Optically Anomalous Crystals

By Bart Kahr* and J. Michael McBride*

The optical symmetry of many crystals is lower than would be expected from their external form and X-ray diffraction data. Recently such *optical anomalies* have been attributed to nonequilibrium structures resulting from kinetically controlled crystal growth. Impurities are incorporated to different extents at various surface sites that would otherwise have become symmetry-related within the bulk crystal. After their discovery by Brewster in 1815, optically anomalous crystals were the subject of lively debate throughout the 19th century among some of the most distinguished contributors to the development of crystallography including Biot, Berzelius, Herschel, Mitscherlich, Frankenheim, Pasteur, Mallard, Klein, Groth, Wyrouboff, Barlow, Brauns, Rinne, Pockels, and Friedel. From a sea of wild speculation two conflicting postulates emerged: that the symmetric form resulted from accidental twinning of segments with lower symmetry, or that the optical peculiarities resulted from stress due to impurities or external perturbations. Neither postulate expresses the present view. Interest in this research waned at the turn of the century, and after 1917 no one pursued Tammann's alternative correct insight. The problem of anomalous double refraction attracted no attention for more than half a century until its recent solution. This review discusses both mineral and organic systems with particular emphasis on the phyllosilicate apophyllite and on 1,5-dichloro-2,3-dinitrobenzene. These nonequilibrium structures relate to questions of crystal order, crystal growth, molecular recognition, and the design of new materials. The review provides a reminder of the enduring value of the polarizing microscope as a research tool in chemistry.

1. Introduction

1.1. What is an Optically Anomalous Crystal?

In a literal sense any crystal whose optical properties deviate from expectation could be called optically anomalous. Descriptions of optical anomalies are scattered throughout the crystallographic literature. Examples from the work of David Brewster, a pioneer in crystal optics at the beginning of the 19th century, range from interference patterns associated with fluid inclusions in diamonds[1] to the variegated interference colors in some types of quartz.[2] However, a phenomenon that seems anomalous to one generation can seem commonplace to a succeeding generation with more sophisticated expectations. For example, some minerals were considered optically anomalous because their sequence of interference colors in convergent light does not follow Newton's scale of colors.[3] Such behavior is now assigned to variation of refractive index with wavelength in highly dispersive minerals.

The most common type of optical anomaly occurs when a crystal's optical symmetry is lower than its apparent structural symmetry, as established by measuring dimensions of the bulk crystal or by X-ray diffraction. Such cases have been

recognized for 175 years but have remained mysterious until quite recently. In this paper we use *optically anomalous* or *anomalous* to refer only to this type of crystal.

The optical symmetry of a crystal can be determined by measuring its refractive index tensor, which depends on its electric polarizability. Most crystals are biaxial (Fig. 1a); they have one direction of maximum polarizability and refractive index (***M***), and a perpendicular direction of minimum polarizability (***m***). Within the plane defined by ***M*** and

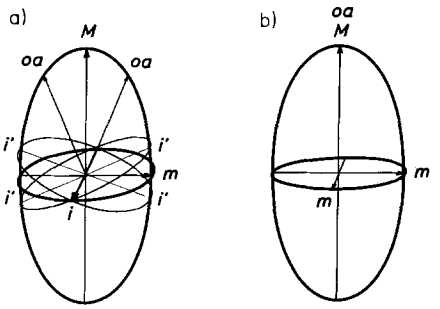

Fig. 1. Refractive index tensors (indicatrices) of a biaxial and a uniaxial crystal.

m there are four other directions (***i'***) whose intermediate polarizability matches that in the third orthogonal direction (***i***). Pairs of these directions together with ***i*** define a *circular section*, a plane within which the polarizability is constant in all directions. The normal to a circular section is called an *optic axis* (***oa***). Plane-polarized light can propagate along an optic axis without becoming elliptically polarized. A crystal is called biaxial when it has two circular sections and two optic axes.[4b]

Figure 1b shows an *axially symmetric* anisotropic crystal (a crystal with only one axis of three-, four-, or sixfold symmetry) in which one polarizability extremum (***M***) must lie along the axis, while the other two orthogonal axes are equivalent in polarizability (***m*** and ***m***). Such a crystal has a single optic axis, parallel to the symmetry axis, and is called *uniaxial*. Crystals with higher symmetry have the same polarizability in all directions and are called *isotropic*. By observing the passage of polarized light through a crystal with a polarizing microscope, or in favorable circumstances with the eye, it is possible to establish its symmetry as biaxial, uniaxial, or isotropic.[4a] When this symmetry is lower than that revealed by morphology or some other technique, the crystal is optically anomalous.

Anomalous crystals are usually twinned. They possess several distinct homogeneous regions, or *sectors*, whose number and relative orientation appear to be determined by the rotational symmetry of the crystal morphology. For example, a crystal with four- or sixfold symmetry should be uniaxial. Anomalous crystals with four- or sixfold morphological symmetry are typically composed of four or six biaxial segments, these being rotated from one another by 90° or 60°, respectively (see Fig. 2). Such twinning is called mimetic, because the composite crystal mimics a single crystal of higher symmetry and shows no reentrant angles between the constituent segments. Most of the hundreds of crystals described as optically anomalous in the literal sense fall into this specific class.

1.2. How Crystal Growth Causes Optical Anomalies

In 1988, while studying the growth of mixed crystals of fatty acid diacyl peroxides in this laboratory, Steven Bert-

Bart Kahr was born in New York City in 1961. He developed an interest in structural chemistry working with David Reingold at Middlebury College. At Princeton University he studied stereochemically unusual molecules with Kurt Mislow, obtaining a PhD degree in 1988. During graduate school he was fortunate to have shared a laboratory with Jeffrey Chance. After two years of crystallographic research in J. M. McBride's laboratory at Yale University, he joined the faculty of Purdue University as Assistant Professor of Chemistry.

Michael McBride was born in Lima, Ohio, in 1940. After undergraduate work at the College of Wooster and Harvard College, he earned the Ph.D. for research on free radical chemistry under Paul D. Bartlett at Harvard University. Since 1966 he has been on the faculty of Yale University. His research on organic solids has emphasized spectroscopic studies of free radical reactions in single crystals and the relationship among molecular structure, reactivity, and the mechanical properties of organic solids. He has an active interest in the history of organic chemistry. In 1987 he shared the Nobel Laureate Signature Award for Graduate Education with his student M. D. Hollingsworth. In 1990 he was Jacob and Erna Michael Visiting Professor at the Weizmann Institute of Science.

man recognized an optically anomalous crystal.[5] Square plates of pure di-11-bromoundecanoyl peroxide have true fourfold symmetry and are thus uniaxial. Inclusion of 5–15% of structurally analogous molecules of an impurity also gave square plates, but examination of these mixed crystals with the polarizing microscope showed that they were mimetic twins. Typical crystals were divided diagonally into four biaxial sectors interrelated by 90° rotation (Fig. 2). X-ray diffraction of single sectors showed that the fourfold symmetry had been broken. We attributed this desymmetrization to selective incorporation of impurity molecules among otherwise symmetry-related sites of the host lattice.

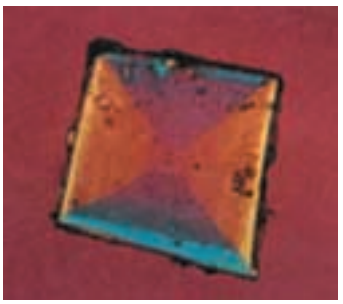

Fig. 2. Sectoring in a mixed crystal of di-11-bromoundecanoyl peroxide containing 15% of the analogue in which one terminal bromine atom is replaced by hydrogen; viewed along [001] between crossed polarizers with first-order red retarder (γ at 45°) [5]. Change in color from one growth sector to the next is due to a difference in orientation of the monobrominated compound caused by kinetic control of molecular addition to the lateral faces. (This same crystal was illustrated in [5], where the impurity was incorrectly identified as having one terminal bromine replaced by a *methyl* group. The effect of the impurity is nearly the same whether bromine is replaced by hydrogen or methyl.)

We were delighted by the prospect of using crystal optics to study this subtle aspect of crystal growth. But we were not surprised by the selectivity, because we had been attempting to apply to our crystals the elegant techniques of Addadi, Lahav, Leiserowitz, and their collaborators, whose comprehensive studies have revealed and exploited analogous selectivity in less symmetrical systems.[6]

It is easy to imagine that enantiomorphous lattice sites should be differently populated by a resolved chiral impurity, since the two kinds of defects must have different energies. It may at first seem surprising that impurity populations should also differ among sites related by a proper symmetry element, such as rotation. Such defects have identical energies, and thermodynamics requires their concentrations to be equivalent in a dilute solid solution at equilibrium. However most real crystals, especially those of solid solutions, are *not* at equilibrium. Once a molecule becomes incorporated into the crystal lattice, it is usually difficult for it to undergo a dramatic change in position or orientation. Thus many structural features of real crystals are controlled by the kinetics of growth rather than by equilibrium thermodynamics. To understand selective population one must recognize that growth occurs at the crystal surface and that most crystal faces lack the full symmetry of the three-dimensional lattice. For example, crystallographic axes are defined near a crystal face only when they are perpendicular to the surface; and even then the face must be flat and free of growth steps. Sites that should ultimately become equivalent by space group symmetry are thus different in structure and energy at the time impurities chose whether or not to occupy them.[7] Sectors of a crystal that have grown through different faces should have different impurity distributions and different optical properties, as illustrated in Section 2.3.2. When two crystal faces are related by symmetry, impurity distributions in the corresponding crystal sectors, resulting from growth through the two faces, should be related by the same symmetry.

After observing the optical anomaly in organic peroxides, we searched the literature for reports of analogous phenomena. We discovered that, although current texts give them little attention, descriptions were common in the 19th century when optical microscopy was the most powerful method of crystallographic analysis. Unsuccessful attempts to resolve these anomalies, which were observed in a wide variety of organic and inorganic crystals, form a consistent thread that parallels the development of crystallography generally. The present understanding of optical anomalies has emerged only over the last dozen years.

Section 2 of this paper outlines the history of the study of optically anomalous crystals within the context of the history of crystallography in the 19th and early 20th centuries. The mineral apophyllite is illustrated specifically. Section 3 discusses the present status of optical anomalies in inorganic and organic systems. Section 4 describes their relevance to current research on molecular recognition, on the kinetics and mechanism of crystal growth, and on rational approaches to designing crystalline materials for technical applications.

2. The History of Optical Anomalies

2.1. Crystal Classification according to Form

The mature development of any science requires a coherent classification of the objects under study. Thus progress in crystallography[8, 9] required classification of crystals. Crystals may be classified according to their external morphology, their physical and chemical properties, or their internal structure. All sorts of information may be relevant: shape, cleavage, chemical composition, color, hardness, density, refractive index, phase transition temperatures, space group symmetry, atomic positions, and many others.

Because the outstanding macroscopic feature of mineral samples is their polyhedral shape, attempts to classify crystals according to form trace back at least to the work of Nicolaus Steno (1638–1687),[10] who articulated a form of the Law of the Constancy of Interfacial Angles.[11] Maurice Cappeller (1685–1769) extended Steno's emphasis on form for the purpose of identification.[12] As in this botanical work, Carolus Linnaeus (1707–1778) sought to classify minerals within a system of genera.[13] Form was the most important organizing principle in his system. In an early attempt to approach the question of internal structure, A. G. Werner (1750–1817) sought a small group of *primary forms* to which the vast array of possible crystal shapes might be referred.[14]

Not everyone agreed that form should be the primary consideration in crystal classification. Romé de l'Isle (1736–1790) thought that form should be supplemented by chemi-

cal analysis, because shape alone was neither unique nor unambiguous. Not only can a single polymorph of a given chemical substance with a particular unit cell structure appear in many different shapes or *habits*, but also different substances can appear as isomorphs displaying the same form.[15] Through his Law of Rational Intercepts René Just Haüy (1743–1822) could relate the various shapes of a given polymorph by showing that crystal faces can be described by small integral indices when referred to three vectors. He further sought by successive cleavages to discover the unique building block, or *molécule intégrante*, for polymorphic crystals.[16] But Haüy sought idealized relationships among a crystal's dimensions and neglected precise goniometry (the quantitative measurement of form) when the results did not agree with his theory.[17] The limitations of his method were emphasized after Wollaston (1766–1828) invented the reflecting goniometer.[18] At the start of the 19th century it was clear that crystallography was in need of a physical method, independent of the measurement of form, that could assist in classification by confirming at least some of the qualitative aspects of crystal symmetry.[19]

2.2. Optical Classification of Crystals

The development of the science of crystal optics in the 19th century revealed the utility of birefringence in crystal classification. The first observation of birefringence or double refraction was reported by Erasmus Bartholinus (1625–1698), who noticed that within a crystal of calcite a single ray of light was split into two.[20] Christian Huygens (1629–1695) realized that one of these rays obeyed the ordinary law of refraction while the other did not and was always contained within a plane defined by the direction of incidence and a special axis, the direction of high rotational symmetry in the rhombohedral crystal.[21] Haüy, undoubtedly because of his own researches with calcite, undertook studies of double refraction and noticed that crystals of other substances with the form of a cube or octahedron lacked this property. Finally Johann Jacob Bernhardi (1774–1850) suggested explicitly that double refraction was directly related to a crystal's form.[22] However only two optical classes were distinguished at this time: crystals that were birefringent and those that were not. There was as yet no distinction between uniaxial and biaxial birefringent crystals.

In 1808 Etienne Malus (1775–1812), while examining a crystal of calcite in sunlight reflected from the windows of the Palais Luxembourg, noticed that the intensity of the two rays varied as a function of the crystal's orientation.[23, 24] He correctly recognized this as the phenomenon of polarization.[25] His discovery that the rays had different polarization greatly assisted studies of doubly refracting minerals, because researchers were no longer restricted to examining large, strongly birefringent crystals in which divergence of the two rays was readily visible.

In 1811 François Arago (1786–1853) discovered that brilliant colors sometimes are produced when a crystal is examined between two polarizers.[26] Immediately after Arago's discovery David Brewster (1781–1868)[27] and Jean-Baptiste Biot (1774–1862)[28] recognized the colors as a signature of *weak* birefringence and began systematic explorations of a wide variety of crystals and biological specimens.[29] Independently they distinguished between uniaxial and biaxial birefringent crystals. They also discerned the connection to morphology, since well formed uniaxial crystals always had three-, four-, or sixfold rotational symmetry.

This new method of analysis inspired Brewster to challenge Haüy's assignments of primive forms to eleven mineral substances[30] and to write:

> "If the physiology of mineral bodies shall ever attain the dignity of a science, its foundations must be laid upon optical results, and its progress directed by the unerring light of optical analysis."[31]

> "If we take a crystal... bounded by six equal square faces, the crystallographer will content himself with calling it a *cube*, but the optical mineralogist will only call it a *cube* when it has *no double refraction*."[30]

The optical classification of crystals as isotropic, biaxial, or uniaxial by Brewster[32] and Biot[33] in the second decade of the 19th century is still valid. One may further assign a biaxial crystal to one of three classes, where both, one, or neither of the directions of maximum and minimum polarizability are fixed by symmetry. This may be accomplished optically because principal directions that are not fixed by symmetry will in general differ for light of different wavelength.[34]

2.3. The First Observations of Optical Anomalies[35b]

2.3.1. *Brewster's Initial Report*

As Brewster was developing his optical classification scheme, he discovered several minerals that appeared to be exceptions and chose to treat them separately. In 1815 he announced to the Royal Society of Edinburgh:

> "Philosophers will no doubt be surprised to learn, that *muriate of soda, fluate of lime,*[*] *the Diamond, Alum* [despite their high symmetry][**] have actually the property of Double Refraction, but under circumstances of such a singular kind, as to entitle them to be regarded as a new class of doubly refracting crystals."[36]

He then described optically anomalous crystals of fluorspar (CaF_2, Fig. 3). To observe the indistinct low-order interference effects of a fluorspar crystal more clearly, he supplemented its birefringence by laying it on a plate of calcium sulfate which by itself between crossed calcite polarizers gave "a *brilliant blue* colour of the second order on Newton's scale." He was surprised to observe that

> "when the cube of fluor-spar remained stationary, there was one portion of it at *m*, which made the *blue* colour [of the $CaSO_4$] *red*... while another portion, at *n*, made the *blue* colour *green*."

[*] sodium chloride, calcium fluorosilicate

[**] Square brackets in quotations indicate interpolations by the authors.

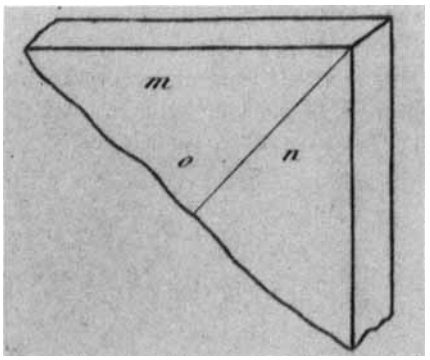

Fig. 3. Brewster's first illustration of an optically anomalous crystal (1815); when superimposed on a calcite crystal that gave a blue interference color, sectors *m* and *n* at the corner of the fluorspar crystal appear red and green, respectively [29].

In this first report of an optical anomaly, the cubic crystal was not only birefringent, it was not even homogeneous, but rather divided into sectors like those of the peroxide crystals (Fig. 2). Brewster speculated that the anomaly had probably originated during crystal growth:

> "If the laws which regulate the crystallisation of these minerals had been allowed an undisturbed operation, it is probable that the crystals would have had a perfect cube or an octahedron for their primitive form, and would have exhibited none of the phenomena of double refraction."

Brewster clearly understood that such optical properties imply a reduction from the symmetry of the crystal form. But he was in no position to identify the nature of the irregularities of growth which produce the deviations. During the next decade Brewster studied other optically anomalous minerals including chabazite,[37] garnet,[38] topaz,[39] and apophyllite.

2.3.2. *Apophyllite*

2.3.2.1. *The Structural Basis for the Optical Anomaly of Apophyllite*

It is worth interrupting the chronological narrative to describe apophyllite in greater detail, because its optical anomalies have been debated from Brewster's time until the present, and understanding these anomalies will help to focus the historical discussion.

Apophyllite is a silicate, empirical formula $KCa_4Si_8O_{20}F \cdot 8\,H_2O$, formed by hydrothermal recrystallization within cavities in rocks derived from lava.[40] The name (Greek: formed of leaves) reflects its ready cleavage perpendicular to the fourfold symmetry axis and its separation into layers on heating. The cleavage is consistent with the sheet structure revealed in 1931 by the X-ray study of Taylor and Náray-Szabó.[41, 42]

Silicate units form the covalent sheet shown in Figure 4. Each Si atom shares three oxygens with neighbors and is connected to a fourth, negatively charged oxygen by a bond that is roughly perpendicular to the sheet. Four silicate units make up a ring surrounding the crystallographic fourfold rotation axis that is perpendicular to the sheet, so that all four "axial" oxygens point toward the same side of the sheet. Axial oxygens of neighboring rings point toward the other side of the sheet.

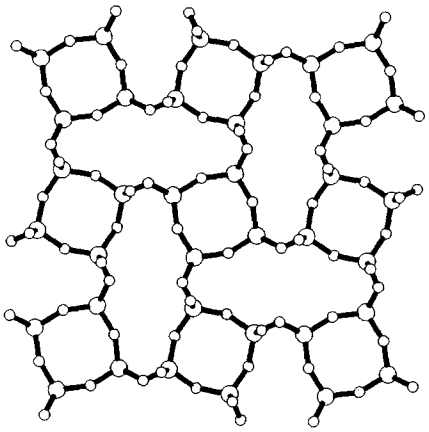

Fig. 4. Silicate units forming a covalent sheet in apophyllite, viewed along [001]. Axial oxygens of the rings in the center and corners of this figure point away from the viewer; those on the other four rings point toward the viewer.

Adjacent sheets are related by mirror symmetry (Fig. 5). Between silicate rings whose axial bonds point toward the mirror is a slightly flattened cube of negative oxygens; between those silicate rings whose axial oxygens point away from this mirror is a roughly spherical void with a diameter of about 8.5 Å. The void accommodates a potassium ion

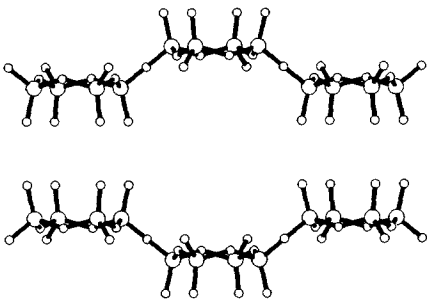

Fig. 5. Adjacent, mirror-related silicate sheets in apophyllite, viewed along [100].

solvated by eight waters, and each cube of negative oxygens holds a square of four calcium ions surrounding a fluoride ion (Fig. 6). Potassium, calcium, and fluoride all lie on the mirror plane between silicate sheets.

As an apophyllite crystal grows, impurities from the hydrothermal medium can be incorporated into its lattice. Some possible substitutions are OH^- for F^- (hydroxyapophyllite), Na^+ for K^+ (natroapophyllite), Mg^{2+} for Ca^{2+}, and Al^{3+} for Si^{4+}.[43] Substitution for F or K does not disturb the local fourfold symmetry, since each lies on a fourfold axis,[44] but substitution for Ca or Si breaks the local symmetry. If growth occurs through a crystal face where a bias consistently inhibits substitution in some of the "symmetry-related" silicon (or calcium) sites, the fourfold

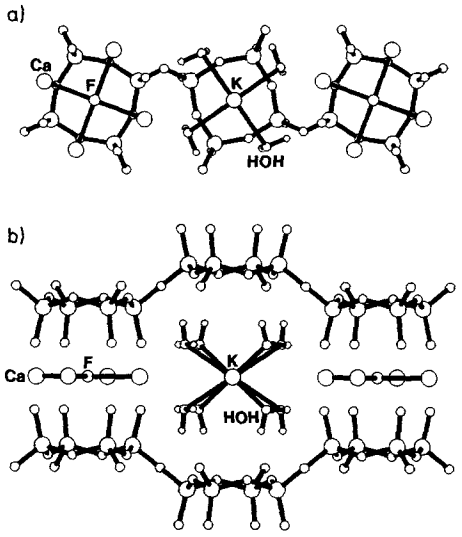

Fig. 6. View of the silicate sheets of apophyllite showing the positions of the water molecules and potassium, calcium, and fluoride ions between them: a) from the top along [001] and b) from the side along [100].

axis would disappear and the corresponding growth sector would be biaxial and optically anomalous.

Idealized patterns for thin sections cleaved perpendicular to the fourfold axis of optically anomalous apophyllite crystals are illustrated in Figure 7. They can be rationalized in

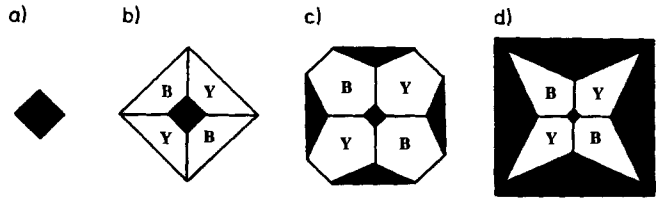

Fig. 7. Idealized patterns in thin sections of an apophyllite crystal (see Fig. 8) successively cleaved perpendicular to its fourfold axis and viewed with a first-order red retarder. Uniaxial sectors appear red (shown as black), biaxial sectors appear blue (B) or yellow (Y). For detailed explanation, see text.

terms of the growth of the crystal shown in Figure 8. The crystal displays three forms, or sets of symmetry related faces (Fig. 8a): two small square {001} or *basal* faces at the top and bottom, four hexagonal {110} or *prism* faces around the middle, and eight pentagonal {101} or *pyramid* faces between the basal and prism faces. Behind each face is a sector of the crystal that grew by deposition of material through that face. Figures 8b–d show the smaller crystal from which the crystal of Figure 8a grew, and the three classes of sectors that were involved in the growth. Figure 8b shows the two basal sectors, Figure 8c the four prism sectors, and Figure 8d the eight pyramid sectors. In indicating colors in Figure 7 we have assumed that when impurities are incorporated through the basal and prism faces they are not selectively ordered in a way that breaks the fourfold symmetry, but that those incorporated through a pyramid face are ordered so that the sector becomes biaxial, with axes oriented relative to the particular growth face. Thus when viewed through a polarizing microscope with a first-order red retarder, material from the uniaxial basal and prism sectors (Fig. 8b,c) appears red, while that from the biaxial pyramid sectors (Fig. 8d) is either yellow or blue.

The section of Figure 7a came from the very top of the crystal in Figure 8a, and thus includes only material from the uniaxial basal sector. Section 7b came lower in the crystal, so

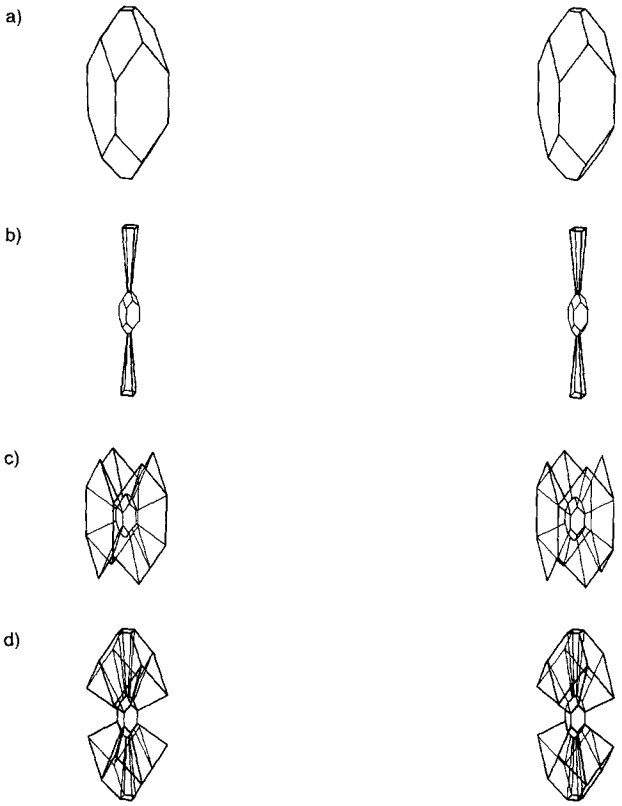

Fig. 8. Stereo views of a typical optically anomalous apophyllite crystal. a) The three sets of symmetry-related faces: two *basal* faces at the top and bottom, four *prism* faces around the middle, and eight *pyramid* faces between the basal and prism faces. b)–d) The smaller crystal from which the crystal of a) grew, and the three classes of sectors that were involved in the growth: b) basal sectors, c) prism sectors, d) pyramid sectors.

a somewhat smaller basal square is surrounded by trapezoidal portions from the four adjacent biaxial pyramid sectors. The octagonal section 7c came lower still so that it intersected both pyramid and prism faces. Thus the small central square is surrounded by hexagonal portions from pyramid sectors while the horizontal and vertical edges include triangular portions of uniaxial prism sectors. Section 7d originated so low in the crystal that it intersected only prism faces. The border is all material from uniaxial prism deposition. The center is a small square from the uniaxial basal sector which is surrounded by portions of four biaxial pyramid sectors.

2.3.2.2. *Brewster and Apophyllite*

Sir David Brewster (Fig. 9), whose name is recalled in Brewster's angle, made many contributions to mineralogy, crystallography, and physical optics.[45] Besides inventing the lenticular stereoscope and the kaleidoscope, he became the first to suggest that spectroscopy be used for chemical

Fig. 9. David Brewster (1781–1868), a pioneer in the development of optics [45], first observed anomalous birefringence in crystals and speculated with keen insight on its origin.

analysis when, after observing that certain lines are removed from the solar spectrum when the light passes through NO_2 gas, he wrote of

> "a general principle of chemical analysis in which simple and compound bodies might be characterized by their action on definite parts of the spectrum."[46]

Brewster, who made so many fundamental scientific contributions, underlined the importance he assigned to his work on the optical anomaly of apophyllite in a striking, if indirect way. Since he held no academic appointment until his 56th year, he was forced to rely on editing and voluminous writing to support his family. In 1819 he launched a new enterprise by founding *The Edinburgh Philosophical Journal*. For the very first paper in this journal Brewster chose his own contribution *On a New Optical and Mineralogical structure exhibited in certain specimens of Apophyllite and other minerals*.[47]

Upon examining slices of apophyllite crystals cut normal to the unique axis of a tetragonal prism Brewster observed figures resembling "tesselated pavements" in which the presumed uniaxial crystal was actually composed of discrete biaxial tiles (Fig. 10a). "The interior conformation of Apophyllite," he conjectured, "presents us with the new fact in crystallography, that a regular crystalline form arises from the union of smaller crystals whose homologous sides are not parallel to each other... The tessellated structure which is possessed by [these crystals] is a property so singular and so distinctive, that I would propose to mark it by the name of *Tesselite*."

In 1821 Brewster published a more detailed *Account of a Remarkable Structure in Apophyllite, with Observations on the Optical Peculiarities of that Mineral*,[48] in which he even used hand-colored plates to illustrate the sectoring. He described new specimens of anomalous apophyllite and drew remarkably prescient conclusions regarding the growth of these unusual objects. It seemed to him that crystal growth by orderly aggregation of identical minute particles must create a body that is

> "homogeneous throughout, possessing the same mechanical and physical properties in all parallel directions... The tessellated Apophyllite, however, could not have been formed by this process. It resembles more a work of art, in which the artist has varied, not only the materials, but the laws of their combination ... The boundaries of these corresponding, though distant zones, are marked with the greatest precision, and all their parts as nicely adjusted, as if some skilful workman had selected the materials, measured the spaces they were to occupy, and finally, combined them into the finest specimen of natural Mosaic."

He went further to emphasize that ordinary twinned crystals

> "...and those compound groups which arise from the mutual penetration of crystals, are merely accidental deviations from particular laws, which govern the crystalliza-

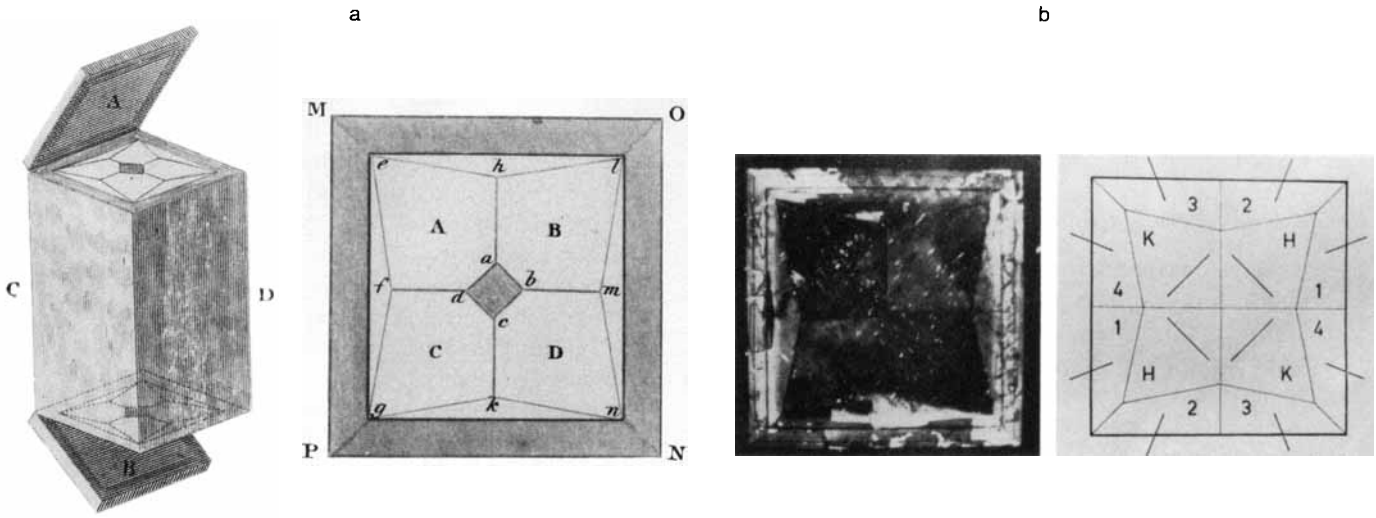

Fig. 10. a) The drawing of Brewster's apophyllite shows on the left a thin section being removed from a square prism, and on the right a projection of that slice revealing nine optically discrete tiles [48]. b) Photomicrograph and diagram of a similar apophyllite section reported in 1965 by Sahama, who attributed the optical inhomogeneities to "penetration twinning" [155].

tions in which they occur... The compound structure of the Apophyllite, however, cannot be referred to these capricious formations. It is itself the result of a general law, to which there are no exceptions, and when more deeply studied, and better understood, it must ultimately lead to the introduction of some new principle of organisation, of which crystallographers have at present no conception."

Brewster was almost correct when he supposed that tesselite must have been assembled in concentric stages (first a uniaxial core, then surrounding biaxial tiles, and finally a uniaxial border), but he was unable to suggest the "new principle of organisation" that could rationalize this sequence of events.

2.3.3. *Berzelius's Chemical Analysis*

Since there might have been a chemical difference between tesselites and other apophyllites, Brewster asked Jöns Jakob Berzelius (1779–1848) to compare their chemical compositions. Not only was Berzelius Europe's leading analytical chemist, he had also been the first scientist to propose a chemical classification of minerals.[49] He recognized silica as capable of forming a "negative" constituent and identified the Silicates, of which apophyllite was an example, as those minerals that contained it.[50] In 1822 Berzelius reported that analyses of anomalous and normal apophyllites agreed for every component within 0.3% (Fig. 11) and he added:[51]

"Differences of this kind, however great be the influence which they exercise upon light, can never constitute differences of species in mineralogy, differences which can only be founded on a real diversity of composition."

4 M. Berzelius *on the Chemical Composition of*

By reducing the Fluo-silicate of Lime into its elements, we obtain

	Tesselite.	Apophyllite of Uto.	Old Method.

Fluoric Acid, -	0.84	0.82	...
Water, - -	16.20	16.20	16.20
	99.47	99.13	99.38

Fig. 11. Analyses by which Berzelius established the chemical identity of Tesselite with apophyllite, as published in Brewster's journal [51].

This assertion drew a stern retort from Brewster:[52]

"Of the three methods of analysis, we conceive the crystallographic method [measuring crystal dimensions] to be the least perfect; the chemical method next to it; and the optical method decidedly superior to both... When the chemist determines that two bodies have the same ingredients, he is ignorant of the manner in which these ingredients are combined. If the analysis of a quadruped and a bird indicated the same elements, he could not discover that these elements formed hair and horn in the one, while in the other they displayed themselves in the finest plumage. The chemist, indeed must fail in detecting structures, because he commences his process by destroying them."

Thus long before chemists spoke of structure Brewster criticized the analyst's neglect of possible isomerism. Berzelius was not to not coin the word "isomer" for another eight years.[53] Insisting on the uniqueness of tesselite Brewster continued:

"It would be a strange abridgment of the privileges of the optical observer, if he were not permitted to designate by a new name a body which possesses one of the most remarkable structures that has ever come under the notice of the mineralogist."

2.3.4. *Biot's Initial Interpretation*

Brewster's work on optical anomalies went largely unnoticed.[54] The only contemporary comments on his observations came from the two other authorities on crystal optics, J. F. W. Herschel (1792–1871)[55] and J.-B. Biot (Fig. 12), a leading French physicist and crystallographer, whose name is recalled in the Biot and Biot-Savart Laws of electromagnetism.

Fig. 12. Jean-Baptiste Biot (1774–1862) attempted the first comprehensive explanation of optical anomalies in crystals with his *Mémoire sur la polarisation lamellaire* (1841) [59, 61]. This theory of Lamellar Polarization was popular but not successful.

Biot and Brewster were rivals of a sort. They exchanged visits and correspondence, referred to one another in writing in the most respectful terms, and tried to collaborate, but they seem to have been fundamentally incompatible. Representatives of nations recently at war, they had a number of common interests which put them at loggerheads, including the mental health of Isaac Newton.[56] Biot took a deep interest in Brewster's "new class of doubly refracting crystals." He attributed the optical anomalies that Brewster had "accidentally" observed to stress caused by rapid cooling or evaporation during crystal growth.[57] For support Biot cited Brewster's own observation that pressure could generate analogous birefringence in animal gelatin and glass (Fig. 13).

Brewster was offended that the fruit of his systematic studies should be termed "accidental" and responded:[36]

"Had M. Biot repeated the experiments to which he alludes... and compared the results with those produced by

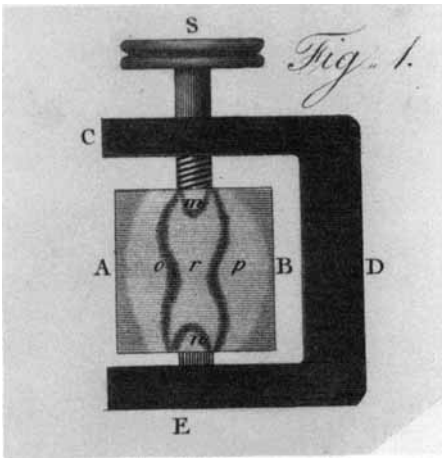

Fig. 13. A piece of glass rendered birefringent by pressure (Brewster, 1815) [81a]. The letters mark progressive changes in the interference colors between pressure points *m* and *n*. A, B = white; *o*, *p* = yellow; *r* is of higher order.

heat and rapid evaporation, he would have instantly seen that the two classes of phenomena are essentially distinct, and could not possibly have the same origin."

Brewster objected both because the birefringence was too strong to be explained plausibly by stress and because the sector boundaries were so regular. In his view some higher law must be at work. Much later Brewster wrote that he had convinced Biot, in a private communication, that the phenomenon was not due to extreme external conditions.[58]

2.4. Twinning Hypotheses

2.4.1. Biot's Lamellar Polarization

Biot undertook an extensive study of optical anomalies that culminated[59] in 1842 in what Brewster called an "elaborate Memoir peculiarly marked by the genius and sagacity of that distinguished philosopher."[60] Biot presented this theory of *polarisation lamellaire* in three lectures to the Academy of Sciences in Paris.[61] In fact lamellar polarization was not theory at all, but rather the hint of an analogy. He suggested that, if a stack of glass slides can impart plane polarization to transmitted light by repeated refraction, it would not be surprising if a stack of crystal lamellae could impart elliptical polarization. Thus a set of lamellae might possess birefringence that individual layers lacked. Biot's distinction between contributions due to the elementary molecular particles and contributions due to the macroscopic crystal structure was central to his theory.

The ready cleavage of apophyllite made it a natural candidate for Biot's analysis. He wrote:

"...aucune corps jusqu'ici connu ne s'est montré plus désespérant pour les cristallographes, ni plus riche en effects optiques pour les physiciens... Sans cette analyse intime et complète, le minéralogiste qui s'arrête aux formes ne connaît pas plus un cristal d'apophyllite, qu'on ne connaît une lettre par son enveloppe, un livre par sa couverture, un écrin par l'étui où il est renfermé... Tous les phénomènes optiques opérés par les diverses variétés de cristaux d'apophyllite résultent de la simultanéité des actions moléculaires... Les premiers dépendant de leur axe double réfraction unique... et les autres de l'existence des systèmes lamellaires..."[*]

Because of the optical complexity of some tesselite samples Biot began to invoke intricate systems of *hypothetical* lamellae, first in apophyllite and then in anomalous crystals of other minerals that showed no independent sign of layering. He proposed that the phenomenon provided a new structural tool:[62]

"Cette manière simple de pénétrer dans l'intime structure du cristal total, décèle une infinité d'accidents de pénétration que l'on ne soupçonnerait jamais par le seul aspect des faces externes."[**]

Biot observed that alum crystals containing ammonia were anomalous, and inferred from his theory that they must be layered. Brewster challenged this interpretation, because alum free of ammonia was optically normal. Since the two alums must be equally lamellar, Brewster reasoned, the double refraction must be due to an inherent property of ammonia and not to lamellar crystal structure.[63] Brewster asserted that despite Biot's ingenuity his lamellar structures were "scarcely to be reconciled with the principles of crystallography."[64]

During the 1820s neither Brewster nor Biot subscribed to the wave theory of light.[65b] Prior to its general acceptance sundry phenomena were explained by invoking new species of polarization.[25] Now defunct ideas of *chromatic polarization, alternate polarization,* and *proportionate polarization* proliferated in the early 19th century. *Mobile polarization* involving elaborate gyrations of the "luminous molecules" as they passed through crystals was another of Biot's bizarre inventions.[28, 66] Lamellar polarization was just such an ad hoc concept, and Biot made no attempt to put the analogy with polarization by a stack of glass slides on a theoretical foundation:[67]

"...je n'ai pas cru devoir taire ces analogies, si éloignées qu'elles pussent être... j'ai pensé qu'il n'était pas inutile d'indiquer les connexions... afin de les présenter aux théoriciens qui auraient l'habilete de les rendre plus intimes, si elles peuvent le devenir."[***]

No theoretician was equal to this challenge. Nevertheless, Biot's reputation and authority attracted the attention of many crystallographers to the problem of optically anomalous crystals. In 1846 a leading German crystallographer Eilhard Mitscherlich (1794–1863) assigned the optical

[*] ...no substance thus far known has been more exasperating for crystallographers, nor richer in optical effects for physicists... Without such an intimate and complete analysis the mineralogist who stops at forms would no more understand a crystal of apophyllite than one understands a letter by its envelope, a book by its cover, or a jewel by the box that contains it... All the optical phenomena... result from the simultaneity of molecular and nonmolecular effects... The former deriving from their unique axis of double refraction, and the others from the existence of lamellar systems...

[**] This simple way of penetrating into the intimate structure of a total crystal reveals an infinity of accidental penetrations that one would never suspect from the external aspect of the faces.

[***] I have not thought it appropriate to silence these analogies, however remote they might be [but rather to] present them to theoreticians who have the skill to make them closer, if possible.

anomaly of sodium chlorate to lamellar polarization and communicated his observations to Biot, who reported them to the French Academy of Sciences.[68] In 1848, the revolutionary year in which he demonstrated resolution of racemate salts in Biot's Collège de France laboratory, the young Louis Pasteur (1822–1895) published a note on sector twinning in crystals of potassium sulphate.[69] M. L. Frankenheim (1801–1869) in Breslau, an independent inventor of the theory of point lattices,[70] also adopted a version of Biot's theory.[71]

2.4.2. *Microscopic and Macroscopic Views*

Over the next thirty years most references to lamellar polarization were in the context of alternative explanations of optical anomalies. Most of the propositions were of two types, *stress theories* and *twinning theories*, each of them related in a way to Biot's thinking.[72]

Stress theories resembled Biot's theory in attributing birefringence to a macroscopic physical source, rather than to a molecular source, but they differed in assuming that the source was anisotropic mechanical stress in a solid continuum, rather than lamellar discontinuities. For example, in his 1855 Breslau habilitationsschrift Marbach suggested that whether or not a crystal was lamellar, its optical anomalies were due to tension as in stressed glass.[73] In a hybrid theory of 1852 Wertheim proposed that crystals without lamellar polarization can acquire it if pressure causes their irreversible separation into layers.[74]

Twinning theories resembled lamellar polarization in supposing that anomalous crystals were composed of many domains, but differed in attributing birefringence to reduced symmetry at the molecular level within each domain. The most successful of these, Mallard's theory of network twinning, is discussed in Section 2.4.3.

During the quarter century that followed Biot's hypothesis, optical anomalies were sometimes attributed to twinning, sometimes to stress. In the decade following the Franco–Prussian War, these views became doctrinaire and strongly polarized along national lines.

2.4.3. *Mallard's Network Twinning*

Perhaps no researcher in the 19th century did more to encourage the microscopic view of the internal structure of crystals than Auguste Bravais (1811–1863). His theory of the point lattices showed how crystals with different external forms might be composed of repetitively translated elemental units. This work inspired Ernest Mallard (1833–1894), Professor at the École supérieure des Mines (Fig. 14),[75] in his efforts to understand anomalous crystals.[76]

Mallard became spokesman for the French view of optical anomalies in 1876 by publishing a comprehensive theory in the *Annales des Mines* that relied heavily on the existence of Bravais lattices.[77] After rejecting lamellar polarization because it depended on a weak analogy and hypothetical crystal fissures,[78] he presented a theory based on a different kind of domain structure.

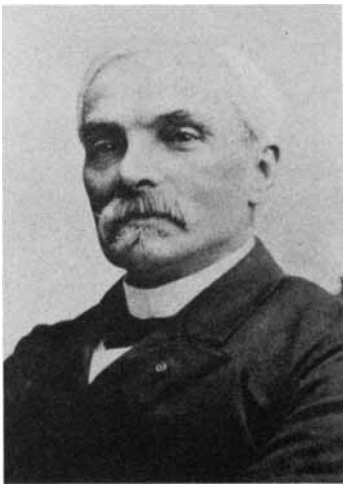

Fig. 14. Ernest Mallard (1833–1894) championed a "twinning model" in his 1876 treatise on anomalous birefringence [77]. Because it required the existence of hypothetical crystalline lamellae, it could be considered a successor to Biot's theory of Lamellar Polarization.

Mallard assumed that optical anomalies and a number of other peculiarities are due to isomorphism. When two different unsymmetrical "integrant molecules" accidentally have similar cell dimensions it is possible to mix them in a single lattice. In the same way, when a single unsymmetrical "integrant molecule" has dimensions that are close to those for a symmetrical cell, it is possible to align differently oriented biaxial domains into a twinned structure that mimics higher symmetry. In Mallard's view, symmetrical crystals can arise from the interpenetration of isomorphous space lattices which have little or nor symmetry. He applied his analysis to several dozen mineral substances with cubic, hexagonal, and tetragonal morphologies.

One of these minerals was apophyllite. More than half a century after Brewster's original report Mallard wrote:[79]

> "L'apophyllite est une des substances dont les propriétés optiques ont le plus excité l'étonnement. Signalées pour la première fois par Brewster, qui a particulièrement examiné les surprenantes figures... à la lumière polarisée parallèle... ces anomalies optiques n'ont reçu encore aucune explication satisfaisante."[*]

Mallard then argued that Brewster's tesselite was simply a twin made up of biaxial sectors. He rationalized the uniaxial regions of apophyllite in terms of accidental compensation of birefringence between interleaved submicroscopic lamellae in different orientations. Had Brewster still been living, he would surely have objected that this "explanation" avoided the fundamental problem: what kind of law determined the exquisite twinning pattern? The modern interpretation explains the pattern in terms of orientation at the crystal surfaces through which different sectors grew, and indeed Mallard noticed that differently oriented sectors in garnet were related to the external growth faces. But he provided no explanation for the mechanism of orientation, and no aspect of his theory endured.

[*] Apophyllite is one of the substances whose optical properties have aroused the most astonishment. Indicated first by Brewster, who examined particularly the surprising patterns... in parallel polarized light... these optical anomalies have still received no satisfactory explanation.

2.5. Stress Hypotheses

2.5.1. External Stress

Brewster had shown as early as 1814 that optically isotropic bodies, like glass and gelatin, become birefringent if stressed anisotropically by irregular heating[80] or compression.[81] A number of researchers assumed that stresses must account for the anomalous double refraction in regularly shaped crystals. Reusch, for example, proposed in 1867 that deposition on the surface of a growing crystal involved an intermediate state analogous to a colloid in that it would contract on solidification. This external stress from the crystal border could be the source of birefringence.[82]

From 1880 the various stress interpretations were dominant in Germany. Their principal exponents were Friedrich Klocke (1847–1884) and Carl Klein (1842–1907) (Fig. 15),[83] professors of mineralogy at the Universities of Marburg and Göttingen, respectively, and their students.

Fig. 15. Carl Klein (1842–1907) believed that external stresses resulting from catastrophic events in a crystal's history could account for anomalous birefringence.

Klocke followed the external stress interpretations of Marbach and Reusch[84] and showed the effects of anisotropic forces on the interference patterns of uniaxial crystals.[85] The stress hypothesis gained considerable impetus when Alfredo Ben-Saude, a student of Klein, allowed gelatins to dry rapidly in molds made in the shape of optically anomalous crystals (Fig. 16). Sections of the dried gelatins were birefringent and showed sectoring analogous to that of corresponding crystal sections.[86, 87] Ben-Saude assumed that rapid crystallization, like rapid drying of the gelatins, caused stress within the crystalline structure.

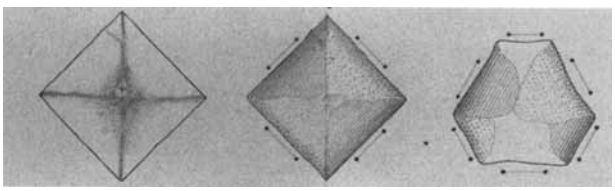

Fig. 16. Sections showing Ben-Saude's attempts to mimic anomalously birefringent crystals with rapidly dried, molded gelatin. Barbells in the center and right figures show indicatrix orientations in the different sectors as observed with crossed polarizers and a first-order red retarder [86].

Klein studied the effects of rapid heating and cooling on crystals, particularly the igneous minerals, boracite and leucite.[88] He subscribed to the theory that cataclysmic events in a crystal's history could account for the anomalies in many cases. As coeditor of the journal *Neues Jahrbuch für Mineralogie*, the principle forum for research on optical anomalies, Klein was an effective spokesman for this point of view, and was widely remembered as its leading proponent.[89]

Klocke, Klein, and Klein's student Friedrich Rinne (1863–1934) each studied and published on anomalous apophyllite. Like every predecessor except Brewster, each of them saw in apophyllite what he expected to see. Klocke[90] and Klein[91] both noted the relationship of the sectors to the external faces. The same relationship was used in Section 1.2 to support the modern view of sectoring by selective incorporation of impurities in apophyllite, but Klocke and Klein interpreted the relationship as evidence for stress exerted perpendicular to the growth faces. Rinne, noting that three different sectors participated in the same etch figure, inferred that they were not separated by the structural discontinuity that might have been expected from Mallard's twinning.[92]

2.5.2. Internal Stress Due to Impurities

Brewster's early speculation that the anomaly of apophyllite might be due to variation in its composition was refuted by the apophyllite analysis of Berzelius. In 1860 Leander Ditscheiner (1839–1903) revived interest in impurities when he suggested that optical properties could be adjusted over a wide range by averaging contributions from two isomorphous components in a mixed crystal.[93]

In 1882 Klocke encouraged his student Reinhard Brauns (1861–1931) (Fig. 17) to enter a university competition, which he won with a study of optically anomalous crystals.

Fig. 17. Reinhard Brauns (1861–1931) attributed anomalous birefringence to internal stress [112]. As a student in Marburg he launched his successful career in mineralogy by studying the role of impurities in this phenomenon.

Brauns continued this work and soon suggested that anomalous double refraction in some simple salts must be due to impurities.[94] Pure crystals of alum and barium nitrate were optically normal, but adding ammonium alum or lead nitrate, respectively, gave optically anomalous crystals. Since so many anomalous crystals were known to contain impurities, Brauns proposed that the cause of the anomalies could indeed be stress, but *internally* imposed stress resulting from a guest species acting upon the mismatched lattice of the host.

Klocke died suddenly in the summer of 1884 at the age of 37. Brauns continued the work in Marburg alone, developing his idea in a dissertation on optical anomalies in 1885,[95] and in a habilitationsschrift on the same subject two years later.[96] Although he focused on stress, in some ways Brauns's understanding of the relationship between impurities and optical anomalies by 1890 was quite similar to our present view:[97]

> "Die Spannungen entstehen durch den Eintritt der zwar isomorphen, aber doch chemisch und physikalisch etwas verschiedenen Substanz... Wenn wir uns vorstellen, dass bei dem Wachsen der Krystalle die Theilchen sich in Ebenen nach bestimmten Richtungen ablagern... so können wir hinzufügen: Die... auftretenden Kräfte ändern in den zu vorhandenen Krystallflächen gehörenden Anwachskegeln das optische Verhalten nach der geometrischen Symmetrie dieser Flächen."[*]

Our present view, like Ditscheiner's, assigns the optical effect to the direct contribution of an impurity rather than to its indirect mechanical influence on the host lattice. Ben-Saude, who showed that some mixed crystals with regular forms were optically normal, continued to favor the theory of external stress,[98] but Brauns faced a more serious challenge from France.

2.5.3. *Criticism of the Stress Hypothesis*

Stress as the explanation of crystal anomalies had been considered and rejected previously, when Brewster discounted Biot's suggestion in 1818.[36] Biot ultimately agreed and reported in his *Memoir on Lamellar Polarization*[59] that when he had shattered an anomalous crystal to relieve the hypothetical stress and reassembled the pieces, they produced the same anomalous effect on light as in the undamaged state.

Mallard published a rebuttal of the German interpretations in 1886.[99] He dismissed Klein's idea that anomalies are caused by rapid cooling, because the boundaries between sectors are sharp, and not gradual as in unannealed glass. He further contended that rapid cooling produces birefringence only in amorphous substances like glass and gelatin. Brauns quickly reported that birefringence is produced by sudden cooling of rock-salt crystals.[100] Mallard tried to dismiss Brauns's hypothesis involving isomorphous impurities by noting that many confirmed solid solutions are not optically anomalous.

Paul Groth (1843–1927) was atypical in Germany because he was inclined favorably toward Mallard's hypothesis.[101] His monumental *Physikalische Krystallographie* shows that he had a deeper appreciation of thermodynamic influence on crystal structure than his contemporaries.[102] Groth wondered how internal tensions could be the cause of the optical anomalies in simple salts grown from solution. He questioned the relevance of the gelatin experiments to crystalline materials because, in his view, any crystal must represent the most stable balance of forces among its constituent particles.[103]

Mallard's crowning achievement was his *Traité de cristallographie géométrique et physique*.[104] The first two volumes covered the geometrical and physical aspects of crystals. The third volume on crystalline assemblages would have addressed optical anomalies and answered his critics most fully. Although the manuscript had supposedly been completed, it was never found after the author's sudden death in 1894.[105]

2.6. The Golden Age of Optical Anomalies

2.6.1. *Explosion of Research on the Optical Anomalies*

The inauguration of Groth's *Zeitschrift für Krystallographie* in 1877 marked the emergence of crystallography as a mature science independent of geology.[106] Groth was concerned with the form and physical properties of all crystalline materials, mineral, organic, and synthetic, regardless of their origin. The *Mineralogical Magazine* was started by the Mineralogical Society of London in 1876. The *Bulletin de la Societé Minéralogique de France* first appeared in 1878, as did Gustav Tschermak's *Mineralogische und Petrographische Mittheilungen* from Vienna. These new journals were required to accommodate the rapid expansion in crystallographic research. Mallard's comprehensive theory was new and controversial, and the time was ripe to support or criticize his hypothesis. Reports of optical anomalies and speculations on their source blossomed about 1880. Figure 18

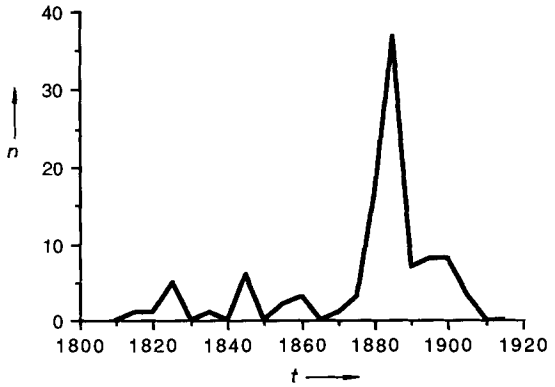

Fig. 18. The rise and fall of interst in research on optically anomalous crystals, based on the 99-reference bibliography of Johannsen (1919). n = number of citations, t = time in years.

[*] The stresses result from inclusion of a substance that is indeed isomorphous, but somewhat different chemically and physically... If we assume that during crystal growth the pieces are added in planes with given orientations... we can conclude [that the stresses will] alter the optical properties of growth sectors related to given crystal faces according to the geometrical symmetry of these faces.

plots the publication dates of the 99 significant papers on optical anomalies from 1815 to 1915 that were reviewed by Johannsen in 1918.[107] The steady stream of publication became a torrent in the 1880s, but it quickly shrank and disappeared about 1900.

The scientific significance of optical anomalies one hundred years ago is underlined by the professional stature of the principle researchers. From 1878 to 1892 six different active participants in the debate served as president of the French Mineralogical Society,[108] and all the principal crystallographic journals were edited by participants: Groth, Klein, Brauns, and Tschermak, as well as Rosenbusch, who edited *Neues Jahrbuch für Mineralogie, Geologie, und Paläontologie*.

2.6.2. Brauns's "Die Optischen Anomalien"

By 1890 the question of the cause and nature of optical anomalies had become so confused and contentious that, at the instance of Ferdinand Zirkel (1838–1912), professor of mineralogy at Leipzig,[109] the Fürstliche Jablonowski'schen Gesellschaft zu Leipzig[110] announced its competition[111] for

> "eine übersichtliche und kritische Zusammenstellung der auf die 'optischen Anomalien' der Krystalle bezüglichen bisherigen Forschungen, sowie die Ausführung neuer Untersuchungen, welche geeignet sind, die Ursachen jener anomalen Erscheinungen näher zu erläutern."[*]

The prize was awarded to Reinhard Brauns, now a privatdozent at Marburg, and his book, *Die Optischen Anomalien der Krystalle*, was published by the Society in 1891 (Fig. 19). This comprehensive 380-page monograph was an example of outstanding scholarship and served to launch Brauns's long and distinguished academic career that would include professorships in Karlsruhe, Kiel, Giessen, and Bonn.[112]

Although the book naturally represented Brauns's point of view, he discussed the contributions of others fully and for the most part fairly. For the title page he chose a motto from Goethe,[113] that evokes both the structure of anomalous crystals and the role he assumed as mediator:

> "Wo Parteien entstehen, hält Jeder sich hüben und drüben;
> Viele Jahre vergehn, eh' sie die Mitte vereint."[**]

He presented detailed discussions of some six dozen substances, most of which were anomalously birefringent crystals with optically discrete growth sectors (Fig. 20). In addition to apophyllite these included mixed crystals of barium nitrate and of alum as well as boracite, leucite, rock salt, garnet, analcime, chabasite, milarite, and pharmacosiderite. Brauns attributed most of these optical anomalies to internal stress resulting from inclusion of isomorphous impurities. But since many of the substances appeared to be pure, he did not insist that all optical anomalies conform to his model. He attributed many examples to external forces in the crystal's past history, such as mechanical compression, rapid cooling, or uneven heating. There were also categories for anomalies associated with solid–solid phase transitions, and for cases where no etiology could be identified.

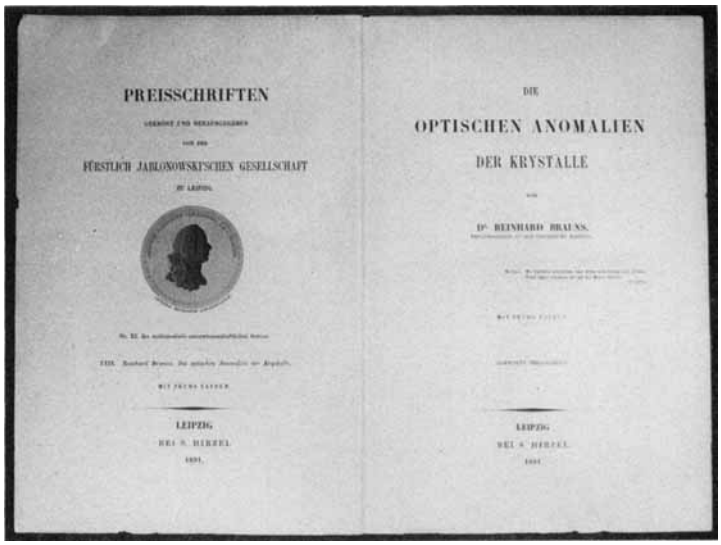

Fig. 19. Title page from Brauns's scholarly classic *Die Optische Anomalien der Krystalle* (1891). The book attempted, and for the most part succeeded, to present research on optically anomalous crystals as a closed subject [35a].

Notably absent was a category for network twinning. After discussing Mallard's hypothesis extensively, Brauns was emphatic in discarding it. He acknowledged that optical complexity could arise from differently oriented lamellae as in micas, but considered it fundamentally different from the sectoring produced by other mechanisms.[114] Despite this bias Brauns's book remains by far the most carefully reasoned, most objective, and most comprehensive source on the 19th century literature.

That Brauns had, for the first time, encapsulated all the experimental and theoretical observations on optical anomalies within a single volume may have given his work more authority than it merited. Subsequent writers frequently cited *Die Optischen Anomalien* as the definitive source,[115] and many of his assignments as to the cause of anomalous birefringence undoubtedly went unchallenged because of the impressive detail and scholarly excellence of the work.

2.6.3. Optically Anomalous Organic Crystals

Of all the anomalous crystals discussed by Brauns, only one was organic. This was strychnine sulfate hexahydrate, whose optical anomaly had been decribed in 1884 by Grigori Wyrouboff (1843–1913), a follower of Mallard in Paris,[116] then reinvestigated by Johannes Martin, a doctoral student of Klein[117] in Göttingen. Martin's dissertation was published in 1891,[118] the same year Brauns's text appeared. In addition to strychnine sulfate (Fig. 21) Martin described optical anomalies in pentaerythritol, benzil, and guanidinium carbonate. Two of these had also been discovered by Wyrouboff.

[*] a critical collection and overview of previous research related to the 'optical anomalies' of crystals as well as of the results of recent research which are appropriate to explain more fully the source of these anomalous phenomena.

[**] Where parties arise, each remains here or there;
Many years pass, before the middle unites them.

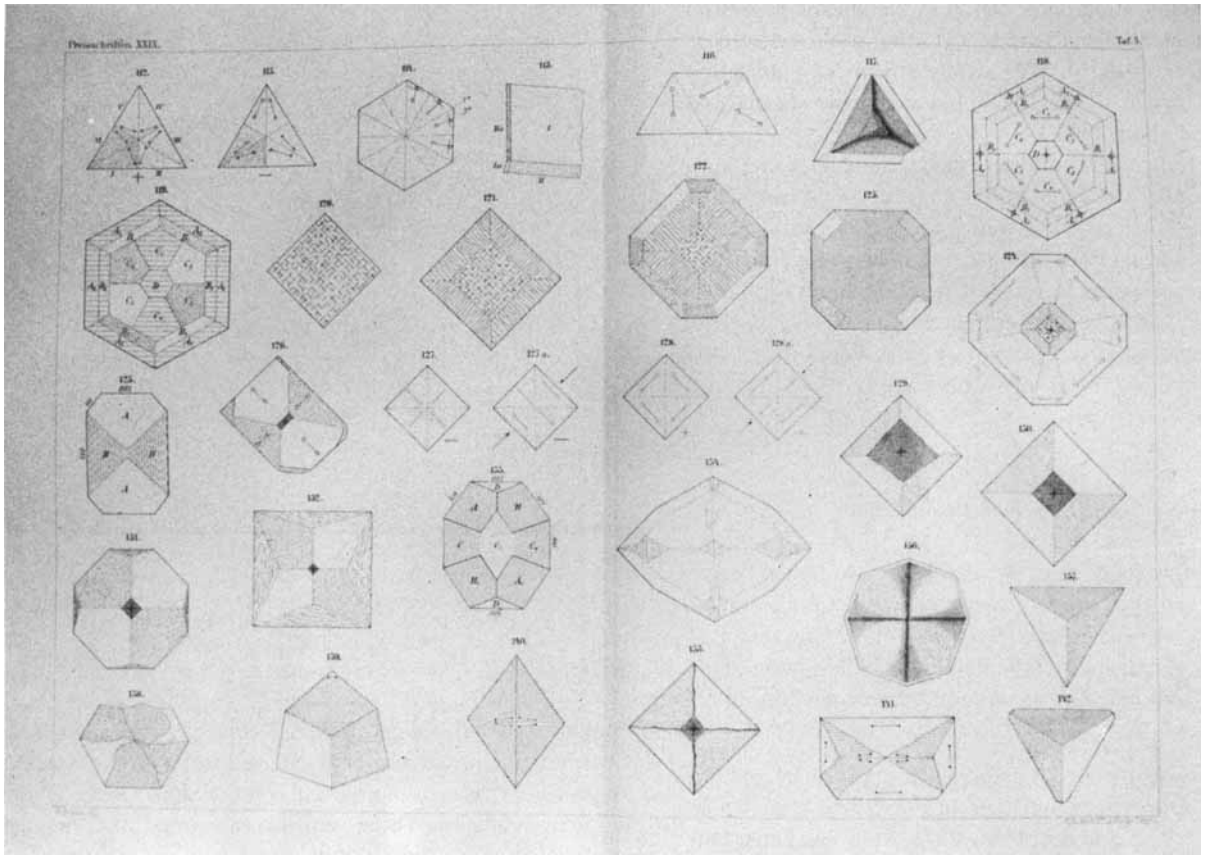

Fig. 20. Typical illustrations of optically anomalous minerals from Brauns's monograph [35a]. These figures, due among others to Mallard, Klein, and Brauns, show chabazite (112–115), apatite (116), diadelphite (117), corundum (118–119), vesuvianite (120–128a), apophyllite (129–132), an isomorphous solution of sodium ammonium sulfate and chromate (133), topaz (134), analcime (135–141), and eulytine (142).

Rejecting Mallard's theory, Martin was inclined toward the stress hypothesis, although he puzzled at how these ostensibly pure substances could give rise to the kind of optical anomaly that Brauns had attributed to solid solutions. To invoke external stress from drastic growth conditions seemed less appropriate for molecular crystals than for minerals. Martin suggested that the inherently isotropic particles were stressed by the "skeleton" of the crystal that had been previously laid down. Wyrouboff, who would later eulogize Mallard as the greatest philosopher of crystallography since Haüy,[106] excoriated Martin's dissertation, which he characterized as a stack of contradictory hypotheses.[119]

Other anomalous organic crystals were discovered at the end of the 19th century and will be discussed in Section 3.2.

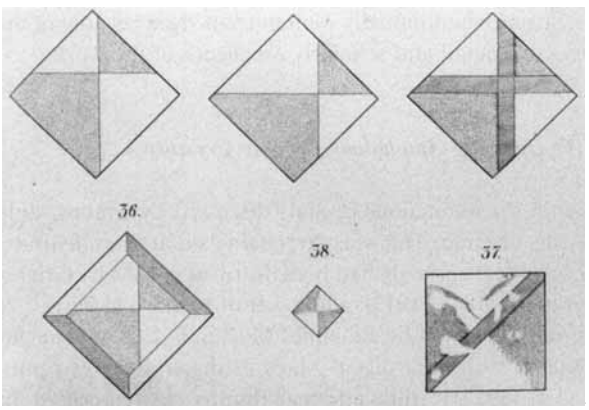

Fig. 21. Illustration from the dissertation of Johannes Martin showing sectored crystals of strychnine sulfate hexahydrate [118]. The complex pattern at the top right was interpreted as a superposition of the two layers with simple hour-glass figures on the left. The "picture-frame" pattern on the lower left has been observed for many substances (cf. Fig. 24c, 28c, d).

2.6.4. Why the Research Waned

By the early 20th century optical anomalies had ceased to be a field for active research, even though the simple modern interpretation described in Section 1.2 had not been considered. Crystallography and mineralogy texts continued to include a short section on optical anomalies, usually deferring to one or more of the accepted hypotheses. In the absence of active research, hypotheses became dogma, even though none of them really explained the facts.

There are at least four reasons for the demise of this line of research:

1. Mallard died in 1894, and his successors in France did not have the prestige or interest to continue the debate.
2. Brauns's monograph was seen as so authoritative that many researchers, particularly in Germany, incorrectly considered the question to be closed.
3. The scientific community became bored with the polemic. Already in 1887 a review had begun, "The never-failing discussion of the optical anomalies of crystals is contin-

ued by R. Brauns, who combats the assertion of Mallard ..."[120]

4. Interest in crystallographic research shifted away from bulk properties toward developing the kind of detailed structural model for crystals that had become so successful for molecules in organic chemistry.

2.7. Arrangement of Atoms within Crystals

Elaboration of the 230 space groups by Fedorov[121] and Schoenflies[122] in 1891 encouraged crystallographers to speculate in more detail about the internal structure of crystals. William Barlow (1845–1934), a self-taught crystallographer who would ultimately derive the space groups independently, tried to relate the external form of crystals to the symmetrical internal arrangement of their constituents.[123] Like other crystallographers since the days of Haüy, Barlow began by using spheres or other bodies to model crystal packing.[124] He ultimately realized that the variability of form reflected in the crystal kingdom could be more closely approximated by packing particles of different size. His close-packed models of dissimilar spheres agree remarkably well with modern models of simple binary salts.[125]

Barlow's 1897 treatment of the internal structure of crystals considered the problem of optical anomalies at length and relied heavily on the viewpoint of Brauns.[126] Like Brauns he believed that one class of optical anomalies derive somehow from solid–solid phase transitions that convert optically normal crystals into anomalous twins.[127] He also devised detailed geometric models that attempted to rationalize the contribution of isomorphous impurities to optical anomalies:[128]

> "Suppose that a linked group [of balls] has cubic symmetry, except that out of twenty-four outermost balls but twenty-two or twenty-three are similar and similarly situated, dissimilar balls making up the twenty-four and occupying places which are symmetrically situated, or nearly so; it is then conceivable that the closest-packing of a number of groups of this description may be one which disregards the slight irregularity and puts the groups together with their centres at the points of a cubic lattice, and with their predominating symmetrically arranged balls forming, as far as they go, a system in cubic symmetry.
>
> In a case of this kind the positions of the irregularities will not be symmetrically distributed; in other words the groups, when the deformities are taken into account, will be found variously orientated and the assemblage will not be strictly—i.e., mathematically—homogeneous, although, owing to the average effect of the deformities being the same in corresponding directions, the general symmetry will not be appreciably impaired."

Thus he visualized not only desymmetrization within each sector, but also the mimetic twinning of sectors that preserves the external morphology. He did not consider how the kinetics of crystal growth might make the desymmetrization systematic.

Writing in 1897 Barlow had little influence on the optical anomalies debate, which was already stale. However, optical anomalies were sufficiently common and considered sufficiently important that his new theory of the internal structure of crystals had to address them.

2.8. X-Ray Studies

X-rays, discovered in 1895, had been applied to crystal structure analysis by 1913. Speculation concerning the internal structure of crystals could now be tested directly. Within ten years optical crystallography had all but vanished as a subject for innovative research, and the problem of optical anomalies was swept aside by the rising tide of X-ray diffraction. In 1927 W. G. Burgers observed that because optical investigations "have led to different conceptions about the constitution [of certain anomalous samples], it is worthwhile to see how far X-rays are able to reveal the true nature of such crystals,"[129] suggesting that optical evidence may be ignored if it contradicts evidence from X-rays.

Apophyllite and other anomalous minerals were studied by X-rays in both Germany and France. By 1926 Friedrich Rinne, who as a student of Klein in Göttingen forty years earlier had studied apophyllite optically, was directing the Mineralogical Institute in Leipzig, where he transformed mineralogy "from a quaint determinative science to a modern branch of applied physics."[130] He was a pioneer in applying X-rays to mineralogy. His Laue photographs of apophyllite and other optically anomalous minerals showed no departure from the expected morphological symmetry (Fig. 22). For him this confirmed Klein's hypothesis that the anomalies were due to stress.[131]

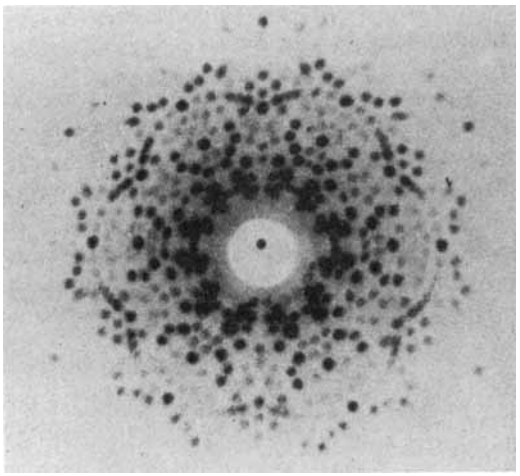

Fig. 22. Rinne's X-ray diffraction photograph of a single sector of optically anomalous milarite [131]. The density and resolution of such Laue photographs was inadequate to reveal small deviations from high symmetry.

In 1931, the year in which the atomic coordinates of apophyllite were first determined by X-ray diffraction,[41] Gossner and Kraus reported Laue photographs that seemed to confirm its tetragonal symmetry.[132] Gossner (1877–1937), a former student of Groth and his successor in Munich, surmised that because anomalous apophyllites have abnormal chemical composition, the substitution of impurities

such as hydroxide for fluoride must cause the anomalies by creating local stress, as Brauns had suggested.

In his 1934 dissertation Raymond Hocart in Strasbourg wrote the last word in a controversy that had lasted sixty years and would soon be forgotten.[133] His research on optically anomalous minerals had been suggested by his adviser, the late Georges Friedel (1865–1933). In addition to formulating Friedel's Law, Hocart's teacher had made his life's work the study of twinned crystals that he had begun in Paris as a student of Mallard. Hocart's historical survey recalled criticisms of stress theories, such as the incompatibility between the existence of distinct birefringent sectors and the continuity of internal stress (Mallard), and the observation of Friedrich Pockels (1865–1913) that certain crystals fracture under considerably less pressure than would be required to generate their observed birefringence.[134] Hocart also noted[135] that

> "Rinne s'efforce de justifier la sensibilité médiocre de cette méthode en rapportant l'altération des propriétés optiques à une déformation des atomes; cette déformation est inaccessible aux rayons X."[*]

After reporting his own much more precise X-ray work Hocart concluded,[136]

> "...la théorie du mimétisme proposée par Mallard s'applique à un certain nombre de cas; dans les mêmes cas la théorie dite des tensions intérieures n'est d'aucun secours pour expliquer les faits connus... Si le cas de l'apophyllite est insuffisamment élucidé, il n'en est pas moins établi que dans les autres exemples cités ici la symétrie du cristal simple est au plus égale à celle qu'on peut déduire des propriétés optiques. Cette symétrie est inférieure à la symétrie extérieure apparente qui est manifestée par le groupement de plusieurs individus en un même édifice."[**]

Although X-ray results confirmed what was seen optically in several anomalous crystals—that for some reason the symmetry of individual sectors was lower than apparent external symmetry of the crystal—they did not address the source of the desymmetrization and the precision of the tesselation. In most anomalous crystals, optical detection of the desymmetrization is more sensitive than X-ray detection, as well as faster and easier. In Hocart's words,[137]

> "...il est regrettable que par l'application des rayons X à l'étude des cristaux l'attention ait été détournée des résultats acquis par les méthodes classiques de la cristallographie."[***]

[*] Rinne is forced to justify the mediocre sensitivity of [his X-ray] method by attributing the alteration of optical properties to a deformation of the atoms which is inaccessible to X-rays.

[**] the mimesis theory proposed by Mallard is applicable in a certain number of cases; in the same cases the so called theory of internal strain is of no use in explaining the known facts... If the case of apophyllite is still unclear, it is at least established that like other examples cited here [boleite, pharmacosiderite, boracite, and senarmontite] the symmetry of the simple crystal is at most equal to that which one would deduce from the optical properties. This symmetry is lower than the apparent external symmetry which results from the grouping of a number of individuals into a single structure.

[***] It is regrettable that by applying X-rays to the study of crystals, attention has been diverted from results obtained by the classical methods of crystallography.

Until very recently the long unsettled debate on optically anomalous crystals seems to have been almost completely forgotten. In 1943 Alfred Neuhaus (1903–1975), Professor of Mineralogy in Darmstadt, reported an optically anomalous sectoring of 1,8-dihydroxyanthraquinone that was not reflected in its X-ray patterns.[138] He cited none of the earlier literature describing crystals with precisely the same optical form, although there had been dozens of references to them in the same journal before he was born. His report was of an isolated phenomenon. In 1951 Neuhaus assumed the Professorship of Mineralogy in Bonn that had formerly been occupied by Brauns.[139]

Between 1945 and 1984 Brauns's classic book on optical anomalies, which remains the most comprehensive source in the field, was cited in the scientific literature only four times, and then only peripherally.[140]

2.9. Tammann's Insight

The closest approach to our present understanding of the phenomenon of optical anomalies was the isolated insight of a physical chemist who made pioneering contributions to the study of heterogeneous systems, crystallization, solid state reactions, and metallurgy.[141] In connection with his interest in alloys, Gustav Tammann (1861–1938, Fig. 23) in Göttingen published a series of papers on mixed crystals.[142] These papers focused on the equilibrium and nonequilibrium distribution of constituents in solid solutions.

Fig. 23. Gustav Tammann (1861–1938) suggested that optically anomalous crystals might be metastable "isomers" of more symmetrical normal crystals, but his prescient ideas were not well regarded by the crystallographic community, nor was X-ray crystallography sufficiently well-developed to test his hypothesis [142].

In a 1917 paper, *Die anomale Molekülverteilung in Mischkristallen als Ursache ihrer anomalen Doppelbrechung*,[*] Tammann discussed the theory of Brauns on internal stress from isomorphous impurities.[143] He speculated that although internal stress should play a role, the ordering of

[*] *The Anomalous Molecular Arrangement in Mixed Crystals as a Cause of their Anomalous Birefringence*

components alone would suffice to cause birefringence. Going further than Barlow he clearly indicated that the arrangements resulted from kinetic, not thermodynamic, control of crystal growth:

> "Die optisch anomalen Mischkristalle können als Isomere der optisch normalen Mischkristalle aufgefaßt werden. Der Grund der Isomerie ist hier eine verschiedene Verteilung der Moleküle in demselben Raumgitter, während er bei der gewöhnlichen Isomerie eine verschiedene Verteilung der Atome im Molekül ist. Die Mischkristalle abnormer Molekül- oder atomverteilung im Gitter sind aus atomistischen Gründen total instabile Phasen, denen kein Zustandsfeld zukommt, in dem sie stabiler als ihre Gitterisomeren mit normaler Molekülverteilung sind."[*]

Tammann did not consider what sort of mechanism might generate the observed asymmetry. In reviewing this paper Brauns criticized[144] its neglect of "die Abhängigkeit der optischen Symmetrie von der geometrischen Symmetrie einer Fläche, in dem Bezirk dieser, wenn sie vorhanden ist."[**] Brauns was almost certainly thinking of the face as a source of stress, rather than as a source of the molecular orientation during crystal growth that would have made Tammann's views congruent with our present understanding. He asserted correctly that there was insufficient evidence to support Tammann's views and concluded that the question should still not be considered settled.

No one developed Tammann's ideas on this subject. As Garner pointed out forty years ago,[141b] numerous aspects of Tammann's work were unconventional and "appear to many of us to be disconnected flights of genius, probably because their point of origin lies beyond our ken." Belated recognition of the correctness of Tammann's insight on optically anomalous crystals may help address Garner's concern that

> "[since] the changing language of scientific thought makes it uneconomic to absorb work done ahead of the time, [it is] problematical whether the theoretical investigations of Tammann will have any better success with a future generation of scientists than they have had with his contemporaries."

3. Current Status

3.1. Mineral Crystals

3.1.1. New Evidence and Understanding

Two kinds of zoning in which chemical composition varies from region to region within a crystal are familiar in mineralogy. One of them involves bands that are analogous to the growth rings of trees and result from changes in the composition of the fluid during crystallization. The other involves differences in composition between sectors that grew through faces that were not related by symmetry.[145] A third, less familiar type of zoning involves symmetry-related sectors that have identical composition but different impurity orientation. Tammann's views on lattice isomers are closely related to the latter and to the "order–disorder" concept which concerns phase transitions between structures with different patterns or degrees of atomic ordering.[146] One difference is that many discussions of order–disorder transitions assume reversibility, which Tammann specifically excluded.[147] Until recently there was no recognition that selective incorporation of impurities, or of disordered host molecules, among differently oriented lattice sites at the crystal surface should play an important role in generating a nonequilibrium structure. Optically anomalous crystals continued to be considered, in terms that had not changed for almost a century, as resulting either from stress or from some unexplained twinning mechanism.[148] Research over the last dozen years has begun to change that perception.

A neutron diffraction study of topaz in 1980 demonstrated symmetry lowering due to orientation of OH bonds.[149] In 1986 Rossman and Aines used polarized FTIR spectroscopy to demonstrate that the optical anisotropy of grossular garnets was associated with a selective orientation of OH ions that was assumed to have been established during crystal growth.[150] In 1988 Allen and Buseck reported X-ray results on similar garnets showing that during growth selective incorporation of Fe^{+3} for Al^{+3} and of Fe^{+2} for Ca^{+2} had lowered the symmetry of individual sectors to "$I\bar{1}$" from $Ia3d$,[151] confirming earlier observations by Takéuchi et al.[152] Although sectoring was easily observed by optical microscopy, it was invisible to the transmission electron microscope.

The most comprehensive recent work on optically anomalous minerals is due to Akizuki et al. In 1978 he explained optical observations on the anomalous feldspar adularia in terms of proposed differences among nominally symmetry-related unit cell sites at growth surfaces.[153] This was the first of a series of impressive papers in which he and his collaborators have rationalized the optical anomalies of more than a dozen minerals, including garnet, apophyllite, and a sample from Strontian, Scotland, of brewsterite, a rare strontium-containing zeolite named for Sir David Brewster.[154]

3.1.2. Present State of the Apophyllite Riddle

Until Akizuki's work, fundamental understanding of the optical anomaly of apophyllite had progressed little since its discovery by Brewster 175 years ago. In 1965 Sahama described an apophyllite from Finland with tesselation almost identical to that described Brewster[155] (Fig. 10b). His conclusions, coming on the sesquicentennial of the first report on optical anomalies, were not significantly more sophisticated that Brewster's. Noting that the optical properties were too regular to be attributed to strain, Sahama went no further than to invoke "penetration twinning" of orthorhombic

[*] Optically anomalous mixed crystals can be understood as isomers of optically normal mixed crystals. Here the basis of the isomerism is a different arrangement of molecules in the same space lattice, while in normal isomerism it is a different arrangement of atoms in molecule. Mixed crystals with abnormal molecular or atomic arrangement in the lattice are on atomistic grounds totally unstable phases; there is no condition under which they are more stable than their lattice isomers with normal molecular arrangements.

[**] the dependence of the optical symmetry on the geometrical symmetry of a face, in the sector in which it occurs.

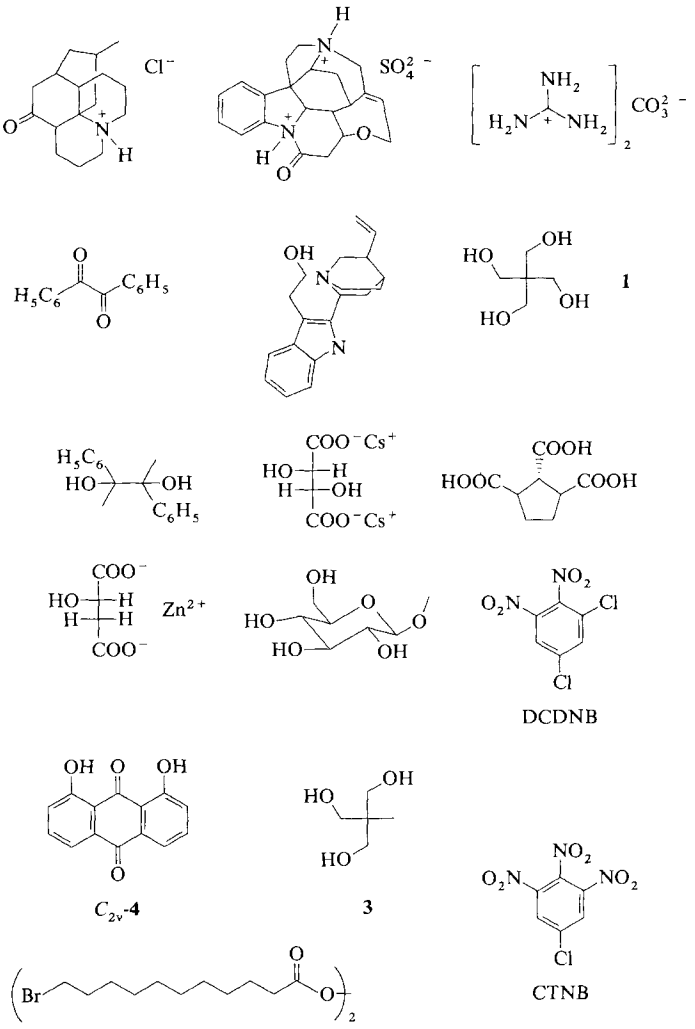
sectors whose "deviation from a strictly tetragonal symmetry must evidently be very slight." In his report of how growth conditions determine the morphology of apophyllite, Kostov mentioned the possible influence of impurities, but did not relate them to a mechanism of symmetry reduction.[156]

The paper of Akizuki and Konno, based on comprehensive, sophisticated optical observation of bulk and surface structures and on chemical analysis, presented a clear explanation of the way in which selective incorporation of impurities at growth sites on particular crystal facets could give rise to the tesselated structure.[157] Since substitution for K or F would not break the tetragonal symmetry, they favored selective substitution of Al for Si (or perhaps selective orientation of the O–H bond) as the source of desymmetrization. That neither of these orderings would have much influence on X-ray scattering is consistent with the failure of repeated efforts to detect the desymmetrization in apophyllite by X-ray diffraction. Although selective substitution of Al for Si seems plausible, there is still no direct evidence to confirm this explanation. We have recently studied growth banding in sectors associated with pyramid faces of an apophyllite from Bergen Hill, New Jersey. An electron microprobe analysis showed that in this sample the biaxial bands are actually *poorer* in aluminum than the uniaxial bands, although the opposite might be expected if biaxiality were due to inclusion of aluminum.[158] Thus Brewster's riddle is still not fully solved.

3.2. Organic Crystals

3.2.1. Literature Survey

Because of our desire to use optically anomalous organic crystals for studying molecular recognition during crystal growth,[5, 7] we surveyed the literature to identify promising systems. There must be a very large number of such crystals. Most axially symmetric organic crystals can probably be rendered optically anomalous by the presence of a suitable impurity. We searched crystal identification tables[159] for axially symmetric crystals that were not optically uniaxial.



Scheme 1. Structural formulas of compounds in Table 1 (in order from left to right).

Since optical properties are no longer commonly reported for organic crystals, it is not surprising that almost all of the cases we found were included in Groth's 72-year-old compendium of crystal data.[160]

Table 1 presents 16 reports of optically anomalous organic crystals in chronological order. In a number of cases we have

Table 1. Optically anomalous organic crystals.

Compound (see Scheme 1 also)	Morphology	Possible Source of Anisotropy	Year	Ref.
lycopodine-hydrochloride · H_2O	trigonal	?	1883	[a]
strychnine sulfate · 6 H_2O	tetragonal	ordering of water of hydration	1884	[176]
guanidinium carbonate	tetragonal	?	1884	[161]

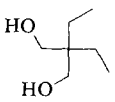
been able to confirm the anomalous phenomenon, and in some we can suggest its source on the basis of preliminary experiments described in this section. Section 3.2.2 summarizes the results from a more detailed study of one case.

For one compound of which we have obtained only uniaxial crystals and three others of which we have grown anomalous crystals, we suspect that the optical anomaly reported in the literature was due to selective incorporation of foreign or misordered molecules during crystallization. These substances are benzil, β-methyl-D-glucoside, pentaerythritol, and deoxypentaerythritol, respectively.

Our recrystallization of commercial benzil (Matheson) from carbon disulfide gave uniaxial hexagonal prisms, rather than the anomalous crystals reported by Martin[118] and by Wyrouboff.[161] His observations were probably due to an oriented impurity, although in our hands dissolving small amounts of benzoin or deoxybenzoin in the crystallizing solution did not give biaxial benzil crystals.

In 1899 Tietze[162] described optically anomalous β-methyl-D-glucoside crystals which he had obtained from Emil Fischer. The anomalous crystals were grown from mother liquors that remained after crystallization of the α isomer from the anomeric mixture of glucosides. The anomaly probably results from selective incorporation of residual α glucoside in the tetragonal lattice of the β anomer, since the α and β anomers of several carbohydrates cocrystallize.[163] We grew optically sectored crystals from an ethanol solution of β-methyl-D-glucoside (Sigma) in the presence of 17.5 mol% of the α anomer. The order of the interference colors in our crystals was considerably lower than in those described by Tietze, however.

Although Martin reported anomalous crystals of pentaerythritol (**1**),[118] pure crystals are genuinely tetragonal and uniaxial; molecules occupy sites of S_4 symmetry.[164] Pentaerythritol is difficult to obtain in pure form,[165] and crystals are almost invariably biaxial and sectored. Impurities of lower symmetry are probably oriented by selective incorporation on particular growth faces. R. L. Carter has grown anomalous crystals from pure pentaerythritol by adding 2-ethyl-2-(hydroxymethyl)butanol (**2**) as an impurity.[166]



2

In 1983 Eilerman, Lippman, and Rudman reported that crystals of 2-(hydroxymethyl)-2-methyl-1,3-propanediol (deoxypentaerythritol, **3**) were isomorphous to pentaerythritol and appeared tetragonal by X-ray diffraction, suggesting that the methyl group was randomly disordered among the four hydroxymethyl sites.[167] However, by polarized microscopy they observed that the crystals were twinned, each plate being divided into four biaxial sectors. They inferred that each sector possessed a monoclinic *C*-centered cell containing four molecules. Together with Carter we have grown crystals from ethyl acetate and collected X-ray data from a single growth sector which shows a much more intricate structure.[168] Our triclinic supercell contains 32 independent molecules.

Traube described optically anomalous crystals of cesium tartrate[169] and of zinc malate.[170] For easy observation of deviation from axial symmetry, crystals should have well-developed faces perpendicular to the symmetry axis. We did not obtain appropriate crystals of these salts. A cation impurity, perhaps rubidium, is a likely source of Traube's observation. Crystals of cesium hydrogen tartrate, prepared from commercial purified CsCl in 1978, showed as much as 0.12% Rb by X-ray fluorescence.[171] Dicesium tartrate and dirubidium tartrate are isomorphous; a modern structure determination assigned the latter crystals to space group $P3_221$.[172]

We confirmed Wyrouboff's report that guanidinium carbonate is biaxial using crystals grown from the commercial salt (Aldrich). An ordered tetragonal structure of the salt in space group $P4_12_12$ has been reported with no mention of the optical anomaly.[173]

In the case of strychnine sulfate hexahydrate we have reproduced the reported anomaly, but we are again uncertain of its source. In 1857 this substance was used in the first demonstration that an organic crystal can rotate the plane of polarized light.[174, 175] Almost 30 years later Wyrouboff noted that the tetragonal crystals were optically anomalous and sectored,[176] an observation confirmed by Martin[118] and by Brauns[35a] (Fig. 21). Under conditions that apparently led to loss of an equivalent of water (heating, storage in desiccator, or long storage in air), the crystals became much more strongly birefringent. More remarkably, they often regained their original optical form on rehydration. We have confirmed these observations by growing crystals from cooled aqueous solution, exposing them to the air for dehydration, and returning them to the refrigerator for rehydration. X-ray data from a single growth sector of the hexahydrate crystal fit a tetragonal cell,[177] but the crystals diffracted poorly, and no further structural information was obtained. On standing at room temperature the crystals became so strongly birefringent that it was impossible to use a compensator to distinguish sectors with different directions of maximum polarizability.[178] The optical anomaly is certainly related to the state of hydration and perhaps to ordering of the waters of hydration. Brauns reported reversible changes in birefringence within a few minutes on transferring crystals between room air and a desiccator. Since a few minutes seems a short time to restore hydration and symmetry throughout a crystal, stress might play some role in this phenomenon.

We have reproduced the optical anomaly of 1,8-dihydroxyanthraquinone (**4**) but can offer no plausible explanation for the phenomenon. In 1943 Neuhaus reported optically sectored crystals.[138] These spectacular square, orange plates grow readily from acetone (Fig. 24). The solution ^1H NMR (500 MHz) spectrum from a single crystal of the quinone (Aldrich) showed no impurity peak larger than 0.5% of the hydroxyl signal from the pure compound. Previous structure determinations assigned the crystals to the space group $P4_1$.[179] Our structure, refined from X-ray intensities of one growth sector, showed no evidence of the desymmetrization that is implied optically.[180]

Rapid crystallization yields a metastable modification of 1,8-dihydroxyanthraquinone in the form of fine fibers. On the basis of vibrational spectroscopy Smulevich and Mar-

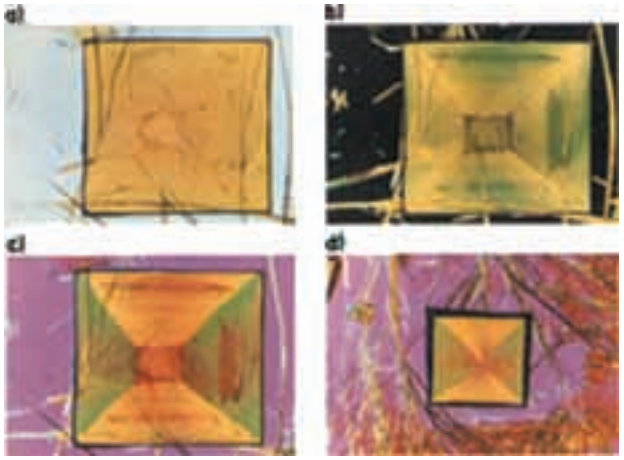


Fig. 24. Plate of 1,8-dihydroxyanthraquinone (**4**; $0.64 \times 0.57 \times 0.02$ mm) grown within 30 minutes from acetone. View along [001] a) directly, b) between crossed polarizers (at 45°), and c) with a first-order red retarder (γ vertical). d) A smaller plate from the same batch. The source of anomalous birefringence in these crystals remains mysterious. Also visible are fine needles, the metastable modification.

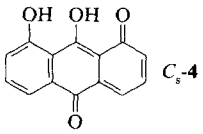
zocchi have argued that the predominant species in the two forms are the tautomers C_{2v}-**4** (see Scheme 1) and C_s-**4**.[181] The needles presumably contain the C_{2v} tautomer, while the plates have hydrogens bound to the oxygens at positions 1 and 9.[182] One might imagine that the minor species in the



C_s-**4**

optically anomalous plates is the C_{2v} tautomer, selectively included in some of the four lattice sites, and that tautomerization, although rapid in solution, is frozen out in the solid state. However, not only did solid-state ^{1}H and ^{13}C NMR spectra fail to reveal a second species in the anomalous plates, the needles and plates gave identical spectra.[183] In neither case was the resolution of the spectra sufficient to draw definitive conclusions.

3.2.2. *1,5-Dichloro-2,3-dinitrobenzene and Its Derivatives*

After this preliminary survey of optically anomalous organic crystals, we studied the reported anomaly of 1,5-dichloro-2,3-dinitrobenzene (DCDNB) in much greater detail. DCDNB (see Scheme 1) is one of more than 70 substituted benzenes whose crystals were described by the mineralogist Ettore Artini (1866–1928) in a series of 10 papers between 1905 and 1918. Artini had undertaken this work in connection with the systematic investigation of aromatic compounds by the organic chemist Wilhelm Koerner (1839–1925), his colleague in Milan. Artini reported that although crystals of DCDNB from many solvents appeared to be tetragonal, microscopy of square (001) sections showed division along the diagonals into four distinctly biaxial sectors related to one another by rotation about [001], the apparent fourfold symmetry axis.[184] He also noted that departure from uniaxial character was small and variable "come spesso accade nelle sostanze otticamente anomale."[*]

We found that crystal plates from ether, chloroform, or benzene invariably showed the twinning described by Artini (Fig. 25). Refined lattice parameters from X-ray diffraction data on each of three of the sectors from a single plate showed an apparently orthorhombic cell with the principal axes in adjacent sectors rotated by 90° about c.[185] At a superficial level the absence of fourfold symmetry in this cell explains biaxiality and resolves the anomaly. That the crystals are multiply twinned may not be surprising, but why do they twin with precisely this pattern? Closer analysis reveals a novel mechanism for twinning that exemplifies the type of molecular recognition during crystal growth that we believe underlies most optical anomalies.

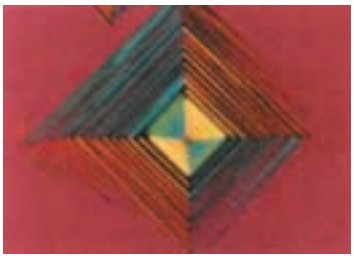


Fig. 25. Terraced plate of DCDNB (0.24 mm diagonal width, 0.024 mm thick at rim of central bright square) grown within 5 minutes by evaporation of $CHCl_3$ and viewed along [001] between crossed polarizers with a first-order red retarder (γ at 45°). In this pure crystal sectoring results from nonrandom disorder of a chloro and a nitro group.

An ordered crystal structure for DCDNB was refined to $R = 0.087$ in space group $P2_12_12_1$. This orthorhombic space group differs from the tetragonal group $P4_32_12$ by the absence of twofold rotational axes in locations close to the molecular C2–C5 axis. Thus 5-chloro-1,2,3-trinitrobenzene (CTNB, see Scheme 1), the analogue of DCDNB in which the chlorine at position 1 has been replaced by a nitro group to make a molecular twofold rotation axis possible, gives crystals in space group $P4_32_12$ that are isomorphous with DCDNB.[186] If the growing crystal of DCDNB were totally unable to distinguish between the 3-chloro and 1-nitro groups flanking the 2-nitro position, the molecule would be incorporated from solution with complete rotational disorder about the C2–C5 axis, and the additional effective molecular symmetry would make the crystal truly tetragonal.

Close inspection of residual electron density after refinement of the $P2_12_12_1$ structure showed peaks consistent with this kind of disorder. Since other crystals have shown disorder from interchange of nitro and chloro positions,[187] it is not surprising that DCDNB has difficulty ordering these two groups. We refined the amount of rotational disorder independently in each of the four molecular sites which are nominally related by symmetry in space group $P2_12_12_1$. This five-parameter model gave much improved agreement with X-ray data collected from an untwinned crystal fragment ($R = 0.065$). The model showed that the minor molecular

[*] as happens frequently in optically anomalous substances

orientation was present in substantial amounts that varied from site to site (32, 31, 15, and 18%, all ±1%).

These population differences that lower the crystal symmetry to $P1$ are due to differences in how molecules from solution were incorporated during growth into the different "symmetry-related" sites of this crystal fragment. The differences can be visualized by examining how molecules are oriented in one of the four molecular layers which stack along [001], the approximate fourfold screw axis of the unit cell. Figure 26a shows five molecules in one layer with the identity of the 1- and 3-substituents (Cl or NO_2) left ambiguous. The molecules are related by *a* and *b* translations. Figure 26b is a graph in which the central square symbolizes a growing crystal plate, and the four surrounding trapezoids represent the four growth sectors formed by adding molecules through the sides of the square to yield a final, larger crystal. Average orientation of the molecules within each sector is indicated by the shading of the circles standing for the 1- and 3-substituents. The ratio of dark to light area in a circle shows the ratio of NO_2 to Cl occupancy of the corresponding position. Ordering of the 1- and 3-substituents within the central square is irrelevant for the following argument, so they are shown as if fully disordered—half light for chloro and half dark for nitro.

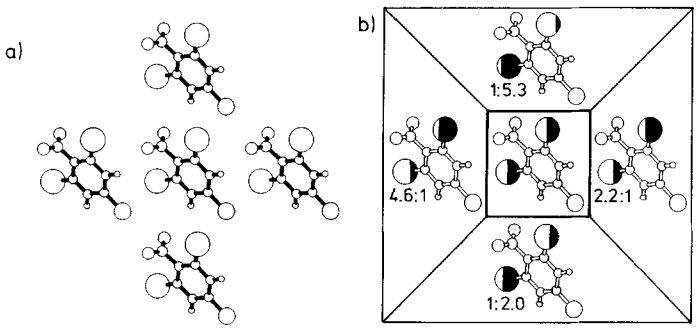

Fig. 26. a) Arrangement of neighboring molecules related by *a* and *b* translation within one layer of DCDNB. The approximate crystallographic fourfold screw axis is perpendicular to the paper, and the approximate molecular twofold symmetry axis joins the 2-nitro group at the upper left to the 5-chloro group at the lower right. The 1- and 3-substituents are indicated by large, nonspecified balls. b) Averaged molecular orientation in each trapezoidal growth sector of a macroscopic crystal. In real crystals the central square representing in the nucleus is much smaller. The average chloro:nitro population ratio at the 1-position is given explicitly for each sector.

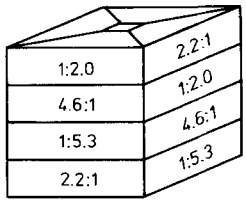
In the bottom and right sectors orientation of chlorine to contact the growth surface of the central square is favored with a bias of ca. 2:1. At the top and left edges the bias is ca. 5:1 in the opposite direction, favoring contact of nitro with the growth surface. Apparently molecules from solution prefer to approach the bottom and right faces with their 1-chloro substituent toward the 5-chloro group of the surface molecules, and to approach the top and left faces with their 3-nitro group toward the 2-nitro group of the surface molecules. The bias favoring nitro–nitro contact (ca. 5:1) seems to be stronger than that favoring chloro–chloro contact (ca. 2:1). This naive picture ignores the role of molecules in adjacent layers and the specific structure of growth sites on the crystal surface (steps, kinks, etc.).[188] It also ignores the solvent. These additional factors will certainly be required to explain the small difference between top and left faces, and that between bottom and right faces.

Within the molecular layer of Figure 26 the resulting crystal is divided into four growth sectors surrounding the core. The division is along diagonal lines traced by corners of the expanding square plate. Each sector has a characteristic ratio of chlorine to nitro populations in position 1, as shown in Figure 26b. The same pattern arises by the same mechanism in the other three molecular layers of the unit cell, except that each is rotated by the fourfold screw axis that passes through the center of the original square. Thus under the 1:2.0 sector (top front in Fig. 27, bottom of Fig. 26) lies a 4.6:1 sector obtained by rotating the layer counterclockwise by 90° from the top layer. Next comes a 1:5.3 sector (180° rotation), and

Fig. 27. Perspective view of a stack of four successive layers of DCDNB showing the sequence of chloro:nitro population ratios in the 1-position of molecules in each sector and layer. Adjacent growth sectors of a macroscopic crystal are rotated by 90° from one another and offset by one layer. This corresponds to the presence of a fourfold screw axis passing through the middle of the square.



the cell is completed by a 2.2:1 sector (270° rotation). Each of the four sectors of the macroscopic 3-dimensional crystal is a stack of the same set of four different orientational populations in the same order, but from sector to sector the entire set is rotated by 90° and displaced by one layer (Fig. 27). The apparent rotation from sector to sector simply results from exchange of major and minor chloro:nitro populations among molecules with *identical framework orientation throughout the multiply twinned crystal.*

Selective incorporation of misordered molecules in pure DCDNB is analogous to many cases where selective incorporation of impurities gives optically anomalous solid solutions. To support this analogy S. H. Tolbert prepared mixed crystals consisting of about 15% of 5-bromo-1,2,3-trinitrobenzene or 1-bromo-5-chlor-2,3-dinitrobenzene in CTNB, the isomorph of DCDNB with genuine fourfold symmetry.[189] Both solid solutions were optically anomalous, and in both cases X-ray diffraction from single growth sectors showed unsymmetrical distribution of the bromine substituent that differentiates guest from host. Bromine occupancy in sites that would have been related by symmetry in the pure host crystal varied from 1% to 27%. As might be expected, the sites with high bromine occupancy were oriented away from the crystal face that was active in growth of the sector.

4. Current Scientific Relevance of Optical Anomalies

4.1. The Challenge of Crystal Synthesis

One of the most challenging problems for modern chemistry is to develop tools for designing and assembling supra-

molecular structures that involve association of many molecules. Molecular crystals are a familiar and important class of these structures. Since the nonbonded interactions that hold molecular crystals together are weaker and less specific than the bonding interactions among atoms and groups within a single molecule, it is not surprising that methods for controlled crystal synthesis lag far behind those for molecular synthesis. Developing reliable methods for crystal synthesis is an important task, because the external habit and unit cell structure of crystals often determine crucial chemical and physical properties of commercially important solids ranging from pharmaceuticals to explosives, and from devices for nonlinear optics and integrated microelectronics to photographic emulsions. Optically anomalous crystals will assist in this effort both by serving as cases where the mechanism of crystal growth is particularly easy to study and by demonstrating new possibilities for tailoring crystal microstructure both at the growth sector and at the unit cell levels.

Twenty years ago Schmidt began discussing "Crystal Engineering" as the solid-state analogue of synthesis design.[190] Many concepts from molecular synthesis in the fluid phase have their analogues in the controlled preparation of crystals. Table 2 lists some comparisons. Specific growth sites at which new molecules add to a crystal surface play a role in the construction of nonbonds that is analogous to the role of reactive intermediates in the construction of bonds. In particular, the formation of a crystal nucleus, or of a screw defect or kink site on a crystal surface, is analogous to initiation of a free radical chain reaction; addition of a molecule to a kink so as to generate a new kink is analogous to propagation. Determining the structure and properties of these sites will be a key element in learning to control crystal growth.

Table 2. Some analogies between molecular and crystal synthesis.

Molecular Synthesis	Crystal Synthesis
synthetic strategy	crystal engeneering
bond construction	nonbond construction
reactive intermediate	growth site
initiation	nucleation
propagation	growth
termination	poisoning
chemoselectivity	guest discrimination
regioselectivity	habit modification
stereoselectivity	defect orientation
optical activity	birefringence

The growth of pure crystals and solid solutions provides several analogues to the types of selectivity that are sought in molecular synthesis. The choice between host and one or several guests for incorporation in a growing crystal is analogous to chemoselectivity. Purification by recrystallization is a familiar and dramatic example of this kind of selectivity. Addition to selected faces, which dictates the crystal habit, is analogous to regioselectivity. Incorporation of a guest in one among several symmetry-related host sites, as in optically anomalous crystals, is analogous to stereoselectivity.[5, 7, 191]

As in the case of molecular synthesis, the development of new techniques for crystal preparation will profit from an improved understanding of mechanism based on careful studies of prototypical cases. For mechanistic studies the birefringence of solid solutions can play a role analogous to that of optical activity in classical studies of fluid chemistry—it provides a permanent optical record of the course of the reaction. Optically anomalous crystals provide an excellent tool for studying the mechanism of crystal growth because the birefringence of individual sectors presents their growth history in a form that is easily read with a polarizing microscope. For example, while the crystal of Figure 2 grew as a square expanding from the center, the crystal of Figure 28 a grew from a nucleus on the lower edge with molecules in the blue region adding through the right face and those in the yellow region through the top face, and the crystal of Figure 28 b grew in a very complex way with blue regions growing through horizontal faces and yellow regions through vertical faces. The crystal of Figure 28 c grew from at least five different nuclei at various times; four of the nuclei grew toward the front of the crystal and the one nearest the center, toward the rear. Enhanced birefringence in picture frames surrounding the crystals of Figure 28 d indicates some change in crystallization mechanism.

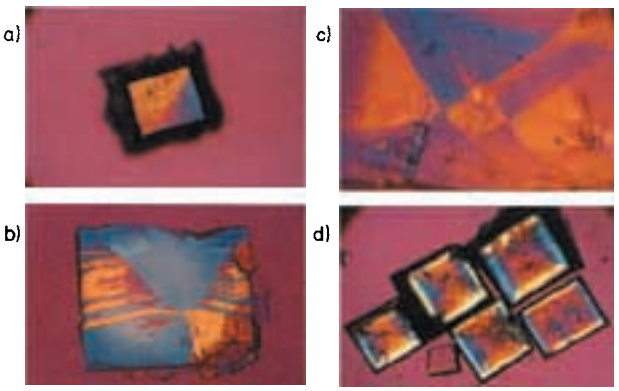


Fig. 28. Crystal plates with curious sectoring. a) Di-11-bromoundecanoyl peroxide containing 15% of the analogue in which one terminal bromine atom is replaced by a methyl group (11-bromoundecanoyl lauroyl peroxide). Although the shape of the rectangle may have been determined by a very thin crystal nucleated at the center, most of the thickening occurred from a nucleus near the left end of the lower edge. b) Pure 11-bromoundecanoyl lauroyl peroxide from acetone/$CHCl_3$. The bent stripes reveal a very complex pattern of crystal growth. c) The same peroxide mixture as in Figure 2. In this case growth occurred from at least five nuclei which occur at different depths in the crystal and thus were active at different times. d) Pure 11-bromoundecanoyl 11′-iodoundecanoyl peroxide. The source of the "picture frame" effect is not yet fully understood.

Birefringence shows not only which face was active during growth of a particular region, but also what kind of symmetry the growth site possessed and how effective it was at ordering the defects. For studies of dilute solid solutions the impurity may be thought of as an "indicator" whose incorporation reveals the growth history of the host. In principle, the same information is present in any solid solution, but strong intrinsic birefringence of the host lattice usually overwhelms the small contribution from unsymmetrically distributed defects. Isotropic or uniaxial hosts provide a blank background against which to view the effect of impurities.

4.2. Design of Desymmetrized Crystals

Optically anomalous crystals are common in both organic and inorganic materials and have even been observed in lunar samples.[192] They should be expected whenever growth kinetics can dictate a nonequilibrium distribution of defects in a high-symmetry crystal. The structure of solid solutions and disordered crystals should always be considered from this point of view. Even when a single crystal appears to have high symmetry, as in the case of DCDNB, single growth sectors can easily belong to the space group of lowest symmetry, $P1$. This realization relates to a general principle for designing crystalline materials: symmetry may be reduced selectively by the introduction of impurities. Symmetry reduction could be useful for developing new technological materials, especially for applications in nonlinear optics,[193] where high symmetry can be deleterious. With increased understanding of surface topography and the mechanisms of crystal growth, it should become possible to design and prepare mixed crystal with more finely tailored microstructures.

4.3. Study of Molecular Reorientation

In cases where a pure crystal is optically anomalous because of nonequilibrium orientation of disordered host molecules, there may be a temperature below the melting point at which the molecules can reorient to achieve the random, symmetrical orientation. The resulting change in birefringence could be used to follow the kinetics of molecular reorientation more easily and in smaller crystal regions than is possible with many spectroscopic techniques.

4.4. Mechanism of Crystal Twinning

The precise cause of crystal twinning is rarely understood.[194] Sometimes it has been attributed to growth of several crystals from a special seed with a higher symmetry than that of the individual crystallites.[194, 195] This cannot be the case for DCDNB because, when a seed cut from a single sector of a twinned crystal was placed in a supersaturated solution of DCDNB in chloroform, it grew into four sectors with the optical orientations predicted by the mechanism outlined in Section 3.2.2. In DCDNB twinning is a natural consequence of the growth kinetics and is not due to a special event or random mistake. The generality of this mechanism merits further study.

4.5. Molecular Recognition

There is great current interest in understanding the way in which weak intermolecular forces operate to allow the components of a supramolecular assembly to recognize one another. Since optical anomalies represent a breakdown of the recognition process during crystallization, investigating them carefully should yield valuable information on intermolecular forces and the mechanism of molecular recognition.

Information on molecular orientation from polarized microscopy is averaged over domains of at least micron dimensions. Standard X-ray diffraction results also represent spatial averages, as in the average Cl/NO_2 ratios depicted in Figure 26. Analysis of diffuse X-ray scattering can provide much more detailed information about molecular recognition by showing specific short-range pair correlations. For a given misordered molecule, diffuse scattering can provide the conditional probability that a particular neighbor is also misordered, rather than just the global probability that molecules in averaged sites are misordered. Following initial work by Flack and Glazer,[196] Welberry has made important theoretical and experimental contributions over the past fifteen years toward understanding short-range order in molecular crystals through diffuse scattering experiments.[197] He and his collaborators have found that local pair correlations can easily be two to four times larger than the average orientational preference revealed by normal Bragg scattering.[198] Optically anomalous, pure crystals like DCDNB, whose growth sectors are easily recognized and could be studied independently, should be particularly well suited for this type of study.

4.6. Value of the Polarizing Microscope

Current studies of optically anomalous crystals demonstrate the value of polarized light microscopy as clearly as investigations in the 19th century did.[199] Fifty years ago the microscope was still recognized as an important tool for chemistry, and students were routinely instructed in its proper use. Although microscopy persists in some areas, such as polymer, liquid crystal, and forensic chemistry, the rise of new analytical techniques and the concentration of academic chemistry on fluid phases have displaced microscopy from most chemistry curricula. McCrone has persistently advocated increased use of the polarizing microscope in analytical chemistry,[200] and growing interest in the solid state should favor a renaissance of this technique, particularly among organic chemists.

Although a microscope may cost 20 to 200 times less than newer tools for studying solids, it is unrivaled for rapid survey of transparent samples, particularly when they are inhomogeneous. Microscopy can be an indispensable adjunct for identifying regions in a solid that are worth more detailed study by other techniques. Without the help of the microscope to identify homogeneous growth sectors, X-ray diffraction can mislead by providing a crystal structure that is averaged over several domains. Microscopy can be as reliable as X-ray diffraction for determining the lattice orientation of a crystal being mounted for spectroscopic study, and it is much faster, but modern reports typically fail to provide relevant simple information on crystal birefringence.

Diffraction methods are unrivaled in providing quantitative structural detail at the atomic level. Still, it is instructive to note that many optical anomalies in mineral samples probably involve Al/Si ordering. These anomalies are easily seen with a microscope, but are nearly invisible to X-rays. Solid-state NMR or neutron diffraction could reveal Al/Si ordering, but both require samples some 10^7 times larger than those necessary for optical microscopy. Quantitative

applications of optical microscopy in organic solid state chemistry would be helped greatly by improvement in simple models for predicting the electric polarizability of molecules.[201]

We are particularly grateful for the contributions of Ms. Sarah Tolbert, Dr. Steven Bertman, and Mr. Randall Carter. This research also benefited greatly from the advice and assistance of Drs. Jay Ague, Fred Allen, Paul Bartholomew, Donald Bloss, Jack Dunitz, Angelo Gavezzotti, Richard Gilardi, Frank Herbstein, Meir Lahav, Antonio Lasaga, Leslie Leiserowitz, John Longhi, Paul Moore, George Rossman, Danny Rye, and Horace Winchell as well as of David Blocher, Ellen Faller, and John Toscano. The work was supported by grants from the Petroleum Research Fund of the American Chemical Society (22712-AC4.6), the National Science Foundation (DMR-8203662), and Merck, Sharp, and Dohme Research Laboratories. In addition J.M.M. was supported by the Office of Naval Research (N00014-89-K-0437) and by a Jacob and Erna Michael Visiting Professorship at the Weizmann Institute of Science.

[24] An account of the discovery is given by F. Arago, in: *Biographies of Distinguished Men 2*, (translated by W. H. Smyth, B. Powell, R. Grant), Longman, Brown, Green, London, **1857**, pp 117–170.
[25] While Malus recognized the phenomenon of polarization, his conceptual framework, prior to the development of the wave theory of light, was that of the Selectionist. He believed that light was composed of bundles of individual rays each endowed with some polarity, and that polarization phenomena could be accounted for by an elaborate system of ray statistics. See: Jed Buchwald, *The Rise of the Wave Theory of Light*, The University of Chicago Press, Chicago, **1989**, pp 41–67.
[26] F. Arago, *Mém. Inst. Paris* **1811**, *11*, 93–134. We now know that this phenomenon is due to the difference in polarizability, refractive index, and velocity for perpendicularly polarized components of light within the crystal. When these two waves recombine on leaving the crystal, they have suffered an amount of dephasing that depends on their wavelength, so that different colors acquire different degrees of elliptical polarization.

Cycloalkadiynes—From Bent Triple Bonds to Strained Cage Compounds

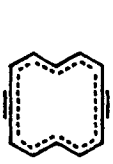
By Rolf Gleiter*

Dedicated to Professor Heinz A. Staab on the occasion of his 65th birthday

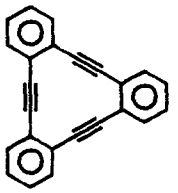
The synthesis of cycloalkadiynes with medium-sized rings may be accomplished by a number of ring-closing and elimination reactions. Information concerning the conformation of the rings as well as the extent of transannular interaction between the triple bonds is obtained by analysis of X-ray crystallographic data and by photoelectron spectroscopy. The diacetylene complexes of Ag^I and Cu^I show hardly any structural change compared to the uncomplexed compounds while the bis(hexacarbonyldicobalt) complexes differ significantly in their structural parameters. Reaction of cycloalkadiynes with dicarbonyl(η^5-cyclopentadienyl)cobalt yields inter- and intramolecular cyclobutadiene complexes. The superphane of cyclobutadiene formed by the intermolecular reaction can be transformed into a number of highly strained cage compounds in few steps. In addition, the variety of such cage compounds can be increased if the reaction of a cyclic diacetylene is carried out with dimethylacetylenedicarboxylate in the presence of aluminum chloride. The intermediate bridged Dewar benzenes eventually lead to propellaprismanes.

1. Introduction

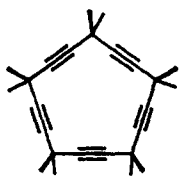
Research carried out on dehydroannulenes in the 60s and 70s initiated chemists' interest in cyclic conjugated alkadiynes and oligoynes.[1] Among the first such compounds to be studied were 1,8-dehydrol[14]annulene (**1**)[2] and 5,6,11,12,17,18-hexadehydrotribenzo[*a*,*e*,*i*]cyclododecene (**2**).[3] Interest was focused on syntheses and properties of novel 4n and (4n + 2) π systems. The ultimate question was



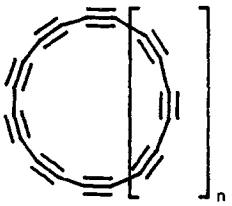
1



2



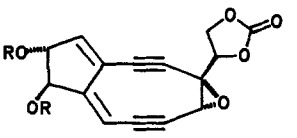
3



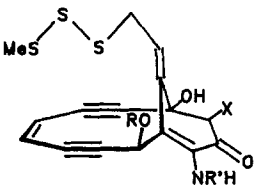
4

whether a triple bond could function as part of an aromatic polyene. Spectroscopic evidence as well as results from X-ray structures could unequivocally confirm this matter.[1] Closely related to the research on conjugated eneynes was the work carried out on pericyclynes,[4] in which the key point was the possible homoconjugation of triple bonds as is seen for example in [5]pericyclyne (**3**). Also related to the early research[1-3] are the attempts to synthesize cyclic polyacetylenes of the generic structure **4** with 18, 24, or 30 carbon atoms.[5] Besides the conjugative effects exhibited by these cycles in their neutral as well as ionic states these compounds are of interest due to their relationship to C_{60}-fullerene.[6]

Another group of compounds which should be mentioned at this point are the recently discovered enediynes with structures **5**–**7** (aglycons of the anticancer antibiotics neocarzinostatin, calicheamicin, and esperamicin).[7] In the decisive step

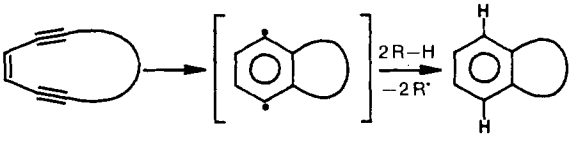


5



6 X = H
7 X = OH

responsible for the biological activity of this type of compound, a Bergman cyclization (**8** → **9**) is postulated, which yields a ring-contracted species.[8] The short-lived diradical **9** acts as a H atom scavenger and presumably is the primary cause of DNA scission.



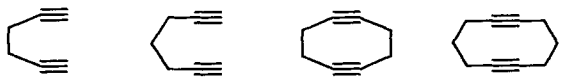
8 **9** **10**

The synthetic potential of open-chain α,ω-diynes and their exploitation as precursors for carbo- and heterocyclic compounds has been extensively reviewed elsewhere.[9]

Our initial interest in cyclic diacetylenes was stimulated by model calculations and spectroscopic measurements in the

[*] Prof. Dr. R. Gleiter
Organisch-Chemisches Institut der Universität Heidelberg
Im Neuenheimer Feld 270, D-W-6900 Heidelberg (FRG)

area of π/σ interactions.[10] Cyclic diacetylenes prove to be ideal model systems for studying such effects, as is evident from the following arguments: Consider the highest occupied molecular orbitals (HOMOs) of cisoid 1,5-hexadiyne (**11**) and 1,6-heptadiyne (**12**). The π molecular orbitals of the two triple bonds in **11** and **12** may be divided into two sets, those that lie in the plane of the molecule (π_i) and those that lie perpendicular to the latter (π_o). Each basis set leads to two



11 **12** **13** **14**

linear combinations, which are either symmetric (π_i^+, π_o^+) or antisymmetric (π_i^-, π_o^-) with respect to the x,z-plane (Fig. 1). Figure 2 shows the corresponding MO energy levels of **11** and **12** compared to those of two propyne molecules separated by distances of approximately 2.6 and 3.0 Å. The splitting

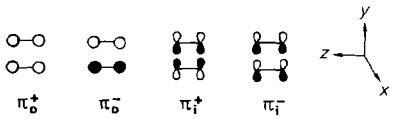


Fig. 1. Schematic representation of the four linear combinations π_o^+, π_o^-, π_i^+ and π_i^-.

of the π_o levels can be easily understood: The difference in energies between π_o^+ and π_o^- is larger for **11** than **12**, because the distance between the triple bonds ($r \approx 2.6$ Å) in **11** is smaller than in **12** ($r \approx 3$ Å). The splitting of the π_i levels, on the other hand, is much smaller in **11** than in **12**.

The reason for these large deviations can be traced back to the different extent of π/σ interaction. In **11** the π_i^+ MO is destabilized in comparison to the analogous MO in the two propyne molecules by interaction with a_1 (σ) of the ethano bridges while π_i^- remains unaffected. In **12** on the other hand π_i^- is mainly destabilized by interaction with the σ frame. The predictions made in Figure 2 can best be tested by examining two model compounds, 1,5-cyclooctadiyne (**13**) and 1,6-cyclodecadiyne (**14**). Photoelectron spectroscopy (PE) is the most appropriate method, since this procedure gives direct information about the energy levels in molecules within the limits of Koopmans' approximation.

These initial contemplations motivated us to synthesize **14** and a number of other cyclic diacetylenes with medium-sized

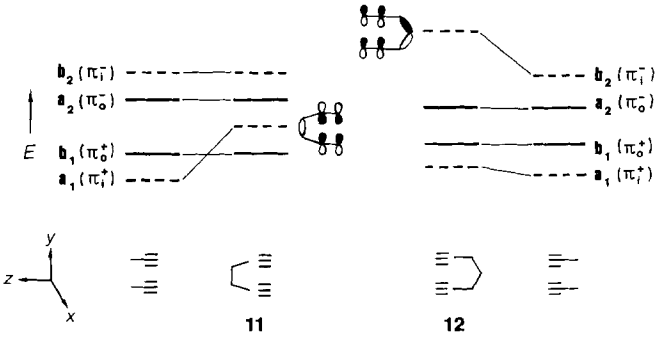

Fig. 2. Correlation between the HOMOs of two propyne units (left, right), 1,5-hexadiyne (**11**), and 1,6-heptadiyne (**12**).

rings.[11] To limit the extent of this review, we will only discuss those cyclic diynes which are generally unconjugated.

2. Synthesis of Cyclic Diacetylenes

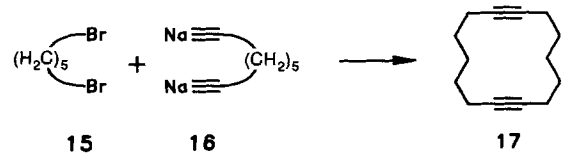
Synthetic routes to cyclic acetylenes with medium-sized rings have been extensively reviewed in the literature.[12, 13] Therefore, these older methods will be referred to only in those cases where they are also relevant to the syntheses of cyclic diacetylenes.

2.1. Cycloalkadiynes from Nucleophilic Substitution Reactions (Ring-Closing Reactions)

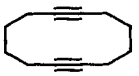
Reaction of α,ω-dihaloalkanes with the dialkalimetal salt (Na, Li) of α,ω-diacetylenes yields cyclic diacetylenes, as is exemplified by the preparation of 1,8-cyclotetradecadiyne (**17**) from 1,5-dibromopentane (**15**) and 1,8-nonadiyne (**16**). Application of this method to the synthesis of 1,7-cyclododecadiyne (**18**) and other C_{13} to C_{16} rings furnishes these products in yields ranging from 10 to 57%.[14, 15] In an analogous fashion 1,6-dioxa-3,8-diyne (**21**)[16] and 1,6-dithia-3,8-diyne (**27c**)[17] may be prepared in one-pot reactions. As an illustration the multistep synthesis of the thia-3,8-diynes **27a–d** will be outlined.[18]

The starting metalated 1,6-heptadiyne derivatives **24a–d** are hydroxymethylated to **25a–d** and then transformed to the dibromides **26a–d**. Thiacyclization to **27a–e** is achieved with either tributyltinsulfide,[19] $NaS_2 \cdot 9H_2O$ (making use of the cesium effect[20]), or NaS_2 on Al_2O_3.[21] The latter method, originally described by Nicolaou and coworkers,

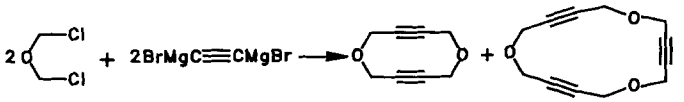
Rolf Gleiter studied chemistry at the University of Stuttgart, completing his Ph.D. in 1964 under F. Effenberger. After postdoctoral stays with P. von R. Schleyer at Princeton University (1966) and R. Hoffmann at Cornell University (1967–1968), he went to Basel and completed his habilitation under E. Heilbronner (1969–1972). In 1973 he accepted the position of Professor for Theoretical Organic Chemistry at the Technische Hochschule in Darmstadt. Since 1979 he has been Professor for Organic Chemistry at the University of Heidelberg. His areas of interest include the bonding relationships in inorganic and organic ring systems and the interactions in nonconjugated π systems as well as those between free electron-pairs in heterocycles and polyketones. In the last few years he has been involved mainly with the syntheses of model compounds, for example cyclic acetylenes, cage molecules, and polyketones.



15 16 17

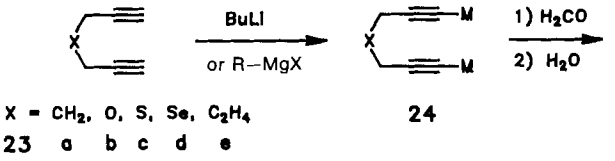


18



19 20 21 22

has been used successfully in the syntheses of cyclic enediynes of type **8**.[8, 21] The preparation of undec-3-ene-1,5-diyne (**31**) illustrates this method (Scheme 1) in which the



X = CH_2, O, S, Se, C_2H_4

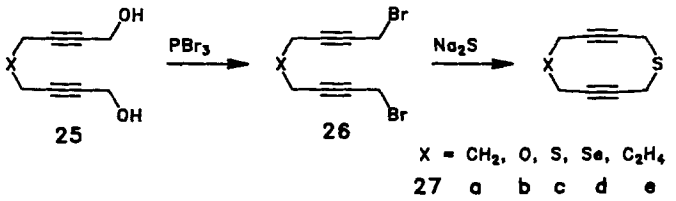
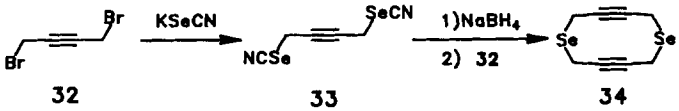
24



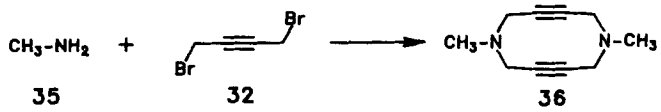
X = CH_2, O, S, Se, C_2H_4

25 26 27 a b c d e

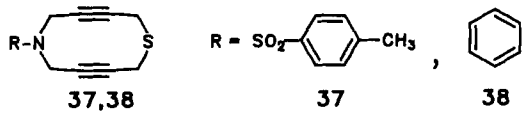
decisive step is a Ramberg–Bäcklund ring contraction (**30** → **31**). A heterocyclic diyne, 1,6-diselena-3,8-cyclodecadiyne (**34**) was prepared by reductively coupling diselenacyanate **33** with dibromide **32** according to Misumi's method.[22] This reaction furnished **34** in up to 50% yield.[18b] The alkyl derivatives of 1,6-diazacyclodeca-3,8-diyne, for example **36**, have been prepared in one-pot reactions from the corresponding alkylamines and **32** in yields of 5%.[23a] In a procedure analogous to that used in the synthesis of **27** the 1-aza-6-thia-3,8-diynes of type **37** and **38** were prepared.[23b, 23c]



32 33 34



35 32 36



37,38 37 38

Recently nucleophilic substitution has also been used to obtain a number of homoconjugated enediynes with C_{10}–C_{12} rings.[24] Scheme 2 outlines this method in the preparation of **41**–**43**;[24b] diynes **39** and **40** were synthesized in an analogous manner. Although the last step of this route gives in some cases only 5% yield, this sequence still provides the easiest access to this type of structure. Earlier attempts at the synthesis of **41** and **42a** failed probably because the final step was carried out in the presence of Cu^I salts.[25, 26]

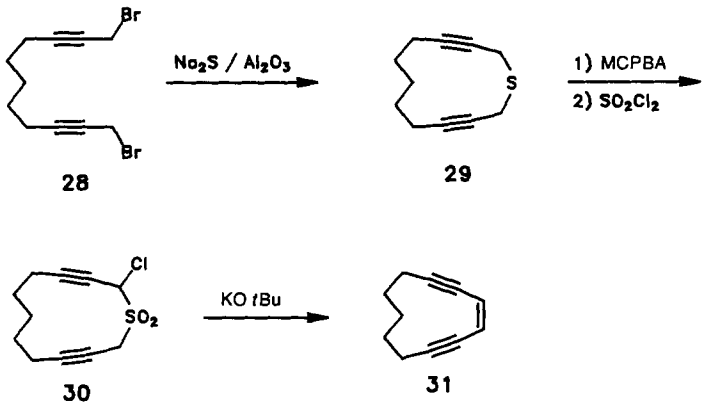
Scheme 2. Synthesis of compounds **41**–**43**.

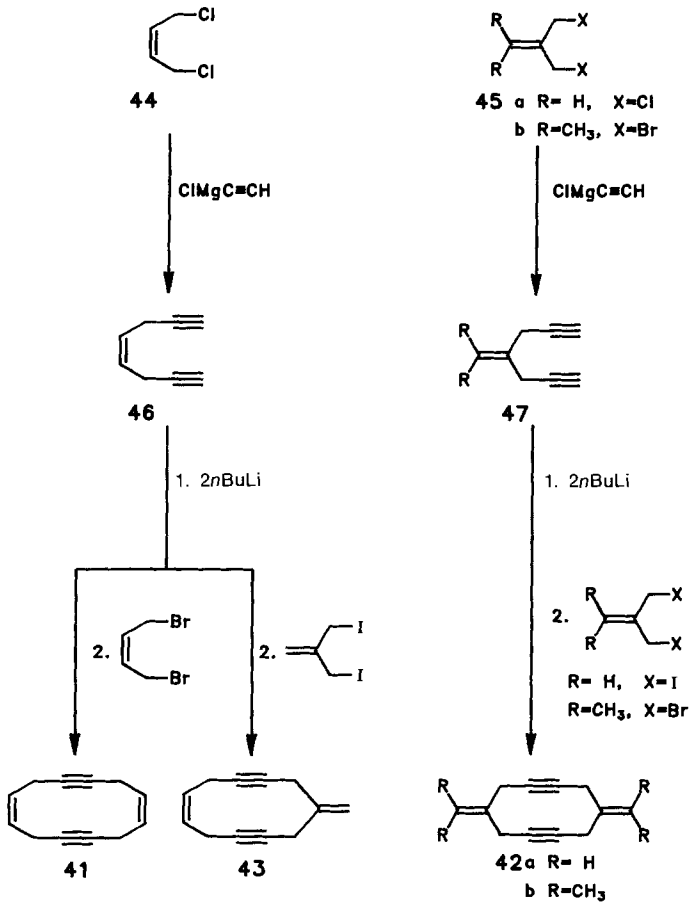


28 29 30 31

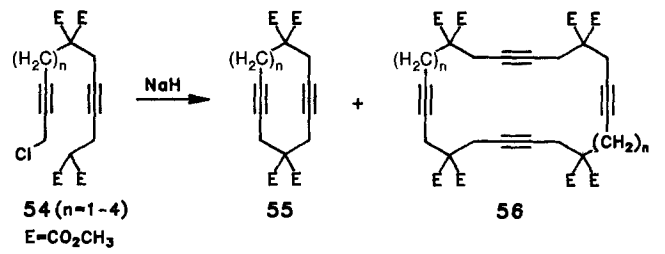
Scheme 1. MCPBA = *meta*-chloroperbenzoic acid.

Other cyclic dialkynes, such as conjugated **50**[27] and **53**,[28] were prepared by nucleophilic substitution reactions via the metalated intermediates **49** and **52**. A nice adaptation of this procedure is the intramolecular nucleophilic attack of a C-H acidic moiety on an electrophilic component as in **54**, leading to the synthesis of the 10–13-membered rings **55** (n = 1–4).[29] Unfortunately the ester groups in **55** can be cleaved only with difficulty or not at all.

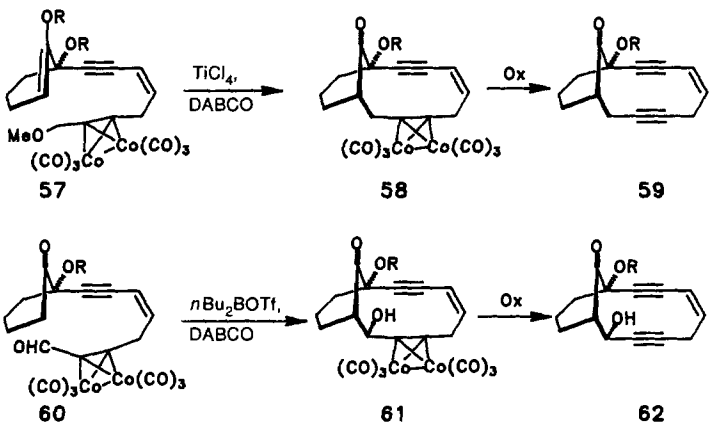
Two methods employed more recently should be mentioned at this point, since they were used in the synthesis of the potential anticancer agents **59** and **62**.[30, 31] In the preparation of **59** the $[Co_2(CO)_6]$ fragment is used to stabilize an



Scheme 3. Tos = $O_2SC_6H_4CH_3$.



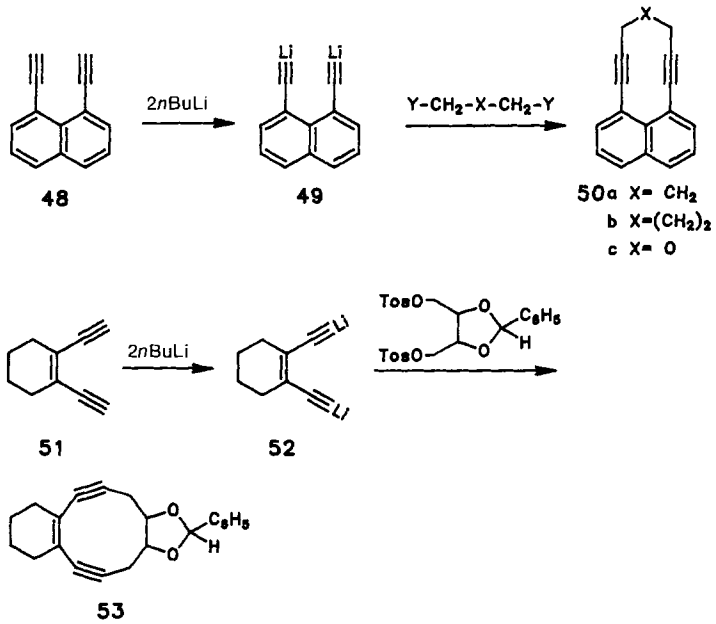
strated by the reaction of dichloroalkylsilanes **63** with alkynyl Grignard reagents furnishing diynes **64**.[32] Another extraordinary reaction is found in the synthesis of **67**–**69**.[33] Remarkably, the strained trisilacyclohepta-1,4-diyne **69** is produced on thermolysis of **68**,[33] thus implying that **67** and **68** are only slightly strained.

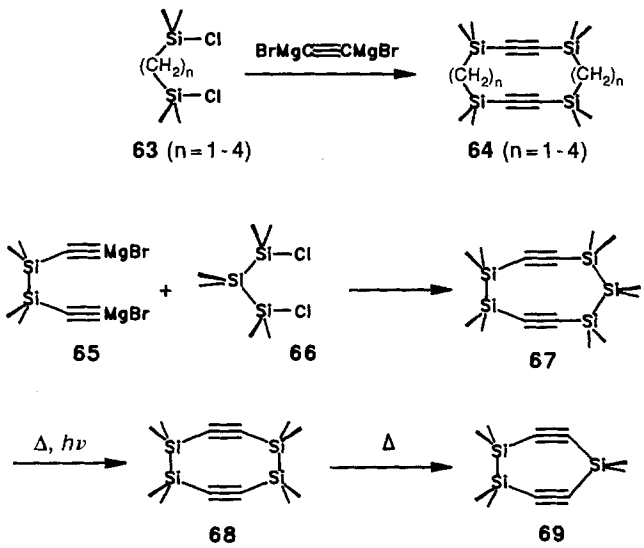


Scheme 4. DABCO = 1,4-diazabicyclo[2.2.2]octane, nBu$_2$BOTf = di-n-butylboron trifluoromethanesulfonate.

intermediate propargylic cationic species. In **60** complexation by $[Co_2(CO)_6]$ leads to activation of the aldehyde group, in this case by stabilizing a partial positive charge in the propargylic position.

Formation of cyclic diacetylenes by nucleophilic substitution is by no means restricted to hydrocarbons, as is demon-

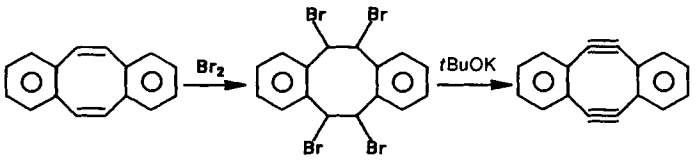




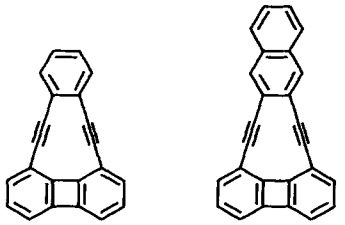
2.2. Cycloalkadiynes from Elimination Reactions

The synthesis of 5,6,11,12-tetradehydrodibenzo[*a*,*e*]cyclooctene (**72**) is illustrative of the elimination of HBr using a

strong base.[34] In an analogous manner **13**[12b] and the cyclic conjugated diynes **73** and **74** were also prepared.[35]

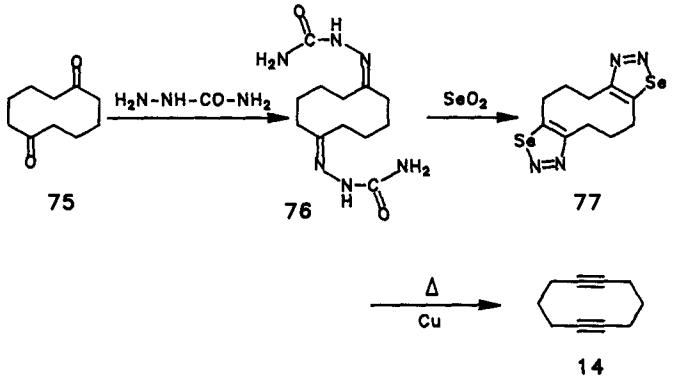


70 **71** **72**



73 **74**

Another important elimination method is the reaction first described by Lalezari et al. in which a selenadiazole is thermolyzed.[12, 13, 36–38] This reaction is used effectively in the synthesis of 1,6-cyclodecadiyne (**14**).[39a] The bisselenadiazole **77** is prepared from 1,6-cyclodecadione (**75**) via the bissemicarbazone **76**. Thermolysis of **77** in the presence of



75 **76** **77** **14**

copper powder provides the desired product, 1,6-cyclodecadiyne (**14**). The depicted reaction sequence leads only to traces of bis(selenadiazole) **78**, the regioisomer of **77**. We attribute this to the fact that *cis,cis*-1,6-cyclodecadiene (**79**)[40] is more stable (ca. 8 kcal mol^{-1}) than the two other conformers of 1,5-cyclodecadiene, **80** and **81**, according to MM2 calculations. The thermolysis of selenadiazoles was used to obtain the diacetylenes **24** and **82**–**86** from the respective cyclic diones and cyclic yneones.

