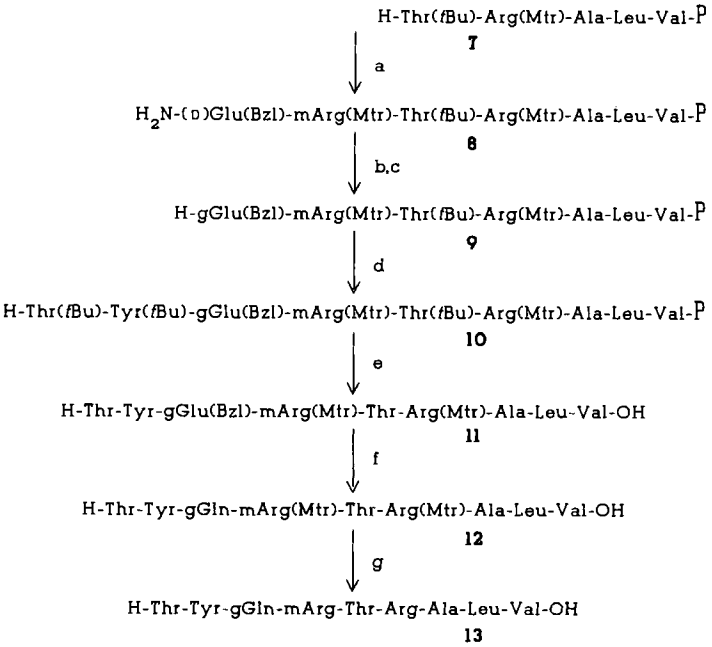


Scheme 1. Synthesis of the glutamyl–arginine pre-retro-inverso dipeptide. a) NaH/DMF, −15 °C to 22 °C, 1 h; b) (*N*-benzyloxycarbonyl)-3-chloropropylamine/DMF, 50 °C, 16 h; c) Pd(C)/H_2, methanol/acetic acid (95:5), 12 h; d) amino-imino-methanesulfonic acid/dioxane/10% Na_2CO_3 aq., 72 h; e) 4 N NaOH/acetone/Mtr-Cl, 2 h; f) H-(D)Glu(Bzl)-NH_2/HOBt/DCC/dichloromethane, 18 h.

The racemic derivative **4** is activated with dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBt) in dichloromethane for coupling to D-glutamic acid α-amide-γ-benzyl ester (H-(D)Glu(Bzl)-NH_2) to yield the pre-retro-inverso dipeptide **5**. The resulting diastereomers **5a** and **5b** can be purified and separated on a silica gel column (eluent: chloroform/methanol 9:1). The identity and purity (>98%) of **5a** and **5b** is confirmed by TLC, HPLC, and ^{1}H NMR and ion spray mass spectrometry (IS-MS).[8] The *C*-terminally free pre-retro-inverso dipeptide **6** can be obtained by cleavage of the *t*Bu ester in trifluoroacetic acid (TFA)/dichloromethane/anisole (50:48:2; 1 h).

H_2N-(D)Glu(Bzl)-m(*R,S*)Arg(Mtr)-OH **6**

The retro-inverso killer-cell epitope (CTL epitope) of the influenza nucleoprotein[3] can be built up by Merrifield synthesis by using **6** as a template (Scheme 2). The *C*-terminal



Scheme 2. Synthesis of the partially modified retro-inverso CTL epitope of influenza nucleoprotein (P = *p*-benzyloxybenzylalcohol–polystyrene–1% divinylbenzene). a) **6**/DCC/HOBt/dichloromethane, 36 h; b) [*I,I*-bis(trifluoroacetoxy)iodo]benzene (TIB)/DMF–H_2O (9:1), 3 h; c) *N*-ethylmorpholine/DMF, 5 min; d) Fmoc-amino acid/DCC/HOBt/DMF, 2 h; e) TFA/thioanisole/thiocresol/water (82:8:8:2), 2 h; f) NH_3/methanol, −15 °C to 22 °C, 100 h; g) TFA/thioanisole/thiocresol/water (82:8:8:2), 40 °C, 1 h. All amino acids are of L configuration except for m(*R,S*)Arg. For the structural formula of H_2N-(D)Glu(Bzl)-mArg(Mtr) see Scheme 1 [7].

resin-bound pentapeptide **7** is synthesized automatically by applying Fmoc-strategy on *p*-benzyloxybenzylalcohol–polystyrene–1% divinylbenzene.[9] After the coupling with template **6**, the Hofmann rearrangement with TIB is applied on compound **8** to generate the 1,1-diaminoglutamate derivative **9**. The resin is washed, neutralized, and the compound immediately elongated to the complete nonapeptide **10**. The retro-inverso nonapeptide is cleaved from the resin and partially deprotected to yield **11**. Ammonolysis of the 1,1-diamino-*O*-benzylglutamate residue produces the 1,1-diaminoglutamine derivative **12**. The final product **13** is obtained by trifluoroacetic acid treatment, followed by preparative reverse-phase HPLC. All compounds with exception of **9** are characterized by HPLC, IS-MS and amino acid analysis.[10] No racemization could be detected for **12** by chiral-phase gas chromatography. Interestingly, the retro-inverso CTL epitope **13** is about 10^5 less potent than the natural antigen, which is active in picomolar level in the in vitro killer assay.[3a] At present we are performing competion as-

says to find out whether the epitope backbone modification leads to blocking of the MHC groove or inhibits the T-cell receptor binding.

Synthesis and Structure of the Cluster $[NaAu_{12}Se_8]^{3-}$: An Inorganic Cryptand Complex**

By *Song-Ping Huang* and *Mercouri G. Kanatzidis**

The increased interest in the synthesis and structural characterization of soluble metal selenide complexes is due largely to the structural abundance and diversity of these compounds.[1–3] Frequently, for a given metal ion M, more than one compositionally and structurally different selenide complex may be formed and isolated from the M/Se_x^{2-} system.[4–7] For example, during our systematic investigation of the reactions between Au^+ and several Se_x^{2-} ($x = 2–5$) ligands, we have isolated and structurally characterized three different species. First, Au^+ can reduce the pentaselenide ligand Se_5^{2-} to yield a Au^{3+} compound $[Au_2Se_2(Se_4)_2]^{2-}$.[5a] Second, when shorter polyselenide ligands such as Se_4^{2-}, Se_3^{2-}, and Se_2^{2-} are used, the seven- and eight-membered rings of dimeric Au^+ polyselenides, $[Au_2(Se_2)(Se_3)]^{2-}$ and $[Au_2(Se_2)(Se_4)]^{2-}$ are formed.[5b] The formation of either seven- or eight-membered rings can be controlled by the selection of a particular ligand size and a suitable organic counterion. This deviates from the general belief that the metal ions, rather than the size of polychalcogenide ligands used, determine the structures of metal complexes isolable from solution.[1–3, 8, 9] In order to avoid the Au^+/Au^{3+} redox chemistry and explore the reactivity of Au^+ towards other selenides, we used the shortest possible ligand, Se^{2-}. In the Au^+/Se^{2-} system, both the redox chemistry and the ligand size effect cease to operate, while a new factor, the interaction of Au^+ with an alkali-metal ion (i.e. Na^+) surprisingly emerges as a structure-directing force. Here we report a novel cluster, $[NaAu_{12}Se_8]^{3-}$ (**1**), which contains a Na^+ ion encapsulated in a cryptate-like fashion.

The structure of $(Et_4N)_3$-**1** was established by single-crystal X-ray diffraction analysis.[10] The crystal lattice comprises Et_4N^+ cations and $[NaAu_{12}Se_8]^{3-}$ anions. The $[NaAu_{12}Se_8]^{3-}$ anion forms an almost perfect cube with twelve linearly coordinated Au atoms positioned at the midpoints of the edges and eight Se atoms, each with trigonal geometry, occupying the corners of the cube, as shown in Figure 1. The captured Na^+ ion is situated on a crystallographic inversion center, which is also the center of the cube; the distances to the Au atoms lie between 3.327(3) Å and 3.467(3) Å. The Au–Se distances are normal and comparable to those found in $[Au_2(Se_2)(Se_3)]^{2-}$ and $[Au_2(Se_2)(Se_4)]^{2-}$.[5b] The affinity of the $[Au_{12}Se_8]^{4-}$ cage for Na^+ is reminiscent of the behavior of the organic-based cryptands.

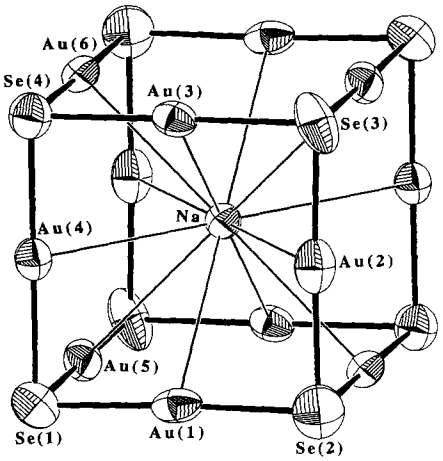

Fig. 1. The structure of $[NaAu_{12}Se_8]^{3-}$ (ORTEP) showing the atom-labeling scheme. Selected bond distances [Å] and bond angles [°]: Au(1)-Se(1) 2.400(7), Au(1)-Se(2) 2.414(8), Au(2)-Se(2) 2.402(8), Au(2)-Se(3) 2.400(8), Au(3)-Se(3) 2.417(7), Au(3)-Se(4) 2.408(6), Au(4)-Se(1) 2.428(7), Au(4)-Se(4) 2.401(6), Au(5)-Se(1) 2.399(7), Au(5)-Se(3) 2.404(7), Au(6)-Se(2) 2.401(7), Au(6)-Se(4) 2.402(6), Na-Au(1) 3.451(2), Na-Au(2) 3.391(3), Na-Au(3) 3.272(3), Na-Au(4) 3.369(3), Na-Au(5) 3.467(3), Na-Au(6) 3.306(2); Se(1)-Au(1)-Se(2) 177.8(2), Se(2)-Au(2)-Se(3) 177.8(2), Se(3)-Au(3)-Se(4) 178.0(2), Se(1)-Au(4)-Se(4) 179.6(2), Se(1)-Au(5)-Se(3) 178.2(3), Se(2)-Au(6)-Se(4) 179.1(2), Au(1)-Se(1)-Au(4) 85.8(2), Au(1)-Se(1)-Au(5) 90.5(2), Au(4)-Se(1)-Au(5) 85.9(2), Au(1)-Se(2)-Au(2) 91.1(3), Au(1)-Se(2)-Au(6) 88.2(2), Au(2)-Se(2)-Au(6) 86.7(2), Au(2)-Se(3)-Au(3) 86.0(2), Au(2)-Se(3)-Au(5) 92.1(2), Au(3)-Se(3)-Au(5) 88.0(2), Au(3)-Se(4)-Au(4) 92.4(2), Au(3)-Se(4)-Au(6) 89.5(2), Au(4)-Se(4)-Au(6) 93.2(2).

The single-crystal X-ray diffractometers used in this work were purchased by a grant from the National Science Foundation (CHE-8908088). We also thank the Center for Electron Optics at Michigan State University for the use of the electron microscope facilities.

$[NaAu_{12}Se_8]^{3-}$ is a rare example of an inorganic cryptate. Although one might be amazed by the structural simplicity of $[NaAu_{12}Se_8]^{3-}$, the assembly and stabilization of this unique complex reveal a chemical logic. First of all, the strong preference of Au^+ for linear coordination and the trigonal pyramidal geometry of Se^{2-} account for the construction of a cube with edges and corners occupied by atoms. In addition, the cavity size of the cube, which is predetermined by both the Au^+ and the Se^{2-} radii, happens to be a perfect fit for an alkali metal ion, in this case Na^+. A feature worthy of note in a cube is that the distances from the center to its corners are longer than the distances from the center to the midpoints of its edges. Consequently, the Na^+ ion must interact with the twelve Au atoms rather than the eight Se atoms. It has been found that the Au^+ has an affinity for the positively charged alkali-metal ions, and these interactions have precedents in other Au^+ chalcogenide complexes, for example $[KAu_9Te_7]^{4-}$,[12] $[K_2Au_4Te_4(en)_4]^{2-}$ (en = ethylenediamine),[12] and $[K_2Au_4Te_4(dmf)_2]^{2-}$ (dmf = *N*,*N*-dimethylformamide).[13] Thus, the formation of $[NaAu_{12}Se_8]^{3-}$ may not be coincidental, but results instead from the combination of cube-cavity size and the tendency of Au^+ to interact with alkali-metal ions. It should be noted that the S^{2-} ligand can also form cubelike molecules with Au^+ or Cu^+ ions.[14, 15] The $[Cu_{12}S_8]^{4-}$ cube is highly distorted on the edges because the Cu^+ ions deviate from the ideal linear coordination geometry because of attractive $Cu\cdots Cu$ d^{10}–d^{10} interactions.[16] However, no alkali-metal ion is encapsulated in either of the compounds.

A comparison of the volume of the $[Au_{12}S_8]^{4-}$ and $[Au_{12}Se_8]^{4-}$ clusters shows that the sulfide cluster is 12% smaller than its selenide analogue (98 Å^3 vs 111 Å^3). This explains why the corresponding $[NaAu_{12}S_8]^{3-}$ cannot be made. It suggests, however, that $[LiAu_{12}S_8]^{3-}$ may be accessible. On the other hand, the volume of the $[Au_{12}Te_8]^{4-}$ (i.e. 136 Å) is 23% larger than that of the $[Au_{12}Se_8]^{4-}$, which suggests that K^+, Rb^+, or even Cs^+ might be good candidates for inclusion. Attempts to synthesize the $[KAu_{12}Te_8]^{3-}$ have resulted in isolation of only the $[K_2Au_4Te_4(dmf)_2]^{2-}$,[13] which contains a one-dimensional array of $[Au_4Te_4]^{2-}$ sheets held together by ionic interactions between K^+ and Au^+. Work with Rb^+ and Cs^+ is in progress.

The encapsulation of the Na^+ ion in $[Au_{12}Se_8]^{4-}$ may not be due only to the right cavity size but also to a tendency of the cube to reduce its high negative charge. When the synthesis was carried out with K_2Se no corresponding $[KAu_{12}Se_8]^{3-}$ species was found, presumably because of the inability of K^+ to fit into the $[Au_{12}Se_8]^{4-}$ cage. The empty $[Au_{12}Se_8]^{4-}$ cage could not be isolated thus far. It should be mentioned that complete encapsulation of sodium ions by metal chalcogenide complexes was also found in $[Na_2\{Fe_6S_9(SMe)_2\}_2]^{6-}$,[17] where the Na^+ ions cause the aggregation of two Fe_6S_9 clusters, and in the recently reported $[Na_2Fe_{18}S_{30}]^{8-}$,[18] where two Na^+ ions are entirely complexed by the toroidal $Fe_{18}S_{30}$ cluster.

The solid-state far-IR spectrum of $[Et_4N]_3$-**1** shows a single absorption at 236 cm^{-1}. This can be unambiguously assigned to the Au–Se stretching vibration. The same assignment was made in the far-IR spectra of $[Au_2(Se_2)(Se_3)]^{2-}$ and $[Au_2(Se_2)(Se_4)]^{2-}$.[5b] A solution of $[Et_4N]_3$-**1** in DMF is brownish yellow and shows a featureless UV/VIS spectrum. This solution gave a single ^{23}Na NMR signal at $\delta = -12.0$ (relative to $NaBPh_4$ in DMF at $\delta = 0$). The upfield shift of the resonance signal indicates not only that the sodium ion remains encapsulated when the cluster dissolves but also that the Na^+ ion is electronically somewhat "naked" compared to the highly solvated Na^+ ion of the $NaBPh_4$ solution. This is a consequence of the special environment of the Na^+ ion in the cube. The ^{77}Se NMR spectrum of $[Et_4N]_3$-**1** in DMF also shows a single resonance signal at $\delta = 758$ (relative to Ph_2Se_2 in DMF at $\delta = 460$). The NMR data suggest that in solution, **1** retains its structural integrity and are consistent with O_h symmetry.

In summary, the polynuclear gold(I) selenide cluster was made by the reaction of AuCN with Na_2Se in the presence of Et_4NCl. The cluster can act as an inorganic cryptand to capture an alkali-metal ion. The stabilization of the cage structure and the apparent importance of interactions between alkali metals and gold raises interesting implications for the exploitation of such interactions in the synthesis of new cagelike compounds.

Experimental Procedure

All manipulations were carried out in a glove box under a nitrogen atmosphere. Na_2Se was prepared by dissolving the stoichiometric amount of the elements in liquid ammonia. Solvents were all dried and distilled under N_2. AuCN was used as obtained.

Addition of 25 mL of diethyl ether to 20 mL of a reaction mixture of AuCN (45 mg, 0.2 mmol), Na_2Se (25 mg, 0.2 mmol), and Et_4NCl (33 mg, 0.2 mmol) in methanol afforded a pale yellow powder. Collection and recrystallization of this product with a slow diffusion technique in DMF/ether solution (ca. 1:1, total volume 20 mL) over a period of two weeks gave amber-colored, cubelike single crystals of $(Et_4N)_3[NaAu_{12}Se_8]$. The overall yield of the synthesis was estimated at approximately 33% based on the AuCN. Semiquantitative elemental analyses of the compound were carried out by energy dispersive X-ray microanalysis (EDS) with a scanning electron microscope. It revealed that the product contains gold and selenium in a 3:1 ratio. The experimentally measured X-ray diffraction pattern of $(Et_4N)_3$-**1** matches that calculated from the X-ray single crystal data, indicating that it is a homogeneous product.

Chemical Attachment of Organometallics to Proteins in Reverse Micelles**

By *Alexander D. Ryabov,* Alexey M. Trushkin, Lidia I. Baksheeva, Raisa K. Gorbatova, Irina V. Kubrakova, Vadim V. Mozhaev, Boris B. Gnedenko and Andrey V. Levashov*

Enzymes capable of a direct electron exchange with an electrode are at present arousing great interest. In increasing numbers, native enzymes have been shown to be electrochemically active under appropriate conditions.[1] These mediatorless electron relays have, however, an effective alternative in the pseudo-mediatorless systems, where a mediator of the electron transport is bound to a redox enzyme.[2, 3] Different mediators are known,[4, 5] but ferrocene derivatives[6] and osmium complexes[7] accommodate best the functioning of FAD-dependent oxidases. The rich biochemistry of ferrocenes[8] also makes elaboration of simple procedures for their attachment to proteins essential. An obstacle here is the low aqueous solubility of ferrocenes, and, as a result, the known procedures[9] are often heterogeneous in nature. Moreover, the modification is usually carried out in the presence of large to moderate concentrations of urea, which causes protein denaturation (unfolding). Such procedures might be rather invasive, since a protein will not necessarily refold into the native conformation.

A possible alternative that eliminates the solubility problem on one hand, and does not involve unfolding on the other, is a reverse micelle "microreactor" successfully used recently for the modification of α-chymotrypsin and other biomolecules with fatty acid chlorides.[10] Now we report on the modification of GO[*] by FcCOOH in the presence of DCC/*N*-hydroxysuccinimide in reverse micelles of AOT in *n*-octane.

The size of the reverse micelle microreactor can be adjusted to any protein by varying the degree of hydration, that is, the water to surfactant molar ratio, $w_0 = [H_2O]/[AOT]$.[11] In our case, the size of the inner cavity corresponded to a two-subunit GO molecule of the molecular mass 160 kDa achieved when the ratio $[H_2O]/[AOT]$ is 23. The correspondence between the size of the inner cavity of reverse micelle microreactor and the enzyme precludes the unfolding, and hence, only surface amino groups of GO are exposed to modification. Such an approach to modification of surface groups seems to be less laborious and more general than that based on oxidation oligosaccharides at the periphery of enzymes.[9d] As a modifier, we used FcCOOH activated by DCC/*N*-hydroxysuccinimide in acetonitrile solvent.[12] Acetonitrile, the molar amount of which is a factor of 75 lower than that of water, probably does not affect the size of reverse micelles but appears to be an important component, since no modification is observed when the activation is carried out in either benzene, or *n*-octane. Activated FcCOOH is readily attached to NH_2 groups of GO solubilized in the aqueous phase of reverse micelles.

The modified GO does not differ much from native GO. Only five ferrocene residues are attached per molecule of GO (electrothermal atomic absorption spectrometry), far fewer than with the procedures involving urea, where usually more than 10 species are introduced.[9] Electrophoregrams of the native and modified enzymes (SDS, polyacrylamide gel) are practically identical. In both cases only the bands from monomeric units of 80 kDa are developed, which rules out aggregation. Measured with the Clark electrode, the kinetics of dioxygen consumption by modified GO resembles that by the native enzyme, but the modified GO is 22% as active as the native one. The modification thus does not change the enzyme crucially. Rather, it introduces a novel feature displayed in Figure 1, where cyclic voltammograms of the ferrocene-bound enzyme are shown both in the absence and in the presence of D-glucose.

Even in the absence of the substrate (trace a, Fig. 1 left), a peak from pendant ferrocene is observed at 0.27 V. The role of ferrocene units as mediators for the electron transfer becomes clear on consecutive addition of D-glucose (traces b–e). The plot of current versus D-glucose concentration is practically linear in the range 0.01–0.15 M. The response also increases with the temperature reaching maximum at 40 °C and then decreases because the enzyme is inactivated. It was interesting to compare the *operational* thermostability of the native and modified GO preparations at 55 °C by measuring the catalytic current. For native GO, we measured the decrease in the peak current in the presence of added FcCOOH and D-glucose. Naturally, only D-glucose was added to modified GO. Both current/time plots yielded the observed first-order rate constants of thermoinactivation (k_{obs}) of $(5.0 \pm 0.2) \times 10^{-4}$ and $(6.0 \pm 0.8) \times 10^{-4}\ s^{-1}$ for native and modified GO, respectively (0.5 M D-glucose, pH 5). Hence, this modification of GO by hydrophobic ferrocene residues does not significantly decrease its operational stability.

The observation of a true ferrocene electrochemical signal (Fig. 1 left, trace a) suggests that the organometallic moiety is pendant, and hence covalently bound to GO through a spacer rather than adsorbed on its surface. The traces ob-

[*] Abbreviations: GO = glucose oxidase, BSA = bovine serum albumin, AOT = aerosol OT [bis(2-ethylhexyl)sodium sulfosuccinate], FcH = ferrocene, FcCOOH = hydroxycarbonylferrocene, DCC = dicyclohexylcarbodiimide, SDS = sodium dodecyl sulfate.

served in the presence of D-glucose are very similar to those obtained by Heller et al. for GO with ferrocene residues covalently attached through a short spacer,[9d] but not to those reported by Cass et al. for the mixtures of native GO and added FcCOOH,[6] for which the current sharply increases with increasing potential, reaching limiting values. No ferrocene signals were detected when the modification of GO was carried out in the absence of DCC and/or *N*-hydroxysuccinimide, and addition of D-glucose did not increase the current, since a small amount of mediator can produce a signal in the presence of the substrate. Noncovalent attachment might be expected for proteins like BSA. In fact, even ferrocene without functional groups (FcH) can be adsorbed on the surface of BSA in the reverse micelle microreactor. Naturally, no activating couple is needed in this case. The preparation isolated is again electrochemically active, but the current is seen at much more positive potentials (Fig. 1 right, trace b) suggesting[13] that FcH is buried inside the BSA globule and, therefore, strongly deshielded by the amino acid residues. Despite this, BSA modified thus, as in the case of covalently modified protein,[14] is able to act as a mediator and couples with native GO (Fig. 1 right, trace c).

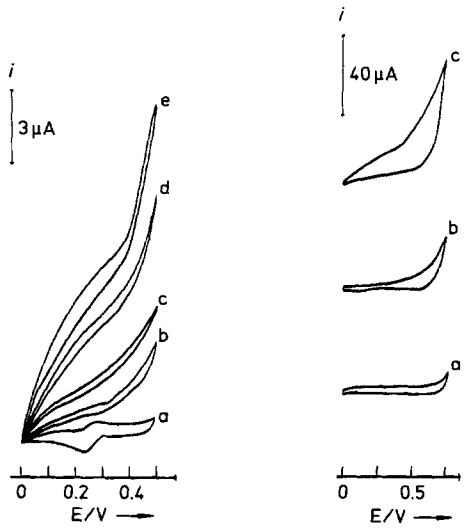

Fig. 1. Left: Cyclic voltammograms of GO modified with FcCOOH at different concentrations of D-glucose: a) 0, b) 0.031, c) 0.046, d) 0.077 and e) 0.154 M. GO 2 mg mL^{-1}. Scan rate 2.5 mV s^{-1}. Right: Cyclic voltammograms of BSA with adsorbed FcH: a) native BSA (2 mg mL^{-1}), b) BSA with adsorbed ferrocene (2 mg mL^{-1}), c) as in b) but in the presence of GO (4 mg mL^{-1}) and D-glucose (0.2 M). Scan rate 5 mV s^{-1}.

In conclusion, the procedures reported enable both covalent binding or adsorption of organometallics on protein surfaces in the reverse micelle microreactors. This may find applications not only in creation of electron relays and new catalysts, but also in the utilization of organometallics as heavy metal probes in electron spectroscopy and other fields of organometallic biochemistry.[8]

Experimental Procedure

GO (β-D-glucose: oxygen 1-oxydoreductase, EC 1.1.3.4) from *Aspergillus niger* and BSA were purchased from Boehringer and Serva, respectively. Dicyclohexylcarbodiimide and *N*-hydroxysuccinimide were obtained from Merck and Sigma, respectively, AOT from Serva, and ferrocene from Reakhim. FcCOOH was prepared as described elsewhere [15]. Cyclic voltammograms were obtained on a potentiostat P-5827M equipped with an XY-recorder. A standard three-electrode cell was used with Ag/AgCl as reference, Pt wire as ancillary, and pyrographite plate (ca. 1.00 cm^2) as working electrode. The latter was always polished with a fine Al_2O_3 powder before the electrochemical measurements. The 2 mL cell was thermostated with water from a 2290 MULTITEMP Thermostatic circulator (LKB). The measurements were made at pH 6.0 (0.1 M phosphate buffer) under aerobic conditions. Potentials are given relative to Ag/AgCl throughout.

GO/Fc-COOH conjugate: GO (30 mg) dissolved in 6 mL borate buffer (0.05 M, pH 9.0) was solubilized in 50 mL of *n*-octane containing AOT (6.67 g, 0.015 mol). Activation of the ferrocene carboxylic groups: FcCOOH (6.3 mg, 0.027 mmol), DCC (6.3 mg, 0.030 mmol), and *N*-hydroxysuccinimide (3.7 mg, 0.027 mmol) were dissolved in 0.25 mL acetonitrile. (Larger amounts of acetonitrile should be avoided because of possible phase separation.) The acetonitrile solution was kept at ca. 5 °C for 30 min, then for 1 h at room temperature, and subsequently added to the enzyme solubilized in reverse micelles of AOT in *n*-octane. The resulting pseudohomogeneous solution was allowed to stand at 20 °C for 24 h and then at 5 °C for 1 h. Cold acetone (100 mL) was added to the mixture to induce the precipitation of GO modified with ferrocene residues. The preparation was centrifuged, thoroughly washed with cold acetone to remove possible admixtures of FcCOOH, and dried in vacuo.

BSA/ferrocene adsorbate: BSA (8.4 mg) was dissolved in the 1.2 mL borate buffer and solubilized in 6 mL of *n*-octane with 1.66 g AOT (0.0038 mol). FcH (1.4 mg, 0.0075 mmol) dissolved in 0.6 mL *n*-octane was added to the micellar solution, and the resulting mixture was kept and worked up as above (18 mL acetone was used).

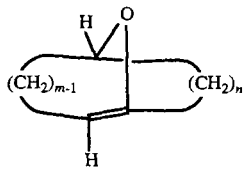
Anti-Bredt Enol Ethers by Transannular Cyclization of Cycloalkynols

By *Heiner Detert, Christina Anthony-Mayer,* and *Herbert Meier**

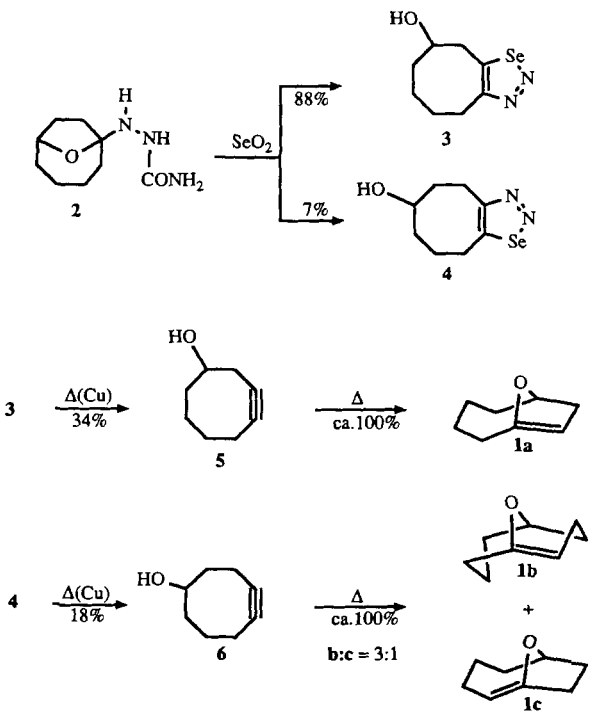
Since the original definition of the Bredt rule,[1] bridgehead olefins have been a challenge for chemists interested in synthesis. Whereas the preparation and the unusual properties of isocyclic anti-Bredt compounds have been the subject of a large number of investigations, heterocyclic systems of this structure variant are almost unknown.[2]

For the isolation of such compounds in pure form, the ring bearing the *trans* double bond must contain at least eight atoms. For the bicyclic enol ethers **1** this condition is satisfied when $m + n \geq 6$. The geometric strain[3] vanishes when $m + n \geq 8$ and $m,n \geq 3$; in oxabicycloalkenes with larger rings, angle deformations should make only a minor contribution to the total steric strain. Of compounds of type **1**, so far only 9-oxabicyclo[3.3.1]non-1-ene ($m = n = 3$), first synthesized by Wiseman, is known.[4, 5]



1 (m,n = 1,2,3...)

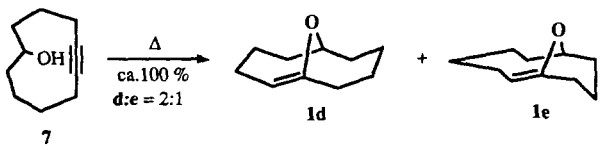
We report here on a new entry to **1** by thermal isomerization of cycloalkynols. In this process the OH group undergoes transannular addition to the triple bond. By starting from cyclooctan-4-ol-1-one semicarbazone, which exists predominantly as an internal semiaminal **2** (readily soluble in dioxane), the 1,2,3-selenadiazoles **3** (m.p. 134 °C) and **4** (oily liquid) can be synthesized.[6] After separation by column chromatography on silica gel, thermolysis at 160–180 °C/15 Torr gives 3-cyclooctyn-1-ol (**5**) and 4-cyclooctyn-1-ol (**6**), respectively.[7]



Above 180 °C the cycloalkynols rearrange completely into the anti-Bredt enol ethers. Whereas **5** is converted regiospecifically into 9-oxabicyclo[4.2.1]non-6-ene (**1a**), **6** gives a 3:1 mixture of 9-oxabicyclo[3.3.1]non-1-ene (**1b**) and 9-oxabicyclo[4.2.1]non-1-ene (**1c**). Although strained cycloalkynes possess a low-lying LUMO,[8] nucleophilic attack of the OH group on the triple bond is unexpected; alcohols normally hydrogenate strained, deformed triple bonds smoothly to double bonds.[9, 10] In this manner (*Z*)-cyclooctene is formed from cyclooctyne.[10]

The anti-Bredt enol ethers are suprisingly stable towards further rearrangements or dimerization. They add water regioselectively under acid catalysis, leading to the corresponding semiacetals and their associated tautomeric cycloalkanolones. Compounds **1a–c** react as electron-rich dienophiles with electron-poor dienes such as tetraphenylcyclopentadienone in inverse Diels–Alder reactions to give the corresponding cycloadducts even at room temperature (with almost quantitative yields).

The question can be raised whether the cycloalkynol–oxabicycloalkene rearrangement is limited to highly strained cycloalkynes, and whether the driving force is the partial relief of strain. For this investigation we have prepared 5-cyclodecyn-1-ol (**7**), again using the selenadiazole method. Compound **7** also rearranges thermally, forming a 2:1 mixture of 11-oxabicyclo[4.4.1]undec-1-ene (**1d**)[11] and 11-oxabicyclo[5.3.1]undec-1-ene (**1e**). This rearrangement is therefore not restricted to strained systems!



7

Compound **7** undergoes a quite different transannular reaction in the presence of acid. Hanack et al. have observed an isomerization with formation of a carbon–carbon bond generating bicyclo[4.4.0]decan-2-one and bicyclo[5.3.0]decan-2-one under these conditions.[12]

Table 1. Selected ^{1}H and ^{13}C NMR shifts of oxabicycloalkenes **1** ($CDCl_3$, TMS int.).

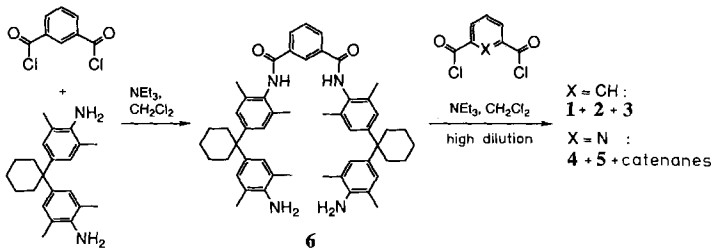
A Binary Quinone Receptor

By *Christopher A. Hunter** and *Duncan H. Purvis*

The photosynthetic reaction centers of purple bacteria contain two quinone binding sites separated by approximately 12 Å.[1] This binary quinone complex functions as a gate between the one-electron chemistry of photoinduced electron-transfer and the two-electron chemistry required to generate stable reduced products.[2] In this communication, we report a supramolecular assembly which has a similar structure and may therefore be capable of performing a similar function.

We recently reported the synthesis of a macrocyclic receptor **1** (Scheme 1), which complexes *p*-benzoquinone by means of H-bonding and π–π interactions (Fig. 1).[3] In addition to the cyclic dimer **1** the reaction also yielded the cyclic tetramer **2** and the [2]-catenane **3**.[4] If 2,6-pyridinedicarbonyl dichloride is used instead of isophthaloyl dichloride in the final step, the cyclic dimer **4** and the cyclic tetramer **5** result (Scheme 1).[5] Catenated products were also obtained, but these have not yet been characterized.



Scheme 1. Synthesis of the macrocyclic receptors.

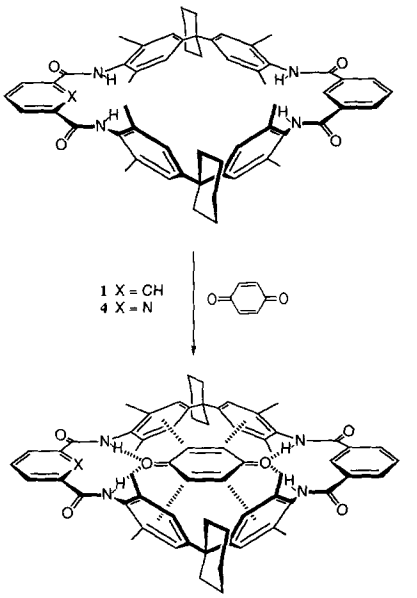


Fig. 1. Complexation of *p*-benzoquinone by **1** and **4**. Intermolecular H-bonds and π–π interactions are shown as dashed lines.

The properties of the cyclic dimer **4** are similar to those of the parent compound **1**: both form 1:1 complexes with *p*-benzoquinone (Fig. 1, Table 1).[6] In contrast, the cyclic tetramers **2** and **5** show very different behavior. The ^{1}H NMR spectrum of **2** is very similar to the spectra of **1** and **6** which suggests that **2** adopts an "open" conformation such as that shown in Figure 2. In contrast, the ^{1}H NMR spectrum of **5** differs significantly from the spectrum of the corresponding dimer **4**. The isophthaloyl signals of **5** are shifted significantly relative to corresponding signals of **4** (Fig. 3). The signals due to the aromatic protons on one side of the ring are shifted upfield which suggests that these protons lie over the face of another aromatic ring. The signal due to the isophthaloyl amide protons is shifted downfield which suggests that these protons are involved in H-bonding. However, the chemical shifts of the pyridyl and diaryl protons of

Table 1. Association constants for *p*-benzoquinone in $CDCl_3$ [M^{-1}] [a].

Compound	K_1	K_2
1	1200	–
2	<1	–
4	1800	–
5	14 [b]	28 [b]

[a] All values are the average of at least five measurements. Errors are ±10%. [b] These values are microscopic association constants which have been corrected for statistical effects. K_1 is half of the observed value and K_2 is twice the experimentally determined value, since in the absence of any cooperativity K_1(observed) = 4 K_2(observed). Errors are ±50% [12].

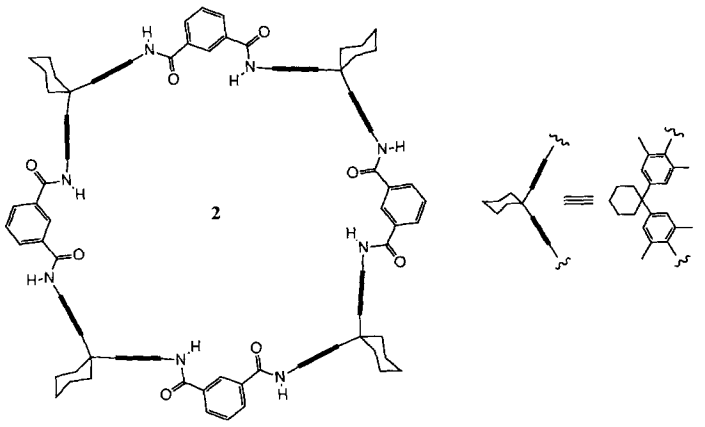

Fig. 2. The open conformation adopted by **2**.

5 are essentially identical to those of **4**. This suggests that these parts of the molecule adopt the same conformation in both compounds, and that they do not interact with the isophthaloyl groups. Thus the two isophthaloyl groups in **5**

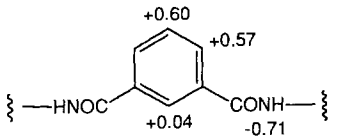

Fig. 3. The changes in ^{1}H NMR δ chemical shifts of the isophthaloyl signals of **5** relative to the corresponding signals of **4**.

must interact with each other, leading to a "folded" conformation (Fig. 4), which is stabilized by two H-bonds and an offset π-stacking interaction.[7]

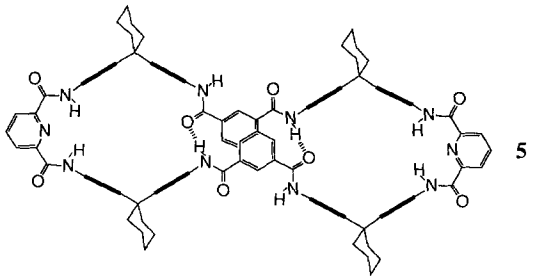

Fig. 4. The folded conformation adopted by **5**.

^{1}H NMR relaxation times provide further evidence for the folded structure of **5** in Figure 4. The pyridine and diaryl protons in **4**, **5**, and **6** all relax at similar rates. However, the T_1 values for the isophthaloyl protons are significantly shorter in **5**, which indicates that these protons are close in space and relax each other. Because of the symmetry of this system, it is not possible to observe this relaxation directly through NOEs.

Molecular mechanics studies of the conformational preferences of the individual subunits provide a clue as to the origin of the difference between **2** and **5** (Fig. 5).[8] The 2,6-pyridyl derivative prefers conformation A which is stabilized by attractive electrostatic interactions between the amide protons and the pyridine nitrogen atom. In conformations B and C, there are unfavorable electrostatic interactions between the pyridine nitrogen and the carbonyl oxygen atoms. In contrast, the lowest energy arrangement for the isophthaloyl derivative is conformation B. These conformational preferences would lead to an open conformation for **2** and a folded conformation for **5** in agreement with the ^{1}H NMR data. Hamilton et al. have recently used a similar effect to control the conformation of 2,6-diacylaminopyridines.[9]

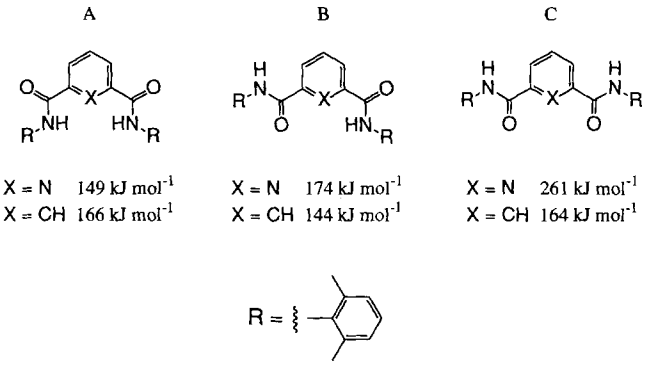

Fig. 5. Conformational preferences of the individual subunits of **2** and **5**. The energies were calculated with the CHARMm force field [8].

These conclusions were tested by subjecting **5** to a NOESY experiment. Figure 6 shows NOESY *f*2 traces through the signals due to the amide protons. NOEs observed in the isophthaloyl subunits are consistent with a type B conformation (Figs. 5 and 6b). In contrast, the signal due to the pyridyl amide protons did not give NOEs to any other aromatic protons which is consistent with a type A conformation (Figs. 5 and 6a).[10] These results provide further evidence for the folded structure of **5** in Figure 4.

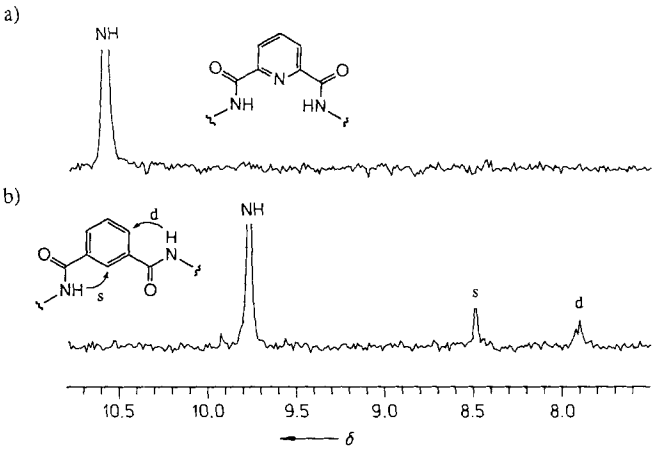

Fig. 6. *f*2 Traces from the 300 MHz NOESY spectrum of **5** in CD_2Cl_2. Interactions leading to NOEs are illustrated on the relevant structures. a) *f*2 Trace through the signal due to the pyridyl amide protons. b) *f*2 Trace through the signal due to the isophthaloyl amide protons.

If **5** does adopt the folded conformation, then it should have two cavities available for the complexation of *p*-benzoquinone. Addition of *p*-benzoquinone to a solution of **5** in $CDCl_3$ caused large changes in the chemical shifts of some of the signals in the ^{1}H NMR spectrum. An exact titration confirmed that **5** binds two molecules of benzoquinone. The

association constants were determined using nonlinear curve-fitting (Fig. 7, Table 1).[11] The titration data in Figure 7b demonstrates that the two binding events are not identical, and the association constants in Table 1 show that there is positive cooperativity in this system.[12] This is a weak allosteric effect and leads to an enhancement of the second association constant by a factor of 2.[12, 13] The benzoquinone signal experiences a large upfield shift on complexation indicating that benzoquinone is in a similar environment to that found in the complexes formed with **1** and **4**.[3]

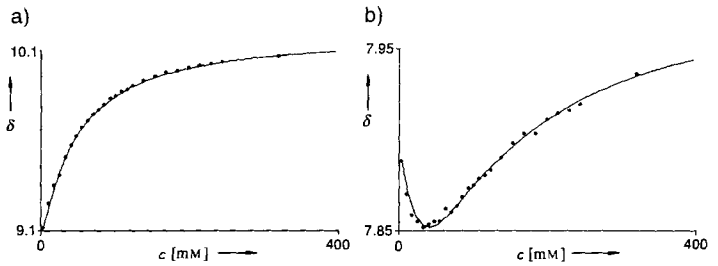

Fig. 7. Titration of *p*-benzoquinone with **5**. The lines were generated by computer-assisted curve-fitting; c = concentration of *p*-benzoquinone. a) Change in chemical shift of the signal due to the pyridyl amide protons. b) Change in chemical shift of the signal due to the isophthaloyl amide protons.

In contrast, addition of a large excess of quinone to a solution of **2** in $CDCl_3$ caused no change in the ^1H NMR spectrum. This confirms that **2** does indeed adopt an open conformation and so cannot complex quinone.

The titration curves in Figure 7 suggest a molecular basis for the observed cooperativity. As far as the pyridyl ends of the molecule are concerned, the first binding resembles the second, producing a simple saturation curve. These NMR signals experience a large downfield shift indicative of H-bond formation. However, the isophthaloyl signal shows quite different behavior. The binding of the first quinone causes an upfield shift of the signal due to the amide protons suggesting a decrease in the extent of H-bonding. The binding of the second quinone causes a large downfield shift indicating an increase in the extent of H-bonding.[14]

These results are consistent with the binding mechanism shown in Figure 8. Complexation of the first molecule of quinone causes a conformational change in **5** so that it can form four H-bonds with the quinone. The conformational change in one of the binding sites pulls the isophthaloyl groups apart and disrupts the intramolecular H-bond in the second binding site. Thus the second quinone molecule does not have to compete with a strong internal H-bond and is complexed more readily. The energy required to effect these conformational changes and break the intramolecular H-bonds would account for the lower association constants observed for **5** as compared with **1** and **4**.

Macrocycle **5** reproduces some of the essential features found in biological macromolecules: 1) The macrocycle folds into a well-defined three-dimensional structure as a result of noncovalent interactions. 2) This folding generates two cavities for complexing substrates. 3) Allosteric interactions make the second binding even more favorable than the first.

These results demonstrate that the conformational preferences of individual subunits can be used to control three-

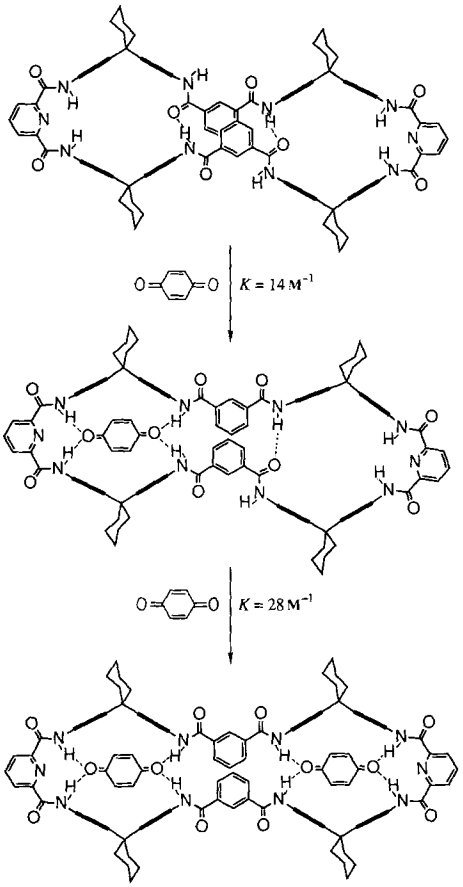

Fig. 8. Complexation of *p*-benzoquinone by **5**. The association constants are microscopic association constants. H-bonds are marked as dashed lines. The dotted line in the 1:1 complex represents a weak H-bond.

dimensional structure and folding in such systems. This should prove useful in the design of future receptors. In the system described here, two quinones are bound in close proximity in an arrangement which is very similar to that found in the quinone-binding domains of the photosynthetic reaction centers of purple bacteria.[1] Similar functional properties may result.

[8] Energy minimizations were carried out with the CHARMm force field (B. R. Brooks, R. E. Bruccoleri, B. D. Olafson, D. J. States, S. Swaminathan, M. Karplus, *J. Comput. Chem.* **1983**, *4*, 187). Solvent was not included. In our hands, this force field failed to reproduce experimental observations for large supramolecular systems due to inadequacies in the treatment of intermolecular forces [4, 7]. However, for relatively small molecules such as those in Figure 5, the force field seems to give results which are reliable at least in a qualitative sense.

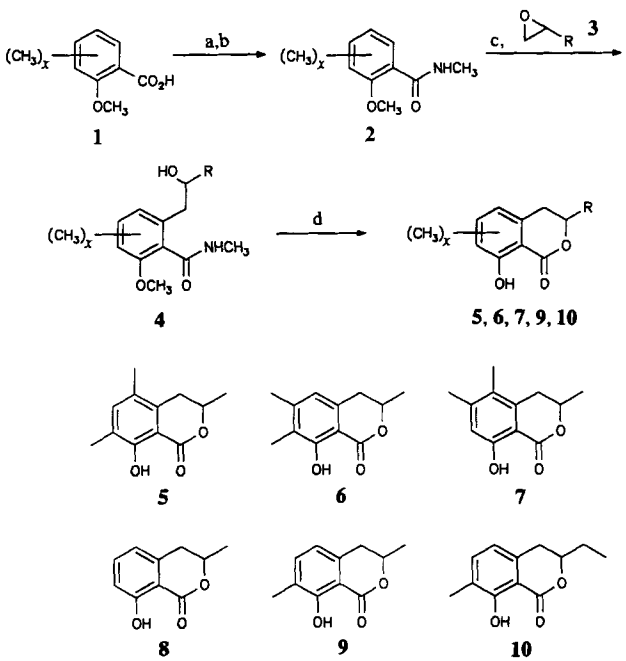
[14] Changes in the geometry of the offset π-stacking interaction may also contribute to the change in the chemical shift of the signal due to the isophthaloyl amide protons.

3,4-Dihydroisocoumarins, a New Class of Ant Trail Pheromones**

By *Hans Jürgen Bestmann*, Friedrich Kern, Doris Schäfer,* and *Matthias Christian Witschel*

Trail pheromones are mainly used by ants for marking the trail between the feeding place and the nest. Until now they have been found mostly in the venom and Dufour glands of the animals, and have been identified as alcohols, aldehydes, esters, nitrogen heterocycles, and terpenoid compounds.[1] The most common ant genera in Germany are *Formica* and *Lasius*, which belong to the Formicinae subfamily (Hymenoptera, Formicidae). Their trail pheromones have hardly been studied at all up to now.[2, 3] They are, however, of general interest, since *Formica* species are important from an entomological viewpoint in many biotopes, and several species of *Lasius* constitute insect pests for humans.

In the species we have studied, unlike other subfamilies, the trail pheromone is found in the hindgut (rectal sac),[1] which has been analyzed by us for the first time. Since the biologically active substance is present only in picogram quantities, identification and structure elucidation were only possible by GC-MS analysis using a solid-phase sampler,[4] and by comparison of mass spectra and GC retention times with those of synthetic material. For the formicine ant, *Lasius niger*, the GC-MS data indicated the possible presence of a 3,4-dihydro-8-hydroxytrimethylisocoumarin with a methyl group in the 3-position of the lactone ring. Compounds **5**, **6**, and **7** were therefore synthesized. The preparation of the 3,4-dihydroisocoumarins proceeded according to Scheme 1, starting from the readily available, substituted 2-methoxybenzoic acids **1**.



Scheme 1. a) $SOCl_2$; b) NH_2CH_3/H_2O, 0 °C; c) 2.4 equiv. *s*BuLi/TMEDA, THF, −78 °C, 4 h, then epoxide **3**/THF, −78 °C → room temperature, 12 h; d) 5 equiv. BBr_3/CH_2Cl_2, −78 °C → room temperature, 12 h, HCl workup, SiO_2 chromatography, Et_2O/PE (1/1).

These were converted into the N-methylamides **2**, which were then lithiated in the *ortho* position with *s*BuLi/*N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) at −78 °C.[5, 6] Reaction of the lithiation product with the corresponding epoxide **3** gave adduct **4**, and subsequent ether cleavage and lactonization with BBr_3[7] led, after column chromatography (SiO_2, Et_2O/petroleum ether (PE) = 1/9), to the 3,4-dihydroisocoumarins **5**, **6**, and **7** (purity by GC >98%) in 10–15% overall yield. When enantiomerically pure epoxides were used, the individual enantiomers could also be obtained, without racemization (*ee* > 95%).

A comparison of the mass spectra (Table 1) of **5**, **6**, and **7** showed characteristic differences caused by *ortho* effects[8] on the arene. The mass spectrum of synthetic **5** was identical with that of the natural product (IV in Fig. 1). In a biotest,[2] **5** triggered trail-following behavior at concentrations of

[**] Pheromones, Part 86. This research was supported by the Deutsche Forschungsgemeinschaft and the Volkswagen Stiftung. We thank Prof. U. Maschwitz (Frankfurt) for the use of his ant colony and Prof. I. Hasenfuss (Erlangen) for the identification of the ant species. – Part 85: H. J. Bestmann, W. Caihong, C. Rehefeld, F. Kern, B. Leinemann, *Angew. Chem.* **1992**, *104*, 353–354; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 330–331.

500 pg/trail. Biological selectivity tests were carried out with both enantiomers of **5**. When trails of the two enantiomers were offered to the ants, the animals always preferred the (*R*) enantiomer, and we therefore assign the (*R*) configuration to the natural product. We found additional isocoumarins in the rectal sacs of several *Formica* species. The monomethyl compound **8** (Mellein)[9] was identified from the red wood ant *Formica rufa*, and it led to trail-following behavior in the biotest.

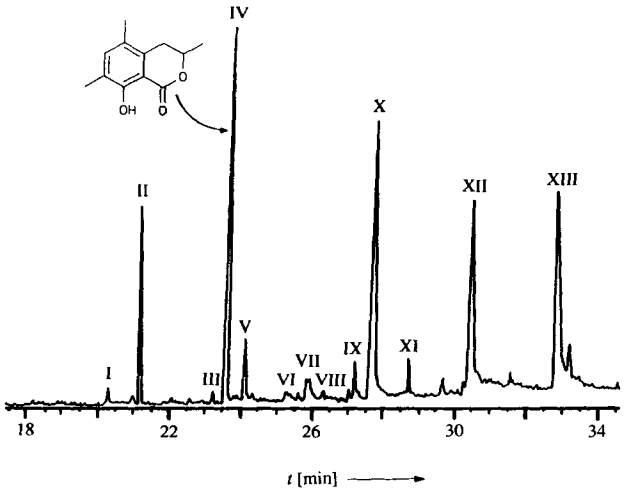

Fig. 1. Reconstructed total ion current chromatogram of forty rectal sacs of the formicine ant *L. niger*. GC-MS combination: Finnigan MAT 90 with Varian GC 3400, carrier gas He 1 mL min^{-1}, EI source 70 eV. Solid-phase sampler without splitting, fused silica capillary column (25m x 0.22mm) with SE-52 coating. Temperature program: 4 min 60 °C, 6 °C min^{-1} to 260 °C. I dodecanoic acid, II dodecyl acetate, III heptadecane, IV 3,4-dihydro-8-hydroxy-3,5,7-trimethylisocoumarin, V tetradecanoic acid, VI isopropyl tetradecanoate, VII octadecane, VIII hexadecanol, IX hexadecenoic acid, X hexadecanoic acid, XI isopropyl hexadecanoate, XII octadecenoic acid, XIII tricosane.

Mellein **8** and compound **5** were also found in *Formica fusca*. However, in this species, trail following could not be induced either by glandular extracts or by the synthetic compounds. In *Formica sanguinea* both the dimethyl derivative **9** and the 3-ethyl-7-methyldihydroisocoumarin occur. Here, too, neither these compounds nor the gland extracts stimulate specific behavior. The syntheses of **9** and **10** were carried out analogously to those of **5**, **6**, and **7**.

Electroantennograms (EAG) of ants have been reported in the literature only very rarely,[10, 11] and never in connection with and chemical–analytical studies. We have carried out electrophysiological tests on the species described, and have compared the results with those of the behavioral tests (Table 2).

All the isocoumarins found in the hindguts of the animals are active in the corresponding EAG, even those of *Formica fusca* and *Formica sanguinea*, for which the chemical signals alone did not induce trail-following behavior. The 8-hydroxydihydroisocoumarins found in various species are active interspecifically in the EAG, although the species-specific compounds have the highest biological activity. Dihydroisocoumarins from other species cannot, however, induce trail-following behavior in the biotest. In *Lasius niger* both (*R*)-**5** and (*S*)-**5** display electrophysiological activity, although the (*R*) enantiomer is the more active of the two, in accordance with the biotest.

Table 2. Components of hindguts of various Formicinae and their biological activity in the EAG and the trail-following test. (+ indicates biologically active, – biologically inactive).

Species	Biologically active components of the hindguts	EAG	Trail-following test
Lasius niger	3,4-Dihydro-8-hydroxy-3,5,7-trimethylisocoumarin(**5**)	+	+
Formica rufa	3,4-Dihydro-8-hydroxy-3-methylisocoumarin (Mellein, **8**)	+	+
Formica fusca	3,4-Dihydro-8-hydroxy-3,5,7-trimethylisocoumarin(**5**)	+	–
	3,4-Dihydro-8-hydroxy-3-methylisocoumarin (Mellein, **8**)	+	–
Formica sanguinea	3,4-Dihydro-8-hydroxy-3,7-dimethylisocoumarin (**9**)	+	–
	3,4-Dihydro-8-hydroxy-3-ethyl-7-methylisocoumarin(**10**)	+	–

The comparison between EAG responses and the behavioral test shows that at biologically relevant concentrations, the receptors located on the antennae are capable even of stereospecific differentiation. This stereospecificity in the primary process of signal uptake is augmented by the fact that in signal processing by the central nervous system, only the signal pattern (information) arising from the pheromone of the correct species will lead to a specific behavior pattern. We assume that the lack of behavioral response to the EAG-active compounds **9** and **10** in *Formica fusca* and *Formica sanguinea* is due to a requirement for additional behavioral rituals, or because chemical components from other glands are absent.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Physical Chemistry from Ostwald to Pauling. The Making of a Science in America. By *J. W. Servos*. Princeton University Press, Princeton, NJ, 1990. XXIII, 402 pp. hardcover $ 49.95.—ISBN 0-691-08566-8

Physical chemistry is not a particularly easy subject to define. In fact, it is difficult to go beyond the obvious and rather vague assertion that physical chemistry is a discipline that is sandwiched somewhere between physics and chemistry. But where physics and chemistry end and physical chemistry takes over has never been adequately defined and probably never can be. In spite of this, however, it cannot be denied that this discipline is now firmly entrenched as a key part of chemistry, and that since the 1930s it has come to be regarded by most chemists as the foundation for all of chemistry. Physical chemistry provides the theoretical underpinning of chemistry; its laws characterize the behavior of a vast array of chemical systems. Its many striking successes have been reflected in the steady growth of the discipline since its initial coalescence in the 1880s. With hindsight, it can now be seen that the emergence of physical chemistry was inevitable. In 1786 the German philosopher Immanuel Kant had suggested that the amount of actual sience in any discipline could be represented by the amount of mathematics that it contained. Perhaps not surprisingly, he concluded that the chemistry of his day would not qualify as one of the natural sciences. We have come a long way since this remark was made. The ever increasing use of mathematics in chemistry over the last two centuries has resulted in chemistry as a whole—and physical chemistry in particular—becoming a highly mathematized discipline. One sign of the inexorable trend towards mathematization has been the establishment of journals devoted to ever more mathematically orientated chemistry. As examples, mention might be made of the *Zeitschrift für Physikalische Chemie* (1887), the *Journal of Physical Chemistry* (1896), the *Journal of Chemical Physics* (1933), *Theoretica Chimica Acta* (1962), and the *Journal of Mathematical Chemistry* (1987).

The book by John Servos traces the development of physical chemistry for the first fifty years of its existence as an organized and separate discipline, that is, it covers the period from the 1880s through to the mid 1930s. The author's prime focus is the emergence of the new discipline on the North American continent. The story of the transmission of physical chemistry from its European homeland to the New World is painstakingly chronicled. It is a story that is not without irony, for, as we all know, that transmission was so effective that ultimately the United States was to eclipse Europe in physical chemistry. The pivotal figure in the establishment of the discipline in America was the German founding father of physical chemistry, the genial and dynamic Wilhelm Ostwald, whose life and times are richly documented in this book. Over a period of some 17 years Ostwald hosted a total of 44 American students in his laboratories at the University of Leipzig. When these returned home they were in many instances to exert tremendous influence, for Ostwald's students included some of the most illustrious names in American chemistry, such as the bonding theorist Gilbert N. Lewis and the Nobel Prize winning experimentalist Theodore W. Richards. Most of them were to eventually occupy powerful positions at prestigious institutions such as Harvard and Yale Universities and the Massachusetts Institute of Technology (MIT).

From Chapter 3 onward the book examines some of the major consequences of the very rapid growth of physical chemistry in the New World during the early part of the twentieth century. As might be anticipated, not all was roses, and strains inherent in the fabric of the discipline began to reveal themselves, and in some cases opened up into yawning chasms. As the author aptly puts it, physical chemistry was beginning to resemble the Holy Roman Empire with its constellation of duchies and principalities that were no longer parts of a functional whole. One rancorous difference of philosophy occurred between the proponents of an ever greater mathematization of the subject and those who felt that mathematics was alien to chemistry. Two former Ostwald students typified the battlelines that were drawn. Arthur A. Noyes at MIT was an enthusiast for all things mathematical, and selected his co-workers on the basis of their grounding in mathematics and physics, whereas Wilder D. Bancroft at Cornell University had a distinct distaste for mathematics, and maintained that physics was no more than "chemistry pure and simple". In spite of such differences, however, both enjoyed successful careers in their respective ways. Noyes was responsible for the construction of the first American institution dedicated to physical chemistry at MIT, which was to become one of only two or three in the world that shaped the contours of the discipline in the early twentieth century. Bancroft was the founder and editor of the *Journal of Physical Chemistry*, became a leading supporter of, and wrote the first monograph on, the Phase Rule of J. Willard Gibbs, and was elected President of the American Chemical Society. Another of the results of the rapid evolution of the field was the marked trend towards fragmentation that became especially evident in research activities. Whereas the pioneers had been jacks of all trades, their successors became increasingly specialized, almost to the point where different sub-disciplines of physical chemistry came to be jealously guarded fiefdoms. The emergence of chemical physics in the late 1920s and early 1930s represented yet another parting of the ways, though in the event it proved to be less traumatic than it might have been. This was largely because the two major American protagonists, Robert S. Mulliken and Linus Pauling, were not given to adversarial tactics, preferring instead a more emollient approach that certainly helped to heal the rift that had arisen between physicists and physical chemists. Their great merit was to present chemical bonding theory in a manner that was both readily understandable to chemists and consistent with quantum mechanics. In performing this signal service to all chemists they accomplished one of the truly great feats of twentieth century chemistry.

All of the above history, and much more, is explored in meticulous detail in this book, In fact, the author presents us with such a mine of information that one is tempted to dip into it time and again. It is not surprising that it took the author some ten years to compile all this material. The book is very well written and the author is to be congratulated on a job well done. I predict that this work will become a classic of its kind, and will remain an important source of reference on the early development of physical chemistry for many years to come. If I have any criticism of this book, it would concern the organization of the abundant material it contains. At times I found it difficult to locate specific facts and information on the lives of the physical chemists it covers. Their lives and their various contributions to physical chemistry tend to be discussed in several different chapters. I would have preferred each of the major figures such as Gilbert N. Lewis and Linus Pauling to have been treated in easy-to-find chapters. However, I would not wish to harp on this minor criticism, for the book as a whole more than compensates us for the time spent reading it. I recommend that this work be read by all who wish to learn something of the origins of physical chemistry in the New World.

Chaotic Evolution and Strange Attractors. By *D. Ruelle*. Cambridge University Press, Cambridge (UK), 1989. VIII, 96 pp., paperback £ 8.95.—ISBN 0-521-36830-8.

The author of this little book is an internationally recognized expert in the theory of complex dynamic systems, especially of turbulence phenomena. In it he summarizes a series of lectures that he delivered in 1987 at the Accademia dei Lincei in Rome. The book is divided into two parts. The first describes the phenomenon of turbulence and discusses some of its characteristics, taking low-dimensional chaotic attractors as an example. Here the author is on familiar ground. Deterministic chaos—a class of irregular states of complex dynamic systems that are extremely sensitive to changes in the initial conditions—has become such a popular area of study during the last five years that every scientist has at least heard of it. The author deals in depth with the fundamental question of how it is possible to conclude, from an irregular time-series of recorded data, that the phenomenon being observed is the result of a chaotic attractor and not of accidental fluctuations. He also introduces the concept of fractal dimensions, which is essential for an understanding of chaotic dynamics.

The second part of the book is concerned with deterministic chaos as viewed from the standpoint of the ergodic theory. Here the author moves to the frontier of present knowledge, as this is one of his specialist topics of research. This inevitably involves a detailed discussion of measurement theory, the mathematical basis of which is far from simple. In developing a description of chaotic dynamics the characteristic exponents are of fundamental importance, and these are directly related to the dimensionality and entropy of the attractors. In the final section the author deals with another topic that is currently much discussed in specialist circles, the phenomenon of "resonances" in dynamic systems, which are caused by singularities in the complex representation of the frequency spectrum. They are directly related to the relaxation behavior of the system as a function of time. As the author himself rightly points out in summarizing his conclusions, the relationship between theory and the treatment of experimental data is covered too briefly in this review. Moreover, this is a field of research that has undergone great developments in the last decade. Still, what more can one expect from a little book of only about a hundred pages?

In it the author gives a very concise and well written summary of the present state of knowledge on the theory of deterministic chaos. It can be recommended to all scientists with an appropriate background and the necessary mathematical knowledge. However, it is not an introduction to this field. Chemists and physicists without previous knowledge who wish to learn about complex dynamic systems should read other texts. There is no lack of suitable introductions to the subject.

Peter Schuster

der Universität Wien (Austria)

The Chemical Synthesis of Peptides. (International Series of Monographs on Chemistry, Vol. 23.) By *J. Jones*. Oxford Science Publications, Clarendon Press, Oxford, 1991. IX, 228 pp., hardcover £ 35.00.—ISBN 0-19-855643-8

The author of this book has estimated that about 5000 people are now engaged in peptide research. The growing importance of peptide chemistry is further underlined by the fact that the number of publications each year in this field has now increased to well over a thousand, and the upward trend is continuing. Starting from the fundamental studies of the structure and synthesis of peptides by the German Nobel prizewinner Emil Fischer, scientific activity in the area of peptide synthesis spans nearly a century. Important milestones in this development include the first laboratory synthesis of a peptide hormone by Vincent du Vigneaud in 1953 (see pp. 115–119 of this book), and ten years later Bruce Merrifield's experimental realization of the ingenious idea of carrying out a peptide synthesis on a polymeric support (pp. 132–156). Many different types of apparatus for synthesizing peptides are now commercially available, and their operation is almost fully automated. This situation, and the more recent application of the DNA recombination technique to peptide synthesis, often convey to outsiders the impression that the problem of synthesizing peptides is completely solved and now belongs to the category of routine methods. That this is a serious misconception is convincingly argued by the author of this book.

The nine-page general introduction explains clearly why synthetic peptides are needed, how structure-activity studies are used to develop peptides for medical purposes, and the advantages of developing peptide chemistry in conjunction with the DNA recombination technique. Furthermore, it should be noted that of the 59 peptide pharmaceutical agents listed in the "red book" in 1990, 29 are produced by chemosynthesis and only nine by modern genetic engineering methods.

The first part of the book deals with the basic principles and the chemistry of peptide synthesis, and the newcomer will undoubtedly regard this as the most important part; it is pleasing that the mechanistic aspects are adequately covered here. In a skillful didactic presentation of material that is expertly chosen from the large fund of information on synthetic methods, the reader is equipped with the essential basic knowledge. The chapter on "Residue-specific Considerations" not only deals with side-chain protection in trifunctional amino acids, but also gives valuable advice on appro-

priate tactics for syntheses using particular building units, and includes a page and a half on the use of enzymes in peptide synthesis.

In the second and third parts the author discusses examples which illustrate the considerable difficulties involved in the strategy of peptide synthesis, and which show that a single generally applicable method does not exist. All the known variants have their advantages and disadvantages, and in the end the success or failure of a synthesis is determined by experience and skill. While not disputing the fact that the Merrifield method has made a very important contribution to progress in the field of peptides and proteins, the author emphatically warns the reader against having too high expectations of this strategy. This is illustrated by a quotation from the sales literature for a commercial synthesizer: "You don't have to be an expert to synthesize a peptide... Simply enter your sequence, ...push 'Start Synthesis', and walk away."

To summarize, the book offers a critical and up-to-date account of the chemical principles of peptide synthesis, and by limiting the subject matter it has been kept very compact. Inevitably a few topics are omitted; for example, the discussion of the Leuchs anhydrides contains no reference to so-called UNCAs. The bibliographies given at the end of each chapter and section are expertly selected, and Appendix B gives a useful further list of references. In Appendix A the many abbreviations are clearly explained. The subject index appears to contain an adequate selection of keywords, but, as in nearly all books, it does not exploit the full potential.

The book is a valuable aid for the newcomer to chemical methods of peptide synthesis, although by its nature it requires the reader to have a basic knowledge of organic chemistry. Its main attraction is that practically every chapter is packed with a wealth of useful detail, a fact that even the specialist will only come to appreciate after studying it closely.

Fachbereich Biowissenschaften
der Universität Leipzig (FRG)

Microscale Techniques for the Organic Laboratory. By *D. W. Mayo, R. M. Pike, S. S. Butcher* and *P. K. Trumper*. Wiley, Chichester, 1991. XVIII, 285 pp., paperback £ 19.20.—ISBN 0-471-62192-7

A significant difficulty that arises in the training of chemistry students is making the transition from techniques suitable for working with relatively large quantities of substances, as already learned, to those needed for carrying out reactions with semi-micro and micro quantities. The failures that so often result would be less serious if, during their basic or advanced practical work, students could learn the rules for working successfully with small quantities of substances. This is the problem that the authors have addressed in the book reviewed here. Under the motto "smaller is better", they have based their discussion on experience gained during a program that has run for about ten years in their own teaching departments. The term "microscale" here refers to quantities in the millimole range, i.e., up to about 200 mg. Practice in using such small amounts of substances has other advantages as well as teaching students to work with special care: it reduces the cost of chemicals, and leads to increased safety, improved air quality in the laboratory, and (of ever growing importance) a reduction in waste disposal problems.

The book is divided into seven chapters. Following a short general introduction and some comments about safety in the laboratory, the authors introduce the apparatus needed for microscale reactions and the basic working techniques. Next comes a short chapter on methods for determining physical properties. An appropriate amount of space is then devoted to methods for isolating and purifying organic compounds, which often determine the difference between success and failure when working with small quantities; all the most important techniques are covered (extraction, distillation, crystallization, and the various forms of chromatography—thin layer, column, gas, and HPLC). The last two chapters deal with the techniques and theoretical background needed for spectroscopic characterization of the compounds that have (hopefully) been isolated by the foregoing methods. Of these two, the chapter on IR spectroscopy is very thorough and detailed, whereas the treatment of NMR spectroscopy is rather cursory. This traditional preference for IR spectroscopy in teaching students does not really imply that IR spectra contain more information for the identification of organic compounds (the authors' remarks on this point are surely not meant to be taken too seriously); it is based rather on the fact that an IR spectrum can be recorded quickly and cheaply, and the student can easily learn the technique.

The main strength of this book lies in the many useful ideas and tips that are included, providing information that is essential for working with microscale quantities. One is reminded here that chemistry is not only a science, but also a craft (and sometimes an art). Thus the book contains much advice that is relatively simple, but not immediately obvious to the student: for example, on how to transfer a small quantity of a substance from one vessel to another. It also describes forms of apparatus that are impressive and of interest for use in the research laboratory, such as a rotating band distillation column, driven by a magnetic stirrer, for separating liquids on the milliliter scale (also used as a cover illustration for the book). The presentation aspects of the book are also pleasing; it is practically free of printing errors and factual inaccuracies, the numerous figures are all of good quality, and the price is not too high. It can therefore be recommended without hesitation as a basis for student practical classes, and will also provide research chemists with many useful ideas.

Houben-Weyl. Methoden der Organischen Chemie. Band E19c: Carbokationen, Carbokation-Radikale. Series Editors: *K. H. Büchel, J. Falbe, H. Hagemann, M. Hanack, D. Klamann, R. Kreher, H. Kropf, M. Regitz* and *E. Schaumann*. Volume Editor: *M. Hanack*. Thieme, Stuttgart, 1990. XVII, 550 pp., hardcover DM 720.00.—ISBN 3-13-219804-8

As the third of the volumes on reactive intermediates in the Houben-Weyl series, that on carbocations and carbocation radicals has now appeared. Following the volume by P. Vogel that was published in 1985, and several review articles covering the field in varying degrees of detail, it was now appropriate to collect together the latest knowledge in a single volume. The introduction (Lenoir, Siehl; 73 pp.) starts with a short historical outline, then describes the preparation of cations in the gas phase and in solution. All the commonly used, and also the more rarely used, methods are described and explained, supported by literature references. Several diagrams showing apparatus for generating cations are in-

cluded, so that the non-specialist too is given some insight into the complexities of this field. Methods for detecting and studying cations are described, devoting special attention and an appropriately large amount of space to NMR spectroscopy, which is the most important method. It is pleasing to find that, as a general principle, efforts have been made to link the experimental data to quantum mechanical calculations (IGLO or geometric optimization methods). In this connection, however, it is regrettable that the theoretical methods have not been given a separate chapter. Also, experience has shown that ab-initio calculations offer an extremely useful and precise tool for determining the structures of carbocations. Apart from this, the introductory chapter is very appropriate as a readily understandable overview for the beginner, as well as giving the specialist a survey of the latest research position.

The main part of the volume covers all the theoretically conceivable forms of carbocations. After dealing with carbocations that are only of theoretical interest, the discussion moves on to the carbocation radicals that are important in preparative electrochemistry. In the chapter on preparative methods for these (Subramanian; 20 pp.), detailed laboratory recipes for syntheses under electrolytic conditions are given, supplemented by extensive tables. 1-Alkenyl cations are treated in great detail (Hanack, Subramanian; 154 pp.); the authors are the leading workers in this area. The next chapter (Lenoir, Siehl; 157 pp.) deals with classical cations having coordination number 3, including alkyl-, cycloalkyl- and heteroatom-substituted cations, as well as aromatic, homoaromatic and special types of destabilized cations; here again there is an emphasis on the preparative aspects. The authors have collected together a remarkable number of reactions that proceed via carbocations as intermediates, in a presentation that includes numerous tables and selected examples of synthetic methods.

Next there is a short chapter (Siehl, Lenoir; 28 pp.) on hypercoordinated non-classical cations. The authors have been remarkably successful in showing the relationship to synthetic chemistry, despite the fact that these species are usually only mentioned in passing as "exotic molecules". The last two chapters are concerned with di- and polycations (Siehl, Lenoir; 14 pp.) and with carbocations in organometallic compounds (Lenoir, Siehl; 3 pp.).

The general subject index is very scanty (5 pp.), making it difficult to search for particular compounds and methods. Moreover, the system used in the formula index is unnecessarily complicated, causing problems when one is searching for compounds. An alphabetical arrangement or a listing according to increasing number of carbon atoms would have made things much easier. Many of the cations have come to be generally known by trivial names; such an excellent book as this should, in my opinion, have been provided with a comprehensive keyword index.

In conclusion I might mention a few unsightly errors. The Coates cation appears in two figures (one below the other) with the different systematic names "Pentacyclo-[4.3.0.$0^{2,9}$.$0^{3,5}$.$0^{4,8}$]non-9-yl-Kation" and "Pentacyclo-[3.3.1.$0^{2,4}$.$0^{3,7}$.$0^{6,8}$]non-9-yl-Kation". This appears not to be an accidental error, since it is stated that the Coates cation is formally a polycyclic derivative of the bicyclo[2.2.1]hept-2-en-7-yl cation. Unfortunately the representations of the trishomoaromatic cations are all incorrect at the critical positions. The equations for the reactions leading to the formation of the bishomoaromatic 7-norbornenyl and 7-norbornadienyl cations are also incorrect. The "λ" nomenclature caused me a certain amount of difficulty when I came across it for the first time, and was unable to find the explanation even after a lengthy search. Also it takes a little time to get used to the names 1-methylethyl cation (instead of 2-propyl cation) and 1-methylpropyl cation (instead of 2-butyl cation). The convention of showing the cationic center in bold type is a useful aid to understanding, but has not been applied consistently. Instead of the adjective "quantenmechanisch" it would be more correct to write "quantenchemisch", since even ab-initio calculations rely on assumptions and approximations, and therefore fall short of exact quantum mechanics. The individual chapters are divided up in a way that is very confusing. It would have been desirable to keep to a uniform system, and to severely limit the number of different levels of sub-headings. The figures are up to the usual high standard found in Houben-Weyl. In a volume containing over 3000 structural formulas, one can excuse the few isolated errors—the vast majority of the formulas are correct. By bringing together a great wealth of data and presenting the information in a clearly understandable form, the authors have succeeded in producing a comprehensive work of reference that will be a valuable aid to everyone concerned with carbocations. Furthermore, the superb compilation of carbocation reactions will be of great value to the synthetic chemist. The inclusion of the rather theoretically and mechanistically orientated topic of carbocations within the Houben-Weyl series, which is usually associated mainly with preparative organic chemistry, has proved highly successful.

Chirality – From Weak Bosons to the α-Helix. Edited by *R. Janoschek*. Springer, Berlin, 1991. XI, 246 pp., hardcover DM 168.00.—ISBN 3-540-33920-4

It is hard to think of a property more fundamental, more ubiquitous, more fascinating than the one that gives rise to the distinction between an object and its mirror image. That property is handedness, or chirality, and it arises whenever an object is not invariant under improper rotation. Such an object must then necessarily exist in two, and only two, isometric but nonsuperposable forms, one "right-handed" and the other "left-handed". Chirality, in its many and varied manifestations, permeates all branches of the natural sciences and of the arts. The present volume is a collection of articles designed to provide an interdisciplinary overview of a small part of this vast subject. Considering the range of subject material covered, the authors have succeeded remarkably well in meeting their objective, that of writing "for anybody with a sound scientific education", and "not [just] for specialists in their respective fields of research".

The discovery, in 1956, that parity is not conserved for the weak interactions governing β-decay has led to our present-day understanding that matter is inherently chiral at the most fundamental level. In the introductory chapter of this collection, Latal describes the nature of elementary particles, develops the Dirac equation and the theoretical basis for the idea that particles and antiparticles possess opposite helicities (as in left-handed electrons and neutrinos, and right-handed positrons and antineutrinos), and shows how the unified theory of electromagnetic and weak forces (involving weak neutral bosons) leads to the prediction of parity-violating effects in atoms. Thus, all atoms are in principle optically active, although the effect is tiny and has so far been observed only in heavy atoms (e.g., Pb, Bi). Translated from the

atomic to the molecular level, the parity-violating weak neutral current perturbation lifts the degeneracy of space-inverted enantiomers. The energy difference is only approximately 10^{-17} kJ mol^{-1}, and corresponds to an excess of just *one* molecule of D- or L-alanine in a racemic mixture of 10^{17} alanine molecules in thermodynamic equilibrium at terrestial temperatures. Ab initio calculations indicate that the predominant isomer has the L configuration. Janoschek argues that this minuscule bias, appropriately amplified, is responsible for the fact that all metabolically functional biopolymers are monochiral, both at the monomer level (L-α-amino acids, D-sugars) and in the helical polymer conformations (right-handed polypeptide α-helix, B-DNA), i.e., that the monochirality of the molecules of life has its origins in the systematic chiral bias of the elementary particles. Various amplification mechanisms are described in support of this thesis. However, the reader is cautioned that "any hypothesis on long term processes such as homochirality evolution will most probably remain experimentally unproven for ever."!

After a brief discussion of Kauzmann's "principle of pairwise interactions", Derflinger gets to the heart of his subject: a vigorous critique of the theory of chirality functions developed by Ruch and Schönhofer that focuses on the concept of "qualitative completeness". He thus revives a controversy that had erupted briefly in the pages of *Theoretica Chimica Acta* in 1978. Because only one side of the story is told in this chapter, the reader needs to be made aware of two rebuttals, neither of them cited here, by Ruch (*Theor. Chim. Acta* **1978**, *49*, 107) and by Mead (*Theor. Chim. Acta* **1980**, *54*, 165). The discussion of two other controversial concepts, "qualitative supercompleteness" and "hyperchirality", is equally partisan in tone. The chapter concludes with a description of a method for enumerating enantiomeric pairs.

Snatzke reports on various methods that are employed to specify the sense of helicity in molecules, points out ambiguities (a short path of a three-dimensional curve can be approximated by either a right- or a left-handed helix), and discusses rules designed to correlate the absolute structures (configurations) of chiral chromophores with the signs of appropriately chosen circular dichroism bands. Surprisingly, there is no reference to the excellent review on helical molecules in organic chemistry by Meurer and Vögtle (*Fortschr. Chem. Forsch.* **1985**, *127*, 1). The theme of absolute configuration is also featured in a chapter by Kratky, in which anomalous dispersion of X-rays is described as the method, pioneered by Bijvoet, used to determine the sense of chirality of molecules in crystals with respect to a macroscopic (absolute) reference frame.

The need for enantiomeric purity is particularly acute in pharmacology and medicinal chemistry. This explains why four of the ten essays in this collection are devoted to strategies for the production of enantiomerically enriched (and, in the limit, enantiopure) compounds. Faber and Griengl describe the use of enzymes as efficient, cheap, and highly enantioselective biocatalysts in the preparation of optically active alcohols, amines, and acids (e.g., enzymatically catalyzed asymmetric reductions of ketones and hydrolyses of *meso* diesters). Winterfeldt distinguishes, and illustrates with examples, three general methods for achieving enantiomeric purity: by resolution of racemates, by reactions whose educts are enantiopure natural products, and by enantioselective reactions or asymmetric syntheses. Brunner discusses the use of chiral transition metal complexes as catalysts in asymmetric syntheses (e.g., hydrogenation of olefins with Rh complexes of Diop). Strategies for the separation of enantiomers by liquid column chromatography are the subject of a chapter by Lindner. The nature of chiral recognition between the mobile and stationary phases determines resolution efficiency; column packings are classified, and compared, according to type: derivatives of biopolymers (e.g., microcrystalline triacetylcellulose), chiral synthetic polymers (e.g., Okamoto's helical poly(trityl methacrylate)), and chiral monomers (e.g., cyclodextrin derivatives).

Although it would be asking too much to expect complete coverage of all aspects of this subject, given its enormous scope, it was nevertheless disappointing to find no mention of topological chirality (the chirality of trefoil knots, catenanes composed of orientated rings, Möbius ladders, and so forth) in synthetic and naturally occuring molecules. I was not able to make much sense of the essay by S. Hoffmann, which I found to be intellectually impenetrable. Most texts of this nature are plagued by errors, and the present volume is no exception (e.g., on p. 171 the "symmetry elements" of ethylene are given as "3σ, $3C_{2v}$ and i"). Despite such shortcomings, however, this volume deserves to be read by anyone interested in this important topic.

Kurt Mislow

Princeton University, Princeton NJ (USA)

Wood and Cellulosic Chemistry. Edited by *D. N. S. Hon* and *N. Shiraishi*. Marcel Dekker, New York, 1991. VIII, 1020 pp., hardcover $ 234.00.—ISBN 0-8247-8304-03

Wood is one of the most important renewable raw materials and energy media. The growth of wood in forests makes a significant contribution to reducing the amount of carbon dioxide in the atmosphere. The carbon dioxide produced from fossil and living carbon sources by burning and respiration can, over long periods, be transformed back into organic compounds. For this reason alone, it is clear that wood chemistry and the use of wood as a chemical raw material is currently of great importance.

Research in wood chemistry now involves many different fields of science, and the published results are often widely scattered; surveys that aim to bring together this knowledge in an ordered way are therefore very useful. The book reviewed here is largely successful in achieving that objective.

The authors, 18 Japanese and four American scientists, are all recognized experts in their fields. The book is divided into three main sections, containing 21 chapters altogether. Part 1, "Structure and Chemistry", starts from the structure and mode of formation (lignification) of the woody tissue of the cell wall in plants, and goes on to describe in turn the chemical properties of each of the wood constituents that are bound together in the natural polymer structure—cellulose, hemicellulose, lignin, and substances present in the wood. Separate chapters are devoted to the chemistry of the bark, and to the chemical characterization of wood and its constituents. This part could have been even further improved by devoting a separate chapter to the biochemistry of wood formation.

In Part 2, "Degradation", some of the chapters deal with topics that have not previously been treated in monograph form, such as coloration and discoloration, and the photochemistry of wood. The degradation of wood by chemical, microbiological, enzymic, and pyrolytic mechanisms is described in a detailed and highly informative way. However, it is disappointing that this part does not also deal with the gasification and liquefaction of wood.

Part 3, "Modification and Utilization", discusses the chemical basis for modifying the properties of wood and cellulose so as to broaden their areas of use, both as constructional materials and as chemical raw materials. The main areas considered are the chemical modification of wood and cellulose, the plastification of wood, wood-polymer composites, and adhesives for wood. There is also a chapter (unfortunately rather too brief) on the use of wood and cellulose as sources of chemicals and energy.

Considered as a whole, the work offers a very good, up-to-date, and in some parts detailed survey of the specialized subject of wood and cellulose chemistry. The large number of authors has resulted in some unavoidable overlapping. A particularly useful feature is the large number of literature references given at the end of each chapter; there is, however, a very marked preponderance of Japanese publications. The book can be recommended for everyone in research and teaching who seeks an up-to-date account of the present state of knowledge regarding the chemistry of renewable raw materials, natural polymers, wood, and cellulose.

Vitamin C: Its Chemistry and Biochemistry. By *M. B. Davies, J. Austin,* and *D. A. Partridge.* Royal Society of Chemistry, Cambridge, 1991. 154 pp., paperback £ 13.50. ISBN 0-85186-333-7

An up-to-date and compact treatise on various aspects of ascorbic acid, this important vitamin, is most welcome, particularly in view of the discrepancy between the biological importance and the limited amount of sound knowledge available, and because of widespread interest on the part of the general public and in the marketplace. The back cover announces this book as just that: the "first" to provide an in-depth, interdisciplinary study of this essential and fascinating compound.

Well, the reader gets only some of this: there is a nice and coherent presentation of the history of scurvy and of the discovery of vitamin C, with due emphasis on Szent-György and on Haworth, with related stories providing good reading (Chapters 2 and 3). Chapter 4 describes the synthesis and manufacture, which, with a yearly output of more than 40000 tonnes, is certainly of quantitative interest. In this chapter one already begins to wonder about the overall scheme of the book, since at the end there is a lengthy section on further chemical reactions that ascorbate can enter into, but without offering a clue as to why this would be of interest.

Chapter 5 is on the biochemistry, and the bottom line is that many actions are being discussed here and there, but there is still much confusion. This is well illustrated by the detailed description of some metabolic pathways, such as the mitochondrial respiratory chain, in lengthy sequences of reactions but only few, if any, clear statements of how ascorbate is chemically involved. AFR, presumably an abbreviation for the ascorbate free radical, is included but not really explained. The few words about the interactions between tocopherol and ascorbate do not reflect current knowledge in this area. Similar comments apply to Chapter 6, on medical aspects: while generally satisfactory, the presentation sometimes doesn't quite make it to the point; I had trouble, for example, trying to understand the passage on page 99 on "vegetarians being in rude health, ascorbutically speaking"(?). The author of this part of the book may not have been from the medical profession, judging from the way some diseases were described. Chapter 7, on inorganic and analytical aspects, was more within the field of expertise, but here the inclusion of four pages on vitamin B_{12} in atomic detail left the reader perplexed, because the connection to the topic, namely vitamin C, was not made clear.

In summary, the book of about 150 pages is attractive initially, but, as even the authors say, the field is still mysterious in several ways. The bibliography could have included some of the more recent literature, e.g. the book for the layman by Linus Pauling ("How to Live Longer and Feel Better"), and the "Handbook of Vitamins" by Machlin. Also, one might disagree that the latest conference of the New York Academy of Sciences on Vitamin C was a "Third World Conference".

der Universität Düsseldorf (FRG)

Ion Exchangers. Edited by *K. Dorfner.* de Gruyter, Berlin, 1991. XXXI, 1495 pp., hardcover DM 680.00.—ISBN 3-11-010341-9

A whole generation of chemists received their first initiation into the subject of ion exchangers from Dorfner's slim volume entitled "Ionenaustauscher". A much weightier book, "Ion Exchangers", has now appeared. In this a team of authors under Dorfner's guidance has covered all the most important aspects of ion exchangers in a single volume of about 1500 pages.

An introduction to the basic principles of ion exchange is followed by several contributions dealing comprehensively with the synthesis of ion exchangers. Here it is pleasing to note that due importance has been given to synthetic organic ion exchange resins, the most commercially important group of materials. All the important areas of industrial application are competently described by experts; these range from conventional water treatment processes to the applications of ion exchangers and polymeric adsorbers in biotechnology. The contribution by Sherrington on the influence of the structure of the polymer on the reactivities of the functional groups is especially worth reading, despite being relegated to an inconspicuous position in the last part of the book. Also there is a short but highly informative section which surveys the literature on ion exchangers in general, and describes the use of computer-based information retrieval methods. All the contributions include many references to original papers. There is an appendix containing an index of commercially available ion exchangers, and the book is completed by a useful subject index.

Published work up to the mid-eighties is covered in considerable detail, but later results have only rarely been included. The editor has been remarkably successful in avoiding overlapping of subject matter; where this has been allowed to occur, it makes it much easier to read a particular article without needing to know the contents of the previous one. There is a certain amount of inconsistency in the nomenclature and units, but it could not have been avoided, and this reviewer did not find it troublesome. The print is clear and legible, and the tables, formulas, figures, and flow diagrams are mainly clear and informative.

However, the frequent careless errors are a nuisance, of which the following are two examples. In the tables on pages 96 and 1297, which are largely identical in content, we

find on the one hand $-N_3^+R$ and Ba^+, and on the other hand $-NH^2$ and $-SO_3^+$. In the lower equation on page 1008 none of the three structural formulas is shown correctly. One could go on at some length listing the mistakes, and unfortunately they often distract the reader's attention from the discussion. A second edition of the book would benefit greatly from more attention being given to such details.

Who ought to buy this book? The high price will certainly deter individuals from buying it privately. However, the new "Dorfner" should be available in all libraries where there is a need for an expert overview of the many different aspects of ion exchangers.

Werner Strüver
Bayer AG
Leverkusen (FRG)

The Kaiser's Chemists. Science and Modernization in Imperial Germany. By *J. A. Johnson*. University of North Carolina Press, Chapel Hill (USA), 1990. X, 279 pp., hardcover $ 39.95.—ISBN 0-8078-1902-6

Under the attractive title "The Kaiser's Chemists", J. A. Johnson here presents a study in scientific history, with particular emphasis on the difficult period of evolution in the politics and organization of science that led up to the founding of the three Kaiser-Wilhelm Institutes (for chemistry, for physical chemistry and electrochemistry, both at Berlin-Dahlem, and for coal research at Mülheim). Based on very thorough studies of original source material, the author provides detailed insights into the events before and during the formation and building of these institutes for basic chemical research, and into the relevant social history. The outstanding role of Emil Fischer comes repeatedly to the fore. The triumvirate of Emil Fischer, Wilhelm Ostwald, and Walter Nernst initiated the first moves towards setting up an imperial institute for chemistry, in analogy to the institute for physics and technology, but this objective then changed due to the influences of many different social forces and needs, with the result that the three institutes named above were already set up even before World War I. Leading German chemists in universities, technical colleges, and the chemical industry were concerned that the dominant world position of German chemistry, both in research and in industry, should be maintained and reinforced by setting up new institutes of this kind. The most important aim was to push forward developments in analytical, inorganic and physical chemistry, and in biochemistry. As neither the Prussian state nor the Reich were prepared to bear much of the cost that would be incurred in setting up these institutes, it was necessary to find sponsors with the required capital resources from within the economy. How the proponents went about this task, the many different interests that were brought together from different sides to support these projects, the role played by the Prusso-German bureaucracy and by Kaiser Wilhelm II through the "Kaiser-Wilhelm-Gesellschaft zur Förderung der Wissenschaften"—all this is described in detail, put into context, and carefully analyzed by Johnson. The institutional innovation process in German science is considered within the context of the "conservative modernization" that was taking place at that time, with the aim of increasing the might of the Kaiser's Germany. With the start of the First World War, chemical research and technology became closely bound up with military interests. This cooperation focussed on the objectives of developing raw materials resources, and producing substitute materials and chemicals for use in war (Fritz Haber). Chemists in universities, technical colleges, the Kaiser-Wilhelm Institutes, and the chemical industry contributed much to prolonging the war that could not be won. In an epilogue the author traces the subsequent fate of some of these chemists in the post-war period. The balance-sheet is dreadful: Emil Fischer's suicide in 1919; Fritz Haber and Richard Willstätter went into exile in 1934 and 1939 respectively; Walther Nernst retired from scientific work in 1933 as a protest against Nazism. The tragedies of German history in the first half of this century are reflected in the personal stories of many of these chemists.

In summary, there is no doubt that in this book the American science historian Johnson has made a valuable and profound contribution to understanding the history of German science in the first two decades of this century.

Alfred Neubauer
Berlin (FRG)

Biocoordination Chemistry: Coordination Equilibria in Biologically Active Systems. (Inorganic Chemistry Series; Series Editor: J. Burgess). Edited by *K. Burger*. Ellis Horwood, Chichester, 1990. ix, 349 pp., hardcover $ 90.00.—ISBN 0-13-179912-6.

This multiauthored text deals with the coordination chemistry of kinetically labile complexes of biological interest, amino acids, peptides, carbohydrates, nucleic acid bases, nucleosides, and nucleoside monophosphates. Such molecules are potential ligands, and a knowledge of their interactions with metal ions is crucial to studies of the role of metal ions and metal complexes in biology.

The first chapter (Noszal) deals with the acid-base properties of bioligands and, in conjunction with Burger's introduction, provides a good general background to the topic. The broad area of complexes of amino acids is discussed by Kiss in an admirable manner, and the chapter will be very useful to anyone wishing to learn about the solution chemistry of complexes of these ligands. Metal complexes of peptides and their derivatives are covered by Sovago in a good discussion of the field.

The chapter on thermodynamic and kinetic aspects of metalloenzymes and metalloproteins (Hirose and Kidani) deals with carbonic anhydrase, carboxypeptidase, Cu–Zn-superoxide dismutase, human transferrin, and ovatransferrin. This chapter seems a little out of place in this volume but provides interesting reading.

It is pleasant to see a chapter on metal complexes of carbohydrates (Burger and Nagy). This has been a somewhat neglected area, and a comprehensive review of carbohydrate complexes has not previously been available, although various aspects of the topic have been covered. Sawyer's 1964 review (*Chem. Rev., 64*, 633) lists 140 references, and the present discussion covers the literature to 1990. The article should help to stimulate further interest in the area.

The final chapter (Lonnberg) deals with proton and metal ion interactions with nucleic acid bases, nucleosides and nucleoside monophosphates. Owing to the vital role of nucleic acids in molecular biology this has become one of the most extensively studied areas of bioinorganic chemistry. For someone seeking an introduction to the area this chapter will be very useful.

The book is well produced with clear diagrams and tables. The literature citations are somewhat eccentric, and I see no very clear reason for the adoption of, for example, "70 Cl", standing for Clelland's publication in 1970. The book sum-

marizes in one volume much of the current literature on the solution chemistry of bioligands with metal ions, which is normally only available in multivolume works such as Sigel's "Metal Ions in Biological Systems" or in the primary literature. It will be a useful reference text for all those having interests in the chemistry of metal complexes in solution. Those seeking structural and spectroscopic data will have to look elsewhere.

Robert W. Hay
Chemistry Department
University of St. Andrews (UK)

Photochromism. Molecules and Systems. (Series: Studies in Organic Chemistry, Vol. 40.) Edited by *H. Dürr* and *H. Bouas-Laurent*. Elsevier, Amsterdam, 1990. XXII, 1068 pp., hardcover HFl 580.00.—ISBN 0-444-87432-1

This book is a collection of review articles by various authors on different aspects of photochromism. It should therefore be regarded less as a textbook than as a general overview, with the emphasis on recent developments in photochromism. It is intended mainly for the specialist, but is also suitable for those coming to this field for the first time.

The monograph begins with a general introduction by H. Dürr, after which comes a survey by G. Gauglitz of the physics and chemistry of photochromic systems. These two articles form important introductions for the non-specialist who wishes to learn about the area, and also for advanced students with an interest in the subject. For the latter, the "Glossary of Terms" at the end of the book will further contribute to a better understanding, and it should also help to bring some standardization of the terminology used in photochemistry. These introductions are followed by the core part of the book, consisting of chapters dealing with photochromic effects resulting from different types of reactions, such as *E–Z* isomerizations of double bonds, electrocyclic reactions, cycloadditions, tautomerism, and photodissociation processes. Next come chapters on photochromism in biological systems, on medium effects, on the use of silver salts in phototropic glasses, and on applications of photochromism. These chapters, which are the work of a large numer of expert authors, include competent treatments of all the most important aspects of photochromism, especially recent developments.

The monograph is very comprehensive and packed with information, consisting of 1068 closely printed pages. One can expect it to remain the standard work on photochromism for some time to come, and it is also a veritable mine of information for chemists, physical chemists, and physicists. However, it can be criticized on a few points. The subject index is very sparse, which is regrettable, as it means that specific information can only be extracted with difficulty. Also, in the bibliographies included with each chapter it would have been desirable, when citing papers in journals that are not readily accessible, to list not only the original reference but also the *Chemical Abstracts* entry. Nevertheless, this attempt at a review of the literature on photochromism can be described as very successful on the whole, and everyone working in the area of photochemistry should have the book close at hand.

Nuclear Magnetic Resonance Fourier Transform Spectroscopy (Nobel Lecture)**

By Richard R. Ernst*

Introduction

The world of the nuclear spins is a true paradise for theoretical and experimental physicists. It supplies, for example, most simple test systems for demonstrating the basic concepts of quantum mechanics and quantum statistics, and numerous textbook-like examples have emerged. On the other hand, the ease in handling nuclear spin systems predestines them for the testing of novel experimental concepts. Indeed, the universal procedures of coherent spectroscopy have been developed predominantly within nuclear magnetic resonance (NMR) and have found widespread application in a variety of other fields.

Several key experiments of magnetic resonance have already been honored by Nobel prizes in physics, starting with the famous molecular-beam experiments by Isidor I. Rabi[1–3] acknowledged in 1944, followed by the classical NMR experiments by Edward M. Purcell[4] and Felix Bloch,[5, 6] honored with the 1952 prize, and the optical detection schemes by Alfred Kastler,[7] leading to a prize in 1966. Some further Nobel prize winners in Physics have been associated in various ways with magnetic resonance: John H. Van Vleck developed the theory of dia- and paramagnetism and introduced the moment method into NMR; Nicolaas Bloembergen had a major impact on early relaxation theory and measurements; Karl Alex Müller contributed significantly to electron paramagnetic resonance; Norman F. Ramsey is responsible for the basic theory of chemical shifts and J couplings; and Hans G. Dehmelt developed pure nuclear quadrupole resonance.

But not only for physicists is nuclear magnetic resonance of great fascination. More and more chemists, biologists, and medical doctors discover NMR spectroscopy, not so much for its conceptual beauty but for its extraordinary usefulness. In this context, a great number of magnetic resonance tools have been invented to enhance the power of NMR in view of a variety of applications.[8–15] This Nobel lecture provides a glimpse behind the scenes in an NMR toolmaker's workshop.

Nuclear spin systems possess unique properties that predestine them for studies of molecules:

1) The atomic nuclei serving as sensors are extremely well localized, with a diameter of a few femtometers, and can report on local affairs in their immediate vicinity. It is thus possible to explore molecules and matter in great detail.

2) The interaction energy of the sensors with the environment is extremely small, less than 0.2 J mol^{-1}, corresponding to the thermal energy at 30 mK. The monitoring of molecular properties is thus virtually perturbation-free. Nevertheless, the interaction is highly sensitive to the local environment.

3) Information on the structure of molecules can be obtained from nuclear pair interactions: Magnetic dipole–dipole interactions provide distance information, while scalar J couplings allow one to determine dihedral angles.

At first glance, it may be astonishing that it is possible to accurately determine internuclear distances by radio frequencies with wavelengths $\lambda \approx 1$ m, since this seemingly violates the quantum mechanical uncertainty relation, $\sigma_q \cdot \sigma_p \geq \hbar/2$, with the linear momentum $p = 2\pi\hbar/\lambda$, as it applies to scattering experiments or to a microscope. It is important that in magnetic resonance the geometric

information is encoded in the spin Hamiltonian, $\mathscr{H} = \mathscr{H}(q_1, \ldots, q_k)$, where q_k is the nuclear coordinates. An accurate structure determination, therefore, boils down to an accurate energy measurement that can be made as precise as desired, provided that the observation time t is extended according to $\sigma_E \cdot t \geq \hbar/2$. An upper limit of t is in practice given by the finite lifetime of the energy eigenstates due to relaxation processes. Thus, the accuracy of NMR measurements is not restricted by the wavelength but rather by lifetimes limited by relaxation processes.

The information content of a nuclear spin Hamiltonian and the associated relaxation superoperator of a large molecule, for example a protein, is immense: It is possible to determine the frequencies of the chemical shifts of hundreds of spins in a molecule to an accuracy of 16–18 bits. Internuclear distances for thousands of proton pairs can be measured to about 0.1 Å. Several hundred dihedral angles in a molecule can be determined with an uncertainty of less than 10°.

The weakness of the nuclear spin interactions, so far described as an advantage, leads on the other hand to severe problems in detection. Large numbers of spins are required to discriminate the weak signals from noise. Under optimum conditions with modern high-field NMR spectrometers, 10^{14}–10^{15} spins of one kind are needed to detect a signal within a measurement time of one hour. The low signal-to-noise ratio is the most limiting handicap of NMR. Any increase by technical means would significantly extend the possible range of NMR applications.

This clearly defines the two goals that had to be achieved during the past three decades to promote NMR as a practical tool for molecular structure determination: 1) Optimization of the signal-to-noise ratio; 2) Development of procedures to cope with the enormous amount of inherent information on the molecule under investigation.

One-Dimensional Fourier Transform Spectroscopy

A major improvement in the signal-to-noise ratio of NMR spectra was achieved in 1964 by the conception of Fourier transform (FT) spectroscopy. The basic principle—parallel data acquisition, leading to the multiplex advantage—was applied already by Michelson in 1891 in optical spectroscopy[16] and explicitly formulated by Fellgett in 1951.[17] However, the approach used in optics, spatial interferometry, is unsuited for NMR spectroscopy, since an interferometer with the necessary resolution would require a pathlength of at least 3×10^8 m.

Weston A. Anderson at Varian Associates in Palo Alto was experimenting in the early sixties with a mechanical multiple-frequency generator, the "wheel of fortune", which was conceived to simultaneously excite the spin system with N frequencies, in order to shorten the performance time of an experiment by a factor N, by recording the response of N spectral elements in parallel.[18] It was soon recognized that more elegant solutions were needed for commercial success.

Numerous possibilities are conceivable for the generation of a broad-band frequency source that allows the simultaneous irradiation of all of the spins of a spin system. We mention four schemes: 1) Radio-frequency pulse excitation, 2) stochastic random noise excitation, 3) rapid scan excitation, 4) excitation by a computer-synthesized multiple-frequency waveform. For each method, a different type of data processing is required to derive the desired NMR spectrum.

The application of radio-frequency (rf) pulse excitation was suggested by Weston A. Anderson to the author for a detailed experimental study in 1964.[19–21] The experiment is outlined in Figure 1. To the sample that is polarized in a static magnetic field along the z-axis, an rf pulse is applied

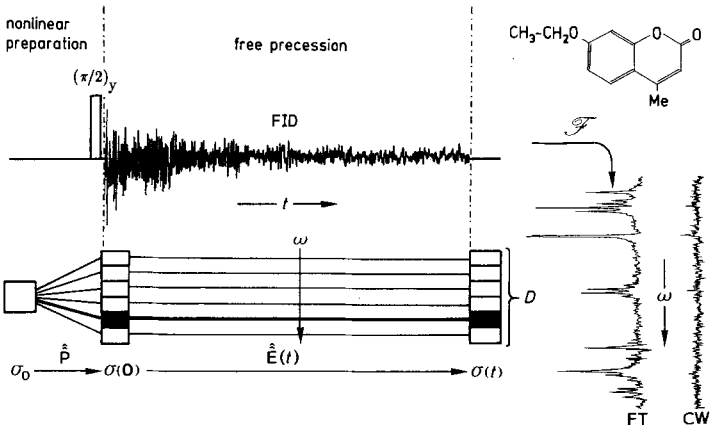

Fig. 1. Schematic representation of pulse FT spectroscopy illustrated by the 60 MHz ^{1}H NMR spectrum of 7-ethoxy-4-methylcoumarin[22]. An initial $(\pi/2)_y$ rf pulse, represented by the rotation superoperator $\hat{\hat{P}}$, excites the transverse magnetization $\sigma(0)$ from the equilibrium state σ_0. Free precession of all coherences in parallel under the evolution superoperator $\hat{\hat{E}}(t)$ leads to the final state $\sigma(t)$. Detection with the detection operator D produces the FID shown (sum of 500 scans) which, after Fourier transformation $\mathscr{F}$ provides the spectrum FT. For comparison, a continuous-wave (CW) spectrum is shown which was also recorded in 500 s under identical conditions.

Richard R. Ernst, born in 1933 in Winterthur, Switzerland, studied chemistry from 1952 to 1956 at the Eidgenössische Technische Hochschule in Zurich (ETH-Z). He worked on his Ph.D. from 1957 to 1962 in the field of NMR spectroscopy under the direction of Professors Hans Primas and Hans H. Günthard. In 1963 he went to Varian in Palo Alto. Five years later he returned to the ETH-Z as Privatdozent for physical chemistry. He became assistant professor in 1970, associate professor in 1972, and full professor in 1976. His many honors include the Gold Medal of the Society of Magnetic Resonance in Medicine (1983), the Ampère Prize (1990), the Wolf Prize for Chemistry (Jerusalem, 1991) and the 1991 Nobel Prize in Chemistry. He is a member of numerous scientific societies and on the editorial boards of many journals. His area of research is the development and application of NMR and ESR spectroscopic methods.

along the y-axis that rotates the magnetization vectors $\boldsymbol{M}_k$ of all spins I_k by $\pi/2$ into an orientation perpendicular to the static field. In the arrow notation[23] with the acting operator, here a $(\pi/2)_y$ rotation, on the top of the arrow this is expressed by Equation (1). The subsequent free induction

$$M_{kz} \xrightarrow{(\pi/2)_y} M_{kx} \tag{1}$$

decay (FID) consists of the superposition of all eigenmodes of the system. The operator D of an observable is used to detect the signal that is Fourier-transformed to separate the different spectral contributions. Figure 1 shows an early example of FT NMR spectroscopy on the sample 7-ethoxy-4-methylcoumarin for which 500 FIDs were coadded and Fourier-transformed to produce the FT spectrum shown.[22] A continuous wave (cw) spectrum obtained by the slow passage through the frequency range was recorded in the same total time of 500 s and is also shown in Figure 1 for comparison of the signal-to-noise ratios.

To please the more mathematically inclined reader, the experiment can also be expressed by the evolution of the density operator $\boldsymbol{\sigma}(t)$ under the preparation superoperator $\hat{\hat{P}} = \exp\{-i\hat{\hat{F}}_y\pi/2\}$ and the evolution superoperator $\hat{\hat{E}}(t) = \exp\{-i\hat{\hat{\mathscr{H}}}t - \hat{\hat{\Gamma}}t\}$. The superoperator $\hat{\hat{F}}_y$ is defined by $\hat{\hat{F}}_y\, A = [F_y, A]$ with $F_y = \sum_k I_{ky}$ where I_{ky} is a component angular momentum operator of spin k. $\hat{\hat{\mathscr{H}}}$ is the Hamiltonian commutator superoperator, $\hat{\hat{\mathscr{H}}}A = [\mathscr{H}, A]$ and $\hat{\hat{\Gamma}}$ is the relaxation superoperator. The expectation value $\langle \boldsymbol{D} \rangle(t)$ of the observable operator D is then given by Equation (2), where $\boldsymbol{\sigma}_0$ represents the density operator of the spin system in thermal equilibrium.

$$\langle \boldsymbol{D} \rangle(t) = \mathrm{Tr}\{\boldsymbol{D}\hat{\hat{E}}(t)\,\hat{\hat{P}}\boldsymbol{\sigma}_0\} \tag{2}$$

The reduction in performance time for *one* spectrum is determined by the number of spectral elements N, that is, the number of significant points in the spectrum, roughly given by $N = F/\Delta f$, where F is the total width of the frequency range and Δf a typical linewidth of a signal. A corresponding increase in the signal-to-noise ratio of $\sqrt{N}$ per unit time can be obtained by coadding an appropriate number of FID signals originating from a repeated pulse experiment. The gain in signal-to-noise can be appreciated from Figure 1.

It has been known for a long time that the frequency response function (spectrum) of a linear system is the Fourier transform of the impulse response (FID). This was already implicitly evident in the work of Jean Baptiste Joseph Fourier who in 1822 investigated the heat conduction in solid bodies.[24] In 1957 Lowe and Norberg proved this relation to hold also for spin systems despite their strongly nonlinear response characteristics.[25]

Stochastic testing of unknown systems by white random noise was proposed in the forties by Norbert Wiener.[26] One could say that the color of the output noise carries the spectral information on the investigated system. The first applications of random noise excitation in NMR spectroscopy were proposed independently by Russel H. Varian[27] and by Hans Primas[28, 29] for broad-band excitation and broad-band decoupling, respectively. The first successful experiments using random noise irradiation led to heteronuclear "noise decoupling",[30, 31] a method that proved to be essential for the practical success of ^{13}C NMR spectroscopy in chemical applications.

In 1970, Reinhold Kaiser[32] and the author[33] independently demonstrated stochastic resonance as a means to improve the signal-to-noise ratio of NMR experiments by broad-band irradiation. Here, the computed cross-correlation function (3) of the input noise $n_i(t)$ and the output noise

$$c_1(\tau) = \overline{n_o(t)\, n_i(t-\tau)} \tag{3}$$

$n_o(t)$ is equivalent to the FID of pulse FT spectroscopy. This is illustrated in Figure 2 for fluorine resonance of 2,4-difluorotoluene. A binary pseudo-random sequence with a

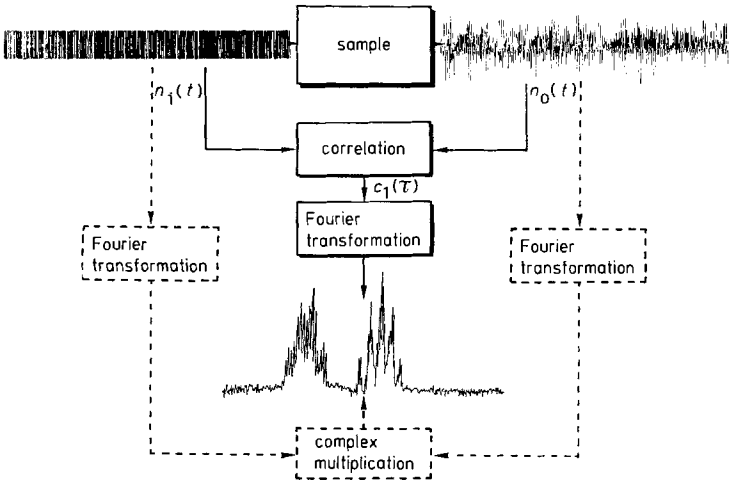

Fig. 2. Schematic representation of stochastic resonance illustrated by the 56.4 MHz ^{19}F NMR spectrum of 2,4-difluorotoluene [33]. Excitation with a binary pseudo-random sequence $n_i(t)$ 1023 points in length generates the response $n_o(t)$. Cross-correlation of the two signals produces $c_1(\tau)$ which, after Fourier transformation, delivers the spectrum shown. In an alternative procedure, which has actually been used in this case, the individual Fourier transforms of $n_i(t)$ and $n_o(t)$ are computed, and the complex conjugate $\mathscr{F}\{n_i(t)\}^*$ is multiplied by $\mathscr{F}\{n_o(t)\}$ to obtain the same spectrum.

maximal white spectrum is used for excitation. Its advantages are the predictable spectral properties and the constant rf power. The low peak-power puts less stringent requirements on the electronic equipment. Disadvantages arise from the simultaneous irradiation and detection which can lead to line-broadening effects absent in pulse FT spectroscopy in which perturbation and detection are separated in time. A further disadvantage, when real random noise is used, is the probabilistic nature of the response which requires extensive averaging to obtain a stable mean value. Higher order correlation functions, such as (4) allow also the

$$c_3(\tau_1,\tau_2,\tau_3) = \overline{n_o(t)\, n_i\,(t-\tau_1)\, n_i\,(t-\tau_2)\, n_i\,(t-\tau_3)} \tag{4}$$

characterization of nonlinear transfer properties of the investigated system.[26] This has been exploited extensively by Blümich and Ziessow for NMR measurements.[34, 35]

A third approach, rapid scan spectroscopy, initially proposed by Dadok and Sprecher,[36] achieves a virtually simul-

taneous excitation of all spins by a rapid sweep through the frequency range.[37, 38] The resulting spectrum is strongly distorted, but can be corrected mathematically because of the deterministic nature of the distortions. Correction amounts to convolution with the signal of a single spin measured under identical conditions or simulated on a computer. An example is given in Figure 3. It is interesting to note how similar a rapid scan spectrum is to an FID except for the successively increasing oscillation frequency.

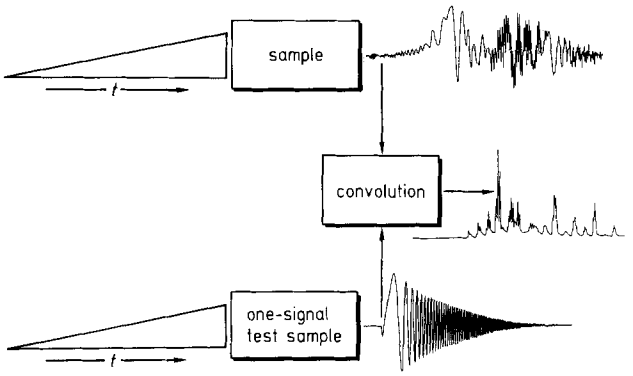

Fig. 3. Schematic representation of rapid scan spectroscopy. The highly distorted sample spectrum obtained by a rapid sweep of the frequency during the time t can be corrected by convolution with the equally sweep-distorted spectrum of a one-signal test sample.

Finally, it is possible by computer synthesis to compute an excitation function with a virtually arbitrary excitation profile. This was originally utilized for decoupling purposes by Tomlinson and Hill,[39] but is also the basis for composite pulse excitation schemes that have proved to be very powerful.[40, 41]

Among the broad-band excitation techniques, pulse excitation is the only one that allows for a rigorous analytical treatment irrespective of the complexity of the spin system. It does not lead to any method-inflicted line broadening as in stochastic resonance nor to correction-resistant signal distortions as in rapid scan spectroscopy of coupled spin systems.[38] Pulse FT spectroscopy is conceptually and experimentally simple, and last but not least, it can easily be expanded and adapted to virtually all conceivable experimental situations. Measurements of relaxation times, for example, require jut a modified relaxation-sensitive preparation sequence, such as a $\pi-\pi/2$ pulse pair of T_1 measurements[42] and a $\pi/2-\pi$ pulse pair for T_2 measurements.[43] Also the extension to the investigation of chemical exchange using the saturation-transfer experiment of Forsén and Hoffman[44] is easily possible.

It should be mentioned at this point that pulse NMR experiments were suggested already by Felix Bloch in 1946 in his famous paper,[6] and the first time-domain magnetic resonance experiments were performed in 1949 by H. C. Torrey[45] and, in particular, by Erwin L. Hahn,[46-48] who may be regarded as the true father of pulse spectroscopy. He invented the spin-echo experiment[46] and devised extremely important and conceptually beautiful solid-state experiments.[49, 50]

Pulse FT spectroscopy has not only revolutioned high-resolution liquid-state NMR spectroscopy, but it has unified NMR methodology across all fields, from solid-state resonance, through measurements of relaxation times, to high-resolution NMR, with numerous spillovers also into other fields such as ion cyclotron resonance,[51] microwave spectroscopy,[52] and electron paramagnetic resonance.[53] It also provided the germ for the development of multidimensional NMR spectroscopy.

Two-Dimensional Fourier Transform Spectroscopy

As long as purely spectroscopic measurements are made for the determination of the eigenfrequencies or normal modes of a system, one-dimensional (1D) spectroscopy is fully adequate. In NMR spectroscopy, this applies to the measurement of the chemical shifts that characterize the local chemical environment of the different nuclei. However, no information can be obtained in this manner on the spatial relationships between the observed nuclei.

There are two important pair interactions in nuclear spin systems, the scalar through-bond electron-mediated spin-spin interaction (J coupling) and the through-space magnetic dipole–dipole interaction (Fig. 4). The J coupling is described by the scalar term $\mathcal{H}_{kl} = 2\pi J_{kl} \boldsymbol{I}_k \boldsymbol{I}_l$ in the spin Hamiltonian. It is responsible for the multiplet splittings in high-resolution spectra of liquids. Under suitable conditions, it can lead to an oscillatory transfer of spin order between the two spins $\boldsymbol{I}_k$ and $\boldsymbol{I}_l$. The magnetic dipole–dipole interaction D_{mn}, on the other hand, is represented by a traceless tensor of second rank. Its average in isotropic solution is zero, and it can lead to signal splitting only in anisotropic media. However, its time modulation causes relaxation processes also in isotropic solution that are responsible for a multiexponential recovery of the spins to thermal equilibrium after a perturba-

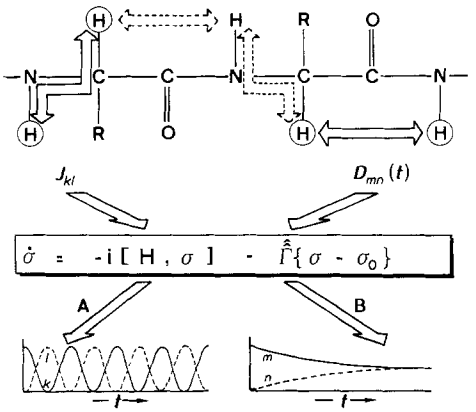

Fig. 4. The two pair-interactions relevant in NMR spectroscopy. The through-bond scalar J_{kl} coupling contributes to the Hamiltonian and leads to a coherent transfer (A) of spin order between spins I_k and I_l. The time-modulated through-space dipole–dipole interaction $D_{mn}(t)$ causes multiexponential cross relaxation (B) between spins I_m and I_n. The two interactions allow a sequential assignment of the resonances of neighboring spins in the peptide fragment shown and the determination of structure parameters. The three-bond J coupling is a measure for the dihedral angle about the central bond, the dipole–dipole interaction for internuclear distances.

tion. Knowledge of these interactions allows one to deduce geometric relations in the molecule in solution[54, 55] and arrangements of atoms in solids. In the optimum case, a complete three-dimensional structure of a molecule can be deduced.[56]

Although these interactions affect 1D spectra, special techniques are needed for their measurement. In the approximation of a linear response, it is impossible by first principles to distinguish two independent signals from a doublet caused by a spin–spin interaction. Experiments to explore the nonlinear response properties of nuclear spin systems have been known since the fifties. In saturation studies with strong rf fields several spins belonging to the same coupled spin system are excited simultaneously yielding multiple-quantum transitions that contain connectivity information.[57] Particularly fruitful were double- and triple-resonance experiments in which two or three rf fields are applied simultaneously, resulting in decoupling and spin-tickling effects.[58–60]

The early multiple-resonance experiments have in the meantime been replaced by multidimensional experiments. Pair interactions among spins are most conveniently represented in terms of a correlation diagram as shown in Figure 5. This suggests the recording of a "two-dimensional spectrum" that establishes such a correlation map of the corresponding spectral features. The most straightforward approach may be a systematic double-resonance experiment whose result can be respresented as an amplitude $S(\omega_1,\omega_2)$ which depends on the frequencies ω_1 and ω_2 of the two applied rf fields.[8, 58]

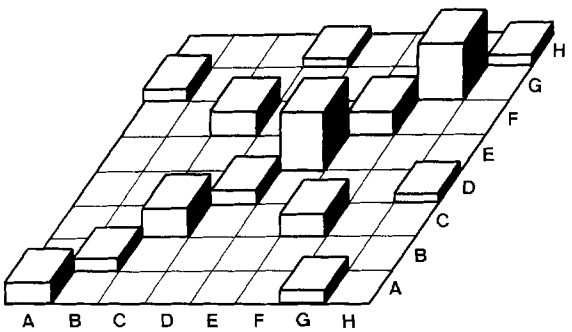

Fig. 5. Schematic correlation diagram for the representation of pair interactions of nuclear spins.

A new approach to measuring two-dimensional (2D) spectra was proposed by Jean Jeener in 1971.[61] He suggested a 2D FT experiment consisting of two $\pi/2$ pulses with a variable time t_1 between the pulses and the time variable t_2 measuring the time elapsed after the second pulse as shown in Figure 6; this is an expansion of the principles illustrated in Figure 1 (see also fig. 10a). Measuring the response $s(t_1,t_2)$ of the two-pulse sequence which is Fourier-transformed with respect to both time variables produces a two-dimensional spectrum $S(\omega_1, \omega_2)$ of the desired form.[62, 63]

This two-pulse experiment by Jean Jeener is the progenitor of a whole class of 2D experiments[8, 63] which can also easily be expanded to multidimensional spectroscopy. Each 2D experiment, as shown in Figures 6 and 7, starts with a preparation pulse sequence $\hat{\hat{P}}$, which excites coherences, that is, coherent superpositions represented by the density operator $\sigma(0)$, that are allowed to precess for an evolution time t_1 under the evolution superoperator $\hat{\hat{E}}(t_1)$. During this period, the coherences are frequency-labeled, so to speak. The subsequent mixing sequence $\hat{\hat{R}}$ performs a controlled transfer of coherence to different nuclear spin transitions that evolve during the detection period as a function of t_2 under the evolution superoperator $\hat{\hat{E}}(t_2)$. Detection is performed with the detection operator $\boldsymbol{D}$ in analogy to Figure 1, leading to Equation (5).

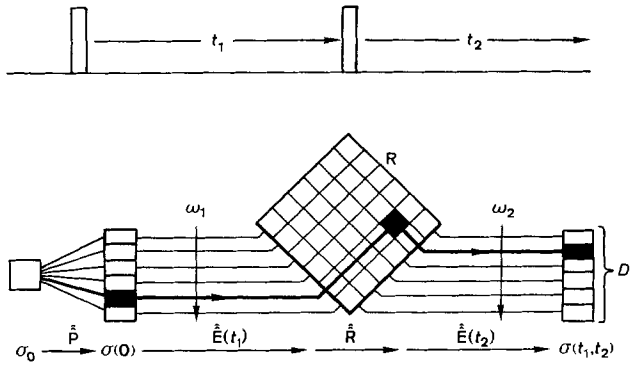

Fig. 6. Schematic representation of a 2D experiment, here with a simple two-pulse sequence. The first pulse excites coherences that precess during t_1 and are transferred by the second pulse to different transitions where the coherences continue to precess with a new frequency. The 2D spectrum obtained by a 2D Fourier transformation of $\langle \boldsymbol{D} \rangle(t_1, t_2)$ is a visual representation of the transfer matrix R.

$$\langle \boldsymbol{D} \rangle(t_1,t_2) = \mathrm{Tr}\{\boldsymbol{D}\hat{\hat{E}}(t_2)\hat{\hat{R}}\hat{\hat{E}}(t_1)\hat{\hat{P}}\sigma_0\} \quad (5)$$

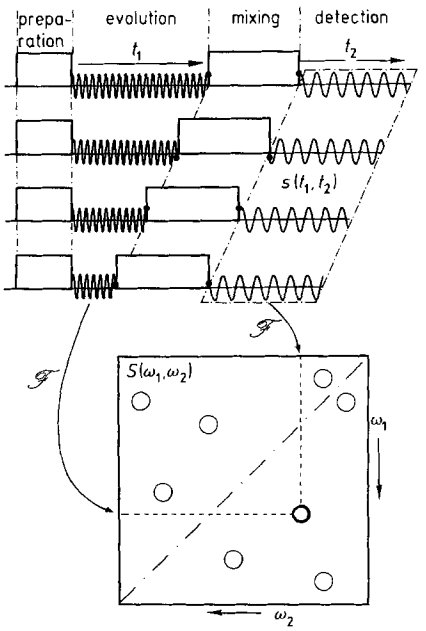

Fig. 7. Schematic representation of a general 2D experiment consisting of preparation, evolution, mixing, and detection periods. The duration t_1 of the evolution period is varied systematically from experiment to experiment. The resulting signal $s(t_1, t_2) \propto \langle \boldsymbol{D} \rangle(t_1, t_2)$ is Fourier-transformed in two dimensions to produce the 2D spectrum $S(\omega_1,\omega_2)$.

It is not sufficient to perform a single two-pulse experiment. To obtain the necessary data $\langle \boldsymbol{D} \rangle(t_1,t_2)$ to compute a 2D spectrum $S(\omega_1,\omega_2)$, it is required to systematically vary t_1 in a series of experiments and to assemble a 2D data matrix that is then Fourier-transformed in two dimensions as is indicated schematically in Figure 7. The resulting 2D spectrum correlates the precession frequencies during the evolution period with the precession frequencies during the detection period, and is a vivid and easily interpretable representation of the mixing process. Diagonal and cross peaks are measures for the elements of the transfer matrix of the mixing pulse sequence in Figure 6.

Among the numerous transfer processes that can be represented in this manner, the most important ones are[8] 1) the scalar J coupling leading to 2D correlation spectroscopy abbreviated as COSY, 2) internuclear cross relaxation leading to 2D nuclear Overhauser effect spectroscopy abbreviated as NOESY, and 3) chemical exchange leading to 2D exchange spectroscopy abbreviated as EXSY.

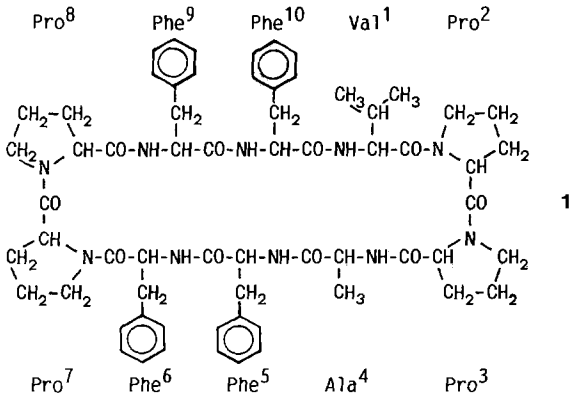
The COSY transfer, which proceeds through J coupling, is truly a quantum mechanical effect that does not find a satisfactory classical explanation. By means of a single $(\pi/2)_x$ rf mixing pulse, as in Figure 6, it is possible to transfer coherence of spin k, which is antiphase with respect to spin l and represented in the density operator by the operator term $2\boldsymbol{I}_{ky}\boldsymbol{I}_{lz}$ into coherence of spin l, which is antiphase with respect to spin k, represented by $-2\boldsymbol{I}_{kz}\boldsymbol{I}_{ly}$ (6), whereby each

$$2\boldsymbol{I}_{ky}\boldsymbol{I}_{lz} \xrightarrow{(\pi/2)_x} -2\boldsymbol{I}_{kz}\boldsymbol{I}_{ly} \tag{6}$$

factor of the product spin-operator can be considered to be rotated by $\pi/2$ about the x-axis. Antiphase coherence of the type $2\boldsymbol{I}_{ky}\boldsymbol{I}_{lz}$ is only formed during the evolution period when there is a direct spin–spin coupling between the spins I_k and I_l (7). This implies that in a two-dimensional correlation

$$\boldsymbol{I}_{kx} \xrightarrow{2\pi J_{kl}\boldsymbol{I}_{kz}\boldsymbol{I}_{lz}t_1} \boldsymbol{I}_{kx}\cos(\pi J_{kl}t_1) + 2\boldsymbol{I}_{ky}\boldsymbol{I}_{lz}\sin(\pi J_{kl}t_1) \tag{7}$$

spectrum there are cross peaks only between directly coupled spins (as long as the approximation of weak coupling holds). It is obvious from Equation (7) that there is no net coherence transfer, e.g. $\boldsymbol{I}_{kx} \rightarrow \boldsymbol{I}_{lx}$, and the cross-peak integral must disappear. In other words, there is an equal number of cross-peak multiplet lines with positive and negative intensity.



1

A COSY spectrum, such as the one shown in Figure 8 for the cyclic decapeptide antamanide (**1**) can be used to find pairs of spins belonging to the same coupling network of an amino acid residue in the molecule. All intense cross peaks

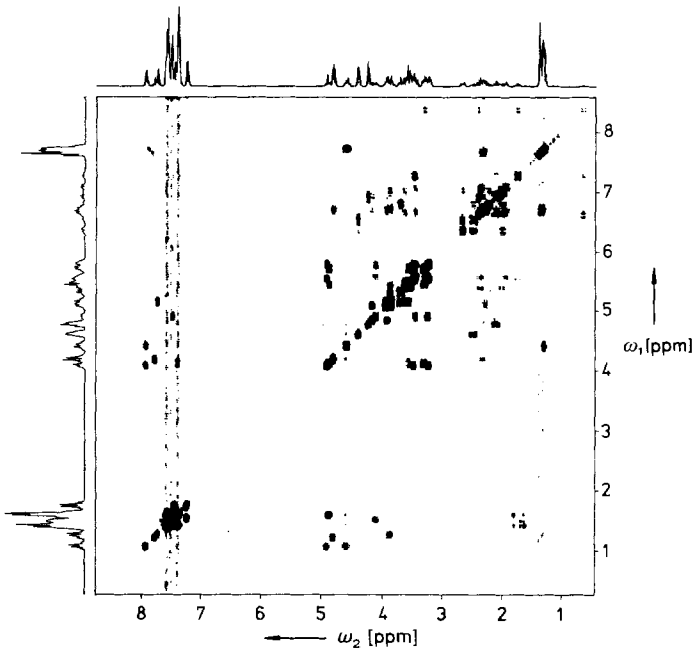


Fig. 8. Phase-sensitive 400 MHz ^{1}H COSY spectrum of antamanide (**1**) in chloroform (at 250 K) in a contour-line representation. Positive and negative contours are not distinguished. The spectrum was recorded by Dr. Martin Blackledge.

arise from couplings over two and three bonds that allow, first of all, the assignment of the pairs of NH and $C_\alpha H$ along the polypeptide backbone (backbone protons), as indicated by C in Figure 9 for the six amino acid residues with NH protons. In addition, it is also possible to assign the protons in the side chains.