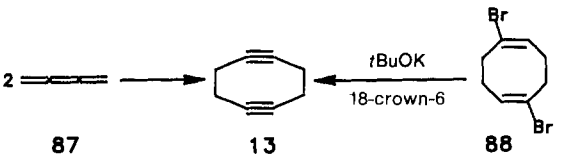
82 **14** **84** **86** **83** **85** **18**

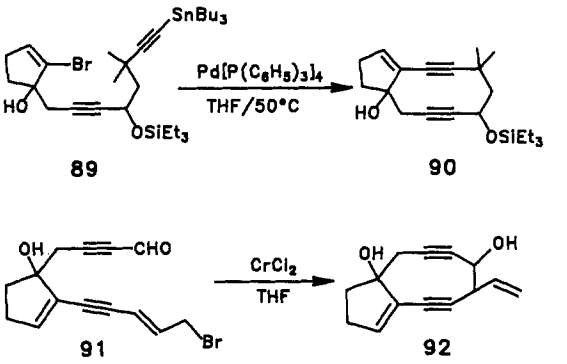
2.3. Cycloalkadiynes from Special Methods

The first reported synthesis of 1,8-cyclooctadiyne (**13**) was achieved by the dimerization of butatriene (**87**).[41] A considerably higher yield is obtained when 1,5-dibromo-1,5-cyclooctadiene (**88**) serves as starting material.[12b] The con-



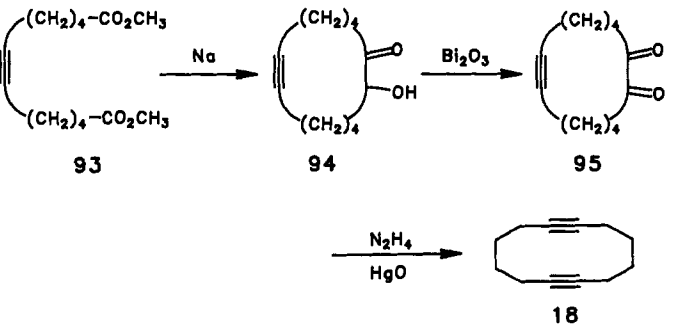
87 **13** **88**

struction of ten-membered rings similar to that of neocarzinostatin was accomplished with the Pd^0-catalyzed coupling reaction of an alkenylbromide fragment with an alkynylstannane.[42] Another interesting coupling reaction is the intramolecular reaction of an allylbromide with an aldehyde in the presence of $CrCl_2$.[43] Even the nine-membered ring of diyne **92** can be closed in this way. The acyloin con-



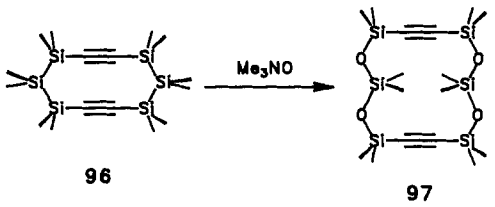
89 **90** **91** **92**

densation has also been used successfully to prepare 1,7-cyclododecadiyne (**18**) in good yields.[44] The attempt to close a ten-membered ring failed, but this ring size is generally not



93 **94** **95** **18**

favored in this reaction. To synthesize the 14-membered ring in **97** the ten-membered ring in **96** was expanded by oxidation.[45] Astonishingly, the final product **97** is isolated in



96 **97**

89% yield, even though this ring expansion probably proceeds through a number of steps.

3. Structures and Spectroscopic Properties of Cyclic Diacetylenes

3.1. Structures of Cyclic Diacetylenes

The most relevant structural parameters of cyclic diacetylenes have been collated in Tables 1–3. Of the diynes whose structures have been investigated 1,5-cyclooctadiyne (**13**) and 5,6,11,12-tetradehydrodibenzo[*a,e*]cyclooctene (**72**) are the most strained. Their structural parameters indicate a strong bending at the sp centers of the eight-membered rings of 20.7° in **13** and 24.3° in **72**. The transannular distances between the triple bonds are reported as 2.597 Å (**13**) and 2.617 Å (**72**). A further consequence of the imposed strain is an elongation of the bonds; the bonds between the two sp^2-hybridized C atoms in **72** are stretched to 1.431 Å, those between the two sp^3 centers in **13**, to 1.57 Å. In the tetrasila-compound **68**, on the other hand, most of the strain is relieved in the long Si–Si bonds. Consequently the bond angles at the sp centers deviate only 11–16° from linearity.

A somewhat smaller deviation from the linear arrangement (between 2 and 13°) is found in the ten-membered cyclic 1,6-diynes (Table 2). With the exception of diyne **64** all of these compounds are found in the chair conformation in the solid state. Depending on the heteroatom incorporated in the bridging unit, the transannular distance between the triple bonds varies between 2.91 Å and 3.5 Å. One should also note that the substituents on the nitrogen atom in **36**[23b] and **37**[23a] are in the axial position in the crystalline state. This also holds for the 1,6-diazacyclodeca-3,8-diyne ring even when it is substituted with bulky isopropyl or *tert*-butyl groups.[48] The 11- and 12-membered rings (Table 3) show deviations of 4 to 9° at the sp centers. The conformations of **17** and **21** have been discussed by J. Dale based on early investigations of their X-ray structures.[40]

3.2. Photoelectron Spectra of Cyclic Diacetylenes

PE spectroscopy is the proper tool for investigating the influence of the length of the bridging units on the trans-

Table 3. Comparison of selected bond lengths in cyclic diacetylenes with 11- and 12-membered rings.

annular interaction of the two triple bonds. This is best demonstrated by comparison of the PE spectra of **13**[59] and **14**[39] (Fig. 3). The predictions made in Section 1 and in Figure 2 are confirmed: For **13** (eight-membered ring) the peak attributed to the π_i^+ MO is at lower energy than that assigned to the π_i^-. Conversely, in **14** (ten-membered ring) the peak assigned to the π_i^- MO is lower in energy than that of π_i^+. In contrast to the small separation of the bands in **13**, a large splitting (1.5 eV) is observed in **14** between π_i^+ and π_i^-. An analogous relationship is observed in the comparison of the PE spectra of **50a** and **50b**.[60] In Figure 4 the energies of the first bands taken from the PE spectra of a series of cyclic diacetylenes are compared. Most noticable is that the

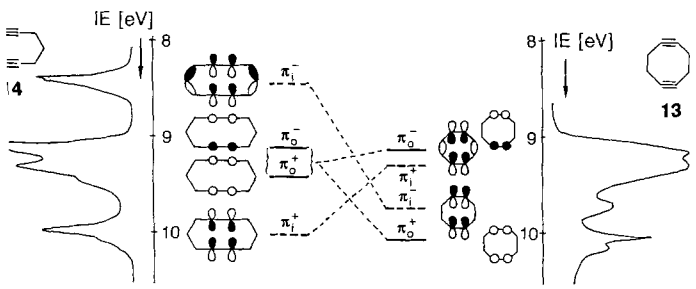

Fig. 3. Comparison of the first bands of the PE spectra of **13** and **14**.

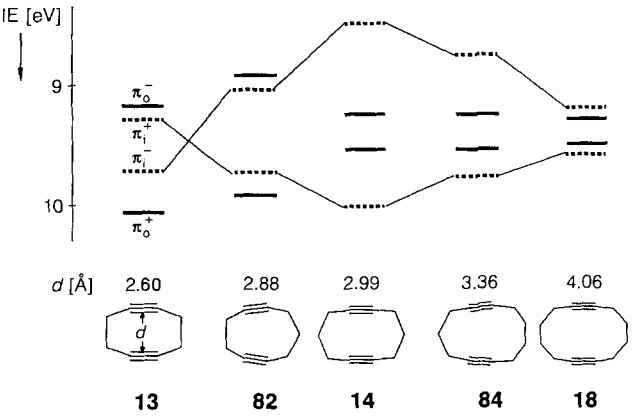

Fig. 4. Comparison of the first bands of the PE spectra of **13**, **14**, **18**, **82**, and **84**.

splitting of the π_i levels reaches its maximum at **14** (ten-membered ring) and then diminishes with increasing bridge length. The splitting observed for the π_o levels remains virtually constant for diynes with transannular distances greater than 3.0 Å between the triple bonds. In the PE spectra of the ten-membered heterocycles (Fig. 5) with the exception of **21**

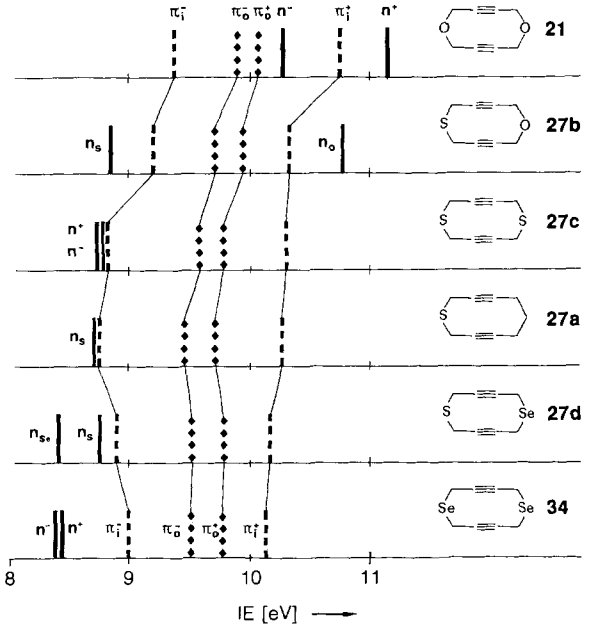

Fig. 5. Comparison of the first bands of the PE spectra of the heterodiynes **21**, **27a–d**, and **34**.

the peak attributed to the HOMO arises from the heteroatom (n) MO. The splitting of the in-plane (π_i) MO energy levels varies from 0.9 to 1.5 eV. The PE spectra of the enediynes **39** and **40** as well as dienediynes **41–43** indicate

that the π_i^+ and π_o^+ linear combinations of the triple bonds interact significantly with the π MOs of the double bonds (homoconjugation).[24]

4. Reactions with Metal Compounds

4.1. Complexation

Figure 3 shows that the highest occupied MO (π_i^-) of 1,6-cyclodecadiyne (**14**) lies in the molecular plane. It seems likely, therefore, that an electrophilic reagent will attack preferentially in this plane.[11] To verify this hypothesis we carried out experiments with the cyclic diacetylenes and a number of electrophilic transition-metal compounds, such as silver trifluorosulfonate [$Ag(SO_3CF_3)$] and copper trifluoromethanesulfonate [$Cu(SO_3CF_3)$].[61] The reaction of **14**, **17**, and **18** with [$Ag(SO_3CF_3)$] in THF yields a colorless, sparingly soluble 1:1 complex. Analogous results are obtained for the precipitates resulting from the reaction of **14** and **18** with [$Cu(SO_3CF_3)$][61]. The characteristic IR and NMR data of the uncomplexed acetylenes are not influenced to any significant amount by complexation with Ag^+ or Cu^+.

The complex $[(C_{10}H_{12})Ag(SO_3CF_3)]_n$ has a two-dimensional layered structure in the crystal. In each of these layers the Ag atoms lie in the molecular plane between two 1,6-cyclodecadiyne rings in chairlike conformations (Fig. 6). This

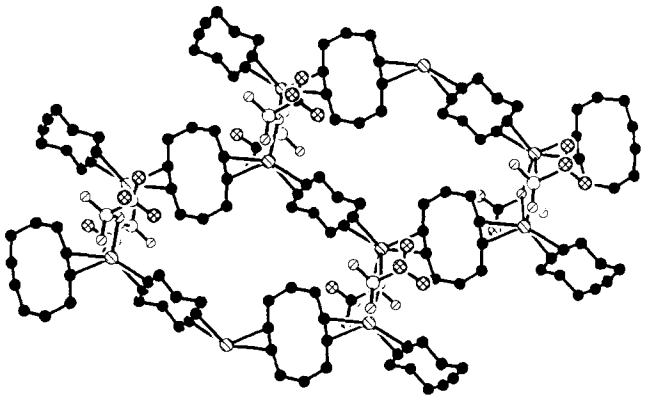

Fig. 6. A section of the polymer structure of $[(C_{10}H_{12})Ag(SO_3CF_3)]$ (view from the top). Carbon ●, silver ⊘, oxygen ⊗, sulfur ○, fluorine ⊘.

experiment supports the prediction mentioned above. The X-ray structures of $([C_{12}H_{16})Ag(SO_3CF_3)]_n$ and $[(C_{12}H_{16})Cu(SO_3CF_3)]_n$ show the 12-membered rings to be connected by respective silver and copper ions. In these complexes two of the three oxygen atoms of the triflate ligand are coordinated to different metal-centers giving rise to a three-dimensional network in the solid state. A similar three-dimensional polymeric structure is found for $[(C_{14}H_{20})Ag(SO_3CF_3)]_n$. In Figure 7 the most important structural parameters of cyclodecadiyne **14** in its uncomplexed and complexed states are compared. A slight elongation of the triple bonds and a small increase of the transannular distance occur upon complexation. Along with the spectroscopic results this implies that the metal cation is only loosely coordinated to the diacetylene.

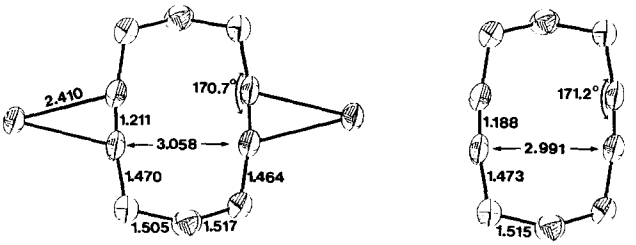

Fig. 7. Comparison of the uncomplexed (right) and complexed (left) structures of 1,6-cyclodecadiyne (**14**).

Cyclic diacetylenes with medium-sized rings react with $[Co_2(CO)_8]$ to form red bis(hexacarbonyldicobalt) complexes[62]. As expected, this type of complexation leads to a substantial change of the structural parameters of the cyclic diacetylene. An example is the complex of 1,6-cyclodecadiyne **14** depicted in Figure 8, in which the Co_2C_2 tetrahedral structure is easily discerned. The large increase in the

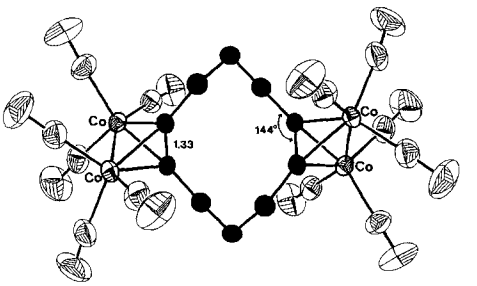

Fig. 8. Structure of $[(C_{10}H_{12})\{Co_2(CO)_6\}_2]$. The carbon atoms of 1,6-cyclodecadiyne ring are filled in for clarity.

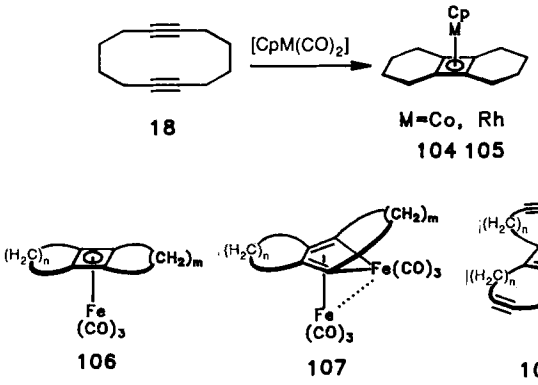
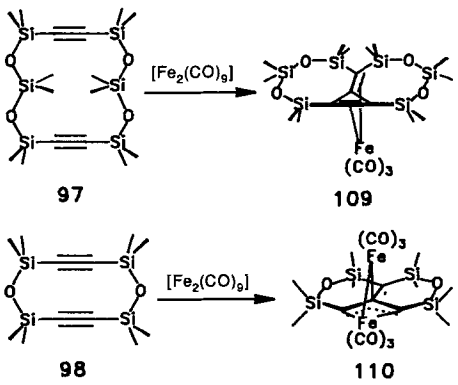
distances between the originally sp-hybridized centers and the concomitant rehybridization at these carbon atoms changes the conformation of the ten-membered ring considerably. The bis(hexacarbonyldicobalt) complexes of **14**, **18**, and **82**–**86**[62] as well as those of **41** and **42** have been prepared. All of these are stable red compounds in the solid state. The formation of complexes with cyclic monoalkynes has already been reviewed.[63]

4.2. Reactions with Formation of Cyclobutadiene Complexes

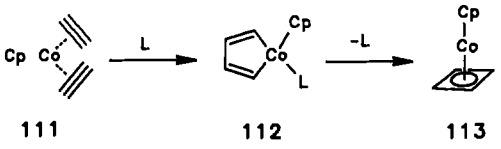
The reactions of cyclic diacetylenes such as **17** and **18** with dicarbonyl(η^5-cyclopentadienyl)cobalt [$CpCo(CO)_2$], dicarbonyl(η^5-cyclopentadienyl)rhodium [$CpRh(CO)_2$], and pentacarbonyliron [$Fe(CO)_5$] have been studied by King and coworkers.[65–68] They reported the formation of tricyclic cyclobutadiene complexes in yields of 40–80% for Co and 15–70% for Rh. One example is the reaction of 1,7-cyclododecadiyne (**18**) with [$CpM(CO)_2$] (M = Co, Rh) leading to **104** and **105**.[64–65] The complexation of [$Fe(CO)_5$] or [$Fe_3(CO)_{12}$] with cyclic diacetylenes is more complicated: Besides tricyclic cyclobutadiene complexes such as **106**, Fe_2 complexes like **107** and **108** could be isolated.[67, 68]



The complexation reactions of the two silaoxadiynes **97** and **98** take a different course. The reaction of **97** with $[Fe_2(CO)_9]$ provides complex **109** in 45% yield. This product may in fact be viewed as a $[Fe(CO)_3]$ complex of a methylenecyclopropene unit.[69] For **98** the same reaction leads to the trimethylenemethane complex **110** in a yield of 34%.[69]

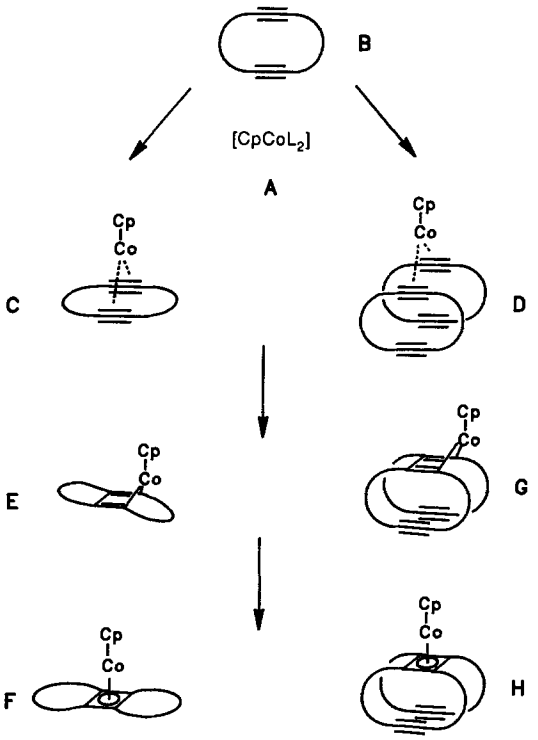


The mechanism of cyclobutadiene formation from two acetylene units in the presence of $[CpCoL_2]$ or $[Fe(CO)_5]$ is postulated to occur via a metallacycle such as **112**, which is formed from diacetylene complex **111**. Metallacycle **112** subsequently rearranges to the cyclobutadiene complex **113**.



MO calculations lend support to this proposed mechanism, since they predict the direct transformation of **111** to **113** to be symmetry-forbidden. Such a conversion would require a considerable amount of electronic activation.[70, 71] Furthermore, this mechanism is supported by research carried out by Wakatsuki and Yamazaki,[72–75] in which they were able to isolate cobaltacycles of type **112** stabilized by a phosphine ligand.

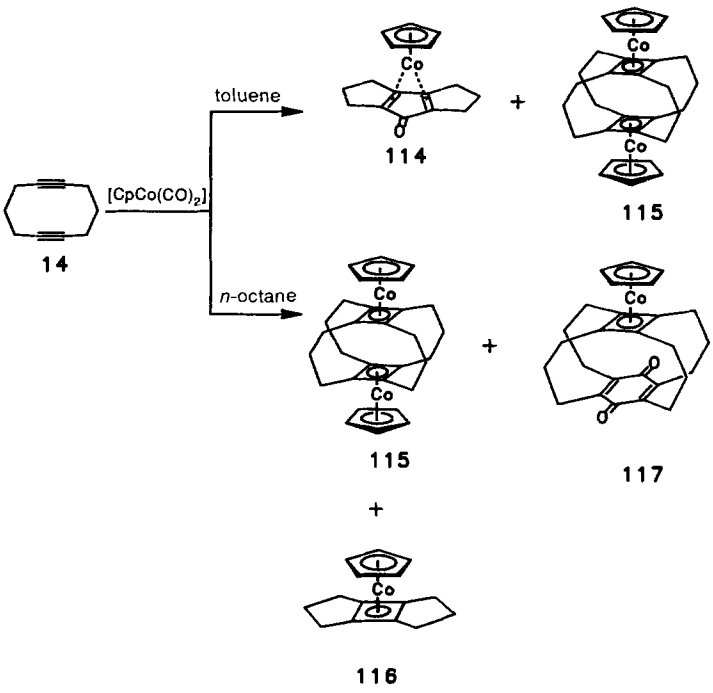
The reaction path **111** → **112** → **113** may be transferred to cyclic diacetylenes (**B**) (Scheme 5). Obviously the intramolecular ring formation (**C** → **E** → **F**) may be hindered if



Scheme 5. Reaction of cyclic diacetylenes with $[CpCoL_2]$.

the bridges between the triple bonds are short (**E**, for instance, is an *anti*-Bredt structure). An alternative path is the intermolecular formation of cyclobutadienes (**D** → **G** → **H**).

To test these hypotheses we carried out a number of reactions with 1,6-cyclodecadiyne (**14**) and $[CpCo(CO)_2]$.[11] When the reaction is carried out in *n*-octane the main product (12% yield) is the superphane of cyclobutadiene (**115**) stabilized on both faces by [CpCo] units.[76] The tricyclic cyclobutadiene complex **116** (6%) and the mixed superphane **117** (0.7%)[76–78] were isolated as side prod-



ucts. When the reaction is conducted in toluene, complex **114** (5%) is formed as well as **115** (2%).

The X-ray structures of all three Co complexes (**115**–**117**) are shown in Figures 9–11.[76–78] The cyclobutadiene rings in **115** and the connecting propano units show C_{4h} symmetry (Fig. 9). In fact, this local symmetry is observed in all the

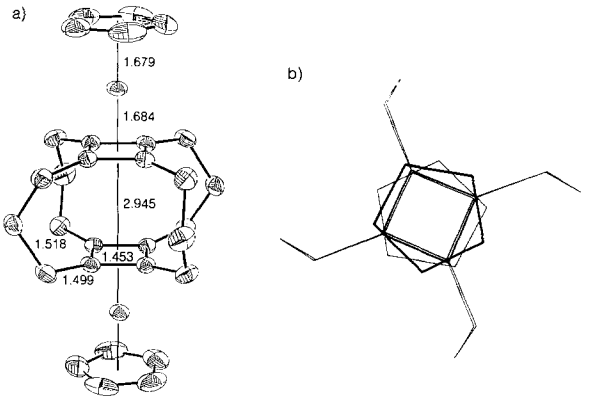


Fig. 9. Structure of **115**; a) side view b) top view.

superphanes prepared from **14** or **42b**. The two complexed cyclobutadiene moieties of **115** are not far apart (2.94 Å). In the structure of **116** the cyclobutadiene unit has distinctly alternating bond lengths caused by the strain from the fused five-membered rings. (Complexed cyclobutadienes usually

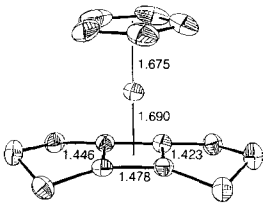

Fig. 10. Most relevant structural parameters of **116**.

have nearly square structures.[66]) The mixed superphane **117** shows a deformation of the quinone ring, in which the CO groups are twisted out of the plane of the double bonds by 27°. Of the seven possible conformations of the propano bridges (Scheme 6) structure **a** is the one observed in the solid state.

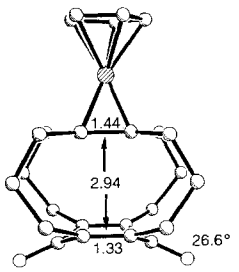

Fig. 11. Side view of the structure of **117**.

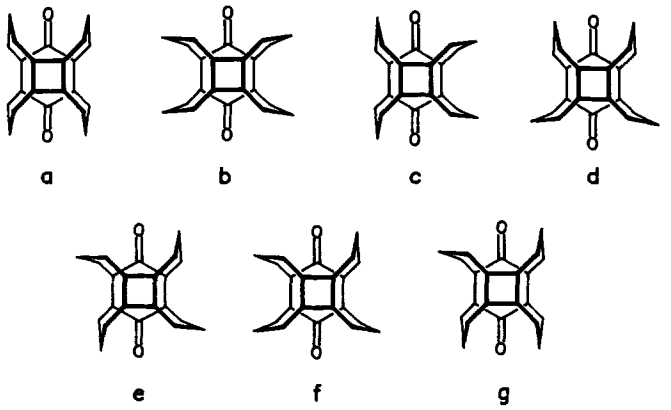

Scheme 6. Conformation of the propano bridges in Co complex **117**.

To determine the influence of a substituted cyclopentadienyl ligand on the Co atom on the reaction between **14** and [R-CpCo(cod)] we allowed **14** to react with the set of Co complexes **118**–**122** under reaction conditions similar to those described previously (refluxing *n*-octane).[79] The correlation between the observed yields of the superphane and the relative chemical shifts of the complexes as determined by ^{59}Co NMR spectroscopy is shown in Figure 12.[79] As a

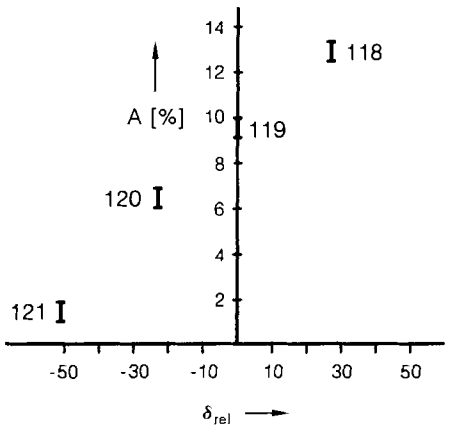

Fig. 12. Correlation between the yields obtained from the reaction of 1,6-cyclodecadiyne (**14**) with [(η^5-R-C_5H_4)Co(cod)]-complexes **118**–**121** and the products' relative chemical shifts, δ^{59}Co.

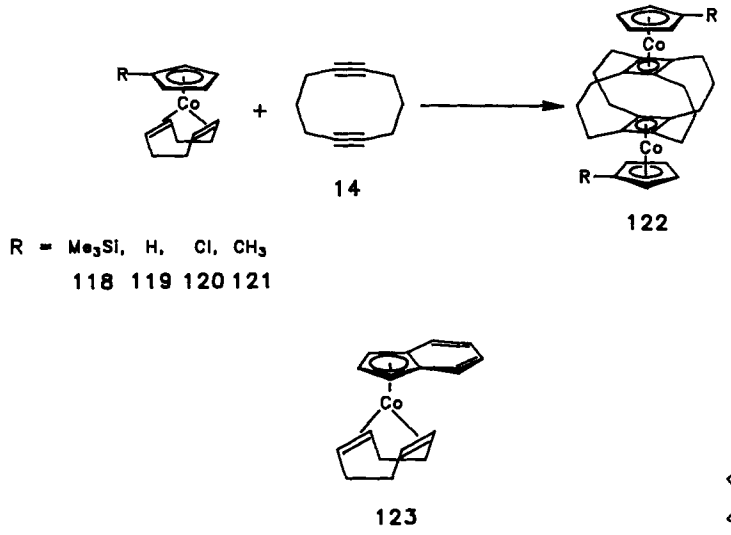
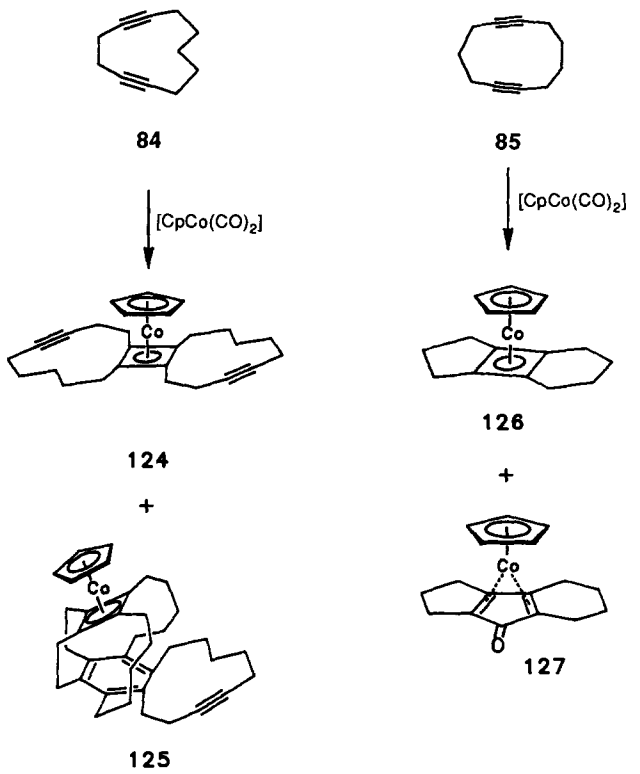
reference for the ^{59}Co shifts in the series of η^5-(cyclopentadienyl)Co(cod) complexes the value δ_{rel} (^{59}Co) of the unsubstituted compound (R = H) was set at zero. This type of correlation was first reported by Bönnemann.[9b] When the reaction was carried out with **123** and **14**, the corresponding cyclobutadiene superphane capped with two indenyl-Co fragments could be isolated in 25 to 30% yield.[79]

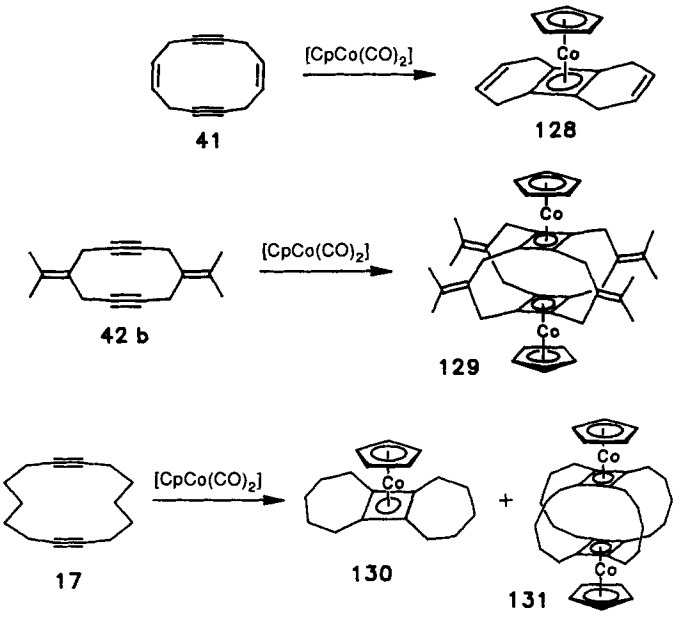
In order to find out more about the competition between the intra- and intermolecular pathways of cyclobutadiene formation and the dependence on the ring strain in the starting compound, two diynes with 11-membered rings, **84** and **85**, were treated with [$CpCo(CO)_2$]. Two intermolecularly formed products (**124**, **125**) were isolated[80] from complexation of **84**.[80] In contrast, if the slightly less strained diyne **85** is complexed, two compounds, **126** (32%) and **127** (2.5%),



arising from intramolecular reaction are formed. The same applies for the dienediynes **41** and **42b**; the less strained compound **41** gives an intramolecular complex **128** (56%), while the reaction between **42b** and $[CpCo(CO)_2]$ leads to formation of the superphane **129** in 10% yield.[81] Yet there

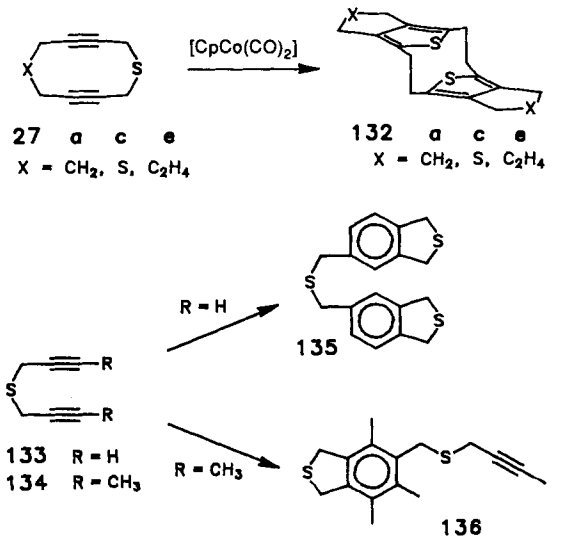


must be other (to date unknown) factors apart from ring strain that influence the outcome of this type of reaction. Even the unstrained starting compound 1,8-cyclotetradecadiyne (**17**) forms not only the intramolecular product **130** (17%)[64] but also superphane **131** (5%).[82] In this context it is of interest that the reaction between **18** and $[CpCo(CO)_2]$ leads only to the tricyclic product **104** (86% yield).[64]



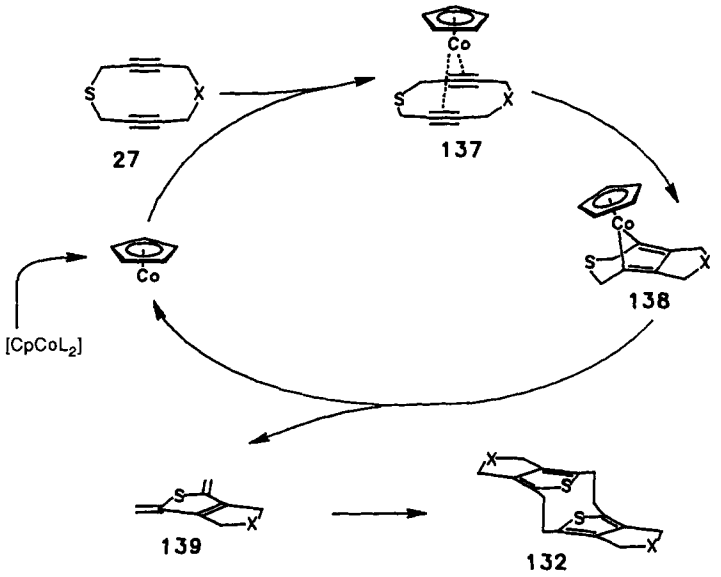
4.3. Reactions between $[CpCo(CO)_2]$ and Heterodiynes

Stimulated by the fascinating results that were observed in the reactions of carbocyclic diynes with ten-membered rings described above, we thought it logical to carry out similar experiments using heterodiynes. Our first attempts with the two components, **21** and $[CpCoL_2]$ ($L = C_2H_4$, CO), were disappointing since we were only able to detect polymeric material.[83] On the other hand, reactions with the sulfur-containing diynes **27a**, **27c**, and **27e** showed promising results. Even when only catalytic amounts of $[CpCo(CO)_2]$ were used, thiophenophane **132** could be isolated (12% for **27a** and **27c**).[18, 84] The configuration of thiophenophane **132b** was established by X-ray structural analysis.[84] We then proceeded in an analogous manner as described previously for the carbocyclic diynes, that is, we examined the influence of ring size on this reaction. In the complexation of **27e** the yield of thiophenophane **132e** is reduced to 6%; for



acyclic diynes exemplified by **133** and **134** [2 + 2 + 2]cycloaddition dominate, and products of constitution **135** or **136**[18] can be detected.

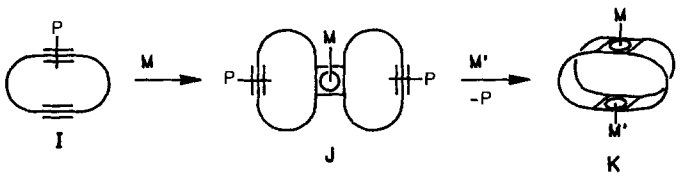
To interpret these results we propose the following mechanism: In the first step the CO or cod ligands of $[CpCo(CO)_2]$ or [CpCo(cod)] are replaced by the cyclic heterodiyne, thus forming **137** in which the two acetylene moieties are η^2-coordinated to cobalt. This complex is then postulated to undergo oxidative addition to **138**. To lead to thiophenophane **132** the next step must comprise a rearrangement of **138**, in which the sulfur and cobalt atoms exchange places. Two modes of reaction are feasible, either a double dyotropic rearrangement[85] or a coordination of sulfur at the metal. The resulting intermediate **139** finally dimerizes to give the desired [2.2](2,5)thiophenophane. In the transformation **138** → **139** the [CpCo] fragment is liberated and completes the catalytic cycle by reaction with further diacetylene to **137**. Therefore



only catalytic amounts of $[CpCoL_2]$ are required for the reaction, which is also in line with the formation of [2 + 2 + 2] cycloadducts[18b] from larger diynyl rings.

5. Stepwise Synthesis of Superphanes

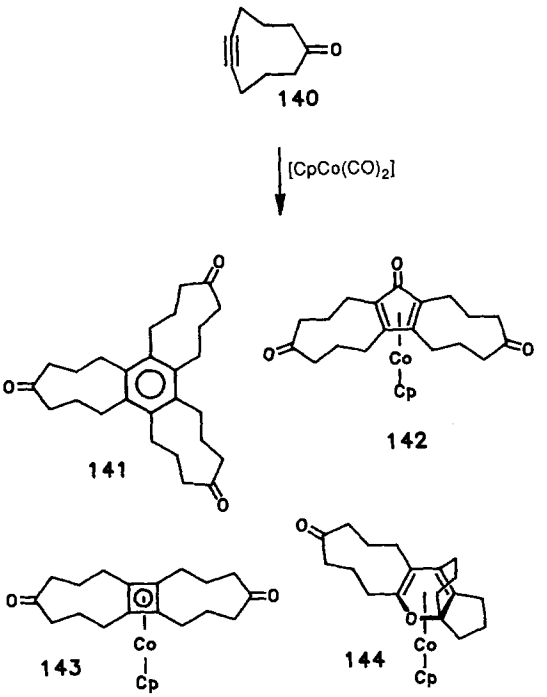
Up to this point our research has shown that a one-step synthesis of superphanes is especially facile with 1,6-cyclodecadiyne rings. Also, it seems that the only metal templates to achieve superphane formation are the $[CpCoL_2]$ complexes. A more general route to the superphane complexes



Scheme 7. P = protecting group, M = metal fragment.

should be possible, if a monoprotected diacetylene (**I** in Scheme 7) could first be dimerized and in a second step cyclized intramolecularly (**J** → **K**).

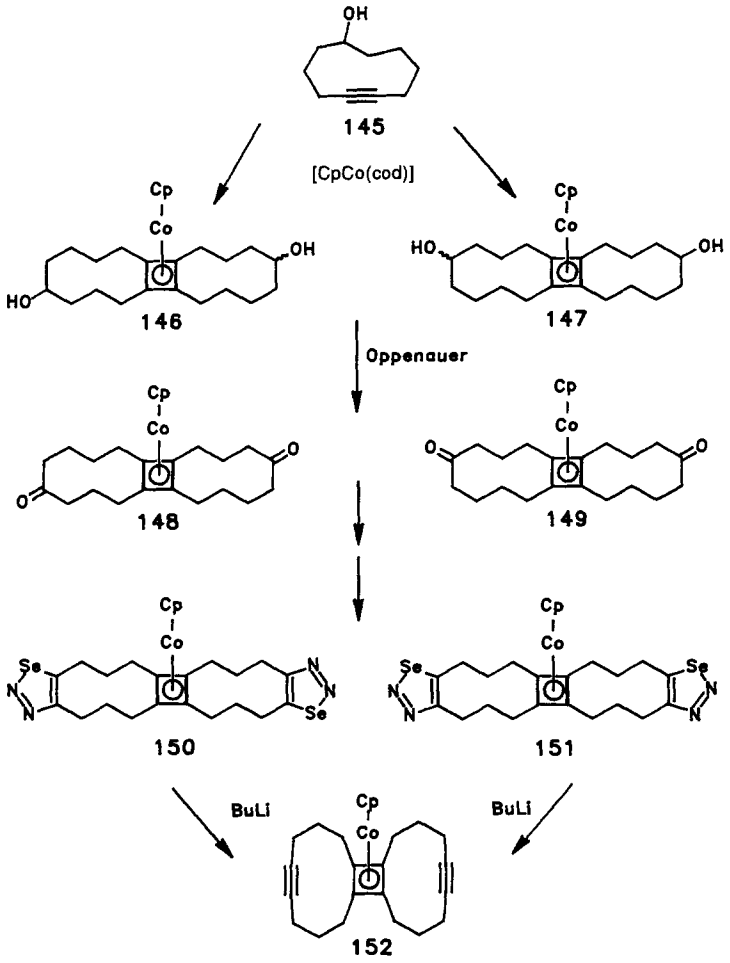
First attempts at dimerizing monosubstituted diacetylenes using $[Co_2(CO)_8]$ failed, and heating them with $[CpCo(CO)_2]$ led to disproportionation.[62] The main reaction of yneones and $[CpCo(CO)_2]$ is the formation of trimers with only a minimal amount of the desired dimerized product.[86]



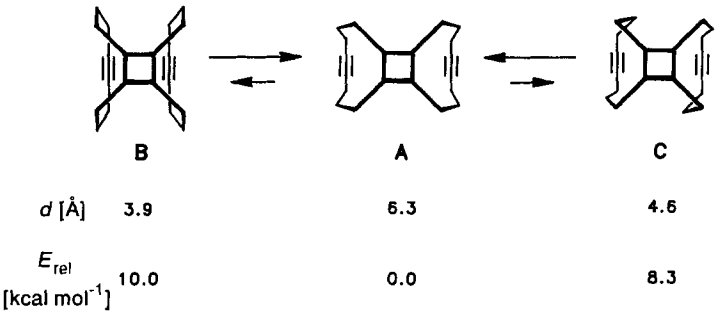
Scheme 8. Attempts at yneone dimerization.

This is demonstrated for 5-cyclononyneone **140** in Scheme 8. Surprisingly, a CO bond participates in a [2 + 2 + 2]cycloaddition to form **144**. We tested this unexpected reaction on a number of open-chain systems[86] and were able to prepare a variety of metal-complexed 2*H*-pyranes.[87]

The use of 5-cyclodecyneol **145** finally led to the stepwise synthesis of metal-stabilized cyclobutadiene superphanes.[88] Dimerization of cycloalkyne **145** to a mixture of isomeric alcohols **146** and **147** may readily be achieved with [CpCo(cod)] in about 40% yield. This mixture is oxidized to the ketones **148** and **149** by the Oppenauer oxidation; at this stage the mixture can be separated, though this is not necessary for the further reaction sequence. Treatment with semicarbazide and SeO_2 gives rise to good yields of only two of the possible four isomeric selenadiazoles. An explanation for the selective formation of **150** and **151** is provided by examination of the solid-state conformation of **148** (Fig. 13, right). The minimum energy conformation of 1,6-cyclodecadiene[40] (Fig. 13, left) has a very similar geometry to that of the ten-membered rings in **148**. We therefore conclude that the formation of the double bonds of the selenadiazole heterocycles occurs predominantly at the 6-position with respect to the cyclobutadiene ring in analogy to **79**. Fragmentation of the mixture with BuLi affords the desired diyne



152. The X-ray structure of **152** (Fig. 14)[78] shows that the triple bonds are 6.3 Å apart, parallel to each other, and in the same region of space. Conformational calculations (AM1) performed on the hydrocarbon skeleton of **152** predict, besides the global minimum **A**, two local minima, **B** and **C**, which are 10.0 and 8.3 kcal mol^{-1} higher in energy. In **B** and **C** the distance between the triple bonds is estimated to be 3.9 and 4.6 Å, respectively.



Scheme 9 shows that **152** may be transformed into a variety of metal-stabilized cyclobutadiene superphanes. Reaction with [CpCo(CO)$_2$] affords the superphane **115** in 80% yield. Remarkably, this reaction is much faster than the corresponding reaction starting with **14** (see Section 4.2.). This lends support to our hypothesis that **152** is an intermediate in the reaction of **114** with [CpCo(CO)$_2$] to **115**. Note also that reaction of **152** with [Cp*Co(CO)$_2$] (Cp* = C_5Me_5) provides good yields of **153**; however, the reaction of **152** with [Fe(CO)$_5$] furnishes the mixed superphane **155** in only 8% yield. The X-ray structure of **155** shows that the propano

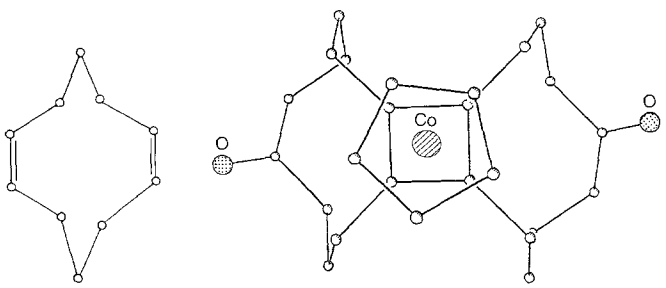


Fig. 13. Comparison of the conformations of **148** (right) and 1,6-cyclodecadiene (**79**) (left) obtained by X-ray structural analysis [78].

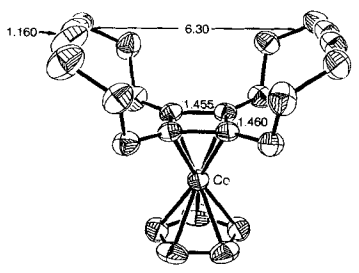

Fig. 14. Structure of **152** [78].

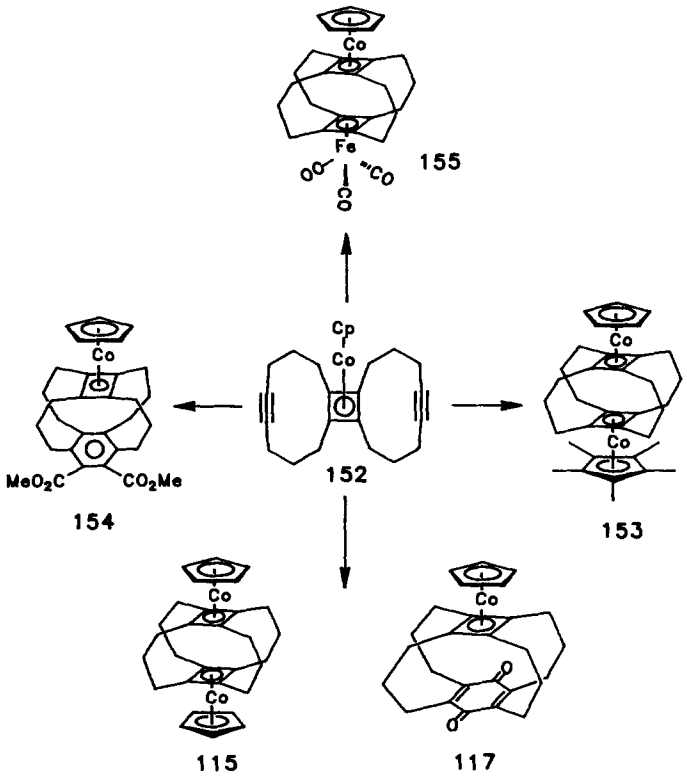


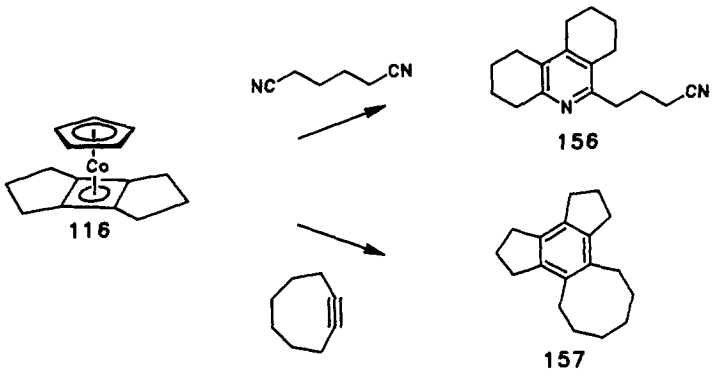
Scheme 9. Cyclization reactions of Co complex **152**.

bridges have the same conformation as that observed in **115**. The distance from the center of the cyclobutadiene ring to the Fe atom (1.77 Å) is identical to that measured for the recently synthesized [2.2](1,3)-cyclobutadienophane, in which both cyclobutadiene moieties are complexed by $[Fe(CO)_3]$ units.[89] The distance between the two cyclobutadiene rings in **155** is 2.98 Å, practically the same as that in **115**. Finally, when **152** is reacted with dimethylacetylenedicarboxylate in the presence of $[CpCo(CO)_2]$, a mixed cyclophane **154** (5%) can be isolated.

6. Reactions of Several Cyclobutadienecyclopentadienylcobalt Complexes

6.1. Reactions of "Rectangular" Cyclobutadiene Complexes

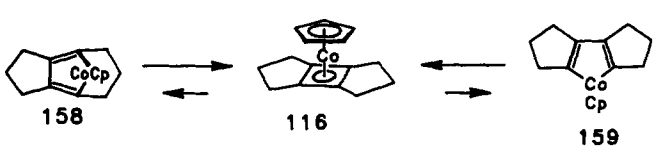
The pronounced alternation of the bond lengths in the cyclobutadiene moiety of $[CpCo(C_{10}H_{12})]$ **116**[76] is unusual considering that complexed cyclobutadienes normally have bonds of equal length.[66] This led us to the assumption that the reactivity of **116** should be enhanced as compared to that of complexes with a square-shaped cyclobutadiene unit. This proved to be true, since **116** is prone to expansion of the four-membered ring when heated with reagents containing triple bonds (Scheme 10) leading to the 6π systems **156** and **157**.[90] Even when the bonds of the four-membered ring are



Scheme 10. Reactions of **116** with reagents containing triple bonds.

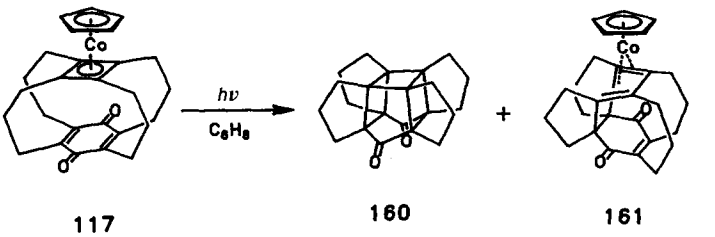
virtually equivalent as in the tricyclic cyclobutadiene complex **104** (see Section 4.2.), analogous ring expansions can be performed.[90]

In explanation of the reactivity of **116** and **104** we assume the cobalt complex **116** is in equilibrium with the cobaltacyclopentadiene derivatives **158** and **159**. Note that this step is equivalent to alkyne metathesis for which intermediates such as metal-stabilized cyclobutadienes have been proposed.[91] The cycloaddition of another triple bond then occurs either directly to **116** or to **159** with prior coordination at the cobalt center. The formation of cyclopentadienone derivatives (for example **114**, **117**, and **127**) in the reaction of cyclic diacetylenes and $[CpCo(CO)_2]$ is also accounted for by this proposed mechanism.



6.2. Reactions of the Cyclobutadiene–Quinone Superphane

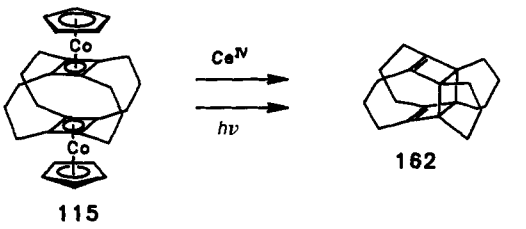
On irradiation of $[CpCo\{C_4(C_3H_6)_4C_6O_2\}]$ **117** a colorless and an orange product are formed in equimolar amounts.[92] The colorless compound **160** exhibits a bishomocubane structure. The structure of the colored



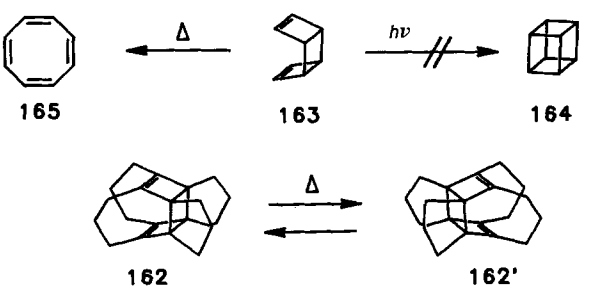
product **161**, which contains a [CpCo] fragment, has been confirmed by X-ray analysis.[92]

6.3. From Cyclobutadiene Superphane to Propella[3$_4$]prismane

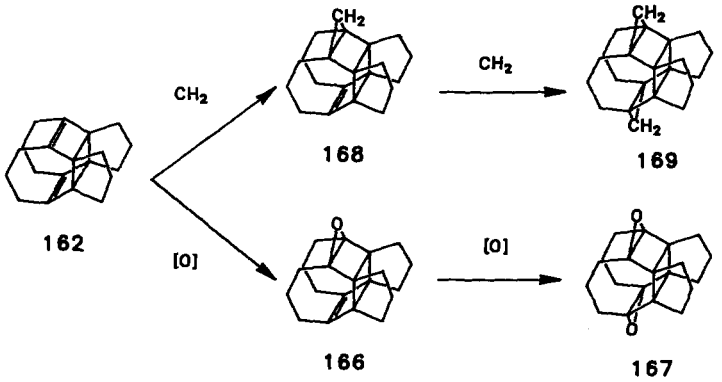
The conversion of the complexed superphane **115** to the bridged *syn*-tricyclo[4.2.0.0^{2,5}]octa-3-7-diene derivative **162** may be achieved either by oxidation with Ce^{IV} or by irradiation.[93] Interestingly, the four propano units of compound



162 alter its properties significantly compared to those of the unsubstituted tricyclooctadiene **163**. On heating, **163** rearranges to cyclooctatetraene **165**.[94] The bridged derivative **162**, on the other hand, undergoes a degenerate Cope rearrangement with an activation energy of 73–75 kcal mol^{-1}.



Because the first ionization potential of **162** lies at relatively low energy (7.6 eV), this compound should be prone to attack by electrophiles. This can be easily confirmed, and Scheme 11 shows that the expected products are formed. With *m*-chloroperbenzoic acid or diazomethane both the monoepoxide **166** as well as the bisepoxide and the propellanes **168** and **169** can be isolated, respectively[95].



Scheme 11. Reactions of **162** with *meta*-chloroperbenzoic acid and diazomethane.

Before we continue the discussion of the photochemistry of **162**, it is worth considering why irradiation of **163** cannot lead to a cubane.[96, 97] The following two arguments can be invoked: 1) The increase in strain energy in the conversion of **163** to **164** is calculated to be about 72 kcal mol^{-1}.[98] 2) The light-induced [2 + 2]cycloaddition of **163** to **164** is only possible with a large amount of (electronic) activation energy.[11] We clarify this point in Figure 15. The orbital sequence of two cyclobutene molecules is depicted on the left, and it can be deduced that their photochemical [2 + 2]cycloaddition is an allowed process.[99] For both the occupied π MOs and the vacant π^* MOs the antisymmetric (with respect to the *x*,*z*-plane) linear combination π_- lies at higher energy than the bonding linear combination π_+. On excitation of an electron from the HOMO (π_-) to the LUMO (π^*_+) the bond order between carbon atoms 1 and 1′ as well as between 2 and 2′ is increased. That is, the reaction is "allowed".[99]

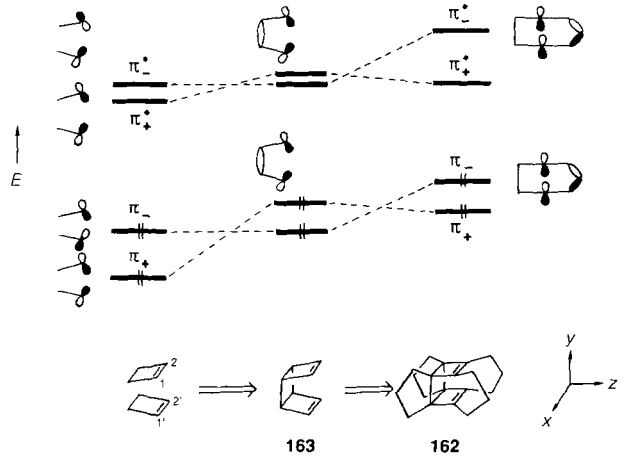


Fig. 15. Correlation between the occupied and unoccupied π MOs of two cyclobutene molecules (left), tricyclo[4.2.0.0^{2,5}]octadiene (**163**) (middle), and **162** (right).

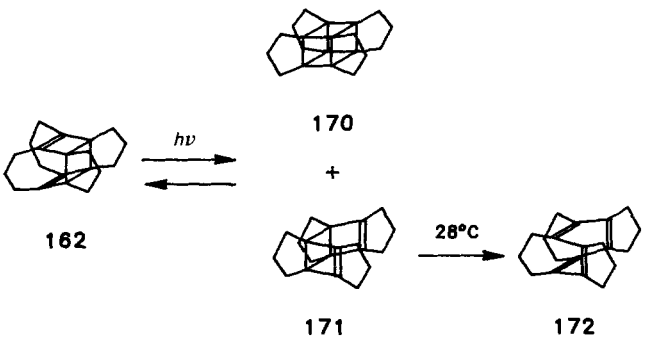
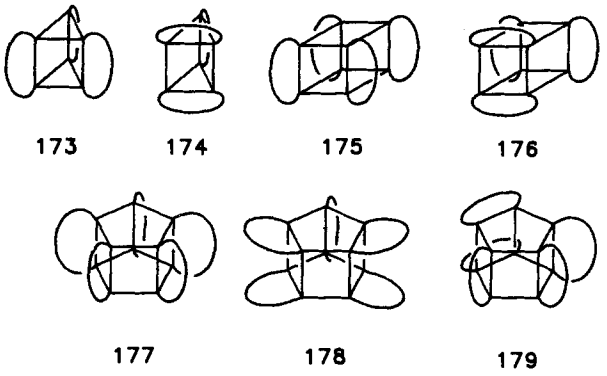
When the two cyclobutene units are connected to *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene (**163**) a strong through-bond interaction is possible and the orbital sequence is switched, so that π_+ and π^*_+ are now higher in energy than π_- and π^*_-.[100] Consequently the [2 + 2]cycloaddition reaction requires considerable (electronic) activation energy, making the reaction therefore "forbidden". To make the process an "allowed" one, the original orbital sequence (π_- above π_+) must be reinstated. One way of achieving this is by bringing the two olefinic sites closer together through the introduction of propano bridges. This has two effects: 1) The greater proximity of the double bonds (3.05 Å in **163** compared to 2.65 Å in **162**) decreases the energetic difference between π_+ and π_-. 2) The propano bridges destabilize π_- (see Figs. 2 and 3) so that an orbital sequence as shown on the right side of Figure 15 results. We can predict that as a result of the better electronic situation, a [2 + 2]cycloaddition is more likely to occur in **162** than in **163**. These qualitative arguments[11] can easily be substantiated by quantum mechanical calculations.[101]

On irradiation of **162** two products are observed,[93] one of which rearranges at room temperature. After purification one of the isolated products was shown to have a very simple ^{13}C NMR spectrum with only three resonances in the high-field region. According to the analytical data of the isolated hydrocarbons the reaction sequence depicted in Scheme 12 is most likely, in which the isolated propella[3$_4$]cubane **170** rearranges in the presence of trace amounts of acids or on heating to **162**. The strain energies calculated by an MM2 force field are as follows:[102] 164.31 kcal mol^{-1} for **162**, 229.20 kcal mol^{-1} for **170** and 181.96 kcal mol^{-1} for **171**. Interestingly the fourfold bridged cyclooctatetraene **172** cannot be obtained by thermolysis of **162**.



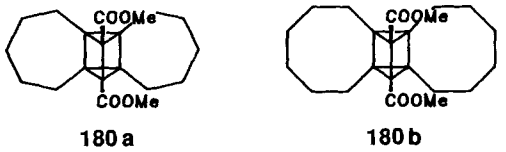
Scheme 12. Irradiation of **162**.

The cubane derivative **170** can be viewed as either a tetramer of cyclopentyne[13] or as the first representative of a new class of compounds termed the propella[n$_m$]prismanes.[11, 93] If the adjacent centers of an [m]prismane are connected by n equivalent atoms or groups of atoms, the isomers **173**–**179** are obtained for the series of [3] to [5]prismanes.

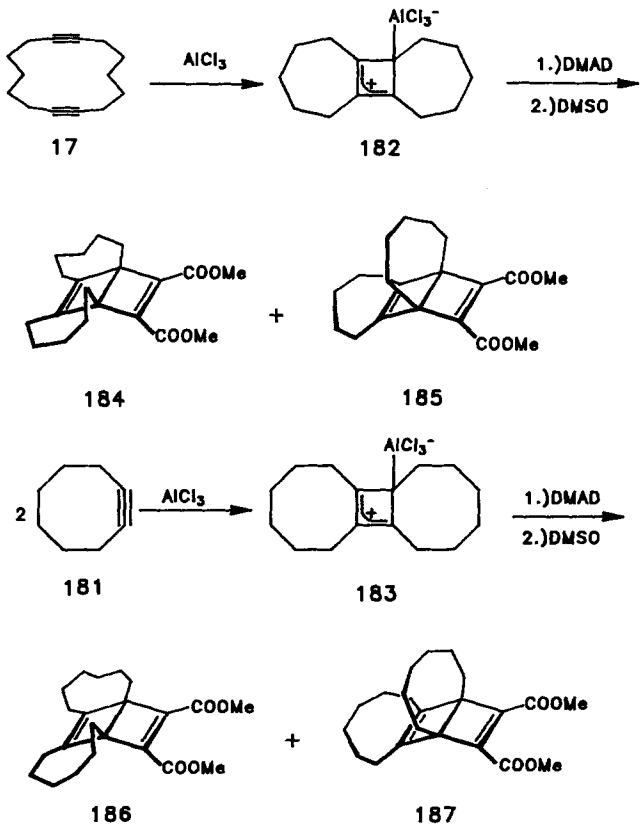


7. Other Propellaprismanes: Propella[n_3]prismanes

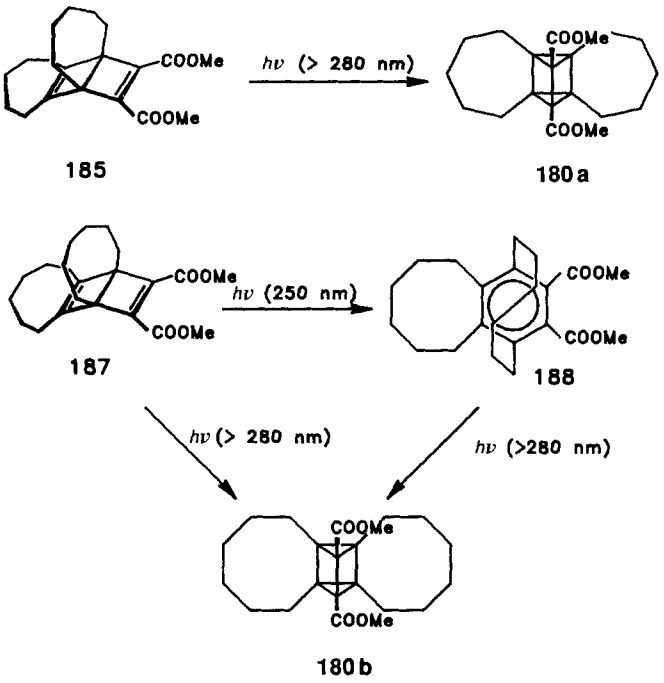
A prismane skeleton in which all adjacent centers are connected by methylene bridges, as for example in **173**, may be constructed starting from mono- or diacetylenes. This section briefly describes the preparation of two promising precursors, the doubly bridged prismane derivatives **180a, b**.



Ideal starting compounds for the synthesis of **180a, b** are 1,8-cyclotetradecadiyne (**17**) and cyclooctyne (**181**). The reaction of these two compounds with $AlCl_3$ in CH_2Cl_2 provides the two expected complexes **182** and **183**.[103-105] Addition of dimethylacetylenedicarboxylate (DMAD) leads to formation of the isomeric Dewar-benzene derivatives **184**–**187** (Scheme 13). The respective isomers **184**/**185** and **186**/**187** are formed in a ratio of 1:1.[106]



Scheme 13. Preparation of bridged Dewar-benzene derivatives from **17** and **181**, respectively.

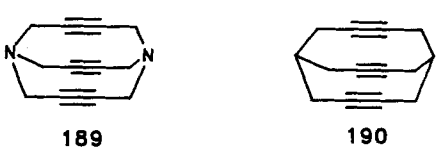


When **185** is irradiated at a wavelength of >280 nm the prismane **179** can be isolated in 15% yield. Irradiation of **187** at $\lambda = 250$ nm leads to the rapid formation of [6]cyclophane **188**. When the wavelength is increased to >280 nm the prismane **180b** is formed, which can also be obtained from **188**.

8. Outlook

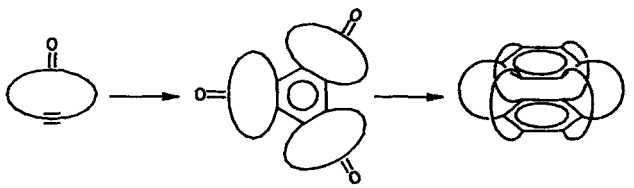
Cyclic diacetylenes with medium-sized rings have been examined for the following two reasons: First, they are valuable model compounds for an extensive examination of transannular electronic effects. Second, they are ideal precursors for novel cyclophanes and strained cage compounds.

Further useful model compounds are the two bicyclic triacetylenes **189** and **190**. Not only are they fascinating structures for the study of transannular interactions, but also good candidates for further conversion with transition-metal fragments.



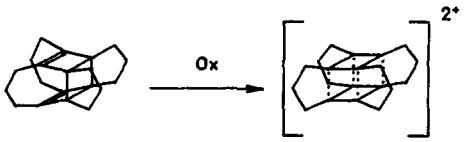
Of all the reactions described in this review the stepwise approach to cyclobutadiene superphanes stabilized by complex fragments shows the most synthetic potential, especially if one considers that up to now only the cobalt and iron

derivatives have been prepared. Closely related to this is an approach to a superphane of benzene[109] by means of a stepwise intermolecular trimerization. Unfortunately, experiments aimed at transforming **192** to **193** have been unsuccessful so far.[108]



191 **192** **193**

It should be possible to rearrange the obtained highly strained and multiply bridged cage compounds (e.g. **166**–**169**, **170**, **180**, and **184**–**187**) either thermally, photochemically, or by reaction with transition-metal complexes. The bridging alkyl units should lead to unusual reaction paths.



162 **194**

Considering the low ionization energy of **162**, its oxidation to **194** seems feasible. Like pagodane[109] the dication **194** is also a molecule of theoretical interest.[101b]

Most of the results described in this review are based on the experimental work of M. Karcher, D. Kratz, H. Langer, R. Merger, K.-H. Pfeifer, G. Pflästerer, J. Ritter, S. Rittinger, W. Schäfer, V. Schehlmann, and B. Treptow. Because of their dedication, creativity, and ability these results could be obtained in only a few years. My special thanks go to my colleagues H. Irngartinger, M. L. Ziegler, and B. Nuber for the numerous X-ray structures. Our work is funded by the state of Baden-Württemberg, the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft (SFB 247), the BASF Aktiengesellschaft, and DEGUSSA. I am indebted to Mrs. P. Schlickenrieder for typing this manuscript.

Field-Effect Transistors as Sensors of Neural Systems

By *Hans-Joachim Galla* *

The active components of the nervous system are the individual nerve cells, the neurons. The human brain contains some 10^{11}–10^{12} of these cells, which communicate with each other and with the target organs. To do this, they must receive input signals from other neurons through the synapses, via chemical transmitters and electrical signals. The excitatory and inhibitory impulses from up to 10^4 synapses are integrated in the cell body of the neuron and are then passed on to the target cell as an electrical signal. The signal itself contains very little information. Rather, this information is found in the coupling of the origin and the target of the signal, that is, in the connections between the nerve cells, in the neural network. To understand how this network functions, we must understand how the many input signals are processed to give one inner signal and how this in turn determines the output signal. It is therefore necessary to measure local electrical voltages on defined neural structures in a noninvasive manner and with high spatial and temporal resolution.

Neurons in cell cultures are the most suitable objects for these studies. Fromherz et al.[1] have succeeded in growing leech neurons on preformed protein paths, about 10 μm in breadth and with defined geometry. The protein was obtained from the extracellular matrix of the leech, mixed with bovine serum albumin, and applied to a microscope slide as an air-dried protein layer. Suitable patterns were produced by UV-lithography, using masks made previously. Although the neurite trees grow with irregular branchings on a homogeneous layer of protein, neurons with linear structures are obtained on linear protein paths, and branched neurons are generated by branched paths. The use of these cell-culture systems allows the study of signal conduction in the neurite tree. The aim of this work is to construct networks with synapses at defined positions.

Membrane potentials may be measured by spectroscopic and electrical methods. Fluorescence techniques[2] may be used: The conduction velocity of the action potential can be followed spectroscopically with "voltage-dependent dyes", which change their fluorescence intensity in the nerve cell membrane with changes in potential. Fromherz and Vetter have shown that the conduction of the action potential by cultivated cells corresponds to the situation in vivo, that is, action potentials that are induced in the region outside the soma are transmitted to the soma and to the periphery with conduction velocities similar to those observed in vivo. The relative changes in fluorescence intensity are small, however, and the sensitivity is regiodependent. Although a resolution of up to 1 μm can be attained by optimization of the chemical structure of the dyes, the method's disadvantages are that it is not possible to stain and measure individual neurons in the network selectively, and that most of the dyes are strongly phototoxic.

These problems can be overcome by establishing a direct electrical contact with the cell. The aim of this more interesting and progressive technique is the construction of a bidirectional connection between semiconductors and neurons, a sort of artificial "silicon–neuron synapse".

The most simple, classical method of making an electrical contact with a cell is to pierce the cell body with a capillary electrode, or insert the electrode lengthwise into the axon, if this has a large enough diameter. The patch-clamp method developed by Neher and Sakmann[3] in the so-called whole-cell mode is more elegant. In this technique, the cell surface is sucked onto a pipette by reduced pressure. When the pressure is reduced further, a membrane fragment is broken out of the cell membrane, creating a connection with low electrical resistance between the pipette and the cell interior. In the study of neural networks, however, both methods have the disadvantage of being invasive, and it is also difficult to maintain the connection for several hours or days. In addition, attaching several electrodes to a cell simultaneously is not easy.

Extracellular electrodes have brought a distinct improvement here. The cells are grown in specially prepared culture dishes on a planar array of electrodes. Microelectrodes about 10×10 μm in size can record action potentials from individual neurons at a distance of 40 μm from the center of the electrode. Using an array of 32 microelectrodes per culture plate, J. Pine[4] could show that action potentials can be detected for individual neurons, and that action potentials may be generated simultaneously by stimulation of the cell body or the neural processes. This method is noninvasive, and the contact between cell and electrode can be maintained for weeks. It is not possible, however, to record synaptic potentials below the threshold level. There is also the danger that signals from several cells may be measured at the same time, and that a current pulse from the electrode may stimulate more than one cell simultaneously.

A further improvement was attained by the so-called loose-patch method,[5] which does not break the membrane

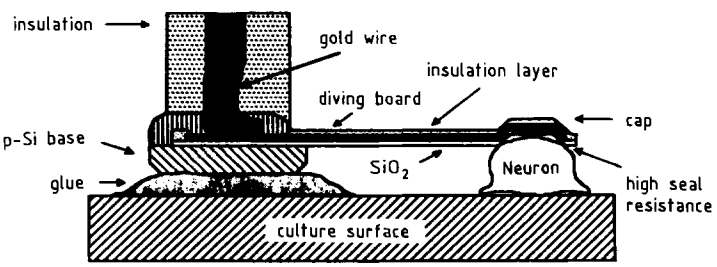

Fig. 1. System for recording and inducing action potentials with a "diving-board electrode". The metal surface forms a cap on top of the neuron with high seal resistance. This set-up corresponds to the loose-patch electrode. The signal obtained is capacitive in nature (from ref.[6]).

Wilhelm-Klemm-Strasse 2, D-W-4400 Münster (FRG)

and is hence noninvasive. This method was significantly improved by the use of the "diving-board electrode", depicted in Figure 1, which creates a permanent connection between the electrode and the cell body. The microelectrode consists of a p-silicon base, which is fixed to the bottom of the culture dish. Contact to the cell surface is made by a long, flexible arm (the "diving board"), which has a gold conductor embedded between two insulating layers. The diving-board electrode can be positioned on several neurons in culture and can be used for long-term multielectrode measurements and stimulations. Action potentials can be recorded with a good signal-to-noise ratio, though here, too, signals below the threshold level are not detected. One major goal remains: measuring an induced action-potential with the same diving-board electrode used to stimulate the cell.

The introduction of field-effect transistors (FETs) as potential probes was a clear step forward in the analysis of signal processing in small neural networks. Fromherz et al.[7] have grown neurons directly on a thin, insulating layer of the gate oxide on n-silicon. The voltage changes in the cell during an action potential affect the source–drain current by capacitative coupling, like potential changes on a metal gate.

Figure 2 shows the object under investigation, a leech neuron, the Retzius cell. The cell body, to which a short piece of

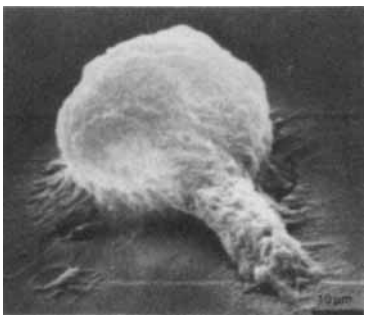

Fig. 2. Raster electron-micrograph of a Retzius cell on a field-effect transistor. The cell covers the poly-L-lysine coated gate. The contours of source and drain are visible. The bar represents 10 μm (from ref.[7]).

the neurite is attached and can still be seen, is in direct contact with the metal-free gate of a p-channel field-effect transistor. In freshly isolated cells, the action potentials are 40–60 mV. The FET was constructed on the surface of n-silicon by diffusion of boron into source and drain. The 1 μm thick insulating SiO_2 layer is opened in the middle, and the channel is filled with a layer of the gate oxide 20 nm thick (Fig. 3 right). The gate was coated with polylysine for improved

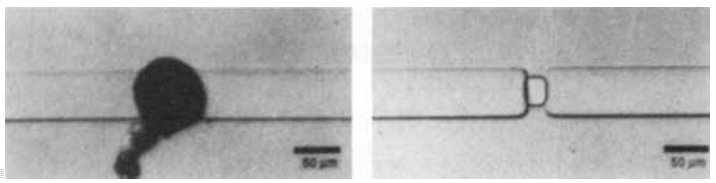

Fig. 3. Left: Top view of the FET with a neuron. Right: Top view of the FET. The distance between source and drain is 16 μm. The insulating layer (1 μm SiO_2) is opened in the middle and filled with a layer of gate oxide 20 nm thick (from ref. [7]).

adhesion, and the neuron was positioned on it with a glass pipette (Fig. 3 left). Figure 4 (top) shows the construction schematically. By capacitive coupling, the cell modulates the source–drain current in a manner analogous to the voltage change at a metal gate. The neuron–Si contact zone is an FET; the change in voltage during an action potential lifts the surface potential of the Si by reducing the density of defect electrons. A clear reduction in the source–drain current is observed (Fig. 4 bottom). The voltage change at the

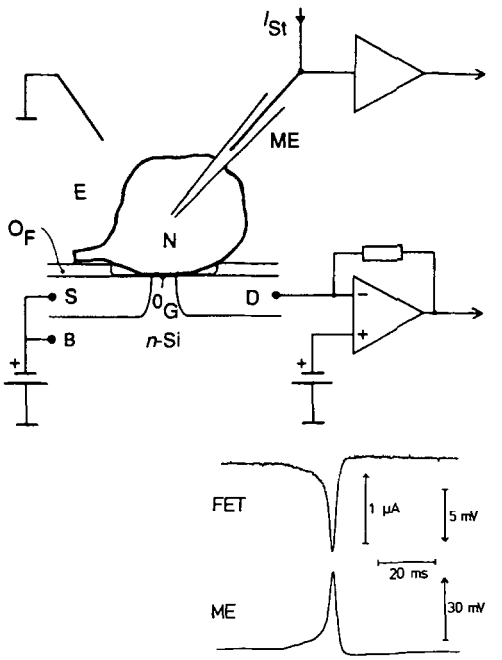

Fig. 4. Top: Schematic diagram of the apparatus. The neuron N is attached directly to the thin gate-oxide layer O_G of a field- effect transistor. Source S and drain D are insulated by a thicker SiO_2 layer O_F. The electrolyte solution E is at ground potential, and the source is held at a positive bias voltage so that a p-channel FET is created. Changes in the membrane potential have a capacitive effect on the insulating layer and modulate the measured source–drain current. The inserted microelectrode ME is only present for stimulation and for comparative measurements of the action potential. I_{st} = stimulation current, B = bulk silicon. Bottom: Measurement of the action potential. The membrane potential measured by the inserted microelectrode (ME) is compared with the source–drain current at the FET (from ref.[7]).

gate amounts to about 25% of the intracellular change in membrane potential (up to 40 mV). The shape of the action potential is retained in the response of the FET. This procedure is suitable for measurement of spontaneous or stimulated action potentials. Fromherz et al. applied a series of stimuli at intervals of 30 ms and observed perfect agreement between the induction signal and the FET response. Signals below the threshold level can also be detected.

There are still problems with this technique. Reproducible coupling between the neuron and the insulating layer is not achieved in all experiments, nor is it always possible to isolate the neurons without damaging them. However, it can already be seen that the direct coupling between neuron and silicon is much superior to metallic microelectrodes (cf. Fig. 1), with extracellular voltage amplitudes of under 1 mV. Whether this method offers advantages over the use of po-

tential-dependent dyes, which can affect cell function, will doubtless soon be reported by the Fromherz group. The goal of measuring electrical potentials in neuron cultures using an array of transistors on a chip with resolutions of 1 μm or less has come within reach. The assumption that bidirectional neuron–silicon synapses could already provide an "on-line" connection to the brain is definitely premature. However, it may be possible in the foreseeable future to interface the nervous system to stimulate paralyzed muscles, for example, or to couple an artificial limb directly to the nervous system of the remaining stump, and hence control it from the brain.[8,9] The establishment of the neuron–silicon synapse is a major requirement in achieving this goal.

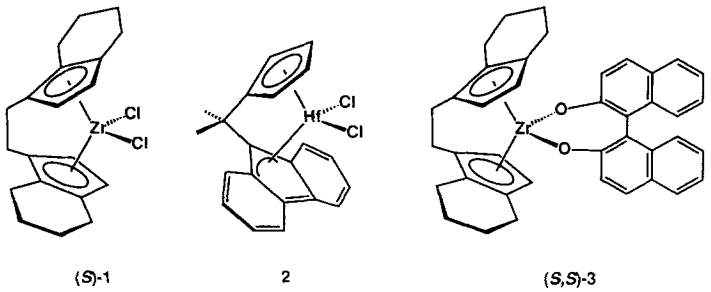
Synthesis of Optically Active Macromolecules Using Metallocene Catalysts

By *Jun Okuda**

Although nature is capable of efficiently producing monodisperse macromolecules in optically pure form, the rational synthesis of organic polymers having a well-defined microstructure and a narrow molecular-weight distribution remains a significant challenge. One of the goals in synthetic chemistry, therefore, is the development of well-characterized subtances which can catalyze the polymerization of unsaturated monomers in a living fashion and, in the case of prochiral monomers, in a stereoselective manner.

Some years ago the cocatalyst methylalumoxane was found to increase the activity of Ziegler–Natta catalysts derived from Group 4 metallocenes considerably.[1] Shortly thereafter the fundamental control of the tacticity of polypropylene through the molecular structure of the transition metal catalyst was reported.[2] Since the pioneering work by Turner et al.[3a], Jordan,[3b] and others it has been established that the cationic 14-electron alkyl $[Cp_2MR]^+$ ($Cp = \eta^5$-C_5H_5) is the active site for chain propagation.[3] Elegant kinetic studies performed recently by the teams of Brintzinger et al.[4a] and of Bercaw et al.[4b] have proved the decisive role of α-agostic interaction of the growing chain with the transition metal center. At present intense effort worldwide[5] is concentrating on evaluating the critical parameters for the stereoregularity of α-olefin polymerization[5a] and finding an explicit relationship between ligand properties of the catalyst and polymer structure.[5b] Thus the use of racemic C_2-symmetrical zircononcene (*R,S*)-[1,1′-ethylenebis(4,5,6,7-tetrahydro-1-indenyl)]zirconium dichloride (**1**) developed by Brintzinger leads to highly isotactic polypropylene. Here an enantiomorphic site control is proposed on the basis of defects within the polymer chain.[2b] On the other hand, the achiral titanocene derivative $[Cp_2TiPh_2]$ gives an isotactic block polymer that is formed by chain-end control. Finally the C_s-symmetrical hafnocene complex **2** with a bridged cyclopentadienyl–fluorenyl ligand system yields syndiotactic polypropylene.[6]



(*S*)-1 2 (*S,S*)-3

Recently Waymouth of Stanford University has demonstrated that it is also possible to produce an optically active polymer using a chiral metallocene catalyst of the Brintzinger type.[7] Although optically active oligomers can be obtained in the presence of a resolved metallocene complex according to the above mentioned procedure,[8] high molecular weight isotactic and syndiotactic polypropylenes generally contain mirror planes and are therefore achiral ("cryptochiral").[9]

Waymouth employed the homogeneously catalyzed cyclopolymerization of 1,5-hexadiene to poly(methylene-1,3-cyclopentane) developed in his group in order to utilize the stereoselectivity of the monomer insertion for the construction of a polymer with main-chain chirality. The cyclopolymerization is a remarkable chain-growth reaction during which a conventional insertion of a vinylic function into the transition-metal–carbon bond is followed by an intramolecular insertion resulting in a cyclization.[10] Thus from 1,5-hexadiene, a polymer chain is obtained in which methylene and 1,3-cyclopentanediyl fragments are arranged in a strictly alternating sequence (Scheme 1). By modifying the catalyst's ligand, control over the diastereoselectivity could be achieved ($[Cp_2ZrCl_2]$ leads to *trans*, $[Cp^*_2ZrCl_2]$ ($Cp^* = \eta^5$-

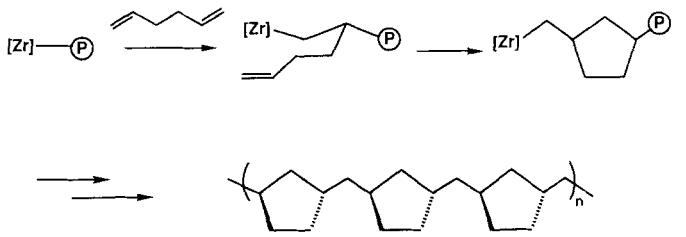
C_5Me_5) to *cis* connection of the cyclopentane fragments). Of the four possible structures of maximum order all but the *racemo*-diisotactic polymer are achiral. The latter does not contain a mirror plane and is chiral due to the main-chain stereochemistry determined by the configuration. Waymouth recognized that by using a chiral catalyst the enantioselective cyclopolymerization of 1,5-hexadiene would be possible. The catalyst used by Waymouth was chiral [1,1'-ethylenebis(4,5,6,7-tetrahydro-1-indenyl)]zirconium 1,1'-binaphtholate (**3**), which had been prepared according to Brintzinger[11] by reacting the racemic dichloro derivative **1** with optically active (*R*)- or (*S*)-1,1'-binaphthol.



Scheme 1. [Zr] = Zr complex fragment, —Ⓟ = polymer chain.

Poly(methylene-1,3-cyclopentane) synthesized in the presence of (−)-(*R,R*)-**3** and methylalumoxane revealed a molar optical rotation of $[\Phi]_{405}^{28} = +50.1°$, whereas the polymer analogously prepared using the enantiomer (+)-(*S,S*)-**3** showed a value of $[\Phi]_{405}^{28} = -49.3°$. These findings are consistent with the formation of polymers with main-chain chirality.[9a]

In summary, Waymouth has for the first time realized the enantioselective synthesis of an optically active polymer starting with an achiral monomer by using an optically active, structurally well-defined metallocene catalyst. His results are promising, since the synthesis of organic polymers in a more rational way through modification of the transition-metal catalyst seems within reach. In addition, Waymouth's study emphasizes that knowledge of well-characterized organotransition-metal complexes offers an unprecedented opportunity for the design of novel polymerization reactions.

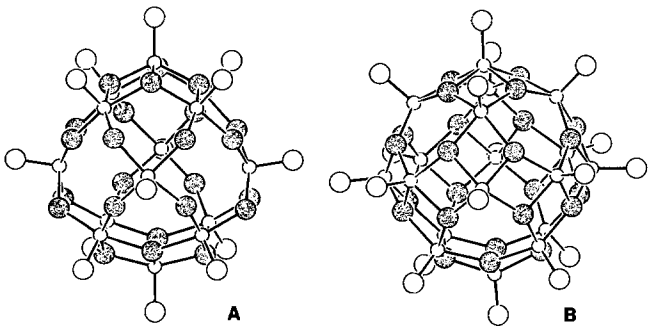
New Directions in Polyvanadate Chemistry: From Cages and Clusters to Baskets, Belts, Bowls, and Barrels

By *Walter G. Klemperer,* Todd A. Marquart,* and *Omar M. Yaghi*

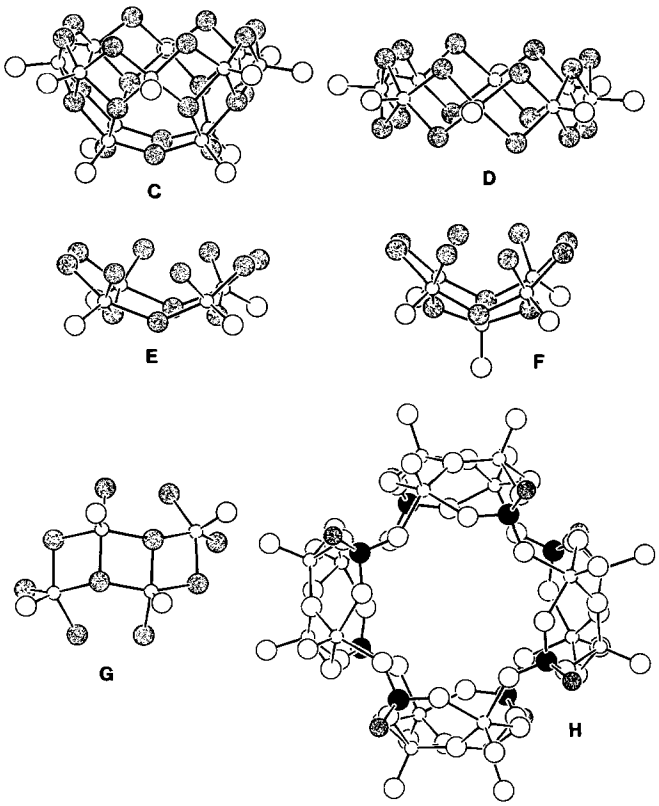
Like other early transition-metal polyoxoanions, large polyvanadates are known to adopt complex cage/cluster structures.[1] The Keggin structure observed in the anion of **1**[2] is typical. Here, the $[V_{14}O_{38}]^{6-}$ cage **A**[**] encapsulates a PO_4^{3-} anion. This cage is defined by 24 bridging oxygen atoms, and 14 of its 18 square faces are occupied by vanadium atoms, each of which is bonded to a terminal oxygen atom. The closely related Schlemper structure was first observed in **2**.[3] Here, the $[V_{18}O_{42}]^{12-}$ cage **B** encapsulates a water molecule. This cage is also defined by 24 bridging oxygen atoms, but all 18 of its square faces are occupied by V=O groups. The Keggin and Schlemper structures are very similar since they are both based on O_{24} cage frameworks. They differ in that the 24 bridging oxygens define the vertices of the O_h rhombicuboctahedron in Keggin structures and the D_{4d} elongated square gyrobicupola in Schlemper structures.[4]

$[(CN_3H_6)_8H][PV_{14}O_{42}] \cdot 7\,H_2O$ **1**

$K_{12}[V_{18}O_{42}] \cdot 16\,H_2O$ **2**



Research in polyvanadate chemistry has very recently expanded beyond classical cage/cluster structures to include hitherto unknown basket, belt, bowl, and barrel structures shown in **C**–**H**. The $[V_{12}O_{32}]^{4-}$ basket **C** contains an acetonitrile molecule in crystalline **3**.[4] The belt-shaped $[V_8O_{24}]^{16-}$ anion **D** is found in **4**,[5] where it encircles an oxalate ion. Two vanadate bowl strutures are also shown: One (**E**) is observed in **5**,[6] where the $[V_4O_{16}]^{12-}$ bowl contains a nitrate ion, and in **6**,[7] where the $[V_4O_{16}]^{12-}$ ion contains a potassium ion. The second, the $[V_5O_{17}]^{13-}$ bowl **F**, contains a Cl^- ion in **7**.[6] In **8**, $V_4O_{14}^{11-/12-}$ units **G** are joined together by CH_3P^{4+} groups to form $[(CH_3P)_8V_{16}O_{56}]^{14-}$ barrels **H** that contain tetramethylammonium cations.



$(NEt_4)_2[V_4O_8(NO_3)(tca)_4] \cdot H_2O$ **5**, tca = thiophene-2-carboxylate

$[K\{V_4O_4(\mu\text{-}O)_4(\mu\text{-}O_2CCH_2t\text{Bu})_4][O_2CCH_2t\text{Bu}] \cdot 2\,t\text{BuCH}_2\text{COOH}$ **6**

$(PhCH_2NEt_2)_2[V_5O_9Cl(tca)_4] \cdot CH_3CN$ **7**

$(NMe_4)_8[H_6(MeP)_8V_{16}O_{56}] \cdot 11\,H_2O$ **8**

These recent developments in polyvanadate chemistry raise interesting questions regarding structural principles. Clearly, the new structures **C**–**F** can be viewed as fragments of classical Keggin and Schlemper cages **A** and **B**, but what about the barrel fragment **G** or the recently reported $[V_{30}O_{74}]^{10-}$,[9] $[V_{22}O_{54}]^{6-}$,[10] and $[V_{18}O_{44}]^{6-}$[10] cages in **9**, **10**, and **11**? What about larger cages that are yet to be

$K_{10}[V_{34}O_{82}] \cdot 20\,H_2O$ **9**

$(NEt_4)_6[HV_{22}O_{54}(ClO_4)]$ **10**

$(NEt_4)_5[H_2V_{18}O_{44}(N_3)]$ **11**

[**] In structures **A**–**G** bridging oxygens are represented by large shaded spheres, terminal oxygens by large open spheres, and vanadium atoms by small open spheres. For the sake of clarity, the CH_3P^{4+} groups in **H** are shaded, and vanadium and oxygen atoms are represented by small and large open spheres, respectively. In the structures **I**–**L** the vanadium atoms are represented by small black spheres and oxygen atoms by large open spheres.

discovered? An answer to these questions is to be found in the infinite sheet (Fig. 1) observed in the V_2O_5 layer structure.[11] Consider first the $[V_4O_{16}]^{13-}$ bowl structure **E**. When flattened out into a sheet, this structure becomes the fragment of the V_2O_5 sheet labeled in orange (Fig. 1) after terminal oxygen atoms have been removed. The barrel fragment **G** is similarly displayed as the green V_2O_5 sheet fragment. In other cases, structures can be flattened into V_2O_5 sheet fragments only after cleaving selected V—O bonds. In the $[V_{12}O_{32}]^{4-}$ basket, for example, eight V—O bonds must be cleaved as in **I**, where terminal oxygen atoms have been omitted for clarity. Only then can the basket be flattened (see **J**) into the red V_2O_5 fragment of Figure 1. Large cage structures can be reduced to V_2O_5 layer fragments in the same way. The $[V_{30}O_{74}]^{10-}$ cage in **9**[9] is reduced to the yellow V_2O_5 fragment at the bottom of Figure 1 after cleaving 15 V—O bonds, as shown in **K** and **L**. The $[V_{22}O_{54}]^{6-}$ (**10**[10]) and $[V_{18}O_{44}]^{6-}$ (**11**[11]) cages both reduce to V_2O_5 fragments that are subfragments of this yellow fragment after 14 bonds are broken. The purpose of the exercise is now clear: by reversing the procedure, it is possible to cut out V_2O_5 sheet fragments, fold them up, and stitch them together to generate new polyvanadate structures. The recently discovered metastable γ'-V_2O_5 polymorph[12] can be derived from the V_2O_5 structure in an analogous fashion by first removing the terminal oxygen atoms, then corrugating the infinite sheet structure, and finally reintroducing the terminal oxygen atoms in new positions.

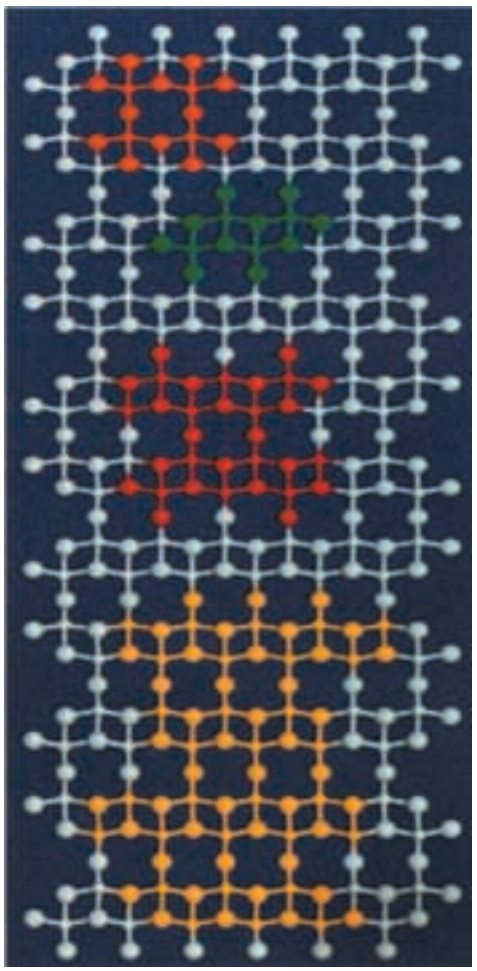

Fig. 1. Fragment of the V_2O_5 layer structure (small spheres represent vanadium; large spheres oxygen; for clarity the terminal oxygen atoms at the square-pyramidal vanadium centers have been omitted). The colored V—O units are observed in new, molecular polyvanadate structures. For details, see text.

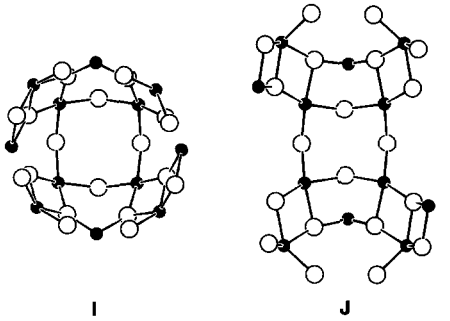

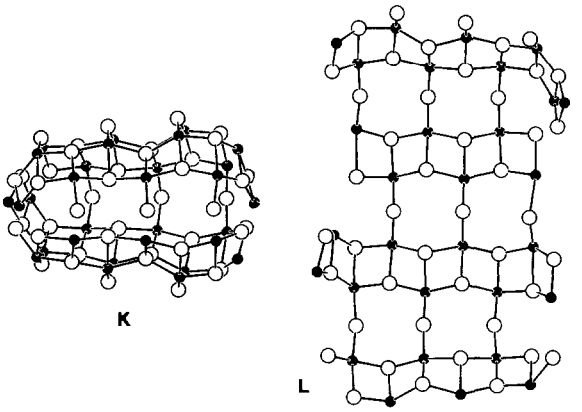

The relationship between V_2O_5 sheets and polyvanadate baskets, belts, bowls, and barrels extends beyond topology into chemistry. The sheets of VO_5 square pyramids found in V_2O_5 and related vanadates such as α-$VOPO_4$[13] are bonded together by weak V—O bonds, 2.8 Å long. As a result, the layers are easily separated to form intercalation complexes.[11, 14] In classical vanadate cages, a similar structural situation is observed. The cage of VO_5 square pyramids in the anion of **2**,[3] for example, is bonded to an encapsulated water molecule by very weak V—O bonds. "Intercalation" chemistry is impossible, however, since the cage framework blocks access to the vanadium coordination sites. Such is not the case with the new structures **C**—**F** and **H**, where access to square-pyramidal vanadium centers is relatively unrestricted, and guest–host chemistry becomes a real possibility. To date, only the $[L \subset (V_{12}O_{32}^{4-})]$ system has been investigated from this point of view,[4, 15] but a rich chemistry can be anticipated given the analogy with the solid oxide guest–host chemistry of zeolites.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes.

The price of the index is DM 98.00, $ 64.00 or £ 37.00. Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.**

Communications may be submitted in English *or* in German. Further details regarding the submission of communications can be found in the "Notice to Authors" reproduced in the January issue of the journal. Copies thereof may be obtained from the editorial office upon request.

Structure of the Tunichrome of Tunicates and its Role in Concentrating Vanadium

By *Ernst Bayer,* Gerhard Schiefer, Dietmar Waidelich, Silvia Scippa,* and *Mario de Vicentiis*

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Tunicates (Urochorda) concentrate vanadium in their blood cells to a million times the concentration in sea water.[1–3] Although the vanadium compound in tunicates was discovered 80 years ago, its structure is still not known. A proven fact is that in *Phallusia mammillata* and *Ascidia nigra* vanadium is predominantly trivalent.[4,5] Apart from the vanadium-containing signet-ring and compartment cells, vanadium-free blood cells (morula cells) are found in *P. mammillata*[6] and *A. nigra*.[7] Nakanishi et al.[8–11] have used a laborious process with low recovery to isolate peptides[12] (which they named tunichromes) from the morula cells of *A. nigra*. The major component was assigned a dipeptide structure incorporating a β-(3,4,5-trihydroxyphenyl)-alanine and a β-(3,4,5-trihydroxyphenyl)dehydroalanine containing a *C*-terminal 3,4,5-trihydroxystyrylamide unit.

Because the peptides of the blood cells are exceptionally unstable and sensitive to oxidation, we have developed a very simple isolation involving few losses for the peptides from *P. mammillata*. The tunichromes were extracted with methanol quite selectively from lyophilized cells and purified by HPLC on polystyrene phases with a recovery rate 80–90% or by capillary electrophoresis, or introduced on-line from HPLC into an ion spray tandem mass spectrometer. In contrast, the separation on reversed phases based on silica gel caused large losses. All operations were performed in an inert atmosphere.

Figure 1 depicts the HPLC separation of the methanol extract. Besides three minor components, a major component was obtained, which was studied by ion spray MS, tandem MS, ^1H and ^{13}C NMR, UV/VIS, and IR spectroscopy. The separation of the methanol extract by capillary zone electrophoresis also proved valuable, as it also provided a major component.

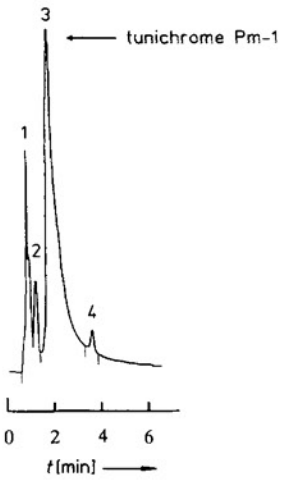

Fig. 1. HPLC of the methanol extract from blood cells of *Phallusia mammillata*. Column: 125 × 4.6 mm, 5 μm Hamilton PRP-1; UV detection at 210 nm; elution with CH_3CN/H_2O (50:50), 1 mL min^{-1}; p = 36 bar.
Fractions: 1, *p*-aminobenzoic acid; 2, sugar derivative; 3, tunichrome Pm-1; 4, tunichrome Pm-2 and Pm-3.

The UV spectrum of the major component shows a maximum at 301 nm and not the maximum at 340 nm found by Nakanishi et al.[9–11] for the tunichrome An-1 isolated from *A. nigra*. Moreover, the tunichrome from *P. mammillata* (Pm-1) has a molecular ion peak of $(M + H)^+ = 558.4$, two Daltons higher than the tunichrome from *A. nigra*, as seen in the ion spray mass spectrum (IMS). The MS–MS spectrum of molecular ion 558 of the IMS spectrum gives the fragmentation scheme illustrated in Figure 2 (top). It shows that tunichrome Pm-1 is dipeptide **1**, constructed from two β-(3,4,5-trihydroxyphenyl)alanine (Topa) molecules and a *C*-terminally bound 3,4,5-trihydroxystyrylamine. The only difference between Pm-1 and the tunichrome from *A. nigra* An-1 lies in the one double bond instead of conjugation between two trihydroxyphenyl residues, but it results in a

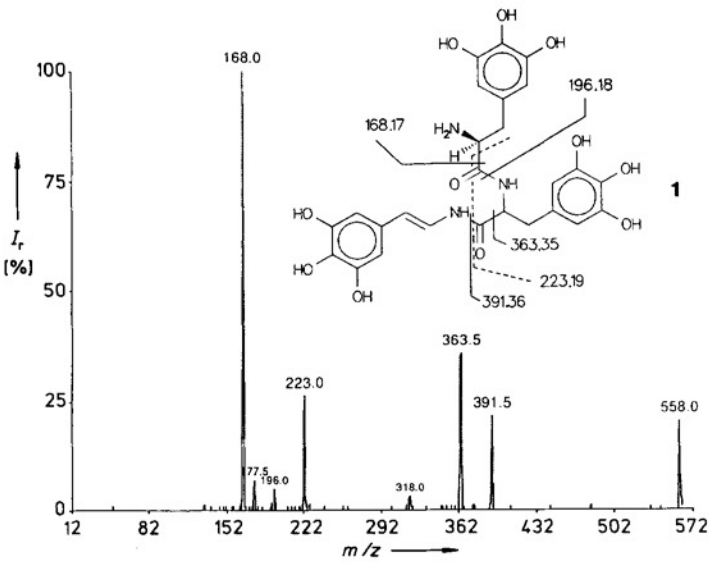

Fig. 2. Top: Ion spray MS (SCIEX mass spectrometer): daughter-ion mass spectrum of molecular ion peak 558 of the methanol extract from blood cells of *P. mammillata*. Bottom: structure and fragmentation scheme of tunichrome Pm-1 (**1**), derived from the ion spray mass spectrum.

dramatic change in conformation and complex formation behavior with vanadium.

The ^1H and ^{13}C NMR spectra of the free tunichrome Pm-1 (**1**) and the peracylated derivative confirm the structural assignment. To determine the stereochemistry of the two asymmetric centers, Pm-1 was hydrolyzed with 5 N HCL at 110 °C, and the 3,4,5-trihydroxyphenylalanine formed was isolated by chromatography and characterized by mass spectrometry. The absolute configuration was established by the positive Cotton effect of the carbonyl band at 215 nm in the circular dichroism (CD) spectrum and confirmed by enantiomer separation on a chiral, thin-layer chromatography plate (Macherey & Nagel). Both chiral centers were shown to have an L-configuration. The stereochemistry of the styrylamide group in the third, dehydrogenated, and decarboxylated Topa was deduced from the ^1H NMR spectrum. The signals of the two vinyl protons at $\delta = 7.12$ and 6.01 show a coupling constant of 14.6 typical for *trans*-olefins. The position of the substituents on the phenyl ring was determined by ^{13}C and ^1H NMR spectroscopy, as well as IR spectroscopy. Topa and synthetic Topa tripeptide served as comparison.

The question whether the tunichrome occurs as complex in the blood cells was answered by a comparison between the NMR spectra of the free tunichrome Pm-1 (**1**) in solution and the ^{13}C CP-MAS NMR spectrum of the lyophilized blood cells in the solid state. As Table 1 shows, the positions of the major signals are in good agreement. Thus the native tunichrome in the blood cells is present as free peptide, and not bound to vanadium.

Table 1. Comparison of the ^{13}C NMR signals from tunichrome Pm-1 (**1**) in CD_3OD with those in the CP-MAS ^{13}C NMR spectrum of freeze-dried cells.

^{13}C NMR (CD_3OD) Chemical Shift	CP MAS ^{13}C NMR	Assignment	
168.5	173.3	amide	CONH
146.2–144.3	145.7		C-3, C-5
132.3–131.6	131.7	arene	C-1
127.3–124.8			C-4
120.5	120.7	styrylamide	C-β
113.2	110.4		C-α
108.3–108.1		arene	C-2, C-6 Topa
104.3	103.5		C-2, C-6 Tosa [a]
55.0	57.3	aliphatic	$CHNH_2$
53.7			CHNHR
37.2	38.9		CH_2CHNH_2
36.8			CH_2CHNHR

[a] Tosa = 3,4,5-trihydroxystyrylamide.

After the major peak of the tunichrome Pm-1 (**1**) a smaller peak appeared in the chromatogram of the methanol extract of the blood cells (Fig. 1). With on-line HPLC–ion spray MS–MS, separation and structure assignment is possible in one step. In the ion spray mass spectrum, apart from the peaks of the tunichrome Pm-1 (**1**) at 558 and Pm-1 adducts at 580 $(M + Na)^+$, 596 $(M + K)^+$, and 638 $(M + H + SO_3)^+$, a peak at $(M + H)^+ = 542$ is observed. A molecular ion peak of 542 is 16 Da lower than that of tunichrome **1**, corresponding to one hydroxyl group less. The molecular ion peak 542 in Figure 3 has an analogous fragmentation pattern to that seen for tunichrome **1**. In addition pairs of fragments are observed, which suggests that two isomeric tunichromes Pm-2 and Pm-3 of molecular mass 542 are involved. These were attributed the sequence isomers with structures **2** and **3** (Fig. 3, bottom). In **2** the *N*-terminal trihydroxyphenylalanine residue is replaced by a 3,4-dihydroxyphenylalanine substituent, while in **3** the *C*-terminal 3,4-dihydroxystyrylamine is replaced by 3,4-dihydroxystyrylamine.

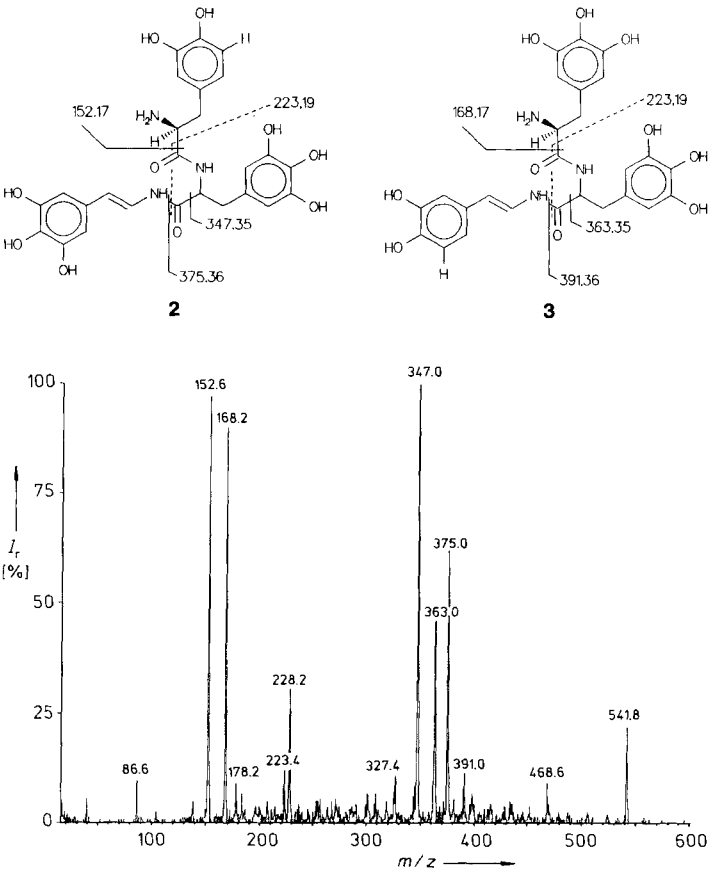

Fig. 3. Top: Ion spray MS: daughter-ion mass spectrum of molecular ion peak 542 of the methanol extract from blood cells of *P. mammillata*. Bottom: structure and fragmentation schemes of tunichrome Pm-2 (**2**) and tunichrome Pm-3 (**3**), derived from the ion spray mass spectrum.

These investigations show that the tunichromes of *P. mammillata* have a lower oxidation state than those of *A. nigra*. In no case could we detect the tunichromes described by Nakashani et al.[9–11] in extracts from fresh blood cells of *P. mammillata*. However, these tunichromes appeared as artifacts during intensive chromatography on silica gel phases or when long reaction times were required for the formation of derivatives, for example, in complete methylation with diazomethane.

Ion spray tandem mass spectrometry[13] of the methanol extracts represents a simple process for testing whether tunichromes are present. We analyzed the blood cells of different tunicates for the presence of tunichromes and found them only in *P. mammillata*, which concentrates vanadium strongly, but not in *Ciona intestinalis*, which concentrates vanadium only weakly, or in the iron-concentrating *Halocynthia papillosa* and *Microcosmus sulcatus*. This suggests that tunichromes are involved in vanadium-concentrating processes. The semiquantitative comparison of the tunichrom content (determined by HPLC) with the sulfate and vanadium content reveals approximately equivalent amounts of the vanadium compound in the vanadium-containing blood cells and tunichrome in the morula cells.

Characteristic for tunichromes is the styrylamide structure, which is possibly formed biogenetically by decarboxylation and dehydrogenation of a tripeptide with three trihydroxyphenylalanines. It is thus possible that vanadium enrichment in the blood cells takes place according to the scheme in Figure 4, in which at first a sulfoconjugate of this tripeptide without the styrylamide structure is present. Such

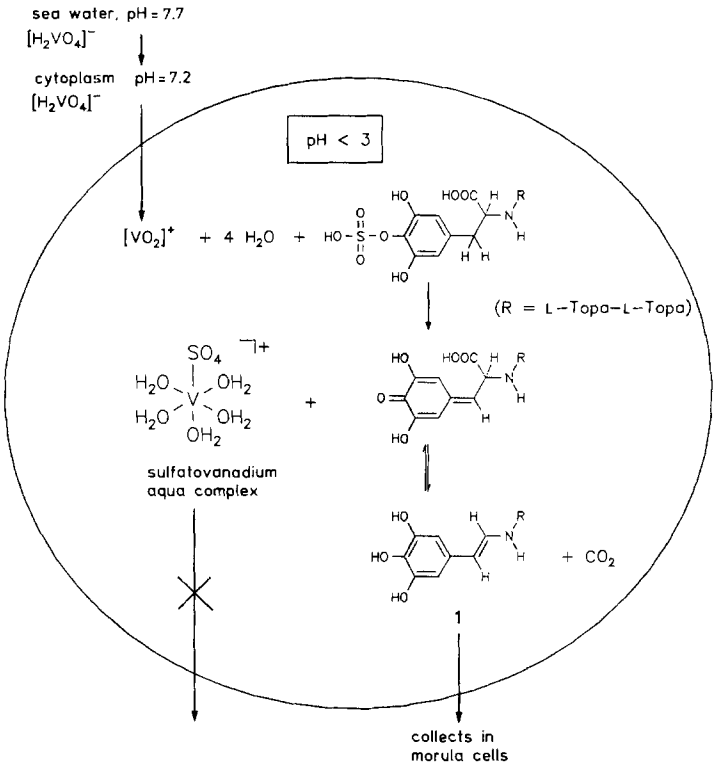

Fig. 4. Proposed scheme for vanadium concentration in blood cells of *P. mammillata*.

a conjugate with **1** has been identified by mass spectrometry. $[H_2VO_4]^-$ from sea water passes into the vanadocytes through the anionic channels of the lipid membrane. In the strongly acidic milieu there, it is present as the $[VO_2]^+$ ion, which can attack the sulfur while itself being reduced to the trivalent sulfatovanadium aqua complex. At the same time the peptide is oxidized to quinone, which undergoes decarboxylation to form styrylamide **1**. Whereas the positively charged sulfatovanadium complex cannot pass through the anionic channels, the tunichrome can leave the now vanadium-containing blood cells and collects in the morula cells.

$[Ni_4(SC_3H_7)_8Br]$ and $[Ni_4(SC_3H_7)_8I]$: Mixed Valent Nickel Thiolates with Integral and Nonintegral Metal Oxidation States**

By *Thomas Krüger, Bernt Krebs,** and *Gerald Henkel**

Dedicated to Professor Peter Sartori on the occasion of his 60th birthday

The thiolato and sulfidothiolato complexes of divalent nickel are of great interest due to their unusual structures and properties. The discovery of nickel-containing enzymes with partial coordination of sulfur to nickel has given the investigation of thiolates new impetus.[1-3]

Although not much is known about the architecture of the nickel sites in enzymes, X-ray absorption spectra of the nickel-containing hydrogenases and the CO-dehydrogenases show that the nickel atom has a planar coordination with up to four cysteine sulfur atoms. Both of these classes of enzymes catalyze redox processes, in which the nickel atoms are proposed to be in oxidation states between 0 and +IV.[1-3] Thus the investigation of electrochemical properties of nickel–sulfur complexes is important in the understanding of these enzymes' mode of action.

We reported recently the preparation and structure of the mixed-valent sulfidothiolatonickel complex $[Ni_8S(SC_4H_9)_9]^-$ in which the nickel has the intermediate oxidation state of +1.25.[4] We could prove for the first time that saturated alkanethiolato ligands are able to reduce nickel under mild conditions and stabilize the metal in low oxidation states.

The reversible oxidation of polynuclear thiolatonickel complexes is also possible if they are cyclic molecules of the general type $[Ni_n(SR)_{2n}]$ ($n = 4-6$).[5,6] In contrast to the open-chain complex anions with the composition $[Ni_n(SR)_{2n+2}]^{2-}$ ($n = 2$, 3, and 6) the cyclic complexes have no terminally bound thiolato ligands which can be irreversibly oxidized at potentials in the range of −200 to −400 mV.[5-7]

We report here the syntheses and X-ray structural analyses of compounds **1** and **2**, which can be obtained from the direct reaction of $[Ni_4(SiC_3H_7)_8]$ with the corresponding halogen.

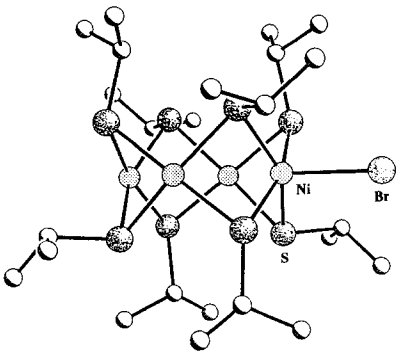

Fig. 1. Molecular structure of **1** (without H atoms). White circles = C atoms, regularly dotted circles = Ni atoms, circles with a heavy random dot pattern = S atoms, circle with a light random dot pattern = Br atom.

According to X-ray structural studies, crystalline **1** and **2** contain one-dimensional infinite chains, consisting of individual $[Ni_4(SiC_3H_7)_8X]$ molecules threaded along their Ni–X axes.[8] Their structures are related to those of the known tetranuclear neutral complexes $[Ni_4(SiC_3H_7)_8]$,[4] $[Ni_4(SC_6H_{11})_8]$,[9] and $[Ni_4(SC_5H_9NMe)_8]$[10] with crystallographic C_2 symmetry (idealized D_{2d}) in which the Ni atoms form a distorted square and thus occupy the centers of the side faces of a tetragonal prism of S atoms. This leads to square-planar Ni–S coordination centers, which are somewhat distorted due to a slight compression of the prism and repulsive Ni ··· Ni interactions. Upon chemical oxidation of $[Ni_4(SiC_3H_7)_8]$ to **1** or **2** the Ni–S frame and the arrangement of the thiolato ligands are basically retained. This reaction is formally an oxidative addition of a halogen radical to one of the four nickel atoms, which can then be considered Ni^{3+} with an axial bond to the halogen atom. As a result the twofold axis in the starting complex is retained (Fig. 1).

The electronic spectrum of $[Ni_4(SiC_3H_7)_8]$ in dichloromethane displays absorptions at 264, 340, and 427 nm. These absorptions are also observed as shoulders in the spectra of **1** and **2**, perhaps as a result of decomposition. An intense band at 292 (**1**) or 296 nm (**2**) is characteristic for the halogenated derivatives and also dominates the spectra of the electrochemically oxidized complex.

Upon crystallization of the bromine derivative the molecules organize in one-dimensional infinite chains along the twofold axes of the space group $C2/c$, resulting in secondary bonding between the halogen and formally divalent nickel atoms of neighboring molecules. The Ni^{3+}–Br ··· Ni^{2+} bridges are unsymmetrical (Ni–Br 2.530(3), Ni ··· Br 3.018(3) Å) and do not support a model with nonintegral oxidation states of the nickel atoms involved.

In contrast, crystalline **2** displays (almost) equivalent bond lengths in the halogen bridges. Apparently there is a bonding mechanism here which makes the two nickel atoms participating in the halogen bridge practically identical. One electron is completely delocalized between the two centers (Fig. 2). In the $Ni^{2.5+}$–I–$Ni^{2.5+}$ bridge of **2** the Ni–I bond lengths of 2.878(3) and 2.824(3) Å are indicative of nonintegral oxidation states of the nickel atoms. A possible disorder of the iodine atoms can be discounted, since all the atoms in the bridge oscillate with similar amplitudes in the bonding direction (Ni3: 0.203 Å; Ni2: 0.216 Å; I: 0.212 Å).

The chainlike arrangement of the molecules in the crystal is apparently stabilized if a small percentage of the oxidized molecules is replaced by the halogen-free species. In crystalline **1** statistically every eighth molecule is exchanged; in **2**, every seventh.[8]

According to our knowledge, the mixed valent dithioacetato complex $[Ni_2(S_2CCH_3)_4I]$[12] is the only other known nickel–sulfur compound with similar symmetric, though somewhat longer Ni–I–Ni bridges (2.928 and 2.940 Å) in the crystal. In this case the two nickel atoms in the almost parallel NiS_4 planes are only 2.514 Å apart, supporting direct electronic interactions by overlap of d_{z^2} orbitals. Comparable metal–metal interactions are not possible in **1** and **2** since the distances between the relevant nickel atoms are prohibitively long (4.121 Å in **1**; 4.111 Å in **2**).

The unusual relationships in these two complexes allow for the first time a comparison between the bonding geometries of mixed valent systems with localized Ni^{2+}/Ni^{3+} centers on one hand and delocalized $Ni^{2.5+}/Ni^{2.5+}$ centers on the other.

The oxidation of $[Ni_4(SiC_3H_7)_8]$ to **1** and **2** has a characteristic effect on the Ni–S framework. The square of Ni atoms in the starting material is stretched along the twofold axes to a rhombus, which is more distorted in **1** due to the localized oxidation states. Simultaneously, the edges are lengthened by roughly 0.06 Å to an average of 2.731 (**1**) and 2.728 Å (**2**).

Interestingly, the average nickel–sulfur bond length depends on oxidation state in a simple fashion. The average Ni–S bond length is 2.210 Å for Ni^{2+} (in **1** and **2**); 2.236 Å for $Ni^{2.5+}$ (in **2**); and 2.255 Å for Ni^{3+} (in **1**). For divalent nickel one thus finds the same values as in the starting molecule.[4] We attribute the observed increase in the nickel–sulfur bond lengths with increasing oxidation, which at first appears unusual, to the gradual strengthening of the bond of an additional axial ligand.

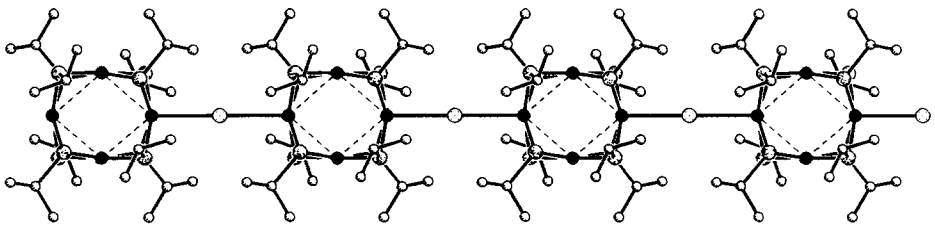

Fig. 2. Structure of crystalline **2** (without H atoms). Regularly dotted circles = I atoms, white circles = C atoms, black circles = Ni atoms, randomly dotted circles = S atoms.

Experimental Procedure

1 and **2**: To a solution of $[Ni_4(SiC_3H_7)_8]$ (0.84 g, 1 mmol) in 20 mL of CH_2Cl_2 was slowly added a solution of Br_2 (0.20 g) or I_2 (0.32 g, 2.5 mmol) in 5 mL of CH_2Cl_2 with vigorous stirring. After the addition was complete the resulting brown-violet (Br_2) or green-brown (I_2) solution was filtered and evaporated to dryness over 2–3 days. In both cases a conglomerate of $[Ni_4(SiC_3H_7)_8]$ crystals

(black, tetragonal needles) and $[Ni_4(SiC_3H_7)_8X]$ (X = Br, I; black hexagonal plates) were obtained.

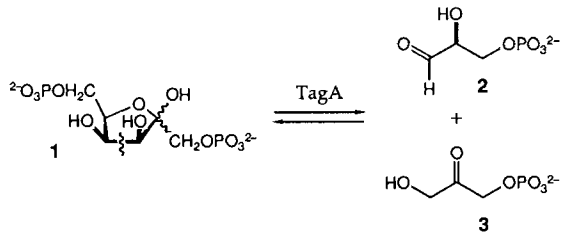
One-Pot Synthesis of Tagatose 1,6-Bisphosphate by Diastereoselective Enzymatic Aldol Addition**

By *Wolf-Dieter Fessner** and *Oliver Eyrisch*

Enzyme-catalyzed C–C bond formations[1] hold much promise for use in asymmetric synthesis because of the potentially high level of asymmetric induction achievable at two stereocenters, the applicability of a convergent synthetic strategy, and the fact that in general no protecting groups are required. A building block scheme[2] for the production of each of four possible diastereomeric dihydroxyacetone phosphate (DHAP) aldol adducts is based on a tetrad of complementary DHAP lyases. So far a broad substrate acceptance and high enantio- and diastereoselectivity have been demonstrated for the D-fructose 1,6-bisphosphate (FruA),[3] L-fuculose (FucA),[2,4] and L-rhamnulose 1-phosphate aldolases (RhuA).[2] The fourth enzyme of this series, a D-tagatose 1,6-bisphosphate aldolase (TagA) involved in the galactose metabolism of cocci, has previously been described to be stereochemically completely nonselective.[5] We report here the isolation and characterization of a highly diastereoselective TagA from *Escherichia coli* and on first results concerning its suitability for asymmetric synthesis.

Based on our experience with other DHAP aldolases of class II (Zn^{2+} dependent) from *E. coli*, we were expecting that galactitol-metabolizing strains of this organism would produce a TagA of the same type. In the crude extract of cells of strain JWL183,[6] which had been grown on this carbon source, an enzyme was indeed detectable, which in the presence of Zn^{2+} ions was able to cleave chemically synthesized[7] D-tagatose 1,6-bisphosphate **1** (ca. 1500 U in 90 g of wet cells from a 10 L culture).[8] The constitutive FruA, which is expressed at a similar level of activity (ca. 1000 U), can be separated quantitatively by anion-exchange chromatography due to its distinct isoelectric points (p*I* TagA 4.4, FruA 5.1). The TagA is obtained free from contaminating side-activities by further application of standard methods of protein purification in about 35% total yield.

The TagA catalyzes the reversible cleavage of **1** to D-glyceraldehyde 3-phosphate **2** and DHAP **3**. The enzyme shows a high substrate-specificity in the cleavage direction; relative to the natural substrate **1** the 4-epimeric D-fructose 1,6-bisphosphate **4** is converted at only 1% of the maximum rate.



Because of comparably strong binding constants ($K_m = 3.3 \times 10^{-4}$ M) **4** acts as a competitive inhibitor for the cleavage of **1**. Although the TagA has a relatively narrow pH profile around an optimum at about 7.5, it still displays sufficient activity (≥40%) within the range of pH 6.5–7.0, most suitable for synthetic applications. The molecular weight is roughly 110 kDa according to the mobility during gel permeation chromatography; a single band at about 28 kDa in the denaturing SDS polyacrylamide gel electrophoresis suggests the presence of a homotetramer, quite like that established for RhuA and FucA.[2]

Priority was given to the development of a novel access to **1**, which was previously available only by a low yielding (ca. 2%), multistep synthesis from D-galacturonic acid.[7] A coupled enzymatic synthesis (Scheme 1) offered the possibility to prepare **1** directly from dihydroxyacetone **5**: After enzymatic phosphorylation of **5** using ATP and glycerol kinase, combined with an economical cofactor regeneration scheme based on phosphoenolpyruvate (PEP),[9] the **3** generated can be partially isomerized in situ into the aldehyde **2** and subsequently added to the latter stereoselectively by the TagA with formation of **1**.

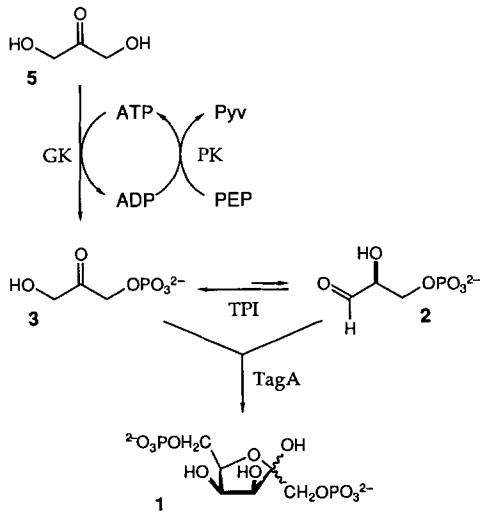
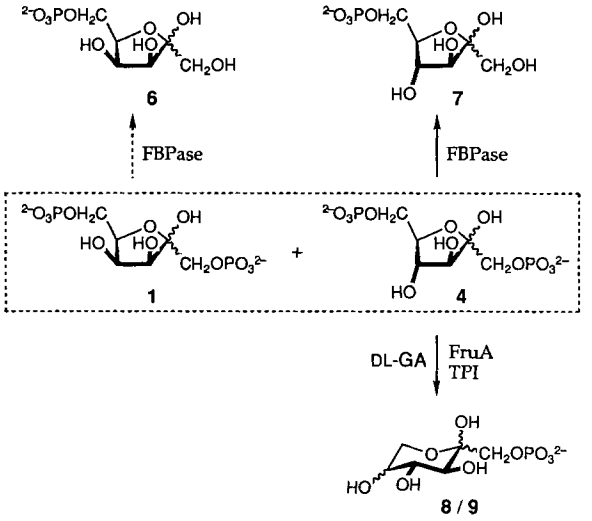
[**] Enzymes in Organic Synthesis, Part 2. This research was supported by the Deutsche Forschungsgemeinschaft (Grant Fe 244/2-1), the Wissenschaftliche Gesellschaft Freiburg, and the Fonds der Chemischen Industrie. We thank Prof. Dr. J. W. Lengeler, University of Osnabrück for the gift of bacterial strains and Dipl.-Chem. G. Sinerius for chemically [7] synthesized **1**.—Part 1: [2].



Scheme 1. Enzymatic one-pot synthesis of D-tagatose 1,6-bisphosphate **1**. Abbreviations: ADP, ATP = adenosine di(tri)phosphate; Pyv = pyruvate; PEP = phosphoenolpyruvate. Enzymes involved are: GK = glycerokinase, PK = pyruvate kinase, TPI = triosephosphate isomerase, TagA = tagatose 1,6-bisphosphate aldolase.

For this route to become preparatively useful the compatibility of each of the catalysts and reactants and also a high equilibrium concentration of **1** is prerequisite. The latter depends not only on the thermodynamic relation to the cleavage products **2** and **3**, but also on their interrelation.[10] Starting from either **1** or **3** we could unequivocally determine the equilibrium constant for addition to be $K_{eq} = [\mathbf{2}][\mathbf{3}]/[\mathbf{1}] = 10^{-3}$ M. As a consequence of the all-*cis* substitution of the furanose forms present in aqueous solution, the adduct is barely favored in the equilibrium. For this reason the yield of **1** cannot significantly exceed a level of 80%, even with reaction parameters optimized. During these investigations we also found that, in addition to the known components, an increasing fraction of **4** is produced rather unexpectedly (Fig. 1). This implies that the TagA in the (reversible) synthesis of **1** also forms a small percentage of the 4-epimer which itself is cleaved only at a significantly lower rate.[10] However, timely termination of the reaction (after formation of 60–65% of **1**) guarantees that the fraction of **4** in the product mixture remains small ($\leq 10\%$).

The separation of **4** would obviously be facilitated by its selective transformation into derivatives of lower charge density. We have checked the following alternatives (Scheme 2): 1) Fructose 1,6-bisphosphatase dephosphorylates **4** selectively in the presence of **1** to provide fructose 6-phosphate **7**; in contrast to the specific enzyme from yeast, the one from rabbit muscle concurrently also converts **1** very slowly into tagatose 6-phosphate **6** ($K_2/K_1 = 5\%$).[10] Although this process can thus be combined with the previously described one-pot procedure, the relatively high price of the phosphatases becomes prohibitive. 2) Preferably after separation of all enzymes, for example by ultrafiltration, FruA cleaves the diastereomer **4** highly selectively; the liberated **3** (in the presence of triosephosphate isomerase) is then recombined with another arbitrarily added, neutral aldehyde (e.g. DL-glyceraldehyde) for quantitative formation of the corresponding ketose 1-phosphates (e.g. the fructose/sorbose derivatives **8**/**9**).[3] After preparation according to either variants, **1** was easily separated by ion-exchange chromatography using $NEt_3H(HCO_3)$ buffer and was isolated in satisfactory overall yield (40% relative to limiting PEP) in 10 mmol quantity as the crystalline tetrakis(cyclohexylammonium) salt of analytical purity. Unequivocal structural proof was obtained by quantitative dephosphorylation of **1** using acid phosphatase for the liberation of authentic D-tagatose.



Scheme 2. Enzymatic differentiation of D-fructose 1,6-bisphosphate **4** in the presence of D-tagatose 1,6-bisphosphate **1**. Abbreviations: DL-GA = DL-glyceraldehyde, FBPase = fructose 1,6-bisphosphatase, FruA = fructose 1,6-bisphosphate aldolase, TPI = triosephosphate isomerase.

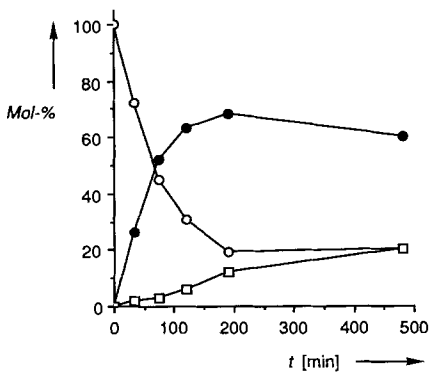


Fig. 1. Product composition during enzymatic synthesis of **1** starting from **3** (200 mM; 50 U mL^{-1} TPI, 8 U mL^{-1} TagA; pH 7.0, 25°C). ○ The sum of triosephosphates **2** and **3**; ● D-tagatose 1,6-bisphosphate **1**; □ D-fructose 1,6-bisphosphate **4**; data refer to mol% of bisphosphates[10].

though this process can thus be combined with the previously described one-pot procedure, the relatively high price of the phosphatases becomes prohibitive. 2) Preferably after separation of all enzymes, for example by ultrafiltration, FruA cleaves the diastereomer **4** highly selectively; the liberated **3** (in the presence of triosephosphate isomerase) is then recombined with another arbitrarily added, neutral aldehyde (e.g. DL-glyceraldehyde) for quantitative formation of the corresponding ketose 1-phosphates (e.g. the fructose/sorbose derivatives **8**/**9**).[3] After preparation according to either variants, **1** was easily separated by ion-exchange chromatography using $NEt_3H(HCO_3)$ buffer and was isolated in satisfactory overall yield (40% relative to limiting PEP) in 10 mmol quantity as the crystalline tetrakis(cyclohexylammonium) salt of analytical purity. Unequivocal structural proof was obtained by quantitative dephosphorylation of **1** using acid phosphatase for the liberation of authentic D-tagatose.

The substrate tolerance of the TagA was evaluated by additional preparative reactions. Like the complementary DHAP aldolases, the TagA accepts a variety of different aldehydes as substrate analogues (e.g. glycolaldehyde, D- or L-glyceraldehyde, acetaldehyde, isobutyraldehyde). In each case investigated so far, product analysis indicated the formation of diastereomer mixtures. Surprisingly, however, instead of the expected products with tagatose configuration at C-3/C-4 (L-*erythro*; $\leq 10\%$) those of the fructose type (D-*threo*; $\geq 90\%$) predominated.

The comparatively high diastereoselectivity of the TagA from *E. coli* thus allows the simple preparative synthesis of the valuable metabolic intermediate **1** and the rare ketosugar D-tagatose. Although the enzyme does not seem to be directly suitable for the proposed building block scheme,[2] its optimization by protein engineering, based on structural motifs of complementary aldolases,[2, 11] presents a rewarding perspective.

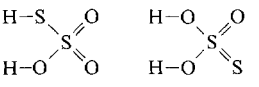
The Structures of Thiosulfuric Acid $H_2S_2O_3$ and Its Monoanion $HS_2O_3^-$ **

By *Karol Miaskiewicz** and *Ralf Steudel**

Inorganic chemistry textbooks present the structure of thiosulfuric acid by either formula **1**[1] or **2**.[2] Both structures have been of speculative nature so far since the molecule $H_2S_2O_3$ has never been observed directly, and consequently structural information is not available. The existence of thiosulfuric acid in strongly acidic aqueous thiosulfate solutions is, however, beyond any doubt[3] and the preparation of nonaqueous $H_2S_2O_3$ solutions has been reported.[4]



The monoanion of thiosulfuric acid may have either the structure $HOS(S)O_2^-$ **3** or $HSSO_3^-$ **4**, derived from **1** and **2**, respectively. Recently, the first hydrogenthiosulfate, $NH_4HS_2O_3$, was prepared and shown by Raman spectroscopy to contain the anion **4**.[5] To establish the equilibrium structures of the free molecules $H_2S_2O_3$ and $HS_2O_3^-$ we have performed ab initio molecular orbital calculations of the species **1** to **4** using a 6-311 G** basis set for geometry optimization and single-step energy calculations according to the 2nd to 4th order of Moeller–Plesset perturbation theory. Zero-point energies have been calculated from 6-311 G** wave numbers scaled by 0.89.[6] The results are shown in Figure 1, and Tables 1 and 2.

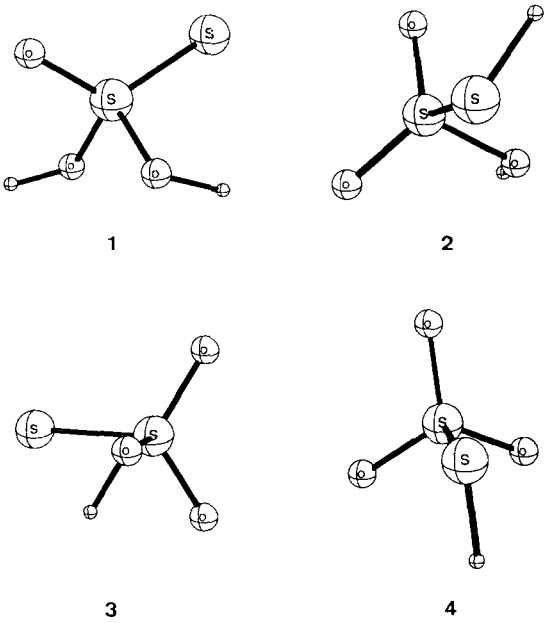


Fig. 1. Calculated structures of two isomers each of thiosulfuric acid, $H_2S_2O_3$ (**1** and **2**), and its monoanion, $HS_2O_3^-$ (**3** and **4**).

$H_2S_2O_3$ and $HS_2O_3^-$ are most stable as the H-S bonded isomers **2** and **4**; however, the energy differences between **2** and **4** and the most stable H-O bonded forms, **1** and **3**, are small (41 and 20 kJ mol^{-1}; Table 1). Isomer **2** which has C_1 symmetry contains an SS bond of length 205.7 pm. The orientation of the OH and SH groups of **1** and **2** is staggered with respect to the neighboring SO and SS bonds. The most stable conformer of **1** has C_1 symmetry[7] with nonequivalent OH groups and an SS bond of distance 198.2 pm, which is about halfway between the established single (205 pm) and double (188 pm) bond distances.[8] The geometries of other rotational isomers of **1** were also optimized; their energies were higher than that of **1** at all levels of calculation mentioned in Table 1.

[**] Sulfur Compounds, Part 147; Part 146: R. Steudel, M. Papavassiliou, F. Baumgart, *Z. Naturforsch. B*, **1991**, *46*, 1674–1678.

Table 1. Absolute and relative energies of two isomers each of thiosulfuric acid, $H_2S_2O_3$, and of its monoanion, $HS_2O_3^-$, as calculated with the 6-311G** basic set.

Isomer	Symmetry	E_{tot} [Hartree] [a]	ΔE_{rel} [kJ mol^{-1}] [b] HF	MP 2	MP 3	MP 4	MP 4 + ZPE [c]
$H_2S_2O_3$							
1	C_1	−1020.774507	18	30	27	34	41
2	C_1	−1020.781246	0	0	0	0	0
$HS_2O_3^-$							
3	C_1	−1020.280137	0	11	5	13	20
4	C_s	−1020.276758	9	0	0	0	0

[a] The total energies (E_{tot}) apply to the Hartree–Fock (HF) level. [b] The relative energies E_{rel} of the most stable isomers have been set equal to zero; ΔE_{rel} is the difference in energy at the corresponding level of calculation. [c] The zero-point energies (ZPE) are based on calculated wavenumbers scaled by a factor of 0.89.

The anion **3** has C_1 symmetry and an SS bond length of 200.1 pm, slightly longer than in the parent compound **1**. The isomeric anion **4** has C_s symmetry and is less stable than **3** at the Hartree–Fock level. If electron correlation is taken into account, **4** is considerably more stable than **3**. The zero-point energies also favor the isomers **2** and **4** (see Table 1). The reliability of the present calculations can be vouched for by the fact that the harmonic vibrational wavenumbers calculated for **4**[9] correlate in a linear fashion with the 11 observed fundamental wavenumbers of the anion of $NH_4HS_2O_3$[5] (correlation coefficient 0.999).

Table 2. Selected bond distances d [pm], bond angles α [°] [a], torsion angles τ [°], and dipole moments μ [D] of **1** through **4**.

	$H_2S_2O_3$ (**1**)	$H_2S_2O_3$ (**2**)	$HS_2O_3^-$ (**3**)	$HS_2O_3^-$ (**4**)
d(S–H)	–	133.0	–	133.0
d(O–H)	94.9	94.9	94.3	–
d(S–S)	191.4	205.7	200.1	215.5
d(S–OH)	156.8	157.7	161.3	–
d(S=O)	141.1	141.2	143.1	143.5
α(S-O-H)	111.3	111.1	107.9	–
α(S-S-H)	–	93.3	–	95.5
τ(S-S-O-H)	156.9	178.8	62.0	–
τ(O-S-S-H)	–	78.6	–	60.0
μ	3.60	3.00	3.24	3.03

[a] The bond angles at the central sulfur atoms of all four species are in the range 99.5–122.4°.

Expectedly, the negative charge of the anion destabilizes the SS bond of **4** compared to **2** as can be seen from the rather large SS bond distance of 215.5 pm. In this respect **4** resembles other sulfur oxyanions like $S_2O_4^{2-}$ (d_{ss} = 239 pm), $S_2O_5^{2-}$ (d_{ss} = 221 pm), and $S_2O_6^{2-}$ (d_{ss} = 215 pm).[8] All these species dissociate at the SS bond on heating. Anion **4** is the key intermediate in the acid decomposition of thiosulfate[10] which starts according to Equation (a).

$$HSSO_3^- + SSO_3^{2-} \rightleftharpoons HSSSO_3^- + SO_3^{2-} \quad (a)$$

The weak SS bond of **4** expedites the transfer of the SH unit to the attacking nucleophilic thiosulfate anion.[11] Reaction (a) is followed by similar sulfur-transfer steps until the chain length of the sulfanemonosulfonate ion ($HS_xSO_3^-$) has sufficiently grown to allow the splitting off of S_6, S_7, or S_8 [Eq. (b)].[12]

$$H{-}S_x{-}SO_3^- \rightleftharpoons S_x + HSO_3^- \quad (b)$$

$x = 6,7,8$

It therefore seems that the instability of thiosulfuric acid in aqueous solution is mainly caused by the high reactivity of its two anions. This explains why the decomposition rate has a maximum at pH 2–4 and why strongly acidic solutions of $Na_2S_2O_3$ decompose only slowly.[3] Nonaqueous solutions of $H_2S_2O_3$ which do not contain the $S_2O_3^{2-}$ or $HS_2O_3^-$ anions should therefore be more stable, which has in fact been observed.[4, 13]

[13] The formation of gaseous $H_2S_2O_3$ (**2**) from H_2S and SO_3 is exothermic by 68 kJ mol^{-1} which follows from the energies of the three compounds calculated at the HF/6-311G** level (H_2S: −398.701237, SO_3: −622.054076 Hartree).

A Germanium Sesquisulfide, $(t\text{BuGe})_4S_6$, without Adamantane Structure

By *Wataru Ando,* Tetsuji Kadowaki, Yoshio Kabe,* and *Motohiko Ishii*

Organo-substituted sesquichalcogenides with Group IV elements $(RE)_{2n}Y_{3n}$ (E = Si, Ge, Sn; Y = O, S, Se) have attracted theoretical and practical interest for a long time.[1–3] These molecules have polyhedral cagelike frameworks: The structure for n = 2 is an adamantane (or tetrahedrane) type **Ia**,[2] for n = 3, a prismane type **II**,[3d, e] for

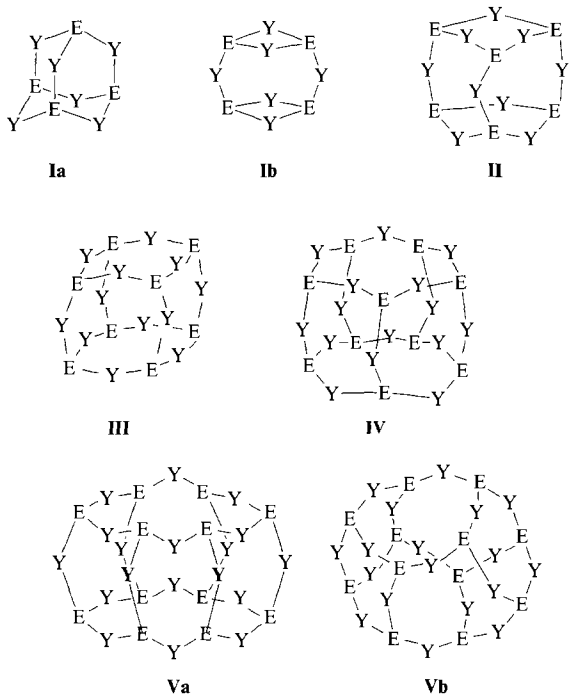
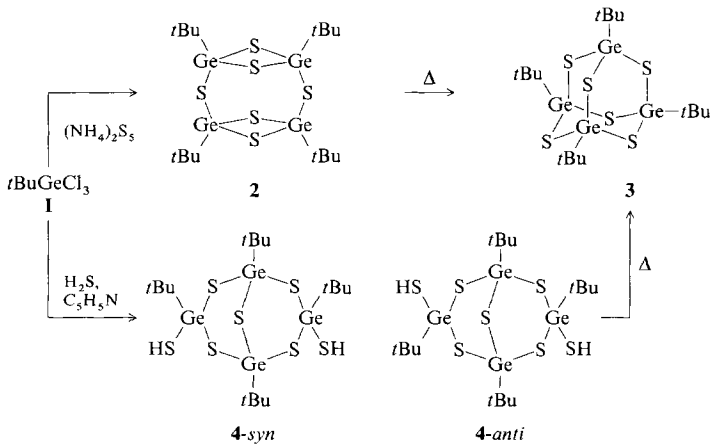
[**] This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan. The authors are grateful to the Asai Germanium Institute for the gift of tetrachlorogermane.

n = 4, a cubane type **III**,[3a] for n = 5, a pentagonal prismane type **IV**,[3a] and for n = 6, a hexagonal prismane type **Va**. The known sesquisulfides and selenides (E = Si, Ge, Sn) have been restricted to those with adamantane-type structures



(**Ia**), while the sesquioxide compounds may display the higher homologous structures (**II**, E = Ge; **III**, **IV**, E = Si). An attempted synthesis of **Va** failed and resulted in the formation of structural alternative **Vb**.[3a-c] The "double decker"-type isomer **Ib**[4] isomeric to **Ia** is regarded as another polyhedral sesquichalcogenide because of the equivalence of its four vertices; however, its existence has never been confirmed.[2b-d,f,i] We describe here the synthesis and X-ray crystal structure of the first germanium sesquicalcogenide of type **Ib**.

Treatment of *tert*-butylgermanium trichloride (**1**) with 2 equivalents of ammonium pentasulfide at room temperature provided sesquisulfide **2** with the stoichiometry $(t\mathrm{BuGe})_4S_6$ in 30% yield after preparative HPLC and fractional recrystallization. Unfortunately neither the ^1H nor the ^{13}C NMR spectra of **2**[5] permit one to distinguish between "double decker" and adamantane-type structures. The adamantane-type isomer **3**, prepared by the reported procedure[2b,e] (heating **1** in benzene at reflux with H_2S/pyridine), showed singlets in its NMR spectrum at the same chemical shifts as those in **2**. On the other hand, the Raman spectrum of **2** exhibits six bands in the range expected for Ge–S framework vibrations (200–650 cm^{-1}), whereas that of **3** shows only two bands.[5] This observation not only distinguishes two isomers but also reveals that the molecular symmetry of **2** (D_{2h}) is lower than that of **3** (T_d).[6] When **2** is heated above 200 °C the five Raman bands (308, 337, 364, 398, and 429 cm^{-1}) fade and one strong band (348 cm^{-1}) appears, which is consistent with the spectrum of **3**. Since compound **2** is thought to be an intermediate in the formation of **3** even in reactions with the H_2S/pyridine reagent system, the reaction was carried out at room temperature under our set of conditions. After preparative HPLC of the reaction mixture bisgermanethiol **4** was isolated in 43% yield; **4** releases one mole of H_2S upon heating to afford **3**. The bisgermanethiol **4** exists as two isomers which could not be separated; the spectral data[5] correspond to two isomers (**4**-*syn* and **4**-*anti*). On one occasion isomerically pure crystals were successfully grown and an X-ray structure[7] of the **4**-*syn* isomer was obtained. On the basis of this structure and 2D-NMR experiments on **4**, we believe that the other isomer is the **4**-*anti* compound shown, which differs from **4**-*syn* by the inversion of one germanium atom bearing an SH group. Therefore the reaction proceeds via completely different intermediates depending on the sulfurization reagents. A milder reagent such as $(NH_4)_2S_5$ might make a kinetically-controlled reaction possible, affording the four-membered cage compound **2**.



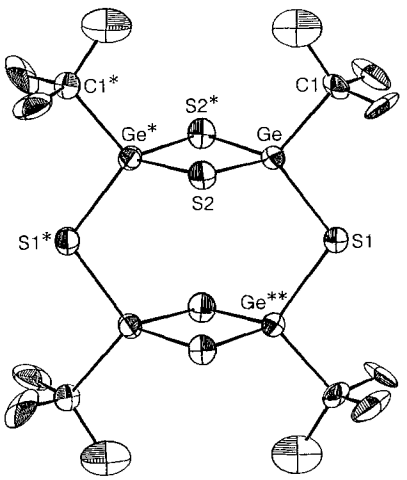


Fig. 1. Crystal structure of **2** (ORTEP). Selected bond lengths [Å] and angles [°]: Ge-S1 2.216(3), Ge-S2 2.243(8), Ge-C1 2.00(1); S1-Ge-S2 114.2(2), S2-Ge-S2* 96.7, Ge-S1-Ge** 108.5, Ge-S2-Ge* 83.2, S1-Ge-C1 103.8(3), S2-Ge-C1 114.9(7).

According to the X-ray structure analysis of **2**,[7] the compound crystallizes in the cubic space group *I*23 and possesses three orthogonal twofold crystallographic axes. The Ge atoms and S atoms form two four-membered and two eight-membered rings; the four-membered rings are perpendicular to the common plane of the two eight-membered rings (Fig. 1). The Ge_2S_2 rings are almost planar. Two twofold axes pass through the midpoints of the four-membered and eight-membered rings. The remaining axes bisect the eight-membered rings through S1 and S1*. Thus the entire molecular structure can be generated by symmetry operations on

one-fourth of the molecule. The packing of the molecules in the unit cell is shown in Figure 2. It is noteworthy that the highly symmetric isomer **3** with an adamantane structure has lower crystal symmetry ($C2/c$)[2f] than **2**. The molecules lie

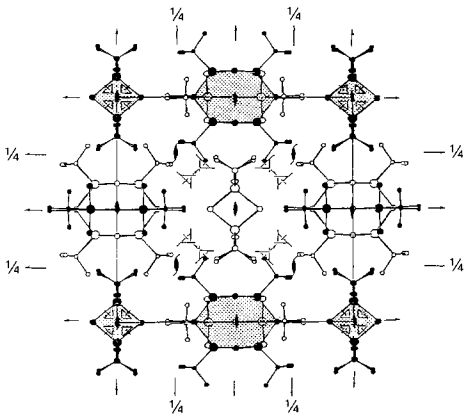

Fig. 2. The crystal packing of **2**. The lower half of the cubic unit cell is shown. Atoms and molecules in the (001) plane are white or without dots, those in the (001/2) plane are black or dotted.

on the twelve edges and the six faces of a cube ($Z = 6$). The eight vertices and the center of the cube are unoccupied to afford a body-centered lattice.

The product ratio of **4**-*syn*/**4**-*anti* varied with experimental conditions. In the C-H COSY and COLOC spectra of **4**-*syn*/**4**-*anti*, the signals of the methyl and quaternary carbons correspond to those of the methyl protons of the appropriate isomer. In both the EI and FAB mass spectra of **4**-*syn*/**4**-*anti* the most intense peak is $[M - H_2S]^+$.

[6] According to group theoretical considerations for $(RGe)_4S_6$, the vibrational modes of molecules with D_{2h} and T_d symmetries are distributed among the following fundamental vibrations: $\Gamma(D_{2h}) = 7A_g(R) + 3A_u(-) + 5B_{1g}(R) + 4B_{1u}(ir) + 3B_{2g}(R) + 5B_{2u}(ir) + 3B_{3g}(R) + 6B_{3u}(ir)$; $\Gamma(T_d) = 3A_1(R) + 3E(R) + 3F_1(-) + 6F_2(ir,R)$.

[7] **2**: $C_{16}H_{36}Ge_4S_6$, $M = 711.21$, cubic, $a = b = c = 16.164(1)$ Å, $V = 4223.0$ Å^3, space group *I23*, $Z = 6$, $\mu(Mo_{K\alpha}) = 46.1$ cm^{-1}, $\rho_{calcd.} = 1.68$ g cm^{-3}, 693 reflections, $R = 0.051$ ($R_w = 0.061$). – **4**-*syn*: $C_{16}H_{38}Ge_4S_7$, $M = 745.29$, orthorombic, $a = 13.904(4)$, $b = 16.340(6)$, $c = 13.438(3)$ Å, $V = 3053.0$ Å^3, space group *Pbcn*, $Z = 4$, $\mu(Mo_{K\alpha}) = 43.2$ cm^{-1}, $\rho_{calcd.} = 1.62$ g cm^{-3}, 993 reflections, $R = 0.070$ ($R_w = 0.082$). The independent reflections [$2\theta \leq 50°$; $|F_0^2| > 3\sigma|F_0^2|$] were measured on an Enraf-Nonius CAD4 diffractometer using $Mo_{K\alpha}$ irradiation and ω-2θ (or ω) scans. An empirical absorption correction based on a series of Ψ-scans were applied to the data (0.934/1.00 for **2**; 0.465/0.999 for **4**-*syn*). The structures were solved by direct methods and all nonhydrogen atoms were refined anisotropically. The hydrogen atoms were not located. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CDS-55660 the names of the authors, and the journal citation.

A Synthetic Receptor for Cyclic Adenosine Monophosphate**

By *Ghislain Deslongchamps, Amalia Galán, Javier de Mendoza,** and *Julius Rebek, Jr.**

Molecular recognition plays a central role in biological processes, and the synthesis of receptors for biorelevant molecules is a rapidly maturing branch of bioorganic chemistry. A number of synthetic receptors for heterocyclic bases,[1–4] carbohydrates,[5, 6] and phosphates[7, 8] employ multiple contact sites on concave surfaces. Those with a cleft-like shape offer particular advantages for molecular recognition since optimal hydrogen bonds can be formed between the concave surface of the receptor and the convex surface of the substrate. Here we report the binding of cyclic adenosine monophosphates (cAMPs) by this type of receptor.

For complexation of the purine nucleus, compound **1** with a molecular cleft featuring two hydrophobic imide functions was developed for simultaneous Watson–Crick and Hoogsteen base-pairing in a triple-helix motif. A 3,6-disubstituted carbazole spacer in **1** poises the two imide functions at an ideal distance and orientation, and the carbazole nucleus allows arene stacking interactions with the complexed guest. The carbazole nitrogen was elaborated to a phosphate-binding site. The bicyclic guanidinium unit, derived from L-asparagine[7, 9, 10] and outfitted with the lipophilic naphthoyl residue, was connected to the carbazole unit with the short two-carbon spacer shown. The receptor was assembled without difficulty (Figure 2) from the tripropylimide acid chloride **4**[11] and diamine **5**; the final coupling reaction of the guanidine derivative to **6** was performed with carbonyldiimidazole (CDI) in dimethylformamide (DMF).[12]

The affinity of receptor **1** toward nucleotide derivatives was determined by liquid–liquid extraction experiments, in which aqueous solutions of cAMP salts (0.11 M) were ex-

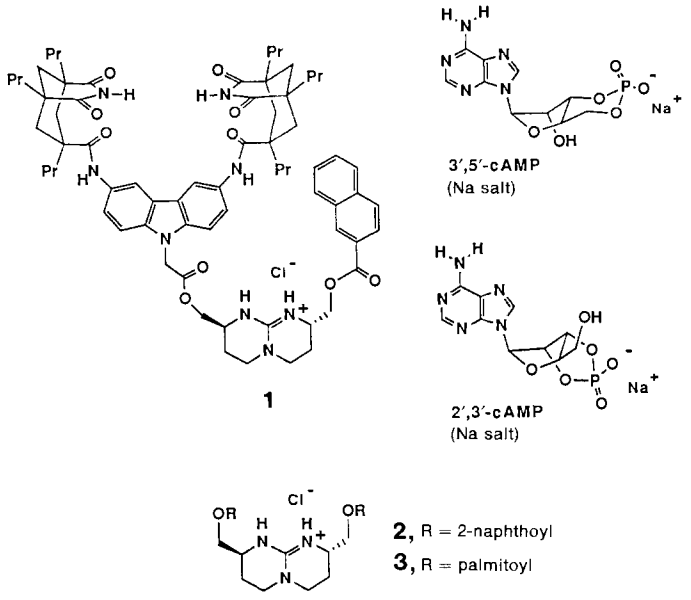
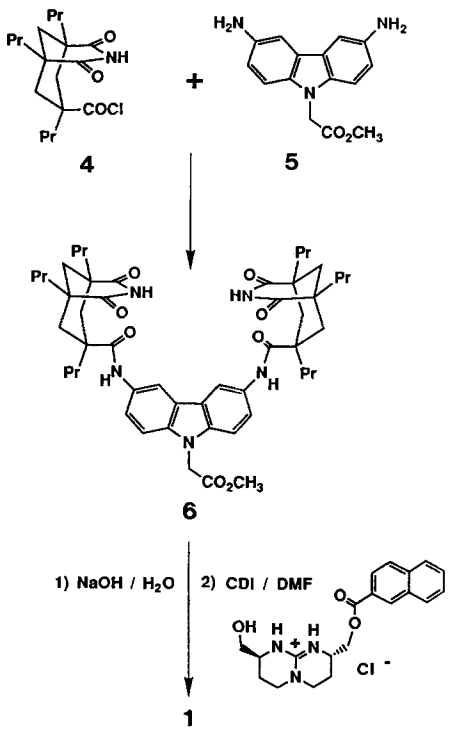
[**] We are grateful to the U. S. National Institutes of Health for support of this work. G. D. thanks the Natural Sciences and Engineering Research Council of Canada for a postdoctoral fellowship. We are indebted to Dr. Marta Bruix (C. S. I. C, Madrid) for the ROESY experiments.



tracted into CH_2Cl_2 solutions of the receptor (2.75 mM). The extraction efficiency (i.e. fraction of receptor molecules occupied by substrate) in the organic phase was determined by NMR integration. Reference extraction experiments were also carried out with the methyl ester **6**, which lacks the phosphate binding site, and with the bis-2-naphthoylguanidinium derivative **2** and the bispalmitoylguanidinium derivative **3**,[9, 10] both of which lack the adenine recognition module.



Receptor **1** displays high affinity for cAMP derivatives (Table 1); it extracts one equivalent of either 2′,3′-cAMP or 3′,5′-cAMP into the organic layer! The extraction ratios are consistent with a 1:1 stoichiometry for the complex, and spectroscopic data support the binding model illustrated in Figure 1. The 600 MHz NMR ROESY spectrum of the complex

Table 1. Liquid–liquid extraction of cAMP and cGMP with abiotic receptors **1**–**3** and **6**. The numbers refer to the percentage of the receptor molecules occupied by substrate in the extraction. A solution of receptor (5.5×10^{-3} mmol) in dichloromethane (2 mL) was shaken for two minutes with a solution of nucleotide (5.5×10^{-2} mmol) in water (0.5 mL). The mixture was centrifuged and the organic layer was removed and evaporated. The residue was redissolved in 4:1 $CDCl_3$:CD_3OD (or in [D_6] DMSO) and analyzed by ^1H NMR spectroscopy.

Receptor	Nucleotide extracted [%]			
	2′,3′-cAMP	3′,5′-cAMP	2,3′-cGMP	3′,5′-cGMP
6	<5	<5	<5	<5
2	50	20	8	<5
3	27	13	<5	<5
1	100	100	60	34

of **1** with 3′,5′-cAMP (in [D_6]DMSO showed (among others) interactions between the spacer NCH_2CO and the carbazole H-1, H-8 signals to H-2′ and H-3′ in the ribose of the guest.

The selectivity, however, is modest: 60% extraction was observed in parallel experiments with 2′,3′-cGMP and 34% with 3′,5′-cGMP. Guanine can undergo only "wobble" base-pairing[13] to the imide functions of the receptor, and the diminished binding strength is consistent with the loss of a single hydrogen bond.[14] In addition, the lower solubility of cGMP in CH_2Cl_2 may also contribute to its lower extraction efficiency.

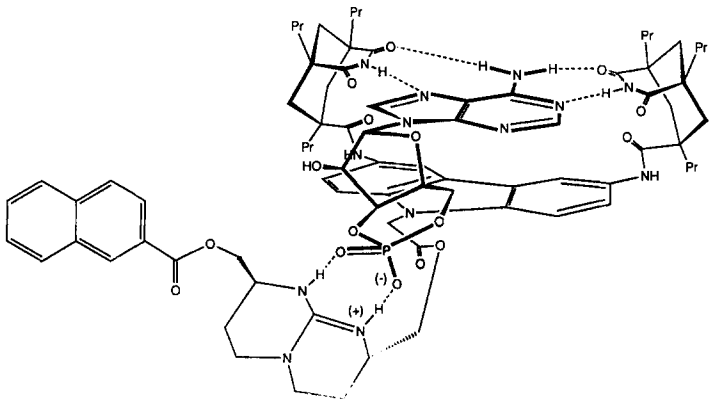


Fig. 1. Proposed binding in the complex of **1** and 3′,5′-cAMP based on NMR spectroscopic data.

Despite its high affinity for the aminopurine nucleus the cleft module of **1** alone did not suffice for the extraction of cAMP (**6** in Table 1). For example, the association constant for the binding of 9-ethyladenine with **6** in $CDCl_3$ is $\approx 50000\ M^{-1}$, and **6** also extracts adenosine (0.3 equiv) and 2′-deoxyadenosine (0.8 equiv) from their aqueous solutions. The esterified guanidinium receptors **2** and **3** are capable of extracting considerable amounts of cAMP into the organic layer, suggesting effective binding of the phosphate ion by the guanidinium function. However, **2**, **3** and **6** were unable to extract significant amounts of cGMP out of water (in the best case, a ca. 8% extraction of 2′,3′-cGMP was detected with **2**).

We have recently developed receptor **1** for the binding of dinucleotides.[15] Transport of nucleotides across membranes[16] should be possible with such receptors.

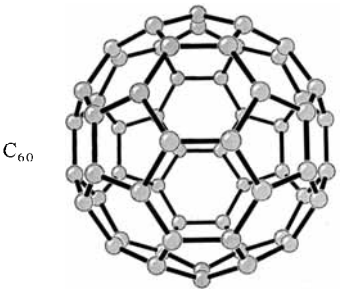
The Stability of Buckminsterfullerene (C_{60}): Experimental Determination of the Heat of Formation

By *Hans-Dieter Beckhaus, Christoph Rüchardt,* Michelle Kao, François Diederich,** and *Christopher S. Foote**

In 1990, Krätschmer and Huffman et al. reported the preparation of macroscopic quantities of buckminsterfullerene (C_{60}), the third allotropic and first molecular form of carbon, by resistive heating of graphite under an inert atmosphere.[1] In the subsequent burgeoning worldwide developments, the cagelike truncated icosahedral structure of C_{60} has been firmly established.[2] This structure was predicted in 1985 by Kroto and Smalley et al. to account for the exceptional stability of the C_{60} species in carbon cluster beams produced by laser vaporization of graphite.[3] Solid C_{60} is indeed of remarkable stability and can be sublimed without decomposition at 400 °C under reduced pressure. The initial exploration of the material properties of this unique molecular structure led to alkali-metal-doped high-temperature superconductors[4] and to a doped organic ferromagnet.[5] Early investigations into the chemistry of C_{60} demonstrated its high oxidation potential[6] and its efficiency in the sensitization of singlet oxygen.[7] Functionalization of the carbon ball is best achieved by nucleophilic[8] and carbene attack[9] at its reactive "pyracyclene double bonds". Osmium and platinum complexes of C_{60}, obtained by bridging these electron-deficient C–C bonds, have been structurally characterized by X-ray crystallography.[10]



Many of the physical properties of buckminsterfullerene including its thermochemical stability was predicted in theoretical calculations initiated by the work of Kroto and Smalley in 1988.[11] The computational assessement of the thermostability of C_{60} by a variety of quantum mechanical and molecular mechanics methods produced greatly diverging results: the calculated heats of formation ΔH_f° at 298 K vary between 973 kcal mol^{-1} (16.2 kcal mol^{-1} per C atom) and 286 kcal mol^{-1} (4.8 kcal mol^{-1} per C atom) (Table 1). The large discrepancy in the theoretical predictions underlines the importance of determining this fundamental thermodynamic quantity by an accurate experimental thermochemical analysis. Here, we report the results of such a study, which was undertaken with 300 mg of C_{60} of highest purity.

Table 1. Computed heats of formation ΔH_f° at 298 K for C_{60} compared to the experimental value ΔH_f° (c) determined for the crystalline state.

ΔH_f° [kcal mol^{-1}]	ΔH_f° per C atom [kcal mol^{-1}]	Method	Ref.
973	16.2	AM1	[13]
869	14.5	MNDO	[14]

545 (ΔH_f^0) (c)	9.1	combustion	this work

[a] 6-31G* SCF energy at STO-3G geometry.

To isolate pure C_{60}, the toluene extract of the soot prepared by resistive heating of graphite under a helium atmosphere was chromatographed on neutral alumina with hexane/toluene (95:5 v/v) as previously described.[6, 12] After evaporation of the solvent, the material was digested in a small amount of hexane and collected by filtration. HPLC analysis (C-18 reversed-phase column, CH_2Cl_2/toluene (70:30 v/v) as eluent) indicated complete separation of C_{60} from C_{70} and the higher fullerenes. For further purification, the material was recrystallized from toluene and subsequently dried at 80 °C/10^{-3} Torr for 5 hours. Final HPLC, MS and ^{1}H NMR analysis showed that all residual traces of solvent had been removed and that the sample of C_{60} was more than 99.9% pure. A toluene-methyl resonance could not be detected in the 360 MHz ^{1}H NMR spectrum recorded in [D_6]benzene, even at the highest signal amplification.

The heat of combustion of C_{60} was measured by oxygen bomb calorimetry. The isoperibolic aneroid microcalorimeter and the experimental procedures have been described previously.[17] Pellets of C_{60} were used with and without

ΔH_c (C_{60}) [kcal mol^{-1}] [f]	−6189.54	−6185.61	−6189.23	−6192.51	−6188.02	−6183.43

[a] $T_h = 25\,^{\circ}C$; $V_{bomb} = 0.0820$ L; $p^i_{gas} = 30.00$ atm (30.40 bar); $m^i_{water} = 0.23$ g; $E_{ign} = 0.55$ cal; $T_i = 23.720\,^{\circ}C - 24.017\,^{\circ}C$; $m_{platin} = 1.159$ g. [b] $\Delta T_c = T_f - T_i + \Delta T_{corr}$. [c] $\varepsilon_{calor} = 340.234 \pm 0.020$ cal K^{-1} ($\pm 0.0058\%$) calibration with benzoic acid. [d] $\varepsilon_{cont}(-T_c) = \varepsilon^i_{cont}(T^i - 25\,^{\circ}C) + \varepsilon^f_{cont}(25\,^{\circ}C - T^f + \Delta T_{corr})$. [e] ΔE_{corr}: sum of the items 81–85, 87–90, 93 and 94 in ref. [18]. [f] Mean value: ΔH_c (1) = −6188.06 kcal mol^{-1} ±1.30 (0.021%).

auxiliary paraffin oil. No trace of soot was detectable in any experiment and the auxiliary material showed no effect on the results (Table 2).

The density of C_{60} ($\rho = 1.78$ g cm^{-3}) was measured to calculate its mass in vacuum. The specific heat (c_p = 0.151 cal g^{-1} at 298 K) was determined by differential scanning calorimetry to calculate the isothermal bomb process. The reduction to standard state was performed in the usual manner.[18] A mean value of ΔH_c° (c) = −6188.06 kcal mol^{-1} for the standard heat of combustion was calculated from six calorimetric runs; the standard deviation of ±1.35 kcal mol^{-1} accounts for all experimental uncertainties. Thus a standard heat of formation ΔH_f° (c) = 544.99 kcal mol^{-1} is obtained for crystalline C_{60}. This corresponds to 9.08 ± 0.02 kcal mol^{-1} per C atom which compares with zero for graphite and 0.4 kcal mol^{-1} per C atom for diamond.

Of all the computational predictions (Table 1), the standard heat of formation calculated with the MM3 force field[19] shows by far the best agreement with the experimental value determined for crystalline C_{60}.[20, 21] It is notable that MM3 calculations, performed on the five possible isomers of the higher fullerene C_{78} that satisfy the isolated pentagon rule, also correctly found the two isomers which are the most stable and can be isolated. Apparently, the parameters of this force field account particularly well for the strain caused by the curvature in fullerene π systems and should therefore be very useful for predicting the entirely unexplored properties of the many higher members in the fullerene family of all-carbon molecules.

[20] It is hardly possible to make a precise estimation of the heat of sublimation of C_{60} for a proper comparison of ΔH_f (g) values obtained by experiment with the results of calculations. Considering the heats of sublimation of a series of polycyclic aromatic hydrocarbons (J. D. Cox, G. Pilcher, *Thermochemistry of Organic and Organometallic Compounds*, Academic Press, London/New York, **1970**) we suggest that the heat of sublimation per carbon atom should in principle be lower for C_{60} than for arenes like pyrene (1.41 kcal mol^{-1}), triphenylene (1.57), 3,4-benzphenanthrene (1.41), chrysene (1.56), tetracene (1.66) or perylene (1.50), because in the crystal the C atoms of the arenes can interact with two layers of adjacent molecules, but those of C_{60} with only one.
[21] *Note added in proof* (December 18, 1991): Recently a value for $\Delta H_{subl.}$ of 40.1 ± 1.3 kcal mol^{-1} for C_{60} at 707 °C was reported by C. Pan, M. P. Sampson, Y. Chai, R. H. Hauge, J. L. Margrave, *J. Phys. Chem.* **1991**, *95*, 2944.

1-*O*-(2-Acetoxyhexadec-1-enyl)choline Iodide, a New Anticancer Agent

By *Werner Kern, Arnulf Lutz, Gerhard Spiteller,** and *W. Jens Zeller**

Recently we proved the presence of α-hydroxyaldehydes **1** (Scheme 1) in a masked form in bovine and swine tissue

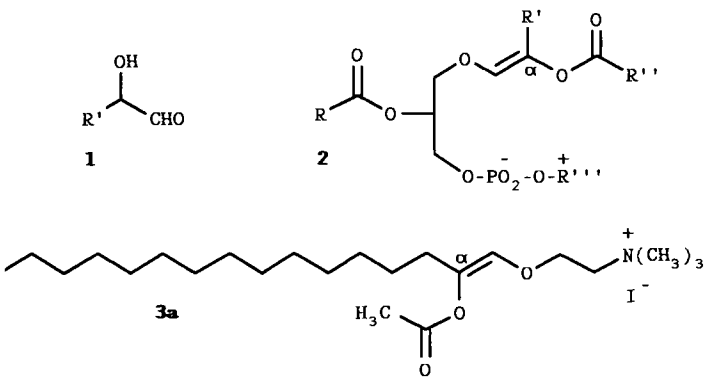
lipids.[1-4] Model studies showed that the α-acyloxyplasmalogens **2** could be precursors to α-hydroxyaldehydes **1**. It is also possible that **1** arises from plasmalogens by means of biological oxidation processes, since our model studies demonstrated that epoxidation of enolethers could produce α-hydroxyaldehydes.[4]



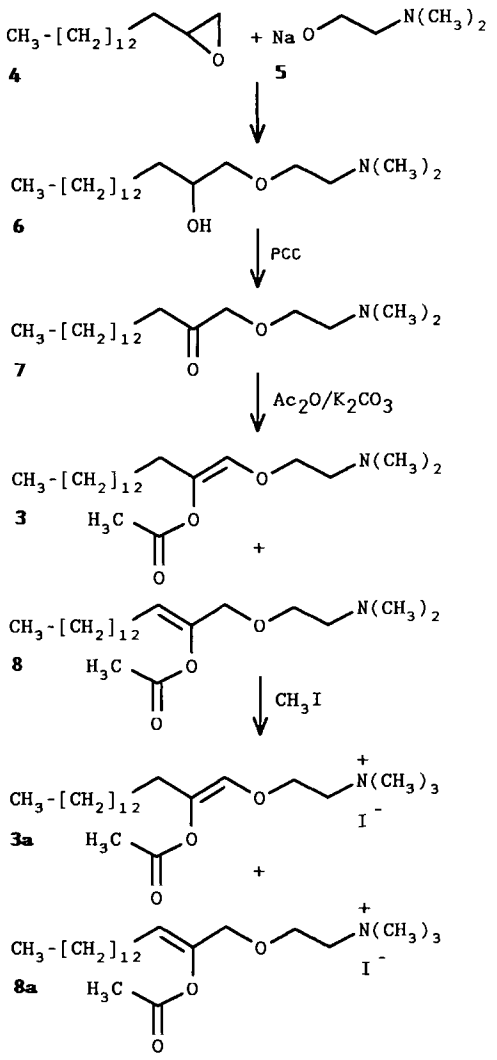
Scheme 1. R,R',R'' = alkyl, R = $CH_2CH_2N(CH_3)_3I$, $CH_3CH_2NH_2$.

Aldehydes have cytotoxic properties, which can be augmented by increasing the carbonyl reactivity.[5-7] However, attempts at combating tumors with unsaturated aldehydes and hydroxyalkenals[6,7] were unsuccessful due to their poor bioavailibility.[6,7] Using the fact that the pH value in tumor tissue drastically decreases upon supply of glucose,[8,13-16] Tietze et al.[8-12] synthesized "prodrugs" in the form of masked aldehydes. These acetalglucosides, stable under physiological conditions, should provide the reactive aldehyde at the place of action when the pH value is lowered.[8-12]

We suspect that the masked α-hydroxyaldehydes, which either are found in the tested cells or arise in them, are natural "prodrugs" along the same lines as those synthesized by Tietze et al.[8-12] As such, masked α-hydroxyaldehydes should display similar cytotoxic properties. To prove our assumption we synthesized the simple model compound **3a**, which has an active enolether–enolacetate structural unit, that is, a masked α-hydroxyaldehyde moiety. In addition a choline residue was built in to ensure the water solubility of **3a**.

First 1,2-epoxyhexadecane (**4**) was treated with the sodium salt of 2-*N*,*N*-dimethylaminoethanol (**5**) following the method of Parker and Isaacs[17] to furnish 1-*O*-(2-hydroxyhexadecyl)-2-*N*,*N*-dimethylaminoethanol (**6**). Ether **6** was converted to 1-*O*-(2-oxohexadecyl)-2-*N*,*N*-dimethylaminoethanol (**7**) with pyridinium chlorochromate (PCC) according to the procedure developed by Corey et al.[18] and Piancatelli et al.[19] Compound **7** underwent reaction with acetic anhydride/K_2CO_3 under the conditions of Barbier et al. [20] providing 1-*O*-(2-acetoxyhexadec-1-enyl)-2-*N*,*N*-dimethylaminoethanol **3** [(*Z*)/(*E*)-isomers].[21] This reaction was unfortunately not regiospecific; besides enolacetate **3** the isomeric compound **8** [(*Z*)/(*E*)-isomers] also arose. This mixture of **3** and **8** was quaternized with methyl iodide and purified by repeated recrystallizations from ethyl acetate. The product mixture, designated C16-AC, consisting of approximately 70% **3a** and 30% **8a** (each with both (*Z*)- and (*E*)-isomers), was tested for inhibition of tumor growth. The results are summarized in Table 1.

The tumor cell lines (ovarian tumors O-342 and O-342/DPP as well as Gliom T 406) with an initial concentration of



1×10^5 cells per mL medium were incubated seven days with C16-AC (70% (*Z*)/(*E*)-isomers of **3a** and 30% **8a**) in the concentrations 0.1, 1.0, 10, and 100 $\mu g\,mL^{-1}$. The cell count was determined after one, four, and seven days from the average counts of three tissue culture dishes. The regression lines for the percentile growth inhibition was determined from the cell counts from day four. Finally the ID_{10}, ID_{50}, and ID_{90} values (ID_x = dose which inhibits growth by x% relative to the untreated control) were determined graphically.

Table 1. Inhibition of growth for the tumor cells lines O-342, O-342/DPP, and T 406 by C16-AC (see text) in vivo [a].

Tumor cell line	Inhibition dose [$\mu g\,mL^{-1}$]		
	ID_{10}	ID_{50}	ID_{90}
O-342	<0.05[b]	0.7	20
	<0.2[b]	1.9	25
O-342/DPP	<0.2	1.8	25
	<0.3	3	30
T-406	<0.05	0.6	25
	<0.05	1.0	25

[a] O-342 is a malignant granulosa cell rat tumor; O-342/DPP is the related subline which is resistent to cisplatin; T 406 is a gliom cell line of human origin. [b] Two independent experiments were conducted per tumor cell type; the results of the individual experiments are presented here.

The results of the chemotherapeutic investigation show ID_{50} values between 0.6 and 1.9 $\mu g\,mL^{-1}$ for all three tumor cell types examined. This proves a significant therapeutic activity for C16-AC in vitro. Comparison of the antitumor effects of C16-AC with those of alkylphosphocholine HePc proved the latter to be ten times less effective.

Unprecedented Stereospecific Ligand Exchange at a W≡W Template**

By *Steven D. Dietz, Nancy W. Eilerts,* and *Joseph A. Heppert**

The stereochemistry of molecules is important in determining their chemical reactivity.[1, 2] The development of novel and more efficient chiral reagents and catalysts for asymmetric synthesis has become the rationale for a wide range of investigations of chiral transition-metal coordination complexes, covering the breadth of the transition elements.[3–5] Unfortunately, it is still difficult to predict the stereochemical outcome of some exchange reactions involving chiral ligands at early transition-metal templates. Our interests have recently focused on the development of 1,1′-bi-2-naphtholate derivatives[6] as chiral auxiliary ligands for early transition-metal complexes.[7] During these studies, we have discovered some unique aspects of the coordination chemistry of this multifaceted bidentate alcoholato ligand.[7] In this communication, we report the first examples of highly stereospecific coordination by a chiral bidentate alcoholato ligand at a d^3-d^3 $[W_2(OR)_6]$ template. Our studies indicate that the stereochemical courses of these reactions are controlled by thermodynamics, producing diastereomeric products in nonstatistical distributions.

The addition of two equivalents of racemic 1,1′-bi-2-naphthol (*rac*-H_2bino) to a solution of $[W_2(OtBu)_6]$[8] in toluene at 0 °C results in the formation of an analytically pure pale-yellow precipitate of empirical formula $[W_2(bino)_2(OtBu)_2]$ (**1a**).[9] The ^{1}H and ^{13}C NMR spectra of the product are invariant over a wide range of temperatures and are consistent with the magnetic equivalence of both the *t*BuO and the naphtholate units. The chemical shift of the *t*BuO ligands (Fig. 1 above), $\delta = 0.1$, is unusual by comparison with the typical value $\delta = 1.6$ for the *t*BuO ligands in $[W_2(OtBu)_6]$.[8] The *gauche* *t*BuO ligands of $[W_2(3,3'\text{-}R_2bino)(OtBu)_4]$ (R = H or Me), which are shielded by a single naphtholate ring, appear at $\delta = 0.70$.[7a] This dramatic upfield shift, $\Delta\delta = 1.15$, indicates that the *t*BuO ligands of **1a** probably lie in the

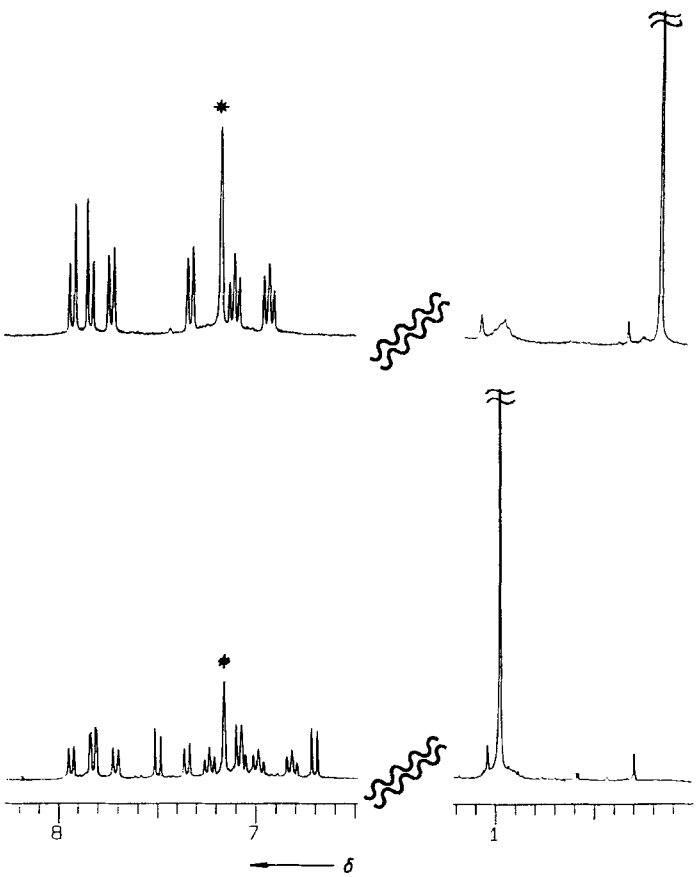

Fig. 1. 300 MHz ^{1}H NMR spectra of the $[W_2(bino)_2(OtBu)_2]$ diastereomers **1a** (above) and **2b** (below). * = C_6D_5H.

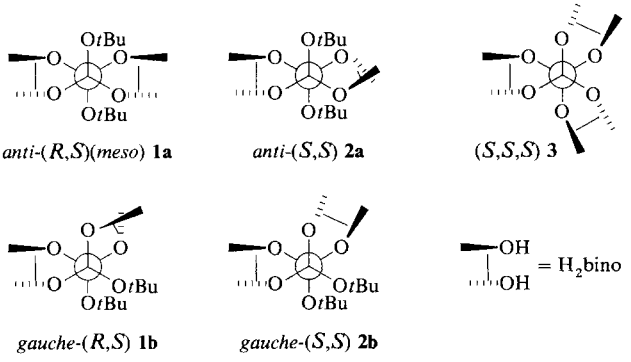
shielding cones of two naphtholato ligands. The symmetry and NMR data allow the assignment of this product as the C_{2h} symmetric *anti*-(*R*,*S*) isomer **1a**. All of the alternative disubstituted isomers, including the *gauche*-(*R*,*S*) complex **1b** and both of the $[W_2(S^*,S^*)\text{-(bino)}_2(O\textit{t}Bu)_2]$ isomers **2a** and **2b**, can be eliminated on the basis of symmetry considerations. Two minor products ($\leq 10\%$ each) are found in the soluble residues of the reaction. One of these products, a highly symmetric compound whose spectrum consists of a single set of naphtholate signals, was later unequivocally identified as tris(bino)complex **3** (vide infra). The second minor product exhibits a single O*t*Bu resonance and signals for two nonequivalent naphtholate units. This could attributed to either the C_2 symmetric *anti*-(S^*,S^*) isomer **1b** or the *gauche*-(S^*,S^*) isomer **2b** of $[(\text{bino})_2W_2(O\textit{t}Bu)_2]$. This minor product was finally assigned as **1b** after **2b** was prepared by an independent synthesis.



gauche-$[W_2(R,R)\text{-(bino)}_2(O\textit{t}Bu)_2]$ (**2b**) was the only observable product of the reaction of $[W_2(O\textit{t}Bu)_6]$ with two equivalents of optically pure (*R*)-H_2bino. The resonance associated with the *t*BuO ligands at $\delta = 1.0$ (Fig. 1 below) is consistent with a single *gauche* interaction between the *t*BuO and naphtholato ligands. The relative instability of $[W_2(R,R)\text{-(bino)}_2(O\textit{t}Bu)_2]$ provides some circumstantial evidence in support of the *gauche* orientation of the *t*BuO ligands. The molecule decomposes in solution at 20 °C with a half-life of thirty minutes, producing isobutene, *tert*-butanol, and significant quantities of the unidentified minor product **3**, originally observed in the synthesis of **1a**. The *gauche* arrangement of the *t*BuO ligands in **2b** may provide an optimal geometry for intramolecular proton transfer in the rearrangement of the two *t*BuO ligands to yield isobutene and *tert*-butanol.

The highly symmetrical "by-product" noted in each of the reactions above is the yellow "homostereoleptic"[9] tris(binaphtholato) complex, $[W_2(S^*,S^*,S^*)\text{-(bino)}_3]$ (**3**). An enantiomerically pure form can be produced in improved yields by reaction of $[W_2(O\textit{t}Bu)_6]$ with three equivalents of (*R*)-H_2 bino. A related product from the reaction of *rac*-H_2-bino and $[W_2(O\textit{t}Bu)_6]$ provides an uninterpretable ^{1}H NMR spectrum, in which traces of **3** can be identified. The formation of **3** through the decomposition of **2b** implies that facile intermolecular ligand exchange is occurring under the conditions of synthesis of **2b**.

Direct evidence of intermolecular ligand migration was obtained by mixing solutions of (*R*,*R*)-**2b** and (*S*,*S*)-**2b** in the presence of *t*BuOH at 0 °C. After several hours at ambient temperature **1a** was the major identifiable product of the reaction, although trace quantities of **3** were also observed. This study confirms that intermolecular ligand migration can occur under the conditions of $[W_2(\text{bino})_2(O\textit{t}Bu)_2]$ synthesis, and that **1a** is thermodynamically more stable than the corresponding *gauche* complex **2b**. Some amount of **2b** is formed during this synthesis of **1a**, since traces of **3**, a decomposition product of **2b**, are found. Based on the results of this crossover study most of (S^*,S^*)-**2b** formed in the initial exchange process is probably converted to **1a**, suggesting that the production of **1a** from *rac*-H_2bino is a result of thermodynamic control.

While these studies serve to rationalize the evident stability of **1a** over **2b**, they do not account for the observed preference for isomers **1a** and **2b** over their *gauche*-(*R*,*S*) and *anti*-(*S*,*S*) counterparts, **1b** and **2a**. We believe that these latter differences in stability originate in the diastereoisomerism of bino bridges across the W-W bond. Figure 2 emphasizes that a bino unit generates two skew axes: 1) the natural skew axis of the chiral bino ligand, which in the case of an (*S*)-bino ligand is always δ configured and 2) the skew axis defined by the chelating O ··· O unit across the W-W axis, which can be either λ or δ. It is clear that an (*S*)-bino

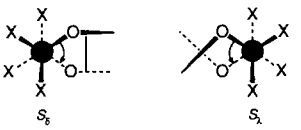


Fig. 2. Structures of diastereomeric chelate complexes of the $[W_2X_4]$ template and the bridging (*S*)-binaphtholato ligand.

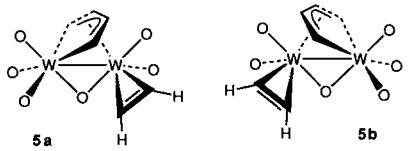
ligand produces significantly different linkage geometries, depending on whether its chelating O ··· O unit bridges the ditungsten unit to give a product with a λ or δ configuration. Attaching the stereochemistry of this structural element as a subscript on the stereochemical description of the chiral bino unit unequivocally specifies the bonding mode; consequently, an (*S*)-bino unit can be linked S_δ or S_λ to the W_2 unit, leading to diastereomeric complexes. Because we have observed a nonstatistical distribution of these bonding modes in the ditungsten products, it seems that there are significant differences in the stabilities of the two bridging structures. The degree of selectivity observed in these exchange processes probably stems from the relative rigidity of the bino ligand, reinforced by the π-donor effects of the binaphtholato ligands. In confirmation of this hypothesis, recent work on bridge formation across the Mo-Mo bond in dinuclear molybdenum complexes containing more flexible chiral diphosphine ligands reports substantially lower diastereoselectivity[10] (approximately 3:1 in the solid state and 2:1 in solution).[10a]

One of the characteristic reactions of the $[W_2(OR)_6]$ template is the formation of stable organometallic complexes derived from the addition of one, two, or three equivalents of acetylene to the ditungsten unit.[11] Reactions between three equivalents of acetylene and **1a** immediately generate a tris(acetylene) complex **4**.

$[W_2(R,S)\text{-(bino)}_2(O\textit{t}Bu)_2(\mu_2\text{-}C_4H_4)(\eta\text{-}C_2H_2)]$ **4**

Although the product has thus far defied attempts at crystallization, features common to other(tris)acetylene ditungsten complexes have been identified by ^{1}H and ^{13}C NMR spectroscopy, including resonances characteristic of the μ_2-C_4H_4 and η^2-C_2H_2 units. The spectroscopic studies also indicate that two diastereomers of the (tris)acetylene complex are formed in a ratio of 2:1. The diastereomers are distinguished by significantly different chemical shifts (at -50 °C)

for the static η^2-C_2H_2 unit ($\delta = 11.59$ and 10.96 for the major product, and 11.32 and 10.76 for the minor diastereomer). The formation of the diastereoisomeric complexes of **4** is readily explained by the presence of chelating chiral ligands in the coordination spheres of the tungsten centers. This leads to the further differentiation of the ordinarily enantiomeric (tris)acetylene skeletons of **5a** and **5b**. These



5a **5b**

acetylene complexes are, to the best of our knowledge, the first examples of diastereomeric derivatives generated on the synthetically versatile $[W_2(OR)_6]$ template.

Experimental Procedure

1a: In a Schlenk flask (25 mL) $[W_2(OtBu)_6]$ (0.70 g, 0.87 mmol) was dissolved in toluene (12 mL), and then racemic binaphthol (0.50 g, 1.7 mmol) was slowly added. The solution was stirred for 12 h; a yellow powder precipitated after about 45 min. The solution was removed by syringe and the yellow powder was washed with cold toluene then dried (0.47 g, 50% yield). ^{1}H NMR (C_6D_6, 20 °C) δ = 7.91 (d, 4H, J = 9.9 Hz), 7.81 (d, 4H, J = 9.6 Hz), 7.71 (d, 4H, J = 7.8 Hz), 7.31 (d, 4H, J = 7.2 Hz), 7.08 (t, 4H, J = 5.7 Hz), 6.91 (t, 4H, J = 6.3 Hz; bino), 0.13 (s, 18H; OtBu). ^{13}C NMR (C_6D_6, 20 °C) δ = 168.2 (C(2,2); bino), 135.2, 131.0, 129.6, 126.9, 126.3, 124.4, 122.0, 121.0, 110.4 (bino), 76.1 ($OC(CH_3)_3$), 31.8 ($OC(CH_3)_3$). Correct C, H analysis.

2b: In a Schlenk flask (25 mL), $[W_2(OtBu)_6]$ (0.70 g, 0.87 mmol) was dissolved in toluene (12 mL), and then (*R*)-binaphthol (0.50 g, 1.7 mmol) was added. The solution was stirred for 16 h and the solvent was removed in vacuo. Redissolving the solid in toluene followed by reduction of the solution volume and refrigeration at −20 °C for 12 h provided a yellow powder (0.51 g, 54% yield). ^{1}H NMR (C_6D_6, 20 °C) δ = 7.94 (d, 2H, J = 7.8 Hz), 7.82 (d, 2H, J = 8.8 Hz), 7.71 (d, 2H, J = 7.9 Hz), 7.49 (d, 2H, J = 8.8 Hz), 7.34 (d, 2H, J = 8.3 Hz), 7.24 (t, 2H, J = 7.5 Hz), 7.15–6.96 (m, 8H), 6.83 (t, 2H, J = 6.6 Hz), 6.69 (d, 2H, J = 8.8 Hz; bino), 0.97 (s, 18H, OtBu). ^{13}C NMR ($C_6D_5CD_3$, 20 °C) δ = 167.8, 167.2 (C(2,2); bino), 135.6, 135.4, 131.0, 130.6, 129.9, 128.2, 127.1, 126.9, 126.8, 126.7, 124.5, 123.4, 122.3, 121.5, 121.4, 121.0 (bino), 80.4 ($OC(CH_3)_3$), 32.5 ($OC(CH_3)_3$). Correct C,H analysis.

3: In a Schlenk flask (100 mL), $[W_2(OtBu)_6]$ (0.374 g, 0.463 mmol) was dissolved in toluene (20 mL), and then (*R*)-binaphthol (0.400 g, 1.397 mmol) was added. The solution was stirred for 20 h and the solvent was removed in vacuo. The residue was taken up in toluene and filtered through a glass frit. The toluene was removed in vacuo and the resulting brown powder was washed with hexane then dried in vacuo. Dichloromethane was added to precipitate a yellow powder (18% yield). ^{1}H NMR (C_6D_6, 20 °C) δ = 7.85, 7.08 (d, 1H, J = 8.3 Hz; H(3,4)), 7.56, 6.18 (d, 1H, J = 8.7 Hz; H(8,5)), 7.21, 6.90 (t, 1H, J = 9.0 Hz; H(6,7)). ^{13}C NMR (C_6D_6, 20 °C), δ = 166.4 (C(2)), 135.4 (C(1)), 130.9 (C(10)), 128.0, 124.8 (C(7,8)), 127.1, 127.0 (C(4,6)), 121.4 (C(9)), 121.3 (C(5)). Correct C,H analysis.

4: $[W_2(bino)_2(OtBu)_2]$ (0.40 g, 0.50 mmol) was dissolved toluene (20 mL) in a small Schlenk flask (50 mL). After the flask was cooled to 77 K, excess acetylene (6 equiv) was condensed onto the frozen solution. The reaction mixture was warmed to room temperature and stirred for 30 min before the solvent was removed in vacuo. The residue was redissolved in hexane, filtered to remove polyacetylene, and the volume of the solution was reduced. During refrigeration at −20 °C, a brown powder was deposited. The ^{1}H NMR spectrum of the powder, which proved to be representative of the bulk sample, was consistent with the presence of two diastereoisomers of **4** in a ratio of approximately 2:1. ^{1}H NMR ($C_6D_5CD_3$, −50 °C), major diastereomer: δ = 11.53, 10.94 (s, 1H; η^2-C_2H_2), 9.82, 9.24 (d, 1H, μ_2-W-CH=CH-CH=CH, J(HH) = 5.0 Hz), 0.98, 0.53 (s, 9H, OtBu); minor diastereomer: δ = 11.30, 10.68 (s, 1H; η^2-C_2H_2), 10.21, 8.09 (d, 1H; W-CH=CH-CH=CH), J(HH) = 5.0 Hz), 1.04, 0.96 (s, 9H; OtBu). ^{13}C NMR ($C_6D_5CD_3$, −50 °C), major diastereomer: δ = 193.5, 179.1 (η^2-C_2H_2), 200.6, 188.0 (W-CH=CH-CH=CH), 87.3, 86.9 ($OC(CH_3)_3$), 30.5, 29.5 ($OC(CH_3)_3$); minor diastereomer: δ = 194.8, 189.5 (η^2-C_2H_2), 198.0, 173.9 (W-CH=CH-CH=CH), 86.8, 85.8 ($OC(CH_3)_3$), 30.6, 29.7 ($OC(CH_3)_3$).

Formation of a Toxic Dimerization Product of 3,4-Dichloroaniline by Lignin Peroxidase from *Phanerochaete chrysosporium***

By *Dietmar Helmut Pieper, Reinhard Winkler,* and *Heinrich Sandermann, Jr.**

Six years ago it was discovered that the white rot fungus, *Phanerochaete chrysosporium*, specialized in breaking down lignin, has the unusual capability to metabolize free chlorinated hydrocarbons and free as well as lignin-bound chlorinated anilines, degrading substantial amounts completely to CO_2.[1] Since then a number of research groups have been working on the possible application of this fungus in biological decontaminations.[2] The extracellular lignin peroxidases (ligninase complex) are often assumed to participate in the degradation of foreign substances. Experimental support for this hypothesis has been found in studies with benzo[*a*]pyrene and chlorinated phenols,[3] but not in the case of the mineralization of DDT (1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane) or chlorinated anilines.[4] To complement our earlier in vivo experiments[1b,5] we have now tested the in vitro conversion of 3,4-dichloroaniline (**1**) by lignin peroxidase obtained from *P. chrysosporium*. A major product formed was identified as 3,4,3',4'-tetrachloroazobenzene (**3**), a substance comparable to 2,3,7,8-tetrachloro-*p*-dibenzodioxin in structure and toxicity.[6]

A lignin peroxidase preparation was obtained from the supernatant of *P. chrysosporium* mycelium grown under carbon-limited conditions.[7] The enzyme was purified by ultrafiltration and repeated washings with tartrate buffer in order

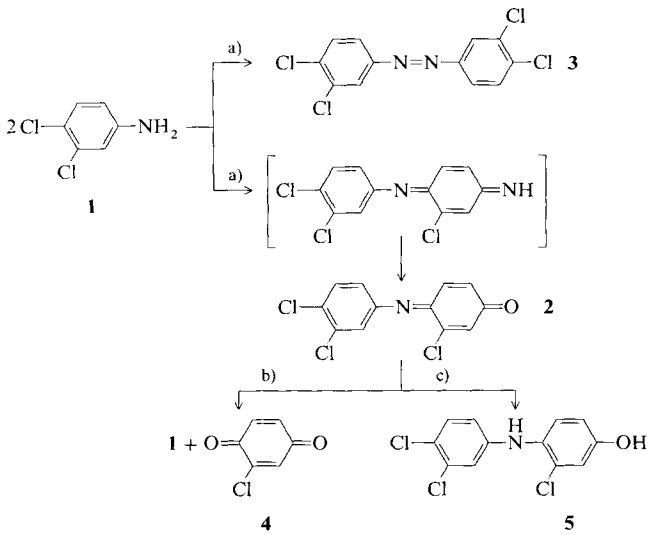
to remove remaining components of the culture medium.[8] The conversion rate of **1** by this crude enzyme in tartrate buffer (50 mM, pH 3.2) was about 30% of that of the standard substrate veratryl alcohol.[8]



Scheme 1. Conversion of 3,4-dichloroaniline **1** to the toxic 3,4,3',4'-tetrachloroazobenzene **3** and 2,3',4'-trichloro-4-hydroxydiphenylamine **5**. a) Ligninase, b) acid catalysis, c) ascorbic acid.

After complete conversion of **1** (1 mL of a 100 mM solution incubated 20 min with 0.02 U lignin peroxidase) the product mixture was analyzed by reversed phase HPLC on an analytical column using an elution gradient. The samples were applied directly to the column in order to prevent artifacts.[9] The analysis showed that a number of nonpolar products were formed (net retention volume of **1**: 2.9 mL; net retention volume of the products > 6 mL). This indicated the occurrence of oligomerization reactions. In order to quantify the reaction by means of radioactivity detection, [^{14}C]-3,4-dichloroaniline was employed as substrate. The subsequent HPLC eluates could account for 95% of the initial radioactivity; 60% was present in the main product **2** (net retention volume 7.6 mL) and 15% in product **3** (net retention volume 14.3 mL). No polar products were formed, in contrast to the results of in vitro experiments with benzo[*a*]pyrene and chlorophenols.[3]

The conversion of **1** on a preparative scale (1 mmol) was performed in phosphate buffer (500 mM, pH 3.2) despite its low buffer capacity. The tartrate buffer system was not used in order to avoid overloading the HPLC column by application of the extractable buffer. Thus 1 L of a 1 mM solution of **1** was allowed to react with lignin peroxidase corresponding to a total activity of 18 U (relative to the conversion of veratryl alcohol). The reaction was initiated by the addition of H_2O_2 in concentration increments of 40 μM. After complete consumption of **1** the reaction mixture was extracted with ethyl acetate. The extract was concentrated, taken up in acetonitrile, and passed through a preparative HPLC column[10] for the separation and purification of products **2** and **3**. By means of UV/VIS and ^{1}H NMR spectroscopy **3** was unequivocally identified as 3,4,3',4'-tetrachloroazobenzene.[11] Product **2** was relatively unstable; acid-catalyzed cleavage (addition of HCl to a final concentration of 0.5 M) led to **1** and 2-chloro-*p*-benzoquinone **4**.

The addition of ascorbic acid to **2** caused a quantitative transformation to **5** (net retention volume under analytical HPLC conditions[9] 6.6 min). This transformation also occurred as a spontaneous reaction. The mass spectrum and the high resolution mass spectrum of **5**, purified by preparative HPLC, verified the molecular formula $C_{12}H_8OCl_3N$.[12] The ^{1}H NMR spectrum indicates that **5** is 2,3',4'-trichloro-4-hydroxydiphenylamine, a compound not previously described in the literature.[13] Its toxicological properties are not known.

The reaction steps leading to the formation of **5** may be deduced from related studies in the literature. The radicals formed from **1** by lignin peroxidase should react by an *N-para*-coupling to *N*-(3',4'-dichlorophenyl)-*p*-2-chlorobenzoquinone diimine. An analogous dimer has been described as a metabolite in the peroxidase-catalyzed conversion of 4-chloroaniline.[14] In this case the corresponding quinone imine was formed by spontaneous hydrolysis. The classification of compound **2** as a quinone monoimine is chemically supported by its spontaneous dissociation to **1** and **4** under acidic conditions.[15] Consistent with this, the reduction of **2** by ascorbic acid led to the formation of **5** (Scheme 1).

The present results show that the enzymatic activity of lignin peroxidase towards **1** leads to its conversion to the highly toxic compound **3** in good yield. Yields between 10 and 15% were obtained in experiments conducted at various pH values (2.5–4.5), with different concentrations of **1** (10–200 μM), and with three buffer systems (tartrate, dimethylsuccinate, and citrate buffers). The production of **3** from **1** with peroxidases was already detected qualitatively.[16] In addition the formation of chlorinated dibenzodioxins and dibenzofurans from chlorophenyls was catalyzed by peroxidases in low yield.[17]

In earlier investigations[1b,5] the in vivo production of **3** from **1** could not be detected under the culture conditions used. It has now been proved that this was a result of rapid conjugate formation, which removed **1** from lignin peroxidase attack. The simultaneous existence of competing toxifying and detoxifying reactions requires an exact control of the reaction conditions for biotechnological applications of *P. chrysosporium*.

First Example of a Chlorophin from an Unexpected Oxidative Ring-Opening of an (Octadehydrocorrinato)nickel(II) Salt **

By *Chi K. Chang,* Weishih Wu, Shuenn-Shing Chern,* and *Shie-Ming Peng**

The presence of *vic*-dihydroxychlorin or its lactone as the heme prosthetic group in d-type cytochromes has recently been elucidated.[1] The diol structure raises the possibility that these green heme compounds might be derived biosynthetically from epoxidation of the porphyrin β–β double bond. In pursuit of such an epoxychlorin, we examined the green compound **1** first reported by Johnson and co-workers,[2] who obtained it from air oxidation of (1,19-dimethyloctadehydrocorrinato)nickel(II) chloride (**2**). Until very recently[3] this was the only known example of epoxychlorin. We discovered that structure **1** is nonexistent; this compound is in fact a totally unexpected and unprecedented tetraaza macrocycle consisting of only three pyrrole units with the fourth pyrrole torn apart and reassembled into an exocyclic furan ring. This structure is so unusual that it represents a new member in the porphyrin family.

Following Johnson's procedure,[2] **2** was stirred in *o*-dichlorobenzene at 150–160 °C in air for about 20 minutes to give a green pigment as the major product (34%) along with a nickel porphyrin **3** (15%). Although the mass spectrum (*m/z* 536) of the green product[4] showed the addition of one oxygen atom to **2**, and its absorption spectrum resembled those of metallochlorins, the chemical reactivities were incompatible with the suggested epoxide structure. For example, it failed to react with methyllithium and could not be reduced by $LiAlH_4$. Since NMR analyses were unable to determine where the oxygen atom had attached, we turned to X-ray diffraction. Crystallization of this compound from a series of solvent systems almost always gave twinned crystals unsuitable for X-ray study. A single crystal was finally obtained from diethyl ether. From its structure (Fig. 1[5]) one can readily appreciate what complicated rearrangements have taken place: The corrin frame has expanded and one angular methyl group has become a methine bridge. The pyrrole α–β bond adjacent to the other angular methyl group was broken, and the vinylic appendage of the broken pyrrole turned through 180° to reattach itself to the macrocycle via an oxide. The resultant structure is a fully conjugat-

ed 18 π chlorin-like skeleton with only three pyrrolic components. In order to highlight the relationship with the parent chlorin we propose the name "furochlorophin" for the new compound, since "chlorophin" has been suggested[6] for the hitherto unknown tripyrryltetraaza macrocycle. The crystal structure showed normal carbon–carbon and metal–nitrogen bond lengths typical of nickel porphyrinoids.[7] The nickel ion is essentially coplanar with the four nitrogens but the molecule deviates noticeably from planarity, for example, by 0.86 Å at C15, 0.57 Å at C16 and particularly for the furan ring by −0.74 Å at C17, −1.58 Å at C18, −1.93 Å at C19, and −1.38 Å at O. The contracted core of Ni porphyrins caused by short N–Ni bonds often results in a warped ring, but nonplanarity in this molecule is additionally attributed to the repulsion between C29 and C30 methyl groups.

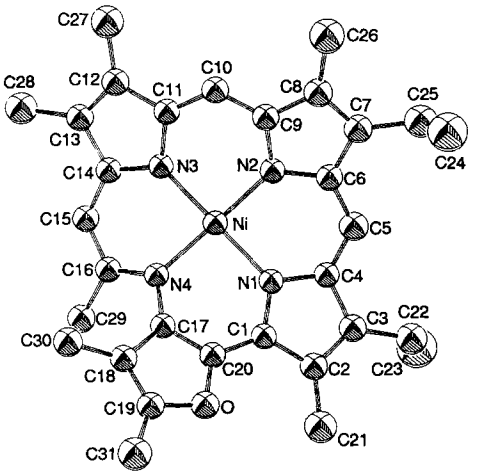

Fig. 1. Structure of **1a** in the crystal. Selected bond distances [Å]: Ni-N(1) 1.945, Ni-N(2) 1.902, Ni-N(3) 1.901, Ni-N(4) 1.908, N(1)-C(1) 1.355, N(4)-C(17) 1.377, N(4)-C(16) 1.372, C(17)-C(20) 1.372, C(17)-C(18) 1.432, C(20)-O 1.377, C(19)-O 1.381.

The initial step proposed for the thermolysis of **2**[2] is a proton abstraction from one of the angular methyl groups by the anion to give the ring fission product **5**, which then cyclizes to **6**. The oxidation of **6** could give rise to porphyrin **3** and **4**, depending on the nature of the original anion. In the present case the fission of the pyrrole α–β bond competes favorably with the cleavage of the angular methyl group. As often the case, the reaction mechanism associated with air oxidation is difficult to establish. No concrete mechanism can be offered at this time for the formation of the furan ring. Possibly an oxophlorin-like intermediate is formed first at C20, as this *meso* position is particularly susceptible to oxidation.[8]

Treatment of **1a** with concentrated sulfuric acid yielded two metal-free derivatives. As deduced by mass spectra and NMR, the major component (60% yield) is the free base furochlorophin (**1b**).[9] In the minor component (20%) the furan ring has opened with the addition of H_2O (most likely structure **7** or its tautomers).[10] The structure of furochlorophin has been confirmed by X-ray diffraction (Fig. 2).[11] The macrocycle is visibly more planar than the Ni complex due to the absence of the short-bond doming effect; the core size of **1b** is also enlarged. This new macrocyclic ligand is easily converted into its Cu^{II}, Zn^{II}, as well as back to the Ni^{II} complex under mild conditions (metal acetate in $CHCl_3$/MeOH). The UV/VIS spectrum of the free base is shown in Figure 3. While the overall features are chlorin-like, there are two notable differences. First, the

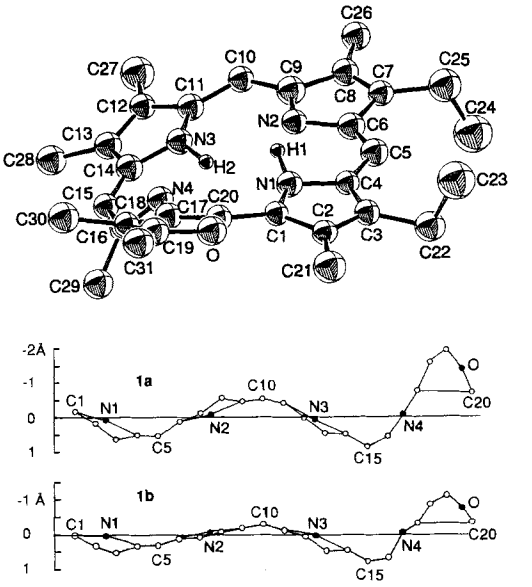

Fig. 2. Structure of **1b** in the crystal. The deviation of the core atoms of **1a** and **1b** from the nitrogen plane is shown by the cylindrical projection plots. The horizontal axis is not to scale.

Soret band as well as the long-wavelength band of **1b** are significantly red shifted (22 nm and 55 nm, respectively, from those of a typical chlorin). Large bathochromic shifts

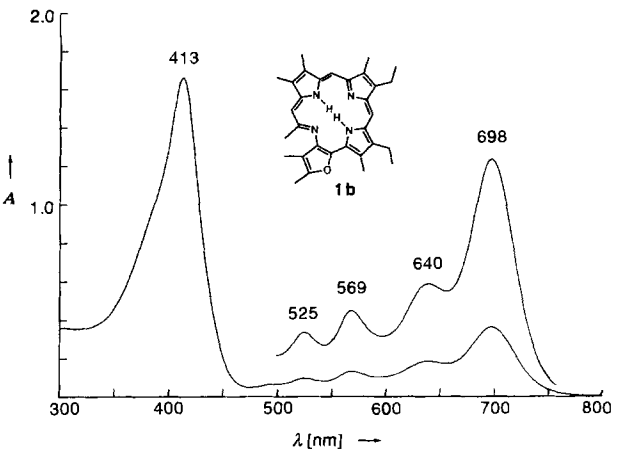

Fig. 3. UV/VIS spectrum of free base **1b** in CH_2Cl_2. A = absorbance.

are also observed in the spectra of metal complexes **1a**, **1c**, and **1d** (Table 1). Second, the extinction coefficients of this series of compounds are relatively small (only about 1/3 of those of corresponding chlorins). The bathochromic shift is probably brought about by an extension of the conjugation by the furan ring. The diminishing HOMO–LUMO gap is

Table 1. UV/VIS data (CH_2Cl_2) for furochlorophin and its metal complexes.

Compound	λ max (ε) [nm ($M^{-1}cm^{-1}$)]				
1b (M = 2H)	413(60700)	526(4900)	569(5800)	641(7200)	699(13000)
1a (M = Ni)	422(41600)	523(3800)	580(4200)		685(18200)
1c (M = Cu)	414(37200) 433(38700)	522(4600)			682(11400)
1d (M = Zn)	440(50300)	513(4500)	583(2800)	638(6300)	683(11800)

also reflected in redox potentials. The furochlorophin **1b** oxidizes to its π cation radical at 0.47 V and reduces at -1.25 V to the anion radical (determined by cyclic voltammetry, versus Ag/AgCl, in CH_2Cl_2). In comparison with etiochlorin I,[12] **1b** is easier to oxidize as well as to reduce by about 180 mV. This smaller redox span correlates well with the observed first absorption band shift. Although the absorption bands of the furochlorophin derivatives have lower extinction coefficients, their bandwidths are broader than those found in chlorins; thus the difference in total oscillator strength between the two systems is less drastic. The decrease in absorption extinction coefficient may be attributable to the reduced rigidity of a macrocycle missing some of the peripheral carbons. Previously Flitsch reported the synthesis of "isobacteriophin", which has two pyrrolic β–β bonds removed; that chromophore also exhibits reduced absorption intensity as compared to isobacteriochlorins.[13]

To our knowledge **1a**–**1d** are the first porphyrinoids that possess a chlorophin core structure. A previous attempt to prepare such compound was not successful.[14] The inherent simplicity of this serendipitous synthesis not only enriches the chemistry of corrinoids[15] but may have potential applications in the emerging photodynamic cancer therapy because of the desirable long-wavelength absorption characteristics of these pigments.

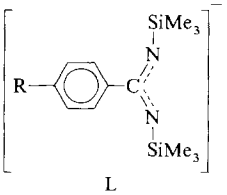
The Synthesis and Structure of an Unusual Uranium Pentachloride Derivative**

By *Michael Wedler, Mathias Noltemeyer,* and *Frank T. Edelmann**

Dedicated to Professor Oskar Glemser on the occasion of his 80th birthday

Uranium pentachloride $(UCl_5)_2$ is a highly reactive compound which is reduced even by aliphatic hydrocarbons to uranium(IV) complexes in a vigorous reaction.[1,2] A selective exchange of one or more chlorine atoms has not yet been possible. We report here the unexpected formation of a uranium pentachloride derivative as well as its structural characterization.

According to investigations by Dehnicke et al.,[3] fully silylated benzamidines $RC_6H_4C(=NSiMe_3)N(SiMe_3)_2$ react with various metal halides with cleavage of $SiMe_3X$ (X = halide) to give metal complexes with benzamidinato ligands L. The reaction of benzamides L-$SiMe_3$ with UCl_4



L

L^1, R = H
L^2, R = Me
L^3, R = OMe
L^4, R = CF_3
L^5, R = Ph

provides the green bis(benzamidinato)dichlorouranium(IV) complexes $[L_2UCl_2]$, which we have previously described.[4,5] In addition, well-formed black single crystals were isolated from the reaction of $MeC_6H_4C(=NSiMe_3)N(SiMe_3)_2$ with UCl_4. This side product apparently arose from the unintentional introduction of air to the reaction mixture. This black compound could be obtained cleanly and reproduceably by controlled oxidation of the reaction

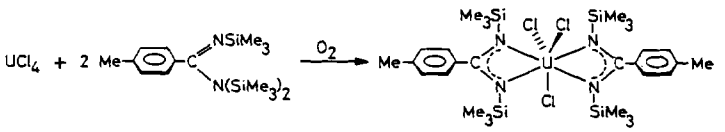
mixture with dry air. According to the X-ray crystallographic data, this compound is $[L^2_2UCl_3]$ **1**, a stable substitution product of uranium pentachloride. The unexpected formation of **1** can be explained only qualitatively.



1

The driving force of the reaction may be the formation of hexamethyldisiloxane. The yield of **1** is about 11% and is limited by the heterogeneity of the reaction, which is conducted as a suspension in hexane. The hexane-insoluble portion consists of a mixture of $[L^2_2UCl_2]$ and $[L^2UCl_3(THF)]$ (^{1}H NMR). According to the IR spectroscopic measurements, further oxidation to a benzamidinatodioxouranium(VI) complex $[L^2_2UO_2]$ does not occur. Only oxidation with molecular oxygen can provide uranium(V) complex **1**. When $AgAsF_6$ is used as oxidant only UF_4 results. The synthesis of **1** from $[L^2_2UCl_2]$ and Cl_2 appears rational on first glance, but is not possible due to the labile N–Si bonds in the ligand system, resulting in the formation of $SiMe_3Cl$.

The reactivity of uranium pentachloride is decreased dramatically by the introduction of the bulky benzamidinato chelating ligands. Complex **1** is noticeably sensitive to moisture, but can be dissolved without decomposition in organic solvents like hexane, toluene, and THF. In dry air **1** is not prone to further oxidation. In the EI-mass spectrum the peak corresponding to the molecular ion appears with low intensity. The coordination geometry of the formally seven-coordinate uranium atom can be described as distorted pentagonal-bipyramidal (Fig. 1.). The U–Cl distances of 252.7(4)

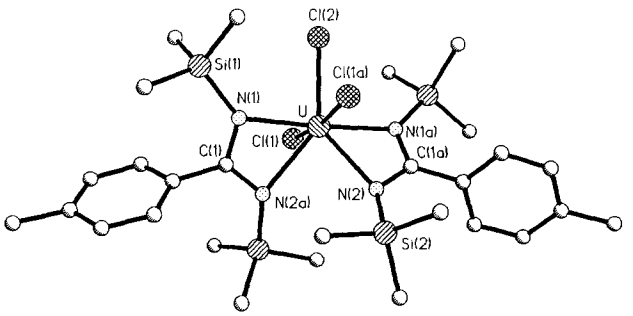


Fig. 1. Structure of **1** in the crystal [6, 7]. Selected bond lengths [pm] and angles [°]: U-Cl(1) 256.8(5), U-Cl(2) 252.7(5), U-N(1) 226.5(8), U-N(2) 237.2(5), C(1)-N(2) 132.3(11), C(1)-N(2a) 131.9(11); N(1)-U-N(2a) 57.5(2), N(1)-U-N(1a) 176.4(3), N(1)-C(1)-N(2a) 115.3(6), Cl(1)-U-Cl(1a) 170.7(2).

and 256.8(5) pm are significantly shorter than that of the benzamidinatouranium(IV) complex $[L^1_3UCl]$ (266.0(9) pm[5]). The same is true for the U–N distances of **1** (226.5(8) and 237.2(5) pm) compared to those of $[L^1_3UCl]$ (241.3(5) and 244.9(19) pm). Two almost linear axes in the molecule are quite noticeable: The C1(1)-U-Cl(1a) and N(1)-U-N(1a) units form angles of 170.7(2) and 176.4(3)°.

Finally we would like to point out an interesting parallel to the organometallic chemistry of uranium. According to our investigations, the steric demands of *N*-silylated benzamidinato ligands L are about the same as those of cyclopentadienyl ligands. Thus the benzamidinato complexes $[L_2UCl_2]$ and $[L_3UCl]$[4,5] correspond to the cyclopentadienyl complexes $[Cp^*_2UCl_2]$ ($Cp^* = \eta^5$-C_5Me_5)[8] and $[Cp_3UCl]$.[9] A Cp or Cp* complex analogous to **1** is not known. The preparation of organometallic complexes of uranium in high oxidation states, for example $Cp^*_2UCl_3$ or $Cp^*_2UO_2$, remains a synthetic goal. The unexpected formation **1** could point the way in that direction.

Experimental Procedure

UCl_4[10] (1.00 g, 2.6 mmol) and $MeC_6H_4C(=NSiMe_3)N(SiMe_3)$[11] (1.85 g, 5.3 mmol) in THF (80 mL) was stirred for 24 h at room temperature under N_2. After the solvent was removed the green precipitate (mainly $[L^2_2UCl_2]$[5]) was suspended in hexane (100 mL). A $CaCl_2$ drying tube was attached to the flask and the reaction mixture was allowed to stir at room temperature for another 5 d, during which time it turned black. The reaction mixture was filtered through a thin layer of Celite and the volume of the filtrate was reduced to about 20 mL. Cooling to −25° provided black crystals (0.25 g, 11%). M.p. = 120° (decomp); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1608m, 1242vs ($SiMe_3$), 1180m, 1155m, 975vs, 841vs ($SiMe_3$), 759s, 710s, 641m, 628m; MS: *m/z* 897 (M^+, 9%), 862 (M^+ − Cl, 2%), 827 (M^+ − 2Cl, 100%), 812 (M^+ − 2Cl − CH_3, 51%); ^{1}H NMR (80 MHz, C_6D_6, 32°): δ = 6.72 (m, 8H, C_6H_4), 1.75 (s, 6H, Me), 0.08 (s, 36H, $SiMe_3$); Correct C,H,N analyses.

The Photochemistry of *N*-Phthaloyl α-Amino Acid Esters: A New Approach to β,γ-Unsaturated α-Amino Acids and Dihydrobenzazepinediones**

By *Axel G. Griesbeck** and *Harald Mauder*

N-Substituted phthalimides have occupied an important place in synthetic organic photochemistry for quite some time. By means of hydrogen abstraction from the appropriate positions (γ or δ to the carbonyl group) and cyclization of the resulting 1,4- or 1,5-diradical, heteropolycycles may be

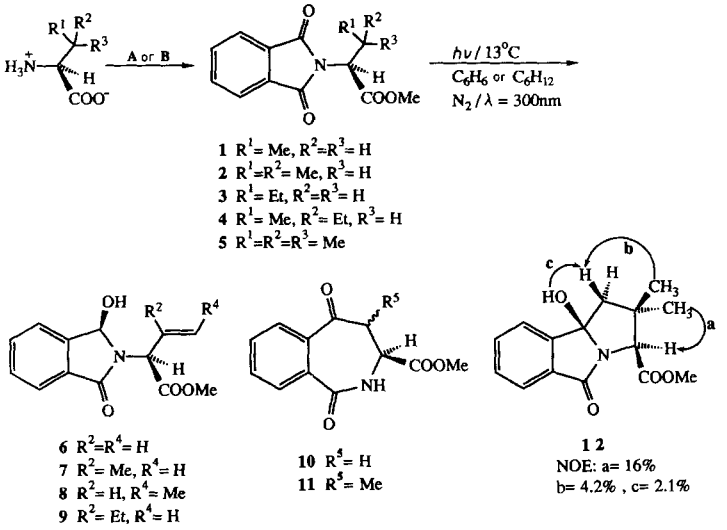
assembled.[1] The irradiation of α-amino acids with a phthaloyl protecting group on the amino function leads exclusively to decarboxylation.[2] We report here the photochemical transformation of the related methyl ester to a palette of highly interesting products.

The *N*-phthaloyl amino acid methyl esters **1**–**5** of (*S*)-2-aminobutanoic acid, (*S*)-valine, (*S*)-norvaline, (2*S*,3*S*)-isoleucine, and (*S*)-*tert*-leucine were synthesized according to a modified literature method[3] by reaction of *N*-ethoxycarbonylphthalimide with the corresponding methyl ester hydrochloride (Scheme 1, Method A). Except for **1** and **5**, these compounds could also be prepared by esterification of the free *N*-phthaloyl amino acid (Method B).



Scheme 1. Synthesis and photochemical reactions of the *N*-phthaloyl α-amino acid methyl esters **1**–**5**. Method A: a) MeOH/HCl, room temperature (RT) (> 98%); b) carboethoxyphthalimide/H_2O/Na_2CO_3 (45–55%). Method B: a) phthalic anhydride, 135° (100%); b) MeOH/HCl, 10° (> 98%).

The irradiation of these compounds in benzene with $\lambda = 300$ nm (Rayonet photoreactor, RPR 3000 Å lamps, 13°, 0.02–0.1 M solutions, 24–75 h until complete conversion of starting material) leads to three types of products: a) photoisomerization products **6**–**9**, b) dihydrobenzazepinedione esters **10** and **11**, and c) the pyrrolizidinone derivative **12**. The photoreaction of compounds **2** and **5** proceeds with high chemoselectivity; the isomerization product **7** (85% yield) and the benzannelated pyrrolizidinone **12** (90% yield) are the only respective detectable products. Both compounds are formed diasteromerically pure (^{1}H and ^{13}C NMR, Scheme 1).

Nuclear Overhauser Enhancement (NOE) measurements of **12** prove that the methoxycarbonyl group is *cis* to the hydroxy group. Saturation of the H atom α to the ester led to the unequivocal assignment of the neighboring diastereotopic methyl groups and H atoms in the methylene group. Analogous experiments showed the olefinic product **7** to have a related configuration, that is the new chiral center arises from two H-transfers to the phthalimidocarbonyl group with the second occurring on the *Si* side (*lk* topicity). In the photoreaction of **5** the transfer of a second hydrogen atom is not possible, thus the radical centers recombine.

A more complex spectrum of products results from the irradiation of *N*-phthaloyl methyl esters **1**, **3**, and **4**. In all cases the products of isomerization as well as ring expansion are generated. All the new compounds could be separated by column chromatography. The product distribution is summarized in Table 1; the physical and spectroscopic data are listed in Table 2.

Table 1. Products of the photoreactions of *N*-phthaloyl α-amino acid methyl esters **1**–**4** [a,b].

Substrate	Product type (a)	Product type (b)	Total yield [%]	Irradiation time [h]
1	**6** (25%)[c]	**11** (75%)[d]	80	75

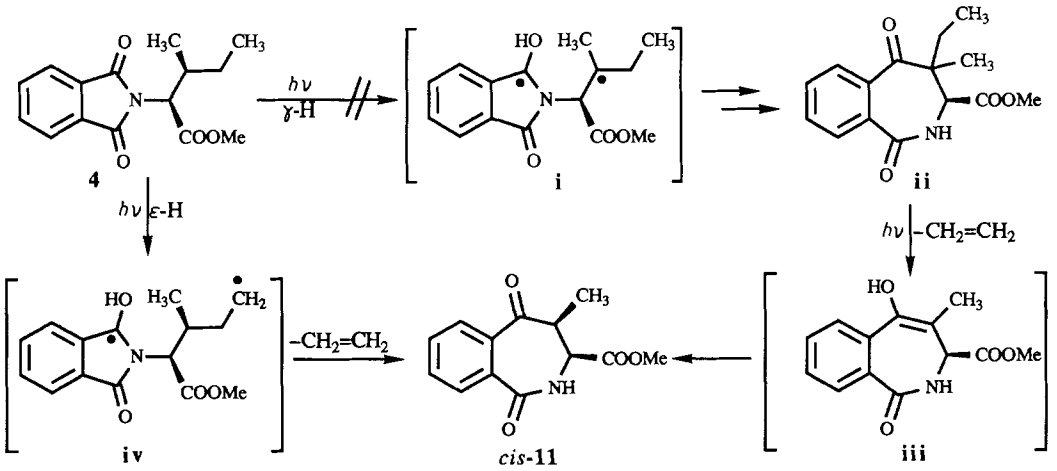
[a] All new compounds provided correct elemental analyses.

The relative configuration of **11** (from the photoreaction of **1**) could be determined by comparison of $J_{H,H}$ coupling constants. The main diastereomer of the dihydrobenzazepinedione, isolated in 50% yield, was identified as the *trans* diastereomer, *trans*-**11** ($^3J_{H,H}$ = 8.5 Hz). *cis*-**11** ($^3J_{H,H}$ = 2.7 Hz) and a mixture of **6a**/**6b** were both collected in 25% yield (Table 1). The formation of this type of product can be explained by the following reaction sequence: γ-hydrogen abstraction (the position is relative to the phthalimidocarbonyl group), cyclization of the 1,4-diradical **i** to the N/O-hemiacetal with a four-membered ring, and ring opening to the benzannelated seven-membered ring **ii** (Scheme 2). This sequence was already postulated by Kanoaka et al. for the formation of the related achiral *N*-alkylphthalimides.[4] In this context it is worth mentioning that amino acid derivatives without H atoms in the δ or ε positions, for example *N*-phthaloyl derivatives of alanine or phenylalanine, do not react even after 100 h irradiation. If the dihydrobenzazepinedione intermediate **ii** in the previous mechanism has an ethyl substitutuent α to the keto group, a second Norrish Type II reaction takes place and ethylene is eliminated. (This is illustrated in Scheme 2 for the isoleucine derivative **4**.) The tautomerization to the final product is highly stereoselective, leading to **11** (from **4**); only the product with a *cis* configuration was isolated.

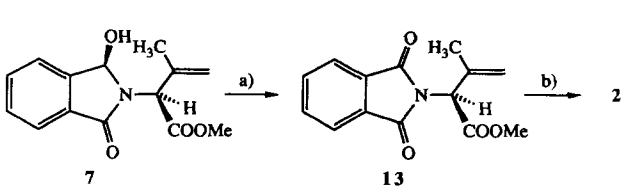


Scheme 2. Formation of *cis*-**11** by photochemical reaction of (2*S*,3*S*)-*N*-phthaloylisoleucine methyl ester **4**.

An alternative to this mechanism is an ε abstraction[5] from **4** and subsequent S_H2 reaction on the 1,6-diradical **iv** (Scheme 2). This would also explain why the ethyl-substituted benzazepinediones **ii** presumed to be intermediates were never observed. This reaction should proceed stereospecifically with configurational conversion, which is also in accord with the relative configuration of product **11**. After irradiation of a 60:40 mixture of the isoleucine derivative **4** and the related *allo*-isoleucine derivative (2*S*,3*S*), 88% of the isomerization product **9** and 12% of a 60:40 mixture of *cis*-**11** and *trans*-**11** were isolated. Analysis of the mass balance indicates that *trans*-**11** arises exclusively from *allo*-**4**. Thus the reaction via a common intermediate like **iii** can be ruled out.

To be certain that epimerization of the α center did not occur during the irradiation of the *N*-phthaloyl amino acid esters, we converted the dehydrogenation product **7** back to **2**. After treatment of **7** with pyridinium chlorochromate (PCC) on alumina[6] for 50–60 h, the *N*-phthaloyl-protected isodehydrovaline methyl ester could be isolated quantitatively. Subsequent hydrogenation with Pd/C provided **2**. Comparison of the optical rotation of **2** to that of the compound from (*S*)-valine indicated a retention of absolute configuration > 95% (Scheme 3). We assume the absolute configuration of the α chirality center is also retained during the irradiation of the other amino acid derivatives.

What is the reason for the remarkably high diastereoselectivity in the formation of products **7**–**9** and **12** from **2**–**5**, a selectivity which was not observed in the photoreaction of the 2-aminobutanoic acid derivative **1**? An analysis of the temperature dependence of the ^{13}C NMR spectrum of compound **5** shows that rotation about the N–C_α single bond has an activation barrier of roughly 12 kcal mol^{-1}. (Two sets of signals are observed in the ^{13}C NMR spectra measured at temperatures below $T_{coal.} = -35\,^{\circ}C$.) The photochemical transformations of *N*-substituted phthalimides proceed via



Scheme 3. Transformation of **7** {$[\alpha]_D$ 6.1 (MeOH, $c = 1.0$)} into **2**: a) pyridinium chlorochromate (PCC) on alumina/CH_2Cl_2 {80%, $[\alpha]_D$ −70.1 (MeOH, $c = 1.0$)}; b) H_2, Pd/C {98%, $[\alpha]_D$ −62.4 (MeOH, $c = 1.5$)}. **2**: $[\alpha]_D$ −66.7 (MeOH, $c = 1.2$)}.

the first excited singlet state.[7] The diradical formed after the abstraction of the first hydrogen atom (in the γ or δ position)[8] in the $^1[n\pi^*]$ excited state of the carbonyl function should therefore be a 1,4- or 1,5-*singlet* biradical. This short-lived intermediate can undergo transfer of the second H atom faster than the rotation about the sterically encumbered N–C_α single bond, thus explaining the high diastereoselectivity in the formation of the second chiral center. The rotational barrier of 2-butanoic acid derivative **1** could not be determined (valine derivative **2** $\Delta G^{\neq}$ ca. 9 kcal mol^{-1}) and accordingly its photoreaction is not stereoselective.

β,γ-Unsaturated α-amino acids are often proposed as enzyme inhibitors[9] (especially isodehydrovaline[10] and vinylglycine[11]). Our synthetic approach to these compounds is much simpler than the previously known procedures and can compete with elegant synthetic routes, for example that reported recently by Duthaler proceeding via *N*-acylthiazolidines.[12]

Stable Intermediates in the Addition and Elimination of $SnBuCl_3$ at Molybdenum Centers by Cleavage or Formation of an Sn–Cl Bond: Crystal Structure of $[Mo(CO)_2(PCy_3)(\mu\text{-}Cl)(\mu\text{-}S_2CPCy_3)(BuSnCl_2)] \cdot CH_2Cl_2$ **

By *Daniel Miguel, Julio A. Pérez-Martinez, Victor Riera,** and *Santiago García-Granda*

We recently reported the preparation of homo-[1,2] and heterodinuclear[3] complexes of Mn and Re containing S_2CPR_3 ligands acting as $\eta^2(S,S')$ and $\eta^3(S,C,S')$ bridges across a metal–metal bond. In a systematic exploration of the coordination properties of the S_2CPR_3 ligands, we focused on the molybdenum complex **1**,[4] attempting to exploit both the facile displacement of the two acetonitrile ligands and the ability of the metal center to coordinate S_2CPR_3 ligands in an $\eta^3(S,C,S')$ pseudoallylic fashion.[5,6] Our goal was to obtain MoSn compounds containing S_2CPR_3 bridges.

$[Mo(CO)_3(SnBuCl_2)(Cl)(NCMe)_2]$ **1**

$[Mo(CO)_2(PR_3)(\mu\text{-}Cl)(\mu\text{-}S_2CPR_3)(SnBuCl_2)]$ **3**

Here we wish to report the reactions leading to compounds of type **3** in which an S_2CPR_3 group acts as an $\eta^3(S,C,S')$ pseudoallylic ligand toward Mo, and as an $\eta^2(S,S')$ chelate toward Sn. To our knowledge compounds of type **3** are the first examples of complexes containing S_2CPR_3 ligands serving as bridges between a transition and main group metal. Both the structural features and the reactions leading to their formation suggest that these complexes can be considered as intermediates in the oxidative addition/reductive elimination of $SnBuCl_3$ at molybdenum centers.

Complex **1** reacts with two mole equivalents of S_2CPR_3 in CH_2Cl_2 at room temperature to give compounds **3a–c** (Scheme 1) which have been characterized by analytical and spectroscopic methods.[7] An X-ray structure determination[8] of a crystal of **3a** (R = *cyclo*-C_6H_{11}, Cy) (Fig. 1) reveals that the molecule can be described as consisting of a $SnBuCl_2$ unit attached to $Mo(CO)_2(PCy_3)$ by a chlorine bridge and an S_2CPCy_3 bridging ligand bonded as an $\eta^2(S,S')$ chelate ligand to Sn and as an $\eta^3(S,C,S')$ pseudoallyl ligand to Mo. The long Mo–Sn distance (3.636(2) Å) precludes the existence of any significant bonding between the two metals. The Mo atom lies in a highly unsymmetrical seven-coordinate environment; the Sn atom is surrounded by six atoms in an octahedral disposition, an unusual coordination for Sn in transition metal–tin complexes.[9] The bridging chlorine atom, Cl(1), is not positioned symmetrically between the two metals but rather much closer to Mo than to Sn. The Mo–Cl(1) distance (2.560(4) Å) is similar to that observed for Mo–Cl (terminal) (2.525(4) Å) in $[Mo(SnCl_2Bu)(CO)_2(Cl)\{P(OMe)_3\}_3]$,[4] while the Sn–Cl(1) distance (2.762(4) Å) is significantly longer than that observed for the Sn–Cl (terminal) bonds (2.407(4) and 2.421(5) Å).

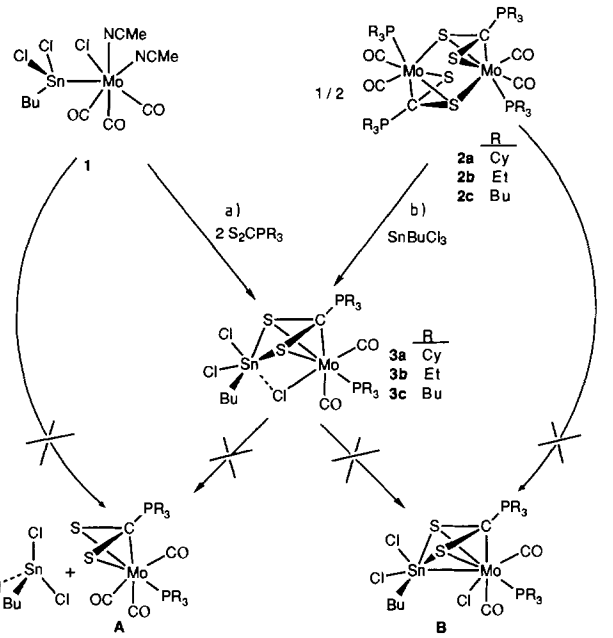

Scheme 1. Synthesis of **3** from **1** or **2**. The reaction of **1** to **A** is the complete reductive elimination of $SnBuCl_3$; that of **2** to **B**, the complete oxidative addition.

This suggests that the Mo–Cl(1) bond is normal and the Sn–Cl(1) bond is weak. A similar bonding relation is found in $[Mo(CO)_3(SnMeCl_2)(bipy)(Cl)]$[10] (bipy = 2,2′-bipyridine), which unlike **3a** contains a Sn–Mo single bond.

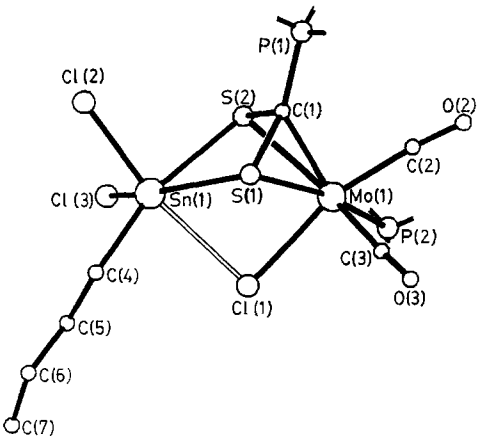

Fig. 1. Structure of **3a** in the crystal. (Hydrogen atoms and cyclohexyl substituents have been omitted for clarity.) Selected bond lengths [Å] and angles [°]: Mo(1)-S(1) 2.496(4), Mo(1)-S(2) 2.579(4), Mo(1)-C(1) 2.16(1), Sn(1)-S(1) 2.720(4), Sn(1)-S(2) 2.538(4), Mo(1)-P(2) 2.562(4), Mo(1)-C(2) 1.93(2), Mo(1)-C(3) 1.95(2), Sn(1)-C(4) 2.13(2); C(2)-Mo(1)-Cl(1) 164.1(5), C(3)-Mo(1)-Cl(1) 96.7(5), C(1)-Mo(1)-Cl(1) 109.7(4), P(2)-Mo(1)-Cl(1) 84.0(1), C(1)-Mo(1)-C(3) 118.2(6), C(1)-Mo(1)-P(2) 136.2(4), S(1)-Mo(1)-Cl(1) 82.5(1), S(1)-Mo(1)-C(2) 110.8(5), S(1)-Mo(1)-P(2) 164.3(1), S(2)-Mo(1)-Cl(1) 83.8(1), S(2)-Mo(1)-C(2) 108.5(5), S(2)-Mo(1)-C(3) 159.1(5), S(2)-Mo(1)-P(2) 100.6(1), C(3)-Mo(1)-P(2) 100.2(5), C(4)-Sn(1)-Cl(1) 87.6(7), C(4)-Sn(1)-Cl(2) 97.6(7), C(4)-Sn(1)-Cl(3) 102.4(6), Cl(2)-Sn(1)-Cl(1) 168.9(2), S(2)-Sn(1)-C(4) 164.1(6), S(1)-Sn(1)-Cl(3) 153.5(1).

Alternatively, the structure of **3a** can be viewed as consisting of a $SnBuCl_3$ group attached to a $Mo(CO)_2(PR_3)(S_2CPR_3)$ fragment similar to that existing in the dinuclear Mo(0) complex **2b** (R = ethyl). As a matter of fact, fresh

$[Mo(CO)_2(PR_3)(S_2CPR_3)]_2$ **2**

solutions of **2** (prepared as reported for **2b** in reference[5]) react with $SnBuCl_3$ in CH_2Cl_2 at room temperature (Reaction b in Scheme 1) to give the heterodinuclear complexes **3** in good yields.

The conversion of **1** to **3** (Reaction a in Scheme 1) involves the total cleavage of the Mo–Sn bond while a weak Sn ··· Cl bond is created; the Mo–Cl bond remains unaltered. Thus the reaction can be considered as an "incomplete" reductive elimination of $SnBuCl_3$ from the coordination sphere of molybdenum. The complete reductive elimination would lead to the formation of $SnBuCl_3$ and the Mo^0 complex **A** as found for the reaction of $[Mo(CO)_3(t\text{Bu-dab})(SnCl_3)(Cl)]$ (tBu-dab = tBuN=CH–CH=NtBu) with an isocyanide CNR′ to give $[Mo(CO)_3(t\text{Bu-dab})(CNR')]$.[11]

On the other hand, the complete oxidative addition of $SnBuCl_3$ to **2** (Reaction b) would give compound **B**. In this reaction one Mo–Sn bond and one Mo–Cl bond are formed while one Sn–Cl bond is cleaved. Instead, we found the reaction product to be complex **3** in which the Sn–Cl bond is relaxed, and one Mo–Cl (but not a Mo–Sn) bond is formed. Compound **3** appears to be, therefore, an intermediate in both the oxidative addition and the reductive elimination of $SnBuCl_3$ at molybdenum(0) centers and more stable than the expected final products **A** and **B**.

Since there is not a direct Mo–Sn bond in **3** and the Mo–Cl ··· Sn bridge is weak, we assume that the two metals are held together by the bridging S_2CPR_3 ligand which precludes the complete reductive elimination of the $SnBuCl_3$ group. We have already discussed the strong interaction between the η^2,η^3-S_2CPR_3 bridges and fragments of dinuclear complexes having a direct metal–metal bond in Mn–Mn and Mn–Re complexes. The metal-metal distances were 2.737(1) Å in $[Mn_2(CO)_6(S_2CPCy_3)]$,[1] 2.830(1) Å in $[MnRe(CO)_6(S_2CPCy_3)]$,[3] and 2.855(1) Å in $[Mn_2(CO)_4(S_2CPCy_3)(dppm)]$ (dppm = bis(diphenylphosphino)methane.[2] In the case of **3a**, the S_2CPR_3 adduct forms a fairly stable bridge between two different metals separated by 3.636(2) Å, showing a remarkable structural flexibility when coordinated in an $\eta^2(S,S')$, $\eta^3(S,C,S')$ fashion. It can be expected, therefore, that these S_2CPR_3 adducts could behave as ligands in other homo- or heterodinuclear systems with or without metal–metal bonds.

Experimental Procedure

Reaction a: To a solution of **1**[4] (0.2 g, 0.37 mmol) in CH_2Cl_2 (20 mL) were added CS_2 (3 mL, excess), and PCy_3 (0.177 g, 0.74 mmol) and the mixture was stirred for 30 min. After evaporation of the solvent in vacuo, the residue was extracted with a mixture of CH_2Cl_2/hexane (1:4). The combined extracts were filtered and concentrated in vacuo to afford **3a** as a dark red microcrystalline solid which was washed with hexane and dried. Yield 54%.

Reaction b: To a stirred solution of $[Mo(CO)_3(C_7H_8)]$ (0.2 g, 0.83 mmol) in CH_2Cl_2 (20 mL) were added CS_2 (4 mL, excess) and PCy_3 (0.397 g, 1.66 mmol). After 10 min $SnBuCl_3$ (0.138 mL, 0.83 mmol) was added and the mixture was stirred again for 15 min. The solvents were then evaporated and the residue was treated as described above. Yield 69%. **3b** and **3c** were prepared analogously.

A Water-Complexed Organolithium Compound: $[LiCH(CN)_2 \cdot H_2O \cdot TMEDA]_\infty$ **

By *Christoph Lambert, Paul von Ragué Schleyer,* Ursula Pieper,* and *Dietmar Stalke*

Lithiated organic compounds are notoriously sensitive to hydrolysis. A dramatic exception, [OxLi · H_2O · TMEDA] (OxH = 2-mercaptobenzoxazole), was reported recently.[1a]

[**] This work was supported by the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. We thank Dr. R. Snaith, Dr. D. S. Wright, and D. Hoffmann for their interest and stimulation as well as Dr. W. Bauer in particular for determining the HOESY spectrum. (TMEDA = N,N,N′,N′-Tetramethylethylenediamine).

First prepared fortuitously, this complex has stimulated the development of synthetic strategies for obtaining other polar metalated organic compounds with aqua ligands.[1b,c] We now report the first structural characterization of an H_2O-containing complex of the lithium salt of a CH- (rather than a NH-) acid: $[LiCH(CN)_2 \cdot H_2O \cdot TMEDA]_\infty$ **1**. The X-ray structure shows several remarkable features: TMEDA is incorporated but $R(CH_3)_2N\cdots Li$ contacts are not evident; a three-dimensional H-bridged network is preferred instead.

Only a few nitriles are found among the many structurally characterized organolithium compounds.[2] Perhaps this is due to the tendency of metal salts with nitrile anions to polymerize.[3] Nevertheless, the relatively low pK_a of malononitrile (pK_a of $CH_2(CN)_2$ in dimethyl sulfoxide (DMSO) $=11$, in $H_2O=11$; pK_a (H_2O) in DMSO $=32$, in $H_2O=15.75$[4]) prompted our attempt to prepare a lithiated organic compound with aqua ligands. The lithiation of $CH_2(CN)_2$ with *n*BuLi in tetrahydrofuran (THF) resulted in the precipitation of an amorphous solid, which did not dissolve upon addition of TMEDA; however, the precipitate did dissolve when a small amount of water was added. The water molecules evidently were incorporated into a less highly aggregated lithiomalononitrile complex.[5] Recrystallization of the isolated product from a 2:1 mixture of THF and diethyl ether gave crystals of **1** suitable for X-ray analysis.[6]

As shown in Figure 1, **1** exhibits a three-dimensional polymeric structure comprising lithiomalonodinitrile, TMEDA, and water in a 1:1:1 molar ratio. The topology of the repeating $(H_2O \cdot LiNCCHCN)_n$ unit is remarkably similar to that in $[LiCH(CN)_2 \cdot HMPA]_\infty$ (HMPA = hexamethylphosphoric triamide) reported by Weiss et al.[2a] Both show the same connectivity of the malonodinitrile anion, the lithium cation, and the hetero atom of the ligand (HMPA in the structure of Weiss et al., water in ours). Our structure is elaborated further by remarkably short intermolecular hydrogen bonds between each of the water hydrogens and a TMEDA nitrogen (the N3···H1 and the N4···H2 separations are 185.4 and 186.0 pm, respectively; the O1···H1 and the O1···H2 distances are 87.4 and 90.4 pm). The electron density distribution shows two maxima of electron density along the N–O vectors. One maximum was refined to give 80% probability of occupation, the other, 20%. Therefore we reasoned that 80% of the molecular units comprise TMEDA-complexed water molecules $[(C_4H_{10}N)NMe_2\cdots HOH\cdots Li\cdots(C_3HN_2)]_n$, while the other 20% resulted from hydrolysis $[(C_4H_{10}N)NMe_2H^+\cdots OH^-\cdots Li^+\cdots(C_3HN_2)]_n$. Support for this partial hydrolysis is provided by an IR spectrum (KBr) which exhibits a small, but sharp OH^- stretching band at 3540 cm^{-1} and a very broad and intense H_2O stretching band at 3600–2600 cm^{-1}. These values are similar to those reported by Jones for $LiOH \cdot H_2O$.[7] In addition we found a split R_3N^+–H stretching vibration at 2370 cm^{-1}.[8]

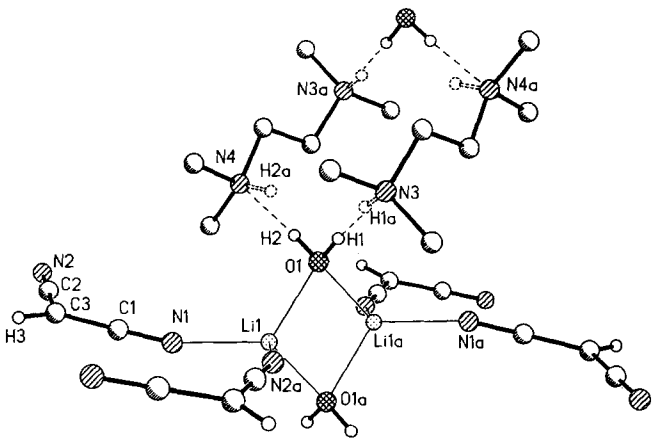

Fig. 1. Structure of **1** in the solid state. Selected bond distances [pm] and angles [°]: Li1-O1 201.8(3), Li1-O1a 197.6(3), Li1-N1 202.1(3), Li1-N2a 202.0(3), O1-H1 87.4(21), O1-H2 90.4(26), O1···N3 272.7(2), O1···N4 276.0(2), O1···H1a 190.5(22), O1···H2a 202.8(26), N3···H1 185.4(21), N4···H2 186.0(22), C1-N1 116.1(2), C1-C3 138.5(2), C2-N2 115.6(2), C2-C3 139.0(3), C3-H3 90.4(24); N1-Li1-N2a 105.7(1), O1-Li1-O1a 90.1(1), Li1-O1-Li1a 89.9(1), N1-C1-C3 178.9(2), N2-C2-C3 179.2(2), C2-C3-H3 118.4(15), C1-C3-H3 121.1(15), C1-C3-C2 120.4(2), Li1-N1-C1 166.7(2), H1-O1-H2 109.0(21).

These features contribute to the binding in the remarkable three-dimensional lattice structure of **1**. In contrast, the HMPA derivative of Weiss et al. has an essentially two-dimensional layer arrangement. Both structures exhibit $-CN\cdots Li^+\cdots NC-$ contacts between different malononitrile anions. The H_2O planes in **1** are approximately perpendicular to the nearly square-planar Li_2O_2 four-membered rings. The lack of TMEDA–Li interactions is unprecedented and is the second remarkable feature of the structure of **1**. Since TMEDA is a bidentate ligand, its complexation to lithium should be favored over that of water.[9] Innumerable solid-state structures of lithium compounds exhibit TMEDA ligand complexation.[10] But the structural preference in **1** results from the ability of water to function simultaneously as donor and acceptor. Each water molecule hydrogen-bonds to two TMEDA molecules and *each* binds two lithium atoms. TMEDA cannot function in this manner. The synergistic binding characteristics of the water molecules result in the preferred coordination in **1**. This emphasizes the point made by Snaith et al.[1c] that pK_a considerations alone are insufficient to determine whether water will be incorporated into lithiated organic solid-state structures.

The structural parameters of the lithiomalonodinitrile unit are in good agreement with those reported by Weiss et al.[2a] We found a planar malonodinitrile anion with an angle sum of 359.9° at C3 and a C1-C3-C2 angle of 120.4(2)° indicating the trigonal planar geometry of the central carbon atom. The average C–C and C–N distances are 138.8 pm and 115.9 pm, respectively. While the C–N distance in **1** is 0.8 pm less than that in malononitrile (116.7 pm),[11] the C–C distance is 8.0 pm less. Similar values are found in other lithionitriles.[2] The Li–N distances (202 pm) are slightly shorter than those in dimeric lithionitriles with a square-planar Li_2N_2 arrangement which exhibit two Li–N contacts per nitrile group (Li–N distances: 204–211 pm).[2b,c] The Li–O distances are 201.8 and 197.6 pm, respectively. Bridging water ligands are rare in solid-state lithium structures. They are present, however, in $LiOH \cdot H_2O$ and in $LiClO_4 \cdot 3H_2O$; the Li–O distances are 197.4 and 212.4 pm, respectively.[12]

While the structure and aggregation state of **1** in solution is of interest, colligative measurements[13] unfortunately are not applicable. A ^6Li, ^1H HOESY spectrum (HOESY = *H*eteronuclear *O*verhauser *E*ffect *S*pectroscopy)[14] of **1** in THF shows one lithium signal and cross peaks with all the signals of the hydrogen atoms (methylene-H, H_2O, TMEDA). This indicates that in THF solution a) lithium is coordinated by water and/or by TMEDA, and b) at least one species with an –HCLi– unit is involved. The observed cross peak between H3 and Li indicating the proximity between these atoms can only be rationalized by a close Li–C3 contact as supported by MNDO and *ab initio* calculations.[15] In the ^1H NMR spectrum at -100 °C in THF, no splitting of

the H_2O signal is detected. This suggests that the proton exchange between the TMEDA nitrogen and the H_2O oxygen atoms is rapid in solution.

Experimental Procedure

To a solution of 428 mg (6.48 mmol) malonodinitrile in 15 mL THF at −78 °C was added dropwise 4.06 mL (6.5 mmol) 1.6 M *n*BuLi in hexane. While the mixture was warmed to −50 °C and stirred for ca. 2 h, a precipitate (occasionally a brownish oil) formed. This dissolved on further addition of 10 mL THF, 4 mL (26.5 mmol) TMEDA, and (in particular) 0.6 mL (33 mmol) water. After stirring for 12 h at room temperature the mixture was filtered. The filtrate was concentrated under reduced pressure to one-third of its original volume. This solution was filtered and cooled to −18 °C. Colorless needles of **1** formed, were washed with ether, and dried in vacuo. Yield: 500 mg (37%). Single crystals were obtained by recrystallization in a 2:1 THF/diethyl ether mixture at 5 °C. Correct C, H, N analyses.

^{1}H NMR (400 MHz, [D_8]-THF, 25 °C): δ = 3.92 (s, 2H, H_2O), 2.33 (s, 4H, CH_2 (TMEDA)), 2.17 (s, 12H, CH_3, (TMEDA)), 1.35 (s, 1H, CH). ^{13}C NMR (100.6 MHz, [D_8]-THF, 25 °C): δ = 131.7 (CN), 58.5 (CH_2 (TMEDA)), 46.1 (CH_3 (TMEDA)), −1.5 (CH). IR(KBr) $\tilde{\nu}$[cm^{-1}] = 2190 m, 2130 m, 2100 m (CN).

Lithiodiphenylmethylisocyanide-(−)-sparteine-bis(tetrahydrofuran): Crystal Structure of a Lithiated Isocyanide**

By *Burkhard Ledig, Michael Marsch, Klaus Harms,* and *Gernot Boche**

Dedicated to Professor Ulrich Schöllkopf

Although lithiated isocyanides have not been systematically investigated for very long[1]—the isomeric lithiated cyanides were discovered one hundred years earlier[2]—their versatility in preparative chemistry is well documented.[3] Experiments aimed at stabilizing a negative charge with an isocyanide group showed that this stabilization is a result of the inductive effect (field effect) of the strongly electronegative sp-hybridized N atom. A conjugative interaction is thus negligible.[4] Further verification was found in quantum mechanical[5,6] and photoelectron spectroscopical[6] investigations of the H_2C^-–NC anion and the metalated isocyanides Li(Na,MgH)CH_2–NC. These studies predicted that in the transition from H_3C–NC to H_2C^-–NC the C–N and N=C bond lengths change only insignificantly (Table 1) and that the anionic C atom remains pyramidal (though with a low inversion barrier of 2.8 kcal mol^{-1}).

Table 1. Structural parameters of H_3C–N=C (experimental) [7] and H_2C^-–N=C (calculated) [5d]; r [pm], ∢ [°].

	r(C–N)	r(N=C)	∢ HCH	∢ HCN	∢ CNC
H_3C–NC	142.4	116.6	109.8	109.1	180
H_2C^-–NC	143.1	115.4	109.9	107.4	175.8

We report here the first structural determination of an isocyanide "anion": lithiodiphenylmethylisocyanide-(−)-sparteine-bis(tetrahydrofuran) (**1** · sparteine · 2 THF). In the crystal **1** · sparteine · 2 THF is monomeric (Fig. 1). The Li atom is bound to C1 of the isocyanide group, to N2 and N3 of the (−)-sparteine ligand, and to O1 of one THF molecule. The second THF molecule is not coordinated to Li.[8] The N1–C1 bond of the isocyanide group (116.2(1) pm) is almost as long as the related bond in the neutral H_3C–NC (116.6 pm, see Table 1) and somewhat longer than the average N–C bond in $C_{sp^2(sp^3)}$-bonded isocyanides (114.6(114.5) pm[13]) as well as the calculated bond length in H_2C^-–NC (115.4 pm, see Table 1). The C2–N1 bond (137.8(9) pm) is roughly as long as the related bond in C_{sp^2}-bonded neutral isocyanides; the mean value calculated from eight compounds is 139.0 pm.[13,14] The sp^2 hybridization of C2, which is deduced from the angle sum of C2 (360°), is due to the conjugation of the negative charge on C2 with the two phenyl rings. The torsion angles are accordingly small (N1-C2-C9-C14 −6(1) and N1-C2-C3-C4 −8(1)°). The C1-N1-C2 angle (178.4(6)°) shows that this unit is almost linear. Thus, the bond lengths and angles in the C^-–NC moiety of **1** · sparteine · 2 THF agree well with the theoretical predictions of $H_2C_2^-$–NC, and the inductive stabilization of the negative charge is structurally proven. The pyramidal geometry about the anionic C atom and the predicted aggregation to a dimer with a Li-C-N-C-Li-C-N-C eight-membered

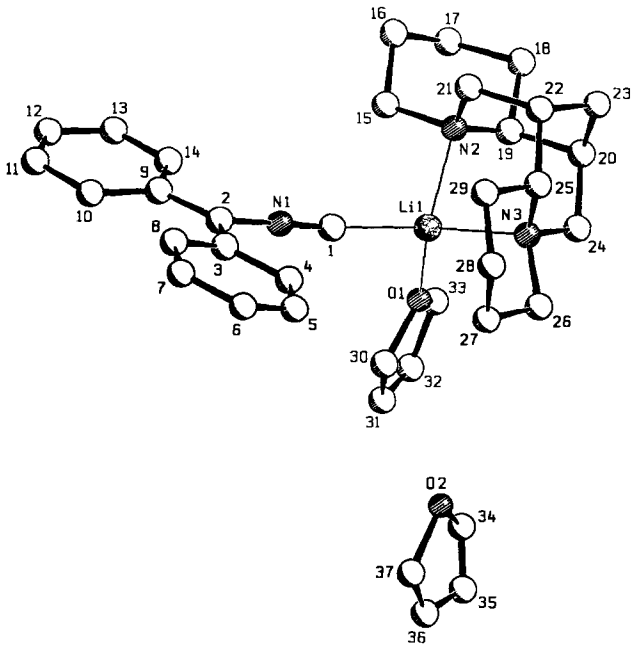

Fig. 1. Crystal structure of **1** · sparteine · 2 THF [8, 12]. Important bond lengths [pm] and angles [°]. (In the numbering of the carbon atoms in the graphic representation the element symbol was omitted.) C2-N1 137.8(9), N1-C1 116.2(10), C1-Li1 210(2); Li1-N2 206.5(13), Li1-N3 210.3(12), Li1-O1 194(2); Li1-C1-N1 176.8(8), C1-N1-C2 178.4(6), N1-C2-C9 113.6(6), N1-C2-C3 116.0(6), C3-C2-C9 130.4(7).

ring is not observed, however, in the case of **1** · sparteine · 2 THF . This is undoubtably due to the influence of the two phenyl substituents (instead of two H atoms) on the anionic C atom. **1** · Sparteine · 2 THF, as the only structurally characterized metalated isocyanide, contrasts dramatically with the large number of structurally characterized transition metal complexes with neutral isocyanide ligands.[15] Most of these contain an almost linear N=C–metal arrangement, the same as that in **1** · sparteine · 2 THF; here the N1-C1-Li1 angle is 176.8(8)°. Remarkably, the short distance between Li1 and the (nonionic!) C1 in the title molecule is only 210(2) pm.

Concave Wrapped Protons: Reagents for Contra-Thermodynamic Protonations**

By *Ulrich Lüning** and *Michael Müller*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

No widely applicable reagent for selective, and in particular stereoselective, protonations is known.[1] A very promising solution to this problem is offered by concave reagents, which are standard reagents of organic chemistry built into concave structural units.[2] The class of compounds that contains pyridine rings in a concave arrangement (concave

pyridines) has already been studied in connection with their substrate-[3] and chemoselectivity[4] in protonation reactions of "nitronate" ions (Scheme 1). Competition between the *C*-protonation of the nitronate ions **1** by protonated, concave pyridines yielding **2** and the Nef reaction[5] affording the carbonyl compounds **4** (soft Nef reaction[4]) is observed in these buffers.

On the other hand, the stereoselectivity of the nitronate ion reprotonation by buffers of concave macrocyclic pyridines (and also by concave 1,10-phenanthrolines **7**, see Table 1) was minimal.[4] But with buffers of 2-aryl-1,10-phenanthrolines **6**, which are not as sterically hindered as a concave pyridine[4] or a concave 1,10-phenanthroline **7**, good stereoselectivities are observed for the reprotonation of the nitronate ions **1**. Table 2 lists these selectivities, as well as the proportion of the (soft) Nef reaction products **4**, for the transformation of anions **1** with buffers of different bases under standard conditions.[6] Using as example the protonation of **1a** by **6c**, we could show that the stereoselectivity depended little on the concentration[7] of the buffer, but strongly on the solvent.[8] Alcohols were the media that provided the largest selectivities.

A comparison of the stereoselectivities in Table 2 reveals three facts: a) Compounds **2** are produced with high stereoselectivity only when bis-*ortho*-substituted 2-aryl-1,10-phenanthrolines **6** are the proton source. b) More reagents react stereoselectively with the cyclic anion **1a** than with the more flexible acyclic anion **1b**. c) In both cases the thermodynamically *less stable* product is favored (*cis*-**2a**, *threo*-**2b**).

How can one explain that the bis-*ortho*-substituted arylphenanthrolines **6**, in particular, react so selectively and that thermodynamically *less stable* products are formed preferentially? The data in Table 2 for 2-phenyl-1,10-phenanthroline (**6a**) and the bis-*ortho*-substituted 2-aryl-1,10-phenanthrolines **6** show a distinct increase in selectivity on the introduction of *ortho* substituents. A possible explanation is that the *ortho* substituents cause a twisting of the molecule. The steric consequence is that the concave (arched) form of the 2-phenyl-1,10-phenanthroline **6a** is supplemented by a similar arched expansion into the third dimension (Fig. 1). In protonated form the proton to be transferred is more strongly shielded in this domed form and the reagent is therefore more selective.

Table 2. Product distribution for the reprotonation of the nitronate ions **1** by substituted 1,10-phenanthrolines **5** and **6** and bimacrocyclic 1,10-phenanthrolines **7**.

[a] The assignment of the diastereoisomers **2b** was achieved by catalytic reduction (Pd/C, $NH_4^+HCOO^-$, MeOH) [18] of one of the isomers to the amine, which was isolated as the hydrochloride in 86% yield. M.p.(crude product) = 193 °C, m.p. (from benzene) = 210 °C. (Lit.: *erythro*-**2b**: 212–212.5 °C [19], 218.1–218.5 °C [20], *threo*-**2b**: 137–138 °C [19]). [b] Homogeneous reaction mixture. [c] Inhomogeneous reaction mixture. [d] The chiral reagent **6f** did not lead to enantioselectivity in the case of **1b**, because the anion mixture **1b** was racemic and formed the *threo* product (*RS*/*RS*, 96%); that is, the intramolecular asymmetric 1,2-induction dominated. The selectivity of **6f** is thus determined only by the steric and not by the chiral properties of the acyl substituent.

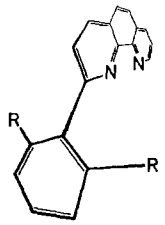

Fig. 1. A twist of the 2,6-disubstituted phenyl ring against the 1,10-phenanthroline unit extends the concave shielding of the proton-binding region of 1,10-phenanthroline into another dimension.

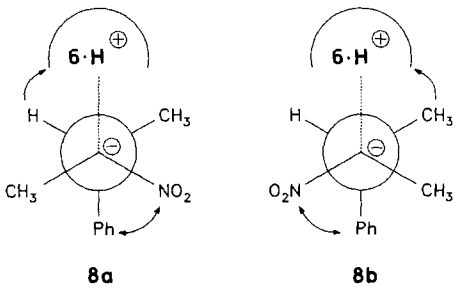
On consideration of the conformation of **6** shown in Figure 1, an equatorial protonation of **1a** appears easier because axial protonation involves interactions with the H atoms in the 3- and 5-position (1,3-diaxial interaction, see ref. [9]). For a discussion of the protonation of **1b**, however, various conformations for the anion must be considered. For steric reasons an *anti* attack with respect to the phenyl ring in **1b** by the protonated concave 1,10-phenanthroline **6** · H^+ is most likely. Since in this orientation the phenyl residue interacts strongly with the (solvated) nitro group, a twisting is probable. In this twisted form the major difference between the two diastereoisomeric transition states **8** is the **6** · H^+/Me or **6** · H^+/H interaction (Fig. 2). Transition state



8a **8b**

Fig. 2. Diastereomeric transition states **8** for the attack of a proton "wrapped" in a concave 2-aryl-1,10-phenanthroline (**6**) on the nitronate ion **1b**.

8a is thus more favorable and leads to the thermodynamically less stable *threo* product.

Thus for protonation of both anions **1a** and **1b** with concave 1,10-phenanthrolines **6** · H^+, the more favorable transition state affords the thermodynamically less stable product. In each case the largest pseudosubstituent in the transition state leads to the smallest substituent, a H atom, in the product. The secret of forming the thermodynamically less stable stereoisomer stereoselectively in protonation reactions lies in "wrapping" the protons[10] in a way that ensures that they will be the larger substituents in the transition state. This is undoubtedly not only true for the protonation of the nitronate ions shown here, but should apply to most other anions too.[11] Moreover, a concave wrapping for hydride ions (H^-) and hydrogen atoms ($H^·$) should also lead to high stereoselectivity, as investigations of reduction reactions of cyclohexanones[9] and stereoselective H-capture by radicals[12] suggest.

Experimental Procedure

For experimental details, see [13]. A solution of potassium-*tert*-butoxide (19 mg, 0.17 mmol), the nitro compounds **2a** or **2b** (0.11 mmol) and [18]crown-6 (51 mg, 0.19 mmol) in 2 mL of dry ethanol was stirred for 15 h [14]. For each reprotonation experiment, 40 µL of this solution was added to mixtures of base (0.22 mmol) and *p*-toluenesulfonic acid monohydrate (11.4 mg, 0.06 mmol) in 1 mL dry ethanol. The reaction mixture was stirred for 16 h at room temperature, whereupon 2 N HCl (0.5–1.0 mL), water (2 mL), and diethyl ether (4 mL) was added and the phases were separated. The aqueous phase was extracted with 4 mL of diethyl ether, and the combined organic phase was washed with ca. 2 mL of water, and dried over $MgSO_4$. The sample was concentrated, and analyzed by gas chromatography (Carlo-Erba 4130, Carlo-Erba GC 6000 Vega or Carlo-Erba HRGC 5300 Mega; column: SE 30/25 m (from the company J&W [15]); 180 °C isothermally or OV 17/15 m temperature program: 160 °C for 5 min and heating at 5 °C per min to 240 °C.

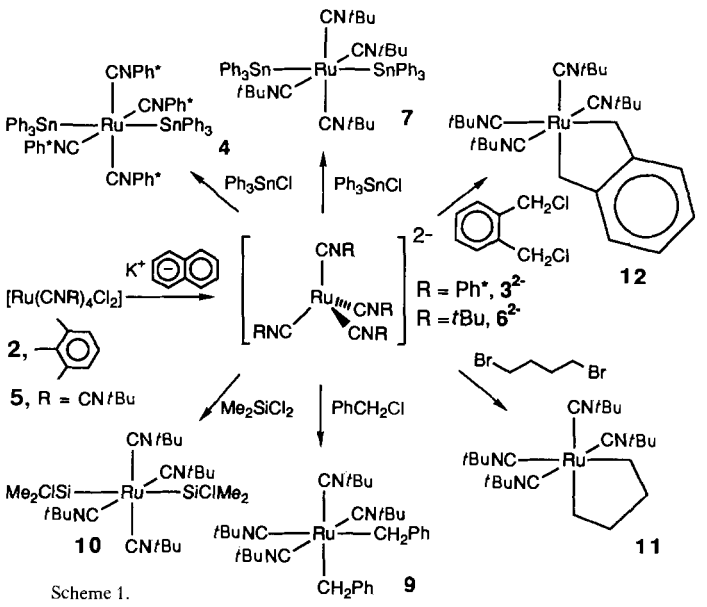
(Isocyanide)ruthenate Analogues of Tetracarbonylferrate**

By *Joseph A. Corella II, Robert L. Thompson,* and *N. John Cooper**

We recently reported the synthesis of K[Co(CNPh*)$_4$] (K-**1**) (CNPh* = 2,6-$Me_2C_6H_3NC$), the first isocyanide transition-metalate.[1] The low frequencies (1890 (sh) and 1815 (vs) cm^{-1}) of the $\nu_{C\equiv N}$ absorptions of K-**1** are consistent with bent rather than linear isocyanide ligands,[1, 2] and we speculated that the ligands bend as a consequence of back-donation from the electron-rich metal into the isocyanide π^* orbitals.[1, 3] Calculations indicate that the π-acceptor character of $CNCH_3$ increases markedly as the CNC angle decreases.[6] The $\nu_{C\equiv N}$ frequencies of $\mathbf{1}^-$ are similar to those of the bent isocyanide ligands in [Fe(CN*t*Bu)$_5$],[4b, c] but well above C=N stretching frequencies. This raised the intriguing possibility that even stronger π backbonding might allow isocyanides to stabilize even lower oxidation states than Co^{-I}. This, and the obvious analogy to the rich chemistry of the tetracarbonylferrate dianion,[7] led us to explore the synthesis of tetraisocyanide complexes of the Group 8 metals in the $-II$ oxidation state. We now report that (isocyanide)-ruthenates $[Ru(CNR)_4]^{2-}$ are accessible as reactive intermediates, and that they undergo oxidative addition reactions with a range of electrophiles (Scheme 1).



Scheme 1.

We synthesized $[Ru(CNR)_4]^{2-}$ complexes by reduction of the Ru^{II} isonitrile complexes $[Ru(CNR)_4X_2]$ **2** and **5**[8] with potassium–naphthalene in tetrahydrofuran (THF). In a typical experiment, K[$C_{10}H_8$] (4 equiv) readily reduced *trans*-[Ru(CNPh*)$_4$Cl$_2$] (**2**) to give a clear, burgundy-red solution. The $\nu_{C\equiv N}$ absorption of **2** at 2140 (s) cm^{-1} had been replaced by bands at 1670 (vs br) and 1580 (s) cm^{-1}, indicative of the formation of a highly reduced (isocyanide)ruthenate, formulated as K_2[Ru(CNPh*)$_4$] (K_2-**3**).[9] Attempts to isolate a salt of $\mathbf{3}^{2-}$ have been unsuccessful to date, but we have been able to chemically derivatize K_2-**3** by oxidative addition of 2 equiv of Ph_3SnCl[1, 10] to give [Ru(CNPh*)$_4$(SnPh$_3$)$_2$] (**4**) in 75% yield. The solubility of **4** in hexane, together with the ^{1}H NMR equivalence of all the CNPh* ligands, strongly suggests exclusive formation of the *trans* isomer.

Our inability to characterize a salt of $\mathbf{3}^{2-}$ by crystallography raises the question whether $\mathbf{3}^{2-}$ contains discrete isocyanide ligands or (*N,N'*-dialkyldiamino)acetylene ligands, which could be formed by a coupling reaction analogous to that observed by Lippard et al. in the reduction of some early transition-metal isocyanide complexes.[11] The IR data fail to distinguish between these possibilities, but three arguments suggest that $\mathbf{3}^{2-}$ contains discrete isocyanide ligands: 1) this is not a sterically crowded environment of the type which favors reductive coupling;[11] 2) the derivative **4** contains discrete isocyanide ligands; 3) we have established crystallographically that the isoelectronic anion in [K(dme)]-[Co(CNPh*)$_4$] is tetrahedral and contains discrete, bent isocyaniide ligands.[12]

The synthesis of dianionic isocyanide complexes of ruthenium is not limited to aryl isocyanides and *trans*-[Ru(CN-*t*Bu)$_4$Cl$_2$][8] (**5**) underwent similar potassium–naphthalene reduction at $-78\,^\circ C$. IR spectra indicated consumption of the starting material, but the highly reduced product was too thermally unstable to be observed spectroscopically. We have, however, provided chemical evidence for the formation of a dianionic isocyanide complex, K_2[Ru(CN*t*Bu)$_4$] (K_2-**6**), since the addition of Ph_3SnCl furnished *trans*-[Ru(CN*t*Bu)$_4$-(SnPh$_3$)$_2$] (**7**) following a workup similar to that used to isolate *trans*-**4**.

Si- and C-centered electrophiles also undergo oxidative addition to K_2-**6**. IR monitoring of the reaction of fresh solutions of K_2-**6** with 2 equiv of $PhCH_2Cl$, CH_3I, or Me_2SiCl_2 at $-78\,^\circ C$ suggested that bisadducts are formed. The presumed dimethyl derivative [Ru(CN*t*Bu)$_4$Me$_2$] (**8**) was too unstable to isolate, but the dibenzyl derivative

Department of Chemistry, University of Pittsburgh
Pittsburgh, PA 15260 (USA)

[**] We thank the U.S. National Science Foundation for generous financial support through Grant 8722424 and Dr. Garry Warnock and Patricia Leach for stimulating discussions.

$[Ru(CNtBu)_4(CH_2Ph)_2]$ (**9**) and $[Ru(CNtBu)_4(SiMe_2Cl)_2]$ (**10**) were both isolated in good yield (78% and 71%, respectively). NMR spectra indicate that **10**, like **4** and **7**, is formed as the *trans* isomer, while **9**, surprisingly, is formed as the *cis*.

Extensions of these reactions to more complex alkyls have already, for example, led to the preparation of five-membered metallacycles. Stoichiometric quantities of α,ω-dihaloalkyls such as 1,4-dibromobutane and α,α'-dichloro-*o*-xylene were added to freshly prepared solutions of K_2-**6** to give the respective complexes **11** and **12** in reasonable yield (40% each).

The accessibility of K_2-**3** and K_2-**6** as reactive intermediates supports our previous suggestion that the ability of isocyanides to stabilize metals in negative oxidation states has been severely underestimated. The chemistry of the (isocyanide)metalates appears as rich and diverse as that of carbonylmetalates. The successful preparation of a range of Sn, Si, and C-centered derivatives of K_2-**3** and K_2-**6** more specifically supports the analogy between these complexes and tetracarbonylferrate. Thus the path to other (isocyanide)-ruthenates with other functional groups has been paved.

Experimental Procedure

4: A solution of **2** (0.35 g, 0.5 mmol) in THF (25 mL) was reduced by dropwise addition of 4.2 molar equiv of a 0.47 M solution of $K[C_{10}H_8]$ in THF (4.25 mL) at $-78\,^{\circ}C$ to give a clear, burgundy-red solution. Dropwise addition of Ph_3SnCl (0.39 g, 1 mmol) in THF (10 mL) gave a clear tan solution, which was warmed to room temperature, and the solvent was removed under reduced pressure. The product **4** was extracted into warm hexane. When the solution was slowly cooled to $-78\,^{\circ}C$, white needles (0.49 g, 0.3 mmol) formed. **7**, **9**, **10**, **11**, and **12** were prepared by procedures similar to those used to prepare **4**.

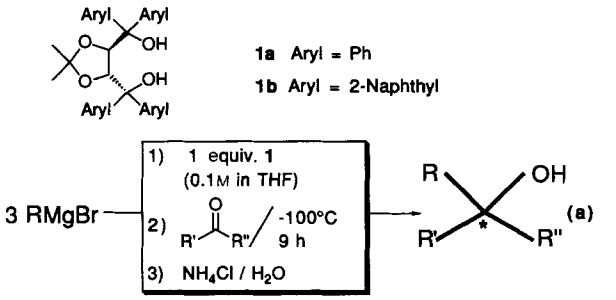
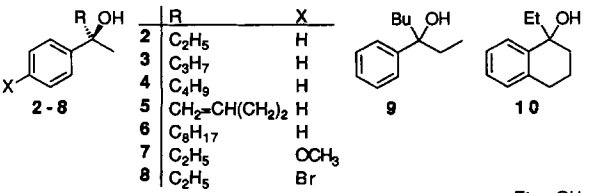
Enantiomerically Pure Tertiary Alcohols by TADDOL-Assisted Additions to Ketones—or How to Make a Grignard Reagent Enantioselective**

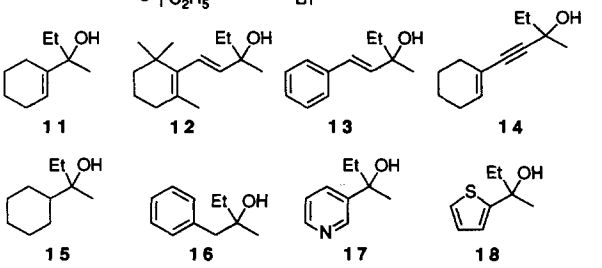
By *Beat Weber* and *Dieter Seebach**

Tertiary stereogenic centers are generally more difficult to generate selectively than secondary ones, as evidenced by the few examples of C–C bond formation with enantio- and diastereoselective nucleophilic addition to ketones.[1] Thus, we were very happy to see that primary alkyl Grignard reagents in the presence of TADDOL (**1**) magnesium alkoxide (TADDOL: $\alpha,\alpha,\alpha',\alpha'$-tetraaryl-2,2-dimethyl-1,3-dioxolane-4,5-dimethanol) add to aryl, vinyl, and alkynyl ketones with enantioselectivities up to >99:1.

The general procedure, which was optimized for acetophenone (products **2**–**8**), is quite straightforward: TADDOL[2] is doubly deprotonated with 2 equivalents of Grignard reagent, and to the resulting solution in THF is added another equivalent of RMgBr (resulting in an approximately 0.1 M diolate and RMgBr solution). The reaction mixture is cooled to $-100\,^{\circ}C$ and a ketone is added to the resulting suspension. After stirring at $-100\,^{\circ}C$ for 9 h, the reaction mixture is given an aqueous workup [Eq. (a)]. The results summarized







in Table 1 were obtained with 0.5 mmol runs, but larger scale reactions are also possible (see the Experimental Procedure).

The following reaction characteristics have been observed to date:

[*] Prof. Dr. D. Seebach, Dipl. Chem. B. Weber
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

[**] The results described herein are part of the projected dissertation of B. Weber; first presented at the ESOC-7 Symposium, Namur (July 17, 1991).

Table 1. Addition of Grignard reagents to ketones in the presence of $(BrMg)_2$ diolates of **1** [Eq. (a)]. Ratios of enantiomers were determined by GC analyses on cyclodextrin capillary columns; >99:1 means that the second enantiomer cannot be detected. The optical rotations are given for $[\alpha]_D^{rt}$ values in methanol.

R in RMgBr and in **2**–**8**	TADDOL	Ketone	No.	Product yield [%]	Ratio of Enantiomers (Rotation)
C_2H_5	**1a**	$C_6H_5COCH_3$ [a]	**2** (X = H)	62	99:1 (+)
C_3H_7	**1a**	$C_6H_5COCH_3$	**3** (X = H)	84	>99:1 (+)
C_4H_9	**1a**	$C_6H_5COCH_3$ [b]	**4** (X = H)	75	>99:1 (+)
$(CH_2)_2CH{=}CH_2$	**1a**	$C_6H_5COCH_3$	**5** (X = H)	60	>99:1 (−)
C_6H_{17}	**1a**	$C_6H_5COCH_3$	**6** (X = H)	58	>99:1 (+)
C_2H_5	**1a**	$4\text{-}(CH_3O)C_6H_4COCH_3$	**7** (X = OCH_3)	76	96:4 (+)
C_2H_5	**1a**	$4\text{-}BrC_6H_4COCH_3$	**8** (X = H)	90	97:3 (+)
C_4H_9	**1a**	$C_6H_5COC_2H_5$	**9**	7	95:5 (−)
C_2H_5	**1a**	α-tetralone	**10**	28	95:5 (+)
C_2H_5	**1b**	α-tetralone	**10**	12	97:3 (+)
C_2H_5	**1a**	1-cyclohexenyl methyl ketone	**11**	56	85:15 (−)
C_2H_5	**1a**	β-ionone	**12**	64	92:8 (−)
C_2H_5	**1a**	(*E*)-4-(phenyl-3-buten-2-one	**13**	40 [c]	85:15
C_2H_5	**1a**	4-(1-cyclohexenyl)-3-butyn-2-one	**14**	88	88:12
C_4H_9	**1a**	cyclohexyl methyl ketone	**15**	trace	62:38
C_2H_5	**1a**	benzyl methyl ketone	**16**	22	75:25
C_2H_5	**1a**	3-acetylpyridine	**17**	50	98:2 (+)
C_2H_5	**1a**	2-acetylthiophene	**18**	43	98:2 (+)

[a] This reaction was run 3 times (0.5–10 mmol scale) yielding **2** with 97.7–98.3% *ee*; 10 mmol scale run see below. [b] At −78 °C: 69% yield, ratio of enantiomers 94:6. [c] In addition to **13** the 1,4-adduct $PhCH(Et)CH_2COCH_3$ was also formed (40% yield, ratio of enantiomers 70:30).

a) Addition of ethyl- and propylmagnesium bromide to acetophenone occurs from the *Re*-face (determined by comparison of the optical rotation of **2** and **3** with literature data[3a]). For this reason all compounds of the same type (**2**–**8**) are shown with (*R*)-configuration.

b) Even with only 0.25 equivalents of the **1a** Mg alkoxide the (+)-enantiomer of **4** was formed preferentially (92:8).[3b]

c) Steric hindrance (especially from iC_3H_7 and tC_4H_9 Grignard reagents, higher aryl ketones, or *ortho*-tolyl methyl ketone) decreases the rate of reaction drastically (products **9** and **10**).

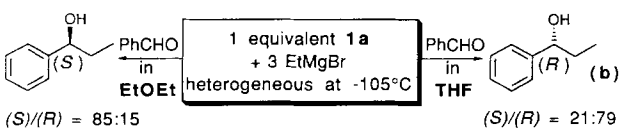
d) With the tetra-β-naphthyl-TADDOL **1b**[2a] the enantioselectivity may be somewhat greater than with the tetraphenyl analogue (product **10**).[3c]

e) Aliphatic methyl ketones do not react as well as aromatic ones (products **11**–**16**).

f) The heteroaromatic methyl ketones 3-acetylpyridine and 2-acetylthiophene give good results (products **17** and **18**).

g) If the solvent is changed from THF to Et_2O (under otherwise identical conditions) stereoselectivity is lost.

h) Stereoselectivity is much lower for reactions with benzaldehyde than with aromatic methyl ketones. However, a reversal of the stereochemical course is observed in this case when the solvent is changed from THF to Et_2O [Eq. (b)].[3d]



The effect caused by the addition of chiral alkoxides to polar organometallic compounds has been thoroughly investigated for Li compounds (LiX effect)[4] and can be rationalized by assuming either aggregate formation $[(metal\text{-}R)_m(metal\text{-}X^*)_n]$ (here RMgOR* as well), or by chiral Lewis acid (R*OMgBr) activation of the ketone in the rate-determining step. Whatever the mechanism of this reaction is (heterogeneous reaction mixture!), the high degree of enantioselectivity obtained in a nucleophilic alkyl-transfer to a keto carbonyl group is unprecedented.

Experimental Procedure

2: In a 250 mL Schlenk tube equipped with magnetic stirring bar and PT100 thermometer, 10 mmol (4.66 g) TADDOL **1a** was dissolved in 40 mL of THF (distilled from K) under argon atmosphere and cooled to −70 °C. To the colorless solution was added 31 mmol (8.9 mL 3.5 M in ether) EtMgBr. The cooling bath was removed, another 70 mL THF added, and the reaction mixture allowed to warm to room temperature. The colorless solution was then cooled to −105 °C[5] resulting in the formation of a colorless precipitate. Under vigorous stirring 9.4 mmol (1.13 g) acetophenone was added. Stirring was continued for 9 h at −105° to −100 °C. Afterwards the reaction mixture was quenched with 40 mL of a saturated NH_4Cl solution and ether was added. The organic layer was separated, washed with brine, and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure and the product was freed from TADDOL by distillation in a kugelrohr apparatus (0.1 Torr, 150 °C). Crude **2** (1.17 g, ratio of enantiomers 99:1) was obtained, containing 20% acetophenone. Pure **2** was isolated after flash chromatography (solvent: pentane/ether 10:1) and distillation. Yield: 0.88 g (62%), ratio of enantiomers 99:1, $[\alpha]_D^{rt} = +17.3$ (neat).

The Phosphorus Ylide CH_2PH_3 is Stable in the Gas Phase**

By *Helmut Keck, Wilhelm Kuchen,* Peter Tommes, Johan K. Terlouw,* and *Thomas Wong*

Dedicated to Professor John L. Holmes on the occasion of his 60th birthday

The phosphorus ylide CH_2PH_3 **1** (methylenephosphorane) is one of the most often discussed hypothetical molecules in the chemistry of organophosphorus compounds. This is because it is the simplest member of the class of phosphorus ylides which have a great synthetic potential in the Wittig reaction.[1] A great number of theoretical studies deal with predictions of the structure, reactivity, and bonding properties of this molecule and its ionized conterpart.[2] According to these reports **1** can formally be represented as a methylene–phosphane adduct in which the C–P bond has partial double-bond character.

$$\underset{\mathbf{1}}{H_3\overset{\oplus}{P}-\overset{\ominus}{\ddot{C}}H_2} \longleftrightarrow \underset{\mathbf{2}}{H_3P{=}CH_2} \qquad CH_3PH_2$$

Although the phosphorus ylide **1** is 237 kJ mol^{-1} higher in energy than its isomer methylphosphane, CH_3PH_2, **2**, the two isomers are separated by a high energy barrier (**2** → **1**: 378 kJ mol^{-1}).[3] The ionized ylide $[\mathbf{1}]^{+\cdot}$ is also less stable than the radical cation $[\mathbf{2}]^{+\cdot}$ but the difference in their energies, $\Delta E = 40$ kJ mol^{-1}, is less than that between their neutral counterparts. Both ions lie in deep potential wells with significant barriers towards dissociation or isomerisation ($[\mathbf{2}]^{+\cdot} \rightarrow [\mathbf{1}]^{+\cdot}$: 220 kJ mol^{-1}).[3]

These theoretical predictions led to the suggestion[3] that the technique of neutralization–reionization mass spectrometry (NRMS)[4] be used to generate **1** by reduction of its radical cation $[\mathbf{1}]^{+\cdot}$. After we first established the structure of the ion $[\mathbf{1}]^{+\cdot}$ using collisional activation (CA) mass spectrometry,[5] we were able to show that its reduction in an NRMS experiment indeed leads to the formation of the elusive neutral ylide **1** as a stable species in the rarefied gas phase. Our experimental findings provide a gratifying confirmation of the theoretical predictions.