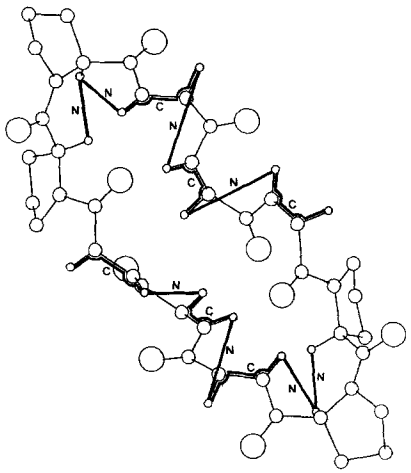

Fig. 9. Assignment of the protons of the backbone of antamanide (**1**) by the combination of COSY (C) and NOESY (N) cross peaks. The missing NH protons in the four proline residues break the chain of sequential C–N connectivities.

The transfers of NOESY and EXSY experiments involve incoherent, dissipative processes that bring the system back to equilibrium in an exponential or multiexponential manner after an initial perturbation. They require an extended mixing time during which the random processes are given a chance to occur. Both processes can be investigated with the same three-pulse scheme (Fig. 10b).[8, 64–67] The mixing period is bracketed by two $\pi/2$ pulses that transform coherence into static spin-order and back into coherence. The exchange processes transfer the spin order between different spins or between different chemical species, respectively. This type of transfer can be understood on the basis of classical kinetic models. The resulting 2D spectrum represents a kinetic matrix with cross-peak intensities proportional to the exchange rate constants of pseudo-first-order reactions.

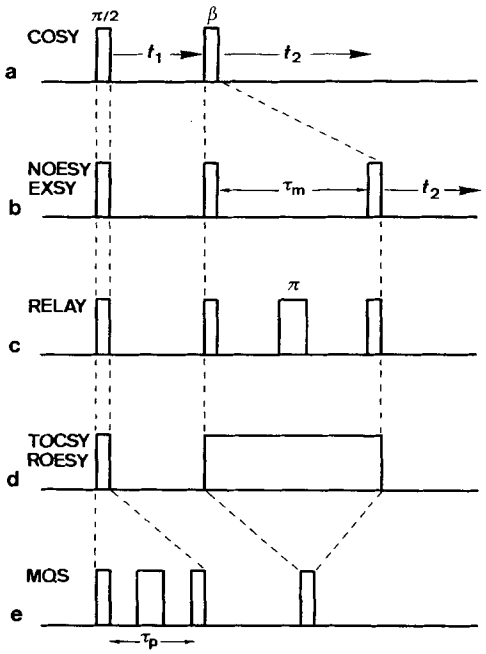

Fig. 10. Pulse sequences for some of the most useful homonuclear 2D experiments: a) COSY, b) NOESY or EXSY, c) relayed COSY, d) TOCSY or ROESY in the rotating coordinate system, e) multiple-quantum spectroscopy.

For the NOESY transfer, the exchange rate constants are given by the cross-relaxation rate constants, which are due to magnetic dipole–dipole interactions, and are proportional to $1/r_{kl}^6$ for nuclear pairs I_k and I_l, and depend on the correlation time τ_c of the tumbling of the molecules in solution. The distance dependence can be used to measure relative or, if τ_c is known, absolute distances in molecules. The NOESY cross peaks thus allow the identification of neighboring protons in a molecule—important, for example, in identifying protons that belong to adjacent amino acid residues in peptides.

A NOESY spectrum of antamanide (**1**) is given in Figure 11. The sequential backbone protons of adjacent amino acid residues with NOESY cross peaks are marked in Figure 9 with N. It is seen in Figure 9 that these together with the protons with *J*- cross peaks from the COSY spectrum (Fig. 8) form two unbroken chains of connectivities that can be used for the identification of the backbone protons. The two chains are not joined because of the absence of NH protons in the four proline residues. The general assessment procedure of proton resonance frequencies based on COSY and NOESY spectra has been established by Wüthrich and his research group.[56]

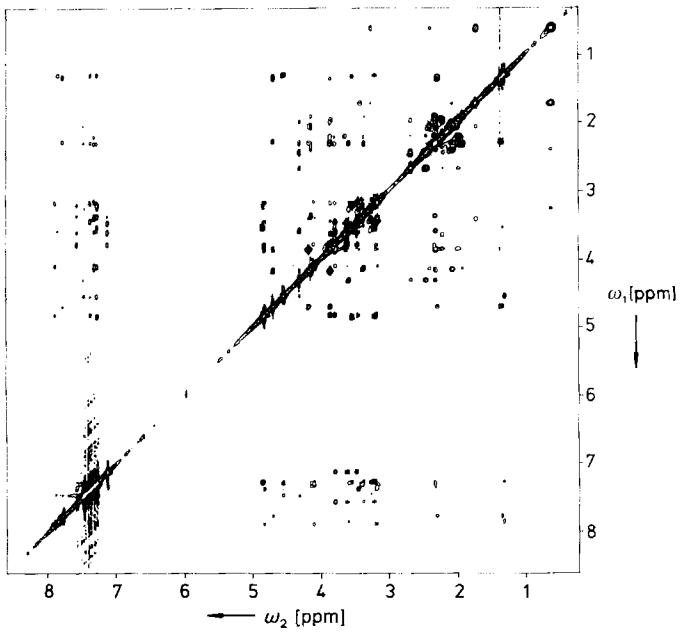

Fig. 11. 400 MHz ^{1}H NOESY spectrum of antamanide (1) in chloroform (at 250 K) in a contour-line representation. The spectrum was recorded by Dr. Martin Blackledge.

Based on a complete or partial set of assigned resonances, it is then possible to deduce information on the molecular structure. Each NOESY cross-peak intensity provides an internuclear distance that can be used in a manual or computerized process to construct a molecular model compatible with the experimental data. In this process it is also possible to employ scalar coupling constants extracted from COSY-type spectra (most conveniently from E. COSY spectra, as mentioned later). According to the Karplus relations,[54] there is a relation between vicinal coupling constants and dihedral angles. Ingenious computer procedures to determine molecular structures based on NMR data were first developed by Kurt Wüthrich and his research team and tested on a large number of small to medium-size proteins.[56, 68–71] At present, mainly two computer algorithms for the structure determination are in use—the distance–geometry algorithm[72, 73] and modifications of it, and the restrained molecular-dynamics algorithm,[74, 75] again with many variations. The structural problem in antamanide (**1**) will be discussed later, as it involves intramolecular dynamic processes that complicate the situation.

Cross peaks in a NOESY-type exchange spectrum can also originate from chemical exchange; the three-pulse experiment of Figure 10b is indeed well suited for the investigation of chemical exchange networks.[64, 65, 76] A distinction of the two types of signals is not possible by inspection of a single 2D spectrum. However, variable-temperature studies are often conclusive. At sufficiently low temperatures

at which chemical exchange becomes slow, only NOESY cross peaks should remain. The two types of signals may also be distinguished in experiments with rotating coordinate systems as mentioned in the next section.

The ^{13}C NMR spectrum of a mixture of *cis*- and *trans*-decalin in Figure 12 is typical for a spectrum showing chemical exchange. The spectrum gives evidence of the well-known

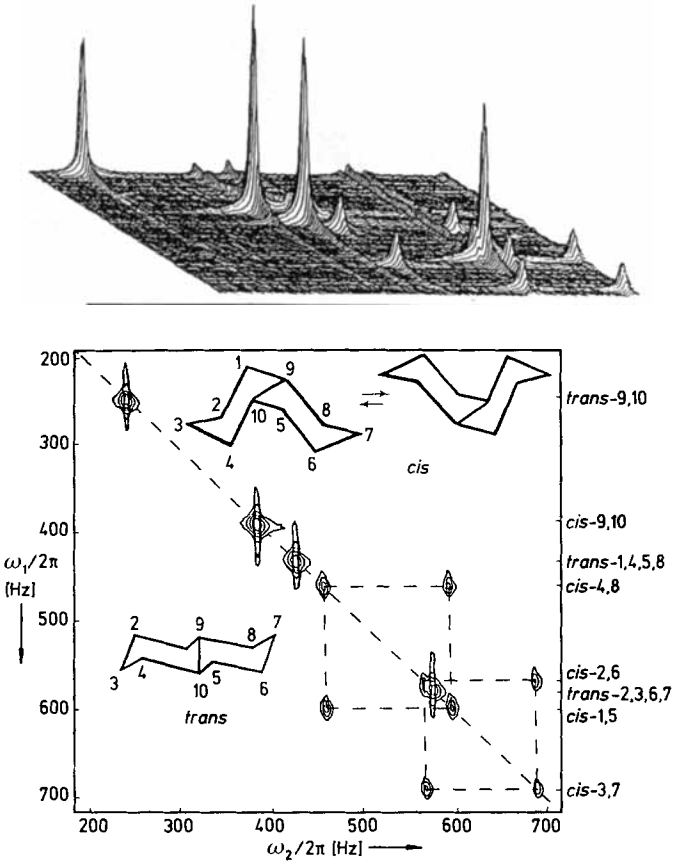

Fig. 12. 2D ^{13}C EXSY spectrum of a mixture of *cis*- and *trans*-decalin recorded at 22.5 MHz and 241 K [76]. Top: Three-dimensional representation (stacked plot). Bottom: A contour-line representation with the assignment of the peaks.

conformational stability of *trans*-decalin, whereas for *cis*-decalin four pairs of carbon spins are involved in a conformational exchange process, giving raise to two pairs of cross peaks.[76]

Modified Two-Dimensional FT-NMR Experiments

Starting from the two prototypical 2D FT NMR experiments, numerous modified, expanded, and improved experiments have been suggested. Many of them have found a place in the arsenal of routine methods for the NMR spectroscopist. A first category of experiments, represented in the upper part of Figure 13, causes extended correlation through two or more transfer steps: Relayed correlation experiments involve two-step correlation, and total correlation spectroscopy (TOCSY) multiple-step correlation. The latter experiment leads to the important class of rotating frame experiments, including rotating frame Overhauser effect spectroscopy (ROESY) an alternative to NOESY. Finally

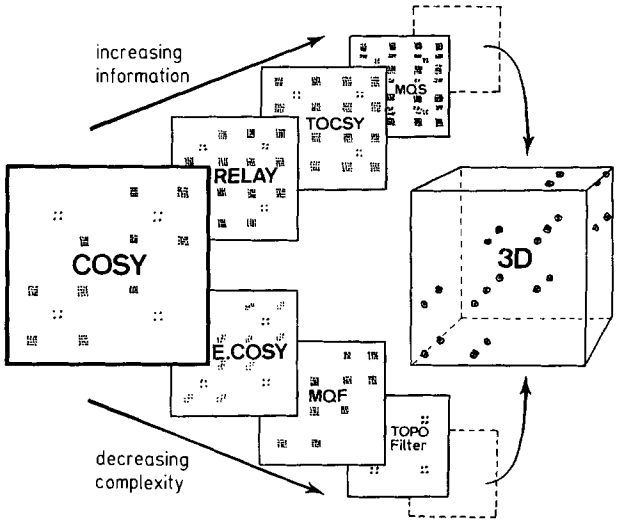

Fig. 13. Extensions of the standard COSY experiment. Relayed correlation, total correlation spectroscopy (TOCSY), and multiple-quantum spectroscopy (MQS) increase the information content, while exclusive correlation (E. COSY), multiple-quantum filtering (MQF), and spin-topology filtration reduce the complexity. Both avenues can lead to three-dimensional spectroscopy.

also multiple-quantum spectroscopy allows one to investigate connectivity in spin systems. A second class of experiments attempts the simplification of spectra by exclusive correlation (E. COSY), multiple-quantum filtering, and spin-topology filtration.

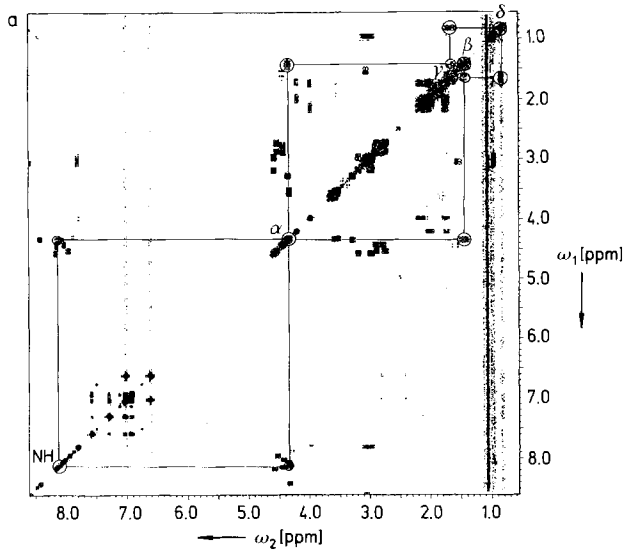
Relayed Correlation

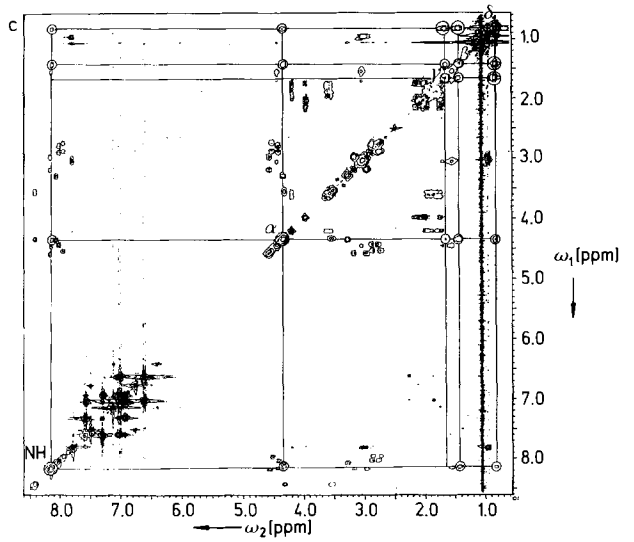
In a standard COSY experiment, coherence is transferred exclusively between two directly coupled spins by means of a single mixing pulse. By a sequence of two $\pi/2$ pulses, as in Fig. 10c, it is possible to effect a transfer of coherence across two sequential couplings from spin I_k to spin I_l through the relay spin I_r.[77, 78] For the relation in (8), $J_{kr}t_1 = J_{kr}\tau_m = J_{rl}\tau_m = 1/2$ is assumed.

$$\begin{aligned} I_{kz} &\xrightarrow{(\pi/2)I_{ky}} I_{kx} \xrightarrow{2\pi J_{kr}I_{kz}I_{rz}t_1} 2I_{ky}I_{rz} \xrightarrow{(\pi/2)(I_{kx}+I_{rx})} \\ -2I_{kz}I_{ry} &\xrightarrow{2\pi J_{kr}I_{kz}I_{rz}\tau_m + 2\pi J_{rl}I_{rz}I_{lz}\tau_m} 2I_{ry}I_{lz} \xrightarrow{(\pi/2)(I_{rx}+I_{lx})} -2I_{rz}I_{ly} \end{aligned} \quad (8)$$

During the extended mixing period τ_m, it is thus necessary to refocus the antiphase character of the I_r spin coherences with respect to spin I_k and create antiphase character with respect to spin I_l to allow for a second transfer by the second mixing pulse. Relayed correlation is useful whenever the resonance of the relay spin I_r cannot be identified unambiguously. With a relay experiment it is then nevertheless possible to assign spins I_k and I_l to the same coupling network (e.g. belonging to the same amino acid residue in a polypeptide chain). It is usually advantageous to refocus the effects of the chemical shift precession during the mixing period by incorporating a central π pulse as shown in Figure 10c.

Relayed coherence transfer is illustrated by 300 MHz ^1H NMR spectra of the linear nonapeptide buserilin, pyro-Glu-His-Trp-Ser-Tyr-D-Ser-Leu-Arg-Pro-$NHCH_2CH_3$. Figure 14a shows a (double-quantum filtered) COSY spec-





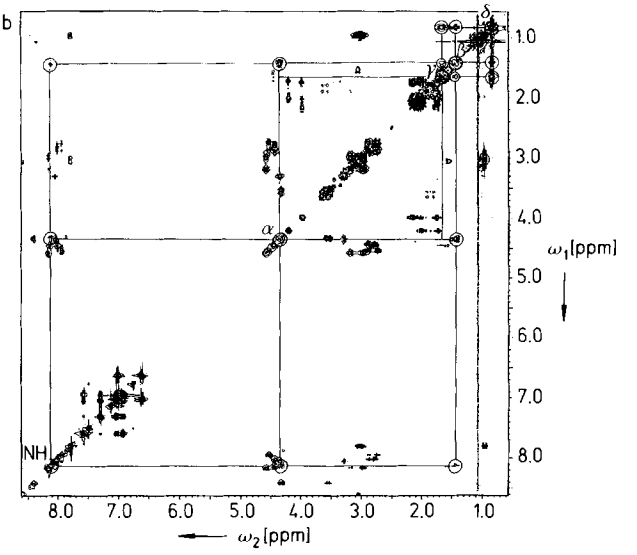


Fig. 14. 300 MHz correlation spectra of the nonapeptide buserilin in dimethyl sulfoxide (DMSO). Phase-sensitive spectra with equal representation of positive and negative contours are shown. The resonance connectivities and the positions of the NH, $C_\alpha H$, $C_\beta H$, $C_\gamma H$, and $C_\delta H$ diagonal peaks are indicated for the leucine residue [79]. a) Double-quantum filtered COSY spectrum with the sequence from Figure 18. b) Relayed COSY spectrum with the sequence from Figure 10c and $\tau_m = 25$ ms. c) TOCSY spectrum with the sequence from Figure 10d, $\tau_m = 112$ ms, and an MLEV-17 pulse sequence applied during τ_m.

trum and Figure 14b the corresponding relayed COSY spectrum.[79] In both spectra, the resonance connectivities for the leucine residue are marked. It is evident that in the COSY spectrum only nearest neighbor protons are connected by cross peaks: NH–$C_\alpha H$, $C_\alpha H$–$C_\beta H^{1,2}$, $C_\beta H^{1,2}$–$C_\gamma H$, and $C_\gamma H$–$(C_\delta H_3)^{1,2}$. On the other hand, in the relayed COSY spectrum, also the next-nearest neighbors NH–$C_\beta H^{1,2}$ and $C_\beta H^{1,2}$–$(C_\delta H_3)^{1,2}$ are connected. The third pair of relayed cross peaks, $C_\alpha H$–$C_\gamma H$, is weak because of the high multiplicity of the $C_\gamma H$ resonance and is not visible in the contour representation of Figure 14b. Similar relayed cross peaks can be found for the other amino acid residues.

Rotating Frame Experiments

By means of an extended mixing pulse sequence, transfer of coherence over an arbitrary number of steps is possible in principle. In particular, continuous wave irradiation leads to the mixing of all eigenmodes of a spin system and correspondingly to transfers of coherence between all of them. This is exploited in total correlation spectroscopy (TOCSY) with the sequence shown in Figure 10d. All spins belonging to the same J-coupling network can be identified with TOCSY.[80, 81] The accurate matching of the precession frequencies of the various spins in the presence of a radio frequency field is crucial in enabling an efficient transfer of coherence. Either very strong radio-frequency fields or specially designed pulse sequences are needed for this purpose.[81] Coherence transfer is possible when the effective average magnetic field strengths B_k^{eff} in the rotating frame are equal to within a J-coupling constant, $|\gamma(B_k^{eff} - B_l^{eff})| < |2\pi J_{kl}|$, corresponding to a strong coupling case in the rotating frame.

The TOCSY experiment is of interest for the assignment of proton resonances to individual amino acid residues in a protein. Of particular value is that its transfer rate is enhanced by a factor of 2 in comparison to COSY or relayed transfer experiments in the laboratory frame.[80] Another property is that, because of the presence of a radio-frequency field, in-phase coherence transfer is possible (9), leading to in-phase cross-peak multiplet structures.

$$I_{kx} \xrightarrow{2\pi J_{kl} I_k I_l \tau_m} I_{lx} \qquad (9)$$

A TOCSY spectrum of buserilin is included in Figure 14c for comparison with the relayed and standard COSY spectra depicted. Again three-step transfers $C_\alpha H$–$(C_\delta H_3)^{1,2}$ and even four-step transfers NH–$(C_\delta H_3)^{1,2}$ are visible here. Some expected cross peaks involving $C_\gamma H$ are missing as before because of the extensive multiplet structure of $C_\gamma H$.

The elimination of the chemical shift precession by the rf irradiation leads not only to the coherent transfer through the J-coupling network, but also to an incoherent transfer of spin order through transverse cross-relaxation. The transverse cross-relaxation terms are, in principle, always present.

However, strong differential chemical shift precession of spin pairs normally causes a quenching of the transfer in the sence of first-order perturbation theory. In the presence of a strong rf field, this quenching is no longer operative and transverse cross-relaxation occurs. This is the transfer mechanism of the rotating frame Overhauser effect spectroscopy (ROESY) experiment.[82]

ROESY has similar properties as NOESY but differs in the dependence of the cross-relaxation rate constant Γ_{kl} on the correlation time τ_c of the molecular rotational motion that modulates the internuclear dipole–dipole interaction responsible for cross-relaxation [cf. (10) and (11) where the spectral density J is defined by (12)]. As usual, ω_0 is the

$$\Gamma_{kl}^{NOE} = \frac{\gamma^4\hbar^2}{10 r_{kl}^6}\left(\frac{\mu_0}{4\pi}\right)^2\left[-\frac{1}{2}J(0) + 3J(2\omega_0)\right] \quad (10)$$

$$\Gamma_{kl}^{ROE} = \frac{\gamma^4\hbar^2}{10 r_{kl}^6}\left(\frac{\mu_0}{4\pi}\right)^2\left[J(0) + \frac{3}{2}J(\omega_0)\right] \quad (11)$$

$$J(\omega) = \frac{2\tau_c}{1 + (\omega\tau_c)^2} \quad (12)$$

Larmor frequency of the two nuclei with the internuclear distance r_{kl}. Equations (10) and (12) imply that Γ_{kl}^{NOE} changes sign for an intermediate correlation time τ_c of $(5/4)^{1/2}\ \omega_0^{-1}$; that is, the cross-relaxation rate becomes small in the neighborhood of this condition. Depending on the viscosity of the solvent and the resonance frequency ω_0, this occurs for globular molecules within a range of molecular mass of 500–2000 Da. Γ_{kl}^{ROE}, on the other hand, is less sensitive to τ_c and remains positive for any molecular mass. The ROESY experiment is therefore of advantage for molecules of intermediate size.

In addition, the different sensitivity of NOE and ROE to τ_c allows one to deduce information on intramolecular mobility by comparison of the two measurements.[83]. An advantage of ROESY over NOESY experiments is that the cross-peak amplitude is negative, while the simultaneously occurring cross peaks due to chemical exchange are positive and allow for an easy distinction as long as the signals do not overlap.

It should be recognized that in the rotating frame coherence transfer through J couplings and cross relaxation occurs simultaneously, whereby TOCSY cross peaks are positive and ROESY cross peaks appear with negative amplitude. This complicates the 2D spectra and calls for separation procedures. The suppression of the coherent transfer through J couplings (TOCSY) is easy, because it is only necessary to mismatch the condition $|\gamma(B_k^{eff} - B_l^{eff})| < |2\pi J_{kl}|$, for example by a slight frequency offset in the presence of not-too-strong rf fields. The cross-relaxation rates are much less sensitive to such a mismatch and a clean ROESY spectrum results.

Obtaining a clean TOCSY spectrum is more demanding because relaxation cannot easily be manipulated. A technique was proposed by C. Griesinger,[84] which relies on a combination of Equations (10) and (11) to set the average cross-relaxation rate constant to zero [Eq. (13)]. A suitable weighting factor p can be found whenever $\Gamma_{kl}^{NOE} < 0$, that is, for sufficiently large molecules with $\tau_c > (5/4)^{1/2}\ \omega_0^{-1}$. This requires the magnetization to move on a trajectory that spends a fraction p of time along the z-axis and a fraction $(1\text{-}p)$ in the transverse plane. For $\tau_c \to \infty$, one finds $p = 2/3$ for $\bar{\Gamma}_{kl} = 0$. A suitable pulse sequence, a modification of an MLEV-17 spin-locking sequence, has been proposed in ref.[84].

$$\bar{\Gamma}_{kl} = p\Gamma_{kl}^{NOE} + (1-p)\Gamma_{kl}^{ROE} \stackrel{!}{=} 0 \quad (13)$$

Another optimized sequence, called "Clean CITY", was developed by J. Briand.[85] A clean TOCSY spectrum of bovine pancreatic trypsin inhibitor (BPTI) using the Clean CITY sequence is compared in Figure 15 with a conventional TOCSY spectrum to demonstrate the efficient suppression of the (negative) ROESY peaks.

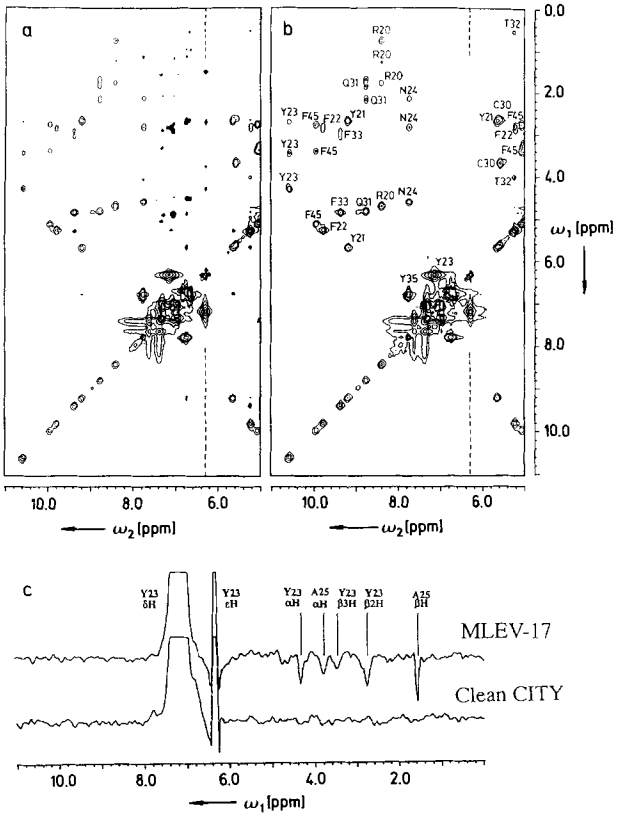

Fig. 15. Phase-sensitive 300 MHz ^{1}H TOCSY spectra of a 15 mM sample of bovine pancreatic trypsin inhibitor in D_2O recorded with a mixing time of 69 ms [85]. a) Mixing process with the MLEV-17 pulse sequence. Negative peaks are shown by contours filled in black. b) Mixing process with the Clean CITY pulse sequence. c) Cross sections along ω_1 through the diagonal peak of Tyr^{23} εH at $\omega_2 = 6.33$ ppm in the spectra a) and b) (marked with broken lines).

Multiple-Quantum Spectroscopy

In the spectroscopy, in general, only those transitions are directly observable for which the observable operator has matrix elements not equal to zero, leading to the so-called allowed transitions. For magnetic resonance in strong magnetic fields with weak cw perturbation or with a free induc-

tion decay in the absence of rf, the observable operator of the transverse magnetization $F_x = \sum_k I_{kx}$ has matrix elements only between eigenstates of the Hamiltonian differing in the magnetic quantum number M by ± 1. Thus single-quantum transitions are the allowed transitions, while multiple-quantum transitions with $|\Delta M| > 1$ are forbidden. Multiple-quantum transitions can, however, be induced by strong cw rf fields that cause a mixing of states[8, 57] or by a sequence of at least two rf pulses (Fig. 10e).[8, 63, 86, 87] Observation is possible again in the presence of a strong rf field[8, 57] or after a further detection pulse.[8, 63, 86, 87]

For spin systems with $I = 1/2$, multiple-quantum transitions invariably involve several spins, and multiple-quantum spectra contain information on the connectivity of spins within the J-coupling network in analogy to 2D correlation spectra. In particular, the highest order transition allows one to determine the number of coupled spins. Relaxation rate constants of multiple-quantum coherences are dependent on the correlation of the random perturbations affecting the spins involved and provide information on motional processes.[88].

A simple instructive example of a 2D double-quantum spectrum is given in Figure 16 to demonstrate the use of multiple-quantum transitions for the assignment of resonances.[89] Along ω_1, double-quantum transitions and along ω_2 single-quantum transitions are displayed for the six-spin system of $[D_3]$3-aminopropanol $DOCH_2CH_2CH_2ND_2$. In general, there are three categories of double-quantum transitions:

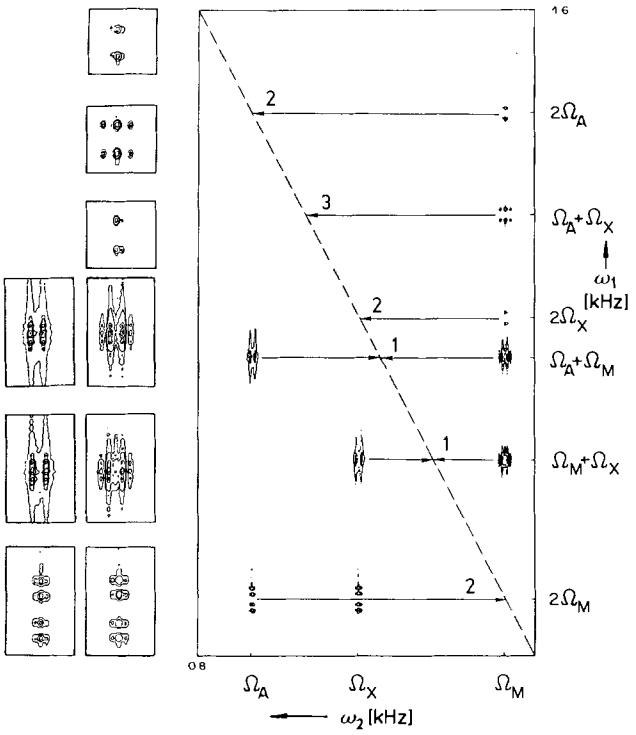

Fig. 16. 90 MHz 2D ^{1}H correlation spectrum of $[D_3]$3-amino-propanol with double-quantum transitions along ω_1 and single-quantum transitions along ω_2. The three types of double-quantum transitions mentioned in the text are indicated. Enlargements of all cross peaks are shown on the left. The spectrum is shown in an absolute value representation (from ref. [89]).

1) Double-quantum transitions involving two directly coupled spins. They lead to pairs of cross peaks displaced symmetrically from the double-quantum diagonal ($\omega_1 = 2\omega_2$) with ω_2 coordinates corresponding to the Larmor frequencies of the two spins (e.g. $\omega_1 = \Omega_A + \Omega_M$, $\Omega_M + \Omega_x$).

2) Double-quantum transitions involving two magnetically equivalent spins. They lead to one or more cross peaks at an ω_1 frequency that intersects the double-quantum diagonal at the ω_2 frequency corresponding to the common Larmor frequency of the two spins (e.g. $\omega_1 = 2\Omega_A$, $2\Omega_M$, $2\Omega_x$, although the spins are magnetically equivalent only within experimental accuracy).

3) Double-quantum transitions involving two remotely coupled spins. They lead to single cross peaks at an ω_1 frequency that intersects the double quantum diagonal at ω_2 equal to the mean of the two Larmor frequencies (e.g. $\omega_1 = \Omega_A + \Omega_x$). These cross peaks carry information identical to that in relayed correlation spectra.

For the practical application it is essential that a multiple-quantum spectrum never contains an array of strong diagonal peaks. It should be mentioned that a beautiful and useful form of a double-quantum experiment is the 2D INADEQUATE spectroscopy proposed by Bax, Freeman, and Kempsell.[90, 91] There, only type 1 peaks can arise.

The methods mentioned so far produce additional cross peaks that provide information not accessible with the standard COSY and NOESY experiments. In the following, techniques are discussed that lead to simplified spectra which may facilitate their interpretation.

Multiple-Quantum Filtering

Selective filtering can be achieved by exciting multiple-quantum coherence, selecting a particular quantum order, and reconverting the selected order into observable magnetization. Depending on the selected order, this leads to multiple-quantum filtering of various orders. The spin-system-selective effect relies on coherence transfer selection rules that limit the allowed transfers for weakly coupled spins:[8, 92]

1) It is impossible to excite p quantum coherence in spin systems with less than p-coupled spins $I = 1/2$.

2) For the appearance of a diagonal peak of spin I_k in a p-quantum-filtered COSY spectrum, the spin I_k must be directly coupled to at least $p - 1$ further spins.

3) For the appearance of the cross peaks between spins I_k and I_l in a p-quantum-filtered COSY spectrum, both spins must simultaneously be coupled to at least $p - 2$ further spins.

Violations of these coherence transfer selection rules occur for strong coupling and for certain special relaxation situations.[93].

In Figure 17, the effect of four-quantum filtering on various four-spin systems is demonstrated. The sample consists of a mixture of the five compounds *trans*-phenylcyclopropanecarboxylic acid (K_4), DL-isocitric acid-lactone ($P_{3,1}$), 1,1-dichloroethane (S_4), 2-chloropropionic acid (C_4), and D-saccharic acid-1,4-lactone (L_4) with the coupling topologies indicated in Scheme 1.[94]

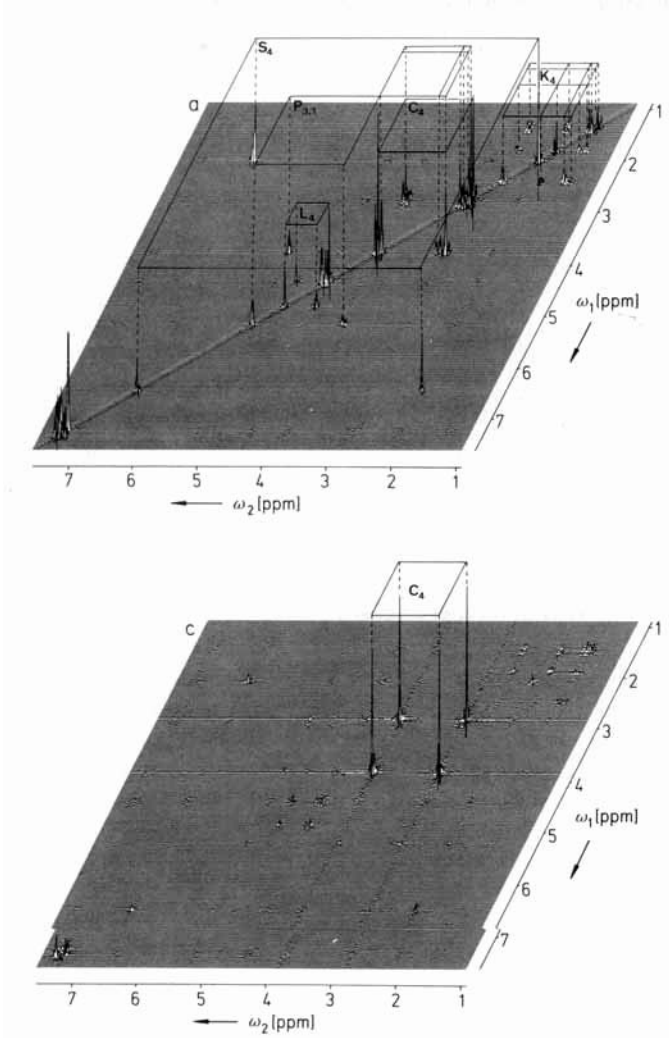

Figure 17a shows a conventional (double-quantum-filtered) COSY spectrum of the mixture, while in Figure 17b the corresponding four-quantum-filtered spectrum is reproduced. The filtering effect can easily be understood based on the given rules and the coupling topologies shown in Scheme 1. The interpretation is left to the reader. Only cross peaks of the molecule with K_4 topology and diagonal peaks of molecules with $P_{3,1}$, S_4, and K_4 topologies remain.

Technically, multiple-quantum filtering exploits the characteristic dependence of a multiple-quantum coherence transfer on the rf phase of the acting pulse sequence.[8, 92, 95, 96] Let us assume a transfer of coherence $c_{p1}(t)$ by a unitary transformation $\boldsymbol{U}(0)$, representing a particular pulse sequence, to coherence $c_{p2}(t)$, where p_1 and p_2 are the orders of

$$c_{p1}(t) \xrightarrow{\boldsymbol{U}(0)} c_{p2}(t) \tag{14}$$

coherence. All rf pulses in the sequence are now phase-shifted by Φ, leading to $\boldsymbol{U}(\Phi)$. Then it can be shown that the resulting coherence $c_{p2}(t)$ is phase-shifted by $(p_2 - p_1)\Phi$. The

$$c_{p1}(t) \xrightarrow{\boldsymbol{U}(\Phi)} c_{p2}(t)\, e^{i(p2-p1)\Phi} \tag{15}$$

phase shift is therefore proportional to the change in coherence order ($\Delta p = p_2 - p_1$). After a series of experiments are performed in which the phase Φ is incremented in regular

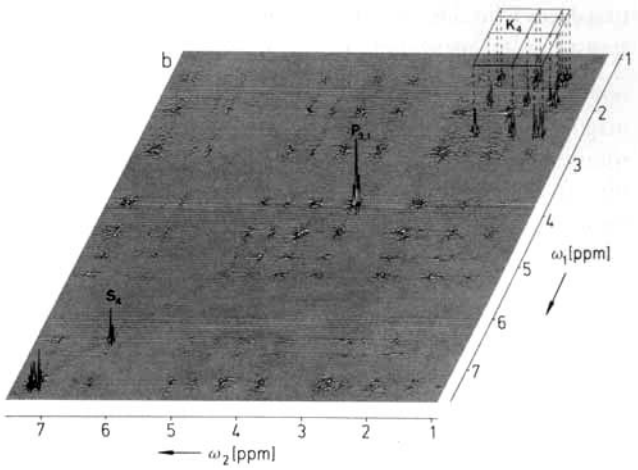

Fig. 17. Multiple-quantum-filtered and spin-topology-filtered 300 MHz ^{1}H COSY spectra of a mixture of the compounds from Scheme 1 containing four-spin systems. a) Double-quantum-filtered spectrum obtained with the pulse sequence from Figure 18. b) Four-quantum-filtered spectrum obtained with the pulse sequence from Figure 18. c) C_4 spin-topology-filtered spectrum obtained with the pulse sequence from Figure 19 (from ref. [94]).

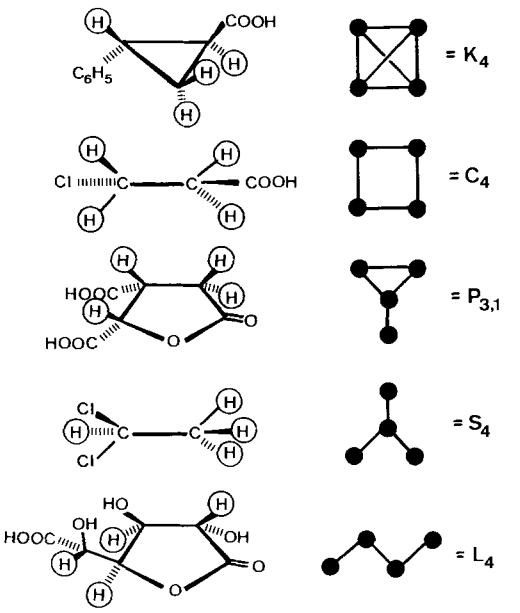
intervals $2\pi/N$ from 0 to $2\pi(N-1)/N$, it is possible to select for a particular Δp by computing the corresponding Fourier coefficient of Δp: Let $s(t,\Phi)$ be the recorded signal of an experiment with phase shift Φ, then we obtain the filtered signal according to (16). The required number of increments

$$s(t, \Delta p) = \sum_{k=0}^{N-1} s(t, 2\pi k/N)\, e^{\frac{-i2\pi k \Delta p}{N}} \tag{16}$$

N of the phase Φ depends on the number of values of Δp that have to be discriminated.[96] It is obvious that unless the initial order of coherence p_1 is known, no particular order of



Scheme 1. The compounds used for the spectra in Figure 17 and their spin-coupling topologies.

coherence p_2 can be filtered out in this manner. Most conventiently the initial state is selected to be in thermal equilibrium with $p_1 = 0$. Then, the entire pulse sequence preceding the point at which a coherence order should be selected must be phase-cycled. For multiple-quantum-filtered COSY experiments, this leads to the pulse sequence shown in Figure 18.

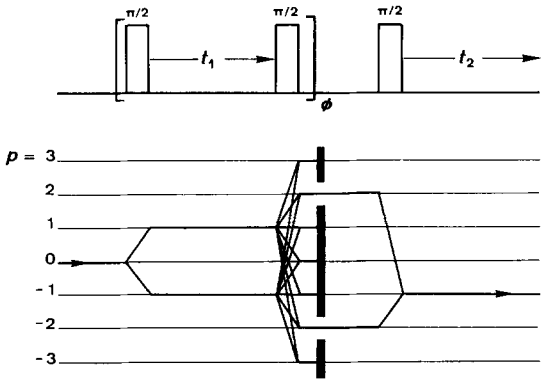


Fig. 18. Pulse sequence for a multiple-quantum-filtered COSY experiment with the coherence transfer diagram for double-quantum filtering. The phase ϕ is incremented systematically in a set of N experiments and the resulting experimental results are combined according to Eq. (16).

Obviously, multiple-quantum-filtering and phase-cycling require N-times more experiments. However, no information is lost, since in each term of Equation (16) just the phase factor is compensated, and identical signals are coadded for the relevant pathways. Thus the longer performance time is refunded in terms of an increased signal-to-noise ratio.

Spin-Topology Filtration

It is may be desirable to enhance the filtering effect illustrated in Figure 17 and to select individual spin coupling topologies. Indeed it is possible to design extended pulse sequences, in combination with multiple-quantum filtration, that are tailor-made for specific spin coupling topologies.[94, 97, 98] A pulse sequence built into a 2D COSY experiment, that is selective for cyclic C_4 spin coupling topologies is depicted schematically in Figure 19. If this pulse sequence is applied to the mixture of compounds with four-spin systems (Scheme 1), the 2D spectrum of Figure 17c is obtained. It shows efficient suppression of all other spin systems. It should be noted, however, that the situation is here rather ideal. Often, these filters do not perform as well because their design relies on all non-zero spin couplings being equal. In

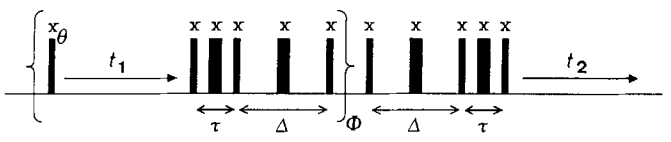

Fig. 19. Pulse sequence for C_4 spin-topology filtration consisting of $\pi/2$ and π pulses. The delays are adjusted to $\tau = 1/(8J)$ and $\Delta = 1/(2J)$, where J is the uniform J-coupling constant. ϕ is phase-cycled for four-quantum selection and θ for the suppression of axial peaks [94].

reality, there are weak and strong couplings that cannot be characterized by topological considerations alone. Often also the intensities of signals decrease during the extended pulse sequences due to relaxation. This limits the practical usefulness of these methods.

Exclusive Correlation Spectroscopy

Multiple-quantum filtering suppresses not only diagonal and cross peaks in 2D spectra but also changes the sign pattern in the cross-peak multiplet structure. By appropriate combination of differently multiple-quantum-filtered 2D spectra, it is possible to simplify the multiplet structure by reducing the number of multiplet components. Exclusive correlation spectroscopy (E. COSY), proposed by O. W. Sørensen, eliminates all multiplet components from a COSY spectrum except for those belonging to pairs of transitions with an energy level in common.[99-101] In practice, it is not necessary to combine multiple-quantum-filtered spectra literally, but it is possible to coadd directly the experimental results from a phase cycle with the appropriate weighting factors.

Figure 20 shows schematically the combination of cross-peak multiplets connecting two spins, I_1 and I_2, in a three-spin system after double- and triple-quantum filtering. The remaining pattern consists of two basic squares with side lengths equal to the active coupling constant J_{12} responsible for the coherence transfer. The displacement vector between the two squares is given by the two passive couplings J_{13} and J_{23} to the third (passive) spin. It should be mentioned that this multiplet structure is identical to the one obtained by a COSY experiment with a mixing pulse with an extremely small flip angle.[102]

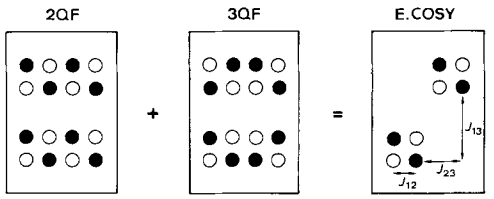

Fig. 20. E. COSY experiment to simplify the multiplet structure of cross peaks. The double-quantum- and the triple-quantum-filtered cross peaks between spins I_1 and I_2 of a three-spin system are combined to produce an E. COSY pattern. Positive and negative multiplet components are distinguished by empty and filled circles.

E. COSY is of practical use whenever the cross-peak multiplet structure must be analyzed for the determination of J-coupling constants. This can be done conveniently by hand by measuring the displacement of peripheral multiplet components[101] or by a recursive contraction procedure on a computer.[103]

Heteronuclear Two-Dimensional Experiments

In addition to the homonuclear 2D experiments discussed so far, at least as many heteronuclear experiments have been

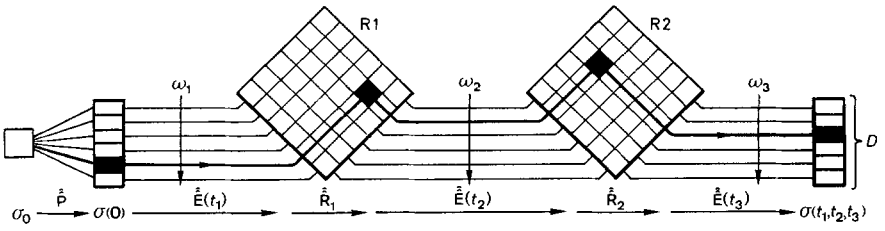

Fig. 21. Schematic representation of a 3D NMR experiment as an extension of Figures 1 and 6. Three evolution periods with the time variables t_1, t_2, and t_3 are separated by two transfer or mixing processes with the transfer matrices R1 and R2. A 3D experiment can be conceived as the contraction of two 2D experiments.

proposed and introduced to the repertoire of routine spectroscopic methods. Of greatest practical importance are heteronuclear shift correlation spectra which correlate the chemical shifts of directly bonded or remotely connected heteronuclei.[104, 105] In this context, so-called inverse detection experiments are of particular interest. Here proton I-spin coherence is observed in t_2 while spin coherence of a less sensitive, less abundant S nucleus evolves in t_1.[104] The most efficient pulse sequences create heteronuclear two-spin coherence that evolves in t_1 and that acquires the frequency information of the S-spin resonance.[106] Also in the heteronuclear environment, relayed coherence transfer[78] as well as experiments in the rotating frame[107] are important. Spin filtering is used for multiplicity selectivity, that is, for distinguishing S spins coupled to one, two, or three I spins,[108] and in the form of J filtering for the distinction of one-bond and multiple-bond couplings.[109] This enumeration of heteronuclear experiments is by no means exhaustive.

Three-Dimensional Fourier-Transformation Spectroscopy

No new principles are required for the development of 3D NMR spectroscopy, which is just a logical extension of 2D NMR spectroscopy. Instead of a single mixing process which relates two frequency variables, two sequential mixing processes relate three frequencies: the original frequency ω_1, the relay frequency ω_2, and the detection frequency ω_3, (Fig. 21). In this sense a 3D experiment can be considered as the combination of two 2D experiments. Obviously a very large number of possible 3D experiments can be conceived. However, only few of them have proved to be indispensible so far.[110–118]

Two applications of the 3D spectroscopy concept have emerged: 1) 3D correlation and 2) 3D dispersion spectroscopy (see also Fig. 13). Three-dimensional correlation is of importance in homonuclear experiments. It has been mentioned that the assignment procedure in biomolecules requires a COSY-type and a NOESY-type 2D spectrum. The two 2D experiments could be contracted into one 3D experiment, combining a J-coupling-mediated transfer and a cross-relaxation transfer. A 3D COSY–NOESY spectrum possesses the advantage that the entire assignment process can be carried out with a single homogeneous data set.[115, 116] It also incorporates redundant information that allows cross checks of the assignments. For obtaining quantitative information, however, 3D spectra are less suited, since all peak intensities are products of two transfer coefficients that are sometimes difficult to separate.

A 3D ROESY–TOCSY spectrum of the linear nonapeptide buserilin is shown in Figure 22 (vf. Fig. 14)[116] A ROESY instead of a NOESY sequence is required for buserilin, as it is a molecule of intermediate size for which the NOE intensities are small. The TOCSY step has the advantage that chains of multiple-step cross peaks extend to nuclei in the side chains are obtained thus facilitating the identification of the amino acid residues.

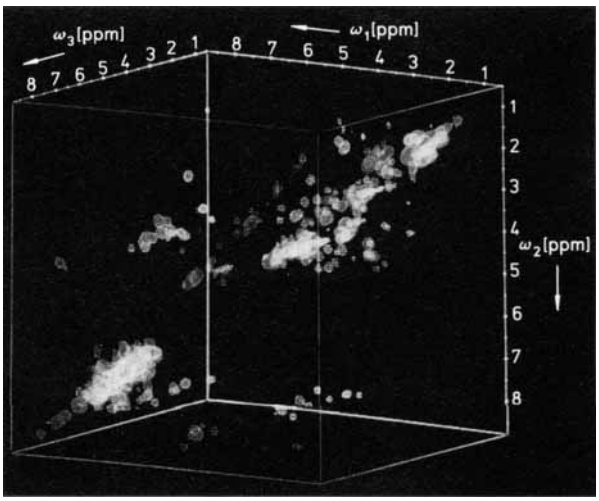

Fig. 22. 3D representation of a 300 MHz 3D homonuclear ROESY–TOCSY spectrum of buserilin in [D_6]DMSO photographed from a computer screen [116].

It should be recognized that recording a 3D spectrum is considerably more time-consuming than two 2D spectra, since two time parameters, t_1 and t_2, must be incremented independently, requiring a 2D array of experiments. Thus the question arises of when it is worth the effort to record a 3D spectrum. This question has been discussed in numerous publications.[116, 119, 120]

Let us consider a particular cross peak in a 3D spectrum that correlates the coherences $\{tu\}$ in the ω_1, $\{rs\}$ in the ω_2 and $\{pq\}$ in the ω_3 dimension. Its intensity is determined by the following product (17) of matrix elements in the eigen-

$$Z_{\{pq\}\{rs\}\{tu\}} = D_{qp} R^{(2)}_{\{pq\}\{rs\}} R^{(1)}_{\{rs\}\{tu\}} (\hat{\hat{P}}\sigma_0)_{tu} \qquad (17)$$

basis of the unperturbed Hamiltonian $\mathcal{H}_0$.[116] A nonvanishing intensity establishes a two-step correlation $\{tu\}$–$\{rs\}$–$\{pq\}$.

The 3D experiment can be compared with two 2D experiments that employ the mixing processes $\hat{\hat{R}}^{(1)}$ and $\hat{\hat{R}}^{(2)}$, re-

spectively. The corresponding intensities are expressed by (18) and (19). If in the 2D spectra the two relevant peaks

$$Z^{(1)}_{\{rs\}\{tu\}} = D^{(1)}_{sr} R^{(1)}_{\{rs\}\{tu\}} (\hat{\hat{\mathbf{P}}}\,\boldsymbol{\sigma}_0)_{tu} \tag{18}$$

$$Z^{(2)}_{\{pq\}\{rs\}} = D_{qp} R^{(2)}_{\{pq\}\{rs\}} (\hat{\hat{P}}^{(2)}\boldsymbol{\sigma}_0)_{rs} \tag{19}$$

with intensities $Z^{(1)}_{\{rs\}\{tu\}}$ and $Z^{(2)}_{\{pq\}\{rs\}}$ can be identified, possibly in crowded regions, the two-step correlation, represented by a 3D peak, could also be established based on the two 2D spectra $\{tu\}-\{rs\}$ and $\{rs\}-\{pq\}$. Provided that $Z_{\{pq\}\{rs\}\{tu\}} \neq 0$ is true, the intensities $Z^{(1)}_{\{rs\}\{tu\}}$ and $Z^{(2)}_{\{pq\}\{rs\}}$ are different from zero when in addition $D^{(1)}_{sr} \neq 0$ and $(\hat{\hat{\mathbf{P}}}^{(2)}\boldsymbol{\sigma}_0)_{rs} \neq 0$ hold. This implies that the relay transition $\{rs\}$ must be excited in the preparation state $P^{(2)}$ and detectable by the observable $D^{(1)}$. For allowed one-spin single-quantum coherences, this condition is fulfilled for single-pulse excitation and direct detection. On the other hand, forbidden multiple-spin single-quantum coherences (combination lines) and multiple-quantum coherences can neither be excited by a single nonselective pulse nor directly detected. Such coherences regularly occur in the ω_2 dimension of a 3D spectrum. The excitation and indirect detection of these coherences in 2D experiments requires special pulse sequences for excitation and detection.

In conclusion, the two constituent 2D experiments deliver the same information on the spin system as the 3D spectrum, provided that 1) the relevant frequencies in the ω_2 dimension of the 3D spectrum can be excited and detected in the 2D experiments, and 2) the cross peaks are not hidden by spectral overlap and can be identified in the 2D spectra. The first condition is normally not severe, as the 2D experiments can be modified for excitation and detection of forbidden transitions whenever required. On the other hand, the limited resolving power of 2D spectra is the most important motivation for justifying 3D (and possibly higher dimensional) spectroscopy.

Because the gain in resolution justifies 3D spectroscopy, it may be worthwhile to introduce a third frequency axis just for resolution purposes, rather than combining two processes relevant for the assignment requiring high resolution in all three dimensions. It is then possible to choose the extent of 3D resolution arbitrarily and optimize the performance time of the 3D experiment. To spread a 2D spectrum into a third dimension, homonuclear or heteronuclear transfers can be used. Heteronuclear one-bond transfers are far more efficient, however, because the strong heteronuclear one-bond couplings prevent leakage to further spins. This allows an efficient transfer, virtually without loss of magnetization. In addition, nuclei like ^{13}C and ^{15}N exhibit large ranges of chemical shifts with high resolving power. The principle of spreading is represented graphically in Figure 23.

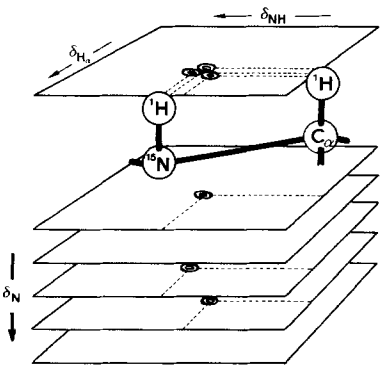

Fig. 23. 3D resolution of a 2D ^1H NMR spectrum by ^{15}N resonance spreading. The NH–$C_\alpha H$ cross peaks are displaced in a third dimension by the corresponding ^{15}N chemical shifts.

A 3D ^{15}N-spread TOCSY spectrum of ribonuclease A is shown in Figure 24. Heteronuclear spreading requires usually

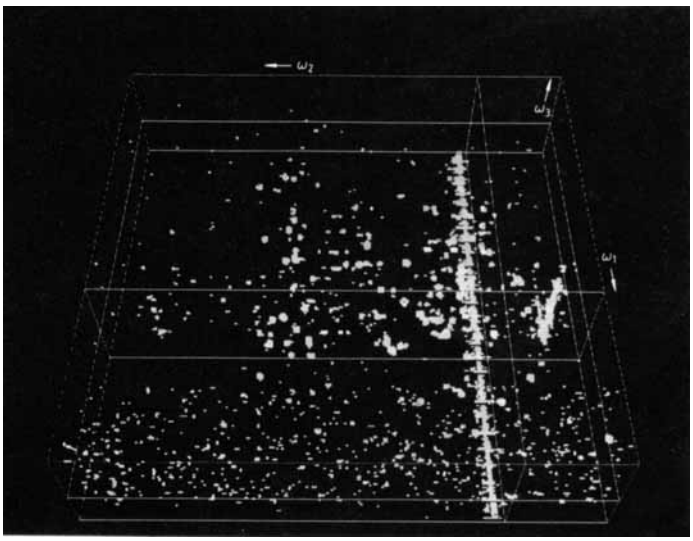

Fig. 24. 3D ^{15}N-spread 600 MHz ^1H TOCSY spectrum of ^{15}N-labeled ribonuclease A in water. The 3D spectrum shows the ^{15}N resonances along the ω_2-axis. The spectrum was recorded by C. Griesinger with the pulse sequence from Figure 25 and processed by S. Boentges. The sample was provided by Prof. S. Benner, ETH Zurich.

isotopic labeling of the molecule. In this case, ribonuclease A was grown in an *E. coli* medium containing ^{15}N-labeled nutrients. The spectrum was obtained with the pulse sequence from Figure 25. Initially proton coherence is excited and

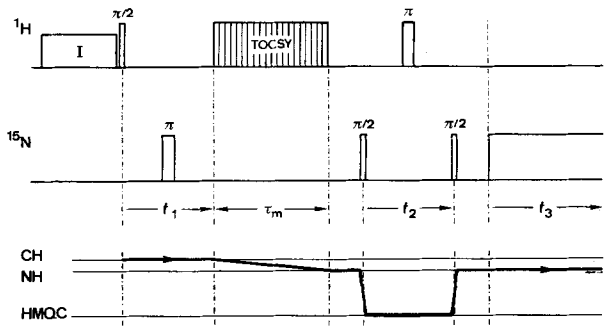

Fig. 25. Pulse sequence for recording a 3D ^{15}N-spread TOCSY spectrum. After presaturation of the water resonance (I), the proton resonances are excited and precess during t_1. After the homonuclear TOCSY transfer from the CH to the NH protons, the coherence is converted into heteronuclear multiple-quantum coherence (HMQC) that evolves during t_2 and acquires ^{15}N shift information. After reconversion to proton coherence, the NH resonances are detected during t_3 under ^{15}N decoupling.

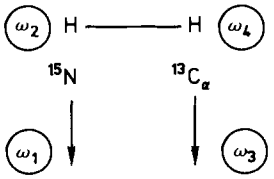
precesses during t_1 under ^{15}N refocusing by the applied π pulse. During the mixing time τ_m, coherence transfer from other protons to the NH protons is effected in the rotating

frame by the application of a TOCSY multiple-pulse sequence. The NH coherence is then converted into ^{15}NH heteronuclear multiple-quantum coherence (HMQC) which precesses during t_2 and acquires ^{15}N resonance information (under proton refocusing). After reconversion into NH proton coherence, detection follows during t_3 under ^{15}N decoupling. For a complete assignment of the proton resonances a ^{15}N-spread NOESY spectrum is required in addition.

The step to 4D spectroscopy[121] is a logical one: In 2D experiments, spins are pairwise correlated, for example NH and $C_\alpha H$ protons. Three-dimensional dispersion uses either ^{15}N or $^{13}C_\alpha$ resonance for spreading the resonances of NH or $C_\alpha H$, respectively. In a 4D experiment, both spreading processes are applied simultaneously (Scheme 2). The order



Scheme 2. Double spreading in 4D experiments.

of the frequencies in the actual experiment is a matter of convenience. Normally, the detection frequency ω_4 refers to proton spins for sensitivity reasons. In most cases, the two spreading coordinates are rather coarsely digitized to limit the performance time, just enough to achieve separation of peaks overlapping in the 2D spectrum. Often 8 to 32 points in each of the two dimensions are sufficient.

Molecular Dynamics Investigated by NMR

The molecular structures determined by NMR spectroscopy in solution, by X-ray diffraction in single crystals, or by other means are invariably motionally averaged structures, whereby the averaging process is strongly dependent on the measurement technique. To interpret experimentally determined structures, some knowledge of the motional properties of the molecule is in fact indispensible. Molecular dynamics is also relevant for its own sake, in particular for the understanding of reactivity and interaction with other molecules. In many cases, active sites in a molecular pocket are only accessible due to the flexibility of the molecule itself.

The characterization of the motional properties of a molecule is orders of magnitude more difficult than the description of an averaged molecular structure. While $3N-6$ coordinates are sufficient to fix a structure containing N atoms, the characterization of molecular dynamics requires $3N-6$ variances of the intramolecular coordinates, $(3N-6)(3N-5)/2$ covariances, and the same number of auto- and cross-correlation functions, respectively. In addition, also higher order correlation functions are needed for a more refined description of dynamics. In practice, a sufficient number of observables is never available for a full description of dynamics. In this sense, the study of dynamics is an open-ended problem.

Numerous techniques are available for obtaining data on dynamics: Debye–Waller factors in X-ray diffraction give hints on the variances of the nuclear coordinates, however, without a measure for the time scale. Inelastic and quasi-elastic neutron scattering deliver correlation functions, but without a reference to the structure. Fluorescence depolarization allows one to determine the motional correlation function of fluorescent groups, such as tyrosine residues in proteins. Ultrasonic absorption gives an indication of the frequencies of the dominant motional modes, but again without a structural reference.

NMR spectroscopy is more universally applicable to motional studies than most of the other techniques. The range of correlation times τ_c that can be covered by various NMR methods is enormous, from picoseconds to seconds and more (Scheme 3).

$1\text{ s} < \tau_c$:	Real-time monitoring after initial perturbation
$10\text{ ms} < \tau_c < 10\text{ s}$:	2D exchange spectroscopy (EXSY)
$100\ \mu\text{s} < \tau_c < 1\text{ s}$:	Lineshape analysis, exchange broadening, and exchange narrowing
$1\ \mu\text{s} < \tau_c < 10\text{ ms}$:	Measurements of relaxation time $T_{1\varrho}$ in the rotating frame
$30\text{ ps} < \tau_c < 1\ \mu\text{s}$:	Measurements of relaxation time T_1 in the laboratory frame
$\tau_c < 100\text{ ps}$:	Averaged parameter values

Scheme 3. NMR methods for the determination of motional correlation times τ_c.

Except for slow motions on a time scale of a millisecond or more for which lineshape analysis, saturation transfer experiments, and 2D exchange studies can be performed, many dynamics studies by NMR rely on measurements of relaxation times. The various relaxation parameters, such as the longitudinal relaxation time T_1, the transverse relaxation time T_2, the rotating-frame relaxation time $T_{1\varrho}$, and cross-relaxation rate constants Γ_{kl} depend on the correlation time τ_c of the underlying random process.

The following discussion shall be restricted to a recent study of the intramolecular dynamics in antamanide (**1**)[83, 122, 123] (see Figs. 8, 9, 11). Antamanide is an antidote for toxic components of the mushroom *Amanita phalloides*. Astonishingly, the antidote is a component of the same mushroom. Indications have been found in early ultrasonic absorption studies[124] that the peptide ring seems to undergo a conformational exchange process with a frequency of about 1 MHz. In the course of extensive investigations of antamanide by Kessler's research group,[125] it has also been noticed that the distance constraints obtained from NMR measurements could not be fitted by a single conformation. In our laboratory Martin Blackledge performed rotating-frame relaxation measurements and localized a hydrogen-bond exchange process with an activation energy of about 20 kJ mol^{-1} and a lifetime of 25 μs at room temperature (unpublished results, see also ref.[126]). With a new dynamic structure determination procedure called MEDUSA,[123] the conformational space of antamanide was investigated more systematically than ever before. 1176 feasible low-energy structures were found. They were combined in dynamically interconverting pairs in an attempt to fulfill all experimental

constraints including NOE distance constraints, J-coupling angular constraints, and specific information on hydrogen-bond dynamics. A large set of feasible structural pairs were constructed. Many pairs are compatible with the experimental data within experimental accuracy. For a more restrictive description of the dynamic system of antamanide, additional and more accurate experimental data is required. Figure 26 shows, as an example, the dynamic pair of structures that fits the experimental data best so far. The two interconverting structures differ primarily in the hydrogen bonds Val^1NH–Phe^9O and Phe^6NH–Ala^4O, which exist only in one of the two conformations (**II**), and in the torsional angles ϕ_5 and ϕ_{10}.

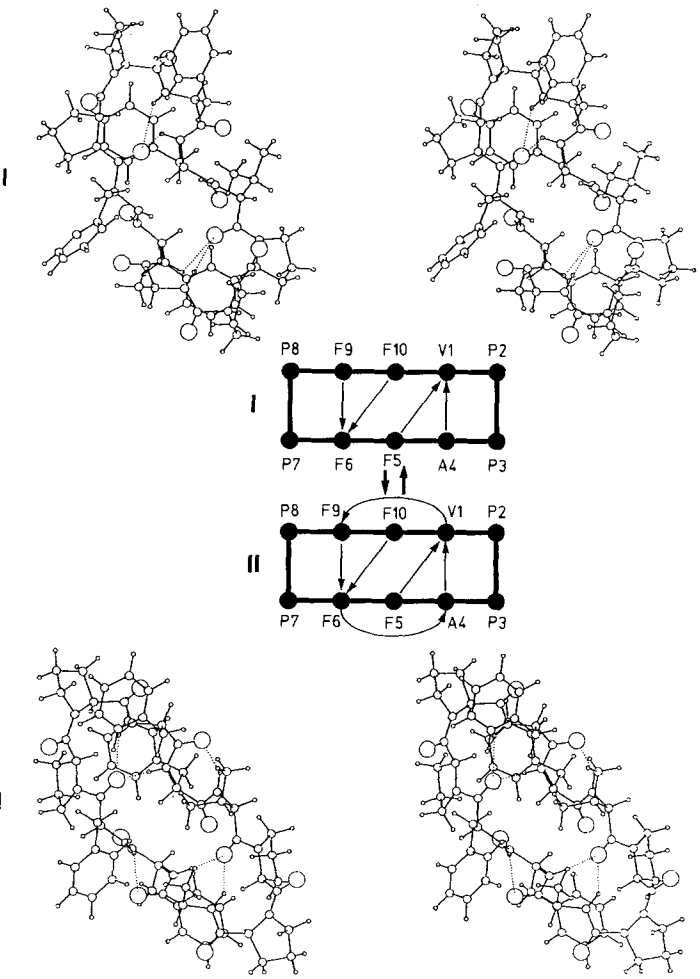


Fig. 26. Pairs of conformers of antamanide that fulfill the experimentally determined structural constraints. The two pairs are shown as stereoplots as well as in abstract form. In the former, hydrogen bonds are indicated by broken lines, in the latter by arrows pointing towards the hydrogen-bonded oxygen atom. The C–C bonds about which the torsion angles ϕ_5 and ϕ_6 are defined are indicated by heavy lines. ϕ_5 is in the lower and ϕ_{10} in the upper half of the stereoplots. (from ref. [123]).

A second study concentrated on the dynamics of ring puckering of the four proline residues in antamanide.[122] The conformation of the five-ring systems can be determined from the dihedral angles χ_1, χ_2 and χ_3 which in turn can be deduced from the vicinal proton–proton J-coupling constants using the Karplus relations.[54] The relevant coupling constants (21 per residue) were determined from E. COSY spectra. Based on these measurements, a model was constructed for each of the proline residues by least-squares fitting. It was found that for Pro^3 and Pro^8 a good fit can be obtained with a single rigid conformation, while for Pro^2 and Pro^7 two rapidly exchanging conformations were required to reduce the fitting error to within an acceptable range. At the same time, measurements of the ^{13}C relaxation time confirmed that Pro^3 and Pro^8 are rigid, while Pro^2 and Pro^7 show dynamic behavior with correlation times between 30 and 40 ps. This implies that the dynamics of the peptide ring and the proline ring are not correlated and proceed on entirely different time scales. The two exchanging conformations found for Pro^2 are shown in Figure 27. It is seen that the conformational changes resemble the up and down movements of the "flap of the envelope" (C_γ).

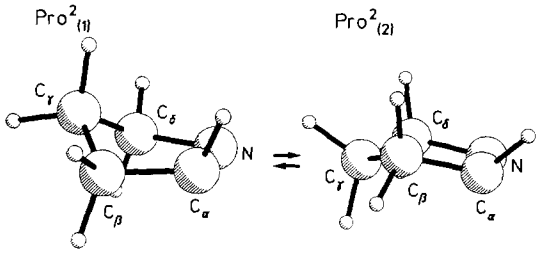

Fig. 27. The two experimentally determined conformations of the amino acid residue Pro^2 in antamanide (**1**) (see ref. [122]).

Magnetic Resonance Fourier Imaging

Magnetic resonance imaging (MRI) has had an enormous impact on medical diagnosis and has rapidly become a powerful routine tool. The basic procedure for recording a 2D or 3D NMR image of an object is attributed to Paul Lauterbur.[127] A magnetic field gradient, applied along different directions in space in a sequence of experiments, produces projections of the nuclear spin density of the object onto the direction of the gradient. From a sufficiently large set of such projections it is possible to reconstruct an image of the object, for example, by filtered backprojection in analogy to X-ray tomography.

A different approach is directly related to 2D and 3D FT spectroscopy. Frequency encoding of the three spatial dimensions is achieved by a linear magnetic field gradient applied successively along three orthogonal directions for the durations t_1, t_2, and t_3, respectively, in a pulse FT experiment.[128] In full analogy to 3D spectroscopy, the time parameters t_1 and t_2 are incremented in regular intervals from experiment to experiment. The recorded signal $s(t_1, t_2, t_3)$ is Fourier-transformed in three dimensions to produce a function $S(\omega_1,\omega_2,\omega_3)$ which is equivalent to a 3D spatial image when the spatial information is decoded using the relations $x = \omega_1/g_x$, $y = \omega_2/g_y$, and $z = \omega_3/g_z$ with the three field gradients g_x, g_y, and g_z. The procedure is illustrated in Figure 28 for two dimensions.

In a further refinement, proposed by Edelstein et al.,[129] the time variables t_1 and t_2 are replaced by variable field

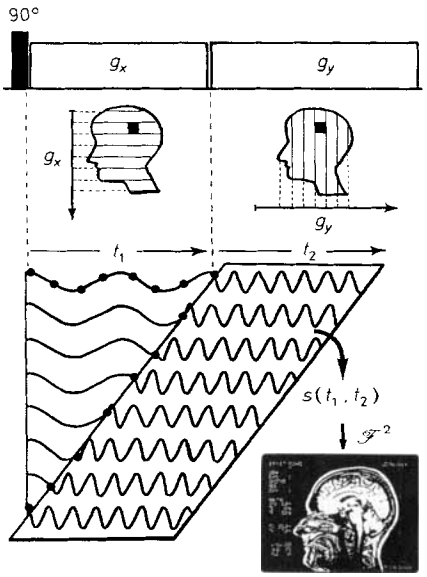

Fig. 28. Schematic representation of Fourier NMR imaging, here shown in two dimensions. Two orthogonal gradients (g_x, g_y) are applied during the t_1 and t_2 periods of a 2D experiment. A 2D Fourier transformation of the data set $s(t_1, t_2)$ produces a 2D image of the investigated subject (R.R.E.).

gradient strengths g_x and g_y applied during a constant evolution time. With regard to the accumulated phase [Eq. (20)] it

$$\gamma = x\, g_x\, t_1 + y\, g_y\, t_2 + z\, g_z\, t_3 \qquad (20)$$

is immaterial whether the evolution time or the field gradients are varied. However, keeping the time t_k constant eliminates undesired relaxation effects.

In medical imaging, 3D experiments have a natural justification, although it is sometimes simpler to apply selective excitation techniques to select a 2D slice through the object to be imaged.[130] Even extensions to higher dimensions are quite realistic. In a fourth dimension, for example, chemical shift information can be accommodated.[131] Also 2D spectroscopic information could be combined with three spatial dimensions, leading to a 5D experiment. No limitations seem to exist for human imagination. However, the practical limits will soon be reached when the required performance times are also taken into consideration.

Conclusion

I am not aware of any other field of science outside of magnetic resonance that offers so much freedom and opportunities for a creative mind to invent and explore new experimental schemes that can be fruitfully applied in a variety of disciplines. NMR spectroscopy is intellectually attractive because the observed phenomena can be understood based on a sound theory, and almost all conceits can also be tested by easy experiments. At the same time, the practical importance of NMR is enormous and can justify much of the playful activities of an addicted spectroscopist.

Most of the credit for the inspiration and execution of the work described should go to my teachers Hans Primas and Hans H. Günthard, to my supervisor Weston A. Anderson, to the inspirator Jean Jeener, and to my co-workers (in more or less chronological order): Thomas Baumann, Enrico Bartholdi, Robert Morgan, Stefan Schäublin, Anil Kumar, Dieter Welti, Luciano Müller, Alexander Wokaun, Walter P. Aue, Jiri Karhan, Peter Bachmann, Geoffrey Bodenhausen, Peter Brunner, Alfred Höhener, Andrew A. Maudsley, Kuniaki Nagayama, Max Linder, Michael Reinhold, Ronald Haberkorn, Thierry Schaffhauser, Douglas Burum, Federico Graf, Yongren Huang, Slobodan Macura, Beat H. Meier, Dieter Suter, Pablo Caravatti, Ole W. Sørensen, Lukas Braunschweiler, Malcolm H. Levitt, Rolf Meyer, Mark Rance, Arthur Schweiger, Michael H. Frey, Beat U. Meier, Marcel Müri, Christopher Councell, Herbert Kogler, Roland Kreis, Norbert Müller, Annalisa Pastore, Christian Schönenberger, Walter Studer, Christian Radloff, Albert Thomas, Rafael Brüschweiler, Herman Cho, Claudius Gemperle, Christian Griesinger, Zoltan L. Mádi, Peter Meier, Serge Boentges, Marc McCoy, Armin Stöckli, Gabriele Aebli, Martin Blackledge, Jacques Briand, Matthias Ernst, Tilo Levante, Pierre Robyr, Thomas Schulte-Herbrüggen, Jürgen Schmidt and Scott Smith. I would also like to thank my technical staff, Hansruedi Hager, Alexandra Frei, Janos A. Deli, Jean-Pierre Michot, Robert Ritz, Thomas Schneider, Markus Hintermann, Gerhard Gucher, Josef Eisenegger, Walter Lämmler and Martin Neukomm; my secretary Irène Müller; and several research groups with which I had the pleasure to collaborate, first of all the research group of Kurt Wüthrich and the group of Horst Kessler. I am grateful for support in the early days from Varian Associates and more recently from the Swiss Federal Institute of Technology, the Swiss National Science Foundation, the Kommission zur Förderung der Wissenschaftlichen Forschung, and last but not least from Spectrospin AG.

Ion Channels for Communication Between and Within Cells (Nobel Lecture)**

By Erwin Neher

The fundamental signal mechanisms for communication between cells of the nervous system were known around 1970. Hodgkin and Huxley[1] had already provided the basis for an understanding of the nerve action potential in 1952. The concept of chemical transmission at synapses had also been experimentally verified by detailed studies on excitatory and inhibitory postsynaptic potentials (see B. Katz[2] for a concise description of the electrical signals in nerve and muscle). The question of the molecular mechanisms underlying these signals was still open, however. Hodgkin and Huxley used the concept of voltage-operated gates for a formal description of conductance changes, and by 1970 the terms Na channel and K channel were used frequently (see review by Hille[3]), although no direct evidence for the existence of channels was available from biological preparations. This was different in the case of artificial membranes. Müller and Rudin[4] introduced 'black-lipid membranes' as experimental model systems, which in many respects resemble the bimolecular lipid membrane of living cells. These membranes are rather good insulators. However, when they are doped with certain antibiotics or proteins they become electrically conductive. R. C. Bean et al.[5] and Hladky and Haydon[6] showed that some of these dopants induce discrete, step-like changes in conductance when they are added in trace amounts. All the evidence suggested that the changes observed in the conductance represent the insertion of single pore-like structures into the membranes.

Similar measurements on biological membranes were not possible at the time, since the methods available for recording currents in living cells typically had background noise levels higher by about a factor of a hundred than the 'single-channel currents' observed in bilayers (see Fig. 1). Indirect methods, however, provided strong evidence that channels similar in conductance to those in artificial membranes should be operative in nerve and muscle cells. Early attempts to count the number of Na channels by tetrodotoxin binding indicated that the contribution of a single channel to Na conductance might be as much as 500 pS. Later, the technique of noise analysis[7, 8] provided more accurate numbers. Anderson and Stevens[9] estimated the conductance contribution of single acetylcholine-activated channels (ACh channels) at the frog neuromuscular junction to be 32 pS. This is close to the conductance of single gramicidin channels as measured by Hladky and Haydon.[6] Thus, it was very tempting to think about better methods for recording currents from biological preparations. There was good reason to hope that an improved technology would reveal a whole 'microcosmos' of electrical signals in a multitude of electrically and chemically excitable cell types. In this lecture I will give a short account of our joint effort to solve this problem, and then focus on further developments to which the solution of the problem led. Bert Sakmann, in the second lecture,[10] will present some of the detailed knowledge that high-resolution current recording provides access to.

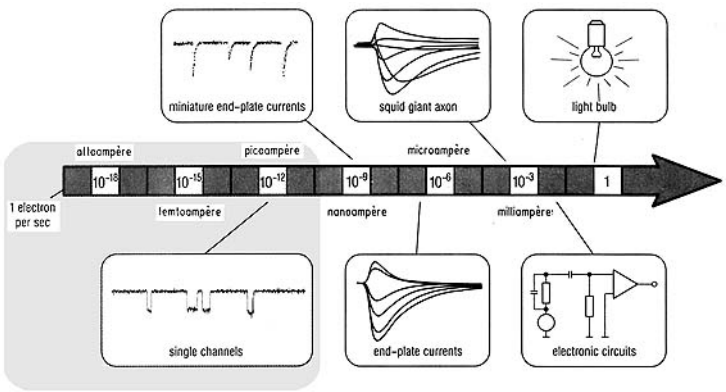

Fig. 1. A graphical representation of the quantity 'current' on a logarithmic scale with representative examples of current signals or current-carrying elements from electronics and biology. The shaded region is that which was dominated by background noise before the development of the patch clamp technique.

Rationale for Using 'Patch Pipettes'

A basic limitation for any current measurement, disregarding instrumentation noise, is the 'Johnson' or thermal noise of the signal source, which for a simple resistor is given by $\sigma_n = \sqrt{4kT\Delta f/R}$ where σ_n is the root-mean-square deviation of the current, k is the Boltzmann constant, T the absolute temperature, Δf the measurement bandwidth, and R the resistance. From this, it is clear that the internal resistance of a signal source (or, more generally, the complex impedance) should be very high for low-noise current recording. Specifically, to record a current of 1 pA at a bandwidth of 1 kHz with 10% accuracy, the internal resistance of the signal source should be about 2 GΩ or higher. We now know that the input resistances of small cells can be as high as that. But early in the seventies the conventional microelectrode techniques required large cells for reliable current measurements, and these typically had input resistances in the range 100 kΩ to 50 MΩ. Thus, it seemed impossible to reach the required resolution with standard techniques and standard preparations. What was required, was a smaller signal source.

With these considerations in mind, we directed our efforts to isolate a small patch of membrane for the purpose of the electrical measurement. I had gained experience with suction pipettes being placed onto the surface of cells for local current measurement in H. D. Lux's laboratory in Munich, where I did my doctoral thesis. Such pipettes had been used before in various contexts for either stimulation of cells or for current measurements.[11–15] It was clear to us, that they should be good tools for single-channel measurements, if

only the 'pipette-to-membrane seal' could be made good enough. The impedance of the patch itself should be higher than required, even for a patch as large as 10 μm in diameter. An incomplete seal, however, is 'seen' by the measuring amplifier in parallel to the patch, and its noise is superimposed onto the patch signal.

Early Single-Channel Measurements

When Bert Sakmann and I started measurements by placing pipettes onto the surface of denervated muscle fibers, we soon realized that it was not so easy to obtain a satisfactory 'seal'. Although Bert Sakmann was very experienced in enzymatically treating cell surfaces through his work in B. Katz's laboratory, and although the work of Katz and Miledi[7] and our own voltage-clamp measurements had shown that denervated muscle should have an appropriate density of diffusely dispersed ACh channels, our initial attempts failed. Our seal resistances were just about 10–20 MΩ, two orders of magnitude lower than desired. However, by reducing the pipette size, and by optimizing its shape we slowly arrived at a point where signals emerged from the background—first some characteristic noise, later on blips which resembled square pulses, as expected. In 1976 we published recordings[16] which, with good confidence, could be interpreted as single-channel currents (see Fig. 2). The fact that similar recordings could be obtained both in our Göttingen laboratory and in Charles F. Stevens' laboratory at Yale, (where I spent parts of 1975 and 1976), gave us confidence that they were not the result of some local demon, but rather signals of biological significance. The square-wave nature of the signals was proof of the hypothesis that channels in biological membranes open and close stochastically in an all-or-none manner. For the first time one could watch conformational changes of biological macromolecules in situ and in real time. However, the measurement was far from perfect. There still was excessive background noise, concealing small and more short-lived contributions of other channel types. Besides, the amplitudes of single-channel currents had a wide distribution, since the majority of channels were located under the rim of the pipette, such that their current contributions were recorded only partially.

We made many systematic attempts to overcome the seal problem (manipulating and cleaning cell surfaces, coating

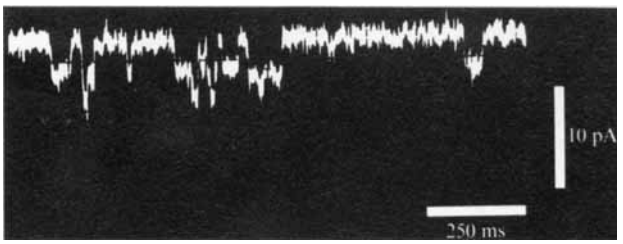

Fig. 2. Early single-channel currents from denervated frog (*Rana pipiens*) cutaneous pectoris muscle. The pipette contained 0.2 μM suberoyldicholine, an analogue of acetylcholine which induces very long-lived channel openings. Membrane potential −120 mV; temperature 8 °C (from [16]).

pipette surfaces, reversing charges on the glass surface etc.) with little success. Nevertheless, some important properties of single channels could be elucidated in the years 1975 to 1980.[17–21]

By about 1980 we had almost given up our attempts to improve the seal, when we noticed by chance, that the seal suddenly increased by more that two orders of magnitude when slight suction was applied to the pipette. The resulting seal was in the gigaohm range, the so-called 'gigaseal'. It turned out that a gigaseal could be obtained reproducibly when suction was combined with some simple measures to provide for clean surfaces, such as using a fresh pipette for each approach and using filtered solutions. The improved seal resulted in much improved background noise.[26] Fortunately, Fred Sigworth had just joined the laboratory. With his experience in engineering he improved the electronic amplifiers to match the advances in recording conditions. Thus, several types of ion channels could rapidly be characterized at good amplitude and time resolution (Fig. 3).

Unexpected Benefits

Solving the seal problem turned out not only to be a matter of improving the electrical recording, but also of providing useful tools for manipulating patches and small cells. Although the physical nature of the 'Gigaseal' is still unknown, we soon realized that it provides not only electrical stability but also a tight mechanical connection between the measuring glass pipette and the membrane. Owen Hamill and Bert Sakmann,[24] simultaneously with Horn and Patlak,[25] found that patches could be removed from cells, by

Erwin Neher, born on March 20, 1944 in Landsberg/Lech, Germany, studied physics at the Technischen Universität München (TUM) and the University of Wisconsin, USA. In 1970 he received his doctorate under the direction of H. D. Lux at the Max-Planck-Institut (MPI) für Psychiatrie and the TUM. After three years as Wissenschaftlicher Assistent at the MPI für Psychiatrie he moved to the MPI für biophysikalische Chemie in Göttingen. He obtained his Habilitation in 1980 in the Faculty of Physics at the Universität Göttingen and has been director at the MPI für biophysikalische Chemie since April 1983. Many distinctions have been conferred on him among them the Nernst-Haber-Bodenstein Prize of the Bunsen-Gesellschaft für Physikalische Chemie (1977), the Gottfried-Wilhelm-Leibniz Prize of the Deutsche Forschungsgemeinschaft (1986), and the Nobel Prize for medicine and physiology (1991). He is member of several academics, including the National Academy of Sciences of the USA and the Akademie der Wissenschaften zu Göttingen.

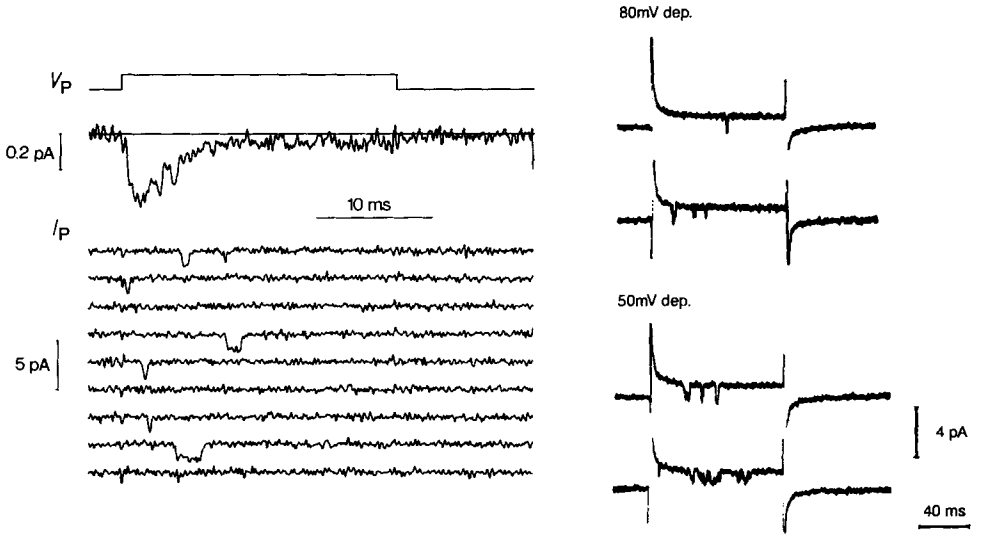

Fig. 3. Early recordings of voltage-activated single channels. The left side shows Na channels (adapted from [22]). The top trace is the voltage protocol. The second trace shows the average response from 300 voltage pulse depolarizations, and the following traces give examples of individual responses. It is seen that in some – but not in all – traces there are individual openings (downward deflection) of Na channels. The patch was hyperpolarized by 30 mV with respect to the rest potential and stimulated with depolarizing pulses of 40 mV. The right side shows individual Ca-channel currents (adapted from [23]). Depolarizing pulses (dep.) as indicated were given from normal resting potential. The pipette contained isotonic Ba solution. Single channel responses are seen superimposed onto a residual capacitive and leak artifact. In the left panel these artifacts were digitally subtracted.

simply withdrawing the pipette. This results in 'excised patches', which are accessible for solution changes from both sides. Alternatively, a patch can be ruptured by a short pulse of suction or voltage without loss of the glass-to-membrane seal. Thus, an electrical connection is established between measuring pipette and cell, with the pipette-cell assembly well insulated against the outside bath. This configuration was termed 'whole-cell recording'. Figure 4 gives a schematic representation of the different procedures and resulting configurations.[26]

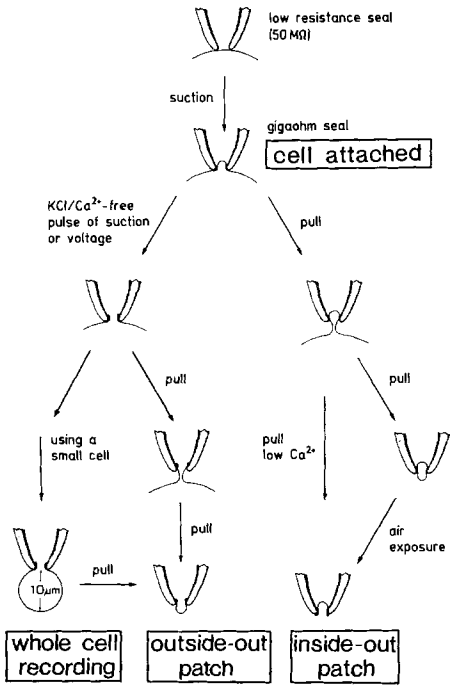

Fig. 4. Schematic representation of the procedures that lead to the different patch clamp configurations (from [26]).

Whole-cell recording is very similar to conventional microelectrode impalement, with, however, some important differences:

1. The leak between cell interior and bath is extremely small, such that this form of penetration is tolerated by cells as small as red blood cells.[27]

2. The electrical access resistance is low (1–10 MΩ) in comparison to that of impalement electrodes (typically 20–100 MΩ for small cells). Thus, voltage-clamp conditions are achieved easily without feedback circuits and additional electrodes, if small cells are used (membrane resistance 100 MΩ–10 GΩ).

3. There is rapid diffusional exchange and equilibration between patch pipette and cell.[28, 29] This provides control over the composition of the medium inside the cell. A cell can easily be loaded with ions, chelators, secondary messengers, fluorescent probes etc., simply by including these substances in the measuring pipette. However, this exchange also implies that the internal milieu is disturbed, and that signaling cascades may be disrupted (see below).

With these properties, 'whole-cell recording' evolved to be the method of choice for recording from most cell-culture preparations and from acutely dissociated tissues. Many cell types, particularly small cells of mammalian origin, became accessible to biophysical analysis for the first time through whole-cell recording, since they would not tolerate multiple conventional impalements. Individual current types could be separated through control of solution composition on both sides of the membrane[30] (see Fig. 5 for an example of whole-cell Ca-channel currents). This development shifted the emphasis of electrophysiological studies away from large-celled preparations, which usually were of invertebrate origin, towards mammalian and human cell types. In the first half of 1981, just before we first published a whole-cell characterization of a small mammalian cell (bovine adrenal chromaffin cells) only five out of fourteen voltage-clamp

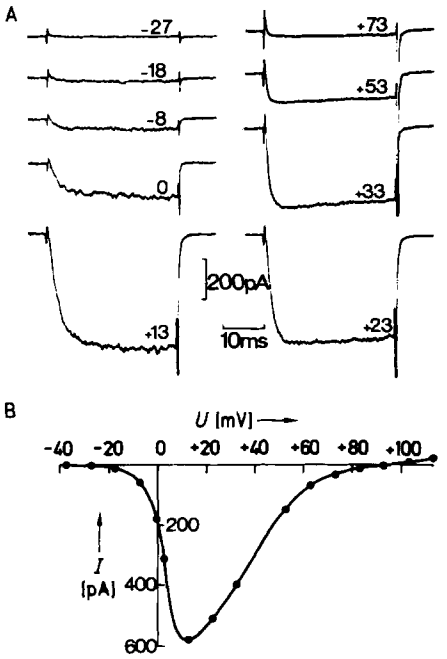

Fig. 5. Whole-cell membrane currents in chromaffin cells bathed in isotonic Ba solution plus 20 $\mu g\,mL^{-1}$ TTX (tetrodextrin). The membrane potential was stepped to values as indicated from a holding potential of −67 mV. The pipette solution contained mainly CsCl and TEA (tetraethylammonium ions). With this solution composition the currents flowing are predominantly carried by Ca channels. Part B shows the current-voltage relationship (from [30]). U = membrane potential, I = plateau current.

studies in the Journal of Physiology were performed on cells of mammalian origin. The first 1991 issue of the same journal alone contained ten voltage-clamp studies on mammalian cells, none on invertebrates, and all using either the whole-cell or single-channel recording techniques.

Disturbing Secondary Messenger Equilibria

All measurement techniques have to deal with a conflict with respect to their objectives. In some instances, one wants to observe a process, disturbing it as little as possible; in other instances one would like to obtain quantitative data under as much experimental control as possible. The two aims are, of course, mutually exclusive. The cell-attached measurement comes close to the first ideal, since it leaves the cell largely intact, and allows one to observe channels open and close, or to record action potentials extracellularly.[31] Excised patches constitute the other extreme, where membrane patches are removed from their natural environment for optimal control of solution composition on both sides of the membrane. The whole-cell recording method is at an intermediate position in this respect. It does provide excellent control over membrane potential, if cells smaller than 20 μm in diameter are used. However, the chemical composition of the internal medium is neither undisturbed, nor is it under good control. We found that small mobile ions typically exchange by diffusion between pipette and cell in a few seconds (for cells of approximately 15 μm diameter and pipettes of 2–5 MΩ resistance). Molecules of intermediate size, like secondary messengers, typically 'wash-out' or 'load' into cells within 10 seconds to a minute, and small regulatory proteins may take several minutes and longer for complete equilibrium.[29]

In retrospect, it seems fortunate that we started our measurements with ACh channels and Na channels, which happen to be relatively robust with regard to diffusible regulatory components. Thus, we initially avoided complications of 'channel modulation'. However, when switching to channels which now are known to be subject to modulation by secondary messengers, G proteins and phosphorylation (such as Ca channels), we soon realized that channel activity would disappear rapidly as a result of the perturbation imposed by the measurement, both in 'whole-cell' and, more so, in excised-patch measurements.[30] Such 'washout' had been observed earlier in studies on dialyzed giant neurones.[32] The prototype of a channel modulated by an intracellular secondary messenger, the Ca-activated K^+ channel was characterized by Alain Marty in 1981. These early studies already showed the ambivalent nature of the new tools: On the one hand there was the advantage of control over intracellular calcium to elucidate the mechanism of Ca modulation. On the other hand there was the loss of cellular function due to the loss of regulators, which at that time were unknown. Subsequently, ingenious use of these tools by many laboratories has revealed a whole network of interactions between channels, secondary messengers, G proteins, and other regulatory proteins (see review by Hille[34]). In order to uncover this network it was necessary not only to record electrically from cells, but also to control or change systematically the concentrations of secondary messengers.[33,35–37] Later on it became possible to impose step-like changes in regulators using caged compounds,[38] or to load cells with fluorescent indicator dyes[39] and regulatory proteins.[40]

All this was made possible by utilizing diffusional exchange between patch pipette and cell or by exposing the cytoplasmic surface of excised patches. Later, ways were found to avoid the adverse effects of 'washout' by making the patch selectively permeable to small ions.[41,42] This technique, at present, seems to be the least invasive method to study the functioning of small cells.

An Electrophysiological Approach to the Study of Secretion

An outstanding property of an electrical measurement with a gigasealed pipette is its high sensitivity. This can be used not only to record currents, but also to study the membrane electrical capacitance, which is a measure of cell surface area. It had been observed before, that membrane capacitance increases under conditions where massive exocytosis of secretory vesicles is expected to occur. Presumably, this is due to the incorporation of vesicular membrane into the plasma membrane.[43,44] The low background noise of the gigaseal measurement made it possible to resolve area changes which result from the exocytotic fusion of single vesicles. This was shown by Neher and Marty[45] for exocytosis from chromaffin cells of the adrenal medulla and by Fernandez, Neher, and Gomperts[46] for secretion of histamine from rat peritoneal mast cells. In the latter case, the granules are somewhat larger, leading to well-

resolved step-like increases in capacitance (see Fig. 6). These records show that capacitance measurement is a *high-resolution* technique. The figure also shows, however, that capacitance is not a very *specific* measure for secretion. This is evident from the fact that there is a continuous, smooth decrease in capacitance before exocytotic events show up. We found[47] that the rate of this decrease depends on the concentration of free intracellular calcium $[Ca]_i$, and that it has many properties expected for pinocytosis.

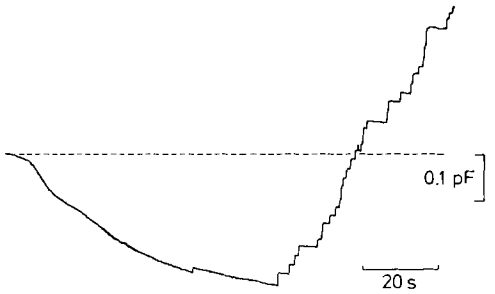

Fig. 6. High-resolution capacitance recording during the onset of a mast cell degranulation. Whole-cell recording from a rat peritoneal mast cell with a pipette containg 20 μM GTP-γ-S. Initially the capacitance slowly decreased, probably due to retrieval of very small pinocytotic vesicles. After some delay degranulation started, leading to a step-like increase in capacitance, each step representing fusion of a single granule (adapted from [47]).

We used capacitance measurement together with current recording and microfluorimetry using the indicator dye (fura-2) to simultaneously study, in a single cell, changes in $[Ca]_i$ and secretion at subsecond time resolution. We were surprised to find quite different effectiveness of regulators of secretion in different cell types (Fig. 7). For chromaffin cells, which in many respects resemble neurons, the classical role of calcium as prime regulator of secretion was fully confirmed.[49] In mast cells, however, which are not electrically excitable, changes in calcium concentration (in the physiological range) had little effect. Ca-independent secretion had been described in a number of inexcitable cell types.[50–52] But for us, who were used to working with electrically excitable cells, it was a shock not to be able to elicit secretion with an intracellular solution buffered to about 1 μM free calcium. Initially, we hypothesized, that the whole-cell configuration resulted in a loss of Ca-dependent regulators by washout – in analogy to early work on muscle contraction in skinned fibers. Later, we learned that cells in the whole-cell recording configuration were still able to secrete, in response to GTP-γ-S, a nonhydrolyzable analogue of GTP.[46] With this response in hand, it was possible to show that calcium, although not able to elicit secretion by itself, was still effective in accelerating an ongoing secretory response. There was no indication of a loss of a Ca-regulator; rather it appeared that the GTP-γ-S stimulus primed the cell to render it more Ca-sensitive.[53]

GTP-γ-S nonspecifically activates intracellular signal pathways, most prominently the dual-signal pathway.[54–55] Using the repertoire of patch clamp methods Penner[56] was able to show that various external secretagogues, which are known to also activate the dual-signal pathway, lead to a characteristic pattern of secretion. This is accompanied by

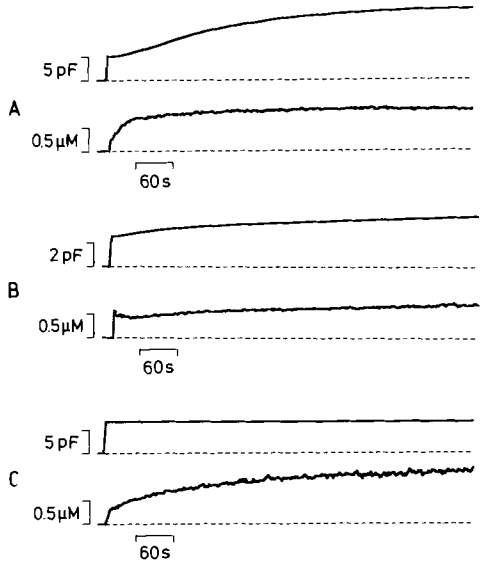

Fig. 7. Different effectiveness of intracellular free calcium in inducing a capacitance increase. Part A represents a measurement from a bovine chromaffin cell. The traces represent the time courses of capacitance (top) and free calcium concentration (bottom; measured by fura-2 fluorescence) following a whole-cell penetration. The concentration of calcium rapidly rises, since the pipette was filled with a Ca-EGTA (EGTA = ethylene glycol-bis(β-aminoethyl ether)-*N*,*N*,*N*',*N*'-tetraacetic acid) mixture adjusted for free calcium of approximately 1 μM. On the capacitance trace the step at the beginning (≈6 pF) represents the initial capacitance of the cell, which becomes 'visible' at the moment of 'break in'. Capacitance then rises about two to threefold due to exocytosis. Part B shows a similar measurement on a pancreatic beta cell, with only little capacitance increase, and part C shows the complete lack of response in a rat peritoneal mast cell (from [48]).

IP_3-induced Ca release from intracellular stores (IP_3 = insitol tris(phosphate). Combining the fura-2 technique with patch clamping one can study the temporal relationship between this prominent transient Ca signal and secretion. In spite of the modulatory effect of calcium described above it was found that there is no strict correlation. The secretory response very often starts well after the peak of the Ca signal. Also, the Ca peak can be abrogated by including EGTA in the patch pipette without drastic effects on secretion (Fig. 8). Phenomenologically this can be explained by the fact that the Ca peak occurs very early at a time when the above-mentioned priming effect of a chemical stimulus has not yet occurred. A sustained phase of increased calcium, which very often follows the Ca-release peak, is more efficient in accelerating secretion, however, since it is more appropriately timed. In terms of molecular mechanisms, the priming is likely to represent the activation of protein kinase C.[56, 58] Additionally, it has been shown that there is another G-protein-mediated pathway, which links a hormonal stimulus to secretion.[56, 59] This link is sensitive to pertussis toxin, and to intracellular application of cAMP.[56]

Our studies on mast cells (see review by Penner and Neher[60]) have taught us that secretory control is not necessarily dominated by calcium, but that rather it involves a meshwork of interacting secondary messenger pathways. In neurons, it appears that changes in calcium[61] or calcium plus voltage[62] largely determine the kinetics of fast secretory events. However, there is increasing evidence that other secondary messengers are responsible for plastic changes in synaptic signals, possibly by regulating the availability of vesicles for secretion.[63] Unfortunately nerve terminals are

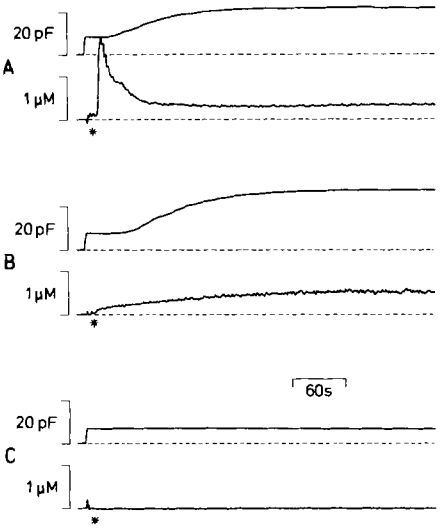

Fig. 8. Responses of mast cells to stimulation by the secretagogue compound 48/80 under different Ca-buffering conditions. The individual panels show combined capacitance calcium (fura-2) measurements similar to those of Figure 7. Panel A shows the 'unbuffered' case. No Ca-buffer was added to the pipette (except for 100 μM fura-2). A Ca transient developed in response to stimulation (asterisk). Secretion typically proceeded mainly during the falling phase of the Ca transient or following it. In panel B an EGTA/Ca mixture (10 mM) was added to the pipette which suppressed the transient, and fixed the Ca concentration to the range 200–500 nM. Nevertheless, secretion proceeded with a time course similar to case A. In panel C 10 mM EGTA was added to clamp calcium to low values. This suppressed both the Ca signal and the secretory response (from [57]).

usually not accessible to the kind of biophysical investigations as described here. However, recent studies on neurosecretory cells reveal new details on the kinetics of Ca-induced secretion.[49, 64–66] They promise to allow a differentiation between the exocytotic event per se and some of the other steps in the life cycle of a secretory vesicle. Together with the ability to control secondary messengers such studies may soon lead to a better understanding of exocytosis and of the molecular processes that direct a vesicle to its site of action.

I am deeply indebted to my teacher in electrophysiology, H. D. Lux, who focused the young physics student's mind onto ion channels, and taught me to use microscopic tools. Superb working facilities in Göttingen were provided by H. Kuhn, O. D. Creutzfeldt, and T. Jovin, who established a Young Investigators Laboratory for Bert Sakmann, F. Barrantes, and myself where we could independently pursue our goals. In more recent years my work was generously supported by a Leibniz Award of the Deutsche Forschungsgemeinschaft.

Elementary Steps in Synaptic Transmission Revealed by Currents through Single Ion Channels (Nobel Lecture)

By Bert Sakmann*

Introduction

The plasma membrane of a cell separates its interior from the extracellular environment and from other cells and acts both as a diffusional barrier and as an electrical insulator. This allows differentiation of cells with specialized functions. Coordinated behavior of multicellular organisms requires exchange of signals between individual cells. Because the signal must be transferred from one cell to another, it must occur by a mechanism that allows it to traverse the insulating cell membrane. Signalling occurs in various ways via specific receptors on the receiving cells and subsequent generation of a transmembrane signal. The nervous system connects cells in a very specific way and signal transmission between individual cells takes place at contacts, called synapses, that are anatomically and functionally highly specialized.

Synaptic signal transmission is used preferentially for rapid communication between cells of the nervous system and those cells of peripheral organs which are responsible for sensory transduction and for the generation of secretory and motor activity.[1, 2] Synaptic transmission includes a chemical step, where the signalling substance, called a transmitter, is released very locally from the "sending", presynaptic cell and then acts transiently on receptors of the "receiving", postsynaptic cell. The receptor is part of an ion channel and mediates, upon occupation by the transmitter, a brief flux of ions across the postsynaptic membrane generating a change in the postsynaptic membrane potential.

The signal that actually initiates the cellular response of the postsynaptic cell is the flux of ions across the postsynaptic membrane. The size, duration and direction of this ion flux, as well as the nature of the ions traversing the postsynaptic membrane, determines whether this response will either activate voltage-sensitive membrane conductances and initiate action potentials, or instead reduce the cells electrical activity. The cellular response may also be determined by a change in the intracellular ion concentrations, in particular the concentration of calcium ions, which act as a second messenger for many cellular responses like contraction or secretion.

The neuromuscular junction is often thought of as a prototypical synapse. At the neuromuscular junction the nerve terminal of a motoneuron releases acetylcholine (ACh) and generates end-plate potentials (EPPs), which in turn activate voltage-sensitive conductances to transmit excitation into other parts of the muscle fiber.[1] The current flow across the end-plate, induced by the release of packets of ACh, results from the superposition of many small individual "elementary" events[3] and there is ample evidence that postsynaptic potentials in other synapses are also generated by the superposition of elementary events.

This article describes the properties of elementary currents underlying postsynaptic potentials as well as their molecular determinants. The focus is primarily on the properties of elementary currents mediating neuromuscular transmission. The neuromuscular junction is the synapse characterized best, both functionally and in its molecular constituents, and most of the techniques for recording single channel currents were developed with the muscle fiber preparation. It has turned out that, apart from important details, a comparable behavior of elementary currents is observed for other transmitter-activated postsynaptic potentials, particularly those activated by glycine, γ-aminobutyric acid (GABA), glutamate and serotonin. These transmitters mediate 'rapid' synaptic transmission in the central nervous system (CNS) and produce postsynaptic potentials lasting milliseconds to hundreds of milliseconds.

Elementary Events

End-plate current noise: The notion of "elementary events" was introduced by B. Katz and R. Miledi when they observed "membrane noise" during recording of membrane depolarization induced by addition of ACh to neuromuscular end-plates of frog skeletal muscle.[3] They suggested that the increase in noise associated with depolarization is the result of the independent superpostion of elementary events generated by random activation of individual acetylcholine receptors (AChRs), each activation causing a minute depolarization.

The size of the conductance change generating an elementary event derived from such noise measurements, assuming a pulse-shaped change in conductance, were estimated to be of the order of 30 to 50 picosiemens (pS) with a duration of only a few milliseconds.[3, 4] This means that the amplitude of an elementary current would be of the order of 3–5 picoamperes (pA). This amplitude is about two to three orders of magnitude smaller than what could be resolved by the intracellular recording techniques available at the time.[5]

Current noise in extrasynaptic muscle membrane: ACh sensitivity is restricted, in normal muscle fibers, to a very small area of the muscle which is located underneath the nerve terminal. Following chronic denervation of skeletal muscle, effected by severing the motor nerve, the entire muscle becomes ACh supersensitive.[6] It is now known that this is due to the incorporation of newly synthesized ACh receptors into the extrasynaptic surface membrane of muscle fibers. Using noise analysis of ACh-activated currents we estimated the average increase in conductance underlying elementary events in denervated frog muscle fibers to be about 20 pS.[7]

The size of the elementary current in denervated fibers was thus smaller (about 60% of normal). The average duration of the elementary event was, however, 3 to 5 times longer than that of elementary events in the end-plate.

Elementary End-Plate Currents are Pulse Shaped

Solving the background noise problem: Denervated, supersensitive frog muscle fibers were thus the preparation of choice for developing methods for recording from single channels and for investigating the basic properties of ion channels by direct measurement of elementary events. The key for the reduction of background noise in the relevant frequency range (up to 1 kHz) was to restrict the measurement to a small membrane area of about 10 μm^2 and to isolate this membrane patch electrically from the rest of the cell membrane by sealing the narrow tip (1 - 3 μm) of the glass pipette tightly onto the membrane ("Gigaseal", Neher, 1991).[5] Pressing the pipette against a normal muscle fiber resulted in seal resistances of less that 1 MΩ and often damaged the fiber. The sealing problem was solved by exposing the fiber to mild enzymatic treatment, which freed muscle fibers from their covering connective tissue and the basal membrane, thus exposing the bare sarcolemma,[8] and by polishing the tip of the pipette with a small heating filament.[9] When the polished tip of the patch pipette was pressed gently against the bare sarcolemmal membrane of single fibers, secured mechanically by a glass hook, seal resistances of 50 to 150 MΩ were obtained. The membrane potential of the fiber was set locally, close to the membrane patch from which the patch current was recorded, by a conventional voltage clamp amplifier with two intracellular microelectrodes (Fig. 1 A).

Single channel currents: Using these precautions to obtain adequately high seal resistances (> 50 MΩ) and using suberoyldicholine, an agonist causing ACh receptors to open for longer periods, we were able to record current blips from denervated frog muscle fibers which were pulse-shaped, and which had many of the hallmarks of the elementary events that had been inferred from noise analysis of ACh-activated currents.[10] Square-shaped currents were also recorded from denervated rat muscle. They were similar to those obtained from denervated frog muscle, and in both preparations the directly measured amplitudes of elementary events agreed reasonably well with the estimated size derived from fluctuation analysis of macroscopic voltage clamp currents.[11]

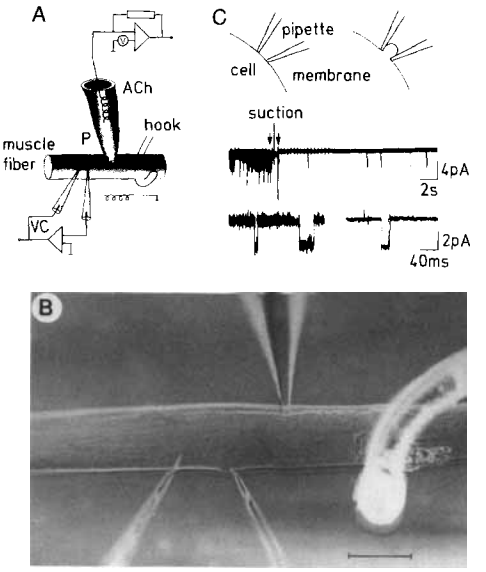

Fig. 1. Recording from a patch of end-plate membrane. A) Schematic diagram of muscle fiber with tip of patch pipette sealed against the cleaned surface of a single muscle fiber. The pipette is filled with extracellular solution and the pipette potential is held isopotential with the extracellular solution by means of feedback circuit. The fiber's membrane potential is clamped to a command value by a two microelectrode voltage clamp amplifier and two intracellular microelectrodes. Patch pipette contains in addition low concentration of acetylcholine (ACh). B) Disjunction of nerve terminal from muscle fiber. Photomicrograph of a single frog muscle fiber with bare end-plate after removal of the nerve terminal. The tip of the patch pipette is touching the end-plate (light streak). Two intracellular microelectrodes are used to locally clamp the membrane potential of the fiber. A glass hook, seen on the right hand side, secures the fiber mechanically. Calibration bar is 50 μm. C) Single channel current recording with seal resistances in the MΩ and GΩ range, respectively. Schematic drawing on top shows the formation of high-resistance seal by application of negative pressure ("suction") to pipette interior. Traces represent records, at two time scales, of elementary end-plate currents from the same membrane patch before (left) and after (right) application of negative pressure to the pipette interior ("suction") which increase the seal resistance of the pipette-membrane contact from 150 MΩ to 60 GΩ [12].

Disjunction of the neuromuscular synapse: To relate the properties of elementary currents to synaptic transmission at the end-plate of *normal* muscle fibers, it was necessary to compare the properties of elementary events with those of miniature end-plate currents (MEPCs). To place the tip of the patch pipette onto the end-plate, the neuromuscular junction must be visible and the nerve terminal, which covers the

Bert Sakmann, born on June 12, 1942, in Stuttgart, studied medicine at the universities of Tübingen, Freiburg, Berlin, Paris, and Munich. From 1968 to 1970 he worked a medical assistant at the Universität München and at the Max-Planck-Institut (MPI) für Psychiatrie in Munich with O. D. Creutzfeldt. After a period with B. Katz at University College London, he obtained his doctorate in 1974 at the Medizinische Fakultät Göttingen, and continued his work at the MPI für Biophysikalische Chemie in Göttingen with O. D. Creutzfeldt. He completed his Habilitation in 1982 and three years later became Director of the Abteilung Zellphysiologie des MPI für medizinische Forschung in Heidelberg. Since 1990 he has also been member of the Fakultät für Theoretische Medizin der Universität Heidelberg. Among his many honors are the Nernst-Haber-Bodenstein prize of the Bunsen-Gesellschaft für Physikalische Chemie 1977, the Gottfried-Wilhelm-Leibniz prize of the Deutsche Forschungsgemeinschaft 1986, and the Nobel prize for Medicine and Physiology 1991.

end-plate in normal fibers, must be removed from the end-plate. This is most easily accomplished by a localized application of collagenase, followed by a gentle stream of Ringer's solution delivered from a pipette with a small (100 μm) tip opening. This procedure resulted in single muscle fiber preparations with their end-plates freely accessible (Fig. 1 B).

Elementary end-plate currents: The elementary events recorded from the end-plate membrane (elementary end-plate current) were about 50% larger in amplitude, but considerably shorter in duration than those measured in the extrasynaptic membrane, as already expected from the fluctuation analysis of ACh-activated currents in normal and denervated fibers.[7] The measurements demonstrated that the elementary end-plate current is a square pulse-like event allowing passage of small cations like Na^+, K^+ or Cs^+ at a very high rate (10^7–10^8 s^{-1}), thus suggesting that these currents reflect the opening of water-filled pores across the membrane.[10]

Some basic properties of end-plate channels became apparent only at this improved resolution, which resulted from the reduction in background noise by establishment of pipette-membrane seals with resistances in the range of several GΩ.[12] Using freshly pulled pipettes and applying slight negative pressure to the pipette interior, thereby pulling the patch of membrane underneath the tip opening into the pipette tip, a molecular contact between the glass and the plasma membrane was established which increased the seal resistance from 50–150 MΩ to 1–100 GΩ. Consequently, the amplitude of the background noise was reduced and rim currents[9] were almost absent (Fig. 1 C). The reduced background noise allowed us to perform recordings of elementary end-plate currents with a band width of up to 10 kHz and to examine quantitatively the fine details of elementary end-plate currents that became apparent at this resolution.

Unitary conductance of the open end-plate channel: Recordings of elementary end-plate currents (Fig. 2 A) indicated that the end-plate channel exists in only two conductance states: either the channel is closed, when there is no agonist occupying the binding site(s), or it is fully open, when the binding site(s) are occupied. The distribution of the amplitudes of a large number of elementary end-plate currents can fitted to a single Gaussian curve (Fig. 2 B) where the remaining variance in the amplitude distribution is mostly due to the remaining background noise of the recording. This confirmed the initial inference that end-plate channels prefer two conductance states, fully closed and fully open (schematic diagram, Fig. 2 A).

Time course of channel closed-open transitions: The time course of the single channel current reports structural transitions of a single macromolecule in real time. An obvious question therefore is whether the time course of the *transition* between the open and closed channel states is measurable (Fig. 2 C): We superimposed the time course of the leading or trailing edge of a single channel current on that of the step response of the recording system. Since no difference was detected, the time course of single channel currents must have been limited by the frequency response of the recording system. The time constant of the channel transition from the closed to the open states is thus less than 10 μs.

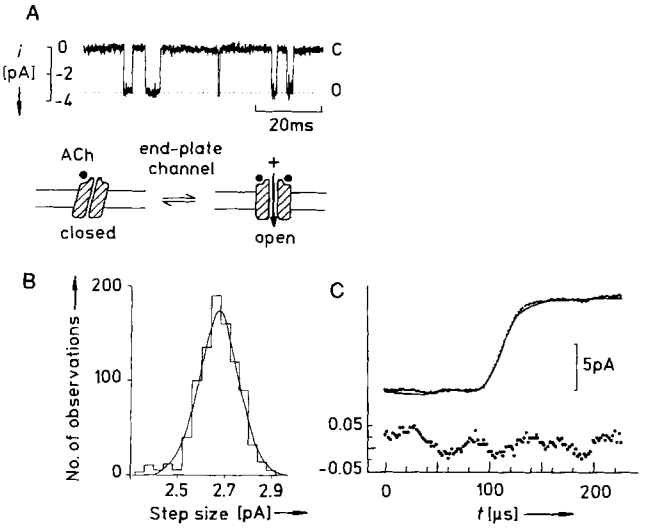

Fig. 2. Elementary end-plate currents. A) Trace of elementary end-plate currents from rat muscle activated by acetylcholine (ACh). Membrane potential was −70 mV. The schematic drawing under the current trace illustrates the opening and closing of an end-plate channel by transmitter binding and unbinding to recognition site on the end-plate channel. The channel is closed in the resting state and is open when two agonist binding sites are occupied by ACh molecules. B) Distribution of elementary end-plate current amplitudes, activated by 200 nM ACh in frog muscle. Histogram is fitted to a Gaussian curve with mean amplitude of 2.69 ± 0.10 pA. C) End-plate channels open rapidly to a unitary conductance. Upper traces show superposition of leading edges of elementary end-plate current (points) and of record of step-test pulse (continuous line, after amplitude scaling) to measure the frequency response of the recording system. Relative difference between the two aligned recordings is shown by open circles (bottom).

Observing the same channel repeatedly: To resolve elementary end-plate currents the concentration of ACh or a related agonist like suberoyldicholine in the pipette, was low (usually below 0.5 μM) to ensure that the opening of end-plate channels was infrequent and individual openings were clearly separated from each other (Fig. 2 A). This implied however that one could not be sure that successive elementary end-plate currents reflect the opening of the same individual end-plate channel, since it is likely that several channels are present in the membrane patch under investigation. In the presence of higher agonist concentrations (for acetylcholine > 5 μM) we found that elementary currents appear in long bursts of several hundreds of milliseconds duration. The reason for the occurrence of current bursts is that the channel can adopt, in addition to the "resting closed" state, an additional, kinetically distinct, closed state designated as "desensitized closed" state. This state is almost absorbing and channels isomerize only occasionally back to the open or "resting closed" states. When this happens the same channel switches back and forth between its "resting closed" and the "open" state repeatedly before it enters again the desensitized closed state[13] thus allowing the observation of several openings and closures of the *same* individual channel. The fact that the amplitude of the elementary currents during such an epoch did not change and that the average durations

of end-plate current were essentially independent of ACh concentration supported the two-state reaction scheme to explain the current recording shown in Figure 2A.

Elementary Steps in Neuromuscular Transmission

Minature end-plate currents and elementary end-plate currents: An obvious question related to the function of the end-plate channel in synaptic transmission is that of the relation between the size and duration of the elementary end-plate currents and that of the synaptic currents. In other words, how is the time course of the end-plate currents related to the gating properties of the end-plate channel?

A simple way to reconstruct the decay of a miniature end-plate current (MEPC), the signal transmitted across the neuromuscular junction following the release of a single vesicle of transmitter, is to align several hundreds of thousands of elementary end-plate currents at their leading edge and superimpose them. The hypothesis behind this procedure is that, following the release from a presynaptic vesicle, the concentration of ACh in the synaptic cleft rises very rapidly (in less than 1 ms) to saturate ACh receptors, and then rapidly decays again to negligible values.[14] If the ACh concentration transient in the cleft is very brief in comparison to the average duration of elementary end-plate currents then the decay of PEPCs would reflect the distribution of the durations of elementary end-plate currents after removal of ACh. In Figure 3 individual elementary end-plate currents are aligned at their leading edges (Fig. 3A). The current generated by superposition of 1000 elementary end-plate currents has a peak of 4.7 nA and decays with a time constant of 2.7 ms (Fig. 3B). These values are similar to those of MEPCs recorded from rat muscle end-plates. This suggests that a single MEPC, which reflects a quantal conductance increase of approximately 50 nS, is generated by the almost simultaneous opening of about one thousand end-plate channels (each with 50 pS conductance), and that the decay of MEPCs is determined to a first approximation, by the average duration of the elementary end-plate currents.

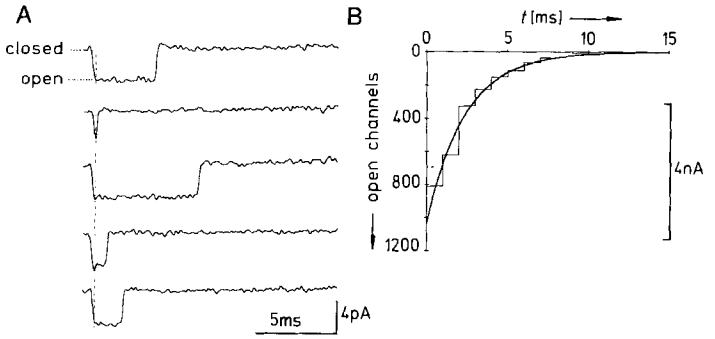

Fig. 3. Elementary end-plate current durations determine the shape of miniature end-plate currents. A) Records of elementary end-plate currents activated by 200 nM ACh in rat muscle fiber aligned at their leading edges to illustrate variation in duration of elementary end-plate currents. B) Average of 1000 superimposed elementary end-plate currents. Individual elementary end-plate currents were digitized and idealized by time course fitting[15] and then digitally superimposed at their leading edges as illustrated in Figure 3A. The continuous line superimposed on the histogram represents single exponential with decay time constant of 2.7 ms.

Elementary currents reflect bursts of single channel openings: The time course of elementary end-plate currents is more complicated in shape than expected from a channel that switches between an open and a single closed state as assumed in Figure 2A. Most elementary end-plate currents, when examined at high time-resolution, are interrupted by very short gaps (Fig. 4a, B), i.e. the current returns transiently to the base line.[15, 16] This behavior is observed in almost all the transmitter- and voltage-gated ion channels investigated so far. In the case of the end-plate channel it reflects the fact that, when the receptor has bound ACh, the channel opens and closes several times before the agonist dissociates from the receptor. The scheme shown in Figure 2A is intended only to illustrate the basic principle of structural transitions of the channel and assumes only one open and one closed channel state. In reality, however, a reaction scheme consistent with the experimental observations involves several closed and open states. The observed behavior of the current during a single elementary event is in fact predicted by a reaction involving transition of the closed, resting receptor to the open state via an intermediate closed state.[17]

Plausible reaction scheme for end-plate channel activation: We investigated the fine structure of these brief transitions for end-plate channels in collaboration with D. Colquhoun. Using the tools of probability theory,[18] it was possible to derive the minimum number of states the channel can adopt and also the rates of transition from one state to another.[15] At least five kinetically distinct states (Fig. 4C) could be discriminated from the measurement of both the open and

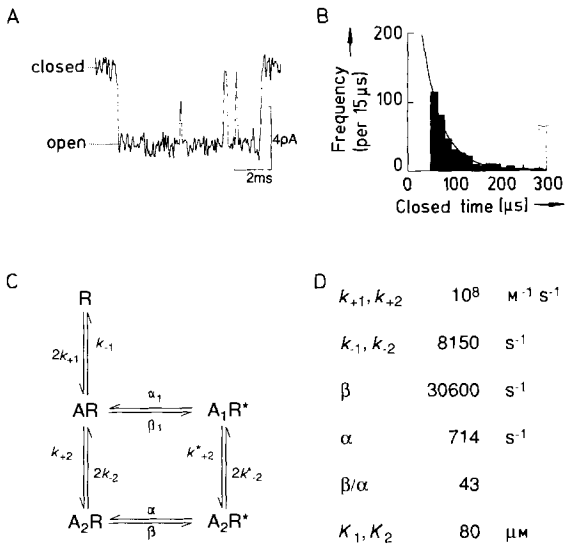

Fig. 4. Reaction scheme for end-plate channel activation by ACh. A) Record of elementary end-plate current activated by suberoyldicholine, an agonist of acetylcholine, to illustrate burst-like appearance of elementary end-plate currents. Note unresolved brief closure. B) Distribution of durations of brief closures measured during elementary end-plate currents. Continuous line represents an exponential curve with decay time constant of 39 µs. C) Reaction scheme for interaction of ACh (A) and end-plate channel (R) comprising five kinetically different states. Conducting states are marked by an asterisk. D) Derived rate constants for interaction of ACh and end-plate channel for the reaction scheme shown in Figure 4C from [15].

closed time distributions at low concentrations of several agonists, and the derived reaction rates satisfactorily described the time interval distributions. It represents a scheme for the gating of the end-plate channel by ACh during normal neuromuscular transmission and is a modification of the scheme proposed initially by Del Castillo and Katz.[19] It comprises a resting, unligated state and four ligated states, two of which are open states. The derived microscopic rate constants (Fig. 4D), which describe the transitions between the various states of the end-plate channel, indicate that the probability of the open channel occurring at high ACh concentrations during neuromuscular transmission (higher than 100 μM) is close to unity. This implies that ACh acts on the end-plate channel as a highly effective transmitter with high efficacy. When an ACh receptor is doubly ligated the equilibrium between the open and the closed states is shifted almost completely to the open state, indicating that the end-plate channel is very effective in rapidly passing current through the end-plate.

Isoforms of End-plate Channels

When recording postsynaptic currents in muscle fibers from young animals we found, in collaboration with H. Brenner, that there is a marked change in the decay time course of MEPCs during postnatal development. This reflects a switch of the functional properties of end-plate channels during this time. Up to postnatal day 8 (P8), the decay of the MEPCs is slower that that of MEPCs recorded in the adult muscle. During the period of P7 to P15 the MEPC decays are described best by the sum of two exponentials; in contrast, after P21 the MEPCs decay equally as fast as in adult fibers.[20, 21] The molecular basis for this difference in synaptic currents is shown in Figure 5. Two classes of elementary currents are recorded from muscle fibers at early postnatal stages. Mammalian skeletal muscle expresses two isoforms of end-plate channels which mediate different elementary end-plate currents,[22] differing both in amplitude and average duration. The expression of these channel isoforms is developmentally regulated. At early stages of development, in the uninnervated muscle, a fetal type of channel with lower conductance and longer average durations of elementary currents predominates. Following innervation a fetal isoform is replaced by the mature adult isoform which has a higher conductance and elementary currents of a shorter duration. Following denervation the fetal isoform is expressed again, suggesting that skeletal muscle expresses a mosaic af AChR channel isoforms and that the composition of this mixture of channel isoforms is under neuronal control (see Sakmann et al. 1992[23] for review).

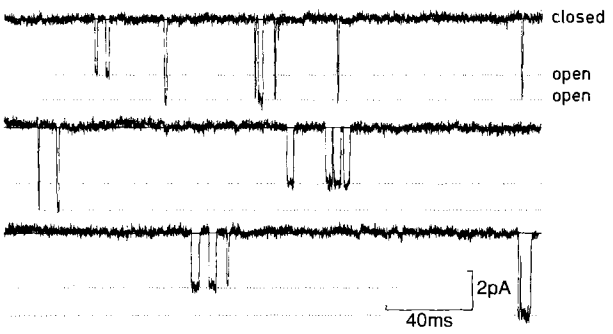

Fig. 5. Two classes of elementary end-plate currents. Record of single channel currents activated by 0.5 μM ACh in postnatal (P8) rat muscle fiber. Two classes of elementary currents, with different amplitudes and average durations, are observed in this patch. The elementary currents with the larger amplitude correspond to end-plate currents observed in adult fibers (> P21), whereas elementary currents of smaller amplitude correpond to those seen predominantly at early postnatal stages (< P8) or in fetal muscle.

Molecular Determinants of Channel Function

Identification of some of the molecular determinants of AChR channel function was achieved using patch clamp techniques and the tools of molecular biology. Biochemical work on *Torpedo* electroplax had shown that the AChR channel is assembled in a pseudosymmetric fashion from several subunits where each subunit contributes to the formation of the channel (see review by Karlin,[24]). In addition it had been demonstrated that recombinant AChR channels can be reconstituted in a functional form in a host membrane by injecting the RNAs that encode constituent subunits into the cytoplasm of *Xenopus laevis* oocytes (see review by Miledi et al.[25]). Following the isolation of the genes encoding the subunits of *Torpedo* electroplax and skeletal muscle AChRs, in vitro synthesized RNAs could be used to direct the synthesis of wild type and mutagenized recombinant AChR channels (see review by Numa[26]). Whole-cell current measurements from oocytes, expressing recombinant AChR channels, though important in showing that only certain subunit combinations would assemble to functional AChR channels, lacked the details necessary to demonstrate the similarity of recombinant and native AChRs or to draw conclusions on more specific structure-function relations. To relate functional properties of native AChRs to structural data, single channel conductance measurements on recombinant AChRs were required.

Because the oocyte plasma membrane is ensheathed by a vitelline membrane, the access of patch pipette tips to the plasma membrane is prevented. The vitelline layer may, however, be removed and the bare oocyte membrane expressed without damaging it, by brief exposure of the oocyte to a strongly hypertonic potassium solution. Oocytes then shrink away from the covering vitelline layer, which can be mechanically removed, leaving the bare plasma membrane.[27] This procedure enabled us to combine single channel conductance measurements with recombinant DNA techniques to identify structural determinants of AChR channel function. Two problems which are closely interrelated – the elucidation of the molecular basis of end-plate channel isoforms and the identification of structural determinants of the channels inner wall – were resolved in collaboration with a group of molecular biologists from S. Numa's laboratory and with V. Witzemann.

Recombinant AChR channel subtypes: The molecular distinction between the two isoforms of the end-plate channel (Fig. 5) was clarified as a result of experiments where the

cRNAs of the five muscle subunits were injected into oocytes, resulting in the functional expression of two AChR isoforms. Following the injection of cNARs encoding the α-, β-,γ-, and δ- or alternatively the α-, β-, δ-, and ε-subunits, two functionally different recombinant channel isoforms were generated (Fig. 6A, B). In their functional properties the two recombinant AChR isoforms resembled closely the two native AChR isoforms observed in muscle membrane.[28] Both the amplitude of single channel currents recorded from oocytes and their average duration (Fig. 6C) were similar to elementary currents observed in bovine or rat skeletal muscle.[28-30] Thus, it seems that native channel

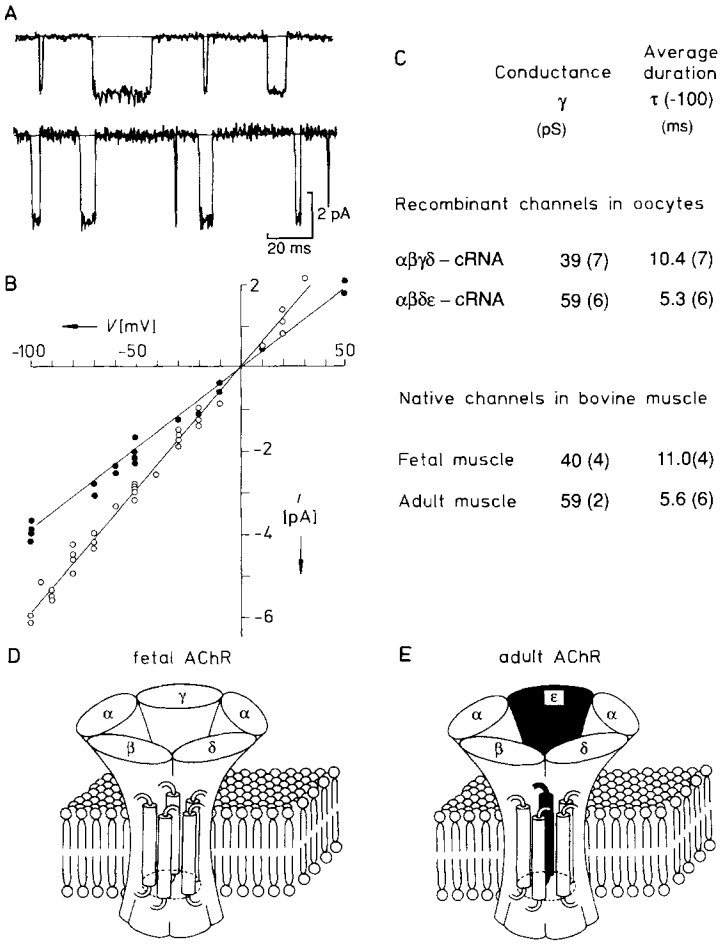

Fig. 6. End-plate channel isoforms are specified by differences in subunit composition. A, B) Single-channel currents and conductance mediated by recombinant AChR channels expressed in *Xenopus* oocytes previously injected with cRNAs encoding the subunit combinations α-, β-, γ- and δ- (upper trace and filled symbols) and α-, β-, δ- and ε-subunits of bovine muscle AChR (lower trace and open symbols). C) Conductance and average open times of two isoforms of recombinant and native AChR channels from bovine skeletal muscle (modified from [28]). D, E) Schematic diagram of the subunit composition of end-plate channel subtypes in fetal and adult skeletal muscle. The structure of the AChR is schematically drawn according to Unwin [31]

isoforms reflect differences in subunit composition of the channel, in the case of the AChR channel an exchange between the γ- and ε-subunit is the molecular difference between the two channel subtypes (Fig. 6D, E).

Differential regulation of γ- and ε-subunits genes: The molecular mechanism underlying the switch in end-plate channel properties effected by the exchange of constituting subunits is a postnatal switch in the expression of the genes encoding the γ- and ε-subunit. Northern blot analysis of total RNAs from muscle at different postnatal ages shows that a reciprocal change in the level of γ- and ε-subunit-specific mRNAs occurs during postnatal development.[32, 33] This differential regulation depends on differences in the regulatory sequences of the γ- and ε-subunit genes and their different responsiveness to neural and myogenic factors.[30, 34, 35] Since in most cells, including neurons, channel isoforms are expressed which often are colocalized in a mosaic-like manner, the regulation of the abundance of channel isoforms by differential expression of subunit genes may be one mechanism by which long-term ("plastic") changes in chemical and electrical excitability can occur (see review by Sakmann et al.[23]).

Molecular determinants of ion transport: The work of Hille and co-workers[36] had indicated that the end-plate channel is a cation-selective pore with a channel constriction of about 6 Å in diameter. The first insight into the molecular determinants of ion transport of the AChR was obtained following the identification of sequence domains in each subunit that may participate in forming the wall of the channel. Conventional whole-cell current measurements from *Xenopus* oocytes, co-injected with wild type and mutagenized AChR subunit specific cRNAs, gave only inconclusive results with respect to the involvement of particular subunit domains.[37] Subunit-specific differences in gating and conductance of various channel isoforms were however detected by single channel conductance measurements from isolated membrane patches where the ion composition and concentration on both membrane faces could be varied.[12] These advantages were exploited to localize functionally important domains in AChR subunits.

Hybrid channels and chimeric subunits: The gating and conductance of recombinant AChR channels assembled from homologous subunits of different species like *Torpedeo californica* and calf (*bos taurus*) depends on the particular combination of subunits cRNAs coinjected.[38] The δ-subunits of bovine muscle and of *Torpedo* electroplax AChR confer slightly different conductances to the hybrid channels when assembled together with α-, β- and γ-subunits of either species.[39] This observation was exploited to construct various chimeric subunits from bovine and *Torpedo* AChR δ-subunits (Fig. 7A, B). Conductance measurements on the recombinant channels carrying different chimeric δ-subunits (Fig. 7C) identified a domain designated as the M2 transmembrane segment to be important for conferring differences in conductance.[39] The most conspicuous difference in the aligned amino acid sequences was in the number of charged amino acids in the extracellular bend bordering the M2 segment (Fig. 7D).

The channels mouths and walls probed by conductance measurements of mutant channels: To precisely locate those amino acids important for ion transport and selectivity we investigated the effect of point mutations in the M2

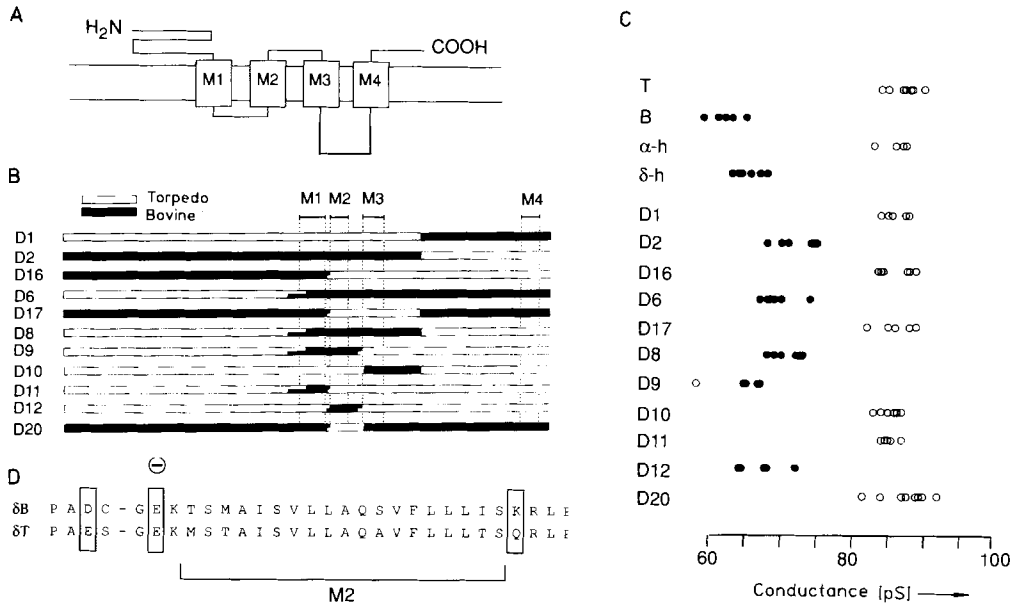

Fig. 7. Localization of M2 segment by single channel conductance measurements of recombinant AChR channels carrying different chimeric δ-subunit constructs. A) Schematic drawing of assumed transmembrane folding of AChR subunits as suggested from hydropathy analysis. N- and C-terminal ends are extracellular. B) Chimeric δ-subunit constructs derived from *Torpedo californica* electroplax and bovine skeletal muscle AChR δ-subunits. C) Single channel conductances of recombinant AChR channels carrying chimeric δ-subunits as shown in Figure 7C (α-h and δ-h represent hybrid channels where α- or δ-subunits were exchanged.) T and B refer to *Torpedo* or bovine muscle wild-type channels respectively. D) Comparison of amino acid sequence of δ-subunits from bovine muscle and *Torpedo* electroplax AChR in their M2 transmembrane segment (single letter code). Note difference in charged amino acids in M2–M3 bend (modified from [39]).

transmembrane segment and the adjacent bends on the con ductances of the mutant channels. Four amino acid positions, homologous in each subunit, were identified where amino acids are localized which are important for cation transport through the open channel and for its selectivity between monovalent cations.

Anionic rings: The M2 transmembrane regions, identified by mapping with chimeric δ-subunits, show a conspicuous clustering of charged amino acids bordering the M2 transmembrane segment in each of the subunits (Fig. 8A). By introducing point mutations at these positions, which changed the charge of the amino acid side chains, we found that largely the net number of negative charges, irrespective in which subunit the mutation was introduced, determines the channel conductance. This suggested that the charged amino acids of the participating subunits present in the bends bordering the M2 segment (Fig. 8A) form three ring-like structures at the extra- and intracellular mouths of the channels, respectively.[40,41]

Channel selectivity: To localize positions where amino acid side chains form the channel wall and in particular those amino acids that form the narrow portion of the channel, we investigated the functional properties of recombinant AChR channels mutagenized within the M2 transmembrane segment. This narrow portion is often referred to as the channel's "Selectivity filter", suggesting that here the interaction of transported ions, and their water shells, with the channels inner wall determines which ions may pass and which may not (see review by Hille[36]). To map amino acids which could be involved in this interaction, the conductances of mutant channels for several cations of different size and mobility were measured (Fig. 8B). These measurements indicated that a major determinant of ion selectivity resides in the residues located in M2 at a position close to the position of the amino acids forming the "intermediate" anionic ring (Fig. 8A). The channel conductance is altered by introducing amino acids with side chains of different bulkiness at this position. Side chains like valine that have larger volumes reduce the conductance, while side chains with smaller volumes increase the conductance.[42] The effect of these point mutations depends on the size and mobility of the ion used to measure the conductance (Fig. 8C), the effects being larger for Cs^+ than for Na^+.[43]

A simple model of the AChR selectivity filter: Single channel conductance measurements on hybrid AChR channels carrying chimeric subunits thus identified the M2 transmembrane segment as one determinant contributing to the formation of the channel's inner wall. Point mutational analysis refined the mapping and identified four positions in each subunit where amino acid side chains are likely to interact with permeating cations. A working hypothesis would be to assume that cations accumulate at the channel's extra- and intracellular mouths because of electrostatic attraction by the negative charges provided by the three anionic rings, whereas anions are excluded because of electrostatic repulsion. The selection between monovalent cation is predominantly due to "sieving" at the narrowest part of the channels constriction, which is formed by amino acid side chains containing hydroxyl groups.

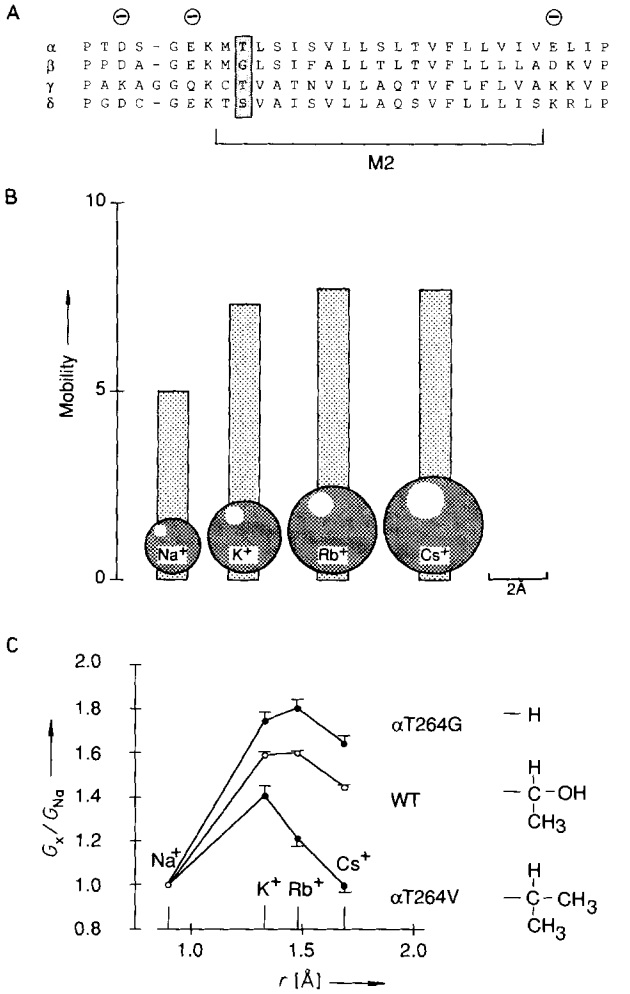

Fig. 8. Localization of selectivity filter of AChR channel by single-channel conductance measurements of recombinant AChR channels carrying mutations in the M2 transmembrane segment. A) Sequence alignment of α-, β-, γ- and δ-subunits of rat muscle AChR in the M2 transmembrane segment and adjacent bends (single letter code). The location of clusters of charged amino acids forming anionic rings at the channels mouths, as identified in *Torpedo* AChRs, are indicated by minus signs above the sequences. The amino acids forming the intermediate anionic ring are located in between those forming the intracellular ring (left) and the extracellular ring (right). The location of amino acids forming the constriction is indicated by the shaded box. B) Schematic representation of sizes and mobility of cations (modified from [44]) used to probe determinants of AChR channel conductance and selectivity. The scale on the left-hand side represents ion mobility $[10^{-4}\,cm\,s^{-1}/(V\,cm^{-1})]$. C) Conductance ratios of wild type (WT) and mutant channels carrying mutations in the cytoplasmic part of the α-subunit M2 segment (indicated by shaded box in A), where a threonine residue is replaced either by a valine (αT264V) or a glycine (αT264G) residue, for different size of cations (modified from [43]).

Ion Channels Mediating Rapid Synaptic Transmission between Neurons

Synapses in the central nervous system (CNS) operate with transmitters which are different from those in peripheral synapses, the most common ones being glycine, GABA, glutamate and serotonin. Moreover CNA synapses fall into two categories, either excitatory or inhibitory. The work of Eccles and his collaborators[45] showed that synaptic communication in the CNS as in the periphery, is mediated by ionic currents that flow across the postsynaptic membrane, generating excitatory or inhibitory postsynaptic potentials (EPSPs and IPSPs). Depending on which ions carry the postsynaptic currents, the respective transmitters are classified as excitatory or inhibitory. Glutamate, serotonin and ACh activate cation currents, carried mostly by Na^+ and K^+ and to a smaller extent by Ca^{2+} under physiological conditions. GABA and glycine activate anion currents, carried under physiological conditions by Cl^-. To characterize the elementary currents underlying postsynaptic potentials in the CNS we initially used isolated neurons obtained from fetal brain, which were kept under cell culture conditions, and which express receptor channels that can be activated by CNS transmitters.

Elementary currents activated by glycine and GABA: An important feature of signal integration in the CNS is the occurrence of postsynaptic inhibition between neurons. This occurs when the electrical activity of a neuron is reduced by IPSPs, which are largely mediated by the transmitters glycine or GABA, which cause an increase in the permeability of the postsynaptic cell to chloride ions. To find out whether ion channels mediate this increase in Cl^- conductance we measured the elementary currents activated by glycine or GABA in neurons isolated from fetal spinal cord and brain. They were freed from their extracellular coats during the isolation procedure and readily allowed the sealing of a pipette tip onto their plasma membrane (Fig. 9A).

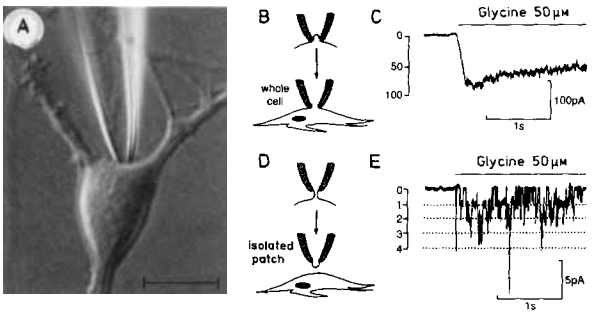

Fig. 9. Noisy whole-cell and square-shaped pulsed elementary currents activated by glycine in isolated neurons kept in tissue culture. A) Photomicrograph of cell body of a cultured neuron and tip of patch pipette touching cell membrane. Calibration bar is 10 μm. B) Schematic diagram of recording configuration to measure whole-cell current from an isolated neuron. C) Record of whole-cell current in response to application of inhibitory transmitter glycine. Note noisy trace during glycine-activated current. Scale on the left refers to number of open channels. D) Schematic diagram of recording configuration to measure elementary currents from outside-out patch, isolated from neuronal cell body. E) Recording of elementary currents in response to glycine application to outside-out membrane patch. Scale refers to number of open channels (modified from [46]).

For the characterization of the ionic requirements and the pharmacology of the currents activated by inhibitory transmitters the "whole-cell" configuration (Fig. 9B) was used, allowing the current through the entire cell membrane to be monitored. Figure 9C illustrates the activation of a membrane current of several hundred pA in a spinal neuron in response to the application of glycine. The current trace becomes "noisy" during glycine-activated current, but elementary currents are not resolvable. Following isolation of an "outside-out" patch (Fig. 9D) the application of glycine at the same concentration activates a much smaller average current, of only a few pA. The superposition of square-

shaped elementary currents is now clearly detectable (Fig. 9E), suggesting that glycine-activated whole-cell currents are generated by the superposition of elementary currents of unitary amplitude and varying duration. The size of glycine-activated elementary currents is in the same range as that of elementary end-plate currents, indicating that CNS transmitters also act by opening ion channels.

Coactivation of GlyR and GABAR channels: Most neurons isolated from fetal CNS have both glycine- and GABA-activated whole-cell currents which are carried by Cl^-. The respective ion channels (GlyR- and GABA-channels) were often co-localized in the same membrane patch (Fig. 10A, B), and their properties were studied by recording single channel currents.

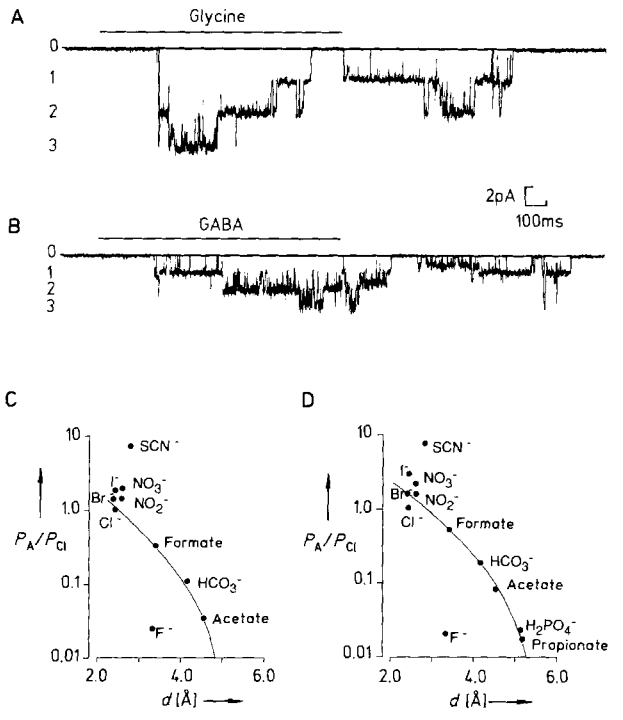

Fig. 10. Coactivation of GlyR and GABAR-channels. A) Single-channel currents activated by glycine in an outside-out patch of mouse spinal neuron. Several GlyR channels are activated in this patch as indicated by scale on left hand side, and elementary GlyR channel currents are superimposed. B) Single-channel currents activated by γ-aminobutyric acid (GABA) in the same patch as shown in Figure 10A. Superposition of elementary currents indicates the presence of several GABAR channels in this patch. C, D) Diameter of narrow part of GlyR and GABAR channels, mapped by reversed potential measurements under biionic conditions with chloride versus inorganic or organic anions of different size. Extrapolated diameters (Stokes diameters) d of constriction of GlyR and GABAR channels are very similar, between 4.8 and 5.4 Å (from [48]).

The GlyR and GABAR channels are different molecular entities[47] which share many functional properties. By measuring the reversed potentials under biionic conditions using different permeant inorganic and organic anions, the diameter of the narrow region of GlyR and GABAR channels was found to be between 4.8 and 5.4 Å at its constriction[48] (Fig. 10C, D). This is comparable to the size of the constriction of the end-plate channel (see review by Hille[36]). The results suggest, in conjunction with structural information obtained from the elucidation of the amino acid sequences of the GlyR and GABAR subunits, that transmitter gated channels are operating according to common principles, possibly being derived from common ancestors (see review by Betz[47]).

Conductance substates of channels activated by CNS transmitters: The elementary currents activated by glycine or GABA are square-shaped pulse events, but in contrast to what we had expected initially, both transmitters opened channels which may adopt several conductance states. Several of these substates are common to both channels; however, the most frequently occurring "main" conductance states are different.[48,49] Glutamate, the major excitatory transmitter in the CNS, also activates elementary currents in the pA-range which fall into several amplitude classes, indicating that glutamate receptor (GluR) channels also adopt substates.[50-52] So far the mechanisms and the possible functional significance of conductance substates remain poorly understood. The analysis of recombinant channels indicates that the receptor channels gated by the major CNS transmitters GABA, glycine and glutamate can show a wide functional diversity. This is probably due to the expression of numerous subunits, which may form both homo- as well as hetero-oligomeric isoforms of channels with subunit-specific properties.[53] A possible, but so far unproven hypothesis would be that channel subtypes are co-localized in the postsynaptic membrane in a mosaic-like fashion and that this may be a prerequisite for the alteration of synaptic effectiveness by changes in the composition of isoforms of the receptor mosaic.

Postsynaptic Currents in Brain Slices

It is important to characterize those receptor channel isoforms that actually mediate postsynaptic potentials in neurons of clearly defined pathways in the intact CNS. In cell culture the cellular identity of isolated neurons is rather ill-defined, and these neurons lack their natural neighbors with which they form specific synapses. Therefore the brain slice technique, pioneered by P. Andersen, was modified to perform whole-cell and single-channel current measurements from neurons in situ, to characterize the quantal conductance changes leading to EPSPs and IPSPs, and the elementary currents underlying them.

Sealing of patch pipettes onto neurons in brain slices: The procedure that allowed us to use patch pipettes for whole-cell and single-channel conductance measurements on neurons in brain slices consisted of a modification of the procedure developed for exposing the end-plates of single skeletal muscle fibers. Initially we used local application of collagenase; however, we found later that a gentle stream of extracellular solution, directed towards the surface of the slice (Fig. 11A), was sufficient to expose the cell body of visually identified neurons (Fig. 11B, C) in almost any part of the brain or spinal cord for recording with patch pipettes.[54]

Quantal transmission in CNS synapses: The recording of stimulated IPSCs from granule cells of the dentate gyrus, as well as the recording of elementary currents from outside-

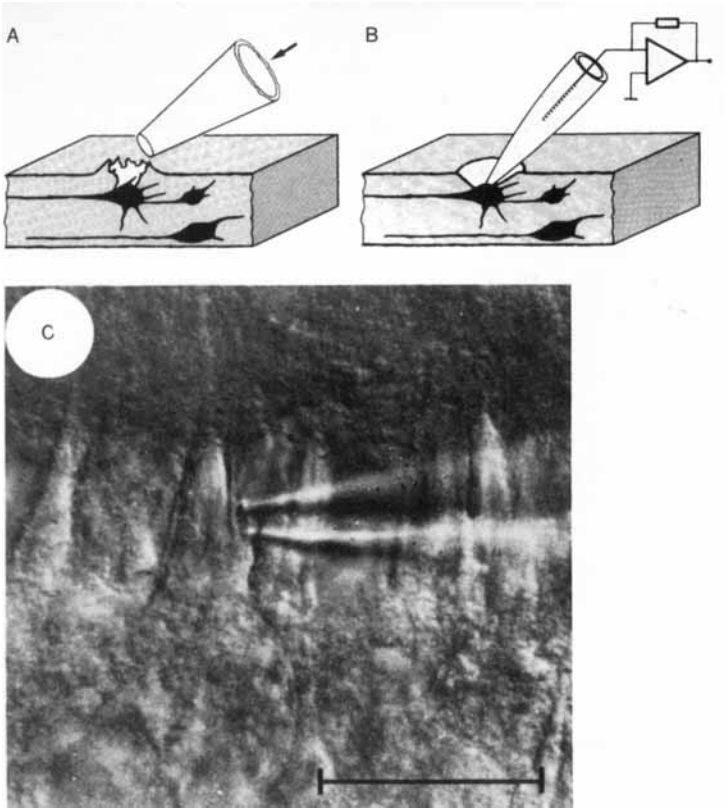

Fig. 11. Exposure of CNS neurons in brain slices for current recording with patch pipettes. A) Schematic drawing of the procedure used to expose the soma of individual neurons in brain slices. The tissue covering the cell body is removed by a gentle stream of extracellular solution delivered from a small pipette. B) Tip of patch pipette is sealed onto exposed cell body. C) Photomicrograph of exposed soma of hippocampal pyramidal neuron in rat brain slice. The tip of the pipette used to deliver a stream of extracellular solution is visible on the right side. Calibration bar is 20 μm. (Modified from [54]).

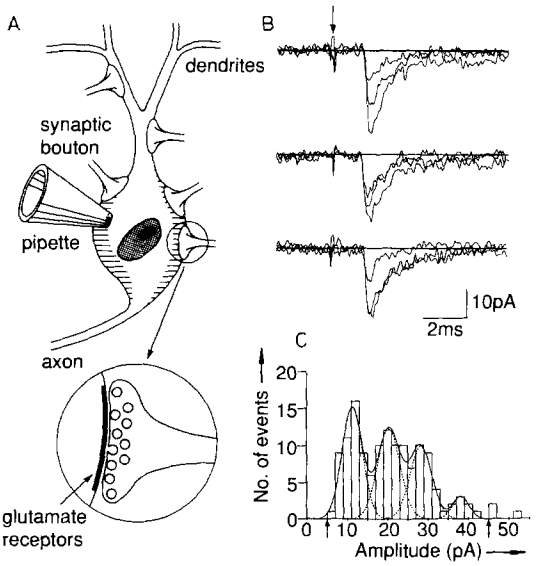

Fig. 12. Excitatory postsynaptic currents in CNS neurons mediated by glutamate acting on glutamate receptors. A) Schematic diagram of whole-cell recording of excitatory postsynaptic currents (EPSCs) from a neuron in the brain slice, where glutamate is released from vesicles to act on postsynaptic glutamate receptors (GluR). B) Examples of stimulated EPSCs mediated by glutamate acting on GluR channels of the AMPA/KA subtype. Time of electrical stimulus delivered to a neighboring neuron is indicated by arrow. Three responses are superimposed in each set of traces to illustrate the fluctuation in peak amplitude of EPSCs in response to constant stimulus. Three uppermost traces correspond to one, two and three quantal events, respectively. C) Amplitude distribution of stimulus evoked EPSCs. Peaks in this distribution indicate that EPSCs are quantal in nature with a quantal change in conductance of the order of 100 pS (from [59]).

out patches, demonstrated the quantal nature of IPSCs mediated by GABA, and showed that the magnitude of the change in conductance occurring during a quantal IPSCs is relatively small (of the order of 100–200 pS). This suggested that only a small number (20 to 40) of postsynaptic GABAR channels are activated by the release of a quantum of transmitter. According to model calculations of the size and time course of IPSCs it appears that the small number of activatable GABAR channels in a single synaptic bouton is the major determinant of this small quantal conductance change.[55–57]

The recording of stimulated EPSCs from neurons where synaptic knobs are located at or close to the cell body, such as in stellate cells in layer IV of visual cortex (Fig. 12A) or in pyramidal cells of the hippocampal CA3 region where mossy fiber terminals form synapses on the shaft of the apical dendrite also demonstrated the quantal nature of EPSCs mediated by glutamate acting on postsynaptic glutamate receptor (GluR) channels of the AMPA subtype.[58, 59] EPSCs are also characterized by a small quantal change of conductance on the order of 100–200 pS (Fig. 12B, C), which most likely also reflects a small number of activated channels.

Gating of GluR channels in CNS synapses: In central synapses the time course of the change in transmitter concentration following axonal release is not known, as is also the case with the density or the kinetic properties of the receptor channels. If the transmitter disappears rapidly from the synaptic cleft, the decay of EPSCs or IPSCs would reflect the distribution of elementary current durations after removal of the transmitter. Alternatively, the decay could reflect desensitization of postsynaptic receptors in the presence of a sustained level of transmitter in the synaptic cleft. To measure the gating properties of postsynaptic receptor channels in the CNS we used a method that allows brief agonist applications to outside-out membrane patches[60] isolated from neurons in an anatomically clearly-defined region of the brain (Fig. 13A, B).

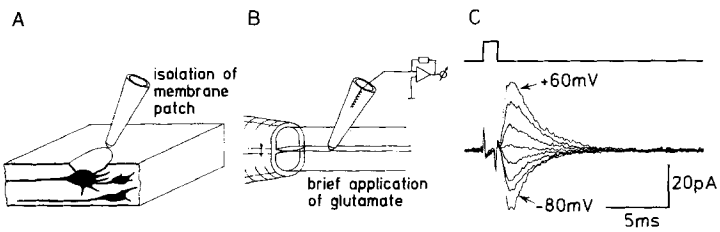

Fig. 13. Characterization of native GluR-channels in CNS neurons of brain slice. A) Schematic diagram of the isolation of outside-out patch from the soma of a neuron in brain slice. B) Schematic diagram of method of brief agonist application to outside-out patch. The tip of the patch pipette, sealed by outside-out patch, is brought close to the opening of a double-barreled application pipette delivering two solutions, one with control solution, the other containing in addition 1 mM L-glutamate. The pipette is moved briefly by 10–20 μm by means of a Piezo-element to expose patch to a pulse of glutamate. C) Family of currents in response to glutamate application to membrane patch isolated from a rat hippocampal cell at different membrane potentials (at 20 mV intervals). Duration of glutamate application is 1 ms as indicated in upper trace. Current rises rapidly (less than 1 ms) to peak. Decay constant of current following removal of glutamate is 2–3 ms.

The experiments showed that although closure of GluR channels by desensitization is fast, it is considerably slower than closure of channels to the resting state following removal of agonist (Fig. 13C).[61] It is, in particular, slower than the decay of EPSCs, for example from excitatory synapses on stellate cells,[59] suggesting that, at least in these cells, the decay of the fast EPSCs reflects predominantly the closure of GluR channels from the open to the resting closed state following rapid removal of transmitter from the synaptic cleft. This implies that glutamate is present only very briefly in the synpatic cleft (less than 1 ms) and that EPSCs are mediated by a GluR channel subtype characterized by short average duration of elementary currents. In spite of this some desensitization of GluR channels may still occur, even during a single EPSC.[62]

Molecular determinants of GluR-channel function: To find out whether the occurrence of functional GluR channel subtypes which mediate rapid synaptic currents is based on the assembly of native channels from different subunit combinations, which may confer different properties to the assembly, we compared, in collaboration with P. Seeburg, the functional properties of native and recombinant GluR channels. Recombinant GluR channels were assembled from different subunits of the AMPA receptor subunit family[63, 64] guided by the pattern of subunit genes which are co-expressed in different parts of the brain.[65]

Comparison of the functional properties of recombinant homomeric and heteromeric GluR channels suggested that properties like the rectification of channel conductance and divalent permeability are dominated by the presence of a particular (GluR-B) subunit in native GluR channels.[66] This dominance was traced to a single amino acid in the putative M2 transmembrane segment.[67–69] The almost ubiquitous expression of the GluR-B subunit gene in CNS most likely determines the conductance properties and the low Ca^{2+} permeability of native GluR channels mediating fast EPSCs. Its differential expression is likely to determine differences in the Ca^{2+} permeability of native GluR channels in different cell types, for example of the cerebellum.[70] In addition to the differential expression of the GluR-B subunit gene an additional mechanism seems to operate in regulating the properties of native GluR channel isoforms. The GluR-B subunit is found in two isoforms differing only by a single amino acid in the M2 transmembrane segment (Fig. 14A–C). The two subunit isoforms confer different conductance properties on heteromeric channels. The difference is most likely due to the editing of the mRNA specific (for the) GluR-B subunit.[71]

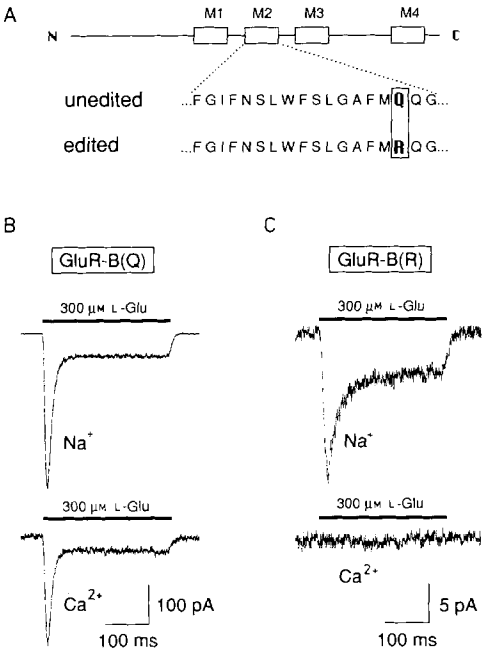

Fig. 14. Characterization of recombinant GluR-channel subtypes expressed in host cell. A) Differences in amino acid sequence of GluR-channel subunits in M2 transmembrane segment of GluR-B subunit. Box indicates amino acid present at Q/R site in the two isoforms of this subunit, GluR-B(Q) and GluR-B(R). The presence of arginine at this site is the consequence of mRNA editing. B) Functional properties of recombinant GluR-channels assembled from unedited GluR-B(Q) subunits. Inward current activated by glutamate is carried both by Na^+ and Ca^{2+}. C) Functional properties of recombinant GluR channels assembled from edited GluR-B(R) subunits. In the presence of high extracellular Na^+ concentrations an inward current is activated, whereas with high extracellular Ca^{2+} concentration no inward current is observed (modified from [68]).

Outlook

Patch clamp techniques are now well established and routinely applied in combination with other techniques like recombinant DNA or fluorimetric techniques to characterize molecular details of the events underlying synaptic signaling between cells. Through the measurement of elementary currents, the biophysical interpretation of the electrical signals which underlie rapid cellular communication across synapses has been simplified and can be partly understood in molecular terms. At the same time single channel conductance measurements have provided evidence for numerous isoforms of receptor channels, as well as for voltage and secondary messenger-gated channels; however the significance of this finding remains to be elucidated regarding synaptic communication in the CNS. It seems that the characterization of the various types of ligand- and voltage-gated ionic channels on the extensive dendritic trees of CNS neurons is necessary for an understanding of their integrative function, i.e. the generation of patterns of electrical activity resulting from IPSPs and EPSPs from many synaptic inputs. Equally important will be the characterization of the ionic channels responsible for the electrical activity of nerve terminals. Patch pipettes could provide the resolution necessary to study the electrical signals in nerve terminals and dendrites. This seems to be a prerequisite if one wishes to understand how changes in synaptic transmission may contribute to changes in funtional connectivity of neuronal pathways during normal and pathological states.

I am greatly indebeted to my teachers in physiology, Otto Creutzfeldt and Bernard Katz, and to the Max-Planck-Gesellschaft for providing ideal research conditions. During the last five years I was supported by the Leibniz Programm of the Deutsche Forschungsgemeinschaft and by an award of the Fondation Louis Jeantet, Geneva.

Soft Matter (Nobel Lecture)**

By Pierre-Gilles de Gennes*

What do we mean by soft matter? Americans prefer to call it "complex fluids". This is a discouraging expression, but it does indeed incorporate two of the major features:

1) **Complexity.** We may, in a certain primitive sense, say that modern biology has proceeded from studies on simple model systems (bacteria) to complex multicellular organisms (plants, invertebrates, vertebrates...). Similarly, from the explosion of atomic physics in the first half of this century, one of the outgrowths is soft matter, based on polymers, surfactants, liquid crystals, and colloidal grains.

2) **Flexibility.** I like to explain this through one early polymer experiment, which was initiated by the Indians of the Amazon basin. They collected the sap from the hevea tree, put it on their feet and let it "dry" for a short time whereby they had boots. From a microscopic point of view, the starting point is a set of independent, flexible polymer chains. The oxygen in the air forms a few bridges between the chains, and this results in a spectacular change: We shift from a liquid to a network structure which can resist tension—what we now call a **rubber** (in french: caoutchouc, a direct transcription of the Indian word). What is striking about this experiment, is the fact that a very mild chemical action induces a drastic change in mechanical properties: a feature typical of soft matter.

Of course, with some other polymer systems we tend to build more rigid structures. An important example is an enzyme. This is a long sequence of amino acids, which folds up into a compact globule. A few of these amino acids play a vital role; they form the "active site" which is built to perform a specific form of catalysis (or recognition). An interesting question (raised long ago by Jacques Monod) is the following: We have a choice of twenty amino acids at each point in the sequence, and we want to build a receptor site in which the active units are positioned in space in some strict way. We cannot just put these active units next to one another, because, if linked directly, they would not realize the correct orientations and positions. So, in between two active units, we need a "spacer", a sequence of amino acids which has enough variability to allow a good relative positioning of the active sites at both ends of the spacer. Monod's question was: What is the minimum length of spacers?

It turns out that the answer is rather exactly defined.[1] The magic number is 13 or 14. With less than 13 units, you will not usually succeed in getting the desired conformation, whereas with more than 14 units, you will have many sequences with can adopt it. The argument is primitive: It takes into account excluded volume effects, but it does not recognize the need for a stable enzyme—namely that the interior should be built preferably with hydrophobic units, while the outer surface must be hydrophilic. However, my guess is that this cannot change the magic number by much more than one unit. Indeed, when we look at the spacer sizes in a simple globular protein like myosin, we see that they are not far from the magic number.

Let us return now to **flexible polymers** in solution and sketch some of their strange mechanical properties. One beautiful example is the four-roller experiment set up by Andrew Keller and his co-workers.[2] In this experiment, a dilute solution of coils is subjected to a purely longitudinal shear. If the exit trajectory is well chosen (in the symmetry plane of the exit channel), the molecules are stressed for long periods. What is found is that, if the shear rate $\dot{\gamma}$ exceeds a certain threshold value $\dot{\gamma}_c$, an abrupt transition takes place, and the medium becomes birefringent. This is what I called a "coil–stretch transition".[3] When the shear begins to open the coil, it offers more grip to the flow, and opens even more... leading to an abrupt transition. Here, we see another fascinating aspect of soft matter—the amazing coupling between mechanics and conformations. Indeed, Keller showed that the chains break rather quickly (at shear rates $\dot{\gamma} > \dot{\gamma}_c$), and do so very near to their midpoint—a spectacular result.

Another interesting feature of dilute coils is their ability to reduce the losses in turbulent flows. This is currently called the Toms effect, although in actual fact, it was discovered even before Toms by Karol Mysels.[4] Together with M. Tabor, we tried to work out a scaling model of coils in a turbulent cascade,[5] but our friends in mechanics think that it is not realistic. Time will tell which answer is correct.

I have talked a lot about poylmers, let me now switch to **surfactants**—molecules with two parts, a polar head which likes water, and an aliphatic tail which hates water. Benjamin Franklin performed a beautiful experiment, using surfactants: On a pond at Clapham Common, he poured a small amount of oleic acid, a natural surfactant which tends to form a dense film at the water–air interface. He measured the volume required to cover all the pond and since he knew the area, he was able to calculate the height of the film—something like three nanometers in our current units. This was (to my knowledge) the first measurement of the size of molecules. Nowadays, when we are spoilt with exceedingly complex toys, such as nuclear reactors or synchrotron sources, I particularly like to describe experiments of this Franklin style to my students.

Surfactants allow us to protect a water surface and to generate beautiful **soap bubbles**, which delight our children. Most of our understanding of these soap bubbles is due to a remarkable team: Mysels, Shinoda, and Frankel who wrote *the* book on this subject.[6] Unfortunately this book is now very hard to find; I very much hope that it will be reprinted.

Long ago Françoise Brochard, Jean-François Lennon, and I[7] became interested in some *bilayer* systems, in which we have two sheets of surfactant, each pointing towards the neighboring water. A related (although more complex) sys-

tem of this type is a red blood cell. For many years it has been known that, when observed under phase contrast, these cells *flicker*. It was sometimes believed that this flicker reflected an instability of a living system under nonequilibrium conditions. Actually it is much simpler: The essential property of insoluble bilayers is that they optimize their area at fixed surfactant number. Thus the energy remains stationary with respect to area, and the surface tension vanishes. This means that the fluctuations in shape of these deflated cells or "vesicles" are huge; the flicker is just an example of Brownian motion for a very flexible object. What Jean-François had done was to measure space–time correlations for the flicker. Françoise then showed that they could be understood from a model containing no surface tensions, but instead only curvature energies plus viscous forces—another good example of soft matter.

This was, in fact, one of the starting points for many studies on surfactant bilayers (pioneered by W. Helfrich) and, on a more formal side, on random surfaces (especially with D. Nelson). One of the great successes in this field has been the invention of the "sponge phase" of **microemulsions**.[8, 9] More generally, it is amusing to learn from these people that there is some overlap in thought between the highbrow string theories and the descriptions of soaps!

Let me now move to another corner in our garden, **liquid crystals**. Here, I must pay tribute first to two great pioneers: 1) Georges Friedel, who was the first to understand exactly what a liquid crystal is and what the main types are, and 2) Charles Frank, who (following some early work of Oseen) constructed the elastic theory of nematics, and described also a number of their topological defects ("disclinations"). Here I will only cover smectics. Observing certain defects ("focal conics") in smectics, Friedel was able to prove that the structure must be a set of liquid, equidistant, deformable layers.[10] From observations at the 100 μm scale, he was thus able to infer the correct structure at the 10 Å scale—an amazing achievement.

Smectics bring me naturally to another important feature of complex fluids, namely that nowadays it is sometimes possible *to create new forms of matter*. The sponge phase mentioned above was an example. Another striking case was the creation of **ferroelectric smectics** by R. B. Meyer (in Orsay, ca. 1975). He thought about a certain molecular arrangement with chiral molecules which should automatically generate a phase (the "C phase") carrying a non O electric dipole. Within a few months, our local chemists had produced the right molecule, and the first liquid ferroelectric was born![11] These materials have already become very important for display purposes; they commute 10^3 times faster than the nematics in our wristwatches.

Another case of far less importance, however amusing, concerns "ferro-smectic" materials constructed by M. Veyssié and P. Fabre. The starting point is a water-based ferrofluid, which is a suspension of very fine magnetic particles. (Ferrofluids were invented long ago by R. Rosensweig, and have amazing properties.) **Ferro-smectic materials** are a type of club sandwich formed from bilayer| ferrofluid| bilayer|... If a system like this is subjected to a magnetic field $\vec{H}$, it is happier when $\vec{H}$ is parallel to the layers. It is then interesting to observe the sandwich (with a polarizing microscope) in the frustrated situation where $\vec{H}$ is perpendicular to the layers. At very low fields, nothing is seen. However, beyond a certain weak threshold $\vec{H}_c$, figures like flowers grow in the field.[12] We understand this as a two-step process: a) Just above threshold there is a chemical undulation instability; b) later, focal conics appear with a basic size imposed by the original undulation, but also with smaller conics (which are required to fill space correctly). This "club sandwich" is reacting to rather weak magnetic fields (ca. 30 Gauss).

Let me mention yet another new animal: the **Janus grains**, first made by C. Casagrande and M. Veyssié. Like god Janus who had two faces, the grains have two sides, one apolar and the other polar. Thus they have certain features in common with surfactants. There is, however, an interesting difference if we consider the films which they make; for instance, at a water–air interface. A dense film of a conventional surfactant is quite impermeable. On the other hand, a dense film of Janus grains always has some interstices between the grains, and allows for chemical exchange between the two sides: that is, "the skin can breathe". This may possibly be of some practical interest.

The first technique used to make the Janus grains was based on spherical particles half embedded in a plastic and silanated on the accessible side.[13] This produces only microquantities of material. A group at Goldschmidt research developed a much cleverer pathway: The starting point is a collection of *hollow* glass particles (which are commercially

Pierre-Gilles de Gennes was born in Paris in 1932. From 1955 to 1959 he was a research engineer at the Atomic Energy Center (Saclay), where he completed his doctorate on neutron scattering and magnetism under the supervision of A. Abragam and J. Friedel in 1957. After a postdoctoral year with C. Kittel at Berkeley in 1959, he became assistent professor in Orsay in 1961, and soon started research on superconductors and later (1968) on liquid crystals. In 1971 he accepted a professorship at the Collège de France, where his attention turned to polymer physics. Starting in 1980 he became interested in interfacial problems, in particular the wetting and adhesion phenomena. Among the many honors he has received are the Ampère prize of the French Academy of Science, the Harvey and Wolf prizes (both from Israel), and the Nobel prize for Physics. He is member of several societies, including the French Academy of Sciences and the National Academy of Sciences of the USA.

available). There the outer surface is hydrophobized, and finally the particles are crushed! The resulting platelets are hydrophilic on one side and hydrophobic on the other. They are irregular but can be produced in tons.

I would now like to consider the style of soft-matter research. One of the most important features is the possibility of carrying out very simple experiments in the spirit of Benjamin Franklin. Let me mention two examples. The first concerns the **wetting** of fibers. Usually a fiber after being dipped in a liquid, shows a string of droplets, and thus, for some time, people thought that most common fibers were nonwettable. F. Brochard analyzed theoretically the equilibria on curved surfaces, and suggested that in many cases we should have a wetting film on the fiber, in between the droplets. J. M. di Meglio and D. Queré established the existence, and thickness of the film in a very elegant way.[14] They created a pair of neighboring droplets, one small, one large and showed that the small one emptied slowly into the big one (corresponding to the capillarity). By measuring the speed of the process, they could determine the thickness of the film which lies on the fiber and connects the two droplets; the Poiseuille flow rates in the film are very sensitive to thickness.

Another elegant experiment in wetting concerns the collective modes of a contact line, the edge of a drop standing on a solid. If one distorts the line by some external means, it returns to its equilibrium shape with a relaxation rate dependent upon the wavelength of the distortion, which we wanted to study. But how could we distort the line? I thought of very complex tricks, using electric fields from an evaporated metal comb, or other, even worse procedures. However, Thierry Ondarcuhu came up with a simple method. First he prepared the unperturbed contact line L by putting a large droplet on a solid. Then he dipped a fiber in the same liquid and obtained (from the Rayleigh instability) a very periodic string of drops. Subsequently, he laid the fiber on the solid, parallel to L, and generated a line of droplets on the solid. Finally he pushed the line L (by tilting the solid) until L touched the droplets; then coalescence took place, and he had a single, wavy line on which he could measure relaxation rates.[15].

I have emphasized experiments more than theory. Of course we need some theory when thinking of soft matter. In fact some amusing theoretical analogies sometimes arise between soft matter and other fields. S. F. Edwards is responsible for one important example.[16] He showed a beautiful correlation between the conformations of a flexible chain and the trajectories of a nonrelativistic particle, the statistical weight of the chain corresponding to the propagator of the particle. In the presence of external potentials, both systems are governed by exactly the same Schrödinger equation! This observation has been the key to all later developments in polymer statistics.

Another amusing analogy relates the smectic A phases to superconductors. This was discovered simultaneously by the late W. McMillan (a great scientist, whom we all miss) and by ourselves. Later, it was exploited artistically by T. Lubensky et al.[17] Here again, we see a new form of matter being created! We knew that type II superconductors let in the magnetic field in the form of quantized vortices. The analogy here is a smectic A phase into which we add chiral solutes. These play the role of the field. In some favorable cases, as predicted in 1988 by Lubensky, this may generate a smectic phase drilled by screw dislocations, the so-called A* phase. This was discovered experimentally only one year later by Pindak and coworkers[18]—a beautiful feat.

Let me now end this sentimental journey into soft matter, with a brief mention of my companions. Some were met along the way, like Jean Jacques, a great creator of liquid crystals, and Karol Mysels, the undisputed master of surfactant science. Some others were with me all the way: Henri Benoit and Sam Edwards, who taught me polymer science; Jacques des Cloizeaux and Gérard Jannink, who have produced a highly theoretical book on this subject. Finally an inner core of fellow travelers, over all forms of land and sea: Phil Pincus, Shlomo Alexander, Etienne Guyon, Madeleine Veyssié, and last but not least, Françoise Brochard, sans laquelle les choses ne seraient que ce qu'elles sont.

The final lines are not mine; they relate to an experiment on soft matter (taken from Eugène Boudin a French painter of the 18th century) which is shown in the figure below. No conclusion could be more appropriate.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes.

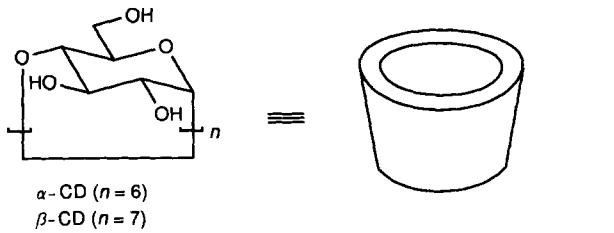
The price of the index is DM 98.00, $ 64.00 or £ 37.00. Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.**

Cyclodextrins, Off-the-Shelf Components for the Construction of Mechanically Interlocked Molecular Systems

By *J. Fraser Stoddart**

If any one theme is beginning to dominate the development of synthetic chemistry these days, it must surely be self-assembly.[1] The spread of this concept, though somewhat belated, into all branches of chemistry is mainly due to the rapidly accelerating growth and acceptance of supramolecular chemistry.[2] Long before chemists were thinking and practicing their own brands of chemistry beyond the molecule with wholly synthetic systems, nature had been extolling the virtues of molecular recognition in the production of sophisticated molecular and supramolecular arrays with linked form and function.

If one class of compound has provided the bridge between the worlds of natural und unnatural hosts, it has been the cyclodextrins—or CDs as insiders call them. Yet, even as they enter their second century[3a] of cultivation by chemists, they continue to fascinate the chemical community.[3b] The reasons are quite simple: They are aesthetic molecules, and they lend themselves to novel experiments. The recent reports[4–7] from four research laboratories in four different countries of the self-assembly of CDs into [2]rotaxanes and polyrotaxanes (Fig. 1) serve to remind us all that there is still a lot of innovation to be forged in and around CDs in the coming one-hundred years.



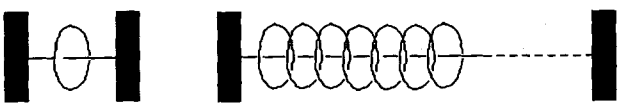


Fig. 1. Schematic representation of α-cyclodextrin (α-CD) and β-cyclodextrin (β-CD) (top), a [2]rotaxane (bottom left), and a polyrotaxane (bottom right).

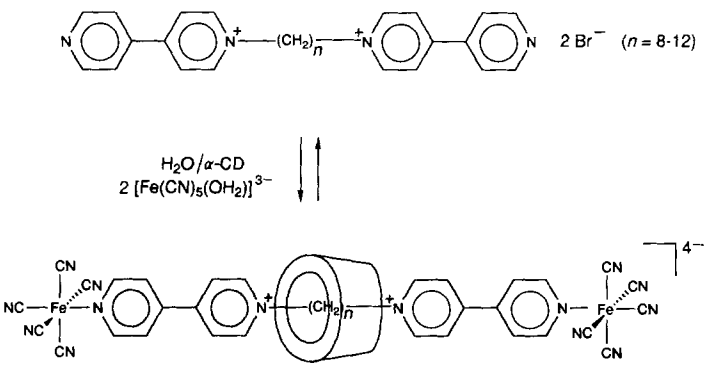
The self-assembly of the [2]rotaxane–metal complexes with α-CD, described by Wylie and Macartney[4] from Queen's University, Kingston, Ontario (Canada), happens (Scheme 1) irrespective of the order of the addition of the components—the α-cyclodextrin, the 1,1″-(α,ω-alkanediyl)-bis(4,4′-bipyridinium) bromide, and the precursor for the $[Fe(CN)_5(OH_2)]^{3-}$ stoppers, solid $Na_3[Fe(CN)_5NH_3] \cdot 3H_2O$,—to an aqueous reaction mixture. Indeed, the [2]rotaxane is formed even when α-CD is added to the dumbbell-shaped component, $[(NC)_5Fe\{bpy(CH_2)_nbpy\}Fe(CN)_5]^{4-}$. This infers a slow dissociation of one of the $[Fe(CN)_5]^{3-}$ stoppers, formation of a semirotaxane, $[\{bpy(CH_2)_nbpy \cdot \alpha\text{-CD}\}Fe(CN)_5]^-$, and its subsequent rapid recomplexation by $[Fe(CN)_5(OH_2)]^{3-}$ to give the [2]rotaxane. Evidence for the formation of a [2]rotaxane is provided by the ^1H NMR spectra, in which the signals of the symmetry-related protons of the $[bpy(CH_2)_nbpy]^{2+}$ unit are split by the end-to-end asymmetry of the trapped α-CD ring. It is very likely that a family of such [2]rotaxanes will now emerge, since the 4,4′-bipyridine thread can be replaced by pyrazine and other stoppers such as $[M(CN)_5]^{n-}$ and $[M(NH_3)_5]^{m+}$ ions with redox-active d^6 metal (M) centers like Co, Ru, Os, and Fe are conceivable.[1,7]



Scheme 1. The [2]rotaxane–metal complex of Wylie and Macartney [4].

The self-assembly of the asymmetric zwitterionic [2]rotaxanes incorporating α-cyclodextrin announced towards the end of last year by Isnin and Kaifer[5] from the University of Miami in Florida (USA), demonstrates a beautifully simple and logical step-by-step approach to what are really quite complicated compounds (Scheme 2). Because alkyldimethyl(ferrocenylmethyl)ammonium cations are known to interact with α-CD and β-CD through their alkyl groups and ferrocene subunits, respectively, the alkyl chain was terminated with carboxyl groups: **1**, $n = 7$; **2**, $n = 11$. Although their binding to α-CD is now pH dependent (for **1** · α-CD $K_a = 425\ M^{-1}$ at pH 2.6; $K_a = 71\ M^{-1}$ at pH 8.0), both are bound in water. The subsequent capping of the carboxyl groups is achieved with potassium 5-amino-2-naphthalenesulphonate with the water-soluble catalyst 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC) to promote amide bond formation. In both cases, the isomeric zwitterionic [2]rotaxanes **3a**, **b** and **4a**, **b** can be isolated from the reaction mixtures in 15% yield. The iso-

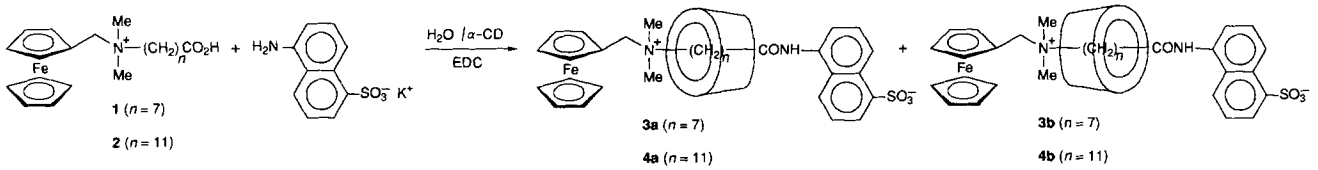

Scheme 2. The zwitterionic [2]rotaxanes of Isnin and Kaifer [5].

mers have since been separated,[8] and the relative orientations of the α-CD ring on the asymmetric dumbbell-shaped component have been established: One isomer is stable but the other one unthreads slowly! Again, the authors recognize the generality of their self-assembly procedure and anticipate the production of "a diversity of rotaxane structures having threaded cyclodextrins."

The isomer phenomenon literally takes on a further dimension in polyrotaxanes, for which the view is growing[8] that CDs might thread under conditions of equilibrium control with alternating orientations, wherein adjacent rings are matched head-to-head, tail-to-tail in order to optimize hydrogen bonding between the neighboring CD units.

In the knowledge[9] that chains of poly(ethyleneglycol) (PEG) thread α-CD beads like a necklace, Harada, Li, and Kamachi[6] at Osaka University in Japan have now succeeded in capping the chain ends of a poly(ethyleneglycol)diamine (PEG-DA; M_w 3450) with dinitrophenyl stoppers. The reaction was carried out in a solution of the PEG-BA in dimethylformamide (DMF) saturated with α-CD and laced with a gross excess (46 mol equiv) of 2,4-dinitrofluorobenzene. After an extensive purification procedure, full characterization of the product, which was obtained in high yield (60%), indicated average molecular weights of 23200 (by ^{1}H NMR) and 26400 (by UV) commensurate with the respective threading of 20 and 23 α-CD rings per polyrotaxane molecule (Fig. 2). This type of molecular structure conjures up the image of a molecular abacus[10] in terms of both structure and dynamics.

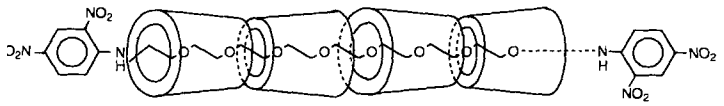

Fig. 2. Schematic representation of the polyrotaxane [6] constructed by Harada et al. by the threading of a poly(ethyleneglycol)diamine (PEG-DA) chain with α-cyclodextrin "beads" and coupling with dinitrophenyl (DNP) stoppers.

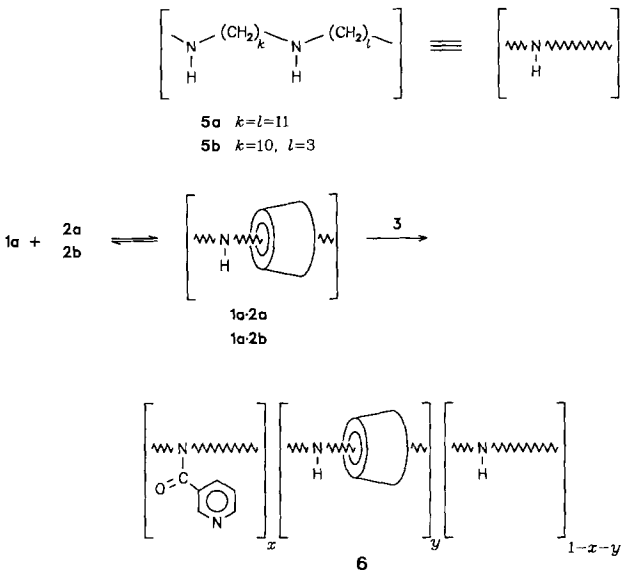
Quite independently, Wenz and Keller,[7] working at the Max-Planck-Institut für Polymerforschung in Mainz (Germany), have demonstrated the threading of CD molecules onto two polymer chains (Scheme 3): poly(iminoundecamethylene) **5a** with a $P_n = 43 \pm 5$ and poly(iminotrimethyleneiminodecamethylene) **5b** with a $P_n = 23 \pm 2$. Both ^{1}H NMR spectroscopy and viscosity measurements revealed that, whereas α-CD threads onto **5a** within a couple of hours, it takes over a week for **5b** to receive its full complement of α-CD rings in aqueous solution. Although equilibrium dialysis of **5a** · $(\alpha\text{-CD})_n$ into its separate components was over within 15 hours, dissociation of **5b** · $(\alpha\text{-CD})_n$ was far from complete after two weeks. When **5b** · $(\alpha\text{-CD})_n$ was treated with nicotinoyl chloride to introduce at least two hydrophilic nicotinoyl blocking groups at arbitrary positions along the poly(iminooligomethylene) chain, a polyrotaxane of M_w 55000 ± 5000 (determined by laser light scattering) was isolated with an average of 37 α-CD rings permanently threaded on to the chain.



Scheme 3. The [2]rotaxanes and the polyrotaxane of Wenz and Keller [7].

These exciting developments surrounding the CDs[11] have been going on against a background of activity in other laboratories on wholly synthetic rotaxanes[12–15] and polyrotaxanes.[16] Self-assembly is the unifying concept in the construction of all these mechanically interlocked molecular systems. As we begin to comprehend the rules of the game for different systems in a range of media, our fundamental understanding of molecular recognition benefits by leaps and bounds. Applications will begin to surface on a somewhat longer time-scale. Suffice it to say at present that there are high hopes for the advent of new materials with both novel forms and functions.

Protein Engineering: Modified Hemoglobin as a Blood Substitute

By *Timm-H. Jessen* and *Rolf Hilgenfeld**

A few years ago, the use of gene technology for modifying and redesigning proteins in order to improve their properties ("protein engineering"[1]), enjoyed generous support by national and international programs. This enthusiasm appears to be gradually waning—today's buzzwords are different ones, such as glycobiology and nanotechnology. And indeed, it seems that some protagonists in the field of protein engineering promised more than they have been able to deliver, at least in the short term. The design of enzymes tailored to fit the requirements for the catalysis of organic reactions with the desirable high stereoselectivity has up to now only been successful in exceptional cases. This is not surprising since our understanding of the relationship between the structure of proteins and their function is still rather limited. While the rapid and spectacular successes, with the exception of a few washing powder proteases, were to a large extent not achieved, protein engineering has now entered a phase of consolidation, during which realistic questions can be treated in a sound scientific manner—and not surprisingly, the fruits of the work are slowly beginning to ripen. This is particularly evident for proteins that are employed as therapeutics, where properties can be adjusted by genetic modification to meet the requirements more effectively. Thus the period of time after injection before human insulin takes effect can be significantly shortened by the specific exchange of certain amino acid residues.[2] Other modifications of the hormone lead to a prolonged activity, thereby reducing the number of injections necessary per day[3]. This, of course, should make life easier for diabetics.

For the rational design of such amino acid exchanges, a precise knowledge of the three-dimensional structure of the protein is necessary. This can be achieved in some cases (for small proteins) by NMR techniques, and in general, by protein crystallography. Thus, the X-ray structure analysis of hemoglobin determined by M. Perutz et al. (MRC, Cambridge)[4] formed the basis for the modification of this blood protein by genetic engineering as reported recently in *Nature* by K. Nagai et al. (MRC), together with reseachers from Somatogen (Boulder, Colorado).[5] With this modified hemoglobin an effective, and at the same time safe, blood substitute seems at last to be within reach after decades of intensive research.

Hemoglobin is crucial for the transport of oxygen in the body. Enclosed in the red blood cells, the protein is supplied with oxygen in the lungs, and delivers it to the respiratory cycle in the capillaries of the tissue. Hemoglobin consists of 2 α and 2 β polypeptide chains ($\alpha_2\beta_2$ tetramer), each including a protoporphyrin IX (the heme) with a Fe^{2+} ion. Local variations in the partial pressure of the gas, allosteric effectors, as well as the cooperativity of the tetramer modulate the oxygen affinity of the hemoglobin in an ideal way.[6] Since hemoglobin is a vital constituent of the blood, its application as a blood substitute seemed logical. There has always been a need for such a substitute in the face of problems associated with blood transfusions (availability, matching of blood groups, and storage stability); however, in recent years this need has become urgent as a result of the emergence of pathogenic viruses.[7]

Since, however, the use of hemoglobin as a blood substitute is not free of problems, other completely different approaches have also been considered. Synthetic oxygen carriers have been developed from perfluorohydrocarbons, which when applied as an emulsion can bind oxygen in quantities proportional to its partial pressure. The low viscosity of the emulsions, as well as the potential to utilize them in cases in which religion prohibits blood transfusions, increased the attractiveness of this approach.[8] At present perfluorooctylbromide is undergoing clinical trials and shows fewer of the potential problems of this class of substitutes—low oxygen capacity, immunogenicity, hepatotoxicity, and insufficient storage stability.[9]

The majority of the research approaches, however, are based on the hemoglobin molecule itself. Already in 1916 an intravenous infusion of a hemoglobin solution was carried out on humans.[10] Hemoglobin can be obtained from erythrocytes whose expiry date has already passed. During the purification process the complete removal of the cell membrane (stroma) must be carried out very carefully because it can induce a strong immune reaction.[11] Even hemoglobin itself shows this immunogenic behavior if it is present in

D-W-6230 Frankfurt 80 (FRG)

large amounts in the plasma instead of in the red blood cells. With the use of hemoglobin from cattle or pigs as a blood substitute the danger of immunotoxicity could be considerably greater.[12]

Hemoglobin can only fulfill its physiological task within the erythrocytes. Only there is 2,3-diphosphoglycerate (DPG) present, the essential allosteric effector for controlling oxygen delivery to the tissues.[13] Also, it is only within the erythrocytes that the concentration of hemoglobin is high enough to ensure the stability of the tetramer. These circumstances cause a fatal synergism as soon as hemoglobin is free in the plasma: its oxygen affinity is so high that the tissue is not supplied with enough oxygen, the oxygenated form of hemoglobin readily decomposes in dilute solution to $\alpha\beta$ dimers,[6] and these are so small (molecular weight of 32 kD) that they are excreted by the kidneys. In large quantities the $\alpha\beta$ dimers can cause severe damage to this organ.[14] Therefore, the efforts to use hemoglobin as a blood substitute have concentrated on its encapsulation in liposomes,[15] as well as on modifications of the protein, which stabilize the structure of the tetramer and at the same time reduce its oxygen affinity. Up to now, chemical crosslinking of the subunits by glutaric or fumaric acid derivatives has been the most successful strategy.[16] However, low yield and purity of the modified hemoglobins, insufficient cooperativity and product stability, as well as problems in clinical trials, have so far limited this approach.[9]

Since the end of the 1970s hemoglobin has also been a focus of genetic engineering. While initially α and β chains were expressed separately, the expression of a fully functional human hemoglobin is nowadays possible in *E. coli* and yeast, as well as in transgenic mice and pigs.[17] Of course, these recombinant hemoglobins cannot be used in unmodified form as blood substitutes, since just like the protein isolated from erythrocytes they display too high an oxygen affinity in the absence of 2,3-diphosphoglycerate and dissociate into dimers. Both problems have now been solved by the researchers at the MRC and Somatogen by using a genetic approach.[5] The *C* terminus of one of the two α chains, in the three-dimensional structure close to the *N* terminus of the other α polypeptide chain, was linked to the latter by a glycine residue. Fortunately this fusion did not cause a substantial reduction of the cooperativity, but it prevented the dissociation into dimers and thus led to a prolonged in vivo half-life of the hemoglobin. Furthermore, the β108 Asn → Lys mutation, which had been found in a naturally occurring hemoglobin with reduced oxygen affinity (hemoglobin Presbyterian),[18] was introduced into the β gene, and thus the oxygen affinity of the recombinant product was indeed reduced. Tests on rats and dogs have so far been very promising.[5]

It is difficult to judge whether the researchers at Somatogen and MRC have taken the lead in the race for an efficient and safe blood substitute with their work. It definitely is a race: at least seven companies are carrying out intensive research and development work in this field in an effort to be the first suppliers on the world market, which is estimated to be worth some 10 billion dollars. Because of this keen competition, very little information is published. This results in some rumor mongering; for example, there have been suspicions about cases of kidney failure in volunteers following the administration of unmodified hemoglobin as recently as 1978 when much was already known about the dangers associated with this approach.[19] To put a stop to such practices and create a greater openness the FDA (Food and Drug Administration) called a meeting of the leading companies and research groups almost two years ago. This resulted in an acknowledged catalogue of requirements that potential blood substitutes must fulfill before they can undergo clinical testing. Somatogen has now met the demand for greater openness with its publication in *Nature*; it remains to be seen whether the genetically modified hemoglobin, which was so successful in animals, will pass the clinical examination.

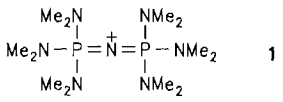
A Safe Synthesis of Diphosphazenium Salts

By *Reinhard Link* and *Reinhard Schwesinger**

Recently we published a short communication entitled "Stable Phosphazenium Ions in Synthesis—an Easily Accessible, Extremely Reactive "Naked" Fluoride Salt".[1] A procedure for the synthesis of the cation **1** was given with nitromethane as solvent. Although conclusive information is not yet available, there is some indication that nitromethane might be explosive in connection with Lewis acids or amines.[2] We therefore recommend the following procedure for production of the **1**-BF_4, the precursor of the fluoride salt.



1

1-BF_4: A finely ground mixture of NH_4Cl (17.83 g, 0.333 mol) and NaCl (50 g) together with PCl_5 (208.5 g, 1.00 mol) was heated at reflux in 300 mL $POCl_3$ with vigorous stirring, until the gas evolution (HCl) ceased (ca. 2 h). The solvent was removed by distillation, and the residue was dried under high vacuum at 20 °C, then taken up in 300 mL of dry chlorobenzene. Dimethylamine (360 g, 8.00 mol, free of primary amines and dried over Na_2O) was then passed into the mixture at −20 °C (delivery tube above the solution). After the reaction mixture had been stored at 20 °C for 7 d, a solution of $NaBF_4$ (36.7 g, 0.333 mol) in 500 mL of water was added to the mixture with stirring. (Caution: The solution may contain traces of hexamethylphosphoric triamide. The organic phase was removed and the aqueous phase extracted once more with 50 mL chlorobenzene. The combined organic layers were concentrated in vacuum. The residue was dried in a high vacuum and recrystallized from water. For the subsequent reaction to give **1**-F, **1**-BF_4 was recrystallized from THF (800 ml) and dried under a high vacuum. Yield 103 g (72%); m.p. 260 °C (decomp.). Correct elemental analysis (C,H,N). ^1H NMR (250 MHz, $CDCl_3$, 30 °C, TMS): $\delta = 2.69$ (m).

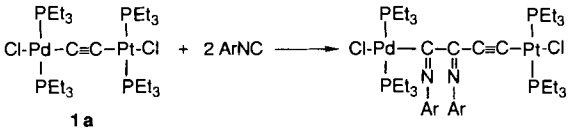
Reaction of Heterodinuclear μ-Ethynediyl Complexes Containing Palladium and Platinum: Multiple and Successive Insertion of Isocyanides

By *Kiyotaka Onitsuka, Takashi Joh,* and *Shigetoshi Takahashi**

Extensive studies have been made on the insertion of isocyanide into M–C bonds of various transition metal complexes.[1] Some transition metal complexes such as $[Ni(CO)_4]$, $[Co_2(CO)_8]$,[2] and Ni^{II} compounds[3, 4b] catalyze the polymerization of isocyanide; however, living polymerization is quite rare.[4]

We previously reported on the selective insertion of two molecules of aryl isocyanides into just one of the two Pd–C bonds of μ-ethynediyldipalladium complexes[5] and on the syntheses of heterodinuclear μ-ethynediyl complexes containing palladium and platinum.[6] We have now examined the reactivity of μ-ethynediyl-PtPd complexes toward isocyanides, and observed that multiple and successive insertions of isocyanides occur at the Pd–C bonds. The heterodinuclear complex **1a**, on treatment with 2 equivalents of phenyl isocyanide in THF under reflux, gave an orange, air-stable complex (**2a**) in 94% yield. The characterization by spectroscopic analyses[7] indicated that complex **2a** was a double-insertion product formed by the selective insertion of two molecules of the isocyanide into the Pd–C bond of **1a**. Similarly, *p*-nitrophenyl isocyanide and *p*-tolyl isocyanide reacted with **1a** to give double-insertion products **2b** and **2c**, respectively.

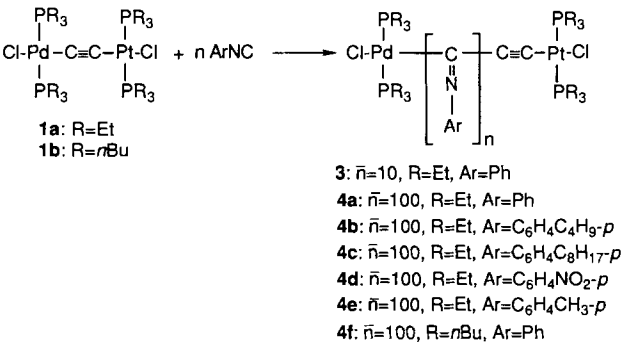


When **1a** was treated with 10 equivalents of phenyl isocyanide under the same conditions, no isocyanide was recovered and an oligomeric complex (**3**) was obtained. The average molecular weight of **3** was determined to be 1850 by vapor pressure osmometry (in benzene), which corresponds to the product derived from one molecule of **1a** and ten molecules of phenyl isocyanide. In the ^1H NMR spectrum the ratio of aromatic protons on PhNC to aliphatic protons on triethylphosphine indicated the same composition for **3**. The IR spectrum of **3** showed absorptions at 2085 cm^{-1} ($\nu_{C\equiv C}$) and at 1640 cm^{-1} ($\nu_{C=N}$); the latter absorption is characteristic of isocyanide polymers.[2, 8] In the ^{31}P NMR spectrum two singlets at δ 18.8 and 21.8 were observed, the latter of which appeared with satellite signals (J = 2350 Hz) due to coupling with the ^{195}Pt nucleus. In general, the spectra of **3** are very similar to those of **2a** (Table 1).

Table 1. Selected spectral data for **1a**, **2a**, **3**, and **7**.

Complex	IR [cm^{-1}]		^{31}P NMR [δ value]	
	$\nu_{(C\equiv C)}$	$\nu_{(C=N)}$	P on Pd	P on Pt ($^1J(^{195}Pt,P)$)
1a	–	–	22.8	19.6 (2518 Hz)
2a	2090	1575	18.7	21.6 (2331 Hz)
3	2085	1640	18.8	21.8 (2350 Hz)
7	2090	1640	17.6	21.0 [a]

[a] The coupling constant could not be determined exactly because of broadening of the signal.



On treatment of **1a** with 100 equivalents of phenyl isocyanide under reflux in THF for 20 h a yellow polymer (**4a**) was obtained in 92% yield. The IR spectrum of **4a** exhibited an absorption at 1660 cm^{-1} ($\nu_{C=N}$), but unfortunately **4a** was insoluble in organic solvents and further characterization was not possible. Hence, **1a** was treated with 100 equivalents of aryl isocyanides containing a long alkyl chain such as an *n*-butyl or *n*-octyl group to afford soluble polymers **4b** and **4c**. The IR and NMR spectra of **4b** and **4c** showed that they have the proposed structures, and gel permeation chromatography (GPC) analyses with polystyrene standards indicated a very narrow distribution of molecular weight $\bar{M}_w/\bar{M}_n = 1.02$ ($\bar{M}_n = 13000$) for **4b** and 1.01 ($\bar{M}_n = 17000$) for **4c**. Thus, the reactions appear to be living polymerizations.

Complex **1a** also catalyzes the living polymerization of aryl isocyanides other than phenyl isocyanide. Similar treatment of **1a** with *p*-nitrophenyl isocyanide and *p*-tolyl isocyanide afforded polymers **4d** and **4e**, respectively. Complex **1b** bearing a tributylphosphine ligand reacted with phenyl isocyanide to give polymer **4f**. On the other hand, alkynepalladium complexes **5** did not yield any polymeric products but only the single-insertion complexes **6**, even when treated with

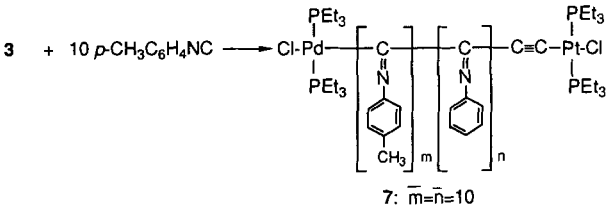
100 equivalents of phenyl isocyanide, which implies that the platinum moiety in complex **1** plays a very important role in the multiple insertion of isocyanides.

Finally, that the reaction of **1a** with isocyanides is a living polymerization has been demonstrated by several experiments. Complexes **2a** and **3** also initiate the polymerization of isocyanides. For example, complex **2a** was treated with 100 equivalents of phenyl isocyanide under reflux in THF to yield polymer **4a** quantitatively, and the reaction of **3** with 10 equivalents of *p*-tolyl isocyanide afforded a soluble block co-oligomer **7** whose structure has been identified by ^1H and ^{31}P NMR spectra.



7: $\bar{m}=\bar{n}=10$

Very recently a living polymerization of alkyl isocyanides with $[\{(\eta^3\text{-}C_3H_5)Ni(OC(O)CF_3)\}_2]$ as catalyst was reported.[4b] The polymers produced in this case, however, have a rather broad distribution of molecular weight ($\bar{M}_w/\bar{M}_n = 1.1-1.6$). Our catalysts are active for aryl isocyanides and yield polymers with a narrow molecular weight distribution. All the complexes **2** and the oligo- and polyisocyanide complexes **3**, **4**, and **7** have the active end-group $Pd(PR_3)_2Cl$. They are thus still "living" and able to undergo further insertion of isocyanides. Hence, these complexes as well as complex **1** provide a novel system for the living polymerization of isocyanides and give polymers designed in terms of molecular weight, composition and sequence.

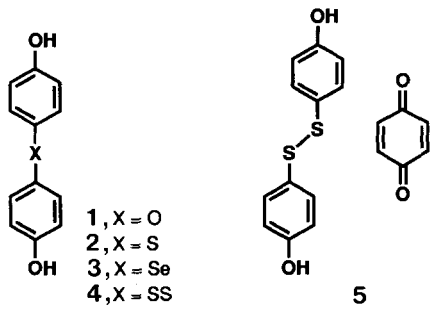
Three-Dimensional Structure of an Unsymmetrical Proton–Electron Transfer System Containing a Disulfide Bond: The Bis(4-hydroxyphenyl)disulfide–Benzoquinone Complex**

By *Kenichi Sugiura, Jiro Toyoda, Hiroshi Okamoto, Kaoru Okaniwa, Tadaoki Mitani, Atsushi Kawamoto, Jiro Tanaka,* and *Kazuhiro Nakasuji**

The hydrogen-bonded charge-transfer (CT) complex, 1,4-benzoquinhydrone, has recently been found to undergo a new phase transition, a cooperative proton–electron transfer (PET), under high pressure.[1] The final state is characterized as the molecular assembly of hydrogen-bonded neutral radicals.[2] Such a transition can be analyzed by measuring the pressure dependence of the O–H and C=O stretching frequencies. In order to obtain a new PET system under milder physical conditions, we synthesized the extended conjugated quinhydrones, 1,5-dihalo-2,6-naphthoquinhydrones, which actually responded to applied pressure.[2] We now report the new component molecules, the bis(hydroxyphenyl)systems connected by the disulfide bond. Bis(4-hydroxyphenyl)disulfide **4** produces an unsymmetrical PET system with three-dimensional structure.



One of the strategies for the design of new PET systems is the substitution of the quinone and hydroquinone skeletons with donor and acceptor groups to make use of the captodative effect in stabilizing the final neutral radicals.[3] However, the attempts to prepare such modified quinhydrones were unsuccessful.[4] In order to develop unsymmetrical PET systems, we designed and synthesized the proton–electron donors **1**–**4**,[5] which are composed of two phenol moieties connected by oxygen, sulfur, selenium, or a disulfide bond. These compounds show the following characteristics: 1) The exchange reactions can be suppressed by the chalcogen atoms, and 2) the twist of the chalcogen–phenyl units affects the crystal packing. The properties of compounds **1**–**4** related to hydrogen bonding and the CT interaction were investigated. The acid dissociation constants K_a of the phenol moi-

ety increase in the order of **1** < **2** ≈ **3** < **4**, as shown in Table 1. This order is consistent with the total electronic effects arising from the inductive and resonance effects of the chalcogen atoms on the phenol moiety.[6] The acidity of **1** is nearly same as that of hydroquinone. Interestingly, the difference between the first and second acid dissociation constants of **2**–**4** are larger than that of **1**. The larger ΔpK_a values indicate that in the S- and Se-bridged molecules the dissociation of the second proton is not as facile as in the O-linked derivatives, since the negative charge in the higher homologues is more delocalized. The electron donor abilities were estimated from the values of the CT transition energies with tetracyanoethylene (TCNE) in acetonitrile (Table 1). These energy values suggest that the donors **1** and **4** are worse donors, and **2** and **3** better donors than hydroquinone.

Table 1. Logarithmic dissociation constants pK_a [a] and CT transition energies E [b] for **1**–**4** and hydroquinone (HQ).

	pK_{a_1}	pK_{a_2}	ΔpK_a	E [eV]
1	11.1	11.2	0.1	2.27
2	10.5	10.9	0.4	2.06
3	10.5	11.0	0.5	2.05
4	10.0	10.5	0.5	2.49
HQ	11.1	11.6	0.5	2.11

[a] The acid dissociation constants were determined potentiometrically with 0.1 N standardized sodium hydroxide solution. The temperature was maintained at 25.0 ± 0.1 °C, and the ionic strength was adjusted to 0.10 M with $NaClO_4$. [b] The charge-transfer transition energies were determined with tetracyanoethylene in acetonitrile.

CT complexes of these donors with various quinone-type acceptors were prepared. The 1:1 CT complex **5** arising from **4** and 1,4-benzoquinone was the only one to form single crystals, specifically, large, cubic, black single-crystals with the dimensions 5 × 5 × 5 mm^3.[7] The crystal structure analysis and the spectroscopic data show that this complex is a unique hydrogen-bonded CT complex (Fig. 1 a).[8] As shown in Figure 1 b, the hydroxyphenyl moiety of **4**, benzoquinone, and the next hydroxyphenyl moiety of **4** are joined by hydrogen bonds. The hydrogen-bonded units are connected by disulfide bonds to form a zigzag chain. In addition, the hydrogen-bonded units stack with a donor–acceptor–donor type of CT interaction to form linear ribbons extended in the [1,1,0] or [1,−1,0] direction (Fig. 1 c). In the crystal, such ribbons are piled alternately with reference to the c axis making a three-dimensional molecular structure (Fig. 1 a, c).

The bond lengths of the benzoquinone component of **5** and uncomplexed benzoquinone differ by only ±0.07 Å.[9] The IR stretching frequencies of **5** ν(C=O) and ν(O–H) (1637 and 3213 cm^{-1}, respectively) are very close to those of benzoquinhydrone (1633 and 3227 cm^{-1} for the average values of monoclinic and triclinic forms of benzoquinhydrone measured in this work).[11] The diheral angle and the S–S bond length for the donor component **4** in **5** are 88° and 2.032 Å, respectively.[12] These data reflect the nonionic nature of **5**. The lowest energy band in the solid-state electronic absorption spectrum for the complex is at 2.28 eV and can be assigned to the CT transition between the hydroxyphenyl moiety and benzoquinone. The intensity of the polarized reflection spectra was largest along the c axis, which is the stacking direction of the donor–acceptor–donor arrangement in the linear ribbons. The transition energy of **5** is higher than that of benzoquinhydrone (2.06 eV). This is consistent with the lower donor ability of **4** relative to hydroquinone, as was measured above. Under high pressure (40 kbar), the OH stretching band in the IR spectrum shifted from 3213 cm^{-1} to 3080 cm^{-1}, and a new band appeared at 2640 cm^{-1}. The CO stretching band also shifted from 1637 cm^{-1} to 1617 cm^{-1}, and an additional band at 1578 cm^{-1} appeared.

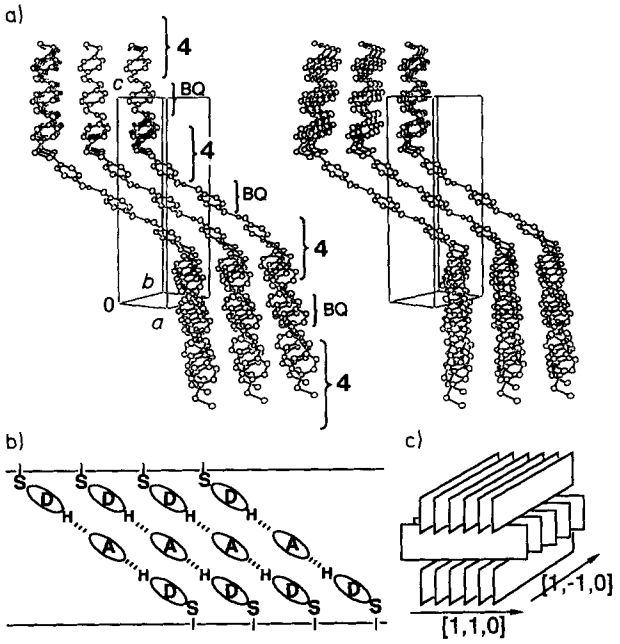

Fig. 1. The crystal structure of **5**. a) Stereoplot showing a section of the molecular packing; BQ = benzoquinone. b) Schematic representation of a linear ribbon. c) Schematic representation of the three-dimensional structure.

Thus, we could show that **5** displays a pressure-dependent IR spectrum. This system should still be characterized in detail on the molecular level. Our next step toward new PET systems will be chemical modification to enhance the electron-donor ability and/or the proton-donor ability in these unsymmetrical PET systems.

Structures of Two Highly Reactive Intermediates upon $LiAlH_4$ Reduction in the Solid State and in Solution: $[(Me_3Si)_2NAlH_3Li \cdot 2Et_2O]_2$ and $[(Me_3Si)_2N]_2AlH_2Li \cdot 2Et_2O$ **

By *Andreas Heine* and *Dietmar Stalke**

Lithium aluminum hydride $LiAlH_4$ is a versatile reducing and hydrogenating reagent in both inorganic and organic synthesis.[1, 2] Although more than 60 functional groups are known to react with $LiAlH_4$, very little is known of the reactive intermediates involved in these syntheses. We report here the isolation of the intermediates **1** and **2**.

$$HN(SiMe_3)_2 + LiAlH_4 \longrightarrow \underset{\mathbf{1}}{1/2\,[(Me_3Si)_2NAlH_3Li \cdot 2Et_2O]_2}$$

$$\xrightarrow[-H_2]{+HN(SiMe_3)_2} \underset{\mathbf{2}}{[(Me_3Si)_2N]_2AlH_2Li \cdot 2Et_2O} \xrightarrow[-H_2]{+2\,HN(SiMe_3)_2}$$

$$\underset{\mathbf{3}}{[(Me_3Si)_2N]_3Al} + LiN(SiMe_3)_2$$

The overall reaction to form the trisubstituted aluminum compound **3**[3, 4] proceeds stepwise, whereby the reactive mono-substituted intermediate **1** and the disubstituted intermediate **2** can be isolated. Although the isolation of **1** and **2** does not necessarily prove that these compounds are intermediates in the reaction pathway suggested above, this is, however, chemically plausible. $LiAlH_4$ was allowed to react with hexamethyldisilylamine in diethyl ether. The reaction mixture was stirred for 24 h at room temperature and filtered, whereupon crystals of **1** were obtained after 3 d at −35 °C. The crystals, were directly mounted onto the diffractometer from mother-liquor at ca. −50 °C, thus permitting an X-ray structure analysis. At approximately −30 °C the colorless crystals start to "effervesce" and turn into a white insoluble powder. We assume that they lose hydrogen. **1** (Fig. 1) is a dimer in the solid state.[5] The aluminum atoms in the central eight-membered $Al_2H_4Li_2$ ring are each coordinated by three hydrogen atoms and a $N(SiMe_3)_2$ ligand. The lithium atoms form two bridges between the two $(Me_3Si)_2NAlH_3$ units via Li–H contacts. Each of them is also coordinated to two ether molecules. The average Li–H

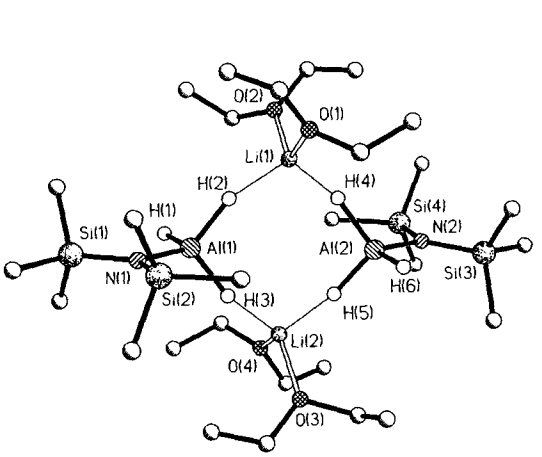

Fig. 1. Structure of the reactive intermediate $[(Me_3Si)_2NAlH_3Li \cdot 2Et_2O]_2$. Selected distances [pm] and angles [°]: Al1-H2 163(4), Al1-H3 158(4), Al2-H4 166(4), Al2-H5 161(4), Al1-H1 158(5), Al2-H6 161(4), Li1-H2 181(4), Li1-H4 174(4), Li2-H3 180(4), Li2-H5 176(4), Al1-N1 185.5 (3), Al2-N2 186.0(3), average Li-O 193.1(8), average Si-N 171.3(3), average H-Al-H 107(2), average H-Li-H 107(2), average Al-H-Li 157(3), average Si-N-Si 125.6(2), average Al-N-Si 117.2(2).

distance in **1** is 177.7 pm and therefore significantly shorter than in solid LiH (204.0 pm)[6] or even $LiAlH_4$ (188–216 pm).[7] To our knowledge, a shorter Li–H contact has only been found (168 and 192 pm, determined by X-ray structure analysis) in $[t\mathrm{Bu}_3\mathrm{AlHLi}]_2$.[8] The shortest Li–H contact (159.6 pm) is found by spectroscopic techniques in molecular LiH.[9] The average Al–H distance of 161.0 pm is in good agreement with the values quoted in the literature.[8, 10–12] Addition of $HN(SiMe_3)_2$ to $LiAlH_4$ in diethyl ether and subsequent refluxing for 3 h followed by stirring for 12 h at room temperature leads to formation of the disubstituted intermediate **2**. Crystals were grown in good yield at −18 °C. Under these conditions the reaction is stopped after substitution of two equivalents of bis(trimethylsilyl)-amine rather than allowing the trisubstituted product **3** to be formed. Crystals of **2** were mounted on the diffractometer at ca. −10 °C and started to effervesce above +5 °C. Presumably they also lose hydrogen. Figure 2 shows the monomeric structure of **2** in the solid state. The most striking feature is the central AlH_2Li four-membered kite-shaped ring, in which the lithium atom bridges the two aluminum-bound hydrogen atoms. The bond angles show that **2** has a relatively strained structure. The average H–Al–H bond an-

gle in **2** (94.3°) is 12.9° smaller than that in **1** (107.2°). The average H–Li–H angle (73.6°), however, is even 33.8° smaller than that in **1** (107.4°). The intramolecular bridging of the lithium atom leads to a longer Li–H distance (average 193.3 pm; but 177.7 pm in **1**), which is comparable to the distance in $LiAlH_4$.[7] The hydrogen atoms are forced close together to the transannular distance of 233.1 pm. Despite this steric strain the molecule does not dissociate in solution. The ^{7}Li-NMR spectrum of **2** shows a ^1J(Li,H) coupling constant of 10.5 Hz (Fig. 3). This is in good agreement with

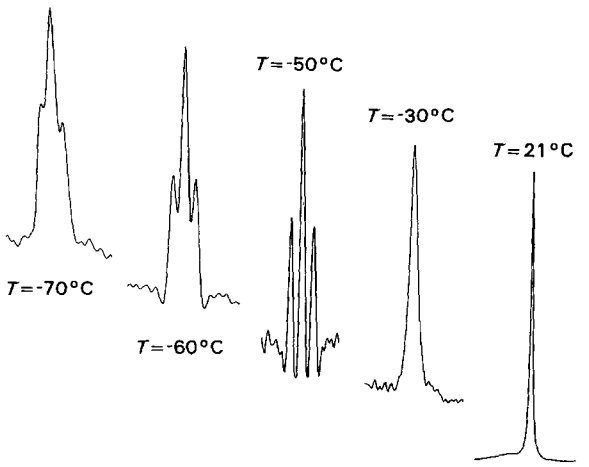

Fig. 3. Experimental ^{7}Li-NMR spectra of **2** at various temperatures. The chemical shift at −50 °C is 0.4, the coupling constant ^1J(Li,H) 10.5 Hz.

the only other known ^1J(Li,H) coupling (8.4 Hz) detected in the ^{1}H/^{7}Li-NMR spectra of [Cp*IrH$_3$Li(pmdeta)] (pmdeta = $(Me_2NCH_2CH_2)_2NMe$).[13] This supports our suggestion[14] that there is more covalent character in bonds to lithium than was previously considered likely. In **2** the ^{7}Li-^{1}H coupling is only resolvable in the temperature window −30 °C to −70 °C. Outside this window the triplet structure of the signal is lost (Fig. 3), at higher temperatures as a result of exchange and at lower temperatures probably as a result of ^{7}Li quadrupole effects. The coupling could not be verified in the ^{1}H-NMR experiment because the hydride signals are too broad. Furthermore, the ^1J(Li,H) coupling could not be observed in **1** at any temperature between room temperature and −120 °C in [D$_8$]toluene. **1** is fluctional in solution.This fluctionality could indicate a monomer/dimer equilibrium superposed on a μ_1 and/or μ_2 and/or μ_3 hydride bridging exchange.

Experimental

1: $HN(SiMe_3)_2$ (7 mL, 33.3 mmol) was added over 8 h to a suspension of $LiAlH_4$ (1.26 g, 33.3 mmol) in diethyl ether (30 mL). The mixture was stirred for 24 h at room temperature. Subsequent filtration furnished a clear solution, storage of which at −35 °C afforded colorless crystals after about one week. ^{1}H NMR ([D$_8$]toluene, ca. 25 °C): $\delta = 0.35$ (s, 36H of $SiMe_3$), 1.08 (t, 24H of CH_2CH_3), 3.35 (q, 16H of CH_2CH_3); ^{7}Li NMR ([D$_8$]toluene, ca. 25 °C): $\delta = -0.37$.

2: A solution of $HN(SiMe_3)_2$ (8 mL, 38.1 mmol) in diethyl ether (20 mL) was added to a suspension of $LiAlH_4$ (0.71 g, 18.7 mmol) in diethyl ether (20 mL). The mixture was stirred for 12 h at room temperature, After the precipitate was filtered off, colorless crystals separated from the clear solution after several days at −18 °C. ^{1}H NMR ([D$_8$]toluene, ca. 25 °C): $\delta = 0.47$ (s, 36H of $SiMe_3$), 0.94 (t, 12H of CH_2CH_3), 3.19 (q, 8H of CH_2CH_3); ^{7}Li NMR ([D$_8$]toluene, ca. 25 °C): $\delta = 0.31$, (−50 °C): 0.4, ^1J(Li,H) = 10.5 Hz; IR: $\tilde{\nu}$ (AlH) = 1754 cm^{-1} (s).

Data were collected on a Siemens-Stoe AED using an oil-coated rapidly-cooled crystal of dimensions 0.5 × 0.4 × 0.2 mm by the $2\theta/\omega$ method ($8° \leq 2\theta \leq 50°$). Of a total of 8921 collected reflections, 8643 were unique and 5201 were employed in structure refinement [$(F > 3\sigma(F))$, data-to-parameter ratio 12.8:1]. The structure was solved by direct methods and refined by full matrix least squares to R and R_w values of 0.070 and 0.069, respectively. **2**: $C_{20}H_{58}LiN_2O_2AlSi_4$, $M = 505.0$, triclinic, space group $P\bar{1}$, $a = 11.225(4)$, $b = 11.416(5)$, $c = 14.460(3)$ Å, $\alpha = 90.15(3)$, $\beta = 100.64(5)$, $\gamma = 112.07(2)°$, $V = 1682(3)$ Å^3, $Z = 2$, $\varrho_{calcd} = 0.997$ Mg m^{-3}, $F(000) = 560$, $\lambda = 0.71073$ Å, $T = 153$ K, $\mu(Mo_{K\alpha}) = 0.219$ mm^{-1}. Data were collected on a Siemens-Stoe AED using an oil-coated rapidly-cooled crystal of dimensions 0.5 × 0.4 × 0.2 mm by the $2\theta/\omega$ scan method ($8° \leq 2\theta \leq 58°$). Of 11310 collected reflections, 8893 were unique and 5793 were employed in the structure refinement ($F > 4\sigma(F)$, data-to-parameter ratio 19.6:1). The structure was solved by direct methods and refined by full-matrix least squares to R and R_w values of 0.055 and 0.058, respectively. In both cases the program used was the SHELXTL-Plus, PC version. All hydrogen atoms were located in a difference Fourier map and were refined using a riding model with common refined U values for chemically equivalent atoms. The terminal hydrogen atoms were refined freely in both structures. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

Total Synthesis of the Carbohydrate Fragments of Esperamicin A_1**

By *K. C. Nicolaou** and *David Clark*

Esperamicin A_1[1] (**1**) is one of the most prominent members of the naturally occurring enediyne anticancer antibiotics.[2] In this communication, we report the total synthesis of both its carbohydrate chains **2** and **3**[3] (Scheme 1) in their

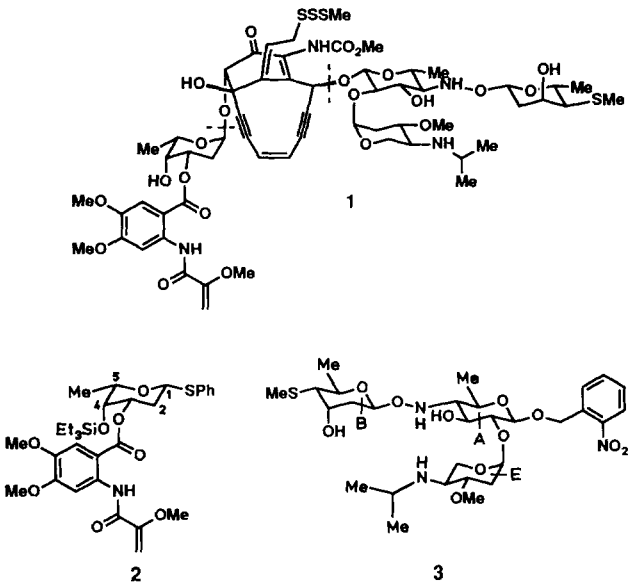
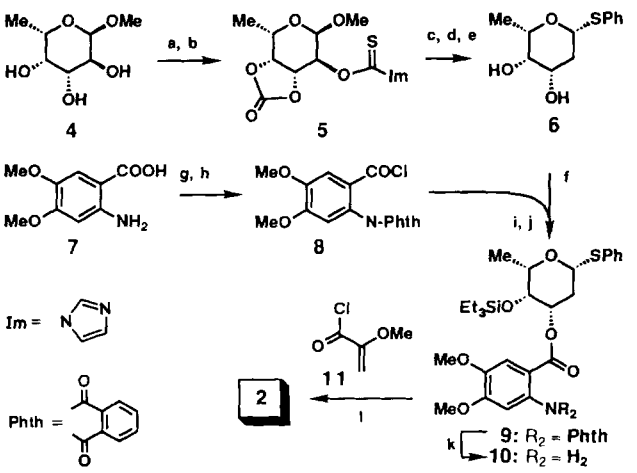
[**] We express our many thanks to Dr. Dee Huang and Dr. Gary Siuzdak of The Scripps Research Institute for their excellent assistance with the NMR and mass spectra. This work was financially supported by the National Institutes of Health and The Scripps Research Institute.

optically active forms and in protected versions suitable for an eventual total synthesis of the natural product.



Scheme 1. The structures of esperamicin A_1 (**1**) and the carbohydrate fragments **2** and **3**.

Scheme 2 depicts the synthesis of fragment **2** starting with the readily available **4** and **7**. Methyl-α-L-fucopyranoside (**4**)[4] was regioselectively converted into intermediate **5**[5] by sequential reaction with carbonyldiimidazole and thiocarbonyldiimidazole. This protected compound was deoxygenated at the 2 position and transformed into **6** by means of Hanessian[6] phenylthioglycosidation and base-induced carbonate removal. The other requisite coupling partner, **8**, was prepared from 4,5-dimethoxyanthranilic acid (**7**) by reaction with phthaloyl chloride followed by treatment with oxalyl chloride. For the coupling of compounds **6** and **8** a cyclic tin dialkoxide derivative was prepared from **6** and then stirred with **8** in the presence of Et_3N. After silylation of the remaining 4-hydroxyl group, compound **9** was obtained regioselectively. Hydrazine-induced removal of the phthaloyl group from **9** smoothly gave the free amine **10**, which was condensed with acid chloride **11**[7] in the presence of Et_3N to afford the desired target **2** (Table 1).



Scheme 2. Synthesis of esperamicin A1 carbohydrate chain **2**. Reagents and conditions: a) 2.5 equiv 1,1'-carbonyldiimidazole, CH_3CN, reflux, 2 h, 76%; b) 1.3 equiv 1,1'-thiocarbonyldiimidazole, CH_3CN, 25 °C, 2 h, 80%; c) 2.0 equiv nBu_3SnH, azobisisobutyronitrile (AIBN, cat.), toluene/dimethoxyethane (DME) (1:1), 110 °C, 1 h, 84%; d) 5.0 equiv $PhSSiMe_3$, 3.0 equiv ZnI_2, 1.2 equiv nBu_4NI, 1,2-dichloroethane, 2.5 h, 70 °C; e) 0.05 equiv NaH, THF/ethylene glycol (20:1), 25 °C, 2 h, 63% for d and e; f) 1.2 equiv nBu_2SnO, MeOH, 65 °C, 1.5 h then solvent exchange with anhydrous THF; g) 1.1 equiv phthaloyl chloride, 2 equiv Et_3N, THF, 25 °C, 2 h, 50%; h) 1.2 equiv oxalyl chloride, CH_2Cl_2/dimethyl formamide (DMF) (100:1), 25 °C, 0.5 h; i) 1.5 equiv **8**, 2.0 equiv Et_3N, THF, 25 °C, 0.75 h, 65% for h and i. j) 1.2 equiv Et_3SiOTf, 1.5 equiv 2,6-lutidine, CH_2Cl_2, 0 °C, 0.2 h, 100%; k) 2.0 equiv hydrazine, 1.0 equiv AcOH, MeOH/CH_2Cl_2 (5:1), 25 °C, 5 h, 83%; l) 3.0 equiv **11** [7], 5.0 equiv Et_3N, THF, 25 °C, 85%.

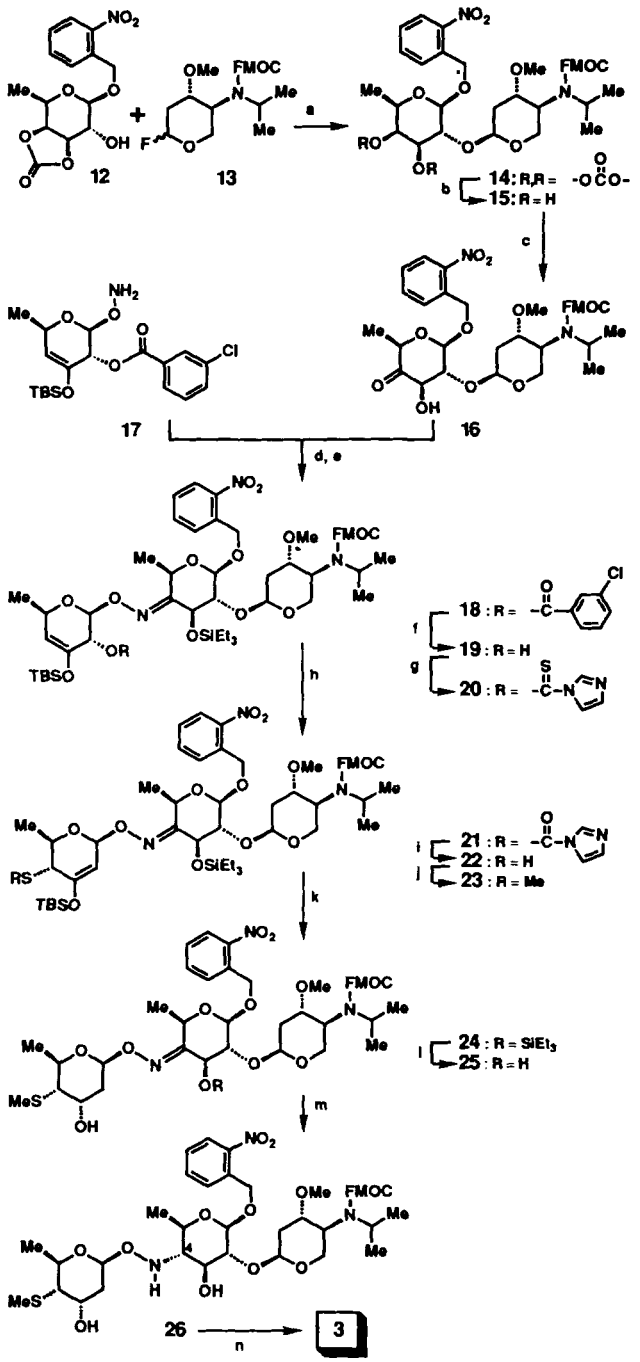
[a] The rings in **3** are denoted by A, B, E. Thus E-2eq stands for the equatorial H on C-2 in ring E.

Scheme 3 summarizes the construction of the trisaccharide **3**. The *o*-nitrobenzyl glycoside **12**[8] was coupled with the glycosyl fluoride **13**[9] to afford disaccharide **14** stereoselectively (α:β anomers, ca. 3:1). The carbonate function of **14** was selectively removed under basic conditions, leading to diol **15**. The hydroxy ketone **16**, obtained from diol **15**,[10] was coupled with the hydroxylamine derivative **17**[11] under acidic conditions, furnishing after silylation trisaccharide **18**.[12] The aryl ester function of **18** was removed with diisobutylaluminum hydride giving **19**, which was treated with thiocarbonyldiimidazole to afford thionoimidazolide **20**. Thermolysis of **20** led, as anticipated,[11] to thioimidazolide **21** by a [3,3]sigmatropic rearrangement. Generation of thiol **22** from **21** by exposure to NaSEt followed by reaction with excess methyl iodide led to the thiomethyl derivative **23**. Selective desilylation of the enol group led to the corresponding carbonyl compound, which was reduced stereoselectively



Scheme 3. Total synthesis of esperamicin A1 carbohydrate fragment **3**. Reagents and conditions: a) 1.35 equiv **13**, 1.0 equiv **12** [8], 2.5 equiv $AgClO_4$, 2.5 equiv $SnCl_2$, 4 Å, molecular sieves, THF, $-78 \rightarrow -20\,^{\circ}C$, 7 h, ($\alpha:\beta \approx 3:1$); b) 0.04 equiv NaH, THF/ethylene glycol (20:1), 25 °C, 0.5 h, 60% for a and b; c) 1.0 equiv nBu$_2$SnO, MeOH, reflux, 1.2 h then 1.0 equiv nBu$_3$SnOMe, 1.0 equiv Br_2, CH_2Cl_2, 25 °C, 76%; d) 0.1 equiv pyridinium *para*-toluenesulfonate, 1.5 equiv **17** [11], benzene, 25 °C, 3 h, 70%; e) 1.2 equiv Et_3SiOTf, 1.5 equiv 2,6-lutidine, CH_2Cl_2, $0 \rightarrow 25\,^{\circ}C$, 0.5 h, 100%; f) 3.0 equiv iBu$_2$AlH, CH_2Cl_2, $-78\,^{\circ}C$, 0.5 h, 95%; g) 3.0 equiv 1,1'-thiocarbonyldiimidazole, CH_3CN, 25 °C, 1.5 h, 86%; h) toluene, 100 °C, 1 h, 100%; i) 1.0 equiv NaSMe, 40 equiv EtSH, CH_2Cl_2, 25 °C, 1.5 h, 95%; j) 50 equiv MeI, 2.5 equiv iPr$_2$EtN, CH_2Cl_2, 25 °C, 1 h, 90%; k) 5.0 equiv AcOH, 1.0 equiv nBu$_4$NF, THF, $-40 \rightarrow 0\,^{\circ}C$, then 3.0 equiv K-selectride, DME/THF (7:1), $-78\,^{\circ}C$, 0.7 h, 67%; l) excess HF · py, CH_2Cl_2/THF (7:1), $-20 \rightarrow 0\,^{\circ}C$, 3 h, 85%; m) 13 equiv $NaBH_3CN$, 13 equiv $BF_3 \cdot OEt_2$, CH_2Cl_2/THF/Et_2O (2:1:1), $-60 \rightarrow -40\,^{\circ}C$, 2 h, 90% (**26**:epi-**26** ≈ 2:1); n) THF/Et_2NH (1:1), 25 °C, 2 h, 81%. FMOC = fluorenylmethoxycarbonyl, TBS = tBuMe$_2$Si.

with K-selectride to afford the desired hydroxy compound **24**. Desilylation of **24** with HF · py gave the hydroxy oxime **25**. The C=N bond of **25** was reduced with $NaBH_3CN$ providing the desired product **26** together with its C4 epimer.[13] Finally, chromatographically purified **26** was deprotected to the targeted trisaccharide chain **3** (Table 1).

[12] In this reaction a single geometrical isomer about the oxime –C=N– bond was obtained; however, its configuration remains unassigned.

[13] The assignment of the configuration at C-4 for compound **26** was based on the observed coupling constants for H-4 ($J_{3,4} = 9.5$; $J_{4,5} = 9.6$ Hz; 500 MHz, $CDCl_3$, $\delta = 2.21$), which indicate a diaxial relationship of this proton with its two neighboring protons. The epimer of **26** exhibited a doublet at $\delta = 2.99$ for H-4 ($J_{4,5} = 4.7$ Hz).

A New Strategy for Solid-Phase Synthesis of *O*-Glycopeptides**

By *Tim Bielfeldt, Stefan Peters, Morten Meldal, Klaus Bock,* and *Hans Paulsen**

In recent years glycoproteins have become a focus of attention because of their wide-ranging biochemical functions.[1] They participate in the recognition and defense mechanisms of cells to a large extent.[2] A recent finding is that leukozytes interact with endothel cells through the mediation of the receptors of the LEC–CAM (lectin cell adhesion molecules) family.[3] Parts of glycoproteins containing saccharide and peptide residues are interesting with respect

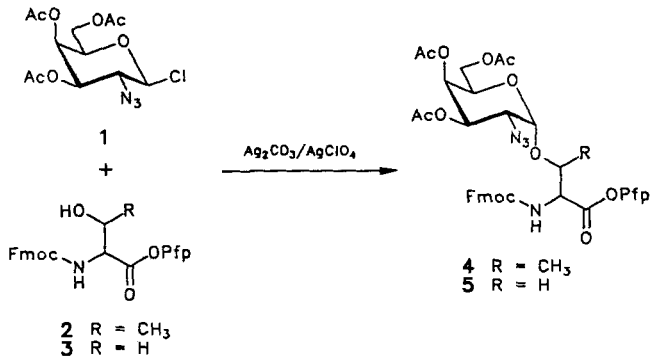
to the function of these segments and the specificity of their further biosynthesis.[4] The isolation of such glycopeptides from natural sources is often difficult. As a rule they are more accessible through chemical synthesis. In an *O*-glycopeptide synthesis, a building block that contains an α-glycosidic bond to an acetylated 2-acetamido-2-deoxy-D-galactopyranose (GalNAc) residue at the hydroxyl group of threonine (Thr) or serine (Ser) is synthesized first for the process in solution, as well as for that in the solid state.[5] The amino acid preferentially contains the orthogonal protecting group pattern fluoren-9-ylmethoxycarbonyl (Fmoc)/*tert*-butyl (*t*-Bu)[6] or Fmoc/pentafluorophenyl (Pfp).[7] This building block containing a saccharide residue can be inserted into a peptide chain in any desired position in a normal solid-phase peptide synthesis.[8]

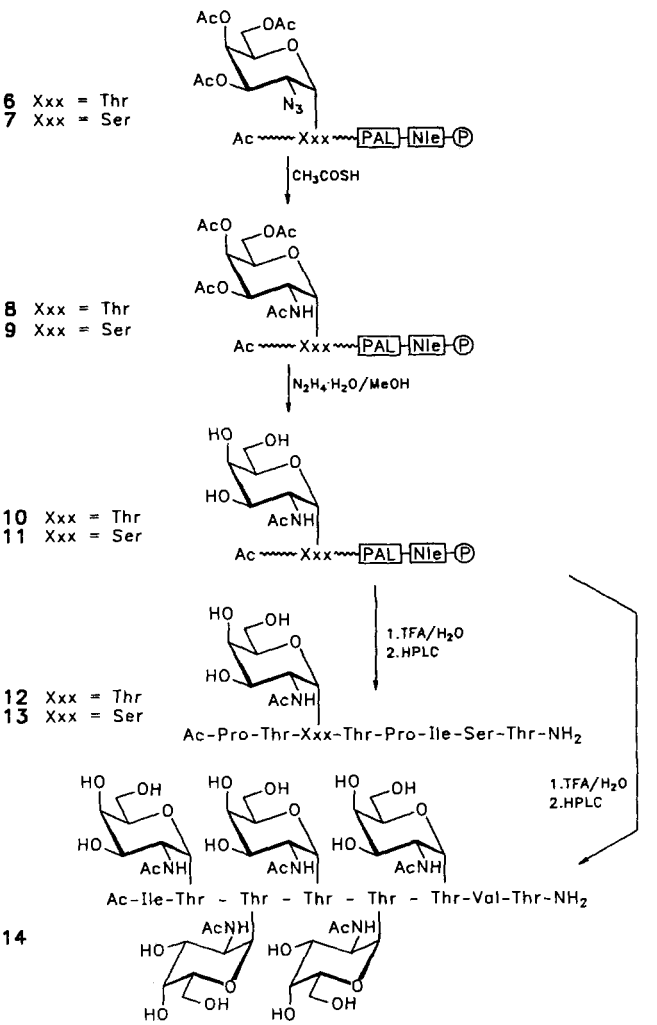
The recovery of the glycosidic amino acid, however, requires a number of steps. To establish the α-glycosidic bond of GalNAc to Thr or Ser, the only possible glycosyl donor is 2-azido-2-deoxy-D-galactose.[9] The transformation into the activated ester of the amino acid then follows after reduction and other steps. We have now developed a new strategy that shortens the synthesis of *O*-glycopeptides drastically. The glycoside synthesis with the 2-azido-2-deoxy-D-galactose donor is carried out directly with the activated ester of the amino acid. Thus a suitable building block containing 2-azido-2-deoxy-D-galactose is obtained in one step and can be utilized directly for peptide synthesis in the solid phase. Peptides carrying α-glycosidically linked 2-azido-2-deoxy-D-galactose residues at any desired site can be prepared by this route. The transformation of the azido groups into acetamido functions can take place after completion of the peptide chain on the solid support. The deacetylation of all sugar residues is also possible on the polymer-bound peptide. In the last step the final glycopeptide is cleaved off from the resin.

The new procedure is realized as follows. The amino acid derivatives **2** and **3** are glycosylated with halide **1**[10] in the presence of $Ag_2CO_3/AgClO_4$ to **4** and **5**.[11] The stereoselectivity $\alpha:\beta$ is 14:1 for Thr and 6:1 for Ser, which is higher than for other amino acid derivatives.[6] Although the acidic function of the glycosyl amino acids is strongly activated by the Pfp residue, the products can be purified by reversed phase (RP)-HPLC with acetonitrile/water (RP-18, 7 μm) without hydrolysis, even in gram quantities (yield: 78% for Thr, 70% for Ser). The glycosides **4** and **5** are characterized by ^{1}H NMR spectroscopy and FAB-MS.[12] They are stable as solids at −20 °C and therefore have good storage properties.



The activated esters **4** and **5** can be used in the solid-phase synthesis directly. Polydimethylacrylamide (P)[13] to which norleucine (Nle) has been attached as internal standard and 5-(4-aminomethyl-3,4-dimethoxyphenoxy)valeric acid as acid-labile peptide amide linker (PAL)[5d,e,14] is employed as resin. On this the stepwise construction of the peptide is performed. The Fmoc cleavage is always carried out with 50% morpholine in DMF (*N*,*N*-dimethylformamide).[15] All *non*-glycosylated amino acids are coupled as 3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl (Dhbt) esters.[16] When the glycosylated building blocks **4** or **5** are employed with the Pfp residue, 3,4-dihydro-3-hydroxy-4-oxo-1,2,3-benzotriazine (Dhbt-OH) is added to increase the rate of coupling, probably through the reacylation to the corresponding Dhbt activated esters. This addition has another advantage: it makes the progress of the coupling reaction visible through the yellow color[16,17] caused by ion pairing between Dhbt-OH and free amino groups of the resin. The reaction is complete when the yellow color disappears. The hydroxyl groups of the *non*-glycosylated Thr or Ser residues are protected as *tert*-butyl ether. In the last step of the glycopeptide synthesis, the *N*-terminus is acylated with acetanhydride (Ac_2O) in DMF (1:7), since *N*-acetyl glycopeptide amides are desired. The polymer-bound glycopeptides **6** and **7** were constructed by this method.

In one step on the resin, all azido groups present in **6** and **7** were reduced simultaneously with thioacetic acid and transformed into *N*-acetyl groups, as shown in Scheme 1. The crux of the transformation is the use of multiply distilled thioacetic acid of high purity (GC > 99%). There are then



Scheme 1. Glycopeptide solid phase synthesis of the compounds **12**, **13**, and **14**. ~~ = peptide chain; other abbreviations are explained in the text.

no side reactions, and the reaction is complete after 48 h. It was followed by IR spectroscopy by observing the complete disappearance of the azido absorption band at $\tilde{\nu} = 2117\ cm^{-1}$ (KBr windows). At the end the resin-bound **8** and **9** were treated with hydrazine hydrate in methanol (1:7) for about 6 h,[5d-f, 17, 18] which deacetylated all sugar residues to **10** and **11**. The cleavage of the synthesized glycopeptides was achieved in 2 h with 95% aqueous trifluoroacetic acid (TFA). The *N*-acetyl glycopeptide amides **12** and **13** were then purified by RP-HPLC and were identical with those prepared along other routes.[19]

Alternatively, the new procedure can be used in a multiple-column or a fully automatic peptide synthesizer.[17, 20] The multiple column process is preferable when several peptide sequences with few sugar residues are required. For example, besides others the glycopeptides **12** and **13** were synthesized[8, 19] and could be obtained pure in high yields of 77% and 72%.[21] In a fully automatic peptide synthesizer the complex structure of **14** with five vicinal sugar residues was synthesized. In this case the peptide synthesis was observed photometrically and could be controlled by the disappearance of the yellow color of the Dbht-OH salt.[17, 20] In the synthesis of the *penta*-glycosylated octapeptide, the reduction of the azido groups and the deacetylation of the carbohydrates also was achieved without difficulty, and **14** was isolated pure in yields of 40%.[21] The ^1H NMR, FAB-MS, and amino acid analysis data are in accord with the structure.[22] This example serves to illustrate the power of the new method. Peptides **12**, **13**, and also **14** are partial structures of the repeating unit of human intestinal mucin,[23] and should be tested for the specificity of the glycosyl transferases.

Deuterium-Induced Phase Transition of an Organic Metal—An Unusual Isotope Effect**

By *Siegfried Hünig,* Klaus Sinzger, Martina Jopp, Dagmar Bauer, Werner Bietsch, Jost Ulrich von Schütz,* and *Hans Christoph Wolf*

In this report the extreme sensitivity[1] of the metallic conductivity of 2-(Me_2-DCNQI)$_2$Cu (DCNQI = *N*,*N*′-dicyanoquinonediimine) to minor structural changes is demonstrated in a striking manner. Whereas the conductivity of the copper salt of non-deuterated 2,5-Me_2-DCNQI increases as the temperature is lowered (to 0.45 K) and reaches 500 000 $S\,cm^{-1}$ at 10 K, the partially or fully deuterated derivative switches from quasi three-dimensional behavior with $\sigma \approx 10^3\ S\,cm^{-1}$ at room temperature to quasi one-dimensional conduction below the transition temperature T_{M-I}. As a result, σ changes by about eight orders of magnitude within a few K.

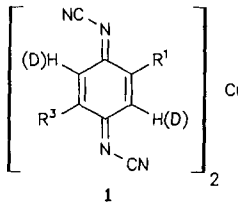
Systematic studies have shown that all of the copper–radical-anion salts **1** derived from 2,5-disubstituted DCNQIs with the combination of substituents $R^1 = R^3$ and $R^1 \neq R^3 = CH_3$, OCH_3, Cl, Br, I crystallize in the same space group, $I4_1/a$, and demonstrate metallic conductivity at least at room temperature.[2] Starting with about 200–1000 $S\,cm^{-1}$ (at room temperature) the conductivity increases steadily with cooling. If the substitution pattern of **1** is determined primarily by the small substituents Cl and Br, then a phase transition to a metal-like semiconductor (for definition see ref.[3]) takes place at $T_{M-I} = 160-230\,K$; the large substituents OCH_3 and I guarantee metallic conductivity down to the lowest temperatures.



1

	R^1	R^3	H/D	T_{M-I} [K]
1a	CH_3	CH_3	H	–
1b	CH_3	CD_3	H	58
1c	CD_3	CD_3	H	73
1d	CD_3	CD_3	D	82
1e	CH_3	Br	H	160
1f	Br	Br	H	160

For this class of materials it is already known that continuous cooling leads to increased compression of the *c* axis of the crystal lattice (for **1a** a total of 2%), while the *a* axis is lengthened minimally (for **1a** about 0.09%).[4, 5] The associated flattening of the nearly tetrahedral coordination of the ligands to copper (enlargement of the coordination angle α; cf. Fig. 1) splits the t_{2g} set of copper 3d orbitals, which are degenerate for ideal tetrahedral coordination, as a result of the reduction in symmetry from T_d towards D_{2d}.[6] When the coordination angle α exceeds a critical threshold (127–128°),[6] the crystal undergoes a phase transition recognizable by an additional discontinuous compression of the *c* axis.[4, 5]

Recently a sevenfold super-diamond structure was revealed for the DCNQI–copper salts.[7a] Closer examination of a super-adamantane unit in the direction of stacking (Fig. 2) shows that the DCNQI stacks associated with four neighboring stacks of copper atoms form a super helix of seven intertwined single helices,[7b] whose spacing in the direction of stacking has the value of the cell constant *c*.

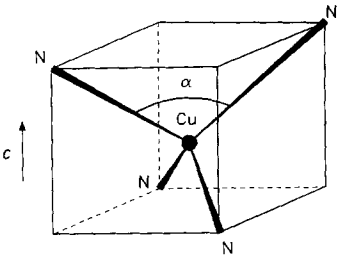


Fig. 1. Coordination geometry of the Cu central atom of the salts (2,5-R^1,R^3-DCNQI)$_2$Cu. N represents the cyano N atoms of the ligands.

The channel formed by the helices is filled by the DCNQI substituents R^1 and R^3; their size thus determines the distance between the individual helices. For the previously described structural type, a direct relationship between the cell constants *a* and *c* and the crucial coordination angle α can be deduced.[8] Combinations of smaller substituents (R^1 = Cl, Br; R^3 = Cl, Me, Br) allow a phase transition; combinations of large substituents (R^1 = I, MeO; R^3 = Cl, Me, Br, I, MeO) prevent one. Thus there is a three-dimensional cooperative interaction of the partners, whose effect on the conductivity is produced by a collective of an "infinite" number of "layers" (DCNQIs).[9]

A thorough analysis of these relationships[8, 10] showed that **1a** occupies a special position. Although the van der Waals volume of the CH_3 group (21.7 $Å^3$) is substantially less than that of Br (25.1 $Å^3$),[11] **1a** (CH_3/CH_3) does not undergo a phase transition until the lowest temperatures, in constrast to **1e** (CH_3/Br) and **1f** (Br/Br). On the contrary, its conductivity increases markedly until 0.45 K[12] and reaches 500000 $S\,cm^{-1}$ at 10 K[13] (cf. Fig. 3). This unexpected stability of **1a** is attributed to the low LUMO energy ($\varepsilon_{LUMO} = -2.42$ eV) and the enhanced donor strength of the n electron pair of the CN group ($\varepsilon_{\sigma n} = -14.51$ eV) relative to **1e** ($\varepsilon_{LUMO} = -2.64$ eV, $\varepsilon_{\sigma n} = -14.64$ eV) and **1f** ($\varepsilon_{LUMO} = -2.85$ eV, $\varepsilon_{\sigma n} = -14.77$ eV.[10]

If all of these explanations are correct, then substituents with electronic properties similar to those of methyl groups but with a smaller volume may possibly trigger a phase transition upon cooling. Both the electronic and the spacial prerequisites are met by CD_3 groups, whose volume at 70 K is about 1.0–1.5% less than that of CH_3 groups.

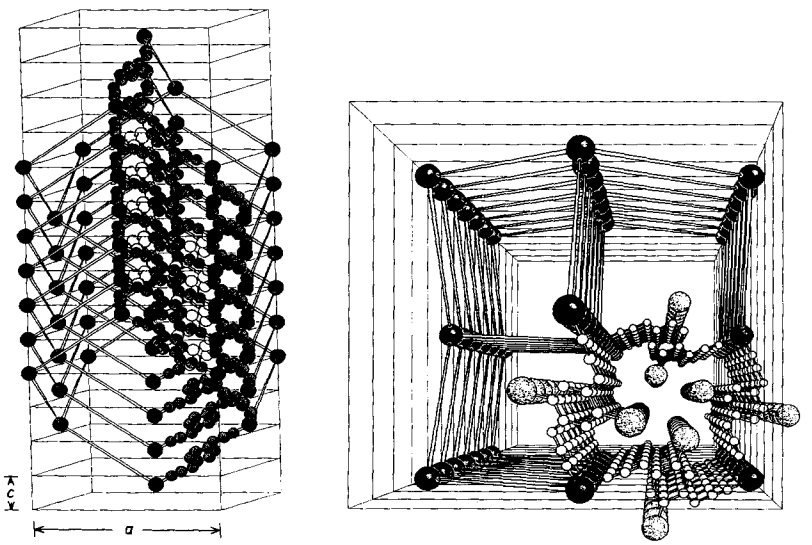

Fig. 2. Sevenfold adamantane super-structures in the crystal lattice of (2,5-R^1,R^3-DCNQI)$_2$Cu (space group $I4_{1/a}$). Cu ions take the place of adamantane C atoms and are connected to each other through the ligands. In both figures three-fourths of the ligands between the copper ions are represented by lines. (SCHAKAL 88B/V16). Left: Side view perpendicular to the direction of stacking. The substituents R^1 and R^3 are not shown. Right: Perspective view in the direction of stacking. The substituents R^1 and R^3 fill the channels.

As a result of the lower zero-point energy, the mean as well as the maximum C–D bond length is less than the comparable values for a C–H bond in the *gas phase*, 0.15% and 0.37%, respectively.[14] Correspondingly, the molar volume of *liquid* CD_4 relative to CH_4 at 100 K is about 1% less;[15] the volume of the unit cell in the *crystalline* state at 70 K is approximately 1.5% less.[16] As the following literature examples show deuteration of the methyl groups in **1a** should result in only minimal *quantitative* changes. H/D exchange in *crystalline* organic charge-transfer (CT) complexes shifts the transition temperature of the structural phase transition from +0.75 K[17] to −15 K.[18] For deuterated superconductors of the BEDT–TTF type an increase in the critical temperatures by 0.28 K to 0.6 K[19] is observed; however, for deuterated $(TMTSF)_2ClO_4$ a decrease of 0.13 K[20] is noted.

In contrast, we report here a dramatic *qualitative* effect, that is, a phase transition from metallic to semiconducting behavior induced by deuteration. Such a phenomenon due to a secondary deuterium isotope effect has not been reported so far.

As is evident from Figure 3, the introduction of deuterium to just one CH_3 group in **1a** ($CH_3/CH_3/H_2$) giving **1b** ($CH_3/CD_3/H_2$) induces a phase transition at 58 K. The two CD_3 groups in **1c** ($CD_3/CD_3/H_2$) trigger this conversion already at 73 K. Even the substitution of the two hydrogen atoms on the ring in **1c** by deuterium to **1d** ($CD_3/CD_3/D_2$) shifts the phase-transition temperature by another 9 K to 82 K.[21] The resulting phase transitions are unusually sharp: The conductivity drops off by a factor of 10^6–10^8 (!) within 1–2 K.[22]

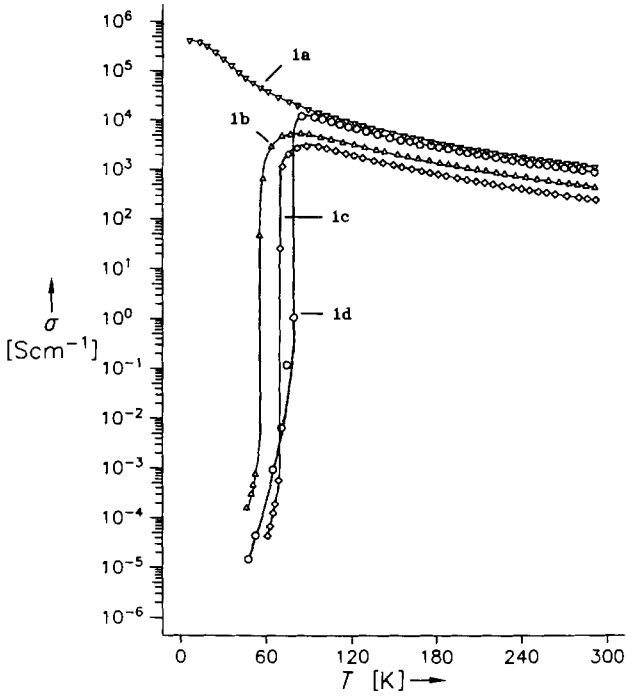

Fig. 3. Temperature dependence of the conductivity σ of **1a** ($CH_3/CH_3/H_2$), **1b** ($CH_3/CD_3/H_2$), **1c** ($CD_3/CD_3/H_2$), and **1d** ($CD_3/CD_3/D_2$) (four-point measurements on single crystals[23].)