Dissociative ionization (electron impact, 70 eV)[6] of *n*-hexylphosphane ($C_6H_{13}PH_2$)[7] abundantly provides ions (*m/z* 48) whose structure was identified[8] as the ylide ion $[CH_2PH_3]^{+\cdot}$, $[\mathbf{1}]^{+\cdot}$. Mass selection of this ion and subsequent collisional activation (collision gas O_2, 80% transmission, *T*) afforded the collisional activation (CA) mass spectrum shown in Figure 1a which features peaks diagnostic for $[\mathbf{1}]^{+\cdot}$ at *m/z* 34 ($[PH_3]^{+\cdot}$) and *m/z* 14 ($[CH_2]$)$^{+\cdot}$. In agreement with the earlier study[8] this CA mass spectrum is significantly different from that of the isomeric radical cation $[CH_3PH_2]^{+\cdot}$, $[\mathbf{2}]^{+\cdot}$, (Fig. 1b).[9] Note that this spectrum does not contain the *m/z* 34 peak characteristic of $[\mathbf{1}]^{+\cdot}$ and that its low-mass region is dominated by the signal at *m/z* 15, characteristic for an intact methyl group.

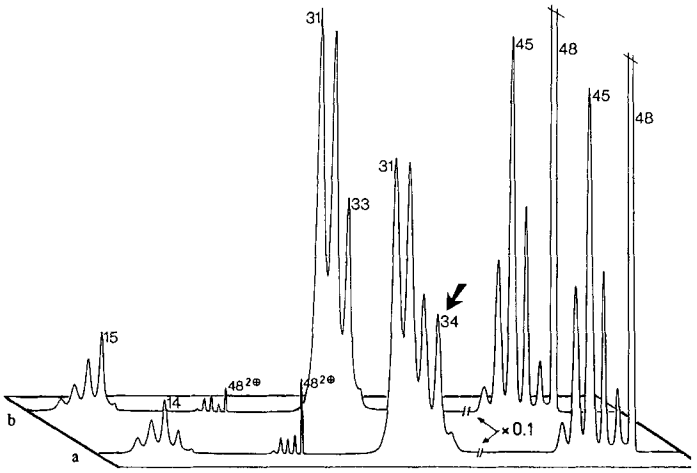

Fig. 1. CA mass spectra of (a) $[\mathbf{1}]^{+\cdot}$ (*m/z* 48) and (b) $[\mathbf{2}]^{+\cdot}$ (*m/z* 48).

A neutralization–reionization (NR) experiment on $[\mathbf{1}]^{+\cdot}$ involving neutralization by electron transfer to cyclopropane (80% *T*,[10]) followed after roughly 1 μs by reionization with O_2 (80% *T*) yields the NR mass spectrum which features an intense "recovery signal" at *m/z* 48 (Fig. 2). Quite likely this reflects the stability of the ylide **1** and may point to relatively favorable Franck–Condon factors in the vertical electron-transfer processes $[\mathbf{1}]^{+\cdot} \rightarrow \mathbf{1} \rightarrow [\mathbf{1}]^{+\cdot}$. Note, however, that the intensity distribution of the peaks in the NR

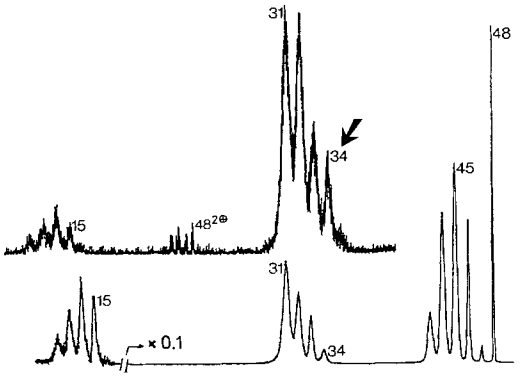

Fig. 2. NR mass spectrum of $[\mathbf{1}]^{+\cdot}$ (*m/z* 48); insert (upper spectrum): the interference-free NR mass spectrum of ions $[\mathbf{1}]^{+\cdot}$ resulting from the sequence $[\mathbf{1}]^{+\cdot} \rightarrow \mathbf{1} \rightarrow [\mathbf{1}]^{+\cdot}$.

spectrum of $[1]^{+\cdot}$ differs considerably from that displayed in its conventional CA mass spectrum (Fig. 1a). In particular, the structure-diagnostic peak-intensity ratios m/z 34: m/z 33 ($[PH_3]^{+\cdot}$ vs. $[PH_2]^+$) and m/z 14: m/z 15 ($[CH_2]^{+\cdot}$ vs. $[CH_3]^+$) have become lower, which may indicate that **1** has isomerized to **2** to a significant extent (NR mass spectrum of **2** in Fig. 3). Alternatively, one may argue that the discrepancies between the two spectra originate from contributions to the NR mass spectrum by dissociation products of **1** which are reionized and recorded as well.[4d-f, 11] Proof of this may be found in the substantial increase in the cluster of peaks m/z 31–34.

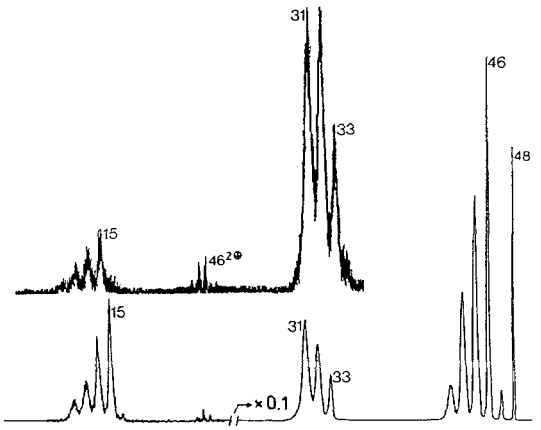

Fig. 3. NR mass spectrum of $[CH_3PH_2]^{+\cdot}$, $[2]^{+\cdot}$ (m/z 48); insert (upper spectrum): the interference-free NR mass spectrum of ions $[2]^{+\cdot}$ resulting from the sequence $[2]^{+\cdot} \rightarrow 2 \rightarrow [2]^{+\cdot}$.

Compelling evidence that the "recovery signal" in the NR mass spectrum of **1** is indeed that of the reionized stable neutral ylide **1** and not its counterpart **2** comes from a multistep collision experiment in which the reionized species **1** and **2** are mass-selected with the third sector (E_2) and then subjected to a CA experiment.[4d-f] These "survivor" CA mass spectra of interference-free reionized **1** and **2**—see inserts in Figures 2 and 3—are almost identical to their characteristic conventional CA mass spectra (Fig. 1).[12] These observations clearly show that upon neutralization of the radical cations both the ylide **1** and its isomer **2** retain their structural identities. The smallest possible phosphorus ylide, CH_2PH_3, has been detected experimentally and shown to be a stable species in the rarefield gas phase.

[11] Contributions like the isomeric purity of the ion flux prior to neutralization and cross sections for the neutralization–reionization process, which may differ widely with mass and structure, may severly hamper the interpretation of the NR spectrum. A case in point is the identification of the chlorine ylide, CH_2ClH: a) P. C. Burgers, J. K. Terlouw in: *Mass. Spectrom.* **1988**, *10*, Chap. 2; b) J. C. Lorquet, B. Leyh-Nihant, F. W. McLafferty, *Int. J. Mass Spectrom. Ion Processes* **1990**, *100*, 465. For the $[CH_3PH_2]^{+\cdot}/[CH_2PH_3]^{+\cdot}$ system the neutralization–reionization cross sections appear to be similar. The results of the multistep collision experiment show that the ylide ion flux is quite pure.
[12] The intensity distributions of the "charge stripping" (CS) peaks (45^{2+}–48^{2+}) in the CA spectra of the reionized isomeric ions are quite different. However, the patterns do not correspond with those of the conventional CA mass spectra. This is not unexpected since collisional reionization may produce ions with different internal energy distributions.

$[Et_4N]_2[\{MO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]$ (M = Mo, W)—Doubly Bridged Complexes with S_7^{2-} and Doubly End-On-Bound H_2NNH_2 Bridging Ligands

By *Zhu Nianyong, Du Shaowu, Wu Xintao,* and Lu Jiaxi*

The chemistry of transition-metal–polysulfido complexes[1, 2] is of broad interest, especially that of the polysulfido–molybdenum complexes in connection with the hydrodesulfurization (HDS) catalysts. These complexes often have surprising structures. Complexes with dinitrogen ligands bridging two metal-centers are also of interest, and the reduction of the N_2 ligand has a number of proposed reaction mechanisms.[3, 4] The feasibility of introducing nitrogenase substrates bonded in a doubly end-on mode as additional bridges between two cubane subunits already bound by a μ_2-S bridge has been demonstrated.[5] Very few doubly bridged complexes with bridging S_7^{2-} ligands[6] or bridging NH_2NH_2 ligands[5, 7] have been reported. The title complexes **1** (M = Mo) and **2** (M = W) contain not only the almost planar zig-zag $[M^{VI}\text{-}H_2N\text{-}NH_2\text{-}M^{VI}]$ unit, but also a doubly bridging S_7^{2-} ligand. In fact **1** and **2** have the longest polysulfide chains of all polysulfido–molybdenum (or tungsten) complexes. Complexes **1** and **2** were obtained from the new reaction system of $MO_2S_2^{2-}/S_x/H_2NNH_2 \cdot 2HCl$ (M = Mo, W), in which the biologically relevant H_2NNH_2 ligand may be introduced. Both complexes, $[Et_4N]_2[\{MO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]$, were characterized by elemental analysis, IR and UV/VIS spectroscopy, cyclic voltammetry[8], and

X-ray structural analysis.[9] Since **1** and **2** are isomorphous, only the structure of complex **1** will be discussed.

In the anion of complex **1**, the two Mo^{VI} centers, which are each coordinated by two disulfide ligands and one double-bonded terminal oxo ligand, are linked by an S_7^{2-} bridge and an H_2NNH_2 bridge (Fig. 1; the S_7^{2-} ligand is statistically disordered at S6 and S7 with an equivalent degree of occupancy of 0.5 for S6′ and S7′. The two S_2^{2-} ligands on Mo2 are also disordered.) The coordination polyhedron of the

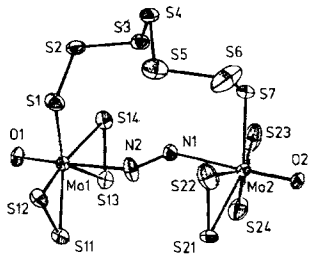

Fig. 1. The structure of the anion $[\{MoO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]^{2-}$ (for clarity only one disordered anion is drawn). Selected bond lengths [Å] and bond angles [°]: Mo1-S1 2.473(1), Mo1-S11 2.386(4), Mo1-S12 2.410(3), Mo1-S13 2.383(3), Mo1-S14 2.380(3), Mo1-O1 1.668(6), Mo2-S7 2.44(2), Mo2-S21 2.46(2), Mo2-S22 2.39(2), Mo2-S23 2.37(1), Mo2-S24 2.47(2), Mo2-O2 1.671(6), Mo1-N2 2.486(8), Mo2-N1 2.491(8), S1-S2 2.030(5), S2-S3 2.031(5), S3-S4 2.046(5), S4-S5 2.015(5), S5-S6 2.24(1), S6-S7 1.93(2), N1-N2 1.40(1), S11-S12 2.029(5), S13-S14 2.047(5), S21-S22 1.95(2), S23-S24 1.94(2); O1-Mo1-N2 175.3(4), O2-Mo2-N1 175.9(3), N2-N1-Mo2 126.7(7), N1-N2-Mo1 125.7(6).

Mo^{VI} centers is a pentagonal bipyramid, whose two apexes are formed by the terminal oxo atom and the coordinating atom of H_2NNH_2 ligand. This type of coordination with a pentagonal-bipyramidal environment around each Mo(VI) atom is often found in other oxodisulfido-molybdate complexes.[10] The five equatorial sulfur atoms of each pentagonal bipyramid are planar to within 0.07 Å, and the S2 and S6 (and S6′) atoms are in a least-squares plane with deviations of 0.08 and 0.1 Å (0.1 Å), respectively. The average Mo–N bond length of 2.489(8) Å is relatively long, due to the *trans* influence[10b] of the Mo=O bond opposite the N atom (average O-Mo-N angle 175.6(4)°). The N–N bond length of 1.40(1) Å is much shorter than that found in free hydrazine which has a staggered conformation. The [Mo(μ_2-H_2NNH_2)Mo] fragment is planar to within 0.11 Å, and the Mo substituents approach an ideal *trans* configuration.

Experimental Procedure

1: Sulfur (0.675 g, 21.04 mmol) was added to a solution of $(NH_4)_2MoO_2S_2$ (1.2 g, 5.26 mmol) in DMF (30 mL) and stirred for 1.5 h. Afterwards, $H_2NNH_2 \cdot 2HCl$ (0.3 g, 2.86 mmol) and Et_4NBr (1.5 g, 7.14 mmol) were added to the solution which was stirred another 4.5 h. The solution was filtered, and the filtrate was layered with 50 mL isopropanol, then left undisturbed at −15 °C for several days. The dark orange precipitate was filtered and recrystallized from MeCN/ether. Dark orange analytically pure crystals were obtained; 1.15 g, yield 44%. Correct analyses were obtained.

2: Following the procedure for **1** $(NH_4)_2WO_2S_2$ (2.0 g, 6.3 mmol), sulfur (0.81 g, 25 mmol), $H_2NNH_2 \cdot 2HCl$ (0.50 g, 4.8 mmol), and Et_4NBr (2.0 g, 9.5 mmol) provided orange-red analytically pure crystals; 0.81 g, yield 22%. Correct analyses were obtained.

An Unusual Interplay Between Macromolecular and Supramolecular Helicity in Polyisocyanates Dissolved in a Chiral Liquid Crystal

By *Mark M. Green,* Dexi Weng, Wen Shang,* and *M. M. Labes*

The stiff and wormlike nature of the widely studied poly(alkyl isocyanates) arises from their stable helical conformations, of which both helical senses are equally populated.[1] In this report we show that the observed change of pitch caused by the dissolution of small amounts of an optically inactive poly(alkyl isocyanate) in a doped, cholesteric liquid crystal can be explained by the surprising induced excess of one helical sense in the polymer caused by the chiral arrangement of the liquid crystal.

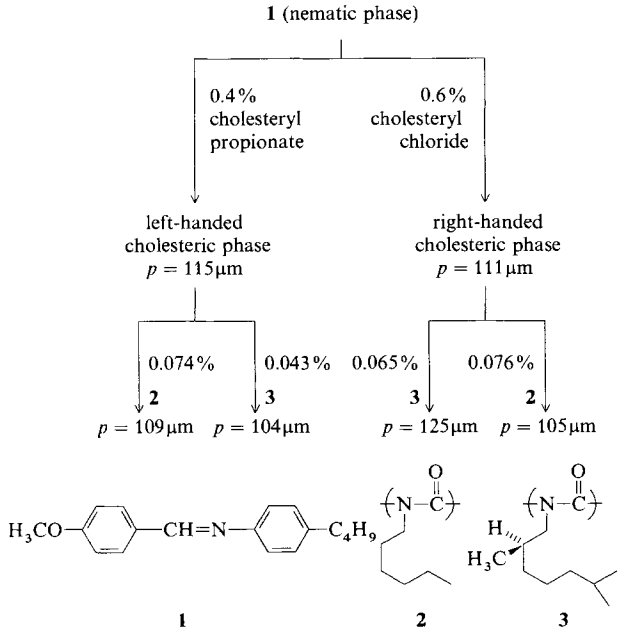
[**] We are grateful to the U.S. National Science Foundation for financial support for the work at Temple University and the Polytechnic University under grants DMR 89-17833 and CHE 90-02536 respectively. Efforts at the Polytechnic University were also aided by financial support from IBM corporation (Almaden Laboratory) and by the Petroleum Research Foundation administered by the American Chemical Society.

The thermotropic nematic *N*-(4-methoxybenzylidene)-4-*n*-butylaniline (**1**) is known to form cholesteric phases with left- or right-handedness upon addition of cholesteryl propionate or cholesteryl chloride respectively.[2] At low concentrations the pitch of the cholesteric array, defined as the vertical distance over which the molecular axis precesses by 360°, is inversely proportional to the concentration of chiral dopant. Scheme 1 shows the effect of the addition of polymeric solutes on the pitch of such cholesteric phases. Small



Scheme 1. Influence of polyisocyanates **2** and **3** on the pitch of doped cholesteric **1**; added quantities in wt%.

amounts of either poly(*n*-hexyl isocyanate) (**2**) or poly((*R*)-2,6-dimethylheptyl isocyanate) (**3**) were added. The data presented in Scheme 1 demonstrate that addition of the optically inactive polymer **2** causes a large decrease in the pitch of both the right- and left-handed cholesteric phases. Addition of the optically active polymer **3** has opposite effects in the oppositely handed cholesteric phases. Varying the concentrations of all the polyisocyanate dopants causes an approximately linear response in the inverse pitch of the cholesteric phases in accord with theory (Fig. 1). Hardly any change in pitch can be detected on addition of atactic polystyrene of two molecular weights (Fig. 1).

The effect of the optically active polyisocyanate **3** on the pitch characteristics of the cholesteric phase of **1** follows from the stereocenter in the side chain, which causes the polymer backbone to adopt a uniform left-handed helical conformation.[3, 4] Chiral nonracemic molecular additives, of which **3** is a rare polymeric example,[5] are known to both alter the pitch of cholesteric phases and to convert nematic to cholesteric phases.[6] Our experiments illustrate this effect; the handedness of **3** is either compatible or incompatible with the left- and right-handed cholesteric phases (Fig. 1).

To be consistent with the effect of the left-handed macromolecular helix of **3**, poly(*n*-hexyl isocyanate) (**2**) should maintain an excess of helices with the opposite handedness in their macromolecular backbones in the two cholesteric phases, i.e. left- and right-handed macromolecular helices for **1** doped with cholesteryl propionate and cholesteryl chloride, respectively (Scheme 1). This would require the cholesteric phase to break the energetic degeneracy of the left- and right-handed

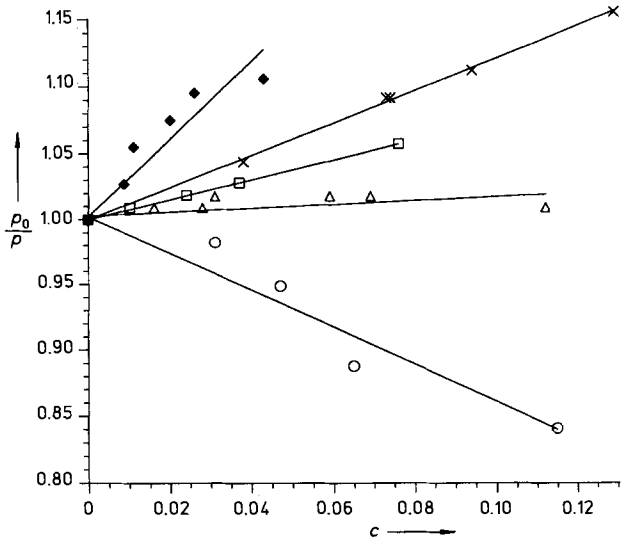


Fig. 1. Relationship between pitch p and concentration c [wt%] of the dissolved polymer in right-handed **1** (doped with 0.6% cholesteryl chloride, CC) and in left-handed **1** (with 0.4% cholesteryl propionate, CP). p_0 = pitch at $c = 0$. ○ = CC/**1**/**3**; □ = CC/**1**/**2**; • CP/**1**/**3**; × CP/**1**/**2**; △ = CP/**1**/polystyrene.

helical conformations of the added **2**, thereby favoring the macromolecular helical state which "fits" best into the supramolecular helix of the cholesteric phase.

In principle this result is not surprising, since one could expect the interaction of the chiral cholesteric phase with the enantiomeric helices of poly(*n*-hexyl isocyanate) to enforce the prerequisite diastereomeric relationship. Nevertheless the sensitivity of the polyisocyanate to the macroscopic chirality of the cholesteric phase is astonishing. For a pitch of a thermotropic cholesteric phase of about 100 μm, as we have here, the twist between contiguous molecules along the cholesteric helical axis is roughly 0.001°. Even if the polymer chain were extended fully along the helical axis of the cholesteric liquid crystal it would only traverse approximately 500 Å (molecular weight 35000),[1] which would correspond to only about a 0.2° turn of the director of the molecules **1** along the cholesteric helical axis. Although the local arrangements of the mesogenic molecules can therefore hardly be distinguished from the achiral nematic state, this is apparently adequate to change the ratio of the left- and right-handed helical states of the poly(*n*-hexyl isocyanate) (**2**). Moreover the displacement of this ratio of macromolecular helical senses must be considerable when one compares the effect of **2** on the pitch to that of the optically active polyisocyanate **3**, which is fully left-handed (Fig. 1).[3, 4]

Since the monomer units between the rarely occurring helix reversals in a poly(*n*-hexyl isocyanate) must take the same helical sense, cooperative interactions arise,[4] which amplify the tiny chiral perturbations per monometer unit. Such cooperativity is responsible for the large disproportionate displacement in the ratio of the helical senses which has been observed experimentally for unusually small chiral influences built into the side chains of these polymers. Although this phenomenon[4, 7] must be at work here it is not the only factor, since analogous pitch changes are observed in oligophenyls, including substituted biphenyls,[8] which share the dynamic racemic quality though not the cooperativity of poly(*n*-hexyl isocyanate).

Although the chiral enforcement of the twist necessary to convert the nematic to the cholesteric phase has been treated theoretically,[9] to our knowledge there is no work on the chiral forces inherent in the cholesteric phase, or for that mat-

ter in the chiral smectic C phase, which could explain the phenomenon reported here.

The observation of these effects in both the substituted oligophenyls[8] and in the polyisocyanates suggests that a wide structural range of dynamically racemic materials may be subject to, and in turn affect, the chiral properties of cholesteric or other twisted liquid crystal states.[8, 10–12]

Experimental Procedure

Poly(*n*-hexyl isocyanate) (**2**) has an average molecular weight of 35000 determined by viscosity and a polydispersity of 1.31 determined by gel permeation chromatography. Poly((*R*)-2,6-dimethylheptyl isocyanate) (**3**) was determined by light scattering to have an average molecular weight of 250000 with unknown polydispersity. Both polyisocyanates were judged soluble in mesogenic **1** by careful inspection of samples under the optical microscope. The solubility of **3** was further confirmed on filtered samples subjected to quantitative analysis by gel permeation chromatography. The two samples of polystyrene had molecular weights of 3050 and 9200.

In the procedure for determining pitch the "fingerprint texture" of aligned cholesteric liquid crystals was observed and measured between crossed polars on a polarization microscope. The thin samples were treated so that the helix axis was parallel to the glass slides. Cholesteryl chloride, cholesteryl propionate, and **1** were obtained from Aldrich or Eastman Kodak, The measurement technique is described in reference [8].

Synthesis and Reactions of Isothiocyanate-Substituted Allenes and 1,3-Butadienes**

By *Klaus Banert,** *Holger Hückstädt,* and *Kai Vrobel*

Dedicated to Professor Adalbert Maercker on the occasion of his 60th birthday

The isomerization of allyl thiocyanate (**1**) to allyl isothiocyanate (**2**) has been thoroughly investigated[1] and is interpreted as a [3,3]-sigmatropic rearrangement.[2] Attempts to transform propargyl thiocyanates of type **3**[3,4] into isothiocyanates analogously by heating gave only decomposition and polymerization products.[3] We now report an isomerization reaction that for the first time provides access to the highly reactive allenyl isothiocyanates **4** and the isothiocyanate-substituted 1,3-butadienes **18**, **22**, and **25**.

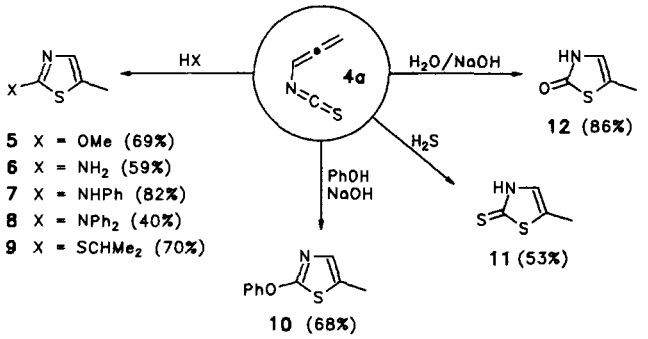
[**] Rearrangement Reactions, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Mrs. E. Reissaus for her cooperation.

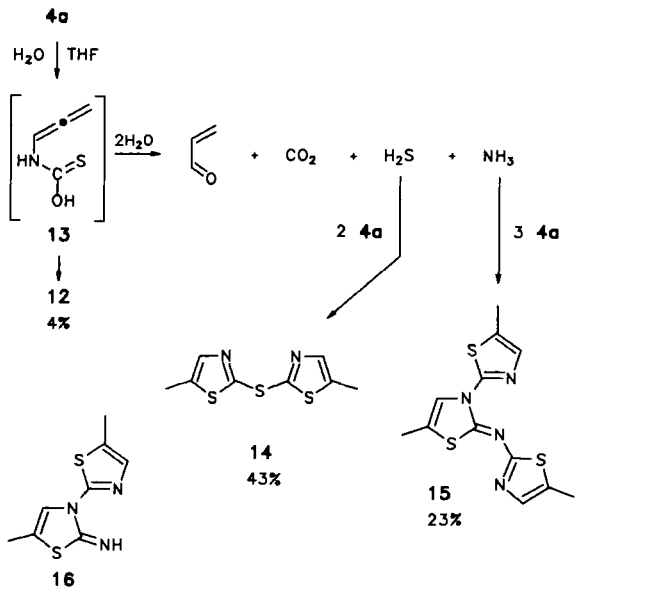
If compounds **3** are warmed to 60–100 °C not as isolated substances,[3] but in dilute solution, they undergo [3,3]-sigmatropic rearrangement to afford the cumulenes **4**. The yields are limited to 7–20% by subsequent polymerization reactions. A much more effective synthesis strategy for **4** is gas-phase thermolysis;[5] for example, **4a** can be obtained in 95–100% yield from **3a** (98% conversion) in a maximum daily yield of 1 mol (for characterization, see Table 1).

In spite of their pronounced tendency to polymerize, the isothiocyanates **4** react with oxygen-, nitrogen-, or sulfur-containing nucleophiles to afford good yields of thiazoles (Scheme 2).[6] In some cases the transformations are highly



Scheme 2. Conversion of **4a** into thiazoles with nucleophiles.

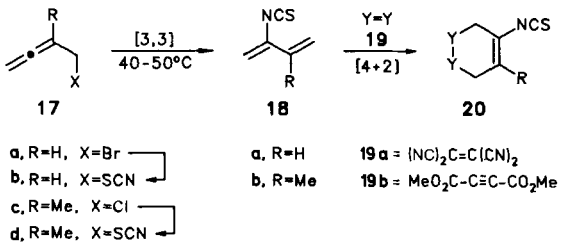
exothermic. Compound **4a** is extremely reactive, as is exemplified by its conversion into **8** with diphenylamine at room temperature. Phenyl isothiocyanate is attacked by this weak nitrogen nucleophile only at 280 °C.[7] Whereas normal isothiocyanates react so slowly with water that they can be purified by steam-distillation, **4a** forms the heterocycles **12**, **14**, and **15** in water/THF (1:2) at room temperature already (Scheme 3). These products are possibly derived from the



Scheme 3. Conversion of **4a** into **12**, **14**, and **15**.

intermediate **13**, which can not only cyclize to afford **12**, but as a labile thiocarbamic acid can also decompose to acrolein, carbon dioxide, hydrogen sulfide, and ammonia. The latter two compounds are more nucleophilic than water and subsequently react with **4a** to afford the major products **14** and **15**.

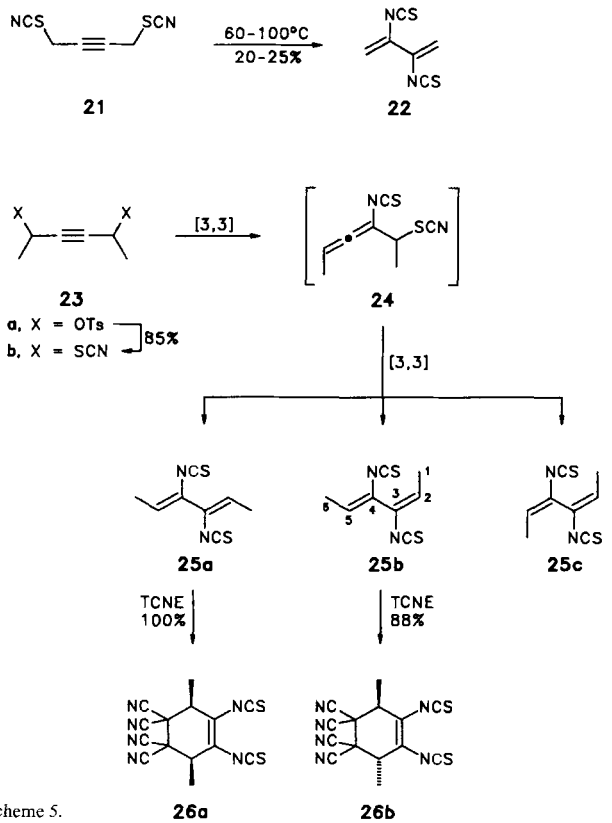
In accord with this reaction pathway, **14** may be prepared in higher yields (77%) from **4a** and H_2S/H_2O or in 99.6% yield from **4a** and **11**. Similarly, the synthesis of **15** takes place from **4a** and less than stoichiometric quantities of aqueous ammonia (88% yield) or from **4a** and **6** (90%). The intermediate for these reactions (**16**) can be isolated.



Scheme 4. Yields: **17b**, 80%; **17d**, quantitative; **18b**, 69% based on **17c**; **20**, 70% based on **17b** and **19a**, 80% on **18b** and **19a**, and 88% on **18b** and **19b**.

Not only propargyl thiocyanates, but also the 2,3-butadienyl thiocyanates **17b** and **17d**, easily accessible from the respective precursors **17a**[8] or **17c**[9] and ammonium thiocyanate, are suitable reactants for rearrangements that direct the isothiocyanate function to a vinylic position. The products are 1,3-dienes (**18**), which undergo [4 + 2]-cycloadditions with the reactive dienophiles **19** (Scheme 4).

Heating of a dilute solution of **21**[10] causes a double [3,3]-sigmatropic isomerization to give **22**, whose yield is limited by subsequent, very rapid polymerization. The instability of the rearrangement product **22** may be the reason why only decomposition occurred on attempts to distill **21**.[10] The chromatographically separable hexadienes **25** are simpler to handle, and their precursor **23b** is easily accessible from ammonium thiocyanate and **23a**.[11] Already on distillation



Scheme 5.

(90 °C/0.001 Torr) **23b** affords the products **25a–c** in almost statistical 1:2:1 distribution (67% yield). If the distillation is conducted at 180 °C/26 mbar, the thermodynamically favored *Z,Z* isomer **25a** predominates (56% yield of **25**, 8:1:1 distribution). Apparently at least the second rearrangement step, **24** → **25**, is reversible at higher temperatures.

As anticipated, on treatment with tetracyanoethylene (TCNE) **25a** reacts considerably faster to **26a** than its stereoisomer **25b** to the cycloadduct **26b**.

Isothiocyanate-substituted 1,3-butadienes can be used as well as the allenes **4** for the synthesis of thiazoles, but also for the preparation of other heterocycles.

Zinc Pyrazolylborate Complexes Relevant to the Biological Function of Carbonic Anhydrase**

By *Adrian Looney, Gerard Parkin,* Ralf Alsfasser, Michael Ruf,* and *Heinrich Vahrenkamp**

The zinc enzyme carbonic anhydrase, which is present in red blood cells, is a biological counterpart of hemoglobin, since it provides for efficient removal of the respiratory product CO_2 by catalyzing the equilibrium between carbon dioxide and bicarbonate [Eq. (a)].[1]

$$CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+ \qquad (a)$$

Numerous studies have revealed the molecular structure and function of the enzyme, its modification, and inhibition.[2] Although details of the active site of the enzyme, consisting of a tetrahedral zinc center coordinated to three histidine imidazole groups and a water molecule $[His_3Zn(OH_2)]^{2+}$, have been determined by X-ray diffraction, it has not proven possible to crystallographically characterize either the enzyme–substrate (i.e. CO_2) complex or other intermediates of the catalytic cycle. As such, mechanistic suggestions concerning the catalytic pathway, which have invoked species with zinc-bound H_2O, OH^-, and HCO_3^- as reactive intermediates, have been guided by kinetic, spectroscopic, and theoretical studies only.[3]

Model studies with simple zinc compounds have been hampered by the difficulty of obtaining low-coordinate aqua- or hydroxozinc complexes;[4] Kimura's recent work is a notable exception.[5] However, using the highly substituted pyrazolylborato ligand HBL_3^- (L = 3-*tert*-butyl-5-methylpyrazolyl), we have recently been able to prepare and structurally characterize the first mononuclear tetrahedral hydroxozinc complex **1**.[6] This complex structurally mimics the $[His_3Zn–OH]^+$ moiety, which has been suggested as the active state of carbonic anhydrase. The hydroxide **1** appears to be well-suited for model reactivity studies related to the function of the enzyme, as borne out by our observations reported here.

Solutions of **1** in benzene react instantaneously with CO_2 resulting in an equilibrium mixture of **1** and a compound tentatively assigned as the hydrogencarbonato complex **2**, which is characterized by ν(CO) absorptions at 1675 and 1302 cm^{-1} in the IR spectrum. The reversibility of this reaction has been confirmed; removal of the CO_2 atmosphere results in rapid regeneration of the hydroxide **1**. In view of this facile interconversion, attempts to isolate the complex **2** as a crystalline solid were performed under CO_2 atmosphere. However, due to its lower solubility, the crystalline product that was isolated under these conditions was the dinuclear carbonato complex **3**. Complex **3** contains a bridging carbonato ligand and is characterized by ν(CO) absorptions at 1587 and 1311 cm^{-1} in the IR spectrum, which differ significantly from those observed for **2**, and a resonance at $\delta = 164.0$ in the ^{13}C NMR spectrum in C_6D_6. The molecular structure of **3** has been confirmed by X-ray diffraction.[7] While it is not unusual for hydroxo complexes to react with CO_2 to form carbonato complexes,[8] this is the first report of a carbonatozinc complex prepared by such a method. Furthermore, the role of the carbonate ion as a bis(unidentate) bridging ligand is also unprecedented.[8, 9]

In view of the lability of the hydrogencarbonato complex **2**, we have explored other methods to isolate a stable analogue. Thus, the methylcarbonato complex **4** was successfully obtained by treatment of the hydroxo complex **1** with dimethylpyrocarbonate as reagent and solvent. The molecular structure of the complex **4** was also determined by X-ray diffraction.[7] Five- and six-coordinate alkylcarbonatozinc complexes have been described previously,[10] but **4** is the first example with tetrahedral coordination and also an excellent structural model for the hydrogencarbonato complex **2**. The structural details of the [Zn-OCO_2] moiety close-

Sloan Research Fellowship (1991–1993) and a Camille and Henry Dreyfus Teacher–Scholar Award (1991–1996). We thank S. Trofimenko, Du Pont, for making the synthesis of the tris(pyrazolyl)borato ligand accessible to us.

ly resemble those of both the dinuclear carbonato complex **3** and the related acetatozinc complex $[\{\eta^3\text{-}HBL_3\}Zn(\eta^1\text{-}OCOCH_3)]$ (L = 3-*tert*-butylpyrazolyl).[11] Furthermore, the similarity of the IR stretching frequencies of **2** (1675 and 1302 cm^{-1}) and **4** (1689 and 1297/1280 cm^{-1}) furnishes good evidence for an analogous coordination mode.

The hydrogencarbonato complex **2**, carbonato complex **3**, and methylcarbonato complex **4** are rapidly hydrolyzed by water in organic solvents to the hydroxo complex **1**. This observation is particularly significant since facile displacement of bicarbonate and the regeneration of the hydroxozinc species is a critical step in the proposed catalytic cycle for carbonic anhydrase.

5a: X = Cl
5b: X = N_3
5c: X = CN

The pyrazolylboratozinc system in **2**, **3**, and **4** models the proposed action of carbonic anhydrase and also imitates the inhibition of carbonic anhydrase activity that is observed in the presence of small anions. Thus, methanol solutions of the hydroxo complex **1** react rapidly with chloride, azide, and cyanide salts, resulting in displacement of the hydroxo ligand and formation of the neutral complexes **5a–c**, which were characterized by spectra and analyses. However, the most well-known inhibitor of carbonic anhydrase, acetazolamide,[12] did not react with **1**.

These experiments indicate the close structural and chemical similarity that exists between the pyrazolylboratozinc system and the carbonic anhydrase enzyme system. In particular, the zinc-bound hydroxo ligand in **1** is observed to be both an efficient nucleophile and good leaving group, and the hydrogencarbonato ligand in **2** is labile, thereby fulfilling the prerequisites for catalytic turnover. The facile interconversions between these complexes provide the first functional model of carbonic anhydrase activity.

Crystal and Solution Structures of the Novel Complex of Sodium Ketimide with Two Ketimine Ligands $[(tBu_2C{=}NNa)_4(HN{=}CtBu_2)_2]$: Stacking of Complexed and Uncomplexed $(NNa)_2$ Rings to give a Highly Distorted $(NNa)_4$ Cubane**

By *William Clegg, Murray MacGregor, Robert E. Mulvey,** and *Paul A. O'Neil*

Lithium ketimides $(R^1R^2C{=}NLi)_n$ have proved to be valuable compounds in two respects. Firstly, they provide a convenient source of free ketimine anions $(R^1R^2C{=}N)^-$ for transfer to other metal and metalloid centers in metathetical reactions.[1] Secondly, their crystal structures serve as models for the ring stacking in lithium structural chemistry.[2] The XLi compounds (X = e.g., alkyl, aryl, enolate, halide) form small, single $(XLi)_n$ ring units which maximize their electrostatic (attractive) contacts in face-to-face stacking arrangements. Hexameric lithium ketimides form stacks of two trimeric $(R^1R^2C{=}NLi)_3$ rings.[3] Prior to the work described

here, monometallic sodium ketimide chemistry[4] was represented by a single report from 1934 on ammonia-contaminated $(Ph_2C{=}NNa)_n$ characterized by N, Na-microanalysis;[5] this preempted the first lithium ketimide study[6] by over thirty years. We investigated the metallation reaction of the ketimine $tBu_2C{=}NH$ with nBuM (M = Li, Na) [Eq. (a)].

$$n\text{BuM} + t\text{Bu}_2\text{C}{=}\text{NH} \rightarrow {}^1/_n\,(t\text{Bu}_2\text{C}{=}\text{NM})_n + n\text{BuH} \qquad \text{(a)}$$

For M = Li the metallation proceeds as expected giving crystalline $(tBu_2C{=}NLi)_6$ in nearly quantitative yield.[7] Reaction mixtures having excess ketimine afford the same solid product. In contrast, when M = Na, two products are detectable: a yellow amorphous material (the major product) which is still under investigation[8] and a few crystals of **1**, an unexpected complex of ketimide and nonmetalated

$[(tBu_2C{=}NNa)_4(HN{=}CtBu_2)_2]$ **1**

ketimine. We suspect the reaction stoichiometry was not exactly 1.0:1.0, since the purity of the nBuNa reactant, freshly prepared from nBuLi and tBuONa,[9] though high, fell short of 100%. Hence, a trace excess of ketimine is available to complex two Na^+ cations in **1**. On deliberately increasing the nBuNa:$tBu_2C{=}NH$ ratio to 1.0:1.5, consistent with the metal:ligand ratio in **1** (4:6), no amorphous material is produced and the yield of **1** (first batch, 46%) is greatly enhanced.

The crystal structure of **1** (Fig. 1)[10] displays a cubane-like (imido-N-Na)$_4$ core. This structure is made up of a stack of complexed and uncomplexed $(NNa)_2$ rings with tetra-

(Na(1),(Na(2)) and tricoordinate (Na(3),Na(4)) sodium, respectively. To optimize stacking the ketimine nitrogens (N(5),N(6)) lie approximately in the same plane as the complexed ring; the N(4)Na(1)N(5) and N(1)Na(2)N(6) bond angles are close to 90°. Complexation weakens the intramolecular ring bonding, expanding the Na(1)N(2)Na(2)N(3) face (perimeter 9.814 Å; cf. 9.224 Å for the uncomplexed Na(3)N(1)Na(4)N(4) face). The deviation from an ideal cube is most pronounced at the Na(4) corner resulting in the shortest N-Na edge lengths for those bonds with Na(4) (sum, 6.853 Å, cf. 6.988 Å for the related Na(3) corner). This strong distortion brings Na(4) into close proximity with a tBu hydrogen atom. Without independently refined hydrogen positions we cannot comment on the significance of this feature except to note that assuming normal tBu C-H geometries, the calculated H···Na length would be remarkably short (2.186 Å). Triply bridged by Na atoms, each imido N center exhibits pseudotetrahedral coordination. The remaining N centers (N(5),N(6)) belonging to nonmetalated ketimine molecules (i.e., retaining acidic N-H bonds) act as monodentate, terminal Lewis bases to two of the four Na^+ ions (Na(1),Na(2)). This is the first example of ketimine → alkali-metal dative bonding. The structure most similar to **1** is the pinacolone-solvated sodium enolate of pinacolone, but even here its $(ONa)_4$ cubane core is solvated by four rather than two molecules which could potentially be metalated.[11]

Evidence that **1** remains intact in [D_8]toluene solution over the wide temperature range examined (193–298 K) comes from ^{1}H NMR spectroscopic studies. The spectrum at 193 K shows the two ketimine (NH) protons downfield (δ = 9.09) and four distinct types of tBu resonances (δ = 1.39, 1.35, 1.03, 0.81) with intensity ratios (36:36:18:18) in agreement with the crystal structure. The first two tBu signals which overlap can be assigned to ketimido ligands associated with N(2),N(3) in the complexed ring (36H) and with N(1),N(4) in the uncomplexed ring (36H). The remaining signals are attributed to the two magnetically nonequivalent tBu groups (18H + 18H) on each (identical) ketimine molecule and are a result of the rigid attachment of the C=N(5)H and C=N(6)H units to the Na(1)N(2)Na(2)N(3) ring. The spectrum at 298 K similarly shows four tBu resonances. Thus both X-ray crystallographic studies and ^{1}H NMR spectroscopic studies confirm the presence of (ketimine)-N–Na donor–acceptor contacts. This is an important distinction from the structural chemistry of organolithium compounds, since Li^+ cations in $(tBu_2C{=}NLi)_6$ resist complexation by stronger donors.[7]

Experimental Procedure

1: An equimolar amount of $tBu_2C{=}NH$ added to a chilled heptane suspension of nBuNa under argon gave an insoluble yellow solid and a yellow solution. The solution was refrigerated (−30 °C) and large yellow crystals identified as **1** formed; 4% yield of first batch (based on ketimine consumption). From the reaction with the 1.0:1.5 molar ratio a 46% yield of **1** was obtained. M.p. = 91–93 °C; satisfactory C,H,N,Na-analyses. Compound **1** decomposes in contact with moisture or oxygen but is nonpyrophoric. Single crystals suitable for X-ray crystallography were sealed under argon in Lindemann capillary tubes prior to data collection.

Unusual Coordination of the 1,3-Diphosphacyclobutadiene Derivative $(i\mathrm{Pr_2NCP})_2$ to Two $[Ni(CO)_3]$ Fragments**

By *Joseph Grobe,* Duc Le Van, Marianne Hegemann, Bernt Krebs,* and *Mechtild Läge*

The chemistry of the phosphaalkynes RC≡P contains many surprises, as the investigations of recent years have shown.[1] In particular, studies on reactivity of *tert*-butylphosphaethyne have uncovered many new aspects in organophosphorus and complex chemistry.[2] Yet phosphaalkyne derivatives with donor or acceptor substituents have hardly received any attention.[1,3] We report here an unexpected reaction of the only recently synthesized di(isopropyl)aminophosphaethyne $i\mathrm{Pr_2NC{\equiv}P}$ (**1**)[4] with tetracarbonylnickel.

On dropwise addition of **1** to a solution of $[Ni(CO)_4]$ in ether, CO evolution is observed, and complex **2**, which contains two $[Ni(CO)_3]$ groups on one of the phosphorus atoms of the 1,3-diphosphacyclobutadiene ring, is formed as exclusive product (monitoring by IR during the reaction and by NMR afterwards).

$$2\ i\mathrm{Pr_2N\text{-}C{\equiv}P} + 2\ [Ni(CO)_4] \xrightarrow[-2CO]{20\,^\circ C} [(CO)_3Ni\{\eta^1\text{-}\mu_2\text{-}(i\mathrm{Pr_2NCP})_2\}Ni(CO)_3]$$
1 **2**

The composition and constitution of the ruby-red crystals of compound **2** were established by elemental analysis, IR and NMR (^1H, ^{13}C, ^{31}P) spectroscopy, and by X-ray structure analysis. The isopropyl groups are shown to be nonequivalent in the ^1H and ^{13}C NMR spectra, which suggests restricted rotation of the R_2N group about the PC–N bond. The sp^2-hybridized C atoms of the cyclic phosphorus ligand are magnetically equivalent; one of the $^1J(P, sp^2\text{-}C)$ couplings is only 3.8 Hz. Two signals of equal intensity are observed in the ^{31}P NMR spectrum ($\delta = 106.3$ and 94.2), and the $^2J(P,P)$ is remarkably small (9.0 Hz). The frequencies of the CO valence bands are ca. 30 cm^{-1} higher than those of the phosphanido-bridged carbonylnickel complexes $[(CO)_3Ni(\eta^1\text{-}\mu_2\text{-}PR_2)Ni(CO)_3]^-$ [5] and are best compared with the CO absorptions of a tricarbonylnickel–phosphaallene compound.[6]

The most important information on the unusual compound **2** is found in the crystal structure analysis.[7] In accord with the NMR and IR data, it shows that both $[Ni(CO)_3]$ fragments are bound to only one P atom (Fig. 1). In the heart

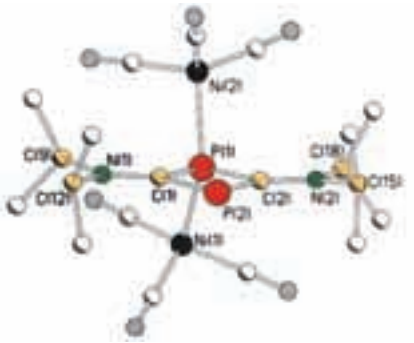

Fig. 1. Molecular structure of **2** in the crystal; important bond lengths [Å] and angles [°]: P(1)-C(1) 1.850(4), P(1)-C(2) 1.855(3), P(1)-Ni(1) 2.271(1), P(1)-Ni(2) 2.271(1), P(2)-C(1) 1.784(3), P(2)-C(2) 1.783(4), C(1)-N(1) 1.304(4), C(2)-N(2) 1.308(4); C(1)-P(1)-C(2) 77.8(2), Ni(1)-P(1)-C(1) 107.2(1), Ni(2)-P(1)-C(1) 109.0(1), Ni(1)-P(1)-C(2) 114.7(1), Ni(2)-P(1)-C(2) 111.3(1), Ni(1)-P(1)-Ni(2) 125.8(1), C(1)-P(2)-C(2) 81.4(2), P(1)-C(1)-P(2) 100.4(2), P(1)-C(2)-P(2) 100.3(2), N(1)-C(1)-P(1) 128.0(3), N(1)-C(1)-P(2) 131.6(3), N(2)-C(2)-P(1) 128.2(3), N(2)-C(2)-P(2) 131.4(3), C(1)-N(1)-C(9) 121.2(3), C(9)-N(1)-C(12) 116.2(3), C(1)-N(1)-C(12) 122.5(3), C(2)-N(2)-C(15) 122.2(3), C(2)-N(2)-C(18) 121.3(3), C(15)-N(2)-C(18) 116.4(3).

of the molecule all ten skeletal atoms of $-[C_2NCP]_2-$ lie in one plane (average deviation: 0.059 Å). This result indicates an extensively delocalized electronic system. The distances P1–C1 and P1–C2 are virtually the same and correspond to the length of a P–C single bond (1.85 Å). In contrast, the practically identical P2–C1 and P2–C2 distances (1.784 and 1.783 Å, respectively) result from a bond order greater than 1. The participation of the lone pairs of the $i\mathrm{Pr_2N}$ substituents in the resonance formulas is confirmed by both the planar environment and the marked shortening of the C1–N1 and C2–N2 bonds (1.304 and 1.308 Å, respectively). The Ni1–P1 and Ni2–P1 distances are equal (2.271 Å) and lie within the range expected for phosphanenickel complexes.

This interesting structure, and likewise the spectroscopic data, prove the presence of a delocalized π electron system. The bonding relationships are approximately represented by

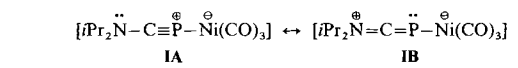
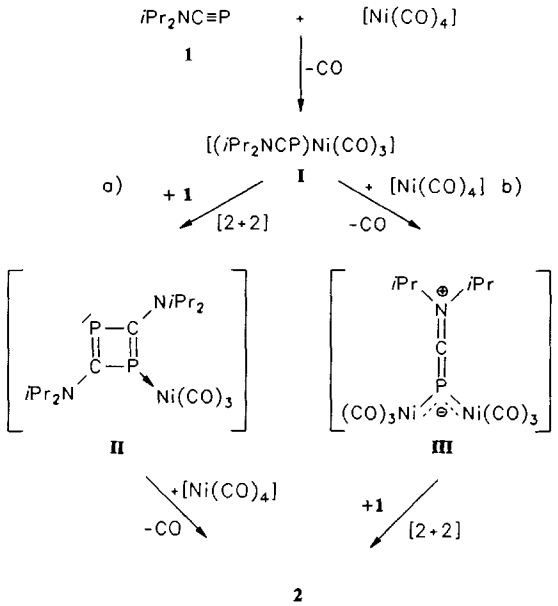
[**] Reactive E=C(p–p)π Systems, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 28: J. Grobe, D. Le Van, T. Grosspietsch, *Z. Naturforsch. B*, **1991**, *46*, 978–984.

the zwitterionic resonance formulas **2A** and **2C** and best described by formula **2B** ([Ni] = [Ni(CO)$_3$]).

This type of coordination of a 1,3-diphosphacyclobutadiene to complex fragments is hitherto unparalleled and documents the influence of the donor substituents NR_2 on the coordinating properties of phosphaalkyne **1**. Complex **2** forms so rapidly that not even IR and NMR spectroscopy can detect intermediates. Thus in principle several reaction paths are possible. Scheme 1 depicts the most probable



routes. Along route a, the mononuclear complex **I** postulated as primary product undergoes a [2 + 2]-cycloaddition with another molecule of **1** to form the 1,3-diphosphacyclobutadiene derivative **II**, which reacts with additional [Ni(CO)$_4$] to give the end product **2**. We favor route b in which the zwitterion **IB** that best represents the bonding situation in **I** forms intermediate **III** with [Ni(CO)$_4$]. This intermediate reacts with another molecule of **1** to yield the complex **2**. These proposals take account of the following



Scheme 1. Proposed routes for the formation of 2.

facts: a) Di(isopropyl)aminophosphaethyne (**1**) shows no tendency to cyclodimerize without activation.[4] b) The coordination of phosphaalkynes and alkynes to transition-metal complexes makes a [2 + 2]-cycloaddition possible.[8] c) *C*-amino substituted phosphaalkenes like $F_3CP{=}C(X)NR_2$ (X = F, OR) react with [Cr(CO)$_5$(thf)] via the isolable mononuclear complexes [(CO)$_5$CrP(CF$_3$)C(X)NR$_2$] to yield the dinuclear complexes [{(CO)$_5$Cr}$_2${P(CF$_3$)C(X)NR$_2$}] containing a 4e donor η^1-μ_2 bridge.[9, 10]

Experimental Procedure

To a solution of [Ni(CO)$_4$] (0.26 g, 1.5 mmol) in 10 mL diethylether was added dropwise at 20 °C in an argon atmosphere a solution of *i*Pr$_2$N–C≡P (**1**, 0.15 g, 1.0 mmol, in 10 mL ether). The reaction mixture was then stirred for 2 h at room temperature, the solvent removed under vacuum, and the residue taken up in ca. 20 mL *n*-pentane. The finely divided nickel which separated was removed in an inert atmosphere on a frit sealed with a 1 cm layer of silanized silica gel. The deep red filtrate was concentrated to 5 mL and stored at −30 °C. After three days the ruby red crystals of complex **2** were isolated. NMR studies of the reaction mixture showed that **2** was the only product of the quantitative reaction of **1**, but workup introduced considerable losses. The isolable yield was only 46%.

Spectroscopic data of **2**: IR (KBr), pentane: $\tilde{\nu}$ (CO) = 2063 (w), 2046 (s), 1991 (vs, br.), 1986 (vs, br.); ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C, TMS): δ = 1.09 (d, ^3J(H,H) = 6.50 Hz, 6H; CH$_3$), 1.33 (d, ^3J(H,H) = 6.94 Hz, 6H; CH$_3$), 3.29 (sept, ^3J(H,H) = 6.94 Hz, 1H; CH), 4.45 (dsept, ^3J(H,H) = 6.50 Hz, ^4J(P,H) = 2.68 Hz, 1H; CH); ^{31}P NMR (36.44 MHz, CDCl$_3$, 25 °C, 85% H$_3$PO$_4$): δ = 106.3 (d, ^2J(P,P) = 9.0 Hz), 94.2 (d, ^2J(P,P) = 9.0 Hz); ^{13}C NMR (75.43 MHz, CDCl$_3$, 25 °C, TMS): δ = 19.9 (s; CH$_3$), 20.4 (d, ^4J(P,C) = 14.8 Hz; CH$_3$), 51.6 (s; CH), 56.7 (d, ^3J(P,C) = 18.2 Hz; CH), 197.7 (d, ^2J(P,C) = 3.4 Hz; CO), 210.2 (dd, ^1J(P,C) = 3.8 and 56.1 Hz, sp^2-C).

Bicyclocalix[4]arenes**

By *Bettina Berger, Volker Böhmer,* Erich Paulus, Amado Rodriguez,* and *Walter Vogt*

Dedicated to Professor Hermann Kämmerer on the occasion of his 80th birthday

Exciting molecules have always caught the interest of chemists.[1] The ever-increasing attention that the calixarenes[2] are receiving[3] over and above the already realized practical applications is probably largely due to fascination caused by the structure of these compounds. Questions related to the conformation,[4–7] the mechanism of conforma-

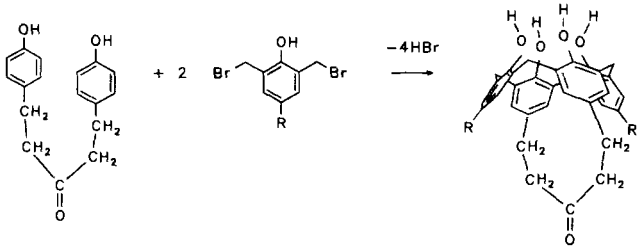
tional interconversion,[7-13] and the fixing of particular conformations by suitable derivatives[14,15] are main topics of experimental[7-9,12,13] and theoretical studies.[11]

If two *para* positions of opposite arene rings in calix[4]arenes are linked by an aliphatic chain,[16] the calix[4]arene system is fixed in the cone conformation. At least temperature-dependent ^{1}H NMR spectra give no indication of conversion to the partial cone or 1,3-alternate conformations, which are in principle still possible. Reinhoudt et al. synthesized similar compounds in which opposite *para* positions were linked by an oligoethyleneglycol chain.[10] In order to prepare these compounds and to increase their stability, the phenolic hydroxy groups were methylated, which increased the flexibility of this calixarene system in comparison to those with free hydroxy groups.[7,9] Here a mixture of the partial cone and cone conformations were found at lower temperatures. For the first time detailed information about the mechanism of conformational interconversion could be obtained from 2D-EXSY NMR spectroscopy (EXSY = chemical *ex*change *s*pectroscop*y*). The limited conformational possibilities (no 1,2-alternate conformation) were helpful in this case.[10]

We were interested in compounds like **3** in which two opposite *para* positions were linked by a methylene-1,3-(2-hydroxyphenylene)-methylene bridge. The additional macrocyclic system formed by the bridge is also a calix[4]arene; thus, molecules of this type can be classified as macrobicyclo- or simply as bicyclocalix[4]arenes.[17] We report here the first examples of such compounds.

Condensation of 1,5-bis(4-hydroxyphenyl)pentan-3-one (obtained by aldol condensation of *p*-methoxybenzaldehyde followed by catalytic hydrogenation of the double bond and ether cleavage) yields, analogously to the known synthesis of bridged calixarenes,[16] compounds with a keto group in the bridge (Scheme 1). The yields of the purified compounds **1**



Scheme 1. **a**: R = CH_3, **b**: R = $C(CH_3)_3$, **c**: R = *cyclo*-C_6H_{11}, **d**: R = C_8H_{17}

(not optimized for particular cases) previously lay between 5 (**1d**, R = *n*-C_8H_{17}) and 37% (**1b**, R = $C(CH_3)_3$). The cone conformation observed for the calixarene part of **1** was not necessarily anticipated, since a partial-cone conformation with intramolecular hydrogen bonds to the keto group is also conceivable. In solution this is deduced from the ^{1}H NMR spectra, which show two doublets for the protons of the methylene bridge independent of temperature, and in the crystalline state from the X-ray structure analysis of **1c** (R = *cyclo*-C_6H_{11}, Fig. 1a).[18] The short bridge orients the two connected phenol units almost parallel to each other. They form angles of 91.2 and 93.5° with the best plane through the carbon atoms of the methylene groups. The corresponding angles for the other phenol units are 137.5 and 157.9°. As Figure 1a shows, the carbonyl group of the bridge points to the side of the phenol group that bends further outward, and forms an angle of 30° with the other phenol unit. The very strong distortion of the cone conformation directs the OH groups of the bridged phenol units outward and those of the two other phenol units inward. Thus, in contrast to free calix[4]arenes, the OH region becomes so polar that layers are formed in the crystal lattice with OH regions directed toward each other. The hydroxy groups are arranged in such a way that besides the intramolecular hydrogen bonds, intermolecular hydrogen bonds cannot be entirely excluded. The weakening of the intramolecular hydrogen bonds (O–O distances 2.88, 3.11, 2.93, and 2.76 Å) relative to those in the nonbridged calix[4]arenes is reflected in their OH stretching frequencies, which lie between 3420 and 3480 cm^{-1}, clearly higher than usually found for calix[4]arenes (about 3150 cm^{-1}).[3]

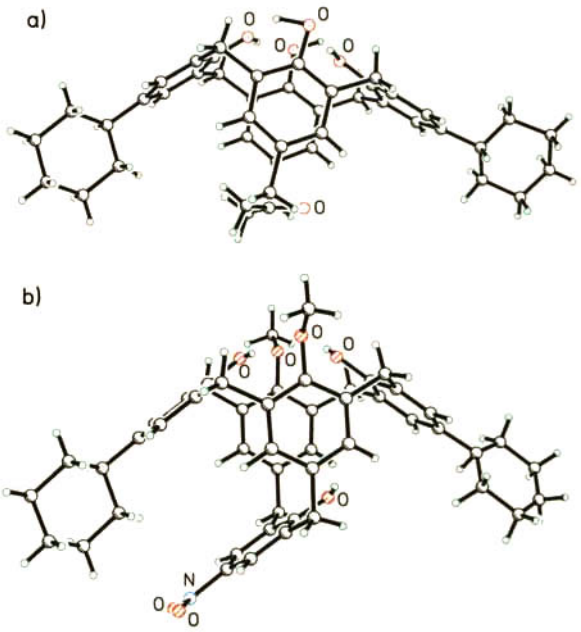


Fig. 1. a) Conformation of **1c** and b) **3b** in the crystal.

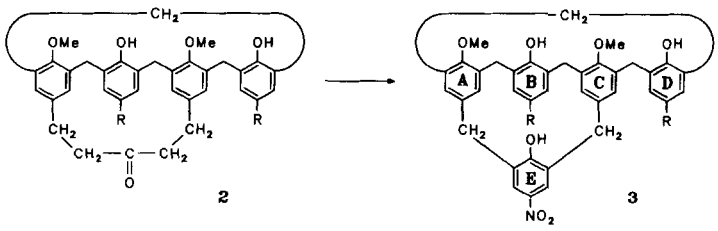
Whereas 1,5-bis(4-hydroxyphenyl)pentan-3-one (like other compounds with the same structural element) reacts smoothly with nitromalonaldehyde under alkaline conditions in a double aldol condensation to yield 2,6-bis(4-hydroxybenzyl)-4-nitrophenol,[19] the construction of a *p*-nitrophenol unit by the same reaction with compounds of type **1** is not possible. We suppose that under these strongly alkaline conditions **1** is present as tetraanion, in which the CH_2 group in α-position to the keto group is no longer CH-acidic enough. Methylation of **1** under mild conditions, even with an excess of methyl iodide, affords only the dimethyl ether **2** (a symmetric compound according to the ^{1}H NMR spectrum). However, this methylation of two hydroxyl groups is sufficient to permit the aldol condensation of **2** with nitro-



Scheme 2. **a** R = $C(CH_3)_3$, **b**: R = *cyclo*-C_6H_{11}.

malonaldehyde. The calixarenes **3** were prepared by this route with 60–70% yield of the purified compounds (Scheme 2).

The compound with R = *cyclo*-C_6H_{11} (**3b**) was characterized by X-ray structure analysis (Fig. 1b).[18] This showed that the methylation of **2** occurred at the two exposed hydroxyl groups of the bridged phenol units. Again, the original calix[4]arene system A-B-C-D is in the cone conformation. The relatively weak hydrogen bonds (O–O distances 3.00, 3.09, 2.96,and 3.12 Å) between the "*endo*" hydroxyl and methoxy groups are apparently sufficient to stabilize this conformation. The newly formed nitrophenol unit E is virtually parallel (7.3°) to one of the nonbridged phenol units, which shows that the CH_2–CO–CH_2 group hardly changed position or orientation on incorporation into the nitrophenol unit. The calix[4]arene systems with "*endo*" hydroxyl and "*exo*" methoxy groups (A-B-C-E and A-E-C-D) thus assume the 1,3-alternate or partial-cone conformation.

However, from the ^{1}H NMR spectrum of **3** in solution a conformation with (on average) C_{2v} symmetry may be deduced. The calix[4]arene part A-B-C-D is present in the cone conformation, which follows from the two doublets at about $\delta = 4.2$ and 3.25 for the Ar–CH_2–Ar methylene groups. The methylene groups on the nitrophenol unit give rise to a singlet ($\delta = 3.45$). One signal each is observed for the aromatic protons of the units D (nitrophenol), A/C (anisol), and B/D (phenol), for the methoxy and *tert*-butyl groups, and the OH groups of the B/D units (overlapping with the signal from the methoxy groups). Apparently the nitrophenol unit is mobile at room temperature and swings through the cavity of the calixarene like the clapper of a bell. As Figure 2 shows, this movement begins to freeze between −50 and −70 °C. At −90 °C two singlets are found for the aromatic protons of each of the units A/C (the *meta* coupling cannot be recognized because of line broadening) and B/D, for the OH groups on B/D, and for the *tert*-butyl groups. In the region between $\delta = 3$ and 4.4 six doublets for the three different (paired) methylene groups are expected in addition to the singlets for the methoxy and hydroxyl groups. Of these 14 signals, 12 are observed in the 200 MHz spectrum (Fig. 2).

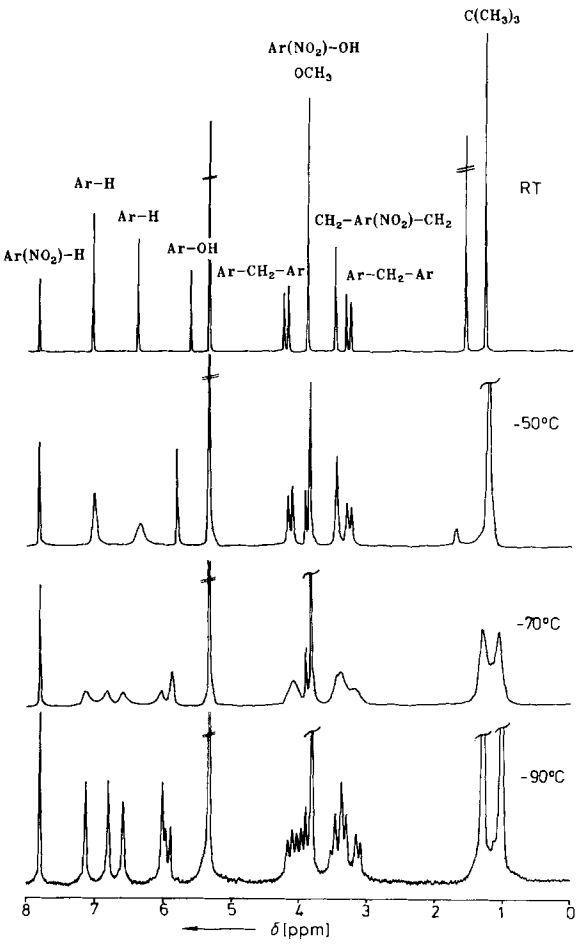


Fig. 2. Temperature dependence of the ^{1}H NMR spectra of **3a**, showing the different flexibilities of the calix[4]arene subunits (the signals for CH_2Cl_2 and H_2O are crossed through). RT = room temperature.

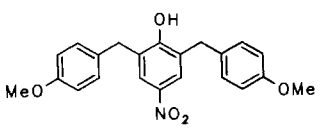
Due to the special situation in molecule **3**, differences in reactivity are expected for the OH groups of the *p*-nitrophenol unit in **3** and in the model compound, 2,6-(4-methoxybenzyl)-4-nitrophenol (**4**). In dioxane the absorption maximum of **4** undergoes a bathochromic shift from 312 to 332 nm on addition of triethylamine, which can be explained by a hydrogen bond between **4** and the amine.[20] On the other hand, the absorption maximum of **3a** at 318 nm (indicating perhaps a weakening of the OH group compared to **4**) is not shifted on addition of triethylamine in concentrations up to 2 M. Apparently the OH group is not accessible to the amine.

However, the cleavage of the proton from the nitrophenol unit is possible with alkali-metal hydroxides in dioxane/methanol (1:1). In the case of **4** the absorption maximum shifts from 322 nm to 425 nm in the presence of small concentrations of LiOH, but nothing else changes significantly if the LiOH concentration is increased to 0.1–0.2 M. The absorption maximum of **3a** ($\lambda_{max} = 322$ nm) also undergoes a strong bathochromic shift ($\lambda_{max} = 446$ nm) at low LiOH concentrations (2×10^{-4}–5×10^{-2} M), but in contrast to the behavior of **4**, an increase in LiOH concentration causes the opposite shift, to shorter wavelengths ($\lambda_{max} = 426$ nm, at [LiOH] = 0.1–0.2 M). In principle the same behavior is observed in the presence of KOH. Smaller differences in the changes in absorption coefficient, resulting perhaps from the size of the cation, should not be overemphasized. The spectroscopic findings thus show that a nitrophenolate ion also forms in the case of **3a**, but that it is less solvated than in **4**, a result which agrees with the molecular structure of **3a**. We are continuing to prepare other compounds of the type **3** in which the building blocks A and C, in particular, are replaced by resorcinol or phloroglucin, in order to make possible a ring of intramolecular hydrogen bonds in the calix[4]arene systems A-B-C-E and A-E-C-D as well.



4

Experimental Procedure

General procedure for the synthesis of **1**: 1,5-bis(4-hydroxyphenyl)pentan-3-one (5 mmol) and the appropriate *p*-alkyl-2,6-bis(bromomethyl)phenol (10 mmol) were dissolved in dry dioxane, $TiCl_4$ (25 mmol) was added, and the volume was increased to 500 mL. The mixture was heated at reflux for 100–140 h under an inert atmosphere (argon). The solvent was then removed in vacuum, and the red-brown residue was dissolved in CH_2Cl_2. Silica gel (50 g) was added to the solution, which was once again evaporated to dryness. The silica gel thus impregnated was extracted in a Soxhlet apparatus (this procedure was repeated once). Thereafter **1** could easily be isolated by flash chromatography without the column becoming clogged.

Physical data for **1b**: Colorless crystals (37%) from *n*-hexane, m.p. = 264–266 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.16 (s, 4H; ArH), 6.51 (s, 2H; ArOH), 6.45 (s, 2H; ArOH), 6.37 (s, 4H; ArH), 4.07 (d, J = 14.4 Hz, 4H; Ar-CH_2-Ar), 3.34 (d, J = 14.4 Hz, 4H; Ar-CH_2-Ar), 2.38 (m, 4H; Ar-CH_2-CH_2), 2.02 (m, 4H; CH_2-CO), 1.41 (s, 18H; *t*Bu); MS: *m/z* 618 (M^+, 100%), 561 (14).

Methylation: The bridged calixarene **1** (0.3 mmol) was heated with CH_3I (0.25 g, 1.8 mmol) and K_2CO_3 (0.25 g, 1.8 mmol) in dry acetonitrile (25 mL) for 24 h at reflux. The solution was cooled, acidified with dilute HCl, and shaken with $CHCl_3$. The organic phase was dried over $MgSO_4$, the solvent removed in vacuum, and the residue purified by flash chromatography (CH_2Cl_2).

Physical data for **2b**: Colorless crystals (80%), m.p. = 272–274 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.96 (s, 4H; ArH), 6.35 (s, 4H; ArH), 5.52 (s, 2H; ArOH), 4.23 (d, J = 13.7 Hz, 4H; Ar-CH_2-Ar), 3.84 (s, 6H; OCH_3), 3.26 (d, J = 13.7 Hz, 4H; Ar-CH_2-Ar), 2.5 (m, 2H; C_6H_{11}), 2.38 (m, 4H; Ar-CH_2-CH_2), 2.03 (m, 4H; CH_2-CO), 1.85 (m, 10H; C_6H_{11}), 1.35 (m, 10H; C_6H_{11}); MS: *m/z* 698 (M^+, 100%), 684 (47).

Reaction with nitromalonaldehyde: Dimethyl ether **2** (0.1 mmol) and sodium nitromalonaldehyde [21] (80 mg, 0.6 mmol) were suspended in ethanol (15 mL), and a solution of Na (20 mg) in ethanol (1 mL) was added at reflux. After some time the mixture became homogeneous. Forty-eight hours later more of the aldehyde (80 mg) was added, and after another 72 h, a further 40 mg. After a total of 120 h the solution was filtered hot, and the filtrate added dropwise to dilute HCl. The precipitate was purified by flash chromatography (silica gel 60/CH_2Cl_2) and finally recrystallized from hexane.

Physical data for **3b**: Colorless crystals (70%), m.p. = 220 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.82 (s, 2H; ArH), 6.83 (s, 4H; ArH), 6.35 (s, 4H; ArH), 5.57 (s, 2H; ArOH), 4.19 (d, J = 13.6 Hz, 4H; Ar-CH_2-Ar), 3.85 (s, 6H; OCH_3), 3.83 (s, 1H; ArOH), 3.44 (s, 4H; Ar-CH_2-Ar), 3.23 (d, J = 13.6 Hz, 4H; Ar-CH_2-Ar), 2.33 (m, 2H; C_6H_{11}), 1.77 (m, 10H; C_6H_{11}), 1.31 (m, 10H; C_6H_{11}); MS: *m/z* 779 (M^+, 74%), 761 (27).

[2] In a narrow sense calix[n]arenes are cyclic compounds in which n = 4 or more monovalent phenolic units coupled by methylene bridges *ortho* to the phenolic hydroxyl groups. The n OH groups are in *endo* positions. We use the name here generally for [1$_n$]-metacyclophanes with *exo* hydroxyl groups (cf. D. W. Chasar, *J. Org. Chem.* **1985**, *50*, 545–546), that is, also for cyclic tetramers obtained from resorcinol and aldehydes.[3] This is justifiable because lately calixarenes containing both *exo* and *endo* hydroxyl groups have been obtained. [17] The name makes clear that *all* macrocyclic ring systems in **3** have a calix[4]arene structure. A "bicyclophane" in which two 1,3,5-substituted benzene rings are linked, not by three 1,3-xylylene bridges as in **3**, but by three ethylene(1,4-phenylene)ethylene bridges was described for the first time byH.-E. Högberg, B. Thulin, O. Wennerström, *Tetrahedron Lett.* **1977**, *11*, 931–934.
[18] **1c**: Single crystals from CH_2Cl_2; $C_{45}H_{50}O_5 \cdot 2\,CH_2Cl_2$, M_r = 840.8, triclinic, $P\bar{1}$, a = 13.276(3), b = 13.615(1), c = 13.673(2) Å, α = 84.85(2), β = 63.51(1), γ = 82.33(2)°, V = 2190.9 Å^3, Z = 2, $F(000)$ = 888, ϱ_{calcd} = 1.274 Mg m^{-3}, μ = 2.85 min^{-1}, T = 293 K, R = 0.100, R_w = 0.0968 [4507 ($>1\,\sigma(I)$) of 4512 independent reflections], $w = 1/\sigma^2(|F|)$ according to the counting statistics, S = 5.53; $-13 \le h \le 13$, $-13 \le k \le 13$, $-13 \le l \le 13$, R_{int} = 0.066. **3b**: Single crystals from *n*-Hexan; $C_{50}H_{53}NO_{70}$ 1/4 C_6H_{14}, M_r = 801.5, tetragonal, $P4/n$, a = 22.239(5), c = 17.453(1) Å, V = 8631.8 Å, Z = 8, $F(000)$ = 3428, ϱ_{calcd} = 1.233 Mg m^{-3}, μ = 0.074 min^{-1}, T = 293 K, R = 0.22, R_w = 0.058 [7244 ($>1\,\sigma(I)$) of 7626 independent reflections], $w = 1/\sigma^2(|F|)$ according to the counting statistics, S = 1.30; $-26 \le h \le 18$, $-26 \le k \le 0$, $-20 \le l \le 0$, R_{int} = 0.0688. The coordinates of only the hydroxyl-hydrogen atoms were determined experimentally. The positions of the remaining hydrogen atoms were calculated and their isotropic temperature coefficients estimated according to the relevant sites. For all other atoms, coefficients of anisotropic temperature factors were used and subjected to refinement. In the last refinement cycle the largest parameter change was smaller than 3(1)% of the standard deviation, and the ten largest maxima of the final difference Fourier synthesis of the electron density lay between 0.28 (0.50) and 0.55 (0.55) e Å^{-3}. The reason for the large difference between R and R_w is that reflections down to 1σ were taken into account in the calculation. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-55724, the names of the authors, and the journal citation.

Three Independent Molecules in the Unit Cell of a Phosphorus Ylide; Changes in the Molecular Geometry on Rotation about the Phosphorus–Carbon Ylide Bond**

By *Hansjörg Grützmacher** and *Hans Pritzkow*

The π interaction between the phosphorus atom and the ylide carbon atom of a phosphorus ylide is described as negative hyperconjugation.[1] This interaction transfers electron density from the occupied p orbital on the carbon atom to the unoccupied σ* orbitals of the phosphorus–ligand (L,X) bonds (Scheme 1); d orbitals on phosphorus fulfill only a polarizing function.[2] The phosphorus–ligand bond in an eclipsed position to the p orbital (P–X) becomes weaker and therefore longer, while the corresponding X-P-C angle opens. The ylidic carbon atom has a pyramidal configuration and the substituents in the x,y plane at phosphorus and carbon assume a *trans*-bent conformation with respect to the P–C(ylide) bond.[3] These theoretical characteristics are

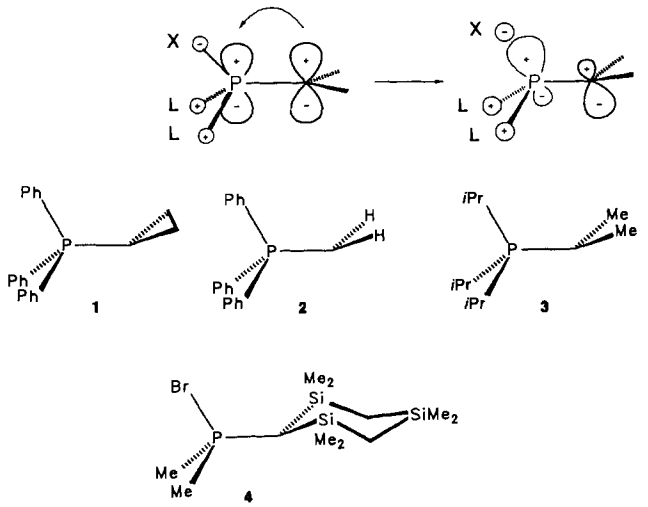
found in the molecular structures of ylides **1**,[4] **2**,[5] and **6**[6] reported in the pioneering work of Schmidbaur et al. (Scheme 1).



Scheme 1.

The phosphorus ylides of the type $R_2XP^+-CR'_2{}^-$ (X = halogen; R, R′ = alkyl, aryl)[7] should be excellent examples in which the above-mentioned characteristics can be studied, because the σ* orbital of the P–halogen bond is energetically low-lying and can accept electron density from the ylidic carbon atom particularly well. Indeed, Fritz, von Schnering et al. detected a dramatic lowering of the bond order of the P–Br bond (0.63) in brominated phosphorus ylide **4**.[8] We now report unambiguous, experimental findings that can be explained by negative hyperconjugation in phosphorus ylides.

The chlorinated phosphorus ylide **5**[9] precipitates from *n*-hexane in the form of yellow crystals. These crystals have three independent molecules, **5a**, **5b**, and **5c**, in the unit cell.[10] The essential difference between them lies in two directly related parameters: torsion about the P–C(ylide) bond and the P–Cl bond length (Fig. 1). In **5c** the p orbital at C1, which is perpendicular to the C4–C1–C5 plane, almost eclipses the P–Cl bond (deviation 7.2°). The P–Cl bond of the three molecules **5a–c** is longest in **5c** (2.235 Å; Table 1) and corresponds to a bond order of only 0.58 calculated by Donnay and Allmann's method.[11] In **5a** the deviation from an ecliptic arrangement is the largest (21.4°) and the P–Cl distance the shortest. The *trans*-bent orientation of the substituents at P1 and C1 becomes more pronounced as the P–Cl distance increases and as the p orbital of C1 and the

[a] In no molecule were the temperature factors for P1 and C1 unusual or of a different order of magnitude. [b] Distance of P1 from the plane defined by C1-C2-C3. [c] Distance of C1 from the plane defined by P1-C4-C5.

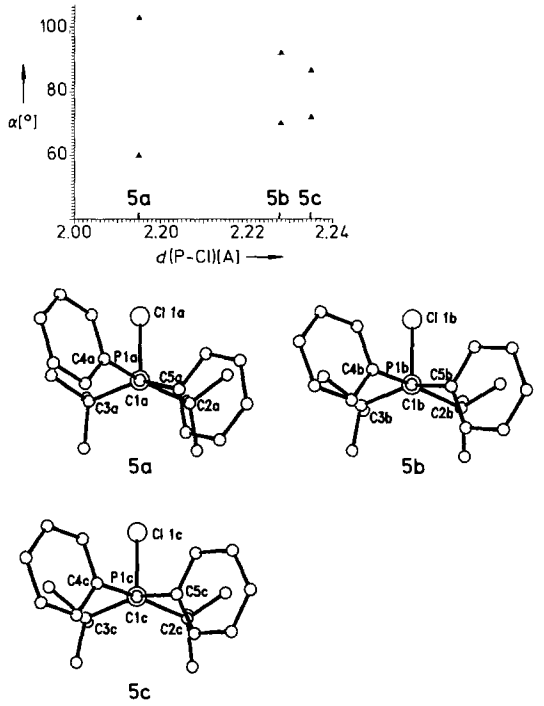

Fig. 1. Top: Plot of the torsion angles Cl1-P1-C1-C4 and Cl1-P1-C1-C5 (α, [°]) vs. the Cl1-P1 distance (*d*, [Å]); below: molecular structures of **5a**, **5b**, and **5c** viewed along the C1–P1 bond; selected bond distances and angles in Table 1.

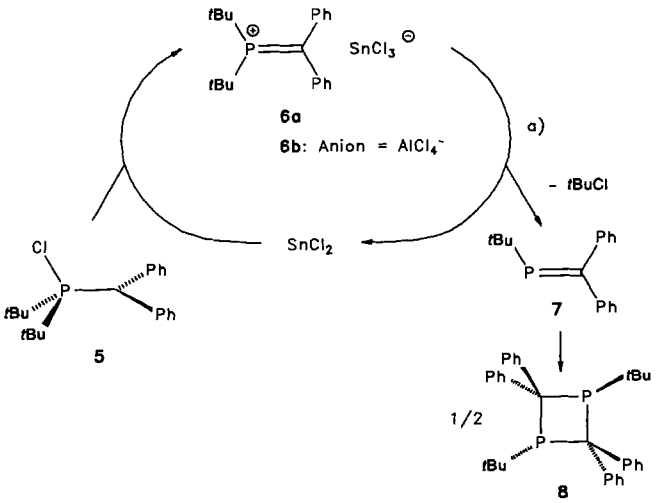
P–Cl bond approach an eclipsed conformation. The molecules **5a–c** correspond to rotamers about the P–C ylide bond on the energy surface. Their experimentally determined bonding parameters provide insights into the changes in molecular geometry in the course of this dynamic process and are in accord with the concept of negative hyperconjugation.

The weakening of the P–Cl bond allows even a relatively weak Lewis acid like tin dichloride to abstract a chloride ion from phosphorus ylide **5**. The methylenephosphonium ion **6a** that contains only hydrocarbon substituents can be isolated as a yellow solid by rapid workup of the reaction solution (Scheme 2). Compound **6b** was isolated with $AlCl_4^-$ as counter-ion in an analytically pure state and characterized



Scheme 2. a) $k = 7.3 \times 10^{-4}\ s^{-1}$, $t_{\frac{1}{2}} = 16$ min.

by NMR spectroscopy and a single-crystal X-ray structure analysis (Fig. 2).[10] The P1–Cl1 distance in **6b** (1.683 Å) is close to that in ylide **5** (1.666 Å) and comparable with the P–C distances in methylenephosphanes RP = CR'_2.[13] The longer P1–C1 distance in **6b** relative to the theoretically calculated 1.624 Å[14] may be attributed to steric hindrance, which is also responsible for the torsion angle of 20° about the P1–C1 bond. Both the carbon atom C1 and the phosphorus atom P1 have a nearly trigonal planar configuration [$\Sigma°$(C1) = 359.6°; $\Sigma°$(P1) = 359°]. The methylenephosphonium salt **6a** is not stable in solution (Scheme 2). It decomposes quantitatively according to a first-order rate law ($k = 7.3 \times 10^{-4}\ s^{-1}$; $t_{1/2} = 16$ min) to methylenephosphane **7** (to the best of our knowledge this compound has not yet been described), *t*BuCl, and $SnCl_2$.

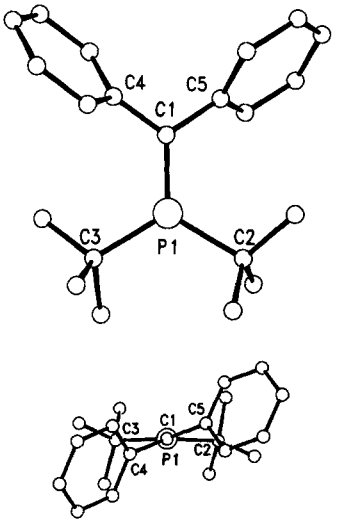


Fig. 2. Molecular structure of the methylenephosphonium cation **6b** in the crystal; selected bond distances and angles in Table 1.

The methylenephosphane **7** may be stored for some time at low temperatures as yellow oil. It was characterized by NMR spectroscopy. At room temperature the oil **7**—pure or in solution—dimerizes to 1,3-diphosphetane **8**. This novel reaction between **5** and $SnCl_2$ represents the first *catalytic* synthesis of methylenephosphanes, and is of preparative interest because the *P*-halogen phosphorus ylides are easily accessible. Studies on the scope of this reaction and its mechanism, in which methylenephosphonium ions[15] play a key role, are under way.

Experimental Procedure

A solution of compound **5** (1.73 g, 5 mmol) in dried and degassed CH_2Cl_2 (15 mL) was added dropwise from a syringe to a suspension of $AlCl_3$ (0.8 g, 6 mmol) in 10 mL CH_2Cl_2, at −78 °C. The resulting yellow solution was filtered immediately without warming and evaporated to dryness in vacuum. The yellow solid residue was suspended in 20 mL hexane and dissolved by adding CH_2Cl_2 (≈ 20 mL). At −30 °C long yellow needles of **6b** crystallize out. Compound **6b** is exceptionally sensitive in solution! **6b**: M.p. = 108–109 °C; $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 183.5; ^1H NMR (CD_2Cl_2): δ = 1.52 (d, $^3J(^{31}P, ^1H)$ = 19.1 Hz, 18H, CH_3), 7.24–7.64 (m, 10H, aromat. H); ^{13}C NMR (CD_2Cl_2): δ = 31.5 (s, CH_3), 49.9 (d, $^1J(^{31}P, ^{13}C)$ = 9.0 Hz, CCH_3), 129.5 (s, *meta*-C), 131.5 (d, $^3J(^{31}P, ^{13}C)$ = 15.1 Hz, *ortho*-C), 134.9 (s, *para*-C), 139.4 (d, $^2J(^{31}P, ^{13}C)$ = 7.4 Hz, *ipso*-C), 178.1 (d, $^1J(^{31}P, ^{13}C)$ = 73.6 Hz, P=C). **7**: $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 289.6; ^1H NMR ($CDCl_3$): δ = 1.01 (d, $^3J(^{31}P, ^1H)$ = 10.7 Hz, 9H, CH_3), 7.02–7.44 (m, 10H, aromat. Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Metals and Their Compounds in the Environment: Occurrence, Analysis and Biological Relevance. Edited by E. Merian. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. xxiii, 1438 pp., hardcover DM 380.00.—ISBN 3-527-26521-X

A person unaware of the problems associated with shortages of essential elements and with excesses of toxic elements is difficult to find. Even newspapers and magazines discuss (not always in the spirit of providing scientifically sound information) the effects of metals and metalloids (or more generally of trace elements) on the environment and on the health of man, animals, and plants. No one, not the common person, not the experts in medical, scientific and technical disciplines, and especially not the servants of the public at all levels of government, can afford not to be informed about these important issues. Unfortunately these issues are in most cases not clear-cut. Rarely was all the information necessary for a decision at the disposal of even the experts, and hardly ever was the available information easily accessible from a single source. This situation has changed: one handy, although rather heavy, volume provides a wealth of information about metals and their compounds in the environment. Should the information presented prove not to be detailed enough, more can be gleaned from the publications given in the references.

"Metals and Their Compounds in the Environment" consists of two parts. The first part (700 pages) covers general aspects in 20 chapters including cycles of metals in nature; production and processing of metals; chemical processes in the environment; relevance of chemical speciation; analytical chemistry; metal concentrations in human samples; bioindicators for monitoring metals; metals and their compounds in water, in the atmosphere, in soils, in sludges and wastes, as well as in the indoor environment; mobilization from sediments; metals in and their effects on plants, animals, and humans; metals in feed and food; essentiality of metals; interactions between metals; cell biochemistry of metals; metallothionines; acute and chronic toxicity, immunotoxicology, mutagenicity, carcinogenicity, teratogenicity, ecogenetics of metals; standard setting, risk assessment, and legislative regulations concerning metals. Environmental radioactivity is not discussed, with the exception of radioactivity associated with uranium, thorium, and their decay products.

The second part (700 pages) provides information about the following elements: Al, As, Au, Be, Bi, Cd, Co, Cu, Cr, Fe, Ga, Ge, In, the lanthanides, Hg, Li, Mg, Mn, Mo, Nb, Ni, Pb, platinum-group metals, Ag, Se, Sn, Ta, Te, Ti, Tl, W, U and its decay products, Th and its decay products, V, Y, Zn, and Zr. Each of these chapters has sections on physical and chemical properties of an element and its environmentally important compounds; analytical methods for their determination; sources, production, important compounds, uses, waste products, and recycling; their distribution in the environment, in foods, and in living organisms; uptake, absorption, transport and distribution, metabolism and elimination in plants, animals, and humans; effects on plants, animals, and humans; hazard evaluation and limiting concentrations; a list of review articles and original publications arranged alphabetically according to authors; and a list of additional recommended literature. A very useful 22-page glossary and a 65-page subject index close this volume.

The editor stated in the preface: "The book aims to provide... a balanced presentation of the topic 'Metals in the Environment' based on up-to-date international scientific knowledge. For this purpose it was necessary to compile, examine, and critically evaluate the most recent comprehensive and widely distributed literature, and present the results in a unified and well-structured form. In addition the conclusions reached at many symposia have been included... Eighty-six scientific experts carried out an interdisciplinary evaluation, incorporating important results from all five continents; previous publications very often only concentrated either on North American or on European literature... An attempt has been made to assess the ecological and toxicological risks on the basis of national and international requirements, for example, recommended exposure limits. In addition to environmental evidence, the discussion is also based on experience from allied fields, such as industrial medicine and clinical chemistry. In controversial cases, in which certain questions have not yet been resolved, diverging opinions have been equally considered as far as possible." What the editor and his co-workers set out to do, they have accomplished. I know of no other book about metals in the environment that presents information in such an up-to-date, compact, and well-structured manner. Whenever summaries and overviews are written, the compression of information leads to losses in details. Experts working on the frontiers of research will certainly find statements in these chapters with which they cannot agree. They might consider formulations to be too general, perhaps somewhat misleading. As a chemist, I found the sections on the physical and chemical properties of the elements and their compounds of nonuniform coverage and quality. Frequently, information is given which does not aid in understanding the connection between the chemistry of an element and its environmental impact; often chemical facts of great importance are not presented; and on occasion incorrect statements are uncritically taken from the literature.

Random examples illustrate this criticism: Aluminum hydroxide with its pH-dependent solubility is not mentioned. Frequently confusion reigns about oxidation number, valency, and ionic charge. The myth about a cationic chemistry of arsenic in the +3 oxidation state in aqueous solution is presented as a fact. To claim that arsenic in trimethylarsine oxide has one of the lowest oxidation states is pushing the oxidation state concept beyond acceptable limits. Incorrect formulas occur infrequently ($NaBiO_6$, AsO_5, As_2Se). The statement that lithium and the other alkali metals do not form stable complexes is much too general. Dimethyl derivatives of selenium and tellurium—important in biological sys-

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0101-0102 $ 3.50+.25/0

tems—are not mentioned, whereas rather exotic compounds ($TeOCl_2$, TeF_6) are included.

These irritating details as well as some halting sentences could (and should) have been corrected during the editing process. A few typing errors also slipped through. Elements that should have been included are barium, silicon, and perhaps fluorine and iodine.

These minor criticisms must not, however, distract from the great value of this volume. I heartily recommend that all who are interested in metals in the environment buy a copy. These include the scientists from numerous fields concerned with effects of metal compounds listed in the preface of this book (geologists, metallurgists, material scientists, chemists, analytical chemists, environmental engineers, security experts, waste disposal engineers, biochemists, biologists, toxicologists, ecotoxicologists, veterinarians, industrial hygienists, physicians, teachers, administrators, and decision-makers) and interested lay people and all those who already own the much shorter first edition of this book in German.

Contrasts in Scientific Style. Research Groups in the Chemical and Biochemical Sciences. By *J. S. Fruton*. American Philosophical Society, Philadelphia PA (USA), 1990. ix, 473 pp., hardcover $ 40.00. – ISBN 0-87169-191-4

This is a thought-provoking book. J. S. Fruton was involved in the pioneering days of classical biochemistry, and writes with a keen awareness of his origins—he dedicated his basic textbook of general biochemistry to Max Bergmann, Leonor Michaelis, Rudolf Schoenheimer and Gerty T. Cori, and the book certainly lived up to these standards. Here he examines the interplay between organization and success in research, taking as examples the outstanding research groups active in organic and medicinal chemistry in Germany between 1830 (Justus Liebig) and 1914 (Emil Fischer), a period that provided clear evidence of the value of basic research for the chemical and pharmaceutical industries. One finds here a remarkably complex interplay between opportunity and initiative, or between different forms of giving and taking. Fruton regards these matters with the detachment of the historian; nevertheless, one senses that his sympathies do not lie with the powerful and forceful team managers and single-minded achievers, but rather with those research groups in which, while certainly a main focus of attention was not lacking, there was also scientific tolerance and a liberal attitude, which made it possible to take up a wide range of topics and to initiate discussion that stimulated new ideas. This occurred, for example, in the groups led by Felix Hoppe-Seyler and Franz Hofmeister (both of whom, interestingly, worked at Straßburg, the German empire's new showpiece university), and also, in a more centralist but nevertheless thoroughly liberal style, in Adolf von Baeyer's group. Here we have the question that is debated time and time again: how does one achieve a "critical mass"? Through a systematic bringing together of talented and compatible scientists, or by a process of generating ideas through the multicolored interests of different individuals? Is success best achieved by a frontal attack with massive forces, or by "minelaying" at the critical spot?—should one opt for a chemists' pile in the manner of Liebig, or aim at the drudgery of making molecules according to the Fischer rules but in the nimbus of the "master", or the less glamorous training of the independent searching mind in a variety of current problem areas—the Hofmeister series—which, although less immediately spectacular, is more enduring and fruitful in the long term? The answer is that one must decide whether the aim is to apply the knowledge gained quickly, or to invest for the future. Here one is concerned with style that makes the man rather than with the idea that is often put forward of a tree of learning branching out from the grand masters of chemistry and forgers of Nobel laurels, which mostly only illustrate the old maxim that eminent teachers tend to gather around them able and well-motivated students.

This is how it was in the days of the old-style professors: they were never far away from the laboratory; they were as much concerned with the novices as with the post-graduate students, and with the "post-docs" who were in many cases only in the laboratory for a few months as visiting colleagues, and they gave practical advice to all of these. Of course, the "bosses" differed widely in their characters. Justus Liebig wanted to force nature to follow his rules, and to that end he set up an almost military organization (it was no accident that chemistry at Gießen had started life in a former guard-room); in the end, however, this only made him, the Chief of General Staff and PR man, severely ill, as evidenced by the less Olympian the daguerrotypes. In a similar way, Emil Fischer, almost systematically staking one claim after another, became prematurely burned out by the grind of chemistry and family problems, yet he led his loyal team, firmly kept in their subordinate roles, to a string of successes along paths known only to him. Again, a size smaller, there was A. Kossel who, although his horizons were more limited, kept on resolutely towards his objectives. In contrast to these is Baeyer, who lived a self-contented and well-balanced life of idiosyncratic professorial grandeur, whose charisma left no room for self-doubt, and whose integrity, even when authoring his colleagues' work, could therefore not be doubted. The fastidious and assertive character Hoppe-Seyler, imbued with the sheer positivism of his time, impressed his contemporaries. Then there was the critically aggressive and highly imaginative W. Kühne, and the impressively relaxed Hofmeister, whose Bohemian poetic streak enabled him to build a successful team—here one finds the roots of the sort of biochemistry that the organic chemists were never able to understand, rhyming "Biochemie" with "Schmierchemie" ("slime chemistry"), even though this was the origin of the crystals that they came to love so much that they shunned all other forms. This situation persisted into the middle of the present century, when the much-vaunted German school of chemistry failed to link up with the emerging field of molecular biology, whereas the British and American chemists turned out to be more adaptable for a number of reasons, partly but not entirely through having no "Schule", and thereby profiting from the biochemical expertise that fled from Germany.

It is very instructive to examine the styles of working that prevailed in different groups. On the one hand are those that are committed to using just a few methods, from which they extract the maximum possible, while on the other hand are the developers of methods, who often are unable themselves to derive the optimum benefit from them. Here one can see many parallels with the present-day development of biochemistry into molecular biology, and there is a sense of déjà vu about this area. An older chemist recalls with amusement the time when the biologists transformed the university faculties against the resistance of the narrow-minded chemist slave-drivers. With hindsight things look different; it is opportunity that determines character, and as results have developed into patentables, personality and

style have become identical—an ironic twist in the social history of science. Only the list of coauthors now looks different—on this, however, one should read Professor Djerassi who has more to say on this subject...

The appendices, in which the subsequent life histories of the members of these seven classic examples of important research groups have been thoroughly investigated and detailed, are impressive, and quantify the theories put forward. Whereas groups of one type have mainly produced scientists useful to industry, and have therefore appeared as an attractive proposition for the market, those of another type can proudly point to an output of academic scientists that is well above average, both in quantity and quality – though many of these were lost to Germany as victims of persecution in the Nazi era. In passing it is interesting to note that although the number of women was still small in those days (we are talking here of the years before 1914!), there were some nevertheless, even though few of them succeeded in rising beyond the level of head of a clinical laboratory (or, with luck, a teacher of Greek after having emigrated).

The contents of the book have been collected together from many sources. However, readers who are already familiar to some extent with the main threads of the development of biochemistry in Germany will not find much information here that is fundamentally new. On the other hand, the particular appeal of this account, which makes it especially interesting for us in Germany, is in the critical discussion that comes from the author's more detached perspective, seen from the viewpoint of the Angloamerican scientific tradition. Also the descriptions of the characters of the protagonists, which are mainly taken not from the anecdotal folklore of chemistry but from correspondence and scientific publications, add a more human side to the facts. Which of us will eventually have a Fruton to write about us?

Finally, this volume provides comforting evidence for those who love books that it is still possible nowadays, if the will is there, to make a book with care: with clear and attractive printing, on good paper with a generous margin, with sewn pages and a substantial binding, and, last but not least, with the characteristic smell of a book. It is satisfying to find here that a substantial content and a durable quality of production each enhance the other.

Lothar Jaenicke
Institut für Biochemie
der Universität Köln (FRG)

Supramolecular Photochemistry. By *V. Balzani* and *F. Scandola*. Ellis Horwood, New York, 1991. 427 pp., hardcover $ 121.00.—ISBN 0-13-877531-1

In the authors' own words, "Supramolecular chemistry is the chemistry of systems (supermolecules) made up of molecular components in the same way as molecules are made up of atoms... Supramolecular photochemistry concerns the control and tuning of the excited state properties of these molecular components and the study of their intercomponent processes... It can be profitably used to make progress towards the understanding of photobiological processes and the design of artificial systems capable of performing useful light-induced functions." Their stated goal is to illustrate the fundamental concepts of this field and to review and discuss some important results and possible applications.

The book is divided into 12 chapters. After an introduction (1. Scope and Limitations) the chapters 2. Principles of Molecular Photochemistry, 3. Supramolecular Properties, and 4. Control and Tuning of Excited-State Properties of Molecular Components provide a basic but sufficient knowledge of the photophysical concepts needed later. Among the topics are a discussion of potential energy surfaces and a concise introduction to the Marcus theory of electron transfer. They are no substitute for one of the more comprehensive monographs on photochemistry but no such attempt is made.

The following chapters are based on the way in which the molecular components are held together and/or interact with one another: 5. Covalently-Linked Systems: Photoinduced Electron Transfer, and 6. Covalently-Linked Systems: Electronic Energy Transfer. These recapitulate and give further details of the underlying physics, as well as numerous experimental examples. The section on electron transfer is very informative, whereas some aspects of electronic energy transfer remain somewhat sketchy. In both chapters figures with experimental data on the distance dependence of each process would be helpful.

Chapter 7. Structural Changes in Photoflexible Systems deals with photoinduced isomerizations of TICT-compounds, stilbenes, spiropyrans and azobenzene-containing molecules. Incorporation of these functional units in crown ethers and other multidentate ligands enables light-induced changes of the complexating properties of these systems. Chapters 8. Ion Pairs, and 9. Electron Donor-Acceptor Complexes and Exciplexes give short introductions to charge-transfer absorption and emission properties and their relationship to thermal charge transfer processes, as well as dynamic and static quenching in these systems.

The following chapters 10. Host-Guest Systems (comprising crown ethers, macrocycles and cyclodextrin inclusion compounds), and 11. Other Systems (cage ligands, catenanes, and related systems) again deal predominantly with complexation of metal ions by these structures for the control of their excited state properties.

Chapter 12. Photochemical Molecular Devices finally develops a very illustrative, conceptual framework of how the systems in earlier chapters can be utilized to design more complex structures with specific photochemical functions and proposes possible experimental realizations.

In style and content the book is partly textbook and partly review article of recent work up to early 1990. Organic systems and systems based on metal complexes are extensively discussed, with the latter in considerably more detail, probably reflecting the authors' own predilection and very extensive work in this field. Occasionally too great an effort is made to present variety and structural differences of many systems instead of focusing on common mechanisms and concepts. The emphasis is on systems with a small number of discrete molecular components. More complex materials such as polymers, liquid crystals, semiconductors, micelles, and films are explicitly omitted. In fact, much of the material would not necessarily be classified as supramolecular, but as building blocks of larger supramolecular systems. The photochemistry is almost exclusively reversible; irreversible chemical change in general constitutes undesirable photochemical degradation. In this sense, the book deals predominantly with what one might call elementary processes of supramolecular photophysics.

Taken as a whole the selection of the material is a sensible one and the discussion comes to the point. It emphasizes the interdisciplinary nature of the subject, linking organic, inorganic, and physical chemistry, and the close relationship between molecular structure and photophysical function.

Great effort seems to have been made to make the text comprehensible for the nonspecialist. Readability is facilitat-

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0101-0104 $ 3.50+.25/0

ed by a large number of illustrative figures, energy-level diagrams, numerous references and cross references, and extensive author and subject indexes. The book presents basic physical concepts in simple terms with little formalism and numerous experimental examples not easily found elsewhere in such breadth. As such, it provides an interesting and comprehensible introduction for the newcomer to this fascinating field and a valuable source of information for the specialist. However, the readership the book deserves could be limited by its prohibitive price.

Garching (FRG)

The Chemistry of Enols. (Series: The Chemistry of Functional Groups; Series editor: *S. Patai*). Volume editor: *Z. Rappoport*. Wiley, Chichester, 1990. xvi, 823 pp., hardcover £ 195.00.—ISBN 0-471-91720-6

The addition to the Patai series of a volume treating enols as a functional group in its own right is clearly warranted by the revolutionary recent advances achieved in the direct investigation of enol chemistry. The editor of this volume has succeeded in engaging leading proponents of recent developments, thus providing a highly competent and informative account of all the aspects usually covered in the series, namely preparation, structure, and reactivity. Personal views given by the individual authors provide a vivid presentation of a lively research area from different standpoints. As a consequence, there is some reiteration of material in different chapters, but, overall, the editor and authors have achieved a consistent and comprehensive presentation of the chemistry of enols. Literature coverage is up to 1988 (in part 1989) and contains nearly 2500 references as well as extensive author and subject indexes providing easy access to up-to-date information. A majority of the references cited are from the last decade, but important early work starting from Erlenmeyer's first contribution to enol chemistry in 1875 is also included. The chemistry of enolates and enol ethers is deliberately excluded.

Chapter 1 on "Theoretical Calculations" by Y. Apeloig provides an exemplary description of the fruitful interactions between state-of-the-art theoretical methods and current experimental research. In Chapter 2 J. P. Guthrie derives increments for the Benson group additivity scheme from the presently available data, and shows how reliably these allow one to estimate thermodynamic parameters of enols. Chapter 3, "The Chemistry of Ionized Enols in the Gas Phase" by F. Tureček, discusses the reversal of keto–enol equilibria in radical cations. In Chapter 4 on "NMR, IR, Conformation and Hydrogen Bonding" by B. Floris the emphasis is on systems with substantial equilibrium concentrations of two or more tautomers; the chapter includes a comprehensive compilation of spectral data as well as studies of the effects of solvent, substituents and temperature on equilibria. In Chapter 5 methods for generating unstable enols in pure form or in higher than equilibrium concentrations are presented by B. Capon. In Chapter 6 reliable keto–enol equilibrium constants are compiled by J. Toullec, and the merits and limitations of various methods for determining these data are critically reviewed. Old and new insight into the kinetics and mechanism of enolization and ketonization is reviewed by J. R. Keefe and A. J. Kresge (Chapter 7). Emphasis is laid on new developments in monitoring ketonization reactions in aqueous solution, general-acid and general-base catalysis, isotope effects, and the pathways of the "uncatalyzed" reactions in protic solvents. Isolable and relatively stable simple enols are discussed by H. Hart, Z. Rappoport and S. E. Biali in Chapter 8. As "simple" enols they consider those lacking stabilizing functional groups such as CO in the β-position, in particular the kinetically stabilized aryl-substituted enols of the type studied by Fuson in the early forties. Chapter 9 on "Photochemical Reactions Involving Enols" by A. C. Weedon covers the numerous reactions which lead to the formation of enols as primary products, as well as the photoreactions of enols themselves. In Chapter 10 the scarce experimental data on enols of carboxylic acids and esters are reviewed by A. F. Hegarty and P. O'Neill. In "The Biochemistry of Enols" (Chapter 11) J. P. Richard focusses on the biochemical reactions of carbonyl compounds which proceed through enol or enolate reaction intermediates, excluding reactions of the stable enol Vitamin C. Unstable tautomers can sometimes be stabilized by complexation; the properties of transition metal–enol complexes are covered by D. Milstein in Chapter 12 "Organometallic Chemistry of Enols". Experimental data on "Structural Chemistry", mainly from single crystal X-ray measurements on isolable enols, are compiled and discussed by G. Gilli and V. Bertolasi in Chapter 13.

The Patai series needs no recommendation as an indispensable source of comprehensive, critical and up-to-date information. It is clearly a must for any chemical library. Unfortunately this situation is being exploited by the publishers: the astronomical price of this volume will discourage most researchers from purchasing their own copy.

Synthesis of Lanthanide and Actinide Compounds. Edited by *G. Meyer* and *L. R. Morss*. Kluwer Academic Publishers, Dordrecht, 1991. xvi, 367 pp., hardcover HFl 220.00.–ISBN 0-7923-1018-7

This compendium of invited reviews is the second in a series of "Topics in *f*-Element Chemistry" edited by Shyama P. Shinha, the first having appeared some six years ago, entitled "Americium and Curium Chemistry and Technology", edited by Edelstein, Navratil, and Schulz. Meyer and Morss have assembled an outstanding array of contributions from several of the more noteworthy contemporaries in the area of synthesis of *f*-element compounds. As they observe in their Preface, "The history of the rare earths has entered its third century; transuranium elements are now a half century old", so we cannot expect contributions from all of the major players in *f*-element chemistry. The fourteen contributions do, however, contain over 1400 citations that do well to encompass much of the previous work. The goal of the editors and authors to compile a review of "tried and true" synthetic techniques has been achieved. Since no single volume of synthetic reviews can ever be complete, we should anxiously await the next volume. What follows are some brief comments on each of the fourteen sections.

John Haschke of Rockwell International presents a very detailed synopsis of *Actinide Hydride* synthesis in which he includes an extensive review of kinetics. An additional section concerning the safe handling of hydrides and reduced actinides was a welcome sight. So often in the literature we neglect the "obvious" safety concerns. A very detailed sec-

tion describing the synthesis of hydrides follows, with only a few noticeable printing errors such as "10 bar" where the author meant "10 μbar", presenting a minor technical problem if one is concerned with storing An–H compounds. Overall, this section provides a very thorough synopsis of current synthetic techniques.

Bernd Müller remarks "...only such routes have been selected that lead to the purest samples of fluorides", in the beginning of his section on *Lanthanide Fluorides*. This review, although perhaps not as detailed in background material as others, emphasizes the cleanest routes to a variety of lanthanide fluorides. Müller has certainly provided the reader with a number of quality synthetic techniques.

The very thoroughly researched review of *Actinide Fluorides* coauthored by Nigel Freestone and John Holloway of Northampton and Leicester, Great Britain, respectively, sports a host of citations numbering well over 400. This review contains not only synthetic techniques but most of the crystallographic data gathered over the lifespan of actinide fluorides research. In the seventeen sections, containing twenty-eight tables, a gallant attempt has been made to include all of the available examples of each of the oxidation states of the actinides and the plethora of compounds therein. It should be noted that this volume has been limited to actinide fluorides; Meyer and Morss would have us wait until the next volume for the other actinide halides together with the lanthanide hydrides.

Gerd Meyer contributes three sections describing the synthesis of lanthanide halides: *Binary Lanthanide(III) Halides, MX_3 (X = Cl, Br, I); Complex Lanthanide(III) Chlorides, Bromides, and Iodides*; and *Action of Alkali Metals on Lanthanide(III) Halides*, the last being coauthored by Thomas Schleid. These sections are a very comprehensive review of this chemistry, a field that has been pioneered by these authors, along with Corbett, Seifert and others. They have included detailed illustrations of their own reaction apparatus as well as a variety of useful phase diagrams and tables.

John Corbett of Iowa State University nicely complements the halide discussion in his section *Conproportionation Routes to Reduced Lanthanide Halides*. Through conproportionation, Corbett, as well as Gerd Meyer and Arndt Simon, has explored the solid state redox chemistry of the lanthanides and scandium. The highly reactive nature of the reduced metal halides, although desirable for novel chemistry, presents several synthetic problems that Corbett has addressed using a special tantalum containment system. Corbett also remarks on the frustrating role of adventitious elements in a variety of reactions, not yielding the reduced binary metal halides, but rather a host of new centered metal clusters—another story for another day.

The second half of the book is devoted to the synthesis of *f*-element oxides, chalcogenides and pnictides. LeRoy Eyring presents a well written review: *The Binary Lanthanide Oxides: Synthesis and Identification*. His review identifies a variety of synthetic means to achieve the desired end. Eyring addresses each element and its achievable oxides by including numerous phase diagrams and stability plots. This section nicely condenses many years of oxide chemistry into one convenient package, and will be an asset to any scientist with a desire to study rare earth oxides.

Rudolf Hoppe and Stephan Voigt coauthor the next chapter entitled *Polynary Alkali-Metal Lanthanide Oxides*, beginning with a synopsis of seven synthetic caveats. They proceed to address these points within several thorough, albeit brief, sections that include much of their own work together with citations from Bärnighausen. Nine tables summarize major sections of this research, and are quite detailed in reaction conditions and references. They conclude this chapter with a glimpse into the most current and future problems in research, perhaps encouraging us to dream of new synthetic schemes.

"This chapter describes the most appropriate synthesis...on the laboratory scale", begins Lester Morss in his contribution *Synthesis of Actinide Oxides*. Morss ascends through the oxidation states of each of the actinide oxides, directing the reader to the most appropriate sources for further review. A section describing the ultramicroscale chemistry required for handling the transplutonics introduces the reader to the complex nature of this chemistry. Although much of this research has been buried in obscure reports, by citing papers that are available in most good collections Morss has delivered a chapter that affords the reader an opportunity to explore this chemistry in detail.

Reginald Gruehn, Giessen, coauthors two chapters concerning *Chemical (Vapor Phase) Transport in Lanthanide and Actinide Oxide and Oxychloride Chemistry*. Uwe Schlaffrath coauthors the first chapter with Gruehn, dealing with the tantalates, oxychlorotantalates and niobates of the lanthanides. This first chapter concentrates on crystal growth techniques perfected in their Giessen laboratory. Utilizing the vapor phase above their reaction mixtures at high temperatures, they discovered that materials of X-ray quality could be grown in the absence of the often interfering salt fluxes. The second chapter, coauthored by Gerhard Schmidt, examines the thorium tantalates and niobates. The theme of vapor phase transport prevails throughout this review, although the cited examples are limited to Cl_2 and NH_4Cl as transport agents. The reader is left wondering why they have limited themselves to these two systems (aluminum halides have been used successfully in zirconium halide systems). In retrospect, this was a well drafted review.

C. E. Bamberger of Oak Ridge National Laboratory has made a valiant attempt to describe the *Synthesis of Phosphates, Carbonates, Titanates and Other Metallates of the Lanthanide and Actinide Elements*, that would have needed four separate chapters to be comprehensive. Bamberger does warn us that this chapter is but a brief summary of current synthetic methods, and offers citations for specific preparative routes. This section represents an updated version of the author's chapter in Freeman and Keller's "Handbook on the Physics and Chemistry of the Actinides" (Elsevier, 1985). It is not clear whether the broad subject matter was an editorial choice, but that is this reviewer's only complaint.

M. Guittard and J. Flahaut of CRNS, Paris, coauthor a well documented chapter on the *Preparation of Rare Earth Sulfides and Selenides*. They provide a variety of historical and contemporary preparative routes, including seven detailed schematic diagrams of reaction vessels. They address the preparation of monosulfides and selenides as well as the polychalcogenide phases. A variety of crystal growing techniques are also introduced. They do not, however, clearly distinguish the best synthetic methods from those that simply "work".

The last chapter describes the synthesis of an important class of compounds. J. C. Spirlet of the Institute for Transuranium Elements, Karlsruhe, discusses the *Synthesis of f-Element Pnictides*. These compounds have afforded physicists and chemists alike an opportunity to probe a variety of unusual physical phenomena. They also present an enormous synthetic challenge owing to the high temperatures employed and, in the case of the actinides, the obvious safety constraints. The author provides a table of known compounds and a variety of detailed synthetic methods. This section is worth reading if only for the ingenious crystal growing techniques.

A section of the scientific community has waited too long for such a collection to be published. This chemistry has developed dramatically since Brown's review "Halides of the Lanthanides and Actinides" (Wiley, 1969), which had been one of only a very few resources for much of this chemistry. Katz, Seaborg and Morss updated their comprehensive series on the "Chemistry of the Actinide Elements" (2nd ed., Chapman and Hall, 1986), but this does not contain detailed synthetic methods for the lanthanide compounds. The Meyer and Morss collection provides a much needed condensed review of current chemical techniques. Aside from only a few inconsequential proofreading errors and the other minor complaints listed above, this book is highly recommended and belongs on the shelf of every chemist studying lanthanides and/or actinides.

Sulphur-Containing Drugs and Related Organic Compounds. Chemistry, Biochemistry and Toxicology. In 6 parts (Volumes 1–3, each with Parts A and B). (Ellis Horwood Series in Biochemical Pharmacy). Edited by *L. A. Damani*. Ellis Horwood, Chichester, 1989. Hardcover. Prices: £ 35.00 each for Vol. 1, Pt. A; Vol. 2, Pts. A and B; Vol. 3, Pts. A and B; £ 45.00 for Vol. 1, Pt. B. Vol. 1, Pt. A: 167 pp., ISBN 0-7458-0215-X; Pt. B: 324 pp., ISBN 0-7458-0216-8; Vol. 2, Pt. A: 163 pp., ISBN 0-7458-0217-6; Pt. B: 175 pp., ISBN 0-7458-0218-4; Vol. 3. Pt. A: 204 pp., ISBN 0-7458-0573-6; Pt. B: 280 pp., ISBN 0-7458-0574-4

The outstanding importance of organosulfur compounds in many different areas of application, and especially in modern chemical synthesis, is sufficiently well known to need no explanation. However, the importance of such compounds in the biological field is an aspect in which the chemist should be no less interested, when one takes into consideration that sulfur plays an essential role in many biochemical processes, that it is estimated to have an average concentration in the biosphere of about 600 ppm, that most microorganisms and plants are capable of reducing its oxidized forms (e.g. sulfate ion), and that sulfur is incorporated into amino acids (usually as cysteine) and into the catalytic centers of many enzymes, and has a functional role in these.

Accordingly, there have been many monographs and books, even some quite early ones, describing the biochemistry of *endogenous* organosulfur compounds (for example, L. Young, G. A. Maw: *The Metabolism of Sulphur Compounds*, Methuen, London 1958; D. M. Greenberg (ed.): *Metabolism of Sulfur Compounds*, Academic Press, New York 1975; J. W. Anderson: *Sulphur in Biology*, Arnold, London 1978; W. B. Jakoby, O. W. Griffith (eds.): *Sulfur and Sulfur Amino Acids* in *Methods in Enzymology, Vol. 143*, Academic Press, New York 1987). On the other hand much less attention was given in earlier publications to the sulfur biochemistry of *exogenous* synthesis products, which have only recently come into greater prominence, and are clearly important from an ecological standpoint. The work reviewed here is aimed specifically at covering this currently important topic, thereby filling a noticeable gap. An attempt has been made to bring together the widely scattered information on the biochemistry of sulfur-containing xenobiotics, i.e. synthetic agents that are used in a wide variety of applications as agrochemicals, pharmaceuticals or other products made on an industrial scale.

This has resulted in a collection of 46 chapters, which are essays rather than encyclopedically arranged compilations, in accordance with the principle that "he who has much to offer will bring benefits to many". The ground covered is remarkably extensive, touching on nearly every aspect of metabolism, of toxicity, and in general of the biochemical fate and mode of action of synthetically produced organosulfur compounds used in many different areas of application. All this is covered in three volumes, each of which is subdivided into Parts A and B. Volume 1 is devoted to the metabolism of sulfur-containing functional groups (with an excellent introduction by the editor to the topic as a whole, namely "Aspects of Sulphur Chemistry, Biochemistry and Xenobiochemistry"). In Volume 2 the analytical, biochemical and toxicological aspects of sulfur xenobiochemistry are described in detail. Lastly, Volume 3 deals specifically with the metabolism and pharmacokinetics of sulfur-containing drugs.

The work has involved a whole team of experts, although it must be added that this has resulted in a lack of uniformity of quality and in some overlapping of subject matter (admittedly with occasional cross-references). However, this does not detract from the work as a whole—on the contrary, the reader can benefit from the different points of view that are presented, and must approach the reading of the work in a comprehensive way. A wealth of literature references is provided, extending from the early years to the latest state of knowledge. Readers familiar with the subject as well as those seeking an introduction to it will get good value from the work and will find that it fulfills their expectations. There is a wealth of information and stimulating ideas, and also much material for teaching purposes. The standard of production, paper quality, typographical layout and printing convey an excellent impression. In brief: the work can be confidently recommended for all libraries concerned with chemistry, biochemistry, pharmacology and pharmaceutical chemistry, and for the corresponding industrial establishments, and not least for reading by individual scientists.

Werner Schroth
Sektion Chemie
der Universität Halle-Wittenberg (FRG)

Plants for Medicines. A Chemical and Pharmacological Survey of Plants in the Australian Region. Edited by *D. J. Collins, C. C. J. Culvenor, J. A. Lamberton, J. W. Loder* and *J. R. Price*. CSIRO Publications, Melbourne, 1990. 320 pp., hardcover $ 70.00.—ISBN 0-643-04992-7

This book presents an overview of the pharmacologically interesting plants of an entire continent. It summarizes the results of a search for new drugs undertaken from 1939 to the end of the 1980s. The motivation for this survey and for the intensification of research in this area was the outbreak of the Second World War. The results were initially reported in a number of different journals and a summary of these reports was begun in 1984. Attention focused on alkaloids and tumor inhibitors with pharmacological studies being carried out not only in Australia but also in America in collaboration with Smith, Kline and French (SKF) and the National Institutes of Health (NIH). The work with the NIH involved the investigation of the antitumor properties of about 1500 species, 122 of which exhibited reproducible activities.

Another focus of interest was the investigation of plants that are poisonous to animals. Particularly noteworthy is the work on pyrrolizidine-containing plants. One result of the work was the cultivation of *Datura myoporoides* and *D. leichardii* for the production of hyoscyamine. In addition to the above-mentioned effects, the plant extracts or their isolated constituents were tested for the following pharmacological activities: effects on the heart and circulation, in particular high blood pressure, spasmolysis, suppression of inflammation, antimicrobial and antiparasitic activity. The comprehensive tables list the results according to plant families. Not only flowering plants but, to a lesser extent, ferns, algae, fungi, and lichens were included in the investigations. A total of 64 plants are pictured on color plates and the book contains 2152 references to the literature. The extensive index is arranged according to plant families, species, authors, and substances.

Although the book only deals with Australian flora, many species and genera occur in other regions of the world and, therefore, it is of general interest to all scientists working with plants of pharmacological importance. In terms of its length, high-quality layout, and color tables, the book is very inexpensive (the price includes airmail delivery). It can be recommended without hesitation.

Pharmakognosie und Analytische Phytochemie
der Universität des Saarlandes
Saarbrücken (FRG)

NMR, NQR, EPR, and Mössbauer Spectroscopy in Inorganic Chemistry. (Series: Inorganic Chemistry; Series Editor: *J. Burgess*). By *R. V. Parish*. Ellis Horwood, Chichester, 1990. 223 pp., hardcover $ 50.95.—ISBN 0-13-625518-3

"NMR, NQR, EPR and Mössbauer Spectroscopy in Inorganic Chemistry" presents fundamentals and applications of these techniques with the aim of helping the inorganic chemist understand and interpret spectra. To the extent that the intended readership stems from the inorganic community, this text is somewhat unique. The book opens with nuclear magnetic resonance methods and considers problems associated with organometallic, phosphorus, and transition-metal hydride chemistry. There is a brief excursion into multinuclear NMR with comments on ^{31}P, ^{13}C, $^{14,15}N$, ^{19}F, ^{27}Al, ^{29}Si and some transition metals. This is followed by a section on special methods, e.g. INDOR, DEPT, INEPT, DANTE, and a few words on two-dimensional spectroscopy. The NMR portion encompasses ca. 110 of the book's 223 pages. A short section on NQR contains comments and data on the halogens, Group 4 elements, and several transition metals, and is followed by a chapter on Mössbauer spectroscopy with emphasis on ^{57}Fe, ^{119}Sn, ^{121}Sb, $^{127,129}I$, ^{193}Ir, and ^{197}Au. The book closes with a discussion of EPR spectra, mainly of transition metal complexes.

Even allowing for the restriction of the subject matter to inorganic systems, it is, of course, impossible to cover any of these subjects in depth. Indeed the author clearly states that this work should not be considered as either a spectroscopic or theoretical treatise, but rather should provide an introduction to these subjects and, presumably, assist the practicing inorganic chemist in his day-to-day contacts with these methods.

The text is easy to read, well illustrated and contains many practical examples which are certain to be of value to a beginning graduate student. There are problems and answers at the end of each section and these will be useful for both students wishing to practice, as well as teachers seeking material for upper-level undergraduate or preliminary graduate courses. Still, there are some problems in presentation and language which might have been avoided: p. 27, it is not likely that the ^{13}C spectra of 2.I and 2.III will yield the same information, as suggested; p. 29, resolution does not necessarily increase with increasing spectrometer frequency (does the author refer to dispersion?); p. 48, it is not at all clear whether the relatively large value for $^{2}J(P,P)_{trans}$ is at all related to the *trans* influence concept; p. 59, for "normal hydrides" T_1 is *not* usually several seconds or more. On a more subjective note, I would have been pleased to see ranges of chemical shift for both ^{13}C and ^{31}P, including the more interesting types of complexes found in the last decade or so, for example, the extremely low field shifts for carbenes and carbynes as well as the very low field resonance positions associated with bridging phosphide ligands. Furthermore, in view of the blossoming literature associated with the NMR of transition metals, more time could have been devoted to this subject. It might have been interesting to bridge the gap between the liquid state (NMR) and the solid state measurements which follow (NQR, Mössbauer) by a few examples of solid-state NMR spectroscopy; however, it is likely that such an excursion would lead to an unreasonable balance. Despite these and other minor problems I feel that, in general, the book will prove useful for students and teachers of inorganic chemistry.

P. S. Pregosin
Laboratorium für Anorganische Chemie
der Eidgenössischen Technischen Hochschule
Zürich (Switzerland)

Particle Beam Microanalysis. Fundamentals, Methods and Applications. By *E. Fuchs, H. Oppholzer* and *H. Rehme*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1990. xv, 507 pp., hardcover DM 215.00.—ISBN 3-527-26884-7/0-89573-505-9

To make effective use of modern instrumental methods in microanalysis requires a considerable knowledge of the fundamentals of these techniques, and a thorough appreciation of their limitations. This book aims to equip the reader with that information. The methods chosen are those that yield structural and chemical information by means of lateral resolution, are commercially available, and are suitable for use in any (well equipped) industrial laboratory. All three authors are internationally recognized scientists active in the area of microelectronics. For this reason the book is confined to those methods that are relevant to applications in the field of semiconductor and thin-film technology. The book succeeds in giving a comprehensive treatment within this limited area.

The standard of production is excellent (printed on acid-free paper), and the book is plentifully illustrated by diagrams and photographs. A clearly set out list of contents and a useful index make it easy for the reader to locate specific topics. The methods whose applications are covered in the book are the various forms of electron microscopy (scanning, transmission and high-resolution transmission electron microscopies, i.e. SEM, TEM, and HRTEM, respectively), those of electron-induced X-ray emission spectrometry (energy- and wavelength-dispersive spectrometries, EDS and WDS respectively, and also electron beam microprobe anal-

ysis), Auger electron spectroscopy (AES), secondary ion mass spectrometry (SIMS), and the testing of complex semiconductor structures using low-energy electron beams. A further chapter giving detailed descriptions of case studies in the microelectronics field completes the book. References to recent monographs afford access to the extensive original literature; additional references to special and company reports are of less value to most readers.

The first part of the book describes the basic principles of the techniques. The reader is given a mixture of detailed information, varying from the highly relevant and interesting to the trivial. This part is difficult to appreciate without a basic knowledge of solid state physics. However, the discussions of the properties of the individual particles used as probes (electrons and positively charged ions) are very useful from the standpoint of the nonspecialist. For those working in this area, the thorough treatment of the interactions of the particles with the sample material will be especially useful; this applies especially to the section on sputtering effects and depth profiles.

Each of the chapters that follow is devoted to a single technique. In each case the experimental principles of the method are first explained, and the latest instruments are described. This is followed by a very useful section on sampling and sample preparation. In these sections, and in those that follow dealing with the interpretation of data, the practical experience of the authors comes clearly to the fore.

The chapter on scanning electron microscopy contains an excellent discussion of contrast mechanisms, and also includes information on channeling and cathode luminescence effects, which many other monographs do not cover. The chapter on tramsmission electron microscopy will not be understandable to readers without any previous knowledge; in particular it does not provide an introduction to geometrical crystallography. Electron diffraction techniques are treated in a similarly inadequate manner. The chapter on X-ray spectroscopy is impressive for its very good description of the operational features of the latest commercial instruments and data processing software, which have now become highly sophisticated. The critical discussion of the quantitative aspects of X-ray spectroscopy is also useful. However, in this chapter, even if not earlier, one becomes aware of a serious shortcoming of the book: there are no tables of numerical data such as scattering cross-sections and other quantities that one needs to know in practice for calculating results from spectra. Giving references to such tables is no substitute for the experimentalist. Through this regrettable omission the book misses the opportunity to be a working tool used alongside the instrument, a role that it would otherwise have filled admirably by virtue of the rest of its contents and their orderly arrangement.

The chapter on Auger spectroscopy again includes an excellent introduction to the technique, and describes how the results are affected by instrumental variables and settings, followed by a detailed treatment of spatially-resolved quantitative Auger analysis. Unfortunately the section on qualitative "spectroscopy" is very brief, which is likely to disappoint readers whose interests lie outside the silicon-chip field, since in these areas quantification is intrinsically more difficult and questionable, whereas qualitative analysis is more important than in the semiconductor field.

The chapter on applications begins with a section on "Analysis Strategy", but unfortunately the reader is only presented with statements of the obvious. Here one would have expected to find a comparative evaluation of the different methods. The examples of applications that follow are well chosen to illustrate the general principles described in the earlier parts of the book. It is here especially that the reader benefits from the practical experience of the authors, who give lively and interesting accounts of work in their own field. An additional useful feature is the inclusion of experimental conditions in some of the figure captions.

On the whole the most impressive aspect of the book lies in the excellent practically-orientated descriptions of the chosen techniques. However, this is not a laboratory handbook, as it does not contain the tables of data that are essential in everyday practice. The book can be recommended for everyone involved in experimental research on semiconductors, whether in industry or universities. With regard to the interpretation of results, as applied to the everyday work of an industrial laboratory, it provides excellent guidance and stimulation for the critical application of these methods. The same is true to a certain extent for the related fields of thin films, surface coatings and information storage. As a general introduction to the techniques the book is only of limited value. Moreover, users with interests in particulate samples, oxide powders or materials that are predominantly organic will find the book less useful.

The book should be useful for preparing advanced lecture courses on instrumental analysis methods, especially as it brings together in a concise form information on physical aspects that would be laborious to extract from other monographs. It should be included in every collection of works on analytical methods, since it instructs the reader, by means of examples, in the interpretation of experimental results.

Robert Schlögl

Chemical Oscillations and Instabilities. Non-Linear Chemical Kinetics. (International Series of Monographs on Chemistry, Vol. 21). By *P. Gray* and *S. K. Scott*. Clarendon Press, Oxford, 1990. xvi, 453 pp., hardcover £ 50.00.—ISBN 0-19-855646-2

Nonlinear chemical reactions under conditions far removed from chemical equilibrium have become a focus of attention during the last few years, and can involve fascinating phenomena such as chemical oscillations, multiple stabilities and chaos on both the time and the spatial axes. The properties of such systems, described by Prigogine as dissipative structures, confer on them the ability for self-organization. The two authors of this book have been involved for several years in fruitful studies of nonlinear processes in the gas phase. This has resulted in a book which shows some of the classical features that characterized the early Russian publications in the area of combustion processes. The authors have included in their overview of the subject their own numerous publications. The lively personality of one of the two permeates the whole book: its aim is to inform, to teach, and to correct inaccuracies—it is never boring.

Taking as an example the cases of quadratic and cubic autocatalysis with a wide variety of boundary conditions, the authors derive numerous analytical solutions to the problem. The topics treated include oscillations in closed isothermal and thermokinetic systems, Hopf bifurcations, relaxation oscillations, the excitability of stationary states, autocatalysis and oscillations in isothermal and nonisothermal continuous flow stirred tank reactors (CSTRs), reaction-diffusion equations for pattern formation (Turing processes), chemical waves, heterogeneous catalytic systems and chemical chaos. Local stability analysis methods using the

Jacobian matrix and its eigenvalues are applied to all these processes. The analytical solutions are illustrated by numerous figures, such as highly informative flow diagrams and phase portraits. In the interests of generality the differential equations are given in dimensionless form. The lucid treatments of Hopf bifurcation and of the excitability of stationary states via nullclines are especially worth mentioning. In the analysis of bistability in a CSTR and the accompanying flow diagrams it is found, interestingly, that recognizable patterns having the appearance of islands (isolas) or mold growths appear.

The second part of the book deals with real chemical systems, with particular emphasis on the well known Belousov–Zhabotinsky reaction and the analysis of the Oregonator model. As examples of gas phase reactions the hydrogen-oxygen reaction, the $CO/H_2/O_2$ reaction and the oxidation of acetaldehyde (also in the CSTR) are discussed, together with models developed for these. The authors are able to show that the understanding of these gas phase reactions has now reached a level similar to that for the Belousov–Zhabotinsky reaction in the liquid state.

Looked at from a teaching standpoint the structure of each individual chapter is in the style of a lecture, and consequently it is sometimes difficult to enter the text at an arbitrary point. On the other hand, a systematic reading proves to be very fruitful. However, the book does not describe the numerical methods that are of such great importance to the practical user, such as the attractor constructions, Poincaré sections, Lyapunov exponents and the dimensionality of an attractor. For these one needs to refer to other textbooks. Also the examples of chemical reactions are rather few, and no biological examples or gas-solid reactions related to technical catalytic processes are given.

This interesting and well written book is intended, as the title indicates, for the chemist with mathematical inclinations who is interested in analytical solutions of simple nonlinear reaction steps. It can be thoroughly recommended.

C_{60}: Buckminsterfullerene, The Celestial Sphere that Fell to Earth

By Harold W. Kroto*

In 1975–1978 the long-chained polyynylcyanides, HC_5N, HC_7N, and HC_9N were surprisingly discovered in the cold dark clouds of interstellar space by radioastronomy. The subsequent quest for their source indicated that they were being blown out of red giant, carbon stars. In 1985 carbon-cluster experiments aimed at simulating the chemistry in such stars confirmed these objects as likely sources. During these cluster studies a serendipitous discovery was made; a stable pure-carbon species, C_{60}, formed spontaneously in a chaotic plasma produced by a laser focused on a graphite target. A closed spheroidal cage structure was proposed for this molecule, which was to become the third well-characterized allotrope of carbon and was named buckminsterfullerene. It has taken five years to produce sufficient material to prove the correctness of this conjecture. There may be a timely object lesson in the fact that exciting new and strategically important fields of chemistry and materials science have been discovered overnight due to fundamental research, much of which was unable to attract financial support, and all of which was stimulated by a fascination with the role of carbon in space and stars. In this account, interesting aspects of this discovery, its origins, and its sequel are presented. The story has many facets, some of which relate to the way scientific discoveries are made.

Molecules with Unsaturated Carbon Bonds

In the early 1970s, the chemistry of carbon in unsaturated configurations became the prime research focus for my group at the University of Sussex.[1] We were interested in free unstable species and reaction intermediates containing C-S, C-P, C-Si, or even C-C multiple bonds. The work originated from an abortive attempt to produce thioformaldehyde ($H_2C{=}S$) by photolysis. However, we switched immediately to thermolytic activation after I heard a lecture in which Don Johnson (from the U.S. National Bureau of Standards in Washington, D.C.) described how he and Powell had made this compound[2] by passing MeSSMe vapor through a quartz tube heated simply by a bunsen burner! This approach worked beautifully; we produced numerous other new compounds containing the C=S moiety such as thioethanal and thioketene by thermolysis of specially synthesised precursors, and characterized them mainly by microwave and photoelectron spectroscopy.[1] These sulfur species possessed a distinctive odor, and I for one have sympathy with the citizens of Freiburg who, according to Noller,[3] forced Baumann and Fromm to abandon their work on these compounds. We gave up our work on seleno analogues for similar reasons after detecting selenopropanal! After success with sulfur/carbon compounds we jumped, in the spirit of Mendeleev, to the next element in the second row of the periodic table, phosphorus. The first phosphaalkenes, $CH_2{=}PH$ and $CH_2{=}PCl$,[4] were produced in 1976 in a joint project with John Nixon; several more followed.[1] Simultaneously, Becker in Germany made $PhP{=}C(t\text{Bu})OSiMe_3$.[5] At this stage I envisaged a simple possible solution to the problem which had been on my mind

since 1964, namely to ascertain whether derivatives of Gier's beautiful molecule HC≡P[6] could be made. I had been fascinated with HC≡P since the day I arrived as a postdoc at the National Research Council (NRC) laboratory in Ottawa and heard Takeshi Oka (who was then also an NRC postdoc) enthuse over a spectrum of this molecule which Kelvin Tyler (another NRC postdoc) had just obtained.[7] It seemed to me that the chemistry of HC≡P and its analogues must parallel that of the nitriles. Transition-metal complexes could probably be prepared, and cycloadditions to generate phosphorus-containing rings would be feasible.[8, 9] The simple approach worked very well, and we produced the first phosphaacetylene derivative, $CH_3C{\equiv}P$,[10] by thermolysis of $EtPCl_2$ (provided by R. Schmutzler). We followed this breakthrough with the syntheses of other XC≡P species (X = Hal, Ph, N≡C, N≡C−C≡C, etc.[11]). It is most satisfying that, as I had originally conjectured in 1964, the phosphaalkynes (and the phosphaalkenes) have subsequently been exploited by ourselves and other groups as synthetic building blocks.

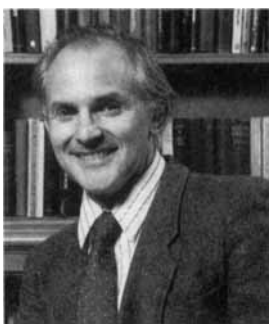
In parallel with our studies of compounds made up of second-row elements and carbon we probed molecules containing chains with C−C multiple bonds. My fascination with such chains developed very early on in a study of the peculiar molecule, carbon suboxide O=C=C=C=O (one subject of my Ph.D. work at Sheffield in the early 1960s with my supervisor Richard Dixon). This stimulated my curiosity in extended carbon chains and the unusual flexibility which they often exhibited; a preoccupation with such molecules has continued to this day. When I flash-photolyzed C_3O_2 a year or two later at the NRC, I ended up with a cell full of black soot and a magnificent spectrum of the C_3 molecule, whose enigmatic patterns had finally been deciphered by Gausset et al.[11] Almost everything about these carbon chains seemed idiosyncratic, and I stored such observations up for the future. These memories were reawakened in the early 1970s by David Walton's work on polyynes at the University of Sussex. David had developed elegant methods for synthesizing long-chain polyynes, based upon silyl-protection techniques which he pioneered in acetylene chemistry.[12–14] He and his students had made the parent 24 carbon-atom species in minute quantities in solution and

H−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−C≡C−H

even a 32 carbon-atom (silyl-protected) polyyne.[13] These chains were precisely what was needed for a study of vibration–rotation dynamics—a topic which had attracted my interest. In my mind they conjured up an image of a microscopic quantum-mechanical cheerleader tossing a very bendy bamboo baton high into the air—and then attempting to catch the violently flexing and turning baton it as it descended. The obvious first compound for microwave study was the cyanopolyyne, HC_5N, because of its expected enormous dipole moment. Walton devised a synthetic route; Anthony Alexander, a "Chemistry by Thesis" student (editorial comment: for an explanation see the acknowledgements at the end of the review), successfully prepared it and measured its microwave spectrum in 1974.[15] This was a wonderful achievement for an undergraduate and a very important one for me, since it was the first molecule to be characterized on our newly acquired microwave spectrometer.

Fig. 1. The dark clouds in Taurus from Barnards 1927 survey, *Atlas of Selected Regions of the Milky Way*, (Ed.: E. B. Frost, R. Calvert), Carnegie Institute, Washington, D.C., 1927. Heiles's Cloud 2 is in the left-hand bottom corner as indicated by coordinate markers.

At about this time spectacular advances were being made in molecular radioastronomy. The black clouds which are smeared across our Milky Way galaxy (Fig. 1) were found to possess long-hidden dark secrets. Townes and co-workers[16] opened the Pandora's box in 1968 and revealed that the clouds are full of identifiable molecules. Astronomers suddenly realized what a key role molecules played in the



Harold Kroto, born in 1939, studied in Sheffield from 1958 to 1964 and received his Ph.D. for his research in the electronic spectroscopy of free radicals with R. N. Dixon. After three years of postdoctoral research at the National Research Council in Ottawa and Bell Laboratories, he started his academic career in 1967 at the University of Sussex in Brighton, where he became full professor in 1985. The most recent distinction Kroto has received is a Royal Society Research Professorship (1991). Since 1990 he has been chairman of the editorial board of the Chemical Society Reviews. His research interests include the spectroscopy of unstable species, carbon and metal clusters and microparticles, as well as interstellar molecules and circumstellar dust. Graphic design is his other passion.

intimate gas dynamics involved in the birth of stars and planets. Apart from well-known species such as ammonia, water, and ethanol—enough for 10^{28} bottles of schnapps in Orion alone—Bill Klemperer ingeniously identified the HCO^+ ion (protonated CO)[17] which had not previously been detected in the laboratory. Thus space served not only as a playground reserved for astronomers, but it now presented chemists with a novel piece of apparatus, indeed a colossal new spectroscopic sample cell, containing a plethora of exotic molecules in a wide range of physico–chemical environments.[18] Shortly after Turner[19] had detected HC_3N by microwave frequencies, I wrote to Takeshi Oka at the NRC; my group had recorded the analogous frequencies of HC_5N, and I wanted to search for the molecule in space. Takeshi and I had worked (1964–1966) in the same laboratory at the NRC during the golden years of that research organization.[*] He replied saying that he was "very, very, very, very, very much interested".

In November 1975 the search for radio waves of HC_5N (with Canadian astronomers Lorne Avery, Norm Broten, and John MacLeod) resulted in the successful detection of a signal from Sgr B_2, a giant cloud of molecules near the center of the galaxy.[20] Although we had been hopeful, we were surprised by our discovery since it had seemed such a long shot. In 1975 molecules with more than three or four heavy (C, N, or O) atoms were assumed to be far too rare to be detectable. However, having found HC_5N in space, we thought that HC_7N might also be present. Walton devised a synthesis of HC_7N, and graduate student Colin Kirby managed the very difficult problem of making it and measuring its spectrum.[21]. By the time Colin (in England) finally succeeded in recording the vital frequency, we were actually working on the radio telescope, since our allotted observing session had already started. Colin telephoned my wife, who wrote the value on an envelope (Fig. 2 left). She then telephoned Fokke Creutzberg, a friend in Ottawa, who also noted it carefully (Fig. 2 right) and transmitted it to us at the telescope site in Algonquin park (Fig. 3). The next few hours were high drama. We dashed out to the telescope and tuned the receiver to the predicted frequency range as Taurus

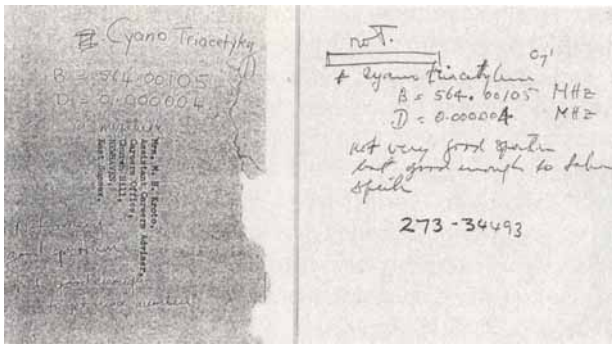


Fig. 2. The envelope (left) and intermediate note (right) with the precious experimental data from which the frequency of HC_7N in space was determined.

[*] Under the guidance of Gerhard Herzberg the NRC had become the Mecca for spectroscopists, and it was here that Cec Costain introduced me to the delights of microwave spectroscopy.

Fig. 3. The 46 m radiotelescope in Algonquin Park, Ontario, Canada with which the long-chain carbon molecules in space were detected.