The phase transition of the deuterated Cu salts can also be proved by electron spin resonance spectroscopy: Below the phase-transition temperature a relatively narrow ESR signal ($\Delta B_{pp} \approx 2 \cdot 10^{-3}$ T) is observed, whose intensity increases drastically with decreasing temperature. The behaviour of other DCNQI–Cu salts is quite different. Whereas the line width of the ESR signal observed for non-deuterated systems increases upon warming from low temperature to T_{M-I} (increase of the three-dimensional movement of the electrons), the line width for the deuterated copper salts is practically constant below T_{M-I}; this supports the assumption of a transition from three-dimensional to an extremely one-dimensional behavior.[24] Despite its high static susceptibility,[*] this signal is not detectable in the metallic region. Because of the three-dimensional movement of the electrons, the spin-orbit coupling leads to extreme line widths.[25]

Apparently **1a** is protected only minimally from a phase conversion by the electronic properties mentioned. Thus slight changes cause the phase transition in the dimensionality of the movement of the electrons. Besides the deuteration described here, the same effect is induced by applying pressure to **1a**.[12, 26] Even 110 bar produces a sharp phase transition at 47 K (or 400 bar at 76 K). The conductivity drops sharply by at least a factor of 10^4, analogous to the observations for the deuterated systems (Fig. 4).[12]

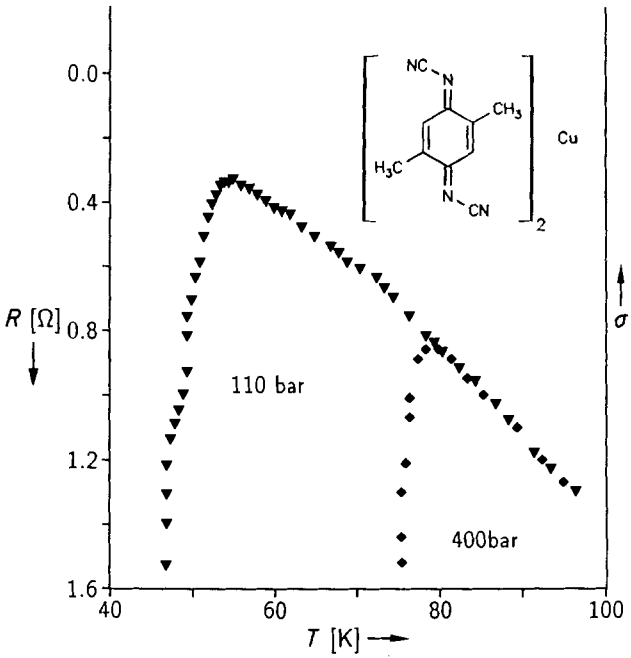

Fig. 4. Pressure dependence of the conductivity of **1a**[12].

Besides the somewhat smaller volume of the CD_3 group, its different rotational barrier could be significant. Studies of crystals of several deuterated compounds (CD_3CO_2Li,[27] CD_3NO_3,[28] and $CD_3C_6D_5$[28, 29]) by inelastic neutron scattering show a marked decrease in the tunnel splitting and thus an increase in the rotation barriers relative to those of the corresponding protonated systems. As a consequence, the motion of the deuterated methyl groups is frozen even at higher temperatures. One argument against this interpretation of our results is that for the reported activation energies at 500–800 K[30] due to intra- and intermolecular hindrance,[31] the motion of the methyl groups of the non-deuterated copper salt **1a** would be too slow at the finite

[*] Note added in proof: At exactly T_{M-I} the static susceptibility exhibits a step in intensity by 1.5×10^{-6} emu g^{-1} to increase considerably with lower temperatures. At 7 K a pronounced peak occurs due to magnetic ordering.

temperature to prevent a phase transition. Further experiments should clarify the situation.

[21] The syntheses will be reported elsewhere. All new compounds provided the expected spectroscopic and analytical data. The extent of deuteration was determined by ^{1}H NMR spectroscopy (250 MHz) and confirmed by mass spectrometry. **1b** (D_3: > 99.5%); **1c** (D_6: > 99.5%); **1d** (D_6: > 99.5%; D_2: 97.3%).
[22] A careful analysis of the IR data of **1d** (C. Pecile, personal communication) conducted parallel to the measurements described here also demonstrated the phase transition. We thank Prof. Pecile for the results and for providing us with 100 mg of **1d** for comparison.
[23] All four-point measurements with $T\downarrow$ and $T\uparrow$ were repeated a number of times on various samples.

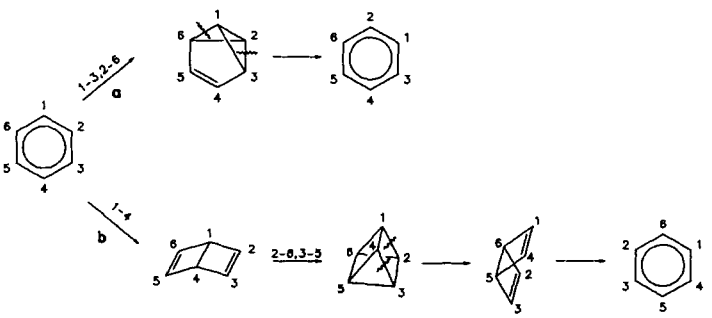
Doubly Bridged Prismane and Dewar Benzene Intermediates in an Unusual Photochemical Rearrangement of Tricyclic Phthalic Esters**

By *Rolf Gleiter** and *Björn Treptow*

Dedicated to Professor Günther Maier on the occasion of his 60th birthday

Irradiation of alkylbenzenes in solution at wavelengths higher than 250 nm usually yields a positional isomerization of the alkyl groups.[1] To rationalize this phenomenon, it is assumed that valence bond isomers of benzene, such as benzvalene, Dewar benzene, and prismane are short-lived intermediates. The involvement of such isomers has been inferred from isotopic labeling experiments.[1] Possible ring transposition processes that give rise to apparent 1,2 and 1,3 shifts are shown schematically in Scheme 1.



Scheme 1. Proposed rearrangements that proceed via valence isomers of benzene as intermediates.

Two motives prompted us to study the mechanism of the light-induced ring transposition in benzene: 1) We thought that the tethering of neighboring centers in a benzene derivative might stabilize one of the intermediates, and 2) we hoped by this "rope trick" to generate those doubly bridged Dewar benzenes and/or prismanes which were not available to date.[2]

We started our investigations with the doubly bridged Dewar benzene derivatives **1**, which could be obtained easily from cyclic alkynes and dimethyl acetylenedicarboxylates.[2, 3] Ir-

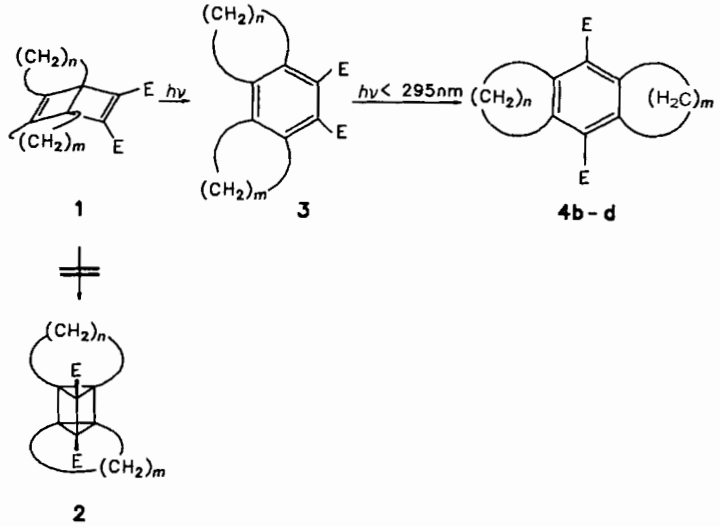
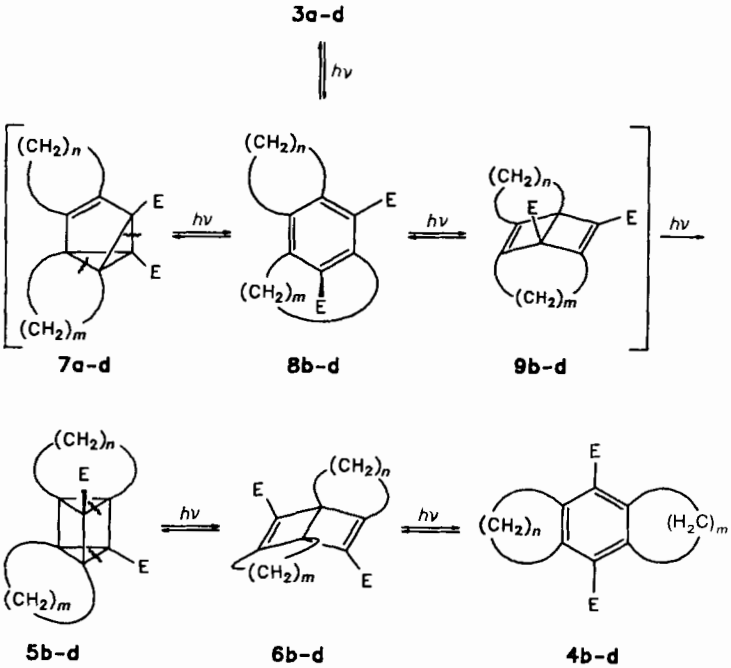
radiation of **1** at wavelengths above 295 nm yielded exclusively the isomeric phthalic ester derivatives **3** (Scheme 2). No trace of the prismanes **2** could be detected, nor was there any hint of a photochemical equilibrium between **1** and **3**. Excitation by the unfiltered light from a high-pressure Hg lamp afforded the isomeric terephthalic esters **4b–4d**. In the case of **3a** no rearranged product was obtained.



Scheme 2. Rearrangements of **1** on irradiation with light with $\lambda > 295$ nm. **a**: $n,m = 4$; **b**: $n,m = 5$; **c**: $n,m = 6$; **d**: $n = 4$, $m = 5$; E = COOMe.

These unexpected results were an impetus for closer investigation. At first we confined our further studies to **3b** because it was the most readily accessible[2] and gave the highest yields of **4b**. A change of the wavelength to 282 nm afforded two other compounds, prismane **5b** and Dewar benzene **6b**. They were unequivocally identified by their ^{1}H NMR, ^{13}C NMR, and UV spectra (see Table 1). They proved to be direct precursors to **4b**, as irradiation converted them rapidly and quantitatively into **4b**.



Scheme 3. Sequence of reactions for the rearrangements of **3b–d** to **4b–d**.

Table 1. Selected spectral data of **1a, d, 3a, d, 4b, c, d, 5b**, and **6b, c**.

1a: ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.79$ (s, 6H), 2.4–1.0 (m, 16H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 163.8, 150.3, 139.1, 57.6, 52.4, 27.0, 25.2, 24.5, 23.3$; UV/VIS (acetonitrile): λ_{max}[nm] (lgε) = 188 (4.23), 235 sh (3.67); correct C,H,O analysis.

1d: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.78$ (s, 3H), 3.77 (s, 3H), 2.35–2.25 (m, 2H), 2.2–1.1 (m, 16H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 163.3, 163.25, 150.4, 149.3, 143.5, 141.4, 62.7, 54.5, 51.6, 51.55, 31.1, 28.8, 28.1, 27.7, 27.65, 26.5, 24.4, 24.2, 22.9$; high-resolution MS: m/z ($M^{\oplus} - CH_3OH$) calcd: 284.1413, found: 284.1386

3a: colorless crystals, m.p. 148–150 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.83$ (s, 6H), 2.78 (t, ^3J(H,H) = 6.0 Hz, 4H), 2.57 (t, ^3J(H,H) = 6.1 Hz, 4H), 1.9–1.6 (m, 8H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 169.9, 139.3, 133.1, 130.1, 52.8, 28.4, 27.7, 23.3, 23.0$; UV/VIS (acetonitrile): λ_{max}[nm] (lgε) = 213 (4.4), 245 sh (3.45), 287 (2.85); correct C,H,O analysis.

3d: colorless crystals, m.p. 86 °C; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.83$ (s, 6H), 2.85–2.7 (m, 8H), 1.9–1.5 (m, 10H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 169.8, 169.3, 145.3, 138.4, 136.7, 133.3, 129.4, 129.2, 52.2, 52.1, 31.5, 31.3, 28.6, 27.9, 27,9, 27.2, 26.2, 23.0$; UV/VIS (acetonitrile): λ_{max}[nm] (lgε) = 216 (4.59), 252 sh (3.79), 288 (3.31); correct C,H,O analysis.

4b: colorless needles, m.p. 149 °C; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.87$ (s, 6H), 2.7–2.55 (m, 8H), 1.9–1.7 (m, 4H), 1.7–1.5 (m, 8H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 171.1, 137.2, 134.4, 51.9, 32.3, 31.8, 27.2$; UV/VIS (acetonitrile): λ_{max}[nm] (lgε) = 208 (4.27), 230 sh (3.70), 282 (3.06); high-resolution MS: m/z ($M^{\oplus}$) calcd: 330.1831, found: 330.1826; correct C,H,O analysis.

4c: colorless needles, m.p. 169 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.88$ (s, 6H), 2.7–2.6 (m, 8H), 1.8–1.6 (m, 8H), 1.45–1.25 (m, 8H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 171.1, 135.5, 135.3, 51.8, 31.0, 29.2, 26.1$; UV/VIS ($CH_2Cl_2$): λ_{max}[nm] (lgε) = 206 (4.62), 230 sh (3.91), 280 (3.19); high-resolution MS: m/z ($M^{\oplus}$) calcd: 358.2144, found: 358.2150.

4d: colorless crystals, m.p. = 118–119 °C; ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 3.88$ (s, 6H), 2.7–2.55 (m, 8H), 1.85–1.5 (m, 10H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 170.8, 137.2, 134.8, 131.0, 52.0, 32.2, 31.8, 27.4, 26.7, 22.4$; UV/VIS (acetonitrile): λ_{max}[nm] (lgε) = 206 (4.59), 228 sh (3.94), 282 (3.29); correct C,H,O analysis.

5b: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.68$ (s, 6H), 2.5–2.35 (m, 2H), 2.25–2.1 (m, 2H), 2.0–1.1 (m, 16H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 170.5, 56.0, 54.5, 50.8, 48.4, 32.3, 28.6, 27.9, 24.5, 24.2$; UV/VIS (*n*-pentane): λ_{max}[nm] (lgε) = 203 (3.85), 270 sh (2.85); high-resolution MS: m/z ($M^{\oplus}$) calcd: 330.1831, found: 330.1827.

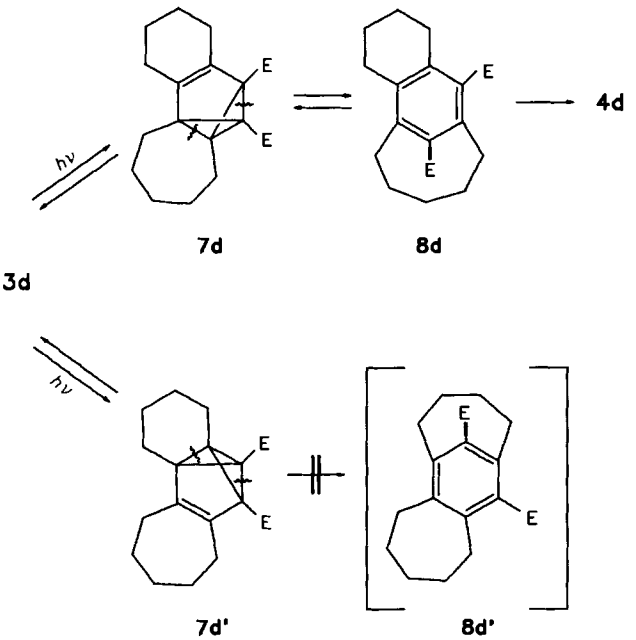
6b: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.71$ (s, 6H), 2.9–2.7 (m, 2H), 2.5–2.35 (m, 2H), 2.1–1.4 (m, 16H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 173.9, 164.2, 134.6, 59.3, 50.8, 31.2, 30.9, 27.9, 27.3, 27.2$; UV/VIS (*n*-pentane): λ_{max}[nm] (lgε) = 218 (4.17), 270 sh (3.47); high-resolution MS: m/z ($M^{\oplus}$) calcd: 330.1831, found: 330.1819

6c: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 3.71$ (s, 6H), 3.0–2.8 (m, 2H), 2.4–2.15 (m, 4H), 2.15–1.3 (m, 18H); ^{13}C NMR (75.47 MHz, $CDCl_3$): $\delta = 174.2, 164.1, 136.8, 60.3, 50.7, 30.4, 27.3, 26.6, 25.9, 24.6, 24.2$; high-resolution MS: m/z ($M^{\oplus}$) calcd: 358.2144, found: 358.2169

For the mechanism of the complete photochemical rearrangement we assume that the benzvalene derivative **7b**, [5]metacyclophane **8b**, and Dewar benzene **9b** serve as additional intermediates. We account for the almost complete conversion of **3b** into **4b** through this complex series of rearrangements as follows: As a result of the short 1,3 bridge, **8b** is extremely bent thus generating considerable strain,[4] which under the given conditions can be relieved either by the back reaction or in several steps via the prismane **5b** to **4b**. The back reaction is usually invoked to explain the transformation of [5]metacyclophanes to 1,2-bridged arenes, although benzvalene intermediates have not yet been observed directly.[5] In our particular case, **8b** can also follow the photochemically allowed sequence in Scheme 3 to yield the relaxed terephthalic ester derivative **4b**. It is noteworthy that the geometry of both Dewar benzene **9b** and prismane **5b** is already inherent in the assumed unsymmetric boat conformation[6] of **8b**. The driving force in this series is the irreversibility of prismane formation (**9b** → **5b**). The interaction of the carbomethoxy groups with the cyclopropane portion of the prismane in **5b** stabilizes the distal bonds,[7] thus allowing fragmentation only to **6b**,

which in turn isomerizes immediately to **4b**. This was corroborated by the fact that irradiation of **5b** did not give rise to any of its precursors but afforded exclusively **4b**. A similar argument can be considered for the decomposition of **7b**. The C–C bond linking the carbomethoxy groups in the bicyclobutane moiety is destabilized for the same reason as above (in this case the interaction is with two vicinal groups), so cleavage of this bond leading to [5]metacyclophane **8b** is kinetically favored over the back reaction, which affords the thermodynamically more stable **3b**.

The postulated intermediates **7b**, **8b**, and **9b** have not yet been detected. We attribute this both to their low equilibrium concentrations and their increased reactivity. As already mentioned, **3a** did not undergo this rearrangement. Even with extended irradiation times and shorter wavelengths (254 nm) only a slow polymerization was observed, probably because the potential [4]metacyclophane **9a** does not exist under the given conditions. All efforts to isolate a [4]metacyclophane derivative have failed so far because of its enormous strain energy.[8, 9] In our case we assume that the path leading to **4a** is interrupted at the second step (**7a** → **8a**). Further evidence for benzvalene **7d** and [6]metacyclophane **8c** was obtained from the fact that **3c** and **3d** did afford their respective terephthalic ester isomers **4c** and **4d**. However, under identical conditions as those used for **4b**,[10] the yields of both **4c** (30% after 12 h) and **4d** (24% after 12 h) were considerably smaller. Because the equilibrium concentration was lower, **5c** could only be identified in the reaction mixture by the typical δ value for the protons of the methoxy groups in the ^{1}H NMR spectrum. In the case of **4d**, none of the intermediates could be fully characterized for the same reason. The reduced rate in both cases can be explained



Scheme 4.

by the postulated intermediates. Firstly, [6]metacyclophane **8c** is distinctly more stable[11] than the lower homologue **8b**, and the strain releasing steps (**8c** → **5c** → **4c**) are thus less forceful. Secondly, it is noteworthy that the conversion of **3d** to **4d** occurred at about half the rate of that of **3b** to **4b** (52% after 12 h). A plausible explanation is given in Scheme 4.

Whereas in the case of **3b** two identical benzvalene intermediates afford **8b**, only the path via **7d** is possible for **3d**, since the path via **7d'** would lead to a highly strained [4]metacyclophane **8d'**. A steric factor (tethering of neighboring centers) is necessary, because irradiation of unsubstituted phthalic ester does not yield terephthalic ester. In conclusion, a tuned interplay of steric and electronic effects is responsible for the creation of doubly bridged prismanes with C_2 symmetry from tricyclic phthalic ester derivatives. Experiments in which the ester groups are substituted by different functions are currently in progress to substantiate the electronic argument.

Template-Controlled Organization of a Fluoride Surface—An Analogue of a Crown Ether in the Reaction of $[\{(\eta^5\text{-}C_5Me_5)TiF_3\}_2]$ with Sodium Fluoride**

By *Herbert W. Roesky,* Mansoreh Sotoodeh,* and *Mathias Noltemeyer*

Dedicated to Professor Klaus Weissermel on the occasion of his 70th birthday

So far in studies concerning molecular recognition, host molecules were applied whose receptor surface comprises almost exclusively oxygen, sulfur, nitrogen, and/or phospho-

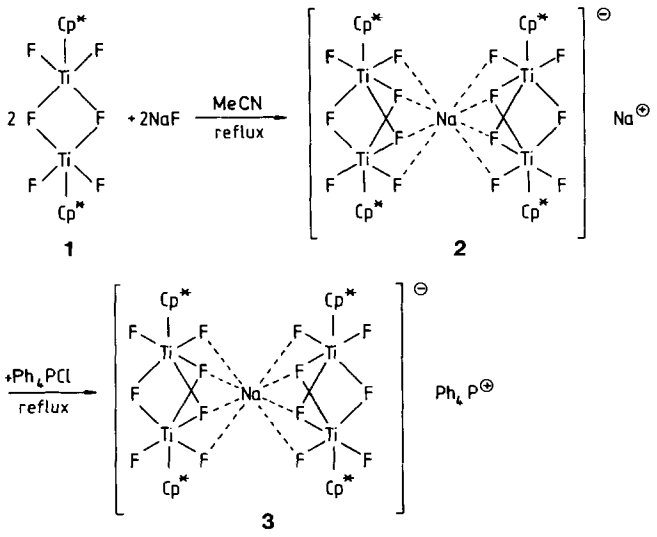
rus atoms.[1-3] For this, the receptor structures were predetermined and could be open, half-open, or closed. We report here a new class of nucleophilic host systems with a "fluoride surface", which forms in a template-controlled manner.

The reaction of $[Cp^*TiCl_3]$ ($Cp^* = \eta^5$-C_5Me_5)[4] with AsF_3 leads to the dimer $[(Cp^*TiF_3)_2]$[5] **1** by chlorine–fluorine exchange. Compound **1** reacts with NaF in MeCN to give **2**.



A third fluoride bridge is formed between the titanium atoms by the incorporation of a fluoride ion in **1**. In the salt **2**, one of the two sodium ions is complexed by two $[(Cp^*TiF_3)_2F]^-$ fragments in such a way that a fluoride surface forms at this sodium ion. By this complexation the two sodium ions become distinguishable. With tetraphenylphosphonium chloride only one sodium ion can be exchanged, and thus $Ph_4P[\{(Cp^*TiF_3)_4F_2\}Na]$ (**3**) is obtained. The nature of the wrapping of the Na^+ ion by two $[(Cp^*TiF_3)_4F_2]^-$ fragments is similar to that in $[Na([12]crown\text{-}4)_2]^+$.[6]

In order to find out whether the starting compound can differentiate between different cations, the corresponding reactions were carried out. We observed that LiF did not react, CsF led to insoluble polymeric products, and KF[7] behaved like NaF.

Indications of the stoichiometric composition of **3** were obtained from the elemental analysis and the ^{1}H NMR spectrum. Whereas the FD mass spectrum only shows the $[Ph_4P]^+$ fragment [*m/z* 339 with 100% intensity],[8] in the ^{1}H NMR spectrum the Ph and the Cp* protons are observed in the integration ratio 1:3.

The details of the structure of compound **3** were obtained from a single-crystal X-ray structure analysis (Fig. 1).[9] The Ti atoms are coordinated in a distorted octahedral fashion. The Na atom is surrounded by eight F atoms, and the Na–F distances [237.8(4) to 253.1(5) pm] lie within the values for ionic compounds[10] (ionic radii: Na^+ 116 pm for coordination number (CN) 8; F^- 128 pm for CN 2, 131 pm for CN 4). The Ti1–Ti2 distance [308.4(2) pm] within the dimeric fragment is ca. 20 pm shorter than the Ti–Ti distance in **1** [329.9(3) pm]. The deviations from the average plane of the four F atoms are ±48 and ±49 pm (the angle between the planes is 7.3°).

The selective cationic exchange in the reactions **1** → **3** allows the conclusion that corresponding reactions occur more frequently in organometallic or even inorganic fluorides.

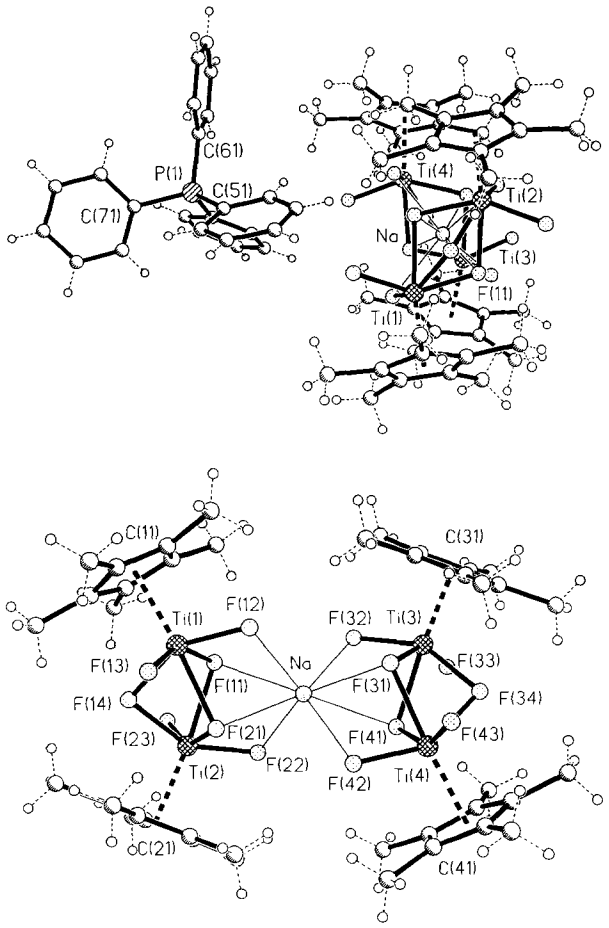


Fig. 1. Crystal structure of **3**. Above: total molecule, below: structure of anion. Selected distances [pm] and angles [°]: Ti(1)-F(12) 186.3(3), Ti(1)-F(21) 221.0(3), Ti(1)-F(11) 199.7(4), Ti(1)-F(13) 183.6(4), Ti(1)-F(14) 202.0(4), Ti(2)-F(11) 221.3(3), Ti(2)-F(22) 186.5(4) Ti(2)-F(23) 184.0(4), Ti(2)-F(14) 202.0(4), Ti(2)-F(21) 199.3(3), Ti(1)-Ti(2) 308.4(2); Ti(1)-F(11)-Ti(2) 94.1(1), Ti(1)-F(14)-Ti(2) 99.4(1), Ti(1)-F(21)-Ti(2) 94.3(1), F(11)-Ti(1)-F(14) 74.1(1), F(11)-Ti(2)-F(14) 69.6(1).

Experimental Procedure

1 (0.5 g, 2.1 mmol) and NaF (0.1 g, 2.1 mmol) were heated to reflux in MeCN (30 mL). After 3 h an orange suspension was formed. For the completion of the reaction it was stirred for a further 3 h at the same temperature. The mixture was allowed to cool and then solid Ph_4PCl (0.2 g,0.6 mmol) was added. The resultant suspension was refluxed and after 30 min the orange solid dissolved. The reflux was continued for a further 3 h, and the reaction mixture was then allowed to cool. The precipitated NaCl was then removed by filtration.

After concentration of the solution to 10 mL and cooling to −5 °C **3** was obtained as orange crystals. Yield 0.4 g, m.p. 230 °C. ^{1}H NMR($CDCl_3$): δ = 1.96 (s), 7.4–8.0 (m); ^{19}F NMR($CDCl_3$): δ = 100 (s), 1 D–MS(70 eV): *m/z* 339 (Ph_4P, 100%); correct elemental analysis (C, H, P, Na).

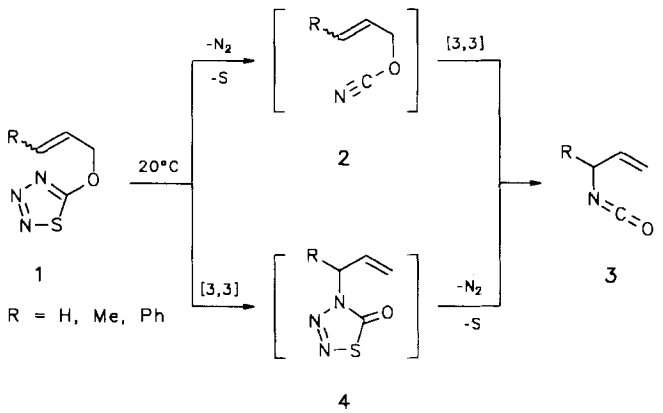
Synthesis of Isocyanate-Substituted Allenes and 1,3-Butadienes by [3,3] Sigmatropic Rearrangements**

By *Klaus Banert** and *Stefan Groth*

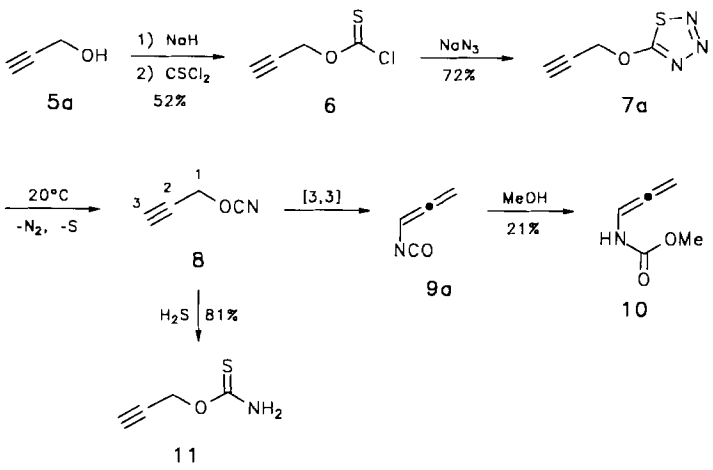
In honor of the 100th birthday of Walter Reppe

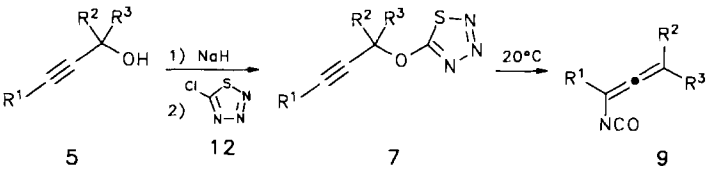
Allyl cyanates of type **2** are considered possible intermediates in the thermal decomposition of thiatriazoles **1** to isocyanates **3**.[1] However, since intermediates **2** have not yet been proved, a reaction path via heterocycles **4** cannot be discounted.[2]



We report here the first direct, spectroscopic observation of a [3,3] sigmatropic cyanate → isocyanate rearrangement; the reactions provide the novel allenyl isocyanates **9** (Scheme 1), the isocyanate-substituted 1,3-butadienes **23** and **27**, as well as the previously unknown thiatriazolones **13** and **15**.

The carbonic acid derivative **6**, readily available from propargyl alcohol **5a**, was treated with sodium azide furnishing heterocycle **7a**. This compound can be isolated and sublimed (**safety shield!**), but it decomposes in solution even at room temperature almost quantitatively to allenylisocyanate **9a**. The decomposition of **7a** in the presence of H_2S led to





Scheme 1. **a**, $R^1 = R^2 = R^3 = H$; **b**, $R^1 = R^2 = H$, $R^3 = Me$ (yield **7b** 61%, **9b** 56%); **c**, $R^1 = R^2 = H$, $R^3 = n\text{-}C_5H_{11}$ (**7c** 69%, **9c** 67%); **d**, $R^1 = H$, $R^2 = R^3 = Me$ (**7d** 34%, **9d** 47%); **e**, $R^1 = Me$, $R^2 = R^3 = H$ (**7e** 67%, **9e** 38%).

the trapping product **11**. When the conversion **7a** → **9a** was followed by NMR spectroscopy, signals of the intermediate **8** were observed (Table 1). The maximum proportion of the short-lived, quasi-stationary intermediate **8** in the reaction mixture was only 5%.

Thiatriazoles **7** can be prepared in a new one-step procedure from the propargyl alcohols **5b–e** by treatment with sodium hydride followed by chlorothiatriazole **12**.[3] The allenyl isocyanates resulting from the decomposition of **7** are not all equally stable: **9a** can only be handled in solution, whereas **9c** can be isolated and distilled under vacuum. Compounds **9** undergo reactions typical of isocyanates such as the nucleophilic addition **9a** → **10**.[4] Thus the allenyl isocyanates are distinguished from the allenyl isothiocyanates prepared only recently,[5] which react with nucleophiles to form heterocyclic products.

The decomposition of **7d** gives not only the main product **9d**, but from a parallel reaction also thiatriazolone **13**, which is less volatile than **9d** and thus easy to separate. Because compound **13** is stable at room temperature it cannot be a precursor for **9d**. Another novel thiatriazolone, **15**, can be synthesized in one step from allyl alcohol **14** by successive treatment with sodium hydride and **12**. The structural assignment was also supported by ^{15}N NMR spectroscopy (Table 1). Product **15** is a distillable liquid, which upon prolonged heating at 100 °C can be decomposed into carbonyl sulfide and an equilibrium mixture of the azides[6] **16** and **17**, as well as nitrogen, sulfur, and isocyanate **18**.[7] The high thermal stability of **15** makes the reaction path **1** → **4** → **3** seem unlikely, and together with the direct proof of **8** lends support to the sequence **1** → **2** → **3**.

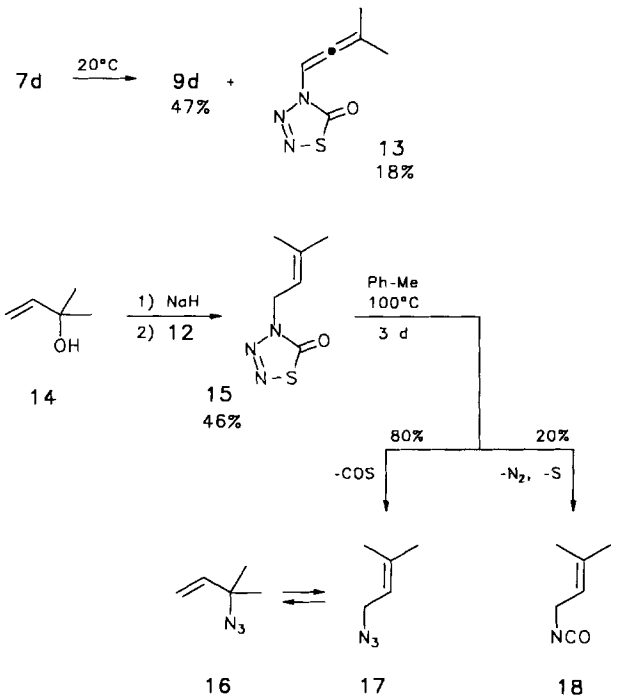
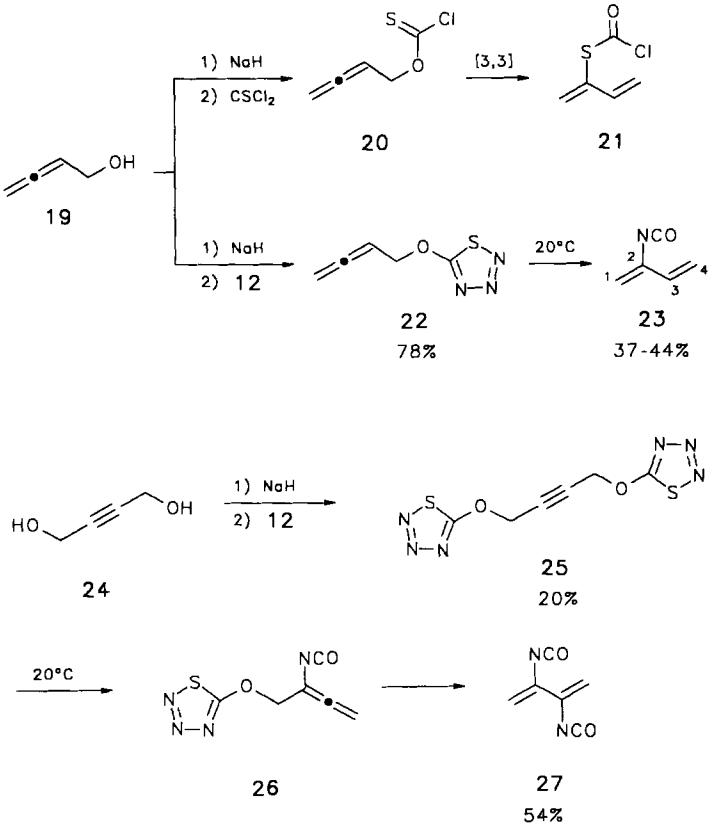
[a] NMR spectra in $CDCl_3$ (unless specified otherwise); ^{1}H NMR at 80, 200, and 400 MHz; ^{13}C NMR at 100.6 and 50.3 MHz; ^{15}N NMR at 40.5 MHz, CH_3NO_2 as external standard; GC-MS at 70 eV.





Not only propargyl precursors but also 2,3-butadienyl compounds are suited for rearrangements directing an isocyante function to a vinylic position. Alcohol **19**[8] was allowed to react with sodium hydride and **12** providing thiatriazole **22** which decomposes to **23**. This one-step synthesis of **22** is not only more convenient, it succeeds where the two-step alternative fails. The carbonic acid derivative **20** is not an appropriate precursor for **22** as it isomerizes to **21** during its preparation from **19**. The thiatriazole **25** obtained from **24** decomposes with loss of nitrogen and sulfur to **27** by a double [3,3] sigmatropic rearrangement. This reaction can be followed by NMR spectroscopy giving evidence of intermediate **26**. In contrast to compound **23**, a distillable liquid, **27** can be handled at room temperature only in solution.

These isocyanate-substituted allenes and 1,3-butadienes may find use as synthetic building blocks as well as applications in macromolecular chemistry.

Experimental Procedure

Thiatriazoles **7b–e**, **22**: A solution of the appropriate alcohol (20 mmol) in Et_2O (20 mL) was added dropwise to a suspension of sodium hydride (0.53 g, 22 mmol) in water-free Et_2O (20 mL) at 0 °C. The mixture was stirred at room temperature for 16 h (3 d for **5d** → **7d**), and was then added dropwise under argon to a solution of **12**[3] (2.92 g, 24 mmol) in Et_2O (50 mL) cooled to −5 to −10 °C. The resulting mixture was stirred at −10 °C for 3 h. All subsequent operations were carried out at temperatures ≤0 °C. The reaction mixture was poured into ice water (100 mL). The organic phase was washed thoroughly with ice water and dried over $MgSO_4$. Et_2O, unreacted alcohol, and excess **12** were removed at 10 Torr and then at 0.001 Torr.

Isocyanates **9b–e**, **23**: Solutions of the appropriate thiatriazole in water-free Et_2O, benzene, chloroform, acetonitrile, or CCl_4 were stirred at room temperature for 5–16 h (3–6 d for **7d** → **9d**) and then recondensed at 0.001 Torr. Depending on the volatility and stability of the product, the solution was concentrated under vacuum or the isocyanate was distilled.

15: Compound **14** was treated with sodium hydride and **12** according to the procedure previously described . After the solution of the product was dried over $MgSO_4$, all the volatile compounds were removed at 10 Torr/20 °C.

Material Properties and Purity of C_{60}**

By *Harald Werner, Daniela Bublak, Ulrich Göbel, Bettina Henschke, Wolfgang Bensch,* and *Robert Schlögl**

Since the production of larger amounts of fullerenes has become possible by means of an electric arc,[1, 2] interest in this new allotropic form of carbon has grown by leaps and bounds.[3] The availability of C_{60} with reproducible quality and the knowledge of the material properties of C_{60} in the solid state are important for reliable research results as well as potential technical applications. C_{60} forms van der Waals crystals with a face-centered cubic structure.[5, 6] Foreign atoms can be deposited in the interstices giving the crystal superconducting properties, for example.[7] Fullerenes can be considered molecular analogues of the microporous carbon materials, which because of their large inner surfaces are used as adsorbents.[8] For the application, storage, and production of fullerenes it is crucial to know if this allotropic form of carbon is also able to absorb substances from the environment and thus change the properties of the crystals.

An indication of such effects is, for example, the fact that we and others have found the experimentally determined densities of the crystals to be too great (1.72–1.78 $g cm^{-3}$).[4, 6, 9] (The density obtained from the X-ray crystal structure analysis of C_{60} is only 1.68 $g cm^{-3}$.) The reports of paramagnetic behavior,[10] paramagnetic impurities,[11] and an "excess" paramagnetism[12] for pure C_{60} are also remarkable. There are several reports of presumed changes in the crystal structure of C_{60} upon recrystallization[13] and the formation of adducts with donor solvents.[3b, 14] Fullerene oxides with an epoxide structure can be obtained from dissolved fullerenes in the presence of oxygen and light[15] or by reaction with oxygen-transfer reagents.[16] In ultrahigh vacuum (UHV) films of C_{60} react below room temperature with low abundancies of oxygen to give carbon dioxide.[17] Evidence of stable adducts of fullerenes and OH or $(CH_2)_x$ ($x = 1-7$) was provided by mass spectrometry.[18]

All these reports point to the relevance of the analogy of fullerenes and active charcoal, and provide reasons for investigating of the material properties of "pure"[19] C_{60}. Possible impurites are solvent and/or components of the air. The following experiments prove their presence in crystalline powders of C_{60}.

Figure 1 shows powder diffraction diagrams of samples of C_{60} treated in different ways. Only the sublimed sample provides a diffractogram that matches the diffraction pattern simulated from the single-crystal data.[6] Positions, intensi-

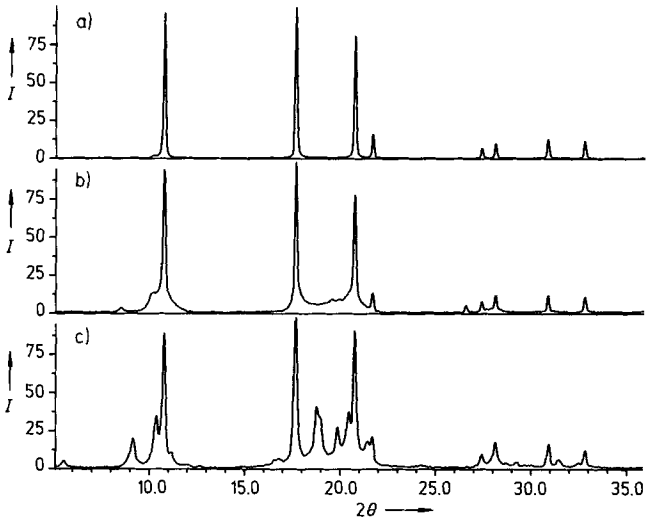

Fig. 1. X-ray powder diffraction patterns of analytically pure (C 99%) samples of C_{60}. The measurements were conducted in sealed capillaries under argon in focussing Bragg-Brentano geometry with monochromated copper radiation. a) After sublimation, b) recrystallized from benzene, c) recrystallized from toluene. The sublimation was carried out in a quartz tube at 1×10^{-7} mbar and 900 K. I = relative intensity.

ties, and widths of the additional reflections of the recrystallized samples correlate with the amount of solvent detected by IR spectroscopy. The position of the main reflections (face-centered cubic lattice with a=1415.2 pm) differs only slightly for the various samples. The additional reflections indicate the formation of partially long range-ordered solvent adducts.

By rigorous drying of the samples under vacuum (10^{-3} mbar at about 350 K, the solvent can be removed until no C–H stretching bands remain in the IR spectrum. However, absorptions in the fingerprint region at 1627, 1537,[20] and especially at 1384 cm^{-1} arise.

The band at 1384 cm^{-1} is intense for sublimed samples and becomes the strongest band in the spectrum when the sample is stored with exposure to light and air; no other absorptions arise, and the C_{60} bands do not change appreciably. The position and the isolated appearance of this band could indicate the formation of a C–O single bond similar to those found in aryl ethers. The X-ray structure analysis of a single crystal obtained by sublimation clearly showed electron density maxima outside the perimeter of C_{60}; these were assigned to statistically occupied oxygen positions distributed over eight hexagonal surfaces.[6]

The presence of paramagnetic impurites in extremely varying concentrations was established by EPR spec-

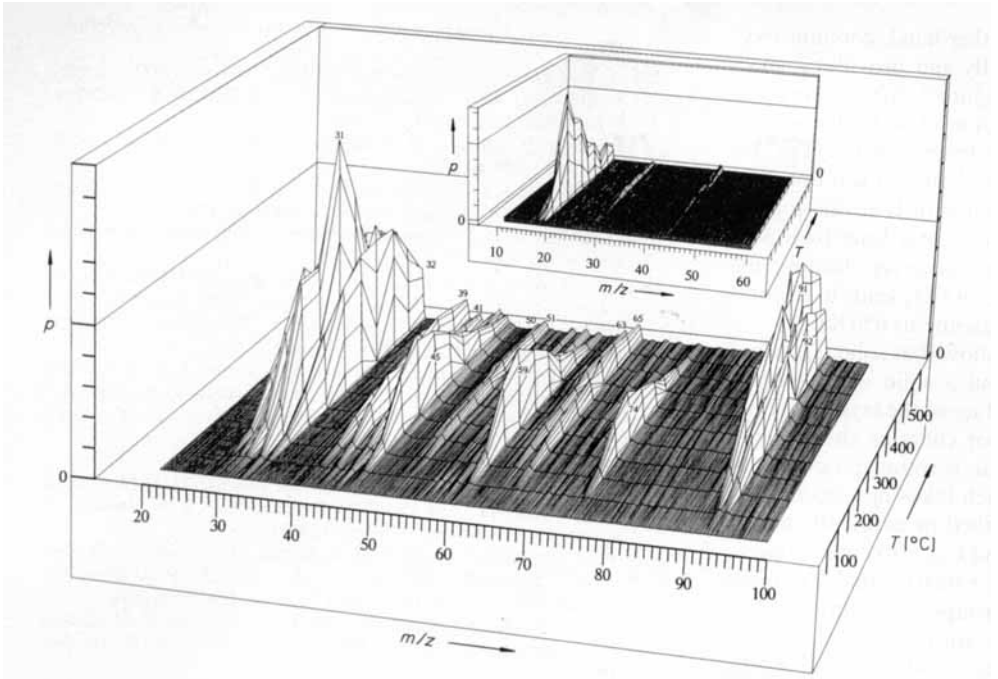

Fig. 2. Summary of the temperature-programmed decomposition experiments followed by mass spectrometry with recrystallized (large picture) and sublimed (small picture) C_{60}. p = pressure in arbitrary units.

troscopy. The parameters of the spectra[22] show that the signals can hardly be attributed to an intrisic spin density[12] of pure C_{60}; rather they indicate paramagnetic impurities that apparently can be removed efficiently but not completely by sublimation.

More detailed information about the nature of the trace impurites is obtained from thermal degradation experiments in UHV.[23] The analysis can be conducted to be either bulk specific or surface sensitive by varying the rate of heating between 1 $K s^{-1}$ and 10 $K s^{-1}$. In Figure 2 the bulk desorption of a C_{60} sample recrystallized from toluene is compared to that of a sublimed sample. Only water and traces of CO_2 and CO were released from the sublimed material at 500 K; no water but oxygen and numerous organic fragments escaped from the recrystallized material in two temperature regions at 523 K and 723 K. The analysis of the peak profile in Figure 2 reveals two series of fragments assigned to diethyl ether (*m/z* 27, 28, 29, 31, 45, 59, 74) and toluene (*m/z* 39, 51, 65, 91, 92). Neither CO nor CO_2 were detected in any significant amounts. Ether had been used to wash the crystals and was apparently incorporated in the crystals in the same way as the actual solvent had been, though the latter escapes primarily at higher temperatures. The high temperatures required for desorption point to considerable binding energies in the van der Waals crystal. It is certainly plausible that these impurites could affect the lattice dynamics of the crystals.[4, 5, 10]

The release of a substantial amount of molecular oxygen from the crystals containing solvent takes place at a different temperature (670 K) than the release of the organic impurities. The oxygen in the crystal is present in a form that does not lead to the oxidation of C_{60} upon thermal activation. This finding is in agreement with the observed stability of molecular C_{60} to oxidation.[3b, 16] Comparison of the oxygen desorption data with the IR spectra reveals that the intensity of the band at 1384 cm^{-1} does not correlate with the amount of liberated oxygen. If the oxygen actually arises from the compound that produces this IR band, then it either reacts in the sublimed material with hydrogen also present[21] to form water, or it binds with the substrate. In material containing solvent the single atoms of oxygen react to give O_2, but never form CO_2. This is in accord with earlier oxidation experiments,[24] in which formation of CO_2 was first observed above 700 K in diluted oxygen.

Desorption experiments with rapid heating rates provide a complementary picture. The data for the sublimed material (a–c) and the recrystallized material (d–f) are summarized in Figure 3. The desorption of toluene (not shown) exhibits the same pattern as seen in Figure 2. The differences in the desorption behavior originate in the various reaction kinetics of oxygen and not from experimental artifacts.

Figure 3a verifies that untreated C_{60} indeed releases molecular oxygen in two temperature ranges, possibly implying that the oxygen is located at different depth (subsurface and bulk) in the crystal. The desorption is complete after

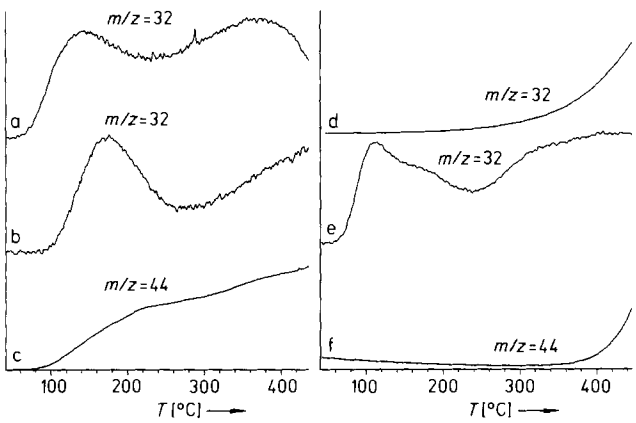

Fig. 3. Temperature profiles of selected mass spectral signals from desorption experiments with crystalline powders of C_{60} after various pretreatments. a)–c) Sublimed material, d)–f) solvent recrystallized and dried C_{60}. See text for details.

the sample is heated once, but oxygen can be readsorbed by treatment of the sample with 200 mbar of O_2 for 2 h at 300 K (Fig. 3b). Thus even the most pure material takes up oxygen from the air or from impure inert gas. Storage under 1 mbar of O_2 for 48 h leads to surface oxidation, as demonstrated by the formation of CO_2 (Fig. 3c); this behavior agrees with the known spectral data.[17]

Recrystallized material, on the other hand, contains oxygen in another binding state initially and provides a spectrum (Fig. 3d) similar to that in Figure 2. After desorption of the solvent, at least from the regions close to the surface, the sample can be loaded like the sublimed material (Fig. 3e) and is then sensitive to oxidation. Spectrum 3f was obtained from a sample that was treated analogously to the sample that provided spectrum 3b and shows that brief treatment with O_2 does not cause oxidation; however, heating the sample under a low partial pressure of CO_2 leads to dissolution in the bulk (decrease in the baseline to 650 K).

In summary, these experiments show that solid C_{60} is not an inert van der Waals crystal, but a solid with complex reaction behavior. The internal surface of the crystal is either saturated with solvent molecules or contains chemisorbed atoms of oxygen. This matches the sorption properties of active charcoal, the surface of which takes up organic substances and/or oxygen in chemisorbed or covalently bound forms.[8] The characteristics of solid C_{60} also correspond to those of a single fullerene molecule, which is capable of binding a large variety of functional groups on its surface.[3b]

The interaction of oxygen atoms with C_{60} can be of various strengths. We identified an epoxide-like binding as the weakest; it can be converted by tempering (sublimation) into a stronger binding mode (aryl ether). These two types of binding differ in their IR data and in their behavior in thermal desorption; their existence is suggested by the data from mass spectrometry, the ESR signals, and the results of single-crystal X-ray diffraction experiments. These oxygen adducts differ markedly from those that produce CO_2 upon thermal decomposition; this latter type forms only slowly on the crystal surface with exclusion of light and moisture and apparently gives rise to the precursor for the total oxidation[17, 18] of C_{60}. The existence of chemically activated oxygen should be taken into account in considering the behavior of C_{60} under catalytically oxidizing conditions.

The differing desorption behavior of the solvents ether and toluene suggests that an intrinsic characteristic of C_{60} is its ability to enter into specific electronic interactions; however, only experiments with thin films can eliminate possible topochemical effects superimposed on this intrinsic property. Until now we have consciously conducted our investigations to avoid a photochemically assisted adsorption—even in the dark the effects of small amounts of foreign atoms are complex enough.

We used a direct current arc with approximately 1.5 kW power and cooled the entire apparatus with a water-jacket. A continuous flow of helium at a total pressure of 140 mbar proved to be advantageous. An air-tight apparatus (leakproof under static high vacuum) and pure helium are extremely important for respectable yields. The crude extract, obtained in a maximum of 15% yield, was separated by chromatography (in the dark, eluting with toluene) into C_{60}, C_{70}, and higher fullerenes. The purity of the fractions was determined by UV/VIS spectroscopy. This highly sensitive method showed that at this point there is only an insignificant amount of fullerene oxide.[15,16] Conventional elemental analysis showed about 99% C and less than 1% H.

[19] Our freshly recrystallized C_{60} [1] showed four IR bands at 1429, 1184, 577, 528 cm^{-1} and one ^{13}C NMR signal in solution at $\delta = 143$ [3a] with a signal-to-noise ratio of 270.

[20] The band at 1627 cm^{-1} was assigned to a skeletal vibration of the aromatic system that is intensified by oxygen;[16] the band at 1537 cm^{-1} is also described in the literature[4,21] and may be due to a C–H vibration of the $(CH_2)_x$ derivatives [18] present in trace amounts. This band is found only in dry samples. The accompanying C–H stretching vibration can be suppressed.[21]

[22] Several samples of nominally pure C_{60} were examined by EPR spectroscopy in the solid state at 200 K. The intensities correspond to spin densities of up to $N \times 10^{-6}$ per C atom, the linewidth B is given in Gauss. The following values for N, g, and B were obtained: Sublimed sample (N=25, g=2.00007, B=4.3), recrystallized sample (N=125, g=2.00211, B=0.90), a mixture of C_{60} and 10% C_{70} (N=125, g=2.00187, B=1.3), sublimation residue (N=1600, g=2.00262, B=0.58).

[23] U. Göbel, W. Bensch, R. Schlögl, *J. Anal. Chem.* **1992**, in press. For the measurements, 10 mg of the crystalline powder was heated on a preheated stainless steel substrate in UHV (1×10^{-9} mbar) with a linear temperature program. The mass spectra of the desorbed material (Balzers QMG 112 quadropole mass spectrometer) were corrected for the background signals. For technical reasons the background signal at m/z 2 is so intense that hydrogen desorption cannot be observed with certainty.

Enantioselective Synthesis of the Antidepressant Rolipram by Michael Addition to a Nitroolefin

By *Johann Mulzer,* Ralf Zuhse,* and *Ralph Schmiechen*

Chirally branched pyrrolidones like Rolipram **1a** are highly active antidepressants with novel postsynaptic modes of action.[1] The advantages of Rolipram over conventional antidepressants are the low required dosage (3×0.75 mg per day) and the absence of uncomfortable and sometimes even dangerous anticholinergic side effects like dryness of mouth,

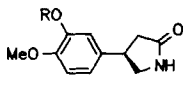
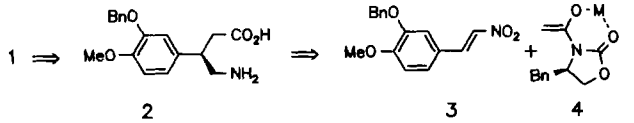
sight problems, and cardiotoxicity. The pharmacological activity depends on the R group and the absolute configuration; for **1a** the (*R*)-(−) enantiomer is the more effective.



(*R*)-**1a**, R=cyclopentyl (Rolipram)
(*R*)-**1b**, R=benzyl
(*R*)-**1c**, R=H

The known syntheses[2] are limited to the preparation of racemates, which are then separated into the enantiomers by chromatography. We describe here the first enantioselective synthesis of each enantiomer of **1a–c** in multigram quantities. Since by Williamson etherification (*R*)-**1c** can be converted to a variety of ethers, this is a key compound in the series. The main preparative problem is the introduction of the chiral center in the aminocarboxylic acid **2**. Among the numerous possibilities (for example, alkylation of a chiral enolate, Claisen or [2,3] sigmatropic rearrangement, opening of an epoxide with a cuprate etc.) we considered the Michael addition of chiral enolate **4** to ω-nitrostyrene **3** to be especially convenient (Scheme 1).[3] As shown in Scheme 2, aldehyde



2 **3** **4**

Scheme 1. Retrosynthetic analysis of **1**.

5[4] was converted into nitrostyrene **6** and allowed to react with the enolate (*R*)-**4** of *N*-acetyloxazolidone **8**.[5] Compound **7** and its C(3′) diastereomer were produced in a ratio of 94:6 (analysis by HPLC and ^{13}C NMR spectroscopy). After a single recrystallization from methanol, **7** was 99+ % diastereomerically pure.[6] The conversion of **7** into (*R*)-**1c** was achieved in one step by catalytic hydrogenation,[7] via the intermediates **2b** and (*R*)-**1b**, which were not isolated. Compound **1c** was alkylated with cyclopentylbromide fur-

nishing **1a**. Since the enantiomer of **8** is also available, the (*S*) series is equally accessible.

The stereochemical course of the addition of **4** to **3** follows the model proposed previously by Seebach et al. for the addition of enamines to nitrostyrenes[8] which is based on the following assumptions: 1. The formal double bonds are *syn* oriented as in **9**/**10**. 2. The donor (NR_2) and acceptor functions (NO_2) are as close to each other as possible, leading to a preference for the reactive intermediate **10** over **9**. Our example deviates significantly from the Seebach model, since instead of an enamine a chiral, metalated O,N-acetal[9] **4** is used. As part of an imide unit the amino function of **4** is a weaker donor than the enolate oxygen. Of the possible reactive intermediates **11** and **12** the latter appears to be favored, in analogy to Seebach's findings. This means, however, that it is not so much the donor effect of the enamine nitrogen that matters for the diastereoselectivity of the addition, but rather its *syn* orientation to the nitroolefin unit. A pericyclic shift of the metal cation to the nitro group as required in the Zimmerman–Traxler mechanism of the aldol addition[10] does not appear to play a role because of the unfavorable ring size (eight-membered ring). The high stereoselectivity in the formation of **7** is also noteworthy, since enolates of type **4** which have no substituents on the C atom, do not react stereoselectively in, for example, aldol additions.[11]

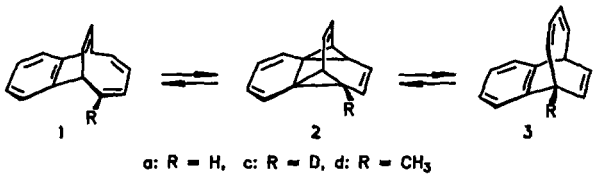
The Benzene Ring as Dienophile in an Intramolecular [4+2] Cycloaddition: Degenerate Rearrangement of 7,8-Benzobicyclo[4.2.2]deca-2,4,7,9-tetraene**

By *Wolfram Grimme,* Thomas Grommes, Wolfgang R. Roth,** and *Rolf Breuckmann*

The π bonds of benzene rings can—at higher temperatures—participate in pericyclic reactions. Besides the well-known Claisen rearrangement,[1] a sigmatropic hydrogen shift[2] and several electrocyclic ring openings[3] involving benzene π bonds have been described. Benzene also functions as diene in some [4+2] cycloadditions.[4] Here we report the first case of a [4+2] cycloaddition in which one of the π bonds of a benzene ring reacts as dienophile.[5]

We chose an intramolecular cycloaddition for the investigation of the role of benzene as dienophile, because this reaction proceeds even with weakly reactive dienophiles for entropy reasons. Moreover, because the cycloaddition at the benzene ring is endothermic and easily reversible, its detection requires a molecule which yields a Diels–Alder intermediate that can return to two different products.

The 7,8-benzobicyclo[4.2.2]deca-2,4,7,9-tetraene **1a** fulfills these prerequisites: The diene bridge is spatially close to the benzene π bond of the bicycle, and the symmetrical cycloadduct **2a** can return to the aromatic state along two paths (formation of **1a** or **3a**). The intramolecular [4+2] cycloaddition with participation of the benzene ring results



a: R = H, c: R = D, d: R = CH_3

in the degenerate rearrangement **1a** ⇌ **3a**, which can be observed only in the substituted compounds **1c, d**.

A high-yielding synthesis for the already known hydrocarbon **1a**[6] was developed, which also gave access to targeted substituted derivatives (Scheme 1). Under irradiation buta-

d) e)

Scheme 1. a) Benzene, *hv* (lamp Q 1200 Hanau), 140 h, 12%. b) CCl_4, 1,3-dibromo-5,5-dimethylhydantoin, 1.6 equiv, 80 °C, 2 h, 72%. c) Dimethylformamide, Zn, 10 equiv, sonation, 7 h, 81%. d) 1) THF, *n*-butyllithium, 1.1 equiv, −78 °C, 10 min; 2) D_2O, 30 equiv, −78 °C to 20 °C, 70%. e) 1) THF, *n*-butyllithium, 1.1 equiv, −78 °C, 10 min; 2) methyl iodide, 4 equiv, −78 °C to 20 °C, 20%.

diene added to naphthalene to afford the [4+4] cycloadduct **4**,[7] which was doubly or triply brominated with 1,3-dibromo-5,5-dimethylhydantoin in the planarizable allylic positions. The 1:1 mixture of **5a** and **5b** obtained was debrominated with zinc, and the products separated by flash chromatography (silica gel, cyclohexane). After halogen–metal exchange with *n*-butyllithium, the bromide **1b** yielded the bicycle **1c, d** deuterated or methylated in position 2 on treatment with D_2O or methyl iodide.

A prior investigation had shown that the thermolysis of **1a** leads to *cis*-4b,8a-dihydrophenanthrene;[8,9] therefore the attempt to detect the rearrangement **1c** ⇌ **3c** had to be performed close to the activation threshold for this thermolysis. Bicycle **1c** (97% D_1) in the gas phase was heated to 235 °C for 93 h, and the crude product was then dehyrogenated with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in CCl_4. The excess DDQ was reduced with cyclohexa-1,4-diene, and the product filtered through silica gel. Separation by gas chromatography furnished the benzobicyclic isomers and phenanthrene in the ratio 3:1. The ^{1}H NMR spectrum of the benzobicyclic isomers revealed a 1:1 mixture of **1c** and **3c** with 81% D_1 deuteration. The [4+2] cycloaddition with the benzene ring as dienophile therefore takes place under the chosen conditions, and leads to the equilibrium distribution of the marked isomers.

The phenanthrene obtained is 64% monodeuterated according to the mass spectrometric analysis, and its ^{1}H NMR spectrum shows that 60% of the deuterium atoms are situated in positions 9 and 10. When the preequilibrium **1c** ⇌ **3c** is considered, these values are in accord with the previously

proposed mechanism[8] for the formation of dihydrophenanthrene from **1a**, in which a 1,5-shift of the etheno bridge is followed by electrocyclic ring opening and new ring formation. This mechanism would yield, after subsequent dehyrogenation, phenanthrene with 72% deuteration (D_1), in which half the deuterium atoms occupy positions 9 and 10.

The kinetic parameters of the rearrangement of the benzobicyclo[4.2.2]decatetraene skeleton were determined for the 1-methyl compound **3d** from an analysis by gas chromatography. **3d** was obtained analogously to **1a**, from butadiene and 1-methylnaphthalene. The primary photoaddition occurs here at both rings of naphthalene, and when the synthesis sequence is complete, **3d** must be separated from its 3′-positional isomer by gas chromatography. Important physical data for the new compounds are collated in Table 1.

Table 1. Some physical data for the compounds **1b–d**, **3d**, and **4a**. ^{1}H NMR spectra at 80 (**1b**, **4a**) or 300 MHz in $CDCl_3$. ^{13}C NMR spectra at 75.5 MHz in $CDCl_3$. Mass spectra at 70 eV. Satisfactory elemental analyses were obtained for **1b**, **1d**, and **3d**.

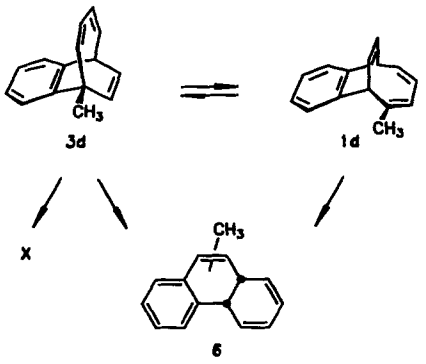
The advantage of determining the kinetics of the rearrangement **3d** → **1d** by gas chromatography in the gas phase is offset by the loss of degeneracy. The more complex course of the reaction is shown in Scheme 2. Of the methyl-*cis*-



Scheme 2. Formation of the methyldihydrophenanthrene derivatives **6**.

4b,8a-dihydrophenanthrene derivatives **6**, the isomer substituted at position 9 or 10 forms over 50%; moreover, **3d** yields an unknown product **X** in small amounts. As the thermolysis of the starting compounds **3d** and **1d** shows, **6** is formed from both, whereas **X** is derived only from **3d**.

The activation parameters of the pertinent Diels–Alder reaction were found for the gas-phase thermolysis in the temperature range between 231 and 301 °C with already described apparatus and techniques.[10] The simulated reaction course of Scheme 2 was fitted to the data in Table 2 by using a Simplex routine for the optimization.[11]

Since the analysis was performed only for **3d**, the resulting activation parameters in Table 3 have a statistical significance only for the reaction **3d** → **1d**;[12] the quoted errors represent a 95% confidence limit.

Table 3. Activation parameters for the thermal rearrangement of **3d** and **1d** in the gas phase (see Scheme 2).

Reaction	E_a [kcal mol^{-1}]	log *A*	$\Delta H^{\neq}$ (265 °C) [kcal mol^{-1}]	$\Delta S^{\neq}$ (265 °C) [cal mol^{-1} K^{-1}]
3d → **1d**	41.2 ± 0.5	12.83 ± 0.2	40.1 ± 0.5	−3.0 ± 0.9
1d → **3d**	43.0	12.81	41.9	−3.0
3d → **6**	43.3	13.28	42.2	−0.9
1d → **6**	41.1	11.20	40.0	−10.4
3d → **X**	46.6	13.85	45.5	1.7

The activation parameters of Table 3 yield a Gibbs activation energy for the rearrangement **3d** → **1d** at 35 °C of $\Delta G^{+} = 41.1$ kcal mol^{-1}; they are valid for the rate-determining step of the reaction, the cycloaddition **3d** → **2d**. The corresponding rearrangements in the parent compound bicyclo[4.2.2]decatetraene and some derivatives take place at this temperature with Gibbs activation energies of 22.3 to 24.2 kcal mol^{-1}.[13] Here the replacement of an olefinic double bond by a π bond of a benzene ring thus increases the Gibbs activation energy by about 18 kcal mol^{-1}. In earlier investigations of pericyclic reactions, such an exchange led to an increase of only about 11 kcal mol^{-1}.[3] Apparently the transition state to the strained cycloadduct **2** in the reaction studied here lies very late on the reaction coordinate and is reached only after substantial loss of resonance energy in the benzene ring.

Photoselective Processes in Cyclooctasulfur Layers: Desorption versus Polymerization**

By *Jens Geyer, Heinrich Stülpnagel,* and *Klaus Rademann**

The photolysis of cyclooctasulfur has been studied at various temperatures and wavelengths. To the known photochemistry of sulfur under the influence of UV light in the 250–400 nm range belongs the appearance of sulfur radicals during the irradiation and polymerization of S_8.[1–6] We report here the dependence of the polymerization of sulfur on the wavelength of irradiating light. A central, unprecedented observation, however, is that desorption of a thin cyclooctasulfur layer is stimulated by light ($\lambda = 255$ nm) in high vacuum. As a result of the observed dependence of desorption rate on light intensity, a purely thermal desorption process at a wavelength of 255 nm can be rejected.

The sulfur layer ($d = 100$ to 700 nm) was generated in a high-vacuum apparatus ($p = 4 \times 10^{-6}$ to 1×10^{-7} mbar) by directing a beam of S_8 molecules onto a polycrystalline gold surface ($T = +20$ to -50 °C). This is a component of the probe of the quartz microbalance that monitors the layer's thickness.

The sulfur condenses as a supercooled liquid that precipitates in the form of droplets[7, 8] above -35 ± 2 °C, regardless of the substrate studied (quartz glass, corundum, gold, stainless steel). Below this temperature a continuous film forms because the supercooled sulfur melt is present as a glass.[9] Previously glass transition temperatures for sulfur of -29 °C[10] and -30 °C[11] were reported.[12]

For the sulfur layer consisting of droplets, an activation enthalpy of 68 kJ mol^{-1} for the evaporation could be calculated from the dependence of the thermal desorption rate on temperature (Ford and La Mer[13] report an enthalpy of evaporation of 78 kJ mol^{-1} for a supercooled sulfur melt). Thermal desorption could not be observed below -36 °C for the continuous glasslike film.

For the droplet film (cf. [7,8]) light-induced desorption was detected for the first time (Fig. 1). The wavelength dependence of this desorption was studied at 255, 328, 382, 436, 545, and 656 nm. The maximum desorption rate (calculated with refererence to the radiative power per surface area) was found at 255 nm (see Experimental). Studies on supercooled sulfur melts by UV spectroscopy were hitherto unknown. Absorption measurements for S_8 in solution such as those of Steudel et al.[14] reveal a double maximum in the range 250–280 nm.

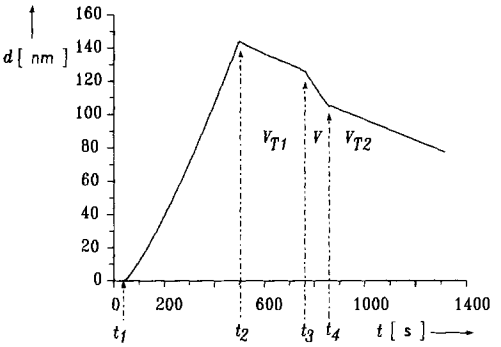

Fig. 1. Growth of the film thickness d with time on adsorption and thermal/light-induced desorption for a S_8 droplet film. $\lambda = 255$ nm, substrate temperature = 0 °C, $p = 4 \times 10^{-6}$ mbar. Desorption rates: $V_{T1} = 61 - 10^{-3}$ nm s^{-1} before irradiation, $V = 215 \times 10^{-3}$ nm s^{-1} during irradiation, $V_{T2} = 59 \times 10^{-3}$ nm s^{-1} after irradiation. t_1: effusive molecular beam source opened, t_2: molecular beam source closed, t_3: UV lamp on, t_4: UV lamp off.

To solve the question whether the desorption of sulfur by UV irradiation at $\lambda = 255$ nm is a purely thermal phenomenon, the dependence of the rate of light-induced desorption on light intensity was investigated. If the influence of the light is exclusively due to a warming of the sulfur film, the dependence of the light-induced desorption rate (V_L) on light intensity should be described by Arrhenius's law; the relationship between light intensity and increase in temperature

is required.[15] V_L depends on the temperature as well as the light intensity, but this fact alone does not prove that the desorption is caused exclusively by a local warming of the sulfur layer. A mechanism with a primary electronic step followed by a temperature-dependent reaction step could also be implicated.[16]

A representative experimental curve (Fig. 2), recorded at a substrate temperature of $-24\,^{\circ}C$ (for which the thermal desorption rate $V_T < 1 \times 10^{-3}$ nm s^{-1}) and showing the dependence of V_L on the light intensity, reveals a linear relationship. In addition the calculated course for a purely thermal

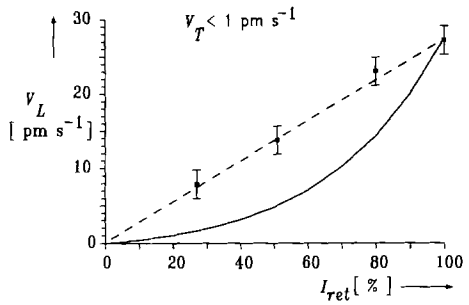

Fig. 2. Dependence of the light-induced desorption rate V_L on light intensity I_{rel} at a substrate temperature T of $-24\,^{\circ}C$; $\lambda = 255$ nm, $p = 4 \times 10^{-6}$ mbar; V_T is the rate of the thermal desorption without any light-induced desorption. The solid line shows the curve calculated from the Arrhenius equation for a purely thermal desorption mechanism.

desorption is superimposed on the graph. The highest value of the intensity (100%) was used in the calculation of V_T according to Arrhenius's law. Likewise, a linear relationship is found at higher temperatures (up to $0\,^{\circ}C$) and therefore at considerably higher V_T (Fig. 3). However, the measurement of V_L is hampered by the rapid increase in thermal desorption with increasing temperature.

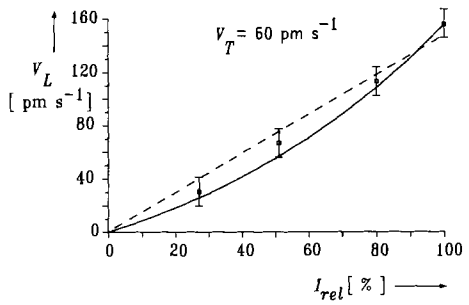

Fig. 3. Dependence of the light-induced desorption rate V_L on light intensity at a substrate temperature T of $\pm 0\,^{\circ}C$; $\lambda = 255$ nm, $p = 4 \times 10^{-6}$ mbar; V_T is the rate of the thermal desorption without any light-induced desorption. The solid line shows the curve calculated from the Arrhenius equation for a purely thermal desorption mechanism.

V_L was also determined at the wavelengths 328 and 382 nm. The following differences with respect to $\lambda = 255$ nm (for the same radiative power per surface area) were discovered: a) V_L is significantly smaller at higher wavelengths (Fig. 4);[17] b) after a short irradiation period, V_T has distinctly diminished from its value before the irradiation (Fig. 4) and c) the homogeneous glasslike film (irradiated at $-43\,^{\circ}C$) is no longer destroyed by heating, or at least only at temperatures higher than $-36\,^{\circ}C$ (cf. [9]). The observations mentioned under b) and c) suggest that the known light-induced polymerization of sulfur is taking place. This supposition is confirmed by solubility studies in CS_2: in contrast to the nonirradiated film, the irradiated sulfur layer dissolves only partially. At $\lambda = 328$ nm the polymerization is more pronounced than at $\lambda = 382$ nm, and at 418 and 437 nm no polymerization can be detected.

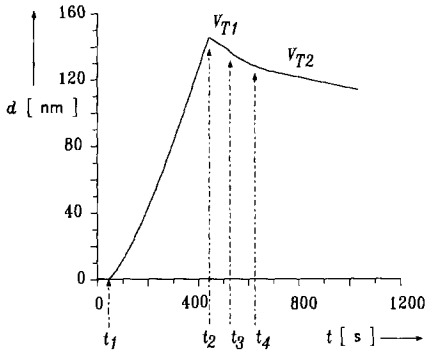

Fig. 4. Growth of the film thickness d with time on adsorption and thermal/light-induced desorption for a S_8 droplet film. $\lambda = 328$ nm, substrate temperature $= 0\,^{\circ}C$, $p = 3 \times 10^{-6}$ mbar. Desorption rates: $V_{T1} = 97$–10^{-3} nm s^{-1} before irradiation, $V_{T2} = 59 \times 10^{-3}$ nm s^{-1} after irradiation. t_1: effusive molecular beam source opened, t_2: molecular beam source closed, t_3: UV lamp on, t_4: UV lamp off. During the irradiation the desorption rate is not constant.

Polymerization is also noticeable for irradiation with light of wavelength 255 nm, but to a distinctly smaller extent than at $\lambda = 328$ or 382 nm. The behavior of the dependence of the light-induced desorption on wavelength, on the other hand, is the reverse: at 255 nm substantially more desorption takes place (a ten- to twentyfold increase in desorption rate) than at 328 or 382 nm.

Experimental Equipment

UV light source: Xe high-pressure lamp from Oriel, 1000 W, model 6271. Radiative power at the substrate's surface: 4–20 mW cm^{-2} at 328 and 382 nm, measured with a Radiometer Rj7100 from Laser Precision Corp., probe Rj P735.

Interference filters: reflection interference filter $\lambda_{max} = 255$ nm, $T_{max} = 79.0\%$, full width at half maximum (FWHM) = 8.9 nm; Transmission interference filter $\lambda_{max} = 328$ nm, $T_{max} = 52.0\%$, FWHM = 5.5 nm; $\lambda_{max} = 382$ nm, $T_{max} = 32.5\%$, FWHM = 8.0 nm; $\lambda_{max} = 436$ nm, $T_{max} = 48.0\%$, FWHM = 21.0 nm; $\lambda_{max} = 545$ nm, $T_{max} = 61.5\%$, FWHM = 20.5 nm; $\lambda_{max} = 656$ nm, $T_{max} = 57.0\%$, FWHM = 20.0 nm.

Monitor of film thickness: Type E5550 from Plano W. Plannet GmbH, Marburg; resolution 0.1 nm, surface area of probe 28 mm^2, temperature control from $+120$ to $-100\,^{\circ}C$.

Vacuum chamber and pumping system: Length of chamber 800 mm, diameter 160 mm, pump stand EXT 100/200 from Edwards.

Effusive molecular beam source: 40 cm long quartz tube, heated by water circulation, filled with α-S_8 (99.999% from Aldrich), inner diameter 20 mm, diameter of the sealable aperture 4 mm, distance from substrate about 50 mm, temperature $+20$ to a maximum of $+79\,^{\circ}C$, corresponding to an α-S_8 equilibrium vapor pressure of 1.1×10^{-3} mbar (at $+79\,^{\circ}C$). The proportion of S_8 rings in the vapor over the subliming S_8 is over 99% [18].

[15] Note that to report the light-induced desorption rate V_L, the thermal desorption rate V_T was subtracted from the total desorption rate after the UV lamp was switched on ($V = V_L + V_T$), because except at low temperatures, thermal desorption plays a role in addition to light-induced desorption.
[16] In this context a study of the composition, structure, and energy of the desorbed particles would be interesting. Our preliminary investigations by mass spectrometry suggest that S_2 and S_6 are the desorbing species. A photolytic cleavage of S_8 rings into smaller fragments was discussed by Steudel et al. [6].
[17] The light-induced desorption rate V_L at 328 and 382 nm was not sufficiently large to permit a study of its dependence on light intensity.

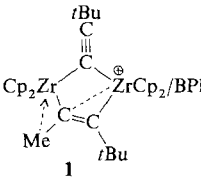
A Structurally Distorted Ligand in an Electron-Deficient Dizirconocene Cation: Unusual 1,2- and 1,1-Dimetallioalkenes**

By *Andrew D. Horton** and *A. Guy Orpen*

Formally 14-electron d^0 complexes $[Cp'_2MR]^+$ (M = Ti, Zr, Hf, Th) relieve coordinative unsaturation at the metal atom by unusual bonding interactions with the ligand R or a labile counteranion. Examples of such interactions include $X\text{–}CH_n \cdots M$ (X = C,[1] Si,[2] B,[3] M[4]), Si–Cl ··· M,[5] and multiple-bond ··· M.[2c, 6] Related α-[7] and β-C–H ··· M[8] agostic interactions may play an important role in the stereoselective alkene insertion. In exploring whether the chemistry of electrophilic $[(C_5Me_5)_2ZrR]^+$ species as agents for RC≡CH oligomerization[2c] could be extended to less crowded C_5H_5 analogues, we have observed formation of electron-deficient binuclear zirconocene cations, which contain unusual bridging hydrocarbon ligands. We report here the first highly distorted planar 1,2-dimetallioalkene complex containing two transition metal fragments, which also contains a μ-alkynyl ligand.

Cationic $[(C_5Me_5)_2ZrR]^+$ complexes are catalytically more active and lead to a higher degree of RC≡CH oligomerization than their neutral scandium analogues.[2c] We postulated that this tendency might be further accentuated if sterically less bulky η^5 ligands were employed as catalysts, since such cations in comparison with C_5Me_5 complexes show increased reactivity with terminal alkynes (e.g. double insertion).[6c] Unexpectedly, the reaction of excess *t*BuC≡CH with a 1:1 mixture of $[Cp_2ZrMe_2]$ and $[PhMe_2NH][BPh'_4]$ (to generate unstable $[Cp_2ZrMe(NMe_2Ph)][BPh'_4]$; Ph′ = 4-$C_6H_4F$) at −30 °C affords, on warming to 25 °C, only a few equivalents of $H_2C{=}C(t\text{Bu})C{\equiv}Ct\text{Bu}$ and unreacted alkyne. If the reaction is monitored by NMR spectroscopy the formation of a single organometallic product **1**, and 0.5 equiv of unreacted $[PhMe_2NH]^+$ is observed. Yellow crystals of **1**-BPh'_4 (80% yield) were obtained from the reaction of a 2:1 ratio of zirconocene and "H^+", and excess alkyne [Eq. (a)].

$$2\,[Cp_2ZrMe_2] + [PhMe_2NH][BPh'_4] + m\ t\text{BuC}{\equiv}\text{CH} \xrightarrow[-30 \rightarrow +25\,^\circ\text{C}]{C_6H_5Br} \quad \text{(a)}$$



$$\mathbf{1}\text{–}BPh'_4 + NMe_2Ph + 2\,CH_4 + H_2C{=}C(t\text{Bu})Me + n\,H_2C{=}C(t\text{Bu})C{\equiv}C(t\text{Bu})$$

The elemental analysis, ^1H and ^{13}C NMR spectroscopy, and the formation of a 2:1:1 mixture of Cp_2ZrCl_2, *t*BuC≡CH, and *cis*-MeHC=CH(*t*Bu), respectively, on addition of HCl to **1** in C_6D_5Br, all suggest that **1** contains two $[Cp_2Zr]$ fragments with *t*BuCC and MeCC*t*Bu ligands. The NMR spectra indicate that the *t*BuCC and MeCC*t*Bu ligands are situated in the equatorial plane between the Cp ligands; the existence of agostic C–H ··· Zr bonding between the methyl group and the Zr atom is, however, only partially supported by the NMR data (^1H NMR: $\delta = -0.30$; ^{13}C NMR: $\delta = -14.6$; $^1J(CH) = 128$ Hz).[8]

The X-ray structure analysis of **1**-BPh'_4[9] shows that the *tert*-butylalkynyl and the alkenediyl ("μ-alkyne") bridging ligands in the binuclear cation are equatorial with respect to the coordination at the Zr centers (Fig. 1). In contrast to the normal, symmetrical, planar structure of 1,2-dimetallioalkenes,[10] the C2–C3 double bond (1.336(14) Å) in **1** has slid relative to the Zr ··· Zr vector so as to bring C2 in contact with Zr2 (Zr2–C2 = 2.486(13) Å). The electron deficiency

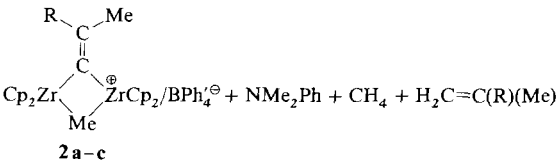
[**] According to the rules for IUPAC nomenclature all radicals and substituents with a metal center as a binding site have the suffix -io (see *Nomenclature of Inorganic Chemistry* (Ed.: G. J. Leigh), Blackwell, Oxford, **1990**, p. 274, Table IX). Therefore, alkenes with two Cp_2RZr substituents are described as dimetallioalkenes.

at Zr1 for the rather weak Zr1–C2 bond of 2.365(11) Å (Zr2–C3 = 2.168(12) Å) is partially compensated by the agostic coordination[2b, 8, 11] of C1–H1A to Zr1 (Zr1–C1 = 2.616(14) Å, Zr1–H1A = 2.27(15) Å), and by the slightly stronger bonding of the μ-alkynyl ligand to Zr1. The alkynyl bridge is slightly asymmetric with the Zr1–C8 bond approximately 0.11 Å shorter than Zr2–C8. The deformation of the 1,2-dimetallioalkene is also shown by the Zr1-C2-C1 and Zr2-C3-C4 angles of 81.6(7) and 145.0(8)°, respectively.

Although the general structural features and bonding parameters for the μ-alkyne interaction with Zr2 are similar to those for the Zr complexes, $[Cp_2Zr(\mu\text{-CCPh})\{\mu\text{-MeCCPh}\}AlMe_2]$[12] and $[Cp_2Zr(\mu\text{-Cl})\{\mu\text{-Me}_3SiCCPh\}AlMe_2]$,[13] recently reported by Erker et al., the asymmetric bonding of the bridging ligands at the metal center in **1** cannot be ascribed to different affinities of the two metals to the ligands, as might be invoked for the Zr–Al complexes. The asymmetric coordination of the MeCC*t*Bu ligand in **1** reduces the electronic unsaturation at Zr2 and also relieves the steric congestion at Zr2 caused by the *t*Bu and Cp ligands. This allows agostic bonding at Zr1, by permitting a closer approach of the methyl group (C1).

Sterically less crowded alkynes, RC≡CH (R = *i*Pr, *n*Pr, 4-tolyl), react with $[Cp_2ZrMe_2]/[PhMe_2NH][BPh'_4]$ (2:1 ratio) at −30 °C to give blue microcrystalline complexes **2**-BPh'_4 (≥70% yield) [Eq. (b)]. If a 1:1 ratio of zirconocene/"H$^+$" is used, identical products are obtained, and, in contrast to the reaction with *t*BuC≡CH, no alkyne oligomers are formed under any conditions. The NMR spectra and the formation of $D_2C{=}C(R)Me$ and CH_3D on treatment of **2a–c** with D_2O show that the complexes **2** contain μ-methyl and μ-alkenylidene ligands which bridge the two Cp_2Zr fragments. The unprecedented alkenylidene unit bridging between two d^0 transition metals has been confirmed by the characteristic C_α and C_β resonance frequencies (e.g. **2a**: δ = 304.9 and 159.1, respectively).[14] Through the μ-alkenylidene coordination the bridging methyl group (**2a**: ^{1}H NMR: $\delta = -1.15$; ^{13}C NMR: δ = 55.7) adopts a bent bonding mode ($\sphericalangle$Zr–C–Zr < 180°) as reflected in the low ^1J(C,H) value of 110 Hz for the methyl group.[15] Since the signals for the protons of the Cp ligands in **2a** and **2b** have identical chemical shifts, and those for the carbon atoms nearly identical shifts ($\Delta\delta$ = 0.1–0.3), it is suggested that the $[Cp_2Zr]$ fragments are relatively symmetrically bridged. This conclusion is supported (more tenuously) by the lack of NMR evidence for an agostic interaction with the alkyl groups of the alkylidene ligands.

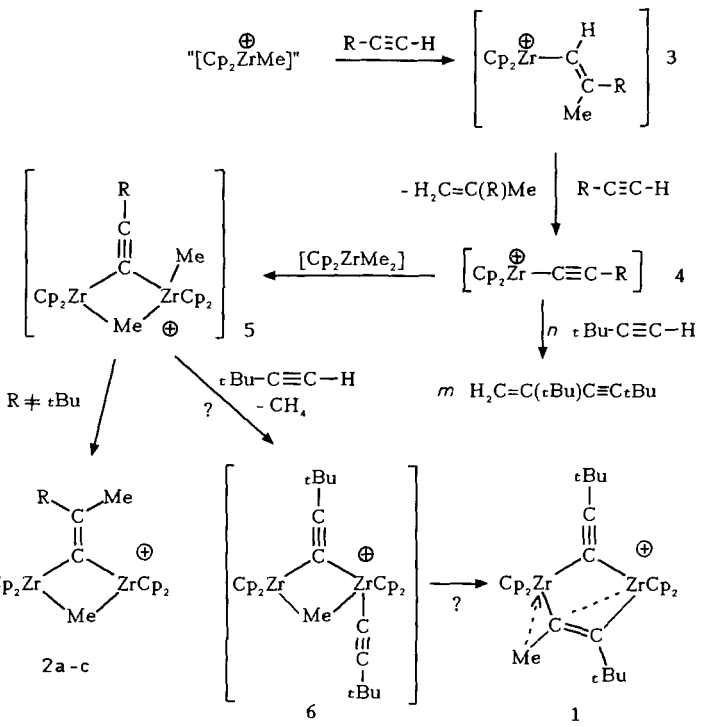
$$2\,[Cp_2ZrMe_2] + [PhMe_2NH][BPh'_4] + 2\,RC{\equiv}CH \xrightarrow[-30 \rightarrow +25\,^\circ C]{C_6H_5Br} \quad (b)$$



2a–c

R = *i*Pr (**2a**), *n*Pr (**2b**), 4-Tolyl (**2c**)

Possible mechanisms for the formation of **1** and **2a–c** are presented in Scheme 1. The likely first step is the alkyne insertion in "$[Cp_2ZrMe(NMe_2Ph)]^+$", to give alkenyl complexes **3**.[2b, 6c, 16] Rapid σ-bond metathesis with the alkyne then liberates $H_2C{=}C(R)Me$ (proven by NMR spectroscopy)



Scheme 1. Possible reaction mechanism for the formation of **1** and **2a–c**. **a**, R = *i*Pr; **b**, R = *n*Pr; **c**, R = 4-tolyl.

and affords the transient alkynyl complex **4**, related to the known $[(C_5Me_5)_2Zr\{C{\equiv}CtBu\}(thf)]^+$.[2c] Trapping of the unsaturated complex **4**[17] by the Lewis base $[Cp_2ZrMe_2]$ may then give a transient dizirconocene intermediate, possibly the μ-alkynyl μ-methyl complex **5**.[4] The rapid insertion of the alkynyl triple bond into a Zr–Me bond in **5** (R ≠ *t*Bu)[18] leads to the μ-alkenylidene complexes **2a–c**. Such insertion appears to be sterically unfavorable for **5** (R = *t*Bu). The formation of **1** may, instead, involve a sterically less demanding σ-bond metathesis reaction between a further molecule of *t*BuC≡CH and a Zr–Me group in **5**, to afford a Zr_2 intermediate with a methyl and two alkynyl ligands, for example, **6** in Scheme 1. "Reductive elimination" of methyl and alkynyl groups[12] in the hypothetical compound **6** could then lead to a MeCC*t*Bu ligand with the required *cis* geometry as found in **1**. Attempts to distinguish these from other possible mechanisms for the formation of **1** and **2a–c** are in progress.

The remarkable sensitivity of these reactions to the steric bulk of both the substituents at the alkyne and cyclopentadienyl ligand is reflected in the selective formation of the catalytically inactive compounds **1** and **2a–c**, in contrast to the catalytic RC≡CH oligomerization observed in reactions of the sterically more crowded $[(C_5Me_5)_2ZrMe]^+$.[2c] Our results suggest that the deactivation of electrophilic d^0 catalysts, by the formation of inactive binuclear compounds,[11b, 19] may also be important in alkene polymerization catalysis, especially when less bulky ligands offer less steric protection to the active species.

Experimental Procedure

1-BPh'_4: A solution of *t*BuC≡CH (0.40 mL, 3.3 mmol) in C_6H_5Br (4 mL) at −30 °C was added to a stirred mixture of $[(C_5H_5)_2ZrMe_2]$ (200 mg, 0.80 mmol) and $[PhMe_2NH][B(4\text{-}C_6H_4F)_4]$ (200 mg, 0.39 mmol). The instantaneously formed purple suspension gave a yellow solution on warming to 25 °C for 5 min. The product was precipitated with hexane, recrystallized from CH_2Cl_2/hexane solution, and dried in vacuum affording pure **1**-BPh'_4 (335 mg, 2 crops; 83%).

2a-BPh$'_4$: Addition of a solution of *i*PrC≡CH (0.30 mL, 3.0 mmol) in C_6H_5Br (6 mL) at −30 °C to a stirred mixture of $[(C_5H_5)_2ZrMe_2]$ (200 mg, 0.80 mmol) and $[PhMe_2NH][B(4\text{-}C_6H_4F)_4]$ (200 mg, 0.39 mmol), followed by warming to 25 °C, resulted in the deposition of a blue microcrystalline solid. Addition of hexane, followed by the recrystallization of the recovered solid from CH_2Cl_2/hexane, and drying in vacuo, afforded pure **2a**-BPh$'_4$ (265 mg; 70%). Compounds **2b**-BPh$'_4$ and **2c**-BPh$'_4$ were obtained analogously; **2b**-BPh$'_4$ contains 10% of cocrystallizing $[(Cp_2Zr)_2(\mu\text{-Me})\{\mu\text{-C}=\text{C}(n\text{Pr})\text{CH}=\text{C}(n\text{Pr})(\text{Me})\}]^+$ (shown by NMR spectroscopy and by the formation of $H_2C=C(n\text{Pr})CH=C(n\text{Pr})(Me)$ with H^+), formed by insertion of *n*PrC≡CH into **3b**; low solubility prevented recrystallization of **2c**-BPh$'_4$. Selected ^{1}H NMR data for cations (also see text). (300 MHz, CD_2Cl_2, 25 °C): **1**: δ = 6.09, 5.92 (s, 10H; C_5H_5), 1.49, 1.29 (s, 9H; CMe_3). ($C_2D_2Cl_4$, 25 °C): **2a**: δ = 6.54 (s, 20H; C_5H_5), 0.82 (d, 6H; $CHMe_2$), 0.39 (s, 3H; C=C(*i*Pr)(*Me*)), −0.18 (sep, 1H; $CHMe_2$). **2b**: δ = 6.54 (s, 20H; C_5H_5), 1.26 (m, 2H; $CH_2CH_2CH_3$), 0.85 (t, 3H; $CH_2CH_2CH_3$), 0.47 (s, 3H; C=C(*n*Pr)(*Me*)), 0.44 (m, 2H; $CH_2CH_2CH_3$), −1.14 (s, 3H; μ-Me). **2c**: δ = 6.63, 6.29 (s, 10H; C_5H_5), −1.10 (s, 3H; μ-Me). Selected ^{13}C NMR data (75.43 MHz, CD_2Cl_2, −30 °C): **1**: δ = 232.5 ($MeCCCMe_3$), 145.9, 127.2 ($CCCMe_3$ or $MeCCCMe_3$), 111.2, 107.9 (C_5H_5), 107.2 ($CCCMe_3$ or $MeCCCMe_3$), 41.7, 29.6 (CMe_3), 29.2, 28.5 (CMe_3). ($C_2D_2Cl_4$, 0 °C): **2a**: δ = 114.2, 113.9 (C_5H_5), 36.7 ($CHMe_2$), 20.4 ($CHMe_2$), 17.6 (C=C(*i*Pr)(*Me*)). **2b**: δ = 306.9 (*C*=C(*n*Pr)(Me)), 153.9 (C=*C*(*n*Pr)(Me)), 114.1, 114.0 (C_5H_5), 56.6 (q, ^1J(C,H) = 109 Hz; μ-Me).

The Crystal Structure of $[(Pyrene^{\bullet-})\{Na^+[(C_2H_5)_2O]\}]$: A Model for Stacked Radical Anion Salts**

By *Wolfgang Jost, Martin Adam, Volker Enkelmann,* and *Klaus Müllen**

The crystallographic description of the ions generated by reduction of aromatic hydrocarbons is generally limited to diamagnetic species.[1-3] Structures of paramagnetic radical anions[4-6] are scarcely known, whereas the radical cation salts[7] of aromatic hydrocarbons, which are easily accessible through electrocrystallization, have been intensively studied. The latter form electrically conducting crystals with stacked structures, and since the charge transport occurs in the direction of the crystal axis, they serve as models for one-dimensional electrical conductors. In our search for corresponding radical anion salts we have now prepared the title compound and characterized it by X-ray structural analysis.

Reduction of pyrene (202 mg, 10^{-3} mol) by sodium in 20 mL of ether at 193 K for twelve hours yielded a deep red solution that contains red needles. The solution was warmed to 298 K and then slowly cooled over 24 h to 253 K. Dark crystals with a metallic luster formed and were stable at room temperature under an inert atmosphere.

The crystal structure analysis revealed the composition as $[(pyrene^{\bullet-})\{Na^+[(C_2H_5)_2O]\}]$ (**1**).[8] As can be seen in Figure 1, a stacked structure is formed in which the pyrene units are tilted away from each other at an angle of 59.6(3)° along the *a* axis. In the cavity generated thereby is situated a sodium cation, which is coordinated to the oxygen atom of the ether molecule at a distance of 2.24(1) Å. Approximately symmetrical to this bond on either side are two contacts of

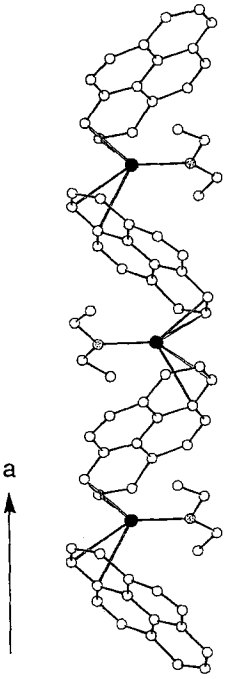

Fig. 1. Section of the polymeric structure of **1** showing the stacking of the pyrene units along the *a* axis. Sodium ions are represented as black spheres, O atoms as dotted spheres, and C atoms as open spheres. For distances and angles, see text.

2.62(2) and 2.79(2) Å to the neighboring pyrene units. Characteristically, the shortest distances are found between counterion and those pyrene carbon atoms that display the highest spin density in the ESR spectrum of the pyrene radical cation.[9]

This structure may be described as a polymeric contact ion pair with a zigzag arrangement of the π electron system. A sodium ion coordinates to every adjacent pair of pyrene rings and has a remarkably small solvation sheath of only one ether molecule. In contrast, the magnesium derivative of an anthracene radical anion[4] is constructed from monomeric contact ion pairs with three solvent molecules and an anthracenide unit. A polymeric anion structure has been described for the diamagnetic sodium fluorenide–bis(tetramethylenediamine); however, here the zigzag aggregation is stabilized by the chelate effect through the nitrogen bases.[10-11] The present radical ion structure, therefore, has no precedent.

A comparison of the crystal structures of pyrene radical anions and radical cations[7] shows that both salts form polymeric stacked structures, but whereas in the anion each pyrene unit is singly charged, in the cation mixed valences are present in which the charge is spread over several units, enabling a high mobility of charge carriers. Adjacent rings in the stacks of the radical cation salts are arranged with very small distances of about 3.2–3.3 Å between them, and the carbon atoms with the highest electron density are in direct contact.

In **1**, a direct orbital overlap is not achieved, which can be readily attributed to the known tendency of small alkali counterions to overlap with conjugated anionic systems[12] and to the mutual coulombic repulsion between the π electron systems. Any potential charge transport will thus be influenced by considerable Coulombic effects, and an electrical conduction in such structures is not anticipated.

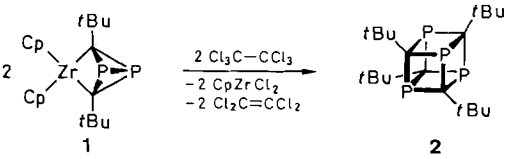
P-Functionalization of the Tetraphosphacubane System**

By *Manfred Birkel, Joachim Schulz, Uwe Bergsträsser,* and *Manfred Regitz**

Dedicated to Professor Fritz Bickelhaupt on the occasion of his 60th birthday

Reactivity studies on the tetraphosphacubane **2** have not been possible so far since this was only accessible in low yield by the thermal cyclotetramerization of tBu–C≡P.[1] This situation suddenly changed with its selective production from the phosphaalkyne dimeric complex **1**[2] by the removal of the zirconium fragment with hexachloroethane,[3] so that we can now report here for the first time the functionalization of the heteroatoms in **2**.



1 **2**

To our knowledge for other cubanes comparable with **2** (Sn–Ph,[4] Si–tBu,[5] Al[6] in place of C–tBu) no reactions are known in which the pentacyclic framework is retained. The participation of the lone pair on the phosphorus atom on the σ P/C framework bond reduces the nucleophilicity at the heteroatom,[7] so that reactions only occur with strong electrophiles and occasionally also only under drastic reaction conditions; the thermally stable tetraphosphacubane can withstand these.

Whereas methyl iodide is not suitable for the quaternization of **2**, the phosphonium triflate **3** (95%) is obtained smoothly with methyl trifluromethylsulfonate; even a large excess of the methylation reagent does not lead to a multiple reaction. Also with twice the molar quantity of nonacarbonyl diiron only one $[Fe(CO)_4]$ fragment is bound to form the complex **4** (56%).

If the NMR data of the cage atoms of **2**[8] are compared with those of **3** and **4** (Table 1), then the signals of the carbon atoms are shifted to lower field and those of the phosphorus

[*] Prof. Dr. M. Regitz, Dipl.-Chem. M. Birkel, Dr. J. Schulz, Dipl.-Chem. U. Bergsträsser

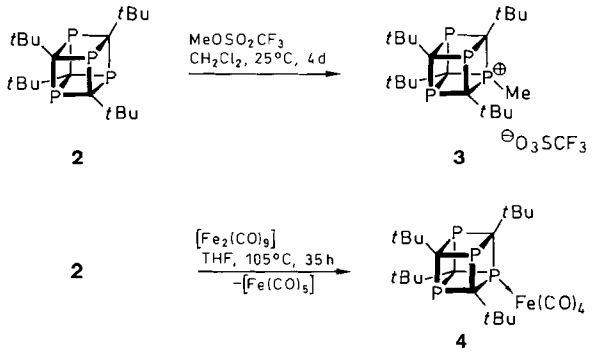
[**] Organophosphorus compounds, part 57. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. Part 56: T. Wettling, U. Bergsträsser, M. Regitz, *J. Chem. Soc. Chem. Commun.* **1992**, in press.



atoms are shifted to higher field (the exception is the fourfold bound phosphorus atom of **4**). The interactions of the lone pair at the P atom with the σ P/C bond,[7] characteristic for **2** and responsible for the extreme positions of the ^{13}C and ^{31}P resonance signals, occur in almost the same way only for a carbon atom as well as its $\lambda^3\sigma^3$-P neighbors. The tetracarbonyl iron complex was additionally confirmed by crystal structure analysis;[9] the molecule has *m* symmetry (Fig. 1).

As in **2**, the inner cyclic C–P–C bond angles in **4** are on average 3° smaller than in the cubane,[10] which naturally results in an opening of the P–C–P angle (Fig. 1). The increase of the exocyclic angles P1–C1–C11 (≡P1–C1′–C11′) and P1–C3–C31 (131.1(3) and 132.5(4)°, respectively, cf. **2**: 122°[11]) is noteworthy, which is almost certainly due to the steric interaction between *t*Bu groups and the [Fe(CO)$_4$] fragment.[11] This effect probably prevents a multiple complexation.

[a] ^1H NMR (90 or 400 MHz, TMS), ^{13}C NMR (100.6 MHz, TMS), and ^{31}P NMR spectra (80.8 MHz, 85% H_3PO_4) in $CDCl_3$. [b] ^1H NMR data for *t*Bu groups were reported only for **5** and **9**; for all other cubanes they are in agreement with the given structure. The same is true for the ^{13}C NMR signals of the *t*Bu groups of **3**, **4**, and **6**–**11**. [c] Due to the low solubility in the usual solvents no ^{13}C NMR spectrum could be recorded. [d] In the mass spectrum (70 eV) a peak occrs for the molecular ion.

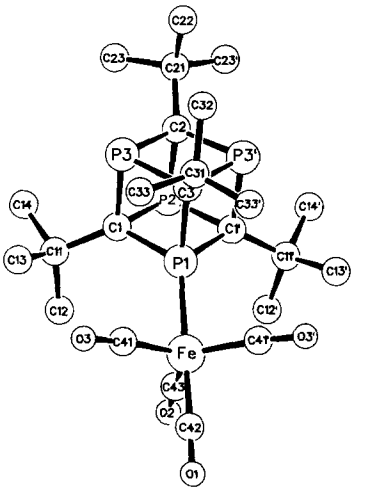

Fig. 1. Crystal structure of **4**. Selected bond distances [Å] and angles [°]: P1-Fe 2.235(2), P1-C1 1.884(4), P2-C1 1.879(4), P3-C1 1.881(4), P2-C2 1.866(6), P3-C2 1.872(4), P1-C3 1.865(5), P3-C3 1.883(4); C1-P1-Fe 127.7(1), C3-P1-C1 87.3(2), C2-P3-C1 86.9(2), C3-P3-C2 86.5(2), P3-C3-P3′ 93.1(2), P3-C1-P1 92.5(2), C11-C1-P1 131.1(3), C11-C1-P3 119.9(3), C21-C2-P2 122.6(4), P3-C3-P1 93.1(2), C31-C3-P3 118.0(2), C1-P2-C1′ 87.4(2), C3-P1-Fe 126.2(2), C2-P2-C1 87.1(2), C3-P3-C1 86.9(2), P3-C2-P3′ 93.7(3), P2-C1-P1 92.8(2), P3-C1-P2 92.6(2), C11-C1-P2 118.6(3), P3-C2-P2 93.3(2), C21-C2-P3 122.9(3), C31-C3-P1 132.5(4), C1-P1-C1′ 86.7(2).

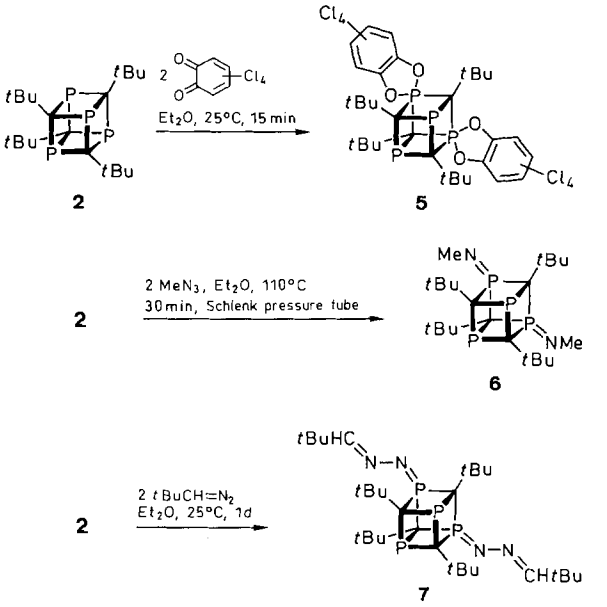
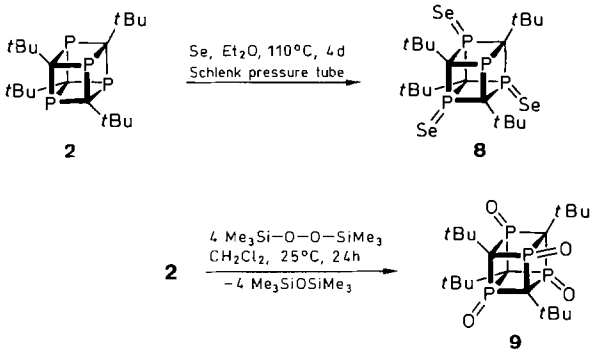
Double functionalization at the phosphorus atom of **2** occurs upon reactions with tetrachloro-*o*-benzoquinone,[12] methyl azide, and 1-diazo-2,2-dimethylpropane. These afford cubanes, which apart from unchanged $\lambda^3\sigma^3$ phosphorus atoms still have phosphorane (**5**, 95%) and iminophosphorane units (**6**, **7**, each 85%). The Staudinger reaction (→ **6**) is successful only at higher temperature.[13] In no case does an excess of reagent lead to further oxidative reactions.



If the ^{13}C and ^{31}P NMR data of the cage atoms of **5**–**7** are compared with those of **2**,[1] **3**, and **4**, respectively (Table 1), then the resonance signals now clearly lie no longer at extreme values, a tendency, which continues with higher degrees of functionalization.

The highest degree of functionalization at the tetraphosphacubane system is achieved by the introduction of elements of Group 16: heating of **2** with an excess of selenium at 110 °C only led to the tris(selenoxo)tetraphosphacubane **8** (90%), however, the reaction of **2** with four equivalents of bis(trimethylsilyl)peroxide afforded the tetraoxide **9** (90%).[14]



2 **8** **9**

The nonfunctionalized phosphorus atom in **8** resonates at $\delta = -45.2$, whereas the ylidic P atoms absorb at $\delta = 41.0$. A crystal structure analysis confirms the structure of **8** (Fig. 2).[9] The distortion from ideal cubic geometry with an

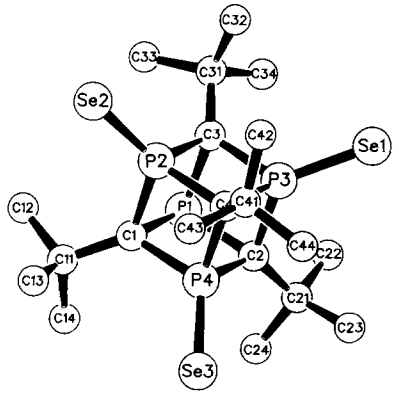


Fig. 2. Crystal structure of **9**. Selected bond distances [Å] and angles [°]: Se1-P3 2.066(3), Se3-P4 2.056(3), P1-C2 1.913(1), P2-C1 1.850(1), P2-C4 1.860(1), P3-C2 1.843(1), P4-C1 1.872(1), P4-C4 1.860(1), Se2-P2 2.056(3), P1-C1 1.914(1), P1-C3 1.901(1), P2-C3 1.856(1), P3-C3 1.863(1), P3-C4 1.859(1), P4-C2 1.828(1); C3-P1-C2 87.1(4), C3-P1-C1 86.7(4), C1-P1-C2 87.2(5), C1-P2-C3 89.9(5), C1-P2-C4 89.5(5), C3-P2-C4 88.7(4), C3-P3-C2 90.3(4), C3-P3-C4 88.5(4), C2-P3-C4 88.6(5), C1-P4-C2 91.1(5), C1-P4-C4 88.8(5), C2-P4-C4 88.9(5).

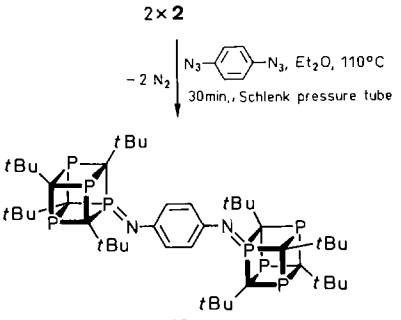
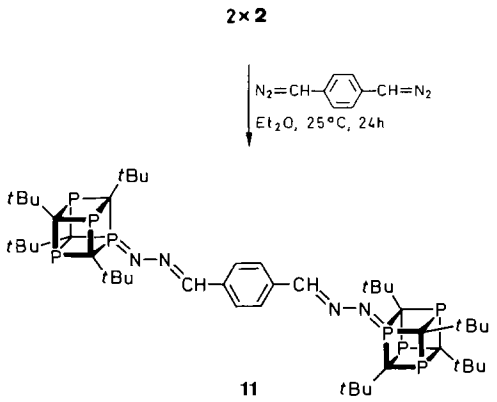
angle opening at the carbon atoms of only 1.2° (the angle at the phosphorus is correspondingly smaller) is not very large in comparison to that of the tetraphosphacubane **2** (4.4°!)[1] The exocyclic P–C–C bond angles at the nonoxidized phosphorus atom are reduced relative to those in **2** (122°)[1] by 4° to 118°. This is the reason why despite an excess of the oxidation reagent [in contrast to the introduction of oxygen (→ **9**) or sulfur[14]] the fourth phosphorus atom retains its $\lambda^3\sigma^3$ character.

The tetraoxide **9** shows high symmetry which is also illustrated by the small number of lines in the ^1H, ^{13}C, and ^{31}P NMR spetra (Table 1). The chemical shifts of the framework atoms (^{13}C NMR: $\delta = 111.2$; ^{31}P NMR $\delta = -8.6$) prove that the original donor phosphorus atoms in **2**[7] now have acceptor properties.



10



11

Two tetraphosphacubane **2** units can be coupled by a double Staudinger reaction with 1,4-diazidobenzene at 110 °C, whereby the phenylene-bridged bis(iminophosphorane) **10** (62%) is formed. Analogous coupling of **2** by twofold phosphazine formation with 1,4-bis(diazomethyl)-benzene affords **11** (52%).

Elemental composition as well as the NMR data (Table 1) prove the constitution of **10** and **11**. Noteworthy in both cases is the high field position of the framework carbon atoms in the ^{13}C NMR spectra, which without exception have $\lambda^3\sigma^3$ phosphorus atoms as neighboring atoms ($\delta = -25.0$ and -24.5, respectively; cf. with **3** and **4**)

Experimental Procedure

All reactions were carried out under argon in Schlenk tubes. Solvent, reaction temperature, and duration can be taken from the appropriate reaction equations. The reactions were monitored by ^{31}P NMR spectroscopy. After concentration, the residues were taken up in pentane and further purified as described in Table 1.

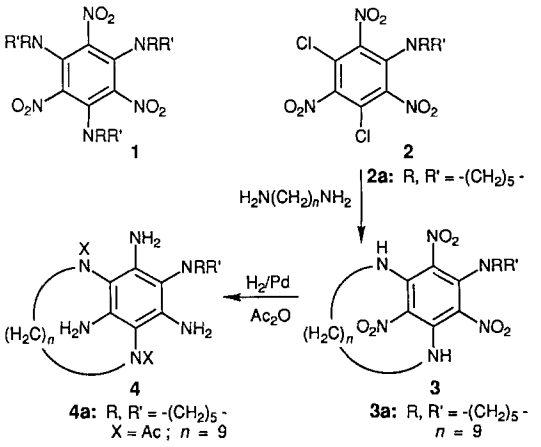
[11] The bending away of the equatorial CO groups at the iron is probably due to the same reason: Fe–C41–O3 (≡Fe–C41'–O3') 174.0(4), Fe–C43–O2 173.7(6)°; as expected the angle Fe–C42–O1 is 179.9(0)°.
[12] Double [4+1] cycloaddition onto **2** is also achieved with azodicarboxylate; for this, the O=C–N=N unit of the latter reacts as a hetero-1,3-diene: pale yellow crystals, m.p. 189° (decomp.): ^{13}C NMR: $\delta = 47.4$ (m, 2 framework C), 68.5 (m, 2 framework C); ^{31}P NMR: $\delta = -10.3$ (s, broad, 2P), -6.7 (s, 2P).
[13] The more electrophilic *p*-tosylazide adds even at room temperature to the monotriazene [colorless crystals, m.p. 187 °C (decomp.)]. In $CDCl_3$ at the same temperature it decomposes slowly with loss of N_2 to the *p*-tosyliminotetraphosphacubane [colorless crystals, m.p. 211 °C; ^{31}P NMR: $\delta = 37.4$ (1P), 141.2 (3P)].
[14] The reaction of **2** with sulfur (in the presence of triethylamine), in which one to four thioxo groups can be introduced depending on the stoichiometry will be the subject of a future report.

Pronounced Conformational Changes in Sixfold Nitrogen-Functionalized Metacyclophanes: Syntheses and Crystal Structures of Two 1,10-Diaza[11]metacyclophanes**

By *J. Jens Wolff,* Stephen F. Nelsen, Douglas R. Powell,* and *Bernhard Nuber*

Many metacyclophanes are strained molecules that have received widespread attention.[1] For steric reasons, the central six-membered ring is forced into a boat conformation, particularly by small bridges. Therefore, many cyclophanes have not been prepared by direct annelation of the bridge, but by ring contraction, rearrangement of bridges, or formation of the benzene ring in the final step.[1] We and others have found the benzene core of tris(donor)-substituted 1,3,5-trinitrobenzene derivatives **1** to be strongly distorted into boat[2a–b, 3] or twist boat[2a–c] forms, mainly for electronic reasons. This propensity for bending could be put to advantage for the facile construction of sixfold nitrogen-functionalized metacyclophanes **3**. They would also be frozen in a boat form for steric resons, unlike compounds of type **1**, which exist as an interconverting mixture of boat and twist-boat forms in solution.[2c] Reduction of the nitro groups in **3**, however, should eliminate the electronic bias for a bent conformation, and **4** should be a strained molecule with an essentially planar benzene ring.[1] As a derivative of hexaaminobenzene, **4** should be easily oxidized and would yield stable cations on appropriate substitution.[4, 5] In this paper, we report on the preparations of **3a** and **4a**, as well as their X-ray crystallographic characterization.



By nucleophilic aromatic substitution of halogen in **2a** with 1,9-nonanediamine, metacyclophane **3a** was obtained in a surprisingly high yield of 67%, without use of special dilution procedures. By this method, a wide range of compounds of type **3** may be synthesized.[6] The X-ray analysis for **3a** (Fig. 1) yields a highly deformed central six-membered ring, adopting a nearly ideal[7] boat conformation; the sum of absolute dihedral angles[8] within the ring is 169.8(1.0)°. To our knowledge, this is the highest amount of distortion found in experimentally accessible cyclophanes and compounds of type **1**. The average length of 1.446(13) Å for the endocyclic C–C bonds is markedly larger than the expected value for benzene derivatives (1.39–1.40 Å); the exocyclic C–N bonds, however, are markedly shortened. For comparison, measured C–N bond lengths for hexakis(dimethylamino)benzene[5] are 1.440, and 1.480 Å for 1,3,5-trinitrobenzene;[9] the corresponding averaged C–N bond lengths in **3a** are 1.311(9) and 1.381(9) Å, respectively. A description of the electronic structure of **3a** is therefore weighted in favor of a [6]radialene form. An additional contribution from a quinoid resonance form is implied by the strong bond-length alternation within the ring: the bonds between C2 and C3, and C5 and C6 are shorter than the other C–C bonds by about 0.03 Å; C1–N1 is shorter than the other C–N(amino) bonds by 0.01 Å. In agreement, the piperidine nitrogen (N1) is planar (the average bond angle α_{av} is 120.0(8)°), and the

[**] Structures of Tris(Donor)-Tris(Acceptor)-Substituted Benzenes, Part 4. This work was supported by Prof. Dr. R. Gleiter (Heidelberg), Deutsche Forschungsgemeinschaft (through SFB 247), and the National Institutes of Health (GM 29549). J. J. W. thanks the Alexander-von-Humboldt-Foundation for a Feodor-Lynen, and the Fonds der Chemischen Industrie for a Liebig fellowship. We would also like to thank the referees for helpful comments. – Part 3: [2a].

two six-membered rings are not twisted relative to each other in order to achieve maximum quinoid donor–acceptor conjugation to the nitro group in *para* position (N4). The nitrogen atoms within the bridge are also in a planar environment. The double-bond character of these short C–N bonds will contribute to the increase in the barrier for ring inversions of the bridge and the unsaturated ring: on the NMR time scale at 298 K the molecule shows neither ring inversion of the "benzene" core – in contrast to **1** – nor ring flip of the cyclophane bridge[10] (in contrast to all-carbon bridged unfunctionalized cyclophanes[1]).

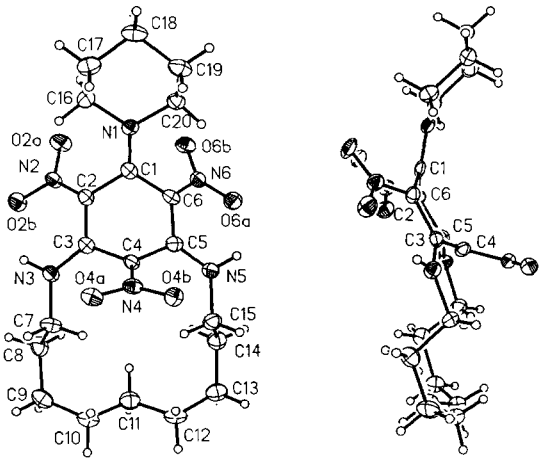

Fig. 1. Two ORTEP views of **3a**; the cosolvating dichloromethane molecules have been omitted for clarity. Selected bond lengths [Å], angles, and dihedral angles [°]: C1-C2 1.463(6), C2-C3 1.429(5), C3-C4 1.456(6), C4-C5 1.447(5), C5-C6 1.423(5), C6-C1 1.459(5), C1-N1 1.304(5), C3-N3 1.316(5), C5-N5 1.313(5), C2-N2 1.373(5), C4-N4 1.385(3), C6-N6 1.386(4); C1 → C3 115.7(3), C2 → C4 114.8(4), C3 → C5 117.5(3), C4 → C6 114.5(3), C5 → C1 116.4(3), C6 → C2 113.8(3); C1 → C4 − 0.5(4), C2 → C5 − 40.0(4), C3 → C6 37.2(5), C4 → C1 5.6(5), C5 → C2 − 44.8(4), C6 → C3 41.7(3).

The semiquantitative "cyanine concept"[11] for systems that evade aromaticity on electronic grounds (Jahn–Teller type distortions) predicts the decomposition of the benzene ring in **3** into two trimethine cyanine subunits. This pattern is frequently encountered in polyamino-substituted benzene dications,[5, 12] and leads to rings in a twist conformation with four short and two long bonds. However, a cross-conjugated quinone with two short and four long bonds is found in **3a** rather than one (at least formally) positively and one negatively charged trimethine cyanine unit, which might be expected in analogy to known structures. A twist conformation is not accessible to **3a** for steric reasons, which may explain the different behavior.[13]

Cyclophane **3a** was reduced catalytically, and the air-sensitive hexaaminobenzene derivative **4** thus formed was protected as its diacetate **4a**. Reduction of the nitro groups restores the aromatic system: **4a** (Fig. 2) contains a "normal" benzene ring with small deviations from planarity (sum of the absolute dihedral angles is 25.3(3.4)°). Nearly two thirds of this torsion is due to the relief of steric congestion resulting from the amino groups and the piperidine ring: the highest values for dihedral angles are found around the C1–C2 and C1–C6 bonds (Fig. 2). For the same reason, the piperidine nitrogen is in an almost planar environment ($\alpha_{av} = 118.3(1.5)°$), and the piperidine ring adopts a position perpendicular to the benzene nucleus. In agreement, the rotation of the piperidine ring around the C–N bound in **4a** is frozen on the NMR time scale at room temperature.[14]

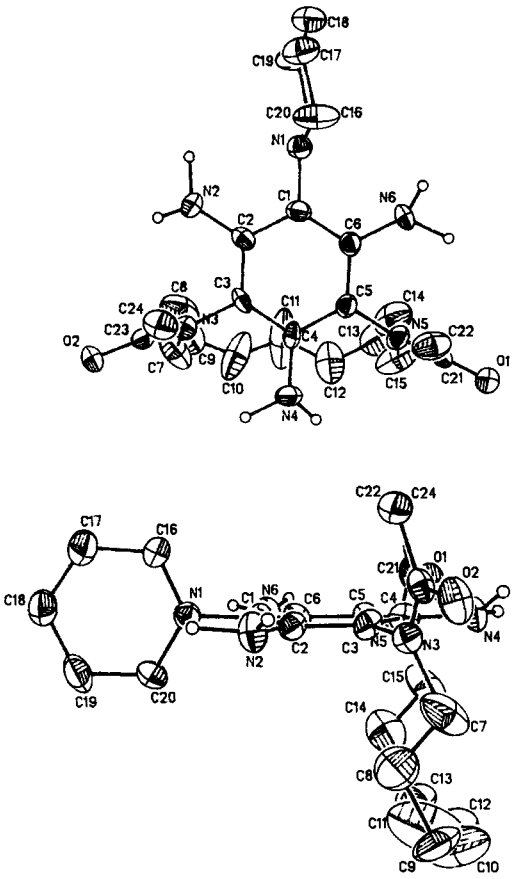

Fig. 2. Two ORTEP views of **4a**; the cosolvating, twofold disordered dichloromethane molecule has been omitted for clarity. Selected bond lengths [Å], angles, and dihedral angles [°]: C1-C2 1.398(15), C2-C3 1.431(16), C3-C4 1.397(13), C4-C5 1.407(14), C5-C6 1.428(16), C6-C1 1.397(14); C1-N1 1.454(15), C3-N3 1.440(13), C5-N5 1.437(12), C2-N2 1.389(13), C4-N4 1.399(15), C6-N6 1.386(14); C1 → C3 117.8(9), C2 → C4 123.0(9), C3 → C5 117.1(10), C4 → C6 121.5(8), C5 → C1 119.2(9), C6 → C2 120.9(11); C1 → C4 − 2.5(15), C2 → C5 − 2.8(14), C3 → C6 3.3(14), C4 → C1 1.7(14), C5 → C2 −7.3(14), C6 → C3 7.7(14).

Both **3a** and **4a** crystallize with inclusion of methylene chloride; cocrystals are often formed with compounds of type **1**.[2a] Work on cosolvates[15] of **1**, **3**, and **4** is in progress.

Experimental Procedure

All new compounds gave correct microanalytical data for C, H, N, Cl.

2a: From 1,3,5-trichloro-2,4,6-trinitrobenzene[16] by reaction with piperidine; m.p. = 196–197 °C (corr.). ^{1}H NMR ($CDCl_3$, 270 MHz): δ = 1.58 (br. m, 6H), 3.06 (br. m, 4H); ^{13}C NMR ($CDCl_3$, 68 MHz): δ = 23.18, 25.80, 52.10, 122.19, 140.58, 142.89, 145.93.

3a: Within two days a solution of 1,9-nonanediamine (395 mg, 2.50 mmol) and dry ethyldiisopropylamine (700 mg, 5.42 mmol) in dry CH_2Cl_2 (40 mL) was added under nitrogen to a stirred, refluxing solution of **2a** (902 mg, 2.47 mmol) in CH_2Cl_2 (300 mL). Heating was continued under reflux for 6 days. After workup, chromatography on basic alumina yielded cyclophane **3a** as a bright yellow powder; m.p. 250–251 °C (decomp., corr.) (740 mg, 1.64 mmol, 66.5%); ^{1}H NMR (CD_2Cl_2, 270 MHz): δ = 1.18–1.50 (m, 10H), 1.63–1.78 (m, 6H), 1.94 (br. m, 4H), 3.40 (ddt, J = 9.5, 14.2, 7.9 Hz, 2H), ca. 3.60 (br. m, 4H), 3.66 (dddd, J = 2.4, 5.9, 8.0, 14.0 Hz, 2H), 10.38 (br.d, J = 7.7 Hz, 2H); ^{13}C NMR (CD_2Cl_2, 68 MHz): δ = 22.23, 23.52, 25.16, 25.72, 26.03, 28.38, 48.55, 55.75, 103.82, 114.15 (double intensity), 152.13 (double intensity), 158.46. X-ray analysis: A yellow prism (0.20 × 0.30 × 0.50 mm) was grown from CH_2Cl_2. $C_{20}H_{30}N_6O_6 \cdot 2CH_2Cl_2$ (620.4); triclinic, $P\bar{1}$, a = 11.121(3), b = 11.560(5), c = 12.817(3) Å; α = 100.34(3), β = 103.12(2), γ = 113.87(2)°, Z = 2; $\varrho_{(calcd)}$ = 1.474 g cm^{-3}. Absorption coefficient = 4.342 mm^{-1}. $F(000)$ = 648. Diffractometer: Siemens P3f, $Cu_{K\alpha}$, −165(2) °C, highly oriented graphite crystal monochromator; 2θ range: 4.0–114.0°, scan type: Wyckoff, scan speed: variable 2.00–12.00° min^{-1} in ω; range: 0.40° (ω). 4194 reflections collected, 3779 independent (R_{int} = 0.0410), 3779 observed ($F > 4.0\sigma(F)$); no absorption correction. Solution by direct methods (Siemens SHELXTL PLUS

(VMS)[17]), full-matrix least-squares refinement. Hydrogen atoms: riding model, isotropic U. Weighting scheme: $\omega^{-1} = \sigma^2(F) + 0.0006F^2$; 345 parameters refined; final R indices (observed and all data): 0.00675 ($R_w = 0.00820$), Gof: 2.38, largest and smallest difference peak (residual electron density primarily around the CH_2Cl_2 molecules): 0.63 and -0.94 eÅ^{-3}.[18].

4a: A suspension of **3a** (300 mg, 0.666 mmol) in ethyl acetate (15 mL) was hydrogenated over 10% Pd/C (100 mg) for 5 days at 65 °C. Acetic anhydride (0.5 mL) was added, and the mixture filtered after 15 min. Chromatography on basic alumina gave the diacetate **4a** (202 mg, 0.454 mmol, 68%); m.p. 290–295 °C (decomp.); ^{1}H NMR ($CDCl_3$, 300 MHz): $\delta = 1.00-1.28$ (m, 8H), 1.33–1.58 (m, 8H), 1.67 (br. s, 4H), 1.93 (s, 6H), 3.01 (m, 4H), 3.66 (centered m, 4H), 3.74 (br. s, 2H), 4.02 (br. s, 4H), ^{13}C NMR ($CDCl_3$, 75.5 MHz): $\delta = 21.46$, 24.21, 25.10, 25.49, 25.94 (double intensity), 27.76, 27.80, 43.69, 50.97, 51.05, 105.02, 114.94, 138.55, 142.95, 173.55. – X-ray analysis: Colorless prisms were grown from CH_2Cl_2/light petroleum by the vapor diffusion technique, and a crystal of $0.15 \times 0.20 \times 0.25$ mm was selected. Slow evaporation of the cosolvating dichloromethane was observed. $C_{24}H_{40}N_6O_2 \cdot CH_2Cl_2$ (529.6); triclinic, $P\bar{1}$, $a = 10.82(1)$, $b = 10.99(1)$, $c = 13.21(1)$ Å; $\alpha = 94.6(7)$, $\beta = 103.28(7)$, $\gamma = 105.10(7)°$, $Z = 2$; $\varrho_{(calcd)} = 1.21$ gcm^{-3}. Absorption coefficient = 0.25 mm^{-1}, $F(000) = 568$. Diffractometer: Syntex R3, $Mo_{K\alpha}$, 25 °C, 2θ range: 3.0–43.0°, scan type: ω. 3403 reflections collected; 1750 with $F > 2.5\sigma(F)$; empirical absorption correction (5 reflections $9.5 < 2\theta < 38.5°$, transmission min. 0.79, max. 1.00). Solution by direct methods (Siemens SHELXTL PLUS (VMS) [17]), full-matrix least-squares refinement. Hydrogen atoms: riding model, isotropic U. 354 parameters refined; R indices (observed data): 0.095 ($R_w = 0.082$), Gof: 3.44, largest and smallest difference peak: 0.38 and -0.29 eÅ^{-3}. The crystal decomposed slightly during the measurement. [18].

Dynamic Motion in $[HFe(CO)_4]^-$ Ions as Observed by Mössbauer Spectroscopy—Evidence for Hydride "Tunneling"**

By *Gary J. Long,* Fernande Grandjean,* and *Kenton H. Whitmire*

Solution[1–3] and solid-state[4–8] MAS ^{13}C NMR spectroscopy (MAS = *M*agic *A*ngle *S*pinning) as well as Mössbauer spectroscopy,[9–11] have proven useful methods in revealing molecular dynamics in organometallic compounds and clusters. Herein, we report the first study of the dynamic motion of the iron atom in several salts containing the $[HFe(CO)_4]^-$ anion by Mössbauer spectroscopy. Hanson and Whitmire[8] have found that MAS ^{13}C NMR spectra of **1** and **2** show dynamic exchange of the axial and equato-

$[(Ph_3P)_2N][HFe(CO)_4]$ **1** $[Et_4N][HFe(CO)_4]$ **2**

rial carbonyl ligands in $[HFe(CO)_4]^-$. This exchange may result from either a Berry pseudorotation[12] or, perhaps more likely, from "tunneling" of the hydrido ligands within the anion ("tunneling" here refers to a change of position not to the tunnel effect in quantum chemistry). These authors reported an activation energy of 29 ± 3 kJ mol^{-1} for the axial–equatorial exchange in **2**. The displacement of the iron atom as determined by Mössbauer spectroscopy provides strong support for the existence of hydride tunneling in the anion.

The Mössbauer spectra at 78 K[13] of **1**, **2**, and the $[Me_4N]^+$ salt **3** are all very similar and show a single quadrupole doublet. In contrast the Mössbauer spectra at 295 K[14]

are quite different; **1** exhibits a quadrupole doublet, **2** exhibits a highly broadened absorption profile, and **3** gives no observable absorption spectrum at this temperature. The logarithm of the area beneath the absorption bands plotted against temperature (Fig. 1) reveals a departure from the expected linear behavior of the Debye model[10] above ca. 240 K for **1**, above ca. 220 K for **2**, and above ca. 180 K for **3**. The very small areas under the absorption bands, and hence recoil-free fractions, observed at higher temperatures, result from a motion of the iron atom. In the case of **2**, the temperature at which the onset of this motion occurs is coincident with the coalescence temperature for the signals of the equatorial and axial carbonyl ligands in the MAS ^{13}C NMR spectrum.[8] Unfortunately, the solid-state structures of **2**[8] and **3** are unknown, but the structure determination[15] of **1** at room temperature reveals that the $[HFe(CO)_4]^-$ ion has a structure which is intermediate between a hydride face-capped tetrahedron and a trigonal bipyramid in which the hydride occupies an axial position.

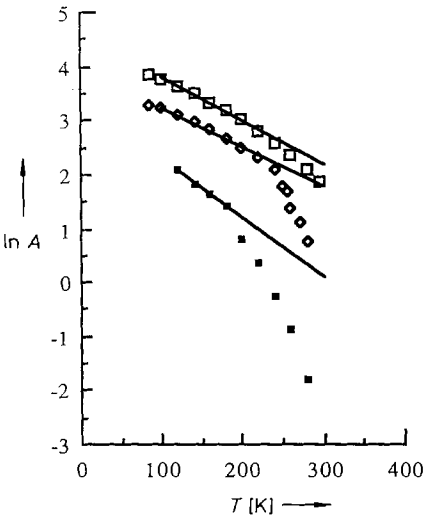

Figure 1. The temperature dependence of the logarithm of the area under the absorption band for **1** (□), **2** (◇), and **3** (■). The logarithmic scale has not been normalized and hence the relative values for the different compounds are arbitrary.

The dynamics of the iron motion, as reflected in the temperature dependence of the logarithm of the area under the absorption bands in the Mössbauer spectrum, may be treated in a fashion similar to that used to understand hydride diffusion in niobium.[16] The temperature dependence of the recoil-free fraction, which is proportional to the area under the absorption band, may be written as Equation (1), where

$$f_{eff}(T) = f_{vib}(T) f_{str}(T) \quad (1)$$

$f_{vib}(T)$ is the normal recoil-free fraction arising from lattice vibrations and $f_{str}(T)$ accounts for the loss of the area under the absorption band due to the local displacement of the iron center during the dynamic process. The magnitude of the dynamic displacements expected for the iron atom, f_{str}, is given by Equation (2), where k is the wavenumber of the

$$f_{str} = \exp(-k^2 \langle u^2 \rangle_{str}/3) \quad (2)$$

14.4 keV γ-ray and $\langle u^2 \rangle_{str}$ is the mean-square displacement of the iron atom. The linear behavior of the Debye model (see Fig. 1), between 85 and 240 K for **1**, 85 and 220 K for **2**, and 85 and 180 K for **3**, yields the Debye temperatures, θ_D, given in Table 1. This table also includes the effective recoil mass M_{eff}, which may be obtained from the temperature dependence of the isomer shift, and the resulting Mössbauer temperature.[10] The observed values of these parameters are

Table 1. Lattice properties of $[HFe(CO)_4]^-$ salts **1**–**3** derived from the Mössbauer spectra.

[a] Determined at 280 K. [b] Too few data points were available to obtain a reliable value. [c] A = area under the absorption bands (Fig. 1).

characteristic of organoiron compounds.[10] At higher temperatures $f_{vib}(T)$ can be calculated from the straight lines in Figure 1. The values of $f_{str}(T)$ and $\langle u^2 \rangle_{str}$ may be obtained from Equations (1) and (2), in conjunction with the measured area under the absorption band and the calculated $f_{vib}(T)$. The resulting root-mean-square iron displacements at 280 K are given in Table 1. In **2**,[15] the Fe–$C_{carbonyl}$ distance is approximately 1.7 to 1.8 Å, and hence the displacement of the iron atom observed at 280 K represents about 15% of the bond length. If we assume similar Fe–$C_{carbonyl}$ lengths in **1** and **3**, a very reasonable assumption, then the corresponding values would be 6 and 20%, respectively. The displacements of the iron atoms observed in **2** and **3** are far larger than would be expected for a Berry pseudorotation and strongly support the hypothesis of tunneling of the hydride ion between the faces of the tetrahedral or pseudotetrahedral $[Fe(CO)_4]$ moiety. This was proposed earlier by Hanson and Whitmire[8] on the basis of their MAS ^{13}C NMR results. A similar "tetrahedral tunneling" mechanism was proposed for the non-quantum mechanical tunneling of hydrido ligands without motion of the other ligands in several octahedral dihydridoiron complexes with phosphorus ligands.[17]

If we assume that the displacement of the iron atom is induced by the hydride tunneling, the change of $\langle u^2 \rangle_{str}$ with temperature[18] is proportional to $\exp(-\Delta E_{act}/k_B T)$, where ΔE_{act} is the activation energy for the displacement of the iron atom and hence for the tunneling. The corresponding activation energies for **2** and **3**, which were obtained from Figure 2, are given in Table 1. The activation energy of 29.2 kJ mol^{-1} for **2** is identical to the value determined from ^{13}C NMR spectroscopy,[8] but substantially smaller than those reported for the octahedral dihydroiron complexes.[17] The very large observed displacement of the iron atom strongly supports a hydride tunneling in preference to the alternate Berry pseudorotation[12] as the mechanism which exchanges the axial and equatorial carbonyl ligands in the solid state. We propose that, simultaneously with the tunneling of the hydrido ligand, the iron atom moves to one of the four apexes of a smaller, perhaps distorted, tetrahedron imbedded within the pseudotetrahedral environment of the carbonyl ligand.

For **2**, the shape of the absorption bands gradually changes from a narrow symmetric quadrupole doublet (85 K)[13] to a broad absorption band (295 K),[14] a broadening which can

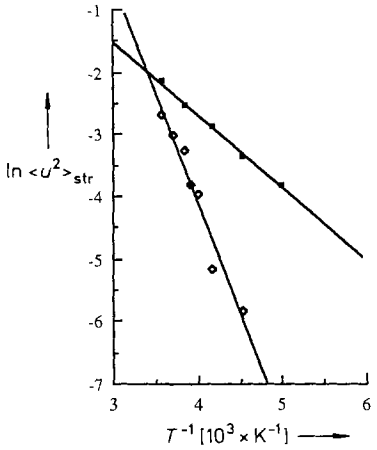

Figure 2. The logarithm of the mean square displacement of the iron atoms versus the reciprocal of the temperature for **3** (■) and **2** (◇).

be attributed to the previously discussed dynamic process. This behavior corresponds to a distinct increase in the symmetry of the electronic arrangement about the iron center, presumably because the hydride tunneling averages the electric field gradient at the iron center to zero. Thus it is possible to use the Tjon–Blume[19] model to fit the observed broadening of the absorption bands in the Mössbauer spectrum. The logarithm of the resulting rate of the dynamic process, versus the inverse temperature, gives an activation energy of 27 ± 3 kJ mol^{-1} for **2**. This value agrees rather well with the 29 kJ mol^{-1} obtained above, especially when one considers that the values are obtained in a completely different fashion. We are currently studying other salts of $[HFe(CO)_4]^-$ in an effort to understand the way in which different cations influence the tunneling process. Furthermore inelastic neutron scattering experiments with deuterated $[HFe(CO)_4]^-$ are planned.

Experimental Procedure

Compounds **1**, **2**, and **3** have been prepared by modifications of previously published procedures. [8, 20] The Mössbauer spectra were recorded as described earlier and the isomer shifts are reported relative to α-iron foil at room temperature. [11]

Molecular Modeling of the Class I Human Histocompatibility Molecule HLA-A2 Presenting an Allele-Specific Nonapeptide from Influenza Matrix Protein**

By *Norbert Zimmermann, Olaf Rötzschke, Kirsten Falk, Didier Rognan, Gerd Folkers, Hans-Georg Rammensee,* and *Günther Jung**

Dedicated to Professor Dietrich Brandenburg on the occasion of his 60th birthday

MHC Class I proteins (*M*ajor *H*istocompatibility *C*omplex) are found on the surface of most human cells. In the immune system their function is to present fragments of proteins of the inside of the cell in an antigen binding pocket to the killer cell receptor. Fragments of endogenous proteins (self peptides) are processed and presented when the cell is healthy. If the cell is attacked by viruses, the cytotoxic T-lymphocytes (CTLs or killer cells) recognize the fragments of foreign viral proteins (CTL epitopes) in the MHC antigen binding pocket and destroy the affected cell. The X-ray crystal structure analysis of the human class I histocompatibility antigen HLA-A2[1] shows an antigen binding site composed of two parallel α-helical domains α_1 and α_2, which are connected with a central antiparallel β-sheet. This forms a deep groove with six prominent pockets, the function of which is thought to be the binding of amino acid side chains of antigenic peptides. Furthermore, the residual electron density found in the peptide binding cleft is assumed to be a mixture of peptides cocrystallized with HLA-A2.

Recently, we found allele-specific oligopeptide motifs by sequencing of self-peptides eluted from MHC I proteins.[2] Alignment of viral proteins with the dominant hydrophobic anchor residues at positions 2, 6, and 9 of the HLA-A2 self-peptides suggested that the nonapeptide GILGFVFTL (from influenza matrix protein) was a candidate for a naturally processed antigenic peptide (Table 1). This nonapeptide was used to model a MHC peptide complex based on the

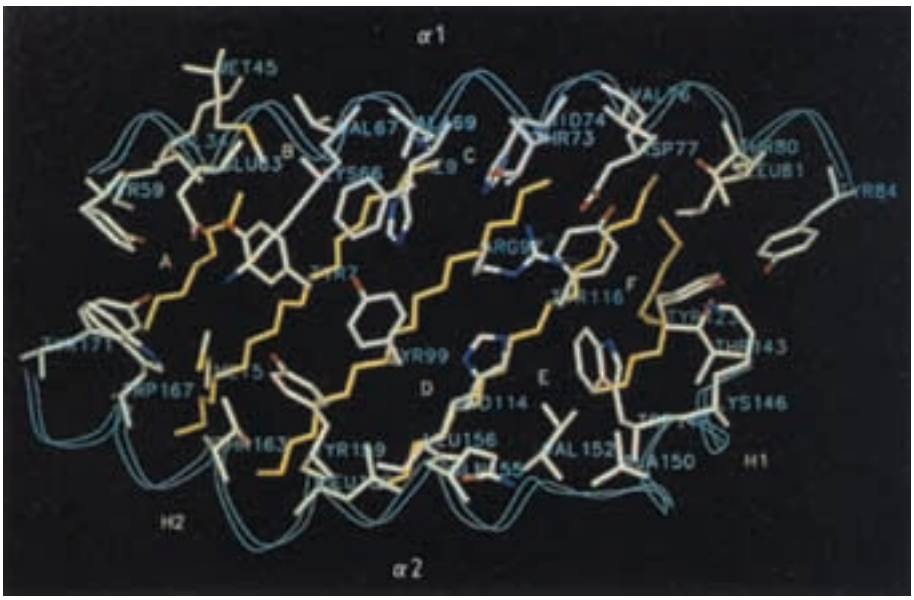

Fig. 1. The HLA-A2 peptide binding site consists of the two α-helical subsites α_1 and α_2 (shown in light blue), and a central antiparallel β-sheet (shown in yellow). All solvent-accessible side chains are indicated by colors typical for those atoms. Prominent binding pockets for antigen side chains are indicated with the letters A to F [1].

subsites derived from the crystal structure of HLA-A2.[1] A molecular dynamics simulation (over 28 ps) in aqueous solution[3–5] was performed to examine the stability and mobility of the constructed complex and to find out the potential recognition sites of the T-cell receptor (TCR).

Starting from the minimized β-sheet conformation for the influenza epitope, we first modeled the hydrophobic interactions of the dominant anchor positions (Ile2 and Leu9), corresponding to the B and F pockets of the HLA-A2 structure (Figures 1–3).[1] Ile2 is located in the hydrophobic B pocket and is surrounded by the allele-specific Met45, Val67, and Phe9 residues. The side chain of Leu9 was modeled in the F pocket of the HLA-A2 molecule, which is bordered by the hydrophobic residues Trp147 and Ile124. The carboxylate function of the *C*-terminus of the antigen Leu9 was docked next to the positively charged Lys146, which is highly exposed and leads from the α-helical "rim" directly towards the binding groove. Strikingly, Lys146 is the only positively charged amino acid in the HLA-A2 binding site which is *not* neutralized with a negatively charged side chain to form a stable salt bridge, as is normally found in globular proteins. Therefore Lys146 is usually predestined to anchor the *C*-termini of the antigenic nonapeptides.[6] In addition, Lys146 is well conserved in both human and mouse MHC class I molecules and could serve as a common binding residue for the charged *C*-termini of T-killer cell epitopes.

Table 1. The HLA-A2 restricted peptide motif as analyzed from the sequencing of HLA-A2 bound self-peptides [2]. Corresponding nonapeptides from protein sequences of viral origin are shown in comparison. The influenza matrix protein sequence most probably represents the natural epitope and was therefore chosen for modeling.

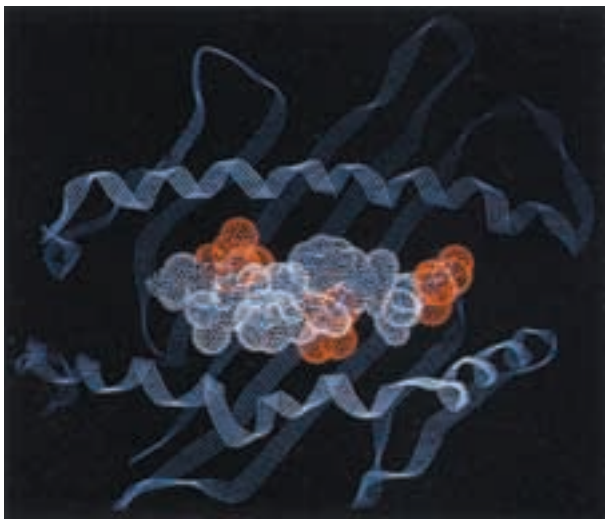

Fig. 2. The nonapeptide CTL epitope GILGFVFTL from influenza matrix protein was modeled into the binding groove of HLA-A2 and additionally minimized as an initial conformation for molecular dynamics simulation. The backbone of the HLA-A2 molecule is shown as a white ribbon while the CTL antigen (with prominent anchor residues Ile2, Val6, and Leu9) is shown as a dotted van der Waals surface (in red).

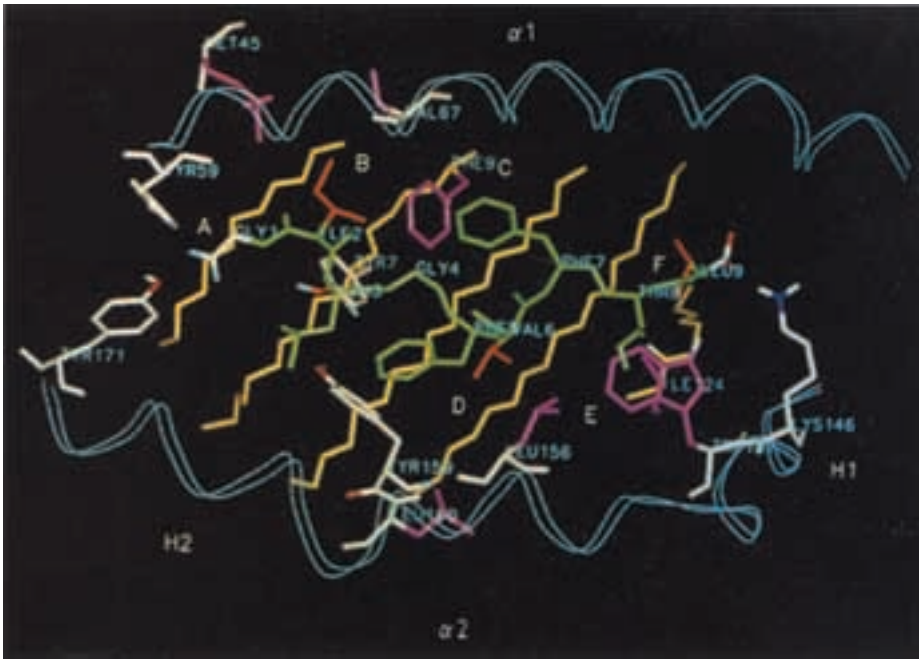

Fig. 3. The detailed model of the complex between HLA-A2 and the GILGFVFTL peptide shows the essential interactions between the prominent HLA binding sites and the CTL epitope. The conserved Ile2, Val6, and Leu9 side chains of the antigen (shown in red) are inserted in pockets B, D, and F, respectively (shown in purple). Pockets C and E remain free. The Leu9 carboxyl group interacts with Lys146, the *N*-terminal amino group with Tyr59 and 171.

According to the results from sequencing self peptides,[2] positions 7 and 8 in the HLA-A2 peptide binding motif are variable. The backbone and side chains of the corresponding Phe7 and Thr8 residues of the influenza epitope were modeled with respect to the minimum interaction energy for optimized hydrogen bonds and van der Waals contacts.

Val6 is an auxiliary anchor residue which was modeled into the hydrophobic D pocket of HLA-A2.[1] This pocket is surrounded by the side chains of Leu156, Leu160, and the rings of Tyr159 and Tyr99, in agreement with a strong peak of residual electron density in this region.[1, 6a] The backbone of the nonconserved residues Phe5, Gly4, and Leu3 has to adopt an extended conformation with a kink between the residues 4 and 5, because the overall length of the peptide's backbone is too long to connect the conserved anchors Ile2 and Val6 with their corresponding pockets (B and D) directly. The conformation of the peptide within this region also corresponds well to the shape of the residual electron density.[1] For this reason, this extended and most exposed part of the antigen should be able to bind to the T-cell receptor (TCR).

The variable, positively charged *N*-terminus of the GILGFVFTL antigen was modeled into the pocket A, forming a hydrogen bond network between the conserved HLA amino acid residues Tyr7, Tyr59, Tyr159, and the variable Tyr171. The pocket A is large enough to accomodate bulky amino acid side chains.

The first conformation of the molecular dynamics simulation was extracted at 1 ps in order to check abrupt changes in geometry due to inappropriate van der Waals interactions resulting from docking before reaching the equilibrium. No significant alteration of the system was observed. The analysis of the trajectories and the energy values of the complex did not show any principle deviation from the proposed nonapeptide–HLA-A2 binding interactions.

As an alternative to the *extended* antigen conformation, we tried to simulate GILGFVFTL in an *α-helical* conformation in the HLA-A2 binding pocket according to published models and suggestions.[7] However, the α-helical conformations neither fitted with the observed shape of the residual electron density,[1] nor did they agree with the geometry of the binding pocket of HLA-A2. The antigen in the α-helical conformation was modeled in such a way that the residues Ile2, Val6, and Leu9 pointed towards the binding pocket and were placed in the hydrophobic pockets as effectively as possible, whereas the three bulky Phe5, Phe7, and Leu3 "epitope residues" pointed towards the TCR recognition site. However, in all the molecular dynamics simulations with α-helical conformations we observed a progressive shift of the antigen out of the binding pocket, suggesting that peptide antigens in α-helical conformations are not able to bind efficiently to the HLA-A2.

In the molecular dynamics simulation with the *extended* conformation of the antigen, both the *C*- and *N*-terminal electrostatic anchor positions 1 and 9 and also the hydrophobic antigen anchors of the side chains in the positions 2, 6, and 9 remain stable with respect to their positions from the crystal structure analysis (Fig. 4), whereas residues 3 to 5,

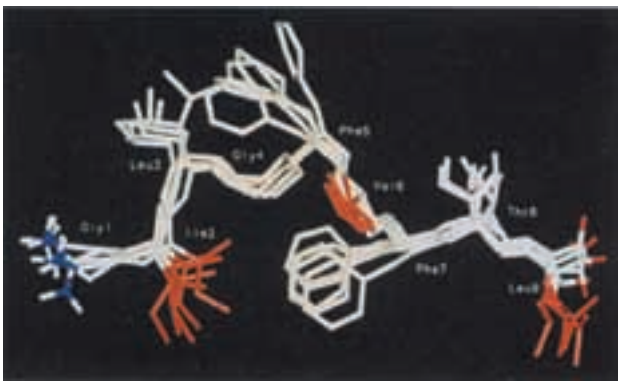

Fig. 4. Overlay of five potential energy minimum conformations of CTL epitope at 1, 7, 12, 14, and 28 ps of molecular dynamics simulation. The RMS deviation between the initial conformation and the molecular dynamics simulation snapshots equates to 0.81, 0.65, 0.81, 1.02, and 0.88 Å for the antigen and to 2.09, 2.09, 2.26, 2.52, and 2.66 Å for the whole HLA-A2 antigen complex.

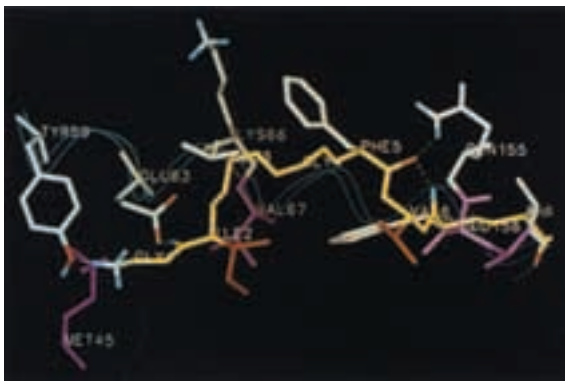
which point towards the T-cell receptor show the expected greater mobility. Two relevant motions observed during the simulation of the HLA-A2 antigen system seemed to be remarkable (Fig. 5a,b): i) The side chain of Leu9 moves towards the middle of the pocket F, a position which is obviously energetically more favorable and also in agreement with the maximum residual electron density at this location.[1] ii) The salt bridge between Glu63 and Lys66 breaks after about 7 ps, following which Glu63 interacts with the polar backbone atoms of Ile2 and Gly1 (12 ps) and finally docks at the charged *N*-terminus of the antigen, forming a hydrogen bond network together with the conserved Tyr residues of the A pocket (28 ps). The loop region between the two α-helical HLA subsites H1 and H2 of the α_2 domains at position Ala150 represents the most exposed point of the HLA structure. This region, in combination with the Gly162 loop, could be responsible for TCR recognition of peptide-loaded MHC molecules.

a)



b)

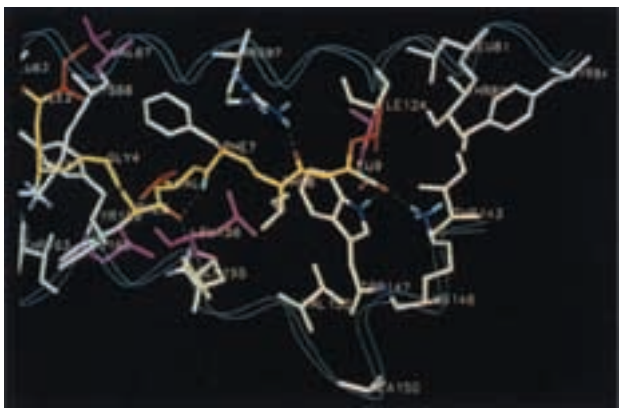


Fig. 5. 12 ps snapshot of molecular dynamics simulation. a) The *N*-terminal amino group of the CTL epitope interacts with Tyr59. Hydrogen bonds are formed between the carbonyl group of Phe5, the Gln155 side chain and the HN proton of Phe7. The antigen backbone is shown in yellow while the B and D pockets are indicated in purple. b) The *C*-terminal carboxyl group of the CTL epitope shows a hydrogen bond network between the positively charged Lys146 residue and Trp147. The carboxyl group of Thr8 is hydrogen-bonded to Arg97.

Summarizing the modeling procedure: Our model of the HLA-A2 antigen complex is in full agreement with the experimental results for HLA-A2[1, 2] and HLA-B27[6] peptide complexes. The maxima of the residual electron density found at the beginning and end of the HLA-antigen binding position reflect the electrostatically fixed *N*- and *C*-termini of the bound antigens. Additionally, the geometry, charges, and the residual electron density peaks of the HLA-A2 pockets A, B, D, and F[1] fit precisely with the prominent anchor residues of our HLA-A2 restricted peptide motif.[2] The charged termini of the antigen in our model are in suitable positions to interact with polar (Tyr59 and Tyr171 at *N*-terminus) and charged (Lys146 at *C*-terminus) HLA amino acid residues at the extreme end of the cleft. Also, all important anchor binding sites are either conserved or at least allele specific in the HLA system. Furthermore, the structure of the antigen backbone between Val6 and Ile2 of the influenza epitope corresponds to the shape of the residual electron density found in this region.[1] Finally, the total length of residual electron density between the *N*- and *C*-terminal link[6] is in agreement with an extended nonapeptide conformation, which is consistent with the length of the self peptides sequenced in our laboratories.[2]

Molecular dynamics investigations of the HLA-A2 antigen complex in aqueous solution revealed the stability of the modeled antigen binding sites and also indicated possible TCR binding sites. Our model, fully supported by experimental results,[2, 6] appears to serve as a basis for site-directed mutagenesis and for labeling experiments, with which the proposed interactions could be confirmed and which should be beneficial for the development of drugs and synthetic vaccines[8] targeted for specific interaction with MHC class I molecules.

[3] Interactive model building was done with the program package SYBYL 5.4 (Tripos, St. Louis, MO, USA) running on a VAX 3500 connected with Evans & Sutherland PS390 and PS350 graphic terminals. Minimization and dynamics simulation of the generated structures was performed with the AMBER 3.0 software [3b] installed on a CONVEX C220 vector computer. For analysis of the generated trajectories from molecular dynamics simulation, we used the animation program ADAPTU [3c] also linked to the Evans & Sutherland graphic stations; b) S. J. Weiner, P. A. Kollman, D. A. Case, C. Singh, C. Ghio, G. Allagona, S. Profeta, P. Weiner, *J. Am. Chem. Soc.* **1984**, *106*, 765–784; c) M. Krug, G. Folkers, *J. Mol. Graphics* **1991**, 119–121.

[4] The three-dimensional HLA-A2 crystal structure at 2.6 Å [1] was retrieved from the Brookhaven Protein data base (F. C. Bernstein, T. F. Koetzle, G. J. B. Williams, E. F. Meyer, Jr., M. D. Brice, J. M. Rodgers, O. Kennard, T. Shimanouchi, M. Tasumi, *J. Mol. Biol.* **1977**, *112*, 535–542, file 3HLA). Due to limited computer resources, only the α_1 and α_2 domains of HLA-A2 from Gly1 to methylamidated Thr182 were taken into account for calculations. In order to simulate the HLA-A2 antigen complex in a waterlike solvent environment, we first minimized the HLA-A2 crystal structure using the AMBER united atom force field for proteins and the TIP3P water model for solvent simulation. A water shell consisting of 1728 water molecules was generated around the HLA solute. Since every single water molecule was calculated explicitly, the dielectric constant during the simulation was set to 1.0. The parameters of 1,4 nonbonding atoms were scaled to 8.0 for Lennard–Jones and 2.0 for electrostatic interactions in order to reproduce "big AMBER" parameters [7]. The partial charge of the oxygen atom in the TIP3P water (Monte Carlo water shell) was set to −0.66. All water molecules more than 5 and less than 1.5 Å from the solute were discarded from the system. After 200 steps of steepest descent minimization a 2000 step minimization according to the conjugate gradient method resulted in a suitable structure ready for docking the influenza epitope GILGFVFTL. Docking was performed interactively, utilizing special SYBYL functions to obtain the optimal HLA-A2 antigen interaction energies, distances, and torsion angles.

[5] In order to examine the stability and mobility of the constructed MHC antigen complex, we performed a 28 ps molecular dynamics simulation in aqueous solution. After minimizing the complex with the protocol [4], Newtons equations of motion were integrated for more than 5000 atoms at a time step of 1 fs, also with AMBER united-atom force field parameters and TIP3P water conditions. Nonbonded interactions were calculated with a residue-based cutoff distance of 10 Å. The list of nonbonding pairs

of atoms was updated every 100 integration steps. Initial random velocity setup of the system was taken from a Maxwell distribution at $T = 300$ K. The simulation temperature was kept constant by coupling the system to a simulated heat bath, rescaling the velocities with a temperature relaxing time of $t = 0.4$ ps. Coordinates and energies were stored on disk after every 100 integrations steps (0.1 ps) resulting in 284 distinct conformations. Evolution of the system's potential energy shows equilibrium conditions after about 14 ps. Extracted conformations were additionally energy minimized to remove the kinetic energy of the system.

[6] a) Nevertheless, as shown in a previous modeling study docking a nonapeptide into the binding cleft of HLA-B27 [6b], there is a certain probability to dock residue 3 into pocket D. However, that docking scheme does not agree with our sequencing results for HLA-A2. Residue 3 of the peptide antigen is not conserved and therefore not predestined for docking in the hydrophobic D pocket. Further modeling studies with different docking schemes may reveal the location of antigen residue 6 more precisely. b) After preparation of this manuscript similar interactions were found modeling a nonapeptide into the binding site of HLA-B27: D. Detection of Subpicomole Levels of Compounds Containing Hydroxyl and Amino Groups with the Fluorogenic Reagent, 2-Naphthoylimidazole**

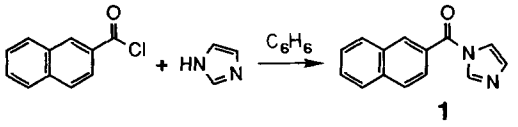
By *Norihiro Ikemoto, Lee-Chiang Lo,* and *Koji Nakanishi**

Highly sensitive methods for the identification of natural products such as oligosaccharides have become increasingly important with the advances in the biosciences. A commonly employed strategy is HPLC analysis following derivatization with a chromophore. Among the various chromophores used to derivatize amino and/or hydroxyl groups,[1] benzoylation[2, 3] has attracted attention because of the strong UV absorbance of the chromophore, ease of derivatization, and stability of the derivatives. The 2-naphthoate chromophore,[4] however, not only possesses these attributes but also exhibits fluorescence, a feature that dramatically enhances sensitivity. To demonstrate the advantages of using this chromophore, we have investigated its application to sugar analysis.

Most methods for compositional analysis of oligosaccharides involve derivatization of the monosaccharides obtained after acid hydrolysis.[3, 5] In the present microscale method, this derivatization scheme consists of a reduction/naphthoylation sequence (Scheme 1, bottom), which was performed on an artificial mixture of nine monosaccharides most commonly encountered in bioconjugates. The resulting alditol pernaphthoates have UV maxima at 234 nm and possess large ε values (in acetonitrile): 254000 for hexanaphthoates and 220000 for pentanaphthoates, that is, 43000 per naphthoate chromophore, a value three times larger than that of the benzoate. Furthermore, the naphthoates exhibit strong fluorescence at 374 nm upon irradiation at 234 nm, which enhances the sensitivity of detection.



aldoses $\xrightarrow{NaBH_4}$ alditols $\xrightarrow[CH_3CN]{1,\ DBU}$ alditol pernaphthoates $\Rightarrow$ HPLC

Scheme 1. Preparation of naphthoyl imidazole (**1**) and the derivatization/analysis scheme. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

The microscale naphthoylation reaction was performed with 2-naphthoylimidazole (**1**, Scheme 1 top) prepared according to a procedure given for cinnamoylimidazole;[6] the latter reagent has proven to be an excellent reagent for the microscale acylation of acyclic polyols.[7] The pernaphthoylation of alditols and other natural products[8] on a 10 nmol scale occurred rapidly and completely, and only minimal amounts of reagent-derived impurities were formed; in contrast, reactions with 2-naphthoyl chloride, pyridine, and dimethylaminopyridine (DMAP) were slower, required heating, and yielded more extraneous impurity peaks. Prepurification of samples of biological origin prior to derivatization and HPLC analysis minimizes the contaminants of biological origin that may have similar spectroscopic characteristics. Figure 1 shows the chromatogram with about 0.4 pmol of sample injected and monitored with a fluorescence detector (see Experimental). The nine alditol naphthoate derivatives are well resolved on a silica gel column. The absence of incomplete derivatization products in the chromatogram indicates high conversion at the 10 nmol scale.[9] The detection limit is about 0.1 pmole (signal-to-noise ratio S/N $\approx$ 5). Because of the high absorption coefficient of 2-naphthoates and multiple derivatization on each

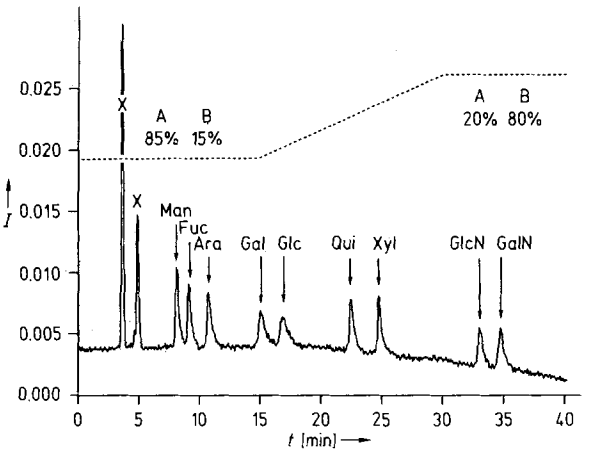


Fig. 1. Chromatogram of ca. 0.4 pmole of pernaphthoate derivatives of mannitol, fucitol, arabitol, dulcitol, sorbitol, quinovitol, xylitol, glucosaminitol, and galactosaminitol (X represents reagent-derived impurities). Solvent A: 0.025% 2-propanol/dichloromethane. Solvent B: 4% acetonitrile/0.025% 2-propanol/dichloromethane. Flow rate: 1 mL min^{-1}. Column: YMC silica gel (4.6 × 250 mm^2, 5 μm). Absorption at 234 nm, Emission intensity I at 374 nm.

[**] This work was supported by National Institutes of Health grants (GM 34509 to KN and 5F32CA08972 to NI). We thank Shaman Pharmaceuticals, Inc. for the use of their fluorescence detector and Bristol-Myers Squibb Company for the use of their beam condenser for CD measurements.

sugar, high sensitivity can still be achieved with UV detection (down approximately to the 1 pmole level, S/N ≈ 2), although it is an order of magnitude less sensitive than fluorescence detection.

Although alditol benzoates have been reported to show poor separation with reverse phase HPLC,[3] the alditol naphthoates could be well separated by normal phase HPLC. Diastereomers differing by one stereocenter, for example, sorbitol/mannitol/dulcitol, xylitol/arabitol, fucitol/quinovitol, and glucosaminitol/galactosaminitol are all well resolved. The amino alditols galactosaminitol and glucosaminitol are retained more strongly by the column than the oxygen sugars and are eluted last. In addition to their higher sensitivity of detection, the good HPLC separation of these 2-naphthoate derivatives offers an important advantage over the use of the benzoate chromophore.

When two or more 2-naphthoate chromophores are present in chiral compounds, exciton coupling interactions are often observed by circular dichroic spectroscopy (CD).[10] The resulting CD curve not only reflects the stereochemistry of the molecule but can be used as an additional handle for structural identification. With the use of a CD beam condenser and a microcell (100 μL, 1 cm), compounds bearing 2-naphthoate chromophores have yielded distinct CD spectra with 50 pmole of sample; ten times more sample is required with a regular CD cell (1 mL, 1 cm).

In conclusion, the advantages of the 2-naphthoate chromophore are evident in the ease of derivatization, the high sensitivity of detection, the good chromatographic behavior, and the possibility of further CD characterization.

Experimental Procedure

Preparation of **1**: Imidazole (0.71 g) was suspended in benzene (40 mL) and cooled to 8 °C. A solution of 2-naphthoyl chloride (1.0 g) in benzene (10 mL) was added dropwise over 10 min, and the mixture stirred for 1 h at room temperature. The reaction mixture was filtered through Celite and lyophilized to afford the product (1.2 g, quantitative).

Mannose, fucose, arabinose, galactose, glucose, quinovose, xylose, glucosamine hydrochloride, and galactosamine hydrochloride (5 μmol each) were stirred for 2 h at room temperature with $NaBH_4$ (10 mg) in water (1 mL). The reaction was quenched with aqueous HCl, and the resulting mixture evaporated six times with methanol. An aliquot (10 nmol of each sugar) was stirred in acetonitrile (0.2 mL) with **1** (10 μmol) and DBU (10 μmol) for 2 h at room temperature. After quenching with water, an aliquot (2 nmol) was evaporated in a silanized test tube. The residue was dissolved in dichloromethane, and aliquots were injected for HPLC analysis [11] (Perkin-Elmer Series 4 Liquid Chromatograph and 7500 Data Station, Shimadzu RF-551 Fluorescence HPLC Monitor).

Tetramethyl-*ortho*-quinodimethane, First Member of a Family of Custom-Tailored Cheletropic Spin Traps for Nitric Oxide**

By *Hans-Gert Korth**, *Keith U. Ingold**, *Reiner Sustmann*, *Herbert de Groot*, and *Helmut Sies*

Nitric oxide, •NO, has been shown to be an intra- and intercellular signal molecule; it regulates vascular tone, is a messenger molecule in the central nervous system, and mediates cytotoxicity of macrophages (see reviews[1–4]). Even if •NO is not itself the "Endothelium Derived Relaxing Factor" (EDRF),[5] it certainly appears to be the active agent released by the EDRF. Nitric oxide also plays an important role in air pollution arising from photochemical and/or combustion processes. Because of the well-recognized importance of •NO, some rather sensitive methods have been developed for its identification and quantitation,[4] for example, the spectrophotometrically monitored •NO-induced conversion of oxyhemoglobin (HbO_2) to methemoglobin (MetHb) [Eq. (a)], monitoring its vasorelaxant activity on arterial segments, and in the gas phase, its chemiluminescent reaction with ozone [Eq. (b)].

$$HbO_2 + {}^{\bullet}NO \longrightarrow MetHb + NO_3^- \qquad (a)$$

$$O_3 + {}^{\bullet}NO \longrightarrow O_2 + {}^{\bullet}NO_2^{*} \longrightarrow {}^{\bullet}NO_2 + h\nu \qquad (b)$$

Nevertheless, despite all this effort there is as yet no method that, even in principle, would be suitable for monitoring •NO production continuously, both *in time and in space*, in cell cultures, perfused organs, and living organisms. The most attractive route to this objective appeared to be a chemical reaction by which •NO (itself a persistent radical) could be converted into a persistent nitroxide radical. The

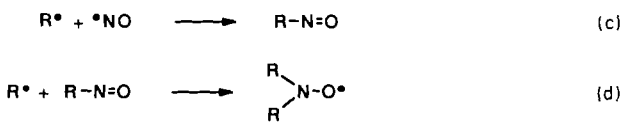
[**] Issued as NRCC No. 33282. We thank Dr. J. C. Scaiano, Ottawa, for a sample of **3** which permitted the initial experiment to be carried out, Prof. A. L. J. Beckwith, Canberra, for a sample of TMIO, and Ms L. Hughes, Ms P. Lommes, and Mr. J.-F. Wang for valuable experimental help. One of us (K. U. I.) wishes to thank the Alexander-von-Humboldt-Stiftung for an Award which gave him both the leisure and the incentive to think about the ways in which nitric oxide might be trapped and imaged in biological systems.

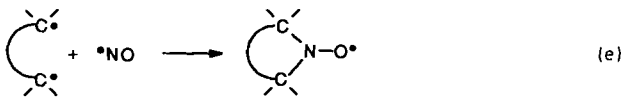
latter could be monitored, quantitated, and imaged by electron spin resonance (ESR) spectroscopy.

Conventional nitrone and nitroso spin traps have proved to be essentially useless as traps for 'NO.[6] This is hardly surprising in view of the very low reactivity of 'NO towards molecules in their ground (singlet electronic) states.

It is well known that 'NO reacts rapidly with carbon-centered radicals to form nitroso compounds[8] [Eq. (c)] and that nitroso compounds are good spin traps for carbo-centered radicals[9] [Eq. (d)].



Conceptually, therefore, a biradical reacting in a cheletropic manner would be an effective 'NO trap, and indeed triplet biradicals have been trapped by 'NO and have formed cyclic nitroxide radicals[10] [Eq. (e)].

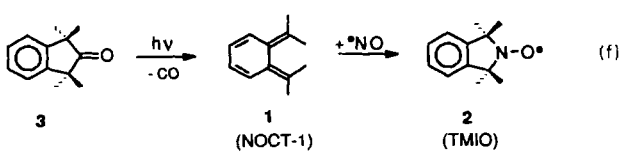


Unfortunately, biradicals with a structure suitable for 'NO trapping are inherently short-lived, with lifetimes generally shorter than 1 μs.[11] Furthermore, they react very rapidly with oxygen.[11, 12]

A double carbon-centered "*biradical equivalent*" was obviously required. This equivalent must react rapidly and efficiently with 'NO to form a persistent, cyclic dialkylnitroxide, but it must not react (at a significant rate) with O_2. Furthermore, the basic structure of the biradical equivalent should be able to be readily elaborated. Such elaboration is necessary so that specific 'NO traps can be synthesized which would be, for instance, water- or lipid-soluble, excluded from or able to pass through cell membranes, or anchored to the surface of a membrane or within the membrane. A family of such 'NO traps would allow the detailed ESR imaging in time and space of 'NO formation under physiological conditions.

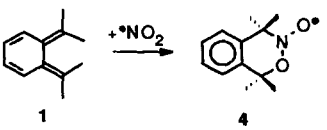
1,2-Bis(*exo*-isopropylidene)cyclohexa-3,5-diene (=7,7,8,8-tetramethyl-*o*-quinodimethane) (**1**) seemed likely to meet the foregoing criteria. This compound has lived up to our hopes of creating a custom-tailored double (cheletropic) spin trap for 'NO; that is, it reacts efficiently with 'NO to produce the expected 1,1,3,3-tetramethylisoindolin-2-oxyl radical (TMIO) (**2**). We have therefore christened it NOCT-1 (*N*itric *O*xide *C*heletropic *T*rap 1). Nitroxide **2** is a radical eminently suitable for quantitative ESR measurements since it is completely stable at ambient temperatures and can be synthesized as a pure compound.[13]

The *o*-quinodimethane **1** was synthesized by photodecarbonylation of 1,1,3,3-tetramethyl-2-indanone (**3**) in pentane, hexane, or acetonitrile solution[14] [Eq. (f)].



The *o*-quinodimethane **1** is a rather short-lived intermediate (half-life at 20 °C about 9 min[15]), which was not, therefore, separated from the reaction mixture.[16] Fortunately, separation proved unnecessary because the unchanged ketone **3** and the major photolysis product, *o*-isopropyl-α-methylstyrene, were both inert toward 'NO.

On mixing a cold, dilute (approximately 10^{-3} M) deoxygenated solution of **1** in an organic solvent with dilute (10^{-2}–4×10^{-5} M) deoxygenated solutions of 'NO (in the same organic solvent), the characteristic three-line ESR spectra arising from two different nitroxide radicals were produced "instantaneously" (i.e., within the time required to start the recording; ca. 1 min). Comparison with the ESR spectrum of authentic **2**[13] under identical conditions proved that one spectral component was indeed due to **2**, since it exhibited exactly the same nitrogen hyperfine splittings and *g* values in the various solvents (e.g., $a_N = 1.452(3)$ mT, $a_{^{13}C} = 0.630(5)$ mT ($4\ ^{13}C$), $g = 2.00589(1)$ in acetonitrile; 14 °C). Thus, 'NO has been trapped according to Equation (f).[17] The second nitroxide signal displayed the characteristic features ($a_N = 2.712(5)$ mT, $a_{^{13}C} = 0.77(1)$ mT ($1\ ^{13}C$), $g = 2.00565(1)$) of an alkoxynitroxide radical. We tentatively assign this spectrum to the nitroxide radical **4**, which would imply that $^{\bullet}NO_2$[18] has also been trapped by **1** [Eq. (g)].



We next employed **1** to monitor 'NO formation by cultured liver macrophages, the *Kupffer cells*. The Kupffer cells were isolated by collagenase perfusion of the liver from male Wistar rats as described previously.[19, 20] In a first series of experiments, approximately 1.5×10^{-7} moles of **1** in 0.2 mL of CH_3CN were injected directly into the buffer solution above the Kupffer cells.[21] After incubation at 37 °C for times between 5 and 60 min, the medium was extracted with 0.8 mL of *n*-hexane, the hexane layer transferred into an ESR quartz tube, and the oxygen removed by bubbling with argon. From all solutions we detected the characteristic ESR signals of **2** (Fig. 1).[22] Despite the relatively unfavorable conditions of this experiment, which arise from the short lifetime of **1** and its negligible solubility in water, the very fact that we could easily detect signals due to **2** shows that we are dealing with a very effective and rapidly reacting cheletropic trap for 'NO. After 30 min[22] the total yield of nitroxide **2** in hexane was about 0.025 nmol,[23] which, in view of the known rate of production of 'NO by Kupffer cells under these conditions (approximately 0.40 nmol per tube in 30 min),[21] implies that we had succeeded in trapping about 6% of the 'NO produced.[24]

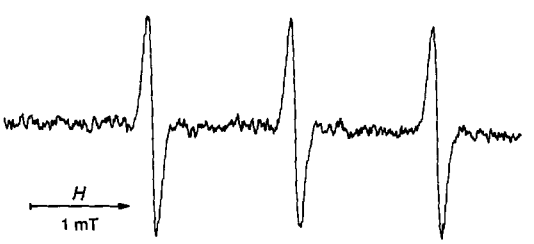


Fig. 1. ESR spectrum (9.5 GHz, *n*-hexane, 14 °C) of **2** obtained after 30 min incubation of Kupffer cells in the presence of **1**.

In a second series of experiments, the same quantity of **1** was added to about 1 mL of *n*-hexane, which was then floated on the aqueous buffer above the cells. The cells were incubated for the same periods of time, and although the $^{\bullet}NO$ had to diffuse through the water layer (ca. 2 mm) to reach **1** in the hexane layer, the ESR spectra characteristic of **2** were obtained, but considerably weaker than in the first series.

Because of its specific physical and chemical properties, NOCT-1 (**1**) is certainly not a practical reagent for monitoring $^{\bullet}NO$ production in biological systems under physiological conditions. However, our intention was simply to show that $^{\bullet}NO$ is trapped by **1** and hence that **1** provides a reasonable basis for the development of a family of structurally related NOCTs. We can safely assume that a water-soluble and longer lived NOCT would be more suitable for $^{\bullet}NO$ monitoring under cell-culture conditions. Such modifications of NOCT-1 are currently being synthesized and evaluated.

In these cell culture experiments, **1** traps $^{\bullet}NO$ and yields a characteristic nitroxide ESR spectrum, although oxygen is necessarily also present. Kinetic experiments show that the lifetime of **1** is not affected by molecular oxygen, solvent polarity, or pH.[25] Of course, even if **1** were to react with $O_2^{\bullet-}$, $HO^{\bullet}$, or any other form of "active oxygen", the product(s) will be ESR silent. The only exceptions to this rule are the $^{\bullet}NO$ and $^{\bullet}NO_2$ radicals.

[6] C. M. Arroyo, M. Kohno, *Free Radical Res. Commun.* **1991**, *14*, 145–155. Although this paper reports formation of an adduct radical from ^{15}NO and $(CH_3)_3CNO$ i.e. $(CH_3)_3CN(^{\bullet}O)^{15}NO$, such radicals are unknown [7]. Furthermore, to account for the complex ESR spectrum that was obtained, Arroyo and Kohno assumed that the adduct radical exists in two forms with different nitrogen hyperfine splittings for each form! Since the two forms are shown as resonance structures this cannot be true. It would appear that the overall chemistry of the $^{\bullet}NO + (CH_3)_3CNO$ reaction must be quite complex.

[16] **1** was detected by low-temperature (−40 °C) ^1H NMR spectroscopy (300 MHz, CD_3CN, TMS), from the signals of its olefinic protons at $\delta = 6.00$ (dd, $J = 7.8$, 3.2 Hz) and 6.85 (dd, $J = 7.8$, 3.2 Hz), which decayed at room temperature in agreement with the reported liftime [15]. The concentration of **1** after 1 h irradiation of a 5.3×10^{-2} mol L^{-1} solution of **3** in CD_3CN was about 7×10^{-4} mol L^{-1}, and that of *o*-isopropyl-α-methylstyrene about 1.0×10^{-2} mol L^{-1}.
[17] Further evidence that **1** represents the active trap was given by experiments where $^{\bullet}NO$ solutions were mixed with solutions of **1** which had been stored for different periods (1–60 min) at room temperature. The intensity of the ESR signal decreased with increasing storage time of the **1**, as expected in view of the known lifetime [15] of **1**.
[18] The formation of $^{\bullet}NO_2$ in these solutions by reaction of $^{\bullet}NO$ with traces of oxygen and/or disproportionation cannot be excluded. It may also be formed by reaction of $^{\bullet}NO$ with **2**. Separate experiments have shown that **2** does react with excess $^{\bullet}NO$ or $^{\bullet}NO_2$ but quite a large excess of these compounds is necessary for a complete suppression of the ESR signals. In contrast, the ESR signals due to alkoxynitroxide **4** are efficiently destroyed by $^{\bullet}NO$ or $^{\bullet}NO_2$.

[20] J.-F. Wang, P. Komarov, H. Sies, H. de Groot, *Biochem. J.* **1991**, *279*, 311–314.
[21] The Kupffer cells were cultured in tubes (5.5 cm^2, Nunc) with RPMI 1640 medium supplemented with 20% (v/v) heat-inactivated fetal-calf serum in a humidified CO_2/air (1/19) atmosphere at 37 °C. After 30 h the cells were pretreated for 18 h with lipopolysaccharides (10 mg mL^{-1}) and with Hank's balanced salt solution, pH 7.4, supplemented with 10 mM glucose and 20 mM Hepes. 1 mM L-arginine was added prior to incubation at 37 °C. Each culture tube contained approximately 7×10^4 Kupffer cells which, under these conditions, released $^{\bullet}NO$ at a rate of 11.6 nmol h^{-1}(10^6 cells)$^{-1}$.
[22] The ESR signal intensity decreased for incubation times longer than 30 min, probably because **2** reacts with excess $^{\bullet}NO$ [18].
[23] Determined by double integration of the ESR signal and comparison with a calibrated spin standard.
[24] A degradation of the ESR signal by a possible reaction of **2** with excess **1** can be excluded on the basis of separate experiments where varying amounts of **1** were added to a solution of pure **2**. If L-arginine is replaced by N^G-nitro-L-arginine the production of $^{\bullet}NO$ by the Kupffer cells in inhibited [20]. In agreement, no ESR signals were detected from parallel experiments in which 0.1 mM N^G-nitro-L-arginine had been added to the cell culture prior to addition of **1**.

Multidentate Macrocyclic Lewis Acids: Release of "[12] Mercuracarborand-4" from Its Iodide Complex and the Structure of Its Tetra(tetrahydrofuran) Dihydrate Complex**

By *Xiaoguang Yang, Stephen E. Johnson, Saeed I. Khan,* and *M. Frederick Hawthorne**

While simple Lewis acids have been used to mediate a wide variety of C–C-bond-forming reactions,[1] multidentate Lewis acids, that is, those with several electrophilic centers, offer the possibility of specific substrate binding accompanied by catalysis with high chemo- and stereoselectivities. Moreover, anion complexation by multifunctional electrophiles is of vital importance to the areas of molecular recognition, enzyme modeling, homogeneous catalysis, and ion transport.[2] Although the complexation of electrophilic guest species has been intensively studied for the last twenty years,[3] anion inclusion complexes had generally been limited to those species in which macrocyclic ammonium salts[4] serve as host molecules for simple anions. More recently, however, several

[**] This work was supported by the National Science Foundation.

multidentate Lewis acids have been reported which can function as host molecules.[5–8] In a new vein, we recently reported the chloride and iodide complexes of the novel macrocyclic tetradentate Lewis acid, [12]mercuracarborand-4(**1**).[9] The synthesis and reactivity of this novel host molecule and the molecular structure of its tetra(tetrahydrofuran)dihydrate complex are described herein.

The synthesis of **1** was achieved in 80% yield by the reaction of $\mathbf{1}\cdot I_2Li_2$ with two equivalents of AgOAc in ethanol at room temperature [Eq. (1)]. The ^1H, ^{13}C, and ^{11}B NMR

$$[(C_2B_{10}H_{10}Hg)_4I_2]Li_2 \xrightarrow[-2\,AgI,\ -2\,LiOAc]{2\,AgOAc} cyclo\text{-}\left(-C\!-\!C\!-\!Hg-\right)_4 \quad (1)$$

$\mathbf{1}\cdot I_2Li_2$ — **1**

spectra of **1** were nearly identical with those of the halide complexes of **1**.[9] No resonance signals for the AcO^- groups were observed, and all the spectroscopic data confirmed that the tetrameric structure of **1** was preserved following the removal of iodide ions from $\mathbf{1}\cdot I_2Li_2$. The ^{199}Hg NMR spectrum of **1** exhibited a broad solvent-dependent signal at $\delta = -1305$ in THF and $\delta = 1205$ in acetone. The solvent and concentration dependence of ^{199}Hg NMR chemical shifts are well documented. The sensitivity of $\delta(^{199}Hg)$ to solvent identity has been ascribed to coordination phenomena.[10] The fact that the chemical shifts of the halide ion complexes of **1** are both solvent and concentration independent[9] suggests that the halide ion complexes of **1** have no vacant coordination sites suitable for solvent coordination. Thus, the solid-state structures[9] with mercury coordinated in a nonlinear fashion are present in solution.

A single crystal of $\mathbf{1}\cdot(THF)_4\cdot 2H_2O$ grown from THF and hexane was selected for the X-ray diffraction study (Fig. 1).[11] The framework of the molecule **1** consists of four

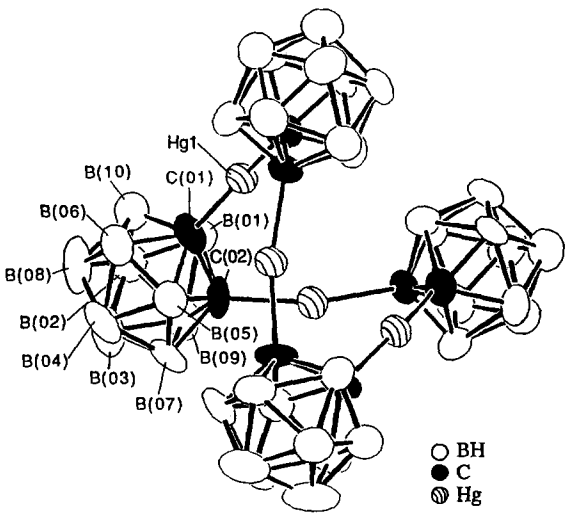

Fig. 1. Structure of the framework of $\mathbf{1}\cdot(THF)_4\cdot 2H_2O$ (ORTEP, with hydrogen atoms, H_2O and THF molecules removed for clarity). Atoms labeled are in the x, y, and z positions of the unit cell; all other atoms are generated by S_4 symmetry of the tetramer. For bond lengths and angles see text.

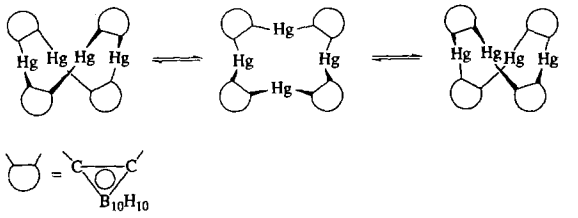
divalent 1,2-$C_2B_{10}H_{10}$ cages linked by the C vertices to four Hg atoms giving a cyclic tetramer. The complex has crystallographically imposed S_4 symmetry, and the four Hg atoms are approximately in a butterfly configuration. Two disordered water molecules related by the S_4 symmetry reside within the host molecule, although no significant interaction was observed between the frameworks of the host molecules and these water molecules.

Each Hg atom in **1** links carbon atoms of two carborane icosahedra (both Hg–C distances are the same 2.09(2) Å). The Hg-C-C angles are 120.3(13)° and the C-Hg-C angles are 167.7(8)°. The distance between the adjacent mercury atoms is 3.654 Å. The dihedral angle Hg-C-C-Hg is 20(2)° which is significantly larger than those found in $\mathbf{1}\cdot ClLi$ (0.0°) and $\mathbf{1}\cdot I_2(AsPh_4)_2$ (5.3 (10)°). The coordination about the Hg atom in $\mathbf{1}\cdot(THF)_4\cdot 2H_2O$ is more nearly linear, and the Hg···Hg distances are shorter than in the halide ion complexes.[9] The Hg-C-C angles are quite similar to those observed in $[(C_2B_{10}H_{11})_2Hg]\cdot(Et_2O)_2$[12] (118.3(3)°) and $[(C_6H_4Hg)_3]$[13] (average 120(3)°), both of which have linear mercury coordination. It is also noteworthy that the mercury atoms are bent away from the cavity present in $\mathbf{1}\cdot(THF)_4\cdot 2H_2O$, while the mercury atoms of the tetramer in $\mathbf{1}\cdot ClLi$ and $\mathbf{1}\cdot I_2(AsPh_4)_2$ are displaced toward the cavity.[9] This flexibility allows the framework **1** to bind donor solvents (e.g. THF) located outside the cavity through its Lewis-acidic mercury atoms. The C-Hg-O angles between the framework **1** and the bound THF molecules are each 95.2(7)°, and each THF molecule is directed away from the center of the cavity. The Hg–O distance is 2.65(2) Å, which is significantly shorter than the Hg–O distances observed in other ether or THF adducts of diorganomercury compounds. The Hg–O distance is 3.050(3) Å in $[(C_2B_{10}H_{11})_2Hg]\cdot(OEt_2)_2$[12] and 2.776 to 3.052 Å in the DME adduct (DME = 1,2-dimethoxyethane) of a macrocyclic mercuric hexafluoroglutarate.[6e]

The solution behavior of **1** in [D_6]acetone at 25 °C was investigated with ^{199}Hg NMR spectroscopy.[14] The observed broad signal may be due to the presence of a variety of conformations of solvated **1** species produced by the rotation of carborane cages as shown in Scheme 1. The incre-



Scheme 1.

mental addition of nBu_4NI to a [D_6]acetone solution of **1** results in the formation of $\mathbf{1}\cdot I^-$ and $\mathbf{1}\cdot I_2^{2-}$ in accord with Equation 2 and as demonstrated by the ^{199}Hg NMR spectra

$$\mathbf{1} \overset{I^-}{\rightleftharpoons} \mathbf{1}\cdot I^- \overset{I^-}{\rightleftharpoons} \mathbf{1}\cdot I_2^{2-} \quad (2)$$

shown in Figure 2. The discrete signals observed here are unique, which means that exchange of I^- among **1**, $\mathbf{1}\cdot I^-$, and $\mathbf{1}\cdot I_2^{2-}$ is not fast on the NMR time scale. In the cases of 1,2-phenylenemercury dichloride and $HgCl_2$, the addition of cloride anion shifted the ^{199}Hg resonance signal down field, and only a single resonance signal was observed[6a, 15] even though more than one species was believed to be present in the solution. When more than two equivalents of tetra-*n*-butylammonium iodide were added to the [D_6]acetone solution of **1**, no further change in the spectrum was observed,

proving that **1**, in agreement with the solid-state structure of $\mathbf{1} \cdot I_2^{2-}$,[9b] is not capable of hosting more than two iodide ions. We thus suggest that the solid-state structure of $\mathbf{1} \cdot I_2^{2-}$ is largely maintained in solution. In contrast to this result, the linear mercuric ion derivatives $Hg(CN)_2$ and HgX_2 co-precipitate with MX (M = Na, K, Rb; X = Cl, Br, I) to from salts with mixed cyanohalogenomercurate ions in which each mercury atom is surrounded by four halide ions in addition to linear bonding to CN^- or X^-.[16]

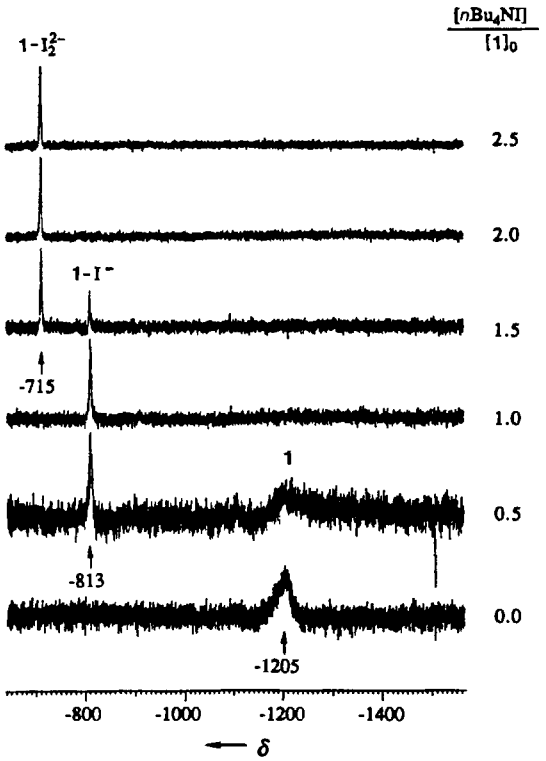


Fig. 2. ^{199}Hg NMR spectra of **1** (0.073 M) in [D$_6$]acetone at 25 °C and the spectra with the sequential addition of tetra-*n*-butylammonium iodide. For details of the measurements see Experimental Procedure and ref. [14].

The synthesis of **1** could only be achieved by the extraction of the halide ions from $\mathbf{1} \cdot I_2Li_2$ or $\mathbf{1} \cdot ILi$ with AgOAc. The reaction of chloride or bromide ion complexes of **1** with AgOAc resulted in incomplete extraction of the halide ions and a low yield of **1**. Longer reaction times permit the destructive oxidation of B–H bonds by Ag^+ ions. The reaction of $\mathbf{1} \cdot I_2Li_2$ or $\mathbf{1} \cdot ILi$ with $AgNO_3$ leads to a nitrate ion complex of **1**. We have previously mentioned[9a] that the efficient synthesis of $\mathbf{1} \cdot X_nLi_n$ (X = Cl, Br, $n = 1$; X = I, $n = 1, 2$) must be due to a template effect in which the halide ion serves as the template, since a trimeric structure is stereochemically more attractive than the tetramer. Indeed, the reaction of *closo*-[1,2-Li_2-1,2-$C_2B_{10}H_{10}$] with $Hg(OAc)_2$ produced a cyclic trimer $[(C_2B_{10}H_{10}Hg)_3]$, [9]mercuracarborand-3, which also binds halide ions and is under investigation.

In summary, the first macrocyclic host molecule with four Lewis acid centers has been synthesized and structurally characterized as its tetra(tetrahydrofuran) dihydrate complex. The demonstrated ability of this host molecule acting as a Lewis acid to bind halide ions as well as nucleophilic organic species promises to find wide application throughout chemistry.

Experimental Procedure

1: $\mathbf{1} \cdot I_2Li_2$ (10 g, 6.1 mmol) in ethanol (50 mL) was treated with AgOAc (2.14 g, 12.8 mmol) at room temperature, and a yellow precipitate immediately formed. After five minutes, the mixture was filtered, the solvent removed, and the residue recrystallized from diethyl ether to give **1** in 80% yield. $\mathbf{1} \cdot (THF)_4 \cdot 2H_2O$ forms on recrystallization from THF/H_2O/hexane; m.p. > 300 °C.

1: ^1H NMR (200 MHz, [D$_6$]acetone, 25 °C): $\delta = 1.0-3.0$ (B–H). ^{13}C NMR (50 MHz, [D$_6$]acetone, 25 °C, decoupled) $\delta = 93$ (carborane-C), signals due to ether and ethanol. ^{11}B NMR (160 MHz, [D$_6$]acetone, 25 °C, $BF_3 \cdot Et_2O$ external, decoupled) $\delta = 0.8, -6.0, -7.6, -9.6$. ^{199}Hg NMR (89.6 MHz, 0.25 M in [D$_6$]acetone, 25 °C, external standard 1.0 M PhHgCl in [D$_6$]DMSO: chemical shift $\delta = -1187$[17] upfield from neat Me_2Hg, decoupled) $\delta = -1205$. IR (KBr): $\tilde{\nu}$ [cm^{-1}] (KBr) = 2556 (B–H).

[11] Crystallographic data for $\mathbf{1} \cdot (THF)_4 \cdot 2H_2O$: $C_{24}H_{76}B_{40}Hg_4O_6$, $M = 1697.64$, tetragonal, space group $I4_1/a$, $a = 22.902(1)$, $c = 11.242(1)$ Å, $V = 5896.66$ Å^3, $Z = 4$(1/4 of the tetramer + THF + 1/2 water molecule per asymmetric unit), $\varrho_{calcd} = 1.91$ g cm^{-3}, $T = 25$ °C, absorption coefficient $\mu = 104.17$ cm^{-1}. Data were collected on a Huber diffractometer, using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), to a maximum $2\theta = 50°$ for the range $0 \le h \le 28$, $0 \le k \le 28$, $0 \le l \le 15$, giving a total of 2604 unique reflections, of which 1686 reflections with $I > 3\sigma(I)$ were retained for structure analysis. The intensity data were corrected for Lorentz polarization, and absorption effects were applied with the transmission factor ranging from 0.82 to 0.96. The structure was solved by heavy-atom methods. All non-hydrogen atoms were refined anisotropically. The final discrepancy index was $R = 0.064$, $R_w = 0.079$ ($w = 1/\sigma^2(F_0)$) for 1686 independent re-

flections with $I > 3\sigma(I)$. $\Delta\varrho_{max} = 4.22$ Å^{-3} in the final difference Fourier syntheisis (located close to the Hg atom). Hydrogen atoms of the water molecules were not included in the refinement. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-56190, the names of the authors, and the jornal citation.

Synthesis, Structure, and Bonding of $[CpCoW_2(OCH_2tBu)_6]$, and Comments on the Combining Properties of CO and CpCo**

By *Malcom H. Chisholm*, Victor J. Johnston, Odile Eisenstein,* and *William E. Streib*

The isolobal analogy and the frontier molecular orbital (FMO) approach are valuable in providing insight into the bonding in organometallic compounds, and they aid in the strategic synthesis of new molecules.[1] The recent report[2] of the preparation and structure of $[Cp^*_2Co_2]$ ($Cp^* = \eta^5$-C_5Me_5) prompts us to report our synthesis and characterization of the title compound **1**, and also to comment on the interesting analogy with the CO-bridged complex **2**[3] that arises from the isolobal relationship between CO and CpCo.

$[CpCoW_2(OCH_2tBu)_6]$ **1** $[W_2(\mu\text{-CO})(OtBu)_6]$ **2**

The reaction between the Jonas compound[4] $[CpCo(C_2H_4)_2]$ and $[W_2(OCH_2tBu)_6(py)_2]$ (py = pyridine)[5] in hydrocarbon solvents at 25 °C gives rise to the formation of **1** in about 50% isolated yield as dark green crystals. The ^{1}H and ^{13}C NMR spectra of **1** in C_6D_6 are consistent with the molecular structure found in the solid state by single-crystal X-ray crystallography.[6] The molecular structure of **1** is shown in Figure 1.

The W_2O_6 skeleton of **1** is essentially identical to that of **2**. The bonding in **2** was previously examined by Fenske–Hall MO calculations[7] and analyzed by the FMO approach wherein the MOs of the $(HO)_2W(\mu\text{-}OH)_2W(OH)_2$ fragments were made to interact with the MOs of CO (Fig. 2).[3b] The

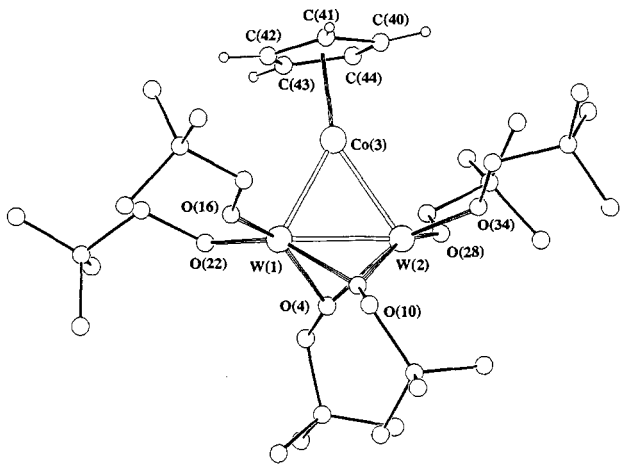

Fig. 1. Crystal structure of **1**. Selected distances [Å]: W-W 2.504(2), Co-W(1) 2.281(4), Co-W(2) 2.340(4), W-$O_{terminal}$ 1.89(2), W-$O_{bridging}$ 2.06(2). The last two distances are average values.

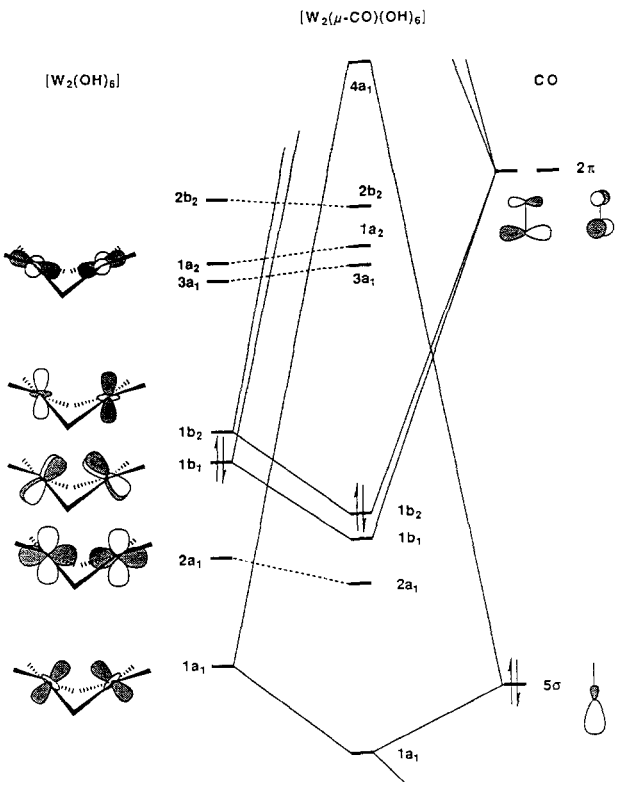

Fig. 2. MO diagram showing the formation of the hypothetical $[W_2(\mu\text{-}CO)(OH)_6]$ molecule from the interactions of the MOs of the fragments $(HO)_2W(\mu\text{-}OH)_2W(OH)_2$ (left) and CO (right). The HOMO is indicated by the pair of arrows.

MOs of **1** have been similarly constructed by the combination of the MOs of the $(HO)_2W(\mu\text{-}OH)_2W(OH)_2$ and CpCo fragments (Fig. 3).[8] The main difference between the bonding in **1** and **2** involves their HOMOs; for **1** this is a Co–(W-W) nonbonding MO whereas in **2** it is a metal-to-carbon bonding MO ($Md\pi \rightarrow CO\pi^*$).

The similarities in the bonding in **1** and **2** which arise from the isolobal nature of CO and CpCo are shown in Scheme 1. Both CO and CpCo have an *a* and an *e* set of orbitals with a total electron count of two. However, the relative energies

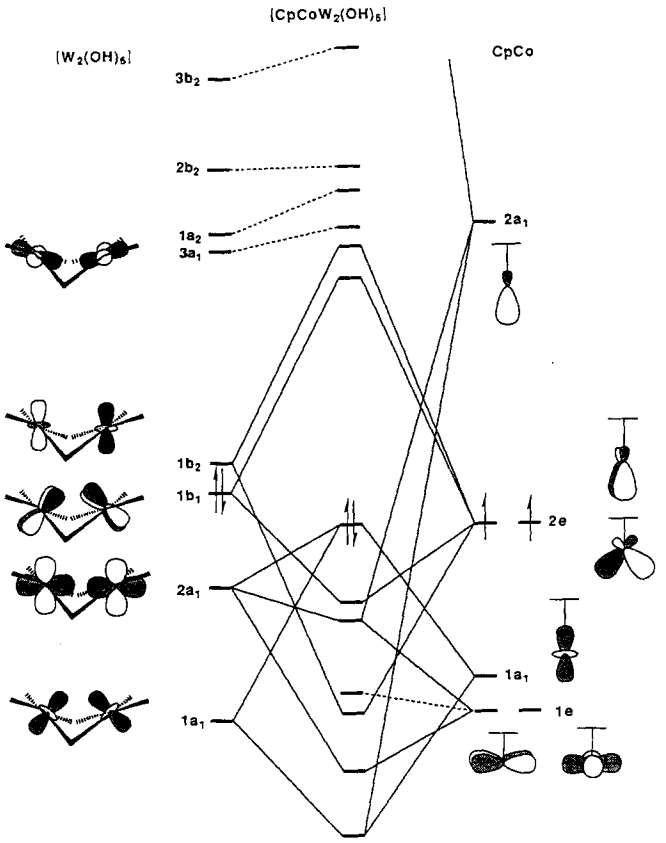

Fig. 3. MO diagram showing the formation of the hypothetical $[CpCoW_2(OH)_6]$ molecule from the interaction of the MOs of the fragments CpCo (right) and $W_2(OH)_6$ (left). The HOMO is indicated by the pair of arrows.

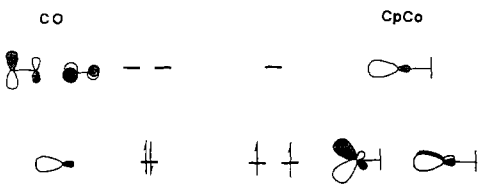
of these sets are inverted. For CO the *a* orbital is the 5σ MO, the lone pair centered on carbon, while for CpCo the *a* orbital is the high-lying valence hybrid orbital of an ML_3 fragment. From the frontier orbitals shown in Scheme 1 we can readily anticipate the bonding in a hypothetical linear [CpCo(CO)] molecule,[9] a spin triplet with a formal Co–CO $\sigma^2\pi^2$ double bond. In the linear $[Cp_2Co_2]$ dimer the relative



Scheme 1.

energies of the σ and π bonding MOs would need to be determined from a calculation. However, from the observed short Co–Co distance[2] it is not unreasonable to formulate a Co–Co double bond arising from four electrons distributed in a σ,π orbital set. Given the observed paramagnetism,[2] a simple one-electron MO description is not valid, since configuration interactions must also be considered.[10] The isolobal analogy and FMO approach are also useful in considering the hypothetical $(CO)_2$ dimer. The initial approach of two CO molecules to give a linear OCCO molecule would lead to repulsive interactions since both σ and σ^* orbitals will be occupied.[1b] However, at short C–C distances the π bonding MO resulting from the interaction of the in-phase CO π^* MOs would fall below the σ^* MO, again leading to a σ, π orbital set occupied by four electrons. In the dianion, $(OCCO)^{2-}$, which has a short C–C distance, there is a formal C–C $\sigma^2\pi^4$ triple bond. In coordination chemistry the $(OCCO)^{2-}$ anion is stabilized by the presence of cations in the lattice[11] or by complexation to a transition metal as an alkyne after the reductive coupling of two carbonyl ligands.[12]

In summary, we have prepared the cluster $[CpCoW_2(OCH_2tBu)_6]$ (**1**) and have noted its structural similarity to $[W_2(\mu\text{-}CO)(OtBu)_6]$ (**2**). The isolobal nature of CpCo and CO leads to interesting analogies in their combinations as illustrated by **1**, **2**, [CpCo(CO)], $[Cp^*_2Co_2]$, and $(OCCO)^{2-}$. The frontier MOs of $[W_2(OR)_6]$ molecules, either in their unbridged ground-state geometries or in bridged excited states, should make them versatile templates for the synthesis of a wide variety of heterometallic clusters, just as it has for the binding of unsaturated hydrocarbon fragments.[13]

Experimental Procedure

All manipulations were performed under a nitrogen atmosphere using dry, oxygen-free solvents. Starting materials were prepared by the literature methods cited.

1: $[W_2(OCH_2tBu)_6(py)_2]$ (1.015 g, 0.97 mmol), $[CpCo(C_2H_4)_2]$ (200 mg, 1.11 mmol) and hexane (20 mL) were stirred at 25 °C for 2 days. The volatiles were removed on the vacuum line, and **1** (480 mg, 0.48 mmol, 49 %) was recrystallized from dimethoxyethane at −20 °C. Correct C,H analysis.

^1H NMR (C_6D_6, 25 °C, 300 MHz): $\delta = 4.68$ (5H;Cp), 4.49 (d, $J(H,H) = 10.2$ Hz, 4H; OCH_2CMe_3), 4.27 (d, $J(H,H) = 10.2$ Hz, 4H; OCH_2CMe_3), 4.17 (s, 4H; OCH_2CMe_3), 1.16 (s, 36H; OCH_2CMe_3), 0.94 (s, 18H; OCH_2CMe_3); $^{13}C\{^1H\}$ NMR (C_6D_6, 25 °C, 75 MHz): $\delta = 80.8$ (5C; Cp), 85.7 (4C; OCH_2CMe_3), 84.4 (2C; OCH_2CMe_3), 34.3 (OCH_2CMe_3), 27.0 (OCH_2CMe_3).

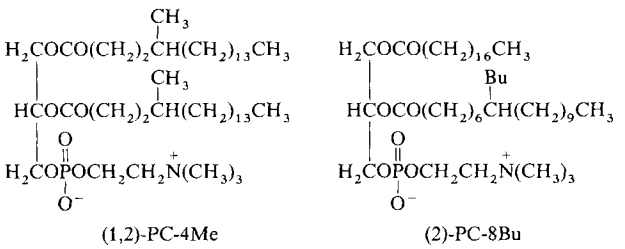
Synthetic Chain-Substituted Phospholipids: Ion Transport Across Their Bilayer Membranes**

By *Fredric M. Menger** and *Patricia Aikens*

Nature has established the means to control, according to conditions, passive diffusion through its membranes. For example, membranes of cold-water marine life are endowed with high levels of "fluidizing" lipids (i.e. polyunsaturates). Control of permeability is also important to drug delivery systems based on lipid membranes with defined leakage rates.[1] Thus, one would wish to examine, systematically, the effect of lipid structure on permeability. The opportunity to do so presented itself after we synthesized a series of phospholipids for calorimetric and film studies.[2, 3] The new lipids possessed 18-carbon chains bearing alkyl substituents of varying size, location, and number. Two examples of such distearoylphosphatidylcholines (with a self-explanatory nomenclature) are shown in Scheme 1. With this set of lipids



Scheme 1. Two examples of phospholipids with branched chains.

in hand, we were able to examine ion flux through their bilayer membranes. As will be described shortly, alkyl branching disrupts the packing of the lipid chains that reside in a more-or-less parallel array within the membrane. The disruption facilitates the passage of ions in a manner dependent on the size and location of the alkyl substituents.

Ion flux was monitored by the same method described in previous work on synthetic ion channels.[4] A branched phospholipid and a fluorescent dye[5] were co-sonicated in a weak buffer (pH = 7.7, 0.1 M KCl).[6] This created unilamellar vesicles with dye both on the inside and outside. The latter was removed by gel filtration. When the external pH was abruptly lowered to 6.7, protons migrated into the vesicles and protonated the dye, thereby eliminating its fluorescence. According to quasi-elastic light scattering, the vesicles had diameters of 35 ± 5 nm.

Typical plots of fluorescence against time for the parent distearoylphosphatidylcholine (DSPC) and the branched (1,2)-PC-8Me are given in Figure 1. In agreement with previous results of Clement and Gould,[7] the fluorescence decreases in a biphasic manner upon HCl addition to the external water. The initial drop in fluorescence corresponds to an electrically uncompensated diffusion of protons into the vesicles.[8] Inward proton flow, which was too fast to measure conventionally, creates a transmembrane potential that drives the ensuing slower step, the outward diffusion of potassium ions. As potassium ions depart, protons are allowed, on a one-to-one basis, further entry.[9] The initial electrical potential is thereby maintained. Although K^+ flux is known to be orders of magnitude slower than H^+ flux,[10] the difference is mitigated by our operating with 0.1 M KCl and pH = 7 and, therefore, with a 10^6 excess of potassium ions over protons.

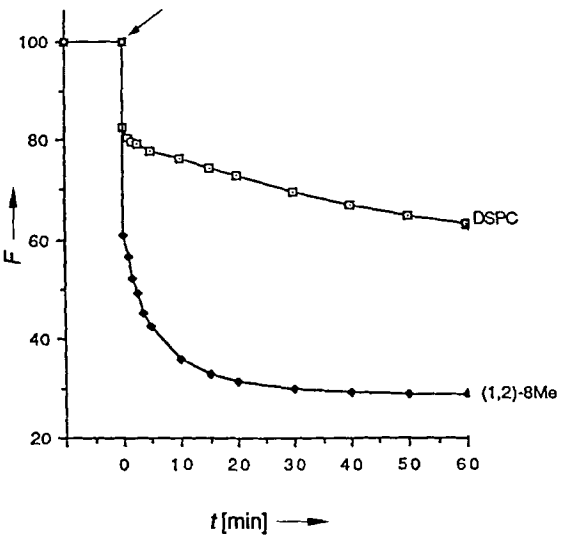


Fig. 1. Fluorescence vs. time graph after HCl was added to vesicles containing a pH-sensitive dye. Plots show how the presence of methyl groups at position 8 of the chains enhances the entry of protons relative to unbranched DSPC. The process is biphasic (the initial fluorescence decrease being too fast to measure by conventional means).

Since outward K^+ flow is a first-order process under our conditions, plots of $\log[F - F_\infty]$ against time are linear [Figs. 2–4]. The intercepts represent the maximum proton-induced potential permitted by a particular membrane. Subsequent K^+ exodus occurs with rates given by the slopes of the plots. Our library of synthetic lipids was sufficiently diverse that we could readily compare systems below and above their phase transition temperature T_c.

[**] This work was supported by the National Institutes of Health.

Figure 2 gives the transport data at 20 °C (below T_c) for DSPC and three lipids alkylated at the 4-position.[11] The intercepts show that the extent of proton entry is modestly dependent on the size of the substituent at position 4. Branching may spread the head-group region, thus permitting entry of water and an increase in the membrane's dielectric constant.[12] A greater electrical potential and concomitant proton entry is, therefore, possible. Alternatively, the substituents may thicken the membrane (in the order Bu > Et > Me > H) and thus enhance its ability to tolerate uncompensated proton flux.

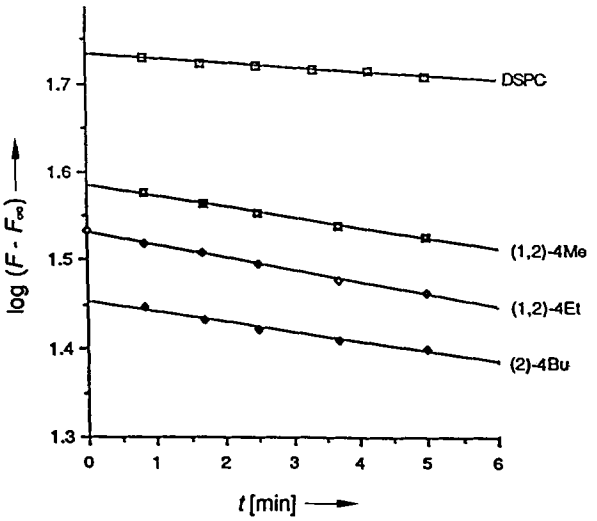

Fig. 2. Comparison of proton entry rates through vesicles composed of three branched lipids and the unbranched DSPC. $T < T_c$. F_∞ = fluorescence at $t \rightarrow \infty$.

The slopes of the four plots in Figure 2 are all similar. Branching clearly has little effect on K^+ exit rates when the membranes are in their gel state. Apparently, no potassium-conducting "channels" are formed across the membrane despite the one or two alkyl substituents per lipid that presumably disrupt the side-by-side packing within the bilayer.

Figure 3 reveals an additional point about vesicle permeability as a function of structure. Methyl substitution at positions 8 and 10 is seen to enhance K^+ flux substantially (15- and 18-fold relative to DSPC), whereas no such effect was observed for substitution at positions 4 and 16. The simplest explanation relates to the fact that our operating temperature of 20° fell below the T_c values of 30.1° and 26.9° for (1,2)-PC-4Me and (1,2)-PC-16Me, respectively. In contrast, the 8-Me and 10-Me derivatives, with T_c values less than 0°, existed in the fluid state. Thus, a locus-sensitive T_c translates directly into a locus-sensitive K^+ flux.[13] This behavior is consistent with an enhanced H^+ and K^+ flux observed when dipalmitoylphosphatidylcholine vesicles were warmed from 32° to the T_c of 42°. Thus, in order to improve membrane permeability, one can either heat or alkylate. As discussed in detail previously,[2, 3] conformational perturbations near the middle of the chain have a particularly potent effect on several membrane properties; permeability must now be added to the list.

A series of lipids with substituents at C8 were examined at 20° where they all existed in their fluid state (Fig. 4). Rates

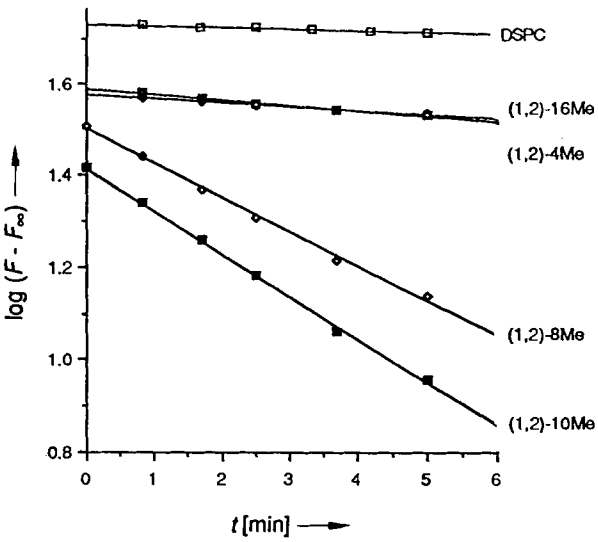

Fig. 3. Dependence of proton entry rates on the location of methyl groups attached to the lipid chains.

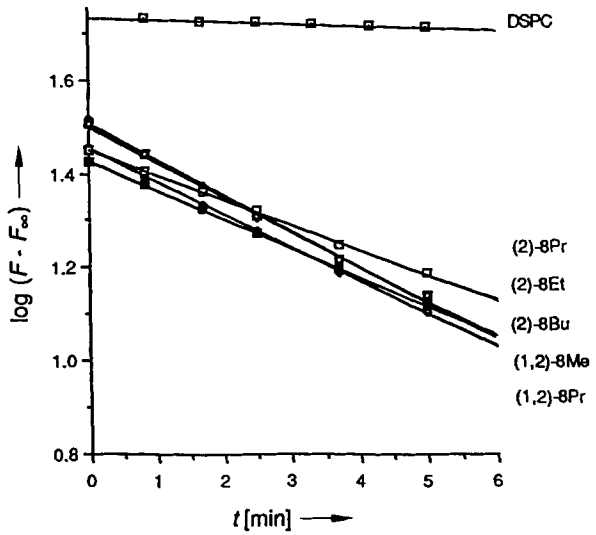

Fig. 4. Dependence of proton entry rates on the size and number of substituents at position 8. $T > T_c$.

of ion flux, although much faster than that of DSPC, are within experimental error of each other regardless of substituent size or number. Rotational disorder induced by alkylation at the critical middle section of the lipid promotes ion movement as does a simple phase transition. The two processes would seem, therefore, to have a common molecular basis.

The Pyrolysis of Tetranitromethane in the Gas Phase

By *Hans Bock** and *László Zanathy*

$C(NO_2)_4$, a colorless liquid boiling at 126 °C, contains more than 65% by weight of oxygen and thus represents one of the most oxygen-rich methane derivatives. In addition to its use as a nitration reagent,[1a] therefore, it serves as an additive to propellants and explosives.[1b,c] For this reason, we became interested in its thermal decomposition in the gas phase,[2] which like all compounds with a tendency to explode such as alkyl azides,[3a] diazo alkanes,[3b,c] or even the shock-sensitive S_4N_4,[3d] can be investigated without risk under nearly unimolecular conditions with photoelectron (PE)-spectroscopy in the gas phase[3e] (Fig. 1).

The ionization pattern of $C(NO_2)_4$, whose gas-phase structure exhibits the rather rare symmetry S_4 determined by electron diffraction[4a] (cf. Fig. 1, upper left), shows six bands with maxima at 12.6, 13.3, 14.32, 17,6, and 18.6 in the intensity ratio 4:6:1:1:4:4. They can be assigned by Koopman's correlation, $IE_n^V = -\varepsilon_j^{AM\,1}$, with eigenvalues calculated with AM 1, to altogether 20 radical cation states of the irreducible representations, $\Gamma_{red} = 5a + 5b + 5e$. Accordingly, the low-energy bands correspond to four oxygen lone-pair ionizations, and the second one to four with dominant n_O contributions as well as three of the σ_{CNO} type.[4b] The geometry-optimized AM 1 calculations reproduce the S_4 structure, yield a heat of formation $\Delta H_f^{AM\,1} = +420\ kJ\,mol^{-1}$, and suggest a charge distribution >C(+0.02)–N(+0.46)–O(−0.23) with partial positive charges at the N centers.[4c]

The temperature-dependent PE spectra[5] of $C(NO_2)_4$, recorded in 30 K intervals (Fig. 1), prove that the decomposition starts at a furnace temperature of 520 K and is complete at 610 K (Scheme 1). The decomposition products, identified unequivocally by their needle-like ionization patterns, are exclusively $^{\bullet}NO_2$, $^{\bullet}NO$, CO_2, and above 580 K, CO; neither O_2 nor N_2 form.

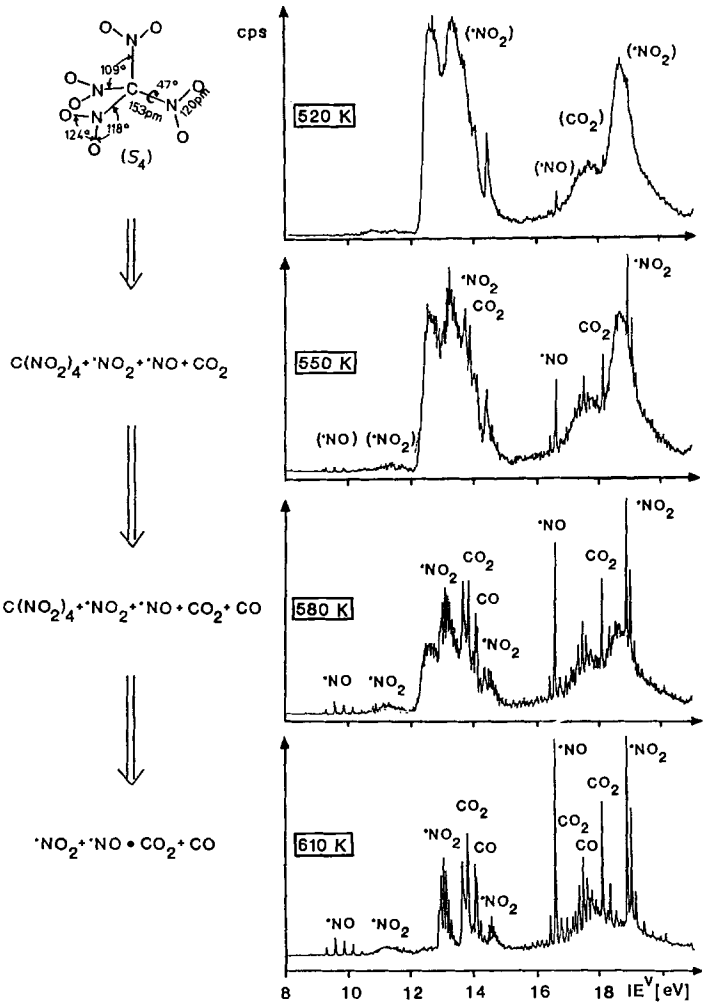

Fig. 1. He(I)PE spectra of tetranitromethane on heating in a flow tube at 10^{-4} mbar to 520, 550, 580, and 610 K (cf. text); cps = counts per second.

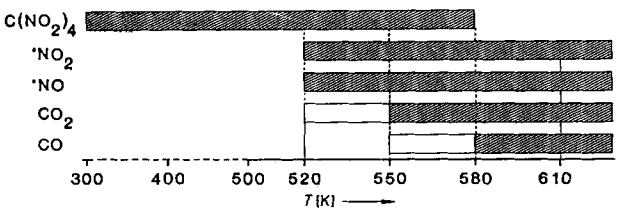
The temperature dependence of the $C(NO_2)_4$ decomposition under nearly unimolecular conditions (Fig. 1) suggests a possible microscopic pathway (Scheme 2).



Scheme 1. Temperature dependence of the product distribution of the $C(NO_2)_4$ pyrolysis at 10^{-4} mbar.

For a discussion of the $C(NO_2)_4$ pyrolysis pathway it must be pointed out that none of the postulated intermediates can be detected, even on decomposition in the internal furnace of the high-performance PE spectrometer,[5a] and therefore their half-lives $t_{1/2}$ must be below 10^{-4} s. The dissociation into $^{\bullet}NO_2$ and trinitromethyl radicals assumed as the initial (Scheme 2) is in accord with the unimolecular decomposition proven in a helium flow experiment.[2] The activation enthalpy for the $^{\bullet}NO_2$ elimination from the energy-rich

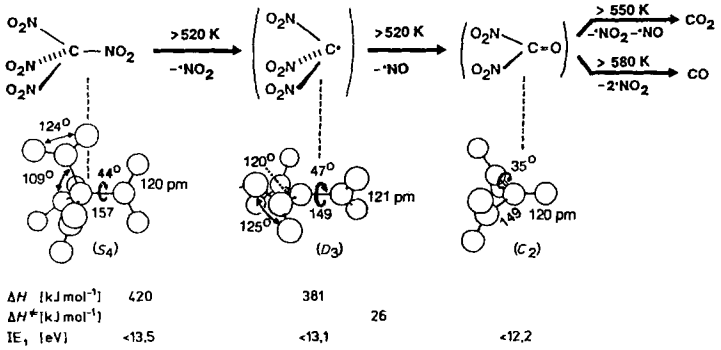

Scheme 2. Proposal for a sequence of steps in the $C(NO_2)_4$ pyrolysis (boldface arrows: PES analysis), supported by AM 1 calculations (cf. text).

$C(NO_2)_4$ estimated by geometry-optimized AM 1 calculations[4c, 7a] is smaller than the kinetically determined one[2] and agrees well with the lower decomposition temperature of only 520 K[7b] observed under the different conditions selected. For the trinitromethyl radical, an enthalpy of formation of 381 kJ mol^{-1} is predicted, as well as a planar D_{3h} structure.[7c] An additional reaction channel in which, after the isomerization $(O_2N)_3C{-}NO_2 \rightarrow (O_2N)_3C{-}ONO$, ·NO is first eliminated to form a $(O_2N)_3CO$· radical can be excluded due to the high isomerization enthalpy predicted by AM 1 calculations (> 500 kJ mol^{-1}[7d]). A subsequent ·NO elimination to form $(O_2N)_2C{=}O$ is postulated as second step (Scheme 2); this second intermediate is also not observed by PE spectroscopy despite its favorable enthalpy of formation and its low first ionization energy estimated by geometry-optimized AM 1 calculations. Nevertheless, among all speculative precursors it best rationalizes the formation of the final products CO_2 and CO in different reaction channels above 500 K and 580 K (Scheme 1 and 2), because not even traces of O_2 or N_2 can be detected.

In addition, the thermal decomposition of gaseous tetranitromethane under reduced pressure has been investigated at solids such as silver wool or charcoal [Eq. (a)] as well as in cothermolyses with added organic compounds.[8a]

$$C(NO_2)_4 \xrightarrow[600\ K]{[Ag]_x} {\cdot}NO_2 + CO_2 + {\cdot}NO + (CO) \qquad (a)$$
$$C(NO_2)_4 \xrightarrow[300\ K]{[C]_x} CO_2 + {\cdot}NO$$

According to the PES band intensities (cf. Fig. 1), only about one third of the ·NO observed in the gas-phase thermolysis is generated at silver wool heated to a furnace temperature of 600 K, in addition to $\cdot NO_2$ and CO_2 as well as traces of CO, a result that indicates a preceding chemisorption at the silver surface. The largest differences are found for the reaction at activated charcoal:[5b] Decomposition takes place already at room temperature, and the only gaseous products formed are ·NO as well as small amounts of CO_2. This suggests coal nitration and oxidation, which are supported by the deflagration of the resulting solid product observed on heating it to 350 K in an additional desorption attempt. A gas-phase nitration could be accomplished by cothermolysis with dimethylamine above 600 K [Eq. (b)].[5b]

$$(H_3C)_2NH \xrightarrow[600\ K]{C(NO_2)_4} (H_3C)_2N{-}NO_2 \qquad (b)$$

Outside the oven-zone, yellow crystals precipitate at the wall of the reaction tube. They are identified as dimethylnitramine by their melting point of 58 °C[8a, b] and their ^{1}H NMR spectrum (CD_3OD/TMS, δ = 2.66 (s)[8b, c]).

The reactive nitration reagent $C(NO_2)_4$ thus belongs to the few compounds, which like azadicarbonitrile ($\rightarrow N_2 + NCCN$[9a]), methyl azide ($\rightarrow N_2 + H_2 + HCN$[2a]) or tetracyano-*para*-benzoquinone ($\rightarrow 2\,CO + 2\,NC{-}C{\equiv}C{-}CN$[9b]) completely decompose on heating into thermodynamically favorable, gaseous components [Eq. (c)]. The reaction energy set free and the simultaneous volume increase, therefore, advise a careful handling.[1b, c]

$$C(NO_2)_4 \xrightarrow{>550\ K} 2\,{\cdot}NO_2 + 2\,{\cdot}NO + CO_2 \qquad (c)$$
$$C(NO_2)_4 \xrightarrow{>580\ K} 3\,{\cdot}NO_2 + {\cdot}NO + CO$$

The thermal decompositions of organic nitro compounds R–NO_2 and R–ONO, which can be investigated without risk under the conditions selected here,[5] provide interesting information. As a striking example, the chemical activation (cf. [3a]) of the propanal generated by thermolysis of allyl nitrite via ·NO elimination is quoted,[10] which decomposes to $H_2C{=}CH_2 + CO$ already 400 K below its decarbonylation temperature. The investigations will therefore be continued with other methane derivatives such as $HC(NO_3)_2$ or $H_2C(NO_2)_2$.[8a]

[7] a) The AM 1 estimate of the activation enthalpy is based on the following approximations: σ_{CN} bond is elongated in steps of 5 pm under full geometry optimization of the remaining molecular skeleton, but without CI refinement. b) For seven thermal fragmentations of various molecules under the same reaction conditions, the linear regression $\Delta H^{\neq}$ (kJ mol^{-1}) = 387 + 0.797 I_D [K] results from the experimentally determined decomposition temperature T_D and the calculated activation enthalpies $\Delta H^{\neq}$ (O. M. Nefedov, V. A. Korolev, L. Zanathy, B. Solouki, H. Bock, *Mendeleev Commun.* **1992**, 67; $\sigma = 0.948$). For $T_D = 550$ K a value $\Delta H^{\neq} \approx 44$ kJ mol^{-1} is obtained. c) Further AM 1 results: $d_{NO} = 121$ pm, charge distribution: >C(−0.02)–N(+0.51)–O(−0.25). d) For an estimate of the isomerization barrier, the angle CNO of 118° at one nitro group [4] was contracted in steps of 6° and each the remaining molecular skeleton completely geometry-optimized. For ∢CNO = 102° the CN bond lengths are stretched only by $\Delta d_{CN} \approx 30$ pm, but the enthalpy difference is already $\Delta\Delta H_f^0 = +506$ kJ mol^{-1}. In addition, the isomerization might be sterically hindered. e) Further AM 1 results (cf. Scheme 2): $d_{NO} = 121$ pm, charge distribution in $(O_2N)_2C=O$: O(−0.11) = C(+0.30)–N(+0.43)–O(−0.27).

Synthesis of *C*-Glycopeptides via Free Radical Addition of Glycosyl Bromides to Dehydroalanine Derivatives**

By *Horst Kessler**, *Valentin Wittmann*, *Matthias Köck*, and *Matthias Kottenhahn*

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

Glycoproteins are widely distributed in living organisms and their carbohydrate part plays a fundamental role in many processes of molecular recognition.[1, 2] The oligosaccharide side chain influences the conformation and solubility of proteins and can prohibit proteolytic cleavage.[3] In most cases the sugar residues form an *N*-glycosidic bond to asparagine or an *O*-glycosidic bond to hydroxy-containing amino acids. Unusual and more stable linkages between carbohydrates and peptides are important for an understanding of the mutual interactions between both moieties.

We now report the facile synthesis of *C*-glycopeptides via free radicals according to the tin-hydride procedure of Giese et al.[4] This new class of compounds[5] is formally derived

[*] Prof. Dr. H. Kessler, Dipl.-Chem. V. Wittmann, Dipl.-Chem. M. Köck, Dr. M. Kottenhahn

reagents were mixed synchronously after they had been warmed to the reaction temperature. The sugars dehalogenated at C1 could be isolated as side products. Slow addition of a solution of Bu_3SnH and AIBN in toluene to the reaction mixture resulted in reduced yields. As expected,[9] the products are exclusively (>97%) α-configurated at the "anomeric center" in the case of the monosaccharides **1** and **2**. Only small amounts of β-*C*-glycosides were formed when lactosyl bromide (**3**) was used (12% when reacting with **4**, 4% with **5**). In contrast to the high diastereoselectivity at the sugar, the hydrogen atom transfer to C2 of the amino acid yields mixtures of epimers. The diastereomeric ratios vary depending on the protecting group at the *N*-terminus of the amino acid. The best selectivity (3.8:1 in favor of the (2*S*)-epimer) is obtained with Boc-ΔAla-OBzl (**6**). The epimeric mixtures can be separated by HPLC. After the removal of the urethane group, gram-scale separation is possible by chromatography on a silica gel column.

To examine the possiblity of higher distereoselectivity through chirality in the dehydroamino acid building block, the enantiomeric dipeptides **7** and **8**, as well as the tripeptide **9**, were used. In all cases, even lower selectivity was observed (Table 1). In addition, the use of α,β-unsaturated carb*amides* results in lower chemical yields. For electronic reasons,[10] addition to a second dehydroalanine unit occurs (e.g., with Fmoc-ΔAla-D-Phe-OBzl (**8**) a single diastereomer of **21**[11] is

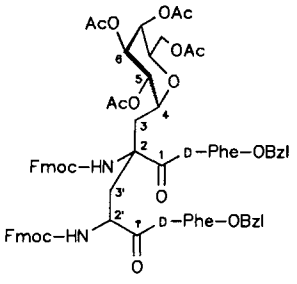
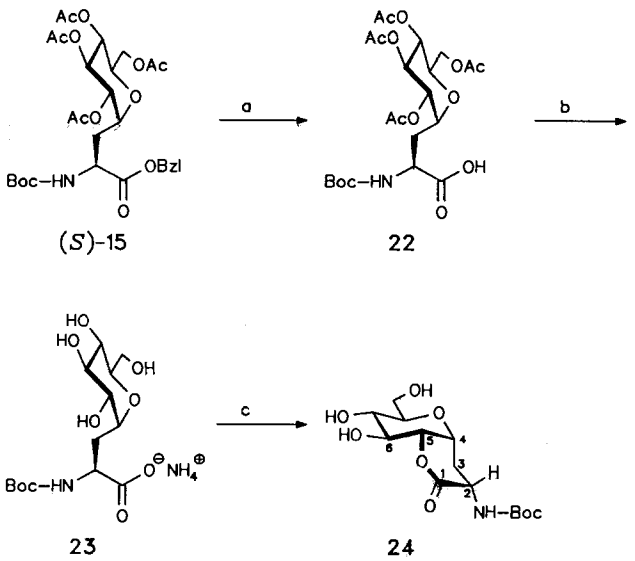
[a] (*S*) and (*R*) correspond to the configuration at C2 of the glycosidized amino acid. The products were characterized by ^{1}H and ^{13}C NMR spectroscopy and FAB-MS. [b] Overall yields of the α anomers after chromatography on silica gel. With the exception of two cases (12% for **16**, 4% for **17**), no β anomer could be detected (limit of detection <3%). [c] Isomeric ratios were determined by integration of corresponding signals in the ^{1}H NMR spectra or the HPLC chromatograms. The configuration at C2 was not assigned for compounds **16** and **17** (see text).



21

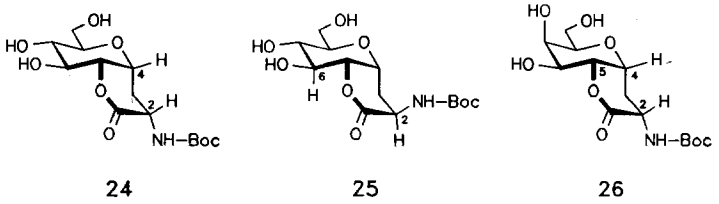
obtained in 53% yield). The higher stereoselectivity can be understood by the principle of double stereodifferentiation.[12]

The determination of the absolute configuration at C2 of the amino acids was carried out by NMR spectroscopy of the conformationally restricted lactones **24**, **25**, and **26** (see Scheme 3) and subsequent refinement by molecular dynamics calculations. The lactones were prepared in three steps starting from the corresponding *C*-glycosyl alanine derivatives (*S*)-**15**, (*R*)-**15**, and (*S*)-**12** (Scheme 2). The assignment of proton and carbon atoms was performed by COSY and HMQC[13] spectra. A mixture of [D_6]DMSO/$CDCl_3$ was used in the ratio 1:2 for the lactones **24** and **26** but 1:1.4 for lactone **25**. Pure [D_6]DMSO could not be used because of overlap in the ^{1}H NMR spectrum. An HMBCS–270 experiment[14] confirmed the cyclization to the δ-lactone ($^3J_{C1,H5}$). ^{1}H,^{1}H coupling constants were extracted from 1D spectra after apodization. The interproton distances were obtained from 500 MHz ROESY spectra[15] with a mixing time of 150 ms. Using these data we could assign both diastereotopic protons at C3. A qualitative inspection of the



(*S*)-**15** **22** **23** **24**

Scheme 2. Typical reaction sequence illustrated for the synthesis of compound **24**. The lactones **25** and **26** were obtained analogously from coumpounds (*R*)-**15** and (*S*)-**12**, respectively. a) H_2, 10% Pd-C, MeOH, room temperature, 1 h; b) NH_3, MeOH, room temperature, 14 h; c) *N*-ethyl-*N*′-(*N*″,*N*″-dimethylaminopropyl)carbodiimide (EDCI), 1-hydroxybenzotriazole (HOBT), dimethylacetamide (DMA)/THF (1:1), room temperature, 14 h. Quantitative yields were obtained for all three reaction steps.

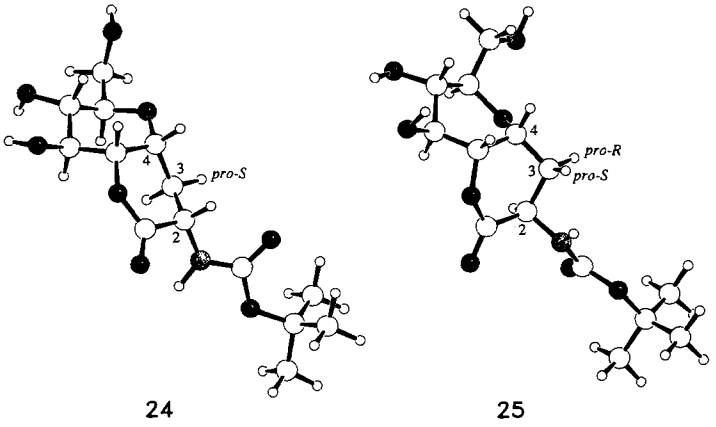


24 **25** **26**

Scheme 3. Formulas of the lactones **24**–**26** synthesized to assign the absolute configuration at C2.

ROESY spectra allows for discrimination between lactones **24** and **25**; a cross peak is observed between H2 and H4 for **24** but between H2 and H6 for **25**. This proves the assignment of the absolute configuration (2*S*) for **24** but (2*R*) for **25**, as shown in Figure 1.

To refine the structures, restrained MD simulations (Discover[16]) were performed by using the interproton distances (25 distances for compound **24** and 16 distances for **25**).[17] The calculated structures (Fig. 1) are in agreement with all measured distances and coupling constants (Table 2). The simulation was then continued for 300 ps without restraints



24 25

Fig. 1. MD structures of the lactones **24** and **25**. Oxygen atoms are filled, and nitrogen atoms are stippled.

and exhibited the stability of the obtained structures. To prove the configuration at C2, a calculation under identical conditions but with exchanged starting configurations was performed. As expected, considerable deviations from the interproton distances obtained from NMR spectroscopy were observed. In lactone **26**, which stems from the galactose series, strong ROEs from H2 to H4 and H5 are observed, proving the (2*S*) configuration as in **24**. Again, additional evidence is provided by the $^1H,^1H$ coupling constants (Table 2). The absolute configurations of the lactosyl compounds **16** and **17** were not determined but assumed to be the (2*S*) epimers from analogy with the main products. Transformation of the *C*-glycosides (*S*)-**12** and (*S*)-**15** into (*S*)-**10**, (*S*)-**11**, (*S*)-**18**, (*S*)-**19**, and (*S*)-**13**, (*S*)-**14**, respectively, indicates the natural (2*S*) configuration at the amino acids for all other major products.

Table 2. Selected $^1H,^1H$ coupling constants for compounds **24**–**26**.

^3J(H,H)	2,3(*pro-R*)	2,3(*pro-S*)	4,3(*pro-R*)	4,3(*pro-S*)
24	13.1	6.5	9.4	6.6
25	6.6	12.1	4.3	3.7
26	12.7	7.6	5.7	8.1

The procedure described here yields nonnatural *C*-glycosyl amino acids and *C*-glycosyl peptides in one step with high diastereoselectivity at the anomeric center, from readily available starting materials. The products exhibit high chemical stability, are suitable as potential glycosidase inhibitors, and provide a method to improve pharmaco kinetic properties of peptides.

General procedure

The protected dehydroamino acid is dissolved in dry toluene (about 0.1 M) together with 1.2–2 equivalents of glycosyl bromide and warmed to approximately 60 °C. Bu_3SnH (1.2–2 equiv) and catalytic amounts of AIBN are added under nitrogen or argon.

After completion of the reaction (monitored by TLC), the solvent is evaporated, the residue dissolved in acetonitrile and extracted three to five times with hexane to remove the tin compounds. The acetonitrile is evaporated, and the remaining oil purified by silica gel chromatography. The products are distereomeric mixtures of L- and D-amino acids.

[17] Restrained MD simulations in vacuum were performed over 150 ps. The time step for the integration of Newton's equations of motion was 1.0 fs. The starting structures were built interactively with INSIGHT. To take into account errors in the ROESY cross-peak intensities and for the interconversion into distanes, 5% were subtracted from the lower and added to the upper bounds. The simulations were performed for 5 ps at 1000 K, then for 10 ps at 500 K, and finally for an additional 135 ps at 300 K. Only the last 100 ps were used for analysis.

A Rh^I-Centered Cage Compound with Selective Catalytic Properties**

By *Hein K. A. C. Coolen, Piet W. N. M. van Leeuwen,* and *Roeland J. M. Nolte**

The development of synthetic catalysts that function according to the principles of enzymatic catalysis is a topic of great current interest. In the last decade examples of such systems—also called synzymes—have been reported.[1] Their number, however, is still limited. Taking nature as a guide, one can design a synzyme by combining a synthetic host molecule with an organic or inorganic catalyst. The objective is to bind a substrate selectively in the host and to achieve catalysis by positioning it in the correct orientation relative to the catalytic center.

In this communication we describe a cage compound with a Rh^I center, which preferentially binds allyldihydroxybenzenes and converts them into the corresponding styrenes and propyl derivatives by isomerization and hydrogenation of the allyl function. The frame of the cage is formed by the cleft molecule **1a**, which can bind catechol and resorcinol.[2] Binding in **1** occurs by π–π stacking and by hydrogen bonding interactions (Fig. 1). The catalytic center of the cage

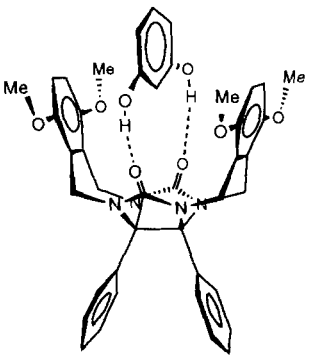

Fig. 1. Structure of the complex of **1a** with resorcinol.

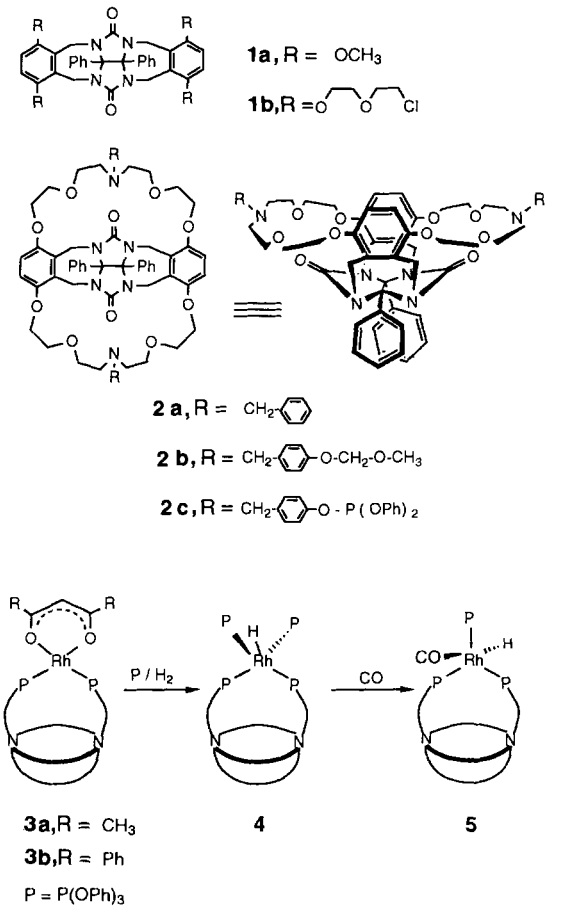
compound is a triphenylphosphite–rhodium complex. The complex $[RhH(CO)\{P(OPh)_3\}_3]$ catalyzes hydroformylation and isomerization reactions.[3] We recently found that $[RhH\{P(OPh)_3\}_4]$ is an isomerization as well as a hydrogenation catalyst. We have succeeded in positioning these complexes above the cavity of compound **1** to form a substrate-selective catalyst.

Synthesis of the cage compound starts from the known diphenylglycoluril derivative **1b**.[4] Double ring-closure of **1b** with two equivalents of *para*-methoxymethyloxybenzylamine[5] in acetonitril resulted in the basket-shaped compound **2b** (71%). Acidic cleavage of the methoxymethyl protecting group in **2b** followed by reaction with $ClP(OPh)_2$ in dichloromethane yielded the bis(triarylphosphite) ligand **2c** in 94% yield. Compound **2c** was fully characterized by elemental analysis and spectroscopic methods (Table 1).

Addition of an equimolar amount of $[Rh(CO)_2(acac)]$ to a solution of **2c** in chloroform resulted in the quantitative exchange of the two carbonyl ligands in the rhodium complex for the phosphites of **2c** and the formation of cage complex **3a**. Cage compound **3b** was prepared in a similar way by using $[Rh(CO)_2(dbm)]$ (Hdbm = dibenzoylmethane)[6]. Space-filling models show that compounds of



type **3** can exist in different conformations, prescribed by the square-planar coordination of the metal in combination with the rigidity of the spacers. In complex **3a** the acetylacetonate

ligand can be *above*, *in*, *partially in*, or *next to* the cavity. In line with this, the ^{31}P NMR spectrum of **3a** shows four doublets at 120.2, 121.2, 121.3, and 121.4 ($J_{Rh,P} = 304$ Hz); the intensity ratio varies with conditions. With more bulky substituents R the diketonate ligand does not fit *inside* the cavity. Therefore, in the ^{31}P NMR spectrum of **3b** only three doublets at $\delta = 119.1$, 120.5, and 120.7 ($J_{Rh,P} = 304$ Hz) are observed. Compounds **3a** and **b** can be isolated by precipitation in hexane (Table 1).

The binding properties of cage complex **3b** were evaluated by monitoring the shift of various cage and guest signals in ^1H NMR titrations.[7] A titration with resorcinol gave an association constant of $K_a = 2850 \pm 300\,M^{-1}$, in good agreement with the value measured for the reference compounds **1a** ($K_a = 2600 \pm 400\,M^{-1}$)[2] and **2a** ($K_a = 2900 \pm 300\,M^{-1}$)[8]. In the case of catechol it was not possible to observe a shift directly because of serious overlap of signals. The association constant for this guest was therefore determined in a competition experiment with resorcinol. The value found, $K_a = 200 \pm 100\,M^{-1}$, is also comparable with that of the binding of catechol in **1a** ($K_a = 60 \pm 10\,M^{-1}$)[2] and in **2a** ($K_a = 70 \pm 30\,M^{-1}$).[8]

Addition of a small excess of $P(OPh)_3$ to **3** in chloroform in the presence of H_2 afforded the hydrido complex **4**. The phosphites in this compound surround the Rh center tetrahedrally, and the hydride is positioned along one of the trigonal axes.[3c, 9] The two P atoms of the $P(OPh)_3$ ligands on the one hand and those of ligand **2c** on the other have almost the same δ and $J_{Rh,P}$ values. Therefore, the $^{31}P\{^1H\}$ NMR spectrum of **4** exhibits one doublet at δ=127.6 with some second order features ($J_{Rh,P} = 229$ Hz) (Fig. 2, left). Because of this nonequivalence combined with the fact that two pairs of faces of the tetrahedron are unequal, the doublet of quintets of the hydride signal in the high-field ^1H NMR spectrum ($\delta = -11.0$, $J_{P,H} = 44$ Hz) is broadened (Fig. 2, right). Even when a large excess of free $P(OPh)_3$ is present, no phosphorus signal of uncoordinated phosphite groups of **2c** was observed. This demonstrates the strong chelate effect of **2c**.[10]

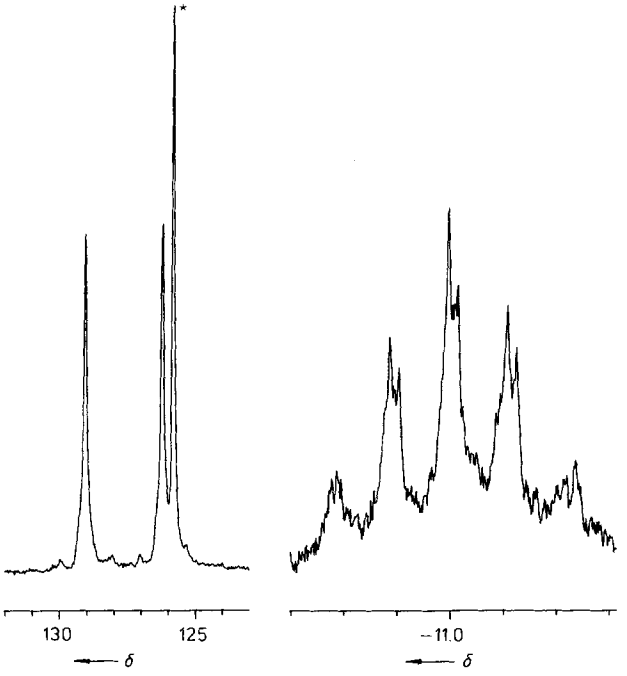

Fig. 2. Left: The $^{31}P\{^1H\}$ NMR spectrum of **4**. The signal marked with an asterisk is due to free $P(OPh)_3$. Right: The hydride region of the ^1H NMR spectrum of **4**.

Bubbling CO through a solution of **4** in chloroform gave the carbonyl hydride cage complex **5**. Compound **5** could also be obtained directly by treating **3a** or **3b** with a mixture of CO and H_2 in the presence of a small excess of $P(OPh)_3$. The model compound $[RhH(CO)\{P(OPh)_3\}_3]$ has a trigonal bipyramidal structure and exhibits only one doublet in its ^{31}P NMR spectrum, because of the equivalence of the P atoms and the very small *cis* P–H coupling.[3c] In the case of cage complex **5**, the $^{31}P\{^1H\}$ NMR spectrum showed a complex doublet at $\delta = 138.6$ ($J_{Rh,P} = 239$ Hz). We attribute this complexity to the nonequivalence of the P atoms in **5**.

Under Ar (1 atm) and in the presence of a small excess of $P(OPh)_3$ a solution of **5** in $CHCl_3$ is able to isomerize an equimolar amount of 4-allylcatechol (**6**)[11] to the corresponding *cis*- and *trans*-methylstyrenes in a ratio of about 1:3. Allylbenzene showed a much lower reactivity under the same conditions (monitored by ^1H NMR spectroscopy; Fig. 3). In two hours 68% of the allylcatechol had been

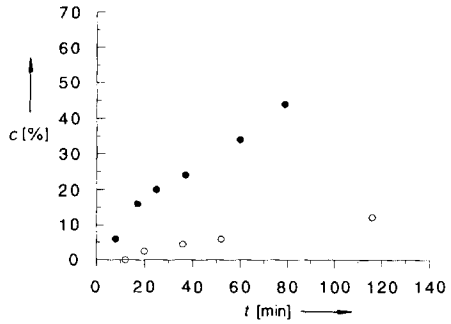

Fig. 3. The isomerization of 4-allylcatechol (●) and allylbenzene (○) in separate experiments by **5**.

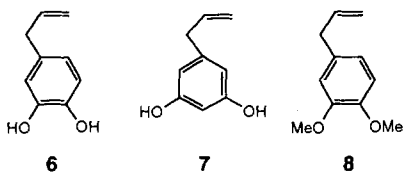
converted, while in the same period only 12% of the allylbenzene had reacted. The conversion of 4-allylcatechol starts immediately, whereas for allylbenzene an induction period of about 10 min is observed. In accordance with the literature,[3e] we assume that the actual catalyst is the hydride **4**. This catalyst is probably generated by the substrate itself: in the first step the propylenic substituent displaces the CO ligand. This explains the induction time of the reaction with the nonbinding substrate. From these results we conclude that the isomerization preferentially takes place *inside* the cavity of **5**.

In order to decide whether the reaction is truly catalytic and to exclude possible electronic effects of the substituents on the substrate we carried out a competition experiment with **4** and a fourfold excess of substrates **6**–**8** in chloroform.



6 **7** **8**

Substrate **8** is not bound in the cavity of **2**. The association constants for **6** and **7**[12] in **2a** were measured by ^1H NMR titrations to be $K_a = 90 \pm 20\,M^{-1}$ and $K_a = 2200 \pm 200\,M^{-1}$, respectively. Under a hydrogen atmosphere ($pH_2 = 1.2$ atm) the substrates were completely converted into products, mainly the propyl derivatives. The conversion and

product formation was followed by gas chromatography. A clear correlation was observed between the rate of conversion and the association constant of the substrate: $t_{1/2}$ of the conversion for **7**, **6**, and **8** amounted to 5, 10, and 38 min, respectively. In individual experiments under the same conditions, substrates **6**–**8** were each converted by $[RhH\{P(OPh)_3\}_4]$ at approximately the same rate ($t_{1/2}$ = 25 min). From these results we conclude that the reaction of the bound substrate is accelerated by **4**, whereas that of the nonbound is delayed.

The fact that **4** can still react with **8** suggests that the rhodium center in the cage complex is not completely shielded from the solution. Work is now in progress to functionalize the top part of **4** with a cap, which may further improve the selectivity of the catalyst.

Scavenger Templates: Synthesis and Electrospray Mass Spectrometry of a Linear Porphyrin Octamer**

By *Sally Anderson, Harry L. Anderson,* and *Jeremy K. M. Sanders**

Recently we described how cyclic porphyrin oligomers can be assembled with amine ligands as templates and demonstrated two complementary roles for a template.[1] A positive template brings together two reactive ends of a single molecule, encouraging intramolecular cyclization, while a negative template holds the ends apart, inhibiting intramolecular cyclization and so encouraging intermolecular reaction (Fig. 1). Here we report a new role for positive templates:

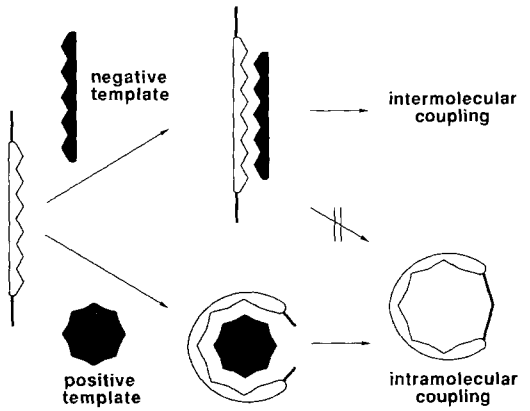

Fig. 1. The use of positive and negative templates to control the outcome of a reaction.

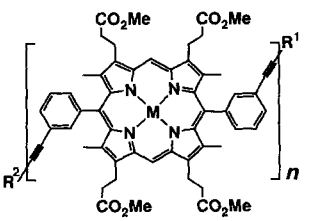
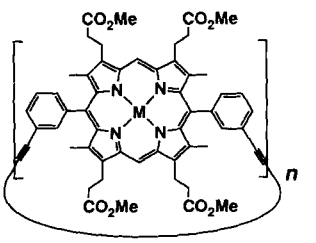
they can scavenge the cyclizable material in a complex mixture and so facilitate the synthesis of linear oligomers.[2] We start by outlining the idea of scavenger templates in general terms and then illustrate its application with the remarkably efficient synthesis of linear porphyrin octamer **1a** from the linear dimer **3a** via linear tetramer **2a**. We also demonstrate



1: $n = 8$ **a**: $R^1 = R^2 = SiMe_3$
2: $n = 4$ **b**: $R^1 = H$, $R^2 = SiMe_3$
3: $n = 2$ **c**: $R^1 = R^2 = H$



4: $n = 2$ $M = Zn, H_2$
5: $n = 4$

the use of electrospray mass spectrometry (ES-MS)[3] to determine the size and the purity of these molecules, which are otherwise rather difficult to characterize.

A common approach to the building-up of linear oligomers is to deprotect one end of a doubly protected oligomer containing n monomer units and couple it to give a fully protected oligomer containing $2n$ units. The cycle can be repeated as required. Partial deprotection gives a statistical mixture of fully protected, monoprotected, and fully deprotected compounds, which creates difficulty in the coupling step: fully protected material is inert, so it does not need to be separated before coupling, but fully deprotected material can couple with monoprotected material, leading to a new reactive oligomer and ultimately to a complex mixture. Conventionally this problem is avoided by separation of doubly deprotected material before coupling, but separation becomes more difficult with longer oligomers and so limits the chain length that can be achieved.

Scavenger templates overcome this problem by preventing fully deprotected molecules from undergoing bimolecular

reactions (Fig. 2): the template accelerates their cyclization; thus they do not survive long enough under the coupling conditions to react with monoprotected material. The separation can now be postponed until after coupling, when it becomes easier because the desired linear compound is twice as massive as the starting material and the cyclic by-product. Any positive template could, in principle, be used as a scavenger template, so the concept could have wide application. For example, it should be possible to use alkali metal cations as scavenger templates for the synthesis of linear oligoethylene glycols.

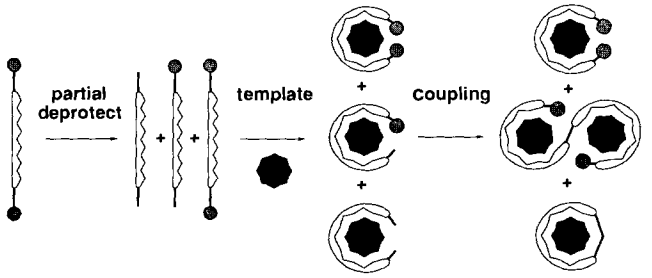

Fig. 2. A scavenger template induces molecules with two reactive end groups to cyclize intramolecularly, so allowing efficient coupling of monoprotected material. Hatched circles represent protecting groups.

Our scavenger-templated synthesis of butadiyne-linked linear porphyrin octamer **1a** involves two cycles of deprotection and Glaser coupling, beginning with linear porphyrin dimer **3a**.[4] In each cycle, tetrabutylammonium fluoride (TBAF) in chloroform was used to remove trimethylsilyl (TMS) protecting groups from the alkynyl substituents on the porphyrins. This deprotection was most efficient with free-base porphyrins, and was followed by metalation with zinc and templated Glaser coupling. After coupling, the zinc was removed with methanolic trifluoroacetic acid (TFA) to facilitate separation of the products.

4,4'-Bipyridyl (bpy) is an efficient template closing linear porphyrin dimer Zn_2-**3c** to cyclic dimer Zn_2-**4**,[4] and can thus be used as a scavenger template in the synthesis of linear tetramer. Half the protecting groups were removed from linear dimer H_4-**3a** with one equivalent of TBAF to give a statistical distribution of dimers, H_4-**3a**, **b**, and **c**. This mixture was treated with zinc acetate to yield Zn_2-**3a**, **b**, and **c** and then subjected to Glaser coupling in the presence of a sixfold excess of bpy. There were just three components in the resulting mixture: cyclic dimer **4**, linear dimer **3a**, and linear tetramer **2a**, the latter being relatively easy to isolate in good purity (Fig. 3). By contrast, in the absence of the bpy template a complex mixture formed, and clean linear tetramer was difficult to isolate in significant yields. Conversions and isolated yields for all reactions are given in Table 1.[5]

Table 1. Product yields [%] in the presence and absence of scavenger templates [a].