(Fig. 1) rose above the horizon (perfect timing). We tracked the extremely weak signals from the cold dark cloud throughout the evening. The computer drove the telescope and stored incoming data, but to our frustration we could not process the data on-line while the telescope was running. The system did, however, display individual ten-minute integrations, and as the run progressed we watched the oscilloscope for the slightest trace of the predicted signal in the receiver's central channel. During the course of these ten-minute snapshots, we gradually concluded that the central channel signal was possibly higher on the average than nearby ones. Desperate for even the faintest scent of success, we carried out a simple statistical analysis in order to determine whether the signal level of the channel was greater than the noise. As the night wore on we became more and more excited, convinced that the signal was significantly more often high than low; we could hardly wait for Taurus to set. By 1:00 a.m. we were too excited and impatient to wait any longer, and shortly before the cloud vanished completely, Avery stopped the run and processed the data. The moment when the trace in Figure 4 appeared on the oscilloscope was one of those that scientists dream about and which, at a stroke, compensate for all the hard work and the disappointments which are endemic in life. The circumstances of this discovery—the arrival of the value of the microwave fre-

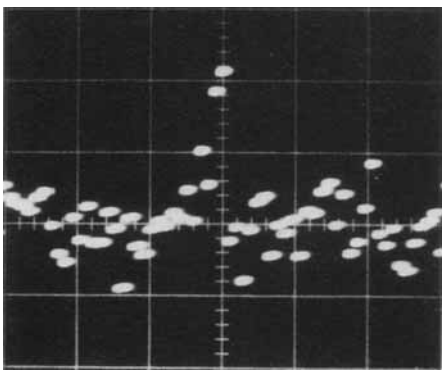

Fig. 4. The first oscilloscope trace of the radio signal emitted by interstellar HC_7N in Heiles's Cloud 2 in the constellation of Taurus (see the coordination markers in Fig. 1).

quency from the UK just in the nick of time, the gradual growth of the conviction that there might be a signal in that central channel of the receiver, and then finally the revelation that we (Fig. 5) had detected an enormous molecule in space[22]—made for a truly cathartic scientific experience. (Modern on-line data processing would have diminished the experience). Obviously, the next candidate was HC_9N, but

Fig. 5. The team at the NRC laboratory just after the detection of HC_7N in space (from left): Avery, Oka, Broten, MacLeod, and Kroto.

its synthesis was a daunting task. Fortunately, Oka developed a beautifully simple extrapolation technique with which he predicted the radio frequencies of HC_9N. Almost unbelievably, we detected this molecule as well![23] Bell et al. later detected even $HC_{11}N$.[24]

The Search for the Source of Carbon Chains in Space

It is not so obvious today, but in 1975–1978 such long-chain molecules were a totally new and unexpected component of the interstellar medium. How such species came to be present was not at all clear. I felt that it was not sufficient just to have co-discovered them; I really wanted to solve the puzzle of how they got there in the first place, and indeed what they were doing there anyway. After all, everything in nature seems to have some role to play. The search for the source of these compounds became something of a preoccupation (even an obsession). By the early 1980s I was convinced that the ion–molecule reactions which Eric Herbst and Bill Klemperer,[25] and Alex Dalgarno and John Black[26] had devised, and which accounted beautifully for almost all other interstellar molecules, really could not explain the origins of chain molecules.[1,18] It gradually became clear to me that red giant, carbon stars must hold the key. Particularly interesting was the spectacular infrared object IRC+10216, discovered by Eric Becklin and his colleagues,[27] which pumps vast quantities of chains and grains out into space. I wondered about this red giant and the fact that it was shrouded in grains and chains, which were formed at roughly the same time,[1,18] and whether "the long chains may be an intermediate form of carbon, between atoms and small molecules such as C, C_2, and C_3, which are well known, and particles with high carbon content such as soot".[1] Perhaps some symbiotic chain/dust chemistry was involved.

The First Visit to Rice University (Easter 1984)

The foregoing account sets out the background for my thoughts about the role of carbon in space prior to my trip to Rice University in Texas during Easter 1984 to visit Bob Curl. Almost the first thing that Curl told me was that I should visit his colleague, Rick Smalley. He enthused over a very recent result obtained by Smalley and his co-workers, who had analyzed the spectrum of the SiC_2 and had shown the molecule not to be linear, as some might have expected, but triangular.[28] (The analogous C_3 species is linear, although only just.[11]) I visited Smalley's laboratory and saw the laser vaporization cluster-beam apparatus which he and his co-workers had recently developed. This powerful technique enabled the mass-spectrometric study of stable clusters formed in a helium-entrained plasma, produced by a pulsed laser focused on a solid target. In this particular experiment silicon carbide was vaporized and the electronic spectrum of SiC_2 observed.[28] I was much impressed by the result but even more by the experimental technique.[29] This method was clearly a major breakthrough in cluster science, since it made refractory clusters accessible for detailed study for the first time. I had already heard of it, but to see the apparatus in operation was quite fascinating. The result of the SiC_2 experiment was particularly interesting to me, because it was consistent with some unusual theoretical results for >Si=C< species[30] obtained at Sussex in collaboration with John Murrell some years earlier. What excited me most, however, was the thought that by simply replacing silicon carbide with graphite, it should be possible to simulate the type of chemistry which takes place in the atmosphere of a carbon star and produce the long carbon chains. As the day wore on I became more and more convinced that the technique was perfect for this purpose and that evening discussed it with Curl. Because of his interest in microwave spectroscopy, he was immediately enthusiastic, and we made plans for a joint project in the hope that Smalley would also be interested. Perhaps we could detect chains with as many as 24–32 carbon atoms related to Walton's polyynes or Hintenberger's equally amazing pure-carbon species (C_{33} etc.), which were detected by mass spectrometry in the early 1960s in a carbon arc.[31] I dreamt that one day it might be possible to detect a chain molecule such as $HC_{33}N$ (which is as long as the chains that Walton had made in a test tube) in space. Curl was particularly excited by the prospect that we could check out an interesting idea of the late Alec Douglas,[32] namely, that carbon chains might be carriers of the famous Diffuse Interstellar Bands—a set of absorption features[33] which have puzzled astronomers and spectroscopists for more than six decades. Because the project was not considered a priority by the cluster group at Rice University at that stage, it had to await a convenient slot in their program.

In the interim, a group at Exxon carried out the basic graphite-vaporization experiment. In the summer of that year (1984) they published a fascinating result: the discovery of a totally new family of carbon clusters C_{30}–C_{190}[34]—

much larger species than those prepared by Walton et al.[12-14] or observed by Hintenberger.[31] This exciting discovery was peculiar because only even-numbered clusters were detected. It is important to note that at this juncture no specific cluster was perceived to be special. In August 1985 (almost 18 months after my visit) Curl telephoned to say that carbon experiments were at long last imminent. He asked whether I wanted to come to Houston to participate or if they should carry out the experiments and send the data to me. One thing was certain in my mind: I had not waited this long to have my experiments carried out by others in my absence; I wanted to do them myself and to direct the operation personally. Therefore I packed my bags and at my wife Marg's expense arrived at Rice University within days.

Second Visit to Rice University— The Discovery of C_{60}

Silicon and germanium cluster studies were on the Rice plate in August 1985 because of their implications for semiconductors. Such experiments were considered to be important because the results might have useful applications (!) The carbon project, on the other hand, was thought to have no possible application (other than for astronomy) and was to be completed quickly, causing as little delay to the semiconductor study as possible. Preliminary measurents on carbon had already been carried out, and the Exxon spectra had been reproduced; nothing untoward was noticed. As soon as I arrived (August 28th) I presented a lengthy informal seminar on everything I knew about carbon in space, stars, and soot. My experiments started on Sunday, September 1st, 1985. I worked in the laboratory alongside two research students, Jim Heath and Sean O'Brien—an exhilarating experience; Yuan Liu was also involved. We toiled late into the night, varying the clustering conditions and monitoring the reactions of the carbon clusters with hydrogen, oxygen, and ammonia—gases which I thought would give rise to polyynylcyanides and other chain molecules. They did! The experiments thus immediately confirmed that the chemistry in red giant stars could be responsible for interstellar carbon chains. Curl and Smalley paid frequent visits to the laboratory. As the experiments progressed it gradually became clear that something quite remarkable was taking place: As we varied the conditions from one run to the next, we noticed that a peak at 720 amu[*] (corresponding to a C_{60} species) behaved in a most peculiar fashion. Sometimes it was completely off-scale; at other times it was quite unassuming. The spectrum recorded on Wednesday, September 4th, 1985 was astounding (Fig. 6). Our reactions were noted in the laboratory record book (Fig. 7a), and I annotated my copy of the printout (Fig. 6). From that point onwards the idiosyncratic behavior of this peak was followed very, very closely (Fig. 7b). When this result appeared, the carbon project—

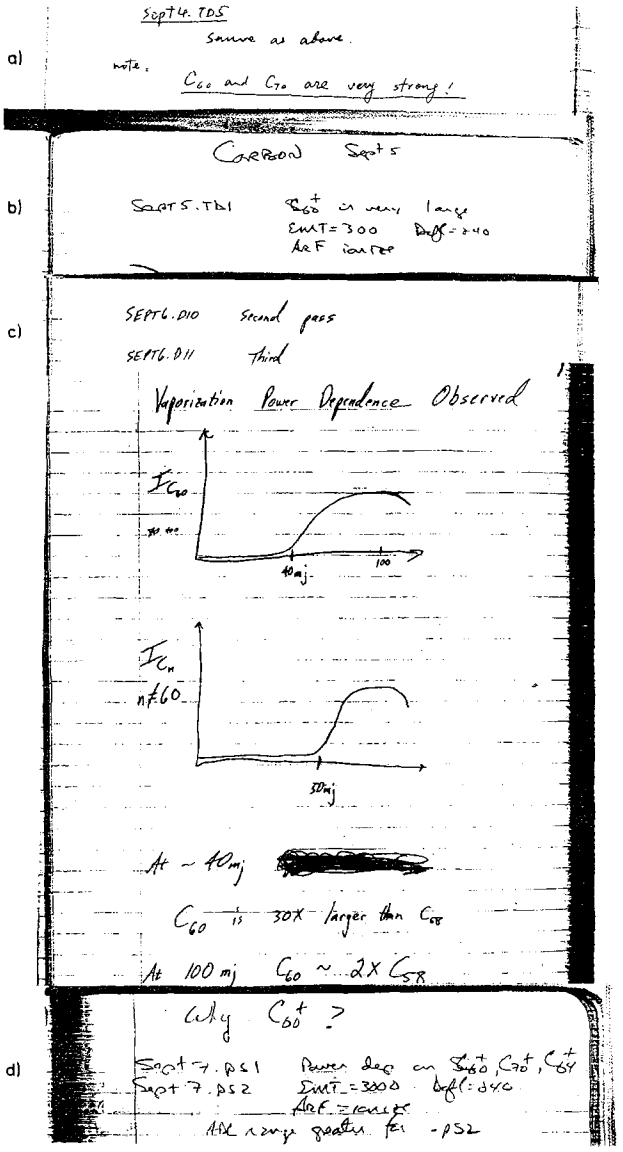

Fig. 7. Entries by Heath, Liu, and O'Brien in the Cluster Laboratory Notebook from the period September 4–7, 1985 when key experiments were carried out at Rice University. a) September 4th: First recorded note that C_{60} and C_{70} were very strong (see also Fig. 6). b) September 5th: C_{60} signal again very strong. c) September 6th: Record of first experiments which specifically aimed at optimization of the conditions for production of a dominant C_{60} signal ("C_{60} is 30 × larger than C_{58}."). d) September 7th: Further power-dependence studies.

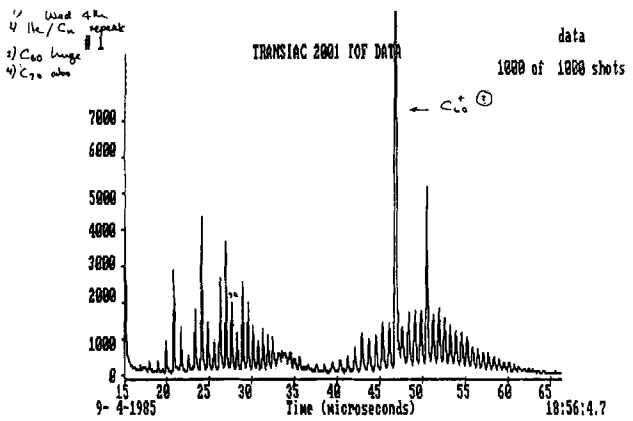

Fig. 6. Annotated time-of-flight (TOF) mass spectrum of carbon clusters produced on Wednesday, September 4th, 1985, the day on which the dominance of the C_{60} signal was first recorded (see also Fig. 7a).

[*] Editorial note: amu = atomic mass unit. According to *Quantities, Units and Symbols in Physical Chemistry* (Ed.: Int. Union of Pure and Applied Chemistry), Blackwell, Oxford, **1989** (Chapter 2.10), amu is the symbol for the unified atomic mass unit m_u and the unit u. In this review the unit amu which is still encountered frequently is used.

for the first time—engendered general interest, and by mutual agreement continuation of the semiconductor program was delayed so that we could concentrate on the remarkable phenomenon which we had uncovered. As the weekend approached our actions, thoughts, and conversations turned more and more to the phenomenon. What might this special "wadge" of carbon be? Smalley had never come across this British term for a cluster and liked it so much that he started to refer to C_{60} as the "Mother Wadge"; the omnipresence of the cluster led me to call it the "Godwadge". On Friday, September 6 during a group meeting, Curl suggested that we should concentrate on identifying the conditions under which the 720 amu peak was most prominent. O'Brien and Heath agreed to work shifts during the weekend. Experiments aimed specifically at optimizing the signal were carried out that same evening, and conditions were immediately found under which C_{60} peak was 30 times stronger than the adjacent C_{58} signal (Fig. 7c). After further optimization (Fig. 7d) the striking spectrum (Fig. 8) was finally obtained. C_{70} is also prominent!

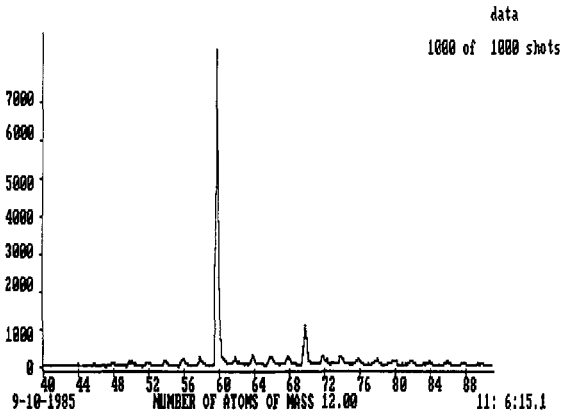

Fig. 8. TOF mass spectrum of carbon clusters under the optimum conditions for the observation of a dominant C_{60} signal.

The Structure of C_{60}(?)

What on earth could C_{60}(?) be? In the days following our discovery of C_{60} (Fig. 6), the signal began gradually to dominate our results as well as our thoughts and conversation. The quest for a structure which could account for this precocious wadge of carbon led to numerous, synergistic [Editorial comment: R. Buckminster Fuller's architectural constructions were based on a vectoral geometry which he called energetic—synergetic geometry. This was founded on a natural philosophy, according to which nature constructs systems of forces such that the maximal strength can be obtained from the minimum effort in construction.] discussions among all five members of the team during those days. The deliberations were particularly intense on Monday, September 9th. As this day wore on and all the ideas which had surfaced during the period were assessed and reassessed, a consensus grew that C_{60} might be some sort of spheroid. One possibility we considered was that the laser had blasted flakes of hexagonal carbon from the graphite surface, and that these hot graphite-like networks had somehow wrapped themselves up into closed cages, thus eliminating the dangling edge bonds and making the cage unreactive. This idea had instant appeal for all. For me this concept brought back vivid memories of Buckminster Fuller's geodesic dome at EXPO '67 in Montreal (Figs. 9 and 10). I had actually

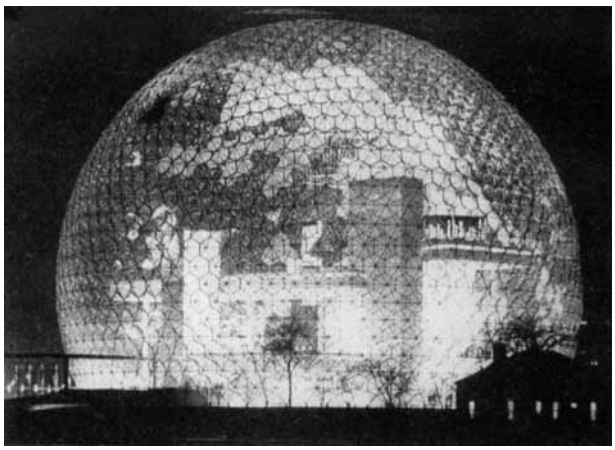

Fig. 9. Photograph (by Michel Proulx) of the geodesic dome designed by Buckminster Fuller for the U.S. exhibit at EXPO '67 in Montreal (taken from *Graphis* **1967**, *132* 379). One of the pentagons necessary for closure is discernable in this photograph.

been inside this remarkable structure at that time and remembered pushing my small son in his pram along the ramps and up the escalators, high up among the exhibition stands and close to the delicate network of struts from which the edifice was primarily constructed. This experience had left an image in my mind which could never be erased. I had collected numerous photographs of the dome from magazines over

Fig. 10. Photograph (by Robin Whyman) of the inside of the EXPO '67 dome in Montreal. One of the pentagons necessary for closure is clearly visible in the middle section, as is the way in which the strut lengths have been adjusted to achieve a smooth round shape.

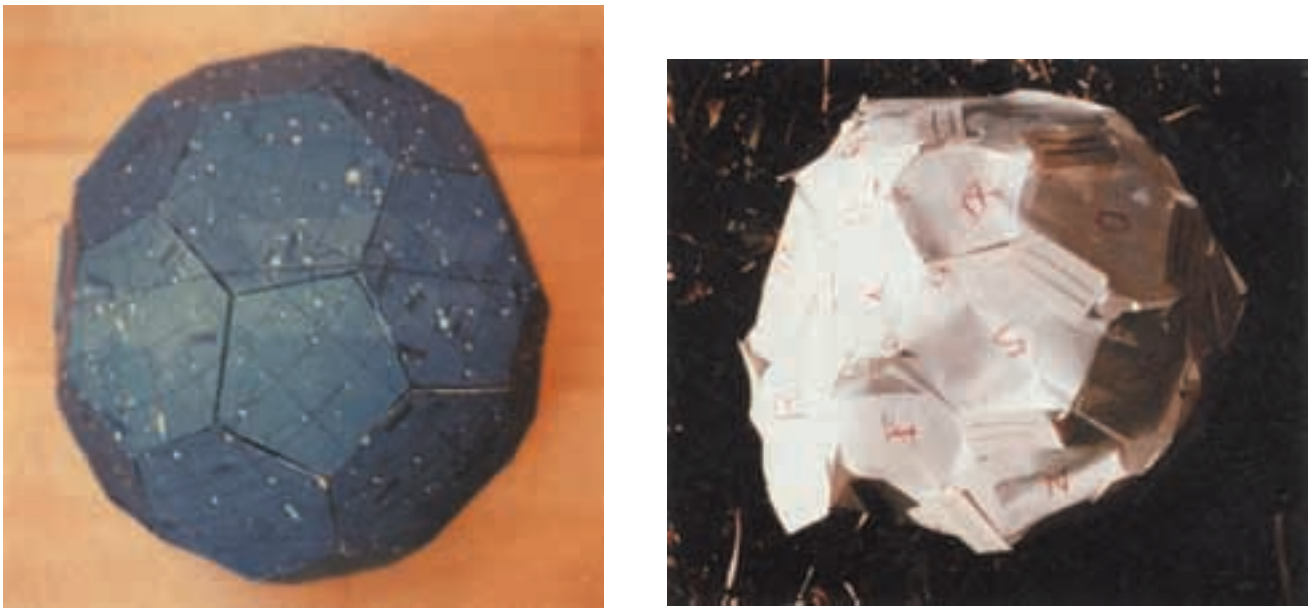

Fig. 11. The two cardboard polyhedra which played key roles in our search for the structure of C_{60} (see text). Left) stardome map of the sky (Buckminster Fuller patented t-icosahedral and other polyhedral world-map projections); right) Smalley's model with 60 vertices and 12 pentagonal and 20 hexagonal faces.

the years from Life, Paris Match, and Graphis. Particularly striking were those in my favorite graphic art and design magazine, Graphis, to which I had subscribed since my university days. As I remembered it, the Graphis pictures (Fig. 9) showed that the dome consisted of a plethora of hexagonally interconnected struts. Indeed, the dome had actually initiated my interest in some of Buckminster Fuller's other projects; I had even been in the process of writing to him with a view to working with him on the organized growth of massive urban structures. However, I did not pursue this, because I was offered a permanent academic position at Sussex at just that time.

As far as C_{60} was concerned, I wondered whether Buckminster Fuller's domes might provide some clue. Smalley also strongly favored some sort of spheroidal structure and suggested that we borrow a book from the Rice University library. We obtained a book by Marks[35] in which geodesic domes of all kinds were described. In addition I had one or two other structural proposals which intrigued me: One was a four-deck model 6:24:24:6 (two coronene-like sheets sandwiched between two benzenoid ones) with a roughly spheroidal shape. It contained 60 atoms, and its symmetry suggested that the dangling bonds might be somewhat deactivated. However, I really could see no reason why this species would be as unreactive as C_{60} appeared to be; a closed-cage solution would certainly be more stable. A second image came to mind several times, most vividly on this particular Monday. This was of a polyhedral cardboard stardome (Fig. 11 left) which I had constructed many years before when my children were young. This map of the stars in the sky was tucked away in a cardboard box (that universal quantum of storage) downstairs in my home far away in England. I itched to get my hands on it and even described its features to Curl at lunch time. I remembered cutting out not only hexagons but also pentagons. I wondered whether I should telephone my wife to ask her to count the vertices in order to ascertain whether, as I half-suspected, they totaled sixty.

The Mexican Restaurant

I was due to return to the UK the next day, so that evening (Monday, September 9th) I thought we should celebrate our extraordinary discovery. I invited the group out to dinner at what had become our favorite Mexican restaurant. During the meal the conversation was naturally dominated by C_{60}(?). We again considered all the ideas which had come up in our deliberations during the days that had passed since the signal had first been noticed. We agreed unanimously on a *closed cage* structure. We talked about Buckminster Fuller's domes, Smalley, about chicken-wire cages, and I reiterated the essentials of the stardome—its spheroidal shape, hexagonal faces, and, in particular, the pentagonal faces. Smalley expressed an interest. After the meal other members of the group went home; I returned to the laboratory in order to study the Marks' book on Buckminster Fuller, but I could not find it. I again considered telephoning home about the number of vertices in the stardome. But it was now far too late since it was well after midnight in the UK.

Very early the next morning Curl telephoned to say that Smalley had experimented with paper models based on the stardome characteristics I had mentioned the previous day. Smalley had come up with something bigger than anything he (Curl) had ever been involved with before. When I got to the laboratory and saw the paper model (Fig. 11 right) which Smalley had constructed during the night I was ecstatic and overtaken by its beauty. It seemed identical to the stardome as I remembered it, and I was quietly pleased that my conjecture had been right all along. Heath and his wife Carmen had also experimented with a geodesic structure modeled out of jelly beans and toothpicks; it was not quite so convincing.[36]

In summary, the quest for a rational explanation of the dominant line in the mass spectrum had reached a climax on Monday, September 9th. Ideas were suggested, refined, or critized in earnest throughout that final day. Buckminster Fuller's domes were invoked, Marks' book was consulted, and the stardome's pentagonal faces introduced at midday

and again in the evening; Smalley and the Heaths experimented further with models during the night after our meal. All this took place in a matter of hours, leaving no time for anything important—other than perhaps Marks' book—to "slip through the cracks".[37] It was most satisfying that synergistic (a Fullerism) teamwork had been involved in the experimental observation as well as in the positing of the structure.

I delayed my flight home for one extra day (until Wednesday, September 11th) in order to help to write the publication. At one point Heath was sitting at Smalley's desk when the telephone rang. A mathematician, whom Smalley had consulted earlier to ask about the structure, informed Heath, "Tell Rick—it's a soccerball!" Almost unbelievably, until that moment, none of us had realized that the C_{60} structure we were proposing had the same symmetry as the modern soccer-(USA) or football (rest of the world). I do not know how I could have been so blind—my only (feeble) excuse was that the modern football was introduced after I ended my serious soccer-playing days. The other members of the team could be excused, since a structure related to the American football really was an unlikely contender, at least at that stage. We immediately purchased a real football and our five-a-side team posed for a photograph (Fig. 12). I also

Fig. 12. The five-a-side Rice/Sussex football team (from left): O'Brien, Smalley, Curl, Kroto, and Heath.

photographed Smalley's paper ball (Fig. 11 right), but when I queried the whereabouts of the Heath model in order to photograph it for posterity, I was informed that it no longer existed because Mary-Joe (another Rice graduate student) had eaten it. So all tangible record of a truly remarkable edifice was lost for all time.

Since the geodesic dome concepts had played such an important part in helping us to arrive at the solution (at least as far as I was concerned), I suggested that we name the compound buckminsterfullerene. Smalley and Curl fortunately agreed, accepting that though the name was long, it did indeed roll smoothly off the tongue. Thus we avoided the fearful international conflict over terminology which would have raged had we named it after a certain well-known ball game. Smalley could not resist putting some alternative suggestions for names at the end of the publication. The name engendered the occasional mild criticism[38] which was dispatched with a little help from Shakespeare.[39] Now that some time has passed, it is satisfying to note how instructive (about geodesy) others have found the name and how flexible it has turned out to be. The whole family of closed cages can be appropriately named—fullerenes.[40] The paper[41] was dispatched by Federal Express to the journal *Nature* on the afternoon of Wednesday, September 11th, 1985.

Five Long Years in the Desert

The ten-hour nonstop flight home to England was a physical and psychological high for me. My first action upon entering the house was to open the cardboard box and take out the stardome which had influenced my deliberations during the search for the structure of C_{60}. It had always looked beautiful; now it positively glowed. When the news of our result spread, Martyn Poliakoff at Nottingham wrote that his friend, David Jones, had already thought of hollow carbon cages. In 1966 Jones had written a delightful article under the pseudonym Daedalus in the journal *New Scientist*[42, 43] in which he had suggested that the high-temperature process in the production of graphite might be modified to generate graphite balloons. This was a typical example of the presciently "crazy" ideas of Jones. I thus learned about the Euler principle, which says that 12 pentagons are needed to close a network and that hexagons alone just will not do. I was introduced to D'Arcy Thompson's elegant book[44] and learned that one could close an even-numbered carbon cage with any number of hexagons (except one, I subsequently learned) provided 12 pentagons were included in the network. The beautiful Aulonia (Fig. 13 photograph from Tibor Tarnai) already knew more than we about these simple (pentagonal) facets of (its) life. This was all fun and truly

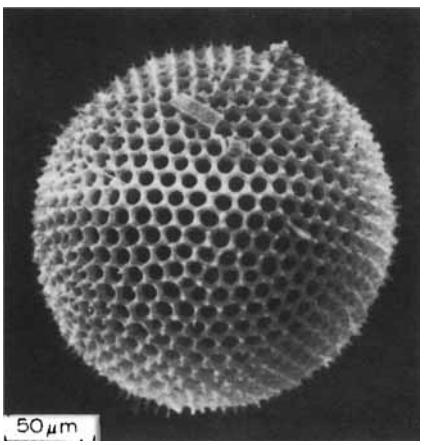

Fig. 13. A siliceous sea creature, *Aulonia hexagona*, appears at first glance to possess a skeleton composed completely of hexagons. Pentagonal structural elements are discernable, however (photograph supplied by Tibor Tarnai).

fascinating, because it became clear that there might even be other (even-numbered) carbon cages—there were certainly other (even-numbered) peaks (Fig. 6), in particular C_{70}. O'Brien and Smalley reached the same conclusions independently. Particularly important were a series of reactivity ex-

periments carried out by O'Brien, which showed that all the even-numbered carbon species were totally unreactive, a result neatly commensurate with closed structures for all the even-numbered cages.[45]

I met David Jones, a most fascinating individual, who epitomizes so much of what the spirit of science should be about. We also learned that Osawa and Yoshida had already thought of C_{60} in 1970 and had even suggested that it might be superaromatic.[46,47] In 1973 Bochvar and Gal'pern[48] also published a theoretical paper on the molecule. Thus it transpired that although there were some most imaginative scientists around, few—other than Orville Chapman at the University of California at Los Angeles (UCLA)[49]—had noticed these pioneering flights of imagination.

Circumstantial Evidence for the Identity of the "Third Man"

The first question stimulated by the realization that we might have found a "third form of carbon" with a hollow, cage structure was obvious: is it possible to trap an atom inside the cage? My early Sheffield background led me to wonder whether iron might form an intriguing ferrocene-like analogue. The day I left, Heath tried to encapsulate iron without success, but the next day he succeeded in detecting a stable $C_{60}La$ complex.[50] This experiment provided the first convincing piece of evidence to support our proposal of the cage structure. Then began what was to become a truly exhausting schedule for me: Every four to six weeks I flew to Houston, and after two to three weeks' work with the group at Rice I returned to the UK and my commitments in Sussex. As soon as I arrived in Houston I would present a group seminar based on ideas which I had developed while in the UK. This schedule continued until April 1987. From the outset the joint Rice/Sussex follow-up program had two clear objectives. First, to make enough C_{60} to prove beyond doubt that our structure was correct and second, to measure the optical spectrum of C_{60} which we had surmised might in some way be responsible for the Diffuse Interstellar Bands.[41] These astronomical features had of course been partly responsible for the carbon-cluster experiment in the first place. These goals were all-consuming and we often talked about "the little yellow (Smalley's guess) or pink (my guess) vial" of C_{60}.

During the late 70s and early 80s I felt that it was simply not enough just to detect the carbon chains; the source must be tracked down. This obsession with the source led ultimately to the discovery of C_{60}. After 1985 I developed a similar attitude to C_{60}. Our discovery of a species which probably had a truncated icosahedral structure was "not enough", and as months and then years passed, confirmation of the structure and its identification in space also became somewhat of an obsession. We (the Rice group and myself) were convinced from the outset that our proposed structure was correct; surely it was too beautiful and perfect to be wrong. However, if for once aesthetics were misleading us, it would be much better if we proved our model wrong ourselves. It is certainly fair to say that the proposed structure was greeted with scepticism by some, though many loved C_{60} and were convinced that we were right from the start. During this period (1985–1990) I examined the problem independently at Sussex, as well as in collaboration with the Rice group, who also made independent studies. In time all these efforts resulted in a mass of convincing evidence in support of our proposal.

From the moment we discovered that C_{60} was stable I had one all-consuming dream: I wanted so solve the molecule's structure by NMR spectroscopy. Because all 60 carbon atoms in buckminsterfullerene are equivalent, the ^{13}C NMR spectrum should consist of a single line. Proof of our radical proposal in such an exquisitely simple manner was to remain elusive for some five years; this goal was almost like a holy grail—far, far beyond reach. I was quite convinced that a clever young organic chemist would accomplish this task. I had one consoling thought, namely that we had been rather successful in the past with a series of molecules whose identifications were based on spectra consisting of single lines: Phosphaethene, $CH_2{=}PH$ (the first phosphaalkene made) had been assigned by its $J = 1 - 0$ microwave line[1,4] and HC_5N and also HC_7N had both been originally single radioline detections in space.[20,22] Then there was, of course, the 720 amu peak in the mass spectrum of C_{60}.[41] How fitting it would be to round it all off by *proving* by another *single* line that C_{60} was buckminsterfullerene.

C_{70} and the Fullerene Family

It is fair to say that I (and perhaps also my colleagues at Rice University) occasionally woke up in the middle of the night and wondered whether I should have to commit suicide if our idea turned out to be wrong. Had we stuck our necks out too far? These thoughts only lasted seconds. I would reassess all the evidence, realize that everything fitted, and go back to sleep convinced more than ever that C_{60} had to be a geodesic cage. Time pased, we made several advances,[51,52] and each time the cage concept clarified our observations. That was important. I remembered hearing Richard Feynman on BBC radio say that it seemed to him that if a radical new theory were right, it would allow the solution of previously unsolved puzzles. I quantified this: If an idea fitted 80–90% of the observations, it was almost certainly right; if more than 10–20% of the details had to be bent to fit, it was almost certainly wrong. Buckminsterfullerene was well up in the first category.

I remember vividly the day on which all my lingering doubts vanished. I was sitting at my desk thinking about the reasons why C_{60} might be stable. The missing piece of evidence in this personal jigsaw puzzle turned out to be so simple, it was almost child's play; indeed it evolved from my playing with molecular models of various conceivable cages. The solution was related to the C_{70} signal which always popped up prominently when C_{60} was strong. I used to call the two species "the Lone Ranger and Tonto"[*] because

[*] The Lone Ranger und Tonto were a famous cowboy and Indian duo from the movies. As a child I saw them every week fighting crime in the Wild West. Bob Dylan immortalized them in the following blues text:
Well the Lone Ranger and Tonto
They are ridin' down the line
Fixin' ev'rybody's troubles
Ev'rybody's 'cept mine.
Somebody must a tol' 'em that I was doin' fine.

they were so inseparable and because C_{60} was always dominant (Figs. 6 and 8). As far as C_{60} was concerned, it seemed no accident that the modern soccerball with the same layout is one of the most, if not *the* most, resilient of constructs, able to survive being kicked around the world (and perhaps around the galaxy). Maybe the football held a simple clue. When I looked carefully at a football, I was struck by the fact that all the (black) pentagons are isolated, whereas all the (white) hexagons are linked. It is known that unsaturated compounds composed of abutting pentagons (the pentalene configuration, Type **II**, Fig. 14), without substituents which allow extended conjugation, tend to be unstable. Curiously, a compound with just such a structure appeared on the cover of *Angewandte Chemie* (July 1987) that very week.

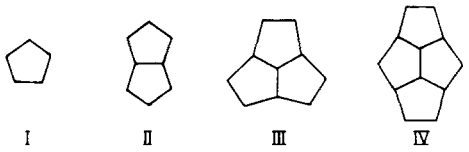

Fig. 14. Isolated and abutting pentagons: **I**, isolated; **II**, fused pair (pentalene configuration); **III**, symmetrically fused triplet (triquinacene configuration); **IV**, directly fused quartet [53].

Since Euler's law requires 12 pentagons for closure, it was also clear that C_{60} was the smallest carbon cage for which all the pentagons could be isolated. O'Brien's reactivity experiments had convinced us that closure was possible, even probable, for all the even clusters. I conjectured that a *pentagon isolation rule* could be formulated to account for the stability[53]; then I began to wonder which was the next cage for which pentagon isolation was feasible.

By playing with the models I saw immediately that it was not C_{62}, and as I added more atoms, try as I would, I could not find cage structures for C_{64}, C_{66}, or C_{68} without abutting pentagons. We had already proposed a structure for C_{70},[50] after Smalley had shown that by splitting C_{60} into two C_{30} hemispheres a ring of ten extra carbons could be neatly inserted, producing a most elegant, symmetric, egg-shaped structure (Fig. 15 right). Suddenly I realized that perhaps this C_{70} cage was the next structure after C_{60} which could close and which also had *isolated* pentagons (Fig. 15). This surprised me. Perhaps closure *necessitated* that 70 be the second magic number! We had stuck our necks out with the C_{60} hypothesis on the basis of a single peak in the mass spectrum, but it now seemed that the cage concept positively insisted that C_{70} *as well as* C_{60} are special.[53] That would be wonderful. A second solution which required both of these particular magic numbers was impossible to conceive, especially since 70 would be an unusual number to be deduced as magic at all, let alone the second in order. I knew that nature would not be that perverse, and thus for first time my conviction that our structure was corrrect became absolute, and I never again doubted that one day we would be vindicated. Indeed in my opinion this result meant that we were home and dry.

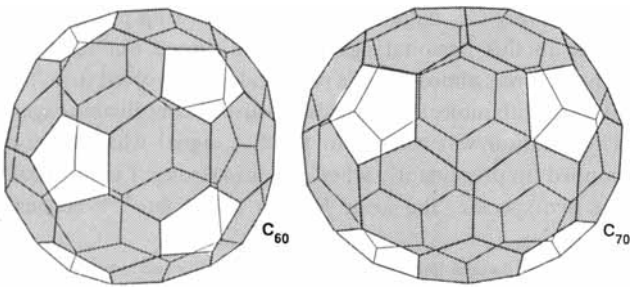

Fig. 15. For species with less than 72 atoms these two structures are the only ones which can be constructed without abutting pentagons. Thus on the basis of the *pentagon isolation principle* and geodesic considerations C_{60} and C_{70} are predicted to be the first and second magic fullerenes. This result together with Figure 8 provided the simplest and strongest circumstantial evidence supporting the closed-cage concept.

I was elated by this line of reasoning, but I really needed proof. I remembered that Tom Schmalz and his colleagues, Klein and Hite, in nearby Galveston had published some elegant graph-theoretical studies on the fullerenes. I contacted him and asked him what he thought about my idea. I was amazed and delighted when he told me that they had been looking at this same problem and had proven that cages composed of 62, 64, 66, and 68 atoms cannot be constructed without abutting pentgagons.[54] So it was true! I told him that I wondered whether the semimagic C_{50} might be the smallest cage able to avoid abutting triplets of pentagons (Type **III**, Fig. 14, Lit.[53]). Schmalz et al. subsequently showed this also to be correct.[54] One Sunday afternoon, sitting in front of the molecular models strewn all over our coffee table at home, I decided to investigate other semimagic numbers. I wondered about C_{32} which had been shown by the group at Rice University to be the first cage relatively stable towards photolysis. I toyed with the idea that it might be the smallest cage able to avoid fused quartets of pentagons (Type **IV**, Fig. 14). I tried to make the smallest model containing such a structure, and as I counted up the atoms I suddenly realized, that it was not C_{32} but a delightfully symmetric C_{28} cage (Fig. 16). I became excited because I knew, that during the Rice/Sussex collaboration period we had occasionally obtained mass spectra in which C_{28} was almost as dominant as C_{60}. At this point it seemed that essentially all the magic numbers would fall into place if these clusters were *all* cages. In particular, I found that I could explain the fascinating spectrum (Fig. 17) published by the Exxon group.[55] Here was all the proof I needed to convince myself that a whole family of cage molecules was sitting around waiting to be discovered. The first somewhat

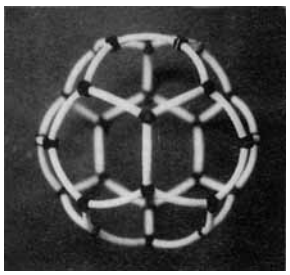

Fig. 16. Molecular model of C_{28}, one of several fullerenes (with 24, 28, 32, 50, and 70 atoms) predicted to be stable on the basis of geodesic and chemical considerations [53]. These magic-number predictions fitted almost perfectly the observations made under certain clustering conditions [51, 55] (see Fig. 17).

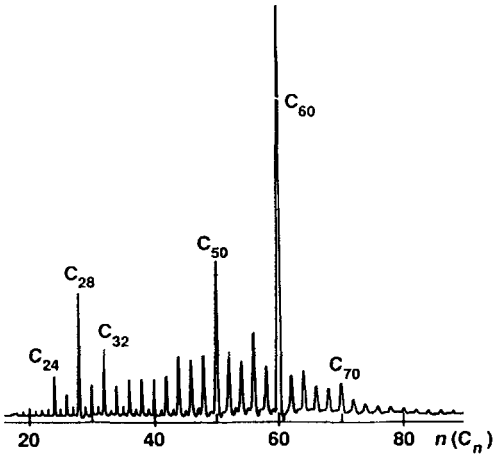

Fig. 17. The particularly interesting mass spectrum of C_n clusters obtained by Cox et al. [55]. The correspondence with the magic fullerene sequence 24, 28, 32, 50, 60, and 70 [53] was the most convincing evidence for the existence of the fullerene *family* prior to the extraction breakthrough. The sharp cut-off at 24 is articularly convincing, since no C_{22} fullerene can exist.

stable member of the family appeared to be C_{24}. This can be explained by the fact that C_{22} cannot exist (I am indebted to Patrick Fowler for pointing out this fact to me) and that C_{20} is the smallest cage and as it has no hexagons at all, almost certainly the least stable. To some extent C_{28} (Fig. 16) became my own personal favorite, because regardless of which of the four threefold axes one views this tetrahedral molecule along, it looks uncannily like Gomberg's famous free radical, triphenylmethyl; this also just had to be right. I knew about Moses Gomberg's discovery from my favorite organic text (Fieser and Fieser[56] which Harry Heaney, my chemistry teacher in school, had encouraged me to buy and read so long ago). It had always amused me to think that on attempting to make the rather mundane compound hexaphenylethane, Gomberg failed (miserably), produced the triphenylmethyl radical, and had to be consoled with becoming known as the father of free radical chemistry instead. This was the sort of "failure" that really appealed to me. If C_{28} is relatively stable, then $C_{28}H_4$ should be a fairly stable hydrofullerene. This seemed not at all farfetched; after all, dodecahedrane which Paquette and co-workers first made[57] is basically the perhydrofullerene of dodecahedrene (fullerene-20), the simplest and probably the least stable of all the fullerenes since it contains no hexagons. At this time I had a telephone conversation about nomenclature with Alex Nickon in which we came to the conclusion that the name "fullerenes" would work well for the family of carbon cages.[40, 53] I gained much satisfaction from the refined concept which was even more appropriate, because Buckminster Fuller had patented constructs of all shapes and sized based on the 5/6 ring principle;[58] some were very similar to the elongated framework of C_{70}. Nickon was just finishing his entertaining book with Silversmith on the origins of the trivial names of compounds.[40]

In Houston a particularly important series of experiments was carried out by Curl, Smalley, and their co-workers which offered further overwhelming evidence for closed cages.[52] One of these was a photofragmentation experiment which provided even-numbered products. Curl had worked out a neat way of explaining how the cages might "spit out" even-numbered (2, 4, 6, ...) carbon chains and then reseal. Another most convincing study showed that when the encapsulation of atoms of various sizes appeared to be successful, the smallest caged species detectable had diameters commensurate with the known sizes of the encapsulated atoms.

C_{60} and Soot

During one of my eight visits to Rice University between August 1985 and April 1987 we considered carefully the reactivity results and developed a hypothetical mechanism for the formation of C_{60}.[45] Heath, O'Brien, and I spent hours in the library digging through an excellent selection of books and journals on carbon. The final version of the mechanism grew out of intense synergistic group discussion. It was also clear that the mechanism might explain soot formation as well. After all in a review on soot, Harris and Weiner[59] had pointed out the complete absence of knowledge of the chemistry involved in soot formation. Thus a fresh idea probably would be welcome. Our mechanism implied C_{60} should be a by-product of soot formation. Curl was apprehensive about introducing the word soot, especially in the title. How prescient were his worries! However, Smalley and I decided to throw caution to the wind—after all, when you have gone as far as you can go (in postulating C_{60} formation in a chaotic plasma), you might as well go further. Our paper met with some criticism.[60] To our delight, however, in 1987 we heard that Klaus Homann's group in Darmstadt discovered that C_{60} was a dominant ion in a sooting flame.[61] (Note: Very recently, a careful study by Howard's group at the Massachusetts Institute of Technology has shown that up to 7% of the soot from a benzene flame consists of fullerenes.[62])

The Giant Fullerenes

One day I decided to spend £300 on ten-thousand sp^2 carbon atoms (molecular models!) The odd eyebrow was raised at Sussex when I said that I was buying them just because I wanted to see what giant fullerenes such as C_{6000} (with a diameter ten times that of C_{60}) looked like. Ken McKay (a graduate student) obtained Coxeter's book[63] and Goldberg's paper[64] and set to work. When he came into my room with models of C_{240} and C_{540} (Fig. 18), I was delighted but perplexed—they were beautiful, but not at all what I had expected. C_{540}, in particular, was not round like Buckminster Fuller's domes, but in fact much more interesting: It was essentially a monosurface which swept between cusps in the vicinity of the pentagons; it had icosahedral symmetry, but was not an icosahedron.[65] Then we realized that its shape might explain[65] the polyhedral patterns in graphite microparticle electron microscope pictures published by Iijima (Fig. 19).[66] The structure of these microparticles could be nicely explained as concentric shells of graphitic carbon in which the shells had giant fullerene shapes. Few of our discoveries have delighted me more than these objects, partly because they are so elegant, but also because the exercise, which was started *purely* for fun and with no serious aim, had yielded such an apparently important result. It was also an object lesson, since I had assumed

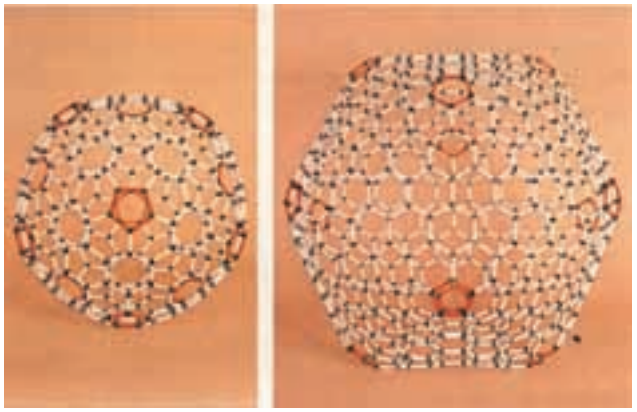

Fig. 18. Molecular models of the giant fullerenes C_{240} (left) and C_{560} (right). The models possess icosahedral shapes rather than perfectly spheroidal ones similar to the geodesic domes. Each of these structures can be considered as an initially flat hexagonal network which has warped into a closed monosurface (of icosahedral symmetry) by 12 pentagonal disclinations giving rise to the cusps.

that the giant fullerenes would be spherical like Buckminster Fuller's domes and had not looked carefully at Iijima's images. Even the most spheroidal giant fullerene (Fig. 19a) was clearly polyhedral (Fig. 19b). To see what one wants to see

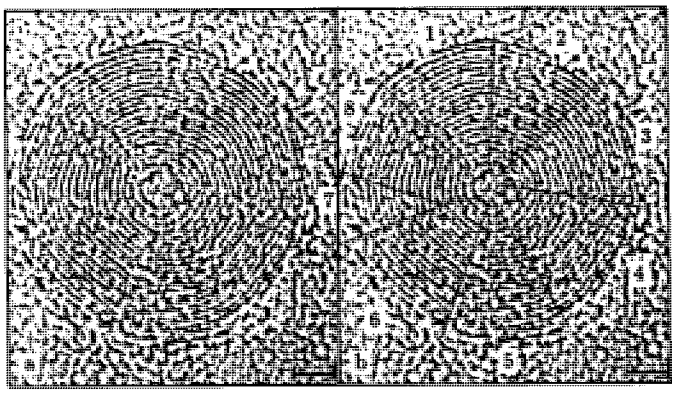

Fig. 19. The image obtained by electron microscopy of an onionlike graphite microparticle observed by Iijima [66] which appears superficially to be spheroidal (a). Careful scrutiny of this image, however, indicates that the object has a polygonal outline consistent with a set of concentric quasi-icosahedral fullerene-like shells (b) [65]. The marker indicates a scale of 20 Å.

rather than what is, is a cardinal sin for a scientist and the temptation is to be resisted at all costs.

The Quest for C_{60}

Until late 1989 the evidence in support of our structure proposal was, to my mind, very convincing, but it could not be deemed anything other than circumstantial. Clearly a macroscopic sample of C_{60} was needed—not just a whisper in a supersonic helium wind, detectable only by that ultrasensitive sensor, the mass spectrometer. At Sussex we sought more tangible evidence. The Science and Engineering Research Council (SERC) funded the construction of a cluster-beam apparatus, which was assembled with Tony Stace; Steve Wood helped us to obtain financial support from British Gas in the form of Collaborative Award in Science and Engineering (CASE) studentship for combustion-related studies. It was this assistance which was ultimately our salvation (vide infra). In a third project conducted with Ken McKay, we probed (by electron microscopy) the films produced by a carbon arc under helium in an old bell jar evaporator. We found that the film microstructure changed as the helium pressure was increased (to ca. 50 mmHg). The quadrupole mass spectrometer, with which I sought to monitor whether C_{60} was produced in this experiment, was the integral part of a modest carbon materials research project which failed to attract support from any funding source (including chemical companies). Because Stace and I had been quite generously funded by the SERC solely for the cluster-beam studies, another application (and indeed a rather applied one) to that source was difficult. Time slipped by and this program faltered even though I had put a great deal of effort into trying to obtain financial support.

The First Paper by Krätschmer, Fostiropoulos, and Huffman

In September 1989 Michael Jura (UCLA Astronomy Department) sent me a copy of a thought-provoking paper[67] (Fig. 20) presented by Krätschmer, Fostiropoulos, and Huffman at a symposium on interstellar dust. This research group from Heidelberg and Tucson had observed four weak but distinct infrared absorptions in a film of arc-processed graphite, which were tantalizingly consistent with the expected spectrum of buckminsterfullerene. From theoretical studies[68] it was known that C_{60} should exhibit only four lines. What was more, the observed frequencies agreed quite well with those predicted. I had long followed the work of this group and knew that they had developed great expertise in studying carbon by spectroscopy. We had occasionally tried related studies, and I was only too aware of how tricky they were. I was sceptical about their result and also rather cha-

SEARCH FOR THE UV AND IR SPECTRA OF C_{60} IN LABORATORY-PRODUCED CARBON DUST

W.Krätschmer, K. Fostiropoulos *Max-Planck-Institut für Kernphysik, Heidelberg, W.-Germany*
and
D.R. Huffman *University of Arizona, Tucson, Arizona, USA*

Carbon dust samples were prepared by evaporating graphite in an atmosphere of an inert quenching gas (Ar or He). Changes of the spectral features of the carbon dust were observed when the pressure of the quenching gas was increased. At low pressures (order 10 torr), the spectra show the familiar broad continua. At high pressures (order 100 torr), narrow lines in the IR and two broad features in the UV emerge. The four strongest IR features are located in the vicinity of the lines predicted for the C_{60} molecule. One of the observed UV features may be related to the known 368 nm transition of C_{60}. It thus appears that at high quenching gas pressures C_{60} is produced along with the carbon dust.

Fig. 20. Annotated copy of the key paper presented by Krätschmer, Fostiropoulos, and Huffman at the conference *Dusty Objects in the Universe* in Capri (1989) [67]. This paper with the appended query was sent to me by Michael Jura (UCLA) who attended this conference.

grined, for had not Ken McKay and I made soot in a bell jar in exactly the same way three years before during the project, which we were forced to abandon through lack of funds?

I decided to resurrect the old and decrepit bell jar and with Jonathan Hare (holder of the British Gas CASE graduate studentship) tried to reproduce the infrared features obtained by Krätschmer et al. Michael Jura's missive arrived around September 1989, just before the start of the Sussex academic year, a time when third year undergraduate projects are needed. It does not matter whether these projects yield results; they should imbue the student with the flavor and excitement of genuine research, that is, the experience of working in the dark, not—as all too often happens—the frantic scramble for results at all costs! I had often initiated the most speculative of projects in this way, and my experience had shown time and time again that important and exciting studies could often start from such inauspicious beginnings. It seemed perfect for Amit Sarkar's third-year project, and he joined Hare on this wildly speculative project. Fairly soon these students succeeded in obtaining the IR bands (Fig. 21), which, although always very weak and highly irreproducible, confirmed the observations of the group from Heidelberg and Tucson. The obsolete apparatus then

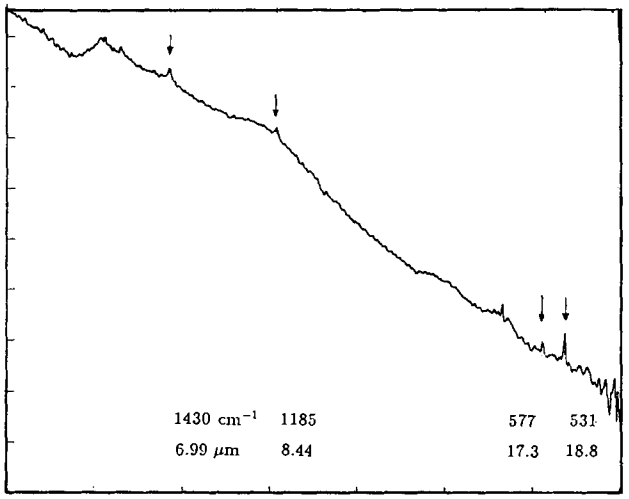

Fig. 21. Infrared spectrum of a film of arc-processed carbon obtained by Hare and Sarkar at Sussex which shows weak but clear (and confirmatory) evidence that the features first observed by Krätschmer et al. [67] (see Fig. 20) and tentatively assigned to C_{60} were real and repeatable.

promptly fell to pieces! After rebuilding it almost completely from scratch, Hare tried to repeat the earlier observations, but consistent results eluded him. Sometimes he obtained the characteristic spectral features, sometimes they disappeared for days or weeks at a time. In retrospect, I suspect that the original discovery of the IR features by Krätschmer et al. could have been made by few other groups. Hare carefully varied every experimental parameter he could think of and finally developed the expertise to produce films which exhibited the telltale infrared features consistently. He wrote to Krätschmer about his efforts and received an encouraging reply containing useful advice. This certainly helped, because it was quite difficult to make films amenable to analysis.

The Dimerization of C_{30}

I spent about one month in the UCLA Astronomy Department around Easter 1990. One day, Mark Morris brought François Diederich from the Chemistry Department to see me. Diederich appeared excited and exhorted me to come to his office because he had something to show me. In response to his manner I somewhat disdainfully quipped, "You've not made C_{60}?" When he replied, "How do you know?". I was startled and suddenly became apprehensive since there was genuine surprise in his voice. When we arrived at his office he showed me an astonishing mass spectrum. In their attempts to make a pure carbon ring of 30 atoms Diederich, Rubin, Whetton, and their co-workers, had found that the molecule spontaneously dimerized to form C_{60} with almost unbelievable efficiency.[69] This staggering result seemed to answer, almost at a stroke, many puzzling questions that had been on my mind for years about carbon chains, their relationship with C_{60}, and soot. But I became even more apprehensive when I comprehended that the UCLA group might be on the verge of obtaining the coveted C_{60} NMR line. Subsequent discussions with David Walton, with whom I had probed aspects of the C_{60} formation mechanism,[70] alleviated my worries; he convinced me that scaling up the UCLA experiment so as to produce sufficient C_{60} for the key NMR measurement presented an anormous challenge.

Mass Spectrometry

I returned to Sussex and by early summer 1990 started to believe for the first time that C_{60} really might be in our sooty deposit. We therefore decided to probe the material by solid-state magic-angle-spinning (MAS) NMR. Indeed Ken Seddon (a Sussex colleague) had encouraged me to do this some years before. Perhaps the single ^{13}C NMR line was close at hand in the black soot, which at least we could now touch. I considered buying the most isotopically pure ^{13}C graphite, but that would have been very expensive, and we had no

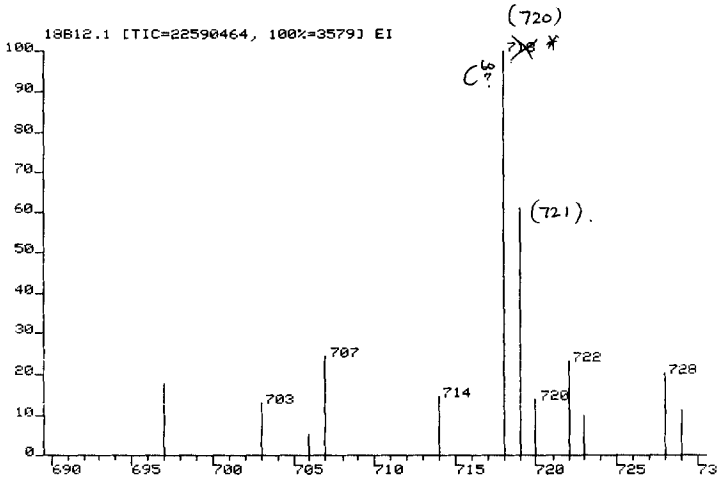

Fig. 22. Part of the FAB mass spectrum of a deposit of arc-processed soot obtained by Abdul-Sada on July 23rd, 1990 at Sussex. The calibration was off by 2 amu; however, the isotope pattern was convincing since the peaks are close to the intensity ratio 1.0/0.66/0.44 expected for $^{12}C_{60}/^{12}C_{59}/^{12}C_{58}\ ^{13}C_2$.

money anyway. The problem of generating enough material for solid-state NMR from the scrapings of thin sooty films, seemed insurmountable, especially since it was so difficult to produce the films in the first place, let alone analyze them. We really needed another way to monitor the samples, so we tried Fast Atom Bombardment (FAB) mass spectrometry. Ala'a Abdul-Sada helped us, and finally we obtained the mass spectrum shown in Figure 22. The signal containing the ^{13}C satellites was really quite convincing, but I wanted the result confirmed. The entry in Jonathan Hare's laboratory notebook on July 26th, 1990 (Fig. 23 top, second sentence) epitomizes many of our problems and requires little further comment.

The Red Solution

During this period we had considered the properties of C_{60}. What form would the compound take? Would it be a high-melting solid or a liquid? Would it be soluble? Benzene was an obvious solvent, since C_{60} should look like benzene from every side (or at least from 20 sides). I remembered the little pink (or yellow) vial of liquid we used to talk about and wondered if the compound might even be volatile. In addition I had often discussed (with Smalley, Rohlfing, and others) how much C_{60} was being made in our experiments. The rough proportion which always seemed to arise was $<1/10000$ of the total amount of carbon. At this level, given the amount of soot available, only a supreme optimist would attempt solvent extraction. Fortunately Hare is one—perhaps partly because he is a physicist working among chemists. On Friday, August 3rd Hare made up a mixture of the soot and benzene in a small vial, which he set aside over the weekend (Fig. 23, second entry). When he came in on Monday morning (August 6th) he noted (Fig. 23, third entry) that the solution looked "slightly red(d)ish" (Fig. 24). The generation of a red solution from pure carbon was scarcely believable. Hare made more material during the next few days and attempted mass spectrometric measurements on extracted material for the first time on Thursday, August 9th (Fig. 23, fourth entry).

possible use of FAB Mass Spect. 26/7/90.

Came back from Scotland Walk to find Fab Mass Spec had been done with exciting results. unfortunately the machine has broken down so we can't repeat.

Results so far.

Seen decent signal @ (12x60) = 720amu !

also ^{13}C is ~1% of natural carbon so calculations show that for C_{60} one 60% sould have One 5%

3/8/90

1) Made approx ½ a (30ml) tube of C_{60}^{6} + Carbon Powder, Actual Volume would be much smaller than this bcos powder is so uncompact.

2) added about 25ml of Benzene and shook mixture

3) allowed to stand for Weekend.

6/8/90

Solution looks slightly reddish, tried to pipet liquid out from top but mixed up.

9/8/90

Vacume lined sample to about 5th of Volume could go lower (ie more concentrated) but we need about this Volume if we want to use IR liquid cell, so will keep to this.

Continued evaporation down to about 4-5 drops (Final ?). FAB showed No C_{60} (720).

Fig. 23. Entries by Hare in his laboratory notebook: July 26th, 1990; August 3rd, 1990; August 6th, 1990; August 9th, 1990.

Fig. 24. Original reddish extract obtained on Monday, September 6th, 1990 (see Fig. 23).

About 10 o'clock the next morning (Friday, August 10th) I received a telephone request from the journal *Nature* to referee a paper by the Heidelberg/Tucson group which I accepted. I was totally unprepared for the bombshell which arrived minutes later by telefax. Following up their own earlier work, Krätschmer, Lamb, Fostiropoulos, and Huffman had successfully sublimed from their carbon deposit a volatile brown material, which dissolved in benzene to give a RED SOLUTION (!!!!!).[71] Crystals obtained from this solution yielded X-ray and electron-diffraction data commensurate with material composed of arrays of spheroidal molecules 7 Å in diameter separated by 3 Å, just as expected for buckminsterfullerene. This beautiful paper even contained photographs of crystals. I was convinced that they had isolated C_{60}, and we had been pipped at the post. Somewhat stunned, I pondered our demise and faxed my report back to *Nature* after lunch. I recommended that the paper be published without delay and requested the editor to convey my sincere congratulations to Krätschmer and his associates.

This was what the British call a difficult moment, but as I slowly surveyed the damage I realized that all was not quite lost. It gradually dawned on me that there was not a single(!) NMR line to be seen in the manuscript (nor was there a mass spectrum. We later learned that they had the mass spectrum, but certain problems had arisen which precluded its inclu-

sion in the manuscript.) At this point we had spent nearly a year struggling independently learning how to make the arc-processed material; we had made our own soot, we had confirmed the presence of C_{60} mass spectrometrically, and we had solvent-extracted the red materal—and all this *before* the manuscript arrived. I decided that we were not going to abandon our efforts now after we had achieved all this. We still had a lot going for us, and I thought we might be able to obtain the desired NMR result. However, now that the Heidelberg/Tucson study was essentially in the public domain it would be transmitted around the world by telefax within hours. I had studiously tried to avoid such situations in science—competition—all my life; my philosophy is to probe areas in which few others, preferably no one, work. That is where, it seems to me, the most unexpected discoveries are likely to be made.

We had to act very quickly if five years of effort were not to be completely in vain. A race must be on because the material was now so easy to make, and it could not be long before other groups, far better equipped than we, recognized that there was one last exquisite prize remaining in the story of the discovery of C_{60}—the NMR line. Our one priceless advantage was that Hare had already made a reasonable quantity of material, and that, at that moment, only the Heidelberg/Tucson group had any at all. We needed help and fast. Roger Taylor, an organic chemist, provided the desperately needed expertise; he separated the material quickly and efficiently. Since our mass spectrometer had broken down again, Hare rushed by train to Manchester with a sample of the precious extract. Numerous frantic telephone calls passed between Sussex and Manchester, because the sample refused to respond to analysis. Then with a key piece of

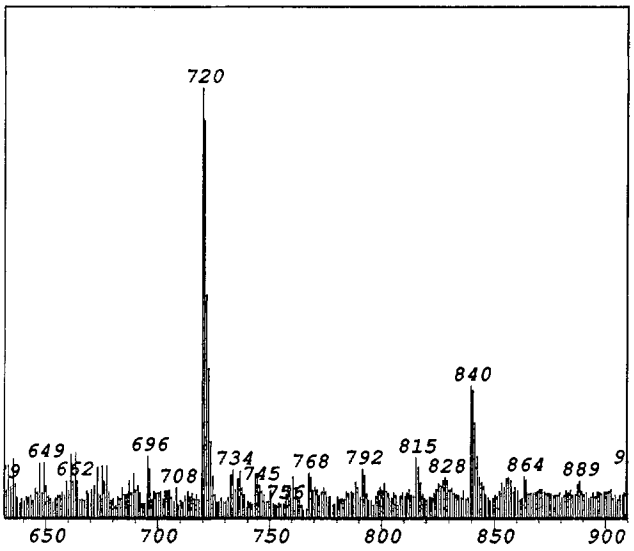

Fig. 25. Part of the FAB mass spectrum of the red extract which confirmed that it consisted mainly of C_{60} and C_{70}. The spectrum also indicates the presence of other fullerenes [72].

advice from Taylor about solubility, the Manchester operators (at Kratos) managed to dissolve the material in the FAB matrix and obtained the FABulous mass spectrum shown in Figure 25. It was hard to believe, but besides C_{60} other fullerenes with 56 to 72 atoms were detected; in particular, C_{70} was abundant. The whole family of fullerenes appeared to be present in the soot, not just C_{60}!

C_{60} is Magenta (Pink?) in Solution

Taylor noted that the extract was soluble in hexane and recognized that he might be able to separate the fullerenes chromatographically. To his delight he found that on an alumina column resolution into two bands, one red, the other magenta, could be achieved. The magenta fraction, (Fig. 26) was a delight to the eye in the delicacy of its color.

Fig. 26. Chromatographic separation of the red extract by Taylor resulted in a magenta C_{60} fraction (left) and a red C_{70} fraction (right).

Its mass spectrum showed a peak at 720 amu, and we sent the sample to Tony Avent for NMR analysis. We were summoned to see our single line (Fig. 27), which Avent assured

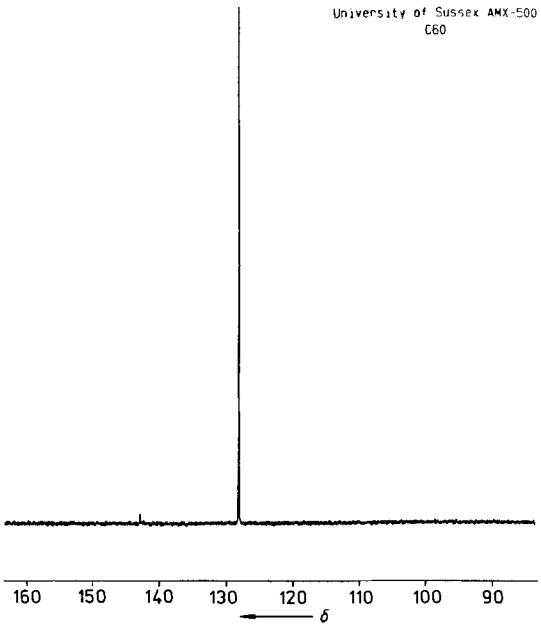

Fig. 27. The first NMR spectrum in which the C_{60} resonance (at $\delta = 143$ ppm) was first identified (barely). The strong line at $\delta = 128$ ppm is (rather appropriately) the resonance of benzene.

us was present. So this was it: a line so small I needed a microscope to see it! Could this insignificant little blip really be the line I had dreamed about for five years? Further work confirmed beautifully that this was the result which we had sought for so long.[72] The joy alleviated almost all the despair I had first felt on reading the paper by Krätschmer et al. One might have thought, as some said, that I should have been pleased to have been proven right when so many had been sceptical. That was not my feeling, probably because I had known ever since the recognition of C_{70} as the second magic fullerene[51] that our structure could not possibly be wrong. I know that my colleagues at Rice University also had no doubts.

What about C_{70}? It turned out to be the icing on the cake, although not without attendent trauma. The wine-red fraction which had masked the pale magenta of C_{60} yielded a mass spectral peak at 840 amu and was clearly C_{70}. According to the expected structure (Fig. 15 right) this compound should exhibit a ^{13}C NMR spectrum with five lines. On Sunday, September 2nd, 1990 I entered the laboratory at the same time as Avent who told me the C_{70} measurement should have just been completed. The spectrum we plotted was sensational—or almost so. There were indeed five lines, but one was in the same position as the C_{60} peak. Could it be that one line was underneath the C_{60} signal? After repeated chromatography to remove the last vestiges of C_{60}, further NMR studies showed the fifth line to be rather different from the others. The resonance of the ten atoms in the waist (Fig. 28c) is more "benzenoid" than the other four resonances.[72] Indeed this line lies dangerously close to the benzene solvent line; had it been a little closer to the benzene signal it would have been swamped and missed altogether. In many ways the five lines of C_{70} are (arguably) more important and significant than the C_{60} singlet. For one thing, they confirm that fullerene carbon atoms are not fluxional; for another, they show that the atoms are not on the perimeter of a monocyclic ring. Both of these cases would lead to a spectrum with a single resonance. Even more important was the fact that the NMR results confirmed the family concept for fullerene cages. It was now clear that a host of stable fullerenes were just waiting to be discovered, as we had long suspected.[53]

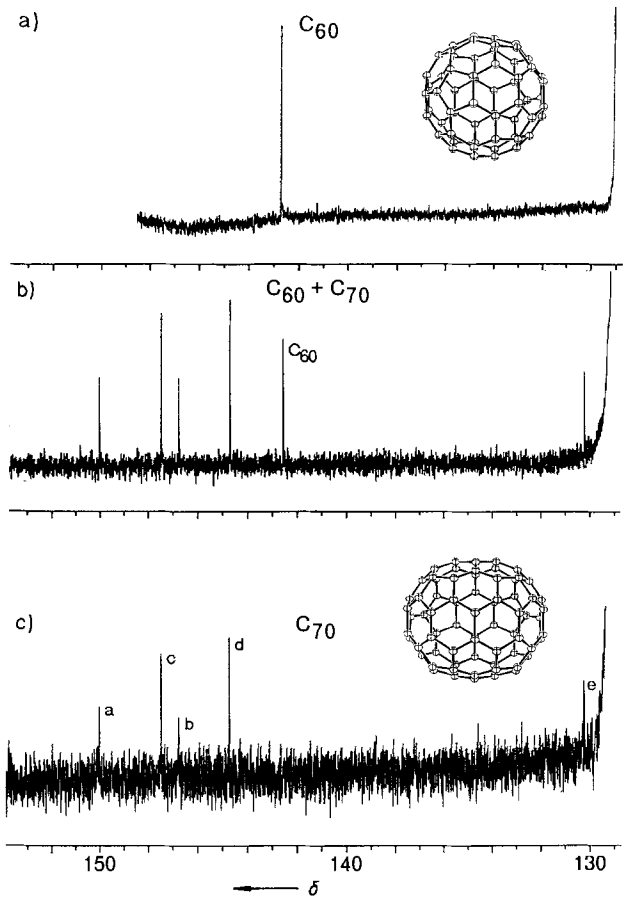

Fig. 28. ^{13}C NMR spectra obtained from chromatographed samples of soluble material extracted from arc-processed graphite: a) spectrum of purified C_{60} (magenta fraction); b) mixed C_{60}/C_{70} sample; c) spectrum of purified C_{70} (red fraction) showing five lines as expected for the symmetric egg-shaped molecule (see Fig. 15).

"The Third Man" is as Elusive as Ever in Space

The elusiveness of C_{60} and my belief that it has been lurking in that blackest of black materials, soot, since time immemorial often reminded me of the role played by Orson Welles in the film "The Third Man". The spirit of this antihero pervades the whole movie although he is seldom seen. Indeed he makes his first appearance late on in the movie in the black shadows of a dark street in Vienna when his face is suddenly illuminated by a light being switched on. For five years C_{60} played a very similar shadowy role—at least as far as I was concerned. My part in the buckminsterfullerene story really started out in space, and this celestial sphere has come down to earth with more of a bounce than a bump; but will it bound back up into space? Is this third form of carbon distributed ubiquitously in space as we surmised the day we found it in the laboratory?[41] Now that we know something about fullerene-60, we should be able to study all its optical properties. It is clear that the UV radiation density in the optically observable interstellar medium is such that the species will be ionized.[73] The possible existence of encapsulated complex ions[73, 74] is quite interesting. However, even with buckminsterfullerene in our hands, we find that this "third man" is as elusive as he ever was in the space between the stars. Perhaps the interstellar form is related to protonated carbon monoxide (HCO^+), which Bill Klemperer identified about 20 years ago.[17] If there are any C_{60} molecules in space there can be little doubt that most will have a proton or some other atom adhering to their surface.[74] $C_{60}H^+$ could probably survive for eons. Other abundant elements, particularly alkali and alkaline-earth metals, must also stick to the surface. Such species will have fascinating optical spectra. For instance, the energy and wavelength of the charge-transfer transition $(C_{60}^+)X \rightarrow (C_{60})X^+$ can be estimated to a first approximation as simply the difference between the ionization potentials of the separated species. For $(C_{60}H)^+$ this transition lies at about 2200 Å. For $(C_{60}Na)^+$ and $(C_{60}K)^+$ the transitions lie in the region of the Diffuse Interstellar Bands[33] and for $(C_{60}Mg)^+$ near zero frequency(!) These observations imply that this and related species will have unusual electrical properties. These processes are probably related to the recently observed superconductivity

of metal-doped fullerene-60 materials.[75] This conjecture is supported by an important new result which comes not from work with bulk material but from cluster-beam studies by McElvaney and Callahan.[76] They found that the gas-phase proton affinity of C_{60} is similar to that of ammonia—a remarkable result! I like to put my trust in intuition; when all else fails it is, after all, our only guide: It is curious to note that some important spectral features of space (the Diffuse Bands) have been visible for decades, yet we do not know what causes them. Now we have discovered that an unexpected molecule, C_{60}, has been under our noses on earth since time immemorial and was invisible until now. It seems to me highly likely that these two observations will turn out to be connected.

Epilogue

Since the time that graphite balloons and C_{60} were twinkles in the eyes of David Jones, Eiji Osawa, and a few other imaginative scientists,[42, 43, 46–48] there have been many significant contributions, both experimental and theoretical, to the first chapter of the buckminsterfullerene story which has just been completed. These have recently been comprehensively reviewed.[77] Figure 12 shows the Rice/Sussex team and Figure 29, the Sussex Buckaneers. These two teams together with the Heidelberg/Tucson team scored many of the goals in the football match which has just ended. Many new teams have now started to play an exciting, but different, ball game. The important difference is that the players can now see what they are kicking.

Fig. 29. The Sussex Buckaneers football team. From left: Kroto, Abdul-Sada, Taylor, Hare, and Walton.

Apart from the successful observation of the "lone" NMR line, two other matters give me a sense of deep pleasure: one was the beautiful color of C_{60} and, furthermore, that it was seen first at Sussex. The second was that apparently no one else appeared to have followed up the early IR results obtained by the group from Heidelberg and Tucson (September 1989). In retrospect I find this astounding; perhaps it was because the work appeared in the astronomy literature, but more likely it was because research today is carried out under such pressure, and our fear of failure is so great (and exacerbated by funding procedures). Few groups enjoy the luxury of working in the dark—a condition which I feel lies at the heart of true scientific endeavor. I have a videotape of a marvellous BBC documentary on Richard Feynman (the greatest lecturer I had ever heard) from the series "Horizon". In one part he talks on essentially this topic. This 50 minute program had the most profound effect on me. At one point Feynmann described how, when he was hired at Cornell, Bob Wilson had told him that it was the university's responsibility whether he accomplished anything—it was their risk(!) It was not for Feynman to worry about, he should amuse himself. In this way he was freed from the psychological burden of doing anything "important", and he was able to relax and do what he most enjoyed—physics and mathematics—just for the fun of it. How lucky he was. I know of few professional scientists today, certainly no young ones, who are in such a utopian scientific environment. What a sad reflection on today's research, especially since we know in our hearts that human beings achieve most when they are free of pressure. We know that small children learn and discover the joys of nature most efficiently during their play.

News of the breakthroughs spread like wildfire during September 1990, and the method of production developed by the Heidelberg/Tucson group was immediately improved upon[78] at Rice University. As soon as it was known that fullerenes are chromatographically separable and that solution NMR is feasible, other groups confirmed these measurements.[79, 80] Don Huffman remarked laconically at a recent symposium, "Everyone is able to repeat these experiments".

A new postbuckminsterfullerene world of round organic chemistry and materials science has been discovered overnight. Almost every day a new paper appears on some novel aspect of fullerene behavior. The group from Rice University has shown that C_{60} forms species such as $C_{60}H_{36}$.[78] Hawkins et al. have made an osmium complex in which the spinning of the fullerene ball is stopped and has enabled accurate bond lengths to be determined.[81] NMR studies by Yannoni et al. have also yielded accurate bond lengths.[82] The radical anion has been polymethylated by Olah's group;[83] platinum complexes have been prepared at DuPont.[84] At AT&T it has been found that the metal-doped material now holds the temperature record for molecular superconductivity.[75] Fascinating differences in the crystal structure of C_{60} have been found which depend upon how the crystals are produced.[77] Foote and co-workers at UCLA have shown that C_{60} transfers light energy efficiently to generate singlet oxygen.[85] Diederich, Whetten, and co-workers have evidence for oxides such as $C_{70}O$.[86] C_{60} is decomposed by light under circumstances which still need to be fully identified.[87] Also interesting is the fact that more fullerenes, such as C_{76} and C_{84}, are being extracted and characterized.[86] The fullerene family has arrived in force, and there are balls of all shapes and sizes for everyone to play with.

This advance is an achievement of fundamental science, not applied science, and serves as a timely reminder that fundamental science can achieve results of importance for strategic and applied areas. The origin of the whole program lay in an interest in aspects of molecular dynamics, allied

with the quest for an understanding of the origin of the carbon chains in space and their possible relationship to circumstellar and interstellar grains as well as soot.[1] These ideas welded together beautifully with the major advance in cluster science brought about by the experimental techniques developed by Smalley and co-workers at Rice University. Krätschmer and Huffman and co-workers were originally motivated by an interest in space dust and, in their recent breakthrough, by astrophysical implications of C_{60}. The C_{60} story has many facets, but more than anything else it is yet another archetypal lesson on the benefits to be gained by supporting pure fundamental science. The field has exploded, and its applications in chemistry and the science of materials are only just starting to be explored. Finally it is worth noting that C_{60} might have been detected 20–40 years ago, perhaps in a sooting flame; one wonders why it took so long.

Another lesson may be learned from these acknowledgements. Important contributions were made in research programs at the University of Sussex (Brighton, UK), the National Research Council (Ottawa, Canada), Rice University (Houston, Texas, USA), the Max-Planck-Institut für Kernphysik (Heidelberg, Germany) and the University of Arizona (Tucson, USA). The discovery of C_{60} is a tribute to not only the international nature of science but also the necessity of interdisciplinary cooperation. The contribution from the University of Sussex to the story started as a consequence of the "Chemistry by Thesis" degree course initiated by Colin Eaborn, which enabled undergraduates (such as Anthony Alexander) to carry out research with supervisors from more than one field. It could only have been successful in the interdisciplinary scientific research and teaching environment which the university pioneered when Sussex was founded in the "optimistic 60s". Sadly this and other courses have been "regulated" out of existence by bureaucrats who have little understanding of how student research expertise is brought to maturity and no awareness of the dire consequences for our future scientific capability. The first part the story could also not have been achieved had chemistry at Sussex been divided into those traditional subsections of organic, inorganic, and physical chemistry. I also had close contacts with astronomers at Sussex, particularly Bill McCrea and Robert Smith. The carbon discoveries resulted from a free-wheeling research program which started with synthetic chemistry (with David Walton, Anthony Alexander, and Colin Kirby) and moved via spectroscopy and quantum mechanics to radioastronomy (with Takeshi Oka, Lorne Avery, Norm Broten, and John MacLeod at the NRC). It moved back to the laboratory and chemical physics (with Jim Heath, Sean O'Brien, Bob Curl, and Rick Smalley at Rice University). In the last phase, key advice came from Michael Jura (an astronomer) which initiated some basic chemistry (with Jonathan Hare, Amit Sarkar, Ala'a Abdul Sada, Roger Taylor, and David Walton). Apart from those mentioned in the text who played direct (and sometimes crucial parts) such as Steve Wood of British Gas, I also acknowledge greatly the help of many others who played indirect parts, particularly graduate students and post-doctoral fellows as well as colleagues such as Tony Stace, Roger Suffolk, and Mike Lappert. Finally I wish to thank Ed Wasserman for some invaluable advice and David Walton in particular for his unfailing help throughout the period of this story and his painstaking assistance in preparing this account.

Two-Dimensional Crystallography of Amphiphilic Molecules at the Air–Water Interface

By Didier Jacquemain, Sharon Grayer Wolf, Franck Leveiller, Moshe Deutsch, Kristian Kjaer,* Jens Als-Nielsen,* Meir Lahav,* and Leslie Leiserowitz*

The advent of well-collimated, high-intensity synchrotron X-ray sources and the consequent development of surface-specific X-ray diffraction and fluorescence techniques have recently revolutionized the study of Langmuir monolayers at the air–liquid interface. These methods allowed for the first time the determination of the in-plane and vertical structure of such monolayers with a resolution approaching the atomic level. We briefly describe these methods, including grazing incidence X-ray diffraction, specular reflectivity, Bragg rods, standing waves, and surface fluorescence techniques, and review recent results obtained from them for Langmuir films. The methods have been successfully applied in the elucidation of the structure of crystalline aggregates of amphiphilic molecules such as alcohols, carboxylic acids and their salts, α-amino acids, and phospholipids at the water surface. In addition, it became possible to monitor by diffraction the growth and dissolution of the crystalline self-aggregates as well as structural changes occurring by phase transitions. Furthermore, the surface X-ray methods shed new light on the structure of the underlying ionic layer of attached solvent or solute species. Examples are given where singly or doubly charged ions bound to the two-dimensional (2D) crystal form either an ordered or diffuse counterionic layer. Finally, the surface diffraction methods provide data on transfer of structural information from 2D clusters to 3D single crystals, which had been successfully accomplished by epitaxial-like crystallization both in organic and inorganic crystals.

1. Introduction

Early in the century, Langmuir demonstrated in a series of elegant experiments that amphiphilic molecules composed of a hydrophobic tail and a hydrophilic head group accumulate at the air–water interface.[1] These films still elicit wide interest because of their importance in the pure and applied sciences. For instance, Langmuir monolayers serve as useful models for elucidating structure and function of biological membranes in their interactions with lipids, steroids, sugars, proteins, and ions.[2] They may also be designed to induce nucleation of organic or inorganic three-dimensional (3D) crystals from molecules or ions present in the subphase by a form of epitaxial growth.[3] In this respect they may be used as models for the study of biological mineralization which involves the use of two-dimensional (2D) surfaces of biological macromolecules to induce the mineral crystallization.[4] The design of monolayers with interfaces which mimic the surfaces of 3D crystals also provides a means of examining crystal surface–solvent interactions in order to understand the effect of the solvent on crystal growth. Furthermore, a knowledge of the characteristics of compressed and uncompressed Langmuir monolayers of water-insoluble amphiphiles should help to unravel the packing characteristics at the air–water interface of water-soluble amphiphiles, where even less is known about their 2D arrangements.[5] In addition Langmuir films are easily transferred to solid supports for the formation of multilayer (Langmuir–Blodgett) films,[6] for potential use as piezoelectric sensors,[7] soft X-ray monochromators, nonlinear optical devices,[8] and in molecular electronics.[9]

Despite the widespread interest in Langmuir films, many of the methods used to characterize their properties do not give direct information on their crystalline packing arrangements. These methods include measurements of surface pressure versus average molecular area,[10] surface potential data,[10] nonlinear optics from surfaces,[11] and IR spectroscopy.[12] Epifluorescence microscopy does furnish some information on crystallinity and morphology on the micron level, but is limited to films of dyes or films containing dye probes.[13] Thus, knowledge on the molecular level of two-dimensional monolayers has been achieved, in the main, from three-dimensional crystals. Indeed, M. Lundquist wrote[14] in a review from 1978: "...there still remains much to be learned especially about the detailed structure of condensed monolayers and regarding the mechanism of molecular rearrangement in monolayer phase transitions. As there are no methods available for direct structure analysis of a monolayer on a water substrate, knowledge of the monolayer structure has, for the most part, been achieved by a sort of translation and application of the knowledge gained from the study of the ordinary three-dimensional state." Only recently, with the advent of intense and well-collimated X-ray beams of variable wavelength from synchrotron sources, has it became possible to obtain direct structural information on the packing of these films by X-ray surface methods.

Here we shall describe some of these new techniques, the information they provide, and review some of the structural results obtained. Emphasis will be placed on monolayer packing arrangements, particularly in terms of the polar head

groups. We shall examine self-aggregation, growth and domain size of 2D crystallites, surface pressure- and temperature-driven phase transitions, and the effect of pH, ions and solute molecules in the aqueous subphase on molecular packing and crystallinity. We shall discuss the role played by electrostatic interactions and structural complementarity in the induction of 3D crystal nucleation at the monolayer–solution interface.

The results obtained so far already necessitate a revision of our basic concepts on properties such as crystallinity, phase assignment, and diffuse and nondiffuse counterionic layers.

2. Surface Sensitive X-ray Methods

The intensity measured in a conventional X-ray scattering experiment is proportional to the number of scatterers, i.e., the irradiated sample volume. This, in turn, is proportional to the penetration depth of the radiation in a sample. For X-rays of about 1 Å wavelength, this penetration ranges from a few micrometers for highly absorbing material to a few millimeters for low absorbing materials. By contrast, the depth to which surface effects persist rarely extends beyond 100 Å. Consequently, scattering from the surface region is so weak compared to that from the bulk that it is completely swamped. A method restricting the penetration depth to the surface region is therefore a prerequisite for all surface diffraction/scattering experiments. This can be achieved by using grazing angles of incidence and employing the phenomenon of total external reflection from the surface.

The refractive index n of matter for X-rays in the 1 Å wavelength range is given by Equation (1),[15] where $\delta = 2\pi\rho r_0/k^2$ ($k = 2\pi/\lambda$ is the X-ray wavenumber and λ is the wavelength). ρ is the electron density and $r_0 = 2.82 \times 10^{-13}$ cm is the classical electron radius. Typically δ is of the order of 10^{-5}. The term β is equal to $-\mu/(2k)$ where μ is the linear absorption coefficient. For X-rays of wavelength $\lambda \approx 1$ Å, absorption is small and $\beta \ll \delta$.

$$n = 1 - \delta - i\beta \tag{1}$$

Consider now a plane wave with wavevector $\boldsymbol{k}_i$ incident at an angle α_i on a planar interface separating a homogeneous medium from the vacuum, as shown in Figure 1. The wave will be partially reflected into the vacuum in the direction given by $\alpha_r = \alpha_i$ and partially refracted into the lower medium in the direction given by α_r'. Snell's law for this case yields Equation (2).

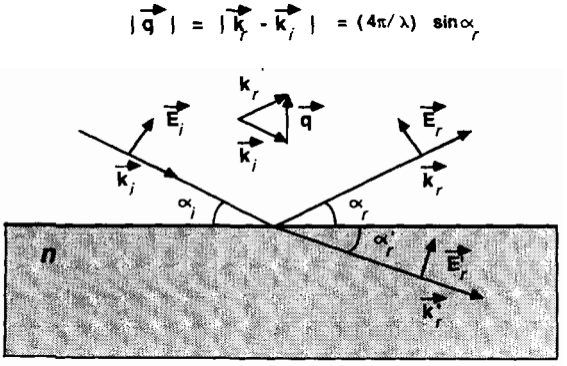

Fig. 1. Refracted (E_t') and reflected (E_r) waves resulting from an incident plane wave with amplitude $|E_i|$ upon an interface between air and a material of refractive index n. Electric fields E are illustrated for one polarization only. The symbol q is the scattering vector, with k_i and k_r the incident and reflected wave vectors of magnitude $2\pi/\lambda$. Note that for $n \lesssim 1$, $\alpha_t' < \alpha_i = \alpha_r$. This provides for total reflection at angles $\alpha_r < \alpha_c$, where α_c is the critical angle for total external reflection.

$$n \cos \alpha_t' = \cos \alpha_i \tag{2}$$

As $n < 1$, for angles of incidence α_i less than or equal to an angle α_c, which is defined as $\alpha_c = \cos^{-1}(n) = (2\delta)^{1/2}$, the well-known phenomenon of total reflection occurs:[16] the incident wave is totally reflected, while the refracted wave becomes evanescent traveling along the surface. The amplitude of the evanescent wave decays exponentially with depth. Figure 2 shows the penetration depth Λ of the X-rays in water versus angle of incidence α_i. For $\alpha_i < 0.5\alpha_c$, the penetration depth is 46 Å independent of the X-ray wavelength. The evanescent wave may therefore be diffracted by crystalline material in a surface layer of that thickness and provides information on its in-plane structure. Such diffraction is called grazing incidence diffraction (GID).[17]

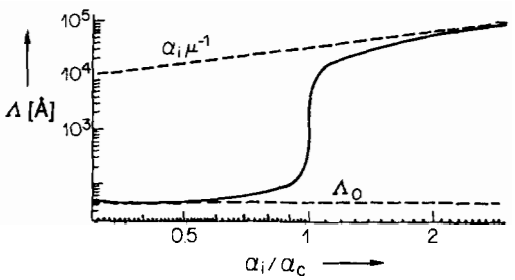

Fig. 2. X-ray beam penetration depth Λ in water at $\lambda = 1.38$ Å versus incidence angle α_i/α_c. The limiting value Λ_0 of the penetration depth for $\alpha_i/\alpha_c \ll 1$ is a characteristic materials constant, ($\Lambda_0 = (\pi r_0 \rho)^{-1/2}/4$), independent of the X-ray wavelength λ. For $\alpha_i/\alpha_c \gg 1$ the penetration depth is $\alpha_i\mu^{-1}$; the linear absorption coefficient μ *does* depend on λ.

In 3D crystals, diffraction from a set of crystal planes with an interplanar spacing d occurs only when the Bragg law is obeyed; namely when, firstly, the scattering vector length $|\boldsymbol{q}|$ (given by $|\boldsymbol{k}_f - \boldsymbol{k}_i| = 4\pi \sin\theta/\lambda$) is equal to $2\pi d^*$, where d^* is the reciprocal of the interplanar spacing d, and, secondly, the normal to the planes bisects the angle between the incident and outgoing beam. This condition may be mathematically expressed in terms of the reciprocal lattice vectors $\boldsymbol{d}^* = h\boldsymbol{a}^* + k\boldsymbol{b}^* + l\boldsymbol{c}^*$ where $\boldsymbol{a}^*$, $\boldsymbol{b}^*$, $\boldsymbol{c}^*$ are the reciprocal vectors of the unit-cell vectors $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, and h, k, l are integers that represent the Miller indices of planes with a spacing d_{hkl}. Diffraction therefore only takes place in 3D crystals when the scattering vector $\boldsymbol{q}$ coincides with (h,k,l) points of the reciprocal 3D lattice (Fig. 3c).

For a 2D crystal there is no selection rule or restriction on the scattering vector component $\boldsymbol{q}_z$ along the film normal. Thus the Bragg scattering extends as continuous rods (BR) through the 2D reciprocal lattice points[18] (Fig. 3b). The finite thickness of the 2D crystal causes the BR to extend over finite $\boldsymbol{q}_z$ intervals. The intensity distribution along these intervals is determined by the vertical electron density distribution in the molecules and is expressed as the Fourier transform of the resulting electron density along the film normal.

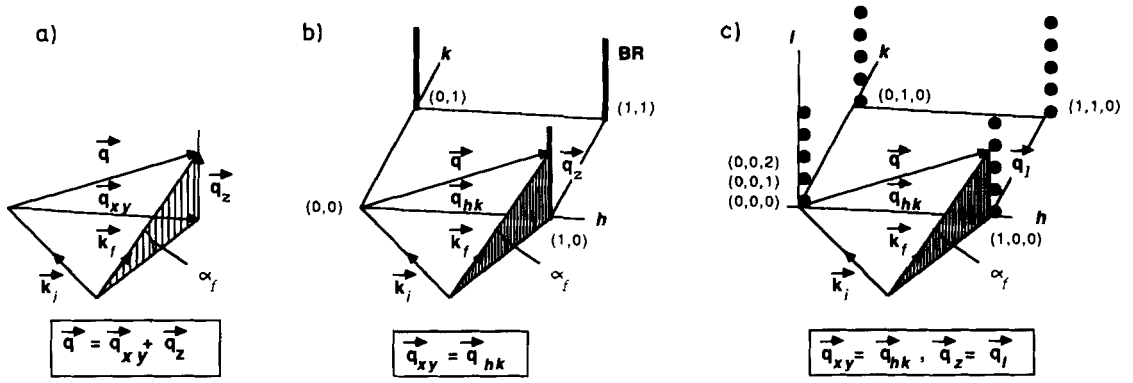

Fig. 3. a) General scattering geometry k_i and k_f are the wavevectors of the incident and diffracted beams respectively. The scattering vector $q = k_f - k_i$ has components q_{xy} parallel to the monolayer plane and q_z perpendicular to it. b) The scattering from a 2D crystalline material in reciprocal space extends in rods (Bragg rods) in the q_z direction, perpendicular to the plane of the monolayer and of its reciprocal 2D net. The scattering vector q must end on an (h,k) Bragg rod for Bragg diffraction. c) The scattering from a 3D crystal in a given orientation lies in reciprocal or q space at the reciprocal lattice points (h,k,l). Diffraction takes place when q coincides with a specific reciprocal lattice point [(1,0,3) in this particular case].

This intensity modulation can now be analyzed to obtain information, for example, on the direction and magnitude of the molecular tilt in the crystalline part of Langmuir monolayers.[19, 20] In addition, detailed information on the electron density distribution in the vertical direction, laterally averaged over both the ordered and disordered parts of the monolayer can be obtained from the deviation of the measured X-ray reflectivity[19, 21] (XR) from the Fresnel law.[16] By combining the methods of GID and XR, the structure of Langmuir films can be accurately characterized. Finally, grazing incidence X-ray excited fluorescence[22] and X-ray standing wave[23, 24] measurements yield information on the location and concentration of ions bound to the monolayer at the liquid interface. We now discuss these methods in some detail.

2.1. Specular Reflectivity (XR)

Specular reflection means that the reflected ray measured is in the plane spanned by k_i and the vector normal to the surface and that $\alpha_i = \alpha_r$ (see Fig. 1). The specular reflectivity of an ideal surface is given by the well-known Fresnel law of optics.[16] In the limit of small angle of incidence,[19, 21] applicable here, it reduces to Equation (3), where $q_z = (4\pi/\lambda)\sin\alpha_i$ is the z component of the momentum transfer and $q_c = (4\pi/\lambda)\sin\alpha_c$ is the critical value of q_z for total external reflection. The complex term arises from absorption effects (see Section 2). Neglecting absorption ($q_z < q_c$) Equation (3) yields $R_F = 1$, that is, total reflection. As q_z is increased beyond q_c, however, R_F decreases and, for $q_z \geq 4q_c$, approaches $R_F(q_z) \approx (q_c/2q_z)^4$. As the range of interest may extend to $q_z/q_c \approx 30$ or more,[19, 21] reflectivities down to 10^{-8} have to be measured. Hence the importance of high-intensity synchrotron sources or high-power rotating anode X-ray generators for XR measurements. Equation (3) is valid only for an ideally flat surface across which the electron density $\rho(z)$ varies steplike between two constant values. If $\rho(z)$ is not a step function, but varies continuously in the surface region, the reflectivity is modified,[19, 21] yielding Equation (4), where ϕ is defined as in Equation (5) and ρ_∞ is the constant electron density in the subphase bulk. Thus, by measuring $R(q_z)$ it is possible in principle to determine $\rho(z)$, the variation of the electron density normal to the surface, and, in particular, that of a monolayer floating on it. The function ϕ is complex, and only its modulus can be derived from the measured reflectivity but not its phase. Thus one is faced with the usual phase problem of X-ray crystallography and therefore to date virtually all specular reflectivity data has been analyzed by fitting a parametrized model density $\rho(z)$ to the measured data applying Equations (3), (4) and (5).

$$R_F(q_z) = \left[\frac{q_z - [q_z^2 - q_c^2 + i(4\pi\mu/\lambda)]^{1/2}}{q_z + [q_z^2 - q_c^2 + i(4\pi\mu/\lambda)]^{1/2}}\right]^2 \quad (3)$$

$$R(q_z) = R_F(q_z)|\phi(q_z)|^2 \quad (4)$$

$$\phi(q_z) = \frac{1}{\rho_\infty}\int \frac{d\rho(z)}{dz} e^{iq_z z} dz \quad (5)$$

One strategy has been to generate $\rho(z)$ as the sum of densities $\rho_i(z)$ from individual atoms at height $z = z_i$ and refine this *atomic model* of the monolayer molecules under suitable constraints.[25, 26] A typical constraint would be that, say, the hydrophobic moiety must tilt as a rigid body, that is, without distorting the a priori assumed internal bond lengths and angles. Adjustable parameters, then, would be the tilt angle of each molecular segment, the height of the molecule above the interface, and the area per molecule.

A computationally slightly simpler strategy presents the monolayer as a stack of slabs,[27] each with a constant density ρ_i and thickness l_i. Two such slabs would be needed for representing a simple fatty alcohol or acid monolayer.[28] When refining such a *slab model*, possible fit parameters would be the densities ρ_i and thicknesses l_i of the slabs.

For either representation of the monolayer, the constant density of the semi-infinite subphase has to be added below the interface. Finally, either model density must be smeared out in the z direction to account for the vertical roughness or diffuseness of the interface. The root-mean-square roughness, σ, is of order of 3 Å and stems mainly from thermally excited capillary waves on the water surface.[19, 21b, 21c] It leads to a Debye–Waller factor $\exp(-q_z^2\sigma^2)$ in $|\phi(q_z)|^2$ (Eq. 5)).

The rather large value of $\sigma \approx 3$ Å (equivalent in normal crystallographic parlance to $B = 8\pi^2\sigma^2 \approx 225$ Å^2) makes it unnecessary to use accurate charge densities for the atoms in the atomic model of $\rho(z)$, so long as each atom contributes its proper charge Z_i, the description will be adequate. Replacing groups of atoms by pseudoatoms is also feasible. Furthermore, since the value of σ is large, the monolayer may be adequately represented by the slab model. This is illustrated in Figure 4, which shows that the density $\rho(z)$ of a fatty acid monolayer may be represented by either model.

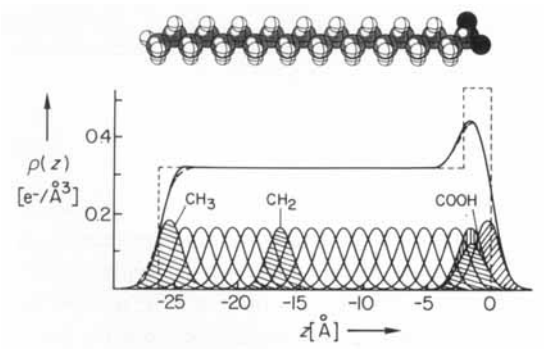

Fig. 4. Top: Space-filling model of a $C_{19}H_{39}CO_2H$ molecule. Bottom: Model electron densities $\rho(z)$. The dashed lines refer to a slab model and a smoothed slab model. The full lines refer to an atomic model using CH_3 and CH_2 as pseudoatoms. The contribution of each pseudoatom (or atom at the CO_2H head group) to the electron density is indicated by Gaussian curves. The two models agree nearly exactly even though drawn for display purposes with an unrealistically small smearing parameter σ of 1 Å.

2.2. Grazing Incidence Diffraction (GID) and Bragg Rods

In the GID geometry (Fig. 5) the angle of incidence α_i of the X-ray beam is kept below the critical angle α_c, limiting the penetration depth of the beam to that of the evanescent wave. Scattering due to the subphase is efficiently eliminated, which allows an accurate measurement of the weak diffraction signal originating from the crystalline monolayer. For all the diffraction patterns measured so far, the monolayers were found to be composed of 2D crystallites randomly oriented on the water surface, that is a 2D "powder". Hence

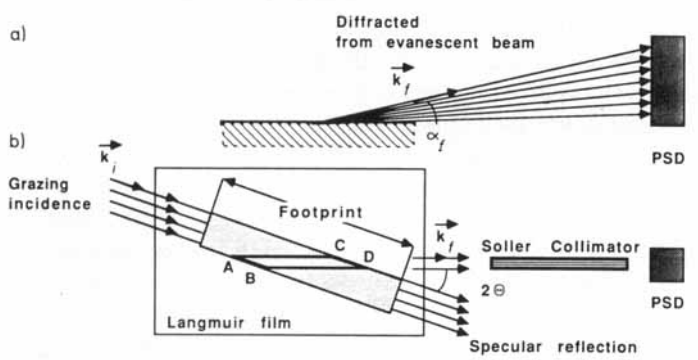

Fig. 5. a) Side and b) top view of the grazing incidence X-ray diffraction geometry. The footprint of the grazing incident beam is indicated by the shaded area. The position sensitive detector (PSD) has its axis along the vertical. Only the cross-beam area ABCD contributes to the measured scattering. The Soller collimator consists of thin vertical absorbing foils stacked together to define the horizontal resolution of the detector.

only a 2θ or q_{xy} scan in the monolayer plane is required to measure the diffraction pattern. The analysis is similar to that of a conventional 3D powder pattern; the reflections can be indexed by two Miller indices, h and k. Their angular positions $2\theta_{hk}$ corresponding to $q_{hk} = (4\pi/\lambda)\sin\theta_{hk}$ yield the repeat distances $d_{hk} = 2\pi/q_{hk}$ of the 2D lattice structure. Their resolution-corrected 2θ-line width (FWHM) Δ yields the 2D crystalline coherence length L through the well-known Scherrer formula [Equation (6)].[29]

$$L = \frac{0.9\,\lambda}{\cos\theta_{hk}\,\Delta} \tag{6}$$

Finally, the square of the molecular structure factor $|F_{hk}|^2$ integrated along the Bragg rod over the window of q_z seen by the detector determines the integrated intensity in the peak.[15] The structure factor F_{hk} is given by Equation (7),[18-20, 30a] where f_j is the scattering factor of the atom j, $\boldsymbol{r}_{x_j y_j}$ is the vector specifying the (x,y) position of the atom j in the unit cell and z_j is the atomic coordinate along the vertical direction.

$$F_{hk}(q_z) = \sum_j f_j e^{i(\boldsymbol{q}_{hk}\boldsymbol{r}_{x_j y_j} + q_z z_j)} \tag{7}$$

More information can be obtained by resolving the variation with q_z along the Bragg rod of the intensity $I_{hk}(q_z)$, given by Equation (8).[18-20, 30a]

$$I_{hk}(q_z) = |V(q_z)F_{hk}(q_z)|^2 e^{-q_z^2\sigma^2} \tag{8}$$

The observed BR intensity I is actually a sum over those (h,k) reflections whose Bragg rods coincide at a particular horizontal 2θ-angle or q_{xy} position.[18-20, 30a] In Equation (8), the most important variation is due to the molecular structure factor $|F_{hk}(q_z)|$. For the simple linear surfactant molecules considered here, the square of the structure factor $|F(\boldsymbol{q})|^2$ is a bell-shaped function which reaches its maximum when the scattering vector $\boldsymbol{q} = (\boldsymbol{q}_{hk}, \boldsymbol{q}_z)$ is orthogonal to the molecular axis. Thus, when the molecules are vertical or tilted in a plane perpendicular to $\boldsymbol{q}_{hk}$, the maximum intensity along the Bragg rod will occur at the horizon, for $q_z = 0$ Å^{-1}. For molecules tilted otherwise, we expect the Bragg rod maximum at a finite q_z, dependent upon both the magnitude and direction of the tilt relative to the in-plane scattering vector $\boldsymbol{q}_{hk}$. The width of the bell-shaped Bragg rod profile measured in a direction parallel to the molecular axis is inversely proportional to the length of the molecule.[19, 20]

The simple description of $F(\boldsymbol{q})$ alluded to above may be improved on by calculating $F(\boldsymbol{q})$ according to an atomic model of the molecule[20, 30a] [Eq. (7) and (8)]. For linear molecules, qualitatively similar results are obtained with both models.[20] The exponential factor [the vertical Debye–Waller factor, Eq. (8)] accounts for the internal thermal motion of the atoms in the molecule, as well as for ripples on the water surface, which lead to roughness of the interface.[19, 21b, 21c] The factor $V(q_z)$ describes the interference of rays diffracted upwards with rays diffracted down and subsequently reflected back up by the interface.[18a] $V(q_z)$ differs from 1 only in the vicinity of $q_z = 1/2\,q_c$, where it contributes a sharp peak to I (cf. Fig. 8 and the related discussion).

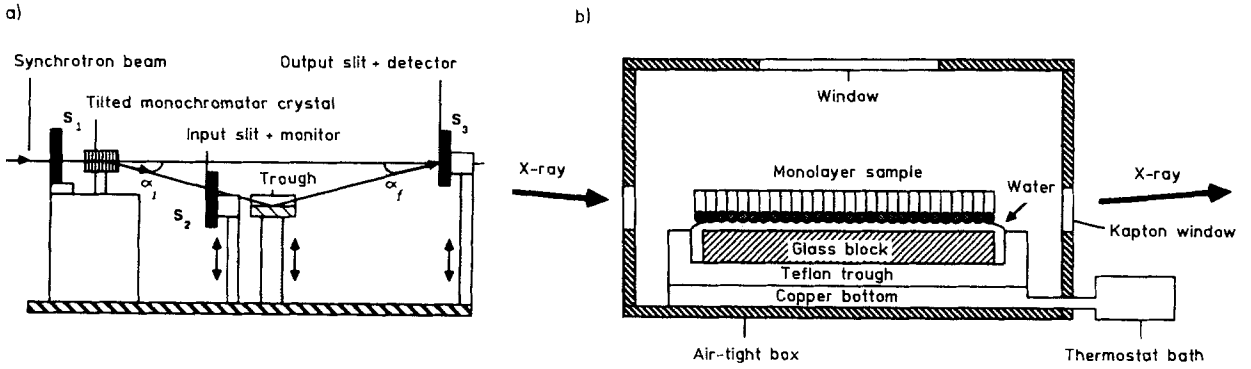

Fig. 6. Example of an experimental setup of a diffractometer for studying liquid surfaces (beamline D4, X-ray synchrotron source at Hasylab, Hamburg). a) Side view of the vertical scattering plane. Beam directions are defined by slits. The monochromatic beam is bent down towards the sample by tilting the monochromator crystal. The incident beam intensity is monitored beyond slit S_2. b) Enlarged view of the trough showing the monolayer sample spread on a thin film of water. The glass block guarantees a thin liquid film (about 0.3 mm thick) and thus effectively reduces surface capillary waves.

While both BR and XR data provide information on the vertical variation of the electron density, there are important differences between the two methods. The BR recorded at a given GID peak position originates solely from crystalline material. This is in contrast with XR, where the reflected signal is an average over *all* of the illuminated area regardless of coverage and in-plane structure. Furthermore, as the molecules in the contributing crystallites have a well-defined orientation relative to $\boldsymbol{q}_{hk}$, the BR profile depends very sensitively on the azimuthal direction of the molecular tilt. XR, on the other hand, averages over all azimuthal angles and hence provides no information on the molecular azimuthal orientation.

We now describe briefly a possible experimental setup (Fig. 6) for the diffraction geometry[31–33] shown in Figure 5. A suitable aperture S_1 is placed in the horizontal synchrotron radiation beam incident from the left (Fig. 6a). A monochromatic beam is selected from the "white" spectrum by Bragg reflection from a monochromator crystal, typically a perfect Ge crystal in the (111) orientation. By tilting the normal to the reflecting planes out of horizontal plane, the monochromatic beam can be bent down to yield a glancing angle with the horizontal liquid surface. The sample is mounted on an elevator so that the liquid surface always intersects the monochromatic beam. A narrow slit S_2 in front of the sample defines a suitable footprint of the beam on the liquid surface. The slit S_3 excludes diffuse scattered background around the reflected beam. This slit together with a scintillation detector is mounted on an elevator situated on a diffractometer arm which is pivoted around a vertical axis through the sample center. For in-plane diffraction measurements the slit S_3 is replaced by a Soller collimator giving 1 or 2 mrad collimation and the scintillation counter by a position-sensitive detector allowing Bragg rod measurements to be made (Fig. 5).

2.3. X-ray Fluorescence Methods

Atoms illuminated by X-rays of energy higher than that of their absorption edges will emit characteristic secondary radiation, the intensity of which is proportional to the number of excited atoms. Thus, by employing monochromatic X-rays of energy higher than, for example, the energy of the K absorption edge of a given ion dissolved in the subphase, it is possible to study the depth dependence of the concentration of that ion in the subphase. From Figure 2, we see that by varying α_i in the vicinity of α_c we can fine-tune the penetration depth of the primary radiation, and hence the depth to which we excite the ions dissolved in the subphase. Roughly speaking, the intensity variation of the secondary radiation will therefore follow the concentration variation with depth of the emitting ions.[34]

The method of near-total external fluorescence (NTEF) presented above provides information on the *vertical* concentration variation of the fluorescing probe ion. A variation on this method involves surface-EXAFS (Surface Extended X-ray Absorption Fine Structure, SEXAFS), where the fluorescence intensity variation is measured while varying the energy of the exciting radiation across the absorption edge of the probe atoms.[22] By keeping the angle of incidence α_i smaller than α_c, the penetration depth is kept to a few tens of Ångstroms. The short-range atom–atom correlation function in the surface layer (which gives a measure of interatomic distances) can be extracted by conventional EXAFS data analysis methods. By observing changes in this function induced by surface pressure variation in a deposited monolayer on the surface of the subphase, the interatomic distances in a layer of ions adsorbed from the subphase at its interface with the monolayer can be determined.[22] Thus a combination of NTEF and SEXAFS can be employed to provide information on both the vertical and horizontal structure of the probe ion near the surface. However, in contrast to GID, the in-plane information provided by SEXAFS is short range only and extends up to second nearest neighbors at most. On the other hand, GID is applicable only if reasonably long-range order exists (≥ 100 Å), while SEXAFS will provide average nearest-neighbor distances even for completely disordered systems.

2.4. X-ray Standing Waves

Standing waves are created when two coherent plane traveling waves are superimposed in the same region of space.[23] This is schematically depicted in Figure 7a, which shows the

resulting standing wave created by interference between an incident plane wave of vector $\boldsymbol{k}_i$ and its reflection from a mirror surface with a wavevector $\boldsymbol{k}_r$.

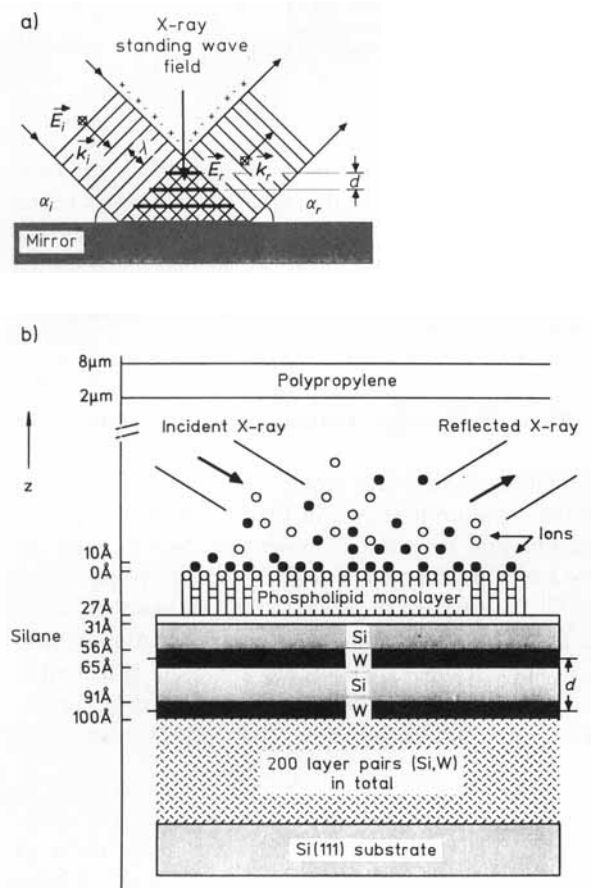

Fig. 7. a) Illustration of the X-ray standing wave field formed by the interference between the incident (E_i) and specular-reflected (E_r) plane waves above a mirror surface. By locating the intersections of the crests (labeled + lines) and troughs (labeled – lines) of the two plane waves, one can easily show that the antinodes of the standing wave are parallel to the mirror surface. Since total external reflection of X-rays (wavelength in Å range) occurs at incident angles α_i smaller than 0.5°, the spacing d typically varies between 100 Å and 1000 Å. b) Scheme showing a phospholipid monolayer deposited on a silanated Si/W layered synthetic microstructure (LSM). In the experiment depicted here [24b], the head group of the phospholipid containing an anionic phosphate group is exposed to solution and attracts zinc ions from a 0.1 mM $ZnCl_2$ aqueous solution. The polypropylene film traps a 2 μm thick water layer.

Conventionally, dynamical Bragg diffraction from perfect single crystals is used to generate an X-ray standing wave, whose period d is exactly commensurate with the diffracting planes of the crystal. For films adsorbed onto the crystal surface, with a thickness of say 20 to 100 Å, one requires long-period X-ray standing waves[24] which may be generated by Bragg diffraction from layered synthetic microstructures (LSM, Fig. 7b). For Bragg diffraction purposes a LSM is fabricated as a periodic layered structure consisting of 10 to 200 layer pairs of alternating high and low electron density materials (such as tungsten and silicon) to yield a diffraction plane spacing varying from 20 to 200 Å (Fig. 7b). Long period X-ray standing waves are also generated by total external reflection when the incident angle is less than the critical angle α_c (Fig. 7a). The period of the standing waves is $d = \lambda/2 \sin\alpha_i$.

To measure the effect of standing waves, an energy-dispersive detector is positioned above the surface and picks up the X-ray fluorescence from atoms adsorbed at the crystal surface or close to it. The fluorescence radiation of these atoms will depend on their positions as the period and phase of the standing wave changes with the angle of incidence of the primary beam. Figure 7b depicts an interesting application of the technique to ion–surfactant interactions: the study of interfaces between adsorbed charged monolayers and the distribution of the counterions in solution.[24b]

3. General Packing Characteristics of Langmuir Monolayers on Water

Before the development of surface X-ray diffraction techniques, knowledge of molecular arrangement in the three-dimensional state was used to increase understanding of the structure and behavior of molecules in the monolayer state, as already mentioned in Section 2. Analogous packing is not always possible however, because of environmental differences between the two- and three-dimensional states. Phase diagrams constructed from surface pressure–area (π–A) measurements for such compounds revealed phase boundaries, depending upon pressure, temperature, and chain length, but could provide little information on the structure of these phases. Now, with recently acquired information from surface-sensitive X-ray techniques, the packing of such Langmuir films can be determined almost at atomic level. Although GID measurements have been carried out on several Langmuir monolayer systems, the monolayer structures corresponding to the complete phase diagrams have been elucidated by GID only for the acids $C_{20}H_{41}CO_2H$ and $C_{21}H_{43}CO_2H$, discussed in Section 3.2. In Section 3.1 we describe one or two examples from each chemical class studied to date: alcohols, amides, carboxylic acids, divalent salts of the latter, α-amino acids, and phospholipids (see Table 1 for their chemical formulas and abbreviations). The latter two classes of compounds possess an asymmetric carbon atom whose chirality is specified by the symbol (*R*) or (*S*).

Table 1. Abbreviations for monolayer compounds discussed here and their chemical formulae

Abbreviation	Full Name	Chemical Formula
C_nOH	aliphatic primary alcohols	$C_nH_{2n+1}OH$
C_nCO_2H	aliphatic primary acids	$C_nH_{2n+1}COOH$
C_nCONH_2	aliphatic primary amides	$C_nH_{2n+1}CONH_2$
$C_{19}CONHC_2H_4CO_2H$	*N*-arachidoyl-β-alanine	$C_{19}H_{39}CONHC_2H_4CO_2H$
DMPE	dimyristoyl-phosphatidylethanolamine	$C_{13}H_{27}COOCH_2CH(OOCC_{13}H_{27})$-$CH_2PO_4^-$, $C_2H_4NH_3^+$
PL	palmitoyl-lysine	$C_{15}H_{31}CONHC_4H_8CHNH_3^+CO_2^-$
PFA	"perfluoro"dodecyl-aspartate	$C_{10}F_{21}C_2H_4OCOCH_2CHNH_3^+CO_2^-$

It is useful at this stage to describe how unit cell dimensions and molecular orientation may be determined from GID data for simple cases. We consider the molecule as a freely rotating alkane chain; in other words, it has cylindrical symmetry. These molecules may pack in three different cell types: hexagonal ($a = b$, $\gamma = 120°$), distorted hexagonal ($a =$

b, $\gamma \neq 120°$) which may be more properly described as centered rectangular ($a' = |\boldsymbol{a} + \boldsymbol{b}|$, $b' = |\boldsymbol{a} - \boldsymbol{b}|$), and oblique ($a \neq b \neq |\boldsymbol{a} + \boldsymbol{b}|$) (Fig. 8). The molecules in a hexagonal cell are aligned vertically relative to the plane of the film, while in the distorted hexagonal cell they are tilted along a symmetry direction and in the oblique cell along an arbitrary direction. As mentioned earlier, all Langmuir monolayers studied

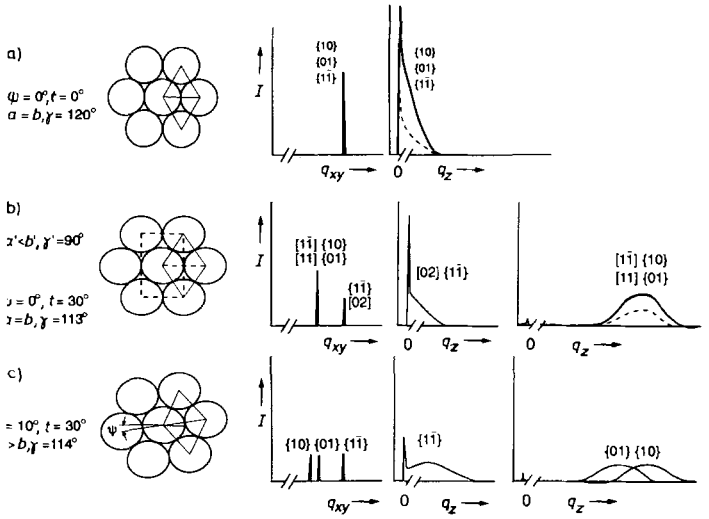

Fig. 8. Three possible structures and diffraction from a monolayer of close-packed, freely rotating alkyl chains. The left column shows schematic top views of the molecular packing in hexagonal, distorted hexagonal, and oblique unit cells. The second column shows the q_{xy}-pattern integrated over the vertical wavevector component q_z, and the last two columns show the Bragg rods integrated over the corresponding q_{xy}. When more than one reflection coincide, the dashed lines represent the intensity from individual reflections as indicated by the Miller indices. The solid line represents the intensity from a two-dimensional powder sample; that is, the sum of the intensities indicated by dashed lines. When the molecular axis is perpendicular to the water surface the lattice is hexagonal [a)], and the $\{1,0\}$, $\{0,1\}$ and $\{1,\bar{1}\}$ reflections are degenerate. The Bragg rod obtained from the single in-plane diffraction peak has its maximum at $q_z = 0\,\text{Å}^{-1}$. When the molecular axis is tilted towards nearest neighbors [b)], the hexagonal structure is distorted to a centered rectangular structure (rectangular notation at the top, distorted hexagonal notation at the bottom). The degeneracy of the three reflections is partially lifted resulting in two peaks. The Bragg rod of the two degenerate reflections $\{1,0\}$ and $\{0,1\}$ ([1,1], $[1,\bar{1}]$ in the rectangular notation) is centered at $q_z \geq 0\,\text{Å}^{-1}$. The Bragg rod of the $\{1,\bar{1}\}$ reflection ([0,2] in the rectangular notation) is still centered around $q_z = 0\,\text{Å}^{-1}$. Finally, when the molecular axis is tilted in a non-symmetry direction, the intersection between the close-packed circular chains and the water surface forms an oblique 2D lattice [c)]. The degeneracy is completely lifted and the peak positions of the three Bragg rods determine the tilt angle as well as the azimuthal angle Ψ unambiguously.

to date by GID consist of "powders" of randomly ordered 2D crystallites on the water surface so that the GID measurements are not made on single crystals. Thus, the diffraction spectra consist of coinciding Bragg rods of reflections (h,k,q_z) and $(\bar{h},\bar{k},q_z)$, the notation $\{h,k,q_z\}$ designating both reflections. In general, the intensity distribution along their two coinciding Bragg rods will be different unless the monolayer structure has twofold symmetry along the vertical axis.

The hexagonal cell has three equivalent lattice spacings d_{hk}: d_{10}, d_{01}, and $d_{1\bar{1}}$. The GID spectrum from these three reflections will appear as a single signal with all corresponding Bragg rods peaking at $q_z = 0\,\text{Å}^{-1}$ (Fig. 8a). The corresponding GID spectrum for the distorted hexagonal cell will comprise two peaks; one a superimposed doublet arising from the coinciding $\{1,0\}$ and $\{0,1\}$ reflections, and the other the remaining $\{1,\bar{1}\}$ peak (Fig. 8b). The separation between

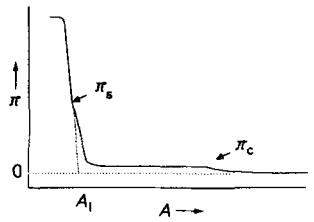

Fig. 9. General shape of a surface-pressure versus area isotherm (π–A isotherm) of a Langmuir monolayer. A_l is defined as the limiting area (i.e., the close-packed area for the molecules at zero pressure). π_s and π_c define transition pressures between phases.

the two peaks depends upon the deviation of the angle γ from 120°. In the oblique cell the degree to which the three reflections $\{1,0\}$, $\{0,1\}$, and $\{1,\bar{1}\}$ are resolved (Fig. 8c), depends upon the deviation from centered rectangular (i.e. distorted hexagonal) cell symmetry.

3.1. Phase Changes Induced by Surface Pressure

A typical pressure–area isotherm of Langmuir films at room temperature is shown in Figure 9. It has long been realised that the kinks in the isotherm (the surface pressures at the kinks are denoted π_c and π_s) indicate phase transitions.[10] The shape of the isotherm and the positions of the kinks are characteristics of a given monolayer. At room temperature the alcohol $C_{21}OH$ and acid $C_{20}CO_2H$ as well as the α-amino acid PFA exhibit isotherms with only one distinct kink at π_s (in the range 15–30 mN m^{-1}), whereas the

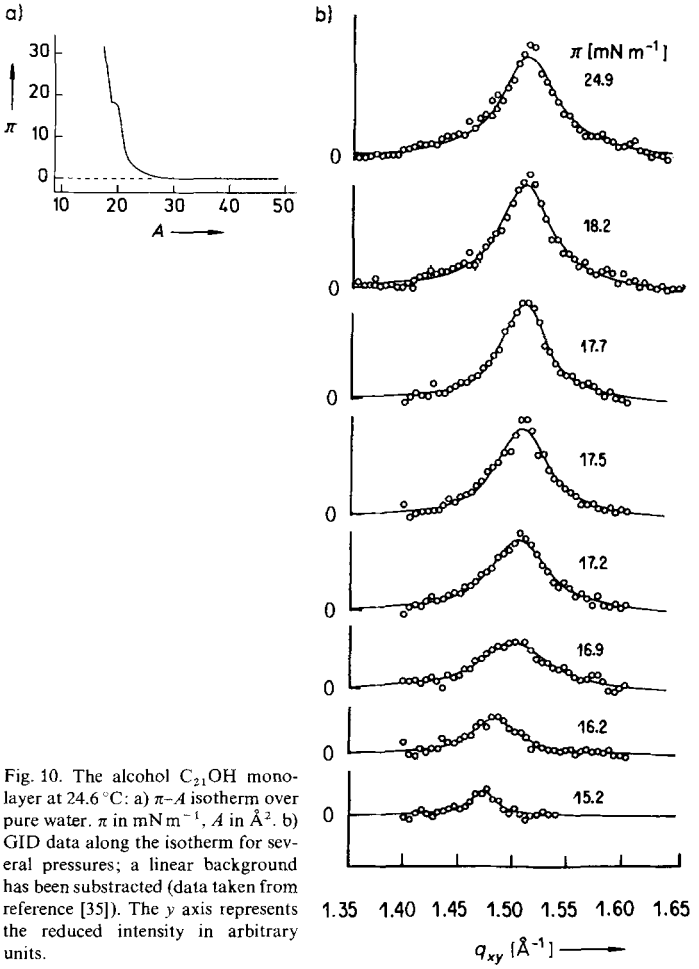

Fig. 10. The alcohol $C_{21}OH$ monolayer at 24.6 °C: a) π–A isotherm over pure water. π in mN m^{-1}, A in Å^2. b) GID data along the isotherm for several pressures; a linear background has been substracted (data taken from reference [35]). The y axis represents the reduced intensity in arbitrary units.

phospholipid compound DMPE has an isotherm with two kinks (π_c in the range 5–10 mN m^{-1} and π_s in the range 20–30 mN m^{-1}). The α-amino acid PL shows no observable kink. It has generally been assumed that a decrease in molecular area induces transitions from gaseous through "liquid-expanded" and "liquid-condensed" to the solid crystalline phases.[10] But the GID data on some systems reveal high crystallinity in the uncompressed state and a tendency towards a reduction of crystallinity with increased pressure. Thus, GID and XR results provide a more accurate description of the phases.

3.1.1. *Fatty Acids and Alcohols*

GID data for henicosanol[35] $C_{21}OH$ shows a single peak in the surface pressure range 15–30 mN m^{-1} and temperature range 15–30 °C (Fig. 10b). The changes in the peak with pressure observed at 24.6 °C (Fig. 10b) are typical of the isotherms measured (Fig. 10a). The gradual loss of intensity below π_s was interpreted[35] as being due to the appearance of *gauche* defects in the hydrocarbon chain. The kink then represents the lowest pressure at which the last of the gauche configurations are squeezed out. At higher pressures all the molecules stand straight with their hydrophobic tails in all-*trans* conformation.

Combined GID, Bragg rod, and XR room temperature measurements on arachidic acid[19, 28] $C_{19}CO_2H$ along the isotherm (Fig. 11) have been interpreted differently; the drop in GID intensity as a function of decreasing surface pressure was accounted for by a continuous change in tilt of rigid parallel molecules.

The low pressure structure was assigned to a distorted hexagonal cell, where molecules tilt toward nearest neighbors. Such a cell yields two diffraction peaks, one corresponding to the $\{1,\bar{1}\}$ reflection and the other to $\{1,0\}$ and $\{0,1\}$. The results reported[35] for $C_{21}OH$ could possibly be interpreted in a similar manner. A definitive answer would require BR and XR measurements of that system.

The GID and XR results for $C_{19}CO_2H$ on pure water allows us to deduce some information on the packing of the carboxyl groups in the compressed ordered state at room

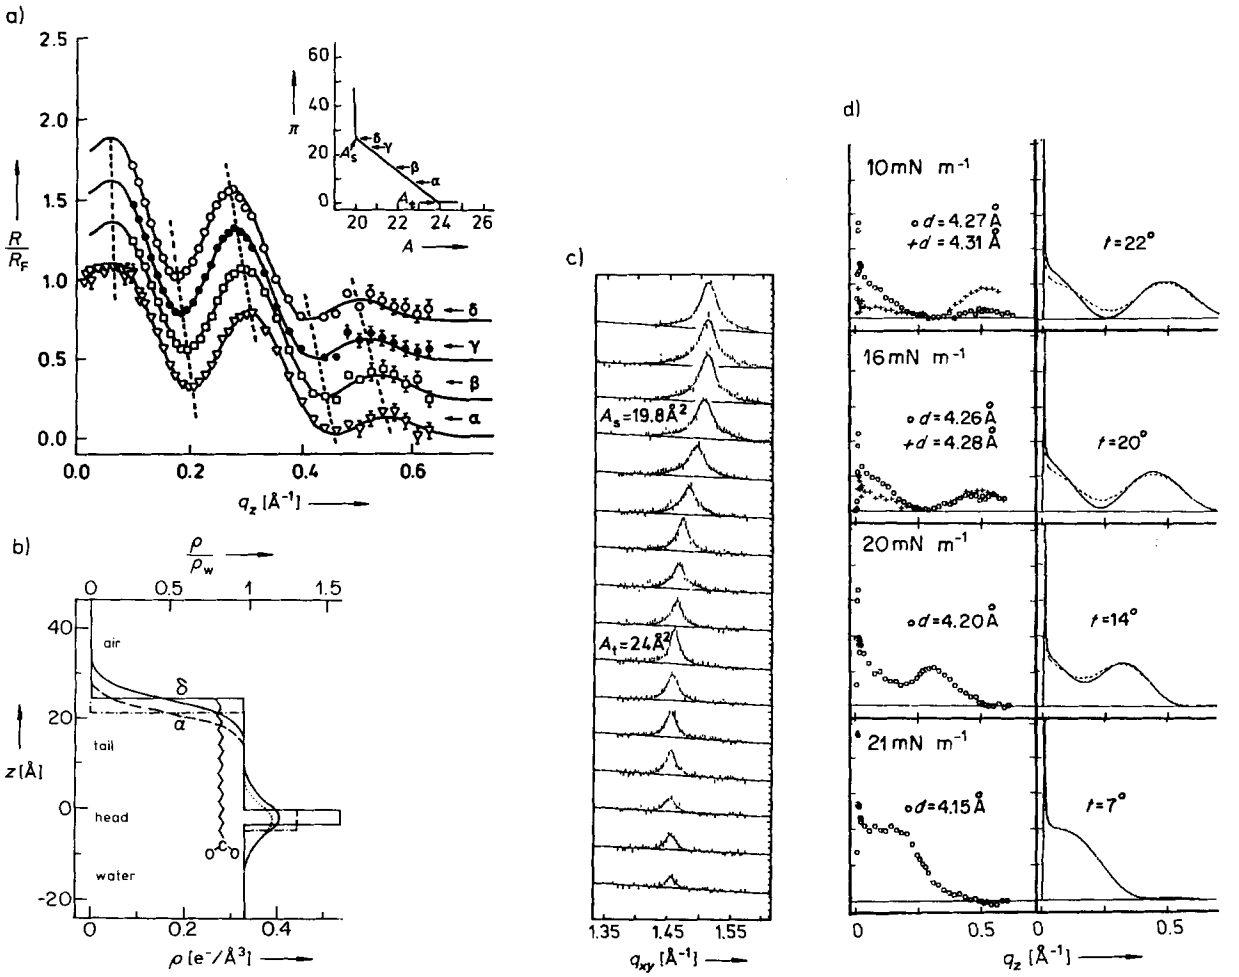

Fig. 11. Arachidic acid $C_{19}CO_2H$ monolayer at room temperature and over pure water: a) Normalized X-ray reflectivity (XR) data for increasing surface pressure (α–δ). The insert shows the π–A isotherm (π in mN m^{-1} and A in Å^2) of the monolayer and indicates the points where the XR measurements were performed. b) Fitted model of the vertical electron density $\rho(z)$. On compression, the monolayer thickness increases while the density remains constant in the tail region as shown by the change from the dashed lines to the full lines. $\rho_w = \rho_{water}$. c) GID data for decreasing mean molecular area; A_s and A_t correspond to the areas marked on the π–A diagram. d) Left: 2D powder Bragg rods observed at surface pressure of 10, 16, 20, and 21 mN m^{-1}. At 20 and 21 mN m^{-1}, the optimal q_{xy} settings for the merging peaks at $q_z = 0$ Å^{-1} and $q_z > 0$ Å^{-1} coincide, but for lower surface pressures they split as indicated by open circles (optimum q_{xy} for $q_z = 0$ Å^{-1}) and crosses (optimum q_{xy} for $q_z = 0.5$ Å^{-1}). Right: Calculated Bragg rod profiles from a slab model in which the molecules tilt towards next nearest neighbors by an angle t. The model parameters were determined essentially from the reflectivity data. The dashed line represents a perturbation of this model: the molecules were tilted in a direction 8° from the symmetry direction.

temperature. The hexagonal cell may at first sight imply complete rotational disorder about the chain axis. Indeed such structural disorder may be assumed for the alcohol $C_{21}OH$. However aliphatic carboxylic acids can hardly support such disorder for it could lead to a short contact $d_{O\cdots O}$ of about 1.5 Å between two adjacent oxygen atoms with their lone-pair electrons directed at each other (Fig. 12). Numerous studies[36] have demonstrated that two such adjacent oxygen atoms have a preferred separation of 3.5 Å. Whether hindered rotation of the acid molecules precludes a hexagonal symmetry (but not a hexagonal cell) is therefore a moot point.

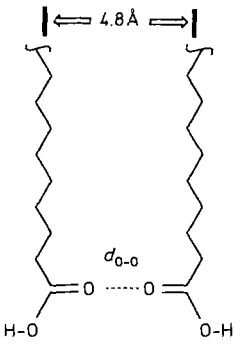

Fig. 12. Close contact ($d_{O\cdots O}$ spacing) between adjacent oxygen atoms of two fatty acid molecules separated by 4.8 Å and related by twofold symmetry.

3.1.2. *Phospholipids*

The extensive surface X-ray studies on phospholipid monolayers have been reviewed in detail in terms of structural changes along the π–A isotherm.[32, 37] We therefore confine this discussion to a brief review of some aspects of the condensed monolayer of α-dimyristoyl phosphatidylethanolamine (DMPE, see Table 1) from the view point of molecular packing (the isotherm is shown in Fig. 13a).

GID measurements[32] yielded a single peak in the pressure range between 10 and 38 mN m^{-1}. The variation with surface pressure of the diffraction peak characteristics is depicted in Figure 13b. The diffraction data for $\pi_c < \pi < \pi_s$ is consistent with coexistence between a nondiffracting liquid phase and a gel phase where the coherence length L increases with pressure. In the condensed phase (above π_s) the coherence length is no more than about 50 lattice distances, so the monolayer forms some crystalline solid phase, but with many defects. For the condensed phase region, the results of the X-ray reflectivity data (Fig. 13c) may indicate an ordering of the head groups.

Although little is known on the packing arrangement of hydrophobic chains and the hydrophilic head group PO_4^--CH_2-CH_2-NH_3^+ moieties, information thereon may be gleaned from the three-dimensional crystal structure of the racemic dilauryl derivative (*rac*-DLPE) whose packing arrangement[38] is shown in Figure 14. The most intense reflection from the layer structure of *rac*-DLPE has a spacing of 4.2 Å, which is the same value as that of the single GID peak observed from the chiral resolved compressed monolayer of DMPE (Fig. 13b, bottom), indicating a similarity in packing of their hydrophobic chains. In the 3D crystal the molecules

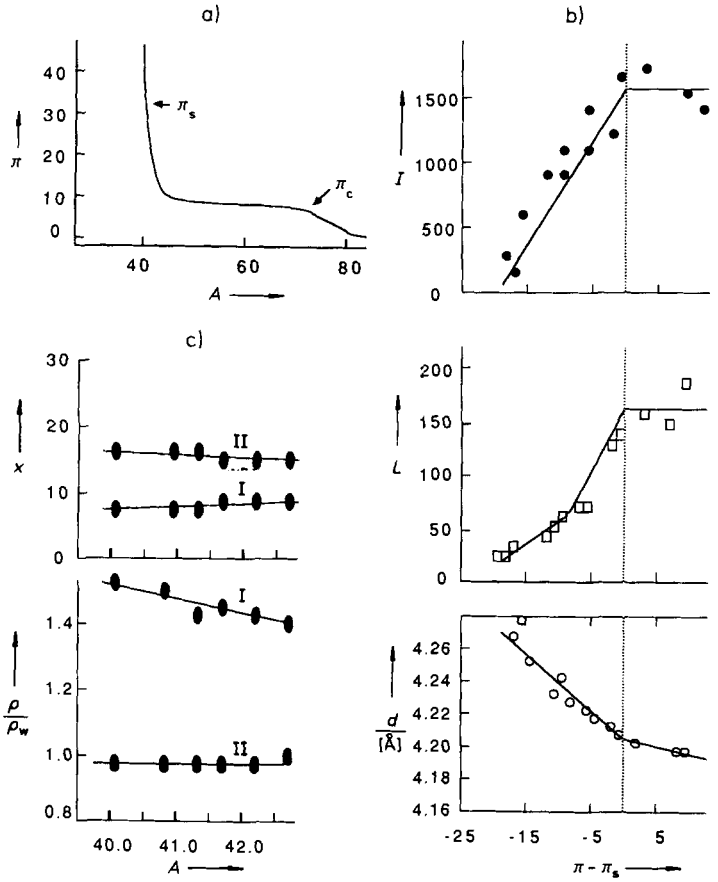

Fig. 13. Phospholipid DMPE monolayer over pure water at room temperature: a) π-A isotherm of DMPE; π in mN m^{-1}, A in Å^2. b) Three parameters extracted from the GID data as a function of surface pressure; the intensity of the integrated GID peak (I in arbitrary units), the coherence length L, and the lattice spacing d. c) Model parameters for the head (I) and tail (II) slabs [thickness x [Å] and electron densities $\rho(z)$ relative to that of water (ρ_w)] used in XR data fitting.

form a bilayer; within each layer the head groups are interlinked by NH···O hydrogen bonds by translation and glide symmetry. This head group packing is also observed in the crystal structure of (2-aminoethyl)phosphate $HO\text{–}PO_3^-$–

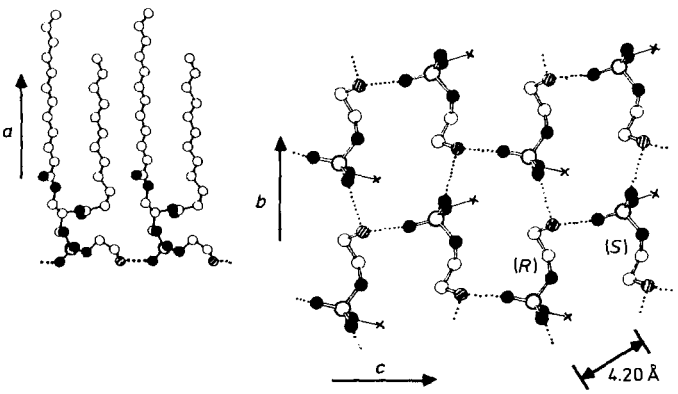

Fig. 14. The layer structure of *rac*-DLPE in its 3D crystal. The hydrogen atoms are omitted. Left: View down the c axis. Right: View down the a axis. For clarity each hydrocarbon chains are represented by a small cross. The molecules are interlinked by NH···O hydrogen bonds (dashed lines) by translation symmetry along the b axis (molecules of the same configuration) and by glide symmetry along the c axis (molecules of the opposite configuration). Note the characteristic 4.20 Å spacing imposed by the molecular packing. ● = O, ⊗ = N, ○ = C,P.

CH_2–CH_2–NH_3^+.[39] It is tempting to think that the head groups of chiral resolved monolayers of DMPE and DLPE would also pack in a pseudoglide arrangement. However, the monolayer study of DLPE and DMPE was performed on the resolved naturally occurring (*S*) enantiomer. Furthermore, the thickness of the layer of the head groups in the 3D crystal structure is 5.5 Å, but in the range of 7.15 to 9.5 Å in the monolayer structures according to the XR data.

3.1.3. α-Amino Acids

The α-amino acid surfactants were used for the oriented crystallization of the α-polymorph of glycine and of NaCl at the monolayer–solution interface (see Section 5). GID and XR measurements were performed on two of these monolayers in order to establish independently the similarity or complementarity of the head-group arrangement of the monolayer molecule and the layer arrangement of the crystal face attached to the monolayer.[25, 26, 30] Here we describe the packing characteristics of two α-amino acid surfactants, PL and PFA (see Table 1).

Palmitoyl-lysine (PL): The NH···O hydrogen bonding arrangement of the α-amino acid head groups NH_3^+-CH-CO_2^- and of the amide groups CO-NH in the chain essentially fixed the monolayer packing. The π–*A* isotherm of the monolayer of PL is shown in Figure 15a. A compressed (about 25 mN m^{-1}) monolayer of PL was found by GID to form crystalline domains with a coherence length of about 500 Å. The diffraction pattern[25] shows two Bragg peaks (Fig. 15c). The calculated GID positions and intensities for the model structure[25, 40] are also shown. Analysis of observed XR data (Fig. 15b) yields a tilt angle of the molecular chain axis of about 30° from the vertical. The deduced cell axes and packing arrangement of PL is shown in Figure 16. The α-amino acid head groups NH_3^+-CH-CO_2^- are arranged in a manner similar to that of crystalline α-glycine or other naturally occurring hydrophobic α-amino acids.[41–43] The linear NH···O hydrogen bonds between amide groups in the chain linking neighboring molecules along the (***a*** + ***b***) director (Fig. 16b) require a 30° tilt of the chain axes, as was independently deduced from the XR analysis.

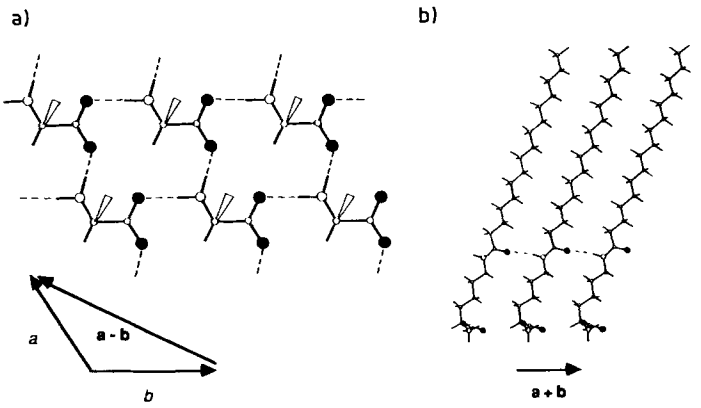

Fig. 16. Views of the model packing arrangement of (*R*)-PL monolayers over pure water; π = 25 mN m^{-1}. a) Perpendicular to the monolayer plane, the hydrophobic chain is represented by a wedge. The NH···O=C(acid) hydrogen bonds are symbolized by dashed lines. b) View along the ***a*** − ***b*** axis showing molecules in a row parallel to the ***a*** + ***b*** direction, interlinked by NH···O=C (amide) hydrogen bonds. ● = O.

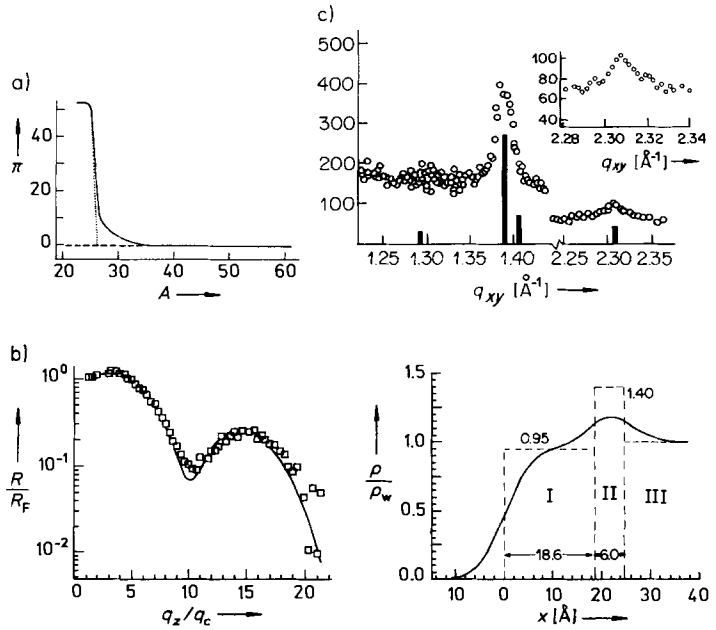

Fig. 15. (*R*)-PL monolayers over pure water at room temperature. a) π-*A* isotherms (π in mN m^{-1} and A in Å^2). b) Left: The measured, normalized *R* values and the theoretical model obtained by curve-fitting. Right: The refined model electron density $\rho(z)$ relative to that of water ρ_w. The PL molecules are modeled by two slabs, one corresponding to the head group (region II) and the other to the hydrocarbon tail (region I). Region III corresponds to the water subphase and z represents the height coordinate. The smoothed model shown as a solid line is obtained with a smoothing factor σ of 3 Å. c) GID of a compressed PL monolayer. The calculated relative intensities of the model (Fig. 16) drawn underneath the peaks are without adjustable parameters except for scale and Debye–Waller factors.