Reactant	Template	H_4-**3a**	H_4-**4**	H_8-**2a**	H_8-**5**	H_{16}-**1a**
H_4-**3a**	bpy	25 (20)	24 (15)	48 (29)	2	0
H_4-**3a**	–	25	7	30	10	0
H_8-**2a**	H_2-**6**	–	–	25 (16)	25 (13)	50 (15)
H_8-**2a**	–	–	–	25	17	36 (0)

[a] Overall yields for deprotection, metalation, coupling, and dematalation. Yields are from ^{1}H NMR analysis of crude reaction mixtures [5], except for those in parentheses, which are for recrystallized isolated material.

The second cycle of scavenger templating converted linear porphyrin tetramer into linear porphyrin octamer: *meso*-tetra-4'-pyridylporphyrin (H_2-**6**) is an excellent positive template for the cyclization of fully deprotected linear tetramer, giving more than 90% conversion to cyclic tetramer,[6] so it

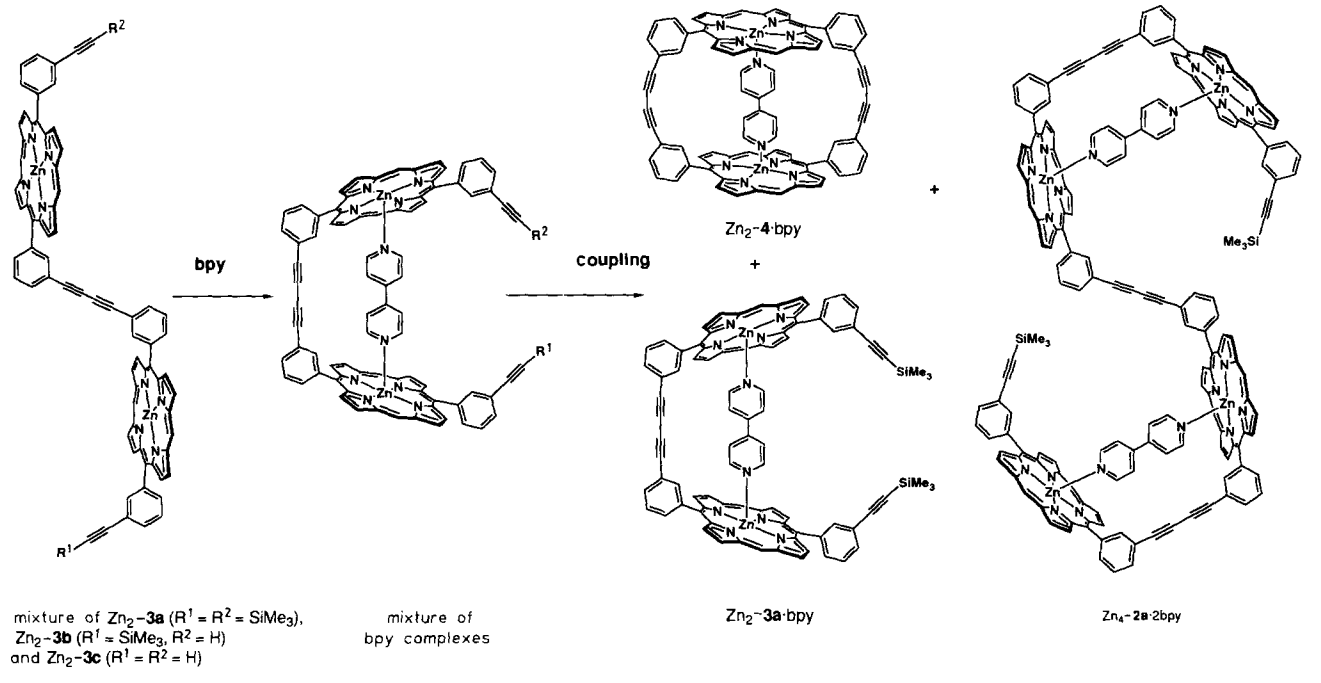

Fig. 3. 4,4'-Bipyridyl (bpy) as a scavenger template in the synthesis of linear tetramer. Zn_4-**2a** · 2 bpy. All porphyrin side chains have been omitted for clarity.

should be an efficient scavenger template for the synthesis of linear octamer **1a** (Fig. 4). Half the protecting groups were removed from linear tetramer H_8-**2a**, and the resulting mixture was metalated with zinc and then coupled in the presence of excess H_2-**6**. After coupling there were just three chromatographically distinct components in the mixture: linear tetramer **2a**, cyclic tetramer **5**, and linear octamer **1a**. Again, in the absence of template an intractable mixture containing higher oligomers resulted (see Table 1). ^{1}H NMR analysis of the crude mixture containing the template showed the presence of 25 ± 5% cyclic tetramer, so essentially all the monodeprotected material (50% with respect to starting material) must have been converted into linear octamer because no other product was detected. This is the theoretical maximum yield. However the isolated yield of pure recrystallized material was much smaller, reflecting the difficulty of separating linear octamer from cyclic tetramer even in this relatively simple mixture. Nevertheless, there are two advantages of using a scavenger template in this type of reaction: the crude yield of coupled product is increased, but just as importantly, the number of by-products which interfere with separation is greatly reduced.

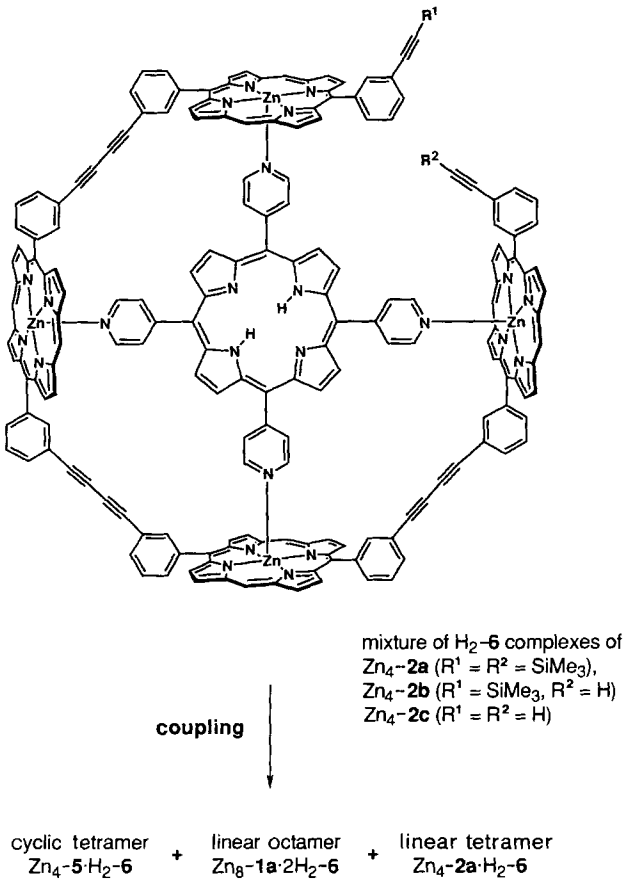

Fig. 4. Tetrapyridyl porphyrin H_2-**6** as a scavenger template in the synthesis of linear octamer Zn_8-**1a** · $2H_2$-**6**. All porphyrin side chains have been omitted for clarity.

Our cyclic porphyrin oligomers have characteristic ^{1}H NMR spectra, but the linear oligomers all have very small similar ^{1}H NMR spectra, making the analysis of mixtures with more than two linear oligomers unsatisfactory. The smaller oligomers give molecular ion peaks in their positive ion FAB mass spectra, but for tetramers only very weak molecular signals are obtained, and when the number of porphyrin units is further increased, no signal is observed. We therefore turned to electrospray mass spectrometry (ES-MS) which has been very successful with a range of large molecules.[7, 8] The compound is dissolved in a suitable solvent and protonated at several sites before injection into the spectrometer and volatilization.[9]

Linear tetramer H_8-**2a** (3783 Da) gave an electrospray mass spectrum with peaks due to the addition of three, four, and five protons: $[H_8\text{-}\mathbf{2a}\text{-}H_3]^{3+}$ (m/z 1262), $[H_8\text{-}\mathbf{2a}\text{-}H_4]^{4+}$ (m/z 947), and $[H_8\text{-}\mathbf{2a}\text{-}H_5]^{5+}$ (m/z 758). Cyclic tetramer gave peaks due to $[H_8\text{-}\mathbf{5}\text{-}H_3]^{3+}$ (m/z 1213) and $[H_8\text{-}\mathbf{5}\text{-}H_4]^{4+}$ (m/z 910). If cyclic oligomers only gave molecular ions with one proton per porphyrin, their spectra would be independent of ring size. This result, however, shows that less protonated molecular ions can be detected, thus allowing different cyclic oligomers to be distinguished. Octamer H_{16}-**1a** gave the spectrum shown in Figure 5. Peaks are observed for the addition of four to nine protons to the octamer, corresponding to a molecular weight of 7421 Da for the most abundant isotope of the neutral molecule. The distribution of ions suggests that the porphyrin units are far enough apart that protonation of each unit occurs independently: perhaps surprisingly, there is no apparent preference for $[H_{16}\text{-}\mathbf{1a}\text{-}H_4]^{4+}$, which would correspond to protonation of alternate units.

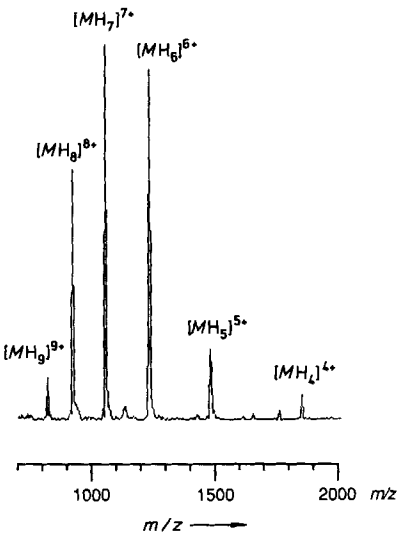

Fig. 5. Electrospray mass spectrum of linear octamer H_{16}-**1a**.

The use of scavenger templates can in principle be applied to the synthesis of any linear oligomer containing an even number of units, provided an effective template can be found that induces cyclization of any doubly deprotected starting material. This leaves the monodeprotected molecule to couple only with itself and hence form the required longer oligomer. The length of oligomer accessible by this method is limited only by our ingenuity in devising suitable templates and the ease with which the final products can be separated.

Experimental Procedure

Linear tetramer H_8-**2a**: Half the protecting groups were removed from H_4-**3a** (250 mg, 127 μmol) with TBAF (1 M in THF, Aldrich), by titrating a solution of the free base porphyrin in $CHCl_3$ (85 mL, 1.5 mM in porphyrin units in $CHCl_3$) with fluoride until about 50% of the TMS groups had been removed, which generally required about one equivalent of TBAF. The reaction was followed by monitoring the ratio of the intensities of the acetylene C–H ($\nu = 3303\ cm^{-1}$) and C = O ($\nu = 1732\ cm^{-1}$) absorptions with FT-IR. The mixture was passed through a short silica column, and then metalated with excess zinc acetate in chloroform refluxing. For the Glaser coupling, a solution of the zinc porphyrins in dichloromethane (500 mL, 0.5 mM per porphyrin unit) was treated with CuCl (1.50 g, 60 equiv), *N,N,N',N'*-tetramethylethylenediamine (2.30 mL, 60 equiv) in the presence of bpy (119 mg, 760 μmol) and stirred in dry air until coupling was complete (monitored by thin-layer chromatography, 15–30 min). The mixture was washed with water, demetalated by treatment with methanolic TFA (10%), washed with water, and concentrated. H_8-**2a** was isolated from the reaction mixture by flash column chromatography and recrystallized from $CHCl_3$/MeOH. Yield: 70 mg (29%). ^1H NMR (400 MHz, $CDCl_3$): $\delta = -2.50$ (s, 8H), 0.26 (s, 18H), 2.53 (s, 48H), 3.10 (br.t, 32H), 3.63 (set of very close singlets, 48H), 4.33 (br.t, 32H), 7.60–8.30 (m, 32H), 10.26 (s, 8H). IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 3303 (C-H), 1732 (C = O). UV/VIS (CH_2Cl_2): λ_{max} [nm] = 332, 410, 507, 540, 574, 625 nm. FAB-MS *m/z* 3783 (M^+), 1892 (M^{2+}). Yield of H_4-**5**: 36 mg (15%) and of reclaimed H_4-**3a**: 51 mg (20%).

Linear octamer H_{16}-**1a**: H_8-**2a** (170 mg, 45 μmol) was partly deprotected and coupled in the presence of a sixfold excess of H_2-**6** according to the procedure described above. The resulting mixture was washed, demetalated and chromatographed, and the products were recrystallized from $CHCl_3$/MeOH. Octamer: Yield: 25 mg (15%). ^1H NMR (250 MHz, $CDCl_3$): $\delta = -2.50$ (s, 16H), 0.25 (s, 18H), 2.49 (s, 96H), 3.12 (br.s, 64H), 3.61 (m, 96H), 4.32 (br.s, 64H), 7.68–8.23 (m, 64H), 10.25 (s, 16H). IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 1732 (C = O). UV/VIS (CH_2Cl_2): λ_{max} [nm] = 332, 411, 506, 539, 574, 625. ES$^+$-MS: *m/z* 825 ($[MH_9]^{9+}$), 928 ($[MH_8]^{8+}$), 1061 ($[MH_7]^{7+}$), 1237 ($[MH_6]^{6+}$), 1485 ($[MH_5]^{5+}$), 1856 ($[MH_4]^{4+}$). Yield: cyclic tetramer: 22 mg (13%); reclaimed starting material: 28 mg (16%).

[4] The protected linear porphyrin dimer H_4-**3a** was prepared by Glaser coupling of partly deprotected monomer. The metalated linear dimer Zn_2-**3c** gives a 1:1 complex with 4,4'-bipyridyl (bpy) (formation constant $\approx 10^6\ M^{-1}$ in $CDCl_3$); the guest in this complex slowly exchanges between excess host molecules on the ^1H NMR chemical-shift time scale at room temperature. The binding of bpy to linear dimer is much stronger than to monomer, but is about 100 times weaker than the binding to cyclic dimer, Zn_2-**4**, presumably because the linear molecule is more flexible. Bpy is a good template for the closure of linear dimer; in the absence of bpy, coupling of Zn_2-**3c** gives 19% conversion to cyclic dimer Zn_2-**4**, whereas with bpy the yield rises to 85%. This result supports the idea that bpy traps the linear intermediate in the formation of cyclic dimer Zn_2-**4** from monomer [1].
[5] These conversions were determined by ^1H NMR spectroscopy of reaction mixtures and are accurate to ±5%. Spectra of pure cyclic oligomers were subtracted from the spectra of the reaction mixtures to determine the proportion of each cyclic component. The relative amounts of the linear components were then estimated from the integration ratios of the difference spectra.

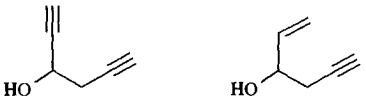
Stereocontrolled Construction of 6 · 5 · 6 and 5 · 5 · 6 Ring Systems by Radical Tandem Cyclization**

By *Uwe Albrecht, Rudolf Wartchow,* and *H. M. R. Hoffmann**

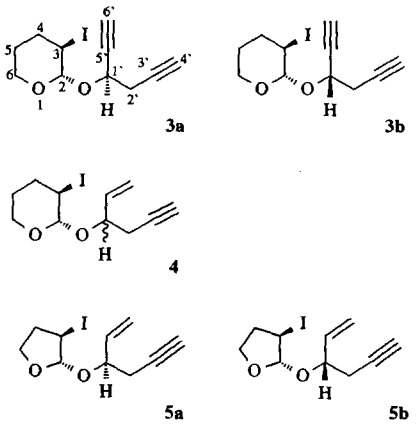
Dedicated to Professor Ekkehard Winterfeldt on the occasion of his 60th birthday

We have devised radical cyclizations,[1] which afford bicyclic and tricyclic pyranofurans and furanofurans in a chemo- and diastereoselective fashion. Reaction of *N*-iodosuccinimide (NIS) and 1,5-hexadiyn-3-ol (**1**) or 1-hexen-5-yn-3-ol (**2**) with 2,3-dihydrofuran and Δ^2-dihydropyran gave



1 **2**

functionalized cyclic α-alkoxy-β-iodo ethers[2, 3] (Scheme 1). In studying radical-initiated cyclizations of these compounds we had to find experimental conditions that allowed us to handle sensitive starting materials and products. To this end, two sets of experimental conditions were investigated in detail.



Scheme 1. Synthesized monocyclic iodoacetals. Compounds **3** were obtained in yields of 50–64%, **4** in 81%, and **5** in 66%. Iodoacetal **4** was obtained as a 1:1 mixture of diastereomers.

Cyclization of diastereomerically pure **3a** induced by BEt_3–oxygen[4] gave a mixture of isomeric bicyclic vinyl iodides **6a**(*E*:*Z* = 1:9) in satisfactory yield and under mild conditions (30–55 °C; Scheme 2). Iodine-free *exo* methylene acetal **7a**, formed as a by-product (5%), could be separated from the iodine-containing products by chromatography (petroleum ether/$CHCl_3$). The selective formation of **6a** and

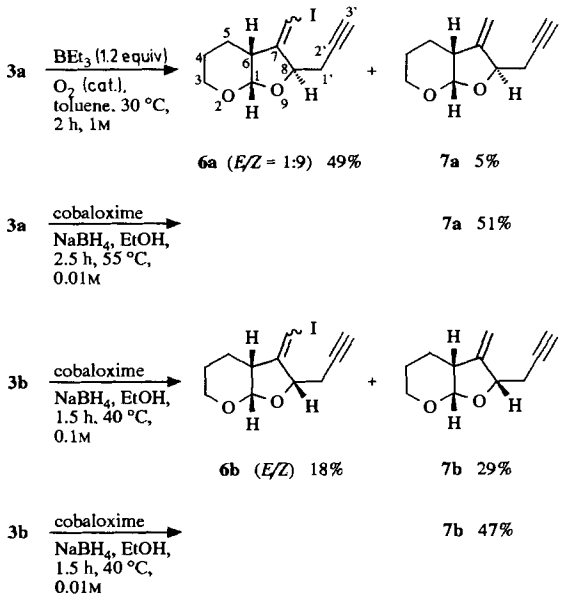
[**] We thank Ulrike Eggert for experimental contributions and the Fonds der Chemischen Industrie for support of this work.

7a proved to be markedly dependent on temperature. At elevated temperatures (80–100 °C) complicated product mixtures arose.

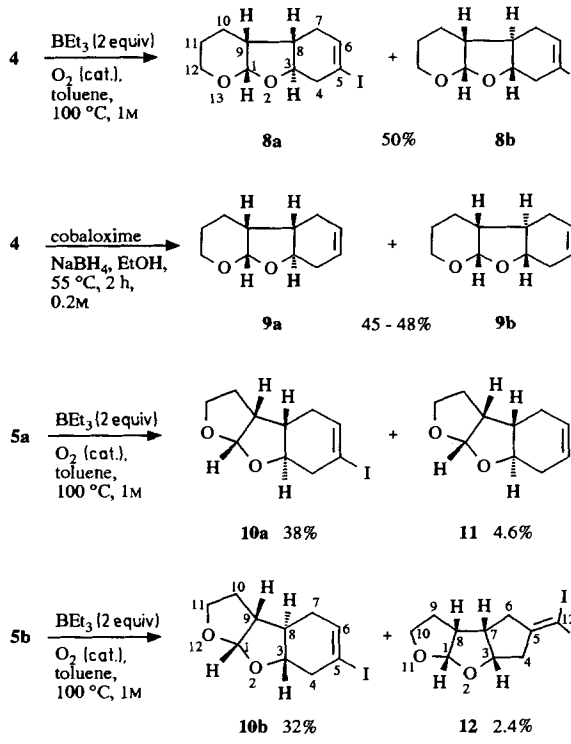


Scheme 2. Monocyclizations of diynes 3. The concentrations given refer to the starting materials.

Similarly, both **3a** and **3b** were monocyclized with cobaloxime under hydrogen-atom-transfer conditions,[2] giving **7a** and **7b**, respectively (Scheme 2). The formation of vinyl iodide **6b** implicates competing intermolecular iodine-atom-transfer,[5] and was favored at higher concentrations of the starting material (0.1 vs. 0.01 M). A second cyclization of the intermediate vinyl radical, for example 6-*endo*-digonal,[6] was not observed; apparently the activation energy required is prohibitively high.

Unlike diynes **3a** and **3b**, the enynes **4** and **5** underwent tandem cyclizations (Scheme 3). The construction of the two ring junctions proceeded stereo- and regioselectively, giving a series of 1,9-*cis*-, 3,8-*trans*-fused tricycles (for numbering of atoms see Scheme 3). The cyclization of **4** with BEt_3 under an argon atmosphere was noticeably very sluggish. Only in the presence of catalytic amounts of oxygen (brief displacement of the argon atmosphere) did the cyclization proceed satisfactorily. Isolation and purification of the tricycles required several chromatographic separations.

Characteristic spectroscopic data of the tricycles are the coupling constants for the 3,8 *trans*- ($^3J = 10$ Hz) and 1,9 *cis*-oriented protons ($^3J = 4-6$ Hz). The structures and relative configurations of **8a**, **8b**, and **12** were further corroborated by X-ray crystallography (Fig. 1).[7]



Scheme 3. Stereocontrolled tandem cyclizations of compounds **4** and **5**. The concentrations given refer to starting materials.

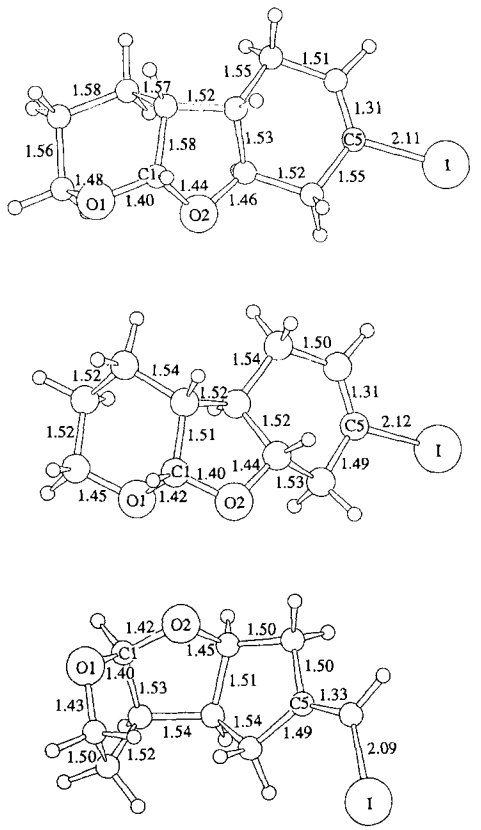


Fig. 1. Crystal structures of **8a** (top), **8b** (middle), and **12** (bottom) (SCHAKAL).

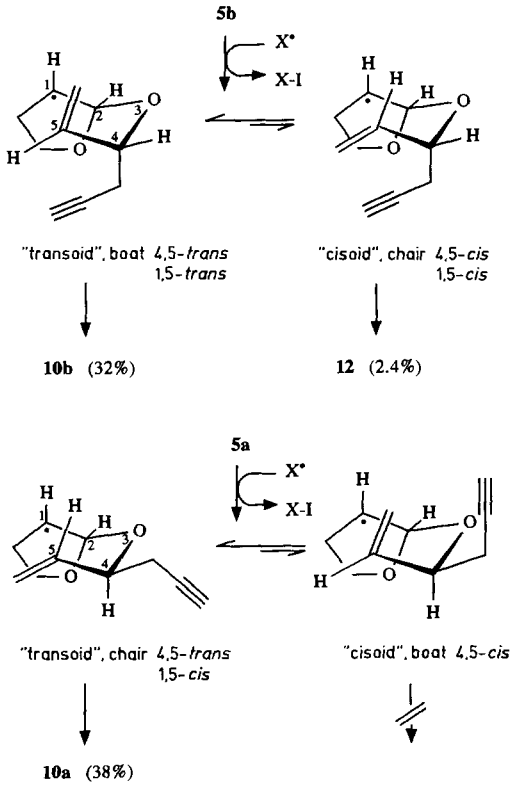
A priori, a 3-oxahex-5-enyl radical generated from **5a** or **5b** can cyclize either via a chair or a boat transition state. In studying carbohydrate systems and changing the configuration of an appendant homoallyl side chain, RajanBabu observed that a boat transition state is feasible provided that the chair alternative is destabilized by an unfavorable eclipsing interaction.[8]

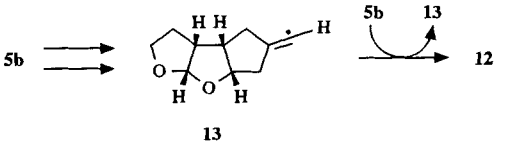
In our investigations, diastereomer **5a** apparently cyclizes preferentially via the chair transition state, in which the methylene group and neighboring propargyl group are transoid. As a consequence, the two hydrogen atoms at C-4 and C-5 are *trans* in tricycle **10a** (numbering in Scheme 4).

The stereochemistry of the formation of **10a** is the "normal" one, and has often been observed in closure to many types of [3.3.0]bicycles.[1]



Scheme 4. Transoid versus cisoid transition states (X• = radical initiator).

On the other hand, the stereochemistry of tricycle **10b** from **5b** is "abnormal", since formation of **10b** requires a boat transition state. If the 3-oxahex-5-enyl radical generated from **5b** adopts the chairlike transition state, the propargyl group and methylene group are in a less favorable eclipsing or cisoid arrangement. Upon ring closure the H atoms on C-4 and C-5 are then necessarily *cis*. A priori, the radical chain reaction can continue with an *endo*cyclic or an *exo*-cyclic ring closure. In this case, the 5-*exo*-digonal closure is faster, as usual, and *cis-syn-cis* dioxatriquinane **12** is isolated as a minor by-product. Formation of **12** may be ascribed to the "kinetic error" of the generation of radical **13**, in which all four substituents of the central tetrahydrofuran moiety are placed on the same face of the ring. The formation of **12**



(Fig. 1) complements the well-known Curran synthesis of *cis-anti-cis* fused triquinanes.[9] With regard to entropy and enthalpy, the formation of the open, basketlike triquinane **12** from monocycle **5b** is remarkable. The product ratio **10b**:**12** = 13:1 corresponds to a preference of the boat transition state by 1.5 kcal mol^{-1}.

If the sequential cyclization of iodo-substituted enyne **4** is conducted at lower temperatures (0–40 °C, BEt_3 method), the second ring closure does not occur, and mainly monocyclization products are formed. Tandem cyclizations were usually carried out at 100 °C (Scheme 3). Only the reaction mediated by cobaloxime/$NaBH_4$ **4** → **9a** + **9b** succeeded under milder conditions (55 °C). Thus, the cyclization sequence is also chemoselective in that the triple bond does not take part in an initial 6-*exo*-digonal cyclization,[1] but later in an unexpected 6-*endo*-digonal ring closure. *Endo*-digonal closure to *trans*-fused bicyclo[4.3.0]nonane derivatives is "tolerated" at higher temperature, because the normally favored 5-*exo*-digonal closure would have to produce a high-energy, *trans*-fused bicyclo[3.3.0]octane system.

Experiments have shown that the replacement of the Bu_3SnH/azobis(isobutyronitrile) (AIBN) method with the BEt_3–oxygen method or cobaloxime-mediated hydrogen-atom-transfer has been instrumental in effecting the double cyclization. Our results demonstrate the power of radical reactions in organic synthesis with respect to multiple formation of carbon–carbon bonds and to chemo-, regio-, and diastereocontrol. The usual preference for the formation of *cis*-perhydroindane[10] is negated by the proclivity of the C-4 propargyl group to adopt a transoid conformation with respect to the neighboring methylene group (Scheme 4). The formation of tricycle **10b** implicates a preferred boat transition state with a pseudoaxial propargyl side chain. To our knowledge, these double cyclizations are the first examples in which a favorable formation of a five-membered ring has been coupled with the less favored formation of a *trans*-fused six-membered ring. The previously unknown 6-*endo*-digonal closure is possible, because the potentially faster 5-*exo*-digonal mode is prevented by ring strain.

Experimental Procedure

The cyclization precursors were prepared as follows: A solution of NIS (1.2 equiv) and the alcohol component [11,12] (1.2 equiv) in CH_2Cl_2 was cooled to −30 °C. The cyclic enol ether was added dropwise, and the resulting mixture was cooled to −70 °C, stirred, and allowed to reach room temperature over 15 h. After aqueous workup, chromatography (silica gel) furnished functionalized monocyclic acetals **3**–**5** (Scheme 2). The products were obtained as mixtures of the diastereomers (1:1), which, except for compound **4**, could be separated.

Cobaloxime-induced cyclization; typical procedure: To a solution of **3b** (200 mg, 0.65 mmol) in abs EtOH (5.6 mL) was added solid $NaBH_4$ (50 mg, 1.3 mmol) and 10 N NaOH (0.1 mL, 10 mmol). Argon was passed through the solution, and several portions of finely powdered cobaloxime (14.6 mg, 0.033 mmol) were added over 1.5 h at 40 °C. The solvent was removed on a rotary evaporator, and after addition of water (10 mL), the product was extracted with Et_2O (3 × 10 mL). The combined organic phases were washed with water (5 mL), brine (5 mL), and dried ($MgSO_4$). After removal of the solvent, the resulting oily residue was chromatographed (silica gel, Et_2O/petroleum ether, 1:10). Iodine-free bicycle **7b** (34 mg, 29%) was separated from vinyl iodide **6b** [36 mg, 18%, (*E*/*Z*) (not assigned), 2:1] by repeated chromatography (petroleum ether/$CHCl_3$). **6b** (major isomer): ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.28 (m, 1H, *exo*-CH_2), 5.25 (d, ^3J = 4 Hz, 1H, H-1), 4.42 (m, 1H, H-8), 3.89 (m, 1H, H_a-3), 3.73 (m, 1H, H_b-3), 2.77–2.58 (m, 3H), 2.21 (br m, 1H), 2.09 (t, ^4J = 2.5 Hz, H-3'), 1.67–1.24 (m, 4H, H-4/H-5). **6b** (minor isomer): ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.13 (dd, ^4J = 2 Hz, ^4J = 2 Hz, 1H, *exo*-CH_2), 5.24 (d, ^3J = 4 Hz, 1H, H-1), 4.56 (m, 1H, H-8), 3.92 (m, 1H, H_a-3), 3.50 (m, 1H, H_b-3), 3.20 (ddd, J = 17 Hz, J = 2 Hz, ^4J = 2 Hz, 1H, H_a-1'), 2.79 (ddd, J = 17 Hz, J = 10 Hz, ^4J = 2.5 Hz, 1H, H_b-1'), 2.73 (m, 1H, H-6), 2.09 (dd, ^4J = 2.5 Hz, ^4J = 2.5 Hz, 1H, H-3'), 1.99–1.37 (m, 4H, H-4/H-5). **7b**: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 5.29 (m, 1H, H_a-*exo*-CH_2), 5.12 (d, ^3J = 4 Hz, 1H, H-1), 5.02 (m, 1H, H_b-*exo*-CH_2), 4.68 (m, 1H, H-8), 3.85 (dm, 1H, H_a-3), 3.41 (dd, J = 11.8 Hz, J = 11 Hz, J = 2 Hz, 1H, H_b-3), 2.73 (m, 1H, H-6), 2.63 (ddd, J = 8 Hz, J = 7 Hz, ^4J = 2.5 Hz, 2H, H-1'), 2.06 (dd, ^4J = 2.5 Hz, ^4J = 2.5 Hz, 1H, H-3'), 2.12–1.32 (m, 4H, H-4/H-5); ^{13}C NMR ($CDCl_3$): δ = 149.63 (s, C-7), 105.43 (t, *exo*-CH_2), 100.79 (d, C-1), 81.47 (s, C-2'), 79.34 (d, C-8), 69.77 (d, C-3'), 64.45 (t, C-3), 43.07 (d, C-6), 27.21, 22.45, 20.45 (t, C-4, C-5, C-1').

BEt_3/O_2-induced cyclization; typical procedure: A well-dried 10 mL two-necked flask equipped with reflux condenser, $CaCl_2$ tube, and septum was charged with a solution of **5b** (700 mg, 2.39 mmol) in abs toluene (2.4 mL) and heated to 100 °C. A solution of BEt_3 (1 M in hexane, 3.6 mL, 1.5 equiv) was slowly added by syringe over 15 min, and the reaction was monitored by thin-layer chromatography. After the reaction mixture was stirred for 45 min, a further portion of BEt_3 (0.5 equiv) was added. After complete reaction (ca. 2.5 h) the solvent was evaporated, and the oily residue was chromatographed (silica gel, Et_2O/petroleum ether, 1:6), giving three fractions. F1 and F2 were purified by further chromatography (petroleum ether/$CHCl_3$); F3 contained mainly the iodine-free tricycle derived from **10b** and impurities, and was not characterized further). Recrystallization of **10b** from Et_2O/petroleum ether afforded colorless crystals, 223 mg (32%), m.p. 90 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.33 (m, 1H, H-6), 5.69 (d, 1H, J = 5.8 Hz, H-1), 4.03 (m, 1H, H_a-11), 3.85 (ddd, 1H, J = 12 Hz, 8 Hz, 5 Hz, H_b-11), 3.53 (ddd, 1H, J = 10 Hz, 10 Hz, 6 Hz, H-3), 2.96 (dm, 1H, H_a-4), 2.71 (m, 1H, H_b-4), 2.45 (m, 2H, H-9, H_a-7), 2.13–1.82 (m, 2H, H_b-7, H_a-10), 1.72 (m, 1H, H_b-10), 1.48 (m, 1H, H-8); ^{13}C NMR ($CDCl_3$): δ = 136.81 (d, C-6), 109.05 (d, C-1), 92.34 (s, C-5), 78.42 (d, C-3), 66.88 (t, C-11), 47.74, 43.41 (d, C-8/9), 45.48, 32.88, 30.58 (t, 3C). NOE effects: H-8 with H_a-7 (5.9%), H_b-4 (4.4%), H_b-11 (5.4%); H-3 with H-9 (2.1%), H_a-4 (4.4%), H-1 (3.9%); H-9 with H_a-10 (10.4%), H-1 (5.3%), H-3 (2.4%); H-1 wih H-3 (3.4%), H-9 (5.2%). Recrystallization of **12** (F2) (Et_2O/petroleum ether) afforded colorless crystals, 17 mg (2.4%), m.p. 71 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 5.96 (m, 1H, H-12), 5.68 (d, ^3J = 4.5 Hz, H-1), 4.63 (dt, 1H, J = 6 Hz, 2 Hz, H-3), 4.04–1.70 (m, 10H); ^{13}C NMR ($CDCl_3$): δ = 153.57 (s, C-5), 110.98 (d, C-1), 85.13 (d, C-12), 70.21 (d, C-3), 69.02 (t, C-10), 46.18, 43.66 (d, C-7/8), 40.51, 37.20, 27.78 (t, 3C).

Novel Iron Carbonyl Telluride Clusters: Synthesis and Characterization of $[Fe_5Te_4(CO)_{14}]^{2-}$ and $[Fe_8Te_{10}(CO)_{20}]^{2-}$ **

By *Lisa C. Roof, William T. Pennington,* and *Joseph W. Kolis**

The molecular chemistry of polyselenides and polytellurides is currently receiving much attention because of the novel coordination properties of the molecules[1], as well as their use as starting materials for new solid-state materials.[2]

Recently we have been studying the reactions of polychalcogenides with transition metal carbonyls and have found that they can react through an internal redox reaction to give a variety of novel products.[3] Electrons are transferred from the zero-valent metal center to the polychalcogenide ion. This results in the oxidative decarbonylation of the metal and reductive cleavage of the chalcogenide chain. While polysulfides and polyselenides can induce complete oxidative decarbonylation, producing high-valent metal centers,[4] polytellurides only seem to oxidize metals to the +I or +II state. Metal–metal bonds can also form, leading to clusters, as in the reaction of Te_4^{2-} with $[W(CO)_6]$ which affords $[\{W(CO)_3\}_6(Te_2)_4]^{2-}$.[5]

We decided to study the reactions of polytellurides with iron pentacarbonyl since previous work has shown that iron carbonyl telluride chemistry is extremely rich.[6] Here we report two examples of this internal redox reaction with the synthesis and characterization of two new iron carbonyl tellurides, namely $[Fe_5Te_4(CO)_{14}]^{2-}$ (**1**) and $[Fe_8Te_{10}(CO)_{20}]^{2-}$ (**2**).

When a fivefold excess of $[Fe(CO)_5]$ is allowed to react with $(Ph_4P)_2Te_4$ in dimethylformamide (DMF) at 85 °C, **1** is formed in reasonable yield as the Ph_4P^+ salt [Eq.(a)].

$$5\,[Fe(CO)_5] + (Ph_4P)_2Te_4 \longrightarrow \underset{(Ph_4P)_2\text{-}\mathbf{1}}{(Ph_4P)_2[Fe_5Te_4(CO)_{14}]} + 11\,CO \qquad (a)$$

The X-ray crystal structure analysis showed that the dark brown crystalline product[7] contains a central $Fe(CO)_2$ fragment, which is bonded to two $[Fe_2Te_2(CO)_6]$ "butterflies" (Fig. 1). The geometry about the central iron can be described as distorted octahedral with a bond angle of 160.7(2)° for Te(2)-Fe(1)-Te(2a). The Te(1)–Te(2) distance is 3.152(2) Å, similar to that in other metal complexes with a butterfly structure.[8]. For Te–Te distances of this length a certain degree of bonding interaction has been proposed,[9] but it may be more accurate to view this short bonding distance as arising from the oxidative addition of the original Te–Te bond to the central iron atom Fe(1). Therefore each tellurium atom is formally assigned a −II oxidation state, the central iron atom +II, and each butterfly iron atom +I. Metal–metal bonds and 3 COs complete the 18e count for the butterfly iron atoms. The Fe(2)–Fe(3) distance is 2.592(4) Å, and the Fe(2)–Te(2) distance is 2.573(4) Å, which are similar to those in other iron telluride compounds with butterfly structures.[6d, 8] Iron chalcogen butterfly structures are well known,[6, 8, 10] and the first, $[Fe_2S_2(CO)_6]$, was reported in 1958.[10a] Since then their reactions have been studied thoroughly.[8, 9, 11]

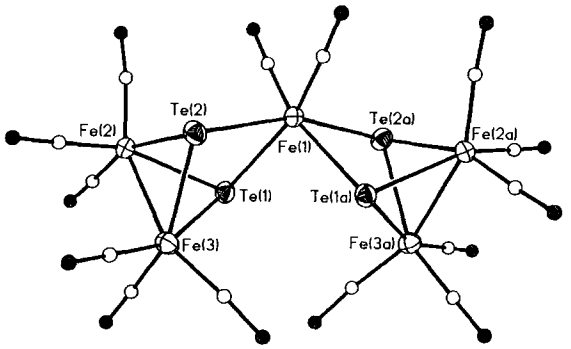

Fig. 1. Structure of **1** in crystals of $(Ph_4P)_2$-**1**. (ORTEP, thermal ellipsoids with 35% probability). Selected distances [Å] and angles [°]: Te(1)-Te(2) 3.152(2), Fe(2)-Fe(3) 2.592(4), Fe(2)-Te(2) 2.573(4), Fe(2)-Te(1) 2.588(3), Fe(1)-Te(2) 2.585(2), Fe(1)-Te(1) 2.675(3); Te(2)-Fe(1)-Te(2a) 160.7(2), Te(1)-Fe(1)-Te(1a) 100.0(1), Te(2)-Fe(1)-Te(1) 73.6(1), Te(2a)-Fe(1)-Te(1a) 73.6(1).

If the reaction is carried out with only a threefold excess of $[Fe(CO)_5]$, compound **2** is formed. A possible balanced reaction is given in Equation (b). Like **1**, product **2** can be isolated as a dark brown crystalline product with Ph_4P^+ as a

$$8\,[Fe(CO)_5] + 3\,(Ph_4P)_2Te_4 \longrightarrow (Ph_4P)_2[Fe_8Te_{10}(CO)_{20}] + 2\,(Ph_4P)_2Te + 20\,CO \quad (b)$$

$(Ph_4P)_2$-**2**

counterion (Fig. 2).[7] The dianion contains two $[Fe_4Te_4(CO)_{10}]$ cubane units connected by a central Te_2^{2-} ligand. The Te_2^{2-} fragment links the two cubes by bonding in

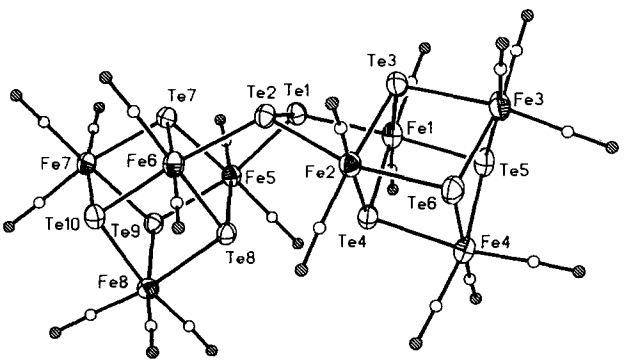

Fig. 2. Structure of **2** in crystals of $(Ph_4P)_2$-**2**. (ORTEP, thermal ellipsoids with 35% probability). Selected distances [Å] and angles [°]: Te(1)-Te(2) 2.828(1), Fe(1)-Te(1) 2.622(2), Te(2)-Fe(2) 2.616(2), Fe(1)-Te(4) 2.587(2), Fe(1)-Te(5) 2.589(2), Fe(4)-Te(4) 2.652(2), Fe(4)-Te(5) 2.630(2), Fe(2)-Te(3) 2.626(2), Fe(2)-Te(6) 2.590(2), Fe(3)-Te(3) 2.643(2), Fe(3)-Te(6) 2.641(2), Fe(1)-Te(3) 2.637(2), Fe(4)-Te(6) 2.615(2), Fe(2)-Te(4) 2.615(2), Fe(3)-Te(5) 2.626(2); Fe(6)-Te(2)-Fe(2) 120.4(1), Fe(6)-Te(2)-Te(1) 101.8(1), Fe(2)-Te(2)-Te(1) 99.3(1), Fe(1)-Te(1)-Fe(5) 123.0(1), Fe(1)-Te(1)-Te(2) 99.9(1), Fe(5)-Te(1)-Te(2) 98.0, Fe(1)-Te(5)-Fe(4) 99.5(1), Te(3)-Fe(3)-Te(6) 80.4(1).

η^2 fashion by donation of lone pair electrons to iron atoms in opposite corners of one face of each cube. The Te(1)–Te(2) bond length (2.828(1) Å) is in the usual range for a Te–Te bond in a metal cluster.[5, 6d] The Fe–Te distances average 2.62(2) Å, and the angles are between 80.4(1)° and 99.5(1)°, so the cubes are only slightly distorted despite the presence of the transannular ditelluride fragment. This is different from the previously reported $[Fe_4Te_4(TePh)_4]^{3-}$ which contains angles varying from 60.2° to 118°.[12] Each iron atom is in an octahedral environment, and has a complete 18e count through bonding with the appropriate number of COs. The dihedral angle between the two cubes is 123.3°.

The chemistry of iron–sulfur cubanes is well investigated because of their presence in the active sites of many enzymes.[13] The neutral parent cubanes $[Fe_4(CO)_{12}(\mu_3\text{-}E)_4]$ (E = S, Se) were structurally characterized in 1982,[14] and several iron–telluride cubanes have also been characterized;[12, 15] however, the type of bridging in **2** is entirely unprecedented. The formation of the neutral cubane $[Fe_4Te_4(CO)_{12}]$ from the dimerization of $[Fe_2(Te_2)(CO)_6]$ has been reported, but this molecule was never structurally characterized.[6b]

Both **1** and **2** are formed by the mild pyrolysis of $[Fe(CO)_5]$ and Te_4^{2-} in DMF. In addition, conversion of **1** to **2** can be achieved by adding elemental Te (4 equiv) to the solution of **1** before workup [Eq. (c)]. This conversion has been monitored in solution by IR spectroscopy and is quite clean. The

$$\underset{\mathbf{1}}{[Fe_5Te_4(CO)_{14}]^{2-}} + 4\,Te \longrightarrow \underset{\mathbf{2}}{[Fe_8Te_{10}(CO)_{24}]^{2-}} \quad (c)$$

CO–Fe–Te system is obviously very versatile, and other intermediate species have been observed in solution. Thus we have shown that neutral $[Fe(CO)_5]$ can be oxidized by polytelluride chains to form very unusual clusters containing reduced tellurides and iron atoms in the +I and +II state.

Experimental Procedure

$(Ph_4P)_2$-**1**: In a typical reaction, $(PPh_4)_2Te_4$ [16] (0.500 g, 0.420 mmol) and $[Fe(CO)_5]$ (0.27 mL, 2.05 mmol) in DMF (10 mL) were stirred at 85 °C for 24 h. The resulting brown solution was filtered, layered with ether (10 mL), and stored at 4 °C for 24 h. After the brown powder that formed was removed by filtration, the solvent was removed under vacuum. The brown oil was redissolved in CH_2Cl_2 (10 mL). Slow addition of ether (5 mL) and storage at 4 °C for 24 h produced a dark brown crystalline product. Yield: 33%. Satisfactory C,H analysis. IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2025(w), 2006(s), 1975(s), 1936(m).

$(Ph_4P)_2$-**2**: The compound was prepared in an analogous way to $(Ph_4P)_2$-**1**. The only changes were that less $[Fe(CO)_5]$ (0.15 mL, 1.14 mmol) was added and the reaction was stirred for 12 h at 85 °C. Yield: 27%. Satisfactory C,H analysis. IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2027(s), 2015(m), 1977(s), 1916(w).

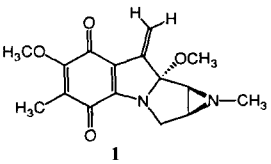
The Total Synthesis of (±)-Mitomycin K**

By *John W. Benbow, Gayle K. Schulte,* and *Samuel J. Danishefsky**

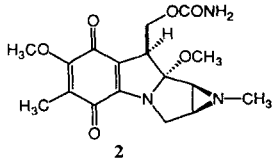
The mitomycins and related aziridine-containing alkaloids have enjoyed remarkable longevity as systems of great fascination to chemists.[1, 2] Continuing interest in this family of compounds arises from the clinical importance of at least one member (mitomycin C) as an anticancer agent,[3] and from the novel structures wherein a confluence of potentially labile functionality is maintained, in metastable form, in a small molecular array.[2] Many laboratories have concerned themselves with the isolation,[1, 4] structure proof,[5] chemistry,[6] crystallography,[7] synthesis,[8] and bioorganic chemistry[9] of various mitomycins.

Not the least fascinating type of mitomycin is exemplified by mitomycin K (**1**), in which the methylene group in the 9 position constitutes still another locus of potential structural vulnerability, not present in the more traditional congeners (cf. *N*-methylmitomycin A (**2**)).

Though total syntheses of the more prevalent mitomycins of the type **2** have been accomplished by Kishi et al. and by Fukuyama et al.,[8e–h] to date no total synthesis directed toward a mitomycin of the type **1** has been registered. Such compounds are of particular interest to us from the standpoint of the mechanism of their bioactivation.[9] In principle,



1

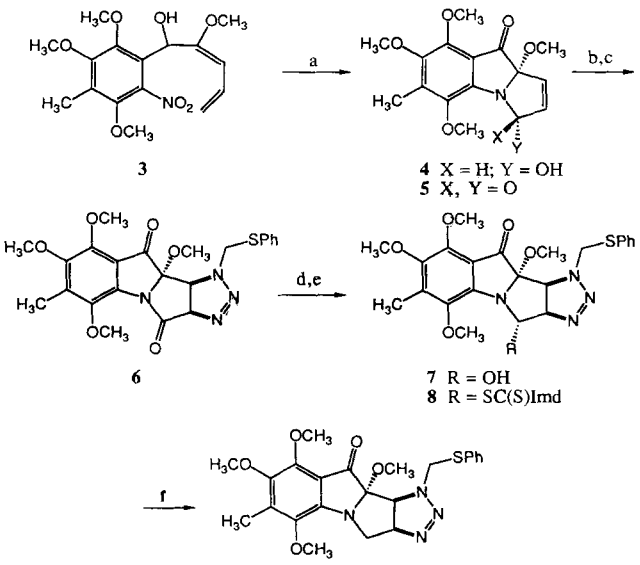


2

it is possible that the presence of the vinylquinone unit confers electrophilicity on these systems even in the absence of reductive activation.[10]

A photochemical route to the framework of the mitomycins (cf. **3** → **4**) has recently been reported.[11] We now describe the total synthesis of (±)-mitomycin K (**1**). While compound **4** contains a significant portion of the mitomycin K structure, some rather challenging and novel chemistry was required to achieve the synthesis of **1**.

Rapid progress was, at first, impeded by our inability to functionalize the C1-C2 double bond of **4** in a constructive fashion.[12] We anticipated[13] that the site of unsaturation in the corresponding conjugated lactam, **5**, could be more generally exploited. Accordingly, compound **4** was oxidized (PDC)[14] to afford a 65% yield of the imide **5**.[15] Indeed, reaction of **5** with (phenylthio)methyl azide[16] at 80 °C gave a 90% yield of the triazoline **6**. The latter underwent reduction with L-Selectride to afford a 77% yield of the hydroxyl compound **7**.[15]



3 — **4** X = H; Y = OH; **5** X, Y = O — **6** — **7** R = OH; **8** R = SC(S)Imd — **11**

Scheme 1. a) *hv*, $\lambda = 350$ nm, THF (45%). b) PDC, Celite, CH_2Cl_2 (65%). c) $PhSCH_2N_3$, PhH, 80 °C (90%). d) L-Selectride (1.25 equiv), THF, −78 °C (77%). e) 1,1'-Thiocarbonyldiimidazole (5 equiv), 4-dimethylaminopyridine (DMAP) (1 equiv), CH_2Cl_2, 35 °C (65%). f) Bu_3SnH (1.70 M), azodiisobutyronitrile (AIBN), PhH, 80 °C (63%). Imd = imidazole.

[**] This research was supported by PHS Grant CA28824. NMR spectra were recorded at the Northeast Regional NSF/NMR Facility at Yale Univeristy, which was supported by NSF Chemistry Division Grant CHE7916210. An NIH Postdoctoral Fellowship to J. W. B. (Grant CA08907-02), is gratefully acknowledged.

Reaction of **7** with 1,1'-thiocarbonyldiimidazole in the presence of DMAP afforded the thiothioxo compound **8**[15] in 65% yield.[17] The curious transformation of **7** → **8** presumably proceeds through rearrangement of the initial thioxo compound into the corresponding thioester. The latter apparently undergoes acyl exchange under the conditions of the reaction to produce **8**. The structure of **8** was secured by an X-ray crystal structure of compound **9** (Fig. 1).[18] Compound **9** was an intermediate in a route which evaluated the possibility of aziridine formation prior to the reduction at C3.[19] However, Barton reduction[20] of **9** led to the allylic amine **10** by a fragmentation pathway.

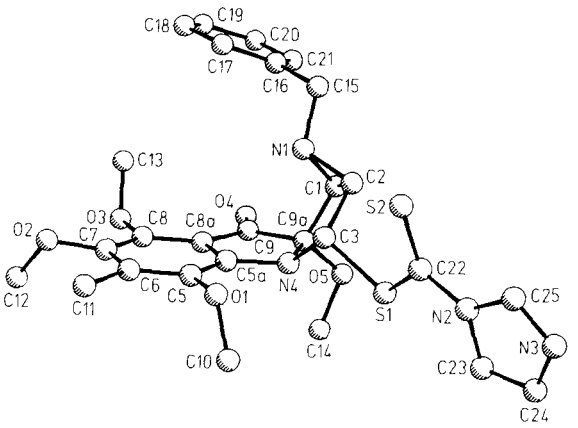

Fig. 1. Crystal structure of **9** (PLUTO).

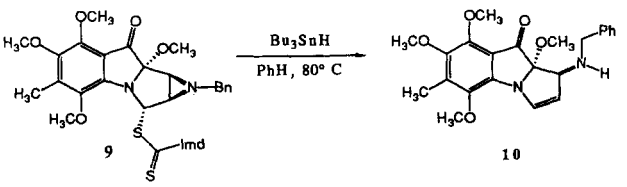
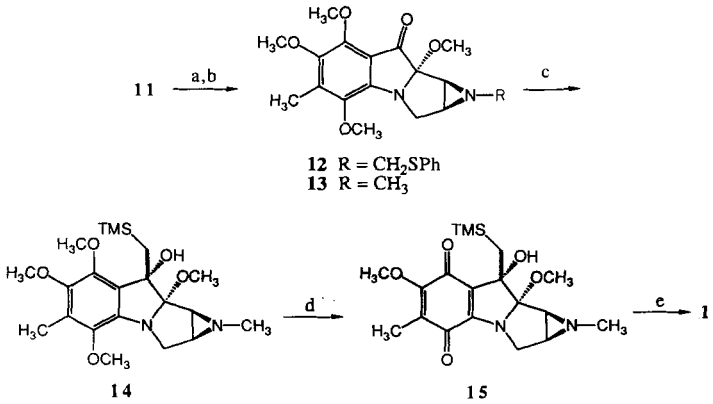
Given the propensity of β-aziridino radicals toward fragmentation, the deoxygenation of a triazoline substrate was investigated. Fortunately, reductive cleavage of the imidazoledithiocarboxyl unit of **8** could be carried out through the agency of tri-*n*-butyltinhydride, thereby affording the deoxygenated compound **11** (63% yield).



Scheme 2. Bn = CH_2Ph.

Photolytic decomposition of the triazoline unit was accomplished (48% yield) by irradiation at 254 nm (Vycor filter).[13] The resultant (phenylthio)methylaziridine **12** when subjected to the action of Raney Nickel in acetone, was converted (70% yield) to the *N*-methylaziridine derivative **13** (Scheme 3). To the best of our knowledge, this represents the first application of (phenylthio)methylazide for the synthesis of *N*-methylaziridines.

The program for installation of C10 began by reaction of **13** with trimethylsilylmethyllithium.[21] This reaction proceeded quite cleanly to give rise to a 90% yield of adduct **14**,[15] apparently as a single stereoisomer. Reaction of **14** with silver(II) picolinate[22] afforded, in low yield, the very interesting compound **15**, which is formally a trimethylsilanol addition product of mitomycin K. In the last step of the synthesis, quinone **15** responded to the action of PPTS in methylene chloride to provide an 81% yield of racemic mitomycin K. The infrared, ^1H NMR, and ^{13}C NMR spectra of racemic synthetic mitomycin K (m.p. 123–125 °C) were identical with those from a sample procured by partial synthesis via naturally occurring *N*-methylmitomycin A.[23]



Scheme 3. a) 254 nm Hg lamp/Vycor filter, PhH in quartz tube (48%). b) Raney Nickel, acetone, 60 °C (70%). c) Trimethylsilylmethyllithium (15 equiv), THF, −10 °C (90%). d) Silver(II) picolinate (6 equiv), NaOAc (10 equiv), CH_3CN/H_2O (8–16%). e) Pyridinium *p*-toluenesulfonate (PPTS), CH_2Cl_2 (81%).

Future research will be directed toward improvements in the yields in this rather concise synthesis. Also of value would be insights into the chemical stability of mitomycin K. Studies pertaining to the mode in which mitomycin K is activated for covalent attachment to its biological receptors are envisioned.

[10] It is conceivable that an appropriate biological nucleophile could undergo a 1,6 Michael addition to the quinone via the exocyclic defin. Subsequent expulsion of the methoxyl group at C9a would provide the corresponding C10-substituted mitosene and provide net activation of mitomycin K without initial activation.

[12] Compound **4** was resistant to standard conditions for reductive amination ($NaCNBH_3$), and attempts to convert the alcohol into a substrate suitable for deoxygenation (i.e. an SPh or OC(S)R group) proceeded with a concommitant loss of the methoxyl group at C9a and formation of pyrrole. Osmylation of the olefin unit was successful and stereospecific. However, the resultant diol with the $1\beta,2\beta$ configuration (as was shown in the antipode) was not suitable for conversion into the required $1\beta,2\beta$-aziridine linkage.

[13] The photolytic conversion of trizolines into aziridines has been reported: a) G. J. Sinta, R. W. Franck, R. J. Kempton, *J. Org. Chem.* **1974**, *39*, 3739; b) P. Scheiner, *Tetrahedron* **1968**, *24*, 2757.

Supramolecular Self-Assemblies of Two-Directional Cascade Molecules: Automorphogenesis**

By *George R. Newkome,* Charles N. Moorefield, Gregory R. Baker, Rajani K. Behera, Gregory H. Escamillia,* and *Mary J. Saunders*

Molecular self-assembly has fundamental ramifications for our understanding of the origin of life,[1] as well as utilitarian applications in material and polymer sciences.[2] Nature provides examples of self-assembly,[3–5] and recent synthetic efforts, in particular by Lehn, et al.,[6] have resulted, for example, in self-recognizing structures termed helicates. In the broad domain of supramolecular chemistry, which is concerned with structures of higher complexity arising from noncovalent, intermolecular interactions,[7] molecular automorphogenesis[8] is the construction of molecules by self-assembly of complementary shapes. By designing and controlling molecular topology for the purpose of self-assembly, a supramolecular automorphogenesis is possible at the next level. This report describes the preparation of a synthetic nonnatural example of a novel automorphogenic suprastructure possessing helical and ribbonlike morphologies.

Our investigation into control over molecular topology and molecular recognition was prompted initially by an interest in controlling the preorganization of specifically designed macromolecules (dendrimers, arborols).[9] The initially chosen sequence[10] utilized carbon as the branching center and involved the amidation of alkyl-substituted methanetricarboxylates (triester)[11] with tris(hydroxymethyl)-aminomethane (Tris). Since the infrastructure of the product resembled architecturally the Leeuwenberg model[12] for trees and the terminal groups consisted of alcohols, we described these molecules as arborols.[10] Others used the term dendrimers for such compounds.[9]

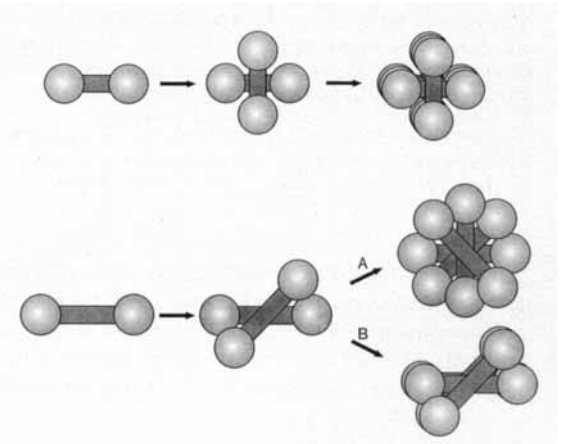

Fig. 1. Postulated stacking arrangements for dumbbell-shaped arborols. Top: orthogonal stacking of the alkane arborols. Bottom: non-orthogonal relationships between adjacent molecules of alkyne arborols lead to **A** helical structures, or **B** ribbon structures.

[**] Chemistry of Micelles, Part 16. We thank Dr. Robert Potter and Dr. Neil Neuberger for their timely advice. This work was supported by the National Science Foundation [DMR 86-00929, 89-06792 (GRN); DCB 88-02011 (MJS)], the donors of the Petroleum Research Fund (administered by the American Chemical Society), the Florida High Technology and Industry Council, and the USF Central Florida Regional Data Center for the aquisition of CHARMm. Part 15: G. R. Newkome, G. R. Baker, R. K. Behera, A. L. Johnson, C. N. Moorefield, C. D. Weis, W.-J. Cao, J. K. Young, *Synthesis* **1991**, 839.

Dumbbell-shaped poly(amidoalcohol)s were prepared[13] possessing two spherical head groups (each containing nine hydroxyl moieties) connected by a two-directional core. Characterization of specific arborols (i.e., [9]-10-[9]) revealed their ability to form thermally reversible, aqueous gels,[13, 14] which were postulated to arise from the propensity of the dumbbells to stack in an orthogonal fashion, thereby forming a tightly packed supramolecular, rod-shaped assembly by self-recognition (see Fig. 1). The resultant rods possessed a uniform diameter of ca. 35 Å, determined by electron microscopy (see Fig. 2a).

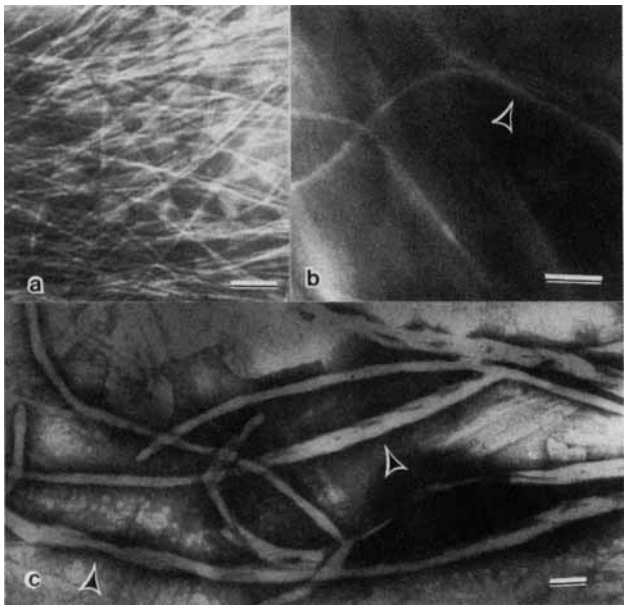

Fig. 2. Electron micrographs of gels of [9]-10-[9] arborol [14] and **4**, negatively stained with 2% phosphotungstic acid and viewed at 50 kV on a Hitachi H 500. a) High magnification (200000 ×) of [9]-10-[9] arborol. Note individual strands of uniform diameter (35 Å), which do not aggregate and remain discrete; bar represents 500 Å). b) Comparably high magnification (220000 ×) of arborol **4** showing individual strands of 30–40 Å and initial associations (arrow) of single polymers; bar represents 500 Å. c) Low magnification of **4** (70000 ×) showing supramolecular associations into large ropelike structures of 300–600 Å diameter. Note twisting "ropes" at arrows; bar represents 1000 Å.

It was postulated that modification of the alkyl chain connecting the two spheres to include a central alkyne moiety, and subsequent polymerization of the *preorganized* stacked cores would lead to a polyacetylene within a hydrophilic sheath creating "molecular wires". Thus, arborol **4** (Fig. 3)

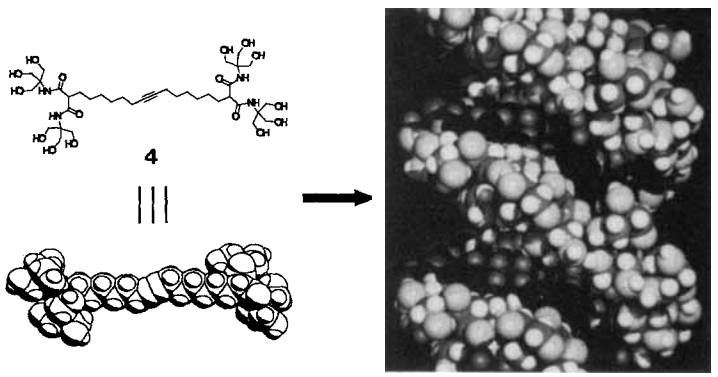

Fig. 3. Formula of arborol **4** and CPK representations of a single molecule and the proposed helical aggregation.

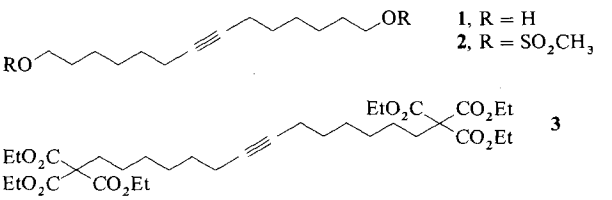
was deemed to possess the structural features necessary for gelation.[14] Incorporation of the alkyne core was accomplished by preparation of the known diol, tetradec-7-yne-1,14-diol (**1**),[15] which was subsequently converted into the corresponding bis(methanesulfonic) ester (**2**: 92%) by treatment with methanesulfonyl chloride and Et_3N in CH_2Cl_2. Characteristic ^{13}C NMR resonances for CH_3 ($\delta = 37.1$) and CH_2O ($\delta = 70.0$), as well as peaks at $\delta = 18.3$ ($C{\equiv}CCH_2$) and 79.9 ($C{\equiv}C$), and the ^1H NMR spectrum ($\delta = 4.17$; t, CH_2O, $J = 6.3$ Hz; 2.96; s, CH_3) supported the structure. Treatment of the dimesylate with triethyl methanetricarboxylate and K_2CO_3 in dimethylformamide (DMF) afforded hexaester **3** (82%). Conversion was evidenced by the classic OCH_2CH_3 patterns in both the ^1H and ^{13}C NMR spectra ($\delta = 1.50$, t, OCH_2CH_3, $J = 7.2$ Hz; 4.25, q, OCH_2CH_3, $J = 7.2$ Hz, and 13.6, OCH_2CH_3; 61.7, OCH_2CH_3). Additional peaks expected in the ^{13}C NMR spectrum: $\delta = 18.4$ ($C{\equiv}CCH_2$), 30.1 ($CH_2C(CO_2Et)_3$), 65.5 ($C(CO_2Et)_3$), 80.0 ($C{\equiv}C$), and 167.2 ($C{=}O$). Finally, treatment of the hexaester with Tris and K_2CO_3 in dimethylsulfoxide (DMSO) afforded the desired alkyne arborol **4** (38%) through amidation and decarbalkoxylation.[14] The structure was supported by ^{13}C NMR resonance signals at $\delta = 18.3$ ($C{\equiv}CCH_2$), 24.1, 28.5, and 28.9 [$CH_2(CH_2)_3CH_2$], 30.2 (CH_2CH), 54.1 (CH), 60.1 (CH_2OH), 62.2 (NHC), 80.2 ($C{\equiv}C$), and 171.0 ($C{=}O$), as well as the disappearance of peaks attributed to the ester groups. Also, characteristic signals at $\delta = 3.75$ (br. s, CH_2OH) and 3.10 (t, CH, $J = 7.1$ Hz) were recorded in the ^1H NMR spectrum.[16]



Upon dissolution of **4** in water, the desired self-assembly resulted in gelation.[17] The similarity of the synthesis of arborol **4** and the known saturated arborols[13, 14] dictates that the supramolecular arrangements should be structurally related. The predominant forces driving aggregation presumably involve hydrogen bonding of the hydrophilic spheres and lipophilic interactions between the backbones of the rodlike interiors. The linear rigidity of the alkyne units of arborol **4** limits the compressibility of the hydrocarbon backbone and disfavors the nearly orthogonal criss-cross stacking observed previously[14] for the saturated alkane arborols. Electron micrographs of gelled arborol **4** revealed the presence of single-stranded, rod-shaped structures (Fig. 2b). These single-stranded aggregations self-replicate as demonstrated by formation of higher order aggregates possessing helical morphologies. Figure 2c shows the growth of helical supramolecular structures with regularly repeating twists and diameters approaching 600 Å. These helical suprastructures were not observed for the saturated arborols possessing the less rigid alkyl backbones; therefore, the linear alkyne spacer probably induces a nonorthogonal ($<90°$) stacking, in which two or more molecules define the helical relationship (Fig. 1, bottom: path A). These coiled or twisted structures possess grooves where other aggregates may interact and become intertwined (see Fig. 3, right). Ribbonlike structures are also possible from a scissorlike stacking (Fig. 1, bottom: path B). Molecular modeling calculations[18] support the postulated stacking arrangements shown in Figures 1 and 3.[19]

Further understanding of the molecular interactions will permit chemical reactions and molecular inclusions within the lipophilic domain. The proposed association of these dumbbell-shaped monomers into helical filaments is similar to the assembly of actin monomers (G-actin) into microfilaments (F-actin). Actin filaments similarly bundle to form supramolecular structures such as stress fibers, acrosomal processes, microvilli, and belt desmosomes. The closest parallel may be to actin "cables" described from the Characean algae,[20] which are tightly associated stable actin bundles.

[16] Because the arborol **4** is hygroscopic, the corresponding acetate was prepared [14] and analyzed.
[17] Gels were formed by adding arborol **4** (100 mg) to H_2O (1.00 mL) and heating the mixture to obtain a clear solution, followed by cooling to 25 °C.
[18] Molecular modeling and minimizations were performed on a Silicon Graphics 4D/50GT workstation using QUANTA/CHARMm software, version 3.0 (Polygen Corporation, 200 Fifth Avenue, Waltham, MA, USA, **1990**).
[19] Four molecules were arranged in the stacking pattern of interest, either scissorlike or helical; CHARMm images were used to simulate an infinite aggregate. Energy minimization (root mean square deviation <0.001) of these starting structures was followed by a burst of molecular dynamics (2000 steps, 1000 K) to generate new randomized structures for subsequent minimization. This process should avoid the local minima problem common to molecular mechanics minimizations. Both stacking arrangements possess an intermolecular separation between alkynes of ca. 4.7 Å. A comparison of the calculated energies of four individual molecules ca. 20 Å apart versus that of either a helical or ribbon arrangement showed the stacks to be ca. 60 kcal mol^{-1} lower in energy.

The Reaction of Unactivated Cobalt Powder with Iodophosphoranes. The Synthesis of $[Co(PMe_3)_2I_3]$ and the Isolation of the "Frozen Transition-State" Complex $[(nBu_3PI)_2(\mu\text{-}I)][(nBu_3PI)(\mu\text{-}I)CoI_3]$

By *Charles A. McAuliffe*, Stephen M. Godfrey, Anthony G. Mackie,** and *Robin G. Pritchard*

In an earlier communication we reported a novel synthesis of transition-metal phosphane complexes by the reaction of coarse-grain metal powders and phosphoranes R_3PX_2, exemplified by $[Mn(PPhMe_2)I_2]$, $[Fe(PPhMe_2)_3Br_2]$, and $[Ni(PMe_3)_2I_3]$. This reaction route clearly has extensive applications, for not only are known complexes produced, but novel isomers of existing complexes and complexes in which the central metal atom is in a rare oxidation state are also obtained.[1]

We have established that the nature of the product is dependent on the metal and both the R and X substituents at the phosphorus atom. This is clearly shown in the reactions which we report here between cobalt powder and the phosphoranes Me_3PI_2 and nBu_3PI_2.

The reactions were carried out by mixing the coarse-grain (20–100 μm) cobalt powder with the phosphoranes (1:2 molar ratio) under anhydrous conditions in diethyl ether under argon (see Experimental Procedure). In the case of Me_3PI_2 a dark green powder forms. As shown in Equation (a), in addition to complex **1** elemental iodine is formed, which could be determined quantitatively by spectrophotometry.

$$Co + 2\,Me_3PI_2 \longrightarrow \underset{\mathbf{1}}{[Co(PMe_3)_2I_3]} + 1/2\,I_2 \qquad (a)$$

Recrystallization of **1** from diethyl ether produced dark green needles, which were suitable for an X-ray structure analysis.[2] The crystal structure of **1** is shown in Figure 1.

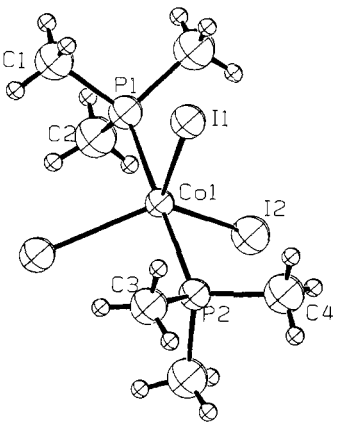

Fig. 1. Structure of **1** (PLUTO). Atoms I(2), Co(1), P(1), P(2), C(1) and C(3) lie on a mirror plane. Selected bond lengths [Å] and angles [°]: I(1)-Co(1) 2.555(1), I(2)-Co(1) 3.543(2), Co(1)-P(1) 2.285(5), Co(1)-P(2) 2.277(4), P(1)-C(1) 1.83(1), P(1)-C(2) 1.83(1), P(2)-C(3) 1.81(2), P(2)-C(4) 1.81(1); I(1)-Co(1)-I(1) 118.17(8), I(1)-Co(1)-I(2) 120.91(4), I(1)-Co(1)-P(1) 90.08(7), I(2)-Co(1)-P(1) 90.0(1), I(2)-Co(1)-P(2) 89.0(1), P(1)-Co(1)-P(2) 179.0(2).

Examples of trigonal bipyramidal cobalt(III) complexes containing tertiary phosphane ligands are known[3–6] but they are rare and are difficult to synthesize. In fact, apart from a rather low-precision X-ray study of $[Co(PEt_3)_2Cl_3]$[4] the cobalt(III) trigonal-bipyramidal phosphane complex described here represents the first such complex that has been characterized by X-ray crystallography. It has also been reported that the cobalt(II) phosphane complex $[Co(PMe_3)_2I_2]$ cannot be oxidized by iodine to produce the cobalt(III) complex **1**;[5] therefore the synthesis of **1** here must arise from the mechanistic pathway of this novel reaction route. Finally, it is also notable that this cobalt(III) complex is obtained in essentially quantitative yield, and no Co(II) species is produced.

In contrast, the reaction of two equivalents of nBu$_3$PI$_2$ with cobalt powder does not produce a conventional metal phosphane complex. The complex **2**[2] (formula $[Co(n\text{-}Bu_3P)_3I_8]$) is the only product we isolated either by carrying

$[(n\text{Bu}_3\text{PI})_2(\mu\text{-I})][(n\text{Bu}_3\text{PI})(\mu\text{-I})\text{CoI}_3]$ **2**

out the reaction at room temperature or at 60 °C. The structure of **2** (Fig. 2) clearly gives some insight into the mechanism of the reaction of iodophosphoranes with metal powders; it represents a "snapshot" of a metal phosphane complex created by the degradation of the phosphorane. The

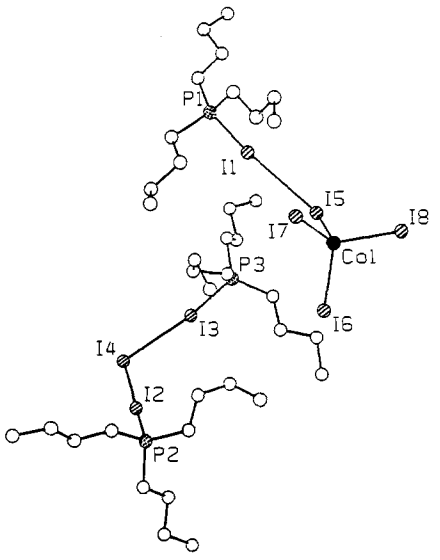

Fig. 2. Structure of **2**. Selected bond lengths [Å] and angles [°]: I(1)-P(1) 2.37(3), I(2)-P(2) 2.37(3), I(3)-I(4) 3.62(1), I(3)-P(3) 2.37(3), I(6)-Co(1) 2.58(2), I(8)-Co(1) 2.69(2), I(1)-I(5) 3.66(1), I(2)-I(4) 3.42(1), I(5)-Co(1) 2.66(2), I(7)-Co(1) 2.59(2); I(5)-I(1)-P(1) 164.9(9), I(4)-I(2)-P(2) 177.8(8), I(6)-Co(1)-I(5) 110.5(6), I(7)-Co(1)-I(6) 109.9(8), I(8)-Co(1)-I(6) 108.1(7), I(7)-Co(1)-I(5) 110.0(7), I(8)-Co(1)-I(5) 109.3(7), I(8)-Co(1)-I(7) 109.0(6).

structures of **1** and **2** also illustrate the subtle dependence on the nature of the phosphorane: Me_3PI_2 produces **1**, whereas nBu$_3$PI$_2$ produces **2**.

The "frozen transition state" represented by **2** shows that only one iodine atom has been abstracted from each phosphorane by the cobalt and no Co–P bonds are formed, which contrasts vividly with the reaction of Co with Me_3PI_2 [Eq. (a), Fig. 1].

There are two discrete fragments in the structure of **2**; the first contains a CoI_4^{2-} moiety bound to a Ph_3PI^+ fragment. This clearly shows that an iodine atom is abstracted from nBu$_3$PI$_2$: the I–I distance in the phosphorane (3.66 Å) is considerably lengthened, but it is still within the range of usual I–I bond lengths when compared to the sum of the van der Waals radii of two iodine atoms.[7–12] There is also a commensurate lengthening of the Co–I bond (2.640 Å) compared with the three terminal Co–I bonds (2.583–2.601 Å). The second fragment of the structure of **2** shows two nBu$_3$PI units linked by an iodine bridge and, once again, this gives some insight into the reaction mechanism for the metal-phosphorane reactions, which are summarized in Equations (b) (not stoichiometric) and (c).

$$n\text{Bu}_3\text{PI}_2 + \text{Co} \longrightarrow [(n\text{Bu}_3\text{PI})(\mu\text{-I})\text{CoI}_3]^- + n\text{Bu}_3\text{PI}^+ \quad \text{(b)}$$

$$n\text{Bu}_3\text{PI}^+ + n\text{Bu}_3\text{PI}_2 \longrightarrow [(n\text{Bu}_3\text{PI})_2(\mu\text{-I})]^+ \quad \text{(c)}$$

If nBu$_3$PI$_2$ and Co[13] are allowed to react in a 1:1 molar ratio, this gives essentially the same product **2**, identified by IR and UV/VIS spectroscopy. However, some new unidentified peaks were present, which suggested the presence of a small amount of impurity. Additionally the compound was contaminated by excess Co which could clearly be seen in the final product.

The complex **2** was not formed from the reaction[13] of nBu$_3$P, Co, and I_2. Instead, a brown oily product formed after approximately six days in dry diethyl ether and was isolated from the reaction mixture. The elemental analysis of this product suggested a compound of formula $[Co(n\text{-}Bu_3PI_2)_2]$; the ^{31}P NMR chemical shift ($\delta = 100.8$) and a Raman absorption band at 205 cm^{-1} indicate the presence of a P–I bond. Interestingly, concentration of the filtrate after the removal of the brown product resulted in the formation of an oily green product whose VIS spectrum is very similar to that of **2**.

The apparently strange connectivity of the atoms in **2** is easily rationalized if the environment of the iodine atoms are considered. Three of these centers (I1, I2, and I3) possess close-to-linear stereochemistry indicating a +I or "metal-like" oxidation state. The angles (101.2, 79.3°) at the other two nonterminal iodine atoms (I4, I5) indicate a normal −I oxidation state for bridging iodo ligands. An overall charge of −1 is thus assigned to the cobalt-containing assembly, of **2** and of +1 to the assembly with three catenated iodines.

In conclusion, these results illustrate the subtlety of the reaction between cobalt metal and iodophosphoranes R_3PI_2. A simple change in the alkyl substituents at the phosphorus atom yields quite different products. The isolation of the frozen transition-state complex gives an insight into the mechanistic pathway of this type of reaction, which halts at **2** when R is nBu, but goes to completion when R is Me to yield a rare example of a pentacoordinate cobalt(III) phosphane complex, **1**.

Experimental Procedure

Strictly anhydrous and anaerobic conditions (argon) were maintained throughout the reactions. **1** and **2** were prepared by the reaction of coarse-grain cobalt powder (20–100 μ) and the appropriate phosphorane (1:2 molar ratio) in dry diethyl ether. Reaction times were approximately 15d at room temperature or 5d under reflux at 60 °C in sealed tubes. In the reaction of $2\,Me_3PI_2$ with Co, a green powder resulted, which was recrystallized from diethyl ehter to produce analytically pure **1**. Dark green-black crystals, m.p. 150 °C, correct elemental analysis (C, H, I).

The low frequency Raman spectrum of **1** was difficult to record because of decomposition of the sample in the laser beam. However, bands were observed at 766, 670 cm^{-1}, ν(P–C) and 126 cm^{-1}, ν(Co–I); unequivocal assignment of a band to ν(Co–P) was not possible. The IR spectrum in the higher frequency region only exhibited bands due to the various stretching, bending, and rocking

vibrations of the methyl groups. The $^{31}P\{H\}$ NMR spectrum of **1** in $CDCl_3$ exhibited only a single extremely broad peak covering the entire spectrum and was essentially meaningless. The VIS spectrum of **1** (2.49×10^{-4} M in diethyl ether) showed the expected bands for a structure with D_{3h} symmetry of electronic ground state $(e'')^4(e')^2(a_1')^0$. Bands were observed at $\lambda \approx 340$ nm, $\varepsilon_{max} \approx 7000$, $P(\sigma) \rightarrow a_1^1$; $\lambda = 390$ nm, $\varepsilon_{max} = 3534$, $e'' \rightarrow a_1^1$; $\lambda = 457.8$ nm, $\varepsilon_{max} = 6611$, $I(\pi) \rightarrow e^1$; $\lambda = 587.2$ nm, $\varepsilon_{max} = 6902$, $P(\sigma) \rightarrow e^1$. The intense color of the complex, and hence high extinction coefficient, are due primarily to the charge-transfer (ligand $\rightarrow$ metal) transitions at $\lambda = 587.2$ nm and 340 nm.

2: In the reaction of $2\,nBu_3PI_2$ with Co, the tube containing the reaction mixture was removed from reflux after approximately 3d and left to stand at room temperature. After a further day green-blue crystals were isolated and identified as **2**. M.p. 82–85 °C, correct elemental analysis (C, H, I, P, Co).

The low frequency Raman spectrum of **2** showed bands at 208 cm^{-1}, ν(P–I) and 142 cm^{-1}, ν(Co–I). A weak band at 113 cm^{-1} is tentatively assigned to ν(I–I). The IR spectrum in the high-frequency spectral region exhibited bands due to various C–C and C–H vibrations, which were generally identical to those observed in the parent phosphorane, nBu_3PI_2. The $^{31}P\{H\}$ NMR spectrum of **2** in $CDCl_3$ showed two signals in approximately 2:1 ratio. The stronger signal occurred at $\delta = 98.3$ and by comparison to the phosphorane nBu_3PI_2, which dissociates in solution, can be assigned to the nBu_3PI^+ ion. This resonance signal is therefore assigned to the cation $[nBu_3P\text{-}I\text{-}I\text{-}I\text{-}PnBu_3]^+$. The weaker signal occurred at $\delta = -94.3$ and is assigned to the anion $[I_3Co\text{-}I\text{-}I\text{-}PnBu_3]^-$. The VIS spectrum of **2** (1.10×10^{-3} M in diethyl ether) showed two bands close together at $\lambda = 715.8$ and 671.1 nm assignable to the transition $^4A_2 \rightarrow 4\pi(P)$ om the tetrahedral Co(II) species. ε_{max} for this transition was calculated to be about 838. However, this could not be experimentally verified since the solution decolorized noticeably during the recording of the spectrum presumably due to the unstability of the complex.

Synthesis and Structure of $Al(OAr^*)_3$ ($Ar^* = 2,6\text{-}tBu_2\text{-}4\text{-}MeC_6H_2$): The First Three-Coordinate Homoleptic Aluminum Aryloxide**

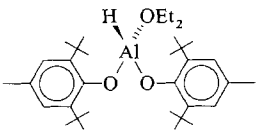
By *Matthew D. Healy* and *Andrew R. Barron**

The tendency towards the maximization of a metal's coordination number by associating to give aggregates containing tetrahedral and octahedral centers is ubiquitous in the chemistry of metal alkoxide and aryloxide compounds.[1] However, the use of 2,6-di-*tert*-butyl-substituted aryloxides has enabled the isolation of a number of monomeric homoleptic aryloxide compounds, $M(OAr)_x$, in which the metal center is in a low coordination environment,[2] and often a low oxidation state.[3] All attempts[4, 5] to prepare a three-coordinate homoleptic aluminum aryloxide compound have been consistently unsuccessful, including resorting to such extreme reaction conditions as thermolysis of $AlEt_3$ in neat 2,6-di-*tert*-butyl-4-methylphenol, HOAr* ($Ar^* = 2,6\text{-}tBu_2\text{-}4\text{-}MeC_6H_2$).[5b] In each case only the bis(aryloxide) compounds, $AlR(OAr^*)_2$, could be isolated. These results suggested perhaps that steric constraints preclude the formation of the *tris*(aryloxide) complex, in contrast to the thiolate analogue.[6] However, we are now able to communicate that $Al(OAr^*)_3$ can be readily prepared by the reaction of HOAr* with $LiAlH_4$.

The reaction of $LiAlH_4$ with three molar equivalents of HOAr* in Et_2O affords a mixture of $Li(OAr^*)(OEt_2)$[7] and **1** [Eq. (a)]. Compound **1** may readily be isolated by fractional crystallization from Et_2O as a moderately air-sensitive colorless crystalline solid.

$$LiAlH_4 + 3\,HOAr^* \xrightarrow{Et_2O} \underset{\mathbf{1}}{AlH(OAr^*)_2(OEt_2)} + Li(OAr^*)(OEt_2) + 3\,H_2 \qquad (a)$$

The room temperature ^1H NMR spectrum of **1** contains peaks due to the aryloxide substituent and coordinated Et_2O only (see Experimental Procedure). However, at -52 °C an additional broad resonance is observed ($\delta = 4.53$), which we assign to the proton of an aluminum hydride.[8] The IR spectrum of **1** shows the presence of a sharp band at 1896 cm^{-1} indicative of a terminal Al–H group.[9] All spectroscopic and analytical data are therefore consistent with the structure as shown in Scheme 1.



1

Scheme 1.

The interaction of **1** with a further equivalent of HOAr* in refluxing toluene allows the isolation of $Al(OAr^*)_3$ (**2**) in quantitative yield [Eq. (b)], as a moisture-sensitive colorless crystalline solid.

$$\underset{\mathbf{1}}{AlH(OAr^*)_2(OEt_2)} + HOAr^* \xrightarrow[-\,Et_2O]{\text{toluene},\ \Delta} \underset{\mathbf{2}}{Al(OAr^*)_3} + H_2 \qquad (b)$$

Cambridge, MA 02138 (USA)

[**] This work is supported by the Aluminum Research Board.

The ^1H and $^{13}C\{^1H\}$ NMR spectra of **2** show resonances due only to the aryloxide substituents, while the $^{27}Al\{^1H\}$ NMR contains a single resonance ($\delta = 3.2$). Although this ^{27}Al NMR signal is in a region normally associated with six-coordinate aluminum centers,[9] it follows the general trend observed for monomeric three-coordinate aryloxide derivatives: $R_2Al(OAr^*)$ compounds have $\delta(^{27}Al)$ resonance, signals around 190, while those for $RAl(OAr^*)_2$ are found at about 100 ppm.[5c] The medium-resolution mass spectrum (70 eV, EI) of **2** exhibits a parent ion (m/z 684) consistent with a monomeric structure in the gas phase. Compound **2** is also monomeric in the solid state, as evident from an X-ray crystal structure analysis.[10]

The molecular structure of **2** (Fig. 1) consists of discrete molecules with no unusual intermolecular distances. The aluminum is three-coordinate trigonal planar [Σ O-Al-O = 359.9(3)°]. The average Al–O distance and Al-O-C angle are 1.648(7) Å and 177.2(5)°, respectively. The arene rings form

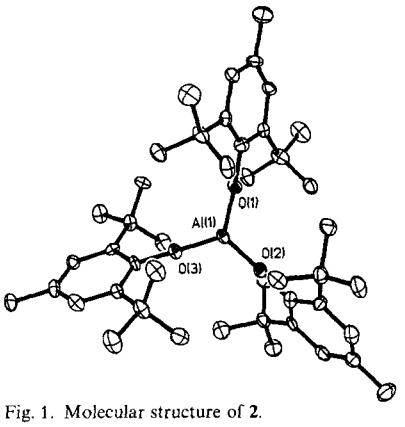

Fig. 1. Molecular structure of **2**.

a propeller-like arrangement around the aluminum, and are canted approximately 56° from the AlO_3 plane. Two molecules of the solvent of recrystallization, CH_2Cl_2, are present in the asymmetric unit. The short Al–O distances are undoubtedly a consequence of three factors. First, the aluminum atom is sp^2 hybridized, whereas sp^3 hybridization is observed in the more common four-coordinate complexes. Second, there is increased s character in the Al–O bond as a result of the near linear Al–O–C bond angle. Third, a $p\pi$–$p\pi$ interaction is present between the vacant Al $3p_z$ orbital (z perpendicular to the AlO_3 plane) and the lone pairs on the aryloxide oxygen centers. This latter interaction may also account for the highly shielded aluminum center, as evident from the upfield resonance signal in the ^{27}Al NMR spectrum.

Experimental Procedure

1: To a suspension of $LiAlH_4$ (5.00 g, 0.125 mol) in Et_2O (400 mL) at −78 °C was added solid HOAr* (82.50 g, 0.375 mol). **Caution:** hydrogen gas is liberated. The reaction mixture was slowly warmed to room temperature and stirred for 12 h. Filtration, followed by fractional crystallization allows for the isolation of **1**. Note that compound **1** is more soluble in Et_2O than $Li(OAr^*)(OEt_2)$ and is thus the second compound to crystallize. Isolated yield: ca. 70%; m.p. 136–140 °C; ^1H NMR (250 MHz, C_6D_6, TMS ext.): $\delta = 7.22$ (4H, s, C_6H_2), 3.68 (4H, m, OCH_2), 2.30 (6H, s, CH_3), 1.59 (36H, s, $C(CH_3)_3$), 0.64 (6H, m, OCH_2CH_3); at −52 °C, $\delta = 4.53$ (br, s, Al-H); $^{13}C\{^1H\}$ NMR (100 MHz, C_6D_6, TMS ext.): $\delta = 154.21$ (O-C), 138.80 (*o*-C), 126.48 (*m*-CH), 126.28 (*p*-C), 66.06 ($O-CH_2$), 35.39 [$C(CH_3)_3$], 31.89 [$C(CH_3)_3$], 21.36 (CH_3), 11.67 (OCH_2CH_3); $^{27}Al\{^1H\}$ NMR (78 MHz, C_6H_5Me, $[Al(H_2O)_6]^{3+}$ ext.) $\delta = 59$ ($w_{1/2} = 5470$ Hz); IR (KBr, Nujol): $\tilde{\nu}$ [cm^{-1}] = 1896 (s), 1460 (vs), 1421 (s), 1387 (m), 1318 (w), 1258 (s), 1203 (m), 1147 (w), 1124 (w), 1088 (m), 1022 (m), 994 (m), 953 (w), 901 (s), 899 (m), 793 (m), 763 (m), 722 (w), 692 (m).

2: To a toluene solution of **1** (4.00 g, 7.40 mmol) was added HOAr* (1.63 g, 7.41 mmol). The reaction mixture was heated at reflux for 12 h. **Caution:** hydrogen gas is liberated. The solution was then cooled, the solvent removed under vacuum, and the residue crystallized from pentane (−20 °C). Crystals suitable for X-ray analysis were obtained from CH_2Cl_2 solution. Yield: ca. 90%; m.p. 116–124 °C; ^1H NMR (250 MHz, C_6D_6, TMS ext.): $\delta = 7.11$ (2H, s, C_6H_2), 2.19 (3H, s, CH_3), 1.51 (18H, s, $C(CH_3)_3$); $^{13}C\{^1H\}$ NMR (100 MHz, C_6D_6, TMS ext.): $\delta = 151.71$ (O-C), 138.51 (*o*-C), 128.64 (*m*-C), 126.77 (*p*-C), 35.45 [$C(CH_3)_3$], 32.49 [$C(CH_3)_3$], 21.25 (CH_3); $^{27}Al\{^1H\}$ NMR (78 MHz, C_6H_5Me $[Al(H_2O)_6]^{3+}$ ext.) $\delta = 3.2$ ($w_{1/2} = 585$ Hz); IR (KBr, Nujol): $\tilde{\nu}$ [cm^{-1}] = 1422 (s), 1390 (m), 1363 (m), 1295 (m), 1265 (s), 1209 (m), 1184 (w), 1157 (w), 1125 (m), 1081 (w), 1026 (w), 977 (s), 941 (m), 909 (w), 889 (w), 859 (m), 810 (w), 802 (w), 768 (m), 727 (w), 659 (m), 634 (w).

Efficient Synthesis of Nanoscale Macrocyclic Hydrocarbons**

By *Jeffrey S. Moore** and *Jinshan Zhang*

Structurally well-defined macrocycles[1] have long attracted the interest of many research groups, especially those studying recognition and selective complexation.[2] Our in-

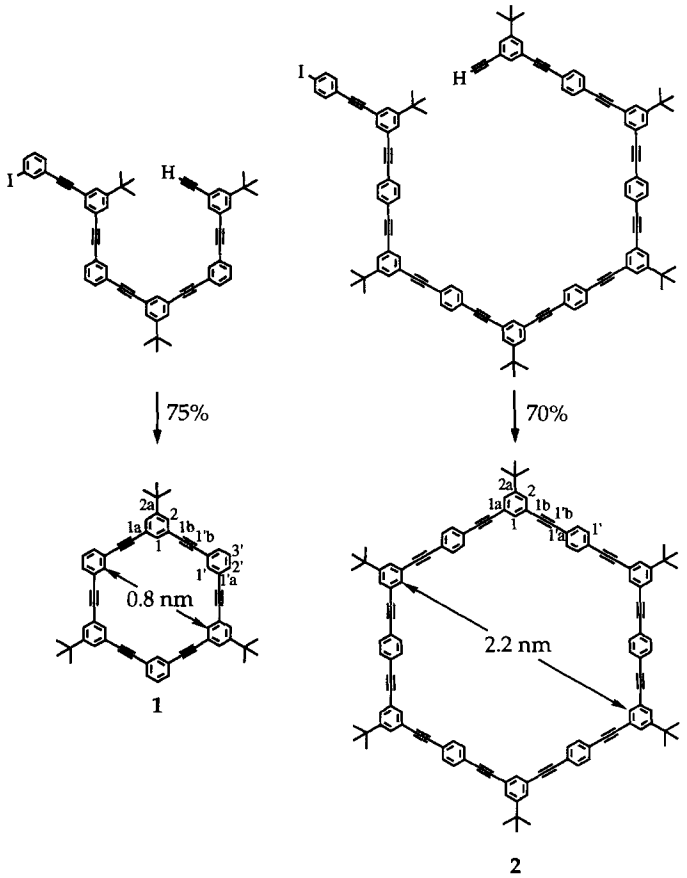
terest in these compounds is as a class of large molecular building blocks[3] that can be used to assemble new materials by a "modular" approach. Rigid toroids constructed from phenylacetylene monomers are ideally suited for this since both the position and orientation (*endo* vs. *exo*) of pendant groups are well defined. Here we describe the efficient synthesis of very large macrocyclic hydrocarbons having internal diameters up to 22 Å.

Our synthesis involves macrocyclization[4] of α,ω-unsymmetrically difunctionalized phenylacetylene sequences. We recently described an efficient preparation of these oligomers in which the chain length, the sequence order of monomers, and end-group functionality can be precisely controlled.[5] These sequences are cyclized by intramolecular palladium-catalyzed coupling[6] by slow addition of the oligomer to solution of the active catalyst. As shown in Scheme 1, both the products with six (**1**) and twelve (**2**) arene units were obtained in high yield (75% and 70%, respectively). In each case, only a single cyclic product was observed. The *tert*-butyl groups were required to maintain adequate solubility. Molecular models show that the inner diameter (hydrogen to hydrogen) of **1** is 8.4 Å while that of **2** is slightly greater than 22 Å. The high yields and absence of other cyclic products for these large ring systems are probably a consequence of the assembly of the rigid,[7] α,ω-difunctionalized sequences prior to the cyclization reaction.



Scheme 1. Synthesis of nanoscale macrocyclic hydrocarbons. Reaction conditions: $[Pd(dba)_2]$, PPh_3, CuI, triethylamine, 70 °C.

There are a number of advantages in using preassembled sequences to synthesize large cyclic structures. The method we describe here should be compared to the more common approach used to prepare macrocycles which involves oligomerization and cyclization in the same reaction flask (i.e. "one-pot" process). Although the one-pot reaction can potentially generate products in a single step, the yield depends strongly on ring size.[4b] As an example, the one-pot synthesis of the parent coumpound of **1** proceeds in only 4.6% yield.[1b] The overall yield for **1** by our route including the synthesis of sequence is nearly an order of magnitude higher. Besides giving low yield, the one-pot process is also limited to products of certain structural types. For example, only cyclic geometries that result from a single type of monomer can easily be realized. Thus, toroidal hydrocarbon **2** could not be prepared from a one-pot reaction but instead would require prior synthesis of the *meta–para* dimer. For these same reasons, products with specific placement of functional groups are not easily prepared by the one-pot process. However, cyclization of a properly functionalized sequence will provide macrocycles with groups positioned according to the sequence order of monomers. The arrangement of *tert*-butyl groups on alternate rings in **1** illustrates this point. Finally, we have recently shown that high yields of large three-dimensional cage molecules can be realized by double cyclization of branched sequences.[8] These structures could probably not be realized using the one-pot approach.

The efficient cyclizations described here, in combination with our phenylacetylene sequence synthesis, offer enormous possibilities for preparing large and well-defined organic structures. The geometric possibilities that can be obtained by cyclization of sequences of phenylacetylene monomer units (combinations of 60°, 120°, and 180° angles) are essentially any framework that lies on the trigonal lattice. Table 1 shows the number of unique planar cyclic geometries that can be obtained from sequences containing three to ten phenylacetylene units.[9] These molecular frameworks should be useful for constructing novel mesogens or building blocks for self-assembled monolayers or rationally designed organic crystals.

Table 1. Relationship between monomer units to be linked and the resulting structure.

Number of monomer units [a]	3	4	5	6	7	8	9	10
Number of possible cyclic geometries [b]	1	1	1	4	5	16	37	120

[a] Monomers are *ortho*-, *meta*-, and *para*-phenylacetylenes. [b] Defined as a "closed path" on a two-dimensional trigonal lattice.

Experimental Procedure

2: A septum-stoppered flask charged with $[Pd(dba)_2]$ [10] (0.15 g, 0.26 mmol), triphenylphosphine (0.41 g, 1.56 mmol), copper(I) iodide (0.05 g, 0.26 mmol) was evacuated and back-filled with nitrogen. Anhydrous triethylamine (75 mL) was added, and the solution was heated to 70 °C. The α-iodo-ω-ethynyl-dodecameric sequence (0.50 g, 3.0 mmol) was taken up in a mixture of triethylamine (25 mL) and benzene (25 mL) and added to the catalyst by a syringe pump at a rate of 2.5 mL h^{-1}. At the end of the addition, the solution was stirred at 90 °C for another five h and then diluted with dichloromethane. The solution was washed with 1 N aqueous HCl, brine, and water and dried over sodium sulfate. After the solvent was removed the residue was purified by flash chromatography (eluting with CH_2Cl_2) and recrystallized (first from $MeOH/CH_2Cl_2$, then toluene) to afford a colorless crystalline solid (**2**) in 70% (0.324 g).

Characterization data for (**2**): ^1H NMR (200 MHz, $[D_6]$benzene): $\delta = 7.84$ (t, $J = 1.3$ Hz, 1H, H-C1), 7.67 (d, $J = 1.3$ Hz, 2H, H-C2), 7.42 (s, 4H, H-C1'), 1.10 (s, 9H, $(CH_3)_3C$-); ^{13}C NMR (90 MHz, $CDCl_3$): $\delta = 151.8$ (C2a), 132.4 (C1), 131.6 (C1'), 128.7 (C2), 123.1 (C1a and C1'a), 91.0 (C≡C), 89.2 (C≡C), 34.7 $(CH_3)_3C$-, 31.2 $(CH_3)_3C$-; MS (FAB) m/z 1539 $[(M + H)]^{\oplus}$. Correct elemental analysis.

Characterization data for **1**: ^{1}H NMR (200 MHz, [D$_6$]benzene): δ = 8.09 (t, J = 1.6 Hz, 1H, H-C1'), 7.98 (t, J = 1.4 Hz, 1H, H-C1), 7.70 (d, J = 1.4 Hz, 1H, H-C2), 7.42 (dd, J = 1.6, 7.9 Hz, 2H, H-C2'), 6.86 (t, J = 7.9 Hz, 1H, H-C3'), 1.10 (s, 9H, (CH_3)$_3$C-); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 151.7 (C2a), 135.3 (C1'), 132.4 (C 1), 131.0 (C 2'), 128.6 (C 2), 128.4 (C3'), 123.6 (C1'a), 123.1 (C1a), 89.8 (C≡C), 88.6 (C≡C), 34.8 (CH_3)$_3$C-), 31.1 (CH_3)$_3$C-); HR MS (70 eV, EI) m/z $C_{60}H_{48}$: calc. 768.3756, found 768.3774. Correct elemental analysis. Crystals of **1** have not provided useful diffraction data.

[9] Combinatorial analysis was used to enumerate planar cyclic geometries derived from sequences of *ortho*-, *meta*-, and *para*-phenylacetylene monomers. This was accomplished by performing a systematic n-step walk on a two-dimensional trigonal lattice. As an example, the four isomers that can be obtained from sequences containing six monomer units are shown below.

Generalized Edshammar Polyhedra for the Description of a Family of Solid-State Structures

By *Sven Lidin*,* *Thomas Popp*, *Mehmet Somer*, and *Hans Georg von Schnering*

In compounds with the general composition M_nX_p with $n \gg p$, component X, which can be a single atom, ion, or molecule, must build discrete units which are to a certain extent embedded in a continuous medium M. The coordination number (CN) of X is always n/p times that of M: CN(X) = n/p CN(M). Hence when CN(M) is high, CN(X) will be very large and the subsequent coordination polyhedra will also be correspondingly large. Here we would like to introduce a new class of space-filling polyhedra which can be utilized in describing structures in which a small number of linear molecules, large atoms, or large ions are coordinated by many monoatomic units. These polyhedra are obtained by the successive interpenetration of cubes along a threefold axis.

First we would like to consider the condensation of two cubes to form a structural unit having common corners. This can be achieved in five different ways, as shown in Figure 1 a–e. The first four cases yield nothing significantly new. They are generated by fusing one, two, four, or eight corners of each cube, leading to shared corners, edges, faces, and finally to a complete overlap. In contrast, the fifth possibility (Fig. 1e) is of greater interest. In this situation, the cubes are interpentrated so that three corners of each cube are fused together.

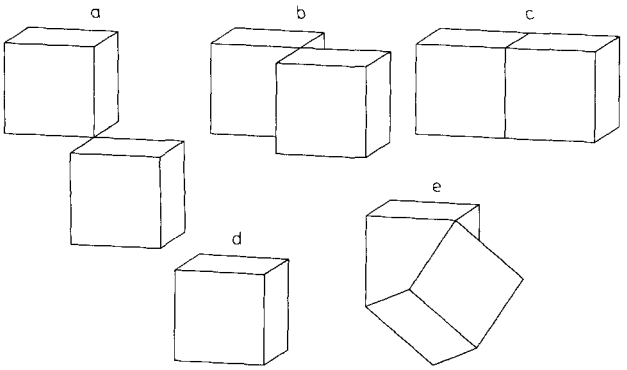

Fig. 1. Two cubes with a) one, b) two, c) four, d) eight, e) three common corners.

A corner of each cube now lies inside the other cube and a structure emerges that is reminiscent of a body-centered cube (bcc). However, the centering is far from perfect; the enclosed point is located closer to the position (1/3, 1/3, 1/3) than to the position (1/2, 1/2, 1/2) of the surrounding cube. The original cubes each possess eight corners, thus sixteen in total. After condensation, only thirteen corners are available. Of these thirteen, two are enclosed by eleven, thus building a new space-filling polyhedron, the Edshammar polyhedron,[11] which will be denoted henceforth by the symbol ^{11}E and the configuration 4^63^6 (Fig. 2a).

The latter designation indicates that the polyhedron is assembled from six squares and six triangles.[12] Certainly this process can be extended further. The condensation of three cubes along a common threefold axis leads to a polyhedron

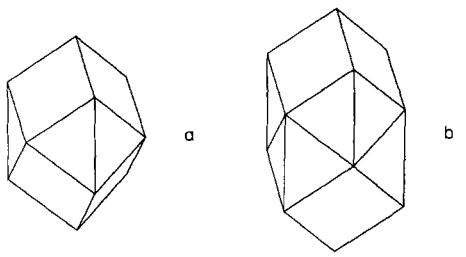

Fig. 2. a) The Edshammar (^{11}E) polyhedron. b) The ^{14}E polyhedron.

with fourteen corners, ^{14}E, having the configuration $4^6 3^{12}$ (Fig. 2b). These polyhedra can be described quite generally with the symbol $^{5+3n}$E and the configuration $4^6 3^{6(n-1)}$ where n is the number of cubes involved in the construction of the polyhedron. These polyhedra are either combinations of hexagonal prisms and cubes (odd n, Fig. 3a) or hexagonal prisms and trigonal bipyramids (even n, Fig. 3b).

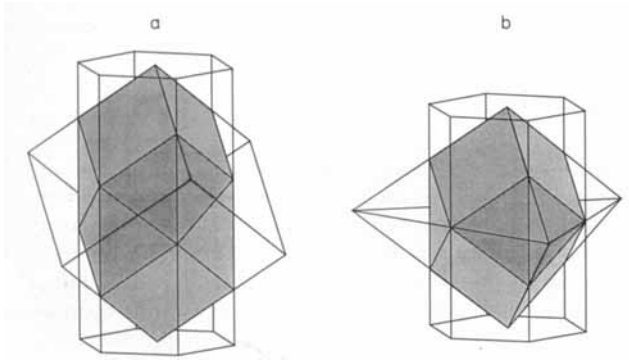

Fig. 3. a) The ^{14}E polyhedron as a combination of cube and hexagonal prism. b) The ^{11}E polyhedron as a combination of trigonal bipyramid and hexagonal prism.

The symmetry of the polyhedra changes with the number n (or the number of corners). When n is odd, $\bar{3}$m symmetry is present, whereas when n is even, the symmetry is $\bar{6}$m2. With increasing n, the polyhedra become more and more tube-shaped. Through a distortion in the direction of the threefold axis, the larger polyhedra like ^{14}E or ^{17}E can be adjusted to coordinate spherical or roughly spherical units (the core).

All the polyhedra of the type $^{5+3n}$E are space-filling. Layers can be constructed by packing the polyhedra perpendicular to the threefold axis whereby the faces of the neighboring hexagonal prisms then coincide. Such layers have a rippled surface (Fig. 4), which is characteristic for a simple packing of cubes perpendicular to the [111] direction.

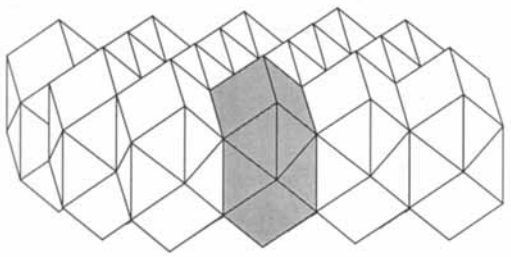

Fig. 4. A close-packed layer of ^{14}E polyhedra.

These layers can now be stacked in a space-filling manner. The stacking of layers of polyhedra consisting, for example, of ^{14}E with alternate layers of cubes or another polyhedra is also possible because they all show the same surface. Actually in nature, very many different stacking structures occur, especially structures where layers derived from $^{5+3n}$E polyhedra alternate with layers made up of cubes.

If these polyhedra are used to describe clusters with $5 + 3n$ atoms on the corners, a maximum of n structural units Z can be enclosed. These units Z may be defects (□), or one or more atoms isolated from one another or linked together. The composition of such a cluster can be formulated as $^{5+3n}EZ_n$ where n indicates how many corners of the original cubes lie in the cavity of the polyhedron.

If the clusters are close packed in solid state then their corners are common to several clusters. Thus the stoichiometric number N of corners is reduced. In a packing of cubes, every corner has the value $N = 1/8$ because it belongs simultaneously to eight cubes, ^{8}E. For the whole cube, N is equal to $8/8 = 1$. In a close packing of ^{11}E polyhedra (Fig. 5), two types of corner atoms exist, namely five corner atoms of type I and six corner atoms of type II, each of which are common to five and six ^{11}E polyhedra respectively: $N_I = 1/5$, $N_{II} = 1/6$; that is, $N(^{11}\text{E-packing}) = 5/5 + 6/6 = 2$. Thus in general for close packings of $^{5+3n}$E polyhedra, $N = n$ is valid.

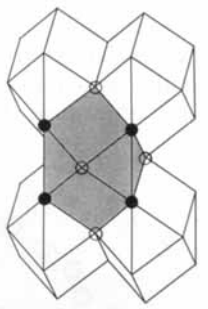

Fig. 5. Close-packing of Edshammar polyhedra. The positions of type I corners are indicated by open circles, type II by filled circles.

The positions of the corners of the polyhedron can be derived directly from the condensation process. The (idealized) polyhedron obtained initially is characterized by two different edge lengths. These edges become closer in length, if the polyhedron is compressed along the threefold axis, or stretched in the plane perpendicular to the threefold axis (Fig. 6). A measure of distortion can be determined from the ratio of the length of the polyhedron along the threefold axis to the length of the orthogonal face diagonal of the "square" face of the polyhedron. This internal axial ratio (c/a) indicates the extent of distortion.

Aside from the states with idealized positions (edges unequal in length, Fig. 6, left) and with identical edge lengths (Fig. 6, center), there are other c/a ratios with special significance. For example, through further compression of the ^{11}E polyhedron, the distance from the center to the two corners on the threefold axis will be the same as the distance from the center to the three corners lying on the (orthogonal) mirror plane. This state ($c/a = 1.154$) is often preferred when a single atom is coordinated by an ^{11}E polyhedron. Table 1 lists the corner positions for these three distinct states.

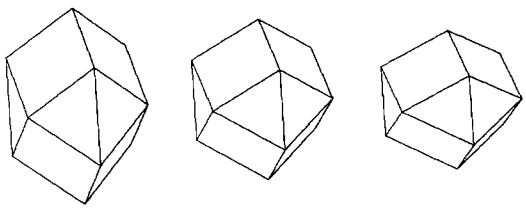

Fig. 6. Edshammar polyhedra. Left: the idealized polyhedron, $\mathbb{P}_{id}$. Center: the polyhedron with identical edge lengths, $\mathbb{P}_{ec}$. Right: the polyhedron with nearly equal distances to the center, $\mathbb{P}_{ez}$.

Table 1. The corner positions of the Edshammar (^{11}E) polyhedron for the three distinct states, $\mathbb{P}_{id}$ ($c/a = 1.633$), $\mathbb{P}_{ee}$ ($c/a = 1.333$), $\mathbb{P}_{ez}$ ($c/a = 1.155$). The relative Cartesian coordinates are given with the threefold axis as z-axis.

In the case of a ^{14}E polyhedron with $c/a = 1.836$, all the corners fall exactly on the positions of a body-centered cubic lattice (bcc), thus building a perfectly spaced substructure of this lattice type (Fig. 7). A considerable number of compounds are known having an axial ratio near this value. Table 2 contains the corner positions for the idealized state, for that with identical edges, and for the bcc state. The most important features of the polyhedra with $1 \leq n \leq 5$ are summarized in Table 3.

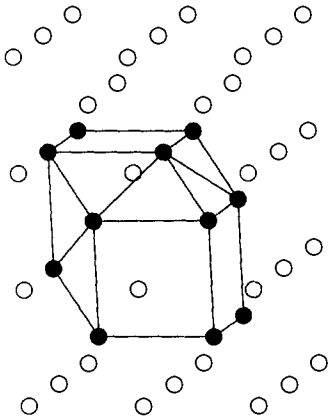

Fig. 7. The ^{14}E polyhedron as a perfectly spaced substructure of the bcc lattice.

Table 2. The corner positions of the ^{14}E polyhedron for the three distinct states, $\mathbb{P}_{id}$ ($c/a = 2.041$), $\mathbb{P}_{ee}$ ($c/a = 1.836$), $\mathbb{P}_{ez}$ ($c/a = 1.1667$). The relative Cartesian coordinates are given with the threefold axis as z-axis.

Table 3. Some important features of the polyhedra. The number of corners corresponds to the coordination number of the whole enclosed structural unit (core). Q is the ratio of the stoichiometric number N to the enclosed core.

Polyhedron	Corners $(5+3n)$	Q	Symmetry	c/a $\mathbb{P}_{id}$	c/a $\mathbb{P}_{ee}$
Cube, ^{8}E	8	1:1	$\bar{3}$m	1.225	1.225
Edshammar-Polyhed. ^{11}E	11	2:1	$\bar{6}$m2	1.633	1.333
^{14}E	14	3:1	$\bar{3}$m	2.041	1.667
^{17}E	17	4:1	$\bar{6}$m2	2.449	2.000
^{20}E	20	5:1	$\bar{3}$m	2.858	2.333

As already mentioned, all the polyhedra of this class are space-filling, also in combination with other polyhedra. Thus the number of possible combinations appears infinitely large, and in addition, the cubes may be empty or occupied by an atom. Indeed we have been successful in finding a multitude of different examples which occur in compounds that exist. In the simplest case only cubes are present. These can all be identical as in CsCl or Po (centered or empty), or several different types can be present like in $Ca(UO_2)O_2$. However, here we want to limit the discussion to structures involving larger polyhedra. Our main focus is directed at binary and ternary alkali metal compounds and a few other systems. Zintl phases, especially, seem to form structures that are based on generalized Edshammar polyhedra. Hyde and Andersson refer to the Edshammar polyhedron to describe the structures of $IrAl_3$ (Na_3As type), LaF_3, and Cu_3P. In these structures, layers of filled ^{11}E polyhedra alternate with layers of empty ^{8}E polyhedra. The composition E_3Z (3:1) results from $^{11}EZ_2$ with $N_1 = 2$ and $Z = 1/2$, as well as $^{8}E\square_1$ with $N_2 = 1$; thus $N_1 + N_2 = 3$ and $Z = 1$. The Na_3As structure type is widespread among alkali metal pnictides. The phosphides, arsenides, and antimonides of lithium, sodium, and potassium show this structure type. Other examples include the bismuthides of sodium, potassium, and rubidium, as well as Rb_3As. In Table 4, the c/a ratios of the ^{11}E polyhedra observed in these compounds are compared to those of the ideal polyhedron (see above), the polyhedron with identical edges, and the polyhedron with nearly equal distances to the center ($\mathbb{P}_{id}$, $\mathbb{P}_{ee}$, and $\mathbb{P}_{ez}$, respectively). In these compounds c/a is close to the value for $\mathbb{P}_{ez}$, as expected for a single-atom core.

Table 4. Axial ratios of the Edshammar polyhedron, ^{11}E, in compounds having the Na_3As type of structure. The c/a ratio is 1.633 for $\mathbb{P}_{id}$, 1.333 for $\mathbb{P}_{ee}$, and 1.155 for P_{ez}.

The Edshammar polyhedron (^{11}E) also occurs in other combinations. In the crystal structures of $Li_{13}Si_4$[4] and Li_7Sn_2, the framework is formed from zigzag chains of ^{11}E and ^{8}E polyhedra. These structures can be derived from the Na_3As type by a mirror operation.[3]

The system obtained by an alternating packing of layers of ^{14}E and ^{8}E polyhedra is especially interesting. In this arrangement three distinctly different compositions can be distinguished (Table 5).

Li_5Sn_2 is an example of such a compound where both the ^{14}E and ^{8}E polyhedra is filled (the ^{14}E polyhedron with Sn_2 dumbbells and the ^{8}E polyhedron with Li atoms). The structure of compounds of the K_4BeX_2 type have already been described in terms of ^{14}E polyhedra.[6] For example in the structure of K_4BeP_2, the ^{8}E polyhedra are empty while the ^{14}E polyhedra are filled by the linear 16-electron anion $[BeP_2]^{4-}$. Finally in the case of UO_2F_2, the ^{14}E polyhedra are empty and the ^{8}E polyhedra filled, a relatively unusual situation. A list of compounds which can be described on the basis of various combinations of polyhedra is given in Table 5. Remarkable is the dependence of the coordination on the c/a value. For all the polyhedra, it seems that its particular ideal c/a value is an upper limit (Table 5).

This method of describing crystal structures offers a simple way to understand the coordination for a great number of compounds that were previously classified under the "irregular" category. This method also allows for the prediction of structures. The Zintl-Klemm rule indicates which compositions are possible. If such a composition is known, only a few spatial arrangements are possible. For example, for the hexagonal structure of K_4BeSb_2, whose single-crystal structure has not been fully determined, three arrangements can be predicted: a close packing of ^{17}E polyhedra, a layered structure composed of ^{14}E polyhedra and empty cubes, or a packing consisting of ^{11}E polyhedra and filled cubes. The combination with ^{11}E polyhedra can be excluded because of size restrictions; the $BeSb_2$ unit is too voluminous for the cavity of such a small polyhedron. The two remaining possibilities differ in symmetry and unit cell parameters; the X-ray powder diffraction pattern is in accord with a close packing of ^{17}E polyhedra. Similar investigations are currently being conducted for the compounds Na_5Pb_2, Na_9Pb_4, $Na_{13}Pb_5$,[27] and Na_5Pb.[28] The positions of the Hg and Pb atoms have already been established while those for the Na atoms are still unknown.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Maximum Entropy in Action. Edited by *B. Buck* and *V. A. Macaulay*. Oxford Science Publications/Clarendon Press, Oxford, 1991. XXVII, 220 pp., hardcover £ 15.00.—ISBN 0-19-853963-0

The purpose of this book is to explain and promote the use of the maximum entropy method, a principle that can be applied to such widely different areas of science as image processing, spectra processing, direct methods of X-ray structural analysis, and statistical thermodynamics. As scientists tend to be polarized into enthusiastic proponents of MEM and skeptics, the appearance of this book is especially welcome. It is based on a series of lectures given by recognized experts during the summer of 1989 in the Physics Department of Oxford University. This has resulted in some lack of uniformity between the individual contributions, and in a few instances of repetition in the introductions; on the other hand, it means that the book is quite up-to-date.

The eight chapters are preceded by the editors' introduction, which gives a brief survey of the information theory approach to entropy (Shannon, 1948) and its relationship to Bayes's probability calculation method (Jaynes, 1959). As mathematical formulas are almost entirely avoided here, the level is suitable for any scientist with broad interests.

In the first chapter ("Of Maps and Monkeys") G. J. Daniell describes the reconstruction of distributions (maps) from sets of measurements that are incomplete or distorted. Examples include one-dimensional NMR spectra, electron density distributions obtained from X-ray scattering data, or images built up from neutron distributions in a Tokamak machine. Bayes's probability theory and the principle of maximizing the Shannon entropy are used to determine the most probable distribution that is consistent with the incomplete experimental data. As well as explaining the theoretical advantages of MEM, its practical superiority to Fourier transformation (FT) is impressively demonstrated for the example of a truncated free induction decay (FID) curve. Unfortunately, however, the example given is based only on a normal FT (with zero-filling but without apodization), which is less suitable for comparison purposes.

The second chapter (J. Skilling) is concerned with two-dimensional image analysis. A mathematically abstract formulation of Bayes's probability theory is used to calculate the probability of an image in order to make it consistent with an incomplete set of experimental data (in this example a γ-ray image of a thyroid gland). The author also describes how a priori knowledge that is already available can be incorporated into the image; thus, in the example of the thyroid gland it was specified that the contrasts (due to differences in the concentration of the γ-emitter) must not be too great. When this image blurring effect (preblur) is taken into account one does, in fact, obtain a better image. Unfortunately, in this example the author fails to compare the technique with Fourier methods that have undergone a corresponding optimization. This is not surprising, however, since one reads in the introductory paragraphs of this chapter that "... MEM is not just a good technique for data analysis from imperfect data, it is *the* technique."

In the third chapter P. Hore deals with one- and two-dimensional NMR experiments. Here the Messianic style of the previous two chapters is mercifully absent, and we have an objective discussion of such matters as resolution enhancement, signal-to-noise enhancement, and truncation of the FID. This is followed by examples in which spectral distortion effects already known to be present (e.g., mixing of the phases in 2D NMR spectroscopy, and offset effects in rotating frame imaging) are eliminated. Lastly the author describes extensions of the algorithm that are specific to NMR, allowing for the presence of negative peaks in the spectrum.

The fourth chapter (S. Davis et al.) is closely related to the preceding one. It contains examples of the analysis of NMR spectra that consist of only a few broad signals (e.g., polymer spectra), followed by Raman spectra and magic angle spinning (MAS) NMR spectra. It is interesting to see how information that one already has about the spectrum, such as the theoretical intensity distribution of rotation side-bands in an MAS spectrum, can be incorporated into the MEM algorithm. However, the example in which an ad hoc modification is introduced into the definition of the Shannon entropy, leading to meaningless spectral constructions, is hardly of more than academic interest.

In the fifth chapter G. A. Cottrell describes some further applications in the reconstruction of one- and two-dimensional distributions, with examples from high energy physics. He gives an impressive account of how the density distribution of neutrons in a neutron beam can be obtained from only 12 centered projections (by using classical "projection reconstruction" methods). In this case it was important to achieve good resolution at the edges of the image (where the intrinsic resolution given by the method of measurement was poor), since the neutrons in this edge region cause damage to the tube wall.

The next two chapters are concerned with certain fundamental topics in theoretical physical chemistry. The sixth chapter (A. J. M. Garrett) has the title "Macroirreversibility and Microreversibility Reconciled", while in the seventh S. F. Gull discusses "Some Misconceptions about Entropy". In the treatment of one-dimensional Brownian motion at the end of the latter article, the topic is extended to include non-equilibrium thermodynamics, providing further confirmation of the impressively wide scope of the entropy maximization principle.

In the eighth article G. Bricogne describes how MEM can be used to improve direct methods of crystal structure analysis. The determination of electron density distributions from scattering data is a classic case of incomplete experimental data, since the X-ray reflections contain no phase information. Direct methods attempt to extract the phase information from a statistical analysis of the peak intensities that can be measured. MEM offers an algorithm for deriving phase information that is considerably better than conventional methods, such as that based on the Edgeworth series. It seems likely that by also using chemical knowledge (for

example, the information that two atoms cannot lie one above the other) one can obtain an improvement over the "random atom model" used in the direct method.

The lack of uniformity, and the inevitable repetitions resulting from the lack of coordination between the individual contributions, cannot detract significantly from the generally very positive impression given by this book, which includes research results extending up to 1991. This fascinating universal concept opens up many new possibilities for the analysis of spectra, images, and X-ray scattering data. Several of the authors extol the virtues of the method too enthusiastically for this reviewer's taste; an extreme example of this tendency was an article in *The Times* (London, 1984), in which it was claimed that MEM analysis would make it possible to record ^{13}C NMR spectra at natural abundance on living animals. However, this is rectified by other chapters that present an objective appraisal. The figures, text, and mathematical formulas are all of an exemplary standard. Because of the wide range of aspects covered in this book, it can be thoroughly recommended, not only for spectroscopists, "imagers", and X-ray crystallographers, but also for all readers with interests in physical chemistry or information science.

An Introduction to Ultrathin Organic Films from Langmuir–Blodgett to Self-Assembly. By *A. Ulman*. Academic Press, New York, 1991. XIII, 442 pp., hardcover $ 65.00.—ISBN 0-12-708230-1

In an article in the journal *Science* in 1936, Irving Langmuir addressed the following words to the international scientific community: "Today... I propose to tell you of a real two-dimensional world in which phenomena occur that are analogous to those described in 'Flatland'. I plan to tell you about the behavior of molecules and atoms that are held at the surface of solids and liquids." One could hardly have a more comprehensive, and at the same time precise, statement of what research in the area of ultrathin organic films is about. No doubt that is why Abraham Ulman has chosen to preface his book with this quotation from Langmuir who, in collaboration with Kathleen Blodgett, developed the Langmuir–Blodgett (LB) technique.

Most of those engaged in research on ultrathin organic films are either chemists or physicists, and it is to these that Ulman's book is directed. In 440 pages the author introduces readers to a field that has developed at a remarkable rate during the last 15 years. This development stems to a large extent from the elegant experiments carried out by Hans Kuhn in the mid-sixties. Those experiments established the basic principles of a supramolecular architecture, and made it possible to position molecules and monomolecular films with separations of the order of 50 Å with a precision better than 5 Å. At that time the experiments confirmed Foerster's prediction of a transfer of energy from a donor dye molecule to a nearby acceptor dye molecule; nowadays they form part of the practical laboratory training of advanced students.

Ulman's book consists of five parts as follows:

1) Techniques for characterizing the intrinsic properties of films and the properties of their surfaces. Here the author describes most of the analytical methods used, starting with the measurement of thickness by ellipsometry, and continuing through scattering techniques for determining the structures of films, to surface characterization techniques such as contact angle measurements, and the most recently developed imaging techniques such as scanning tunneling microscopy and atomic force microscopy. Only a few methods are not mentioned; one of these is the vibrating quartz crystal technique for measuring the mass of material deposited on a surface.

2) Preparing monomolecular films and transfering them onto solid supports (Langmuir–Blodgett films). Here "film balance" techniques are described, whereby molecules are spread on the surface of a liquid to form a monomolecular layer, which is subsequently compressed into a close-packed state, and this film is then transfered onto a solid support. This section also describes the preparation of substrate surfaces, the transfer process, and the types of materials that have so far been used to make Langmuir–Blodgett films. Ulman attempts to relate the molecular structures, transfer conditions, and substrate properties to the properties of the resulting films, so far as this is possible from the details given in the original papers. The types of amphiphiles discussed include both substances of low molecular mass and polymers.

3) Preparing monomolecular and multimolecular films by self-assembly (SA) techniques (chemi- and physisorption). In this section Ulman draws a rather arbitrary (but, nevertheless, commonly accepted) distinction between LB films and those described here. The term "self-assembly" is meant to imply that the molecules spontaneously form an ordered structure on the surface of the substrate. In contrast to the LB technique, no film balance is needed; instead, the adsorption takes place directly from the solution. The focus of interest is therefore the kinetic aspects, which are here discussed in detail. The cost of the apparatus needed to lay down a monomolecular film by this method is considerably less than with the LB technique. However, if one wishes to build up multimolecular films the choice of compounds that can be used is severely limited, since the bonding between successive layers is usually covalent.

4) Model calculations for monomolecular film systems. In this short section the author outlines the current position regarding the theoretical description of two-dimensional molecular aggregates. It becomes apparent that methods for calculating or predicting the properties of these complex systems are still at an early stage of development. The dilemma is that the results obtained using simplified models are of doubtful value, whereas the established methods cannot be applied to systems with such a large number of degrees of freedom.

5) Potential applications of ultrathin films. This section reviews the importance of ultrathin films for materials science. Although at present (October 1991) there are only two commercial products on the market that are based on LB or SA films, there is an enormous amount of scientific and industrial interest in these systems. The most promising forms of supramolecular architecture are the polar film systems, which have applications in nonlinear optics and as pyroelectric detectors for infrared radiation. Other potential fields of application are in photoresists or electronresists, in sensors, in optical data storage, in gas separation, in friction reduction, and in conducting films.

The book is essentially what its title promises: an introduction. It includes about 1900 references to original papers and reviews. The literature coverage extends to the end of 1989, and is quite comprehensive. However, contrary to what one might expect from the title, Ulman restricts the discussion to Langmuir–Blodgett and self-assembly systems. Other important types of layered films, such as self-supporting (e.g., liquid crystalline) films, films consisting of lipid

double layers, or films prepared by spin-coating or vapor deposition techniques, are not mentioned. Also the subject index is definitely a weak point, as it is neither sufficiently comprehensive nor suitably constructed to do justice to the contents. Often it is easier to locate a topic by searching for the relevant chapter in the contents list. Despite these criticisms, the book can be recommended to everyone who seeks an up-to-date survey of the area of LB and SA films, but does not expect to find here a work of reference providing a detailed solution to every problem—the field of ultrathin films is still too new for that.

Inorganic Biochemistry of Iron Metabolism. (Ellis Horwood Series in Inorganic Chemistry). By *R. R. Crichton*. Ellis Horwood, New York, 1991. 263 pp., hardcover $85.95.—ISBN 0-13-728742-9

Although it is well known that iron is essential for virtually all forms of life, there are still many unanswered questions concerning the metabolism of the metal. In this book, Professor Crichton provides a useful survey of current understanding, with the first nine chapters dealing with the topics of general iron biochemistry, iron uptake, transport, storage and homeostasis, and then iron imbalance and its effects in relation to human health treated in the last three chapters. The area the book covers is so vast that it is impossible to provide precise details of all the known and postulated biochemical pathways involved in iron metabolism within the book's 263 pages. Instead the author has furnished us with an excellent bibliography which reflects his wide reading in the field, and upon which he draws frequently within the text, making this an invaluable source-book. There are one or two places where this system falls down, such as in the discussion of hemoprotein structures in Chapter 2, where it is not made clear which references relate to the protein structures discussed, but in general the references are helpful and up-to-date, which will be appreciated by the intended readership of researchers and advanced students.

A much more serious problem occurs in the first chapter, where the relevant inorganic chemistry of iron is considered. Unfortunately the very first page contains much which is simply wrong. It is well-known that iron(III), for example, can have coordination numbers greater than the maximum of six suggested. It is also inadvisable to describe a five-coordinate stereochemistry as octahedral! For any worker not familiar with ligand field therory, the account of "weak- and strong-field ligands", and the unwise attempt to describe them simultaneously in terms of the "soft/hard principle", will probably leave him bewildered. Those who are used to such approaches are probably best advised to treat this first page as an unfortunate misinterpretation of the theory and ignore it completely.

The chapters that deal more with the microbiology and biochemistry involved in metabolic processes may seem hard to digest for chemists, at least on a first reading. However, for those interested in understanding iron metabolism such topics are an essential part. Professor Crichton is obviously quite at home with many of these areas, and his straightforward style helps in leading us through some of the more involved chapters, such as those on "Microbial iron and intracellular release" (Ch. 3) and "Iron assimilation in plants and fungi" (Ch. 4).

The chapter on "Intracellular iron storage" (Ch. 8) is perhaps somewhat shorter than would be expected in view of the author's involvement in this field, but it is here more than anywhere else that Professor Crichton's often anecdotal style comes to the fore. I doubt that any British scientist could suppress a smile when reading the implied comparison between the contemporaneous Oxford chemists who have been dubbed "Iron Lady" in recognition of their rather different achievements.

The book ends with a consideration of the clinical aspects of iron imbalance. The problems of anemia and iron overload are described with their medical consequences. Then the roles iron plays in mechanisms of oxidative damage, which may lead to a variety of medical conditions, such as inflammatory arthritis, induced by the presence of unwanted free radicals, are discussed. Finally, the possible relationship between iron imbalance and infection is considered.

In summary, this book provides a useful addition to the existing literature. It is a readable account of a large and complicated subject and will provide researchers with many useful literature sources. The author's statement in his preface that his long association with iron has not bred contempt "but rather an increasing wonder at what iron, associated with low molecular weight and protein ligands, and often with metal and other nonmetal cofactors, can do in biological systems", is evident from the text. Although the book may raise more questions than it can answer, we are left with a clear idea about where our problems in understanding iron metabolism lie, and also how these problems have been approached to date.