"Perfluoro"dodecylaspartate (PFA): The behavior of PFA upon compression is similar to that of arachidic acid in that the molecular tilt angle is continuously reduced with increasing surface pressure.[30a] However, the system revealed some original features. At low surface coverage (points α, β, γ on the isotherm in Fig. 17a), molecules of PFA self-assemble in large crystalline domains, in which they are arranged in an oblique cell and tilted by about 22° from the surface normal towards nearest neighbors (Fig. 18), as deduced from the three observed reflections in Figure 17d. Upon compression the three peaks first merge into a doublet (Fig. 17c) and then into a singlet (Fig. 17b), indicating that the symmetry of the cell, but not of the monolayer structure, goes from oblique (Fig. 17d), through distorted hexagonal (Fig. 17c), to hexagonal (Fig. 17b; see also Fig. 8 and the related discussion).

The molecular behavior of monolayers of PFA during a compression–decompression cycle can be explained with a knowledge of the head-group packing before compression.[30a] The hydrogen-bonding pattern of the α-amino acid head groups of uncompressed PFA was constructed from the known motifs of the 3D crystal structures of neopentylglycine,[5b] (*S*)-alanine,[44] and *rac*-alanine.[45] The major feature of this motif is the participation of intercalated, ordered water molecules interlinking adjacent hydrogen-bonded ribbons of PFA molecules (Fig. 18). The molecular area, which is dictated by the head group, is 30.9 Å^2 as compared with the cross-sectional area of the fluorocarbon chain

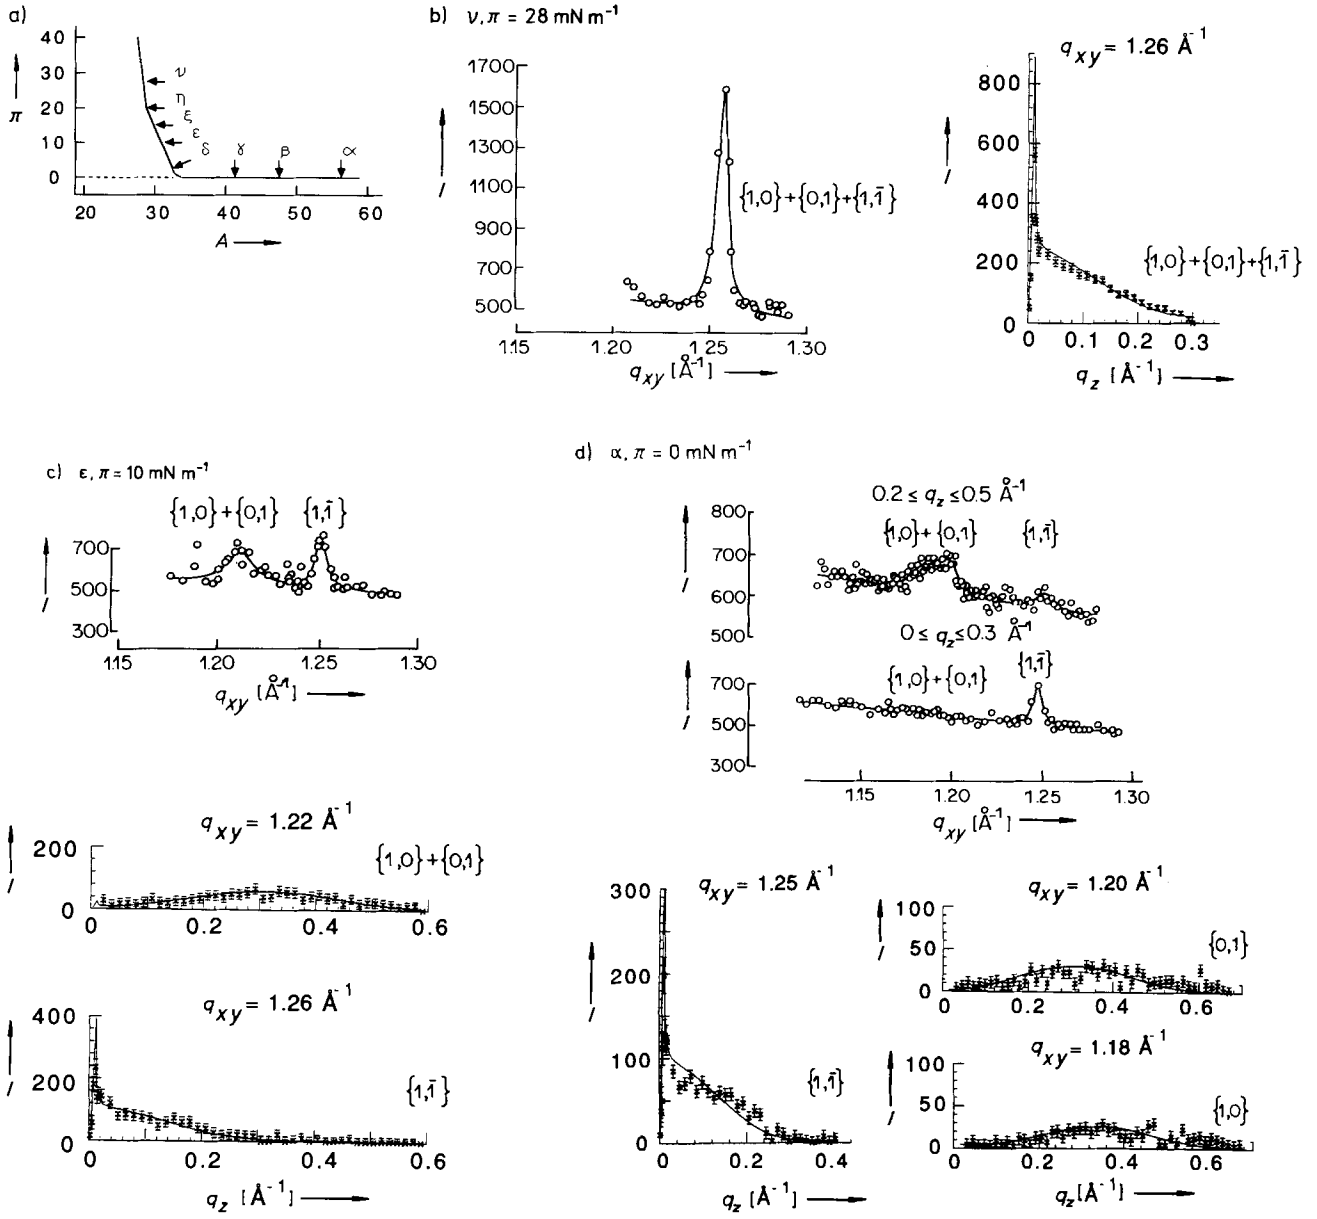

Fig. 17. PFA monolayers over pure water at room temperature. a) π-A isotherm (π in mN m^{-1} and A in Å^2). The points (α–ν) indicate where GID measurements were made. (b–d) A selection of GID measurements positions, ν, ε, and α) confirming the three observed 2D crystal symmetries (see also Fig. 8) when increasing the surface pressure. Left (b) or top (c,d): GID peaks. The Miller indices are indicated. Bottom: Bragg rod profiles measured on the GID peaks. Reflection positions and indices are given. Note that for position α in d) the GID peaks were measured for two different q_z intervals; furthermore, the Bragg rod intensity profiles have a different scale than in b) and c). In all cases, the solid line is the model fitted to the data. I = intensity in counts.

(28.5 Å^2). Upon increasing the pressure the molecular area is reduced and the water molecules are probably partially squeezed out of the hydrogen-bonded layer. At high pressure, hexagonal cell dimensions are imposed by the close contact between the fluorocarbon chains. Release of the surface pressure causes a dramatic decrease in coherence length L, an increased tilting of the molecules, and finally the disappearance of any observable diffraction, which is probably linked to the dynamics of the building process of a new bonding layer akin to the original one.

3.1.4. *Enantiomeric Mixtures of α-amino Acid Monolayers*

A little of the opposite enantiomer present in the chiral resolved monolayer of PL causes the GID peak to disappear (Fig. 19a). This indicates that the lattice of the monolayer becomes sufficiently distorted to reduce the crystalline coherence length drastically. The effect was explained by the inclusion of say an (*S*) molecule in a lattice of (*R*) molecules. Figure 19b shows that to reduce the resulting bad intermolecular contacts, the structure becomes distorted. Thus an appreciable fraction of the molecules in the monolayer are misaligned when even as little as 3% of the opposite enantiomer is added. The pure racemate also did not give a diffraction pattern at room temperature. Here we might have expected an arrangement in which the (*R*) and (*S*) molecules are interlinked in a layer by glide symmetry as observed in the crystal structure of hydrophobic *rac*-α-amino acids.[15, 45] We cannot rule out small ordered domains of this type in the solid solution of a pure PL racemate.

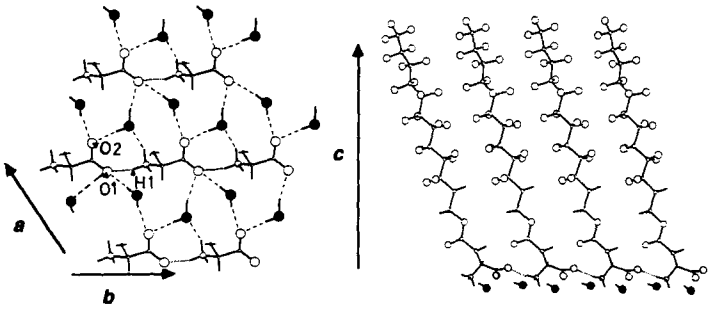

Fig. 18. Model of the arrangement of the self-assembled crystallites of a PFA monolayer over water at $\pi = 0\,mN\,m^{-1}$. Left: View perpendicular to the monolayer (i.e., along the c axis), showing hydrogen bonding of head groups and water molecules. O1 and O2 are oxygen atoms of the carboxylate groups; each forms hydrogen bonds with two water molecules. O1 forms a hydrogen bond with H1 of the NH_3^+ moiety of the neighboring molecule. The molecular chains are omitted for clarity. Right: View along the a axis showing the attached layer of water molecules and the projection of the chain tilt in the $(1,\bar{1})$ plane. • = oxygen atoms of the water molecules.

In contrast, the molecular area of compressed PFA monolayers (28.5 Å^2) imposed by the perfluorinated chain is larger than the molecular area observed in compressed monolayers of PL (24.3 Å^2) or in the crystal structure of glycine (25.5 Å^2). Therefore the more open head group arrangement of PFA is in keeping with the observation that racemic mixtures of compressed PFA display a very intense diffraction peak.[40b]

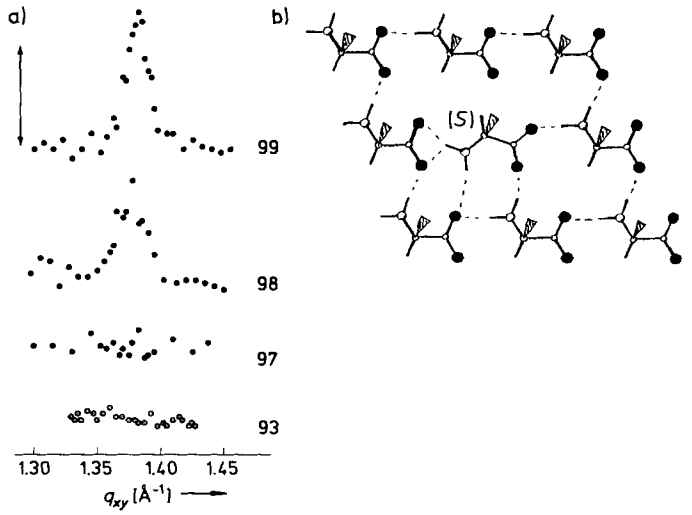

Fig. 19. a) GID data of mixed chiral monolayers of PL. The percentage of the (*S*)-enantiomer in the mixture is indicated on the right. The length of the double-sided arrow represents 200 counts. b) A PL molecule of (*S*) configuration surrounded by PL molecules of the opposite (*R*) configuration in a possible packing arrangement. All the chains are assumed to be related by translation and are indicated by wedges, so that the distortion of the hydrogen bonding (- - -) around the (*S*) isomer is visible. • = O.

Addition of the opposite enantiomer does not affect the crystal packing of PFA as it does for PL, since the distortion introduced in the hydrogen-bonding at the head group does not play a decisive role in the molecular packing of the compressed PFA monolayers.

3.2. Phase Changes Induced by Temperature

There is a wealth of macroscopic data available on temperature-induced phase transitions in Langmuir films, yet little reliable structural information on the molecular level. Only recently is such information becoming available from GID data. For example, the results on monolayers of fatty acids and fatty alcohols indicate a reduction in rotational disorder when the temperature decreases. Indeed, the diffraction pattern at high surface pressures (30 $mN\,m^{-1}$) for Langmuir films of the alcohol $C_{21}OH$ and the carboxylic acid $C_{20}CO_2H$ upon cooling from 30 °C to 0 °C shows additional peaks (Fig. 20a,b), indicative of a change from hexagonal to a centered rectangular cell.[46] The change was attributed to a pronounced reduction of librational motion of the molecule about its chain axis. Diffraction data on the acid monolayers $C_{21}CO_2H$[47] and $C_{29}CO_2H$,[48] and on the alcohols $C_{23}OH$, $C_{30}OH$, and $C_{31}OH$[48] at a temperature of 5 °C in the compressed state showed that the molecules of the film are vertically aligned.

The phase diagrams of the homologous series of long-chain fatty acids C_nCO_2H have been studied by means of pressure–area isotherms.[49] The phase diagrams of the series seem to be almost identical, provided that the temperature scale is shifted by 5–10 °C for each additional CH_2 moiety: extending the chain length has the effect of lowering the temperature. The available GID data,[19, 28, 47, 50, 51] taken as a whole, seem to confirm this conjecture. The phase diagram of docosanoic acid ($n = 21$) is reproduced in Figure 21. The acid $C_{21}CO_2H$ is convenient because nearly all the phases are observable at temperatures between 5 and 30 °C. Two independent synchrotron GID studies determined the structure of all the phases of docosanoic acid[47] and henicosanoic ($n = 20$) acid.[50] As the diffraction results were similar, we report here only those observed with docosanoic acid monolayers.

In each phase, the molecules are oriented with their long axes parallel and form a 2D crystal structure (Fig. 21), albeit with positional coherence lengths ranging from 50 Å at high temperature to more than 1000 Å at lower temperatures. The higher temperature structures may be similar to the mesophases found in liquid crystals. The L_2 phase has molecules tilted towards nearest-neighbors on a centered-rectangular net. On compression, at temperatures above ca. 25 °C one enters through a second-order phase transition into the hexagonal phase LS with vertical molecules. At these temperatures, indirect evidence suggests that the molecules are free rotators. At lower temperatures, compression leads from the L_2 phase through a first-order phase transition to the L_2' phase, again with tilted molecules on a centered-rectangular net, but with the molecules inclined towards next-nearest neighbors. Further compression leads to the phase S with vertical molecules on a centered-rectangular net. We note that lowering the temperature has the effect of reducing the symmetry of the high pressure phase from hexagonal (LS phase) to distorted hexagonal (S phase). One may speculate that the symmetry is reduced because the molecules have become hindered rotators. Below ca. 10 °C at high pressure, one observes the CS phase which has the same symmetry as the S phase. The CS phase, however, has long positional coherence lengths (> 1000 Å), a small area per molecule (18.6 Å^2), and a very low compressibility. It may be compared to 3D crystalline structures of alkanes well below their melting points, in which the molecular backbones are locked in a herringbone pattern.[52]

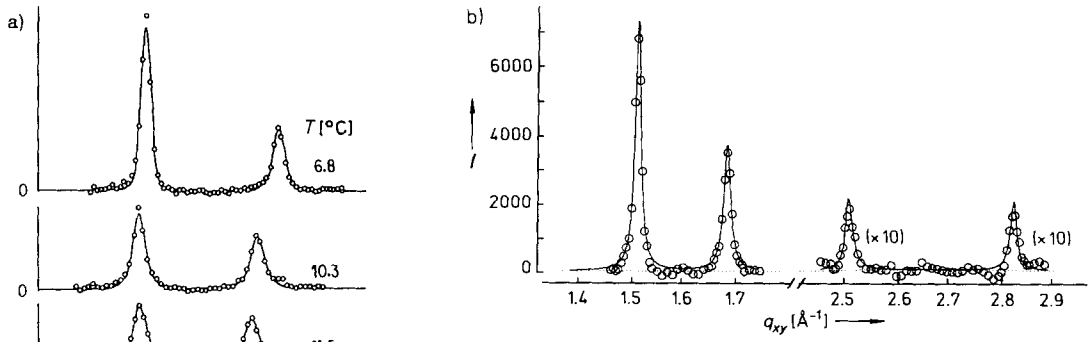

Fig. 20. a) GID data for a monolayer of the alcohol $C_{21}OH$ over pure water (from reference [35]) taken along the isobar at 30 mN m^{-1}. The peak intensity increases with decreasing temperature. The peak splitting is due to the transition from a hexagonal to a distorted hexagonal net. A linear background has been substracted. b) GID data for a monolayer of the acid $C_{20}CO_2H$ over pure water (from reference [46]) at 5 °C and $\pi \approx 35$ mN m^{-1}. Under these conditions the diffraction spectra of the alcohol and the acid are identical. A linear background has been subtracted. In addition to the two reflections observed in a) for 6.8 °C, two higher order reflections are shown here with 10 × magnification.

3.3. Crystalline Self-Assembly of Noncompressed Monolayers

The degree of crystalline order in biological lipid membranes in solution is probably low. But we may expect a high degree of order in self-aggregated clusters of amphiphilic molecules at the water surface because of the constraints imposed: a "flat" surface and solvent in contact only from the hydrophilic side. Direct evidence is now available from GID, but only for water-insoluble species. For soluble species, characterization by X-ray diffraction has not yet been achieved, possibly because of the low scattering power of these molecules. In addition, the range of crystallinity of the clusters may be very small. Nevertheless, evidence for aggregation comes from specular reflectivity data;[53] evidence for some degree of ordering comes from oriented epitaxial crystallization in the subphase at the solution surface.[5] More recently a remarkable observation was made by fluorescence microscopy:[54] two-dimensional faceted crystals of sodium dodecyl sulfate with sides of the facets as long as 50 μm could be seen on the water surface for a concentration of 0.055% by weight, which is far below the critical micelle concentration (0.25% by weight). For water-soluble surfactants, only reflectivity measurements yield structural information on the molecular level, which we now describe in some detail.

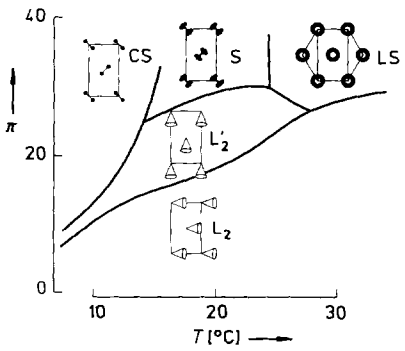

Fig. 21. π–T phase diagram of docosanoic acid ($C_{21}CO_2H$, also called behenic acid) monolayers over pure water. See text for an explanation of the structures.

Neutron reflectivity measurements (Fig. 22a) performed on a soluble surfactant, decyltrimethyl ammonium bromide (DTAB) at the air–solution interface[53] provide some information on the self-organization of the system. They indicate a vertical alignment of DTAB molecules, yielding a layer thickness of about 16 Å for concentrations varying from 0.002 to 0.01 M. Since the extended chain plus head group is about 17 Å thick, the molecules are assumed to lie in one layer as shown in Figure 22b. At a concentration of 0.05 M, where the monolayer is essentially complete, the reflectivity measurements yielded a film thickness of about 21 Å. This was explained in terms of a staggered arrangement reducing the electrostatic repulsion (Fig. 22b, bottom).

X-ray reflectivity measurements of norleucine solutions and surface tension measurements of several hydrophobic α-amino acids (for example, leucine, valine, isovaline, phenylalanine) and α-amino octanoic acid suggested accumulation of the molecules at the air–water interface.[5] Concrete evidence for organized 2D clusters of these molecules at the air–water interface was obtained by crystallization experiments:[5] they promote formation of α-glycine crystals at the water surface and growth through specific faces. The occurrence of these faces can be controlled by choosing the additive; thus a direct correlation is established between organized aggregates of the hydrophobic α-amino acid at the surface and the face of α-glycine through which the crystal grows.

If these short-chain hydrophobic α-amino acids spontaneously aggregate at the interface, Langmuir monolayers such as palmitoyl-lysine (PL) and "perfluoro"aspartate (PFA), which also induce α-glycine crystallization, should behave similarly. PL in the uncompressed state at room tem-

perature did not yield any diffraction signal.[25] But uncompressed PL with an average molecular area 10–15 times greater than its molecular area in the compressed state induced oriented crystallization of α-glycine, suggesting ordered monolayer domains.[3b, 3c] Apparently these domains at room temperature are too low in coherence length to be detected by surface diffraction. In contrast, as mentioned earlier, self-assembled crystalline domains of PFA were detected by GID with only 50% surface coverage. The fluorine

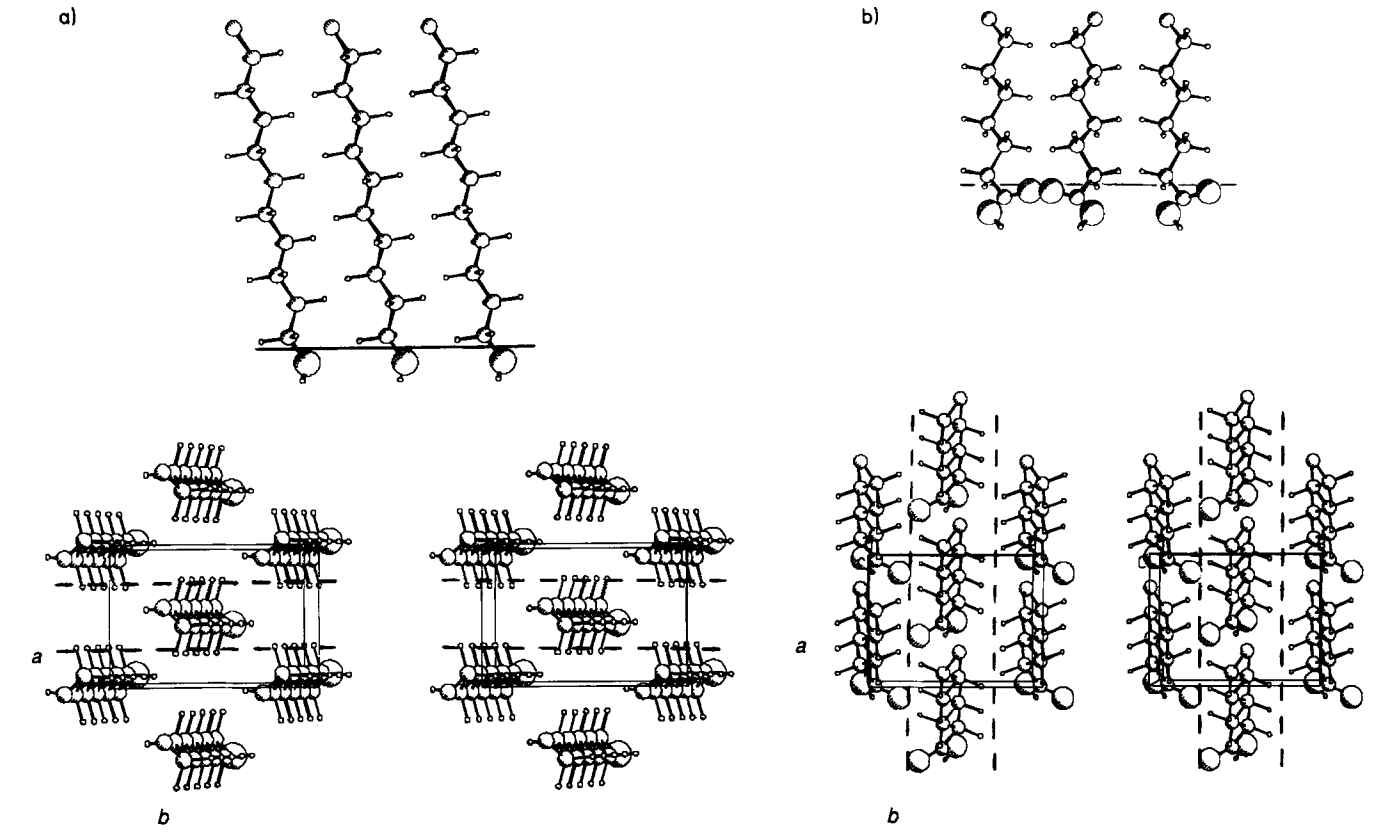
atoms, which induce a helical conformation in long fluorocarbon chains,[55] render these chains stiffer than aliphatic hydrocarbon chains and lower the possibility for conformational disorder. Hence, Langmuir monolayers of fluorinated molecules were characterized by a higher crystallinity than their hydrocarbon counterpart. GID data of fluorinated monolayers of PFA[30a] and $C_{10}F_{21}CH_2CO_2H$[56] suggested the coexistence of crystalline and dilute disordered phases; in dilute phases the PFA molecules have a molecular area of about 100 Å^2 and $C_{10}F_{21}CH_2CO_2H$ molecules an area of 2000 Å^2, indicating a gaseous state. This result may be compared with results obtained for arachidic acid monolayers ($C_{19}CO_2H$) at room temperature and at low surface pressure[47] where in the tilted solid phase the molecular area is 24 Å^2; this phase coexists with a fluid phase of molecular area 31 Å^2.

Lowering the temperature has considerably enhanced the tendency for high crystalline order in the uncompressed state, presumably by reducing molecular motion and so enabling effective intermolecular interactions. Low temperature GID studies were performed on several monolayers C_nX with different head groups X, such as $C_{23}OH$, $C_{30}OH$, $C_{31}OH$, $C_{29}CO_2H$, $C_{19}CONH_2$, and $C_{19}CONHC_2H_4CO_2H$. The probable packing characteristics of these spontaneously formed crystallites were extracted from the GID data.[48] We present here a brief description of the packing arrangements of the alcohols (X = OH), the acid (X = CO_2H) and the amide (X = $CONH_2$) monolayer. These packings were deduced by taking advantage of the known 3D crystal structures of molecules with long hydrocarbon chains. This strategy is meaningful since these 3D structures can be described as stacks of layers of molecules; thus the molecular arrangement in a single layer may well resemble that of the monolayer.

Long-chain alcohols and acids possess layered 3D crystal structures. In each layer the molecules are related by a glide so that neighboring hydrocarbon chains have parallel mean axes, but are in a mutually perpendicular orientation when viewed down the mean axis; the arrangement is described as orthorhombic orthogonal.[52] Common to all these structures are the parameters of the orthorhombic subcell, which is a projection of the unit cell onto a plane perpendicular to the molecular axis.[52] The subcell may be regarded as rectangular with dimensions $a_s = 4.98$, $b_s = 7.42$ Å, corresponding to a cross-sectional area of 18.48 Å^2. Remarkably, the calculated 2D cells of the monolayers projected onto a plane perpendicular to the molecular axis perfectly match the orthorhombic subcell of the 3D crystal structures. Following this observation and the diffraction data analysis, it was deduced that the alcohol and the acid monolayer molecules appear in the orthorhombic orthogonal packing, that is, they are related by a glide in a primitive rectangular cell as shown in Figure 23a and 23b. In this arrangement, the hydrogen atoms of adjacent hydrocarbon chains intermesh, thus ensuring close packing of the chains.[52] Further, the molecular chain axis is parallel to the glide plane so that intermolecular contacts between methylene CH_2 groups of the glide-related molecules are the same along the chains.

In 3D crystal structures of long-chain primary amides,[57] the interactions between the molecules are controlled by a network of hydrogen bonds at the $CONH_2$ head groups. The same feature applies to the motif proposed for the monolayer crystallites. The chains are stacked by translation with the molecular axis tilted at an angle of 18° to the normal to the *ab* plane (which is parallel to the water surface) in the direction of the 4.69 Å translation axis (Fig. 23c). The molecules are related by translation in a *c* centered rectangular cell. Thus, the monolayer space group is *c*1. The exact molecular orientation is determined by the fact that the $CONH_2$ amide



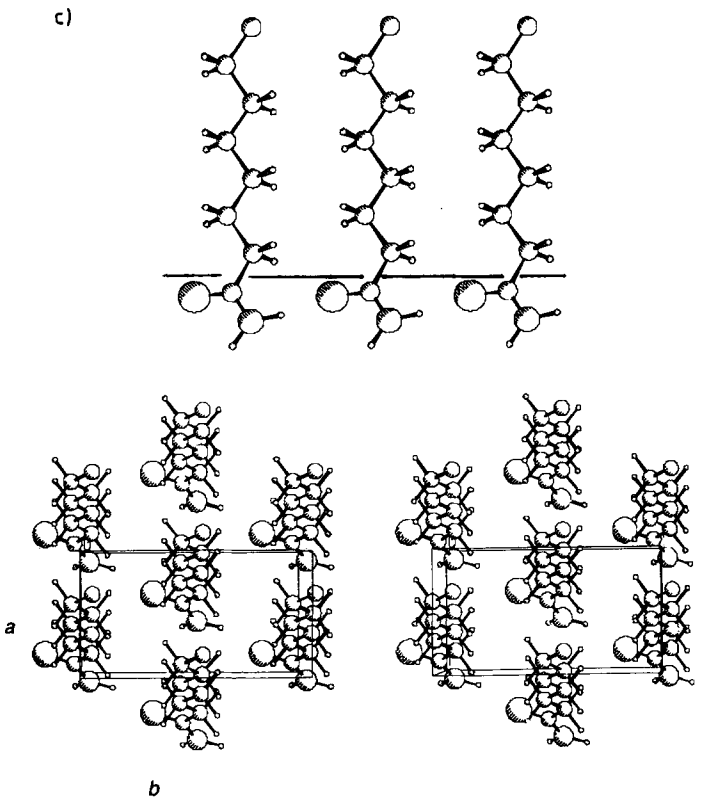


Fig. 23. Models of the hydrocarbon chain packing in the alcohol, carboxylic acid, and amide crystallites formed at 5 °C over pure water. Bottom: Stereoscopic view of the packing arrangement, seen perpendicular to the water surface; top: a side view along a direction parallel to the water surface (indicated by a solid line). For clarity only the head group and maximally eleven methylene groups CH_2 of each molecule are shown. On the last carbon atom drawn the hydrogen atoms are omitted. The rectangular cell (a,b) is indicated. The glide symmetry elements, when present, are shown as dashed lines. For convenience the origin of the unit cell is placed halfway between adjacent glide planes. a) Alcohol monolayers ($n = 23, 30, 31$). Since the molecules are tilted along the b axis ($t = 9.5°$), the projected cell down the mean molecular axis onto the water surface is given by $a_s = 4.99$ Å, $b_s = 7.53$ Å $\cos 9.5° \approx 7.43$ Å. b) Triacontanoic acid monolayer C_nCO_2H ($n = 29$). Since the molecules are tilted along the a axis ($t = 26.8°$), the projected cell down the mean molecular axis onto the water surface is given by $a_s = 5.53$ Å $\cos 26.8° \approx 4.94$ Å, $b_s = 7.44$ Å. c) Arachidamide monolayer ($n = 19$). Here $t = 18°$, $a = 4.69$, $b = 8.69$ Å.

groups form NH $\cdots$ O hydrogen bonds parallel to the diagonal (**a** $\pm$ **b**) (Fig. 23c).

The positional correlation lengths of all the crystallites were found to be anisotropic;[48] they extend over only 35 to 95 spacings parallel to the molecular tilt direction, but over 135 to 270 spacings perpendicular to it. These results suggest that the monolayer crystallites are strips elongated perpendicular to the molecular tilt direction. The same observation was made in the L_2 phase of behenic acid[47] (cf. Fig. 21 and the related discussion). It would be interesting at this point to understand the relationship between the amphiphilic structure and the monolayer crystal morphology.

4. Influence of Ions and Solutes on Monolayer Organization

4.1. Solute Binding and Its Effect on Growth and Dissolution of Monolayers

The binding of solute molecules to hydrophilic groups of monolayers allows us not only to probe the solutes effect on the growth, stability, and dissolution of 2D crystals, but also

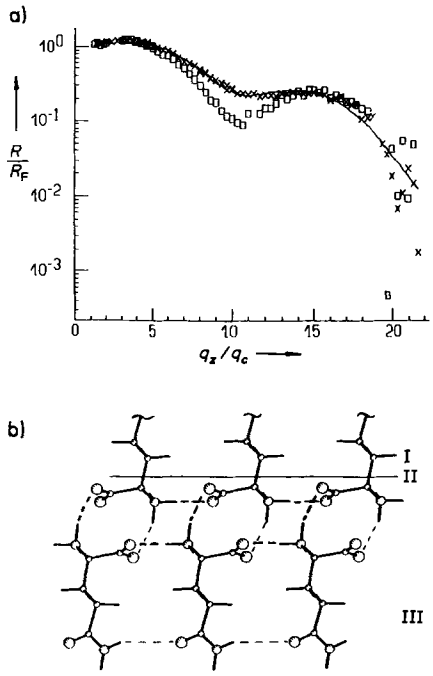

Fig. 24. a) Reflectivity data of compressed monolayers of (*R*)-PL over water (□) and over an unsaturated solution of (*S*)-glutamine (0.137 M, ×). b) A model of surface enrichment of glutamine at the interface (II). Only a short segment of the hydrophobic chains (I) are represented. Hydrogen bonding (– – –) between amide groups of neighboring glutamine molecules, and between the glutamine layer (III) and the monolayer is shown.

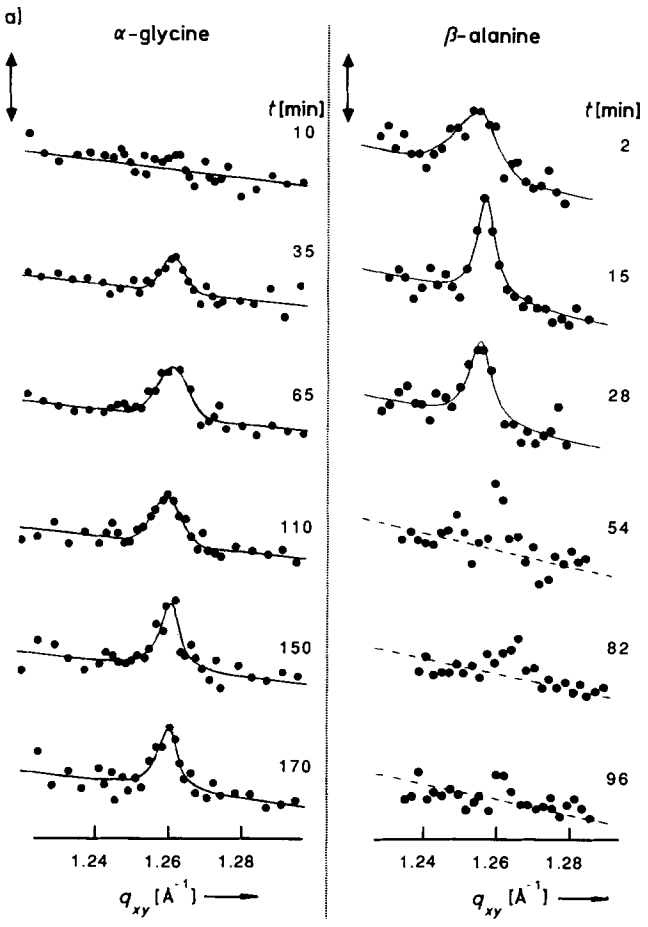
to simulate interactions between the surface of a 3D crystal and solvent or solute molecules.



To date it has not been possible to monitor the process of nucleation and crystallization of layered 3D structures such as α-glycine or other amino acids from the air–water interface. But it is possible, with unsaturated solutions of these compounds, to show that the solute binds to the monolayer in a way that mimics the formation of the nucleating crystal's first layer. Indeed, XR studies showed that even in unsaturated solutions of amino acids, the solute molecules bind to the interface. Reflectivity measurements were made on monolayers of PL over a dilute aqueous solution of glutamine $NH_2COC_2H_4CH(NH_3^+)CO_2^-$.[40] Advantage was taken of the possibility that glutamine may bind to the monolayer through NH···O bonds as well as to neighboring glutamine molecules by NH···O (carboxylate) and NH···O=C (amide) hydrogen bonds (Fig. 24b). The reflectivities of a monolayer of palmitoyl-(*R*)-lysine over the solution or over pure water are quite different (Fig. 24a). Analysis of the two data sets shows that as many as a quarter of the sites below the head groups are occupied by glutamine. The result is in qualitative agreement with the model shown in Figure 24b.

Addition of a solute to the subphase can deter crystalline self-aggregation of monolayers, allowing its growth to be monitored as a function of time. The left part of Figure 25a shows that 10 minutes after a PFA monolayer was deposited over an unsaturated solution of α-glycine, no diffraction peak was observed. This is in contrast to the observation made when PFA was deposited over a pure water subphase.[30] It took around 30 minutes before crystalline domains could be detected. This inhibition can be understood from the top part of Figure 25b, which shows how one glycine molecule can bind to two neighboring molecules of the α-amino acid monolayer with very strong hydrogen bonds, hindering their assembly. The formation of this complex is in kinetic competition with that of the crystalline

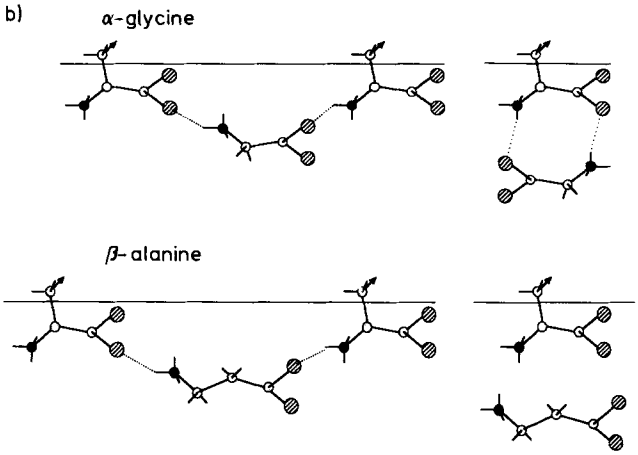


Fig. 25. Uncompressed monolayer ($\pi = 0\ mN\,m^{-1}$) of PFA with an average molecular area of 45 Å^2 over various solutions. a) GID measurements as a function of time after spreading. Left: Over α-glycine solution (0.015 M). Right: Over β-alanine solution (0.005 M). Note the increase in crystallinity in the former, and the decrease in the latter as indicated by the different time evolution of the peak. The length of the double-sided arrow represents 200 counts. b) Left: Schematic drawings of "bridging complexes" between PFA monolayer molecules and the solute molecules for α-glycine (top) and β-alanine (bottom). hydrogen-bonded bilayer which is composed of quasi-cyclic dimers of PFA and α-glycine (Fig. 25b, top right). That this bilayer is eventually formed is deduced from the following observations: firstly, glycine forms oriented crystals attached to monolayers of PFA, denoting formation of a bilayer at the onset of crystallization;[3] secondly, monolayers of PFA over glycine solutions maintain their crystallinity after compression and decompression, unlike PFA over pure water;[30b] finally X-ray reflectivity measurements of monolayers of PL over glycine solutions showed that the glycine molecules accumulate at the interface,[40c] which is indirect evidence for the formation of an incomplete bilayer, as in the experiment with glutamine.

Use of β-alanine NH_3^+-CH_2CH_2-CO_2^- instead of glycine as a solute molecule had an entirely different effect on the 2D crystals of uncompressed PFA; this amino acid did not strongly inhibit growth, but caused a complete dissolution of the PFA crystals within two hours as shown by GID measurements (Fig. 25a, right). This dissolution can be rationalized in terms of a strong interaction of β-alanine with the amino acid head groups of adjacent surfactant molecules leading to a disruption of the 2D crystal (Fig. 25b, bottom). It is noteworthy that because of a molecular mismatch, β-alanine can hardly form a hydrogen-bonded cyclic dimer with the amino acid head group of the monolayer and certainly not a hydrogen-bonded counterlayer commensurate with the monolayer, as can glycine (Fig. 25b, bottom).

4.2. Ion Binding from Solution

The interfacial region between a charged surface and an electrolyte is central to many processes such as those occurring during electrodeposition, ion transport through biological membranes, preparation of Langmuir–Blodgett films,[6] biomineralization,[4] and induced oriented nucleation of inorganic systems[3c, 3d] under Langmuir monolayers. X-ray reflectivity measurements demonstrated that metal ions in the solution interact closely with the charged monolayer head groups at the interface.[28, 58] However, it was still an open question whether the ion distribution near such charged, ordered surfaces was crystalline. In a recent study,[24b] the interface between a phospholipid monolayer and a $ZnCl_2$ aqueous solution was measured with X-ray standing waves. The technique, described in Section 2 is sensitive to the ion distribution normal to the surface and allows the distinction between a vertically nondiffuse ionic layer (Helmholtz model) and diffuse ionic layers (Gouy–Chapman and Stern models). It was concluded that the double layer at the phospholipid membrane–aqueous interface is diffuse along the

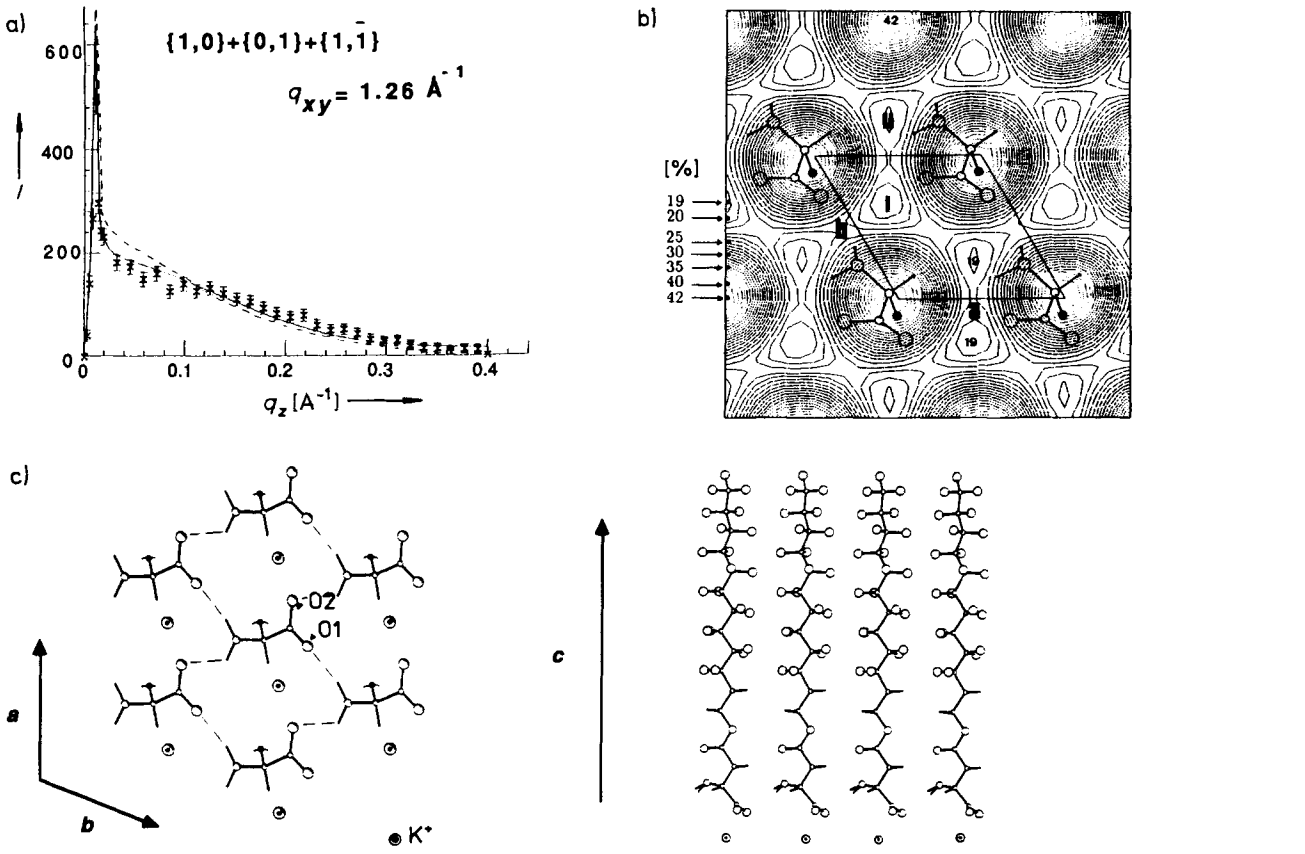

Fig. 26. Uncompressed PFA monolayers over KOH subphases (pH = 11.5; room temperature; π = 0 mN m^{-1}). a) Bragg rod scan measured on the GID peak (whose reflection assignment and position is indicated) with a calculated fit including (solid line) and excluding (dashed line) the contribution of K^+ ions. b) *R*-factor contour map (interval 1%), which expresses the fit between the calculated and observed data, obtained from BR fits as a function of the lateral position of the K^+ ion in the PFA hexagonal unit cell at a fixed *z* coordinate. The two sites with the lowest *R* factors (19%) labeled I and II are potential sites for the K^+ ion. The model (Fig. 26c) favors site I for the K^+ ion. c) Model of the uncompressed monolayer of PFA over K^+ ions. Left: View along the *c* axis (perpendicular to the monolayer) showing the hexagonal net of K^+ ions bridging the oxygen atoms O1 and O2 of two neighboring molecules. Right: View along the *a* axis showing the attached layer of K^+ ions (water molecules possibly interleaved in the ionic layer are not shown here).

normal to the film. GID measurements of lead–arachidate[59] monolayers at room temperature did not demonstrate the existence of laterally ordered or nondiffuse layers of Pb^{2+} counterions. Liquid surface EXAFS experiments on manganese–stearate films[22] at room temperature yielded a Mn–Mn nearest neighbor distance at the surface in the compressed phase only, indicating at least short-range order.

A weak indication of lateral order of ions is provided by GID data of uncompressed monolayers of PFA over a HCl solution[30a] at a pH of 1.5. A model was proposed in which the Cl^- ions were partially intercalated between neighboring NH_3^+-CHR-CO_2H sites, participating in attractive $NH^+ \cdots Cl^-$ and $COH \cdots Cl^-$ interactions. This model also explains the high molecular area of 31.6 Å^2, compared to the value of 28.5 Å^2 over basic subphases (discussed below), which imposes a tilt of the molecule of 25° from the vertical according to the GID data. The model is also in keeping with the observation that in 3D crystals of glycine · HCl, the molecules appear in a layered arrangement with intercalated Cl^- ions.[60]

PFA monolayers on highly basic KOH subphases (pH = 11.5) yielded results favoring a laterally ordered bilayer.[30a] The presence of the K^+ ions induces all molecules to be assembled into crystals even in the uncompressed state, with the molecules aligned vertically in a hexagonal cell. According to an analysis of the GID data (Fig. 26a,b), the K^+ ions occupy ordered sites bridging oxygen atoms of adjacent molecules (Fig. 26c). The XR measurements on compressed monolayers at high pH over KOH indicate excess electron density just below the head group. This excess density is consistent with one K^+ ion and one H_2O molecule per head group. Upon compression, lateral pressure introduces defects in the randomly oriented islands, causing a reduction in crystallinity. It is possible that the distortion occurs at the periphery of the crystallites due to strong electrostatic interperipheral forces between anion–cation bilayers of neighboring crystallites. It is noteworthy that in both systems, PFA over acidic and basic subphases, the counterions retain the original molecular packing and a long-range crystalline order is maintained after decompression. This is in contrast with results for films over pure water.[30a]

As mentioned earlier, lowering the temperature has the effect of reducing molecular rotational disorder and enhancing crystalline self-aggregation. Indeed, a GID study of uncompressed cadmium arachidate monolayers over a subphase with its pH adjusted to 8.8 with ammonia demonstrated the presence of an ordered Cd^{2+} layer[61] with a coherence length of 1000 Å at temperatures lower than 9 °C. The diffraction spectrum showed ten distinct peaks (Fig. 27), seven of which were attributed to the Cd^{2+} layer. The remaining three peaks were deduced to stem from the arachidate layer, on the basis of their Bragg rod profiles and q_{xy} positions. The diffraction peaks of the Cd^{2+} lattice, whose BR profiles were flat and extended, indicative of a thin monoatomic layer, could be indexed according to a 2 × 3 supercell of the arachidate cell. Such a supercell demands three cadmium ions, given a 1:2 molar ratio of cadmium ions to acid molecules. The two lattices are shown in Figure 27c. The calculated diffraction peaks due to the refined positions of three Cd^{2+} ions in the supercell are shown in Figure 27b. In contrast to films of cadmium arachidate, a film of calcium arachidate

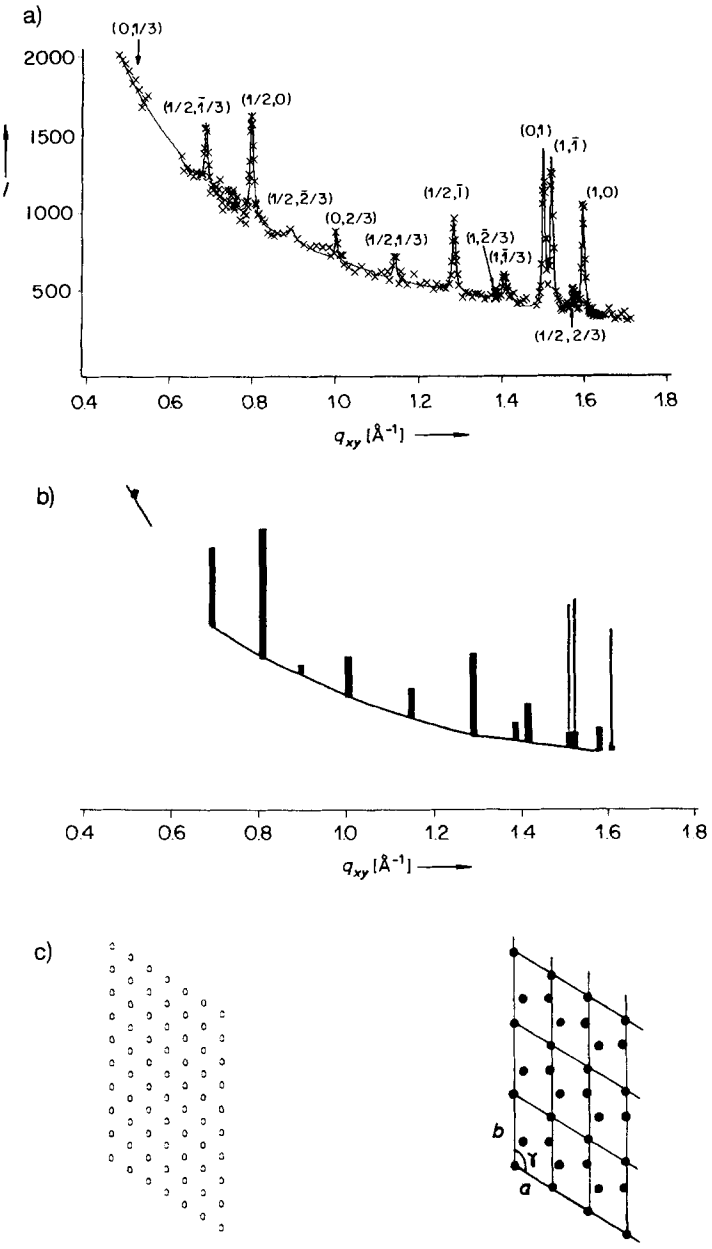

Fig. 27. Arachidic acid monolayer ($C_{19}CO_2H$) over a 10^{-3} M $CdCl_2$ subphase (pH = 8.8) in the uncompressed state ($\pi = 0$ mN m^{-1}) and at low temperature (9 °C). a) GID peaks and assignment of reflections. Reflections with integer indices correspond to scattering arising from arachidate moities, and those with fractional indices to scattering from a 2D layer of Cd^{2+} ions. b) Calculated powder pattern for the cadmium net superimposed on background scattering. The peaks labeled with thin lines are the arachidic triplet. c) Two-dimensional lattices of arachidate (left) and cadmium ions (right). The cadmium cell is a 2 × 3 supercell of the arachidate cell. The positions of the Cd^{2+} ions in the cell are marked as filled circles.

over water at low temperatures did not provide direct evidence for an ordered Ca^{2+} layer.[62] Nevertheless, the Ca^{2+} ions did induce high crystallinity of the uncompressed phase at high pH; the molecules were aligned vertically. These results agree with the conclusions of a recent surface-potential and surface-pressure study of ionic interactions with fatty acid monolayers:[63] whereas monolayer ordering is induced by covalent binding between carboxylate (CO_2^-) and metal ions in the case of Cd^{2+}, Ca^{2+} ions do not exhibit such an ordering effect because their interactions with carboxylates are mainly ionic in nature. The adsorption of ions at the

monolayer molecules and the resulting structural variations in the monolayer were also studied recently by GID.[64] The structural changes in henicosanoic acid monolayers induced by the introduction of Cu^{2+} or Ca^{2+} ions into the subphase were investigated.

5. Transfer of Structural Information from Langmuir Monolayers to Crystals

Langmuir monolayers have been shown to induce oriented crystallization from solution of proteins[65, 66] and other organic and inorganic compounds.[3] As mentioned in the introduction, these studies were motivated by their revelance to crystal nucleation, to two-dimensional ordering at the water surface of soluble hydrophobic molecules, and to biomineralization. The crystal systems studied to date include α-glycine,[3a] sodium chloride,[3c, 3d] calcium carbonate,[4a-d] parahydroxybenzoic acid,[67], hexagonal ice,[68] barium sulphate,[69] and silver propionate.[70] Mechanisms for crystallization through particular faces (oriented crystallization) involve structural fits and electrostatic attractions. Information on the monolayers used and the type of crystal face nucleated are listed in Table 2 for some of these crystal systems.

5.1. Inorganic Crystals and Biomineralization

Electrostatic interactions between Langmuir monolayers and crystals have been invoked to account for the oriented growth of inorganic salts. A first example is given by the oriented nucleation of NaCl crystals under α-amino acid monolayers such as PFA. NaCl precipitates from aqueous solution in a cubic cell ($a = 5.64$ Å) exhibiting six (100) faces. But when crystallized under α-amino acid monolayers at pH ≈ 7, crystals were found to be attached to the monolayer by the less stable (110) face (Fig. 28a).[3d, 30] This face is composed of alternating rows of Na^+ and Cl^- ions, separated by 2.82 Å. This distance is very close to the separation of 2.8 Å between rows of NH_3^+ and CO_2^- moieties in PFA. Thus we envisage an electrostatic attraction between small domains of a (110) surface layer of NaCl and the zwitterionic α-amino acid head groups of PFA at pH ≈ 7. At high pH (>10), PFA monolayers induce crystallization of NaCl from the metastable (111) face. A pure (111) face of NaCl exposes a singly charged layer consisting entirely of either Na^+ or Cl^- ions (Fig. 28b). This selectivity was explained in terms

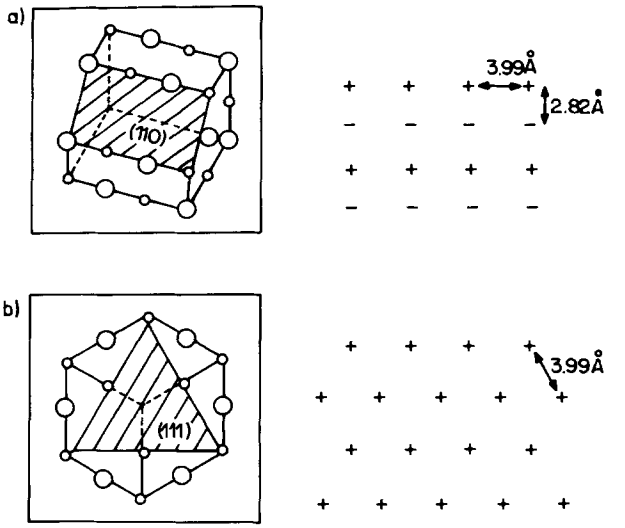

Fig. 28. Schematic representation (left) and point charge distribution (right) of faces of a NaCl crystal. a) The (110) face. b) The (111) face. o = Na^+, ○ = Cl^-.

of a simple electrostatic interaction between the CO_2^- charged monolayer surface and an underlying layer of Na^+ ions which induces a homogeneous surface potential for (111) nucleation. The lattices of the PFA monolayer and the (111) layer are not similar. There is a possibility of interleaving ordered water in the first attached layer of Na^+ ions, which could play a role in inducing oriented nucleation of the (111) face since OH groups can form OH···Cl^- hydrogen bonds with Cl^- ions in the second layer.[60]

As mentioned earlier, GID results on PFA monolayers over HCl solution at low pH was interpreted in terms of a partial intercalation of Cl^- ions within the head-group layer.[30] Thus, rows of positive (NH_3^+) and negative (Cl^-) charges are created at the surface, simulating the repeat mo-

Table 2. 3D crystals induced by monolayers at the air–water interface

tif of the charge distribution in the (110) face. Indeed, at low pH, NaCl crystallizes from its (110) face attached to the PFA monolayer.[30]

The influence of structured organic surfaces on oriented growth has a strong bearing on biomineralization.[*] Addadi, Weiner, and co-workers[4e] have studied the effect of β-pleated sheet proteins on crystallization of calcite. They demonstrated oriented calcite nucleation probably arising from a combination of electrostatic and structural requirements. To elucidate this result on a molecular level, Mann and co-workers studied the induced oriented crystallization of $CaCO_3$ under monolayers of stearic acid[4a, 4b] and other amphiphiles such as amines.[4c, 4d] Whereas crystallization of $CaCO_3$ in the absence of a monolayer of acid or amine results in rhombohedral calcite crystals, the stearic acid monolayers give rise to oriented nucleation of the less stable hexagonal polymorph of vaterite from the (001) face. We present here a model for the interface, based on the crystallization results of NaCl below a monolayer and the structural data of cadmium arachidate and calcium arachidate monolayers. The double layer comprising the stearic acid molecules and the calcium ions must be neutral, implying a 2:1 stochiometry as confirmed by X-ray and neutron reflectivity studies of the fatty acids over $CaCl_2$ and $CdCl_2$ solutions.[28, 58] Thus the repeat area per Ca^{2+} ion must be twice that of the stearic acid molecule. As mentioned earlier there is as yet no direct evidence of order in a layer of Ca^{2+} counterions. The density of such a Ca^{2+} layer is low and we may assume at least one to two interleaving water molecules per Ca^{2+} ion, which is consistent with X-ray reflectivity data.[28, 62] The water molecules would screen neighboring Ca^{2+} ions and form $OH\cdots O$ hydrogen bonds with the monolayer carboxylate groups CO_2^- above and carbonate ions CO_3^{2-} below the Ca^{2+} layer (Fig. 29a). According to GID data of calcium arachidate,[62] the arachidate molecules stand up straight even in the uncompressed state. Thus, the orientation of the CO_2^- groups is similar to that of the CO_3^{2-} groups in vaterite.

The hydrogen-bonded $OH\cdots OCO_2^{2-}$ system tends to be coplanar as in the crystal structure of $Na_2CO_3 \cdot 3/2\ H_2O_2$.[80] This preference would promote bound carbonate molecules oriented perpendicular to the Ca^{2+} layer. Vaterite has a crystal structure with carbonates oriented in this way (Fig. 29b), while the orientation of the carbonates in the calcite structure is different. This may account for the preferred nucleation of vaterite.

An alternative model for the preferential formation of vaterite involving an epitaxial relationship between the (001) face of vaterite and the 2D lattice of calcium stearate appears to be plausible since the *a* and *b* axes of vaterite are 7.15 Å, approximately 1.5 times the length of the *a* and *b* axes of the calcium arachidate monolayer. On such a basis, one may envisage a supercell common to both layers which is a 2×2 reconstruction of the vaterite lattice and a 3×3 reconstruction of the arachidate lattice. In such a cell, although the net charge brought in by the nine carboxylate groups is -9, the net charge brought in by the twelve calcium ions is $(+\ 24/2) = +12$ since each calcium ion contributes one charge to the neutralization of the carboxylate layer and one charge to the neutralization of the carbonate layer. There is no simple way to reconcile this charge difference.

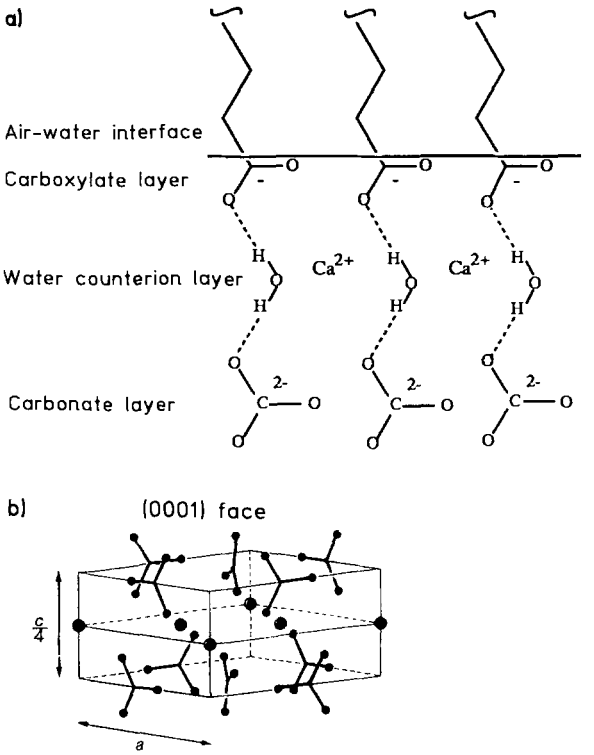

Fig. 29. a) Schematic representation of a calcium stearate monolayer, showing interleaved water molecules in the low density cationic layer which form hydrogen bonds with the carboxylate layer at the interface and with a carbonate layer in the subphase. In this layer the carbonate ions are oriented as in the (0001) layer structure of vaterite. b) Vaterite subcell showing the stereochemical arrangement of the carbonate ions perpendicular to the (0001) face (from [4a]). $a = 7.15$, $c = 17.00$ Å. ● = O atom, ● = Ca^{2+} ion.

5.2. Crystallization of Molecules under Monolayers with a Similar Head Group

An excellent structural fit between the head groups of the monolayer and the attached crystal layer is illustrated by the α-amino acid monolayer/glycine crystal system (Table 2). Glycine crystallizes in a bipyramidal habit (Fig. 30a) from aqueous solution in a monoclinic centrosymmetric arrangement. The glycine molecules form hydrogen-bonded layers (Fig. 30b). Such a layer may be easily replaced by a monolayer of resolved, chiral α-amino acid surfactant molecules provided the cross-sectional area of its hydrophobic chain is not larger than that of glycine (25.5 Å^2). Indeed glycine crystals grow stereospecifically from several α-amino acid Langmuir monolayers whose hydrophobic chains meet the above criterion.[3a, 3b] For example, the packing arrangement of the glycine head groups of the monolayer of PL, whose GID pattern[25] is shown in Figure 15, agrees very well with the layer structure of glycine.

The epitaxial crystallization of *para*-hydroxybenzoic acid (Table 2) under monolayers of *para*-alkoxybenzoic acid provides an example of how molecules in solution impose a change of monolayer structure probably at the onset of crystal nucleation. The *para*-hydroxybenzoic acid head groups of the monolayer change their orientation with respect to the

[*] Editorial comment: also in this issue is a review by L. Addadi and S. Weiner on "Control and Design Principles in Biological Mineralization".

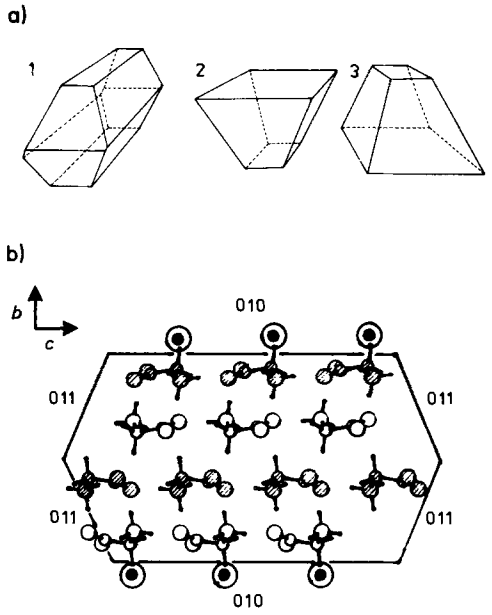

Fig. 30. a) Morphology of the pure α-glycine crystal grown from aqueous solutions (1) and at the monolayer solution interface (2 and 3). b) Crystal structure of α-glycine. An (*R*) α-amino acid monolayer induces the (010) face. An (*S*) α-amino acid monolayer induces the (0$\bar{1}$0) face. The hydrogen atoms of both faces are circled.

hydrocarbon chains so as to lie flat on the water surface, thus mimicking the (401) surface layer of the *para*-hydroxybenzoic acid crystal. It is noteworthy, as in the case of the α-glycine/monolayer system, that the crystals do not exhibit well-developed (401) faces in solution.

5.3. Nucleation of Ice by Monolayers

Pure water can be supercooled to temperatures as low as −40 °C. Therefore the induction or inhibition of the nucleation of ice, in particular through the role of auxiliaries such as membranes or proteins, has far-reaching ramifications for both the living and nonliving world. Promotion of ice nucleation has been exploited for the induced precipitation of rain by clouds seeded with silver iodide.[71] On the other hand, the promotion of ice nucleation by frost bacteria in crops can result in wide scale damage.[72]

Several mechanisms have been proposed to explain the promotion of ice nucleation such as a lattice or structural match between substrate and nucleated ice crystal[73] or an electric field present in the substrate, which orients the water molecules.[74] Experiments were conducted to design two-dimensional surfaces that raise the ice nucleation temperature. These experiments involved freezing of drops of water covered with monolayers of aliphatic alcohols (C_nOH) or carboxylic acids (C_nCO_2H). The structure of hexagonal ice[75] may be described for the oxygen atoms in terms of layers parallel to the *ab* plane where $a = b = 4.5$ Å, $\gamma = 120°$ (Fig. 31). Advantage was taken of the observation that at 5 °C uncompressed Langmuir monolayers of $C_{23}OH$, $C_{30}OH$ and $C_{31}OH$ over water pack in a distorted hexagonal net[48] ($a = b = 4.48$ Å, $\gamma = 113°$) that is similar in dimension to the *ab* lattice of hexagonal ice at 0 °C. The largest mismatch between the two lattices is 10% along the $a + b$ diagonal. The uncompressed monolayer of the carboxylic acid $C_{29}CO_2H$ has axial dimensions[48] $a = b = 4.6$ Å, $\gamma = 107°$. For this system the largest mismatch with ice is, once again, in the $a + b$ direction, but with a value of 27%. A structural similarity can be proposed for the OH head groups of the alcohol monolayer and the *ab* layer structure of ice; however, no such similarity exists for the corresponding carboxyl head groups of the fatty acid monolayer.

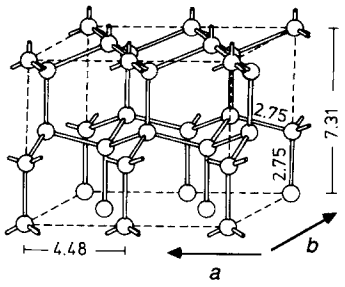

Fig. 31. Crystal structure of hexagonal ice (from [79]). The oxygen atoms of the water molecules are denoted by spheres and the disordered OH···O hydrogen bonds by rods. The hexagonal *a* and *c* axes are specified ($a = b = 4.48$, $c = 7.31$ Å).

The results of the ice nucleation temperature ("freezing point") measurements (Fig. 32) show that aliphatic chain alcohols are more efficient ice nucleators than the corresponding carboxylic acids.[68] Moreover, the freezing point

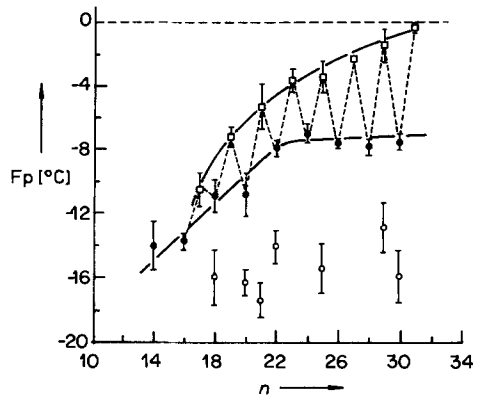

Fig. 32. Freezing points Fp of drops of supercooled water covered by monolayers of alcohols C_nOH (● = *n* even, and □ = *n* odd) and carboxylic acids C_nCO_2H (○). Freezing point curves are drawn separately for alcohols with *n* odd and *n* even. The error bars for each point were derived from 10 to 20 freezing point measurements.

is sensitive not only to chain length but also to chain parity (i.e., *n* odd or even) of the alcohol $C_nH_{2n+1}OH$ (Fig. 32). This trend suggests that at the temperature of ice nucleation the orientations of the alcohol OH groups in the odd and even analogues are not the same.

6. Outlook

The study of structures at interfaces has received an enormous boost with the recent development of surface X-ray diffraction methods using synchrotron radiation. Research in the crystallography of thin organic films should encompass a variety of exotic projects. For example, so far all the studies have been directed towards amphiphilic molecules bearing long hydrocarbon or fluorocarbon chains. With the

present advances in synchrotron techniques, it may soon be possible to obtain diffraction spectra from water-soluble amphiphilic molecules. Experimental results from oriented crystallization, chemical reactivity, and spectroscopic measurements suggest that molecules such as short chain α-amino acids, benzoic acids, or cinnamic acids form ordered clusters at the air–water interface.[5, 76]

The X-ray methods should allow one to test for the presence of lateral crystalline order in monolayers consisting of a collection of molecules engineered to construct a designed and well-defined lattice. Thus, these methods are intimately linked to the development of techniques to control and perfect the structure of Langmuir films on the molecular level. Perhaps we shall obtain a deeper insight into chemical transformation at the air–water interface by correlating the packing structure of reactant and product. An example of the latter is the topochemical photopolymerization of diacetylenes in monomolecular layers as studied by Göbel and Möhwald.[77] Another natural extension of these studies is the investigation of packing arrangements of amphiphilic molecules at organic solvent–water interfaces, as in emulsions. In such a system, the surface created by terminal groups of the hydrophobic chains makes van der Waals contacts with the organic solvent similar to those found for an alkane in a bilayer membrane.

The X-ray methods should in principle also be applicable to complex biological systems at interfaces which may involve enzymatic transformations or antigen–antibody interactions and where periodic order is present. Here we mention the elegant studies by Kornberg,[65] Ringsdorf,[66] and others, who monitored by electron-microscopic and fluorescence methods the dynamics of these interactions. We hope that deeper insight into some of these systems may be obtained by diffraction studies.

So far, most of the experiments had been carried out with "2D powders" at the smooth air–water interface. It is also possible to study the structure of thin organic films deposited on smooth solid supports.[78a] Recently, the structure of self-assembled monolayers on smooth mica coated with gold were determined in great detail.[78b] One may also anticipate, in the not too distant future, obtaining diffraction spectra from single crystals of these amphiphilic molecules and so providing structural information almost at the level of atomic resolution.

We thank Isabella Weissbuch, Ronit Popovitz-Biro, and Susan Weinbach for fruitful discussions. Control and Design Principles in Biological Mineralization

By Lia Addadi* and Stephen Weiner*

The control of crystal formation has been developed to a remarkable degree by many organisms. Oriented nucleation, control over crystal morphology, formation of unique composites of proteins and single crystals, and the production of ordered multicrystal arrays, are all well within the realm of biological capability. Understanding the control and design principles in biomineralization is a fascinating subject that may well contribute to the improved fabrication of synthetic materials on the one hand, and to the solution of many serious pathological problems involving mineralization, on the other.

1. Introduction

Organisms have been using minerals in one way or another for at least 3500 million years. Evidence of this earliest form of mineral manipulation is preserved in the form of fossil stromatolites found in sedimentary rocks. Stromatolites were communities of bacterialike prokaryotic organisms that both trapped and indirectly induced minerals to form around themselves. Since this time organisms slowly improved their ability to control mineral formation, until some 540 million years ago when within a period of "only" a few million years a multitude of primarily multicellular organisms began to produce mineralized skeletal structures. During this crucial period in the evolution of biomineralization, the basic structural patterns for skeletal formation were fixed, although it has been postulated that some of the underlying principles used for mineralization itself were acquired from ancestral organisms.[1]

Today the phenomenon of biomineralization is widespread; members of all five kingdoms of organisms are able to produce minerals that serve a wide variety of functions. The sheer volume of calcium carbonate and amorphous silica produced by marine organisms dominates important aspects of the chemistry of the oceans and, indirectly, that of the atmosphere as well. These minerals have accumulated in huge quantities at the bottom of the oceans and over time have contributed substantially to the record of sedimentary rocks on earth.

The enormous diversity of this phenomenon among living organisms, as well as the fact that the processes used possibly reflect eons of evolutionary adaptation, implies that much can be learned about mineral formation from these organisms, in particular, control of crystal formation. Furthermore, many of the mineralized tissues formed by organisms have advantageous mechanical properties. This in turn raises the possibility that some of the design principles used could be applied in the fabrication of superior synthetic materials. It is with these futuristic ideas in mind, that we have chosen to focus this review on the underlying principles used by organisms in controlling both amorphous and crystalline mineralization, as well as on the manner in which ordered crystalline arrays may be formed.

To accomodate readers with little or no knowledge of biomineralization, we begin with short overviews of the minerals and macromolecules involved in these processes. We have also integrated a number of short reviews or excursuses which elaborate on aspects of the biology discussed in the main text. This biology in itself emphasizes the solid-state structures involved and neglects many very important topics related to the activities of the cells that direct all these processes; the hormones and other molecules that communicate between the mineralizing cells and the remainder of the organism; and the elaborate and sophisticated processes involved in ion uptake and transport to the sites of deposition. Good sources of information on these topics are provided by Simkiss and Wilbur[2] and Evered and Harnett.[3]

The current understanding of biomineralization in vivo is of a descriptive nature. The underlying principles invoked are for the most part derived from observations in vitro. Understanding how a whole ordered array of macromolecules and crystals that make up a biological material are produced is well beyond our current knowledge. We can, as always, speculate about this, and indeed we do. The body of this review therefore describes control over specific aspects of mineralization. At the end we try to bring different concepts together and focus on how ordered crystal arrays may be formed in vivo.

2. The Minerals Formed by Organisms

More than sixty different minerals are known to be formed by living organisms. These include amorphous minerals, inorganic crystals, and organic crystals.[1] Calcium minerals represent some 50% of all known biogenic minerals, presumably reflecting in one way or another calcium's abundance in the ocean as well as its widespread use in cells as a messenger. The latter function requires very low intracellular concentrations of calcium and its efficient removal to the cell exterior by membrane pumps.[4] The fact that two of the three major skeleton-reinforcing minerals, calcium carbonate (calcite and aragonite) and calcium phosphate (dahllite), are calcium minerals may reflect the exploitation of the calcium ions pumped out.

Only a few of the amorphous minerals fulfill skeletal functions, the major exception being amorphous silica. Silica skeletons are formed in huge quantities by photosynthetic marine plants called diatoms, the single-celled marine protozoans, radiolarians, certain sponges, and many terrestrial plants (Fig. 1).[5, 6] Amorphous minerals, in particular amorphous calcium carbonate and phosphate, are often used as temporary storage depots for ions essential for cellular

metabolism. A host or organisms, many of which form no other mineralized deposits, have such special storage cells.[7] A fairly common and somewhat unusual use of amorphous minerals is as a repository for embedding toxic metals, which are then removed together with the host mineral by release from the cell. The most common host mineral is amorphous calcium pyrophosphate.[8]

Crystals are used by organisms in many different ways. One very common use, mostly by mobile organisms, is in gravity perception. Mineral deposits located in cavities surrounded by sensory cells are able to move around much like plumb bobs, and their relative movements are tracked by the sensory cells.[1] Single crystals of the magnetic iron oxide, magnetite, are used by bacteria, algae, and many animals to monitor the earth's magnetic field, usually for navigational purposes.[9] The size of these crystals is generally constrained to around 100 nm to assure that they function as single magnetic domains.[10] The most common use of crystals is in the form of multicrystalline arrays, primarily to form elaborate skeletal structures. The order of the crystals in these arrays can be quite extraordinary, a property we will address in this review.

3. The Macromolecules Used by Organisms for Controlling Mineralization

In 1967 Veis and Perry[11] discovered a most unusual protein in the dentin of vertebrate teeth. It is composed of about 40 mole percent aspartic acid and 40 mole percent phosphoserine. This unusually acidic polymer is closely associated with the mineralization process, but its precise function is still not known.[12] Since then, acidic proteins and glycoproteins, usually rich in aspartic acid and often containing glutamic acid, phosphorylated amino acids, and acidic sulfated polysaccharides have been found in the mineralized tissues of many organisms.[1] Their widespread distribution among organisms from different kingdoms is one of the reasons why Weiner et al.[13] proposed that their use in controlling mineralization evolved long before the advent of skeletal formation some 540 million years ago. These macromolecules are now considered to be key components in the mineralization process.

No really acidic macromolecules have been fully characterized in terms of primary and secondary structures, let alone tertiary structures. Many technical problems are associated with the manipulation of these highly charged polymers. Several partial sequences of amino acids have been reported, consisting of runs of poly-Asp[14] and alternating sequences with Asp at every second residue.[15] The proteins, and in some cases their associated sulfated polysaccharides, interact with calcium,[16] and in fact calcium appears to facilitate the formation of β-sheet structures in these macromolecules.[17] It should be noted that many proteins from mineralized tissues have been sequenced, including those of vertebrates[18] and to a lesser extent those of the spicules of larval sea urchins.[19] Many of these do not have unusually acidic compositions, although some do display repeating sequences, which could conceivably interact with a regular crystal lattice. It is also interesting to note that in bone, the most studied of all mineralized tissues, no highly acidic proteins comparable to those found in abundance in dentin and nonvertebrate mineralized tissues have yet been found.

The acidic macromolecules are often intimately associated with more hydrophobic macromolecules, which generally form extensive three-dimensional structures. These framework macromolecules vary from tissue to tissue and hence presumably also fulfill specific mechanical or other functions. Common examples of such framework molecules are type I collagen in bone and dentin, α-chitin–protein complexes in arthropods, and β-chitin–protein complexes in the shells of mollusks and brachiopods.[1, 13]

Lia Addadi, born in Padua (Italy) in 1950, studied organic chemistry at the Università degli Studi di Padova from 1968 to 1973. She then transferred to the Weizmann Institute of Science (Israel) where she completed her Ph.D. in 1979. After her postdoctoral stay with J. R. Knowles at Harvard (1981–1982) she returned to the Weizmann Institute and became Associate Professor in 1988. She received the Kennedy Award of the Weizmann Institute for Ph.D. students (1978), the G. M. J. Schmidt Prize for her Ph.D. thesis (1981), the Ernst David Bergmann Prize in Chemistry (1986), and the Annual Award of the Israel Chemical Society (1989). Her research interests include the mechanisms of biomineralization, pathological crystallizations, solid-state stereochemistry, and the interactions of proteins with crystal surfaces.

Stephen Weiner was born in 1948 in Pretoria (South Africa) and studied geology and chemistry from 1966 to 1972 at the University of Cape Town (South Africa) as well as geochemistry at the Hebrew University in Jerusalem. He completed his Ph.D. in the area of biomineralization and geobiology at the California Institute of Technology in Pasadena (California) in 1976. After a two-year postdoctoral stay at the Weizmann Institute of Science, Weiner stayed on and became Associate Professor in 1985 and Professor for Biomineralization and Archeological Chemistry in 1990. He received the Shmuel Jaroslavsky Prize in 1980 for his studies on the biogeochemistry of mineralized tissues and the Ernst David Bergmann Prize for Chemistry in 1984. Weiner co-authored a book on biomineralization.

4. Filling Space with Mineral: Amorphous versus Crystalline Materials

A key step in the control of mineralization employed by almost all organisms is the initial isolation of a space. Then under controlled conditions minerals are induced to form within the space.[20] The space is usually delineated by cellular membranes, vesicles, or predeposited macromolecular matrix frameworks. Filling up these spaces with amorphous minerals would appear to require a quite different strategy as compared to filling space with crystalline material.

The definition of an amorphous material is equivocal. From a theoretical point of view, amorphous materials are those that lack any structural regularity beyond the first coordination-sphere. From the practical point of view, however, the definition of amorphous depends on the technique used to detect crystallinity or the lack thereof, whether X-ray, infrared, or extended X-ray absorption fine structure (EXAFS). The distinction between an amorphous and a crystalline material with short-range order is thus not well defined. For space-filling purposes the problem is not too relevant, since the presence of short-range order at the molecular level does not influence the overall isotropic behavior of the solid phase. Hence the long-range interactions inside the bulk of the material are on the average the same in all directions. A consequence is that amorphous materials as well as materials with short-range order can easily be molded into desired shapes. The difference between these two types of materials is relevant, however, when one considers amorphous-to-crystalline phase transitions. The presence of very small, ordered domains may well play a dominant role in the transformation pathway and thus determine the nature of the mature phase. This question will be addressed in Section 8 concerning polymorphism.

A single crystal is characterized by the regular three-dimensional repetition of a basic structure which optimizes molecular interactions in a typically anisotropic fashion. The anisotropy of the unit cell is reflected in the anisotropic growth of the crystal. In other words, where interactions between molecules or ions are weaker, growth is slower.[2a] This in turn gives rise to a characteristic morphology for each crystal.[21] The development of particular crystal faces, ignoring interactions with the environment, is the result of a slower rate of deposition of crystal planes in these particular directions as compared to other directions. A similar observation, in a very intuitive way, can be made for the cleavage of a crystal. A single crystal will fracture more easily along crystallographic planes which are held together by relatively weak interactions. The fracture will follow the path of least resistance and propagate smoothly along flat surfaces.

Amorphous and crystalline materials thus present very different properties in terms of filling space. The absence of long-range repetitive structure in amorphous materials is associated with a number of possibly advantageous properties: the absence of a preferred direction of growth, the absence of preferred fracture planes, and the absence of well-defined faces. Possible mechanical advantages of crystalline phases, on the other hand, include lower solubility, higher density, and ordered surface and bulk structures, all of which may be associated with desired physical properties.

There are very few known cases in biomineralization where the intrinsic properties of crystals are directly exploited. The classic example is magnetite in magnetotactic bacteria. Here the magnetic properties of the single crystals and their size, which corresponds to that of a single magnetic domain, are used for the passive orientation of the bacteria in the earth's magnetic field. The optical properties of crystals may also be exploited by organisms for special purposes. Single crystals of calcite functioned as lenses in the eyes of the extinct trilobites;[22] uric acid crystals act as reflectors in the cuticles (shells) of certain scarab beetles, giving them a fantastic gold color.[23] These examples are, however, more the exception than the rule. Most crystalline phases are used for mechanical purposes, where the crystallinity is manipulated for controlling the growth of the mineral phase rather than exploited for its intrinsic properties. In view of this, the problem of the choice of amorphous or crystalline mineral phases in biomineralization may be reformulated in a way which is admittedly extreme, but serves the purpose of clarifying the above points.

1. For minerals that are stable in the amorphous state under normal conditions, the amorphous phase may be preferable for mechanical and space-filling purposes.

2. For minerals that are metastable in the amorphous state and spontaneously transform into crystalline materials, two options exist. Either the amorphous phase is stabilized, or special mechanisms are used to control the growth and properties of the crystalline phase and, if necessary, overcome its disadvantages.

The best example of the first class of compounds is amorphous silica and of the second class, calcium carbonates and phosphates.

4.1. Filling Space with Amorphous Materials

Amorphous materials have also been described as frozen liquids. Amorphous solids are generally formed spontaneously by oxide elements with intermediate electronegativity, where the bond character can be described as a mixture of ionic and covalent. The elements of common glass-forming oxides are found mostly in groups III, IV, and V of the periodic table. This particular type of bonding allows these oxides to form structures that can be regarded as three-dimensional polymers built of polyhedra joined at the corners.[24] The polymeric structure also accounts for the high viscosity and low solubility of the material, and both characteristics contribute to its kinetic stability. Amorphous silica is a classic representative of this class of compounds. The small coordination-number of the atoms and the linkage of the polyhedra at their corners, and not edges or faces, allow the formation of open structures in which the Si-O-Si angles can vary without distorting the SiO_4 tetrahedra themselves. Silicon is transported in the body fluids in the soluble form of silicic acid and is polymerized in situ by formation of Si-O-Si bonds and the partial loss of water. Silica dissolution thus involves a true hydrolysis reaction.[5, 25] These factors allow silica to be deposited and shaped into the often fantastically sculpted structures of diatoms (Fig. 1 above) and radiolarians, or to be woven into delicate basketlike structures in the choanoflagellates.[26] In many land plants, in particular

the grasses, portions of the plants are filled with silica[6] (Fig. 1 below). The silica acts as an abrasive, discouraging herbivores from feeding freely upon the grasses. Simpson[27] observed that when the grasses evolved the ability to silicify in the Miocene epoch, the structure of horses' teeth changed in order to adapt to this new reality.

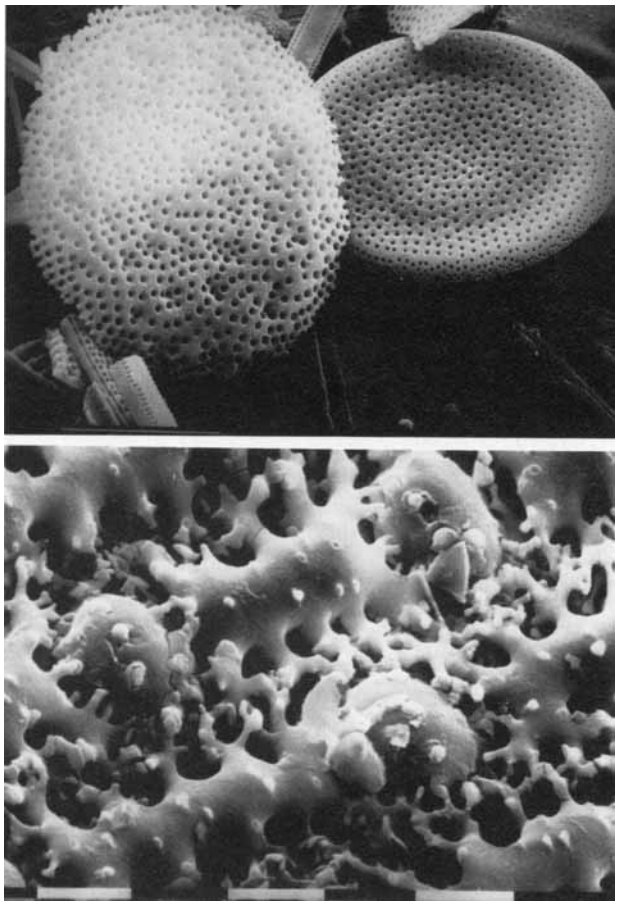

Fig. 1. Amorphous silica deposition by the marine diatom *Thalassiosira lentiginosa* (obtained from a deep-sea core; above) and by a wheat plant *Triticum aestivum* (below). The silica impregnates the cell walls, the organic material has been totally removed, and only the mineralized outlines of the cells are observed. In the upper photograph the line along the bottom edge represents 20 μm; in the lower photograph the scale bar is marked in 10 μm intervals.

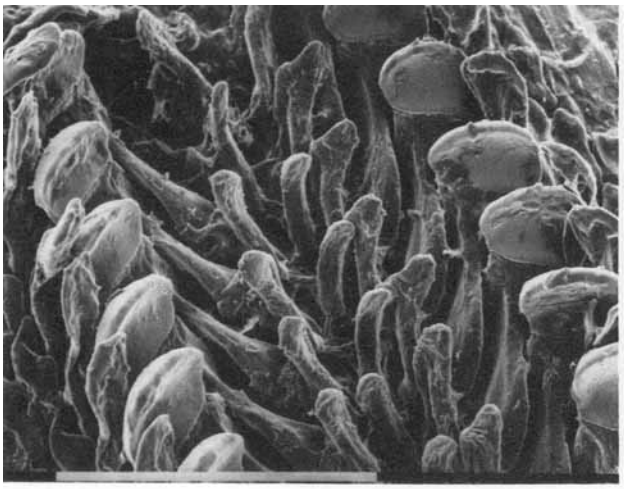
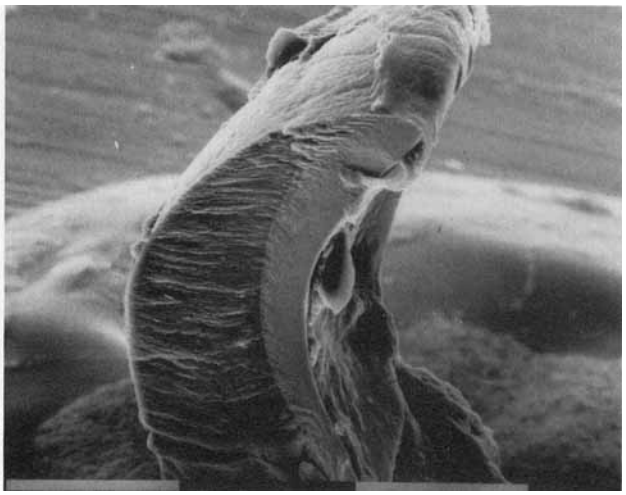
Amorphous calcium carbonate and phosphate present a variety of most intriguing problems. These materials crystallize easily in a number of polymorphic crystalline forms, and their transformation from the amorphous to the crystalline phase under close to physiological conditions is not only thermodynamically favored, but kinetically fast.[28] The presence of these amorphous minerals as "stable" phases in organisms is not a manifestation of poor control over mineralization, but rather the result of deliberate inhibition of crystallization. The organism must invest energy to prevent these phases from crystallizing. The reason for the use of amorphous calcium phosphate or carbonate in intra- or extracellular temporary storage sites is probably because of its higher solubility (relative to the crystalline form) which makes it readily available for reuse. In the case of the chiton (a class of mollusks) teeth, the amorphous calcium phosphate is stabilized for some ten days, and only then does it transform into dahllite[29] (Excursus 1). This implies that there is a precise control over the rate and timing of the transformation. A number of examples are known in which amorphous materials are used for the construction of hard parts. The gill supports of the bivalve *Neotrigonia*[30] or the stylets of nemerteans (ribbon worms),[31] used like a harpoon for capturing prey, are both composed of amorphous calcium phosphate. The question of how these organisms prevent the material from crystallizing remains unanswered, although many inhibitors are known to be able to perform this task in a more or less specific way. This point will be discussed further in Section 8. Why organisms use a relatively soft amorphous material for such purely structural functions in the first place is a complete mystery.

Excursus 1: The Chiton Radula: A Natural Laboratory for the Study of Mineralization Dynamics

The chiton, a primitive member of the mollusk phylum, is found on rocky ocean shores all over the the world. It has a tonguelike tooth plate, called the radula (Fig. A, upper left), which it uses for scraping the surfaces of rock for food. In 1962 Lowenstam discovered that these teeth are capped by a layer of the hard magnetic iron-oxide mineral, magnetite.[88] Magnetite has subsequently been found in many organisms, in particular in those which are migratory. The crystals are part of a navigation system and are used to detect the orientation of the earth's magnetic field.[9]

The chiton wears down its teeth at a rate of roughly one to two rows per day.[89] New teeth are formed at the same rate, and the entire radula, containing about 100 rows of teeth, is in effect an assembly line for teeth. The radula of the chiton offers an ideal subject for the study of the dynamics of the mineralization process, because each row represents about a day's worth of tooth construction.[90] The basic stages are described here for the *Chitonida*,[89] since the details differ in different taxa. An individual tooth is essentially composed of three layers (Fig. A, upper and lower right) each of which differs mineralogically. At the first stage of tooth formation, cells form a capsulelike structure with a central cavity. The matrix framework is constructed in this extracellular space. After the construction of about ten rows of teeth the cells introduce iron atoms into the framework which precipitate in the outer tooth layer as the hydrated iron-oxide mineral, ferrihydrite. Within two or three rows, the ferrihydrite converts to magnetite. This process continues until the whole outer layer is filled with magnetite. Around the thirtieth row of teeth another iron-oxide mineral, called lepidocrocite, precipitates in a thin zone beneath the magnetite layer. Finally the core of the tooth begins to fill in with amorphous calcium phosphate, which is somehow stabilized for about ten rows, then begins crystallizing within a single row of teeth. The crystals continue to grow and/or the lattice becomes more ordered (infrared spectra cannot differentiate between these two possibilities) until the mature teeth are used and discarded. The most curious observation is that the crystals of dahllite are more or less aligned with the matrix sheet, suggesting that the structured matrix surface induces and controls the transformation process.[29]





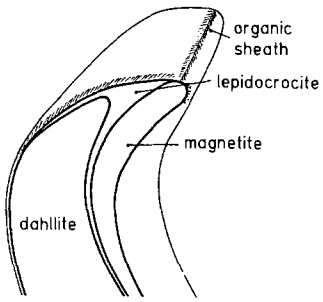


Fig. A. Upper left: View of the mature portion of the radula of the chiton, *Acanthopleura haddoni* showing five rows of teeth. Only the spoon-shaped objects are mineralized. Upper right: The fractured cross section of an individual mineralized tooth. The scale bars are marked in intervals of 1 mm (left) and 0.1 mm (right). Lower right: Schematic illustration of the three different layers of the tooth and their mineralogical compositions (compare with photograph upper right).

The chiton radula has proved to be a gold mine of information in biomineralization, and many of the most basic concepts now widely accepted for mineralization in most other tissues have their origin in the studies of this most interesting mollusk. Radula mineralization processes are still not completely understood, and many fundamental questions remain to be answered.

4.2. Filling Space with Crystalline Materials

Notwithstanding the possible advantages of using amorphous materials, the large majority of mineralized tissues contain a crystalline material. The simplest way to fill a space with crystals is to create as high a local supersaturation as possible, and then induce nucleation, or let the system spontaneously reach a state of lower energy by crystallization, while at the same time removing the excess solvent. If the concentration of metastable solute is high, and if crystallization is rapid and the crystals formed are small, then the resultant mineral phase, although crystalline, may not be too different from that of an amorphous material. This situation is observed in spherulites of calcium carbonate which spontaneously form in metastable supersaturated solutions. "Droplets" of calcium carbonate and water separate from the solution and with time, or upon drying, crystallize to give rise to spherulites of one of the three polymorphic modifications of calcium carbonate—calcite, aragonite, or vaterite.[32] The organization of the crystals in the spherulite is sometimes surprisingly ordered, and the overall shape, though variable, is typically round, as predicted by the requirement of liquid drops to reach minimal surface energy (Excursus 2). The problem with this type of crystallization is that it is not easy to control and is difficult to reproduce. Furthermore, if the crystals formed are larger, then their packing is progressively less compact. The presence of pores reduces the mechanical integrity. Control of the physical characteristics requires slow crystallization. Two main pathways are used in nature to improve control over crystal formation: the use of single crystals and the formation of ordered crystal arrays.

Excursus 2: Spherulitic Crystallization in Biology

Spherulites are crystal aggregates formed from rapidly crystallizing solutions. They are easily formed in vitro from highly supersaturated solutions of $CaCO_3$, and the crystal aggregates may develop remarkably ordered structures (Fig. B, lower left). The polymorph of $CaCO_3$ often formed is the very metastable form, vaterite. Spherulitic structures are produced by many different mineralizing organisms, including red calcareous algae, pennatulid sea fans, scleractinian (stony) corals, and birds (in egg shells).[1] It is of interest to note that the formation of avian egg shells and scleractinian coral skeletons are both among the most rapid mineralization processes known.

Probably the most common form of spherulitic mineralization occurs inside small spherical intracellular vesicles where the crystals function as temporary storage sites for ions important in the organism's metabolism. Such specialized cells, often referred to as calcium cells, are found in many different animals, most of which do not have any other form of mineralized deposit.[7] The crystals nucleate at a central point and grow out radially. The vesicle membrane presumably inhibits further crystal growth. Note that in the

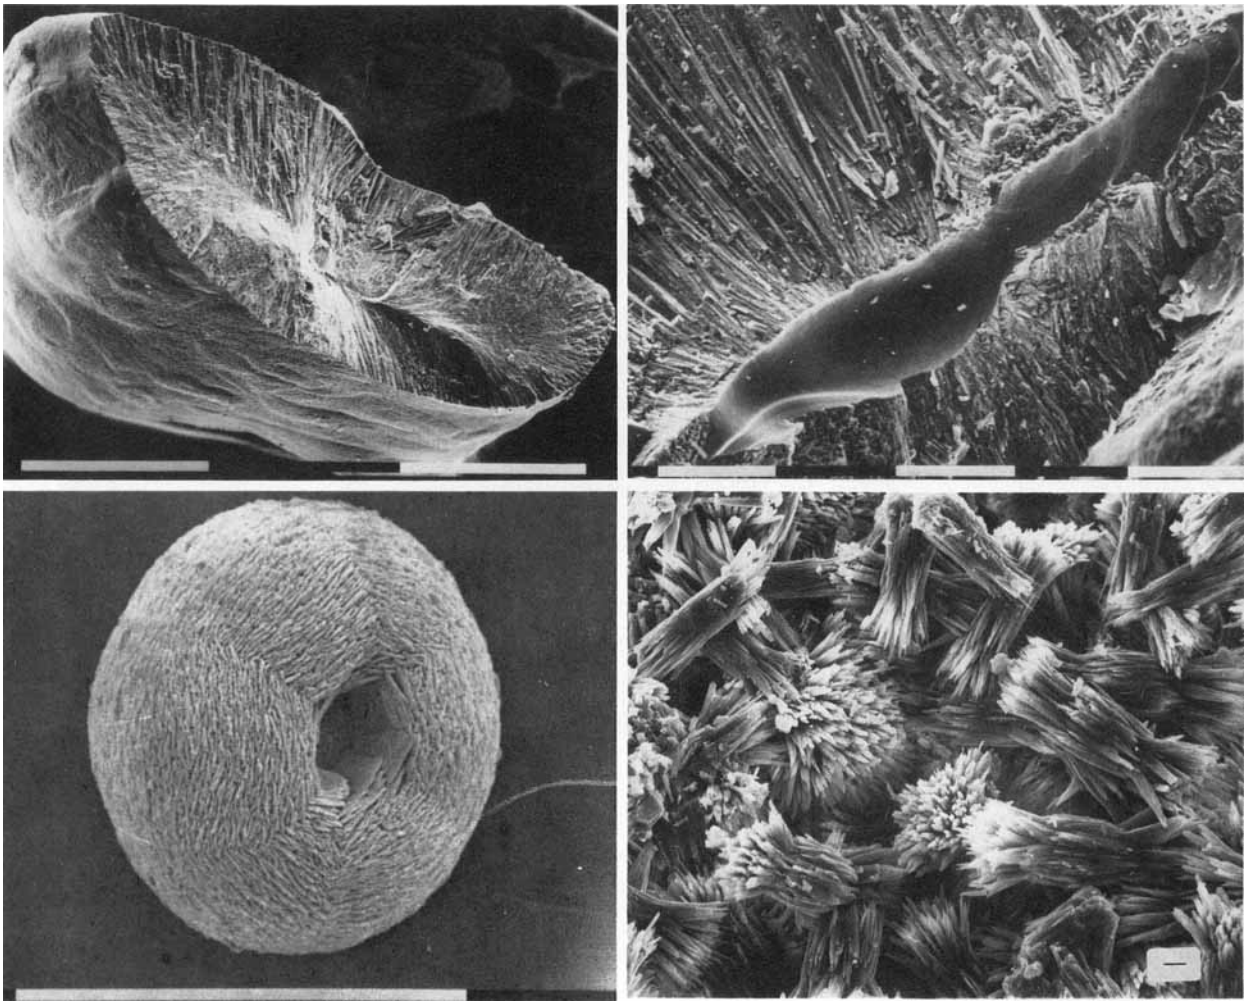

Fig. B. Upper left: Aragonitic otolith (sagitta) from the bony fish, *Seriphus politus*. The otolith is fractured revealing the central surface from which the aragonitic crystals nucleate. (The scale bar is marked in 1 mm intervals.) Upper right: The fracture surface and the radiating aragonitic crystals at higher magnification. Lower left: Spherulite formed in vitro composed of vaterite crystals. (The scale bars are marked in intervals of 0.1 mm in the photographs at the upper right and lower left.) Lower right: The aragonitic spherulites precipitated in the chamber of the cephalopod mollusk, *Nautilus pompilius*. Field width: 135 μm.

small extracellular matrix-vesicles of mineralizing cartilage, the carbonate apatite crystals rupture the membrane and continue growing outside the vesicle.[91]

This type of spherulite formation from only one nucleation site has been modified by a variety of organisms, such that spherulitic growth is induced by nucleation sites distributed on a surface. The otoliths of fish are good examples (Fig. B, left and upper right).[78] Otoliths are millimeter-sized, flat bodies in the inner ear. They are usually composed of aragonite or vaterite and function in sound reception, as well in the sensing of gravity and acceleration.[92] The crystals nucleate on an organic surface and grow with their *c* axes more or less ($\pm 10^\circ$) perpendicular to the surface.[78] A similar phenomenon occurs in egg shells, composed of calcite, and scleractinian corals, composed of aragonite.

A most interesting case of spherulitic mineralization occurs in the well-known mollusk, the pearly *Nautilus*. Its aragonitic shell is produced under very well-controlled conditions. In contrast, spherulitic aragonitic crystals precipitate out of the fluid present inside the shell chambers. (Fig. B, lower right).[76] These chambers are part of the buoyancy system and contain gas which is pumped in or out. Some of the extinct relatives of the modern *Nautilus*, the ammonites, partially or totally filled their chambers with spherulitic crystals to control their specific gravity and orientation in the water column.[93] Spherulitic mineralization in biology thus appears to provide a means of rapidly filling relatively large volumes with minerals.

5. Single Crystals

The formation of an entire object from a single crystal has the advantages of maximal packing, excellent order, and homogeneity. Only one major taxonomic group, the echinoderms have opted for this solution (Excursus 3). By definition, a single crystal is characterized by a unit cell, the smallest building block that incorporates all the basic spatial and symmetry relations between atoms and molecules. The unit cell is repeated in space by translation along the main crystal axes, giving rise to a perfect three-dimensional lattice, which ends abruptly at the boundaries of the crystal faces. In such an ideal crystal the faces are macroscopically and microscopically parallel to the planes with lowest surface energy. A real crystal differs, however, from this ideal description. The surface of a crystal growing in solution is in active

contact with its environment, including solvent, solute, and impurity molecules. The surface layer is thus probably never as ordered as the bulk. Even within the crystal the perfect translation between unit cells exists only over a short distance, called the coherence length, after which it is perturbed by mistakes or dislocations. A real crystal has thus a characteristic coherence length and mosaic spread, parameters which describe the deviation from perfect order in terms of frequency of mistakes and overall misalignment between perfect domains.

Domains separated by domain boundaries can be defined at a microscopic level inside each real crystal. The definition of a single crystal presents a problem similar to that encountered in the definition of an amorphous material, namely that the definition depends on the technique used to measure the property in question. This is not a semantic issue. Some organisms have acquired the ability to manipulate these properties of single crystals.

The echinoderms form most of their skeletal elements, namely spines, plates, ossicles, and other structures, from calcite (Excursus 3). Each skeletal element diffracts X-rays as a good single crystal.[33] In the case of the sea-urchin spine the average misalignment between unit cells over the whole skeletal element is as low as 0.15°.[34] The fenestrated and convoluted morphology of the element, as well as the smooth curved surfaces are certainly not reminiscent of a single crystal. Observations of the in vivo growth of the spicules of sea-urchin larvae[35a] and electron microscopic studies of test (external shell) formation in adult sea urchins,[35b] indicate that each skeletal element is the product of a single nucleation event. This is quite remarkable when one considers that many of these elements are centimeters in size. Shimizu and Yamada[36] proposed an alternative multinucleation process for the regeneration of a spine, which would require nucleation sites to be aligned to within 0.2° over enormous distances. Towe[37] has suggested that skeletal elements undergo recrystallization to form the macroscopic "single" crystal. Well-aligned nucleation sites are known to occur in biology (e.g. nacreous layers of certain bivalves), but their degree of misalignment is much greater[38] (roughly 10°) than in the echinoderm calcitic elements. This dilemma highlights an important aspect in understanding this single-crystal phenomenon, namely determining both the sequence of events that occur in the formation of a skeletal element and the nature of its final state.

Excursus 3: Crystals that Form in Vesicles—*Echinodermata* and *Coccolithophoridae*

Vesicles are widely used by organisms to delineate a space for mineral formation. The vesicles can be located within the cell or less commonly outside the cell, and their sizes range from submicrons to centimeters! Both amorphous and crystalline minerals are formed in vesicles, and in the case of the latter they can be either single crystals or multicrystalline. Two of the most fascinating examples of crystal growth in vesicles occur in the *Echinodermata*—the sea urchins, brittle

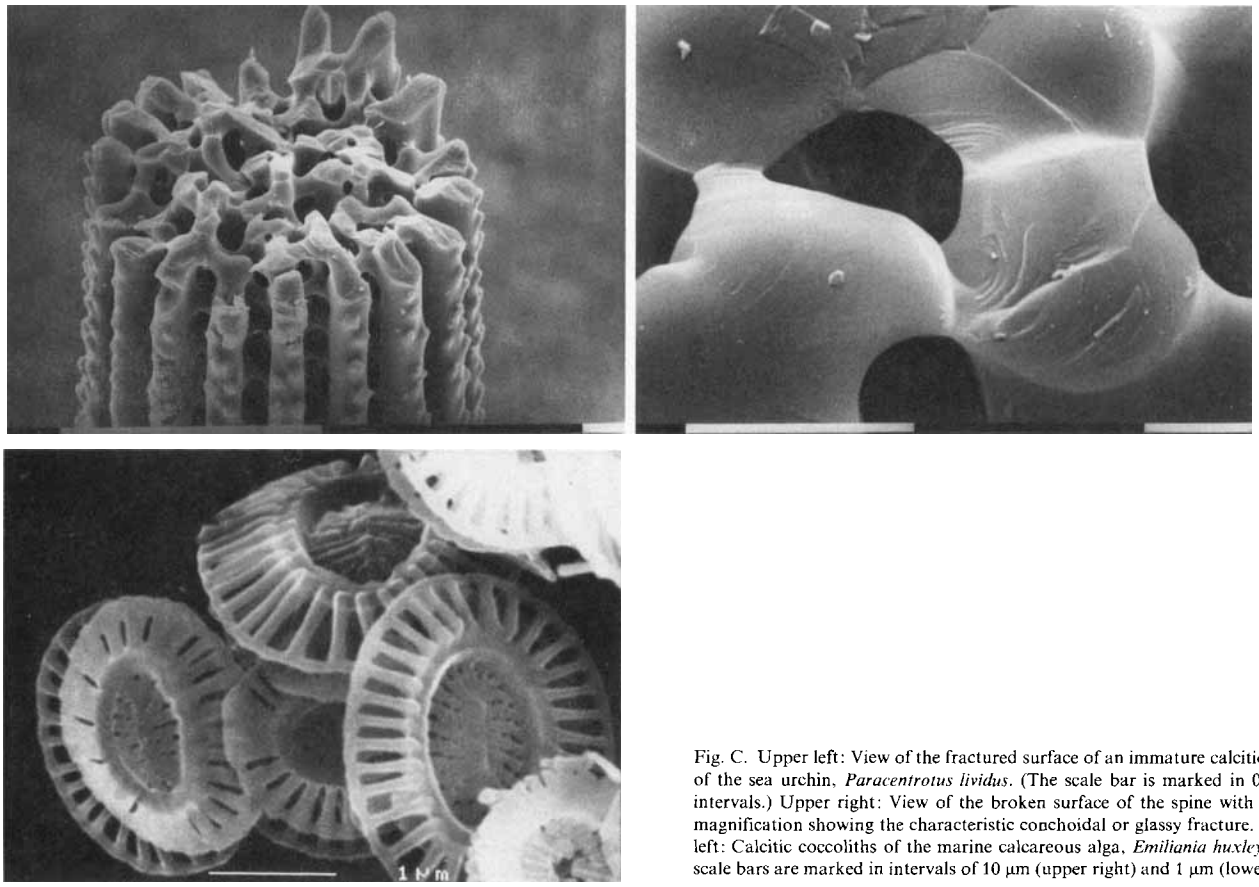

Fig. C. Upper left: View of the fractured surface of an immature calcitic spine of the sea urchin, *Paracentrotus lividus*. (The scale bar is marked in 0.1 mm intervals.) Upper right: View of the broken surface of the spine with higher magnification showing the characteristic conchoidal or glassy fracture. Lower left: Calcitic coccoliths of the marine calcareous alga, *Emiliania huxleyi*. The scale bars are marked in intervals of 10 µm (upper right) and 1 µm (lower left).

stars, and sea cucumbers—and the *Coccolithophoridae*, calcareous marine algae extremely abundant in the world's oceans.

The echinoderms form large single crystals of calcite intracellularly within very large vesicles (Fig. C, upper left). This is achieved by many cells fusing their cell-wall membranes together to create a large vacuole, inside which the mineralizing vesicle forms.[35] The stages of crystal formation are best described for the sea-urchin larvae, since these can be grown in laboratory cultures. The calcite crystal is nucleated inside the vesicle and has a triangular shape. The crystal then begins to grow in three different directions, each of which is along the *a* crystallographic axis, and forms a so-called triradiate spicule (see Section 9). Then quite amazingly, the spicule is rotated into a specific orientation after its initial formation.[94] At a later stage one of the arms changes its growth direction by 90° to continue growing along the *c* axis direction. Presumably the vesicle shape determines the direction of crystal growth but still "takes into account" crystallographic considerations—a delicate interplay between biology and crystallography.

Each skeletal plate of the adult sea urchin also has its origin most probably in a single nucleation event[95a] and then grows intracellularly to sizes of up to a centimeter or so. The spines are basically similar in structure to the plates but can reach sizes of up to 25 cm, and yet each one is still a single crystal.[95b] The crystal has a highly convoluted shape (Fig. C, upper left) with all its surfaces being smooth and curved, features never normally associated with a single crystal. Even more puzzling is the fact that the fracture surfaces of the calcite of the spine do not resemble the smooth and straight cleavage planes of inorganic calcite; they are curved and stepped and are very similar to the conchoidal fracture surfaces of amorphous glasses[37] (Fig. C, upper right). The sea urchin also has a set of five continuously growing teeth. These teeth are composed of calcite, but in their cores the magnesium content reaches more than 40 mole percent. The cores still retain the structure of calcite and not that of dolomite [$(Ca,Mg)CO_3$].[64] Despite the fact that the tooth has a highly complex fine-structure and is the product of many nucleation events, X-ray diffraction shows that all its crystals are well aligned.[64, 96]

The *Coccolithophoridae* are single-celled photosynthesizing algae which cover their outer cell-wall with layers of calcitic coccoliths (Fig. C, lower left). Each coccolith is formed intracellularly in a specialized vesicle, and upon completion is transported through the cell membrane to the outer surface.[97] An individual coccolith is in itself a highly complex structure. Its overall shape is that of a flat spherical scale, but the detailed morphology is intricate and highly species-specific.[98] A scale is in fact composed of some 20 or more individual elements, each of which is a single crystal of calcite.[99] The crystals nucleate on the rim of an organic base plate. A highly acidic polysaccharide containing both carboxylate and sulfate groups, which is able to bind calcium, is located within the mineral phase and possibly in the membrane itself.[100] Coccolith formation is thus an example of a highly ordered array of crystals being formed in association with a structural framework and acidic macromolecules. All this takes place within a vesicle inside a single cell.

5.1. Reinforcing Single Crystals Against Fracture

Sea-urchin skeletal elements demonstrate yet another challenging paradox. A single crystal of inorganic calcite cleaves easily along the hexagonal (104) planes. Sea-urchin skeletal elements do not cleave in this way, despite the fact that they are most respectable single crystals (Excursus 3). Instead they fracture with difficulty (relative to pure calcite), producing what is described as a conchoidal fracture normally found in amorphous glasses.[37] Acidic proteins are present inside the elements in the amount of 0.02 wt %.[39, 40] Significantly, the proteins are occluded inside the mineral phase and can be liberated only by dissolution. They are all soluble in water and do not form continuous sheaths of material as in the organic matrices of mollusk shells, for example. Experiments on crystal growth in vitro, as well as synchrotron X-ray measurements of crystal texture, show that the acidic proteins reside at the boundaries of crystal domains; the average coherence lengths (about 1500 Å) are significantly smaller than those of pure calcite crystals (about 4500 Å).[34] During crystal growth the proteins preferentially adsorb on defined crystallographic planes parallel to the *c* crystallographic axis of the crystal (Fig. 2).[40] The resulting synthetic crystals also cleave with a conchoidal fracture very similar to that of the spines themselves. Interestingly, acidic proteins extracted from a mollusk shell do not adsorb preferentially on the same crystallographic planes of calcite and do not affect single-crystal cleavage in the same fashion.[40] In this latter case the artificial crystals are more fragile, and their cleavage follows the set of regular {104} cleavage planes.

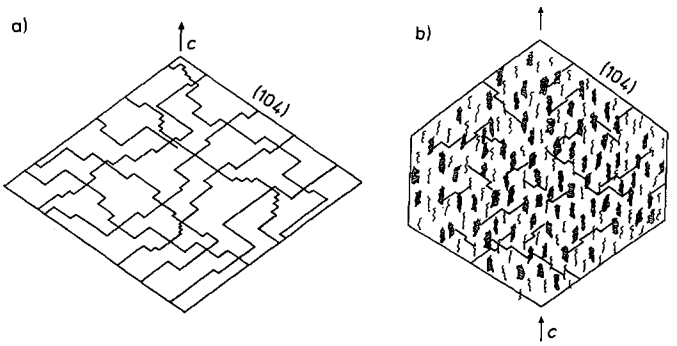

Fig. 2. Schematic representation of cleavage patterns in a) a pure calcite crystal; b) a calcite crystal with intercalated sea-urchin proteins. The cleavage planes are always parallel to the (104) faces. The protein is occluded on the three symmetry-related sets of {110} planes parallel to the *c* axis.

Although we do not yet have sufficient information on the compositions and structures of mollusk and sea-urchin acidic proteins, differences in the manner in which the proteins influence crystal growth may well reflect the functions they fulfill. We proposed that the sea-urchin proteins reinforce the crystalline material against fracture (Fig. 2) by controlled intercalation on planes oblique to the cleavage planes. Whether the mechanical reinforcement is due to direct intervention of the protein in deviating or absorbing a progressing fracture, or is limited to the modification of crystal texture induced during growth, is as yet unknown. This

solution adopted by nature to circumvent a problem intrinsic to the material used for construction is both new and surprising. It will be interesting to check whether it is unique.

6. Control Over Crystal Morphology

Biogenic minerals are perhaps best known and appreciated for their almost endless variety of shapes, many of which bear no resemblance to their inorganic counterparts (Excursus 4). Almost nothing is known about the manner in which this is achieved in vivo, except that it is likely to involve charged polymers such as proteins, polysaccharides, or a combination of both.

Interactions between charged polymers and growing crystals may or may not be specific. We define a nonspecific interaction as one in which the charged polymer interacts with all surfaces of a given crystal; in a specific interaction, on the other hand, one surface is favored over the others. Specific interactions are most likely to occur when relatively weak interactions are involved, since even slight differences in recognition will tend to be amplified. As the ionic character of the crystal and polymer surfaces increases and the interaction strengths are enhanced, particularly by the cooperative action of many charged groups on the macromolecule, the effect on crystal growth becomes less and less specific. This phenomenon has been observed in vitro for polyelectrolytes such as polyaspartate and polyacrylate on growing calcite crystals,[41] for acidic polysaccharides on sodium chloride,[42] and for chondroitin sulfate on hydroxyapaptite[43] and sodium urate.[44] The inhibition mechanism can be envisaged as a blanket-blocking or -poisoning of crystal steps and kinks over the entire surface of the growing crystal.

When the macromolecule is part of a flexible vesicle, physical contact with the external envelope is probably not sufficient to arrest growth because of the strong tendency of crystals to complete lattice layers having a minimal surface energy. For example, the single magnetite crystals of magnetotactic bacteria develop well-defined faces,[45] even though they are presumably in contact with the inner surface of the vesicle in which they form.[46] A chemical interaction is probably required to stop crystal growth inside a flexible envelope at any stage of layer completion. If an inhibitor is immobilized in a membrane structure, physical contact can cause chemical inhibition. Inhibition can also conceivably be achieved by the cooperative effect of the many carboxylate and phosphate groups of the lipids composing the membrane itself. This type of inhibition by immobilized molecules has the additional advantage of being active only when the crystal touches the membrane and not interfering with growth prior to that. It may account for the smooth and curved mineral skeleton of echinoderms and some coccolithophores (Excursus 3).

Crystal morphology can also be modified by the adsorption of impurities from solution onto specific crystal surfaces. This was known even before X-rays became the conventional tool for determining crystal structure.[47] Mechanisms of inhibition involved in the control of crystal morphology have been elucidated at the molecular level in a systematic series of studies on organic crystals and tailor-made inhibitors, performed by the solid-state group at the Weizmann Institute.[48] It was shown that such inhibitors are adsorbed selectively on specific crystal planes at lattice sites where a part of the molecule, identical to the substrate molecule, can fit into the regular arrangement of the surface layer. The remainder of the inhibitor molecule, which does not match the crystal structure, emerges from the surface and perturbs the regular deposition of the next layers, thus slowing growth in this direction. Crystal morphology is determined by the relative rates of growth of the crystal in different directions. It can thus be controlled at will by engineering the appropriate inhibitors.[49] Conversely, information about the crystal planes specifically interacting with inhibitor molecules can be deduced by analysis of the morphological modifications caused by the inhibitor upon crystal growth. This morphological tool can thus be exploited to obtain information on the interactions between crystal surfaces and biological macromolecules present in solution. This is independent of the possible function of the morphological modification itself.

The "impurities" thought to be active in changing the morphology of biological crystals are the acidic macromolecules or a subset thereof. In a series of experiments crystals were grown in vitro in solutions containing small quantities of the proteins.[50] The results showed that some but not all acidic proteins interact specifically with certain faces of growing crystals and alter their morphology. For this to occur the proteins must have, at least in part, regular β-sheet structures. Furthermore, it has been observed that acidic proteins from a variety of mineralized tissues often interact preferentially with crystal faces containing a certain structural motif, be they crystals of dicarboxylic acid salts,[50] calcite,[40] phosphate esters,[51] or the calcium phosphate minerals octacalcium phosphate[52] and dahllite.[53] The common feature of these motifs is that the anionic groups of the crystal form chains with alternating calcium ions, and their oxygen atoms are oriented more or less in the plane of the face, with their backbone perpendicular to it. In vivo the proteins could also act from solution in a similar way. The fact that similar stereochemical features were identified on the interacting faces in different systems is a hint that general rules of interaction between crystals and acidic macromolecules may exist.[54]

Excursus 4: Biological Control of Crystal Morphology

One of the hallmarks of biomineralization is the control of crystal morphology. The vast majority of organisms produce crystals of one specific mineral type and a uniform morphology at a particular tissue site. The same organism may produce the same mineral but with different morphologies at different tissue sites. An excellent example is the shell of a fresh-water bivalve (Fig. D, upper left), which is composed of two layers with differently shaped aragonitic crystals. Neither of the crystal shapes resemble aragonite crystals formed inorganically in the magnesium-rich Dead Sea (Fig. D, upper right). Many marine calcareous algae form aragonite under poorly controlled conditions, and their crystals (Fig. D, lower left) indeed resemble the inorganic aragonitic crystals (Fig. D, upper right).

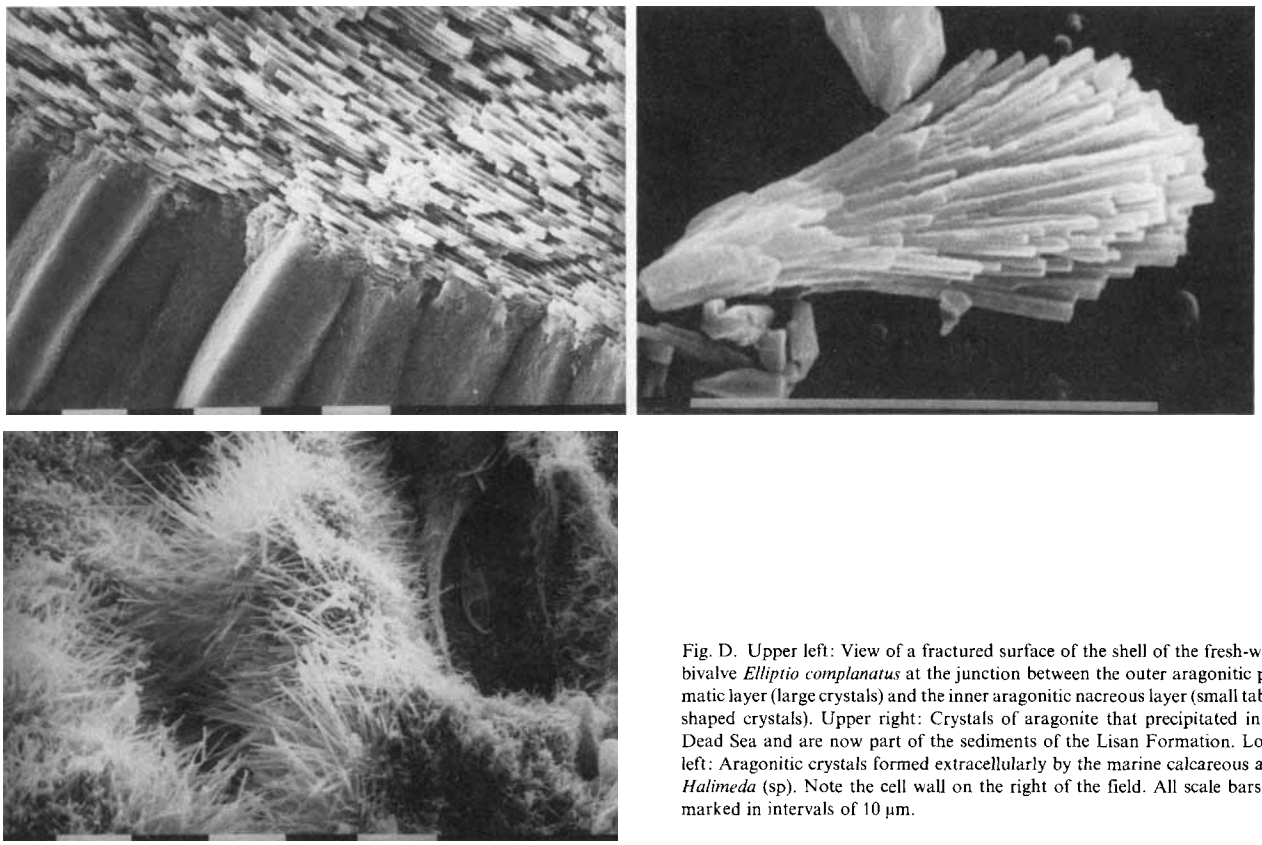

Fig. D. Upper left: View of a fractured surface of the shell of the fresh-water bivalve *Elliptio complanatus* at the junction between the outer aragonitic prismatic layer (large crystals) and the inner aragonitic nacreous layer (small tablet-shaped crystals). Upper right: Crystals of aragonite that precipitated in the Dead Sea and are now part of the sediments of the Lisan Formation. Lower left: Aragonitic crystals formed extracellularly by the marine calcareous alga, *Halimeda* (sp). Note the cell wall on the right of the field. All scale bars are marked in intervals of 10 μm.

Examples of species-specific crystal morphologies abound in biology. These include the magnetic crystals of magnetotactic bacteria,[101] which generally have well-defined crystal faces but in different proportions and hence difference morphologies. Some species, however, form bullet-shaped crystals with rounded surfaces.[45] Both types of crystals form in membrane-bound vesicles.[46] Different plants produce crystals of calcium oxalate monohydrate (whewellite) and dihydrate (weddelite) with species-specific morphologies.[102] Single-celled marine animals called *Acantharia* produce beautifully symmetrical (20fold symmetry!) skeletons composed of strontium sulfate (celestite). Three different spicule shapes are used to assemble the structure. Even though the main shaft of the spicule is curved, the ends that fit together at the hub of the complex have straight faces which correspond to well-defined crystal planes.[63] These spicules also form inside vesicles.

Crystal morphology is almost always a genetically defined property of a mineralized tissue. Little is known about the advantages of one morphology over another. Except for very basic observations about crystals forming in spaces delineated by lipid bilayers or macromolecular assemblies with well-defined shapes, almost nothing is known about the in vivo methods used by organisms to control crystal morphology. Almost all our knowledge to date is based on in vitro experiments.

7. Control Over Nucleation

The key to the formation of many mineralized tissues is control of nucleation. Crystals grown at specific locations and with well-defined orientations can best be exploited for producing optimal materials. The control of nucleation is sometimes fairly easily demonstrated by inspection of tissue ultrastructure, but how it is achieved is certainly one of the most fundamental questions to be addressed in biomineralization.

7.1. Specially Designed Nucleating Proteins

Conceptually the use of specific proteins adsorbed on a rigid substrate is a good strategy for nucleation, because nucleation will not occur until the nucleating macromolecule is in the correct place. This in turn requires that the nucleator is not only able to induce crystal nucleation but also able to also locate itself at a specific site on the framework scaffold. In the case of the nacreous layer (Excursus 5) the driving force of this process might be due to an alternating sequence within the acidic proteins.[113] When the chain adopts a β-sheet structure, the more hydrophobic residues form a surface which is adsorbed onto the scaffolding protein. The scaffolding matrix, also a β-sheet structure, holds and probably partly governs the folding of the soluble protein (Fig. 3). The acidic residues point towards the solution and form the nucleation site. They bind calcium ions in a layer, which constitutes the interface with the about-to-be-formed crystal. The formation of this initial two-dimensional calcium layer dictates that the nascent crystal will form with its *c* axis perpendicular to the nucleating surface. In vitro experiments using acidic macromolecules from mollusk shells show that when bound to a rigid substrate, some but not all of these proteins are able to induce the nucleation of calcite

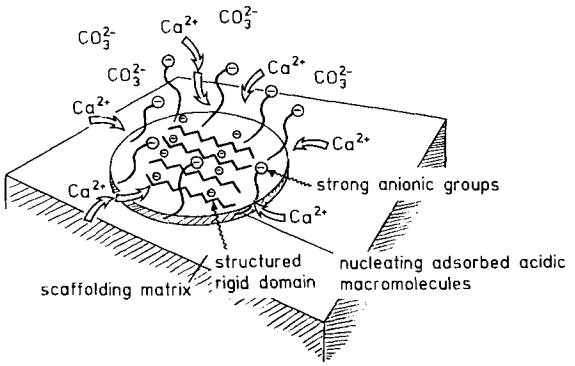

Fig. 3. Schematic representation of a nucleation site in the nacreous layer of a mollusk shell. The soluble acidic protein is immobilized by adsorption on the scaffolding matrix. Nucleation ensues by the cooperative action of flexible concentrating groups and structuring rigid domains.

crystals with their c axes perpendicular to the plane of the nucleating substrate[50] (Fig. 4). This is the most common orientation in vivo for calcite as well as aragonite. In both structures the c axis is perpendicular to layers of calcium and carbonate[54] (Fig. 5).

There is evidence, albeit indirect, for specific nucleating proteins in the nacreous layer (Excursus 5), but for almost all other tissues their existence is still hypothetical. In bone, for example, the crystals are located in spaces within the collagen fibril. Unless they are nucleated on the fibril surface and then grow into the fibril, there is little or no space available within the fibril for a nucleating molecule. At this stage, we limit ourselves to a description of the properties that contribute to controlled nucleation, based on in vitro studies of mollusk acidic glycoproteins.

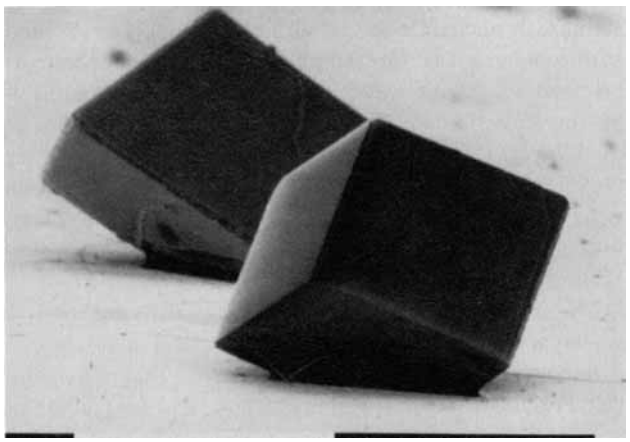

Fig. 4. Synthetic crystals of calcite nucleated from mollusk-shell acidic proteins adsorbed on an artificial substrate. The crystals are oriented with their c axes perpendicular to the substrate and assume the typical cleavage rhombohedron morphology of nonbiogenic calcite. (The scale bar is marked in 0.1 mm intervals.)

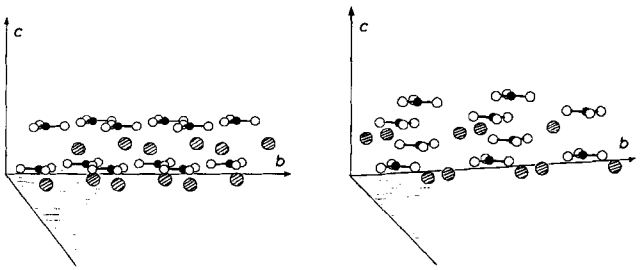

Fig. 5. Partial structures of calcite (left) and aragonite (right). The (001) layers in contact with the nucleating surface are represented. The calcium layers are practically identical; The difference between the two structures is reflected in the positions of the carbonate ions. Hatched circles are Ca ions; black circles, C atoms; and white circles, O atoms.

7.2. Conformation and Rigidity

Acidic soluble proteins can be nucleating in the adsorbed state but inhibit crystallization when present in solution. This ensures that crystallization will not take place in the wrong place and at the wrong time. Inhibition of crystallization from solution is guaranteed by the flexibility of the polypeptide chain in solution. We proposed that nucleation on the substrate is catalyzed by an array of carboxylate groups of aspartic acid residues locked in an ordered and rigid conformation.[55] In solution an extended sheet is not stable and rigid enough to be a good substrate for formation and stabilization of crystal nuclei. This hypothesis is supported by data from diverse fields. Flexible polyelectrolytes are well-known inhibitors of crystal nucleation and growth.[56] On the other hand, it has been observed that the same groups immobilized in a monolayer are selective nucleators of crystals[57, 58] from planes matching the monolayer surface structure. In experiments with tailor-made polymeric inhibitors, it has also been shown that an array of side chains, which match the structure of a mature crystal, selectively inhibit its nucleation when they are present in solution.[59]

In an attempt to understand the mechanism of oriented nucleation we have studied some model systems, including polycarboxylates in various conformations.[41] We observed that polyaspartate, which was adsorbed with partial β-sheet structure onto sulfonated polystyrene films, induces nucleation of calcite from the calcium (001) plane. Adsorbed polyacrylate with a random conformation, does not have the same effect, and polyglutamate with a small proportion of β-sheet structure relative to polyaspartate has an intermediate effect. All three polymers are strong inhibitors of calcite nucleation and growth from solution, because they adsorb onto the surface of the calcite crystallites or nuclei and retard and/or disrupt their growth.

It is interesting that the behaviour of these relatively small polymers and surface-active proteins is opposite to that of large globular proteins, yet the basic mechanisms involved are the same. Human serum albumin acts in vitro from solution as a nucleator of crystals of sodium urate monohydrate,[60] with the involvement of a number of carboxylate groups on its surface. The protein is large and stable enough to produce rigid domains on its surface even in solution. These stabilize the crystal's nuclei by interaction with their cation layer. On the other hand, adsorption of the protein on polystyrene films results in the total loss of this nucleating power. The adsorbed protein undergoes partial denaturation upon adsorption,[44] probably concomitant with disruption of the integrity of the nucleating domains.

7.3. Cooperative Interactions

An additional element that has been identified in the nucleation mechanism is the cooperativity between the array of structured, rigid carboxylates mentioned above and anionic sulfate groups attached to flexible oligosaccharide chains. Sulfated polysaccharides linked to polypeptide chains (proteoglycans) are present in cartilage and are involved in the osmotic equilibrium of the tissue through cation concentration. In the nucleation of calcium carbonate crystals the same effect has been postulated;[61] calcium ions are directed to the fixed carboxylate positions, where crystallization ensues by further carbonate binding[55] (see Fig. 3). The feasibility of such a process has been demonstrated in model systems of flexible polystyrene sulfonate chains and adsorbed polyaspartate with β-sheet structure. Again, the same process cannot occur in solution because of the lack of organization created by the restriction of mobility in the absorbed state.

Sodium cations are abundant in sea water and in the fluid found between the mantle and the shell (extrapallial fluid) of mollusks. Their concentration (0.5 M) is much higher than that of calcium, and as a result they interfere with the interactions between calcium and acidic proteins in solutions.[62] The composition of the actual fluid in contact with the matrix before crystal nucleation is, however, unknown. One may speculate on the existence of an additional possible mechanism which would ensure that crystallization occurs only when desired; this could be achieved by selective removal or supply of disturbing cations like sodium at the nucleation site. It is well known that ion separation can be accomplished by biological membranes. The marine protozoans *Acantharia* filter strontium from sea water against an enormous concentration gradient to build their strontium sulfate skeletons. They are capable of discriminating Sr from Ca ions, which are similar to Sr ions but much more abundant.[63] Sea urchins build their skeletons out of magnesium-containing calcite, parts of which contain as much as 40 mole percent Mg.[64] The calcite of mollusk shells generally contains very little magnesium. Clearly Mg contents are also well controlled.[65] It is therefore conceivable that sodium may be selectively removed, in order to activate certain proteins at the nucleation site by allowing them to interact more strongly with calcium.

8. Control Over Polymorph Type

Many organisms exert total control over the type of polymorph precipitated, and biology abounds with examples of organisms crystallizing a compound with a certain structure at one site and with a second structure at a different, often adjacent site.[1, 2] We do not understand how this is achieved, nor what advantages one polymorphic material offers over another.

According to the rules of thermodynamics, crystallization is favored when the absolute value of the bulk energy of the crystal nucleus is equal to or greater than the energy of interaction with the environment (surface energy). A solution, which is supersaturated with respect to the stable but not the metastable polymorph of a certain material, can yield crystals of the stable polymorph only. On the other hand, if the solution is supersaturated with respect to more than one crystalline form, all of them can precipitate. The equilibrium condition of lowest energy is obtained when all the less stable polymorphic forms transform into the most stable one. These considerations are only thermodynamic. It is known, however, that both the formation of a particular polymorph and the transformation of one phase into another can be kinetically controlled.[66]

In principle, crystallization of a metastable polymorph can be achieved by two opposing mechanisms: inhibition of nucleation of the stable form or preferred nucleation of the metastable form. There are many examples involving organic molecules of the former[59] and very few, if any, of the latter method of control.[58]

It is most convenient to study these processes using organic molecules, because they are easier to manipulate stereochemically. A tailor-made additive, resembling the mature crystal structure of the stable form and not the metastable form, can delay nucleation of the former sufficiently to allow crystallization of the less stable phase.[59] These experiments also support the notion that supersaturated solutions contain aggregates with a variety of different structures, some of which at least resemble the different mature crystal forms. When the crystallization of some of these is selectively inhibited, the growth of the others is kinetically favored. In an analogous manner, organized surfaces matching one polymorph on a certain crystal plane can in principle selectively stabilize its nuclei. Organized surfaces of monolayers[67] and surface aggregates[68] of amphiphilic molecules operate as crystal nucleators and can influence polymorph choice following this mechanism. It has been shown that stearate monolayers induce the nucleation of vaterite, an unstable polymorph of calcium carbonate. The induction mechanism is not completely understood, but a dependence on the orientation of the carbonate ions to the (001) nucleating plane has been proposed.[58]

The most widespread examples of the determination of crystal polymorphs in biomineralization occur in the calcium carbonates, calcite, aragonite, and vaterite. Thermodynamically, calcite is the most stable polymorph at normal atmospheric temperatures. Aragonite is less stable than calcite, and the most unstable polymorph is vaterite. The stabilities of calcite and aragonite in water are very similar, yet organisms are able to manipulate them with the highest precision. The presence of other doubly charged ions, such as magnesium and strontium, favor the formation of aragonite and calcite respectively.[69] Aragonite has a denser structure, which probably cannot accommodate the smaller magnesium ion, because of the larger hydration sphere associated with the ion during adsorption at the growing crystal sites. Magnesium can, however, be accomodated inside calcite, where it acts as an inhibitor of crystal growth. Sea water has high concentrations of Mg, and aragonite is indeed the polymorph formed spontaneously from sea water. Polymorphism may thus be regulated at the chemical level by adjusting the foreign ion composition and by kinetically preventing growth of the stable polymorph. On the other hand, control can also be envisaged at the nucleation level. We note, however, that the (001) layers of calcite and aragonite from which the crystals are most often nucleated, are practically

identical in terms of the positions of their calcium ions. Selective nucleation of one of the two polymorphs would probably have to include specification of the position of the carbonate anions as well (see Fig. 5).

The calcium phosphate minerals present another classic dilemma in our understanding of biomineralization. The dahllite (carbonate apatite) crystals of bone display a whole series of inconsistencies. They are not stoichiometric compounds,[70] their crystal dimensions ($\sim 200 \times 500 \times 30$ Å^3)[71] imply a very high surface/bulk ratio, and their crystal morphology, namely irregularly shaped, thin plates[71] elongated in the direction of the *c* axis,[71] does not reflect the symmetry of the hexagonal structure. The persistence of a "memory effect" of precursor phases has been proposed in order to explain some of these phenomena.[72] Indeed the phase diagram of calcium phosphate shows a wealth of different forms, whose formation and transformations are functions of pH, temperature, concentration, and presence of foreign inorganic and organic components.[73] The most likely precursor of apatite, octacalcium phosphate, has a structure almost identical to that of hydroxyapatite in one layer in the (100) plane[72] (Fig. 6). However, the hydroxyapatite layers are intercalated by hydrated layers also parallel to (100). These must be removed for the ions to assemble into the apatite structure. Although much is known about the behaviour of these systems in vitro, little is known yet about the nature and history of the nucleating crystals in bone.

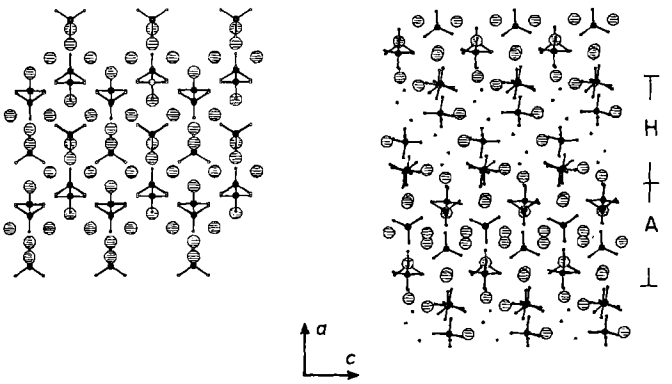

Fig. 6. Packing arrangements of hydroxyapatite (left) and octacalcium phosphate (right) in the (010) plane. In the structure of octacalcium phosphate the hydrated layer H is intercalated between "apatite layers" A in the (100) plane. Hatched circles are Ca ions; black circles, P atoms; and small white circles, O atoms. The *a* and *c* axes apply for both structures.

The concept of the transformation of one phase into another with a possible memory effect raises interesting possibilities regarding the transformation of amorphous phases into crystalline ones. Such transformations are known to occur in biology;[1] One of the best documented examples concerns chiton teeth (Excursus 1). Can the presence of very small domains of short-range order within an amorphous structure govern its transformation to a mature crystalline phase?[74] If this is possible, then the conditions of precipitation of the original amorphous phase or the presence of trace constituents may influence the short-range order domains and consequently the nature of the mature phase long before the final transformation. Removal of inhibitors or a change in the environmental conditions can then trigger crystallization allowing these prenuclei to grow.

9. Filling Space with Crystal Arrays: The Design of Biological Materials

The formation of mechanically sound mineralized tissues by organisms requires sophistication, and in fact it took nature thousands of millions of years to acquire this ability. Depending upon the degree of sophistication involved, it requires confining a space, controlling ion input, constructing a nucleation site, and controlling crystal morphology and orientation—processes which we have discussed individually. Here we conclude this review by surveying some of the products of these combined activities, namely the mineralized biological materials themselves.

Perhaps the simplest approach of all for organisms to form a material involves confining a space, pumping ions into it, and inducing crystals to form around nonspecific, randomly located nucleation sites. The product is a mineralized mass of spherulites. Examples of such materials are the spicules protruding from the mantle girdle of the chiton[75] (Fig. 7 upper left), the cameral deposits of the *Nautilus*[76] (Excursus 2), and the reinforced walls of the calcareous alga, *Halimeda*[77] (Excursus 4). The end-product is rather porous, has little or no internal organization, and in many ways resembles a synthetic ceramic.

By controlling the nucleation sites, and in particular by distributing them in some sort of regular manner, a significantly more ordered tissue can be formed, still on the basis of spherulites. Examples in which this strategy is used are fish otoliths[78] (Excursus 2) and avian eggshells[79] (Fig. 7 upper right). In the eggshell the nucleation site is controlled by organic molecules, including sulfated polysaccharides that form rounded structures. The calcite crystals nucleate with their *c* axes more or less perpendicular to the surface. Because the nucleation site is very close to the inner membrane, the crystals are prevented from growing in this direction. Crystals oriented in other directions stop growing upon contact with crystals from a neighboring nucleation site, or when they reach the distantly located outer membrane. Thus many of the crystals show a pseudo-preferred orientation simply because of the geometry of the available space. The packing density of this product is most certainly improved.

The previous examples involve the formation of multiple crystals at a single nucleation site. Much more control can be achieved when only one crystal is produced from a single nucleation site. In biology this phenomenon tends to occur concomitantly with the isolation of the local space around the nucleation site, such that an individual crystal forms in its own predefined space. The ideal example of this is the mollusk prismatic layer (Fig. 7 lower left), in which individual crystals of calcite, or less frequently aragonite, form in their own framework.[80] Mollusk mineralized tissues formed in this way generally comprise more than 95% mineral, less than 5% matrix,[81] and have a high density and excellent order. The crystal size is usually in the range of microns or submicrons.

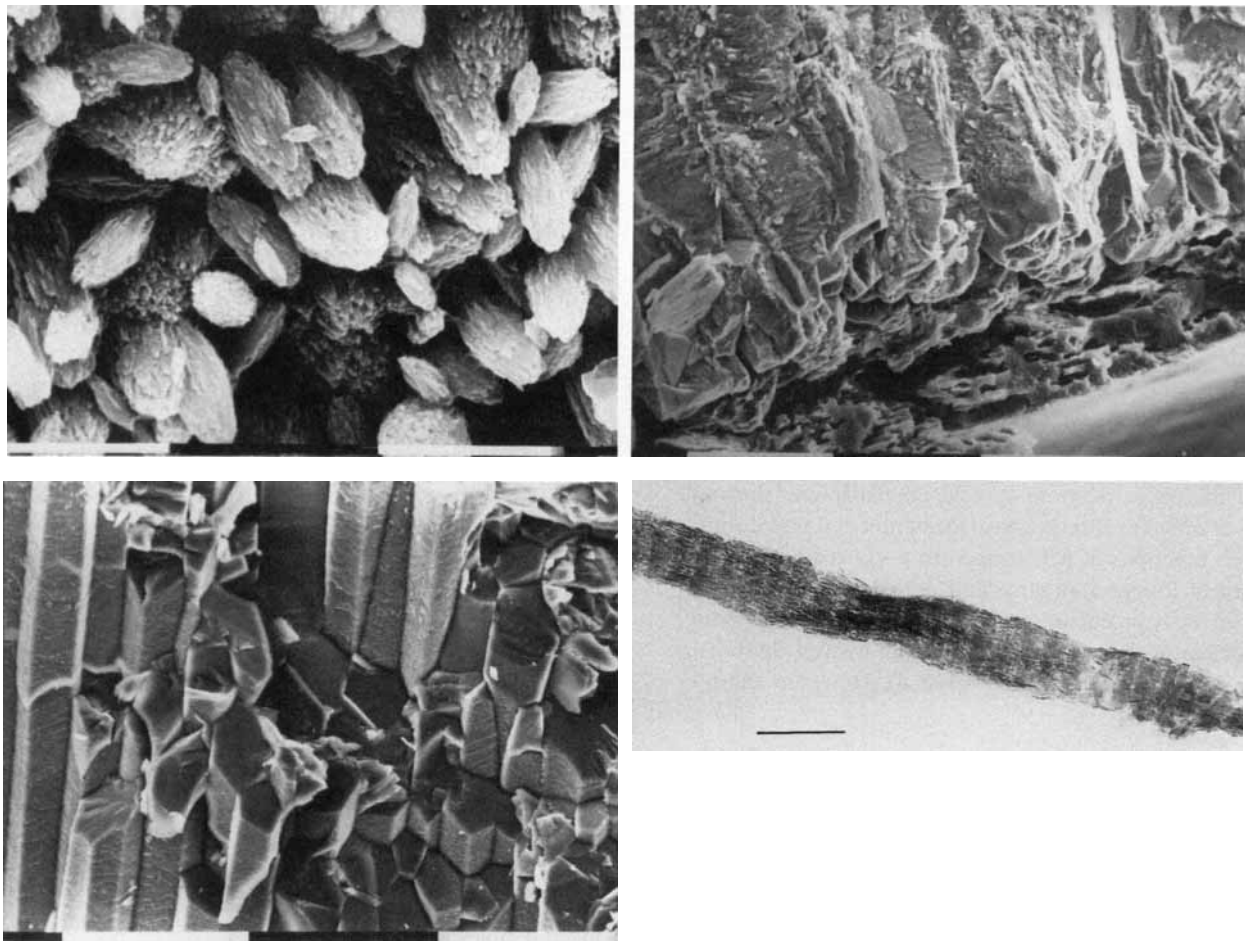

Fig. 7. Examples of four different approaches used by organisms for filling space with crystal arrays. Upper left: Aragonitic spherulites that make up the girdle spicules of the chiton *Acanthopleura haddoni* (Mollusca). The spherulites show no preferred orientation and are loosely packed (the scale bar is marked in 10 μm intervals). Upper right: View of the cross section and inner surface of the shell of a domestic hen's egg. In the lower part the nucleation centers of the calcite crystals can be seen, and in the upper part, the fusing of the crystals into columnar structures. (The scale bar is marked in 0.1 μm intervals.) Lower left: The calcitic prismatic outer layer of the shell of the bivalve, *Atrina serrata*. Each calcitic crystal nucleates from a single site and grows inside an organic matrix framework (not seen). (The scale bar is marked in 0.1 mm intervals.) Lower right: View from a transmission electron microscope of an individual lyophilized, but unstained mineralized collagen fibril from a turkey leg tendon. The electron density observed is due to the presence of the thin plate-shaped dahllite crystals located preferentially in the gap regions of the collagen fibril, thus revealing the characteristic banding pattern. The fibril is twisted such that in one region the crystals are viewed edge-on, and in other areas, face-on. The collagenous framework in which the crystals grow is not seen. (The line corresponds to 2.00 nm.)

In the formation of mineralized collagen fibrils, the building block of bone, dentin, and mineralized tendons, similar processes are involved, but the scale of the product is very different. Individual plate-shaped crystals of dahllite, just a few hundred Å in length and width and only 20 to 30 Å thick[71] are nucleated at specific sites on or within the collagen fibril. They grow into a preformed space within the fibril, which has the shape of a thin groove or channel.[82] These grooves do prevent the crystals from growing, but only momentarily.[83] The crystals continue to push their way into the overlap zone of the fibril.[84] The collagen framework apparently yields and the crystals essentially create their own space (Fig. 7 lower right). This was demonstrated by neutron-diffraction studies which showed that as the crystals grow the triple-helical collagen molecules come closer together; the average separation distances between collagen molecules is thereby reduced from about 15 to 12 Å.[85] Bone is a highly ordered composite material; the matrix comprises some 20% of the tissue by weight, mineral, 60 to 70%, and water, the rest.[86] The mechanical properties of bone—such as Young's modulus (the modulus of elasticity), bending strength, and work of fracture—are all directly related to the proportion of mineral present,[87] a parameter which is under strict biological control.

Another highly ordered tissue useful for illustrating design principles is the mollusk nacreous layer (Excursus 5). Here, too, nucleation involves the induction of a single crystal per nucleation site, but unlike many other tissues, the orientation of the crystal is completely controlled in all three dimensions relative to the structure of the matrix substrate. The crystals rapidly grow with their *c* axes perpendicular to the nucleating surface and adopt the normal acicular (needle-like) morphology of aragonite (Excursus 5). They stop growing in this direction when they meet the next prepositioned matrix layer and then only grow laterally. They stop growing altogether either when adjacent crystals touch each other or when they meet a matrix surface—as yet an unresolved issue. A most curious property of nacre results from the fact that some mollusks, such as the gastropods, do not control the relative orientations of neighboring crystals, except in the direction of the *c* axes. Individual crystals are, however, still specifically oriented with respect to the matrix substrate. In

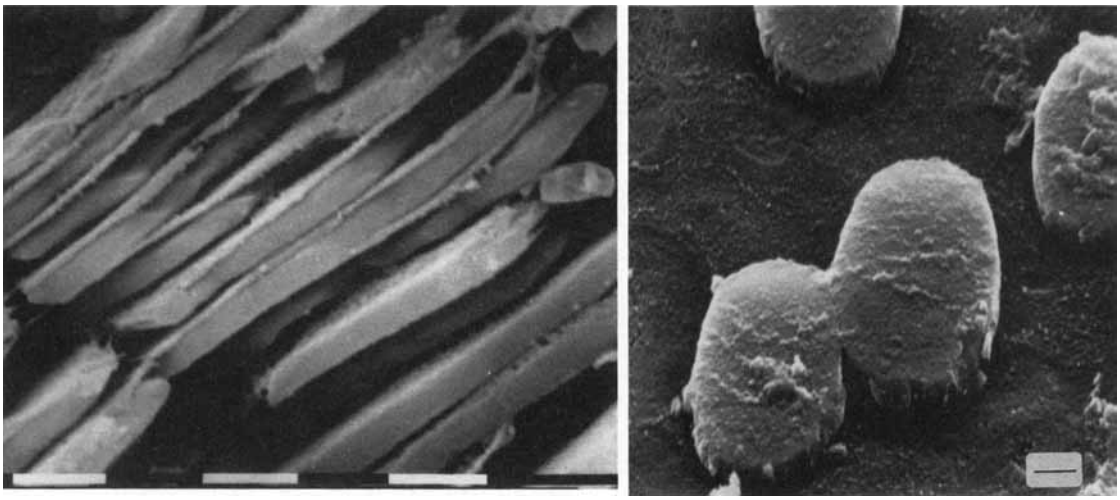
contrast many bivalves and the cephalopod *Nautilus* do orient neighboring crystals such that their *a* and *b* axes are preferably aligned, in addition to the orientation of the *c* axes. Two bivalve species, *Neotrigonia margaritacea* and *Pinctada margaritifera*, are known to control the orientation of their *a* and *b* axes remarkably well.[38] It would be most interesting to determine whether the order of these crystal arrays offers any advantages, mechanical or other.

The more sophisticated space-filling strategies used by organisms rely heavily on the intervention and abilities of the cells themselves over and above the presumably exquisite structural design properties of the associated matrix macromolecules. These are properties which are well-nigh impossible to mimic in synthetic systems.

Excursus 5: The Mollusk Shell Nacreous Layer

The nacreous layer is responsible for the pearly luster of the inner surfaces of many mollusk shells and, of course, for the much admired pearl itself. The luster arises from the interference patterns of light passing through the alternating layers of uniformly thick aragonite crystals and organic matrices (Fig. E, upper left). The shell layer is formed by mantle cells which first assemble an organic matrix framework within the extracellular space composed primarily of layers parallel to the shell surface.[103] Each layer is in itself composed of no less than five sublayers (Fig. E, lower left).[104] The core is a highly ordered β-chitin–protein complex, whose proteins are rich in glycine and alanine and have a β-sheet structure similar to that of silk fibroin. The chitin polymers and the protein polypeptide-chains are orthogonally aligned forming a plywoodlike construction.[105] The surfaces of this core are coated with a layer of proteins rich in aspartic acid, possibly also with β-sheet structure.[106] Nucleation of the aragonite crystals takes place at a specific site on the surface which is known to have unique calcium-binding properties and to be rich in sulfur, presumably in the form of sulfate.[107] The nascent crystals grow rapidly in the direction of their *c* axes, initially appearing to have the normal acicular morphology of aragonite (Fig. E, upper right). When the crystals reach the surface of the next matrix layer they stop growing in the *c* axis direction, but continue growing laterally. The shape of the laterally growing crystals in the bivalve *Neotrigonia* are spherical (Fig. E, upper right), suggesting a nonspecific interaction with additives in solution. The growing crystals exhibit different shapes depending upon the species involved, implying more specific or less specific interactions.

The mollusk nacreous layer was the first mineralized tissue in which the spatial relations between crystal and organic matrix substrate were determined in three dimensions.[105, 108] It was shown that the *a* axis of the aragonite is aligned with the direction of the chitin polymer, and the *b* axis, with the protein polypeptide-chains of the core. It is assumed that the acidic surface proteins at the nucleation site are also aligned in a regular manner vis-a-vis the crystal, and that they are responsible for the observed spatial relation. Even though this is certainly a case of the oriented growth of a crystal on a substrate, actually proving that this is indeed true epitaxy requires more information on the structure of the nucleation site itself—one of the most challenging goals in the field of biomineralization.



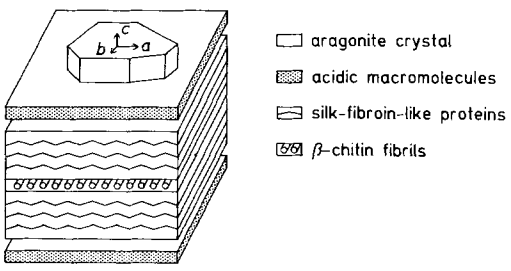


Fig. E. Upper left: Fractured surface of the aragonitic nacreous layer of the cephalopod, *Nautilus pompilius*. The surface was fixed and then etched for about a minute in EDTA to reveal the thin organic matrix-layers between the thicker aragonitic tablets. (The scale bar is marked in intervals of 1 μm.) Lower left: Schematic illustration of the structure of an individual matrix layer with its associated crystal. It can be seen that the crystallographic *a* and *b* axes of the aragonite are aligned with the macromolecular matrix constituents (printed with permission from Oxford University Press). Upper right: The surface of the growing nacreous layer of the bivalve *Neotrigonia margaratifera*. The oval-shaped aragonitic tablets growing laterally can be recognized. The rough texture on the tablet surfaces may represent the initial stages of formation of the next layer. The organic matrix is not distinctly seen in this preparation. (The line on the lower right of the picture represents 1 μm.)

10. Concluding Comments

The diversity in texture, composition, and scale of mineralized biological materials is enormous. These materials are adapted to a wide variety of functions. They may not, however, necessarily represent the "perfect" solution to each specific functional requirement; evolutionary limitations exist that restrict the extent to which mineralized materials can be optimally designed. Understanding the principles involved in their construction and modes of function is a fascinating subject in its own right. Furthermore, identifying the underlying mechanisms common to the formation processes of different mineralized materials provides insight into key underlying biological phenomena. The results of such investigations may well be a rich source of ideas for improving our ability to fabricate synthetic materials.

We thank the U.S.-Israel Binational Science Foundation and the U.S. Public Health Service (Grant DE 06954) for their support.

Phosphorus Nitrides—the Cinderella of Phosphorus Chemistry?

By *Otto J. Scherer**

In the latest edition of the monograph on phosphorus compounds by D. E. C. Corbridge,[1] which contains over a thousand pages, the chapter on molecules comprising only phosphorus and nitrogen atoms is merely three pages long. Besides the explosive azides[2] $P(N_3)_3$ and $P(N_3)_5$ characterized in solution by ^{31}P NMR and IR spectroscopy, only a few phosphorus nitrides of tri- and pentavalent phosphorus were described in a more or less complete manner (Scheme 1).

$$:P{\equiv}N: \qquad \dagger P{=}N\dagger_n \ (n = 2,3,\infty) \qquad P_3N_5$$
$$\mathbf{A} \qquad\qquad \mathbf{B} \qquad\qquad\qquad \mathbf{C}$$

Scheme 1. The phosphorus(III) nitrides **A** and **B**, and the phosphorus(V) nitride **C**.

In the thoroughly investigated, monomeric, gaseous phosphorus(III) nitride (**1**), synthesized according to Equation (a),[3] the P≡N bond length (1.49 Å) has been determined by

$$P_3N_5(s) \xrightarrow[-N_2(g)]{1050\,K} 3\,PN(g) \quad \mathbf{1} \qquad (a)$$
$$(Cl_2PN)_3(g) \xrightarrow[-6\,AgCl(g)]{6\,Ag(l)/1300\,K}$$

microwave spectroscopy and differs only slightly from the calculated value of 1.462 Å.[4]

The dimer $(PN)_2$ has not yet been detected experimentally, but SCF calculations predict as most stable form a molecular structure with D_{2h} symmetry.[5] Distinctly more stable than *cyclo*-$(PN)_2$ is the trimer $(PN)_3$, which forms by trimerization of **1** on warming the krypton matrix from 10 K to 40 K.[6a] Both the IR spectrum[6a] and theoretical studies[3] indicate a planar six-membered ring structure with D_{3h} symmetry.

The reaction of **1** with metal atoms of the copper group yields complexes **2** and **3**, characterized as yet only by IR spectroscopy and displaying η^1-P and μ-P coordination respectively[6b] [Eq. (b) and (c)]. An alternative interpretation of the IR data of **3** suggests a *cyclo*-$(PN)_2$ molecule containing an η^4-coordinated silver atom.[3]

$$:P{\equiv}N: \xrightarrow[10\,K,\,Krypton]{M=Cu,\,Au} :N{\equiv}P: \rightarrow M \leftarrow :P\ N: \quad \mathbf{2} \qquad (b)$$
$$:P{\equiv}N: \xrightarrow[10\,K,\,Krypton]{M=Ag} \mathbf{3} \qquad (c)$$

The molecule PNO was prepared by cocondensation of PN and O_3, also in a noble gas matrix. IR studies and ab initio calculations show that PNO is surprisingly more stable than NPO.[4]

Although Stock and Hoffmann synthesized phosphorus(V) nitride P_3N_5 (**C**) as early as 1903 by ammonolysis of tetraphosphorus decasulfide P_4S_{10},[7] its structure is still unknown. The same applies for polymeric phosphorus nitride $(PN)_n$, which forms from monomeric PN as well as from a reaction of PH_3 and N_2 or PCl_3 and NH_3.[1]

Starting with the preparation and refinement of the crystal structure of $LiPN_2$ (**4**),[8a] a lithium phosphorus(V) nitride whose PN_2^- substructure is isoelectronic with SiO_2 (isosteric to β-cristobalite) and which forms a three-dimensional network of corner-sharing PN_4 tetrahedrons (P–N = 1.65 Å), W. Schnick and co-workers have just achieved two breakthroughs in the field of ternary phosphorus(V) nitrides:

They allowed the binary nitrides P_3N_5 and Li_3N to react with each other and obtained $Li_{10}P_4N_{10}$ (**6**),[8c] as well as **4**[8a] and the compound Li_7PN_4 (**5**), whose PN_4^{7-} substructure is isoelectronic with PO_4^{3-} and affords "isolated" tetrahedral PN_4 anions ($\bar{d}$(P–N) = 1.71 Å). Compound **6** can also be synthesized from $LiPN_2/Li_3N$ or Li_7PN_4/P_3N_5 in a high-temperature solid-state reaction (700–720 °C, 5 days). $Zn_7[P_{12}N_{24}]Cl_2$ (**7**), a sodalite with a phosphorus–nitrogen framework, is also surprisingly simple to prepare[8d] [Eq. (d)].

$$7\,ZnCl_2 + 12\,NH_4Cl + 4(NPCl_2)_3 \xrightarrow[-48\,HCl]{700\,°C,\,2d} Zn_7[P_{12}N_{24}]Cl_2 \qquad (d)$$

The $P_4N_{10}^{10-}$ ion of **6** illustrates the principle of isoelectronic molecules in a simple but fascinating way (Fig. 1). The pendant of molecular phosphorus(V) oxide P_4O_{10} has ideal T_d symmetry in the solid state. The terminal P–N bonds (P1–N2 = 1.58 Å) are clearly shorter than the bridging bonds (P1–N1 = 1.68 Å). In the solid state the $P_4N_{10}^{10-}$ ions are arranged similarly to a zinc blende structure, result-

ing in a considerably more favorable packing than in P_4O_{10}.[8c]

The $[P_{12}N_{24}]$ framework of **7**, analogous to sodalite $Na_8[Al_6Si_6O_{24}]Cl_2$, is constructed from $[P_4N_4]$ and $[P_6N_6]$ rings (P–N = 1.64 Å), which in turn resemble the typical capped octahedrons of the sodalite type's secondary construction feature—the so-called β cages. A chloride ion surrounded tetrahedrally by Zn^{2+} ions is found in the center of each cage.

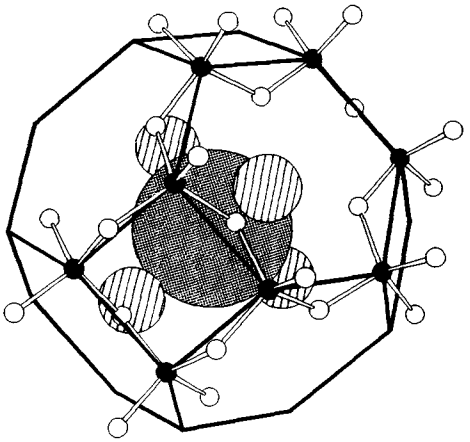

Fig. 2. Section of the crystal structure of $Zn_7[P_{12}N_{24}]Cl_2$ (**7**). The spheres are represented as follows: P = black, N = white, Cl = shaded, Zn = hatched.

As a result of their varied applications, for example, as ion-exchange resins, components of detergents, molecular sieves, and particularly as catalysts,[9a] zeolites still enjoy today an unrestricted interest shown to almost no other class of substances in inorganic chemistry. Their scientific importance is impressively documented by many up-to-date monographs, review articles on their topology and geometry,[9b] as well as the theoretical aspects,[9c] and not least by the ten-year old journal "Zeolites".

Against this background the nitrido sodalite **7**, a zeolite in which for the first time the ubiquitous oxygen in the anionic substructure is replaced by nitrogen, opens fascinating perspectives. With this new class of phosphorus(v) nitrides, the phosphorus nitrides that have been treated so shabbily in the past have become equals with their "sister" compounds in phosphorus chemistry and are expected to thrive. Strong indications for this are already to be seen in the lithium-ion conductivity[10] of $LiPN_2$ (**4**) and Li_7PN_4 (**5**).

Structure and Reactivity of Silicon Clusters in the Gas Phase

By *Thomas Lange** and *T. Patrick Martin**

The rich variety of properties found for clusters – that is, small aggregates consisting of three to some hundreds of atoms – has attracted the attention of chemists and physicists alike. It is hoped that some of these properties can be incorporated into new solid materials composed of clusters. The recently available fullerenes are a first example. The continually diminishing size of semiconductor structures in microelectronics gives silicon clusters a special interest. Because the structure of clusters cannot at this time be determined directly from diffraction experiments, indirect methods must be used, for example, the observation of the chemical behavior of the Si_n clusters.

Reactions of Si_n clusters can be examined by allowing previously mass-selected Si_n^+ ions to interact with a reaction gas under controlled pressure and temperature conditions for a certain period of time. Figure 1 illustrates this method for the reaction of Si_n^+ ions with ethylene.[1, 2] Analysis of the products reveals how many and which types of reaction steps have taken place. From the clusters produced by laser evaporation (A), Si_{40}^+ ions were "extracted" with a quadrupole mass spectrometer (B). After the Si_{40}^+ clusters passed through the ethylene-filled chamber, the reaction products show up in the mass spectrum as $Si_{40}^+(C_2H_4)_m$ clusters with $m = 0,1,2$

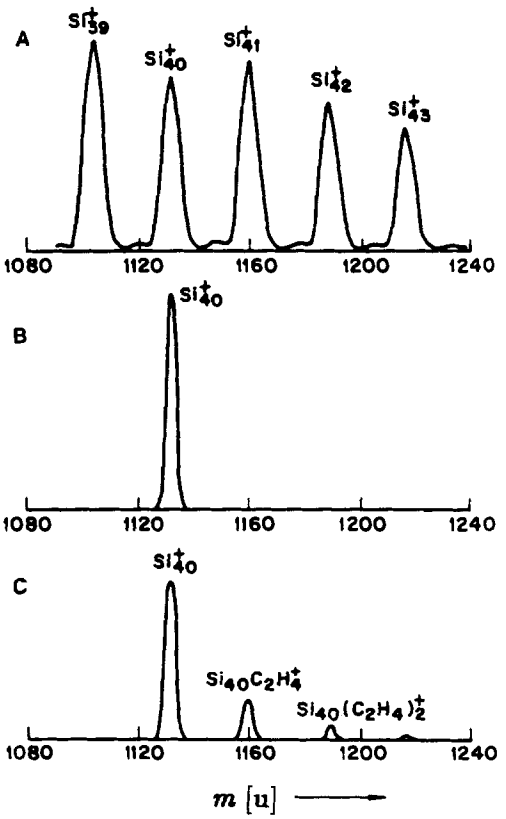

Fig. 1. Method for the determination of the reactivity of Si clusters, demonstrated for Si_{40}^+. A: Part of a Si_n^+ mass spectrum. B: Mass spectrum after the selection of Si_{40}^+ clusters. C: Mass spectrum after reaction of Si_{40}^+ clusters with ethylene. The reactivity of Si_{40}^+ towards ethylene can be calculated from the ratio of the Si_{40}^+ and $Si_{40}^+(C_2H_4)$ intensities.

Heisenbergstrasse 1, D-W-7000 Stuttgart 80 (FRG)

(C). The reactivity of the Si_{40}^+ cluster with ethylene could be determined from the ratio of the Si_{40}^+ and $Si_{40}^+(C_2H_4)$ intensities.

Reactions of Si_n^+ clusters with C_2H_4, CO, O_2, NH_3, and H_2O show that the surface of Si clusters is far less reactive than the surface of the solids.[2, 3] While dangling bonds on the solid surface play an important role, it must be assumed that the cluster surface has a lower dangling-bond density. The example of Si_{10}^+ shows that this assumption is plausible:[4] A ten-atom bulk fragment from the silicon lattice is shown on the left of Figure 2. The atoms have a maximum of three binding partners, indicating at least one dangling bond. In the middle and on the right are two structures that represent, according to calculations, two (almost equal) minima of the total energy. In both structures the number of Si bonds have increased considerably. The structures of larger clusters have not until now been calculated with the same degree of reliability. However, their inertness may probably be attributed to an analogous reconstruction of the cluster surface accompanied by a corresponding reduction of the number of dangling bonds. In this way, the chemical behavior of these clusters allow qualitative conclusions about the structure of small Si_n clusters. At what size a silicon cluster takes on the crystal structure of a solid is presently not known.

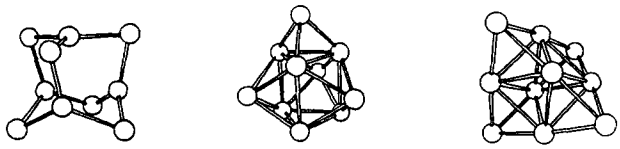

Fig. 2. Left: Bulk fragment of 10 Si atoms. Middle and right: Two structures of Si_{10} with minimal total energy. They are both approximately 5 eV more stable than the bulk fragment.

The determination of the structure of silicon clusters is made more difficult by the fact that Si_n clusters with a fixed number of atoms need not always have the same structure. After attaining a certain size, a continual reconstruction of the cluster's surface to the most favorable configuration during the growth process is no longer possible. This leads to the occurrence of structural isomers. Smalley et al.[5] and Jarrold et al.[6] have shown that such isomers can be distinguished from one another in spite of their mass equality. Both groups took advantage of the different chemical characteristics of isomers. Jarrold et al. observed that most of the Si_n^+ clusters in the size range $11 \leq n \leq 50$ show (at least) two distinct reaction rates with C_2H_4. Smalley et al. found a similar behavior for the reaction of Si_{39}^+ clusters. Both groups succeeded in showing that some of the less stable isomers could be converted thermally into the stable forms. This heat treatment was achieved either by laser annealing (Smalley et al.) or by melting the clusters with energy-rich collisions with noble gas atoms (Jarrold et al.). In some cases the more stable isomer even has a higher reactivity than the isomer from which it is produced. For instance, the more stable isomer of Si_{26}^+ shows enhanced reactivity, whereas in the case of Si_{39}^+, it proved to be less reactive.

In a few cases, it is even possible to predict the structure of a cluster based on these chemical experiments. Jarrold et al. discovered that the reactivity of small Si_n^+ ions towards a series of reactant gases showed strong irregularities as a function of n. Clusters that consist of 13, 14, and 23 atoms show a 10–100 times smaller reactivity towards C_2H_4 than the other clusters.[1] When H_2O is chosen as reactant,[7] clusters with $n = 11$, 13, 14, 19, and 23 prove to be particularly inert. The same is valid for the reaction of clusters containing 13 and 14 atoms with O_2.[8] It is assumed that this behavior of the clusters is caused by special structures that have very few dangling bonds. Exactly 13 atoms are needed for an icosahedral structure. Structures with $n = 19$ and $n = 23$ are obtained by adding caps on faces of this icosahedron. This icosahedral growth sequence provides a plausible explanation for the inertness of the corresponding clusters. However, the structure responsible for the inertness of the Si_{14}^+ cluster is still not known. For larger Si_n clusters, Smalley et al. observed an analogous series of particularly unreactive clusters ($n = 21, 25, 33, 39, 45$).[9] In this size range, however, the prediction of specific structures is even more speculative (see the following Highlight.)

These results for silicon reflect the present state of cluster research in general. The goal is to examine and understand the physical and chemical characteristics of smallest particles of condensed matter. Technological application of these results with silicon is not to be expected in the near future. Nevertheless, first experimental attempts in this direction have already been made: Jarrold et al. succeeded recently in depositing mass-selected Si_{10} clusters on surfaces and in characterizing them chemically[10] and electronically.[11] The day may yet come when silicon clusters will play an important role in microelectronics.

Si_{60}, an Analogue of C_{60}?

By *Christian Zybill**

The isolation of semiconductor clusters is an elusive goal, which could contribute to the understanding of quantum size effects (the size dependent variation of optical or magnetic properties of cluster molecules). Particularly silicon clusters Si_n with $n \leq 100$ formed by either laser vaporization of elemental silicon or ion-sputtering techniques have been investigated intensively in the gas phase by mass spectrometry or FT-ICR-spectroscopy (FT-ICR = Fourier Transform Ion Cyclotron Resonance). The applied methods include photofragmentation and collision-induced dissociation studies, photoelectron spectroscopy of negative ions, and chemical techniques such as ion–molecular reactions of both positive and negative ions and kinetic studies. The stability of the observed cluster ions depends on the cluster size;[1] particularly for the "magic number" clusters[2] Si_4^+, Si_6^+, Si_{13}^+, Si_{19}^+, Si_{21}^+, Si_{25}^+, Si_{33}^+, Si_{39}^+, Si_{45}^+ and Si_{60}^+ a significantly reduced reactivity is found.

Researchers in the fields of cluster chemistry and main-group chemistry avidly follow the advances in the understanding of structures of silicon clusters. Ab-initio calculations on HF- and UHF-level reveal the ground-state geometries (Fig. 1).[3,4] Si_3 is bent, Si_4 has a rhombohedral ground state geometry, Si_5 is trigonal bipyramidal, and Si_6 distorted (C_{2v}) octahedral. Si_7 has a pentagonal-bipyramidal form as ground state, similar to Li_7, Na_7, or Ag_7.[5] The most probable structure for Si_8 is a bicapped octahedron with two additional silicon atoms capping two opposite faces. However such a D_{3d} form has a triplet ground state and undergoes a Jahn–Teller distortion to give a geometry with C_{2h} symmetry. A similar Jahn-Teller effect occurs for the tricapped octahedron of Si_9 and results in symmetry reduction of the cluster from C_{3v} to C_s. Finally, Si_{10} is described by a tetracapped octahedron with T_d symmetry.

All clusters with more than five silicon atoms form (three-dimensional) cages constructed by consecutively adding face-bridging silicon atoms. In contrast, the analogous carbon clusters have two-dimensional linear or cyclic structures.

The structures of silicon clusters differ significantly from the cubic diamond type structure of elemental silicon and do not represent sections of the bulk crystal lattice. Thus for instance, a bulklike adamantane structure for Si_{10} is energetically about 100 kcal mol^{-1} less stable than the given compact C_s structure, because of too many undercoordinated surface atoms (dangling bonds). The calculated structures of "naked" silicon clusters are relatively closed and allow max-

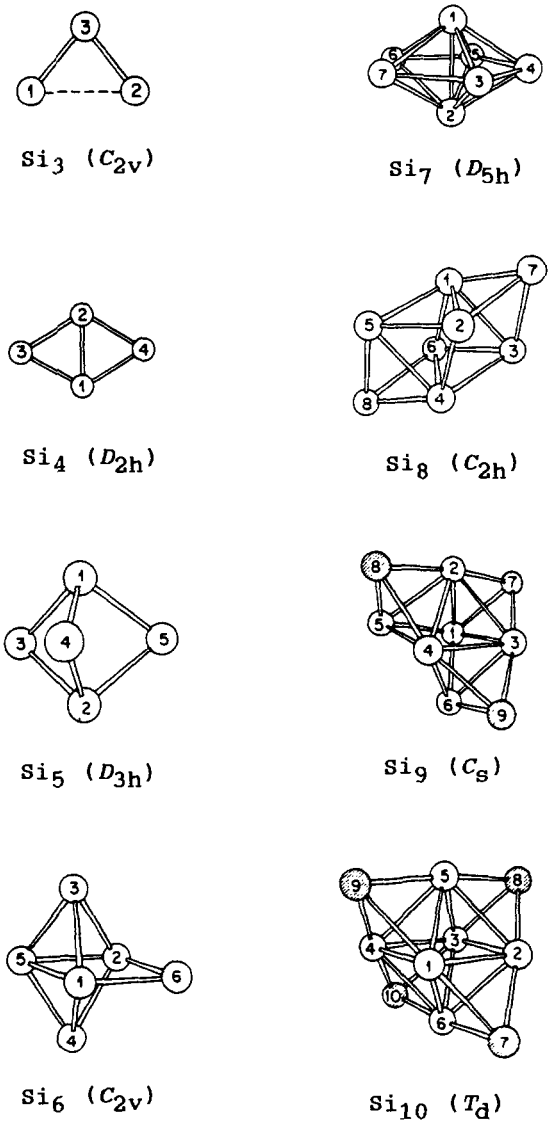

Fig. 1. Calculated structures for Si_3–Si_{10}.

imum coordination numbers of six, which are known to occur in the high-pressure phase of silicon (β-tin structure; approximately octahedral coordination[6]).

Semiempirical calculations also allow a description of the structures of larger stable clusters like Si_{39}^+ and Si_{60}^+.[7–10] The prediction for Si_{39}^+ is a toruslike structure with a stack of six planar Si_6 rings and three additional face-capping silicon atoms forming the top of the torus (Fig. 2). The calculations suggest that the angular strain energy (90° bond angles) can be partially compensated by charge delocalization in the planar rings.[11]

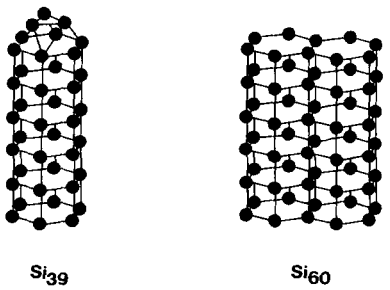

Fig. 2. Proposed structures of Si_{39}^+ and Si_{60}^+ (from [11] and [13], respectively).

In contrast to the structure of buckminsterfullerene (C_{60}),[12] the proposal for Si_{60}^+ is a stack of six planar bicyclic (silanaphthalene) units [d_{Si-Si} 2.356 Å (intraplanar), d_{Si-Si} 2.439 Å (interplanar distance)]. A variety of arguments are given in favor of this structural model:

1. The proposed Si_{60} polyhedron explains the observed selective fragmentation pattern of the Si_{60} cluster into unstable Si_{20} units and subsequently into Si_{10} fragments. The Si_{10} fragment ions (base peak of the mass spectrum) rearrange to the known C_s structure of Si_{10}.
2. The Si_{60} cluster is significantly stabilized by electronic conjugation within the Si_{10} planes.
3. All silicon atoms with the exception of the atoms at both faces on top and bottom of the cluster are four-coordinate.[13]

Gas-phase reactions of silicon clusters have been studied by several research groups (Bondybey, Jarrold, Bower, and Smalley; see the preceeding Highlight). Depending on the size of the cluster and the reagent applied, either cluster degradation (etching with O_2, WF_6, XeF_2, NO_2, ClF_3, NH_3[14]), cluster construction (reaction with CH_3SiH_3[15]), or chemisorption (e.g. ethylene or methane on Si_{25}^+)[16] have been observed. The rate constants and activation parameters are unique, differing significantly from the known parameters for the [111] silicon surface; for instance Si_{25}^+ is much less reactive toward C_2H_4 and O_2 (high activation barrier) than bulk silicon.

Recently some rare and distinct examples of thermodynamically stable Si_8 clusters have been synthesized in the laboratories of Masamune et al. and unequivocally characterized by single-crystal structure determination in the solid state as well as by ^{29}Si-(COSY)-NMR in solution. Similar germanium cluster compounds have been introduced by Weidenbruch et al.[17] Furthermore, Sekiguchi, Kabuto, and Sakurai have isolated stable derivatives of hexagermaprismane.[18] However, these cluster compounds are not directly comparable with the "naked" silicon clusters in the gas phase, since all silicon atoms at the vertices of a polyhedron are four-coordinate, and the bonds are satisfied by bulky substituents.[19]

In the case of C_{60}, the first evidence for the existence of this unique and fascinating molecule was obtained in 1985 by mass spectrometry by Smalley and Kroto.[20a] The isolation of substantial amounts of C_{60} followed shortly thereafter in 1990 by Krätschmer et al.[20b] However, the isolation of Si_{60} still seems rather unlikely.

Inhibition of Fruit Ripening by Antisense-RNA Technology

By *Peter Eckes**

The goal of plant breeding is the improvement of plants or plant products. Among the criteria of quality are the resistance of plants to pests, crop yield, and the taste of plant products. Because these characteristics are determined primarily by genetics, plant breeders attempt to bring about new traits by altering the genetic information of a plant. Until recently this was done by crossbreeding with other varieties or closely related species, followed by selection of the desired trait. This is a tedious and lengthy procedure, because in the mixing of all the genetic information of two plants, undesired traits may also be carried on to the next generation. The undesired traits must then be eliminated by several other crossbreedings with the mother plant. A more direct approach to the improvement of plants would be a great advantage.

Molecular biology offers new vantage points: the channeling of a specific gene in the plant genome has already led to plants with new characteristics, for example tolerance to herbicides or resistance to insects. It is also conceivable to develop plants of improved quality by the targeted activation or inactivation of specific metabolic pathways.

The so-called antisense-RNA technology is one biological method which can prevent the expression of a specific gene. The principle of this method is based on the formation of an antisense ribonucleic acid (antisense RNA), which is complementary to the RNA (sense RNA) of the protein to be inhibited. The translation of the sense RNA is blocked by its complement, and thus the expression of a certain trait is prevented (Fig 1).

In principle there are two methods of introducing antisense RNA into the cell. Attempts at channeling short oligonucleotides complementary to the target RNA directly into eukaryotic cells have been made in the medical field.[1] In another method used especially in plants, an antisense gene is built into the genome from which the antisense RNA is then transcribed. In the first method the correctly targeted supply of sufficient quantities of oligonucleotides and their instability in the cell pose great difficulties. The insertion of antisense genes into the genome, at least in humans, involves ethical problems besides the technical. Within the plant domain, however, this method is desirable and is already practiced.

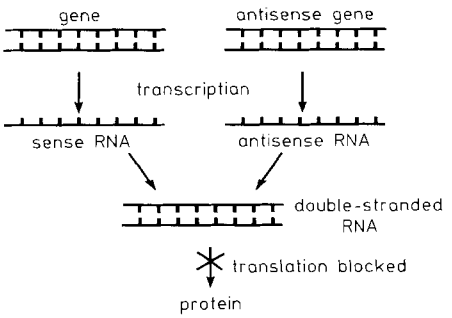

Fig. 1. Mechanism of the inactivation of a trait by antisense RNA.

The regulation of gene expression by antisense RNA also occurs in nature in prokaryotes.[2] In the bacterium *Escherichia coli*, for example, replication of plasmids is regulated by the interaction of sense and antisense RNA. The first proof that the antisense-RNA principle could also be applied in the inactivation of gene expression in eukaryotes was furnished in 1984. Izant and Weintraub[3] showed that the expression of a thymidine-kinase gene, which had been injected in cultivated mouse cells, could be significantly reduced when a plasmid, which produced the antisense RNA of that same gene, was coinjected. This experiment led to the idea of blocking the expression of a naturally occuring gene in higher organisms with antisense RNA and thus change the phenotype (observable characteristics) of the organism. The results of this strategy in plants were first published in

1988.[4] The chalcone-synthase gene of a petunia, whose product is involved in the production of flower pigments, was "turned off" by the introduction of a chalcone-synthase antisense gene. The resulting petunias displayed varying amounts of flower pigmentation depending on the degree of gene inactivation (Fig 2).

Fig. 2. Flowers of petunia plants with varying degrees of inactivation of the synthesis of chalcone synthase caused by antisense RNA.

An American group has recently succeeded in suppressing the ripening process in tomato fruits with antisense-RNA technology.[5] Ripeness is an important factor in the storage and transportation of fruits like bananas, peaches, oranges, and tomatoes. These fruits are harvested unripe, they ripen during transportation, and they must then be delivered to the consumer immediately. If the transportation takes too long or refrigeration is insufficient, the fruit delivered to the stores may be overripe or even rotten and not marketable. Especially in warmer climates this results in large crop losses.

The ripening process of the tomato is induced by the signal compound ethylene. In the tomato plant, ethylene is produced from methionine via many intermediates. The rate-determining step in the biosynthesis of ethylene is catalyzed by the enzyme aminocyclopropanoic acid synthase (ACC synthase). This enzyme brings about the transformation of *S*-adenosylmethione to 1-aminocyclopropane-1-carboxylic acid, the direct precursor of ethylene. The American research group succeeded in inhibiting the formation of ACC synthase in genetically altered tomato plants so that the amount of ethylene in the fruit was reduced by 99.5%, and thus the fruit did not ripen.

The authors conducted their experiment in the following manner: The cDNA of an isolated ACC-synthase gene from a tomato was fused in inverted orientation to a promoter, which leads to constitutive expression in plants (35S-transcript promoter of the cauliflower mosaic virus). The gene was then integrated with molecular biological methods in the genome of tomato plants where it was to produce the antisense RNA of ACC synthase.

Of the 43 genetically altered plants produced in this procedure three showed a marked reduction of the C_2H_4 synthesis and a delay in fruit-ripening. Molecular biological analyses were conducted on the homozygotic (genetically identical) offspring of the plant which displayed the greatest inhibition of C_2H_4 biosynthesis. DNA investigations with the so-called Southern Blot method proved that ten copies of the antisense gene of ACC synthase were integrated in the genome of these transgenic plants. The naturally occurring ACC-synthase gene is known to occur only once in the genome. In contrast to the fruits of the unaltered control plants, transgenic fruits produced ACC-synthase antisense-RNA as expected. In the transgenic tomatoes the analogous sense-RNA could be detected in only minute amounts relative to that in the control plants. The RNA of a polygalacturonase gene, whose genetic product also contributes to fruit-ripening, was not affected.

The ethylene production in the tomato fruit starts 48–50 days after fertilization. After another ten days the fruits are red and ripe. In the fruits with antisense RNA, the C_2H_4 production was decreased by 99.5%, and the fruits were not ripe even 120 days after fertilization. The ripening process of the transgenic fruit could be initiated by exposure to ethylene or propylene (10 μL per L air) for a number of days. One- or two-day exposure did not provide the desired result; after exposure for seven days, however, the fruits were red and soft and had developed their natural aroma. The expression of the antisense RNA and inhibition of the sense RNA was not affected by the exposure to the gas. This reversal of the effect produced by the antisense RNA by the exposure to C_2H_4 shows that ethylene triggers fruit-ripening and is not merely a by-product.

These experiments illustrate how the synthesis of a metabolic product in plants can be blocked efficiently by means of antisense-RNA technology. ACC synthase is well suited for this method; because of its short half-life of roughly 25 minutes, new enzyme must be constantly produced. Inhibiting its translation (protein biosynthesis) thus leads quickly to an enzyme deficit.

An inhibition comparable to that described previously was accomplished by Hamilton et al.[6] by blocking the synthesis of ACC oxidase, the enzyme responsible for the conversion of ACC to ethylene. This was also achieved with antisense-RNA technology. The fact that the ripening process halted by antisense RNA can be activated by exposure to ethylene makes this system commercially attractive. The ripening can be timed exactly, and the losses due to fruit rotting from extended transportation times or insufficient refrigeration can be reduced.

Antisense-RNA technology is theoretically applicable to a broad range of organisms for shutting off undesired activities controlled by genes. Corresponding experiments have been conducted in many areas of molecular biology. For example, it was attempted to block the genes of viruses pathogenic to humans or plants with the analogous antisense molecules and thus prevent the spread of the virus. Antisense molecules may also lead to the switching off of oncogenes (genes capable of converting a normal cell into a cancerous cell) and thereby become relevant in cancer therapy. These experiments are far from commercial application, since the degree of effectiveness can not be predicted with reliability. This leads to the general problem connected with antisense technology, namely that the mechanisms in higher organisms are not yet well understood. According to the current

model, the sense RNA binds to the complementary antisense RNA; the resulting double-stranded molecule is then rapidly broken down by nucleases. Unlike in bacterial systems the existence of a double-stranded RNA consisting of sense and antisense strands has not been proved unequivocally. It was recently discovered that the introduction of additional sense-genes into the genome of plants can also lead to an inactivation of gene expression. Thus the principles controlling antisense effects appear to be even more complex.

Nevertheless, the example of the inhibition of fruit-ripening by antisense-RNA technology shows that after modifications with molecular biological methods, principles found in nature (e.g. control of plasmid replication in bacteria by antisense RNA) can be applied to other systems (e.g. plants), resulting in improved properties of a crop.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes.

The price of the index is DM 98.00, $ 64.00 or £ 37.00. Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.**

Communications may be submitted in English *or* in German. Further details regarding the submission of communications can be found in the "Notice to Authors" reproduced in the January issue of the journal. Copies thereof may be obtained from the editorial office upon request.

Microcalorimetry of the Spin-Transition Systems $[Fe(bts)_2(NCS)_2]$ and $[Fe(2\text{-}pic)_3]Cl_2 \cdot EtOH$ in the Range $15\,K < T < 300\,K$ **

By *Ralf Jakobi, Harald Romstedt, Hartmut Spiering,* and *Philipp Gütlich**

Dedicated to Professor Joseph Grobe on the occasion of his 60th birthday

Thermodynamic investigations of solid-state phase transitions of any type require exact measurements of heat capacity as a function of temperature. In such investigations of organic and inorganic solids with poor thermal conductivity substantial difficulties may arise, especially when only small amounts of material are available and when the phase transition should be followed over a wide temperature range, for example from 300 to 4 K.

The thermal spin transition in iron(II) complexes, High Spin (HS)⇌Low Spin (LS),[1] occurs in solids frequently below room temperature, in many cases even below the temperature of liquid nitrogen.[2] Measurements of the heat capacity $C_p(T)$ of spin-crossover compounds were first conducted by Sorai and Seki on $[Fe(phen)_2(NCS)_2]$ and $[Fe(phen)_2(NCSe)_2]$ (phen = 1,10-phenanthrolene).[3] The Nernst calorimeter employed required 15–20 g samples. Both compounds displayed a pronounced anomaly in the $C_p(T)$ curve at the temperature of the spin transition. The increase in entropy responsible for the spin transition was explained by the increased spin-multiplicity relative to that of the LS state and the changes in the molecular vibrations in the HS state. The anomaly in the heat capacity of $[Fe([D_2]2\text{-}pic)_3]Cl_2 \cdot EtOD$ ([D$_2$]2-pic = 2-picolylamine with a deuterated amino group) could be accounted for almost quantitatively by the spin transition.[4] Calorimetric measurements (according to the DSC method in the range of 150 to 300 K) have been reported for a few other spin-crossover systems,[5] but the authors discussed only the qualitative aspects of the transformation enthalpy and entropy. We have investigated the iron complexes **1** and **2** with a new microcalorimeter, which we introduce here.[6] It enables us to contribute to the understanding of the thermodynamics of the spin transition.

The sample chamber of the calorimeter is built into a cryostat (CryoVac, Troisdorf) and can reach temperatures between 4.2 and 300 K. The construction of the calorimeter

$[Fe(bts)_2(NCS)_2]$ bts = 
1

$[Fe(2\text{-}pic)_3]Cl_2 \cdot EtOH$ 2-pic = 
2

allows the simultaneous measurements of a sample and a reference. Both compounds are placed on sapphire sample holders, which are supplied with coated electrical heating units and thermocouples for temperature measurement. By exact measurement of the thermopotential the temperature can be determined with a resolution of up to 0.001 K.

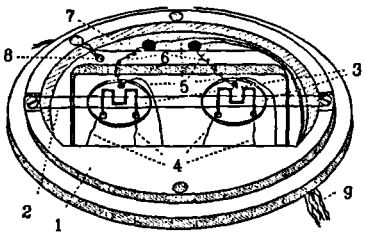

Fig. 1. The sample chamber of the calorimeter. 1 – Gold-plated copper baseplate, 2 – cotton thread, 3 – sapphire sample-holder with coated heating elements, 4 – gold wires for the heater, 5 – thermocouple wires, Chromel, 6 – thermocouple wires, Au/0.03% Fe, 7 – Mylar foil, 8 – silicon diode, 9 – electrical leads (inner diameter of the chamber ca. 10 cm).

Blueprints for the basic construction of the microcalorimeter were kindly provided by E. Gmelin (Max-Planck-Institut für Festkörperforschung, Stuttgart (FRG)). However, this version of the apparatus is best suited for measurements of heat capacities for substances with good heat conductance, but not for measurements on poorly conducting compounds like organometallic and coordination compounds. We have extended the preparation and measurement techniques beyond the original instrument design by E. Gmelin[7–9] and have developed a new method of data reduction and interpretation.

The entire measurement was controlled by use of an Atari ST computer (operating system RTOS, program language PEARL). In the measurement of the heat capacity the temperature of the sample/holder system is raised by a short heat pulse, and the thermal relaxation is observed until the temperature difference ΔT between the holder and sample reaches zero. Since the system is under vacuum during the measurement, the energetic contact between the sample holder and the environment is made by electrical leads and by the radiation of heat. Problems arise for poorly conducting samples, since the sample temperature deviates significantly from that measured for the holder. The decay curves $\Delta T(t)$ are then no longer simple exponential functions. We could take this into account with a new measurement technique, an improved sample preparation, and a new method of data analysis. In our procedure single crystals are wrapped in aluminum foil which has been coated with a mixture of powdered graphite and Apiezon-N grease. This way heat contact with the entire crystal surface is established and the radiation of heat is also independent of the radiation properties of the

sample. Polycrystalline samples are mixed with powdered graphite and sealed in aluminum pans, similar to the sample preparation for DSC measurements.

A complication in the measurement of poorly heat-conducting samples is that after the heat pulse the temperature of the sample/holder system is a function of location and time. Thus the decay curves depend on the thermal conductivity λ, that is on the given sample, its geometry, and also the temperature (due to the temperature dependence of λ). If the thermal relaxation in the sample is not taken into account, errors of up to 50% of the true value of the heat capacity may occur for one sample.

For this reason the data analysis was developed so that the total thermal relaxation of the sample and its holder could be accounted for. The sample is formally divided into layers of constant (or only time-dependent) temperature. The solution of the related system of differential equations is the temperature decay of the sample holder as a function of the specific heat C_p and the specific thermal conductivity λ of the sample. Fitting this expression to the measured temperature-decay curves by the least-squares method provides C_p and λ. The error in C_p was found empirically to be in the range of 2–4%. The accuracy is comparable to that of the DSC method; however, we can approach temperatures as low as 10 K, whereas measurements on commercially available DSC instruments have a lower temperature limit of roughly 110 K. All of the software for the regulation of the measurement and the data manipulation techniques briefly described here were developed in our laboratory. The calorimeter was calibrated with copper, silicon, and benzoic acid.

In the first test measurements on 22 mg of polycrystalline NH_4Cl, which shows an order–disorder transition at $T = 256$ K, the literature values[10] (obtained from measurements on 21 g NH_4Cl by the Nernst method) were reproduced quite well.

After that we started the first measurements on spin-crossover compounds. Complex **1** (coarse crystalline sample, ca. 20 mg) shows a noticeable anomaly in the $C_p(T)$ curve in the spin-transition range (roughly 210 K) (Fig. 2), as is expected from thermodynamic considerations.[4] Thus we refute the report by Kulshreshta et al. in which DSC measurements on the same compounds did not show a peak.[12]

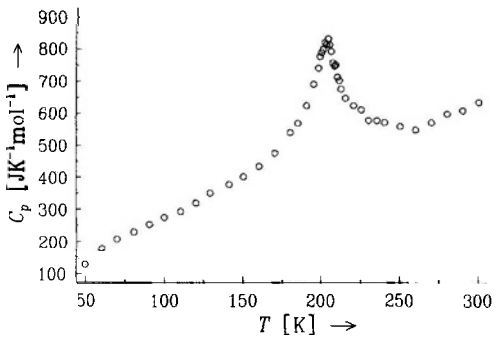

Fig. 2. Specific heat C_p of **1** as a function of temperature (coarse crystalline sample, ca. 20 mg).

We conducted measurements on a single crystal (21 mg) of the spin-crossover system **2** in the temperature range of 15 to 300 K. This system is of special interest because the thermal spin transition occurs with a plateau (step) between 113 and 121 K;[13] its cause has been a matter of speculation so far. Heat capacity measurements of complex **2** were already conducted by Sorai and Kaji[14] with a Nernst calorimeter on a sample almost 1000 times larger (15 g, polycrystalline) than ours. In Figure 3 the two sets of results are compared. Our experiment on the small sample shows a greater amount of scattering of the data points relative to that of Sorai and Kaji; however, the overall curves are in impressively good agreement. As is shown in the expanded region between 100 and 150 K, the resolution measured with our microcalorimeter in the region of the double peak resulting from the step of the spin transition is higher than that recorded with the Nernst calorimeter. This satisfying result demonstrates that the microcalorimeter introduced here can be used for thermodynamic investigations of solids, even if the samples conduct heat poorly, if limited amounts of the sample are available, or if single-crystal measurements are desired. Measurements may also be conducted at temperatures as low as 10 K, as we have shown here.

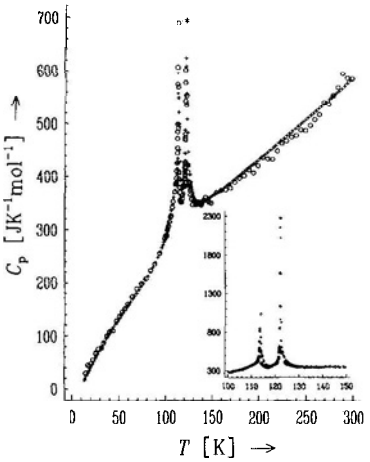

Fig. 3. Specific heat C_p of **2** as a function of temperature. +: Measurement made by Sorai and Kaji (coarse crystalline sample, ca. 15 g); o: our measurement on a single crystal (ca. 21 mg). The inset shows an expansion of the region of the spin transition between 114 and 121 K.

The heat-capacity measurements on system **2** have enabled us to perform a thermodynamic treatment of the spin transition.[15] Of special note is the indication that the step in the spin transition may be caused by cluster formation or the formation of a sublattice. This can be concluded from the observation that the entropy of mixing is markedly smaller in the temperature range of the step than would be expected for a statistical distribution of HS and LS molecules.

For the first time the specific thermal conductivity $\lambda(T)$ of a spin-crossover system could also be determined from the same calorimetric measurements. Figure 4 shows $\lambda(T)$ for **2** and also for the related zinc complex. For the latter, λ is quite

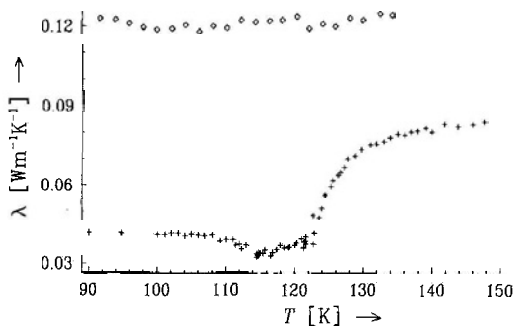

Fig. 4. Specific thermal conductivity λ of **2** (+) and $[Zn(2\text{-pic})_3Cl_2 \cdot EtOH$ (◇) (single crystals). Since reference measurements do not exist, the absolute values are not certain. However, the change of λ in the iron complex is significant.

temperature-independent in the temperature range shown. The iron complex **2** displays a change in the thermal conductivity by a factor of two at the spin transition.

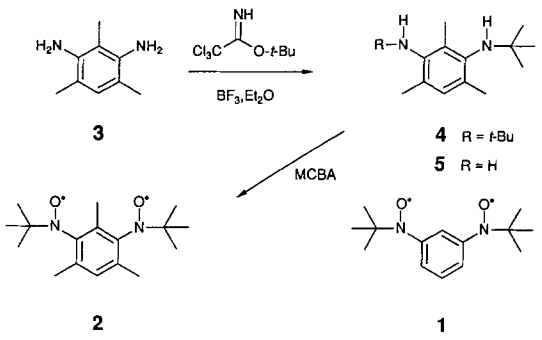
Stable *N,N'*-Di-*tert*-butyl-*meta*-phenylene-bisnitroxides—Unexpected Ground-State Singlets**

By *Maya Dvolaitzky, Robert Chiarelli, André Rassat**

m-Xylylene and related compounds have been predicted and shown[1, 2] to be ground-state triplets. A related bisnitroxide **1** behaves similarly, but unfortunately it undergoes spontaneous decomposition.[3] In order to obtain a more stable diradical, we have prepared the trimethyl derivative **2**. Steric hindrance is expected to prevent the reaction between two diradicals **2** and to twist the *t*BuNO groups, which should lead to atropoisomerism.[4] As described below, two isomers of **2** were isolated. Both were found to have a singlet ground-state in contrast to the unsubstituted bisnitroxide **1**[3] and other *m*-xylylene-related compounds.[1, 2]

N,N'-di-*tert*-butyl-2,4,6-trimethyl-*m*-phenylenediamine (**4**) was obtained from the commercially available diamine **3**, by the adaptation of a procedure used for the synthesis of *tert*-butyl ethers and *tert*-butyl esters[5] (Scheme 1). Under various experimental conditions, *tert*-butylation of **3** gave a mixture of unreacted diamine **3**, mono-*tert*-butylamine **5**, and the di-*tert*-butylamine **4** in roughly a 2:7:1 ratio. Although its yield was always very low (2%), pure **4** was easily isolated by thin layer chromatography (TLC) on silica gel. Product **4** was characterized by ^{1}H NMR and mass spectroscopy. Oxidation of **4** smoothly gave **2** in 55% yield.

TLC of an ethereal solution of **2** on silica gel (*n*-hexane/ethyl acetate 3:1, two elutions) gave two products, **2A** and **2B** (R_f = 0.29 and 0.34) isolated in a ratio of about 2:1. Eluted first, **2B** is an amorphous solid; eluted next, **2A** is crystalline and may be recrystallized as fine needles from *n*-hexane. The interconversion of the two isomers is rapid in solution (TLC detection). Without solvent, even at −20 °C, pure amorphous **2B** gave crystalline **2A** within a few days. Crystalline **2A** remains unchanged.[6]



Scheme 1. MCPBA = *m*-chloroperbenzoic acid.

Frozen solutions of either diradical display the characteristic $\Delta m = 1$ and $\Delta m = 2$ spectra with hyperfine structures[7] (Fig. 1). A weak invariable signal of a monoradical can be seen in the central part of the $\Delta m = 1$ spectra, especially at 10 K; this implies that both diradicals are more than 99% pure. From 100 to 10 K the signal/noise ratio decreases dramatically with temperature, and below 5 K no triplet signal could be detected for either isomer—primary evidence of their singlet ground-states. Figure 2 shows the temperature-dependence of $2D$, the larger component of the dipolar tensor (in millitesla) and of the corresponding average interelectronic distance d (in Angstrom), ($D = 27810\, d^{-3}$)[8], for **2A** and **2B**. These values differ slightly from those of **1** ($2D$ = 36.6 mT; d = 5.34 Å)[3] and of a related bisnitroxide ($2D$ = 24.0 mT; d = 5.83 Å).[9]

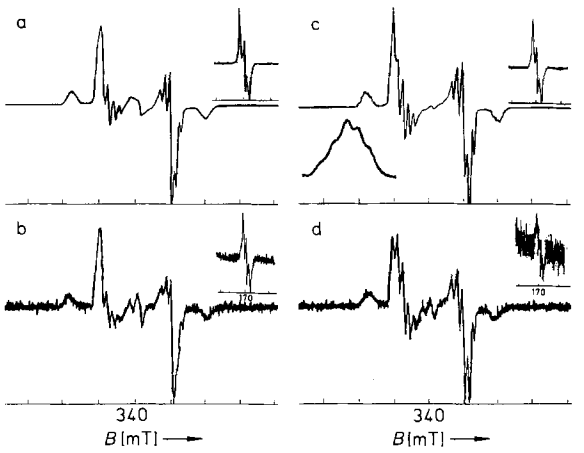


Fig. 1. ESR $\Delta m = 1$ spectra of isomer **2A** at a) 100 K and b) 10 K, and of isomer **2B** at c) 100 K and d) 10 K. The insets in the upper right of a)–d) shows the corresponding $\Delta m = 2$ signals; inset lower left in c) shows an enlargement of the first line with hyperfine structure. Solvent: ethanol.

In order to determine the ground-state multiplicity and the singlet–triplet separation $2J$, the classical method of investigation, the determination of the temperature-dependence of the intensity of the $\Delta m = 2$ transitions,[3] was conducted. Since both biradicals were pure in this study, the $\Delta m = 1$ transition was also considered. Using a dual-sample cavity

24, Rue Lhomond, F-75231 Paris Cedex 05 (France)

[**] This research was supported by the Centre National de la Recherche Scientifique (Project CNRS URA 1110).

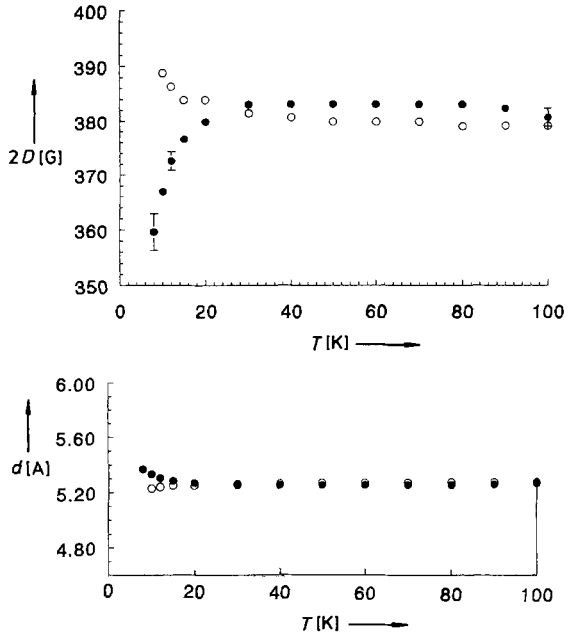

Fig. 2. Dependence of $2D$ (top) and d (bottom) on T for isomers **2A** (○) and **2B** (●).

with a reference, we measured the intensities (obtained by double integration of the ESR signal) I of the sample in ethanol (at temperature T) and I_{ref} of the reference (at room temperature). Figure 3 shows IT/I_{ref} and I_{ref}/I versus T for **2A** and **2B** at $\Delta m = 2$ and $\Delta m = 1$. The experimental curves were fitted to the Curie–Weiss law $I^{-1} = C_1^{-1}(T - \theta)$ ($40\ K < T < 100\ K$ for **2A** and $50\ K < T < 100\ K$ for **2B**), and to the Bleaney–Bowers expression, $I^{-1} = T(3 + e^{-2J/kT})C_2^{-1}$,[3,10] ($10\ K < T < 100\ K$, for both isomers)

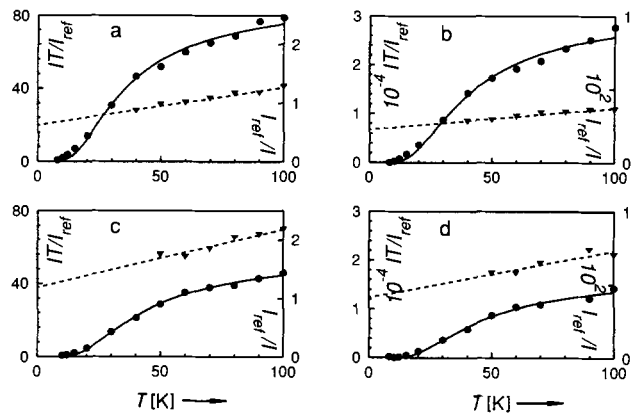

Fig. 3. Temperature-dependence of IT/I_{ref} (left axis, ●) and I_{ref}/I (right axis, ▼) in arbitrary units for isomer **2A** a) $\Delta m = 2$, b) $\Delta m = 1$, and isomer **2B** c) $\Delta m = 2$ and d) $\Delta m = 1$. Solid and dashed lines are the theoretical curves for the Bleaney–Bowers expression and the Curie–Weiss law, respectively.

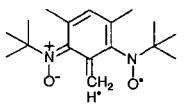
Table 1. Best-fit parameters of the Curie–Weiss and Bleaney–Bowers expressions:

	2A		**2B**	
	$\Delta m = 2$	$\Delta m = 1$	$\Delta m = 2$	$\Delta m = 1$
θ [K]	−96	−156	−118	−129
C_1 [a]	154	69186	100	31358
$2J/k$ [K]	−66	−75.5	−81	−86
C_2 [a]	371	131809	235	72217

[a] C_1 and C_2 are the constants of the Curie–Weiss law and the Bleaney–Bowers expression, respectively (arbitrary units).

(Table 1). Since the Curie–Weiss approximation is valid for $T \gg |\theta|$ or $T \gg |2J|/k$, a condition not satisfied here, it only gives a qualitative indication of the sign of θ.

These results clearly show that both isomers are ground-state singlets. This is rather surprising for an *m*-xylylene derivative. In our case, conjugation in both isomers is probably prevented by steric hindrance, that is the electrons are localized on oxygen. However, the conjugation in the two perchloro isomers studied by Veciana et al.[2] is also prevented by steric hindrance, and the two compounds are ground-state triplets. One may wonder if antiferromagnetic superexchange[11] may take place by hyperconjugation of the methyl groups, or in valence-bond language if the contribution of structure **I**, although nonplanar, may stabilize the singlet state relative to the triplet.



I

Experimental Procedure

General methods: ^1H NMR spectra were recorded on a Bruker instrument at 200 MHz (TMS standard). ESR spectra were obtained on a E 300 Bruker spectrometer equipped with a variable-temperature accessory (Oxford Instrument) and a data acquisition system. Measurements were performed using a dual-sample cavity with 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl as reference. The spectra were obtained at a microwave power of 20 mW ($\Delta m = 2$) or 10 mW ($\Delta m = 1$). Absence of saturation was checked, especially at low temperature. The solution samples were degassed by a freeze-pump-thaw cycle and sealed under vacuo.

4: $BF_3 \cdot Et_2O$ (40 μL) was slowly added by syringe over 1 h to a stirred solution of **3** (0.15 g, 1 mmol) and *tert*-butyl-2,2,2-trichloroacetimidate (0.4 mL, 2.2 mmol) in dry C_6H_{12}/CH_2Cl_2 2:1 (6 mL). Stirring was continued for 18 h. TLC on silica gel (*n*-hexane/AcOEt 3:1) showed three spots ($R_f = 0.64$, 0.30, 0.06). Solid sodium hydrogencarbonate was then added to the reaction mixture, and the mixture was filtered. The solid was washed with C_6H_{12}/CH_2Cl_2 (2:1). The filtrate was concentrated to dryness providing about 0.3 g of a yellow waxy solid. In order to remove the trichloroacetamide, the product was suspended in *n*-hexane. After filtration, the solid fraction was resuspended in C_6H_{12}/CH_2Cl_2 (2:1) and filtered again. Evaporation of both filtrates in vacuo gave 0.194 g crude product, which after preparative TLC on silica gel (*n*-hexane/AcOEt 3:1) provided 5 mg of noncrystalline diamine **4** (2%); $R_f = 0.61$; CI-MS m/z 263 ($M^{\oplus} + H$); ^1H NMR ($CDCl_3$): $\delta = 1.17$ (s, 18 H; *t*Bu), 2.21 (s, 6 H; 4,6-CH_3), 2.31 (s, 3 H; 2-CH_3), 6.83 (s, 1 H; 5-H).

2: To a stirred solution of diamine **4** (4.4 mg, 0.017 mmol) in ether (1 mL) was added dropwise a solution of *m*-chloroperbenzoic acid (0.572 g, 3.3 mmol) in ether (3 mL). After the reaction mixture had been stirred 28 h at room temperature, dilute aqueous sodium carbonate was added. The orange-pink ether fraction was washed to neutrality with water and dried over sodium sulfate. TLC on silica gel (0.25 mm thickness, on aluminum foil) with *n*-hexane/AcOEt (3:1) (two elutions) gave crystalline **2A** (1.8 mg) and amorphous **2B** (0.9 mg); $R_f = 0.29$ and 0.34, respectively. CI-MS: m/z 293 ($M^{\oplus} + H$); Total yield 55%. **2A** was recrystallized from *n*-hexane to give fine needles. Because of the lack of material, microanalysis and melting point were not carried out.

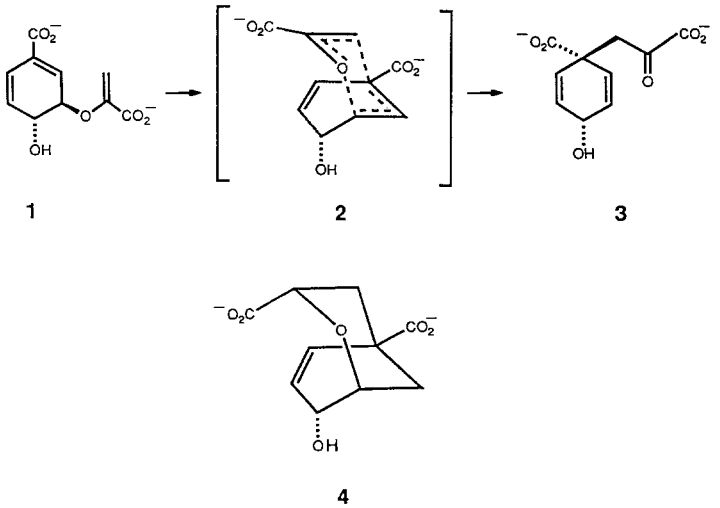
Activation Parameters and Stereochemistry of an Antibody-Catalyzed Claisen Rearrangement**

By *David Y. Jackson, Michael N. Liang, Paul A. Bartlett,* and *Peter G. Schultz**

The formal [3,3]sigmatropic rearrangement of chorismate **1** to prephenate **3** (Scheme 1), a key step in the biosynthesis of aromatic amino acids in bacteria and plants, is catalyzed by the well-studied enzyme chorismate mutase from *Escherichia coli*.[1-4] The rate of the enzymatic reaction, which has been demonstrated to proceed through a chairlike transition-state,[5] is approximately 3×10^6 times faster than that of the uncatalyzed reaction.[1] The thermal rearrangement also proceeds through a chairlike transition state in which the carbon–oxygen bond is broken substantially before the carbon–carbon bond begins to form; this rearrangement is characterized by an enthalpy ($\Delta H^{\neq}$) and entropy ($\Delta S^{\neq}$) of activation of 20.5 kcal mol^{-1} and -12.9 cal mol^{-1} K^{-1}, respectively.[6-8]



1 **2** **3**

4

Scheme 1. Claisen rearrangement of chorismate **1** to prephenate **3** and structure of the transition-state analogue hapten **4**.

Recently we[9] and others[10,11] demonstrated that antibodies raised against the bicyclic transition-state analogue **4**[12] also catalyzed the Claisen rearrangement of chorismate to prephenate. One antibody, 1F7, catalyzed the stereospecific conversion of the (−)-isomer with a rate acceleration of 250 over the uncatalyzed reaction. The activation parameters ($\Delta H^{\neq} = 15$ kcal mol^{-1} and $\Delta S^{\neq} = -22$ cal mol^{-1} K^{-1}) indicate that the antibody functions by reducing $\Delta H^{\neq}$ for the reaction with a counterproductive decrease in $\Delta S^{\neq}$.[10,11] A second antibody, 11F1-2E11, accelerated the rearrangement 10^4 fold over the uncatalyzed process.[9] For this antibody, mechanisms involving a cationic substituent effect or general acid catalysis were ruled out. We now report that this second antibody, 11F1-2E11, stereospecifically catalyzes the Claisen rearrangement of (−)-chorismate with an entropy of activation of nearly zero, supporting the notion that conformational restriction plays an important role in this antibody-catalyzed reaction.

We anticipated that an antibody generated against hapten **4**, which mimics the conformationally restricted chairlike transition-state configuration[12], should act as an entropy trap by restricting the rotational degrees of freedom required to form the transition state. In order to define the entropic contribution to catalysis by the catalytic antibody 11F1-2E11, the temperature dependence of k_{cat} was determined (Lineweaver–Burk analysis, Fig. 1). The rate of the rearrangement was measured spectrophotometrically (absorption at $\lambda = 270$ nm) at pH 7 (5 mM NaCl, 50 mM Na_2HPO_4) at six temperatures from 5 °C to 41 °C and corrected for the uncatalyzed rate.[9] The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were calculated from the Arrhenius equation ($k_{cat} = Ae^{-E_a/RT}$) to be 18.3 kcal mol^{-1} and -1.2 cal mol^{-1} K^{-1}, respectively ($\Delta G^{\neq} = 18.7$ kcal mol^{-1}). Interestingly, monoclonal antibody 11F1-2E11 reduces $\Delta H^{\neq}$ by 2.2 kcal mol^{-1} and increases $\Delta S^{\neq}$ by 11.7 cal mol^{-1} K^{-1} ($\Delta\Delta G^{\neq} = 3.3$ kcal mol^{-1} at 10 °C) relative to the uncatalyzed process. The observation that the antibody–substrate complex proceeds to product with an entropic barrier of nearly zero argues that the antibody constrains the substrate in a favorable conformation for the rearrangement.[13] The fact that the antibody also lowers the $\Delta H^{\neq}$ might reflect the use of antibody binding energy to induce strain in the substrate,[14] or perhaps electrostatic stabilization of the transition state. A comparison of the activation parameters for the uncatalyzed, antibody-catalyzed, and enzyme-catalyzed processes is shown in Table 1. Both the enzyme and antibody 11F1-2E11 increase the $\Delta S^{\neq}$ to nearly zero. The enzyme reduces $\Delta H^{\neq}$ an additional 2.4 kcal mol^{-1} relative to antibody 11F1-2E11. An interesting question is whether a similar reduction in $\Delta H^{\neq}$

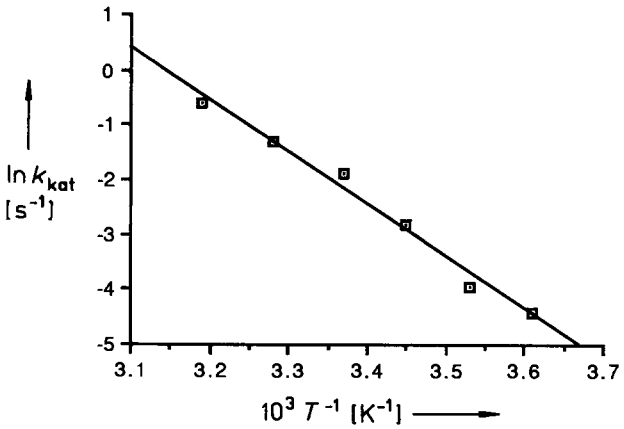

Fig. 1. Arrhenius plot of the temperature dependence of k_{cat}.

Table 1. Kinetic parameters for the uncatalyzed, antibody-catalyzed, and chorismate mutase-catalyzed Claisen rearrangements of chorismate **1** to prephenate **3**.

Parameter	Uncatalyzed [1]	Antibody 1F7 [11]	Antibody 11F1-2E11 [9]	Chorismate mutase [2]
k_{cat} [min^{-1}]		0.072	2.7	810
K_m [μM]		51	260	290
K_i [μM]		0.6	9	0.15
k_{cat}/k_{uncat}		250	10^4	3×10^6
$\Delta G^{\neq}$ [kcal mol^{-1}]	24.2	21.3	18.7	15.9
$\Delta H^{\neq}$ [kcal mol^{-1}]	20.5	15	18.3	15.9
$\Delta S^{\neq}$ [cal mol^{-1} K^{-1}]	−12.9	−22	−1.2	0.0

can be achieved for the antibody-catalyzed process by genetic selection and screening experiments.

If the antibody binding site is complementary to the bicyclic chair-shaped hapten **4**, then the reaction should be stereospecific. In order to test this notion racemic chorismate was synthesized by a previously described procedure.[15] A sample of (+)-chorismate was obtained by kinetic resolution of (±)-chorismate using the enzyme chorismate mutase.[10, 16] Unreacted (+)-chorismate was isolated by preparative HPLC and coeluted with authentic (−)-chorismate. The optical purity of the (+)-chorismate was determined to be 94% by optical rotation. The relative rates of conversion of (+)-chorismate, (±)-chorismate, and the natural (−)-chorismate were measured at 10 °C in the presence of catalytic antibody 11F1-2E11 (Fig. 2). The preference of antibody 11F1-2E11 for the natural (−)-chorismate to the synthetic (+)-chorismate is greater than 40:1 (after correction for enantiomeric purity), similar to the results of Hilvert and coworkers for antibody 1 F 7.[10]

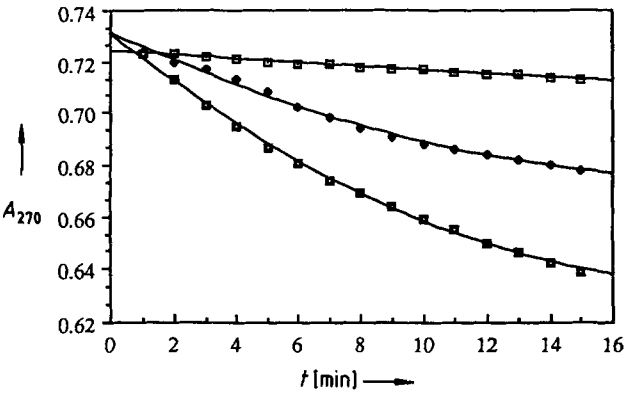

Fig. 2. Antibody-catalyzed conversion of (−)-chorismate (□), (+)-chorismate (○), and (±)-chorismate (◆). A_{270} = absorption at λ = 270 nm. The curvature is due to substrate depletion. Approximately 25% of the substrate is consumed in 15 min.

These results suggest that the diversity of the immune response may provide a number of mechanistic alternatives for a particular antibody-catalyzed reaction and consequently increased insight into the nature of biological catalysis. X-ray crystallographic analysis and genetic cloning and sequencing experiments will further define the mechanism of this catalytic antibody.

[16] To a solution of 2 mL (±)-chorismate (25 mM) in 100 mM *N*-ethyl morpholine-2-(*N*-morpholino)ethanesulfonate buffer, pH 7.5, at 25 °C was added chorismate mutase (10 units). A small aliquot (50 μL) was removed and diluted 1:10 with the same buffer. The reaction was monitored spectrophotometrically at 270 nm until no further increase in absorbance was detected (after ca. 10 min). Unreacted (+)-chorismate was isolated by preparative HPLC (50 mM triethyl ammonium acetate, pH 5/CH_3CN) and the structure confirmed by NMR spectroscopy.

The Neutralization of $HeC_{60}^{\bullet+}$ in the Gas Phase: Compelling Evidence for the Existence of an Endohedral Structure for $He@C_{60}$**

By *Thomas Weiske, Thomas Wong, Wolfgang Krätschmer, Johan K. Terlouw,* and *Helmut Schwarz**

Dedicated to Professor Fred W. McLafferty

One of the most interesting features of buckminsterfullerene, C_{60},[1] is its 7 Å diameter internal cavity[2] which could act as a "molecular container"[3] for atoms and provides a potential environment for *endohedral* chemistry[4] (chemistry inside the cage). Indeed, fullerene–metal complexes of the type MC_{60} (M = La, Ni, Na, K, Rb, Cs) and LaC_x (x = 60, 70, 74, 82) have been generated by Smalley and co-workers[5] in laser vaporization experiments on graphite doped with metal salts. Initially there was some debate about the location of the metal atom[6] (*endo* vs. *exo* complex). However, comparison with the characteristics of exohedral fullerene complexes of the type MC_{60}^+ (M = Fe, Co, Ni, Cu, La, VO), the exclusive products of ion/molecule reactions at thermal energy,[7] convincingly shows that in the experiments of Smalley et al.[5] the metal atom becomes incorporated during the cluster formation process and endohedral fullerene–metal complexes are obtained. For these endohedral complexes the symbol $M@C_x$ has been recommended.[5c]

Mass spectrometric studies using the techniques of collisional-induced dissociation or laser-induced photodissociation revealed that complexes of the type $M@C_{60}^{\bullet+}$ (and also complexes with higher fullerenes) lose C_2 and multiple units thereof while the loss of M is not observed (Scheme 1). In contrast, the *exohedral* complexes lose the metal upon activation, and C_m losses are not observed.

In a fundamentally different experiment we[8] and later other groups[9] showed that the noble gas atoms He and Ne can also be incorporated into $C_{60}^{\bullet+}$ and $C_{70}^{\bullet+}$, respectively.[10] This occurs when molecular beams of highly accelerated $C_x^{\bullet+}$ ions are fired through a stationary noble gas. The resulting

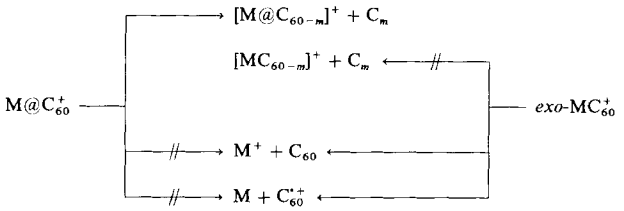
$MC_x^{\bullet+}$ complexes (M = He, Ne) fragment upon excitation to produce C_m and not M (Scheme 1), which would be expected only for an endohedral association complex. In addition, theoretical arguments favor this structure in which the noble gas is located inside the cage and is prevented from leaving its prison by a barrier of more than 8 eV.[8, 9] However, the



Scheme 1. Typical reactions of fullerene–metal complexes. m = 2, 4, 6...

staunchest critics may only be convinced that the noble gas–fullerene complex ion has an endohedral structure when the corresponding neutral species can be shown to exist. Experimental evidence that neutral noble gas–fullerene complexes have a finite lifespan would leave no doubt that the noble gas atom is physically trapped inside the cavity.

We report here a gas-phase experiment with the technique of neutralization–reionization mass spectrometry (NRMS)[11] in which a beam of $C_{60}He^{\bullet+}$ ions was successfully neutralized and subsequently reionized. The experimental conditions impose a minimum lifespan of about 90 μs on the neutral $C_{60}He$ complex, and the results show definitely that both the neutral complex and the precursor ion must possess the endohedral structure, represented as $He@C_{60}$ and $He@C_{60}^{\bullet+}$, respectively.[12]

All experiments were carried out on the four-sector mass spectrometer[13] schematically shown in Figure 1. The experimental evidence summarized in the spectra shown in Figure 2a–d was obtained from the following experiments. A mixture of C_{60} and C_{70} (containing > 90% C_{60}) was evaporated by heating the sample of 550 °C, and the vapor ionized by

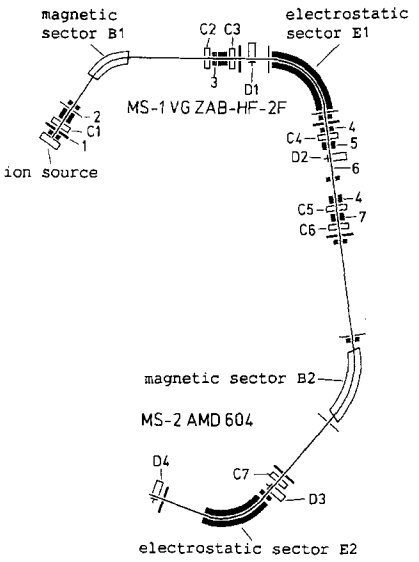


Fig. 1. Schematic diagram of the BEBE Tandem mass spectrometer at the TU Berlin [13]. electron impact (70 eV). The resulting ions were accelerated to 5000 eV, and magnet B1 was scanned (at constant E1) over the m/z range 714–734 under conditions of double focusing ($m/\Delta m$ = 1000, ion detection at D2). This yielded the partial mass spectrum displaying the molecular ion region of $C_{60}^{\bullet+}$ shown in Figure 2a.

The $C_{60}He^{\bullet+}$ were generated by collisions of the high energy $C_{60}^{\bullet+}$ ions (E_{kin} = 5000 eV) with quasi-stationary ^4He target atoms in collision cell C3 (transmission 40%). The center-of-mass collision energy of the C_{60}/He complex[8, 9] made this reaction endothermic by about 27 eV. Thus the accelerating voltage of the source-generated $C_{60}^{\bullet+}$ ions used for the synthesis of $C_{60}He^{\bullet+}$ was raised to 5027 eV so that $C_{60}He^{\bullet+}$ ions produced by collision with ^4He in C3 passed through electric sector E1 which remained set for the transmission of 5000 eV ions.

With ^4He in collision cell C3 and the concomitant raised accelerating voltage but otherwise identical conditions, a scan of B1 yielded the partial spectrum shown in Figure 2b: as in the first experiment, B1 transmitted the various isotopomers of $C_{60}^{\bullet+}$, but because of the kinetic energy constraint imposed by E1, this sector primarily transmitted the $C_{60}He^{\bullet+}$ particles generated in C3 to detector D2. (The diffuse background in Figure 2b arises from ions that lost kinetic energy in inelastic collisions between $C_{60}^{\bullet+}$ and He but did not incorporate helium).

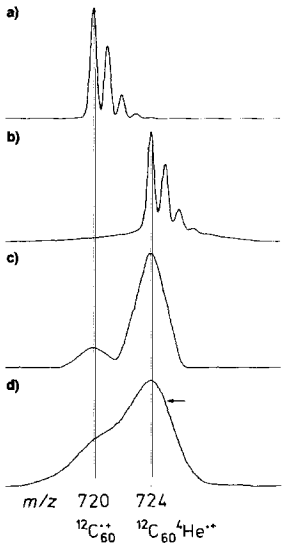

Fig. 2. Sequence of experiments (details in text): a) molecular ion region of $^{12}C_{60-x}{}^{13}C_x^{\bullet+}$ (x = 0 – 4), b) generation of $^{12}C_{60}He^{\bullet+}$, c) "purification" of m/z 724, d) NR experiment on $C_{60}^{\bullet+}$ and $C_{60}He^{\bullet+}$. Figure 2d represents an accumulation of about 400 spectra; for each spectrum approximately 6.3 ions were detected. The ratio of the number of ions in Fig. 2c to Fig. 2d is calculated as 6×10^4:1. The arrow indicates the recovery signal for $^{12}C_{60}{}^4He$.

This is demonstrated by the spectrum shown in Figure 2c: Under the conditions which lead to the spectrum shown in Figure 2b, B1 was set for optimal transmission of $^{12}C_{60}^{\bullet+}$ ions (m/z 724 in Fig. 2b). Then B2 was scanned over the appropriate mass range to separate $C_{60}{}^4He^{\bullet+}$ from the mixture of $C_{60}{}^4He^{\bullet+}$ (85%) and $^{12}C_{60}^{\bullet+}$ (15%) ions transmitted by E2. The voltages applied to sectors E1 and E2 were such that optimal transmission occurred for ions of 5000 eV translational energy and the signals were measured at D4.

The presence of the doublet signal (Fig. 2c) is an enormous advantage for the NR experiment since the $C_{60}^{\bullet+}$ component

acts as a mass marker. This avoids the problem of imprecise mass assignment that occasionally arises when using the "linked-scan" method. For the neutralization of the $C_{60}^{\bullet+}$ and $C_{60}He^{\bullet+}$ ions (Fig. 2d) an experiment analogous to that described for the spectrum in Figure 2c was performed as follows: To obtain the highest possible yield of neutral species in the electron transfer processes, a neutralization gas was used whose ionization energy (IE) lies close to the IE of C_{60} (7.6 eV)[14] (condition of near resonant electron transfer). From a great many neutralization experiments on $C_x^{\bullet+}$ clusters[15] $(CH_3)_3N$ (IE = 7.8 eV)[16] proved to be of the best reducing agents for $C_{60}^{\bullet+}$. Thus collision cell C5 was charged with $(CH_3)_3N$ at a pressure that reduced the beam transmission to approximately 10%. All unreacted ions were removed from the beam by maintaining the deflector electrode at 1000 eV so that only the beam of neutral species entered collision cell C6. In this cell a fraction of the neutral species was reionized by collision-induced ionization with $(CH_3)_3N$ as a target gas. Since the energy required for the collision-induced reionization was taken from the translational energy of the m/z 724 ion beam, the voltage applied to sector E2 was reduced slightly so that the $C_{60}He^{\bullet+}$ signal was detected at optimal transmission.

As shown in Figure 2d, the recovery signal for $C_{60}He$ shows up very clearly. This demonstrates unequivocally the existence of a species with the composition $C_{60}He$ for which the endohedral structure $He@C_{60}$ is the only conceivable physical arrangement. This result makes neutral $He@C_{60}$ the first identified noble gas–carbon compound.[17]

Considering the vertical nature of the electron transfer processes in neutralization–reionization experiments,[18] we conclude that the $He@C_{60}^{\bullet+}$ ionic complex also has the endohedral structure. In addition, the noble gas–fullerene complexes $MC_x^{\bullet+}$ (M = He, Ne; $x = C_{52}$–C_{70}) exhibit the same characteristics as $He@C_{60}^{\bullet+}$ in gas phase experiments [see Eqn. (a)] and must thus also have the endohedral structure.[19]

On the Bonding in Carbosilanes**

By *Andreas Savin,* Heinz-Jürgen Flad, Jürgen Flad, Heinzwerner Preuss,* and *Hans Georg von Schnering*

Two problems among the variety of studies on the structural chemistry of the carbosilanes have attracted particular attention:

1. Does a through-space Si–Si bond exist in 1,3-disilacyclobutane? For example, in octachlorohexasilaasterane $Si_6C_6H_8Cl_8$ the bond lengths d(Si–C) = 189, d(Si–Si) = 261 pm and bond angles Si-C-Si = 87.2, C-Si-C = 92.7° are observed, in a hexadecamethyloctasiladispiro[5.1.5.1]tetradecane $Si_8C_{22}H_{56}$, d(Si–C) = 192, d(Si–Si) = 262 pm and Si-C-Si = 85.9°.[1] The Si–Si distances in these compounds are respectively 26 and 27 pm larger (11%) than a single bond (235 pm in silicon).

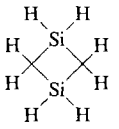
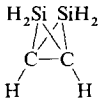
2. Does the very large C–C distance of 178 pm in 1,1,3,3-tetramethyl-2,4-bis(trimethylsilyl)-1,3-disilabicyclo[1.1.0]-butane represent a C–C bond?[2] Here d(C–C) is 24 pm (16%) longer than a single bond.

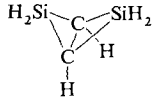
To answer these questions we applied the electron localization function (ELF)[3] to pure carbosilanes **1** and **2**.



1



2a



2b

The distribution of the electron pairs is influenced by the antisymmetry of the wave-function: the presence of one electron at position r lowers the probability of finding another electron with parallel spin in its vicinity (Pauli repulsion). A measure of this probability is the electron localization function. The value of the function approaches 1 when the wave-function allows the electrons to avoid each other and tends toward 0 when the electrons are forced to remain there in the same neighborhood around r. The regions of space in which the ELF values are high can be associated with the concepts bond, lone pair, or inner electronic shell.[3,4]

Technical details: The ELF was calculated at the Hartree–Fock level. The Hartree–Fock calculations themselves were performed with the program MOLPRO[5] using pseudopotentials.[6] The structural optimization did not yield a planar structure for **1**; instead the molecule was shown to be slightly folded. Nevertheless, since the energy difference between the planar and folded structure is small, the planar structure will be discussed. The calculated structural parameters of disilacyclobutane **1** (d(Si–C) = 189, d(Si–Si) = 264 pm, Si-C-Si = 88.7, C-Si-C = 91.3°) agree well with experimental parameters.[1]

The structural optimization of **2** shows that the Hartree–Fock calculation yields too small a C–C distance (166 pm). If the configurational space is extended to include another orbital, the bond energy sinks to 49 kJ mol^{-1} and d(C–C) lengthens to 179 pm. The structure is virtually identical from a CASSCF or a MCSCF calculation, which takes into account only promotion from the localized C–C bonding orbital into the C–C antibonding orbital. This arises from the C–C antibonding character of the included orbital. We wish to emphasize that this orbital was determined by energy optimization. Furthermore, in the improved calculation the following parameters are obtained: d(Si–C) = 181 pm, C-Si-C = 59.1, Si-C-C 60.5°, and 51.0° for the angle between the silacyclopropane planes (for comparison the experimental values:[2] 184 pm, 58, 61, 58°).

For the graphical representation[7] of the ELF in selected planes a published convention[2] was used. The electron density appears as "cloud" against a black background. The color of the points corresponds to the ELF value: analogous to the representation of altitudes in maps, high values are white, low values blue, and intermediate values are brown and green. The pictures do not show the inner shells; only the valence electron density is depicted.

In disilacyclobutane $C_2Si_2H_8$ (**1**) the angle Si-C-Si (88.7°) is smaller than C-Si-C (91.3°). According to the ELF, however, this effect is not attributable to a directly bonding Si–Si interaction, since a blue-green region of low ELF values lies between the Si atoms (Fig. 1a). But ELF provides an alternative explanation for the small Si-C-Si angle. The ELF

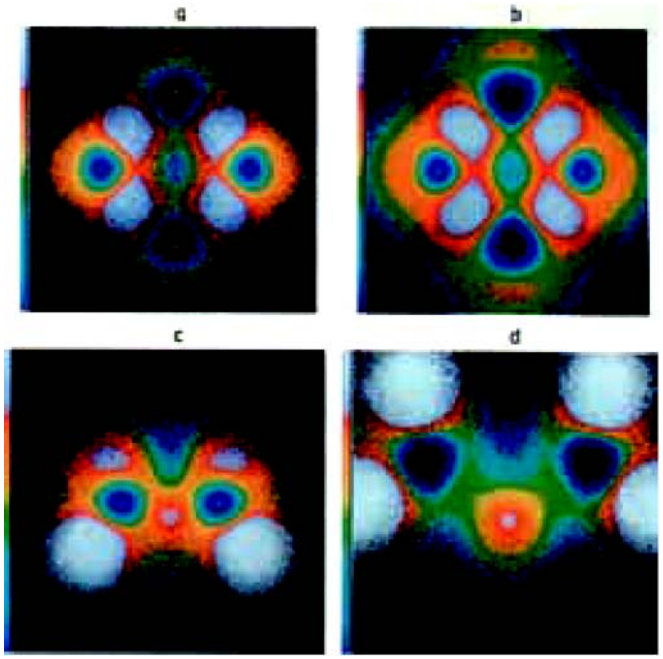


Fig. 1. Electron density ρ (as "cloud") and ELF (shown by color; scale at the left of the frames) in selected planes of the molecules **1** and **2**. a) and b) The plane containing the four-membered ring in **1**; to emphasize the structure of ELF the adjacent value-ranges in b) are depicted alternately bright and dark. The positions of the C and Si stoms are marked by white crosses: C left and right, Si top and bottom. The region between the Si atoms is characterized by a blue-green "valley". This implies that there is no direct Si–Si bond. The ELF maximum lies distinctly off the topological connecting lines of the C_2Si_2 ring (see Fig. 2). c) and d) The two mirror planes of **2** (the views correspond to **2a** and **2b**, respectively). The plane in c) contains the two C atoms and the H atoms bound to them; the SiH_2 wings lie above and below the illustrated plane. The small white region in the middle corresponds to the weak (bent) C–C bond, the large white regions at lower left and right to the C–H bonds, and the smaller white regions above the (blue) C atoms to fragments of the C–Si bonds. The plane in d) contains both Si atoms and the H atoms bound to them. No white region lies between the Si atoms. In the middle below the Si atoms, the plane intersects the C–C bond (small white region below the line joining the C atoms, which is perpendicular to the plane illustrated).

maxima (M and M′) lie outside the C_2Si_2 ring (Fig. 1b). As the calculation shows (Fig. 2), the Si–M and C–M distances differ and the M-C-M′ and M-Si-M′ angles are approximately 109.5°. These different lengths correspond to the different sizes of Si and C. The topological angles formed by the lines joining the Si and C nuclei (C-Si-C = 91.3° > 90° and Si-C-Si = 88.7° < 90°) arise naturally from *combining atoms of varying size and local bond angles of about 109.5° to form an "eight-membered ring" C-M-Si-M′-C-M-Si-M′*. One can

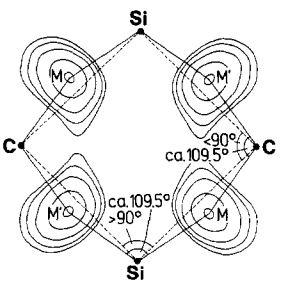

Fig. 2. ELF of **1** as contour diagram. Only the values 0.80, 0.84, 0.88, 0.92, and 0.96 are depicted. The dotted lines of the topological connections between the atoms represent the classical bonds with bond angles close to 90°. The solid lines join the C and Si nuclei with the ELF maxima M and M′. The resulting angles are indicated (see text).

easily verify this result half quantitatively using a model kit as analog computer. The different sizes of C and Si are simulated with tetrahedral joints whose arm lengths differ[8] and the atoms are joined by flexible bonds (bent bonds).

In disilabicyclo[1.1.0]butane $C_2Si_2H_6$ (**2**) the region between the two C atoms does have a high ELF value (Fig. 1c and 1d). This confirms the previously described bond.[2] The relatively small region of high ELF values implies a weak bond, in agreement with the long bond length. The white ELF maximum is also clearly off the straight topological C–C connecting line. Its position is remarkably close to that of the bent bond derived from the simple structural model.[2] As expected, there is no bond between the Si atoms (Fig. 1d).

Electron Localization in Solid-State Structures of the Elements: the Diamond Structure**

By *Andreas Savin,* Ove Jepsen, Jürgen Flad, Ole Krogh Andersen, Heinzwerner Preuss,* and *Hans Georg von Schnering*

The methods for obtaining localized orbitals—often used in the chemistry of molecules to describe bonding—can be used in principle for solids as well (in methane and in diamond, for example). They can lead, however, to several equivalent sets of orbitals for a given structure and are nonunique in this case. This ambiguity occurs, for example, in monomeric monocycles such as benzene, or in an infinite polyene chain.[1] In solids ambiguity often arises on account of the higher coordination, and localized orbitals are therefore used only rarely. An analysis in positional space can nevertheless be performed when instead of the equivocal localized orbitals, the electron localization function (ELF) is used. In this work we have calculated ELF for crystalline solids for the first time.

The electron localization function was introduced by Becke and Edgecombe as a measure of the probability of finding an electron in the neighborhood of another electron with the same spin.[2] ELF is thus a measure of the Pauli repulsion. The explicit formulation is given in Equation (a)

$$\mathrm{ELF} = [1 + [K(r)/K_h(\varrho(r))]^2]^{-1} \qquad \text{(a)}$$

The parameter K is the curvature of the electron pair density for electrons of identical spin, $\varrho(r)$ the density at (r), and K_h the value of K in a homogeneous electron gas with density ϱ. The ELF values lie by definition between zero and one. Values are close to 1 when in the vicinity of one electron, no other with the same spin may be found, for instance as occurs in bonding pairs or lone pairs. Small values are typical for the region between two electron shells (Pauli principle). In a homogeneous electron gas, ELF = 0.5.

The method of local density functionals (LDF)[3,4] has proved exceptionally reliable for studies on solids. But in LDF the pair density and its curvature K are not explicitly defined. ELF may, however, be interpreted differently from (a), in order that the determination of its value is compatible with the LDF method. In this method (Kohn and Sham[6]) the single particle density matrix γ [Eq. (b)] is determined by energy minimization for a given electron density $\varrho(r)$ [φ are

$$\gamma(r,r') = \sum_i^N \varphi_i(r)\ \varphi_i(r') \qquad \text{(b)}$$

orbitals, N is the number of electrons; $\gamma(r,r') = \varrho(r)$]. Because $\gamma(r,r')$ occurs only in the expression for the kinetic energy T [Eq. (c), ∇ is the Nabla operator], the pertinent information

$$T = \tfrac{1}{2}\int \nabla_r\, \nabla_{r'}\gamma(r,r')|_{r=r'} \mathrm{d}^3r \qquad \text{(c)}$$

is contained in the three-dimensional kinetic energy density $t(r,r')$ [Eq. (d)] and the six-dimensional function $\gamma(r,r')$ is not required.

$$t(r) = \tfrac{1}{2}\nabla_r\, \nabla_{r'}\gamma(r,r')|_{r=r'} \qquad \text{(d)}$$

The function $t(r)$ cannot exceed a certain threshhold,[7] which is defined by Equation (e). This minimum value occurs

$$t(r) \geq \frac{1}{8}\frac{|\nabla\varrho|^2}{\varrho} \qquad \text{(e)}$$

when the orbitals are proportional to $\sqrt{\varrho}$. According to the Pauli principle this is possible for at most two orbitals, one

with α and one with β spin. Thus in general the deviation is positive [Eq. (f)]. We shall call it the Pauli kinetic energy

$$t_P(r) = t(r) - \frac{1}{8}\frac{|\nabla\varrho|^2}{\varrho} \qquad \text{(f)}$$

density.[8] In some regions of space t_P tends toward zero, and we say that here the electron pairs are localized. Using t_P we can find a well-defined measure which corresponds to the ELF calculated from the Hartree–Fock approximation [Eq. (g)]. The parameter $t_{P,h}$ represents the value of t_P for a homogeneous electron gas with density $\varrho(r)$.

$$\mathrm{ELF} = [1 + [t_P(r)/t_{P,h}(\varrho(r))]^2]^{-1} \qquad \text{(g)}$$

For the graphical representation we used, as we did previously for molecules, a program[10] that depicts the electron density and ELF values by the density of the points and their color, respectively. As in a map the colors range from blue (small ELF values) through green, yellow, and brown, to white (high ELF peaks). The background is black. Of the calculated electron density, only the valence electron density is illustrated. For this reason the (white) regions arising from the inner shells around the nuclei are missing in Figure 1. Instead each nucleus is surrounded by a blue-violet bubble.

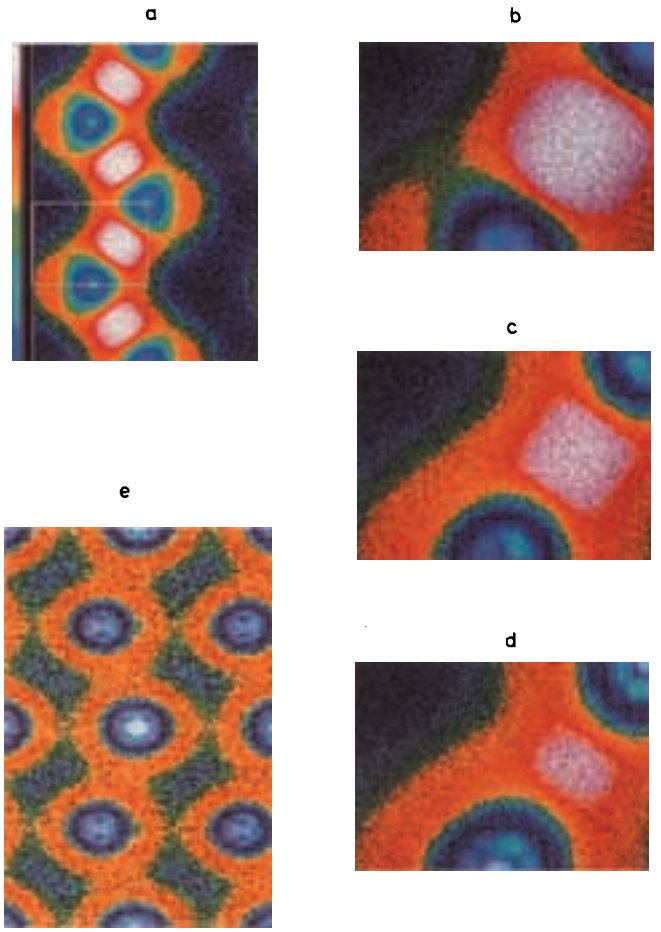

Fig. 1. Valence electron density ϱ (as "cloud") and ELF (depicted by color) for elements with diamond-type structures and for β-Sn. (Increasing ELF scale: blue, green, yellow, brown, white; background black; the blue regions around the nuclei arise from the missing inner shells) a) Diamond: the white regions represent C–C bonds; the small framed exerpt shows the section for the frames b) to d). b) Silicon. c) Germanium. d) α-Sn. e) β-tin; the white regions are no longer visible, and the chains show only a moderately high localization (orange-yellow). Interactions exist between the chains.

In this first report on ELF for solids, the diamond structure is investigated. Figure 1 shows the electron density and the ELF in the (110) plane. This plane contains the zig-zag chains of directly connected atoms and the essential details of the three-dimensional structure. In Figure 1 a (diamond) regions of high localization (white) are seen on the lines joining the C atoms—the electron pair of the C–C bond. The framed exerpt serves to illustrate the differences when the atoms are Si, Ge, and α-Sn (Figs. 1 b–d). Along this series the white regions of the covalent bonds become smaller, and the green waist (Si, Fig. 1 b) gives way to a brown area. The effect is to create channels of evenly distributed localization analogous to an electron gas. Here we should point out that the topology of the wavy, three-dimensional, blue-green region corresponds completely to that of the space-dividing periodic nodal surface D*, which in turn is determined by the three-dimensional symmetry alone.[11] Thus there exists a three-dimensional periodic surface of the same electron density[11] as well as a corresponding surface of identical ELF values that has nothing to do with the contours of the atoms, but is defined only by the symmetry of the translational group.

The tetragonal structure of metallic tin (β-Sn) is related to the diamond structure. Also present are the essential details of the (110) plane. The zig-zag chains of the diamond structure meet in this plane. Figure 1 e shows that in metallic β-Sn, the (white) regions of high localization have disappeared, and joining the chains are found (yellow) regions of localization similar to an electron gas. The change in the electron localization function along the series from carbon to tin thus shows spatially the characteristic transition from covalent to metallic bonding.

Molecular Imaging of Alkanol Monolayers on Graphite**

By *Stefan Buchholz* and *Jürgen P. Rabe**

The adsorption behavior of long-chain alkanes and alkyl derivatives on the basal plane of graphite has been of considerable interest as a model for molecular adsorption. Measurements of the adsorption isotherms have shown that alkanes, alkanols, and fatty acids adsorb from nonpolar solvents as densely packed monolayers with the molecules parallel to the basal plane of graphite. The monolayers are stable against further adsorption over a broad concentration range.[1-3] With scanning tunneling microscopy (STM) the direct in situ structure characterization of such[4-8] and similar[9-10] monolayers has become possible recently (see the review on STM investigations of molecular systems).[11] We report here on the structure and dynamics of monomolecular adsorbate layers of long-chain alkanols on graphite.

Figure 1 displays highly ordered areas in monolayers of octadecanol ($C_{18}H_{37}OH$), tetracosanol ($C_{24}H_{49}OH$), and 1,12-dodecanediol ($HOC_{12}H_{24}OH$). The molecules are packed parallel to each other in lamellae. From the width of the lamellae it can be deduced that they exhibit all-*trans* conformations. At the lamellae boundaries a displacement of half the molecular width is observed. The comparison of STM images before and after the adsorption of the monolayers shows that both the long axes of the molecules and the lamallae boundaries are oriented parallel to basis vectors of the graphite lattice. The angle of 60° between the molecular axes and the lamellae boundaries corresponds very well to a displacement of neighboring alkyl chains by two methylene units. Since the plane containing the carbon backbone is almost perpendicular to the substrate[7] only every second methylene unit is in direct contact with the graphite surface. The repeating unit of two methylenes amounts to 254 pm and agrees well with the periodicity observed along the alkyl chains by STM. In the octadecanol and the dodecanediol (Fig. 1a,c) predominantly herringbone structures are observed, while for the longer chain alkanols tetracosanol (Fig. 1b) and triacontanol ($C_{30}H_{61}OH$, Fig. 4) the long axes of the molecules in neighboring lamellae are parallel to each other. The fact that the shorter chain alkanol and the alkanediol exhibit the herringbone structure indicates that the tilted arrangement favors hydrogen bonding whereas the parallel arrangement allows a stable packing of the alkyl chains. In addition, small differences in the interaction energy of the monolayer with the substrate may influence the packing behavior.

In the case of the tetracosanol (Fig. 1b) in particular, neighboring lamellae boundaries clearly exhibit different image contrast, indicating a bilamellar structure. This difference is less obvious in the case of octadecanol but the bilamellar structure is also likely there, since only in that case can all hydroxyl groups partcipate in hydrogen bonds. In general hydroxyl groups and oxygen functionalities (e.g. carboxyl groups) do not produce a distinctly different image contrast from alkyl chains.

The monolayers of the monofunctional alkanols exhibit many defects—the areas shown in Figure 1a,b are the largest defect-free domains that have been observed. The reason is the tilted arrangement of the molecules in the lamellae, which allows a dense packing also at the domain boundaries. Hence, the line tensions at the domain boundaries are relatively small, similar to the case of 1,4-didodecylbenzene.[6] Figure 2a,b shows a domain boundary of a monolayer of tetracosanol and octadecanol, respectively. At the domain boundary of the tetracosanol, the direction of the displacement of neighboring molecules parallel to each other is reversed. In the octadecanol case shown here every second lamella encounters the lamella of a different domain at an obtuse angle, due to the herringbone structure. The CPK model displayed in Figure 3 shows that also in this case the molecules are able to pack densely without breaking hydrogen bonds. 1,12-Dodecanediol also exhibits a herringbone pattern, but in this case such a domain boundary would involve a loss of hydrogen bonds. Therefore such defects would be highly energetic and should occur rarely, if the development of the defects is not kinetically controlled. Indeed in the case of the diol, whose packing is highly stabilized

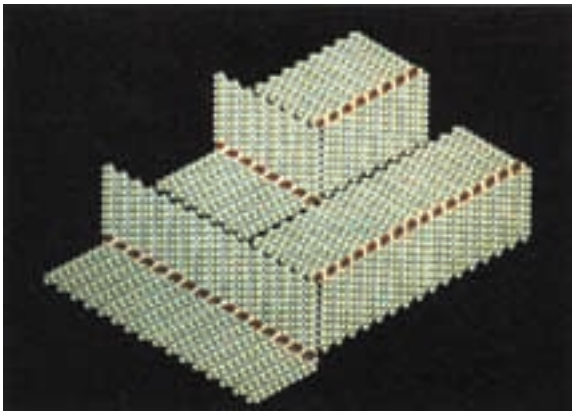

Fig. 3. CPK model of the domain boundary of the octadecanol monolayer shown in Figure 2b.

through the hydrogen bonds, not a single domain boundary has been observed on an area of several μm^2.

Another type of domain boundary often observed is shown in Figure 4a, which displays the STM image of a monolayer of triacontanol. At these domain boundaries the lamellae of one domain encounter those of another at an obtuse angle. Here also a dense packing of the molecules is observed. Corresponding to the lamella boundaries in the

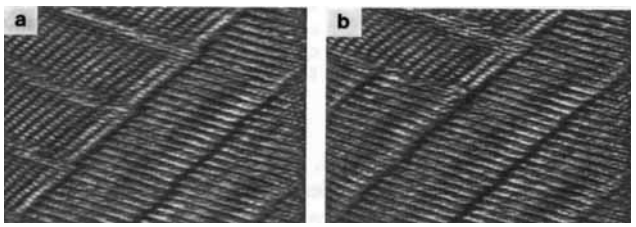

Fig. 4. STM images of domain boundaries in a triacontanol monolayer (image size: 13.9 nm × 10.3 nm).

left domain, the molecules in the right domain are shifted by one graphite repeat unit, thereby allowing adaptation to the contour of the left domain. This displacement in the right domain is extended over a few lamellae. Figure 5 shows an enlargement of such a displacement within the domain. Close to the region shown in Figure 4a a corner of the left domain could be recorded (Fig. 4b).

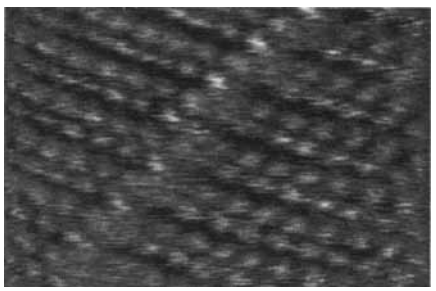

Fig. 5. STM image of a displacement at a lamella boundary in a triacontanol monolayer. The image has been recorded close to the domain boundary shown in Figure 4a (image size: 2.9 nm × 2.3 nm).

Often the domain boundaries described above are observed in combination with each other resulting in very complicated defect patterns. As an example, Figure 6a shows an image of a tetracosanol monolayer with a domain that consists of only two lamellae in one and probably seven molecules in the other direction. In such defect-rich areas of the monolayers reorientations occur very often, resulting in noisy pictures. Occasionally we succeeded in imaging the metastable states with high resolution before (Fig. 6a) and after (Fig. 6b) the reorientation (see also Ref. [6, 7]). Such reorganizations of the monolayers are probably combined with a desorption of at least part of the affected molecules. The reorientation processes are too fast to allow their details to be followed.

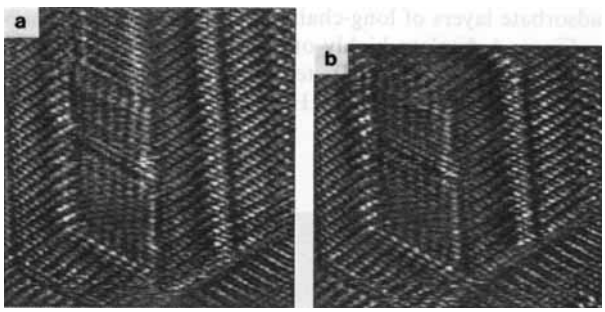

Fig. 6. STM images of a defect-rich area in a tetracosanol monolayer. Image b) was recorded only a few seconds after image a). In this time the monolayer was reorganized in the upper part of the image. (Image sizes: a) 11.5 nm × 12.3 nm; b) 11.5 nm × 10.9 nm).

Long-chain alkyl derivatives are often contaminated with homologous impurities, if no extensive purification is performed. As shown in Figure 7 such impurities can be included in the monolayers. Above one lamella (A) of triacontanol

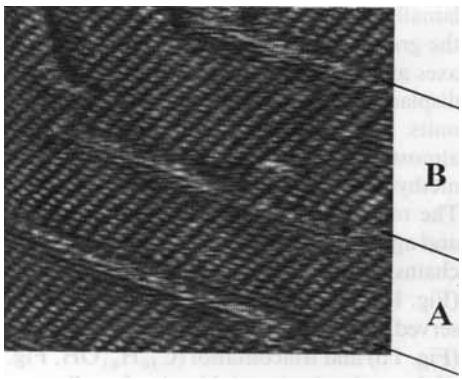

Fig. 7. STM image of a triacontanol monolayer containing a longer chain impurity. Whereas the width of lamella A is as expected for triacontanol, lamella B is significantly broader. The molecules in lamella B have a length of 40 methylene units. Furthermore, imbedded in lamella A are two longer molecules. Adjacent to them in lamella B are two shorter triacontanol molecules allowing a dense packing despite the defect (image size: 10.5 nm × 9.3 nm).

molecules there is a broader lamella (B), in which the impurities are enriched. Whereas in lamella A 15 repeat units are observed along the molecules, corresponding to the length of the triacontanol molecules, in lamella B the molecules con-

sist of 20 repeating units corresponding to a length of 40 methylene units. In addition, one can recognize that two molecules of the longer chain impurity are included in lamella A. Adjacent to them in lamella B are two triacontanol molecules allowing a regular packing in the following lamellae.

The present investigation has shown what detailed information on structure and dynamics of monomolecular alkanol adsorbate layers can be obtained by scanning tunneling microscopy. The packing pattern in monodomains as well as at domain boundaries indicate the importance of hydroxyl end groups for the packing of primary alkanols with up to 30 carbon atoms. In particular the patterns at the many domain boundaries are consistent with a tendency to form as many hydrogen bonds as possible. Reorganizations of the domain structure could be followed on a millisecond timescale, and finally the inclusion of single molecules of an impurity into the monolayer could be observed for the first time.

Experimental

For the basics of scanning tunneling microscopy see [11–13] and for technical details of the instrument used here, [14]. All images were recorded in the variable current mode with a tunneling current of 1 nA and a bias of 1 +/− 0.5 V (tip positive). In this regime no pronounced dependence of the image contrast on the bias was observed. Tunneling currents higher than 1 nA resulted generally in images with higher noise levels, whereas with lower currents only poor image contrast was obtained. The scanning frequencies in x and y direction were 200 and 0.3 Hz, respectively, equivalent to 1.5 s per image at a resolution of about 200 × 200 pixels. The data was recorded continuously on video tape [14]. Tunneling tips were mechanically formed from platinum/iridium wire. Only those allowing atomic resolution on graphite were used for the studies of the monolayers.

Imaging of the monolayers was performed at the interface of graphite with a solution of the appropriate alkanol in 1-phenyloctane. The alkanol solutions were prepared from concentrated solutions after removing undissolved material by filtration and subsequent dilution by 10% with pure solvent.

1-octadecanol (99%), 1-tetracosanol (99%), 1-triacontanol (96%), 1,12-dodecanediol (99%) were purchased from Aldrich and used without further purification.

The Trapping of Iron Hydroxide Units by the Ligand "heidi": Two New Hydroxo(oxo)iron Clusters Containing 19 and 17 Iron Atoms

By *Sarah L. Heath* and *Anne K. Powell**

Compounds containing extended arrays of iron centers linked by oxide and hydroxide ions are common in nature. Examples include the core of the iron-storage protein ferritin, which can accommodate up to 4500 iron atoms and a variety of iron minerals as well as rust. The importance of such materials has fueled efforts to synthesize and characterize smaller hydroxo(oxo)polyiron complexes to serve as models. Although a variety of interesting polyiron complexes has resulted, including structures with eight,[1] ten,[2] and eleven[3] iron centers, as well as the heterometal cluster $[Fe_{16}MO_{10}(OH)_{10}(O_2CPh)_{20}]$, M = Mn or Co,[4] none has exhibited the known features of the naturally occurring compounds.

We describe here the synthesis and characterization of three iron complexes with the ligand heidi (H_3heidi = $N(CH_2COOH)_2(CH_2CH_2OH)$); two of these complexes are examples of a new type of hydroxo(oxo)iron cluster, in which the close-packed cluster core is enclosed in a shell of ligands which are complexed to further iron atoms. X-ray crystallography[5] reveals these clusters to contain 19 and 17 iron atoms; thus **1** and **2** are the largest polyiron complexes of this type characterized to date (Fig. 1).[6]

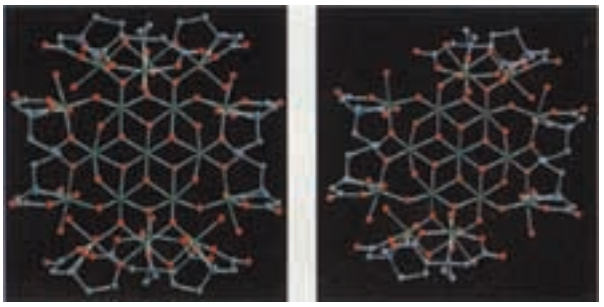

Fig. 1. The crystal structures of **1** (left) and **2** (right); Fe shown in green, O in red.

$[Fe_{19}(\mu_3\text{-}O)_6(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_8(heidi)_{10}(H_2O)_{12}]^+$ **1**
(FW = 3352.78)

$[Fe_{17}(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_{10}(heidi)_8(H_2O)_{12}]^{3+}$ **2**
(FW = 2894.82)

The number of iron atoms in clusters **1** and **2** is determined by the arrangement of Fe/heidi units around the core structure common to both compounds. This cluster core consists of an $[Fe_7(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_4\{(\mu_3\text{-}O)Fe\}_2]^{13+}$ unit. In **1** this is surrounded by ten iron heidi units linked to the core by μ_3-O, μ_2-OH, and alkoxo bridge units from the heidi ligands. This shell, formulated as $[Fe_{10}(heidi)_{10}(H_2O)_{12}(\mu_3\text{-}O)_4(\mu_2\text{-}OH)_4]^{12-}$, gives an overall charge of 1+ to **1**. The vacant sites on the peripheral iron centers are taken up with water molecules so that each iron atom is octahedrally coordinat-

[*] Dr A. K. Powell, S. L. Heath
School of Chemical Sciences
University of East Anglia
Norwich NR4 7TJ (UK)

symmetry-related Fe/heidi units are absent and consequently two μ_2-OH units replace two of the μ_3-O units in **1**. The formula of the cluster shell is $[Fe_8(heidi)_8(H_2O)_{12}(\mu_3\text{-}O)_2(\mu_2\text{-}OH)_6]^{10-}$, giving **2** an overall charge of 3+. The heidi ligand coordinates in a tetradentate fashion but never associates with one Fe exclusively. Instead its alcohol function

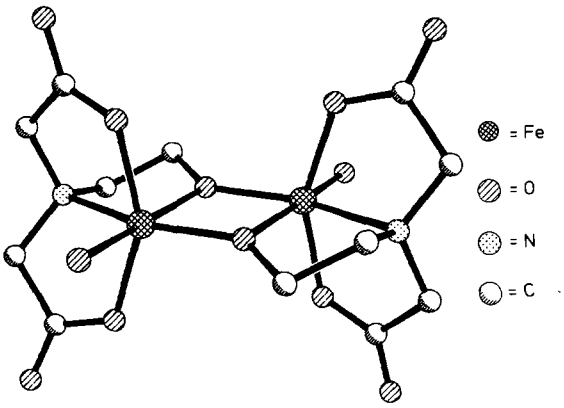

Fig. 2. The crystal structure of the alkoxo-bridged dinuclear complex **3**.

forms a μ_2-alkoxo bridge to a neighboring iron center. This behaviour is also demonstrated by the dinuclear iron complex **3** as illustrated in Figure 2.

$[Fe(heidi)(H_2O)]_2$ **3** (FW = 495.99)

The cluster core common to **1** and **2** (Fig. 3) derives from $\{(Fe(OH)_2)^+\}_n$. This can be visualized by the replacement of the iron atoms of the two $[(\mu_3\text{-}O)Fe]^+$ units of the cluster core by protons to give the structure $[Fe_7(\mu_3\text{-}OH)_6(\mu_2\text{-}OH)_6]^{9+}$. If the six outer μ_2-OH ions are then thought of as

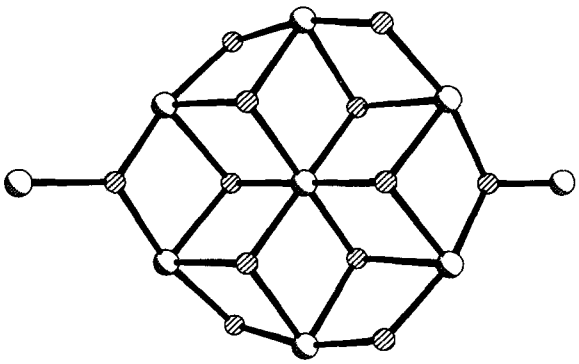

Fig. 3. The core unit common to **1** and **2**. Open circles represent Fe atoms.

extending this as a network by binding to further $\{FeOH\}^{2+}$ units, an infinite two-dimensional array of $\{Fe(OH)_2\}^+$ units results in which the Fe ions occupy octahedral holes in a hexagonal close-packed array of OH ions; this is equivalent to the AX_2 structural type found in CdI_2 or $Mg(OH)_2$.

The relationhip of the cluster core to the AX_2 structural type is illustrated in Figure 4. Normally the final hydrolysis product of Fe(III) salts is goethite, $\{Fe(O)OH\}_n$, whose structure is related to that of the cluster core by the replacement of half of the μ_3-OH bridges with μ_3-O bridges; these,

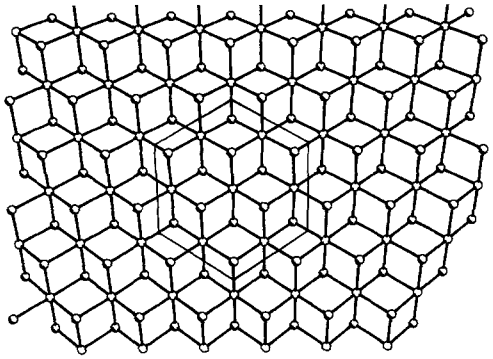

Fig. 4. The central core of **1** and **2** shown in the context of the AX_2 structural type.

in turn are hydrogen-bonded to the protons of the hydroxide ions in the next layer. The use of the charge, denticity, and bite-angles of the encapsulating ligands to dictate structural type probably finds parallels in biology in biomineralization processes. The transition-metal compound $[Mn_{10}O_{14}(tren)_6]^{8+}$ (tren = $N(CH_2CH_2NH_2)_3$) also possesses an AX_2 core-structure, although here the metal is in the III and IV oxidation states.[7]

EXAFS measurements of the Fe/O core of ferritin have been interpreted in terms of a hydroxo(oxo)polyiron compound in which the Fe centers are surrounded by six O atoms (Fe–O distance 1.9 Å) and a further six Fe centers (average Fe–Fe distance 3.1 Å).[8] More recent analyses of this Fe shell have indicated interactions with iron atoms roughly 2.9 and 3.5 Å distant.[9, 10] In **1** and **2** the average Fe–Fe distance is 3.1 Å, with the shortest being 2.95 Å, and the longest, 3.46 Å. Although the ferritin core is often likened to the mineral ferrihydrite, there is some controversy about the exact nature of the iron sites in this mineral.[11–14] Therefore compounds such as **1** and **2** whose construction models biomineralization processes should help in understanding the formation and constitution of naturally occuring hydroxo(oxo)polyiron compounds.

Experimental Procedure

Clusters **1** and **2** were prepared by adding H_3heidi (1 equiv, 2.5 mmol) to a solution of $Fe(NO_3)_3 \cdot 9H_2O$ (2 equiv, 5 mmol) in water (30–40 mL). The resulting solution was treated with pyridine (6 equiv, 15 mmol) and left to crystallize. Elemental analysis: found, C 16.9, H 4.4, N 4.3, Fe 26.5%; calculated for $C_{108}H_{332}Fe_{36}N_{22}O_{226}$, C 17.1, H 4.4, 4.1, Fe 26.6%.

Adjustment of the heidi: Fe ratio to 1:1 yields **3** exclusively. Elemental analysis: found, C 28.87, H 4.02, N 5.54, Fe 21.72%; calculated for $C_{12}H_{20}N_2O_{12}Fe_2$, C 29.41, H 4.53, N 5.72, and Fe 22.79%).

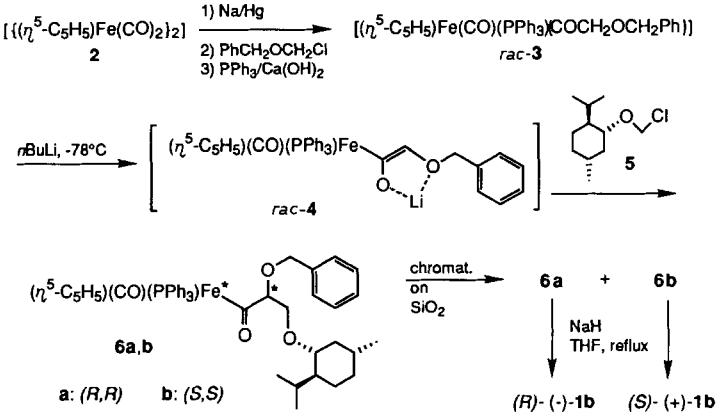
synthesized by the method of Brunner and Schmidt,[2] but an efficient procedure for their preparation is not yet available.

We were interested in the enantiomerically pure α-benzyloxyacryliron(II) complex (**1b**), because Michael addition and subsequent alkylation of the intermediate enolate leads to α,α-dialkyl-α-hydroxycarbonyl derivatives, a class of compounds that are difficult to prepare in optically active form. We therefore developed a process that yielded the two optical antipodes (*R*)-**1b** and (*S*)-**1b** in gram quantities from inexpensive starting materials in good yield (Scheme 1).

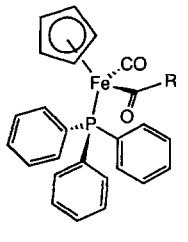


Scheme 1. Synthesis of α-benzyloxyacryliron(II) complexes (*R*)-**1b** and (*S*)-**1b**.

New Chiral α-Benzyloxyacryliron(II) Complex for Asymmetric Synthesis of α,α-Dialkyl-α-hydroxycarbonyl Compounds**

By *Felix Stolz, Peter Strazewski, Christoph Tamm,* Markus Neuburger,* and *Margareta Zehnder*

Davies et al. have shown[1] that a series of diastereoselective alkylations of carbonyl compounds can be performed with high selectivity by using an iron(II) complex of type **1** as chiral auxiliary. To our knowledge, in the past the only accessible enantiomerically pure starting materials for the preparation of derivatives was the acetyliron complex [(η^5-C_5H_5)CO(PPh_3)Fe($COCH_3$)] (**1a**). Both the (*S*)-(+) and the (*R*)-(−) forms are commercially available, but when their high molecular weight and the difficulty of regenerating the auxiliary in optically active form are taken in to account, they are rather expensive. Both configurations can also be



(*R*)-**1**

a: R = CH_3

b: R = $C(OCH_2Ph)=CH_2$

c: R = $HC=CHCH_3$

Compound *rac*-**3** was prepared by a known procedure from [{(η^5-C_5H_5)Fe($CO)_2$}$_2$] (**2**) in 42% overall yield.[1b,3] Deprotonation with *n*-butyllithium followed by a highly stereoselective alkylation of the intermediate enolate *rac*-**4** with chloromethyl (−)-menthyl ether (**5**) afforded **6a** (less polar) and **6b** (more polar). The relative configuration of the centers Fe* and α-C* were assumed to be (*R**,*R**) or *l* (like) on the grounds of the presumed configuration of the (*E*) lithium enolate **4** (cf. Davies et al.[1b–c]). The *u*-diastereomers [(*R**, *S**) or unlike)] are in principle also possible, but were not observed in the ^{1}H NMR spectrum of the product mixture. A single flash-chromatographic separation on silica gel (toluene/ether/pentane 90:5:5) furnished the virtually enantiomerically pure products in 43 (**6a**) and 42% (**6b**) yield. The elimination of (−)-menthol from **6a** and **6b** was achieved with sodium hydride under retention of configuration at the iron atom. After filtration over a short column (neutral Al_2O_3), precipitation of the only iron complex

present with *n*-pentane yielded (*R*)-(−)-**1b** or (*S*)-(+)-**1b** (from **6a** and **6b** respectively) in preparative amounts as amorphous, air- and moisture-insensitive solids in 87–92% yield (Fig. 1).[4]

The crystal structure of racemic **1b** has been solved (Fig. 2). As in the corresponding (*E*)-crotyliron complex **1c**,[1d] it reveals that the β carbon atom is oriented *s-cis* to the carbonyl oxygen atom of the same ligand. The *anti* arrangement of the two carbonyl oxygen atoms is the only possible one for steric reasons.[1d–e]

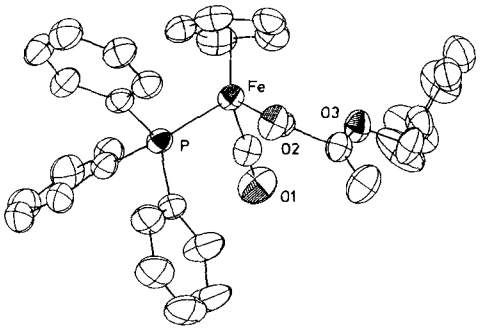

Fig. 2. Structure of (*R*)-**1b** in the solid state. Thermal ellipsoids represent 30% probability. Carbon atoms are complete ellipsoids; heteroatoms have a sector removed.

Compound **1b** was butylated in β position with *n*BuLi (two equivalents are required for complete conversion—cf. Davies et al.[1f]), and the resulting lithium enolate **7** trapped in situ with water, methyl iodide, or ethyl iodide (Scheme 2). The reaction mixture was filtered over a short column (neutral Al_2O_3), and the alkylation products precipited on addition of *n*-pentane. The yields determined at this stage lay between 76 (**10a,b**) and 88% (**8a, b**). The diastereoselectivity of the reactions was estimated from ^1H NMR spectroscopy and the preparative separation of the product mixture. The enolizable acyl derivatives **8**, like **6a,b**, were stable on silica gel, but **9** and **10** required separation on neutral Al_2O_3. The selectivity lay between 80 and 95% *ds*. In the case of **9a** and **b** (prepared from (*R*)-(−)-**1b**) the exact ratio (17:83) could be established by gas chromatography on permethylated β-cyclodextrin of the final product **14** formed on removal of the chiral auxiliary and the benzyl function. The ratio of **8a**:**8b** (7:93) was determined by HPLC (Si-60, 0.3% ether in hexane).

The racemic major product **9b** could also be crystallized. The crystal structure (Fig. 3b) shows that the *l* diastereomer was formed preferentially, as expected from the structure of **1b**. After methylation the acyl ligand rotated approximately 180° around the (OC)–(α-C) bond, allowing the smallest α substituent, the methyl group to point in the direction of the triphenylphosphane ligand. Additional noteworthy features of the crystal structure are the changes in some angles ($O{\equiv}C{-}Fe{-}COR$ is wider and $O{\equiv}C{-}Fe{-}PPh_3$ narrower than in **1b**) and the remarkable rigidity of the pentyl side chain.[5] The chirality of the propeller geometry of the triphenylphosphane ligand follows the general rule in both crystal structures:[1e] the screw in the (*R*) complex is clockwise and in the (*S*) complex counterclockwise.

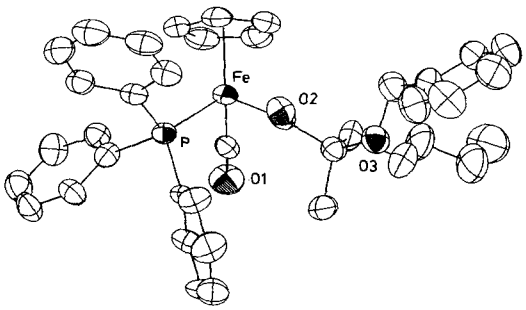

Fig. 3. Structure of (*R*)-**9b** in the solid state. The thermal ellipsoids represent 30% probability. Carbon atoms are complete ellipsoids; heteroatoms have a sector removed.

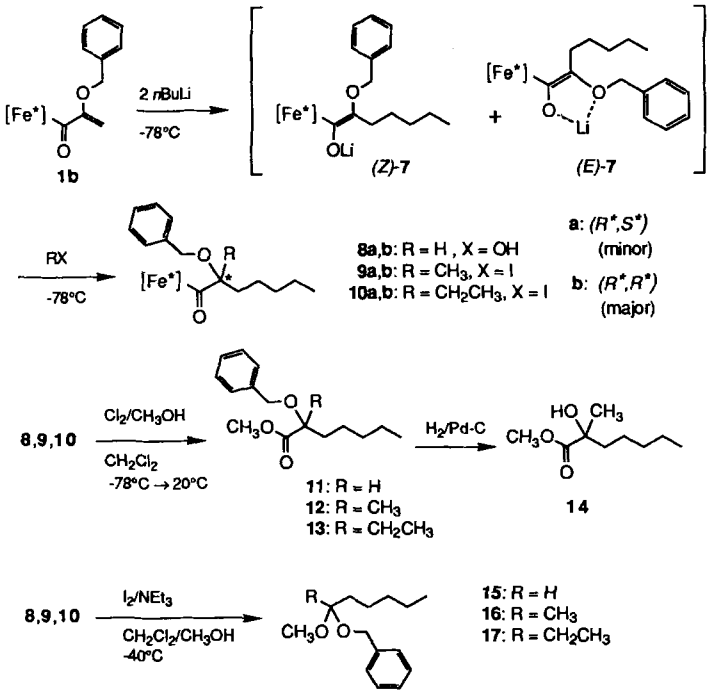

Scheme 2. Alkylation of (*R*)- or (*S*)-**1b**, followed by cleavage of the acyl ligands from iron. ([Fe*] = [(η^5-C_5H_5)CO(PPh_3)Fe]).

Both the extremely high diastereomeric selectivity of the alkylation of *rac*-**3** and the usually absolutely selective alkylations and protonations of comparable substrates[1d,g] show that in complexes **1** the chiral auxiliary does not even permit sterically nondiscriminating electrophiles to attack from the triphenylphosphane side. The diminished stereoselectivity of the alkylation of **1b** thus requires a different explanation. The ^1H NMR spectrum of **1b** suggests that in solution even at room temperature the complex exists virtually exclusively in the cisoid conformation, as in the solid state. Addition of *n*BuLi forces the enolate **7** into the (*Z*) configuration (Scheme 2). Then (**Z**)-**7** is alkylated stereospecifically to the *l* diastereomer. However chelation of the two oxygen atoms by a lithium ion in the (*E*) enolate **7** (as in enolate **4**) must lead specifically to the *u* diastereomer. Since two equivalents of *n*BuLi are required for complete conversion, it seems that the first equivalent of *n*BuLi merely coordinates to **1b**. The delayed onset of the red coloration typical of enolate formation supports this hypothesis. Apparently this type of activation is a prerequisite for the *n*-butylation of **1b** in β position. It is feasible that the presence of lithium ions simultaneously causes a partial isomerization to the transoid isomer of **1b**, which in turn reacts with the second equivalent of *n*BuLi to yield (*E*)-**7**. A greatly enhanced reactivity to *n*BuLi of the

mere traces of transoid conformer present would be another, but unlikely explanation.

The diastereoselectivity of the reaction presents no problem for synthesis, because the less polar side products **8a**–**10a** are separable by chromatography with minimum losses. Absolute diastereomeric purity of the products is attainable, and after cleavage of the acyl ligands enantiomerically pure α-benzyloxy-α,α-dialkylcarbonyl compounds are obtained.

The oxidative cleavage of the α-benzyloxyacyl ligands from the iron complex with bromine and methanol proved to be problematic at first. As Davies et al.[1c] had reported earlier, the bond between C(acyl) and α-C tends to break instead of the Fe-C(acyl) bond, forming not the desired methyl esters **11**–**13**, but the benzyl methyl acetal **15** or the ketals **16**, **17** that are shortened by one carbon atom. We therefore studied various cleavage conditions in order to bias the product composition. The most common cleavage reagent, bromine, yields varying mixtures of esters and acetals or ketals depending on the added mole equivalents of reagent and the reaction time. *N*-bromosuccinimide affords almost exclusively the acetal or ketal, but in poor yield. Iodine or bromine with added triethylamine furnishes exclusively the acetal or ketal (82% for **16**). However, with chlorine gas in dichloromethane the ester forms exclusively (54% for **12**).

[6] The experimental details of the syntheses for all compounds and their physical and spectroscopic characterization will be published later. They are part of the proposed dissertation of F.S.

Enzymatic Preparation of Enantiomerically Pure *N*-alkyl Amino Acids**

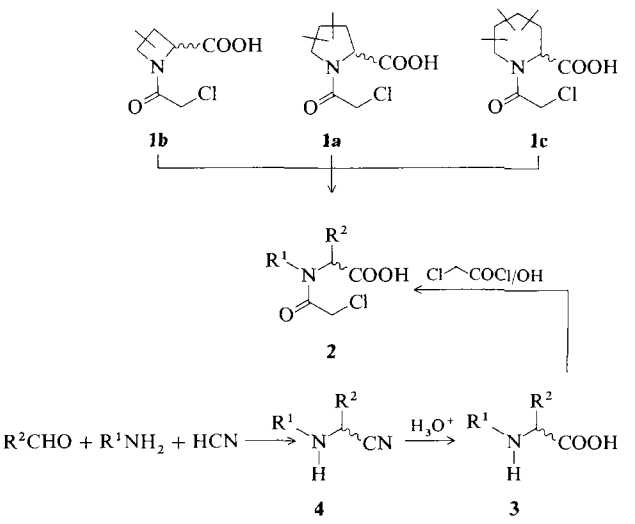
By *Ulrich Groeger*,* *Karlheinz Drauz*, and *Herbert Klenk*

N-alkyl-L-amino acids L-**3**, and more particularly *N*-methyl-L-amino acids, are important building blocks of peptide and depsipeptide antibiotics.[1] They also occur free in biological material, as for instance, *N*-methyl-L-tryptophan in the seeds of *Abrus precatorius*.[2] Although preparation of optically inactive or racemic compounds **3** presents no problem, synthesis of the enantiomerically pure compounds L-**3** is laborious and sometimes provides unsatisfactory yields.[3]

One possible route to enantiomerically pure amino acids is the enantioselective hydrolysis of appropriate racemic *N*-acetylamino acids catalyzed by an aminoacylase from *Aspergillus oryzae* or from porcine kidney (acylase I, EC 3.5.1.14), as for instance is used in an industrial process to prepare L-methionine or L-valine.[4] Although acylase I displays high selectivity for a wide spectrum of substrates, this system has limitations. Replacement of the hydrogen on the amine nitrogen atom by an alkyl group causes loss of enzymatic activity. Thus *N*-acylated secondary amines such as *N*-acylated proline (**1a**) or *N*-acylated *N*-alkylamino acids cannot be hydrolyzed by this method.[5]

Recently we isolated and characterized a new bacterial *N*-acyl-L-proline-acylase, whose high enantioselectivity (*ee* > 99.8%) makes it suitable for preparing L-proline from **1a**.[6] This enzyme also hydrolyses only the L-enantiomer of *N*-acetyl and *N*-chloroacetyl derivatives of azetidine-2-carboxylic acid (**1b**) and pipecolic acid (**1c**), thus enabling the enzyme-catalyzed resolution of these compounds.[7]

Compounds **1a**–**c** are *N*-acylated cyclic secondary amines. Ring-opening leads to the corresponding *N*-acylated, straight-chain secondary amines **2**. The precursors **2** can be prepared as racemates in good yield from **3** in a modified Strecker synthesis via *N*-alkylaminonitriles **4** (Scheme 1, Table 1).