Preparation and Properties, Reactions, and Applications of Radialenes

By Henning Hopf* and Gerhard Maas*

Dedicated to Professor Günther Maier on the occasion of his 60th birthday

Radialenes are alicyclic compounds in which every ring atom is sp^2-hybridized and carries an exocyclic C–C double bond. Because of their unusual topology and electronic structures these hydrocarbons have aroused the interest of both preparative chemists and theoreticians. Although considerable progress has been achieved recently, directed and efficient syntheses of these molecules remain a challenge. The study of their chemical behavior offers vast opportunities. Very recently materials scientists have become interested in these unusual compounds in their search for organic conductors and ferromagnets.

1. Introduction: Nomenclature and Structural Variety

The all-*exo*-methylenecycloalkanes **1**–**4** represent the first members of a homologous series of compounds with the general formula C_nH_n. In contrast to their constitutional isomers with endocyclic, linearly conjugated double bonds such as benzene and cyclooctatetraene, the radialenes possess an uninterrupted cyclic arrangement of cross-conjugated π systems. They are hence closely related to the so-called dendralenes,[1] acyclic and cyclic cross-conjugated polyenes derived from 3-methylene-1,4-pentadiene (**5**).

Radialenes are a relatively recent class of compounds.[2, 3] Hexaethylidenecyclohexane was the first reported example: its synthesis was published in 1961.[4] The first [3]radialene, triisopropylidenecyclopropane was described in 1965.[5] Among the parent systems, **1** was prepared in 1965,[6] **2** in 1962,[7] and for **4** three independent syntheses were reported in 1977/78.[8–10] Whereas [5]radialene **3** has evaded preparation so far, a derivative has been obtained as recently as 1986.[11] Of course, the radialenes—and the cross-conjugated systems in general (e.g. dendralenes[1] and fulvenes)—have always been overshadowed by the linearly conjugated polyenes and the arenes in preparative and industrial organic chemistry. However, in recent years interest in this class of compounds has increased significantly because new methods of synthesis make radialenes more accessible, and they are potential candidates for the construction of organic conductors and ferromagnets. Meanwhile enough information on synthesis and the chemical, physical, and structural properties of the radialenes has accumulated to justify a compact overview over this group of compounds.[12]

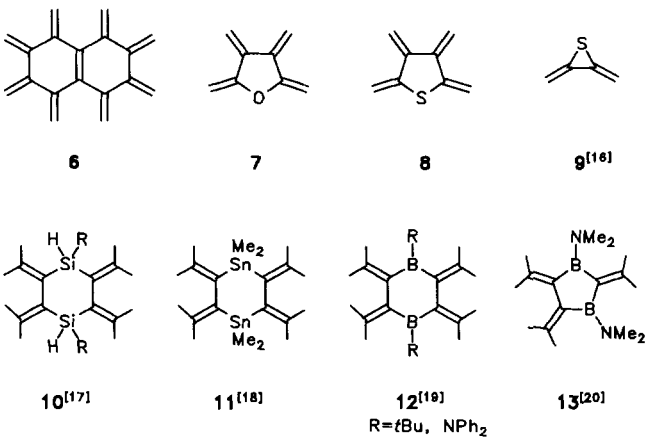
The highly symmetrical structure of **1**–**4** suggested by their constitutional formulas is not only aesthetically appealing but also stimulates the fantasy of the chemist. It is thus not surprising that the search for a fitting trivial name for

 © *VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992* *0570-0833/92/0808-0931 $ 3.50+.25/0*

these regular structures with the double bonds "radiating" from the central ring led to the name "radialene(s)".[2] Although this term was coined originally for the hexamethylenecyclohexane **4**,[3] it was quickly adopted for the whole series. To differentiate between its various members, the number of the exocyclic[*] double bonds was put in parentheses in front of the word radialene ([*n*]radialene: $n = 3$:**1**, 4:**2**, 5:**3**, 6:**4** etc.)

The fate of trivial names is that their use is not exactly defined and can hence cover a considerable range of meanings. Thus nowadays molecular frameworks that only show a more or less pronounced topological resemblance to the hydrocarbons **1**–**4** are often also called radialenes. This approach originates from a proposal by Hart[13] to call all ring systems—including condensed, polycyclic, and heterocyclic ones—with the highest possible number of exocyclic double bonds radialenes. Thus the so-called naphtharadialene **6**,[13] which has been postulated as a reactive intermediate (covered in more detail in Section 2.5), contains only sp^2-hybridized ring atoms, but does not consist exclusively of exocyclic methylene groups. In "furano-" (**7**[14, 15]) and "thiophenoradialene" (**8**[15]) the maximum number of exocyclic double bonds is present; however, the cyclic array of π electrons found in [5]radialene **3** is interrupted by the presence of a ring heteroatom. The presence of the maximum number of exocyclic double bonds and the structural element of a cross-conjugated π system is a common feature of all the compounds **6**–**8**.

The radialene terminology becomes entirely unsatisfactory for the polyalkylidene heterocycles **9**–**13**, which are lacking the typical cross-conjugated π systems. A relationship to the radialenes may at best be postulated for the 1,4-diboracyclohexane derivative **12** ($R = NPh_2$) and for the 1,3-diboracyclopentane **13** because of the double-bond character of the B–N bond ($> B-\ddot{N} < \leftrightarrow > \ddot{B}=\overset{+}{N} <$).



A concise definition of the term "radialene" is thus indispensable. Although molecules of this type are evidently amenable to IUPAC nomenclature, the further use of the term radialene, which so vividly conveys the molecular structure, appears desirable. As is obvious in many other areas of

[*] A class of compounds that contains exclusively "exocyclic" double bonds again gives us cause to point out that the prefix *exo* in this context is not only misleading but incorrect. Double bonds within ring systems can either be part of the ring, that is, both sp^2-hybridized carbon atoms are ring atoms (in that case one is dealing with an *endo*cyclic double bond), or the double bond is located as a substituent outside the ring (i.e., it is *exo*cyclic). In the past A. von Baeyer preferred to call this bonding situation *a*cyclic (A. von Baeyer, *Ber. Dtsch. Chem. Ges.* **1894**, *27*, 436–454). For the case discussed here in which only one olefinic carbon atom is part of the ring, and the other one is located outside it, he proposed the term *semi*cyclic. The resistance towards this (in our view very) convincing proposal could not be overcome, although another attempt to popularize it has been made (G. Zinner, *Chem. Ztg.* **1985**, *109*, 436). We hence yield to the present usage of the term exocyclic.

Henning Hopf was born in 1940 in Wildeshausen/Lower Saxony, Germany. After studying chemistry at Göttingen University (B.Sc. 1963), the University of Wisconsin in Madison, USA, (M.Sc. 1965, Ph.D. 1967 with H. L. Goering), and spending postdoctoral years at Marburg and later Karlsruhe with H. Musso he completed his habilitation in 1972. In 1975 he accepted a position as associate professor at Würzburg University, and in 1978 became full professor of chemistry and director of the Institute of Organic Chemistry at the Technical University of Braunschweig, where he is still working. His research, for which he has received several awards, for instance a Karl Winnacker Scholarship and the prize of the Akademie der Wissenschaft zu Göttingen, concentrates on one hand on the preparation of all types of highly unsaturated hydrocarbons and the study of their chemical and spectroscopic properties, and on the other on the study of the mechanisms of high-temperature pyrolyses of hydrocarbons.

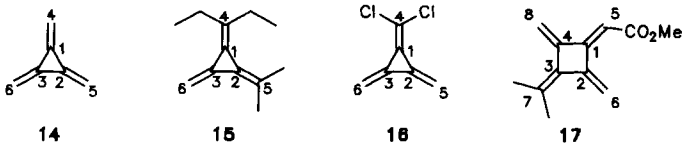
G. Maas, born in 1949 in Riegelsberg, Sarre, Germany, studied chemistry at the Saarbrücken and Heidelberg universities (Diplom 1971) and received his Ph.D. degree at Saarbrücken in 1974 with M. Regitz. From 1974 to 1976 he was Justus-von-Liebig scholar at the newly founded University of Kaiserslautern, and after a postdoctoral year with P. J. Stang at Salt Lake City (USA) he completed his habilitation in 1982 in Kaiserslautern. In 1986 he became assistant professor and in 1992 extraordinary professor at Kaiserslautern. His fields of interest are reactive intermediates, in particular carbenes, transition-metal-catalyzed decompositions of diazo compounds, the use of resonance-stabilized cations in synthesis, organosilicon chemistry, electron-rich allenes, as well the X-ray structural analysis of molecular compounds.

chemistry as well, the continuously growing structural complexity has led to steadily increasing nomenclature problems, and—in turn—to a rich trivial nomenclature.[2] Very likely, one will be forced to include the latter into the official IUPAC rules one day. Since it is also likely that the chemical significance of the radialenes will grow, we would like to present some proposals for their nomenclature without aiming at completeness. To begin with, we propose to employ the radialene nomenclature rather restrictively in order not to jeopardize its descriptiveness and simplicity of use. There is ample precedent for this approach in organic chemical nomenclature, as illustrated by trivial names such as prismanes, rotanes, asteranes, fenestranes, etc.

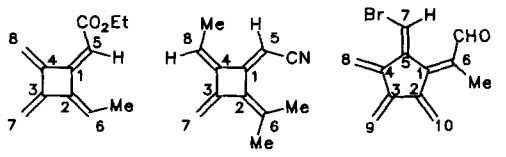
We thus propose the following definition:

Radialenes are alicyclic compounds in which all ring atoms are sp^2-hybridized and carry—as far as possible[21]—exocyclic carbon–carbon double bonds.

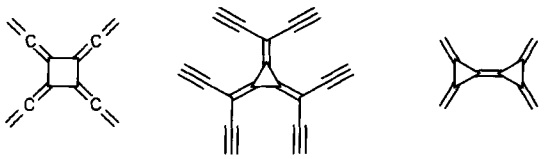
To number the various carbon atoms of a radialene we propose to differentiate between an "inner" and an "outer" ring; the numbering is continued at the periphery after the inner ring atoms have been counted. This principle is illustrated by formula **14** for [3]radialene. For substituents the usual IUPAC rules apply. Thus hydrocarbon **15** is termed 4,4-diethyl-5,5-dimethyl[3]radialene, and the dichloro compound **16** is called 4,4-dichloro[3]radialene. Analogously, the ester **17** is 5-methoxycarbonyl-7,7-dimethyl-[4]radialene. If diastereomers are encountered, the usual *E*/*Z* nomenclature is employed; for example, derivative **18** is (5*E*,6*Z*)-5-ethoxycarbonyl-6-methyl[4]radialene, **19** (5*Z*,8*Z*)-5-cyano-6,6,8-trimethyl[4]radialene, and **20** (7*E*,6*Z*)-7-bromo-6-formyl-6-methyl[5]radialene. Whereas for hydrocarbons like **21** the conventional nomenclature is more convenient (tetrakis(ethenylidene)cyclobutane), we prefer the radialene name for **22** (4,4,5,5,6,6-hexaethynyl[3]radialene), a possible building block for novel carbon networks. Needless to say, radialenes may be part of bi- or polycyclic structures. This is illustrated by the hydrocarbon **23**, for which again, however, a designation along conventional lines (tetramethylenecyclopropylidene) seems preferable to its designation as a radialene.



14 **15** **16** **17**

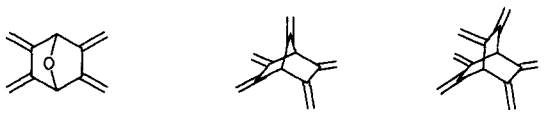


18 **19** **20**



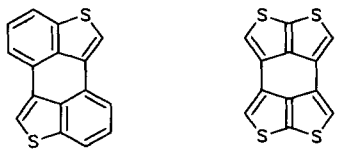
21 **22** **23**

A certain family relationship exists between the [*n*]radialenes and the bicyclic polyenes **24**, **25** ([2.2.1]hericene[22]), and **26** ([2.2.2]hericene), which recently have been discussed comprehensively by P. Vogel.[23] The element of π cross-conjugation has been lost in these systems; instead they are interesting model compounds for the study of homoconjugation and hyperconjugation effects in 1,3-dienes.



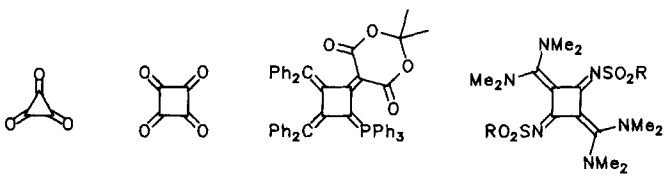
24 **25** **26**

Certain valence-structure formulas of benzo-condensed derivatives of **1**–**4** also suggest a radialene topology. Because of the extended delocalization of the π electrons in the aromatic sextet, such systems (e.g., alkylidenecyclopropparenes,[24] benzocyclobutarenes, perylene, triphenylene, trimethyleneindane and its derivatives) basically may not be considered as radialenes. On the other hand, the thiophene condensed compounds **27**[25] and **28**,[26] which are isoelectronic with perylene, may certainly be regarded as true [6]radialenes, if one takes into account the double-bond fixation that has been observed for **28** by X-ray structural analysis.

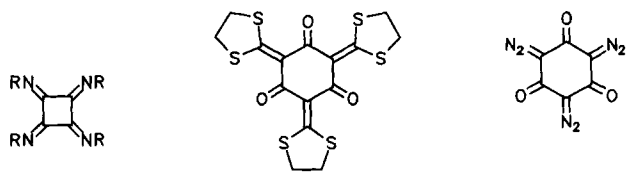


27 **28**

Radialenes whose methylene groups have been replaced partially or fully by heteroatoms, as in **29**–**35**, may be looked upon as heteroanalogs of the radialenes; **29**, for example, would be trisoxa[3]radialene. However, for the (still unknown) carbonyl compounds **29** and **30** and related systems the term "oxocarbons"[27] has been so firmly established, that we propose not to change it.



29 **30** **31**[28] **32**[29]



33[30] **34**[31] **35**[32]

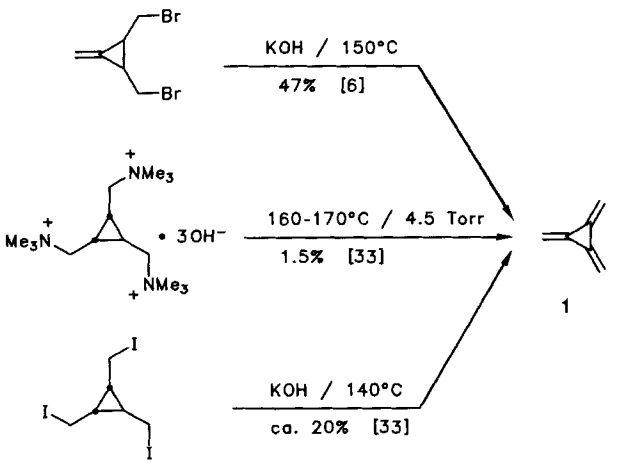
Consequently, the oxocarbons as well as sulfur, nitrogen, and other heteroanalogous compounds derived therefrom (including only partially substituted radialenes) are beyond the scope of this review.

2. Methods of Preparation

Altogether one still gains the impression that the directed synthesis of the [*n*]radialenes is not a trivial affair, especially not if the control of the stereochemistry of the exocyclic double bonds is also desired. It therefore comes as no surprise that the vast majority of the known radialene derivatives carries two identical substituents at the exterior carbon atoms. Two general synthetic strategies dominate: on the one hand, olefin-forming reactions at an already existing cycloalkane skeleton, and on the other, thermal and metal-induced cyclooligomerization reactions of suitable [*n*]cumulenes. The latter method has turned out to be the more variable and successful one so far, although it (still) cannot compete in product selectivity with the former (see Sections 2.2 – 2.4). In the following sections we shall discuss the various syntheses of the different radialenes separately.

2.1. [3]Radialenes

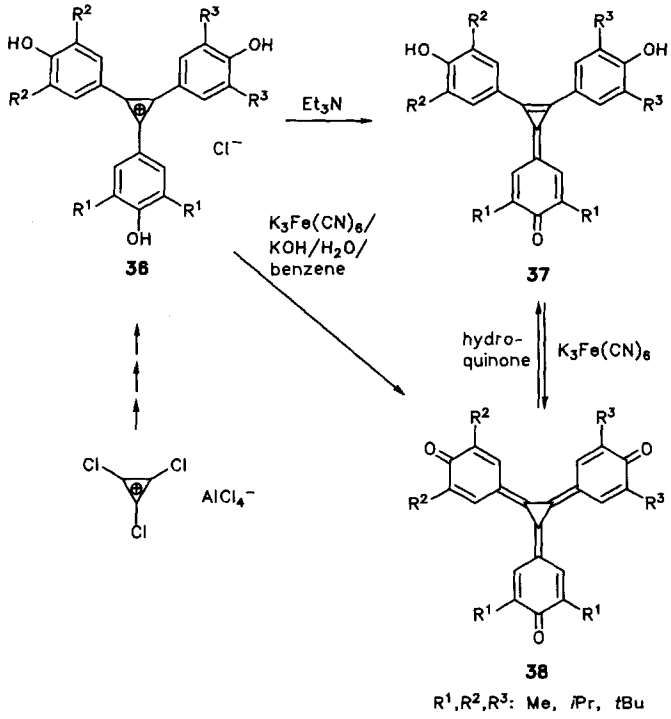
The parent compound is accessible by classical olefin-forming elimination reactions from appropriately substituted cyclopropanes (Scheme 1). The low (at best fair) yields are



Scheme 1. Synthetic approaches to [3]radialene (**1**). In all cases the product was collected at −78 °C.

not surprising in view of the rather drastic reaction conditions, as well as the high propensity of **1** to undergo polymerization (in the presence of oxygen,[33b] in CCl_4 at 0 °C, and on warming the vapor to room temperature[6]). An attempt to prepare hexaphenyl[3]radialene by threefold HBr elimination from tris(bromodiphenylmethyl)cyclopropane failed because this precursor could not be obtained.[34]

R. West et al. have developed the chemistry of [3]radialenes with quinoid substituents, as illustrated by the synthesis of tris(4-oxo-2,5-cyclohexadienylidene)cyclopropane **38**.[35] At first all chlorine substituents of the trichlorocyclopropenyl cation are successively replaced by 4-hydroxyaryl groups. The salt **36** thus formed is next deprotonated to the diaryl(oxocyclohexadienylidene)cyclopropane **37**, which is finally oxidized to the [3]radialene derivative **38**. The se-



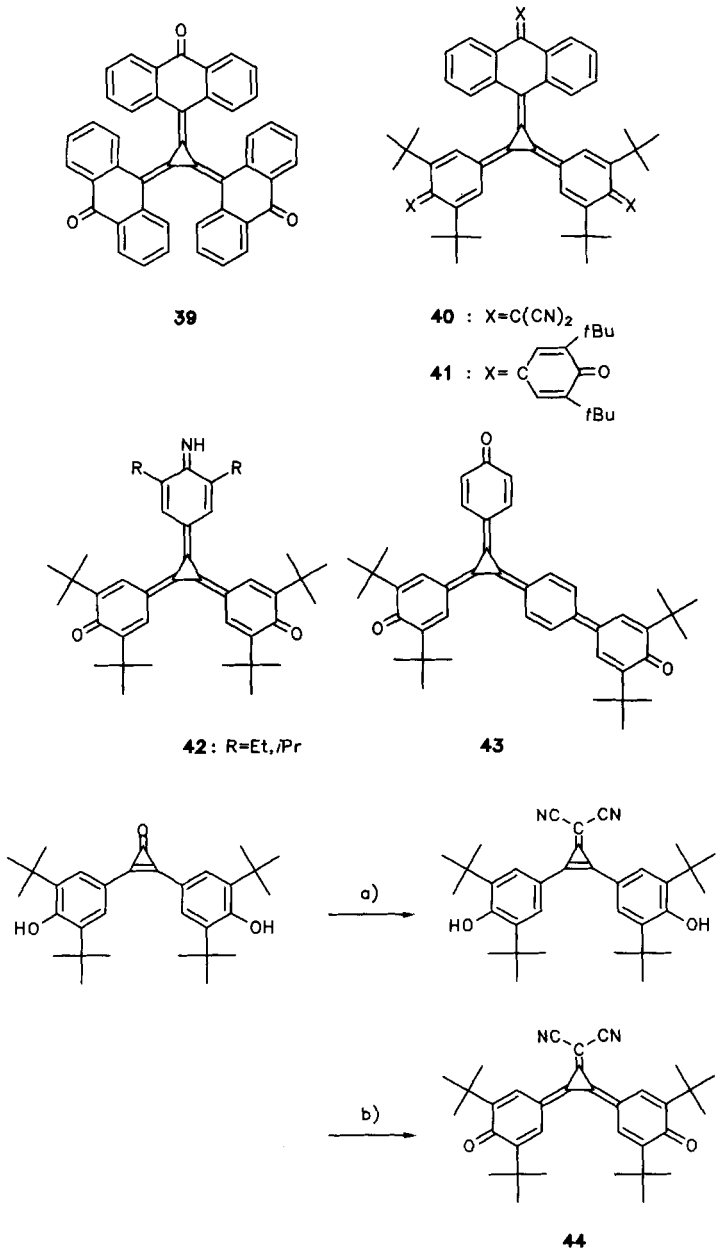
Scheme 2. [3]Radialene with quinoid substituents.

quence **36** → **37** → **38** may also be carried out as a one-pot process. The stability of the deeply colored products increases with growing steric shielding of the carbonyl groups. Thus the methyl derivative ($R^1 = R^2 = R^3 = Me$) has been shown to exist only in solution, whereas the all-*tert*-butyl compound is stable in air up to 250 °C.

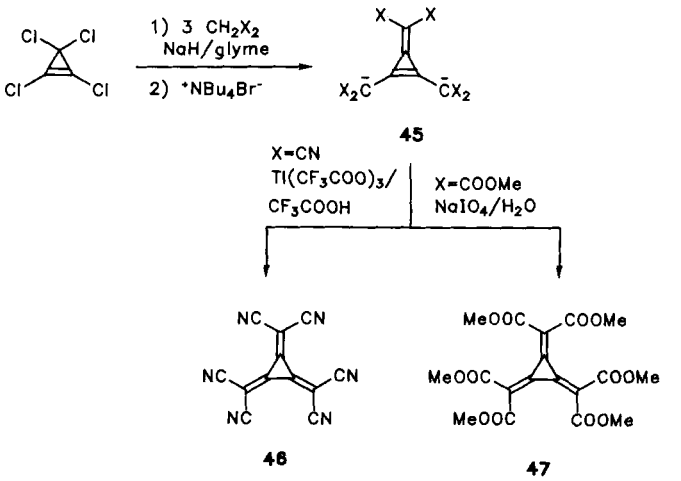
By analogous routes [3]radialenes with other quinoid substituents have been prepared, for example, **39**,[36] **40**,[37] **41**,[38] **42**,[39] and **43**.[40] In contrast to the other compounds, **43** decomposes readily to form unidentified products; it was hence characterized only in solution.

By a related synthetic method [3]radialenes that carry—besides the two quinoid substituents—a methylene group with two electron-accepting substituents[41] have also been prepared. The golden-yellow dicyanomethylenebis(4-oxo-2,5-cyclohexadienylidene)cyclopropane **44** (Scheme 3) is a case in point.

An oxidation reaction also constitutes the key step in the preparation of hexacyano[3]radialene **46** and hexakis(methoxycarbonyl)[3]radialene **47**.[42] In this synthesis the dianions **45**,[43] which are readily accessible from tetrachlorocyclopropene and malononitrile and malonic ester, respectively, are oxidized in two successive one-electron steps (Scheme 4). Whereas **47** forms stable yellow crystals, it is difficult to obtain **46** in pure from. Freshly synthesized samples are radiant yellow, but turn brown on contact with air and blue when treated with several solvents. Both KBr and NaI reduce **46** to the radical anion and the dianion **45**.

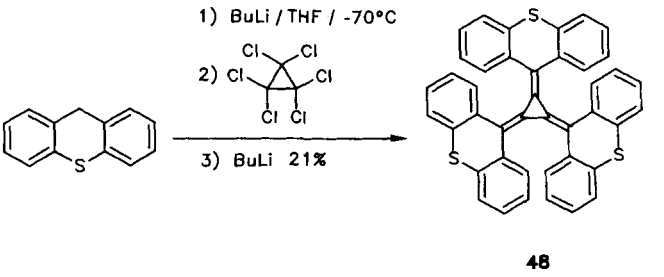


Scheme 3. Synthesis of the [3]radialene **44**. a) $CH_2(CN)_2$, Ac_2O, reflux, β-alanine; b) $K_3[Fe(CN)_6]/H_2O/OH^-/CHCl_3$.

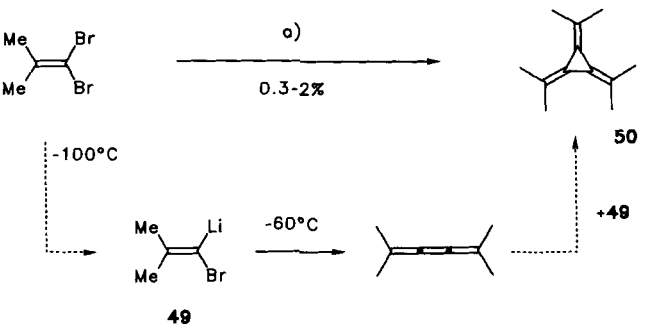


Scheme 4. Synthesis of hexacyano- (**46**) and hexakis(methoxycarbonyl)-[3]radialene (**47**).

The blue radialene **48** may be prepared from hexachlorocyclopropane. Although structurally related to **39**, it constitutes an electron-rich [3]radialene.[44]



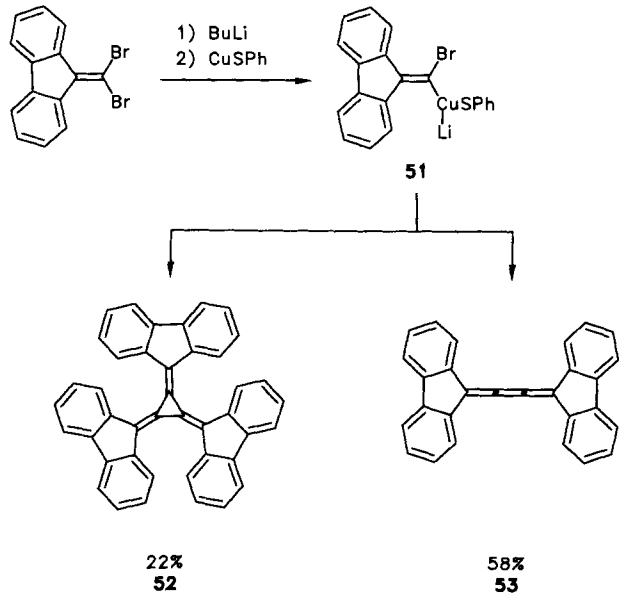
The [3]radialenes discussed so far were prepared from substituted three-membered rings; we now want to discuss methods in which the radialene is formed during the cyclopropane-forming step. Cyclopropanation of a butatriene by an alkylidenecarbene or -carbenoid intermediate, for example **49**, constituted the first synthesis of a [3]radialene by Köbrich et al.[5] (**50**, Scheme 5). The yield is very small though (about 17%), one reason being that the cyclopropanation takes place preferentially at the outer double bonds of the butatriene. This approach has not as yet been generalized. The attempt to cyclopropanate tetra(*tert*-butyl)butatriene with isopropylidenecarbene failed, most likely because of the steric shielding of the cumulene system.[45]



Scheme 5. Synthesis of the [3]radialene **50** and likely intermediates. a) 1) *n*BuLi (1.25 equiv)/THF/−110 °C; 2) −110 °C → −65 °C; 3) *n*BuLi (0.75 equiv).

Copper and nickel carbenoids, which may also be obtained from 1,1-dihaloalkenes, can cyclooligomerize directly to provide radialenes. For example, the lithium cuprate **51** yields the [3]radialene **52** (black-red crystals with a metallic luster). However, the main product of this reaction is the butatriene **53**. If other Cu^I salts are employed for cuprate formation ($CuI \cdot PBu_3$, $CuBr \cdot Me_2S$, CuCN), **53** is produced almost exclusively at the expense of the radialene.[46] As shown by a control experiment, the mechanism of formation of **52**—in contrast to the reaction course summarized in Scheme 5—is very likely not the cyclopropanation of **53**.

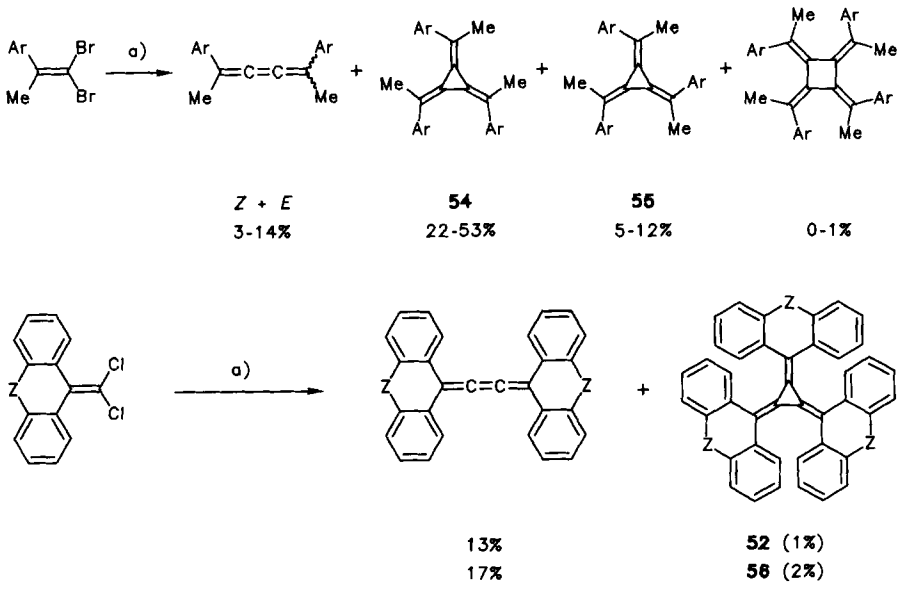
Unlike **51**, the cuprate derived from 1,1-dibromo-2-methylpropene does not form a [3]radialene, but rather [4]- and [5]radialenes (Section 2.2). Likewise, the cyclooligomerization of the analogous nickel carbenoids is very strongly substituent-dependent (Scheme 6). Sterically demanding



substituents suppress the formation of the higher radialenes and favor [3]radialene production (**52**, **54**–**56**[47a]). Even tris-(2-adamantylidene)cyclopropane may be prepared by this route (with a yield of 64%![47b])

hexadiyne in good overall yield, can also be performed readily. An elegant, although probably not an everyday method for the synthesis of **2** is provided by the thermal [4 + 2] cycloreversion of **60**. [4]Radialene may be kept for extended periods of time in dilute solutions at −78 °C under exclusion of air. At room temperature dimerization sets in rather quickly in solution, and exothermic polymerization took place during an attempt to isolate neat **2**. Towards oxygen the compound is also very sensitive.

Some substituted [4]radialenes have been prepared from cyclobutane precursors as well. Fourfold deprotonation of the tetrakis(4-pyridinio)cyclobutane **61a** yields the highly symmetrical [4]radialene **62a** in a single step as red, poorly soluble crystals[52] (Scheme 8). The presence of the ethoxycarbonyl group at the pyridine nitrogen atom is a prerequisite for the success of this synthesis. This is illustrated by the observation that the deprotonation of the salt **61b** under concomitant dehydrogenation leads to the cyanine **63** or the dication **64**, depending on the reaction conditions. The radialene **62b** could only be generated from **64** by electrochemical reduction.[53] On fourfold deprotonation of **61b** with sodium hydride in dimethylacetamide under exclusion of oxygen, a red solution is formed, which according to its absorption spectrum very probably also contains the radialene. When air is admitted the color immediately changes to blue, and **64** is formed.[53]



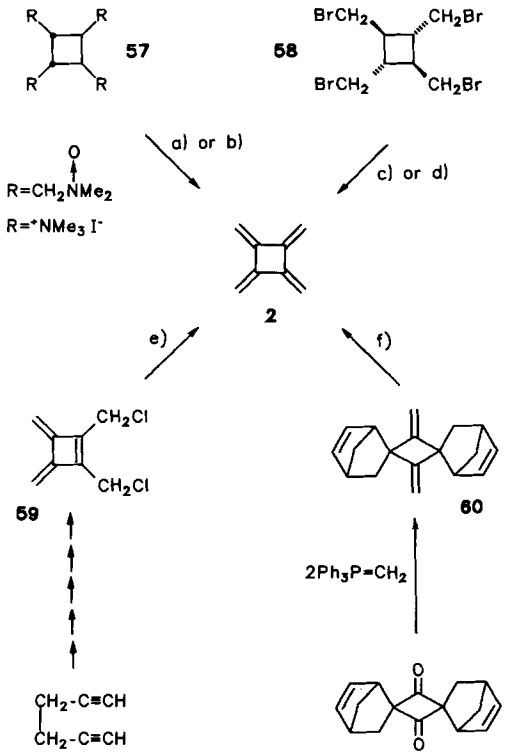
Scheme 6. [3]Radialenes by cyclotrimerization of nickel carbenoids. a) Activated nickel (5–10 equiv), THF, sonication. Ar = C_6H_5, 4-ClC_6H_4, 4-CNC_6H_4; Z = CH_2, O.

2.2. [4]Radialenes

In the same manner in which [3]radialene **1** is obtained from functionalized three-membered ring compounds, cyclobutane derivatives serve as starting materials for [4]radialene (**2**). In fact, all presently known syntheses of **2** employ cyclobutane precursors as starting materials (Scheme 7). Whereas the fourfold β-elimination in **57** is unsatisfactory, HBr elimination from **58** is preparatively useful, especially in its gas-phase variant.[48] The 1,4-dehalogenation of **59**, which in turn may be prepared from 1,5-

The synthetic potential of bis(alkylidene)cyclobutanediones and tris(alkylidene)cyclobutanones for preparing [4]radialenes is amply illustrated by the transformation of **65** and **66** into the four- to sevenfold phenyl-substituted radialenes **67**–**69** and **70**, **71**[54] (Scheme 9). In view of the simplicity of the synthetic steps it is surprising that this route has not been used more often so far. Octaphenyl[4]radialene could not be prepared by this approach, though (see below).[54]

A bis(ethyne) variant of the reductive 1,4-dehalogenation **59** → **2** is provided by the transformation of **73** into **74**.[55] The precursor **73** may be readily prepared from **72** by a



Scheme 7. Preparation of [4]radialene **2**. a) 250 °C, vacuum, 1–2% [7]; b) 115 °C; **2** isolated impure [7]; c) NaOEt, EtOH, 0 °C, > 50% [7]; d) KOH, 150 °C [48, 49]; e) Zn, $BuOCH_2CH_2OCH_2CH_2OBu$, 50 °C, 77% [50]; f) 680 °C, 5×10^{-5} Torr (flash vacuum pyrolysis), 65% [51].

palladium-catalyzed C–C coupling reaction (Scheme 10). Moreover, this method seems to offer many opportunities to vary substituents.

5,6,7,8-Tetravinyl[4]radialene **76** owes its existence to a rather unusual series of steps (Scheme 11). It is formed from the tricyclic cyclobutadiene derivative **75** by consecutive elec-

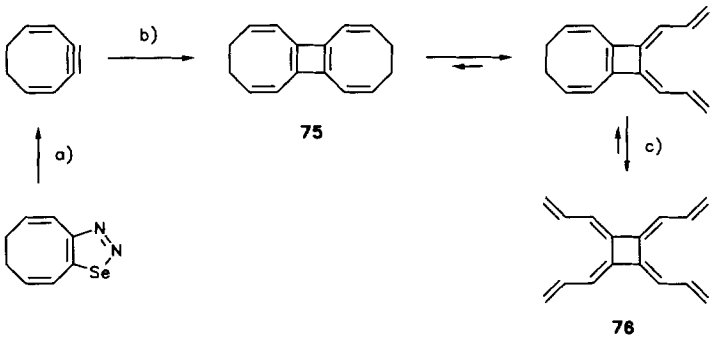
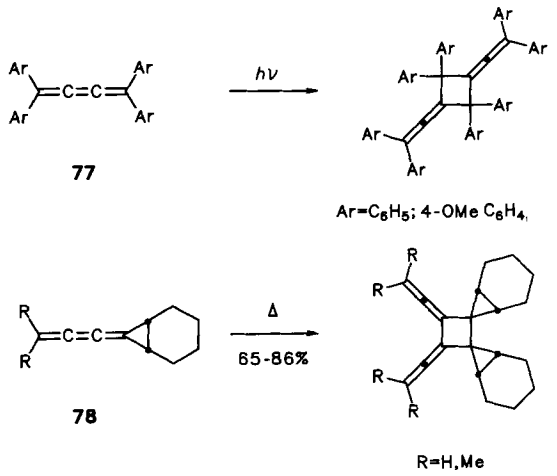
trocyclic ring openings of the two cyclooctatriene rings. Since **76** starts to polymerize slowly under the conditions of its formation, it could not be isolated in pure form. Its structure was established by NMR spectroscopy.[56]

If the thermal [2 + 2] cyclodimerization of allenes is taken as model, the higher [*n*]cumulenes should be ideal precursors for [4]radialenes, especially since butatrienes and their higher homologs are known today in considerable number.[57] However, the parent compound has already been a disappointment. On thermal activation butatriene does not dimerize to **2**, but provides, inter alia, 1,5-cyclooctadiyne.[58] Silyl-, stannyl- and germyl-substituted butatrienes do not undergo any thermal dimerization whatsoever.[59] Two re-

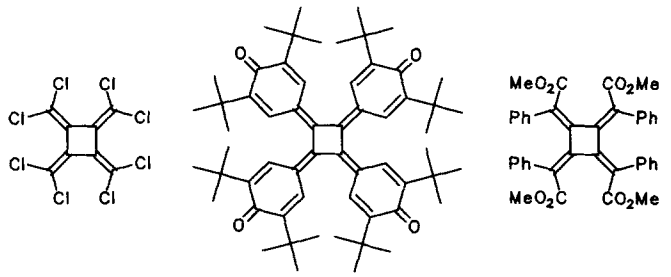


Scheme 11. Synthesis and valence isomerization of 5,6,7,8-tetravinyl[4]-radialene **76**. a) Cu powder, 180 °C; b) chloroform, $t_{1/2}$ (27 °C) = 2 h; c) several days.

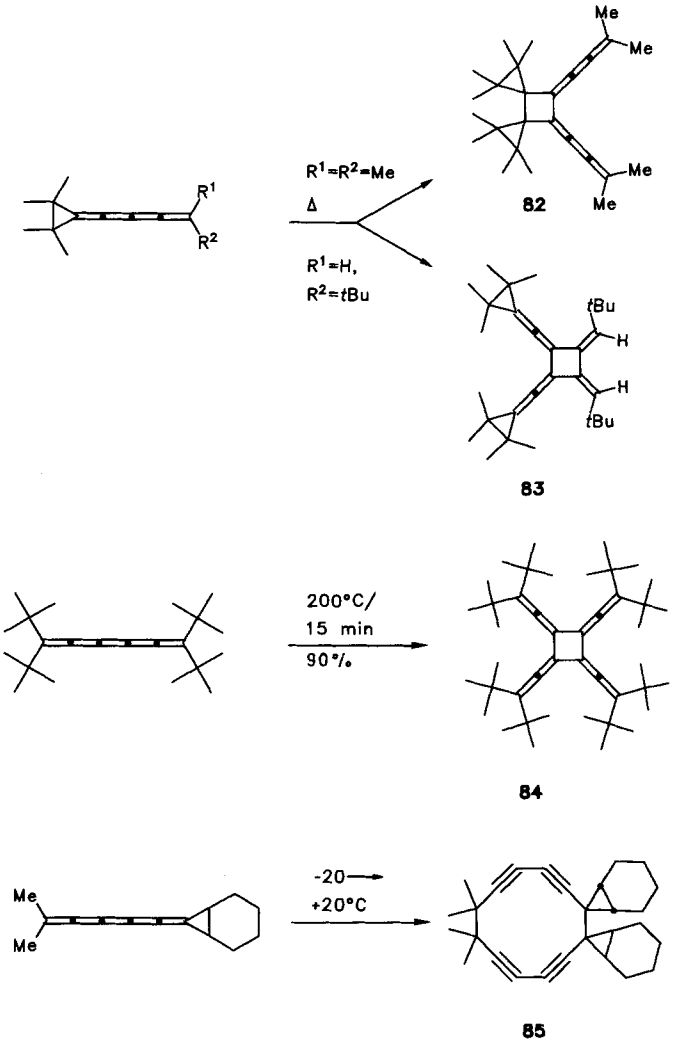
ports describing thermal dimerization of butatriene derivatives to [4]radialenes had to be corrected after an X-ray structural analysis of the products was carried out. Thus the cumulenes **77**[60] (on irradiation in the solid state) and **78**[61] (thermally) do not dimerize via their central double bond but by way of their terminal C=C bond, to provide a head-to-tail dimer in the former, and a head-to-head dimer in the latter case.



Acyclic butatrienes apparently only dimerize thermally to [4]radialenes if they carry electron-accepting substituents. This is at least borne out by the successful syntheses of **79**[62] (100 °C, 49%), **80**[63] (150 °C, 25%), and **81**[64] (110–120 °C, solid state, 75%) from the corresponding [3]cumulenes.

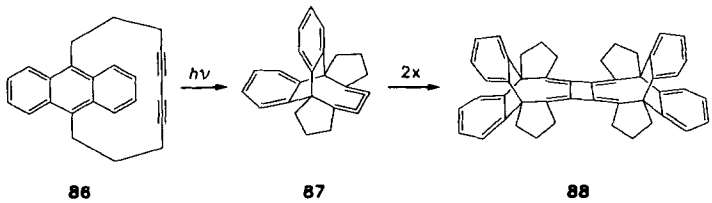


The thermal activation of [4]- and [5]cumulenes (Scheme 12) leads to radialenes in some cases (**83**,[65] **84**[66,67]); in others different cyclodimers are obtained (**82**[68], **85**[61,69]). The reasons for this divergent behavior are unclear, especially since the changes in the substituents of **82** and **83** appear to be marginal at first glance.

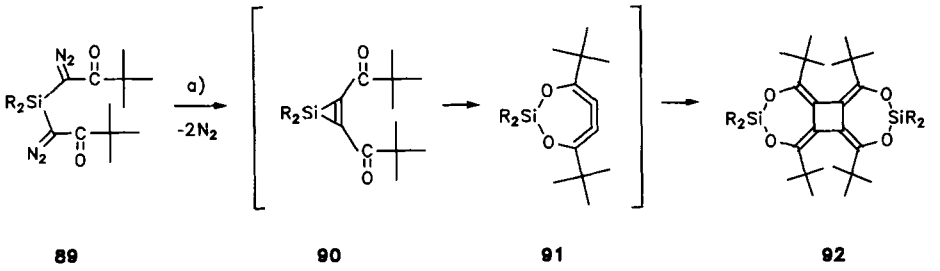


Scheme 12. Radialenes by thermal dimerization of [4]- and [5]cumulenes.

Cyclic 1,2,3-trienes show a behavior as complex as that of their acyclic counterparts. The smallest cyclic [3]cumulene isolated so far, 1,2,3-cyclononatriene, polymerizes when its solutions are concentrated.[70] 1,2,3-Cycloheptatriene, generated as a reactive intermediate, does not dimerize thermally to the corresponding [4]radialene,[71] but does so in the presence of Ni^0 as will be shown below. On the other hand irradiation of [10](9,10)anthracenophane-4,6-diyne (**86**) quantitatively yields the [4]radialene derivative **88**. It is safe to assume that its formation rests on the dimerization of the 1,2,3-cyclooctatriene **87** produced as an intermediate.[72]



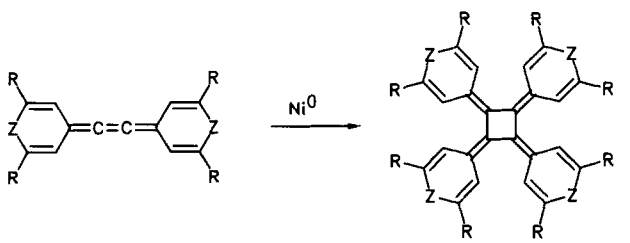
A completely unexpected observation was made when the (1-diazo-2-oxoalkyl)silanes **89** were decomposed either photochemically or in the presence of transition-metal catalysts; the tricyclic [4]radialenes **92** were produced as the sole products.[73] Presumably the silaheterocycles **90** and **91** are passed en route as shown in Scheme 13. The 1,3-dioxa-2-sila-4,5,6-cycloheptatriene **91** could at least be trapped as a [2 + 4] cycloadduct with furan.



89 **90** **91** **92**

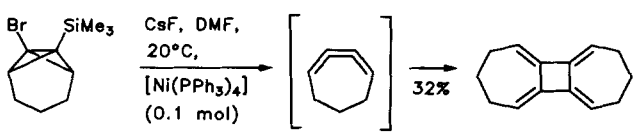
Scheme 13. Postulated intermediates during the formation of the [4]radialenes **92** from **89** (R = Me, *i*Pr). a) Catalysis by either CuO_3SCF_3 or $Pd(OAc)_2$; R = Me: 38–40%; R = *i*Pr: 5–9%).

West et al.[74] opened up a new, efficient, and apparently widely applicable route to [4]radialenes with the Ni^0-catalyzed dimerization of **93** to **80**, (R = *t*Bu, Z = C=O), which was first imitated in the conversion of **94** to **95** (R = Me, Z = CMe_2).[75] Depending on the nature of the substituent(s) of the [3]cumulene the following catalyst systems were shown to be particularly effective: $[Ni(CO)_2(PPh_3)_2]$, $[Ni(PPh_3)_4]$ (usually produced in situ by reduction of $[NiBr_2(PPh_3)_2]$), and $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene). Conditions and yields for the conversion **93** → **80** are as follows: $[Ni(PPh_3)_2(CO)_2]$ (5 mol%), benzene, 80 °C, 4 h, 95%; $[Ni(PPh_3)_4]$ (20 mol%), benzene, 80 °C, 18 h, 50%; for the purely thermal cyclodimerization the yield is 25% (see above).



93 **80**
94 **95**

Under the influence of Ni^0 even butatriene derivatives dimerize which cannot be thermally induced to form [4]radialenes, for example, 1,2,3-cycloheptatriene (**96** → **97**[76]) and tetramethylbutatriene.[77, 78]



96 **97**

In the latter case a delicate balance exists between cyclodimerization and cyclotrimeriziation. Whereas both $[Ni(PPh_3)_4]$ and $[Ni(CO)_2(PPh_3)_2]$ invariably lead to mixtures in which the [6]radialene predominates,[77] with $[Ni(cod)_2]$ as the catalyst the choice of the solvent alone can determine whether the [4]- or [6]radialene is the major product[78] (Scheme 14, Table 1). A spotlight on the mecha-

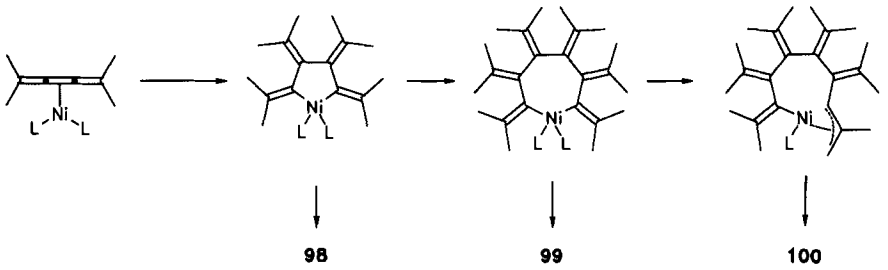
Table 1. Reaction conditions and yields for the Ni^0-catalyzed cyclooligomerization of tetramethylbutatriene to **98**–**100**.

Ni^0 catalyst	Solvent	*T* [°C]	Yield [%]		
			98	**99**	**100**
$[Ni(PPh_3)_4]$	benzene	50	7	–	19
$[Ni(PPh_3)_4]$	DMF	50	2	14	12
$[Ni(CO)_2(PPh_3)_2]$	benzene	80	7	2	30
$[Ni(cod)_2]$	toluene	20	–	–	–
$[Ni(cod)_2]$	DMF	20	–	–	–

nism of the reaction is provided by the 1:1 reaction of tetramethylbutatriene with [(bpy)Ni(cod)] (bipy = 2,2'-bipyridine).[79] Under these conditions the metallacycle **101** is isolated, from which octamethyl[4]radialene **98** is formed in high yield by reductive elimination of the metal atom. Replacing the nickel atom by CO (→**102**) or acetylene dicarboxylate (→**103**) is also possible. Products of type **102** ("6-oxa[5]radialenes") are occasionally also formed during the $[Ni(PPh_3)_2(CO)_2]$-catalyzed cyclodimerization of higher cumulenes (see below). Synthesis and reactivity of the nickel heterocycle **101** support the reaction mechanism shown in Scheme 15[77b] for the Ni^0-initiated cyclodimerization and cyclotrimerization of [3]cumulenes.



Scheme 15. Mechanistic details of the Ni-mediated cyclooligomerization of [3]cumulenes. L = PPh_3, $PnBu_3$.

The regioselectivity of the Ni^0-initiated cyclodimerization of the hexapentaenes strongly depends on the type of substituents present, as is the case for the thermal variant (Scheme 16[55, 67, 80]). A steric influence is undeniable here. Thus the tetra-*tert*-butyl derivative exclusively dimerizes via its central double bond (although **104** is obtained more efficiently by the purely thermal dimerization, see above), whereas the sterically less demanding substituents allow the dimerization to take place at the lateral sp–sp double bond. Whether in this case the head-to-head (**105**) or the head-to-tail dimer (**106**) is produced, appears again to be a question of the steric circumstances. The formation of the oxaradialene **107** evidently only occurs with those cumulenes for which the radialene formation requires forcing reaction conditions.

A logical extension (Iyoda et al.[77]) of the cyclodimerization of butatrienes shown in Scheme 14 has considerably extended the preparative possibilities of radialene synthesis. In this approach 2,3-dihalo-1,3-butadienes or 1,4-dichloro-2-butynes are dehalogenated with Ni^0 complexes to the corresponding butatrienes, and the latter transformed by the same nickel complexes to [4]- and [6]radialenes, respectively. This one pot variant, in which the cumulene is generated in situ and subsequently cyclooligomerized, provides far better yields than the process shown in Scheme 14. Yields and product ratios depend critically on the nature of the Ni^0 catalyst, the solvent, and the kind of halogen substituent of the substrate.[77b] For example, best results for the preparation of **98** were obtained when 3,4-dibromo-2,5-dimethyl-2,4-hexadiene is treated in THF with a catalyst generated in situ from $[NiBr_2(PPh_3)_2]/Et_4NI/Zn$ (0.5:2:5; 72% **98**, 1% **99**, 7% **100**). On the other hand, with $[Ni(PPh_3)_4]$ (67 mol%), prepared in situ from $[NiBr_2(PPh_3)_2]/Zn/PPh_3$ the same diene in DMF mainly yielded the [6]radialene (5% **98**, 63% **99**).

Iyoda's method has also been employed to synthesize several new peralkylated [4]radialenes.[77b] Very electron-rich [4]radialenes are available by this route as well.[81–84] Thus the purple–brown tetrakis(1,3-dithiol-2-ylidene)cyclobutane **110** has been prepared by both cyclodimerization of **108**[81] and cyclization of **109**[82] (Scheme 17).

1,1-Dibromoalkenes may also serve as precursors for [4]radialenes. However, the success of the Ni^0-initiated (for

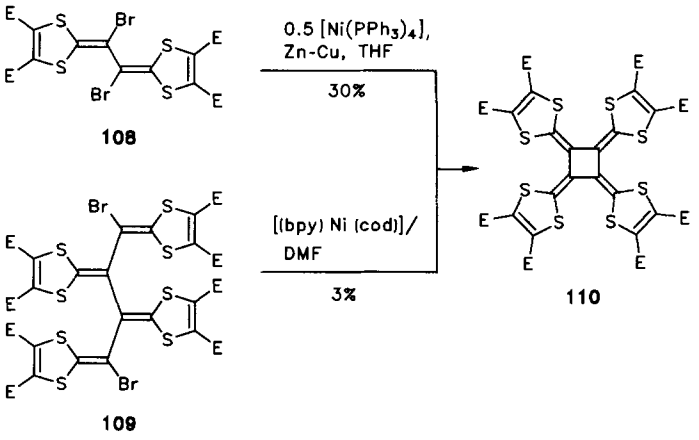
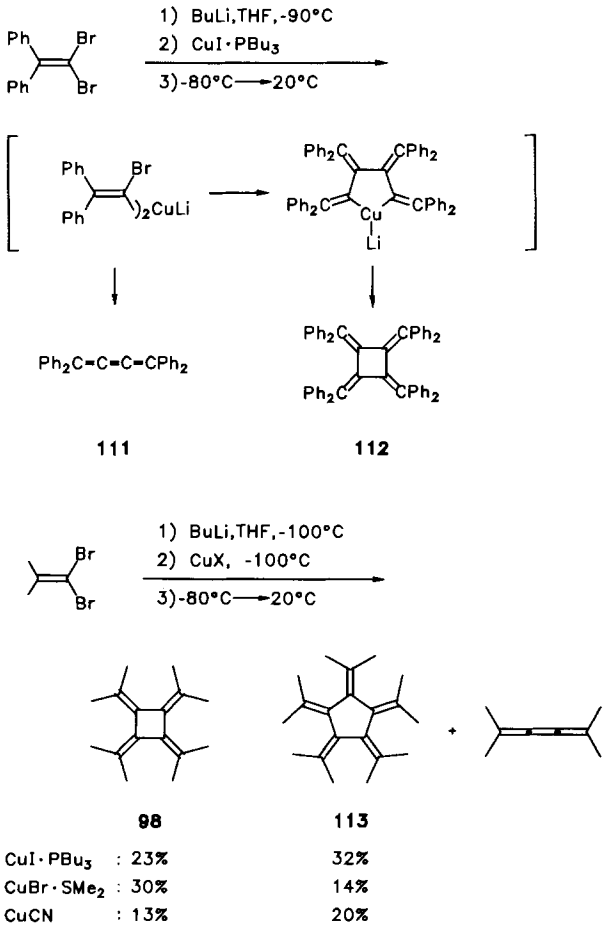


Scheme 17. Preparation of electron-rich [4]radialenes. E = COOMe.

mal) cyclotetramerization is only fair at best.[47, 77b] More suitable starting materials are the lithium bis(1-bromoalkenyl)cuprates. Depending on the Cu^{I} compound and the molar ratios, the thermal decomposition of these carbenoids leads to their (formal) dimers, cyclotetramers, and cyclopentamers (Scheme 18). This is the only known method for the preparation of octaphenyl[4]radialene (**112**).[85] Considerable amounts of tetraphenylbutatriene **111** are also formed (the

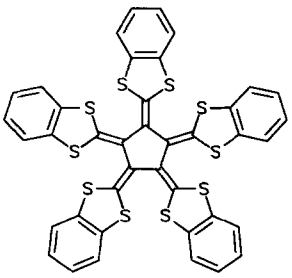


Scheme 18. The copper carbenoid route to [4]- and [5]radialenes.

Ni^{0}-catalyzed dimerization of **111** could not be achieved[77b]. When 1,1-dibromo-2-methylpropene is the starting material, the formation of octamethyl[4]radialene (**98**) competes with that of decamethyl[5]radialene (**113**).[86]

2.3. [5]Radialenes

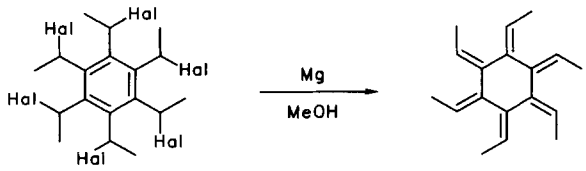
The parent compound **3** is still unknown. Several attempts to prepare it either in analogy to [4]radialene by multiple β-elimination of suitably functionalized cyclopentane derivatives[87] or by a retro-Diels–Alder decomposition[88] have failed so far. The first derivative, decamethyl[5]radialene (**113**), has been synthesized by the formal cyclopentamerization of nickel[47] or copper carbenoids (Scheme 18).[86] However, the scope of this method for the preparation of other [5]radialenes appears to be limited, since with growing size of the substituents [4]- and [3]radialenes become the preferred reaction products.[47] The preparation of pentakis(1,3-benzodithiol-2-ylidene)cyclopentane (**114**) starting from **108** has also been accomplished.[89]



114

2.4. [6]Radialenes

Hexaethylidenecyclohexane **117** (all-*E*-7,8,9,10,11,12-hexamethyl[6]radialene) is regarded as the first [*n*]radialene to be reported in the chemical literature. It was prepared in 1961 by treatment of the hexachloride **115** or the hexabromide **116** with magnesium in methanol.[4, 90]



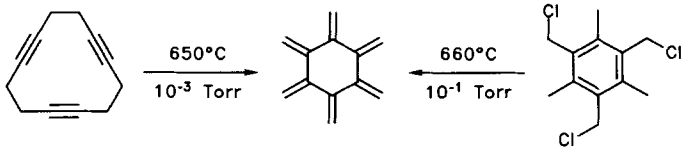
115: Hal = Cl
116: Hal = Br

117

Since for the generation of the hydrocarbon six halogen–carbon bonds have to be cleaved, the isolated yields of **117** (ca. 30%) are acceptable. If, instead of **116**, the corresponding hexabromohexa-*n*-propylbenzene derivative is employed, the hexaethyl[6]radialene (hexapropylidenecyclohexane) corresponding to **117** is isolated.[91] According to the authors[91] the hexaalkyl[6]radialenes prepared by this

route are stereochemically homogeneous and exist in the shown "waterwheel" configuration. Whereas the latter has been confirmed for **117** by an X-ray structural analysis (see Section 3.1), the question whether other diasteromers are also formed in the above elimination reactions should be reinvestigated with the more sensitive analytical techniques of today. This aspect would also be of interest in view of the conformation and configuration of the substrates and the reaction mechanism. Finally, the generalization of this altogether very convenient method is desirable. The hexaalkyl[6]radialenes are stable solids, which may be sublimed and manipulated in the presence of air.

This behavior contrasts strongly with that of the parent hydrocarbon [6]radialene (**4**), for which in short succession several methods of preparation were published (Scheme 19).[8, 9, 10] While the thermal isomerization of 1,5,9-

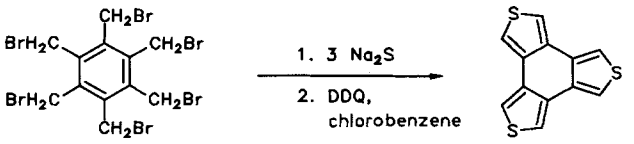


118 **4** **119**

Scheme 19. Preparation of [6]radialene **4**.

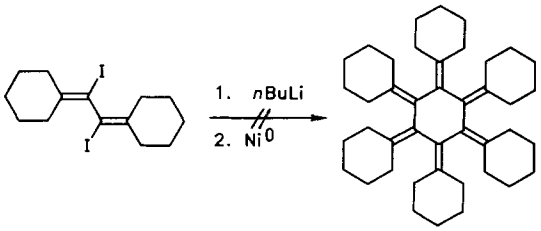
cyclododecatriyne **118** to **4**[8, 92] has negligible practical importance because of the difficulties in obtaining the starting material **118**, the thermal dehydrochlorination of the commercially available 2,4,6-tris(chloromethyl)mesitylene, a process discovered practically simultaneously by two research groups,[9, 10] constitutes a preparatively useful method. Since reproducible yields of up to 48% are obtained, **4** has become the starting material for other transformations, which will be reported in Chapter 4.3.[93]

The thieno-condensed [6]radialenes **27**[25] and **28**[26] have already been mentioned in the Introduction. Benzene[1,2-*c*:3,4-*c'*:5,6-*c'*]trithiophene (**121**), which may be prepared from hexakis(bromomethyl)benzene (**120**) by conventional transformations[94] (DDQ = 2,3-dichloro-5,6-dicyano-*p*-benzoquinone), belongs to the same class of compounds.



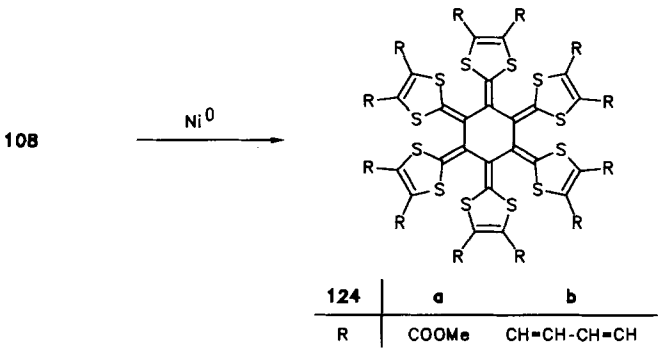
120 **121**

In spite of the successes already mentioned (see Scheme 14, preparation of **99**), the formation of [6]radialene derivatives[77-79] by Ni^0-catalyzed trimerization of [3]cumulenes is at present only of limited practical importance. Although experimentally this route is undemanding, its scope has not been investigated, and it suffers form lack of selectivity and the formation of secondary products (hydrocarbon **100** in the above case). Whether Iyoda's in situ method (see above, Section 2.2), which allows the preparation of permethyl[6]radialene from 3,4-dibromo-2,5-dimethyl-2,5-hexadiene in excellent yields (63%),[77b] can be developed further remains to be seen. Sobering is the observation that the diiodide **122** cannot be converted to the hydrocarbon **123**,[77] but



122 **123**

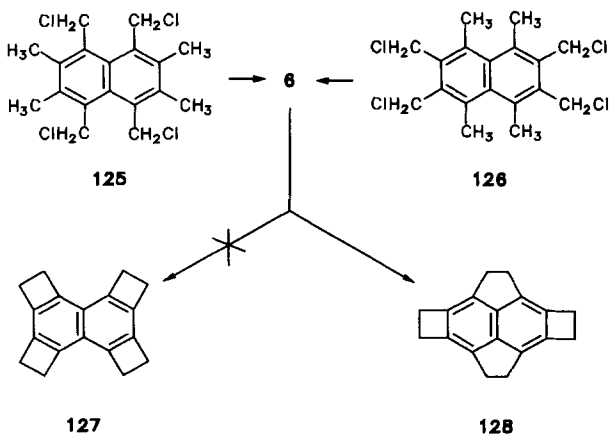
stimulating the fact that the dibromide **108**, which has already been mentioned several times, may be trimerized with $[Ni(PPh_3)_4]$/Zn–Cu in DMF in acceptable yields (35%) to hexakis(methoxycarbonyl)hexakis(1,3-dithiol-2-ylidene)-cyclohexane (**124a**).[96] The benzo-annelated derivative **124b** was prepared by an analogous route and indeed in 72% yield.[96]



124	**a**	**b**
R	COOMe	CH=CH-CH=CH

2.5. Higher Radialenes

The chapter of the "higher" radialenes practically constitutes an empty page at the present time, since radialenes with a larger "circumference" than the six-membered ring are



125 **126**

127 **128**

Scheme 20. Generation of naphtharadialene **6**.

unknown. Hart's „naphtharadialene"[13, 97] (1,2,3,4,5,6,7,8-octamethylene-9,10-didehydrodecalin, **6**) still counts as the sole representative of this group of radialenes; it is formed as a reactive intermediate by thermal gas phase dehydrochlorination at 620 °C and 10^{-4} Torr from either the tetrachloride **125** or its isomer **126** (Scheme 20). Evidence for the intermediate generation of **6** may be seen in the isolation of **128**, which is produced as the stable final product in ca. 15% yield in these pyrolyses. Since it was impossible to distinguish between **128** and the also conceivable isomeric hydrocarbon **127** by spectroscopic methods, the structure of **128** had to be secured by X-ray structural analysis.

3. Structure, Bonding, and Spectroscopic Properties

3.1. Structure and Bonding

According to electron diffraction measurements[98] as well as IR and Raman spectra,[99] [3]radialene **1** is a planar molecule with D_{3h} symmetry (see Section 3.3). From the vibrational spectra D_{4h} symmetry is derived for [4]radialene **2**.[49] The molecular symmetry and the conformation of the central ring for substituted radialenes may be inferred from a remarkably large number of crystal structure analyses (Table 2).

In hexamethyl[3]radialene the D_{3h} symmetry of the parent system is not noticeably perturbed. [4]Radialenes possess a planar cyclobutane ring as long as there is no steric strain between substituents. If this is the case, however, a more or less pronounced folding of the four-membered ring is caused, and the $>CR_2$ groups point alternately "up" and "down". The also conceivable structure of a planar ring with a propeller-type substituent arrangement has not been encountered as yet. So far for [5]- and [6]radialenes with the exception of the special case **28**, only structures are known in which steric hindrance between the substituents does not allow a planar radialene skeleton. The chair-type conformation of the sterically hardly hindered hexakis(ethylidene)cyclohexane seems to indicate that the parent molecule **4** prefers this conformation as well.

The high molecular symmetry of substituted radialenes in many cases may be inferred from their NMR, IR, and Raman spectra. An exception is provided, for example, by hexakis(methoxycarbonyl)[3]radialene, whose IR and Raman spectra indicate that the molecule—unlike the hexacyano derivative—does not have D_{3h} symmetry.[42]

The lengths of the exo- and endocyclic bonds of [4]radialenes and higher radialenes correspond to the values normally encountered for C=C and $C_{sp^2}-C_{sp^2}$ bonds, respectively. The endocyclic bonds in [3]radialene and its hexamethyl derivative show the expected shortening to approximately 1.45 Å, an effect which is also reproduced by ab initio calculations.[104, 105] The cyclic arrangement of the π systems of the radialenes led to early speculations on whether in these molecules a stabilizing or destabilizing cyclic electron delocalization was present as encountered in the annulenes. Numerous theoretical investigations involving especially π resonance energies (calculated according to different approaches[106]), total π-electron density indexes,[107] and the absolute and relative hardness[108] as criteria have been concerned with this problem. One result from these studies is that all radialenes are nonaromatic. The occurrence of localized endocyclic single bonds and exocyclic double bonds, as indicated by many calculations[109] as well as structural studies, in addition to the nonplanarity of the substituted higher radialenes clearly speak against the delocalization of the π-electron density.

The introduction of trigonal centers into three-membered rings leads to a pronounced increase in strain energy, whereas in the higher membered ring only small effects are observed.[110] A quantitative comparison of the parent compounds **1**–**4** has hitherto been impossible because of lack of experimentally determined thermochemical data. Only for **1** has an enthalpy of formation $\Delta H_f^0 = 396.12$ kJ mol^{-1} been determined from the fragmentation pattern of the molecular ion $\mathbf{1}^+$ generated by photoionization or electron impact (EI). From this value a strain energy of 226.3 kJ mol^{-1} could be derived,[111] a number which is 56 kJ mol^{-1} smaller than the one estimated from the increase in strain energy when going

from cyclopropane to methylenecyclopropane and assuming that this effect is additive when introducing the second and third double bond.[112]

3.2. Electronic Spectra

The long-wave UV absorption maxima of the parent compounds **1** and **2** (Table 3) show a pronounced bathochromic shift relative to the maximum for 1,2-dimethylenecyclopropane (λ_{max} = 232 nm) and 1,2-dimethylenecyclobutane (λ_{max} = 248 nm), respectively. This corresponds to the influence of extended conjugation known from linear polyenes. In a qualitative way the differences mentioned may be rationalized by a PMO model (PMO = *P*erturbational *M*olecular *O*rbital), in which the π MOs of **1** and **2** are obtained by a linear combination of the π MOs of an s-*cis*-butadiene and an ethylene unit (→**1**) and two s-*cis*-butadiene units (→**2**);[23] for quantitative calculations of the electronic transitions in radialenes see [3, 113]. The short-wavelength absorption maximum of [6]radialene points towards a chair conformation of the molecule, in which extended conjugation between the π systems is impossible.

Table 3. UV absorption maxima of radialenes **1**, **2** and **4**, and long-wavelength absorption maxima of some substituted radialenes with extended π conjugation.

Radialene	Solvent	λ_{max} [nm] (lg ε)	Ref.
1	gas phase	289 (3.97 ± 0.09)	[114]
2	ethanol	208 (4.70 [a]), 263 (3.84), 271 (3.90), 281 (3.84), 296 (3.62)	[7]

52	CH_2Cl_2	615 (4.72), tailing up to 800 nm	[46]
80	cyclohexane	595 (4.35)	[63]
95	cyclohexane	496 (4.34)	[75]

[a] For the determination of the extinction coefficient, see ref. [7].

The UV spectra of the permethylated radialenes are very similar to those of the parent systems if one takes the bathochromic shift caused by the alkyl groups into account. As can be seen from Figure 1 the longest wavelength absorption maximum is shifted to shorter wavelengths with growing ring size. By extension of the π conjugation the longest wavelength absorption maxima may be shifted very far into the visible region. Several examples illustrating this point are given in Table 3.

The photoelectron spectra of **1**[114] and **2**[48] as well as those of the permethylated derivatives of [3]-,[115] [4]-,[116] and [6]radialene[117] have been measured and the electronic configurations of the various molecular ions have been assigned on the basis of MO calculations. Of importance for the ease of oxidation to the radical cation (cf. Section 4.5) is the observation that the substitution of the H atoms in [4]radialene by eight methyl groups causes a decrease of the first vertical ionization potential from 8.35 to 7.30 eV.

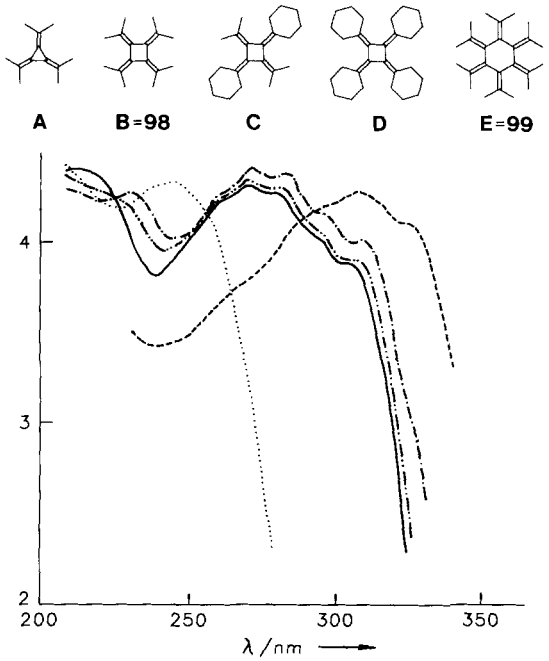

Fig. 1. Electronic spectra of peralkylated radialenes (from [77b]). – – –**A**, —**B**, – · · · · –**C**, – · – · –**D**, · · ·**E**.

3.3. IR and Raman Spectra

The IR and Raman spectra of **1**,[99b] **2**, and [D_8] **2**[49] as well as of octachloro[4]radialene[118] have been analyzed carefully. From these data the molecular symmetry of **1** and **2** could be established unequivocally. For **79** the solution spectra are compatible with D_{2d} symmetry, from which the molecule deviates only slightly in the crystalline state (see Table 2). Table 4 summarizes the C=C stretching modes and their assignments for **1**, **2**, **79**, and several peralkylated radialenes.[77b] The symmetrical stretching modes, which in the Raman spectra are observed at highest frequencies, are

Table 4. Intensity and assignment of C=C stretching modes in some radialenes.

[a] Abbreviations: vs = very strong, s = strong, m = medium, w = weak, vw = very weak; p = polarized, dp = depolarized. [b] All spectra were measured for KBr pellets, unless stated otherwise. [c] Liquid, −65 °C. [d] Gas phase, room temperature. [e] Polycrystalline solid, −190 °C. [f] In CCl_4.

IR inactive for the examples shown. The high frequency of the symmetrical C=C valence vibration for **1** is found in the typical range for methylenecyclopropanes and dimethylenecyclopropanes (see for example reference [5b]). In [4]radialene this vibration is registered at only slightly higher frequency than that of alkenes of the general structure $R_2C{=}CH_2$ (1680–1630 cm^{-1}).

3.4. NMR Spectra

NMR spectroscopic data characterize the radialenes as typical alkenes (Table 5). Thus the exocyclic protons of **1**, **2**, and **4** appear at practically the same chemical shifts as those of ethylene. It is immediately obvious that there is no ring current effect—another indication that a cyclic delocalization of π electrons does not exist in the radialenes. In the ^{13}C NMR spectra of the parent molecules **2** and **4** the ring carbon atoms are shifted downfield by $\Delta\delta = 47$ and 35 relative to the shift of the exocyclic carbon atoms. The chemical shifts, however, do not differ very much from those of methylenecyclobutane ($\delta = 148.8$ and 105.2) and methylenecyclohexane ($\delta = 149.2$ and 106.9).[119] The substitution of the olefinic hydrogen atoms by methyl groups results in the typical substituent effects—deshielding of α- and shielding of β-carbon atoms. Both effects, though, are considerably less pronounced in the permethylated radialenes than in simple alkenes.

Table 5. ^1H and ^{13}C NMR chemical shifts of radialenes (in $CDCl_3$ or CCl_4).

Radialene	$\delta(^1H)$ $=CH_2$ or $=C(CH_3)_2$	$\delta(^{13}C)$ $C_{ring} = C_{exo}$		Ref.

4. Reactivity

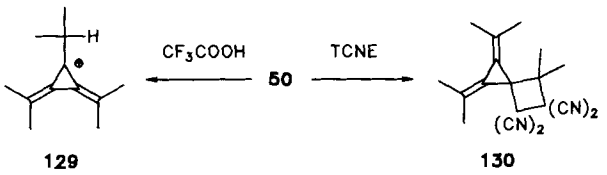
In Section 2 we mentioned the extreme sensitivity of the parent systems **1**,[6, 33b] **2**,[7, 50] and **4**[9] towards molecular oxygen (formation of oxygen-containing polymers) as well as their high thermal lability. Radialene **1** polymerizes in CCl_4 already at 0 °C, **2** undergoes dimerization in ethanol at 20 °C, and microcrystalline **4** may decompose violently even at 20 °C. Up to now, these unpleasant properties have greatly discouraged efforts to study the reactivity of these radialenes in a broad and systematic manner (perhaps with the exception of **4**), and have nearly completely precluded their use as building blocks in organic synthesis. The more highly substituted the radialenes are, the more stable they become; permethylated radialenes can be considered as perfectly stable under normal conditions (perhaps with the exception of the moderately oxygen-sensitive hexamethyl[3]radialene[5]).

Radialenes **1**, **2**, and **4** have in common a relative stability towards dilute mineral acids and strong bases. Their chemical behavior is dominated by addition of electrophiles and cycloaddition of electron-poor components; some differences exist, however, in the outcome of these reactions.[120] In the following, we shall discuss the characteristic reactions of the individual classes of radialenes separately, and then turn our attention to the interesting redox properties of functionalized radialenes.

4.1. Reactions of [3]Radialenes

On catalytic hydrogenation of [3]radialene (**1**) with Pd/C, ring-opening occurs and a mixture of 3-methylpentane and 3-methyl-2-pentene is formed. With a $Rh{-}Al_2O_3$ catalyst, a small amount of all-*cis*-1,2,3-trimethylcyclopropane was obtained besides the alkane mentioned and isomeric C_6H_{12} alkenes.[33b] The reaction with $PdCl_2 \cdot 2\,PhCN$ yields a sparingly soluble, structurally unidentified complex having the composition $C_6H_6Cl_2Pd$.[33b] No further reactions of **1** appear to be known.

When hexamethyl[3]radialene **50** is dissolved in trifluoroacetic acid, cation **129** is formed, which has been characterized by its electronic spectrum ($\lambda_{max} = 480$ nm).[121] In this respect, **50** resembles hexamethyl[6]radialene (see Section 4.3). With tetracyanoethylene (TCNE), **50** forms the [2 + 2] cycloadduct **130**; as intermediate, a violet-blue charge-transfer complex can be observed.[5b]



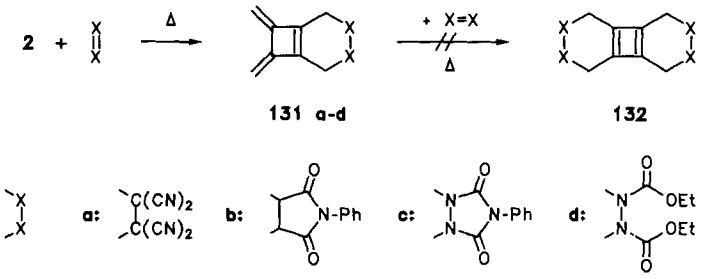
129 **130**

4.2. Reactions of [4]Radialenes

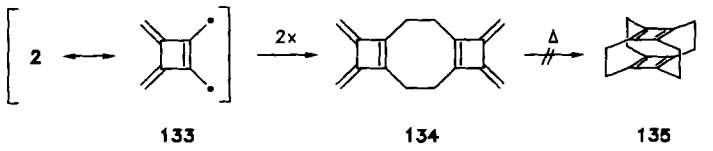
Among all radialenes reported so far, [4]radialene (**2**) is the most thoroughly studied, because of its comparably easy preparation (Scheme 7, Section 2.2) and its convenient manipulation. This hydrocarbon can be kept for an unlimited time at −78 °C, and because of its high volatility it can be easily transferred and dosed by the usual high-vacuum techniques.[7, 50]

As a twofold diene system, **2** lends itself as a component for repetitive Diels–Alder additions, and in their pioneering papers in the early sixties, Griffin and Peterson already reported [2 + 4] cycloaddition reactions with **2**.[7] Thus, [4]radialene reacts with TCNE as a dienophile to give the 1:1 adduct **131a** (0 °C, ethanol, 50% yield), and with *N*-phenylmaleimide; **131b** is obtained analogously (25 °C, 100%).

The 2:1 addition resulting in the tricyclic cyclobutadiene derivatives **132a** and **132b** is not observed. Even the more reactive dienophiles "*N*-phenyltriazolinedione" (4,5-dihy-



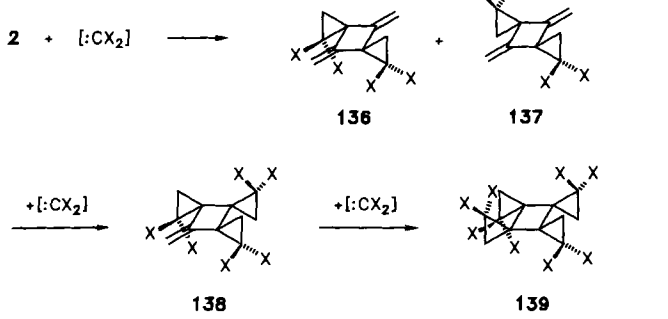
dro-4-phenyl-3*H*-1,2,4-triazol-3,5-dione, NPTD) and diethyl azodicarboxylate at −78 °C cannot overcome the activation barrier presented by the antiaromatic character of **132**, and the cycloaddition reaction again stops at the stage of **131 d** (90%) and **131 c** (46%), respectively.[50] When the temperature is raised to 20 °C, a reaction channel is opened for **2** that has already been observed at its original preparation, namely, a dimerization resulting in cyclooctadiene derivative **134**.



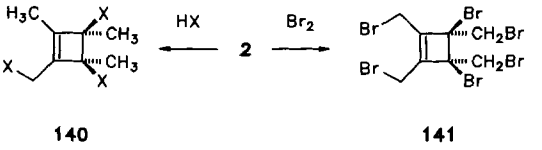
The latter reaction represents a formal [4 + 4] cycloaddition that is symmetry-forbidden as a concerted process. It is probably a stepwise, radical process[50] originating from the resonance structure **133**. Gas phase pyrolysis of **134** at 220 °C leads back to **2**;[87] the desired intramolecular cycloaddition yielding the [2.2.2.2]cyclobutadienophane **135** is avoided, presumably for the same reasons which explain the failure of **131** to act as a diene in the (intermolecular) Diels–Alder reaction.

Another type of cycloaddition, carbene addition to **2**, has provided a simple connection between the chemistries of radialene and rotane.[122] With dichlorocarbene ($:CCl_2$), generated from chloroform by the Makosza method, a product mixture is obtained in pentane (2 h, room temperature, 74% yield), from which the two bisadducts **136** (33%) and **137** (41%) can be isolated by chromatography.

When the product mixture is treated again with dichlorocarbene, trisadduct **138** (X = Cl, 54%) and octachloro[4]-rotane (**139**, X = Cl, 30%) are obtained; the alternating arrangement of the CCl_2 groups in **139** has been established by an X-ray crystal structure analysis.[122] Addition of dibromocarbene ($:CBr_2$) to **2** is not only distinctly slower, but it also stops at the stage of **136** and **137** (X = Br in both cases), apparently for steric reasons. Therefore, it is not surprising that methylene transfer to **2** with diazomethane/copper(I) chloride yields **138** and **139** (X = H in both cases). It should be mentioned, however, that better preparations of these hydrocarbons exist.[123]



Hydrochlorination and hydrobromination (−78 °C, ether), as well as addition of bromine (−20 °C, CCl_4) were the first ionic reactions of **2** described.[50] These reactions, which yield trisadducts **140** (X = Cl: 68%; X = Br: 50%) and **141**

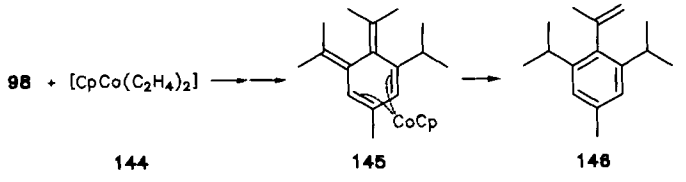


(68%) in good yields, can be interpreted as a 1,4-addition to one of the two 1,3-butadiene subsystems of **2**, followed by two 1,2-addition reactions. As expected, these polyhalogenated cyclobutenes undergo thermal isomerization to the corresponding butadienes by an electrocyclic ring-opening reaction.[50]

The high reactivity of **2** in solution or in the pure state contrasts with its high thermal stability in the gas phase: the tetraene survives flash pyrolysis in a quartz tube unchanged up to 850 °C! A transformation starts only at temperatures above 880 °C, from which mainly styrene (ca. 60%) and small quantities of phenylacetylene, *o*-xylene, toluene, and benzene are obtained. No mechanistic details of these far-reaching reorganizations of the carbon framework of **2** are known.[50]

Octamethyl[4]radialene (**98**) behaves towards TCNE analogously to the parent system **2** by readily yielding a Diels–Alder adduct of type **131 a**. Similarly, the corresponding 1:1 product **142** results from the reaction with NPTD, but in addition a 2:1 adduct is obtained that has the betaine-type constitution **143** according to an X-ray structural analysis.[78]

Another surprising result is provided, when **98** is treated with the cobalt complex **144**, since a catalytic rearrangement of **98** to 2-isopropenyl-1,3-diisopropyl-5-methylbenzene (**146**) is observed, rather than the expected exchange of the ethylene ligand. Whereas no intermediates for the conversion of **98** into **146** have been detected in toluene at 60 °C, the complex **145** is isolated when the reaction is carried out in THF at the same temperature, and it is considered as an intermediate of this very far-reaching isomerization.[124]

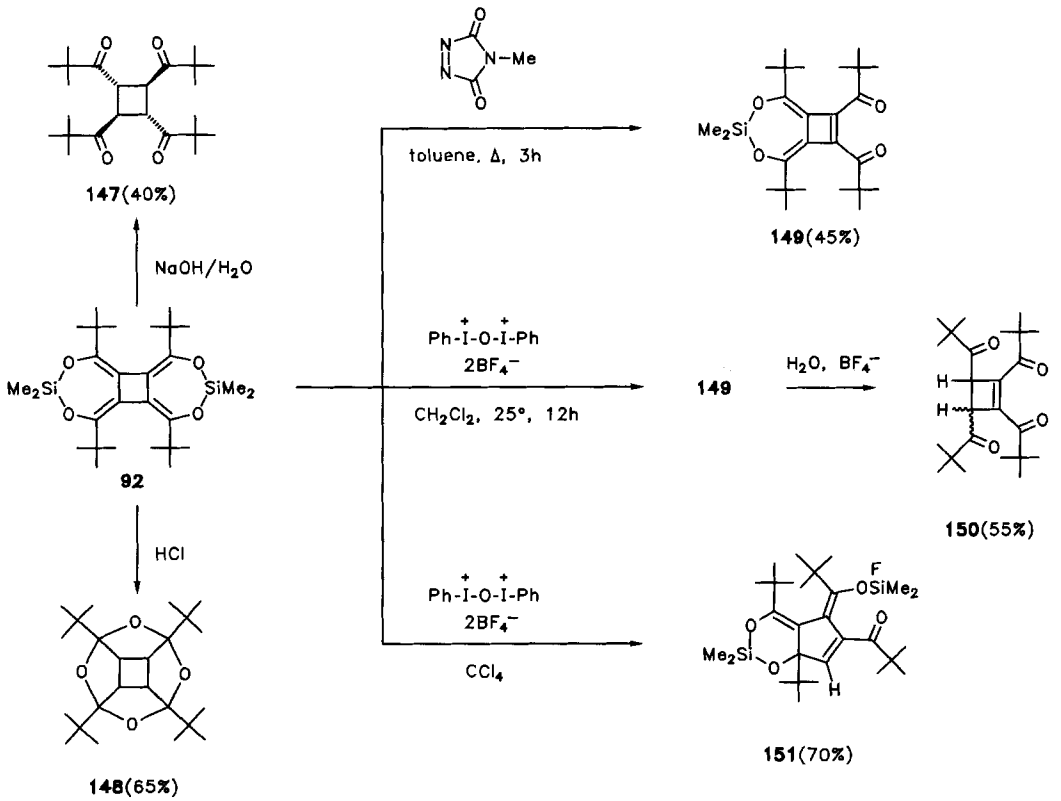


The highly functionalized [4]radialene **92** also displays a variety of partly surprising reactions. Hydrolytic cleavage of the silyl enol ether functionalities in an alkaline medium yields the all-*trans*-tetrapivalolylcyclobutane **147**, whereas acid catalysis leads to the pentacyclic polyether **148**, presumably via the all-*cis* isomer of **147**.[73a]

4.3. Reactions of [5]- and [6]Radialenes, and Higher Radialenes

Except for some findings such as the isomerization of the naphtharadialene **6** to **128** (Section 2.5), studies of the chemical behavior of the higher homologues of **2** have so far been limited to the [6]radialenes. Not very surprisingly, most results have been acquired for the easily accessible and stable alkyl derivatives of [6]radialene, for example **117**.

Just like [4]radialene (**2**), **117** is susceptible to ionic addition and (presumably concerted) [2 + 4] cycloaddition reactions (Scheme 22). In a reversal of its mode of formation, **117** is converted into hexabromide **116** quantitatively by addition of bromine.[4, 90, 126] The transformation may be formu-

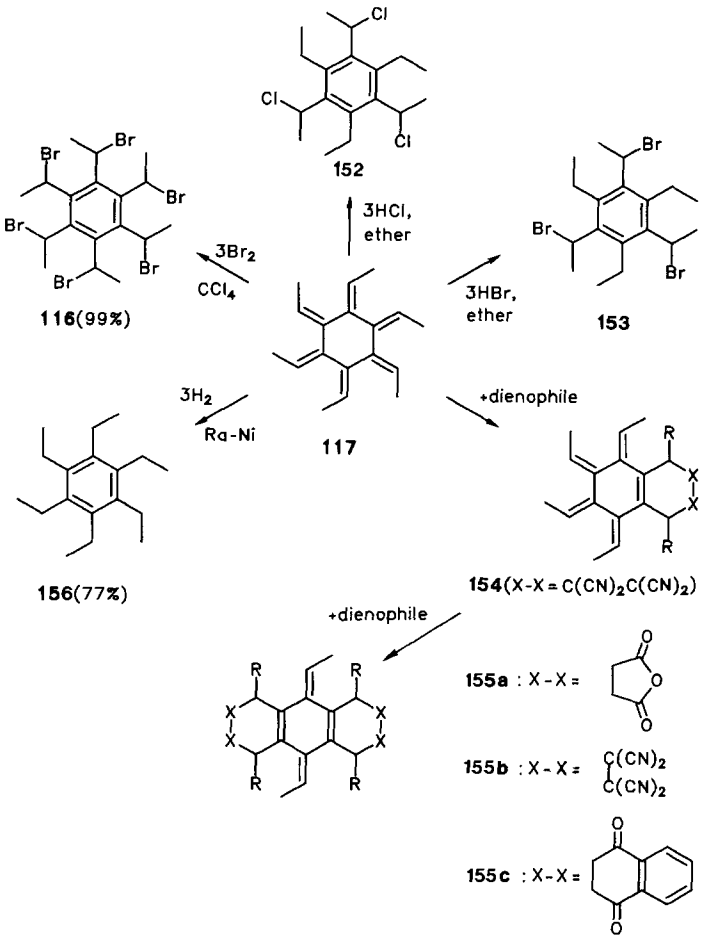


Scheme 21. Reactions of the electron-rich [4]radialene **92**.

Not surprisingly in view of its nonplanar diene units, **92** does not undergo [4 + 2] cycloaddition with *N*-methyltriazolinedione. Instead oxidative desilylation takes place to form **149**. Not unexpectedly, a repetition of this transformation, which would convert **149** into a cyclobutadiene, does not occur. The same oxidative desilylation of **92** also takes place with iodonium salt $(Ph\text{-}I^+\text{-}O\text{-}I^+\text{-}Ph) \cdot 2\ BF_4^-$ in dichloromethane, this time followed by a desilylation to yield **150**. Surprisingly, the bicyclic compound **151**, identified by an X-ray structural analysis, is obtained when the reaction is carried out in tetrachloromethane. Although the mechanistic details are not known, an impurity always present in the reagent seems to account for the reorganization of the molecular framework of **92** and formal addition of HF.[125]

lated as a sequence of 1,4-additions; this reaction mode also prevails on addition of hydrogen chloride or bromide to give **152** and **153**, respectively.[90] In highly acidic solutions (H_0 ranging from -5 to -7), the monoprotonated form of **117** is generated.[3] Diels–Alder reaction with **117** initially yields products **154**, which in principle can undergo a second cycloaddition to afford either angularly annelated (*meta*-type) or linearly annelated (*para*-type) 2:1 adducts.

Experimentally, various dienophiles—including *p*-benzoquinone, dimethyl acetylenedicarboxylate, acrylates, acryl- and crotonaldehyde,[127] besides the compounds shown in Scheme 22—lead only to the linear 2:1 cycloaddition products **155**. Monoadducts **149** most often cannot be isolated,[128] which is attributed at least in part to the reaction conditions applied. Under the harsh conditions originally used (reflux-

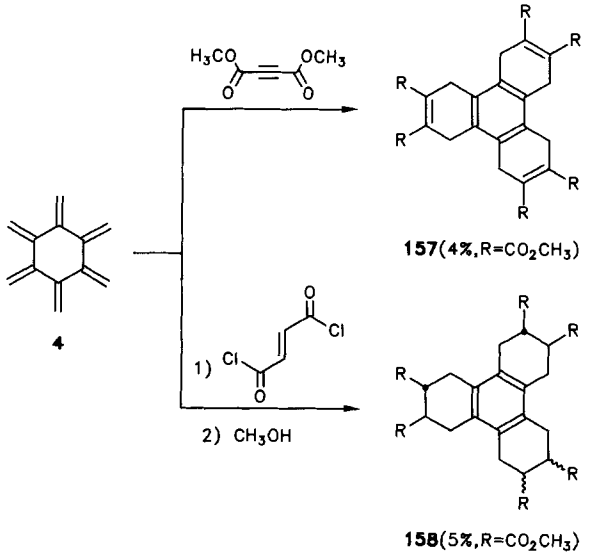


Scheme 22. Addition reactions with hexamethyl[6]radialene (117). Yields [%]: **155a**, 80; **155b**, 76; **155c**, 30. Ra-Ni = Raney nickel.

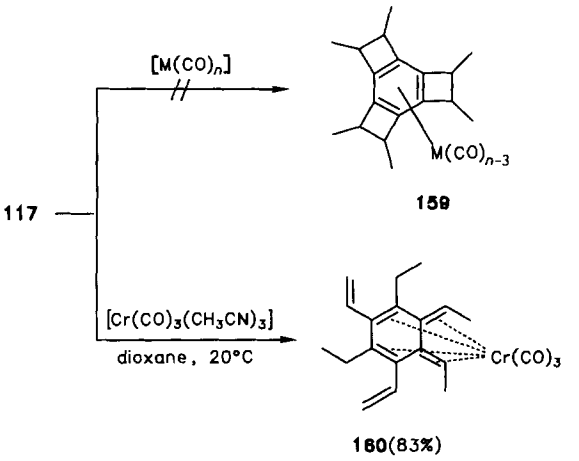
ing xylene, extended reaction times), only polymer resins were obtained,[90] whereas in low-boiling solvents (ether, tetrahydrofuran, benzene), the expected adducts were formed normally in good yield.[127, 128] Polymer formation is likely to be attributed to the fact that 2:1 adducts **155**, the linear rather than the angularly annelated constitution of which has been established both by spectroscopic methods and chemically,[129] are *p*-quinodimethane derivatives; the tendency of the parent *p*-xylylene to undergo oligomerization and polymerization is well known.[130] The absence of *o*-quinodimethane derivatives resulting from the *meta* addition mode is probably due to steric hindrance between the substituents. Addition reactions of hexaethyl[6]radialene (hexapropylidenecyclohexane) are analogous to those of **117**; however, since they proceed more slowly, 1:1 adducts such as **154** can be isolated without difficulty.[91] Catalytic hydrogenation of **117** yields hexaethylbenzene (**156**), as expected.[90]

The reactions of the sterically unbiased [6]radialene (**4**) are very similar to those of **117**. Hydrogenation leads to hexamethylbenzene,[8, 10] addition of dimethyl acetylenedicarboxylate yields **157**,[9] and an isomer mixture of **158** is obtained from the reaction with fumaroyl chloride followed by methanolysis.[9, 131] In contrast, the sterically shielded double bonds of dodecamethyl[6]radialene (**99**) are unreactive towards dienophiles, even towards the extremely strong dienophile NPTD.[78]

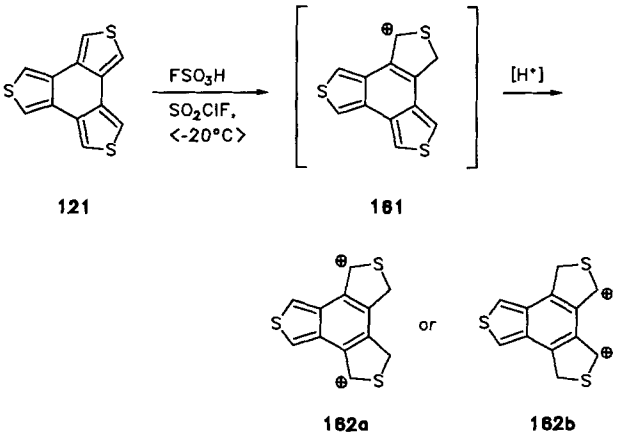
The reaction of **117** with tris(acetonitrile)tricarbonyl-



chromium in dioxane at ambient temperature produces **160** in good yield, and not the expected chromium complex **159**. The identity of the product, which is derived from the radialene by a twofold 1,5-H shift, has been established by X-ray structural analysis.[132]



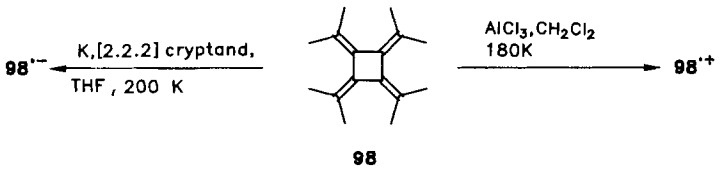
The tris(thiophene) compound **121** seems to be the only more complex [6]radialene that has aroused closer attention. Protonation with fluorosulfonic acid generates a dication with the structure **162a** or **162b**,[94] presumably via the monocation **161**, which is not observed.



4.4. Redox Properties of Radialenes

Because of their cross-conjugated π system, the radialenes represent multistep redox systems; this feature has been investigated more intensively than any other aspect of their chemical reactivity. The ease of generating individual reduced or oxidized species and their stability depend on both the substituents at the radialene framework and the possibility of generating a planar π system in which the charge(s) can be delocalized as far as possible.

Thus, the parent compounds **1**, **2**, and **4** have been transformed by photoionization into the molecular cations in the gas phase (Section 3.2), but no electrochemical redox reactions in solution are known. For octamethyl[4]radialene (**98**) the first vertical ionization potential is significantly lower than for **2** (Section 3.2), and as expected, **98** is more easily oxidized to the radical cation. However, the kinetic instability of the radical ions in solution at room temperature is indicated by the irreversibility of both the oxidation step (+1.3 V vs. saturated calomel electrode (SCE)) and the reduction step (−2.6 V)[116] in the cyclic voltammogram. Nevertheless, the radical anion and the radical cation have been generated under the conditions indicated in Scheme 23



Scheme 23. Oxidation and reduction of **98**.

and have been characterized by their nearly congruent ESR and ^{1}H electron nuclear double resonance (ENDOR) spectra.[116, 133]

The stability of the radical cations of peralkylated [3]radialenes is similar to that of **98**. For example, the radical cation of hexamethyl[3]radialene (**50**) has been generated in an organic glass by γ irradiation, whereas the radical cation of tris(2-adamantylidene)cyclopropane is formed irreversibly under the conditions of cyclic voltammetry.[47b]

The ability of substituents to stabilize individual redox species is illustrated for substituted [4]radialenes in Table 6. The possibilities range from the as yet unknown, extremely electron-poor octacyano[4]radialene (**163**), whose dianion has been isolated as a stable tetrabutylammonium salt, to the electron-rich [4]radialenes tetrakis(1,4-dihydropyridin-4-ylidene)- and tetrakis(1,3-dithiol-2-ylidene)cyclobutane, which can donate up to four electrons. In between is the five-step redox system of **95**, for which fully reversible one-electron transfers between the dianion and the dication can be realized. Only in the case of **62a** is the stepwise oxidation to the cyclobutadiene **62aD** bearing four cationic substituents fully reversible (Scheme 24). In the redox equilibrium **62aC** ⇄ **62aD**, the radical trication dominates (> 99.99%); this species as well as the dication **62aB** (a squaric acid derivative) most likely represent fully delocalized systems.

Acceptor-substituted radialenes in general can be reduced easily to the radical anion and the dianion. Typical examples

Table 6. Observed redox stages of substituted [4]radialenes A (• = initial charge state of the radialene; the numbers are the potentials in volt versus Ag/AgCl. Figures in parentheses indicate irreversible electron transfer steps.

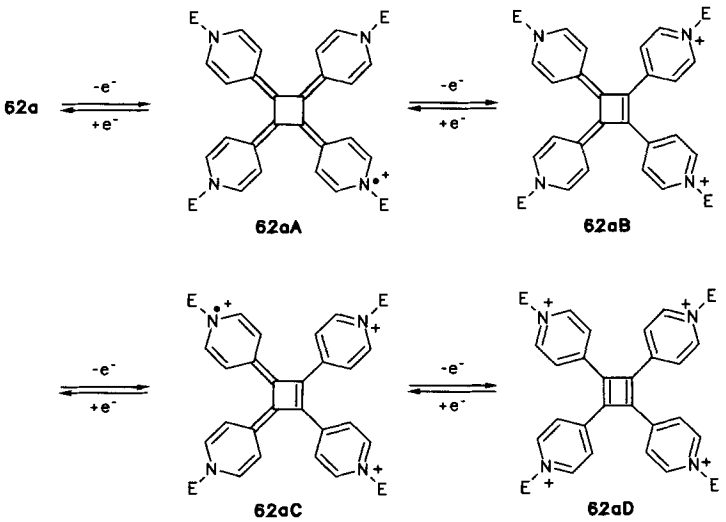
[a] Potential vs. SCE. [b] The dianion was generated by twofold deprotonation of 1,2-dimethyl-3,4-dimethylencyclobutene with *n*-BuLi/TMEDA. Electron-transfer processes seem to occur beside other reactions on trapping with methyl iodide. [135] No electrochemical transformations of 2^{2-} into **2** or vice versa are known. [c] Determined by PE spectroscopy. [d] The first oxidation step of the radialene is a two-electron transfer.



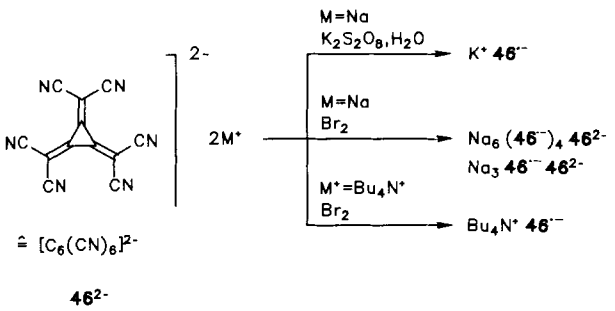
Scheme 24. Radialene **62a** as a fully reversible, five-step redox system. E = COOEt.

are represented by [3]radialenes **46** and **47** (see below), tris(9-fluorenylidene)cyclopropane (**52**; two reversible one-electron reductions: $E_{1/2}$ vs. Ag/AgCl: −0.27 and −0.75 V[46]), the West type [3]radialenes bearing *para*-quinoid substituents such as **38**–**44**, and the [4]radialene **80**. The latter compounds normally display two well-defined, reversible one-electron steps (exception: two-electron reduction of **40**[37]); the first reduction step occurs at relatively high (positive) potential.[37–40, 41a, 41c, 63, 136, 137] In agreement with theoretical predictions,[138] these radialenes therefore represent strong electron acceptors. If one takes into account the

potentials of the two reduction steps, they represent oxidizing reagents which, in general, range between chloroanil and DDQ.[139] It is therefore no surprise that the tris(oxocyclohexadienylidene)cyclopropanes **38** are reduced by hydroquinone to the bis(4-hydroxyaryl)cyclopropanes **37** in a reversal of their original synthesis (see Scheme 2). The analogous reduction of the anthraquinone derivative **39**, however, requires Sn/HCl.[36]

Many of the radical anions of radialenes bearing *para*-quinoid substituents are persistent in solution (THF, dichloromethane) and have been characterized by their ESR spectra.[37–39, 41a, 41c, 63, 137, 140] Since the two-step reduction process may be accompanied by a striking color change, these systems have been proposed as candidates for use in electrochromic displays.[41c]

Hexacyano[3]radialene (**46**) is a very strong electron acceptor,[141] which is reduced to $\mathbf{46}^{\bullet-}$ and $\mathbf{46}^{2-}$ extremely easily (see Section 2.1). A number of salts containing the radical anion $\mathbf{46}^{\bullet-}$ have been isolated. Typically, the radical anion is obtained form the dianion $\mathbf{46}^{2-}$ by one-electron oxidation, but under certain conditions, complex salts containing both $\mathbf{46}^{\bullet-}$ and $\mathbf{46}^{2-}$ are also formed[142] (Scheme 25). In contrast to **46**, hexakis(methoxycarbonyl)[3]radialene (**47**) can be prepared without difficulty; on reduction with iodide, radical anion $\mathbf{47}^{\bullet-}$ is passed as a short-lived intermediate.[142]



Scheme 25. One-electron oxidation of the dianion of **46**. a) Recrystallization from ethanol.

Focusing on electron-rich radialenes, Yoshida et al. have investigated those containing sulfur as the donor atom.[87] In the homologous series of the radialenes bearing 1,3-dithiol-2-ylidene units, large differences in the electrochemical oxidation behavior have been observed (Tables 6 and 7), the most remarkable feature being the apparent four-electron oxidation step of the [5]radialene **114**. Oxidation of the [3]radialene **48** with $Tl(CF_3COO)_3$ leads via $\mathbf{48}^{\bullet+}$ (detection in the ESR spectrum) to the isolable dicationic salt $\mathbf{48}^{2+} \cdot 2\ CF_3COO^-$, which has a singlet ground state and a thermally accessible triplet state only 0.07 eV above the singlet state.[141, 142]

5. Radialenes as Building Blocks for Organic Conductors and Organic Ferromagnets

Among organic materials displaying metallic conductivity, molecular π donor–acceptor complexes, whose prototype is the system TTF · TCNQ (TTF = tetrathiafulvalene, TCNQ = tetracyanoquinomethane), must be named first alongside radical cation salts of type D_mX_n (D = donor, X = charge-compensating closed-shell anion, $m > n$), some of which even have superconducting properties.[143] The high conductivities of these systems are not reached, however, when electron-rich radialenes (Table 6) are used as the donor components. The charge-transfer (CT) complex **164** · $(TCNQ)_2$ has a specific electrical conductivity (compressed pellet, room temperature) of 0.032 S cm^{-1},[81a] while that of the complex formed from **164'** and four TCNQF (TCNQF = tetracyanotetrafluoroquinodimethane) units is 0.075 S cm^{-1}.[84] Single crystals of these complexes have not been obtained so far.[89a] The [3]radialene **48** and the [6]radialene **124b** do not form CT complexes with the common electron acceptors.

The perchlorate and hexafluorophosphate salts of the radical cation of **164** (benzo-1,3-dithiol-2-ylidene instead of 1,3-dithiol-2-ylidene) have been obtained as very small single crystals by electrocrystallization. Their electrical conductivity at room temperature is 1 S cm^{-1}, but the temperature dependency is characteristic of semiconductors.[89a]

Since the radialenes used have nonplanar structures (see Section 3.1), the somewhat disappointing results obtained so far are not unexpected. Hopes for higher conductivities rest upon the CT complexes or radical cation salts of the as yet unknown tris(1,3-dithiol-2-ylidene)cyclopropane, which is expected to be a planar compound. The [6]radialenes **27**[125] and **28**[126] should also be ideal donor components. They form complexes with iodine, and a close similarity between perylene and **27** exists as regards the conductivity and low stability. The specific electrical conductivity of the 1:1 complex of **28** and iodine is relatively high (0.11 S cm^{-1}[126]).

The quest for ferromagnetic molecular solids[144] is currently being pursued actively in several research groups. The first organometallic complex exhibiting ferromagnetism, $[Fe^{III}(C_5Me_5)_2]^{\bullet+}$ $[TCNE]^{-}$, has been reported only recently.[146, 147] Ferromagnetic coupling in a molecular solid is essentially equivalent to stabilization of a triplet state. Several models have been suggested to achieve this property.[147c] McConnell in 1967[148] proposed as candidates those ionic charge-transfer complexes built up in alternating chains of radical cation donors and radical anion acceptors, in which either the donor or the acceptor has a neutral triplet ground state; back charge-transfer would then mix some triplet character in the ground state, leading to ferromagnetic coupling of the spins of adjacent ions.

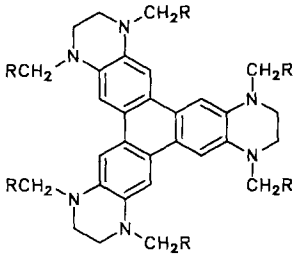
An extension and generalization of McConnell's model was put forward by Miller and Epstein.[145, 147c] They stated that "assuming the electron-transfer excitation arises form the partially occupied molecular orbital (POMO), to achieve ferromagnetic coupling in a molecular solid via the McConnell mechanism a stable radical (neutral, cations/anions, or ions with small diamagnetic counterions) must possess a degenerate POMO that is not half-filled, and the lowest excited state formed via virtual charge transfer (retro or forward) possesses the same spin multiplicity and mixed with the ground state."[147c] The degeneracy of the further orbitals may be accidental or imposed by symmetry; in the latter case, the doubly degenerate POMOs require the symmetry D_{2d} or C_3 or that of a higher point group for the species bearing the unpaired electron(s).

Within this conceptual framework, radialene-containing CT complexes have also been investigated. The DuPont group has used the (diamagnetic[149]) radical anion $\mathbf{46}^{\bullet-}$ to prepare 1:1 CT complexes with organometallic cations such as $[Fe^{III}(C_5Me_5)_2]^{\bullet+}$,[150] $[Fe^{III}(C_5Me_4H)_2]^{\bullet+}$,[151] $[Os(C_5Me_5)_2]^{\bullet+}$,[152] and $[(\eta^6\text{-}C_6Me_3H_3)M]^{\bullet+}$ (M = Fe, Ru);[153] however, none of those complexes displayed ferromagnetism.

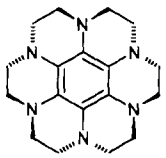
Several electron-donating radialenes with an odd-fold symmetry axis have been envisaged as components of organic ferromagnets: hexakis(dimethylamino)[3]radialene, tris(1,3-dithiol-2-ylidene)cyclopropane, the [3]radialene **48**, and the [5]radialene **114**. Whereas the two first-mentioned radialenes are still unknown and **48** does not form donor-acceptor complexes, the complexes of **114**, whose dication is a ground-state triplet, with several strong acceptors do not have the 1:1 stoichiometry required[147b, c] for alternating $D^{\bullet+}A^{\bullet-}D^{\bullet+}A^{\bullet-}\cdots$ linear chains according to the McConnell model for ferromagnetism.[89b] Thus, the temperature-dependent variation of the paramagnetic susceptibility in the solid complexes **114** · 2 DDQ and **114** · 4 TCNQF indicated a weak antiferromagnetic interaction between the radical components. The complex **114** · $(\mathbf{46})_2$, on the other hand, is diamagnetic.[89b]

Breslow's adaptation of the McConnell model aimed at the use of antiaromatic dications with triplet ground states. In that case, a forward charge transfer $D^{\bullet+}A^{\bullet-} \rightarrow D^{2+}A^{2-}$ is required.[154] Donor-acceptor complexes $\mathbf{165}^{\bullet+} \cdot \mathbf{46}^{\bullet-}$ and $\mathbf{166}^{\bullet+} \cdot \mathbf{46}^{\bullet-}$ were prepared.[155] The hexacyano[3]radialene radical anion was chosen as the acceptor not only to match the redox potentials of the components but also in the hope that it would help to preserve the C_3 symmetry of the donor ions in the crystal structure of the complex, since the donor dication is in a triplet ground state only due to its threefold symmetry axis. However, both complexes showed antiferromagnetic, not ferromagnetic, ordering.

The hexaaminobenzene derivative **167** reacts with $\mathbf{46}^{\bullet-}$ to form the ionic complex $\mathbf{167}^{2+} \cdot \mathbf{46}^{2-}$.[156] In contrast to **165** and **166**, dication $\mathbf{167}^{2+}$ has a singlet ground state; however,



165 : R = CF_3
166 : R = CHF_2



167

its temperature-dependence of the magnetic susceptibility differs from that of other essentially diamagnetic complexes with the same dication by a pronounced upturn of the magnetic susceptibility above about 150 K. This behavior, which in combination with results of ESR measurements suggests the presence of a thermally populated triplet excited-state species beside excited triplet $\mathbf{167}^{2+}$, is not yet understood in detail. The failure to generate ferromagnetism in the radialene-based (as well as in other) materials may have a number of causes;[145, 147b, 147c, 155] their enumeration is beyond the intention of this review. Suffice it to say that promising concepts for building organic ferromagnets do exist, but that the search must go on for appropriate building blocks, and these include novel radialenes as donor or acceptor components.

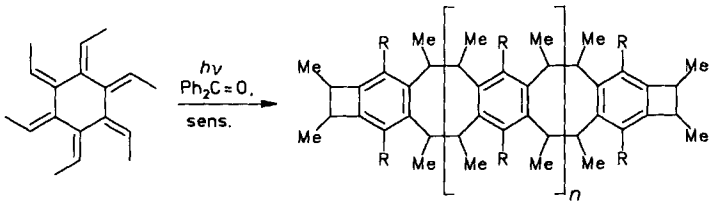
6. Outlook

Thanks to the considerable progress which has been made in the radialene area especially very recently, this class of highly unsaturated compounds is about to relinquish the status of exotic molecules. As we have shown above, the parent radialenes as well as their alkyl and aryl derivatives can often be obtained by simple and efficient syntheses. Structural and spectroscopic properties of the radialenes are now known, and even theoreticians devote time to them.

On the other hand, the lack of general and versatile syntheses for radialenes bearing functional groups suitable for further transformations, especially acyl-substituted radialenes, and the absence of diastereoselective syntheses (see Introduction) still constitute the major shortcomings in preparative radialene chemistry.

As for the chemical reactivity of the radialenes, the general behavior has emerged, but large gaps can still be located. For example, by virtue of their polyolefinic character the radialenes should be interesting objects for photochemical investigations; however, there are hardly any reports on the photochemistry of radialenes. One of the exceptions is a surprising

sensitized photooligomerization of **117** (Scheme 26) that may probably be taken as a first hint that radialenes can be the building blocks for polymers. According to the molecular weight determination, a hexamer is formed, which has been assigned structure **168**.[157] No products of a "vinylic polymerization" are formed when **117** is heated in the presence of radical initiators or on exposure of γ radiation.



117 **168**

Scheme 26. R = Et, CH_2=CH, CHMeCHMe (as bridge between two aryl rings); sens. = sensitizer.

Some radialenes may also be suitable ligands for novel transition metal complexes; the few experiments described so far represent but a modest beginning.

For highly unsaturated compounds, the question of toxicity and especially of cancerogenic potential must usually be answered. In view of the novelty of this substance class, it comes as no surprise that the data are scarce. At least it has been established that hexamethyl[6]radialene (**117**) is not carcinogenic.[158]

Our expectations on the usefulness of radialenes in materials sciences are positive but not overly optimistic. As we have shown in Section 5, radialenes have not yet been successful as building blocks of organic conductors and ferromagnets. Investigations on the structural motives responsible for the assemblage of low-dimensional molecular crystals of organometallic donor-acceptor complexes are still in their infancy,[153, 159, 160] and among the radialenes, only the radical anion and dianion of hexacyano[3]radialene have been used. Further research on this topic could provide results on which the design of tailor-made complexes with defined magnetic, electrical, and optical properties can be based. Will radialenes ever find an application in practical displays, will they become building blocks of organic conductors (eventually superior to other organic metals) or ferromagnets? Answers to such questions cannot be given at present; since numerous promises to produce radialene-based "new materials" have not been fulfilled in the past, the general attitude tends to be pessimistic. However, we consider it most desirable, particularly under these auspices, to do fundamental research on these highly unsaturated cross-conjugated π-electron systems.

Our own research on radialenes has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Volkswagenstiftung. We are very grateful to BASF AG, Degussa, Hoechst AG, and Baeyer AG for providing us with financial support and chemicals. The names of our co-workers, to whom we express here our sincere thanks for their efforts in a not always facile research area (e.g., experiments with often small quantities of highly reactive and highly sensitive compounds), are found in the references. Our thanks also go to Martin Vogtherr, who has undertaken the laborious task of drawing the formulas.

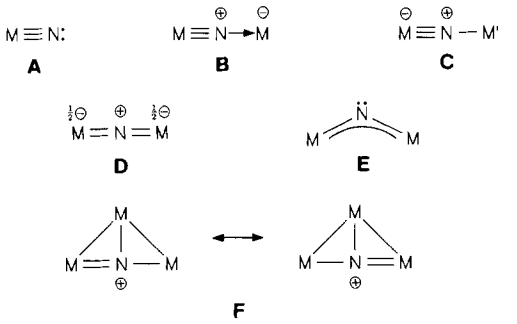
Nitrido Complexes of Transition Metals

By Kurt Dehnicke,* and Joachim Strähle

In the past decade new syntheses and numerous structural determinations have enlivened studies in the still relatively young field of nitrido-transition-metal complexes. Aside from the terminal function of the nitrido ligand M≡N:, this group also occurs as linear μ_2-bridging ligand in symmetric and asymmetric coordination; examples are known with almost right-angled bridge function; and, finally, it also functions as μ_3-bridging ligand. Accordingly, the fresh impulses given to synthetic chemistry by nitrido complexes are also many-sided: such complexes are used, inter alia, for the preparation of phosphaniminato and thionitrosyl complexes as well as for the synthesis of metallaheterocycles of the type MN_3S_2 and MN_3P_2 with delocalized π-systems. In technetium chemistry complexes with terminal nitrido group are employed as radiopharmaceuticals, and, owing to the strong *trans* influence of the M≡N: group, nitrido complexes of molybdenum are suitable as catalysts in olefin metathesis. Finally, nitrido complexes are also of wide interest in theoretical studies.

1. Introduction

The following article surveys the development of the chemistry of nitrido complexes containing transition metal–nitrogen multiple bonds. It constitutes an updated continuation of our previous review article published in 1981.[1] Up to that time only complexes with the terminal nitrido ligand **A** and complexes with linear asymmetric and symmetric bridges **B** and **D**, respectively, were known, while in the meantime complexes containing bent bridges **E** with bond angles as small as 91.3° have been synthesized, and in many cases the unusual T-shaped bridge arrangement **F** in trinuclear complexes with metal–metal bonds could also be prepared. Scheme 1 gives an overview of the hitherto established bonding functions of the nitrido-ligand.



Scheme 1. Bond functions of the nitrido ligand demonstrated so far. **A** = terminal, **B** = asymmetric, linear bridge of the donor-acceptor type, **C** = asymmetric linear bridge with covalent bond, **D** = symmetric, linear bridge, **E** = bent bridge, **F** = T-shaped arrangement.

Nitrido-complexes have also been treated in detail by Nugent and Mayer[2] in a monograph on Metal-Ligand Multiple Bonds. The present article does not deal with nitrido-complexes with interstitial N-atoms, as met with, e.g., in $NEt_4[FeRu_3N(CO)_{12}]$[3] or $[(Ph_3PAu)_5N]^{2+}$.[4]

2. New Synthetic Strategies

2.1. Reactions with the Bromide of Millon's Base

Dominant among the new methods for the synthesis of nitrido-transition-metal complexes are the reactions of metal halides with nitride transfer reagents, which represent ligand exchange reactions. One such reagent is Millon's base, $[Hg_2N]OH$, which is readily accessible in anhydrous form,[5] and despite its polymeric structure and consequent sparing solubility is astonishingly reactive. For example, the bromide of this base reacts with tungsten hexachloride in boiling carbon tetrachloride with formation of the binuclear μ-nitrido-complex $[W_2NCl_9]$[7] [Eq. (1), Scheme 2 (top)], which upon heating furnishes $WNCl_3$,[1] a compound also accessible via other routes [Eq. (2)].

$$2WCl_6 + [Hg_2N]Br \longrightarrow [W_2NCl_9] + HgCl_2 + HgClBr \quad (1)$$

$$[W_2NCl_9] \xrightarrow{130\,^\circ C} WNCl_3 + WCl_6 \quad (2)$$

The halide nitrides can be separated from the accompanying mercury halides by heating in vacuo. In this way, starting from the metal pentachlorides, the chloride nitrides of molybdenum(v) and tungsten(v) were also obtained for the first time [Eq. (3), M = Mo, W].[8, 9]

$$[MCl_5]_2 + [Hg_2N]Br \longrightarrow [M_2NCl_7] + HgCl_2 + HgClBr \quad (3)$$

This reaction can also be extended to the synthesis of bromide nitrides. Thus, on heating tungsten hexabromide with $[Hg_2N]Br$ in dibromomethane, $WNBr_3$ is smoothly obtained,[10] from tungsten pentabromide the corresponding $[W_2NBr_7]$,[10] (Scheme 2, below) and from molybdenum tetrabromide the nitrido complex of tetravalent molyb-

[*] Prof. Dr. K. Dehnicke

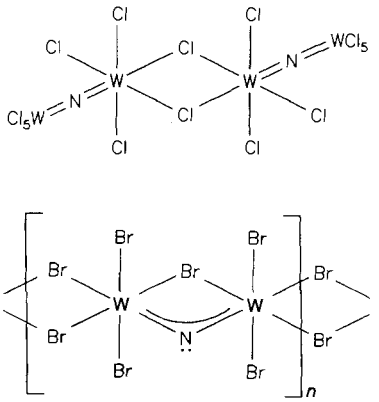
denum[10] [Eq. (4)]. All these reactions proceed almost quantitatively and are thus also suitable for the synthesis of ^{15}N-labeled complexes.[7]

$$2MoBr_4 + [Hg_2N]Br \longrightarrow [Mo_2NBr_5] + 2HgBr_2 \quad (4)$$

According to the IR spectra and magnetic susceptibilities the halide nitrides are coupled both via nitrido- as well as via halogeno-bridges, whereby high M–N bond orders are realized even in the case of compounds with bent M–N–M bridges (Scheme 2).



Scheme 2. Schematic structure of the compounds $[\{W_2NCl_9\}_2]$ (top) and $[\{W_2NBr_7\}_n]$ (bottom).

The complex $[Mo_2NCl_7]$, obtainable by reaction (3), can be oxidized with chlorine in $POCl_3$ to give the mixed valent Mo^V/Mo^{VI} chloride nitride $[Mo_2NCl_8]$, which can be converted by reaction with tetraphenylphosphonium chloride into $(PPh_4)_2[\{Mo_2NCl_9\}_2]$.[11] The structure of the anion

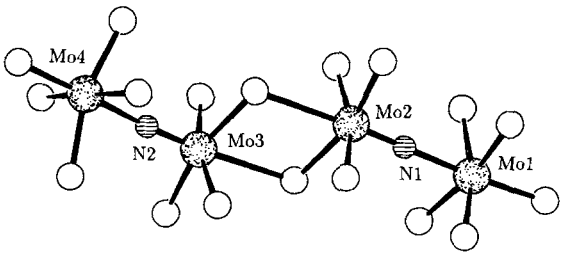


Fig. 1. Structure of the anion $[\{Mo_2NCl_9\}_2]^{2-}$. The white spheres are Cl atoms

(Fig. 1) compares with that of the $[\{W_2NCl_9\}_2]$ molecule, however the Mo–N–Mo bridge with Mo–N distances of 167 and 212 pm is markedly asymmetric.[11] The anion can therefore be regarded as a donor–acceptor complex of $[MoNCl_4]^-$ and $MoCl_5$. Indeed, it can be readily prepared from these components in dichloromethane.[11]

Also $[W_2NCl_7]$ can be oxidized with chlorine to the mixed valent complex $[W_2NCl_8]$, which, unlike $[Mo_2NCl_8]$ reacts with PPh_4Cl with formation of the dianion $[W_2NCl_{10}]^{2-}$.[9] A crystal structure analysis of the $AsPh_4^+$ salt[12] revealed eclipsed arrangement of the equatorial chlorine atoms and a linear W–N–W axis with W–N distances of 171 and 203 pm, consistent with the formulation $W{\equiv}N^{\oplus}{-}W^{\ominus}$. Unclear is which of the two tungsten atoms is pentavalent; possibly it is the one with the short W–N bond, since with d^1 configuration one has to reckon with Jahn–Teller stabilization which can be effective along the fourfold axis. Consistent with this is the conspicuously short W–W distance of 373.3 pm, which is significantly shorter than in W–N–W bridged tungsten(VI) complexes such as $[WNCl_3 \cdot POCl_3]_4 \cdot 2POCl_3$[1] with W–W distances of 386.0 pm. A W–W distance of 372.8 pm analogous to that in the $[W_2NCl_{10}]^{2-}$ ion was also found in the tetrameric anion of $(NHMe_3)_2[\{WO_2Cl_2(H_2O)\}_4] \cdot 2H_2O$ in which tungsten(V) and tungsten(VI) atoms are likewise coupled via linear W–O–W bridges.[13]

Kurt Dehnicke was born in 1931 in Köln. He studied chemistry from 1950 to 1955 in Leipzig and was awarded his doctorate in 1957 at Stuttgart for research on boron trifluoride adducts of amino acids under the supervision of J. Goubeau. In 1965 he habilitated in inorganic chemistry with work on the chemistry of compounds containing electropositive chlorine. Two years later he accepted a position as professor at the University of Marburg. In 1989 he was awarded the Wilhelm Klemm Prize of the German Chemical Society. His main areas of research are transition-metal complexes with metal–nitrogen multiple bonds, alkyne complexes of transition metals in high oxidation states, and polyselenido and polytellurido complexes.

Joachim Strähle, born 1937 in Dresden, studied chemistry in Stuttgart from 1958 to 1963, and was awarded his doctorate in 1965 for research on metal azide halides and metal nitride halides under the supervision of K. Dehnicke. After three years with G. Brauer in Freiburg and five years with H. Bärnighausen in Karlsruhe (introduction to crystal structure analysis) he habilitated in 1973 with a treatise on the synthesis and crystal structures of metal–nitrogen compounds. In the same year he took up an appointment at the University of Tübingen as Head of the Department of Inorganic Structural Chemistry. As successor to W. Rüdorff (1975) he has occupied the chair for Inorganic Chemistry I at Tübingen since 1976. The areas of research carried out by his group concerned the synthesis and crystal structure analysis of mixed transition metal gold clusters, coordination compounds with nitrogen donor ligands, and metal fluoride nitrides.

2.2. Reactions with $N(SiMe_3)_3$ and with $N(SnMe_3)_3$

Silylated and stannylated amines, even though infrequently used, are very efficient nitride transfer reagents. Tris(trimethylsilyl)amine reacts with tungsten hexachloride in the cold to give very pure $[W_2NCl_9]$ [Eq. (5)], at room temperature to give $WNCl_3$[14] [Eq. (6)].

$$2\,WCl_6 + N(SiMe_3)_3 \xrightarrow{T<20\,^{\circ}C} [W_2NCl_9] + 3\,ClSiMe_3 \quad (5)$$

$$WCl_6 + N(SiMe_3)_3 \xrightarrow{T\approx 20\,^{\circ}C} WNCl_3 + 3\,ClSiMe_3 \quad (6)$$

There are indications that the reactions (5) and (6) proceed with stepwise cleavage of trimethylchlorosilane. In the case of $[MoNCl_4]^-$ the reaction stops at the first substitution step. The reaction product $[MoNCl_3\{N(SiMe_3)_2\}]^-$ can be isolated as the tetraphenylphosphonium salt[15] (Fig. 2). Besides the very short Mo–N distance of the nitrido ligand (164.8 pm), which corresponds to a Mo≡N triple bond, the Mo–N bond of the amido ligand (193.7 pm) also has a remarkable amount of π-bond character. Accordingly the geometry around the nitrogen atom N1 is planar (Scheme 3).

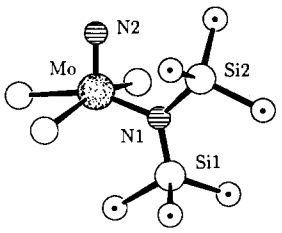

Fig. 2. Structure of the anion $[MoNCl_3\{N(SiMe_3)_2\}]^-$. The white spheres attached to the Mo atom are Cl atoms, the spheres with central dots and attached to the Si atoms are C atoms of the methyl groups.

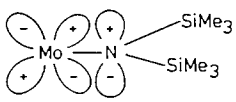

Scheme 3. Planar environment at the N atom of the amido ligand due to partial π-bonding of the Mo–N bond.

The metal–nitrogen bond has even more π-bond character in the monomeric nitreno-complex[*] $[Cl_3V^{\ominus}{\equiv}N^{\oplus}{-}SiMe_3]$ (obtainable via an alternative route from VCl_4 and Me_3SiN_3) with a V–N–Si bond angle of 177.5° and very short V–N bond length of 159 pm, corresponding to a V≡N triple bond.[16]

The $[W_2NCl_9]$ complex accessible via reaction (5) reacts with tetraphenylphosphonium chloride with formation of $[W_2NCl_{10}]^-$, in which, as in $[W_2NCl_{10}]^{2-}$[9, 12] eclipsed arrangement of the equatorial chlorine atoms is observed[14] (Fig. 3).

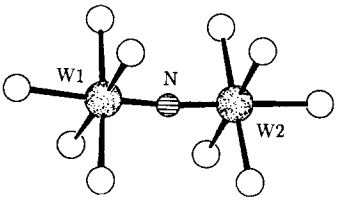

Fig. 3. Structure of the anion $[W_2NCl_{10}]^-$. The white spheres are Cl atoms.

Other than in the $[W_2NCl_{10}]^{2-}$ ion the two tungsten atoms are now coupled via an almost symmetrical nitrido bridge with a W–N–W bond angle of 173° and W–N distances of 179 and 188 pm, corresponding approximately to double bonds. The marked *trans* influence of the nitrido ligand, expressed in the 9 pm longer W–Cl distances in comparison to the usual W–Cl bond lengths in *cis* position. Similar conditions are found in the anion of $(PMe_3Ph)_2[Ta_2OCl_{10}]$,[17] which is isoelectronic with the $[W_2NCl_{10}]^-$ ion. Here the Ta–Cl distances $Ta{-}Cl_{ax}/Ta{-}Cl_{eq}$ (ax = axial, eq = equatorial) differ by only 4 pm because of the smaller *trans* influence of the oxo ligand of the Ta–O–Ta bridge.[17]

In dichloromethane solution the $[W_2NCl_{10}]^-$ ion slowly decomposes with cleavage of tungsten hexachloride and formation of the trinuclear μ-nitrido complex $[W_3N_2Cl_{14}]^{2-}$[18] [Eq. (7)].

$$2[W_2NCl_{10}]^- \longrightarrow [W_3N_2Cl_{14}]^{2-} + WCl_6 \quad (7)$$

The structure analysis shows an almost linear arrangement of the skeletal atoms and eclipsed position of all twelve equatorial chlorine atoms (Fig. 4). The W–N distances at the central tungsten atom W2 (207 pm) compare very closely with the value expected for single bonds, whereas the other two W–N distances (184 pm) can be regarded almost as double bonds. The reason for the relatively long W–N bonds at the central tungsten atom might be due to the competition of the two N atoms for the electrons of the d_{z^2} orbital.

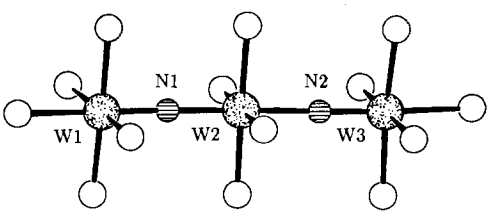

Fig. 4. Structure of the anionic μ-nitrido complex $[W_3N_2Cl_{14}]^{2-}$. The white spheres are Cl atoms.

If one of the chlorine atoms in $[W_2NCl_9]$ is substituted by the bidentate chelate ligand of the dichlorophosphate ion an unusual bridging of the W–N–W axis with simultaneous narrowing of the W–N–W bond angle to 166.2°[19] occurs (Fig. 5).

[*] In this article, complexes with linear $M{\equiv}\overset{\ominus}{N}{-}\overset{\oplus}{X}$ arrangement (sp-hybridized N atom) are designated as nitreno complexes, those with bent M=N̈-X arrangement (sp^2-hybridized N atom) as imido complexes [1].

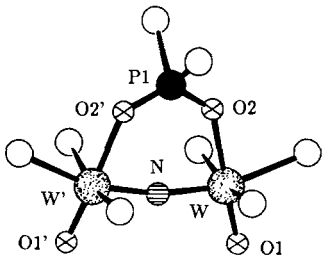

Fig. 5. Structure of the anion $[Cl_3OWNWOCl_3(O_2PCl_2)]^{2-}$. The white spheres are Cl atoms, the crossed spheres O atoms, the black sphere a P atom.

An even smaller M–N–M bond angle of 128° is found in the structure of the cyclic complex $[\{Cp^*TaN(Cl)\}_3]$ ($Cp^* = C_5Me_5$) forming an almost planar six-membered Ta_3N_3 ring, and which can be regarded to a first approximation as triazatritantalabenzene[20] (Fig. 6). The Ta–N

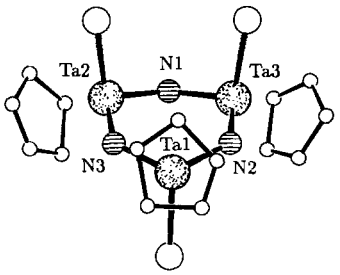

Fig. 6. Structure of the benzene-analogous nitrido complex $[\{Cp^*TaN(Cl)\}_3]$. For clarity, the methyl groups attached to the Cp* ligand have been omitted. The C atoms are depicted as small white spheres, the Cl atoms as large white spheres.

distances vary only very little in the range from 184 to 191 pm, corresponding approximately to Ta=N double bonds, if one regards the value of 185 pm in the anion of $(NH_4)_3[Br_5Ta{=}N{=}TaBr_5]$[1] as reference.

The compound was obtained in the form of shiny yellow crystals upon reaction of $[Cp^*TaCl_4]$ and $N(SnMe_3)_3$ at 50 °C in toluene[20] [Eq. (8)]. The corresponding methyl compound $[\{Cp^*TaN(CH_3)\}_3]$ is formed upon ammonolysis of $[Cp^*TaMe_4]$[21] [see Eq. (12)].

$$3[Cp^*TaCl_4] + 3N(SnMe_3)_3 \longrightarrow [\{Cp^*TaN(Cl)\}_3] + 9Me_3SnCl \quad (8)$$

The unusual stability of benzene-analogous cyclic trimers of metal nitrides had been predicted shortly beforehand by R. Hoffmann et al.[22] (see Section 6).

2.3. Reactions with Ammonia

Reactions of metal halides with ammonia generally lead to mixtures of substances owing to the formation of ammonium halide as by-product. Thus, for example, ammonolysis of niobium pentabromide leads to a mixture of amido- and imido-derivatives and NH_4Br, and, upon heating at 220 °C simultaneous sublimation of the ammonium bromide and formation of a bromide nitride $[Nb_6Br_9N_7]$ of unknown structure occurs.[23] To overcome this problem a new synthetic strategy was developed in which the ammonium halide itself is used as reactant. In this way it was possible to synthesize the binuclear μ-nitrido-complexes $(NH_4)_3[Nb_2NBr_{10}]$ [Eq. (9)], $(NH_4)_3[Ta_2NI_{10}]$ and $(NH_4)_3[W_2NBr_{10}]$ [Eq. (10)] by reaction with the pentahalides of niobium and tantalum as well as with tungsten hexabromide at temperatures between 300 and 420 °C.[24]

$$2NbBr_5 + 4NH_4Br \longrightarrow (NH_4)_3[Nb_2NBr_{10}] + 4HBr \quad (9)$$

$$6WBr_6 + 14NH_4Br \longrightarrow 3(NH_4)_3[W_2NBr_{10}] + 20HBr + N_2 \quad (10)$$

According to the crystal structure analysis of $(NH_4)_3[Nb_2NBr_{10}]$ the anion has D_{4h} symmetry and a linear, symmetrical nitrido bridge with Nb–N distances of 184.5 pm, as would be expected for double bonds.[24]

Roesky et al. overcame the problems of the ammonolysis of metal halides in another way when they treated the trimethyl derivative $[Cp^*Ti(CH_3)_3]$ with ammonia, and were able to prepare a titanium imide nitride in good yields according to Equation (11) via elimination of methane.[25]

$$3[Cp^*Ti(CH_3)_3] + 4NH_3 \longrightarrow [\{Cp^*Ti(NH)\}_3N] + 9CH_4 \quad (11)$$

According to the structure analysis the nitrido-ligand N1 links all three titanium atoms, while the imido ligands form μ_2-bridges between the Ti-atoms[25] (Fig. 7). The Ti–N1 distances of 191 pm indicate a small amount of π-bonding character.

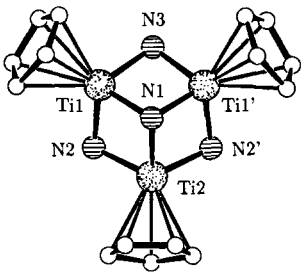

Fig. 7. Structure of the imidonitrido complex $[\{Cp^*Ti(NH)\}_3N]$. For clarity the methyl groups attached to the Cp* ligand and the H atoms at the imido groups have been omitted.

The previously mentioned $[\{Cp^*TaN(CH_3)\}_3]$ could be obtained in a similar way from $[Cp^*Ta(CH_3)_4]$ and excess ammonia in benzene at 20 °C[21] [Eq. (12)].

$$[Cp^*Ta(CH_3)_4] + NH_3 \longrightarrow \tfrac{1}{3}[\{Cp^*TaN(CH_3)\}_3] + 3CH_4 \quad (12)$$

The binuclear μ-nitridoosmium(IV) complex $[(NH_3)_5Os{-}NOs(NH_3)_5]Cl_5 \cdot H_2O$ is formed in astonishingly good yields in a strongly exothermic reaction upon treatment of solid $(NH_4)_2[OsCl_6]$ with hydrazine hydrate.[26] The reaction in-

volves disproportionation of hydrazine into N_2 and NH_3, so that it can be formulated as in Equation (13).

$$2(NH_4)_2[OsCl_6] + 14NH_3 + H_2O \longrightarrow [Os_2N(NH_3)_{10}]Cl_5 \cdot H_2O + 7NH_4Cl \quad (13)$$

Owing to the strong *trans* effect of the nitrido ligand of the linear Os–N–Os bridge, the *trans* NH_3-ligands can be readily replaced, so the complex can serve as starting material for the synthesis of complexes of the type $[X(NH_3)_4OsNOs(NH_3)_4X]Cl_5$.[26] Interestingly, reaction (13) takes another course if the components are allowed to react with each other in the reversed order. Addition of solid $(NH_4)_2[OsCl_6]$ to hydrazine hydrate then leads to formation of the dinitrogen complexes $[Os(NH_3)_5(N_2)]Cl_2$ and $[Os(NH_3)_4(N_2)_2]Cl_2$.[26]

A similar result as depicted in Equation (13) is observed however in the albeit experimentally more time-consuming reaction of $(NH_4)_2[OsCl_6]$ with concentrated aqueous ammonia at 150 °C in a Carius tube. After 9 days the μ-nitrido complex $[Os_2N(NH_3)_8Cl_2]Cl_3 \cdot 2H_2O$ was obtained.[27]

The result of the reaction of $(t\text{BuCH}_2)_3\text{Ta}{=}\text{CH}t\text{Bu}$ with ammonia at room temperature in benzene[28] [Eq. (14)] is

$$(t\text{BuCH}_2)_3\text{Ta}{=}\text{CH}t\text{Bu} \xrightarrow{NH_3} \tfrac{1}{5}[\{(t\text{BuCH}_2)_2\text{TaN}\}_5] + 2\text{CMe}_4 \quad (14)$$

most remarkable. The product crystallizes from toluene together with one coordinated NH_3 molecule and with the composition $[\{(t\text{BuCH}_2)_2\text{TaN}\}_5] \cdot NH_3 \cdot 2C_7H_8$; a crystal structure analysis indicated the unusual T-shaped coupling of three of the five nitride groups and two μ_2-nitrido bridges with a very small bond angle of 98°[28] (Fig. 8).

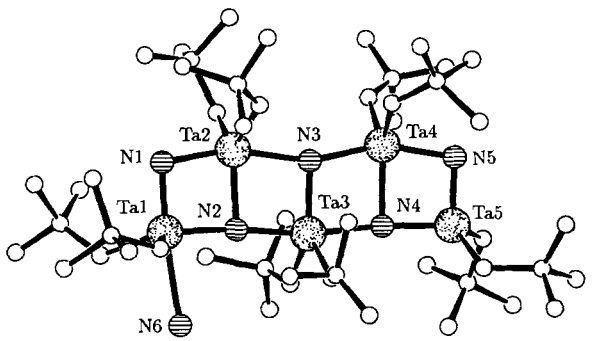

Fig. 8. Structure of $[\{(t\text{BuCH}_2)_2\text{TaN}\}_5] \cdot NH_3$. The white spheres are C atoms.

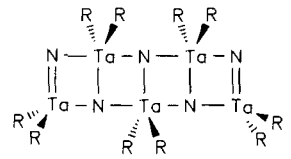
The Ta_5N_5 skeleton is almost planar; it is best formulated as in Scheme 4. The edge-sharing Ta_2N_2 units reproduce the coupling motif of cubic TaN, into which the compound can be converted by heating at 820 °C.[28]

For further details on the T-shaped coupling of metal atoms and on nitrido bridges with very small bond angles, see also Section 3.4.



Scheme 4. Schematic representation of the Ta_5N_5 framework in $[\{(t\text{BuCH}_2)_2\text{TaN}\}_5]$.

2.4. Reactions with Nitrogen Trichloride

Reactions with nitrogen trichloride do not present any danger when carried out in CCl_4 solution; their use for the synthesis of nitrido complexes is, however, somewhat limited, but in the few cases where they can be used they are very efficient. Aside from the previously described synthesis of $[ReNCl_4]$ from $ReCl_5$[1] and the reaction of $MoCl_5$ with NCl_3, which led to $[MoNCl_4]_2$,[29] none of the known metal chlorides was found to react with NCl_3.

In contrast, reactions of the hexacarbonyls of molybdenum and tungsten with excess nitrogen trichloride led in almost quantitative yields to the synthetically very useful *N*-chloronitreno complexes [Eq. (15), M = Mo, W].[30, 31] The *N*-bound chlorine atom in these compounds has a marked ($\delta+$)-character. Thermolysis accordingly leads with cleavage of chlorine to the chloride nitrides $MNCl_3$[30, 31] [Eq. (16)].

$$2[M(CO)_6] + 4NCl_3 \longrightarrow [\{Cl_4M{\equiv}N\text{-}Cl\}_2] + N_2 + Cl_2 + 12CO \quad (15)$$

$$[\{Cl_4M{\equiv}N\text{-}Cl\}_2] \longrightarrow 2MNCl_3 + 2Cl_2 \quad (16)$$

To our knowledge this is the most efficient entry to the chloride nitrides $MoNCl_3$ and $WNCl_3$, which in turn are the most important starting substances in the complex chemistry of the nitrides of molybdenum and tungsten.

The partial positive character of the *N*-bound Cl atom is also manifested in the capability of the pentachloro derivative $[Cl_5W{\equiv}N\text{-}Cl]^-$ as PPh_4^+ salt to bind a chloride ion[32] (Fig. 9). The chloride ion coordinates with formation of a linear Cl_3-bridge between two anions.

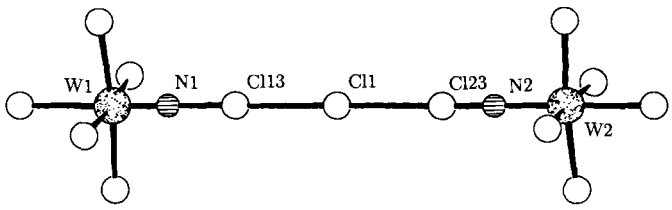


Fig. 9. Structure of the binuclear *N*-chloronitrene complex with the bridging chloride ion $[\{Cl_5W(NCl)\}_2Cl]^{3-}$.

2.5. Oxidation of Coordinated NH_3-Ligands

An elegant entry to nitrido complexes of osmium and chromium was opened up by the reaction of strong oxidizing agents such as cerium(IV)[33] [Eq. (17)] or sodium hypochlorite[34] [Eq. (18)] with complexes containing NH_3 ligands.

Reaction (17) corresponds to an oxidation of the osmium atom from +III to +VI, reaction (18) to an oxidation of the chromium atom from +III to +V. In exactly the same way it was also possible to synthesize the first nitrido complexes of manganese(V), namely [MnN(ttp)] and [MnN(oepMe$_2$)] [ttp = 5,10,15,20-tetra-*p*-tolylporphyrinate(2−); (oepMe$_2$)$^{2-}$ = α-γ-dimethyl-α-γ-dihydrooctaethylporphyrinate].[35, 36]

$$[Os(NH_3)_6]^{3+} + 3Ce^{4+} + H_2O \longrightarrow [:N{\equiv}Os(NH_3)_4(OH_2)]^{3+} + 3Ce^{3+} + 2H^+ + NH_4^+ \quad (17)$$

$$[Cr(ttp)(OH)(NH_3)] + OCl^- \longrightarrow [:N{\equiv}Cr(ttp)] + Cl^- + 2H_2O \quad (18)$$

According to crystal structure analyses the metal atoms in the porphyrinato complexes are fivefold coordinated, with extremely short M≡N: distances of 156.5 pm in the case of the chromium complex[37] and 151.2 pm in the case of the manganese complex.[36] Upon chlorination of the NH_3 ligand in the phthalocyaninatomanganese complex [(NH_3)Mn(OH)pc] with elemental chlorine, which leads according to Equation (19) to the corresponding nitridomanganese(V) complex, intermediary formation of the *N*-chloronitreno complex [(ClN)Mn(pc)] with manganese(IV) is assumed.[38]

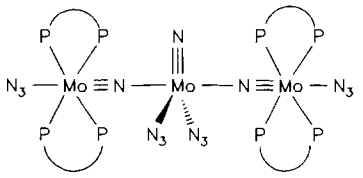
$$2[(H_3N)Mn(pc)(OH)] + 2Cl_2 \longrightarrow 2[:N{\equiv}Mn(pc)] + 2H_2O + 4HCl \quad (19)$$

2.6. Thermolysis and Photolysis of Azido Complexes

The chemistry of coordinated azide groups was reviewed in 1985.[39] Many of the known decomposition reactions of azides, which lead to nitrido complexes, are thermally induced.[1, 39] The conversion of an azido ligand M−N_3 into a nitrido ligand M≡N: via N_2-cleavage is accompanied by a two-step oxidation of the metal atom. The formation of the nitrido complex [$MoN(N_3)$(dppe)$_2$][40] (dppe = $Ph_2PCH_2CH_2PPh_2$) observed in the reaction of [$Mo(N_2)_2$(dppe)$_2$] with trimethylsilyl azide would therefore suggest [$Mo(N_3)_2$(dppe)$_2$] as being the initial product. In the nitrido complex the Mo–N distance to the nitrido ligand (179 pm) is remarkably long; it corresponds almost to a double bond.[40]

In the synthesis of the corresponding tungsten complex [$WN(N_3)$(dppe)$_2$], the authors found evidence of a radical reaction following previous replacement of N_2 by Me_3SiN_3.[41]

The synthesis of *trans*-[$MoN(N_3)$(depe)$_2$] (depe = $Et_2PCH_2CH_2PEt_2$) starting from *trans*-[$Mo(N_2)_2$(depe)$_2$] proceeds analogously; however, in this case, formation of the linearly bridged, trinuclear complex [{$MoN(N_3)$(depe)$_2$}$_2$$MoN(N_3)_2$] with a bond angle of 156.3° at the central molybdenum(V) atom is also observed (Scheme 5).[42] The terminal Mo≡N: bond (167 pm), as expected, is somewhat shorter than the Mo^{IV}≡N bridge-bond length (170 pm).



Scheme 5. Schematic representation of the linearly bridged, trinuclear complex [{$MoN(N_3)$(depe)$_2$}$_2$$MoN(N_3)_2$].

Cyclovoltammetric measurements show a reversible one-electron reduction of the molybdenum(V) atom with a potential ($E^{0\prime}$) of −2.10 V relative to ferrocenium/ferrocene in THF solution.[42]

Thermolysis of the tetraazidepyridine complex of molybdenum leads to the corresponding monomeric triazidonitrido complex with fivefold coordinated molybdenum atom[43] [Eq. (20)], whereas reaction of the tetrachloroterpyridyl

$$[Mo(N_3)_4(py)_2] \longrightarrow [MoN(N_3)_3(py)] + N_2 + py \quad (20)$$

complex with trimethylsilyl azide leads, after partial Cl/N_3 exchange, to the azido-chloro-nitrido complex [$MoN(N_3)_2$Cl(terpy)][44] [Eq. (21)]. In this complex, the

$$[MoCl_4(terpy)] + 3Me_3SiN_3 \longrightarrow [MoN(N_3)_2Cl(terpy)] + N_2 + 3ClSiMe_3 \quad (21)$$

molybdenum has an unusual pentagonal-bipyramidal environment with the chloro ligand in the axial position[44] (Fig. 10).

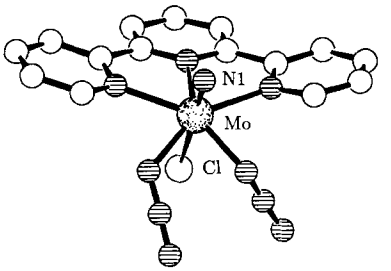


Fig. 10. Structure of the nitrido complex [$MoN(N_3)_2$Cl(terpy)]. With exception of the atom labeled as Cl, all white spheres are C atoms.

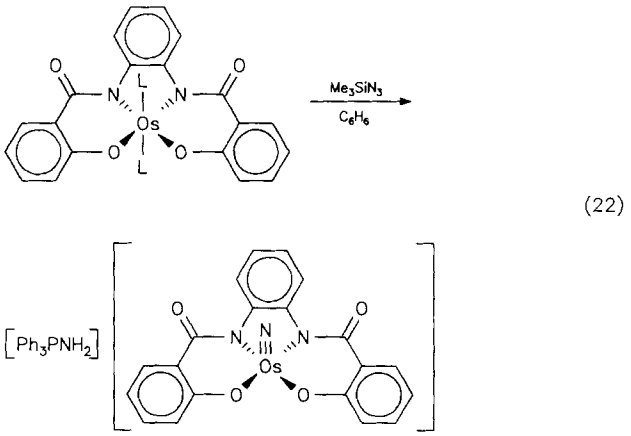
The nitridoniobium(V)-complex [{$NbNCl_2 \cdot SMe_2$}$_n$] could be prepared in a corresponding way by reaction of trimethylsilyl azide with the niobium(III) complex [$Nb_2Cl_6(SMe_2)_3$].[45] Osmium(IV) complexes can also be readily oxidized with trimethylsilyl azide to give nitridoosmates(VI), as shown by the example in Equation (22) (L = PPh_3).[46]

The origin of the $[Ph_3PNH_2]^+$ ion can be explained by hydrolysis of the $SiMe_3NPPh_3$ formed at the same time by Staudinger reaction.

Addition of $(NEt_2H_2)[S_2P(OMe)_2]$ to a mixture of [$MoCl_3(thf)_3$] and trimethylsilyl azide leads to formation of orange-brown crystals of the tetrameric complex [{$Mo^VN[S_2P(OMe)_2]_2$}$_4$], the sole example of a square Mo_4N_4 unit with four symmetric Mo=N=Mo bridges.[47] The Mo–N bond distances are, within statistical deviation, equal and with a value of 186.5 pm correspond very well with the value ex-



(22)

pected for double bonds. Consistent with this finding, the observed ferromagnetism is explained in terms of a superexchange mechanism.[47]

The photolytic decomposition of a chromium azide was first described in 1981.[48] Irradiation of azido-*N*,*N*'-ethylenebis(salicylaldiminato)chromium(III) with light of wavelength 320 nm smoothly furnished a nitrido chromium(v) complex[48] [Eq. (23)].

$$[Cr(N_3)(salen)] \cdot 2H_2O \xrightarrow{h\nu} [CrN(salen)]\ H_2O + N_2 + H_2O \qquad (23)$$

Later, Groves et al. obtained by photolysis of the azido-tetra-*p*-tolylporphyrinatochromium(III) complex in CH_2Cl_2 solution the corresponding nitrido complex of pentavalent chromium in which, according to the crystal structure analysis, the chromium is fivefold coordinated and the nitrido ligand is in the apical position.[37] In an analogous way azidometal(III)porphyrins of chromium, manganese and iron were also converted into the corresponding nitrido complexes [MN(ttp)],[49] and from [Cr(N$_3$)(bpb)] [bpb = 1,2-bis[2-pyridinecarboxamido(2−)]benzene] the nitrido complex [CrN(bpb)] was obtained.[50]

2.7. Reactions with Trithiazyl Chloride

Some nitrido complexes are best prepared by reaction of metal chlorides with the readily accessible trithiazyl chloride $(NSCl)_3$. Initially, chlorothionitreno complexes are formed in which the $[\ddot{N}{=}\ddot{S}{-}Cl]^{2-}$ ligand, which does not exist in the free state, is bound at the metal atom with linear arrangement of the elements M–N–S as $M{=}\overset{\ominus}{N}{=}\overset{\oplus}{\ddot{S}}{-}Cl$.[51] An example is provided by the reaction with tungsten hexachloride[52] [Eq. (24)].

$$2WCl_6 + \tfrac{2}{3}(NSCl)_3 \longrightarrow [\{Cl_4W(NSCl)\}_2] + 2Cl_2 \qquad (24)$$

Some of the initially formed chloronitreno complexes furnish the corresponding nitrido complexes under gentle, thermally-induced conditions [Eq. (25–27)].[53, 54]

$$[\{Cl_4Mo(NSCl)\}_2] \xrightarrow{130\,^\circ C} 2MoNCl_3 + 2SCl_2 \qquad (25)$$

$$PPh_4[Cl_5Mo(NSCl)] \xrightarrow[CH_2Cl_2]{20\,^\circ C} PPh_4[MoNCl_4] + SCl_2 \qquad (26)$$

$$[(Cl_3PO)ReCl_4(NSCl)] + AsPh_4Cl \xrightarrow[CH_2Cl_2]{20\,^\circ C} AsPh_4[ReNCl_4] + POCl_3 + SCl_2 \qquad (27)$$

Reduction of the chlorothionitreno complex used as educt in Equation (27) with triphenylphosphane leads in good yields to a nitridorhenium(v) complex[55] [Eq. (28)].

$$2[(POCl_3)ReCl_4(NSCl)] + 9PPh_3 \longrightarrow 2[ReNCl_2(PPh_3)_2] + 3PPh_3Cl_2 + 2PPh_3S + 2POCl_3 \qquad (28)$$

This complex had already been prepared earlier by Chatt et al. by reaction of $Na[ReO_4]$ with hydrazine dihydrochloride in the presence of PPh_3;[56] according to the structure analysis[57] the rhenium atom is fivefold coordinated with a coordination geometry between trigonal-bipyramidal and tetragonal-pyramidal. In contrast, the corresponding nitrido complex with the less bulky dimethylphenylphosphane, $[ReNCl_2(PMe_2Ph)_3]$, contains sixfold coordinated rhenium with one of the chloro ligands *trans* to the nitrido group.[58]

In attempts at the transhalogenation of the chlorothionitreno complexes of molybdenum and tungsten with trimethylbromosilane only $[WCl_4(NSCl)]$ could be converted into the bromo complex $[WBr_4(NSBr)]$, whereas the molybdenum compound reacted smoothly and quantitatively with formation of $MoNBr_3$[59] [Eq. (29)]. Reaction (29) opens up a simple preparative entry to $MoNBr_3$ compared to the synthesis from $MoBr_4$ and iodine azide.[1]

$$[\{MoCl_4(NSCl)\}_2] + 10BrSiMe_3 \longrightarrow 2MoNBr_3 + S_2Br_2 + Br_2 + 10ClSiMe_3 \qquad (29)$$

The transhalogenation of $[\{Cl_4Mo(NSCl)\}_2]$ with sodium fluoride in acetonitrile solution in the presence of [15]crown-5 as phase transfer reagent at 80 °C also led to a nitrido complex[60] [Eq. (30)].

$$[\{MoCl_4(NSCl)\}_2] + 12NaF + 2[15]crown\text{-}5 \xrightarrow{80\,^\circ C} [Na([15]crown\text{-}5)]_2[(MoNF_4)_2] + 2SF_2 + 10NaCl \qquad (30)$$

The compound crystallizes as ion triplet (Fig. 11), in which the sodium atoms coordinated fivefold by the crown ether molecules form short Na···F contacts to the axially arranged F atoms of the $[(MoNF_4)_2]^{2-}$ ion.

The Na···F distances of 234 pm are only slightly longer than in the sodium fluoride structure (230.7 pm). The molybdenum atoms of the anion are coupled via asymmetric fluoro bridges with Mo–F distances of 198 and 245 pm, whereby the long Mo–F bond is a result of the strong *trans* influence of the terminal nitrido ligands. The small Mo–F–Mo bridge angle of 109° is unusual, since up to now only bridging angles

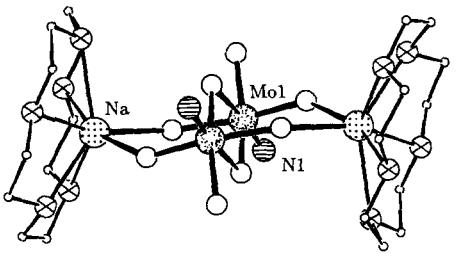


Fig. 11. Structure of the ion triple $[Na([15]crown-5)]_2[(MoNF_4)_2]$. The white spheres are F atoms, the smaller white spheres C atoms, and the crossed white spheres O atoms.

between 132° and 180° have been observed for fluorides of 4d and 5d metals.[61]

2.8. Direct Syntheses from the Elements

Kniep et al. were able to prepare the ternary nitrido complexes $Li_6[MN_4]$ (M = Cr, Mo, W)[62] and $Ba_3[MN_4]$ (M = Mo, W)[63] from the elements by high-temperature syntheses; the complexes were obtained as pale yellow to reddish-brown, moisture-sensitive single crystals. According to the crystal structure analyses only slightly distorted $[MN_4]^{6-}$ tetrahedra are present, in which the bond lengths (M = Cr, 176–178 pm; M = Mo, 185–189 pm; M = W, 189–193 pm) have marked π-bond character.

2.9. Special Synthetic Methods

The $[VNCl_3]^-$ ion, isoelectronic with the $VOCl_3$ molecule, is obtained upon reaction of $[Ph_3PNPPh_3]Cl$ with $[Cl_3V{\equiv}N\text{-}SiMe_3]$ in dichloromethane[64] [Eq. (31)].

The V≡N bond (6.9 $N\,cm^{-1}$) has an equally large valence force constant as the V≡O bond in the $VOCl_3$ molecule.[64]

$$[Ph_3PNPPh_3]Cl + Cl_3VNSiMe_3 \longrightarrow [Ph_3PNPPh_3][VNCl_3] + ClSiMe_3 \quad (31)$$

Also the reactions of $Cl_3VNSiMe_3$ with bases such as 2,2′-bipyridyl (bpy), pyridine (py) or quinuclidine (quin) lead to a cleavage of chlorotrimethylsilane and formation of the complexes $[VNCl_2(bpy)]$,[64] $[VNCl_2(py)_2]$[65] and $[VNCl_2(quin)_2]$, respectively.[65]

On the other hand, the trimethylsilylimido complexes $[MCl_2(NSiMe_3)L_3]$ (M = Mo, W; L = phosphane) and $[WCl_2(NSiMe_3)_2L]$ show no tendency to be converted into the corresponding nitrido complexes.[66] The pyridine complex $[VNCl_2(py)_2]$ (Fig. 12) is also formed upon heating the cyclothiazeno complex $[\{VCl(N_3S_2)(Py)_2\}_2]$ in toluene.[67] According to crystal structure analyses the $[VNCl_2(py)_2]$ complexes are stacked into columns via alternating long $V{\equiv}N\cdots V{\equiv}N$ bridges with V–N distances of 160 and 256 pm.[65, 67]

With bulky amino bases such as quinuclidine, monomeric, readily soluble complexes with fivefold coordination at the

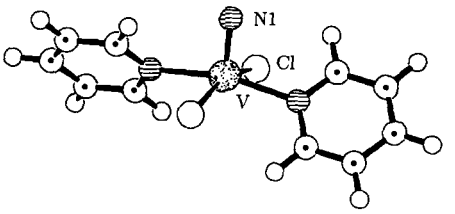

Fig. 12. Structure of the complex $[VNCl_2(pyridine)_2]$. The white spheres are Cl atoms, the smaller white spheres H atoms, and the spheres with central dot C atoms.

vanadium atom are formed. The V≡N distance of 157 pm in $[VNCl_2(quin)_2]$ corresponds to a triple bond.[65]

The reaction of molybdenum(II) benzoate with trimethylsilyl azide in the presence of PPh_4Cl led in an unexpected redox reaction with participation of the solvent dichloromethane to the azidochloronitrido complex $[\{MoN(N_3)_3Cl\}_2]^{2-}$[68] [Eq. (32)].

$$[Mo_2(O_2CPh)_4] + 2PPh_4Cl + 4CH_2Cl_2 + 8Me_3SiN_3 \longrightarrow (PPh_4)_2[\{MoN(N_3)_3Cl\}_2] + 4Me_3SiOC(O)Ph + 2C_2H_4Cl_2 + 4Me_3SiCl + 2N_2 \quad (32)$$

In contrast to the monomeric structure of the tetraazidonitrido complex $[MoN(N_3)_4]^-$,[69, 70] the chloro derivative $[MoN(N_3)_3Cl]_2^{2-}$ is coupled via the α-N-atoms of two azido groups to give a centrosymmetric dimer with Mo–N distances of 208 and 260 pm[68] (Fig. 13). The long Mo–N

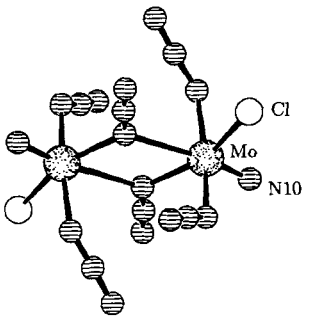

Fig. 13. Structure of the anion $[\{MoN(N_3)_3Cl\}_2]^{2-}$.

distance is in the *trans* position to the terminal nitrido ligand, whose Mo≡N distance of 164 pm corresponds to a triple bond.

A surprising redox reaction also forms the basis of a new alternative method for the synthesis of the nitrido complex $[\{MoNCl_3 \cdot POCl_3\}_4]$, which was obtained by heating the phosphoryl trichloride solvate $[MoCl_5 \cdot OPCl_3]$ with urea in boiling carbon tetrachloride[71] [Eq. (33)].

$$4[MoCl_5 \cdot OPCl_3] + 2OC(NH_2)_2 \longrightarrow [\{MoNCl_3 \cdot OPCl_3\}_4] + 2CO + 8HCl \quad (33)$$

Surprisingly, the elimination of $PhSO_2Cl$ from the nitreno complex $[Cl_4Mo{=}NSO_2Ph]$ also takes place in reverse to the

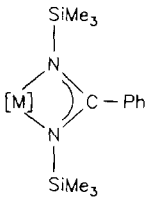
electrophilic addition of $PhSO_2Cl$ to the nitrido function (cf. Section 3.2) upon reaction with $[Ph_3PNPPh_3]Cl$ in dichloromethane[72] [Eq. (34)].

$$[MoCl_4(NSO_2Ph)] + 2[Ph_3PNPPh_3]Cl \longrightarrow [Ph_3PNPPh_3]_2[MoNCl_5] + PhSO_2Cl \quad (34)$$

An unusual entry to a nitridotungsten complex was found upon attempting to prepare an amidinato complex from tungsten hexachloride and *N,N,N'*-tris(trimethylsilyl)benzamidine[73] [Eq. (35)].

$$WCl_6 + [Ph-C(NSiMe_3)N(SiMe_3)_2] \longrightarrow [WNCl_3 \cdot NC-Ph] + 3\,ClSiMe_3 \quad (35)$$

Whereas numerous metal halides react with the silylated benzamidine to give amidinato complexes of type **G**,[74]



G

reaction (35) does not stop at this stage but leads, with further cleavage of $ClSiMe_3$ and formation of benzonitrile, to the nitridotungsten complex, which crystallizes as the tetramer.[73] The acetonitrile solvate $[WNCl_3 \cdot NCCH_3]$, which was obtained by reaction of tris(trimethylsilyl)amine with the *N*-chloronitrenotungsten complex, also crystallizes as the tetramer[75] [Eq. (36)].

$$3[WCl_4(NCl)(CH_3CN)] + N(SiMe_3)_3 \longrightarrow 3[WNCl_3 \cdot NCCH_3] + \tfrac{1}{2}N_2 + 1\tfrac{1}{2}Cl_2 + 3\,ClSiMe_3 \quad (36)$$

With an original metathetic reaction of *tert*-butylcarbonitrile and $[(tBuO)_3W{\equiv}W(OtBu)_3]$ leading to cleavage of the W≡W bond, Schrock et al. were able to prepare at one and the same time a nitrido complex and a carbyne complex of tungsten(VI)[76] [Eq. (37)].

$$tBu-C{\equiv}N + [(tBuO)_3W{\equiv}W(OtBu)_3] \longrightarrow [(tBuO)_3W{\equiv}N] + [(tBuO)_3W{\equiv}CtBu] \quad (37)$$

According to the crystal structure analysis the nitrido complex contains W≡N–W chains with markedly alternating W–N bond lengths[77] (Fig. 14). The corresponding molybdenum compound has a comparable structure with Mo–N distances of 166 and 286 pm.[78]

The rare trigonal-bipyramidal coordination was previously only observed in the structure of the trinuclear

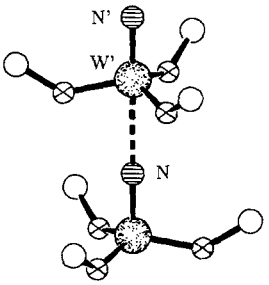


Fig. 14. Section of the polymeric structure of $[(tBuO)_3W{\equiv}N]$. The white spheres are C atoms, the crossed spheres O atoms. For clarity, the methyl groups of the *t*Bu residue have been omitted.

nitrenonitrido complex $CPh_3^+[Ph_3C-N{\equiv}WCl_4(\mu\text{-}F)WNCl_2(\mu\text{-}F)Cl_4W{\equiv}N\text{-}CPh_3]^-$ (Fig. 15), and in the structure of the trinuclear molybdenum complex $[\{\mu\text{-}MoN(N_3)_2\}\{NMo(N_3)(depe)_2\}_2]$[42] already described in Section 2.6.

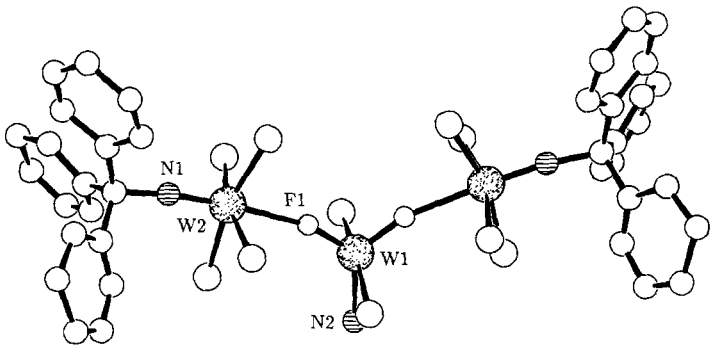

Fig. 15. Structure of the anion $[WNF_2Cl_2(Cl_4WNCPh_3)_2]^-$. The smaller white spheres which bridge two W atoms are F atoms; the larger white spheres attached to the W atoms are Cl atoms. The white spheres which are coordinated to the N atoms are C atoms of the triphenylmethyl groups.

Reactions of *tert*-butyl isocyanate with the dioxo complexes $[RuO_2Cl_3]^-$ and $[MO_2Cl_4]^{2-}$ (M = Ru, Os) in the form of their tetraphenylphosphonium salts in boiling acetonitrile led to some surprising results. The air-stable nitrido complexes $PPh_4[MN(tBuNC(O)NtBu)Cl_2]$ are formed which contain a *N,N'*-ureato(2–)-chelate ligand[80]

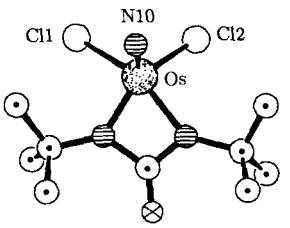

Fig. 16. Structure of the anion $[OsN(tBuNC(O)NtBu)Cl_2]^-$. The spheres with central dot are C atoms, the crossed spheres O atoms.

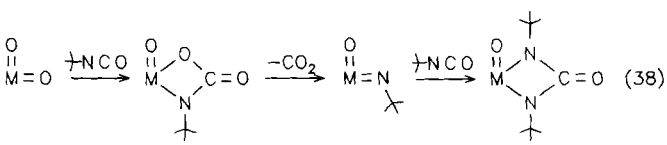
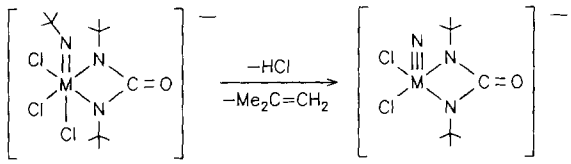
(Fig. 16). The formation of the ureato ligand most likely proceeds via an imido complex as intermediate [Eq. (38)].



(38)

The ureato complex can subsequently react with a further molecule of *tert*-butyl isocyanate to give an imido complex, from which the nitrido ligand is finally formed by elimination of 2-methylpropene and HCl[80] [Eq. (39)].



(39)

3. Chemical Reactions of the Nitrido Complexes

Many of the chemical reactions dealt with here lead with retention of the nitrido function to novel nitrido derivatives so they are also to be grouped under the heading of new synthetic routes. In other reactions the nitrido function itself serves as reactive group, and enables the synthesis, in particular, of new metallaheterocycles.

3.1. Addition of Lewis Bases

The uncomplexed halide nitrides, such as $MoNCl_3$, $WNCl_3$, $ReNCl_3$, $MoNBr_3$, and $WNBr_3$, despite their polymeric structures, have Lewis acidity. They react with various Lewis bases with formation of well-defined donor-acceptor complexes. Of the uncomplexed halide nitrides, the only compound crystallographically characterized is $MoNCl_3$, which forms $[MoNCl_3]_4$ units in the lattice; these are associated via chloro bridges $MoCl_2Mo$ to form a layer lattice.[81] In reactions with Lewis bases the formation of tetrameric molecular structures $[MNCl_3 \cdot D]_4$ (D = donor molecule) is preferred. Since all halide nitrides MNX_3 can form tetrameric units with Lewis bases, these compounds presumably have the same structure as $MoNCl_3$.

In the reaction of $WNCl_3$ with hydrogen azide as Lewis base only every second tungsten atom coordinates with the α-N-atom of HN_3. This leads to only some of the chloro bridges of $WNCl_3$ being ruptured, and a band structure results[82] (Fig. 17).

Upon coordination with trichloroacrylonitrile a degradation of the polymeric structure of $MoNCl_3$ down to a dimeric unit occurs, and terminal nitrido ligands result[83] (Fig. 18).

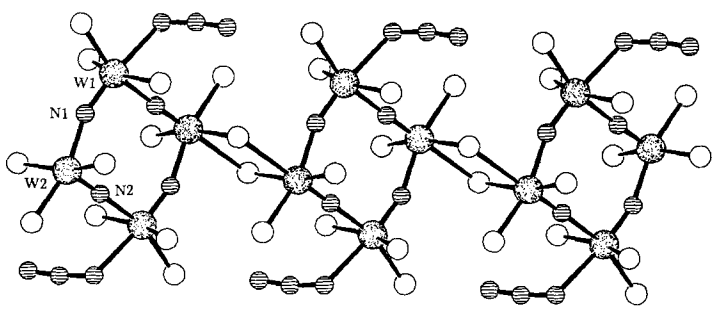


Fig. 17. The coupling of the tetrameric complex $[\{WNCl_3 \cdot 0.5HN_3\}_4]$.

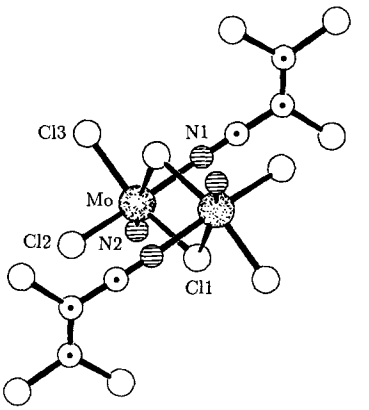

Fig. 18. Structure of the dimeric complex $[\{MoNCl_3 \cdot NCC_2Cl_3\}_2]$. The white spheres are Cl atoms, the spheres with central dot C atoms.

The Mo–Cl distances of 240.7 and 276.0 pm in the $MoCl_2Mo$ bridges are markedly different, the long Mo–Cl distance being determined by the *trans* influence of the nitrido ligand.

Bifunctional donor solvents suitable for chelation, such as dimethoxyethane, lead in the reaction with $MoNCl_3$ to monomeric complexes which are readily soluble in organic solvents (Fig. 19). The Mo–O bond to the O atom, which is

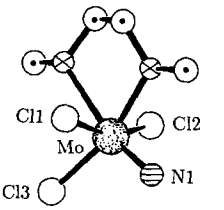

Fig. 19. Structure of $[MoNCl_3(MeOC_2H_4OMe)]$. The spheres with central dot are C atoms, those that are crossed O atoms.

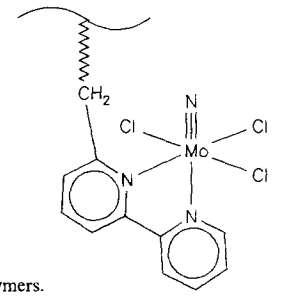
in the *trans* position to the nitrido ligand, is long (247 pm) because of the *trans*-influence, whereas the Mo–O bond length of the *cis* O-atom is 215 pm.[84] Polymers with attached $MoNCl_3$ units can be obtained if the polymer bears, e.g., bipyridyl residues as functional groups[85] (Scheme 6).



Scheme 6. $MoNCl_3$ moieties bound to polymers.

Reaction of the halide nitrides with anionic bases leads finally to the known monomeric complex ions $[MNX_4]^-$[11] with C_{4v} symmetry and with the M≡N group in the axial position. The absence of association of the $[MNX_4]^-$ ions is,

on the one hand, a result of the repulsive negative charge, but also a result of the frequently employed counterions PPh_4^+ or $AsPh_4^+$, which because of their bulkiness counteract an association. However, if instead, one uses the $[Cl_3PNPCl_3]^+$ ion, then also $[MoNCl_4]^-$ ions can stack in columns[86] (Fig. 20).

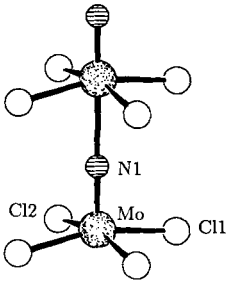


Fig. 20. Section of the chain structure of $[MoNCl_4]^-$.

The long Mo–N bond (243 pm), however, corresponds to only a very weak interaction.

Especially interesting is the acceptor behavior of the binuclear nitridoporphyrinatoiron complex $[Fe_2N(tpp)_2]$ (H_2tpp = 5,10,15,20-tetraphenylporphine), which according to the EPR spectrum has an A_1-ground state with two equivalent iron centers of formal oxidation state $Fe^{+3.5}$.[87] Addition of one mole of pyridine leads to non-equivalence of the two iron atoms, indicating an Fe^{IV} center with coordinated pyridine and coordination number six and an Fe^{III} center with coordination number five. Equivalence of the two iron centers occurs again only at high pyridine concentrations.[87] At low temperatures even an O_2 molecule can add to $[Fe_2N(tpp)_2]$,[88] whereby, according to the ^{57}Fe-Mössbauer spectra, the two iron atoms become non-equivalent again. The formation of the 1:1 adduct, which however can only be described as a weak interaction,[88] could be demonstrated by an EPR spectrometric titration.

The electronic properties of the complex $[Fe_2N(tpp)_2]$ are similar to those of complexes of the type $[Fe_2N(pc)_2]$ (H_2pc = phthalocyanine)[89] (see also Section 6). These complexes can easily be oxidized with bromine, trifluoroperoxoacetic acid or nitric acid to the air-stable radical cations $[Fe_2N(pc)_2]^+$ with Fe^{IV}-centers.[89] Like the corresponding porphyrinato derivatives[90] they serve as model substances for the mode of action of hydroperoxidase enzyme.[91]

3.2. Addition of Lewis Acids

The addition of Lewis acids to nitrido complexes has hitherto attracted relatively little interest. In all known examples the addition takes place at the nitrido ligand. Already known for some time are addition reactions of boron trihalides to rhenium(V) complexes which lead to complexes of the type $[X_2Re{\equiv}N{-}BY_3(PEt_2Ph)_3]$ (X = Cl, Br; Y = F, Cl, Br).[92] Later, the corresponding methylphosphane derivative $[Cl_2Re{\equiv}N{-}BCl_3(PMe_2Ph)_3]$ was crystallographically characterized.[93] According to the crystallographic analysis the structural group $Re{\equiv}N{-}BCl_3$, as in the analogous nitreno

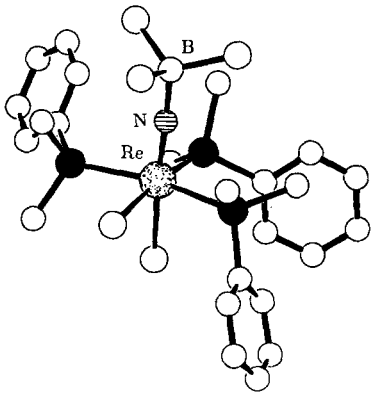

Fig. 21. Structure of the borylnitrene complex $[Re(NBCl_3)Cl_2(PMe_2Ph)_3]$. The white spheres which are coordinated to the B and Re atoms are Cl atoms; the white spheres coordinated to the black P atoms are C atoms.

complexes $M{\equiv}N{-}R$,[1,2] is linear with sp-hybridized N atom (Fig. 21).

The addition of the BCl_3 molecule causes a stretching of the Re–N bond length from 166 pm in the nitrido complex $[ReNCl_2(PMe_2Ph)_3]$ with terminal $Re{\equiv}N$ group[58] to 173 pm.[93] At the same time the *trans*-influence of the $NBCl_3$ ligand—compared to the nitrido ligand—decreases very strongly, as evidenced by the difference in the Re–Cl bond lengths between *cis* and *trans* Re–Cl bonds, which is only 4 pm in the boryl complex, whereas in the nitrido complex a difference of 20 pm was found.[58]

A much smaller tendency for the addition of boron trihalides is observed in the case of the nitridorhenium(VI) complexes. Whereas BCl_3 adds neither to $[ReNCl_4]^-$ nor to $[ReNBr_4]^-$, with boron tribromide a stable adduct is obtained. It is formed upon transhalogenation of the chloro complex with excess boron tribromide.[94] [Eq. (40)].

$$3\,AsPh_4[ReNCl_4] + 7\,BBr_3 \longrightarrow 3\,AsPh_4[Br_4Re{\equiv}N{-}BBr_3] + 4\,BCl_3 \qquad (40)$$

Above 200 °C the bromo complex loses BBr_3 leading to formation of $AsPh_4[ReNBr_4]$.[94]

Despite the weakening of the Re–N bond by the addition of the boron trihalides, a shift of ν(ReN) to shorter wavelengths is generally observed in the IR spectra. Thus, this band changes its position from 1099 cm^{-1} in the spectrum of $AsPh_4[ReNBr_4]$ to 1170 cm^{-1} after addition of BBr_3.[94] The effect is due to a vibrational coupling with the B–N stretching vibration, which in turn has a long-wave shift.

The electrophilic attack of the triphenylcarbonium ion on the nitrido function of molybdenum, tungsten and rhenium complexes leads to the synthesis of imido complexes [Eq. (41)].

$$M{\equiv}N{:} + CPh_3^+ \longrightarrow [M{\equiv}N{-}CPh_3]^+ \qquad (41)$$

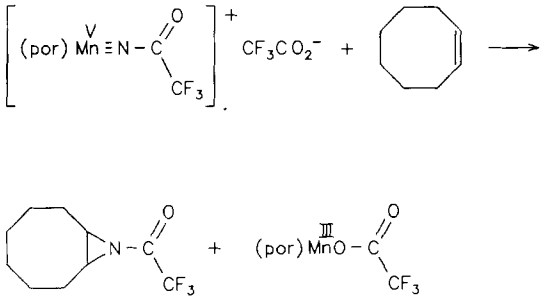
First examples of such syntheses were found by Chatt et al. on using as starting material the dithiocarbaminato complexes $[MoN(S_2CNMe_2)_3]$ and $[ReN(S_2CNMe_2)_2(PMe_2Ph)]$.[95] The structure analysis of the molybdenum complex $[Mo(NCPh_3)(S_2CNMe_2)_3][BF_4]$ threw light on the

pentagonal-bipyramidal coordination at the molybdenum atom with the Mo≡N-CPh_3 group in the axial position.[95]

Also other electrophilic reagents such as PhCOCl, Ph-SO_2Cl, ArSCl, ArCl and $R_3O^+BF_4^-$ react in a similar way at the nitrido function[95] (Ar = aryl, R = Me, Et).

Of importance is the activation of nitrogen and its transfer to olefins in the reaction of nitrido-porphyrinato (por) complexes of manganese by reaction with trifluoroacetic anhydride. An electrophilic addition takes place at the nitride-nitrogen with formation of a 'nitrenoid'-manganese-porphyrinate[96] [Eq. (42)]. This can then react in a second step with olefins to give aziridines[96] [Eq. (43)].

$$[(por)Mn{\equiv}N{:}] + O(COCF_3)_2 \longrightarrow [(por)Mn{\equiv}N\text{-}C(O)CF_3]^+[CF_3CO_2]^- \quad (42)$$



(43)

Reaction (43) can be regarded as the aza-analogous epoxidation of olefins. Kinetic studies have shown that the previous reaction (42) depends very strongly on the basicity of the porphyrinato group and on the steric conditions at the Mn≡N function.[97]

More complicated is the reaction of $CPh_3^+BF_4^-$ with the chloronitridotungstate $AsPh_4[WNCl_4]$, which is accompanied by a partial Cl/F exchange that leads to a trinuclear nitrenonitrido complex $CPh_3^+[Ph_3C\text{–}N{\equiv}WCl_4(\mu\text{-}F)\text{-}WNCl_2(\mu\text{-}F)Cl_4W{\equiv}N\text{–}CPh_3]^-$ (Abb. 15) [Gl. (44)], associated via the two F atoms.[79]

$$3[WNCl_4]^- + 3CPh_3BF_4 \longrightarrow CPh_3^+[(WNF_2Cl_2)(Cl_4WNCPh_3)_2]^- + 2BF_3 + [BF_4]^- + 2Cl^- \quad (44)$$

A surprising result was observed in the reaction of $[Cl_3PNPCl_3]Cl$ with $WNCl_3$, in which initially the expected chloronitrido complex was formed; however, this slowly rearranges in a secondary reaction to a phosphoraniminato complex[98] [Eq. (45)].

$$[Cl_3PNPCl_3]Cl + WNCl_3 \longrightarrow [Cl_3PNPCl_3][WNCl_4] \longrightarrow [Cl_5\overset{\ominus}{W} = \ddot{N}\text{–}\overset{\oplus}{P}(Cl_2)\text{-}\ddot{N}{=}PCl_3] \quad (45)$$

Also this reaction can be regarded as electrophilic attack of one of the P atoms of the cation at the nitrido ligand. The atoms of the W–N–P–N–P chain of the phosphoraniminate are almost coplanar, and the P–N bonds, the lengths of which differ only slightly, point to a through conjugation of this chain[98] (Fig. 22).

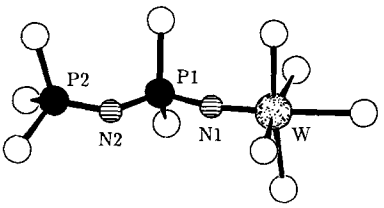


Fig. 22. Structure of the phosphoraniminato complex $[Cl_5WNP(Cl_2)NPCl_3]$. The white spheres are Cl atoms.

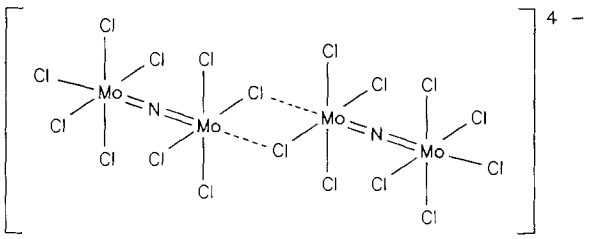
The phosphoraniminato ligand $[P_2N_2Cl_5]^-$, unknown in the free state, is isoelectronic with the molecular phosphazene P_2ONCl_5, which also has a planar atomic skeleton and comparable bonding parameters.[99]

Addition of molybdenum pentachloride to the chloronitridomolybdates $[MoNCl_4]^-$ and $[MoNCl_4]^{2-}$ leads to the formation of μ-nitrido-complexes. Whereas the complex $[Mo_2NCl_9]^-$ with Mo^V and Mo^{VI} centers formed with $[MoNCl_4]^-$ contains a highly asymmetric $Mo^{VI}{\equiv}N\text{–}Mo^V$ bridge (see Fig. 1), the spectroscopic findings for the $[Mo_2NCl_9]^{2-}$ ion accessible from $[MoNCl_4]^{2-}$ indicate presence of largely symmetric $Mo^V{=}N{=}Mo^V$ bridges[100] (Scheme 7).

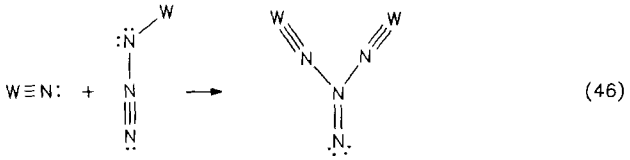


Scheme 7. The Structure of $[Mo_2NCl_9]^-$ units associated to dimers.

Similarly, structures associated to dimers are also found in the case of the previously mentioned $[W_2NCl_9]$ (Section 2.2), as also in the case of the $[Nb_2OCl_9]^-$ ion isoelectronic with $[Mo_2NCl_9]^{2-}$.[101]

A nitrido bridge Re≡N–Au is formed between two different metal atoms upon addition of the AuCl molecule accessible from [Au(CO)Cl] to the nitrido function of $[Cl_2Re{\equiv}N(PMe_2Ph)_3]$.[102] As the crystal structure analysis shows, the resulting μ-nitrido complex $[Cl_2Re{\equiv}N\text{–}AuCl(PMe_2Ph)_3]$ has a structure analogous to that of $[Cl_2Re{\equiv}N\text{-}BCl_3(PMe_2Ph)_3]$[93] with the metallanitrene function in *trans*-position to a Cl ligand and meridional arrangement of the phosphane ligands.[102] Whereas the formation of this complex is to be regarded as addition of AuCl to the nitrido function, the complex $[(Me_3SiO)_3V{\equiv}N\text{-}Pt(Me)(PEt_3)_2]$ prepared by Doherty et al.[103] by reaction of $[(Me_3SiO)_3V{\equiv}N\text{-}SiMe_3]$ with $[FPtMe(PEt_3)_2]$, despite an analogous atomic sequence in the bridge V≡N-Pt (compared to Re≡N-Au), is a metallanitreno complex.

The remarkable bond relationship of the β-N-atom of the covalently bound azido ligand of $[W(N_3)Cl_5]$ to the nitride function of $WNCl_3$ can also be regarded as addition of a Lewis acid[104] [Eq. (46); here, both the formal charges as well as the chlorine atoms are omitted].



(46)

In the presence of tetraphenylarsonium chloride this reaction leads to the μ-isotetrazenido(4−) complex of tungsten(VI) [Eq. (47)].

$$2\,AsPh_4Cl + WNCl_3 + [W(N_3)Cl_5] \longrightarrow (AsPh_4)_2[Cl_5W(\mu\text{-}N_4)WCl_5] \quad (47)$$

The $[N_4]^{4-}$ ligand couples the two tungsten atoms via short W–N bonds (average length 164 pm) and two relatively long N–N bonds (149 pm)[104] (Fig. 23).

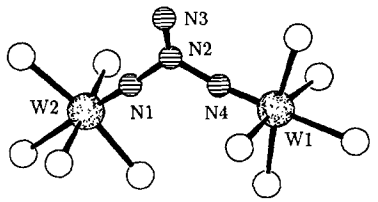


Fig. 23. Structure of the μ-isotetrazenido(4−) complex $[Cl_5W(\mu\text{-}N_4)WCl_5]^{2-}$. The white spheres are Cl atoms.

The long N–N bonds signal the ready thermal cleavability of nitrogen. The $[N_4]^{4-}$ bridge ligand can derive from the deprotonated, unknown isotetrazene, which is isoelectronic with urea and with the well-characterized tetrazene, $H_2NN{=}NNH_2$.[105]

3.3. Substitution Reactions

Starting materials for ligand exchange reactions which proceed with retention of the nitrido function are mostly chloronitrido complexes in which the Cl ligands can, by suitable choice of reaction partners, be partially or completely substituted. We shall now describe some typical examples from the wide spectrum of preparative possibilities.

A suitable reagent for the preparation of fluoronitrido complexes is anhydrous silver fluoride in acetonitrile. Treatment of the chloronitrido complex with this reagent leads to the formation of extremely moisture-sensitive fluoronitrido silver complexes in the form of their readily soluble acetonitrile solvates[106] [Eq. (48)].

$$MoNCl_3 \quad CH_3CN + 4\,AgF \xrightarrow{CH_3CN} [Ag(CH_3CN)_2][MoNF_4] + 3\,AgCl \quad (48)$$

Also alkali-metal fluorides such as NaF or KF can be used for the fluorination if the reactions are carried out in acetonitrile in the presence of suitable crown ethers. The fluoronitrido metalates are formed in which their cations form ion pairs or triplets owing to the anisotropic coordination by the crown ether molecules. An example is reaction (49), which goes to completion very rapidly at room temperature.[107]

$$[WCl_4(NCl)] + 5\,KF + [18]\text{crown-6} \longrightarrow [K([18]\text{crown-6})][WF_5(NCl)] + 4\,KCl \quad (49)$$

The positively charged Cl atom on the nitreno ligand is not exchanged (Fig. 24).

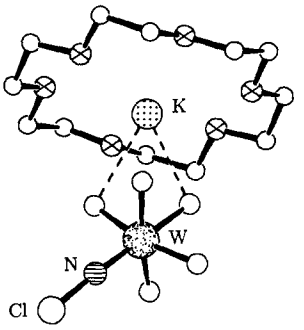

Fig. 24. Structure of the ion pair $[K([18]\text{crown-6})][F_5W(NCl)]$. Crossed spheres are O atoms, smaller white spheres in the crown ether C atoms. The white spheres which are bound directly to the W atom are F atoms.

A crystallographically characterized ion triplet is shown in Figure 11. Occasionally chloride nitrides have also been allowed to react with elemental fluorine, whereby the nitrido function remains intact despite the drastic reaction conditions. Thus, reaction of $ReNCl_4$ with fluorine yields mainly red $[ReNF_4 \cdot ReF_5(NCl)]$[109] [Eq. (50)] besides small amounts of yellow crystals of $ReNF_4$, which is also accessible from ReF_6 and trimethylsilyl azide.[108]

$$2\,ReNCl_4 + 8\,F_2 \longrightarrow [ReNF_4 \cdot ReF_5(NCl)] + 7\,ClF \quad (50)$$

The two Re components are coupled by an asymmetric fluorine bridge with Re–F distances of 188 and 228 pm, respectively[109] (Fig. 25).

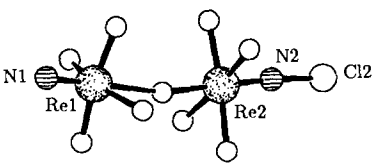

Fig. 25. Structure of the molecular complex $[ReNF_4 \cdot Re(NCl)F_5]$. With exception of the labeled Cl2 atom, white spheres are F atoms.

The long Re1–F bond is in the *trans*-position to the nitrido ligand $[{\equiv}N{:}]^{3-}$, which therefore exercises a much larger *trans* influence than the nitreno ligand $[{\equiv}N\text{-}Cl]^{2-}$. The short

Re2–F bond remains almost unaltered compared to the free molecule $[ReF_5(NCl)]$.[108]

A Cl/Br ligand exchange can generally be achieved quite readily with the help of trimethylsilyl bromide, especially if the chloro ligands are complexochemically enfeebled by excess negative charges [Eq. (51), M = Mo, W].[110]

$$[MNCl_4]^- + 4\,BrSiMe_3 \longrightarrow [MNBr_4]^- + 4\,ClSiMe_3 \quad (51)$$

Occasionally ethyl bromide is also suitable for ligand exchange; however, longer reaction times of up to eight days are required[111] [Eq. (52)].

$$AsPh_4[RuNCl_4] + 4\,EtBr \xrightarrow[80\,^\circ C]{CH_3CN} AsPh_4[RuNBr_4] + 4\,EtCl \quad (52)$$

Nitrido derivatives of molybdenum and tungsten with alkoxy ligands can be prepared by reaction of the *tert*-butyloxy derivatives obtainable from the metathetic reaction (37) with alcohols bearing sterically less demanding residues R[76, 77] [Eq. (53)].

$$[(t\mathrm{BuO})_3M{\equiv}N{:}] + 3\,ROH \longrightarrow [(RO)_3M{\equiv}N{:}] + 3\,t\mathrm{BuOH} \quad (53)$$

The complex $[NBu_4][OsN(OSiMe_3)_4]$,[112] readily accessible by reaction of $[NBu_4][OsNCl_4]$ with $NaOSiMe_3$, has proven to be an excellent starting material for the synthesis of organo-substituted nitridoosmium(VI) complexes. Alkylmagnesium and -aluminum compounds with $R = CH_3$, CH_2Ph, CH_2CMe_3, and CH_2SiMe_3 are suitable as alkylating reagents.[112] The crystal structure analysis of $[NBu_4][OsN(CH_2SiMe_3)_4]$ shows the anion in a slightly distorted C_4 symmetry with the nitrido ligand in the apical position (Os≡N = 163 pm) and the methylene C atoms in the basal plane (Os–C = 212–214 pm).[113]

Attempts to prepare anionic nitrido complexes $[(t\mathrm{BuO})_4M{\equiv}N{:}]^-$ starting from the chloronitridometalates (M = Mo, W) were unsuccessful owing to the bulkiness of the organic residues. Instead, these reactions proceed according to Equation (54).[114] In contrast, no problems were encountered in the synthesis of the corresponding anionic phenolato complexes[114] [Eq. (55)].

$$PPh_4[MNCl_4] + 3\,NaO\,t\mathrm{Bu} \longrightarrow [(t\mathrm{BuO})_3M{\equiv}N{:}] + PPh_4Cl + 3\,NaCl \quad (54)$$

$$PPh_4[MNCl_4] + 4\,NaOPh \longrightarrow PPh_4[(PhO)_4M{\equiv}N{:}] + 4\,NaCl \quad (55)$$

Attempts to convert the chloride nitrides into alkoxidonitrido complexes with alcohols led, even in the presence of bases, via loss of the nitrido group to formation of homoleptic alkoxido complexes. If diols are used as reactants, trischelates of molybdenum(VI) can be obtained[114] [Eq. (56)].

$$MoNCl_3 + 3\,HO{-}CH_2{-}CH_2{-}OH \xrightarrow{DBU} [Mo(OCH_2CH_2O)_3] + 3\,DBU \cdot HCl + NH_3 \quad (56)$$

DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene

By comparison, the reactions of thiophenolates with nitridorhenium(V) complexes present no problems. Thus, complexes of the type $[ReNCl_2(PR_3)_n]$ ($PR_3 = PPh_3$, $n = 2$ or PMe_2Ph, $n = 3$) react with 1,3,5-triisopropylthiophenol (Htipt) in the presence of triethylamine smoothly according to Equation (57),[115] and with sodium thiophenolate according to Equation (58) to give the thiophenolato complexes.[115]

$$[ReNCl_2(PR_3)_n] + 2\,Htipt \xrightarrow{NEt_3} [ReN(tipt)_2(PR_3)_n] + 2\,HCl \quad (57)$$

$$[ReNCl_2(PR_3)_n] + 4\,Na(tipt) \xrightarrow{THF} Na_2[ReN(tipt)_4] \cdot 2THF + 2\,NaCl + n\,PR_3 \quad (58)$$

In some cases substitution reactions can also be achieved by exploiting the chelate effect of neutral multidentate donor molecules. Thus, $AsPh_4[ReNCl_4]$ reacts with 2,2′-dipyridyl in dichloromethane solution via exchange of a chloride to give the uncharged molecular complex $[ReNCl_3(bpy)]$[116] [Eq. (59)], while reaction of $[OsNCl_4]^-$ with the tridentate chelate terpyridyl in boiling acetone even leads to the cationic nitrido complex $[OsN(terpy)Cl_2]^+$[117] [Eq. (60)].

$$[ReNCl_4]^- + bpy \longrightarrow [ReNCl_3(bpy)] + Cl^- \quad (59)$$

$$[OsNCl_4]^- + terpy \longrightarrow [OsN(terpy)Cl_2]^+ + 2\,Cl^- \quad (60)$$

Other than in the terpyridyl complex $[MoNCl(N_3)_2(terpy)]$,[44] in which the nitrido ligand is in the *cis*-position to the terpyridyl chelate ligand (Fig. 10), in the osmium complex the nitrido ligand is in the *trans*-position to the N atom of the central terpyridyl ring[117] (Fig. 26). This leads to an

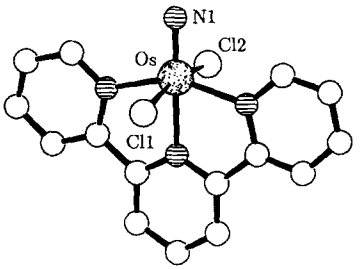

Fig. 26. Structure of the cation $[OsNCl_2(terpy)]^+$. With exception of the labeled Cl atoms, white spheres are C atoms.

enormous stretching of this Os–N bond by 85 pm compared to the two other Os–N distances to the terpyridyl ligand.[117] As in other d^2-configurated complexes with π-bound ligands[118] the nitridoosmium complex is also diamagnetic, corresponding to a marked energetic separation of the d-orbitals according to $d_{xy} < d_{xz}, d_{yz}$.[117]

Also the μ-nitridoruthenium complex $K_3[Ru_2NCl_8(H_2O)_2]$ can be converted in a slow reaction, via replacement of the chloro ligands by ethylenediamine, into the cationic complex $[Ru_2N(en)_5]Cl_5 \cdot H_2O$[119] (Fig. 27). The bridging of the two ruthenium atoms by one of the ethylenediamine chelates leads to only a slight bending of the Ru–N–Ru bond angle to 174.6°.

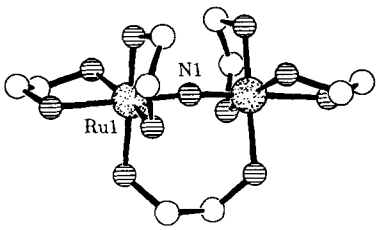

Fig. 27. Structure of the cationic μ-nitrido complex $[Ru_2N(en)_5]^{5+}$. White spheres are C atoms.

Substitution of the chlorine atoms of the polymeric chloride nitrides $MoNCl_3$ and $WNCl_3$ by sterically demanding diphenylamido groups led to the first monomeric molecular nitrido complexes with four-coordination at the metal atom[120] [Eq. (61)]. The steric requirements of the NPh_2

$$MNCl_3 + 3\,LiNPh_2 \xrightarrow{THF} [MN(NPh_2)_3] + 3\,LiCl \qquad (61)$$

groups lead to a structural peculiarity: whereas in all other nitrido complexes the large π-electron density of the M≡N: bond leads to :N≡M–X bond angles which are larger than those of the regular geometric arrangement, the N≡Mo–N bond angles in the structure of $[MoN(NPh_2)_3]$ (100.5°) are

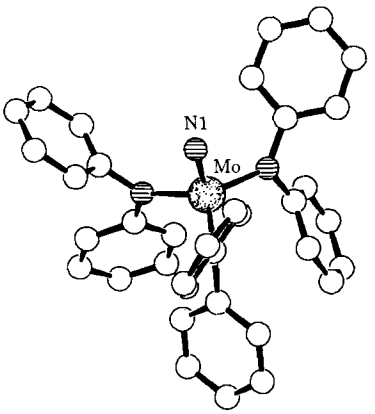

Fig. 28. Structure of the diphenylamidonitrido complex $[MoN(NPh_2)_3]$. The white spheres are C atoms. One N atom is masked by a phenyl ring.

smaller than the ideal tetrahedral angle, while the bond angles N–Mo–N (114.9–119.6°) are correspondingly larger than the tetrahedral angle[120] (Fig. 28). The Mo≡N bond length (163.4 pm), however, remains unaltered.

In the case of nitrido complexes whose nitrido function is not sensitive towards proton-active reagents such as water, alcohols etc., there are far more numerous possibilities for derivatization by substitution of the halogeno ligands. This is true in particular for the nitrido complexes of technetium and osmium.

Thus, e.g., reaction of $AsPh_4[OsNCl_4]$ with sodium cyanide in THF/methanol furnishes the mixed complex $[OsN(CN)_4(OH)]^{2-}$ in which the OH^- ligand is *trans* to the nitrido ligand.[121]

Owing to the strong *trans* effect of the Os–N group, the OH^- ligand is readily replaced by CN^- when the complex is treated with excess sodium cyanide, thus affording the pentacyanonitrido complex $[OsN(CN)_5]^{2-}$.[121]

The structure of the cyano complex corresponds entirely to that of the long-known $[OsNCl_5]^{2-}$ ion;[122] the *trans* influence of the nitrido ligand is reflected in the long Os–C bond to the *trans* CN^- ligand, which, with 235 pm, is 27 pm longer than the Os–C distances of the equatorially arranged cyano ligands.[121] In solution at room temperature the complex shows an intense phosphorescence at 550 nm upon excitation with light of wavelength 300–400 nm.[121]

The remarkable inertness of the nitrido function in technetium complexes towards proton-active reagents permits a wide variety of substitution reactions. Starting materials for this purpose are frequently the readily accessible nitrido complexes $AsPh_4[TcNCl_4]$ with C_{4v} symmetry of the $[TcNCl_4]^-$ anion[123] or $[TcNCl_2(PPh_3)_2]$ with trigonal-bipyramidal geometry at the technetium atom and *trans* arrangement of the phosphane ligands. The structure of this molecular complex was first elucidated only recently[124] (Fig. 29).

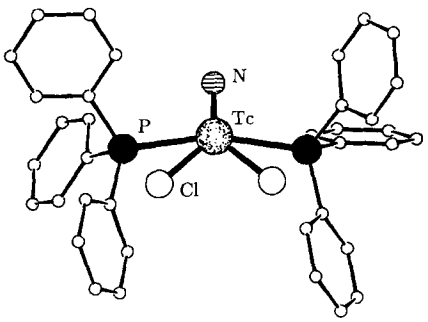

Fig. 29. Structure of the nitrido complex $[TcNCl_2(PPh_3)_2]$. The C atoms are scaled down.

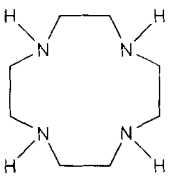
Thus, for example, cyclam (Scheme 8) reacts with $[TcNCl_2(PPh_3)_2]$ smoothly according to Equation (62) with displacement of the two phosphane ligands and one chloro ligand and formation of a cationic complex.[125]



Scheme 8. The cyclam ligand.

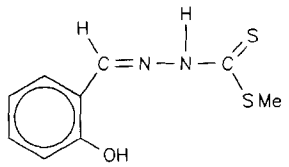
$$[TcNCl_2(PPh_3)_2] + cyclam \longrightarrow [TcNCl(cyclam)]^+Cl^- + 2\,PPh_3 \qquad (62)$$

With the cyclam derivative 1,4,8,11-tetraazacyclotetradecane-5,7-dione (H_2L), substitution with elimination of HCl already takes place at 40 °C in CH_2Cl_2/EtOH [Eq. (63)].

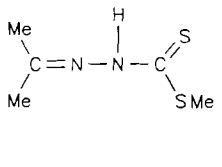
$$[TcNCl_2(PPh_3)_2] + H_2L + 3\,H_2O \longrightarrow [TcN(L)(H_2O)]\cdot 2\,H_2O + 2\,HCl + 2\,PPh_3 \qquad (63)$$

In $[TcN(L)(H_2O)] \cdot 2H_2O$ the technetium is surrounded in a distorted octahedral fashion by the four equatorially arranged N atoms of the cyclam ligand (distances Tc–NH 213 pm, Tc–N 205 pm) as well as axially by the nitrido ligands (Tc≡N 161 pm) and the O atom of the water molecule. Owing to the strong *trans* influence of the nitrido ligand the aqua ligand is only very loosely bound.[125]

Also other proton-active chelating reagents such as dithiacarbamide or azomethine derivatives react with $[TcNCl_2(PPh_3)_2]$ in a very similar way with elimination of HCl. Thus, the reactions with the carbamide derivatives H_2L^3 and HL^2 in boiling benzene lead to the molecular



(H_2L^3)



(HL^2)

complexes $[TcNL^3(PPh_3)]$ [Eq. (64)] and $[TcN(L^2)_2]$ [Eq. (65)], respectively.[126]

$$[TcNCl_2(PPh_3)_2] + H_2L^3 \longrightarrow [TcNL^3(PPh_3)] + PPh_3 + 2HCl \quad (64)$$

$$[TcNCl_2(PPh_3)_2] + 2HL^2 \longrightarrow [TcN(L^2)_2] + 2PPh_3 + 2HCl \quad (65)$$

In these two complexes the technetium is surrounded in a distorted tetragonal-pyramidal fashion, with the nitrido ligand in the apical position[126] (Fig. 30).

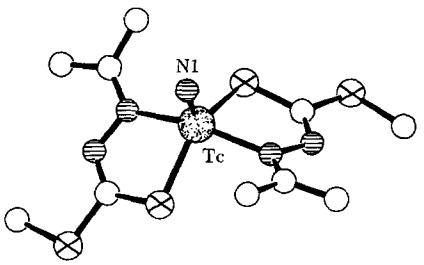


Fig. 30. Structure of the dithiocarbamido complex $[TcN(Me_2CNNC(S)SMe)_2]$. The white spheres are C atoms, the crossed spheres S atoms.

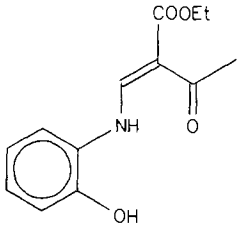
Analogous results could be achieved with the tridentate chelating reagent H_2ecbap (Scheme 9) in methanol[127] [Eq. (66)].

$$[TcNCl_2(PPh_3)_2] + H_2ecbap \longrightarrow [TcN(ecbap)(PPh_3)] + PPh_3 + 2HCl \quad (66)$$

The tridentate ligand coordinates with the ligator atoms ONO as rigid planar group[127] (Fig. 31).

The chloronitrido complexes of technetium, $[TcNCl_4]^-$ and $[TcNCl_5]^{2-}$, are suitable for substitution reactions even



Scheme 9. Structural formula of the tridentate ligand H_2ecbap (*N*-(2-ethoxycarbonyl-3-oxobut-1-en(1)yl)-2-aminophenol, non-IUPAC name).

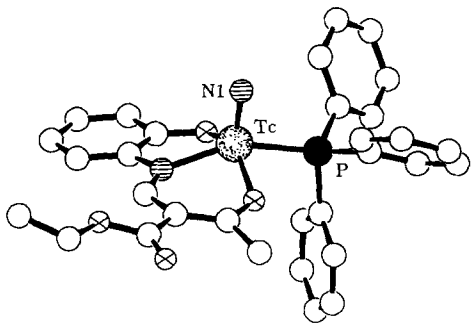


Fig. 31. Structure of the nitrido complex $[TcN(ecbap)(PPh_3)]$. The white spheres are C atoms, the crossed spheres O atoms.

in aqueous medium, since, in each case, the nitrido ligand is insensitive to hydrolysis. This could be exploited in the remarkable synthesis [Eq. (67)] of the nitridooxotechnetium complex coupled via oxo- and oxalato bridges[128] (Fig. 32).

$$4AsPh_4[TcNCl_4] + 6H_2C_2O_4 + 2H_2O \xrightarrow{H_2O/acetone} (AsPh_4)_4[Tc_4N_4O_2(C_2O_4)_6] + 16HCl \quad (67)$$

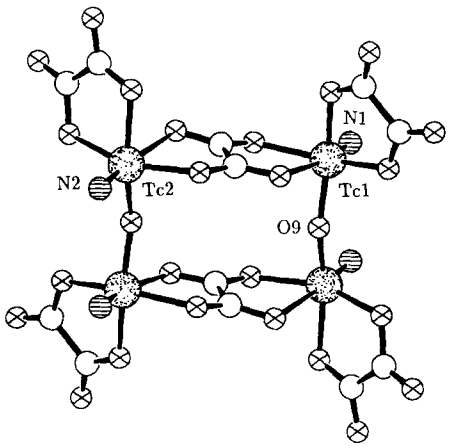

Fig. 32. Structure of the tetranuclear nitrido complex $[Tc_4N_4O_2(C_2O_4)_6]^{4-}$. The white spheres are C atoms, the crossed spheres O atoms.

With hydrogen peroxide it was even possible to synthesize the first nitridoperoxo complex[129] [Eq. (68)].

$$2Cs_2[TcNCl_5] + 5H_2O_2 \longrightarrow 2Cs[TcNCl(O_2)_2] + 6HCl + 2CsCl + 2H_2O \quad (68)$$

In this reaction the substitution is accompanied by an oxidation of the technetium from Tc^{VI} to Tc^{VII}. The structure of the anion (Fig. 33) can be best described in terms of a

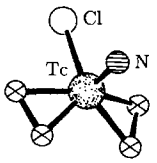

Fig. 33. Structure of the nitridoperoxo complex $[TcNCl(O_2)_2]^-$. The crossed spheres are O atoms.

distorted pentagonal pyramid,[129] but to a first approximation also in terms of a pseudotetrahedral arrangement.

In contrast, the substitution reactions of the $[TcNCl_4]^-$ ion are more frequently accompanied by a reduction of the technetium to Tc^V. Examples are the reaction with 8-quinolinethiol, which leads to the molecular complex $[TcN(C_9H_6NS)_2]$ with fivefold coordinated technetium atom[130] or the reaction with 1,1-dicyanoethene-2,2-diselenolate $[(NC)_2C=CSe_2]^{2-}$, in which the technetium(V) complex $[TcN(Se_2C=C(CN)_2)_2]^{2-}$ with tetragonal-pyramidal coordination is formed. The chelate ligands bound via their selenium atoms are arranged equatorially, whereas the nitrido ligand occupies an apical position.[131]

3.4. Redox Reactions

Investigations of redox reactions of nitrido complexes, particularly of molybdenum, have attracted special attention in model concepts concerning natural N_2-assimilation. The molybdenum atom participates in redox processes from the N_2-fixation at the metal center through to the nitrido complex Mo≡N:.[132, 133] Electron transfer reactions of nitridoosmium complexes have recently also gained importance.

The nitridomolybdenum(VI) complex $[MoNCl_4]^-$ can be readily converted into the corresponding molybdenum(V) complex in CH_2Cl_2 solution even with iodide as reducing agent[134] [Eq. (69)]. According to the crystal structure anal-

$$2\,PPh_3Me[MoNCl_4] + 3[PPh_3Me]I \longrightarrow 2[PPh_3Me]_2[MoNCl_4] + [PPh_3Me]I_3 \quad (69)$$

ysis the $[MoNCl_4]^{2-}$ ion retains the C_{4v} symmetric structure of the $[MoNCl_4]^-$ ion. The Mo–N bond length remains virtually unchanged (163.4 pm), whereas the Mo–Cl distances, owing to the higher negative charge of the ion, are 5.5 pm longer than in the singly charged ion. This bonding situation is also reflected in the results of the EPR spectrum, in which the $g_\perp$ parameter with a value of 1.984(1) is significantly lower than in the corresponding oxomolybdenum(V) compounds, and can be interpreted as an expression of the strong Mo≡N π bond.[134]

On the other hand, the sterically very crowded thioarene complex $[ReN(tipt)_4]^{2-}$ (tipt = 2,4,6-triisopropylbenzenethiolate) can be oxidized very easily with atmospheric oxygen to the corresponding rhenium(VI) complex $[ReN(tipt)_4]^-$.[135]

The reduction of $MoNCl_3$ in THF solution also proceeds with retention of the tetrameric structural unit of the solvates of $MoNCl_3$, as has been demonstrated crystallographically, e.g., with the dibutyl ether solvate $[MoNCl_3 \cdot OBu_2]_4$.[136] Upon reaction of $[MoNCl_3 \cdot thf]_4$ with an equivalent amount of sodium naphthalide in the presence of [15]crown-5 the tetrameric molybdenum(V) complex $[\{MoNCl_3 \cdot thf\}_4]^{4-}$ could be isolated[137] [Eq. (70)].

$$[\{MoNCl_3 \cdot thf\}_4] + 4NaC_{10}H_8 + 2([15]crown\text{-}5) + 4THF \longrightarrow [Na([15]crown\text{-}5)Na(thf)]_2[\{MoNCl_3 \cdot thf\}_4 \cdot 2THF + 4C_{10}H_8 \quad (70)$$

The compound is an ionic ensemble which is formed by direct contacts of chlorine atoms of the complex anion $[\{MoNCl_3 \cdot thf\}_4]^{4-}$ each with two differently associated sodium ions[137] (Fig. 34).

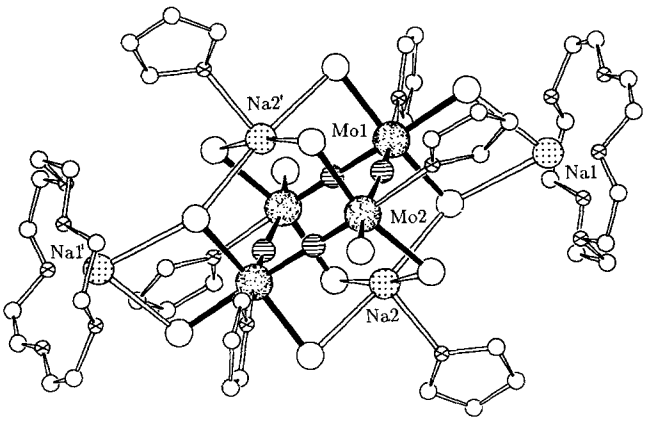

Fig. 34. Structure of the ionic ensemble $[\{Na([15]crown\text{-}5)Na(thf)\}_2][\{MoNCl_3 \cdot thf\}_4]$. The large white spheres are Cl atoms, the small white spheres C atoms, the crossed spheres O atoms.

The sodium ions Na1 are, on the one hand, each coordinated by five O atoms of the crown ether molecule, and, on the other, by two chlorine atoms of the tetrameric anion, so a coordination number seven results for these sodium ions. The sodium ions Na2 are square-pyramidally coordinated, namely by four chlorine atoms, which form the pyrimid base, while the apical position is occupied by the O atom of a tetrahydrofuran molecule.

The Mo–N distances in the $[\{MoNCl_3 \cdot thf\}_4]^{4-}$ ion can, as in the comparable molecular complexes, be interpreted as triple and single bonds. However, from the EPR spectrum, in comparison to the spectrum of the $(PPh_3Me)_2[MoNCl_4]$ complex with monomeric anion, a doubling of the orbital moment can be concluded. This is a result of the weakening of the Mo≡N bond, which is determined by the bridging function of the nitrido ligand.[137]

The unusual tetranuclear tungsten complex, $[W_4N_4(NPh_2)_6(OC_4H_9)_2]$,[120] is formed under reducing conditions in the reaction of $WNCl_3$ with $LiNPh_2$ [cf. Eq. (61)] in the presence of butyllithium in THF. According

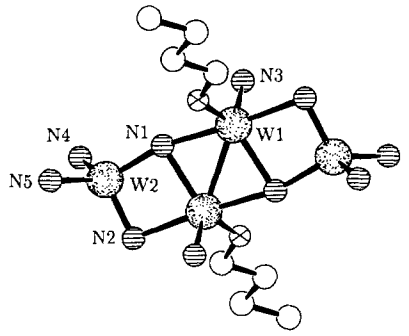

Fig. 35. Arrangement of the framework atoms of the complex $[W_4N_4(NPh_2)_6(OC_4H_9)_2]$ without phenyl groups of the amido ligands. White spheres are C atoms, crossed spheres O atoms.

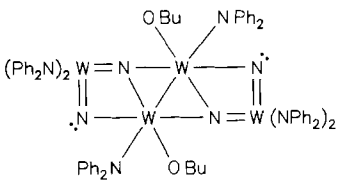
to the crystal structure analysis[120] (Fig. 35) the two tungsten atoms W1 and W2 are coupled one under the other via a W–W single bond (253.5 pm) (corresponding to d^1 configuration). The two remaining tungsten atoms have the oxidation number +VI; they are coupled via two unusual nitrido bridges (N1 and N2) with the W–W dumbbell. The nitrido ligand N2 has a W–N–W bond angle of only 91.3°, the smallest such angle observed so far. The nitrido ligand N1 has a T-shaped bridging function, which has already been observed occasionally. The bonding situations are best formulated as in Scheme 10.



Scheme 10. Bond situation in $[W_4N_4(NPh_2)_6(OBu)_2]$ (schematic).

Other complexes with the T-shaped bridging ligand are shown in Scheme 11.

In all these cases we have complexes in which the μ_3-N ligand couples metal atoms, which, in turn, form metal–metal bonds. An exception is the pentameric complex $[(t\mathrm{BuCH_2})_2\mathrm{TaN}]_5$[28] (cf. Section 2.3).

$[Mo_4(\mu_3\text{-}N)_2(\mu_2\text{-}O\mathit{i}Pr)_2(O\mathit{i}Pr)_{10}]$[138]

$[Mo_3(\mu_3\text{-}N)(O)(CO)_4(\eta\text{-}C_5H_5)_3]$[139]

$(PPh_4)_2[W_3(\mu_3\text{-}N)(O)(\mu_2\text{-}NCl)Cl_9]_2$[9]

Scheme 11. Complexes with nitrido ligands which form T-shaped bridges.

The previously mentioned complex $[AsPh_4]_2[OsN(CN)_4(OH)]$[121] (cf. Section 3.3) has proven to be a strong oxidizing agent in flash photolysis experiments with laser excitation of 355 nm. The self-quenching process of the excited state can be formulated as in Equation (71).[121]

$$[Os^{VI}{\equiv}N]^* + [N{\equiv}Os^{VI}] \longrightarrow [Os{\equiv}N\cdots N{\equiv}Os] \longrightarrow 2[Os^{V}{\equiv}N] \quad (71)$$

The cationic nitridoosmium(VI) complex $[OsN(terpy)Cl_2]^+$ can also be very readily reduced electrochemically through four oxidation states to give the amminoosmium(II) complex[117] [Eq. (72)], which is easily oxidized by atmospheric oxygen to the cationic complex $[Os^{III}(NH_3)(terpy)Cl_2]^+$.[117]

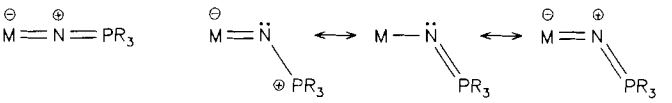
$$[OsN(terpy)Cl_2]^+ + 4e + 3H^+ \longrightarrow [Os(NH_3)(terpy)Cl_2] \quad (72)$$

3.5. Nitrides as Educts for the Synthesis of Phosphoraniminato Complexes

Phosphoraniminato complexes are compounds containing the ligand $[NPR_3]^-$ **H**, which is isoelectronic with compounds of the type OPR_3 **I**, and thus far could not been observed as uncoordinated ion.

H **I**

The known phosphoraniminato complexes of various transition metals which were discussed in detail in a recent review[140] contain the structural group $MNPR_3$, mainly in a linear arrangement (**J**); but M–N–P angles of up to 130° are also known (**K**).



J **K**

Reactions of nitrido complexes with phosphanes are often suitable for their syntheses; these are interpreted as nucleophilic attack of the phosphorus atom at the nitrido ligand[141] (Scheme 12).

$$M{\equiv}N{:} + {:}PR_3 \longrightarrow \overset{\ominus}{M} = \overset{\oplus}{N} = PR_3$$

Scheme 12. Nucleophilic attack of the P atom at the nitrido ligand.

The phosphorus atom is oxidized (change in oxidation state by two), the metal correspondingly reduced.

More recent examples for the phosphoraniminato complexes accessible in this way are the reactions of $ReNCl_4$ with triphenylphosphane to give $[(Ph_3P)Cl_4Re(NPPh_3)]$,[116] the formation of $PPh_4[MoCl_5(NPCl_3)]$ from $PPh_4[MoNCl_4]$ and PCl_3/PCl_5,[142] and the reaction of $MoNCl_3$ with trimethylphosphane in CH_2Cl_2, which already takes place at room temperature[143] [Eq. (73)].

$$Mo^{VI}NCl_3 + 4PMe_3 \longrightarrow [Mo^{IV}(NPMe_3)Cl_2(PMe_3)_3]Cl \quad (73)$$

The Mo–N–P bond angle in the structure of the first cationic phosphoraninimato complex (167.6°)[143] corresponds to that in the most frequently observed structure type **J**.[140]

On prolonged standing in CH_2Cl_2 solution, this Mo^{IV} complex undergoes a remarkable transformation; besides the bis(trimethylphosphane)iminium ion, a μ-nitridomolybdenum(IV) complex is formed[143] [Eq. (74)]. In the structure

$$2[Mo(NPMe_3)Cl_2(PMe_3)_3]Cl \longrightarrow [Me_3PNPMe_3]^+[\{MoCl_3(PMe_3)_2\}_2N]^- + 2PMe_3 \quad (74)$$

of the anion (Fig. 36) the Mo–N–Mo axis is almost symmetrical and nearly linear (bond angle 175.3°).[143]

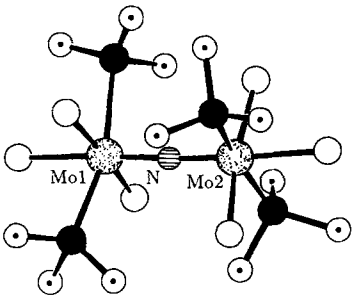


Fig. 36. Structure of the anionic μ-nitrido complex $[\{MoCl_3(PMe_3)_2\}_2N]^-$. The white spheres are Cl atoms, the black spheres P atoms, the spheres with central dot C atoms.

Cyclic metallaphosphazenes could be prepared in good yields for the first time by reaction of bis(aminodiorganophosphane)iminium chloride with the chloride nitrides $MoNCl_3$ or $WNCl_3$[144, 145] [Eq. (75)]. Crystal structure investigations of the acetonitrile solvates revealed the presence of almost planar MN_3P_2 rings with delocalized P–N bonds.[145, 146] Still unclear is whether the nitrogen of the ammonium chloride that is formed stems from the metal chloride nitride or from an amino function of the iminium ion. The synthesis of the cyclotungstaphosphazene $Cl_3\overline{WNPPh_2NPPh_2N}$ starting from tungsten hexachloride and $[H_2NPPh_2NPPh_2NH_2]Cl$, which leads to elimination of HCl, would suggest that it originates from the $MNCl_3$ component.[146]

$MNCl_3 + [H_2NPR_2NPR_2NH_2]Cl \longrightarrow$  $+ NH_4Cl$ (75)

(M = Mo, W)

The formation of bis(phosphane)iminium ions from phosphoraniminato complexes was previously only observed on starting from a molybdenum complex with *cis* phosphoraniminato ligands[147] [Eq. (76)].

$$cis\text{-}[MoCl_4(NPPh_3)_2] \longrightarrow [Ph_3PNPPh_3]^+[MoNCl_4]^- \quad (76)$$

A further example of a cationic phosphoraniminato complex could be prepared by reaction of the terpyridyl complex *trans*-$[Os^{VI}(terpy)Cl_2N]Cl$ with triphenylphosphane [Eq. (77)] and was crystallographically characterized as the PF_6^- salt.[148]

$$[Os^{VI}(terpy)Cl_2N]^+ + PPh_3 \longrightarrow [Os^{IV}(terpy)Cl_2(NPPh_3)]^+ \quad (77)$$

In this case the Os–N–P bond angle of 132.5° lies at the lower limit of the previously known values. Only in the complex [Mo(NO)(NPMePh$_2$)(dttd)] [dttd = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(2−)] is it somewhat smaller (129.7°).[149] Also remarkable is the length of the Os–N bond of 209 pm,[148] which corresponds to a single bond.

3.6. Nitrides as Educts for the Synthesis of M–N–S Sequences

Some nitrido complexes can be converted by reaction with elemental sulfur or with S_2Cl_2 into thionitrosyl complexes [Eq. (78), (79)]. Suitable educts are dithiocarbamato complexes of molybdenum $[MoN(S_2CNR_2)_3]$ with sevenfold coordinated molybdenum atom as well as nitrido complexes of rhenium and osmium.[150]

$$[MoN(S_2CNR_2)_3] + \tfrac{1}{8}S_8 \longrightarrow [Mo(NS)(S_2CNR_2)_3] \quad (78)$$

$$[ReNCl_2(PR_3)_3] + \tfrac{1}{2}S_2Cl_2 \longrightarrow [Re(NS)Cl_3(PR_3)_2] + PR_3 \quad (79)$$

According to structural investigations the thionitrosyl ligand is bound in linear arrangement $\overset{\ominus}{M}=\overset{\oplus}{N}=S$ with the metal center (for a review see Ref. [151]).

The reaction of $ReNCl_4$ with tetrasulfur tetranitride leads to an interesting product. Initially, a chloro-bridged polymerized product $[ReCl_2(NS)(NSCl)]_\infty$ is formed which can be resolved with tetraphenylarsonium chloride in dichloromethane to give the dianion $[ReCl_4(NS)(NSCl)]^{2-}$.[152] According to the structural analysis (Fig. 37) the anion contains both a thionitrosyl as well as a chlorothionitrene ligand[152] (cf. also Section 2.7).

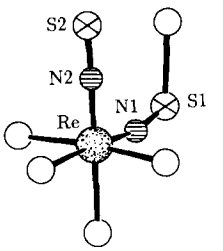

Fig. 37. Structure of the anionic chlorothionitrenethionitrosyl complex $[Cl_4Re(NSCl)(NS)]^{2-}$. The white spheres are Cl atoms.

Also remarkable is the reaction of molybdenum chloride nitride with trithiazyl chloride, which is in equilibrium with its monomer in solution. A cyclothiazenomolybdenum

derivative [Eq. (80)] is formed whose chloro bridges are detached with tetraphenylphosphonium chloride to give the monomeric anionic derivative[153] [Eq. (81)].

$$2\,MoNCl_3 + 4{:}N{\equiv}S\text{-}Cl \longrightarrow [\{Cl_3Mo(N_3S_2)\}_2] + 2\,Cl_2 \quad (80)$$

$$[\{Cl_3Mo(N_3S_2)\}_2] + 2\,PPh_4Cl \longrightarrow 2\,PPh_4[Cl_4Mo(N_3S_2)] \quad (81)$$

According to the crystal structure analyses of the $AsPh_4^+$ salt[154] and the PPh_4^+ salt,[155] which are not isotypic, the

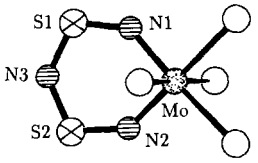

Fig. 38. Structure of the anion $[MoCl_4(N_3S_2)]^-$. The white spheres are Cl atoms.

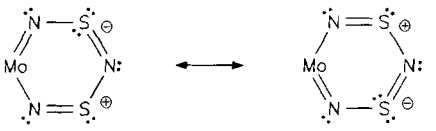
molybdenum atom is component of a planar six-membered MoN_3S_2 ring (Fig. 38), whose S–N distances are almost equal in length and can be described in terms of delocalized π-bonds.

For a review of ring compounds of this type see Ref. [156].



Scheme 13. Resonance structures of the planar six-membered MoN_3S_2 ring.

4. NMR Spectroscopic Investigations

Very little has been reported in the past few years concerning NMR spectra of nitrido complexes. ^{95}Mo-NMR spectra disclose a wide range of the values of the chemical shift through its dependence on the coordination number, on the electronegativity of the ligands, and on the charge of the complexes[157] (Table 1).

Table 1. Chemical shifts δ and line widths b of nitrido complexes [157] in ^{95}Mo-NMR spectra [a].

[a] Measurements in CH_2Cl_2, external standard 2 M $Na_2[MoO_4]$ in D_2O, pH 11. [b] Solution in acetonitrile. The complex $[\{MoNCl_3 \cdot CH_3CN\}_4]$ is formed in this solvent.

The largest deshielding is observed in the $[MoNCl_4]^-$ ion with fivefold coordinated molybdenum, the least deshielding in $[MoN(S_2CNMe_2)_3]$ with coordination number seven.

^{15}N-NMR investigations have been carried out on a few nitrido complexes of molybdenum, tungsten, and rhenium[7, 158, 159] (Table 2). Also these measurements show a

Table 2. ^{15}N-NMR data of nitrido complexes.

Complex	Solvent	δ [a]	Ref.
$[ReCl_2(^{15}N)(PnPrPh_2)_2]$	CH_2Cl_2	85.8	[158]
$[ReCl_2(^{15}N)(PMe_2Ph)_3]$	CH_2Cl_2	68.2	[158]
$[ReCl(^{15}N)(dppe)_2]Cl$ [b]	CH_2Cl_2	67.1	[158]

trans-$[MoCl(^{15}N)(dppe)_2]$	THF	166.8	[159]
trans-$[MoBr(^{15}N)(dppe)_2]$	THF	190.6	[159]
$[W_2(^{15}N)Cl_9 \cdot CH_3CN]$	CD_2Cl_2	211.2	[7]
$[\{W(^{15}N)Cl_3 \cdot CH_3CN\}_4]$	CD_2Cl_2	222.7	[7]
$PPh_4[W(^{15}N)Cl_4]$	CH_2Cl_2	258.8	[7]
$PPh_4[W_2(^{15}N)Cl_{10}]$	CH_2Cl_2	251.0	[7]

[a] Chemical shifts relative to nitromethane. [b] dppe = $Ph_2PCH_2CH_2PPh_2$.

strong dependence of the values of the chemical shift on the coordination number at the metal center and on the type of ligands. The strongest shielding is experienced by the nitrido ligand in the complex $[Mo(^{15}N)(S_2CNEt_2)_3]$ with sevenfold coordinated molybdenum atom, which has its complete equivalent in the large extent of the shielding of the ^{95}Mo nucleus in this compound (see above). The N-nuclei of the nitrido ligands in the tungsten compound are the most strongly deshielded. Tungsten is thus a particularly strong π-electron acceptor towards the nitrido ligand, as is also reflected in the IR spectra by very short wave W–N stretching frequencies and correspondingly large valence force constants. Thus, e.g., in the ions $[MNCl_4]^-$ an M–N valence force constant of 8.00 N cm^{-1} is calculated for M = Mo and of 8.15 N cm^{-1} for M = W.[7]

5. Catalytic Activity of Nitrido Complexes

Nitridomolybdenum(VI) complexes such as $[MoNCl_3(OPPh_3)_2]$ or $[NBu_4][MoNCl_4]$ together with ethylaluminum chloride as cocatalyst are very efficient catalysts for olefin metathesis.[160] For example, pent-2-ene is rapidly converted into but-2-ene and hex-3-ene [Eq. (82)], whereby the high

$$\underset{(46\%)}{2\,CH_3\text{-}CH{=}CH\text{-}C_2H_5} \rightleftharpoons \underset{(27\%)}{CH_3\text{-}CH{=}CH\text{-}CH_3} + \underset{(27\%)}{C_2H_5\text{-}CH{=}CH\text{-}C_2H_5} \quad (82)$$

initial rate of the reaction is impressive. It is assumed that the course of the olefin metathesis proceeds via the initial formation of a carbene complex. An organylation of the $MoNCl_3$ precatalyst followed by α-H-elimination with reduction to an active carbenenitridomolybdenum(IV) complex fragment is conceivable as catalyst formation reaction[160] [Eq. (83)].

$$[Mo^{VI}NCl_3(OPPh_3)_2] + (2 + x)C_2H_5AlCl_2 \longrightarrow [Mo^{IV}N(CHCH_3)Cl \cdot xC_2H_5AlCl_2] + 2[Cl_3Al \leftarrow OPPh_3] + C_2H_6 \quad (83)$$

This assumption is supported by the isolation of the carbeneoxotungsten complex $[\{WO(CHCMe_3)(PMe_3)Cl_2\}_2]$, which likewise catalyzes the olefin metathesis, albeit less efficiently.[161]

On the basis of theoretical considerations R. Taube and K. Seyferth came to the conclusion that the strong π-donor action of the nitrido ligand favors the form **M** of the carbene complex with d^2_{xy} configuration over the form **L**, which is

L **M**

essential for the subsequent reaction with the olefin.[162] This can then lead via the intermediate step of a metallacycloalkane to the metathesized olefin.[162]

The nitrido complexes, which have hitherto only been little exploited for catalytic purposes obviously present a challenge for the future. Whereas the development of homogeneous catalysts based on oxo complexes, for which $[CH_3ReO_3]$ is mentioned as key substance, has already led to excellent results in the metathesis of functionalized olefins,[164] in olefin epoxidation with H_2O_2[165] or even in the olefin synthesis from aldehydes, cyclic ketones etc.,[166] the catalytic potential of nitrido complexes still awaits recognition. Optimism accrues from a comparison of oxo function and imido function, which are isolobal (Scheme 14).

$$M=\ddot{O} \longleftrightarrow \overset{\ominus}{M}\equiv\overset{\oplus}{O}:$$

$$M=\ddot{N}-R \longleftrightarrow \overset{\ominus}{M}\equiv\overset{\oplus}{N}-R$$

Scheme 14. Comparison of the isolobal oxo and imido ligands.

Carbenimido complexes such as $[Mo(NtBu)(CHtBu)(OR_2)]$[167] ($R = CH(CF_3)_2$), like oxo complexes, have also proven to be effective as catalysts in olefin metathesis. Recently, the catalytic activity in the metathesis of terminal and functionalized olefins of a carbyneruthenium complex, $[Ru(CtBu)(CHtBu)(OR_2)]$[168] ($R = C(Me)(CF_3)_2$) was reported on for the first time. Since the carbyne function is isolobal with the nitrido ligand (Scheme 15), correspondingly modified properties are also to be expected for nitrido complexes. The above mentioned examples are a good indication of this being the case.

$$M\equiv C-R \longleftrightarrow M\equiv N:$$

Scheme 15. Comparison of the isolobal carbyne and nitrido ligands.

6. Bonding Situations in Multinuclear Nitrido Complexes

As has already been shown, binuclear, oligomeric chain or ring-shaped as well as polymeric complexes can be formed by the bridging function of the nitrido ligand. The nitrido bridge can be symmetrical or asymmetrical, linear or bent (see Scheme 1).

R. Hoffmann et al. have devoted several studies to the bonding situations in multinuclear complexes with nitrido bridges[22, 169, 170] and have examined the geometric and electronic properties using extended Hückel MO calculations. They also compare the nitrido bridges with fluoro, oxo-, and carbido-bridges.

In the case of binuclear porphyrin-analogous model complexes $[(N_4)Fe\text{-}X\text{-}Fe(N_4)]$ with X = O, N, C, the calculations[169] show that when X = O two and when X = N one d electron of the Fe ions is located in antibonding Fe–X–Fe orbitals. Due to a bending of the bridge the orbitals of these electrons are energetically lowered, but at the same time an occupied non-bonding level is slightly raised. This indicates that a bent oxo bridge leads to an energetically more favorable situation, whereas in the case of the nitrido bridge the lowering of the only singly occupied antibonding orbital cannot compensate the opposing effect in the non-bonding MO, so that the frequently observed linear arrangement is preferred. However, the calculated bending of Fe–O–Fe bridge is in fact only observed when this is stereochemically allowed. Thus, the oxo bridge is linear for example in the phthalocyaninato complex [(pc)Fe-O-Fe(pc)].

In the carbido complex $[(N_4)Fe{=}C{=}Fe(N_4)]$ the antibonding Fe–C–Fe MOs are unoccupied, so a linear bridge results, as is found in [(tpp)Fe=C=Fe(tpp)][171] and [(pc(Fe=C=Fe(pc)].[172] Naturally, the Fe–X bond strength increases with decreasing number of antibonding electrons. Hence, the strongest Fe–X bond is found in the carbido bridge.

In binuclear complexes the symmetrical M=N=M bridge with equal M–N distances is preferred, whereas in polymeric and most of the oligomeric nitrido complexes the nitrido bridges $M\equiv\overset{\oplus}{N}-\overset{\ominus}{M}$ are, as a rule, asymmetrical. In addition, a pyramidalization of the equatorial plane L_nM ($n = 3, 4$) formed by the central metal atom and the *cis* oriented ligands occurs.

R. Hoffmann et al.[170] show, in the case of complexes with a d^0- or d^1-electron configuration at the central atom, that this is the result of a second-order Jahn–Teller effect, in which, due to a HOMO-LUMO interaction, the HOMO is lowered with respect to its energy and the LUMO is raised. The HOMO-LUMO interaction is thereby all the more stronger the smaller the energy difference between the two MOs. This increases with increasing electronegativity of the bridge ligand X, so that also the asymmetry of the bridge decreases along the series X = C, N, O, F. This is confirmed by structure analyses. Fluoro bridges are usually symmetric, nitrido bridges, on the other hand, asymmetric. Polynuclear complexes with carbido bridges have so far not been synthesized. Here, highly asymmetric bridges should occur.

Since the highest occupied MOs are two degenerate M–X π-orbitals, the gain in energy by the second-order Jahn–Teller effect leads in the first instance to a strengthening of

the π-bond, whereas the M–X σ-bond is influenced only slightly. Rather it stabilizes the symmetrical bridge bonding.

In the case of the hitherto unknown polymeric nitrido complexes with two or more free d-electrons on the transition metal, according to calculations symmetrical nitrido bridges should occur, since here the antibonding M–N π* levels are filled and the Jahn–Teller effect cannot be effective.

Similarly as in the case of the polymeric nitrido complexes $[MNL_3]_n$ and $[MNL_4]_n$, a second-order Jahn–Teller effect also leads in the case of tetrameric complexes to stabilization of the less symmetric structure with alternating M–N distances. Calculations show, in the case of the model compound $[\{MoNCl_3(OH_2)\}_4]$ an energy gain of about 193 kJ mol^{-1} on going from the complex with symmetrical nitrido bridges to the complex with alternating Mo–N distances, in which the weakly bound aqua ligands are then arranged *trans* to the Mo≡N triple bond.

In the transition from a nitrido bridge to an oxo- or fluoro bridge the extent of distortion decreases with increasing electronegativity of the bridge ligand, since the energy difference between HOMO and LUMO increases and therefore the second-order Jahn–Teller effect becomes weaker. $[NbF_5]_4$ has indeed symmetrical fluoro bridges. Likewise, in the cyclic tetrameric phosphazenes $[PNX_2]_4$ the corresponding orbitals are energetically so different that no second-order Jahn–Teller effect occurs, thus explaining the equalized P–N bond distances.[122]

Interesting is a comparison of the polynuclear nitrido complexes and linear and cyclic $(CH_2)_n$ polyenes.[122] It emerges that the known nitrido complexes are related to the polyene analogues polyacetylene, allyl and pentadienyl cation and cyclooctatetraene. This structural relationship is explained by the similarity of the π-systems, which is evident in particular in nitrido complexes, since the difference in electronegativity between metal and bridging N atom is small.

Thus, it appears that binuclear nitrido complexes with symmetrical nitrido bridges correspond to the allyl system. Trinuclear complexes such as $[W_3N_2Cl_{14}]^{2-}$[118] containing the structural group W≡N-W-N≡W are comparable with the pentadienyl cation, $[\{MoNCl_3\}_4]$[81] corresponds to cyclooctatetraene, and the polymeric nitrido complexes $[ReNCl_4]_n$,[173] $[MoNCl_4^-]_n$[86] and $[(RO)_3WN]_n$[77] have alternating M–N distances, as is the case in polyacetylene.

The most interesting conclusion which R. Hoffmann et al.[122] drew from the comparison of multinuclear nitrido complexes with organic polyenes was the prediction that a cyclic, trimeric nitrido complex $[\{L_nMN\}_3]$ ought to be stable and in analogy to benzene should presumably have equal M–N distances.

A little later Roesky et al.[120] then synthesized the nitrido complex $[\{Cp^*TaN(Cl)\}_3]$, which can be regarded as triazatritantalabenzene, and shows almost equal Ta–N distances of 184 and 191 pm.

Mononuclear complexes MNL_4 almost always have a tetragonal-pyramidal structure. Exceptions are provided by the complexes $[WNCl_2F_2]^-$[179] and $[TcNCl_2(PPh_3)_2]$[124] with trigonal-bipyramidal structure and the nitrido ligand in equatorial position. In this connection, R. Hoffmann et al.[170] investigated the question of a change in structure in the sense of a Berry pseudorotation. The calculations show that the tetragonal-bipyramidal structure with the nitrogen atom in the apical position is only about 12–13 kJ mol^{-1} more stable than the trigonal-bipyramidal alternative. This explains why, for example, steric effects such as are effected by the phosphane ligands in $[TcNCl_2(PPh_3)_2]$,[124] can stabilize the trigonal-bipyramidal arrangement.

For a trigonal bipyramid with the N atom in the axial position there is likewise a local minimum, which however lies at higher energy than in the case of the equatorial arrangement.

A pseudorotation should, according to calculations, be easily possible in the case of a d^0–d^2 electron configuration of the metal; in the case of d^3–d^7 electron configuration it is symmetry forbidden.

7. Outlook

Nitrogen is an extremely versatile element, which, owing to its manifold bonding and coordination possibilities, also promises a diversified chemistry in the future. Thus, the chemistry of the nitrido complexes has developed extensively in the past few years. This is due in the first instance to the many new synthetic methods which have opened up entries to nitrogen compounds. It is expected that this development will continue in the coming years, since the known synthetic methods are still not exhausted and surely new ones will be added. Possibly also new nitrido complexes of the previously little investigated main group elements will be found. Also in the area of catalysis it can be expected that nitrido complexes will find application as effective catalysts. Finally, the search for preceramic materials will give new impetus to the chemistry of the nitrides of main and sub-group elements.

We thank the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie for generous support of our work. Thanks are also due to our co-workers for their enthusiastic and invaluable cooperation. We also thank Mrs. E. Niquet for preparing the SCHAKAL diagrams.

In Vitro Selection of Specific Ligand-binding Nucleic Acids**

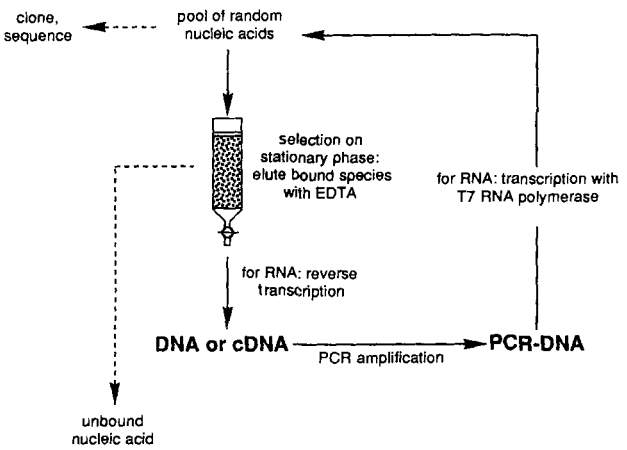
By Michael Famulok* and Jack W. Szostak*

In vitro selection is a method that allows the simultaneous screening of very large numbers of nucleic acid molecules for a wide range of properties from binding characteristics to catalytic properties; moreover, the isolation of the very rare functional molecules becomes possible. Binding sites between proteins and nucleic acids, for example, have been evaluated by this methodology in order to gain information about protein/nucleic acid interactions. Structure and function of catalytic RNA ("ribozymes") has been studied by in vitro selection and has led to new ribozymes with improved catalytic function. Substrate specificity of catalytic RNA has been changed and has led to a ribozyme that cleaves DNA. Other applications include the isolation of nucleic acids that bind specifically to small organic molecules and of RNA molecules that form triple helices with double-stranded DNA. In this article we discuss the background, design, and results of in vitro genetic experiments, which bridge biochemical/molecular biological and organic chemical approaches to molecular recognition.

1. Introduction

The rational design of nucleic acids with tertiary structures complementary to a given chemical structure is currently unattainable because it requires not only the ability to predict the three-dimensional structure corresponding to a given sequence, but also the ability to anticipate changes in structure that might occur upon ligand binding. The design of nucleic acid structures complementary to ligands of unknown structure is, by the very nature of the problem, impossible. Nevertheless, it is now possible to routinely isolate DNA and RNA molecules that bind tightly and specifically to a wide range of ligands, including proteins, other nucleic acids, and small organic molecules. This development is the result of new techniques that sidestep the whole issue of design by allowing the isolation of very rare molecules with specified ligand-binding properties from extremely large pools of random sequence nucleic acids.[1] These in vitro selection methods were recently developed independently in several different laboratories for a wide range of applications, from the evaluation of protein binding sites on nucleic acids, to the study of the structure and function of catalytic RNAs.

The methodology is conceptually straigthforward: first, a large library of completely random oligodeoxynucleotides, or a library of degenerate oligodeoxynucleotides containing as many variants as possible of a sequence of interest, is generated by chemical synthesis.[2] If desired, this library of DNA sequences may be converted into a library of RNA sequences by in vitro transcription. The pool is then subjected to selection steps that will result in enrichment of the molecules of interest. Since only a very small fraction of the random or degenerate sequences will be functional, complete purification in one step is not usually possible. The pool of molecules resulting from each selection step is therefore amplified so that further enrichment of the functional molecules can be achieved in additional selection cycles. Amplification is achieved through the polymerase chain reaction (PCR),[3] or in a transcription-based step. Successive selection and amplification cycles result in an exponential increase in the abundance of functional sequences, until they dominate the population (Scheme 1).



Scheme 1. Selection for ligand-binding RNA molecules by means of affinity chromatography. For the selection of DNA sequences, reverse transcription and transcription are not needed, but asymmetric PCR or single-strand purification is required to prevent combination of complementary strands into inactive duplex DNA.

In vitro selection can be applied to the analysis of known nucleic acid sequences; for example, it provides a rapid way of identifying important residues that cannot be changed without loss of function, whether in a protein binding site on a DNA molecule, or in an RNA catalyst. However, this method can also be applied to more difficult problems, such as the isolation of novel nucleic acid molecules that bind very specifically to targets ranging from small organic molecules to large regulatory proteins. The de novo isolation of functional sequences with catalytic activity is an even bigger challenge currently being addressed in several laboratories.

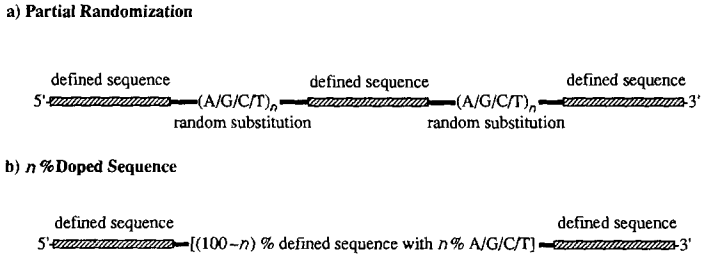
[**] Important technical terms have been explained in a glossary in Section 5.

An immediate advantage of in vitro selection over standard in vivo genetic methods is that the selection conditions, binding specificity, or the reactions for which catalysis is to be selected are independent of any constraints imposed by cellular physiology. Another major advantage of in vitro selection is that pools as large as 10^{15} different species, or even larger, can be screened for functional sequences, greatly increasing the likelihood of generating at least one molecule with the desired properties.

2. Design of In Vitro Selection Experiments

An in vitro selection experiment may begin with either completely random sequences, or with a library of partially randomized sequences.

Partial randomization would normally be applied to the analysis of the structure of a known functional sequence, or to the isolation of a variant sequence with altered properties. A certain percentage of random nucleotides may be incorporated into part or all of the sequence to be studied, or alternatively a short region of a longer, defined sequence may be completely randomized. In either case, a family of closely related sequences is created (Scheme 2).



Scheme 2. Examples of partially randomized sequences: a) Partial sequences within a defined nucleic acid sequence are substituted by completely randomized short sections. b) The nucleic acid sequence is synthesized so that a certain percentage of nucleotides is randomly introduced in a defined sequence. In principle this describes the synthesis of a sequence of nucleic acids with an extremely high mutation rate.

After the selection of a functional pool, comparative sequence analysis allows the identification of positions that can be classified as a) variable, and thus not necessary for the selected function, b) highly conserved, which indicates their functional importance, c) covarying with another position, which indicates an interaction between these positions.

The de novo isolation of nucleic acid receptors with specificity for particluar biomolecules or small substrates requires a large initial library of completely random sequences, flanked by defined primer binding sites that allow the amplification of the selected molecules (Scheme 3).

Scheme 3. Schematic representation of synthetic DNA oligonucleotides designed for transcription into a library of RNA molecules containing random sequence inserts.

In order to maximize the probability of the presence of substrate-specific tertiary structures, the general strategy is to start with a pool of maximum complexity.[4] With automated oligonucleotide synthesis,[5] a complexity of roughly $10^{13}-10^{15}$ different DNA molecules can be generated.[6, 7] Principles for the design of in vitro selection experiments and pool syntheses have been described.[8]

3. Applications

3.1. Selection for DNA Protein Recognition

The first report of the in vitro selection of random DNA sequences came from Oliphant et al.,[9] who performed affin-

Michael Famulok, born in 1960 in Fulda, Germany, studied chemistry at the University of Marburg from 1981 to 1989), where he obtained his Ph.D. in 1989 with Prof. G. Boche. In 1989 and 1990 he did postdoctoral work with Prof. J. Rebek, Jr. at the Massachusetts Institute of Technology, in the field of molecular recognition by abiotic receptor molecules. Thereafter he joined Prof. J. W. Szostak as postdoc. (1990–1992) to study in vitro selection. He is now completing his Habilitation at the Department of Biochemistry, University of Munich. His research interests are the molecular recognition of ligands by nucleic acids and nucleic acid catalysis.

Jack W. Szostak was born in 1952 in London, England. He attended McGill University in Montreal, Canada, from 1968 to 1972, where he received his B. Sc. His Ph.D. work (1972–1977) was carried out at Cornell University in the laboratory of Prof. Ray Wu. After postdoctoral work there, he moved to the Dana-Farber Cancer Institute and Harvard Medical School as an Assistant Professor, where he worked on recombination and chromosome structure. He is now Professor of Genetics at Harvard University and Massachusetts General Hospital in Boston. His research interests concentrate on the structure and function of RNA enzymes and the origin of life.

ity chromatography of random DNA sequences; however, the selection steps were carried out one after the other, without amplification. The analysis of the selected sequences was done by ligation into a plasmid, transformation, and cloning. Thus, the system can be described as in vitro selection/in vivo amplification. This selection system was applied to the isolation of DNA sequences that bind to the protein GCN4, a transcriptional activator protein that binds within the promotor region of many yeast genes coding for enzymes required for amino acid biosynthesis. A sequence of nine base pairs was thought to be important for GCN4 binding. To examine the details of the site specificity and the role of flanking nucleotides, a randomized 23 nucleotide region of DNA was synthesized, flanked on each side by different restriction sites. Single-stranded DNA was synthesized chemically and used as a template to make radioactive double-stranded DNA (dsDNA), which then was selected on GCN4-derivatized agarose in the presence of a carrier DNA. Bound DNAs were then eluted, digested with restriction enzyme, and subjected to three more cycles of chromatographic selection. After the final selection, 0.01% of the input-DNA was recovered. Cloning and sequencing revealed that 40 out of 43 clones contained the symmetric sequence TGA(C/G)TCA; six of these seven bases were present in the three other clones. Such a high degree of conservation indicates that the most significant GCN4/DNA-contacts are likely to occur in this region.

The first experiment to combine in vitro selection and in vitro amplification was reported in 1989 by Kinzler and Vogelstein, who selected for DNA sequences that contained binding sites for the transcription factor TFIIIA.[10a] Instead of synthetic random DNA, they used highly fragmented human DNA as the source of their initial pool; this DNA was derivatized with restriction site linkers to facilitate subsequent cloning and sequence analysis. Selection for DNA fragments containing binding sites was achieved by immunoprecipitation of protein–DNA complexes with anti-TFIIIA antibodies; the selected DNA was then amplified by PCR. By comparison of the sequences of the selected molecules a consensus binding site could be identified. In similar experiments the binding site of the human GL1 zinc-finger protein was determined.[10b]

A system for the selection of protein-binding DNA molecules based solely on in vitro techniques and synthetic DNA was described by Thiesen and Bach.[11] As a model protein for their studies they used a fragment of the DNA-binding human transcription factor SP1. The chemically synthesized DNA pool contained twelve random nucleotides flanked by defined primer binding sites. Double-stranded DNA was synthesized by PCR, incubated with the SP1 fragment, and the DNA–protein complexes were bound to nitrocellulose filters. A related oligonucleotide with defined SP1 binding sites was used for comparison and competition-binding assays. Bound DNAs were eluted with a zinc-chelator that denatures the zinc-finger domains of the SP1 protein, and the recovered DNA was amplified by PCR.[12] After five cycles of selection, 19 out of 20 cloned oligoucleotides showed binding to SP1. The relative affinities of some of these DNAs were tested in the presence of competitor DNA by bandshift electrophoresis. Two sequences, S2 and S3, showed up to ten times tighter binding than the known binding site used as competitor DNA. Sequencing of several cloned DNAs revealed striking sequence similarities. Some selected binding sequences differed in only one base from the SP1 consensus sequence GGGGCGGGGC. S2 and S3, the sequences with the highest affinity to SP1, showed mutations in three different positions.

3.1.1. Characteristics of Binding by Basic Helix-Loop-Helix Proteins to DNA

A third variation on the theme of DNA–protein recognition was reported by Blackwell and Weintraub,[13] who used cycles of in vitro selection and PCR amplification as above, but avoided the labor of cloning and sequencing many individual selected DNAs by simply sequencing the entire pool of DNA molecules as a mixture. Blackwell and Weintraub studied the DNA-binding sequence of several basic helix-loop-helix (bHLH) proteins, such as MyoD. The bHLH proteins are a family of transcriptional activators containing a conserved set of basic amino acids that are important for DNA recognition and are immediately adjacent to a region thought to form a helix-loop-helix (HLH) structure involved in oligomerization.[14] MyoD is responsible for the induction of muscle-specific genes in muscle cells, while other bHLH proteins induce different sets of tissue-specific genes in other tissues.[15] However, MyoD and all other known bHLH proteins bind in vitro to the consensus DNA sequence CANNTG.[16]

To see whether the different in vivo effects of these proteins might be due to differences in their DNA binding specificities, Blackwell and Weintraub performed a series of in vitro selection experiments. A pool of synthetic DNA molecules was generated containing the CANNTG consensus, in which the two central and several flanking positions were completely randomized. This mixture of DNA sequences was incubated with the protein (MyoD, E2A, E52, or heterooligomers of these proteins), and DNA–protein complexes were isolated by the electrophoresis mobility shift assay. After PCR amplification of the recovered DNA, the final pool of DNA was sequenced as a pool without prior cloning. This technique saves much time and effort, because it provides the possibility of reading out any bases that are required for specific recognition in addition to the defined CANNTG sequence directly from the sequencing gel.[17] The defined bases serve to ensure that the protein is similarly aligned on each DNA molecule. Unimportant bases or bases that are not involved in base-specific interactions remain as a mixture in the pool, and show up as a mixture in the sequencing ladder. This rapid analysis method enables the easy screening of mutant proteins generated by in vitro translation for any changes in their binding behavior. On the other hand, sequencing a mixture of sequences rather than individual clones means that some information may be lost if a pool contains different sequences that bind equally well.

3.1.2. In Vitro Selection Involving Immunoprecipitation

The purification of DNA–protein complexes by immunoprecipitation was used as an in vitro selection system by

Pollock and Treisman.[18] The great advantage of this approach is that the protein whose binding site is being defined need not be available in pure form. These authors used cell extracts as a source of the transcription factor SRF (serum response factor) and an in vitro translation system as a source of the *fos* oncoprotein. The selection strategy was similar to that used in the experiments described above: a 26 base region of randomized DNA was flanked by 25 nucleotide (nt) primer binding sites. The crude extract was incubated with the DNA pool and a competitor DNA (to decrease the formation of nonspecific complexes with pool DNA), whereupon the SRF- or *fos*-DNA complexes were isolated with SRF- or *fos*-specific antibodies. Bound DNA was purified, PCR-amplified, and reselected; after several cycles individual molecules were cloned and sequenced.

This approach will be particularly useful for the study of DNA-binding proteins that require post-translational modification or association with other proteins for correct DNA recognition. In such cases, protein obtained from bacterial over-expression systems may give misleading results. The ability to use material obtained by in vitro translation means that the effect of mutations in the protein on the DNA-binding specificity will be much easier to study, since mutant proteins can now be generated entirely in vitro (by PCR mutagenesis of a cloned gene, followed by in vitro transcription and in vitro translation).

3.2. In Vitro Selection for RNA Molecules for Protein Recognition

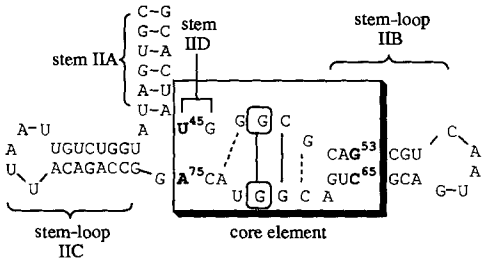
Protein binding sites on DNA are relatively simple to define since most DNA regulatory elements conform to the well-defined structures of the B-type double helix. In contrast, protein recognition mechanisms of RNA can make use of structural features found in the primary, secondary, or tertiary structure of the RNA. Detailed knowledge of the structural requirements can sometimes be achieved by means of phylogenetic studies, if sufficient sequence data exist.[19] Covariations may be found that allow conclusions to be drawn about the secondary or tertiary structure of the binding site. However, if there is insufficient variation between the available sequences, it will not be possible to deduce the relevant structure. Computer-generated secondary structures of RNA may be helpful in such analyses, but often fail to predict functionally important structures.[20] The Rev protein is an example: sequenced HIV isolates showed only very slight variation in the region of the Rev binding site, and several different foldings of the sequence were possible. In such cases, in vitro selection may be an excellent method of obtaining functional sequences that are sufficiently divergent for interesting structural information to be extracted by comparative sequence analysis.

3.2.1. The Rev Binding Site

The Rev protein of HIV and other closely related retroviruses mediates the transport of the mRNAs for *gag*, *pol*, end *env* from the nucleus to the cytoplasm in infected cells and is therefore essential for the replication of these viruses.[21] Rev binds within a 66 nucleotide (66 nt) long segment in the mRNA to be transported; however, the exact location and structure of the binding site were controversial.[22] Bartel et al. used an in vitro selection approach to address these issues.[23]

To avoid the selection of completely unrelated structures that happen to bind to the protein, the 66 base Rev binding element was not completely randomized; rather, the pool was synthesized so that 65% of the bases would be wild type, 30% not wild type, and 5% deleted. This degree of degeneracy was chosen so that nucleotides that played an important role in the binding site could be recognized as being conserved, while unimportant positions would vary extensively. Moreover, it was hoped that interacting bases could be recognized by covariation. The synthetic DNA template was amplified by PCR and then used to generate an RNA pool by in vitro transcription with T7 RNA polymerase. Selection was carried out by purification of RNA protein complexes on nitrocellulose filters. Bound RNA was eluted and amplified by reverse transcription to generate cDNA, followed by PCR amplification of the DNA and T7 transcription to regenerate an RNA pool. In order to measure the average affinity of the pool RNA for Rev, relative to the wild type binding sequence, a limiting amount of Rev was incubated with an excess of a mixture of pool RNA and a shorter wild type RNA. The partitioning of Rev protein between the two RNAs showed that the final selected pool (generated by three rounds of selection and amplification) actually bound Rev three times better than the wild-type RNA and 460 times better than the initial degenerate pool.

Cloning of 31 sequences from the final pool gave 18 monoclonal RNAs that bound as well or better to Rev than wild type RNA. One sequence showed 10 times better binding than the wild type. All of the conserved bases were found in two segments (U45 to G53 and C65 to A75). These segments represent the core of the Rev binding site; they pair with each other to form a stem-bulge-stem secondary structure (Scheme 4).



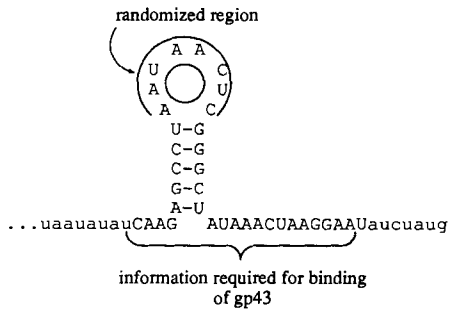
Scheme 4. Secondary structure of the 66 nucleotide long Rev responsive element, as determined by comparative sequence analysis of selected Rev binding RNAs. The boxed area shows the binding motif for the Rev recognition. The G:G base pair is indicated by the circles.

Seven out of the ten bases in the bulged region are highly conserved, indicating essential RNA–RNA or RNA–protein contacts. Further analysis of covariation G48 and G71 suggested that the formation of a nonstandard G48:G71 base pair was very important for Rev recognition. A single G → A substitution in either one of these positions dramatically reduces Rev binding, whereas the A:A double mutation fully

restores binding. This result leads to the conclusion that the bases of the base pair are not recognized by Rev directly. Although A:A and G:G are able to form isosteric base pairs,[24] they are completely different in the geometry of accessible hydrogen-bond donors and acceptors. Presumably, the geometry of the sugar–phosphate backbone is changed by the purine:purine pair and this change—or one of its consequences—is recognized by Rev.

3.2.2. Variation of the RNA Binding Sequence of T4 DNA Polymerase

The DNA polymerase of bacteriophage T4 (gp43) binds to a 36 nt sequence within its own mRNA and represses its own translation.[25a] Part of this region is a helix of five base pairs closed by a loop of eight nucleotides[26] (Scheme 5).



Scheme 5. The 36 nucleotide long RNA binding site for the T4 DNA polymerase (gp 43). In the stem-loop structure shown here eight nucleotides of the loop were randomized.

In order to determine the roles of the loop bases in DNA–polymerase binding, Tuerk and Gold randomized the 8 nt wild-type sequence of the loop and selected for functional sequences.[25b]