Scheme 1. For R^1, R^2 see Table 1.

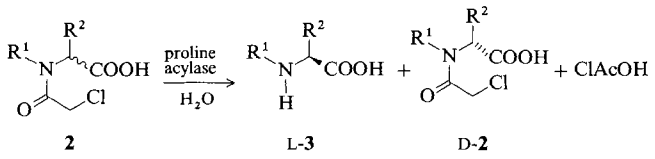
e	C_2H_5	C_2H_5	10	52	82
f	CH_3	C_3H_7	30	43	79
g	C_2H_5	C_3H_7	20	62	89
h	CH_3	C_4H_9	35	47	84
j [a, b]	CH_3	CH_3	98	–	–
L-**k** [a]	CH_3	$CH(CH_3)_2$	57	–	–
L-**l** [a]	CH_3	$C_2H_3(CH_3)_2$	94	–	–

[a] These compounds were synthesized from the appropriate *N*-methylamino acids. [b] α-H replaced by CH_3.

To our knowledge an acylase-catalyzed resolution of **3** was unknown and impossible in the past with aminoacylases from bacteria, moulds, or porcine kidneys because of their substrate specificity.[8] In order to prepare enantiomerically



2 L-**3** D-**2**

Scheme 2. For R^1, R^2 see Table 1.

pure L-**3**, we therefore subjected *N*-chloroacetyl-*N*-methyl-DL-alanine **2a** to cleavage by *N*-acyl-L-proline-acylase (Scheme 2). Figure 1 shows the progress of the acylase-catalyzed hydrolysis of **2a** and its corresponding L-enantiomer L-**2a**. After 1 h L-**2a** was completely hydrolyzed, whereas **2a** was hydrolyzed to an extent of 48%. Prolonging the reaction time did not improve the conversion (49% after 2 h), indicating that, as with **1a–c**, only the L enantiomer of **2a** was hydrolyzed.[6,7] This was confirmed by gas chromatography on the chiral phase Lipodex D of a doubly derivatized *N*-methylalanine (*N*-methyl-*N*-trifluoroacetylalanine methyl ester) obtained from **2a**. The reaction product was identified as *N*-methyl-L-alanine (L-**3a**, *ee* ≥ 89%). We therefore synthesized further precursors **2** to test their reaction with this acylase.

The enzyme hydrolyzes **2a–c** with high activity (Table 2); for instance, **2a** is converted faster than **1a**, which is considered to be one of the best substrates.[6,7] With increasing length of the *N*-alkyl residue (**2a–c**), and of the alkyl residue of the amino acid side chain at the α-carbon atom (see **2a**, **d**, **f** and **2b**, **e**, **g**), the activity decreases. Alkyl substituents in α position of a chain length of more than two C atoms (**2f–h**) or branched residues (L-**2k**, **l**) cause a total loss of activity. In these cases the substituents apparently block access to the active site of the enzyme. The crucial influence on activity stems from the substituents on the α carbon: a proton, an alkyl group, and a carboxy group are essential substituents, since *N*-acetyl-*N*-methylglycine **2i** and **2j** are not hydrolyzed; the necessity for a free carboxy group in α-position has already been shown[6,7] and confirmed.[9]

Table 2. Substrate specificity of the *N*-acyl-L-proline-acylase relative to *N*-acyl-*N*-alkylamino acids **2**. The reaction conditions are described in the legend of Figure 1.

Substrate (20 mM)	Relative Activity	Conversion [%]
L-**1a** [b]	100	100
L-**2a**	175	100
2a	115	49
2b [c]	82	–
2c [c]	27	–
2d	10	50
2e [c]	2	–

[a] **2f-2j**, L-**2k**, and L-**2l** were not hydrolyzed. [b] L-**1a**: relative activity ≡ 100. [c] These compounds were also hydrolyzed chemically under the same reaction conditions. For this reason the conversion for the enzymatic reactions could not be determined. The enzyme activity was determined by the difference between runs with and without enzyme.

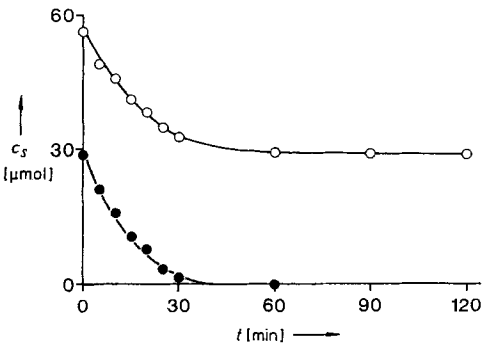


Fig. 1. Kinetics of the hydrolysis of L-**2a** (●) and **2a** (○). The reaction mixture (3 mL) contained 0.3 mmol of Tris-HCl (pH = 7), 30 or 60 μmol respectively of substrate, and 0.23 U of purified *N*-acyl-L-proline-acylase from *Comamonas testosteroni* DSM 5416. The specific activity of the purified enzyme with *N*-acetyl-L-proline as substrate was 115 U mg^{-1} at 30 °C and pH = 7.0. The unit U represents the amount of enzyme that catalyzes 1 μmol of L-proline per minute, and was determined by ninhydrin detection of the product L-proline according to Yaron and Mlynar [10]. The samples were incubated at 30 °C and the reaction stopped at predetermined times by the addition of an aliquot of 2 N HCl. The precipitated protein was separated by centrifugation at 11 000 rpm for 10 min, the supernatant diluted 1:50 with HPLC eluent (7% (v/v) acetonitrile in 0.01 M sodium heptanesulfonate/phosphoric acid, pH = 2.2), and L-**2a** and **2a** were determined quantitatively by HPLC over an RP-8 column with the same eluent at a flowrate of 1 mL min^{-1} at λ = 210 nm. c_s = substrate concentration.

These compounds were also hydrolyzed chemically under the same reaction conditions. For this reason the conversion for the enzymatic reactions could not be determined. The enzyme activity was determined by the difference between runs with and without enzyme.

Because of the substrate specificity of the hitherto known aminoacylases,[5,8] a gap existed in the acylase-catalyzed synthesis of enantiomerically pure *N*-alkyl-L-amino acids L-**3** from the appropriate *N*-acylated racemic precursors **2**, which we are able for the first time to close with this reaction. The substrate spectrum of the enzyme is restricted, but it should be possible by microbiological screening to isolate similar aminoacylases with a broader substrate spectrum, thereby opening the door to enzyme-catalyzed preparation of *N*-alkylamino acids **3** even wider.

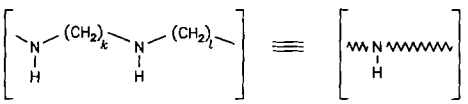
Threading Cyclodextrin Rings on Polymer Chains**

By *Gerhard Wenz** and *Bruno Keller*

The ability of cyclodextrins like α-cyclodextrin (**1a**) and β-cyclodextrin (**1b**) to include smaller guest molecules has been the subject of numerous investigations[1] since Cramer's extensive work in this area.[2] Depending on its ring size, a cyclodextrin molecule has room for one or two guest molecules;[3] if the guest is long enough, one or two cyclodextrin rings may be threaded along it.[4] The stringing of *many* cyclodextrin rings on a polymer chain has never been unequivocally proven.

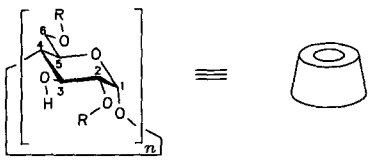
We report here the first threading of cyclodextrin rings on poly(iminooligomethylene)s. Since the resulting polymeric inclusion compounds are highly soluble in water, the kinetics of the threading and unthreading could be examined for the first time. The structure of these polymeric inclusion compounds could be clearly proven by their conversion to polyrotaxanes.[5]

Poly(iminoundecamethylene) **2a** and poly(iminotrimethylene-iminodecamethylene) **2b** were obtained in almost quantitative yields by reductions of poly(11-undecaneamide) and poly(trimethylenedecanediamide) with $BH_3 \cdot Me_2S$.[6] Polymers **2a** and **2b** are soluble in water at pH values < 6. No indication of aggregation was observed for solutions with sufficient ion strength.[7] The degree of polymerization for **2a** was $P_n = 43 \pm 5$ (number average); for **2b**, $P_n = 23 \pm 2$ and $P_w = 60 \pm 12$ (weight average).[8]



2a $k=l=11$
2b $k=10$, $l=3$

The reactions of the polymeric guest molecules **2a** and **2b** with hosts **1a** and heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (**1c**) were conducted under homogeneous conditions[7] and could thus be followed by ^1H NMR spectroscopy and viscometry. The ^1H NMR spectrum of a mixture of **1a** and **2a**[7] differs distinctly from the spectra of the individual components (Fig. 1a–c). The signal at $\delta = 3.95$ attributed to



1a $n=6$, R=H
1b $n=7$, R=H
1c $n=7$, R=Me

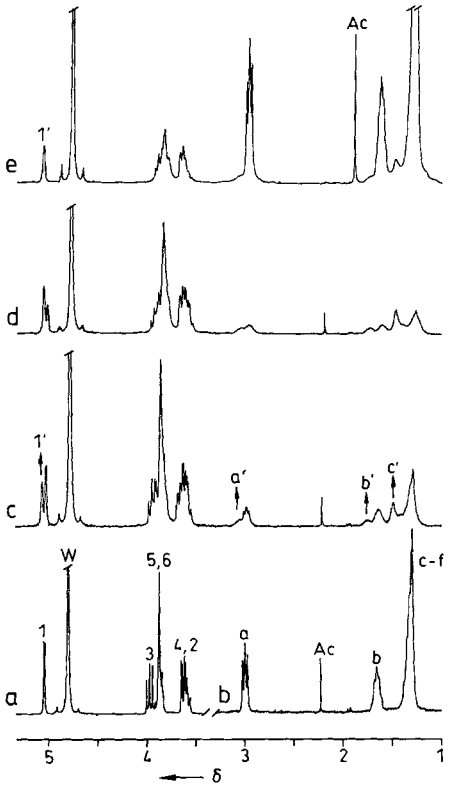


Fig. 1. Part of the ^1H NMR spectra at 20° for a) **1a**, b) **2a**, c) 45 mM **1a** + 45 mM **2a** after 5 min, d) 45 mM **1a** + 45 mM **2a** after 3.5 h, e) **4a**[7]; W = water, Ac = acetate.

Ackermannweg 10, D-W-6500 Mainz 1 (FRG)

[**] This research was supported by the Bundesminister für Forschung und Technologie (BEO 0319055A), Henkel KGaA, and Wacker-Chemie GmbH. We thank B. Müller for the light-scattering measurements, A. Kühn for GPC measurements, and Prof. Dr. G. Wegner for helpful discussions.

a hydrogen in the cavity (H-3) vanishes, while a new signal at $\delta = 3.85$ arises. Similarly the signal of H-1 is shifted from $\delta = 5.04$ to $\delta = 5.08$. This shift could be attributed to conformational changes in **1a** upon inclusion. In addition, new signals at $\delta = 3.10, 1.75$, and 1.50 show up and are attributed to included **2a** (H-a', H-b', and H-c', respectively).

The observed downfield shifts of ^{1}H NMR signals of the guest molecule upon inclusion are not unusual.[9] It is more surprising that the chemical shifts of these new signals do not depend on the concentrations of **1a** and **2a**. In general the inclusion of low-molecular-weight guests is revealed by the continuous shift of the signals of one component upon variation of the concentration of the other due to signal averaging.[10] Since this averaged signal is not seen in the reaction of **1a** with **2a**, the individual inclusion steps must be slow on the NMR time scale. Averaged NMR signals were also not observed for the inclusion of α,ω-bis(1-pyridinium)alkanes in **1a**. This was attributed to the steric hindrance of the bulky cationic end-groups.[9] In our case the cationic ammonium groups (at pH 4.6) apparently also present steric barriers for the host molecules. Even more surprising is the change in the ^{1}H NMR spectra of **1a** with **2a** or **2b** over time. The spectrum of the system **1a** + **2a** is stable after 1.5 h (Fig. 1d);[11] that of **1a** + **2b**, after 170 h.

Viscosity measurements[7] also provide support for the slow equilibration (Fig. 2). System **1a** + **2a** has a constant viscosity after 2 h;[11] **1a** + **2b**, after 210 h. In comparison, the reaction of the larger host **1c** with **2a** or **2b** is complete after the mere mixing of the components.

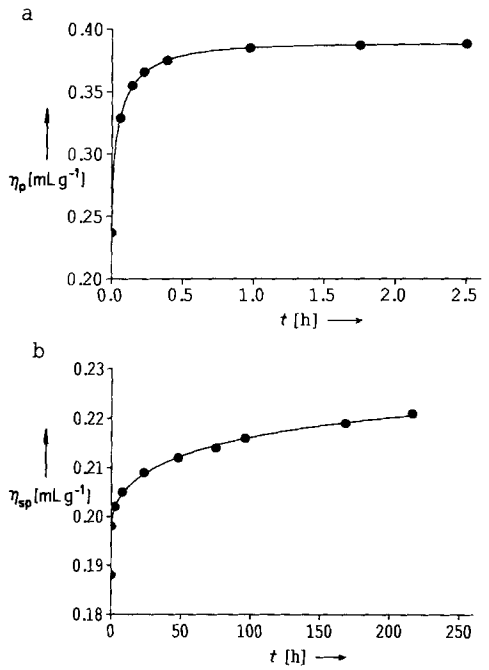

Fig. 2. Specific viscosity η_{sp} at 25° for a) 11.8 mM **1a** + 11.8 mM **2a** and b) 9.5 mM **1a** + 9.5 mM **2b** as a function of time t.

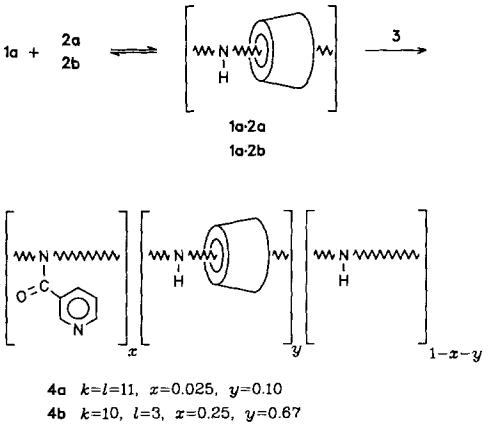
The extremely long reaction times of **1a** with **2a** and **2b** implies a mode of inclusion in which the rings are strung on the polymer chain, since each individual ring molecule must find a chain end in order to be threaded. Once strung along the polymer chain the rings must move towards the middle of the chain to make room for the next rings.

The formation of the polymeric inclusion compounds **1a** · **2a** and **1a** · **2b** according to Scheme 1 should be an



4a $k=l=11$, $x=0.025$, $y=0.10$
4b $k=10$, $l=3$, $x=0.25$, $y=0.67$

Scheme 1.

equilibrium reaction analogous to the formation of monomeric ones. Thus the continuous removal of **1a** from the equilibrium mixture should lead to the dissociation of **1a** · **2a** and **1a** · **2b**. In order to observe this dissociation we removed **1a** from the equilibrium mixture by dialysis.[12] The total concentration of cyclodextrin was determined by optical rotation measurements (Fig. 3). Although the dialysis of free **1a** was complete after 1.3 h,[13] the dialysis of the equilibrium mixture of **1a** · **2a** proceeded much more slowly after a fast initial period. This fast rate at the onset is due to excess **1a**, the slow progression thereafter, due to the slow dissociation of **1a** · **2a**. The unthreading of all the rings takes 15 h for **1a** · **2a**;[13] this process is far from complete after two weeks for **1a** · **2b**.

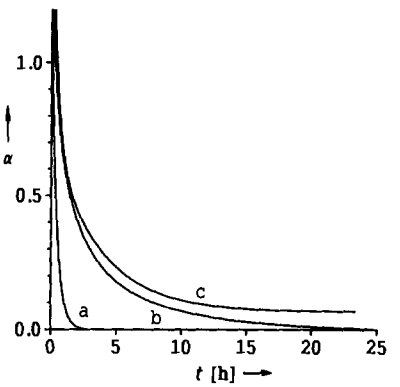


Fig. 3. Dialysis experiments[12]: Optical rotation α as a function of time t for a) 11.8 mM **1a**, b) the polymeric inclusion compound **1a** · **2a** from 23 mM **1a** and 15.4 mM **2a**, and c) the crude polyrotaxane **4a** from 23 mM **1a** and 15.4 mM **2a** after reaction with nicotinoyl chloride.

The low rates of formation and dissociation of these polymeric inclusion compounds and the marked dependence on the structures of the host and guest molecules may be indications for the threading but do not provide conclusive proof. Complex equilibria could also exist for nonspecific aggregates of host and guest molecules. By closing the polymer chain, however, one should be able to differentiate between the threaded and aggregated host molecules. Threaded rings become permanently bound upon closure of the chain; rings simply attached along the chain do not.

To completely close a polymeric inclusion compound, two bulky substituents must be attached to the ends of the chain. The attachment of at least two "blocking groups" at arbitrary positions on the chain would prevent unthreading

along a part of the chain and would be much easier to carry out. The nicotinoyl group was chosen as a blocking group since it is sufficiently hydrophilic. After the reaction of nicotinoyl chloride · HCl **3** with **1a** · **2b** the reaction mixture was dialyzed. The optical rotation of the mixture did not approach zero but rather stabilized at 0.065° (Fig. 3). Thus permanently bound α-cyclodextrin is present in product **4a**. The integration of the signals of the ^{1}H NMR spectrum of **4a** (Fig. 1d) indicates a concentration of 10 mol% cyclodextrin and 2.5 mol% nicotinoyl groups. The absence of the signal at $\delta = 5.04$ indicates that all the α-cyclodextrin units are threaded. All the cyclodextrin signals are sharp and identical to those of **1a** · **2a**. Since the structure of these rings is retained and since the rings are bound permanently, we believe that **4a** is a polyrotaxane.

Only those rings on the chain between the two blocking groups remain threaded. The probability of finding at least two blocking groups on *one* chain increases with the conversion x of the blocking reaction. Thus the relative amount y of permanently bound rings should increase with x. This is the case. From the reaction of **1a** · **2b** with **3** polyrotaxane **4b** is obtained in 43% yield with $x = 25$ mol% blocking groups and $y = 67$ mol% cyclodextrin rings per basic unit. The molecular mass of **4b**[7] $M_w = 55000 \pm 5000$ g mol^{-1} was found by light scattering; this corresponds to a degree of polymerization $P_w = 55 \pm 5$, in good agreement with that of **2b** ($P_w = 60 \pm 12$). Thus 37 cyclodextrin rings are permanently threaded in **4b**. By this synthesis of polyrotaxanes **4a** and **4b** we demonstrate not only the threading of rings **1a** on the chains **2a** and **2b** but also a promising new approach to polyrotaxanes.

Experimental Procedure

2a: Reprecipitated[6] Nylon 11 (6.0 g, 32.8 mmol, Aldrich) was suspended in dry THF (100 mL) and heated to reflux under inert gas. A 2 M solution of $BH_3 \cdot Me_2S$ in THF (55 mL, 110 mmol, Aldrich) was added dropwise over 1 h. The reaction mixture was heated 1 d at reflux. The THF was distilled off, water (100 mL) added, and the mixture heated at reflux 1 h. The reaction mixture was allowed to cool to 20° and glacial acetic acid (60 mL) was added. The mixture was stirred 1 h at room temperature and heated 3 h at reflux. The cooled solution was added dropwise to a 10% NaOH solution (2 L). The precipitate was removed by filtration, washed with water, dried in vacuum, and extracted with $CHCl_3$ in a Soxhlet apparatus. The extract was added dropwise to diethyl ether (1 L). Polymer **2a** precipitated and was filtered and dried in vacuum. Yield 5.2 g (94%), white powder, m.p. = 108°; Elemental analysis: C 78.03, H 13.56, N 8.38; calculated for $C_{11}H_{23}N$: C 78.03, H 13.69, N 8.27; Viscometry[7] (using Huggins' plot of the specific viscosity): $[\eta] = 91.7$ mL g^{-1}, $k_H = 0.28$; ^{1}H NMR (300 MHz, HOD)[7]: $\delta = 1.29$ (m, 14H; H-c to H-f), 1.65 (m, 4H; H-b), 3.00 (t, ^3J(H,H) = 7.8 Hz, 4H; H-a); ^{13}C NMR (75.46 MHz, $CDCl_3$, TMS): $\delta = 27.4$ (C-c), 29.6 (C-d, e, f), 30.2 (C-b), 50.2 (C-a); IR ($CHCl_3$-film): $\tilde{\nu}$ [cm^{-1}] = 3273 (N-H), 2920 (C-H), 1463 (C-H), 1128 (C-N).

2b: Poly(trimethylenedecanediamide)[14] (6.0 g) was converted to **2b** in an analogous manner to the preparation of **2a** from Nylon 11. Yield 5.04 g (95%), white powder, m.p. = 86 °C; Elemental analysis C 73.40, H 13.05, N 12.91, calculated for $C_{13}H_{28}N$: C 73.52, H 13.29, N 13.19; Viscometry (see **2a**): $[\eta] = 81.8$ mL g^{-1}, $k_H = 0.18$; ^{1}H NMR (HOD)[7]: $\delta = 1.30$ (m, 12H; H-c bis H-e), 1.66 (m, 4H; H-b), 2.09 (m, 2H; H-B), 3.03 (t, ^3J(H,H) = 7.7 Hz, 4H; H-a), 3.11 (t, ^3J(H,H) = 7.9 Hz, 4H; H-A); ^{13}C NMR ($CDCl_3$, TMS): $\delta = 27.4$ (C-c), 29.6 (C-d, e), 30.2 (C-b), 30.5 (C-B), 48.6 (C-A), 50.2 (C-a); IR ($CHCl_3$ film): $\tilde{\nu}$ [cm^{-1}] = 3260 (N-H), 2919 (C-H), 1467 (C-H), 1129 (C-N).

4a: Polymer **2a** (0.13 g, 0.77 mmol) and **1a** (1.12 g, 1.16 mmol) were dissolved in buffer[7] (20 mL). The solution was stirred at 20° for 24 h. The pH of the solution was adjusted to 6.3 with $NaHCO_3$, and **3** (0.286 g, 1.6 mmol, Aldrich) was added in small portions. During this addition the pH of the solution was held between 5.7 and 6.4 by further addition of $NaHCO_3$. After 16 h the solution was diluted to 50 mL and dialyzed with 2% acetic acid (24 h) until the optical rotation remained constant and with water (2 h) [12]. The product was then freeze-dried. Yield: 0.148 g (71%), white solid; Elemental analysis: C 63.23, H 10.38, N 4.99, calculated for $(C_{11}H_{23}N)_1(C_{36}H_{60}O_{30})_{0.1}$-$(C_6H_4NO)_{0.025}(C_2H_4O)_{0.5}$: C 63.21, H 10.47, N 4.80; 1H NMR (HOD)[7]: $\delta = 1.30$ (m, 13.6H; H-c to H-f), 1.50 (m, 0.4H; H-c'), 1.65 (m, 3.6H; H-b), 1.75 (m, 0.4H; H-b'), 1.95 (s, 1.5H; acetate), 3.00 (t, ^3J(H,H) = 7.7 Hz, 3.6 H; H-a), 3.10 (m, 0.4 H; H-a'), 3.67 (m, 1.2H; H-2', H-4'), 3.85 (m, 1.8H; H-3', H-5', H-6'), 5.09 (m, 0.6H; H-1'), 7.6, 8.0, 8.6 (3m, 0.1H; nic.).

4b: Polymer **2b** (0.29 g, 1.37 mmol) and cyclodextrin **1a** (4 g, 4.1 mmol) were added to a buffer solution[7] (20 mL) and stirred at 20° for 14 d. Compound **3** (0.79 g, 4.4 mmol) was added in small portions and the pH of the solution was maintained between 5 and 7 by addition of 5 M KOH. After 16 h the reaction was worked up analogously to that leading to **4a**. Yield: 0.565 g (43%), white solid; Elemental analysis C 48.94, H 7.43, N 3.11, calculated for $(C_{13}H_{28}N_2)_1$-$(C_{36}H_{60}O_{30})_{0.67}(C_6H_4NO)_{0.25}(C_6H_4O)_2$: C 50.65%, H 7.70%, N 3.12%; ^{1}H NMR (HOD)[7]: $\delta = 1.29$, 1.50, 1.65, 1.75 (4m, 16H; H-b', H-c', H-b to H-e), 1.95 (s, 6H; acetat), 2.08 (m, 2H; H-B), 3.00, 3.10 (2m, 5.6H; H-a, H-A, H-a'), 3.2–3.5 (m, 2H; $-CH_2-NR-C=O$), 3.67 (m, 8H; H-2', H-4'), 3.86 (m, 12H; H-3', H-5', H-6'), 5.09 (m, 4H; H-1'), 7.60 (m, 0.25H; nic.), 7.95 (m, 0.25H; nic.), 8.62 (m, 0.5H; nic.). nic. = nicotinoyl.

Selectivity Control By Temperature Variation in the Formation of Isotactic vs. Syndiotactic Polypropylene with a Titanocene/Alumoxane Catalyst**

By *Gerhard Erker** and *Cornelia Fritze*

The syndioselective polymerization of α-olefins with vanadium catalysts probably proceeds by a different mechanism (2-1 insertion) than with Ziegler catalysts.[1] A few homogeneous catalyst systems based on the group 4 metallocenes, which direct the usual mode of polymerization (1-2 insertion), have led to the production of syndiotactic polypropylene as well.[2] In the past the few exceptional cases of syn-

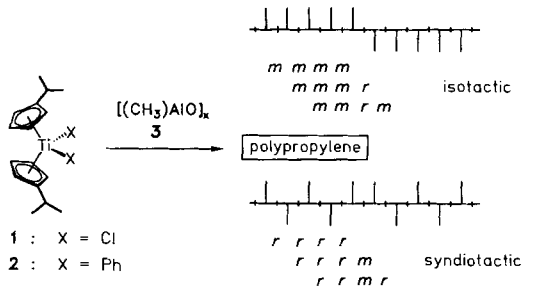
dioselective propylene-polymerizations by catalysts that usually deliver isotactic polypropylene have been explained by special structure/selectivity relationships. However, it was often not adequately considered that the selectivity of two competing processes may be temperature-dependent. Only when the influence of the reaction temperature has been determined is the discussion of the relationship between the structure of the catalyst system and the resulting selectivities meaningful.

For this study we have used homogeneous titanocene/alumoxane propylene-polymerization catalysts derived from achiral bent-metallocene complexes. The stereocontrol of the C–C bond formation is controlled here by the chiral end of the growing polymer-chain at the active metal-center alone (chain-end control).[3] We have found an example in which the change of the dominant mode of block polymerization from isotactic to syndiotactic can be accomplished by simply varying the reaction temperature.

We treated isopropylcyclopentadienyllithium with 0.5 mole equivalents of $TiCl_4$ to obtain $[(C_5H_4iPr)_2TiCl_2]$ **1**. The reaction of **1** with two mole equivalents of PhLi in ether provided $[(C_5H_4iPr)_2TiPh_2]$ **2**. The activation of **2** with a large excess of methylalumoxane **3** in toluene/propylene (5:1) at −50 °C furnished an active homogeneous Ziegler catalyst for propylene polymerization (Scheme 1).[4] The isotactic block-polymer obtained was similar to the product of propylene polymerization with $[Cp_2TiPh_2]$/**3** according to Ewen.[3] Polymerization with the system **2**/**3** at −50 °C provided a polypropylene PP1 ($\bar{M}_\eta \approx 16000$), which was stereochemically characterized by a statistical analysis of the ^{13}C NMR methyl signals (pentade analysis). In addition to the dominant isotactic *mmmm* pentade signal, resonances arising from *mmmr* and *mmrm* units in a 1:1 intensity ratio were found (Fig. 1). This characterizes the structural defects of the stereoregular polymer (isotactic block-polymer, see Scheme 1) as resulting from chain-end control. A randomly occuring mistake was not corrected, but rather propagated until another "erroneous" insertion of the prochiral olefin into the growing chain occurred.



Scheme 1.

The intensity distribution of the ten ^{13}C pentade signals of PP1 can be described satisfactorily by Bernoulli statistics. The decisive statistical factor σ describes the probability of the formation of a *meso*-type dyad (*m*) upon the incorporation of a propylene monomer by formal insertion in the metal–carbon bond at the active catalytic center. For pure chain-end control the three possible limiting situations can be correctly described by this single statistical parameter (isotactic: $\sigma = 1$; atactic: $\sigma = 0.5$; syndiotactic: $\sigma = 0$). The polypropylene PP1 formed by **2**/**3** at −50 °C has $\sigma = 0.80$; this corresponds to an average isotactic block length $[\langle m \rangle_{n,\sigma} = (1-\sigma)^{-1}]$ of about five monomer units.[5]

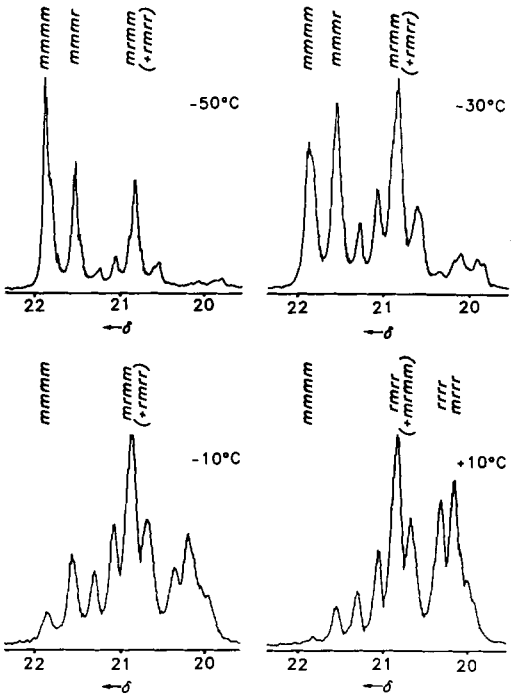


Fig. 1. ^{13}C NMR spectra (methylpentades) of polypropylenes (PP1–PP4) obtained from the **2**/**3** catalyst system at −50, −30, −10, and +10 °C.

As expected, polymerization with the catalyst system **2**/**3** at −30 °C provided a less isotactic polypropylene (PP2: $\sigma = 0.69$, see Table 1). At −10 °C an almost atactic polymer was obtained (PP3: $\sigma = 0.48$). This trend towards smaller σ values continued with increasing temperature. At +10 °C slightly syndiotactic polypropylene was produced (PP4: $\sigma = 0.39$, $\bar{M}_\eta \approx 12000$). This became further evident by the almost complete absence of the *mmmm* resonance signal in the methyl region of the ^{13}C NMR spectrum (Fig. 1). Moreover, the intensity of the *rrrr* signal is markedly increased. The ratio of the intensities of the *rrrm* and *rrmr* signals is nearly 1:1 as is expected for an appreciably syndiotactic block-polymer (Scheme 1). The average syndiotactic block-length of PP4 is estimated at about three monomer units.

In the temperature-dependent crossover from the production of isotactic to syndiotactic polypropylene the overall reaction mechanism does not basically change. The mechanistic uniformity of this reaction system becomes apparent upon plotting the logarithm of the quotient of σ ($\triangleq$ probabilty of the formation of the "isotactic" *m* dyad) and $(1-\sigma)$ ($\triangleq$ probability of the formation of the "syndiotactic" *r* dyad) versus T^{-1}. For the experimentally accessible range of

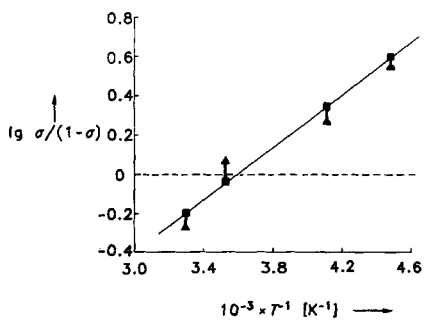

Fig. 2. Arrhenius plot of the stereoselective production of polypropylene. Catalysts: ■ **2**/**3**, ▲ **1**/**3**.

temperatures (-50 to $+10\,^{\circ}C$) the Arrhenius plot provides a straight line (Fig 2).[6]

We have tested the competition constants $\sigma(1-s)^{-1}$ obtained at these four temperatures independently by means of a second access to the same catalytically active species. An active propylene-polymerization catalyst is obtained from **1** and excess **3**. Although the activities of this system differ from those of the catalyst system **2/3**, the selectivities are almost the same (Table 1). The good agreement of the results of the two independent measurements (**1/3** and **2/3**) (Fig. 2) shows that the temperature-dependent competition constants $k_{isotact} \times (k_{syndiotact})^{-1}$ determined by this necessarily indirect procedure are quite reliable.

Table 1. Comparison of selected parameters of the propylene polymerization with the metallocene/methylalumoxane catalysts from **1** (PP1–PP4) and **2** (PP1′–PP4′).

PP	1	1′	2	2′	3	3′	4	4′

[a] Activity in g[PP] g[titanium complex]$^{-1}$ h^{-1}.

How can one explain the temperature-dependent change in the formation of isotactic and syndiotactic polypropylene in a reasonably simple uniform mechanistic picture? According to the widely accepted mechanistic description of the stereoselective propylene-polymerization with homogeneous metallocene/alumoxane catalysts,[7] the α-olefin adds to a catalytically active alkylmetallocenyl cation[8] in such a way that the alkyl group of the α-olefin (CH_3) and the α substituent of the alkyl group (P = polymer chain) α-bound to the metallocene are oriented *trans* to each other (intermediate **4** in Scheme 2). (An α-agostic interaction[7a,d] could induce an effective transfer of chirality from the polymer chain to the reactive center). If the 1-2 insertion at the titanocenyl cation follows the usual rules for nucleophilic additions to prochiral sp^2 carbon centers, then it can be assumed that the olefin will rotate to minimize the steric interactions during the C–C bond formation.[9] Competing intermediates **5** (*anti* orientation of CH_3 and P) and **6** (CH_3 and P *gauche* to each other) may thus arise. From **5** C–C bond formation with concomitant switching of the coordination site of the σ-bound hydrocarbon ligand at $[(RCp)_2Ti]^+$ leads to a conformer to which the next addition of olefin can occur with the same relative topicity as in the formation of **4** (*re*, *re* in Scheme 2). This leads to isotactic polypropylene. In contrast the analogous process starting from **6** leads directly to a conformer to which the addition of the olefin proceeds with opposite topicity (*si* following *re* in Scheme 2), thus now favoring the formation of the syndiotactic polymer.[10]

The formal mathematical analysis of the Arrhenius plot of this reaction system (Fig. 2) yields differences in the activation parameters of the two competing pathways of $\Delta\Delta H^{\ddagger} = 2.9 \pm 0.1$ kcal mol^{-1} and $\Delta\Delta S^{\ddagger} = -11 \pm 1$ cal mol^{-1}K^{-1}. The polymerization of propylene with the bis(isopropylcyclopentadienyl)titanium/alumoxane catalyst system is thus probably another example of the counteracting influences of the activation enthalpy and entropy sometimes observed for very fast reactions. In this case the competing pathway exhibiting the less negative activation entropy can dominate over the enthalpically favored alternative at sufficiently elevated temperature.[6]

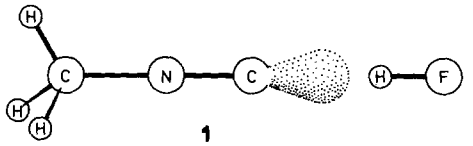
[10] In preliminary experiments the corresponding Arrhenius plots were determined for the polypropylene production with metallocene/alumoxane catalysts based on $[Cp_2TiCl_2]/[Cp_2TiPh_2]$; $[(C_5H_4Me)_2TiCl_2]/[(C_5H_4Me)_2TiPh_2]$; and $[(C_5H_4tBu)_2TiCl_2]/[C_5H_4tBu)_2TiPh_2]$. In all cases a more complicated picture emerged. Plots of $\lg \sigma(1-\sigma)^{-1}$ versus T^{-1} yields in each case two linear regions with differing slopes. According to Scharf and Pracejus[6] one can assume that a second level of stereoselection is kinetically significant here. In the proposed reaction (Scheme 2) this could be the primary step, i.e. the (reversible) addition of the prochiral olefin to the electrophilic metal center.

Observation and Properties of a Hydrogen Bond to Carbon in a Short-Lived, Gas-Phase Complex of Methyl Isocyanide and Hydrogen Fluoride**

By *A. C. Legon,* D. G. Lister*, and *H. E. Warner*

We report here the rotational spectrum of a short-lived $CH_3NC\cdots HF$ complex with C_{3v} symmetry frozen on the 10 μs timescale in a coaxial, pulsed supersonic expansion of CH_3NC/Ar and HF/Ar mixtures. This is the first characterization of a hydrogen bond to an isocyanide group in the gas phase.

Hydrogen bonds can form either by interaction with a nonbonding (n) electron pair on a terminal atom of a proton acceptor B or with a π-bonding electron pair on B. Such bonds involving the π-electron density between carbon atoms have been characterized extensively, first in solution[1, 2] through shifts $\Delta\nu_{OH}$ in the OH stretching frequencies of $\pi\cdots HO$ and pseudo-$\pi\cdots HO$ systems and then in the gas phase in ethyne$\cdots$HCl,[3] ethene$\cdots$HCl,[4] and cyclopropane$\cdots$HCl[5] by rotational spectroscopy. Hydrogen bonds to n electron pairs on terminal carbon atoms are less common. Isocyanides were first shown to form hydrogen bonds with suitable donors by infrared and NMR spectroscopy in solution.[6, 7] Consideration of the electronic structure $-\overset{+}{N}\equiv\overset{-}{C}$ of the isocyanide group[6, 7] suggested that bonding to carbon rather than nitrogen is favored, but the solution-phase work did not provide information regarding geometry. Some recently proposed empirical rules,[8] successful in rationalizing the angular geometries of a wide range of hydrogen-bonded dimers $B\cdots HX$, predict that the hydrogen bond in, for example, methyl isocyanide–hydrogen fluoride (**1**) should be to the nonbonding (n) electron pair localized on the C atom rather than to one of the π-electron pairs in the NC triple bond, and that at equilibrium the HF molecule should lie along the axis of the n electron pair as envisaged in the conventional model (**1**). Indeed, in a corollary to the rules,[9] it is proposed that the molecular axis of HF in dimers $B\cdots HF$ may be used as a probe of the direction of the n electron pair. The rules are based on investigations by rotational spectroscopy which normally provide[10] unequivocal answers to the question of the binding site and yield the angular geometries and further quantitative properties of hydrogen-bonded dimers in effective isolation.



1

A difficulty arises when one attempts to apply these rules to complexes of isocyanides with acids HX, the obvious model systems for a hydrogen bond to carbon. Rapid addition reactions of anhydrous hydrogen halides (X = Cl, Br, I) to isocyanides have been reported.[11] The rapid reaction of CH_3NC with HF was demonstrated by monitoring the gas mixture with infrared spectroscopy,[12] and we have confirmed recently that on mixing gaseous CH_3NC and HF there is a virtually instantaneous precipitation on the vessel walls. The problem of high reactivity can be overcome, however, by using a fast mixing nozzle in conjunction with Fourier-transform microwave spectroscopy.[13] The essence of the method is to keep the components separate until they expand into the Fabry–Pérot cavity of the spectrometer. Any short-lived complexes of CH_3NC and HF formed on mixing are frozen on the ca. 10 μs timescale in the collisionless phase of the supersonic expansion. These species can then be probed, identified, and their properties obtained from the rotational spectrum.

The complex $CH_3NC\cdots HF$ was formed by coaxially mixing a pulsed jet of CH_3NC/Ar with a continuous jet of HF/Ar. Frequencies of transitions attributed to the ground-state rotational spectrum of $CH_3NC\cdots HF$ accurately obeyed the symmetric-top expression [Eq.(a)]. The observed frequencies, the residuals of their least-squares fit by Equation (a), and the rotational constant B_0 and the centrifugal distortion constants D_J and D_{JK} determined from this expression are recorded in Table 1 together with the corresponding data for the isotopomer $CH_3NC\cdots DF$. Transitions from levels with $K \geq 2$ had an unobservable intensity because of the low effective temperature of the expansion. In $K = 0$ transitions there was little evidence of hyperfine splitting due to ^{14}N nuclear quadrupole and H,F nuclear spin–nuclear spin coupling, and only a suggestion of these effects was seen in $K = 1$ transitions (Fig. 1). Model calculations made by assuming unchanged ^{14}N nuclear quadrupole[14] and H,F spin–spin

$$\nu = 2B_0(J+1) - 4D_J(J+1)^3 - 2D_{JK}K^2(J+1) \qquad \text{(a)}$$

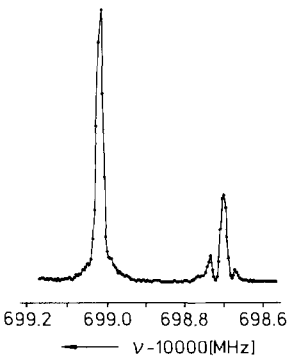

Fig. 1. Frequency spectrum of the $J = 3 \leftarrow 2\, K = 0$ and $K = 1$ transitions of $CH_3NC \cdots HF$ in the range of 10698.6 to 1069 MHz. This power spectrum was obtained by averaging 1003 gas pulses over a period of eight minutes. The data points are separated by 3.90625 kHz and have been joined by straight lines. No Doppler doubling effect is seen when the fast mixing nozzle is used. Partial resolution of hyperfine structure is apparent on the $K = 1$ transition centerd at 10698.71 MHz (see text).

coupling[15] constants from the free molecules CH_3NC and HF predict a very complicated hyperfine structure for the $J = 3 \leftarrow 2$, $K = 0$ transition, for example, with two-thirds of the intensity of the many components falling within ± 10 kHz of the unperturbed frequency. This is consistent with the observed full width at half height of approximately 20 kHz (see Fig. 1). The partial resolution for the $K = 1$ component seen in the spectrum is also as predicted but is too complicated to analyse.

The spectrum is characteristic of a symmetric top and establishes that the complex has C_{3v} symmetry. The magnitude of the change ΔB_0 in B_0 on D/H substitution is consistent only with the order of the nuclei $CNC \cdots HF$ along the symmetry axis and establishes that the intermolecular link is through a hydrogen bond to carbon as in **1**. The model geometry $CH_3NC \cdots HF$ with $r(C \cdots F) = 2.840$ Å proposed below predicts a value $\Delta B_{calc} = 22.5$ MHz, in excellent agreement with $\Delta B_0 = 22.6$ MHz. The other possible C_{3v} complex, $CH_3NC \cdots FH$, would require $r(C \cdots F) = 2.828$ Å and $\Delta B_{calc} = 77.9$ MHz, however. Quantitative properties of $CH_3NC \cdots HF$ are also available from the spectroscopic constants in Table 1.

Table 1. Observed and calculated rotational transition frequencies and spectroscopic constants of $CH_3NC \cdots H(D)F$ in the ground state.

		$CH_3NC \cdots HF$		$CH_3NC \cdots DF$	
$J+1 \leftarrow J$	K	ν_{obs} [MHz]	$\Delta\nu$ [kHz] [a]	ν_{obs} [MHz]	$\Delta\nu$ [kHz] [a]
$2 \leftarrow 1$	0	7132.7013	−1.6	7042.2509	−0.2
	1	7132.5025	0.5	–	–
$3 \leftarrow 2$	0	10699.0043	−0.6	10563.3268	−2.1
	1	10698.7054	1.9	10563.0430	2.3
$4 \leftarrow 3$	0	14265.2488	1.3	14084.3512	1.7
	1	14264.8440	−1.7	14083.9635	−1.7
		B_0 [MHz] [b]	1783.1823(4)		1760.5691(6)
		D_J [kHz] [b]	0.825(14)		0.795(24)
		D_{JK} [kHz] [b]	50.2(3)		48.0(4)

[a] $\Delta\nu = \nu_{obs} - \nu_{calc}$. [b] Standard errors in units of the least significant digit.

First, the distances $r(C \cdots F) = 2.840$ Å can be obtained by fitting the rotational constant of either $CH_3NC \cdots HF$ or $CH_3NC \cdots DF$. A familiar model[16] is used to allow for the zero-point oscillations of the CH_3NC and HF subunits, assuming the same oscillation amplitudes as those of the isomeric complex $CH_3CN \cdots HF$[16] and the same geometries as those of the monomers.[17–19] The $C \cdots F$ distances obtained should be compared with 2.752 Å ($CH_3CN \cdots HF$) and 2.750 Å ($CH_3CN \cdots DF$).[16] The difference Δr between $r(C \cdots F)$ and $r(N \cdots F)$ of $CH_3NC \cdots HF$ and $CH_3CN \cdots HF$ is apparently a measure of the difference of the van der Waals radii of C and N atoms.[20] The accepted value 1.4 Å for the van der Waals radius of the N atom then allows the estimate of 1.5 Å for the radius of the C atom. Secondly, the hydrogen-bond stretching force constant k_σ can be determined from D_J by Equation (b)[21]

$$k_\sigma = (16\pi^2\mu B^3/D_J)(1 - B/B^{CH_3NC} - B/B^{HF}) \qquad (b)$$

where $\mu = m^{CH_3NC}m^{HF}/(m^{CH_3NC} + m^{HF})$. When ground-state rotational constants B^{CH_3NC}, B^{HF}, and B^{DF} of the monomers are employed[17–19, 22] the resulting values are $k_\sigma = 19.9(3)$ and $20.5(6)$ Nm^{-1} for $CH_3NC \cdots HF$ and $CH_3NC \cdots DF$, virtually the same as for $CH_3CN \cdots H(D)F$.[16] The wavenumbers $\tilde{\nu}_\sigma = (2\pi c)^{-1}(k_\sigma/\mu)^{1/2}$ for the stretching mode σ are correspondingly 158(1) and 158(2) cm^{-1}.

It is possible that the short-lived, hydrogen-bonded C_{3v} complex $CH_3NC \cdots HF$ characterized in this work is the intermediate first formed in the addition reaction of HF to CH_3NC.

Experimental Procedure

Rotational spectra were observed with a Balle–Flygare Fourier-transform microwave spectrometer with a pulsed nozzle.[23, 24] The fast mixing nozzle consisted of a pair of coterminal concentric tubes attached to the outlet of a Series Nine (General Valve Corp.) solenoid valve, as described in detail elsewhere.[13] A mixture of roughly 3% CH_3NC in Ar was pulsed into the outer tube at a rate of about 3 Hz from a pressure of 2 atm and mixed with a continuous flow of 30% HF (Argot International plc) in Ar at a pressure of 1 atm issuing from the exit of the inner tube. Methyl isocyanide was prepared by dehydration of *N*-methylformamide[25] and purified by distillation under reduced pressure. DF was prepared in situ by exchange of HF with D_2O on the walls of the stainless-steel mixing tank.

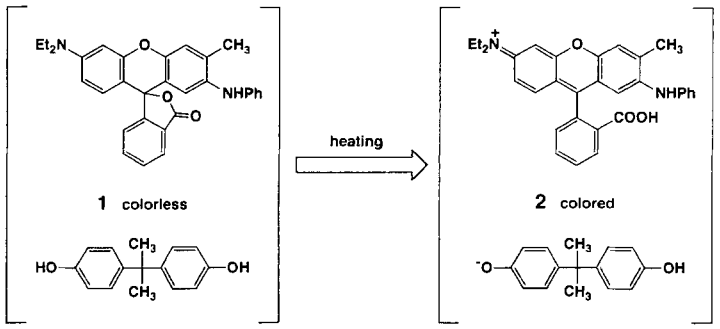
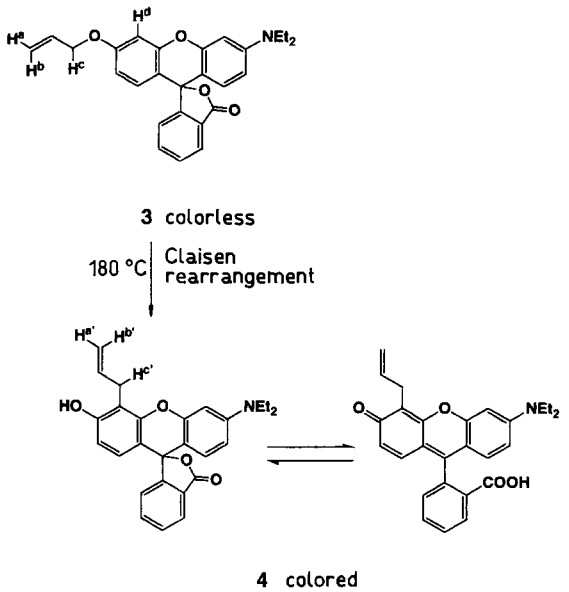
New Thermo-Response Dyes: Coloration by the Claisen Rearrangement and Intramolecular Acid–Base Reaction

By *Masahiko Inouye,* Kikuo Tsuchiya*, and *Teijiro Kitao*

Fluoran dyes have been widely used as pressure- and heat-sensitive dyes for carbonless paper and paper for fax systems, for example.[1] The coloration occurs when the dyes react with acid, normally phenolic compounds, upon heating (Scheme 1). To retain the colorless form before heating, the dyes must be protected from contact with acid. Indeed, this often causes technical problems and restricts the use of organic mediums such as polymer films. Here we introduce a class of purely thermally activated dyes, which color only upon heating without the addition of any other component. Our strategy utilizes the fact that upon heating, neutral allyl aryl ethers generate acidic phenol groups by the Claisen rearrangement.[2] Phenol groups thus generated undergo intramolecular acid–base reaction, which in turn causes the ring-opening of the lactone groups and the coloration (Scheme 2).



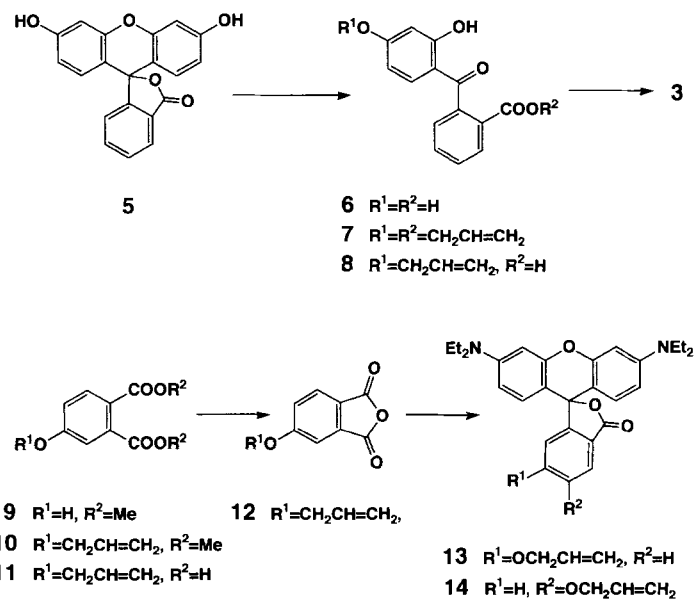
Scheme 1.



Scheme 2.

These new of dyes (**3**, **13**, and **14**), possessing both allyloxy and amino groups, were made in several steps from commercially available starting materials (Scheme 3).

The dyes thus prepared did not absorb above 400 nm in several solvents, indicative of the closed lactone forms. Heating the solutions (ca. 180 °C), however, caused changes in their absorption spectra, and new absorption bands above 400 nm appeared (Fig. 1a). These new absorption bands were attributed to the products of the Claisen rearrangement on the basis of the following NMR and isolation experiments: A solution of **3** in [D_6]dimethyl sulfoxide (DMSO) was heated (ca. 180 °C), and ^{1}H NMR spectra were measured as a function of time. New resonances appeared $\delta = 3.0$ to 5.8, which were attributed to *C*-allyl groups because of their high-field shifts relative to those of *O*-allyl groups (Fig. 1c). In the aromatic region the signal for H^d decreased, showing that the Claisen rearrangement occurred at the position depicted in Scheme 2. Furthermore, after purification by silica-gel column chromatography, the colored product **4** displayed an intense stretching band at 3300–3700 cm^{-1} in the infrared spectrum characteristic of the phenolic OH group.



Scheme 3.

On the other hand, the absorption spectra (DMSO) of **3** and even the conventional acid-sensitive dyes such as **1**, which is a so-called one-dye black, showed no changes in the presence of a large excess of phenolic compound (intermolecular acid–base reaction), because of competitive proton capture with the highly polar solvent. In such cases a strong acid, for example trifluoroacetic acid (CF_3COOH), was needed for coloration.

Our method enabled the use of synthetic resins as solvating mediums for the dyes. Thus a composite film consisting of polymethylmethacrylate (PMMA) (50 wt%) and **3** (50 wt%) was prepared from a toluene/THF (1:1) solution on glass substrates. When the colorless film was heated, a change in the absorption spectra similar to that observed for

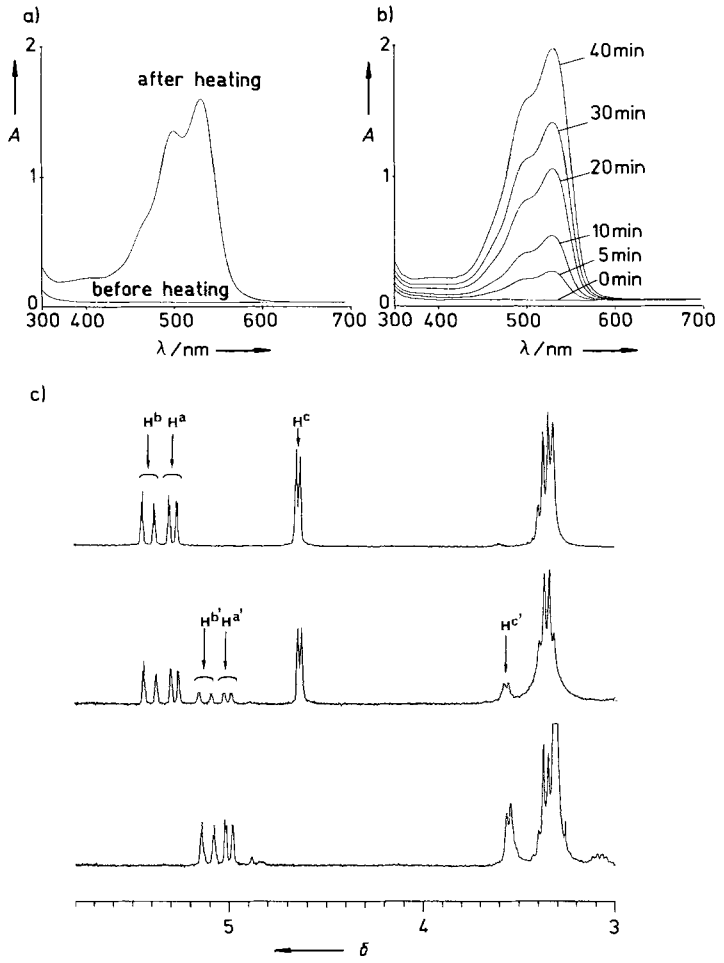

Fig. 1. The electronic absorption spectra of **3** before and after heating a) in DMSO and b) in the PMMA film. The spectra of **13** and **14** in DMSO were similar to that of **3**. **3**: λ_{max} = 530 nm, (ε = 3400) and 500 (ε = 2900); **13**: λ_{max} = 565 nm (ε = 6500); **14**: λ_{max} = 563 nm (ε = 9700). c) ^{1}H NMR spectra of **3** (270 MHz, [D$_6$]DMSO) δ = 3.0–5.8 before heating (top) and after heating for 4 h (middle), and of the isolated product **4** (bottom).

the solution was observed (Fig. 1 b). This colored film (red) is stable; even after more than 7 months in the presence of air its absorption bands did not change.

This new type of thermo-response dye may find several new applications in information-storage and thermally activated recording systems. The design of molecules which possess a lower temperature-response and/or different absorption bands in the colored forms (color variation) has great practical value.

Experimental Procedure

3: A solution of **5** (20 mmol) and KOH (400 mmol) in water (30 mL) was heated at reflux for 5 h. The reaction mixture was cooled to 0 °C, acidified with concentrated HCl, and extracted with ether. The ether extract was concentrated to dryness, and the product crystallized from CH_2Cl_2 (ca. 50 mL) to give **6** (86%). A suspension of **6** (10 mmol), allyl bromide (20 mmol), and K_2CO_3 (20 mmol) in acetone (100 mL) was heated at reflux for 6 h. After the solvent was removed, the reaction mixture was suspended in water. Extractive workup with ether followed by column chromatography (silica gel; eluent: hexane/ethyl acetate, 10:1) gave **7** (51%). A solution of **7** (10 mmol) and KOH (75 mmol) in ethanol (95%, 100 mL) was heated at reflux for 2 h. After the solvent was removed, the reaction mixture was dissolved in water and acidified with 6 N HCl. Extractive workup with ether gave **8** (100%). A suspension of **8** (0.5 mmol), *N*,*N*-diethyl-*m*-aminophenol (0.5 mmol), and $K_2S_2O_7$ (2.5 mmol) in xylene (2.5 mL) was heated at reflux for 6 h. The solvent was removed, and the reaction mixture was basified to pH 11 with aqueous NaOH solution. Extractive workup with ether followed by column chromatography (silica gel; eluent: hexane/ethyl acetate, 4:1) gave **3** (49%); m.p. = 108–110 °C; IR (KBr), ν = 2970, 1760, 1630, 1610, 1550, 1515, 1500, 1425, 1245, 1210, 1100 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.17 (t, J = 7.3 Hz, 6 H), 3.36 (q, J = 7.3 Hz, 4 H), 4.56 (ddd, J = 1.2, 1.8, 5.5 Hz, 2 H), 5.31 (ddd, J = 1.2, 3.0, 10.4 Hz, 1 H), 5.42 (ddd, J = 1.8, 3.0, 17.1 Hz, 1 H), 6.04 (ddd, J = 5.5, 10.4, 17.1 Hz, 1 H), 6.35 (dd, J = 2.4, 8.5 Hz, 1 H), 6.45 (d, J = 2.4 Hz, 1 H), 6.56 (d, J = 8.5 Hz, 1 H), 6.59 (dd, J = 2.4, 8.6 Hz, 1 H), 6.66 (d, J = 8.6 Hz, 1 H), 6.76 (d, J = 2.4 Hz, 1 H), 7.19 (d, J = 6.1 Hz, 1 H), 7.59 (ddd, J = 1.2, 6.1, 7.3 Hz, 1 H), 7.65 (dt, J = 1.2, 7.3 Hz, 1 H), 8.01 (dd, J = 1.2, 7.3 Hz, 1 H). **4**: M.p. 138–141 °C; IR (KBr): ν = 3400, 2970, 1755, 1640, 1590, 1520, 1450, 1430, 1400, 1350, 1280, 1215, 1125 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.19 (t, J = 6.7 Hz, 6 H), 3.39 (q, J = 6.7 Hz, 4 H), 3.66 (d, J = 6.1 Hz, 2 H), 5.10 (dd, J = 1.8, 10.4 Hz, 1 H), 5.19 (ddd, J = 1.2, 1.8, 17.1 Hz, 1 H), 5.96–6.10 (m, 1 H), 6.40 (dd, J = 1.2, 9.2 Hz, 1 H), 6.48 (d, J = 1.2 Hz, 1 H), 6.52 (d, J = 8.6 Hz, 1 H), 6.58 (d, J = 8.6 Hz, 1 H), 6.67 (d, J = 9.2 Hz, 1 H), 7.18 (dd, J = 1.2, 6.1 Hz, 1 H), 7.55–7.66 (m, 2 H), 8.04 (dd, J = 1.2, 6.1 Hz, 1 H).

13/**14**: A solution of **9** (100 mmol) in acetone (150 mL) was added dropwise to a suspension of allyl bromide (120 mmol) and K_2CO_3 (120 mmol) in acetone (150 mL) at 50 °C. The reaction mixture was heated 4 h, then filtered and concentrated to give **10** in quantitative yield. A solution of **10** (17.7 mmol) and KOH (40 mmol) in ethanol (50 mL) was heated at reflux for 2 h. After the solvent was removed, the reaction mixture was dissolved in water. This aqueous solution was washed with ether and acidified with 1 N HCl (pH < 4). Extractive workup with ether afforded **11** (99%). 4-Allyloxyphthalic anhydride (**12**) was prepared by the dehydration of **11** in toluene with the Dean-Stark apparatus (67%). A mixture of **12** (1.0 mmol) and *N*,*N*-diethyl-*m*-aminophenol (6.0 mmol) was heated (ca. 140 °C) for 24 h. Cooling followed by column chromatography (silica gel; eluent: ethyl acetate) gave **13** (10%) and **14** (14%). **13**: M.p. = 83–87 °C; IR (KBr): ν = 2960, 1750, 1610, 1540, 1515, 1425, 1330, 1260, 1215, 1115, 1100 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.17 (t, J = 7.3 Hz, 12 H), 3.36 (q, J = 7.3 Hz, 8 H), 4.47 (dd, J = 1.2, 5.5 Hz, 2 H), 5.25 (dd, J = 1.2, 10.4 Hz, 1 H), 5.35 (dd, J = 1.2, 17.1 Hz, 1 H), 5.89–6.02 (m, 1 H), 6.34 (dd, J = 2.4, 8.6 Hz, 2 H), 6.43 (d, J = 2.4 Hz, 2 H), 6.61 (d, J = 8.6 Hz, 2 H), 6.62 (d, J = 2.4 Hz, 1 H), 7.09 (dd, J = 2.4, 8.6 Hz, 1 H), 7.88 (d, J = 8.6 Hz, 1 H). **14**: M.p. = 197–199 °C; IR (KBr): ν = 2960, 1750, 1610, 1540, 1515, 1485, 1425, 1350, 1330, 1305, 1270, 1230, 1200, 1120, 1070, 1010 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$): δ = 1.17 (t, J = 7.3 Hz, 12 H), 3.35 (q, J = 7.3 Hz, 8 H), 4.65 (ddd, J = 1.2, 1.8, 5.5 Hz, 1 H), 5.35 (td, J = 1.2, 10.4 Hz, 1 H), 5.48 (ddd, J = 1.2, 1.8, 15.9 Hz, 1 H), 6.09 (ddd, J = 5.5, 10.4, 15.9 Hz, 1 H), 6.33 (dd, J = 2.4, 8.6 Hz, 2 H), 6.43 (d, J = 2.4 Hz, 2 H), 6.61 (d, J = 8.6 Hz, 2 H), 7.09 (d, J = 8.6 Hz, 1 H), 7.21 (dd, J = 2.4, 8.6 Hz, 1 H), 7.42 (d, J = 2.4 Hz, 1 H).

All other new compounds provided spectra (^{1}H, ^{13}C NMR, IR) and elemental analyses in agreement with their structures.

Molecular Mechanisms of the Reduction of NO to NH_2OH at Mo–S Centers**

By *Dieter Sellmann** and *Bernd Seubert*

The enzymatic conversion of NO_3^- to NH_3 is catalyzed by various metal-oxidoreductases,[1] of which several nitrate[2] and nitrite reductases[3] have been more precisely characterized. With certainty, molybdenum and iron centers

[**] Transition-Metal Complexes with Sulfur Ligands, Part 83. This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. –Part 82: D. Sellmann, P. Lechner, F. Knoch, M. Moll *J. Am. Chem. Soc.*, in press.

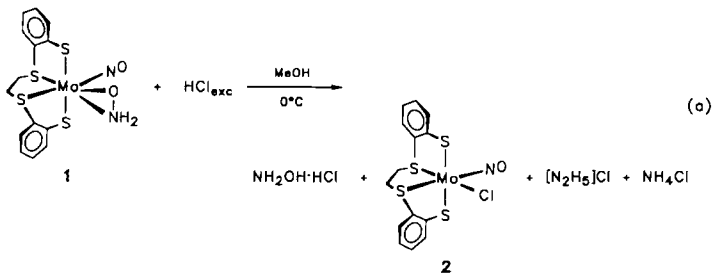
in sulfur-dominated coordination spheres have been proven in these enzymes, and in nitrite reductases iron isobacteriochlorin and iron–heme groups have also been shown to occur.[4]

The 8e reduction of NO_3^- to NH_3 is postulated to proceed by 2e steps via NO_2^-, NO, and NH_2OH. These intermediates are assumed to function as ligands of the enzyme metal-centers, but almost nothing is known at present about the molecular processes of the individual steps.

Previous investigations showed that in complexes ML (M = Fe, Ru, Os; L = amine ligand) NO ligands can be reduced electrochemically to NH_3,[5] and a series of one-electron-transfer steps were discussed for these reductions. NH_2OH was established as an intermediate in the NO reduction; however, intermediates with complexed NH_2OH could not be isolated. For thermodynamic reasons it can be assumed that in the conversion of NO_3^- to NH_3 the $3e-3H^+$ reduction of NO to NH_2OH is a key step, since in this step the formation of the energetically favored N_2 must be avoided.

In order to gain a more detailed insight into the enzymatic mechanism, nitrosyl complexes are needed as model systems that allow a stepwise reduction of the NO ligands and the complete characterization of all intermediates. With the complex fragment [Mo(NO)('S_4')] ('S_4'$^{2-}$ = 2,2'-(ethylenedithio)dibenzenethiolate) we have now succeeded in achieving a stepwise and, in principle, catalytic reduction of NO to NH_2OH.

As recently reported, [Mo(NO)$_2$('S_4')] can be converted to [Mo(η^2-NH_2O)(NO)('S_4')] **1** in a $2e-2H^+$ reduction in which the NO ligand is hydrogenated to an η^2-hydroxylaminyl ligand *without* participation of the metal's electrons.[6] This η^2-NH_2O ligand could now be released with concomitant formation of the Mo^{III} complex [Mo(Cl)(NO)('S_4')] **2** according to Equation (a). $[N_2H_5]Cl$ and NH_4Cl are formed as by-products.



(a)

Complex **1** thus characteristically differs from the acid-stable NH_xO complexes (x = 1,2) that arise upon the protonation of NO complexes.[7]

Since **1** possesses a Mo^{II} center,[6] **2**, however, a Mo^{III} center, the formation of NH_2OH is an H^+-coupled 1e reduction of the NH_2O ligand as outlined in Equations (b) and (c); in this case, the electron comes from the metal center. (In assigning the oxidation states of the Mo centers, NO was regarded as a neutral 3e donor and the 'S_4' ligand as a dianion. The assignment of the oxidation states of Mo in **1**, **2**, and [Mo(NO)$_2$('S_4')] **3** is supported by ^{95}Mo NMR chemical shifts.[6,8])

$$NH_2O^{\bullet} + H^+ \xrightarrow{+e^-} NH_2OH \qquad (b)$$

$$Mo^{II} \xrightarrow{-e^-} Mo^{III} \qquad (c)$$

For the reaction mechanism, protonation of **1** to give [Mo(NH_2OH)(NO)('S_4')]$^+$ can be discussed as the primary step. Subsequent 1e transfer and release of the NH_2OH ligand yield the complex fragment [Mo(NO)('S_4')]$^+$, which is stabilized by coordination of Cl^- and formation of **2**. Primary protonation of **1** is further indicated by the observation that **1** reacts quickly with the strong acids HBr and HI, very slowly with the weaker acid HF, and not at all with the weak acid HCN.

The by-products NH_4Cl and $[N_2H_5]Cl$ may arise from subsequent reactions of the liberated NH_2OH according to Equations (d) and (e).[9] Identification of these products was

$$3\,NH_2OH \xrightarrow{[H_2O]} NH_3 + N_2 \xrightarrow{[HCl]} NH_4Cl \qquad (d)$$

$$NH_2OH + NH_3 \xrightarrow{[H_2O]} N_2H_4 \xrightarrow{[HCl]} [N_2H_5]Cl \qquad (e)$$

achieved by ^{1}H NMR spectroscopy and by specific color reactions.[10] For this purpose, the product mixture obtained from the reaction according to Equation (a) was concentrated to dryness and extracted with D_2O. The ^{14}N NMR spectrum of the D_2O extract (Fig. 1) showed $[NH_3OH]Cl$ to be the major product, while $[N_2H_5]Cl$ and NH_4Cl were detected in only minor amounts.

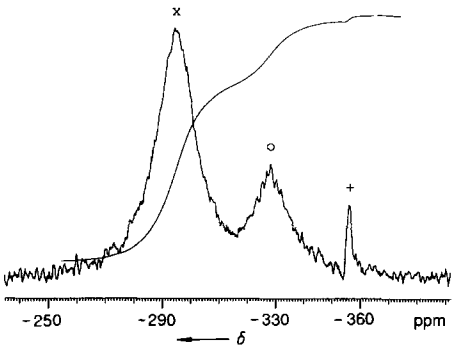


Fig. 1. ^{14}N NMR spectrum of the D_2O extract of the products of reaction (a) (× = $[NH_3OH]Cl$, o = $[N_2H_5]Cl$, + = NH_4Cl).

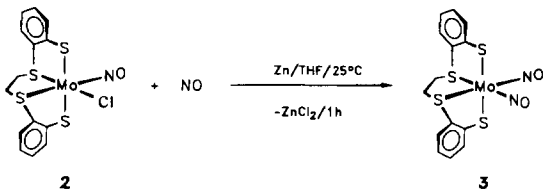
The reaction according to Equation (a) is thus the final step in the reduction of an NO ligand in **3** to free NH_2OH. Ultimately, this reduction could be conducted catalytically, since **2** was converted into **3** by reductive nitrosylation [Eq. (f)].



(f)

Accordingly, the cycle in Scheme 1 provides a model for the molecular course of the $3e-3H^+$ reduction of NO to NH_2OH in oxidoreductases with metal–sulfur centers. Two steps can be clearly distinguished: the $2e-2H^+$ reduction which bypasses the stage of the energetically favored N_2 and the $1e-1H^+$ reduction yielding free NH_2OH.

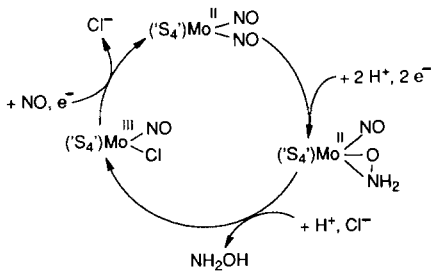

Scheme 1. Reduction of NO on the complex fragment [Mo(NO)('S_4')]; exc = excess.

Our results show that in the reduction of NO to NH_2OH at the [Mo(NO)('S_4')] fragment, intermediates may be obtained in preparative amounts and completely characterized, and that the enzymatic reduction of NO to NH_2OH should be favored at coordinatively flexible and redox-active molybdenum centers in sulfur-dominated coordination spheres.

Experimental Procedure

All procedures were carried out under N_2 and with dry, N_2-saturated solvents. **2**, NH_2OH: A yellow suspension of **1** · THF (1.035 g, 1.92 mmol) in MeOH (65 mL) was cooled to 0° and HCl gas was bubbled through the mixture for 15 min. The color changed immediately to red-violet. The suspension was stirred for 1.5 h at room temperature before N_2 gas was bubbled through in order to remove dissolved HCl. Complex **2** was filtered off as a dark-brown powder, washed with MeOH (50 mL) and Et_2O (20 mL), and recrystallized from boiling THF. 840 mg (93%) black-violet crystals. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1670 (NO); ^{14}N NMR (CD_2Cl_2) : δ = 44 (NO); FD/EI-MS: *m/z* 471 (M^+). Correct elemental analysis.

The filtrate of the reaction mixture was concentrated to dryness. Extraction of the residue with 5 mL of H_2O or D_2O provided a mixture of the salts $[NH_3OH]Cl$, $[N_2H_5]Cl$, and NH_4Cl, which were characterized by their IR, mass, and ^{14}N NMR spectra. ^{14}N NMR (D_2O): δ = −295.5 ($[NH_3OH]Cl$), −329.0 ($[N_2H_5]Cl$), −355.4 (NH_4Cl). $[NH_3OH]Cl$ in the aqueous extract was also identified by its reaction with a solution of Fe^{III}/HCHO.[10] Relative yields (estimated from NMR spectra): $[NH_3OH]Cl$ 68, $[N_2H_5]Cl$ 29, and NH_4Cl 3%.

3 from **2**: NO gas was bubbled through a suspension of **2** (745 mg, 1.59 mmol) and Zn (52 mg, 0.80 mmol) in THF (50 mL) for about 1 h until the color of the suspension had changed from violet to orange-brown. If no change in color occurred, some fresh Zn powder was added. The reaction mixture was then filtered, the filtrate evaporated to dryness, the residue taken up in CH_2Cl_2 (30 mL), and **3** precipitated by the addition of Et_2O (70 mL). Yield 220 mg (30%); IR (THF): $\tilde{\nu}$[cm^{-1}] = 1770, 1680 (NO); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1760, 1665 (NO); FD/EI-MS: *m/z* 464 (M^+).

En Route to Synthetic Phosphodiesterases: Supramolecular Phosphoryl-Transfer Mediated by Amidinium–Phosphate Contact Ion-Pairs**

By *Michael W. Göbel,* Jan W. Bats,* and *Gerd Dürner*

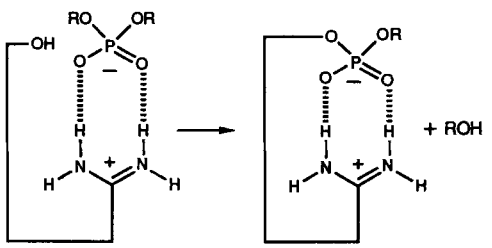
Dedicated to Professor Gerhard Quinkert on the occasion of his 65th birthday

Amidinium and guanidinium ions associate with carboxylates and phosphates forming hydrogen-bonded contact ion-pairs with well-defined structures. In the crystalline state[1,2] the cation and the O=P–O fragment are arranged almost in a coplanar fashion with symmetrical N–O distances (ca. 2.9 Å). The stability of the ion pairs in solution is dependent on the polarity of the solvent and its ability to form hydrogen bonds. Thus, in water the ion-pair stability is low;[3] however, in aprotic media association constants up to $1.4 \times 10^5\ M^{-1}$ have been recorded.[2]

Contact ion-pairs involving arginine side-chains play an important role in biochemistry.[4,5] In the active site of staphylococcal nuclease, for instance, the phosphodiester to be cleaved interacts with two arginine cations; because of their positive charges these residues not only bind the substrate but also facilitate the nucleophilic attack of water:[6,7] electrophilic catalysis.

Inspired by this example we are trying to design simple "synthetic phosphodiesterases"[8] on the basis of amidinium–phosphate ion-pair complexes (Scheme 1). As a first step we studied the reaction of amidinium alcohol **1**[9] with **2** to give **4**. This reaction proceeds via ion pair **3** and is markedly faster than the control reaction of **2** with **5**.

On addition of associating anions to **1** one observes a concentration-dependent downfield shift of the ^1H NMR



Scheme 1. Principle of supramolecular transesterification within an ion-pair complex.

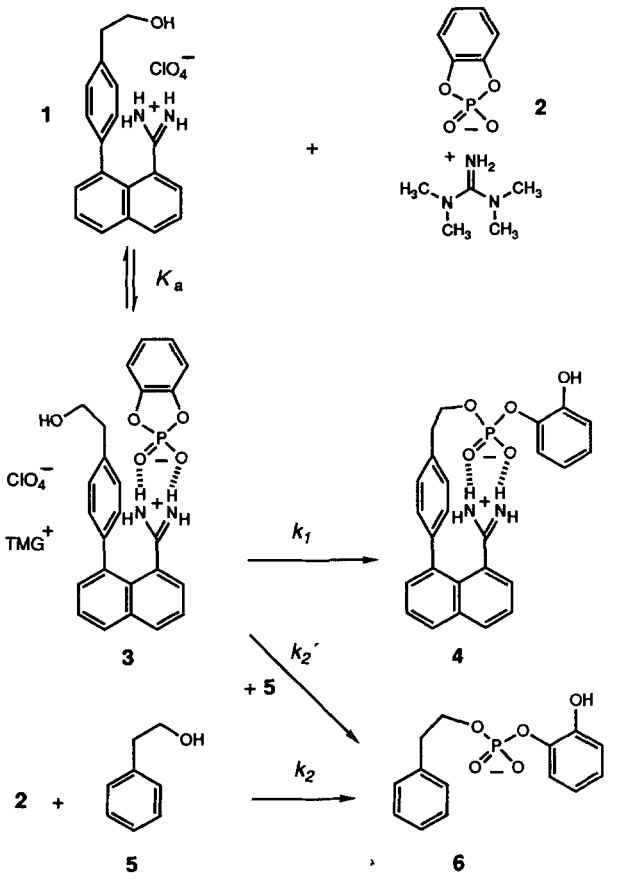
signal of those amidinium hydrogens parallel to the biaryl axis ("axial"). Thus, the association constant K_a of ion pair **3** could be determined by NMR titration of **1** with the tetramethylguanidinium (TMG^+) salt **2**. In [D_7]DMF the value of K_a is 200($\pm$ 30) M^{-1} but is reduced to only 14 M^{-1} in [D_6]DMSO (both values 30 °). In contrast, the substantial downfield shift of the NH_{ax} signal of product **4** is independent of concentration. Compound **4** is thus assumed to be an inner ion-pair in solution.



The crystal structure analysis of **4** provides further details[10] (Fig. 1). Due to the close proximity of the phenyl and amidinium groups these substituents are forced apart and the naphthalene frame is twisted. The torsion angle between the phenyl and naphthalene planes is 58°. In the barely disturbed ion-pair substructure, the unsubstituted oxygen centers of the phosphate group form hydrogen bonds with the cation 2.86 and 2.92 Å in length.

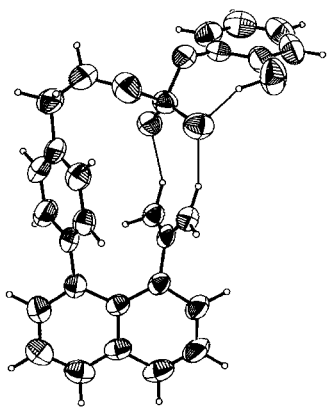


Fig. 1. Crystal structure of **4** [10].

Due to ring strain **2** is one of the most reactive phosphodiesters;[11] yet in its reaction with phenylethanol **5** and diisopropylethylamine in DMF, **2** opens very slowly to **6** ($k_2 = 2.2(\pm 0.2) \times 10^{-7}$ M^{-1} min^{-1}, 30°, 0.25 M base, analysis by HPLC). The reaction of **2** with amidinium alcohol **1** (30°, 0.25 M base in DMF) is much faster and follows a Michaelis–Menten-type saturation kinetics when the phosphate concentration exceeds the amidinium concentration (Fig. 2). This demonstrates that the phosphorylation of **1** is not an intermolecular but rather a supramolecular (quasi-intramolecular) process within ion pair **3**. Accordingly, the saturation curve (Fig. 2) can be predicted satisfactorily from the association constant K_a. If **1** is employed as an acetate instead of a perchlorate—the acetate counterion has a higher affinity to the amidinium group than the cyclophosphate in **2**—the reaction is strongly inhibited as expected.

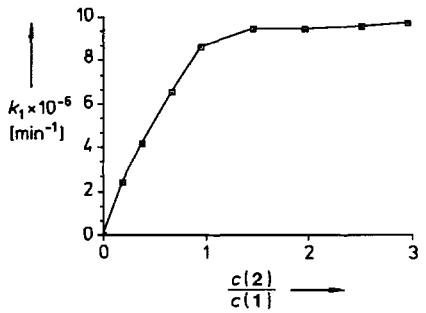

Fig. 2. Rate of the phosphorylation of **1** versus the concentration relationship $c(2)/c(1)$

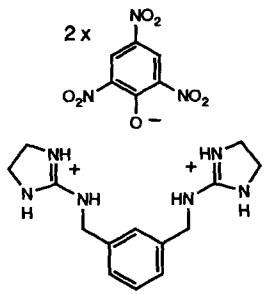
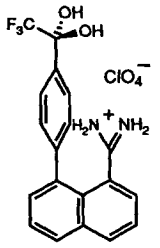
The first-order rate constant measured at complete saturation for the quasi-intramolecular reaction of **3** was determined to be $9.9(\pm 0.4) \times 10^{-6}$ min^{-1}. To allow a comparison with k_2 of the control reaction the product $K_a k_1 = 1.98 \times 10^{-3}$ $M^{-1} min^{-1}$ can be used, which describes the second-order rate constant for the reaction of **1** and **2** at high dilution. $K_a k_1$ corresponds to the expression $k_{cat} K_M^{-1}$, well known in enzyme kinetics. The data show that **1** has a 9000-fold rate advantage over uncharged alcohol **5**. The effective molarity of the hydroxy group of **3** as expressed by $k_1 k_2^{-1}$ is 45 M.

The substantial acceleration of the phosphorylation reaction is due not only to the spatial proximity of the reacting groups in complex **3** but also to electrophilic activation of the phosphodiester by the coordinating amidinium ion (see staphylococcal nuclease). This coordination accelerates both the conversion of **3** to **4** and the intermolecular reaction of **3** with phenylethanol **5** and is comparable to electrophilic catalysis by coordinated metal-ions. As a result, the phosphorylation of **5** in the presence of amidinium salt **1** again shows a saturation effect when the phosphate concentration exceeds the amidinium concentration. For the reaction of **5** with ion pair **3** the constant k_2' is roughly 25 times greater than the constant k_2 for the free cyclophosphate **2**[12] (each measured at 30 °C, 0.25 M base in DMF). The addition of

one equivalent (relative to **2**) of bis(guanidinium) salt **7** accelerates the control reaction even more than 2000-fold. In the next step on the way to "synthetic phosphodiesterases" ke-



7



8

tone hydrates of type **8** will be used for the reversible binding of H_2O.

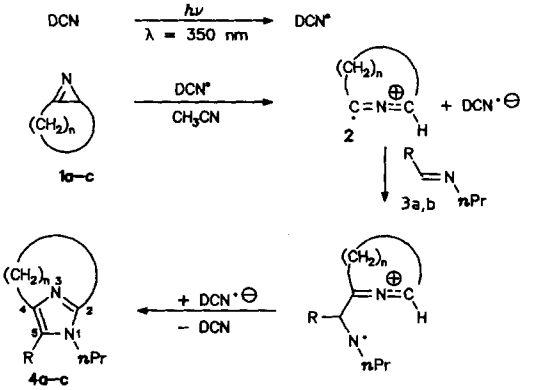
A New Synthesis for Imidazolo- and Pyrrolophanes by [3 + 2]Cycloaddition with Azaallenyl Radical Cations**

By *Felix Müller* and *Jochen Mattay**

Since the development of supramolecular chemistry the interest in cyclophanes and heterocyclophanes has grown steadily because of their possible use as receptor models and their application in phase-transfer catalysis.[1] Our recently published method, the [3 + 2]cycloaddition of azirines with olefins and imines by means of Photoinduced Electron Transfer (PET),[2] provides a new approach for the synthesis of heterocyclophanes.

The reaction is conducted under PET reaction conditions:[3] the electron acceptor 1,4-naphthalenedicarbonitrile (DCN) is excited by irradiation with light $\lambda = 350$ nm in the presence of azirine **1**, leading to the DCN radical anion and a reactive azirine radical cation. This latter species opens to the linear 2-azaallenyl radical cation **2**.[4] In a two-step process **2** adds to double bonds and their equivalents. Addition of **2** to the C=N bond of an imine under these conditions leads via a dihydroimidazole to an imidazole.[2, 5] Bicyclic azirines **1a–c** react with imines **3** to give [n](2,4)imidazolophanes (Scheme 1, Table 1).



Scheme 1. **1a**, n = 4; **1b**, n = 5; **1c**, n = 6; **3a**, R = *n*-propyl; **3b**, R = phenyl. **4a–c** see Table 1.

Table 1. Isolated imidazolophanes.

Compd.	n	R	Yield
	4	*n*-propyl	no reaction
4a	5	*n*-propyl	2%
4b	6	*n*-propyl	27%
4c	6	phenyl	2%

The bridge must comprise at least five methylene units for the reaction to succeed. Reasonable yields may be obtained for products with bridges of at least six methylene units and appropriate substituents next to the N atom, as in **4b**. The

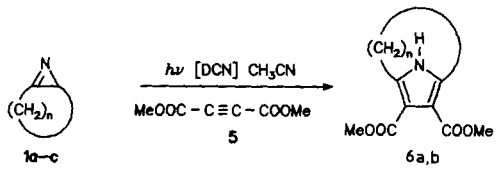
[**] Radical Ions and Photochemical Charge-Transfer Phenomena (Series A), Part 33, and Cycloadditions (Series B), part 37. This work was supported by the Deutschen Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the state of Nordrhein-Westfalen. We also thank Bayer AG, Philips Bildröhrenwerke AG, and Heraeus AG for generous gifts of chemicals and equipment. – Series A, Part 32: E. Bischof, J. Mattay, *J. Photochem. Photobiol. A.* **1992**, *63*, 249–251; Series B, Part 36: K. Langer, J. Mattay, A. Heidbreder, M. Möller, *Liebigs Ann. Chem.* **1992**, in press.

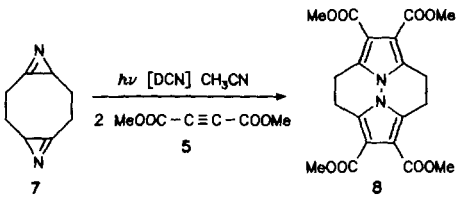
preparation of imidazolophanes using the classic approach, 1,3-dipolar cycloaddition, is not possible.[6] The PET-catalyzed cycloaddition is therefore the first method allowing access to imidazolophanes with short bridges.[7]

Short-bridged [n](2,5)pyrrolophanes have been known for a long time and are readily available, for example by the Paal–Knorr synthesis.[8] The PET-promoted method, on the other hand, enables the preparation of 3,4-substituted pyrrolophanes in acceptable yields. The reaction of 2-azaallenyl radical ions with acetylenes leads to pyrroles. The azirines **1a–c** react with dimethyl 2-butynedioate **5** to give pyrrolophanes **6a–b** (Scheme 2).



Scheme 2. n = 4: no reaction; **6a**, n = 5: 9% yield; **6b**, n = 6: 56% yield.

The trend in yields here resembles that of **4a–b**. Compounds with very short bridges could not be obtained. However, for the preparation of [6](2,5)pyrrolophanes this reaction is satisfactory. In order to obtain a [2,2](2,5)pyrrolophane in an analoguous fashion we prepared the tricyclic bisazirine **7**. Reaction under the standard PET-conditions leads not to the expected pyrrolophane but rather to the 3,4,7,8-tetrahydro-8b,8c-diazacyclopent[*f,g*]acenaphthylene **8** (15% yield).[9] A product arising from the annelation of only one azirine was not found in the reaction mixture. The mechanism of this reaction is not yet known.



These examples show that new target molecules in heterocyclic chemistry may be obtained by PET-catalyzed [3 + 2]cycloadditions of azirines.

Experimental Procedure

The azirines **1a–c** and **7** were prepared according to ref.,[10], the imines according to ref.[11]. Azirines cooled at −18 °C are stable for 4–6 weeks. DCN was prepared as described in ref.[12]. Compound **7** was obtained as a mixture of two diastereomers, which were not separated before subsequent experiments. Dimethyl 2-butynedioate was obtained from Merck.

A solution of the azirine (0.3 mmol) and the imine or dimethyl 2-butynedioate (1.0 mmol) in acetonitrile (10 mL) was poured into a Duran tube. 1,4-Naphthalenedicarbonitrile (0.1 mmol, 18 mg) was added. The reaction solution was deoxygenated by argon bubbling, the tube was sealed, and the solution was irradiated with a Rayonet photochemical reactor (λ = 350 nm) for 16 hours. The solvent was evaporated and the residue separated by flash chromatography on alumina (Merck Neutral Act. 1) using diethyl ether as eluent. In the case of **7** 0.15 mmol azirine were employed.

Calculation of Molecular Dynamics for Peptides in Dimethyl Sulfoxide: Elimination of Vacuum Effects**

By *Michael Kurz, Dale F. Mierke*, and *Horst Kessler**

Modern NMR techniques used to determine structurally relevant parameters[1] and subsequent molecular dynamics (MD) simulations[2] are the most important means of determining molecular conformation in solution. Until recently most MD simulations were performed without the inclusion of the solvent (in vacuo). For many peptides these types of simulations yield hydrogen bonds for which there is no experimental evidence. For example simulated cyclic hexapeptides often contain γ turns. Normally only two β turns would be expected in these peptides. The additional γ turns form along the length of the peptide and cause a strong kink in the

Lichtenbergstrasse 4, D-W-8046 Garching (FRG)

[**] This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

molecule. But such a structure has never been observed in X-ray structural analysis.[3] In our calculations of the C_2-symmetric model compound *cyclo*-(D-Ala^1-Ala^2-Ala^3-D-Ala^4-Ala^5-Ala^6-) we show that additional γ turns are caused by vacuum effects, which can be eliminated by MD simulations including solvent.

All MD simulations were performed with the GROMOS program package.[4] The parameters for dimethyl sulfoxide (DMSO) were taken from an X-ray structure[5] and a microwave spectroscopic study.[6] Further details are described in ref. [7] The application of these parameters in the MD simulations results in hydrogen bonds between DMSO and the peptide, which are in agreement with the X-ray structural data of a cyclic peptide reported by Karle et al.[8]

Restrained MD simulation of the model compound *cyclo*-(-D-Ala^1-Ala^2-Ala^3-D-Ala^4-Ala^5-Ala^6-) was first carried out for a 100 ps trajectory. 30 distances obtained from a 500 MHz ROESY NMR spectrum (150 ms mixing time) were used. Only the last 60 ps were used for the analysis. A C_2-symmetric conformation with two βII' turns was obtained in which the D-amino acids occupy the position i + 1 (Fig. 1a). In addition two γ turns with hydrogen bonds between D-Ala^1-NH and Ala^5-O as well as D-Ala^4-NH and Ala^2-O respectively were also populated; these lead to the molecular kink mentioned above (Table 1).

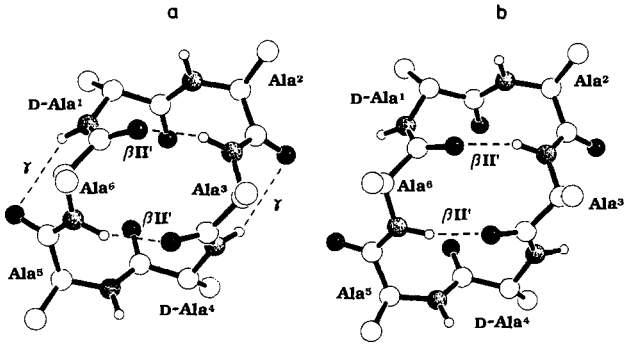

Fig. 1. Structure of *cyclo*-(-D-Ala^1-Ala^2-Ala^3-D-Ala^4-Ala^5-Ala^6-) after 100 ps MD simulation a) in vacuum, b) in DMSO.

Table 1. Intramolecular hydrogen-bonds obtained during the MD simulations in vacuum and in DMSO [a].

H bond between	and	Turn type	Distance [b] [pm]	Angle [°]	Population [%]
Vacuum					
Ala^3-NH	Ala^6-O	βII'	303	153	97
Ala^6-NH	Ala^3-O	βII'	303	153	97
D-Ala^1-NH	Ala^5-O	γ	335	135	58
D-Ala^4-NH	Ala^2-O	γ	335	135	54
DMSO					
Ala^3-NH	Ala^6-O	βII'	291	165	91
Ala^6-NH	Ala^3-O	βII'	297	160	90

[a] The criterion for a hydrogen bond is a donor–acceptor distance < 350 pm and an N-H-O angle > 120°; [b] N-O distance.

A restrained MD simulation including the solvent DMSO was performed using the "vacuum structure" as the starting conformation. The molecule was placed in a solvent box containing 116 DMSO molecules. This corresponds to a concentration of 100 mmol L^{-1}, which is comparable to the experimental conditions (roughly 50 mmol L^{-1}). A step size of 2 fs using the SHAKE algorithm was applied. First we calculated 10 ps at 300 K with a force constant of 2500 kJ mol^{-1} nm^{-2} for the restraints and a strong coupling to the heat bath (the temperature relaxation time was 0.01 ps). Then an additional 40 ps were simulated with the same force constant but weaker coupling to the heat bath (temperature relaxation time 0.1 ps). Finally the force constant was reduced to 1000 kJ mol^{-1} nm^{-2} and another 50 ps were used for the analysis.

During this simulation in DMSO the two γ turns disappeared (see Table 1) and the molecule flattened (Fig. 1b and Fig. 2). The intermolecular hydrogen bonds which appeared between the peptide and solvent during the MD simulation are listed in Table 2.

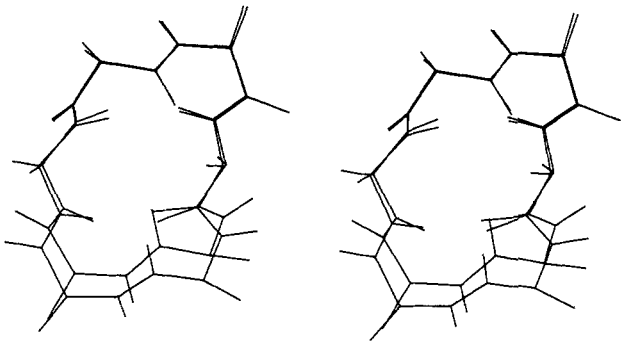

Fig. 2. Superimposed stereoplots of the structures of the cyclohexapeptide in vacuum and in DMSO. The two structures are superimposed so that amino acids 1 and 2 are overlayed.

Table 2. Intermolecular hydrogen bonds between peptide and DMSO(solv) during the MD simulation in DMSO [a].

H bond between	and	Distance [pm]	Angle [°]	Population [%]
D-Ala^1-NH	solv^{55}-O	288	152	72
D-Ala^4-NH	solv^3-O	282	169	86
Ala^2-NH	solv^{26}-O	281	168	85
Ala^5-NH	solv^{45}-O	284	169	86

[a] The criterion for a hydrogen bond is a donor–acceptor distance < 350 pm and an N-H-O angle > 120°.

Free MD simulation (without restraints) was continued for another 50 ps in solvent to prove the stability of the obtained structure. Essentially no structural change was observed. Finally an additional restrained MD simulation of the molecule in vacuo was performed resulting in a reappearance of the γ turns.

The distances in both structures, in vacuo as well as in DMSO, are in good agreement with the distances obtained from the ROESY spectrum. However, the temperature coefficients for the amide protons indicate only two intramolecular hydrogen bonds (Ala^3-NH/Ala^6-NH: $\Delta\delta/\Delta T = -1.3 \times 10^{-9}$ K^{-1}, D-Ala^1-NH/D-Ala^4-NH: $\Delta\delta/\Delta T = -8.7 \times 10^{-9}$ K^{-1}, Ala^2-NH/Ala^5-NH: $\Delta\delta/\Delta T = -8.0 \times 10^{-9}$ K^{-1}). These results indicate that the amide protons which are involved in the γ turns in the "vacuum structure" are exposed to the solvent. This latter fact is much better represented by that calculation including the solvent.

We observed the same effect for numerous other cyclic hexapeptides. The differences between the structures in vacuo and in DMSO increase with decreasing size of the amino acid side-chains in position i. Obviously larger substituents are better able to shield the charges of the polar groups.

Our experience shows the following general approach to be most advantageous in the determination of the preferred conformation in solution:

1. As a first approximation restrained MD-simulation in vacuo is performed. To search a larger conformational space it is recommended to use different starting structures and to calculate also at higher temperatures using different force constants for the restraints. In our experience MD simulation in vacuo without any restrictions yield structures which disagree with the experimental data. For peptides it is advisable to reduce the vacuum effects by reducing the charge on amide protons exposed to the solvent (information obtained from the temperature gradients of the NMR chemical shift of the amide protons) and by fixing the side chains in the dominant rotamer population (information obtained from homo- and heteronuclear coupling constants).[9]

2. The structure thus obtained is used for restrained MD simulation including the solvent. The solvent should not be represented merely by a hypothetical dielectric constant but should rather be included explicitly in the molecular dynamics.

3. An MD simulation in solution without restraints may then follow. This calculation proves if the structure is stable or moves to a structure quite different from the conformation obtained using experimental data.

In all of these calculations one must bear in mind that a static picture as shown in Figure 1 is only a crude approximation of reality, because it is obtained from an average of a constantly changing conformation (trajectory). In the case discussed here the observed vacuum effects are significant for the entire trajectory. MD simulations for small and polar molecules should therefore always be performed including solvent.

$BaNb_7O_9$, a New Oxoniobate with Double Layers of Corner-Sharing Nb_6 Octahedra**

By *Gunnar Svensson,** *Jürgen Köhler,** and *Arndt Simon*

We recently reported on the compound $K_4Al_2Nb_{11}O_{21}$[1] whose structure consists of two condensed Nb_6O_{12} clusters connected by a common apex atom of the two Nb_6 octahedra. This structure represents the first step to building chains, sheets, and, ultimately, the three-dimensional NbO structure in which the octahedra share all apices with their neighbors. In the meantime, the cluster condensation concept[2] has been illustrated by many examples, especially within certain reduced oxide systems, such as structures with edge-sharing Mo_6 octahedra[3–5] and with corner-sharing Nb_6 octahedra.[6–8] We report here the new compound $BaNb_7O_9$, which holds a special intermediate position in the path to higher dimensionality in reduced oxoniobates, since in it the first structural step towards the transition from two- to three-dimensional systems is attained.

Electron microscope investigations on the Ba-Nb-O system[9] have shown that a "phasoid"[10, 11] exists containing a large variety of different structural assemblies with corner-sharing condensed Nb_6 octahedra, for example chains made up of four units and double layers. It was therefore of interest to attempt to develop such structural variants in compounds of stoichiometric composition. After extensive efforts the formation of $BaNb_7O_9$ was achieved at temperatures above 1800 K by additional use of $BaCl_2$ flux.[12] The size of the crystals formed under these conditions were just large enough (diameter < 0.01 mm) for a single-crystal structure determination.[13]

The structure of $BaNb_7O_9$ is made up of double layers of corner-sharing Nb_6 octahedra of composition Nb_7O_8 sandwiched between BaO layers (Fig. 1). The structure can be

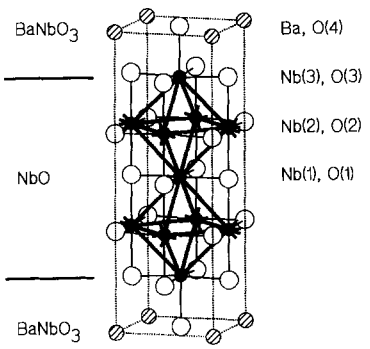

Fig. 1. Projection of the crystal structure of $BaNb_7O_9$ with its double layer of corner-sharing Nb_6 octahedra (the further connection of the Nb atoms is indicated).

envisioned as "intergrowths" of BaO and NbO or perovskite $BaNbO_3$ and NbO. The former description is simpler but does not account for the interconnection of the BaO layers with the NbO layers. In the latter description one can easily understand the interrelations between $BaNb_7O_9$, $BaNb_4O_6$, and $Ba_2Nb_5O_9$ which along with NbO and $BaNbO_3$ all belong to the homologous series $Ba_nNb_{n+3m}O_{3n+3m}$ (n = number of perovskite layers, m = number of NbO layers with complete octahedra).

The Ba atoms in $BaNb_7O_9$ are surrounded by a cuboctahedron of 12 O atoms, as in the known $Ba_{0.95}NbO_3$,[14] and the average Ba–O distance of 292 pm is only slightly longer than the respective Ba–O distance of 289 pm in $Ba_{0.95}NbO_3$. The distance from the central Nb(1) atom to the eight neighboring Nb(2) atoms is 298 pm and thus longer than both the Nb(2)–Nb(2) and Nb(2)–Nb(3) distances (297 pm and 290 pm respectively). These are all comparable to the Nb–Nb distances found in NbO (297 pm). The Nb–O distances are between 209 and 212 pm as in the other members of the homologous series.

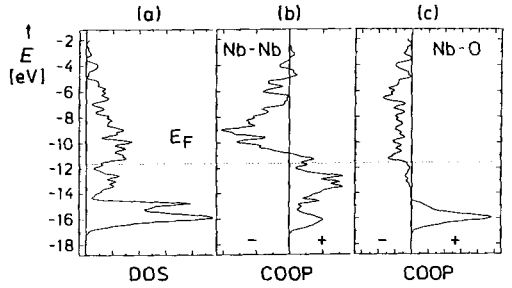

Fig. 2. a) Density of states (DOS), b) COOP diagram for Nb-Nb interactions, and c) COOP diagram for Nb-O interactions in $BaNb_7O_9$.

According to the charge balance for the ionic borderline case, 19 electrons occupy Nb–Nb bonding states (per Nb_7O_8 double-layer unit). Band-structure calculations (Extended-Hückel approximation,[15] parameters for Nb,[16] Sr parameters[17] were used for Ba) lead to the results illustrated in Figure 2. The density of states (DOS) at the Fermi level E_F shows the compound to be metallic (Fig. 2a). As the COOP (crystal orbital-overlap population) curves show, the bands with Nb–Nb bonding character are nearly full (Fig. 2b); this is at the cost of partial occupation of bands with Nb–O antibonding character (Fig. 2c). The Nb–O bonding states lie at −16 eV. The small band at −14.8 eV is of purely (nonbonding) O 2p-character and typical for perovskites[18] as well as evident in the band structure of NbO.[19] The occupation of all Nb–Nb bonding states and partial occupation of Nb–O antibonding states in $BaNb_7O_9$ reflects the situation found in isolated Nb_6O_{12} clusters possessing the maximum of 16 valence electrons in Nb–Nb bonding states.[20] Usually one finds that the magic number of 14 valence electrons[21–23] will completely fill just the purely bonding states. Likewise, in NbO,[19] $BaNb_4O_6$, and $K_4Al_2Nb_{11}O_{21}$[1, 24] not all of the Nb–Nb bonding states are occupied, and strongly Nb–O antibonding states are found directly above the Fermi level. Further reduction of the Nb_7O_8 layer in $BaNb_7O_9$, for example through substitution of Ba by La, should not be possible, because this would necessitate not only the occupation of Nb–Nb bonding but also strongly Nb–O antibonding states.

An entire series of structures with isolated Nb_6O_{12} clusters is now known.[21–23, 25–27] The first step in the condensation of Nb_6 octahedra through shared corners in $K_4Al_2Nb_{11}O_{21}$[1] has been mentioned already. Hypothetical oligomers of the general composition $Nb_{5n+1}O_{8n+4}$ for $n > 2$ (n = number of octahedra) are still unknown; however, the infinite chain of corner-sharing Nb_6 octahedra in $BaNb_5O_8$ was recently found.[7] Quadruple chains of octahedral units are obviously present in $Ba_4Nb_{17}O_{26}$[28] although a refinement of this crystal structure must still be performed. The Nb_6 clusters are connected by four shared corners into single layers in $BaNb_4O_6$, $Ba_2Nb_5O_9$,[6] and $Sr_2Nb_5O_9$[29]. In the structure of $BaNb_7O_9$ presented here, the Nb_6 clusters are connected by five shared corners into a cluster double-layer. Certainly further intermediate stages between the two extremes of isolated Nb_6O_{12} clusters on the one side, and the NbO structure with completely corner-sharing Nb_6 octahedra on the other, are forseeable.

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.

years. The useful properties of these aluminosilicates are based particularly on the characteristic topology of the tetrahedral skeletal structures, which have the general composition TO_2 (T = Al, Si).[1] Instead of aluminum and silicon, many other elements such as B, P, Fe, Cr, Sb, As, Ga, Ge, Ti, Zr, and Hf can be incorporated as central atoms of the tetrahedrons in the zeolite lattice.[1, 2] These modifications succeed in tailoring the catalytic properties of zeolites for certain reactions.[2] However, hardly any proven facts on the exchange of elements of the anionic part of the lattice are known. Yet the replacement of oxygen by other electronegative elements such as nitrogen should be a promising method of modifying the properties and potential applications of this class of substances.

Recently we prepared pure, crystalline HPN_2 through the ammonolysis of P_3N_5 in thick-walled quartz ampules under pressure [Eq. (a)]. The required NH_3 was formed in situ in another compartment of the apparatus by treatment of Mg_3N_2 with NH_4Cl [Eq. (b)].[3]

$$P_3N_5 + NH_3 \xrightarrow[6d,\ 30\ bar]{580\,^\circ C} 3\,HPN_2 \qquad (a)$$

$$Mg_3N_2 + 6\,NH_4Cl \xrightarrow{400\,^\circ C} 3\,MgCl_2 + 8\,NH_3 \qquad (b)$$

The structural investigation [3] shows a $[PN_2^-]$ skeleton isosteric with β-cristobalite, as has been found in $LiPN_2$.[4] Since these phosphorus(v) nitrides have structural similarities with silicates, the possibility of constructing zeolite-like P–N structures occurred to us. In fact, we succeeded in replacing Mg_3N_2 by Zn_3N_2 in the HPN_2 preparation and we obtained a new compound with composition $Zn_5H_4[P_{12}N_{24}]Cl_2$ in quantitative yield[5]. Analogously to HPN_2, a phosphorus(v) nitride had formed with molar ratio P:N = 1:2, while zinc from $ZnCl_2$, which is volatile under the given conditions, was incorporated into the solid while it forms. A complete exchange of the hydrogen atoms in the product was achieved afterwards through treatment with $ZnCl_2$ accompanied by evolution of HCl [Eq. (c)].

$$Zn_5H_4[P_{12}N_{24}]Cl_2 + 2\,ZnCl_2 \xrightarrow{700\,^\circ C,\ 3d} Zn_7[P_{12}N_{24}]Cl_2 + 4\,HCl \qquad (c)$$

Surprisingly however, the title compound $Zn_7[P_{12}N_{24}]Cl_2$ can also be prepared by reaction of the inexpensive starting materials NH_4Cl, $ZnCl_2$, and $(PNCl_2)_3$ [Eq. (d)].

$$7\,ZnCl_2 + 12\,NH_4Cl + 4(PNCl_2)_3 \xrightarrow{700\,^\circ C,\ 3d} Zn_7[P_{12}N_{24}]Cl_2 + 48\,HCl \qquad (d)$$

In all preparations $Zn_7[P_{12}N_{24}]Cl_2$ forms as a fine crystalline and colorless powder insoluble in water and acid. Only in a special autoclave system[6] does $Zn_7[P_{12}N_{24}]Cl_2$ decompose in dilute sulfuric acid (190 °C, 10 bar, 2 d; the phosphorus(v) nitride hydrolyses to ammonium hydrogen phosphate).

The powder diagram of the title compound indicates a cubic structure; the similarity to the powder diagram of sodalite $Na_8[Al_6Si_6O_{24}]Cl_2$ is evident.[7] The Rietveld refinement of the crystal structure of $Zn_7[P_{12}N_{24}]Cl_2$ on the basis of the powder diffraction data[8] confirmed the suspected analogy.[9] It shows that phosphorus and nitrogen form a sodalite-like framework of corner-sharing PN_4 tetrahedrons (Fig. 1). The P–N distance of 163.6(7) pm is comparable with that in $LiPN_2$ (164.5(7) pm).[4] Also the experimentally determined P-N-P bond angle (125.8(4)°) agrees with the corresponding angle in $LiPN_2$ (123.6(8)°).[4] This result is in

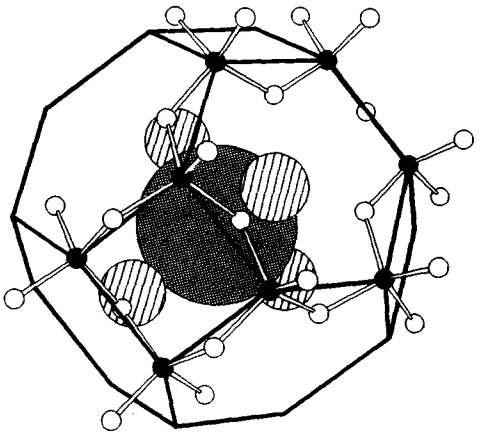

Fig. 1. Section of the crystal structure of $Zn_7[P_{12}N_{24}]Cl_2$. The $[P_{12}N_{24}]$ framework of the sodalite type is constructed from $[P_4N_4]$ and $[P_6N_6]$ rings (P–N 163.6(7) pm). In the center of each β cage is a Cl^- ion, surrounded by tetrahedrally arranged Zn^{2+} ions (Zn–Cl 259.6(2) pm). The Zn^{2+} ions are coordinated in a distorted tetrahedral manner by one Cl^- ion and three N atoms (Zn–N 196.0(8) pm). Size of Zn and Cl correspond to the respective ionic radii. P: black, N: white, Cl: gray, Zn: striped.

accord with the topological similarity between the P–N part of the structure in $LiPN_2$ (analogous to β-cristobalite) and the P–N structure found here: in both cases the network skeletons include PN_4 tetrahedrons linked through all four apexes by corner-sharing. However, whereas three-dimensionally bonded $[P_6N_6]$ rings occur exclusively in the β-cristobalite variant ($LiPN_2$), in the sodalite framework $[P_4N_4]$ rings are also found. The two types of rings together form capped octahedrons (β cages), which are typical building units of the sodalite type structure (Fig. 1). Situated at the center of each β cage is a Cl^- ion, in a tetrahedral environment of Zn^{2+} ions. Every metal cation has, besides the Zn–Cl contact (259.6(2) pm), three contacts to nitrogen atoms of the P–N framework (Z–N 196.0(8) pm) forming a distorted tetrahedron. In each case the contact distances correspond to the sum of the ionic radii.[10] Comparison of the composition of $Zn_7[P_{12}N_{24}]Cl_2$[5] with that of $Na_8[Si_6Al_6O_{24}]Cl_2$ reveals a statistical occupation of the Zn positions (occupancy factor 7/8). However, a part of the Zn^{2+} ions may be replaced by two protons each. The P–N sodalite described here has a phase width of $Zn_{(7-x)}H_{2x}[P_{12}N_{24}]Cl_2$ ($0 \le x \le 2$). A continuous increase in the lattice constant is observed with increasing zinc content. Other metals such as Co, Ni, and Yb were also built into the P–N sodalite in place of zinc, as described by Equation (d).

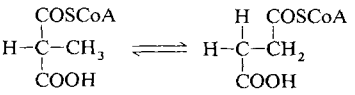
Radical Intermediates in the Coenzyme B_{12} Dependent Methylmalonyl-CoA Mutase Reaction Shown by ESR Spectroscopy**

By *Ymin Zhao, Peter Such,* and *János Rétey**

Methylmalonyl-CoA mutase catalyzes the reversible rearrangement of (2*R*)-methylmalonyl-CoA to succinyl-CoA by migration of the COSCoA group [Eq. (a)].[1] Both the proposed reaction mechanisms and the role of coenzyme B_{12} are still controversial. Some experiments with model compounds suggest a radical mechanism,[2] and others a nonradical mechanism.[3] The crucial initial step, the abstraction of a hydrogen atom from the nonactivated methyl group, could not yet be detected in any model reaction. From the chemical point of view a radical mechanism for this step is the more plausible.



(a)

In some coenzyme B_{12} dependent enzyme reactions, a radical intermediate has been detected by ESR spectroscopy,[4–9] but the enzymes involved, ethanolamine ammonia lyase, diol dehydratase, and nucleoside triphosphate reductase, unlike methylmalonyl-CoA mutase and several other coenzyme B_{12} dependent mutases, do not catalyze rearrangements of the carbon skeleton. The only report[10] on an ESR study of the methylmalonyl-CoA mutase contains negative results. Since extremely pure methylmalonyl-CoA mutase is available in appropriate quantities, we again attempted to detect radicals in the enzymatic system.

Methylmalonyl-CoA mutase (5.3 mg, 35 nmol, 120 U) and coenzyme B_{12} (adenosylcobalamin, 0.1 mg, 63 nmol) in 15 mL of potassium phosphate buffer (0.1 M, pH 6.8) was incubated in a quartz ESR tube ($d = 2$ mm) for 5 min at 25 °C under argon. After addition of (*R,S*)-methylmalonyl-CoA (1.5 mg, 1.7 μmol) the samples were incubated for a further minute and then placed in liquid nitrogen. To avoid any possible photolysis, the samples were protected from light.[11]

Figure 1 A shows the ESR spectrum of methylmalonyl-CoA mutase coenzyme B_{12} holoenzyme. There is no clear signal visible above the noise level. Only in the presence of substrate does a distinct ESR signal appear at 320 mT (Fig. 1 B). The width and complexity of the signal makes the exact *g*-factor difficult to determine. Peaks are present between $g = 2.16$ and 1.86, the point of inflection is at $g = 2.06$. The assignment of the signals to definite paramagnetic species is not yet possible. Reported values for the *g*-factor of vitamin $B_{12r}(Co^{II})$ are 2.00 and 2.30[12] while that of a free alkyl radical is 2.002. We assume that in the enzyme-bound state a hitherto unknown interaction between such paramagnetic species exists. Besides the dependence of the ESR spectrum on the substrate, two further factors speak against the effect being an artifact. With synthetic substrate analogues we obtained similar ESR signals, though different in detail.[13] Comparable spectra, broad and difficult to interpret, were observed for a ternary complex of ribonucleotide reductase, coenzyme B_{12}, and guanosine-5′-triphosphate (GTP).[9]

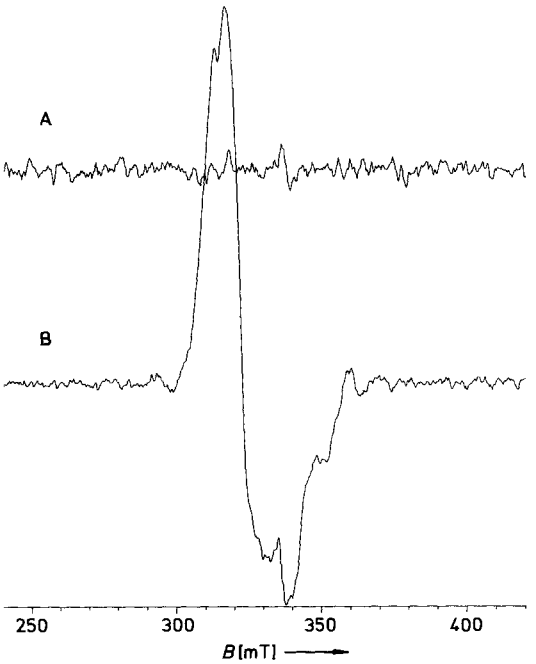


Fig. 1. A: ESR spectrum of the methylmalonyl-CoA mutase coenzyme B_{12} holoenzyme. B: ESR spectrum of the methylmalonyl-CoA mutase coenzyme B_{12} holoenzyme after addition of substrate (methylmalonyl-CoA)

Our experiments confirm that the homolysis of the cobalt–carbon bond of the coenzyme takes place only after addition

of the substrate. The homolysis must therefore be induced by a change in conformation of the enzyme protein. Probably an equilibrium between substrate and product (succinyl-CoA), or the enzyme-bound intermediate, is immediately established at the active site. The position of this "internal" equilibrium is unknown and can differ considerably from the equilibrium of the free substrates. To our knowledge this communication reports the first direct proof of radicals in a coenzyme B_{12} dependent rearrangement of the carbon skeleton.

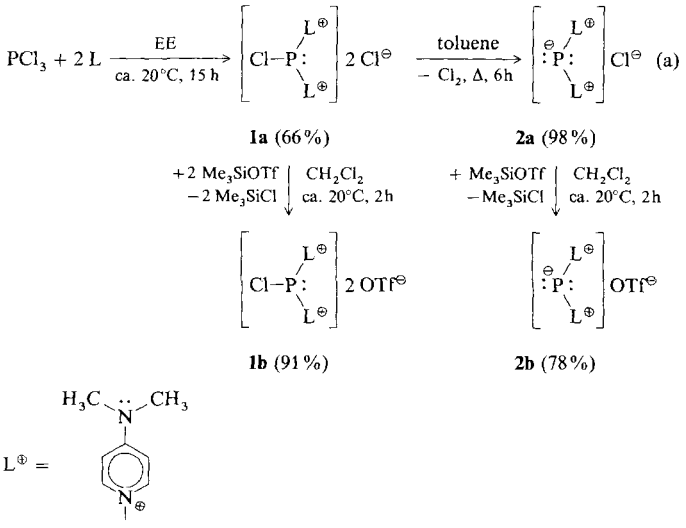
Electrostatic Activation of Nucleofuges: Cationic Leaving Groups**

By *Robert Weiss** and *Stefan Engel*

We have shown that the redox potentials of quinonoid oxidizing agents can be shifted dramatically to positive values by cationic substituents.[1] The nature of the dependence of this phenomenon on the number and spatial arrangement of the positive poles revealed that it was dominated by an F effect.[2] This effect causes a stabilization of the dianionic (reduced) form of the quinones by the cationic substituents. The electrostatic nature of the effect suggests that it can be used to stabilize any anionic system, which could have a direct bearing on the electrostatic activation of anionic nucleofuges.

We now report on poly-onio-substituted phosphorus compounds among which cationic leaving groups are found for the first time. Our experience with quinonoid systems[3] led us to conduct the poly-onio substitutions with 4-dimethylaminopyridine (DMAP, symbolized by L in the reaction equations).[4]

The reaction of PCl_3 with two equivalents of DMAP in ethyl acetate (EE) according to Equation (a) yielded the bis(onio)-substituted phosphane **1a** as isolable, hygroscopic salt. (The spectroscopic data of this and all other new compounds are given in Table 1.) The dicationic structure of **1a** follows from its quantitative transformation into the analytically pure bis(trifluoromethanesulfonate) (abbreviated bis(triflate), **1b**) with Me_3SiOTf ($OTf = O_3SCF_3$).



Both in the solid state and in solution, the salt **1a** loses one equivalent of chlorine slowly at room temperature and fast when heated. The novel bis(onio)phosphide **2a** results and can be transformed into the corresponding triflate **2b** by anion exchange with Me_3SiOTf. The spontaneous chlorine loss is interpreted as an S_N2 (Cl) reaction with redox character, in which the bis(onio)phosphide functions as a potent *cationic* nucleofuge. If all the ionically and covalently bound chlo-

Table 1. Spectroscopic data of the compounds **1**–**7** [a].

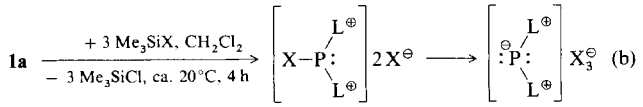
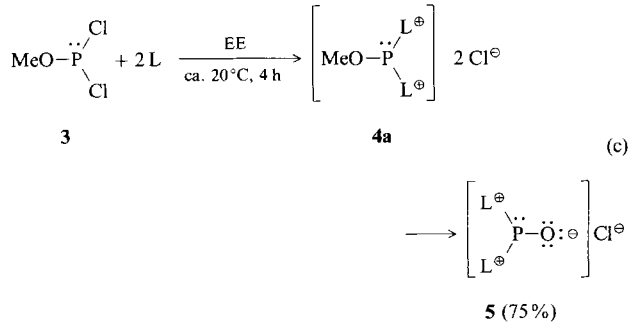
[**] This work was supported by the Fonds der Chemischen Industrie.

rine in **1a** is exchanged for bromine or iodine [Eq. (b)], the stable trihalogenides **2c, d** form spontaneously in high yields via the nonisolable dicationic salts **1c,d** in an analogous S_N2 (Hal) reaction at room temperature.



1c, $X^{\ominus} = Br^{\ominus}$ **2c** (77%)
1d, $X^{\ominus} = I^{\ominus}$ **2d** (82%)

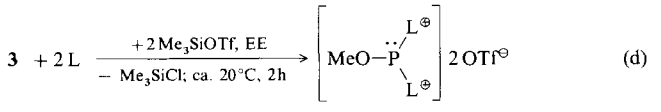
The reduction $P^{III} \rightarrow P^{I}$ summarized in Equations (a) and (b) is without precedent. The driving force is the optimal stabilization of the phosphide center in salts **2** by the F and I effects of the cationic substituents. An increase in the oxidation state of phosphorus should increase the nucleofugality of the novel leaving groups **2**. The idea was pursued with derivatives of phosphoric and phosphorus acid analogous to **2**. The attempt to synthesize the methoxy-substituted dication salt **4** (analogous to **1**) from methyl dichlorophosphite **3** and two equivalents of DMAP at room temperature again yielded a structurally novel, stable salt, bis(onio)phosphite **5**, as the only product [Eq. (c)]. Under the activating influence



3 **4a** (c)

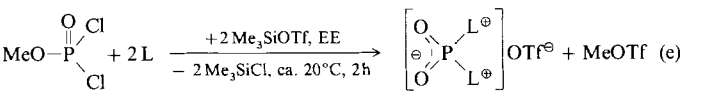
5 (75%)

of the onio substituents, a demethylation similar to the Arbuzov reaction occurs, but already at the stage of the trivalent P(III) derivative. That the site of the cleavage in this S_N reaction is the C–O and not the P–O bond of **4a** is controlled by the relative polarities and bond strengths of these bonds. If the same reaction is performed in the presence of two mole equivalents of Me_3SiOTf according to Equation (d), good yields of the corresponding dicationic salt **4b** are obtained.



4b (86%)

The viability of this bis(triflate) confirms that the cationic leaving group in **4** is better as nucleofuge than Cl^-, but worse than OTf^-. A reaction of **6**, the phosphorus(v) derivative corresponding to **3**, with DMAP according to Equation (e)[5,6] yields as exclusive product the bis(onio)phosphate triflate **7**[7] besides one mol equivalent of methyl triflate, which is detectable in solution (CH_2Cl_2) and can be trapped quantitatively. The latter is formed in an "Arbuzov reaction" in which the triflate ion functions as nucleophile and the bis(onio)phosphate ion in **7** as *cationic leaving group*.



6 **7** (88%)

In this remarkable dealkylation reaction, the cation in salt **7** is a better leaving group than the triflate ion. Our results show that the electrostatic stabilization of the electron density of a nucleofuge by two adjacent onio substituents is exceptionally effective. We anticipate that the method can be extended to other element combinations and charged states, increasing the nucleofugality even further.

Experimental Procedure

All manipulations were performed in an inert nitrogen atmosphere in dried solvents. No melting points were determined on account of the extreme hygroscopic nature of the samples. All reported compounds gave correct elemental analyses.

General method to prepare the chloride salts: DMAP (20 mmol) was dissolved in EE or CH_2Cl_2 (100 mL) and treated with the appropriate P–Cl compound (10 mmol). The precipitate was filtered off and dried at 0.01 Torr.

2 is obtained by gradual dropwise addition of a solution of DMAP (10 mmol) in EE (75 mL) to a solution of PCl_3 in EE (5 mL). The triflates are prepared by dissolving DMAP with the corresponding amount of Me_3SiOTf.

[**] This research was supported by a grant from the Bundesministerium für Forschung und Technologie under contract No. 05339 GAB/3 and the Fonds der Chemischen Industrie. I am grateful to Prof. Dr. B. Krebs for further support and to the Starck Company (Dr. Peters) for a Ta donation.

bonding descriptions. This is documented by the multitude of seemingly simple compounds such as TaS_2,[1] $NbSe_2$,[1] and $NbSe_3$[2]. The observed phase transitions and structure changes of even the simplest possible chalcogenides of the MS type (e.g. $V_{1-x}S$, $Nb_{1-x}S$)[3,4] are not yet completely understood.

The above examples show that almost all research on early-transition-metal chalcogenides has been restricted to sulfides and selenides, whereas tellurides have been mostly neglected. This may have historical reasons[5]—many minerals and traditionally investigated materials are of sulfidic origin—but may as well have resulted from the assumption that there are no significant differences between sulfides, selenides, and tellurides. Recent findings, however, indicate that the chemistry of the tellurides is significantly different from that of its lighter homologues.[6] The chemical uniqueness of the tellurides is indicated even by a formal comparison of the binary chalcogenides. The trichalcogenides MQ_3 (M = Nb,Ta)[2,7] exist only for Q = S and Se; the tetratellurides MTe_4 (M = Nb,Te),[8] on the other hand, have no counterparts among the sulfides and selenides. Reports on the chain compound Ta_4SiTe_4 give some indication of the structural variety that may be expected.[9] The examples, however, are not restricted to the area of solid-state research. Among the soluble sulfides and selenides we find no analogues for the polytelluride anion $NbTe_{10}^{3-}$;[10] and no Te analogues for textbook classics such as $Mo_3S_{13}^{2-}$ are known.[11]

Attempts to reduce MTe_2 with 3d metals lead to the layer compounds $TaFe_{1+x}Te_3$ ($x \approx 0.15$),[12] M_2FeTe_4 (M = Nb, Ta),[13] $M_2M'Te_4$ (M = Nb, Ta; M' = Fe, Co, Ni),[13,14,15] $Ta_2M_3Te_5$ (M = Ni, Pd)[13a,b,16], and $TaCo_2Te_2$.[17] An unexpected finding in these investigations was that Peierls-type distortions which dominate the structures of many low-dimensional chalcogenides[1c] were rarely observed. The structure of the title compound $TaNi_2Te_2$, however, shows that Peierls distortions[18] occur in metal-rich tellurides as well. The structure of $TaNi_2Te_2$ corresponds to the undistorted type, the structure of $TaCo_2Te_2$, to the distorted one.

$TaNi_2Te_2$ is synthesized at 950 °C from the elements.[19,20] A striking feature is the layer character of the structure. This is particularly surprising, since the metal:tellurium ratio is 3:2, and the compound has to be considered metal-rich. The shortest Te–Te distance between the layers is 3.795 Å; the layers are held together by Van der Waals forces only. Each unit cell contains two $TaNi_2Te_2$ layers, which are stacked along the *c* axis and related by an *n* glide plane. In Figure 1 a projection of the structure along *b* is shown above; a central projection of a single layer along *c* is shown below.

The layer character of the compound accompanies an anisotropy of its properties. This is immediately clear from the crystal structure and is supported by the results of tight-binding band structure calculations.[21] The energy bands along special lines of the Brillouin zone corresponding to space directions within a $TaNi_2Te_2$ layer, cross the Fermi level, but the bands in directions perpendicular to the layers are dispersionless and do not cross the Fermi level. Thus $TaNi_2Te_2$ can be regarded a two-dimensional metal.[22]

One possible description of the structure of $TaNi_2Te_2$ starts with the identification of *cis-trans* chains of Ni atoms running parallel to the crystallographic *a* axis. The Ni–Ni distances within the chain are 2.407(2) Å and 2.524(2) Å (see Fig. 1 below) and are thus comparable with Ni–Ni distances in Ni metal[23] and in several related compounds such as $Ta_2Ni_2Te_4$[13,14,15] and $Ta_2Ni_3Te_5$.[13] However, even in closed-shell molecular clusters such as $[Ni_8S(SC_4H_9)_9]^-$[24] and $[Ni_8Hg(PPh)_6(PPh_3)_4][Ni_8(PPh)_6(PPh_3)_4]$[25] comparable Ni–Ni distances are observed. The *cis-trans* Ni chains are connected by Ta atoms which are attached to six Ni–Ni bonds in a side-on fashion. Thereby each Ta atom obtains eight Ni neighbors; Ta–Ta separations of 3.370(1) Å and 3.566(1) Å allow significant Ta–Ta interactions. Each Ni atom has four Ta and two Ni neighbors. The tellurium atoms are situated above and below the $TaNi_2$ layers in such a way that every two Ni and two Ta atoms (μ_4-Te) or four Ni atoms and one Ta atom are bridged by tellurium (μ_5-Te).

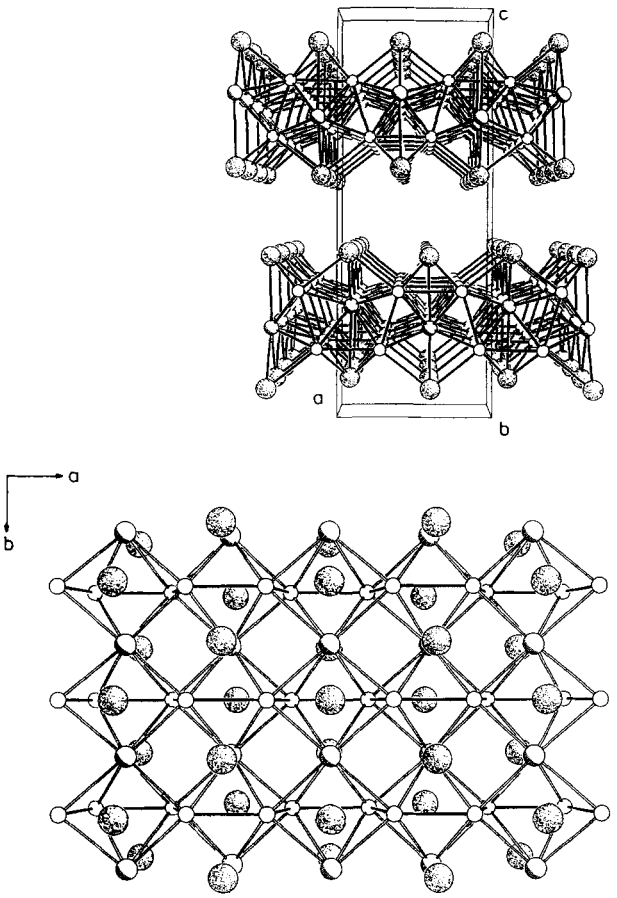

Fig. 1. $TaNi_2Te_2$: Above: Perspective view of the structure along [010]. Below: Projection of a single layer along [001]; large dotted circles: Te; medium-size hatched circles: Ta; small circles: Ni.

A possible alternative description starts with pinpointing a square (4^4) net of Ni_2 dumbbells which span a plane parallel to the crystallographic *a,b* plane. The $d_{Ni\text{-}Ni}$ distance within the dumbbells is 2.407(2) Å; the Ni–Ni distance between the dumbbells is $\approx$ 3.5 Å; the main axis of each dumbbell is oriented parallel to the crystallographic *c* axis. A 30° or −30° tilt of the Ni_2 dumbbells with respect to an axis parallel to *b* leads to alternation of the Ni–Ni distances along *a* ($d_{Ni\text{-}Ni}$: 2.524(2) and 3.952(2) Å). Distorted in this way the Ni_2 net is interpenetrated by an (idealized) square-planar net of Ta atoms ($d_{Ta\text{-}Ta}$: 3.566(1) Å). The $TaNi_2$ metal layer is capped top and bottom by Te layers.

Because of the high coordination numbers of the metal atoms and the many short metal–metal contacts we do not expect a crystal field splitting of the d orbitals which can be described easily. In addition, we encounter difficulties in assigning formal oxidation numbers. If one assumes tellurium to be Te^{-II}, then four formal charges have to be distributed

over one Ta and four Ni atoms. Figure 2 shows the computed density of states (DOS) for $TaNi_2Te_2$ and the contributions of Ta, Ni, and Te. The Ta- and Te-centered energy bands have a high dispersion, the Ni-centered bands, much less. The majority of the states around the Fermi level is centered on the metal atoms. A Mulliken population analysis shows that (except for the Ta–Te bonds) the Ta–Ni and Ta–Ta bonds are strong. In contrast, the computed Ni–Ni overlap populations are almost zero.[26]

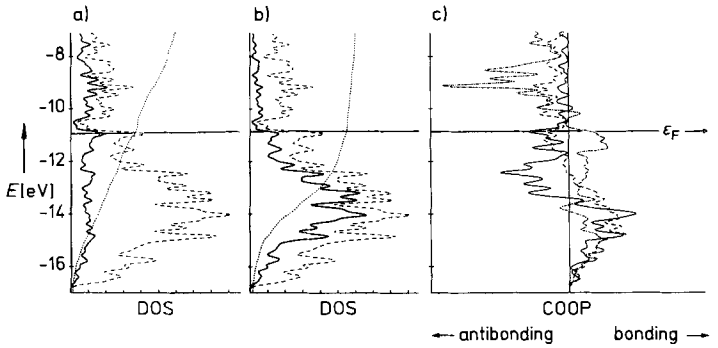

Fig. 2. Density of states (DOS) for $TaNi_2Te_2$: a) total DOS (broken line) and Ta contribution. b) Total DOS (broken line) and Ni contribution. The dotted lines represent integrations over the occupation of the orbital in question. c) COOP (Crystal *O*rbital *O*verlap *P*opulation) curve (average Ta-Ta, Ta-Ni and Ni-Ni overlap populations); solid line: Ni-Ni, dashed line: Ta-Ni; dashed-dotted line: Ta-Ta. The Fermi level is marked by a horizontal bar.

A better understanding of the $TaNi_2Te_2$ structure and the governing electronic factors can be obtained by a comparison with the closely related structure of $TaCo_2Te_2$ (Fig. 1 below and Fig. 3). Whereas in $TaNi_2Te_2$ the Ni atoms are

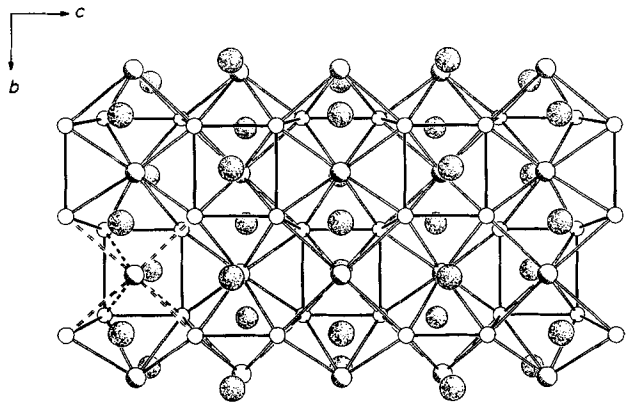

Fig. 3. $TaCo_2Te_2$: Projection of a single layer along [001]; large dotted circles: Te, medium hatched circles: Ta, small circles: Co.

equidistant along b ($d_{Ni\text{-}Ni}$: 3.566 Å), the $TaCo_2Te_2$ structure is distorted in such a way that Co atoms of two neighboring *cis-trans* chains pair up: one observes alternating short and long Co–Co distances between the *cis-trans* chains ($d_{Co\text{-}Co}$: 2.852(2) and 3.756(2) Å). The structural distortion is reflected in the Ta–M′ distances as well: in $TaCo_2Te_2$ the Ta–M′ distances which were uniform in $TaNi_2Te_2$ ($\bar{d}_{Ta\text{-}Ni}$: 2.733 Å) are derived into groups of shorter ($\bar{d}_{Ta\text{-}Co}$: 2.582 Å, bold dashed lines around Ta in Fig. 3) and longer ($\bar{d}_{Ta\text{-}Co}$: 2.843 Å, open dashed lines around Ta in Fig. 3) Ta–Co distances.

The pairing distortion in $TaCo_2Te_2$ can be viewed in a simple manner as a consequence of a Peierls instability. This interpretation is based on the idea that in spite of metal–metal bonding and the high coordination number of M in the TaM_2Te_2 layers, a fraction of the valence electrons (depending on M) is used to form quasilocalized M–M bonds. In this simple picture Ni–Ni bonding and antibonding states should be occupied in $TaNi_2Te_2$ (see Fig. 2c). Therefore no bonding Ni–Ni contacts are observed along b. Moving on to $TaCo_2Te_2$ we formally remove electrons from M–M antibonding states, and M–M (i.e. Co–Co) bonding interactions can develop in the corresponding spatial direction.

A more specific picture of the electronic factors which are responsible for the distortion can be obtained from the computed band structure.[27] Figure 4a shows the energy bands of $TaNi_2Te_2$ along the symmetry lines $X-\Gamma-Y$ of the Brillouin zone. Because the Fermi level crosses several bands, metallic properties are expected for this material. Note the high dispersion of several bands in the energy range between -10 eV and -11 eV and the distinct energy gap above -11 eV at X. Since one of the unit-cell translations is doubled as a consequence of the pairing distortion when we move from the $TaNi_2Te_2$ to the $TaCo_2Te_2$ structure, the corresponding reciprocal lattice-translation is halved, and the energy bands are "backfolded" along this line ($\Gamma-Y$, Fig. 4b).[18b,c] The representations in Figure 4a, 4b are therefore equivalent; the only difference is a doubling of the unit cell. Figure 4c shows the energy bands of $TaCo_2Te_2$ along the corresponding symmetry line ($\Gamma-Y$).

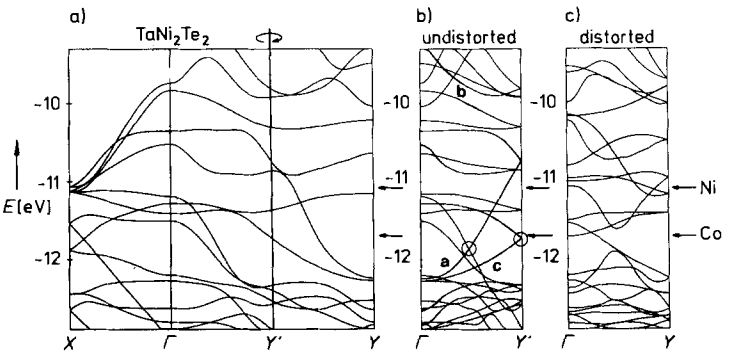

Fig. 4. Band structure of TaM_2Te_2. The Fermi level for $TaNi_2Te_2$ and $TaCo_2Te_2$ is indicated by an arrow. Energy bands for a) the undistorted $TaNi_2Te_2$ structure along the symmetry lines $X-\Gamma-Y$ of the Brillouin zone (2D); b) the undistorted structure, but with a unit cell which is doubled along the b direction; one obtains the backfolded band structure along $\Gamma-Y$; c) the distorted structure ($TaCo_2Te_2$).

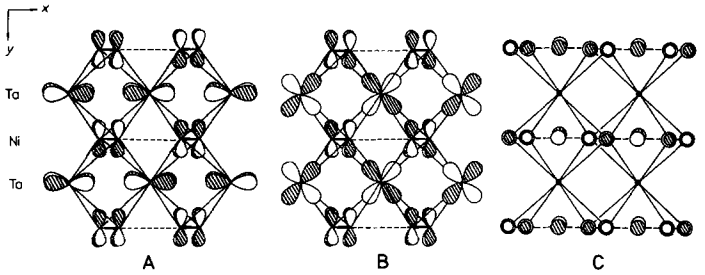
The band structures of the undistorted and distorted structures (Fig. 4b and 4c) differ in the following points: 1) The band crossing close to the Fermi level which was possible in the undistorted structure for symmetry reasons is avoided in the distorted $TaCo_2Te_2$ structure. 2) One of the bands which is located around -12 eV in the $TaNi_2Te_2$ structure is higher in energy in the $TaCo_2Te_2$ structure type and is located just above the Fermi level. A better description of the electronic driving force for the observed structural change can be given by an analysis of the crystal orbitals at the zone center. In simplified form **A** and **B** show the composition of the bands labeled **a** and **b**, which cover the energy range from -12 eV to -10 eV and undergo several avoided crossings. At the zone center (Γ, ($k=0$)), band **a** has a Ni–Ta bonding maximum and runs "uphill"; at Γ, band **b** has a Ni–Ta antibonding maximum and runs "downhill". Upon relieving the translational symmetry which is present in the undistorted structure, mixing of these two bands (and sever-



al others) leads to an electronic stabilization through Ta–M interactions.[28] This interpretation is consistent with the appearance of two different groups of Ta–M′ distances in the $TaCo_2Te_2$ structure and the computed increase in the corresponding Ta–M′ overlap populations.[26] **C** shows the composition of the bands labeled **c**. At Γ the $5p_z$ orbitals of the Te atoms are located in the nodal plane of the $3d_{z^2}$ orbitals of the Ni atoms. Their mixing with $5p_y$ orbitals of Te as a consequence of the reduction in symmetry leads to an increase of antibonding Ni–Te interactions and increases the energy of the corresponding band.

Based on total energies the distorted structure type is more stable by 0.26 eV for M = Fe; for M = Co and Ni the undistorted structure is preferred by 0.69 and 2.34 eV, respectively. The computed energies indicate the correct trend, although the numerical values are not correct. $TaFe_2Te_2$ is predicted to adopt the distorted structure type.

A Dramatic Difference in the Reactivities of Alkoxido- and Aryloxidorhenium Complexes in Insertion Reactions**

By *Robert D. Simpson* and *Robert G. Bergman**

Due to the increasing recognition of their importance as intermediates in the metal-catalyzed functionalization of olefins and the hydrogenation of organic carbonyl groups, systematic studies of the synthesis and chemistry of complexes with metal–oxygen single bonds are beginning to appear.[1] We report here the synthesis and reactions of several new octahedral low-valent aryloxido- and alkoxidorhenium complexes, whose M–O bonds display profoundly different reac-

[**] We are grateful for financial support of this work from the United States National Institutes of Health (Grant No. GM-25459). R. D. S. expresses his gratitude for a Squibb Fellowship (1990–1991). We wish to thank Prof. Milton Orchin for his willingness to disclose results before publication.

tivities. Unlike their anionic tungsten relatives, our neutral *aryl*oxidorhenium complexes react only very slowly with CS_2 and other electrophiles, and then only when the first step involves dissociation of another ligand. In contrast, analogous reactions of neutral (unfluorinated) *alk*oxide complexes apparently do not require the generation of a site of coordinative unsaturation at the metal center. CO_2 and CS_2 react exceedingly rapidly at temperatures as low as $-40\,^{\circ}C$, and kinetic experiments indicate that these transformations take place by attack of the electrophile directly at the oxygen atom of the alkoxido ligand.

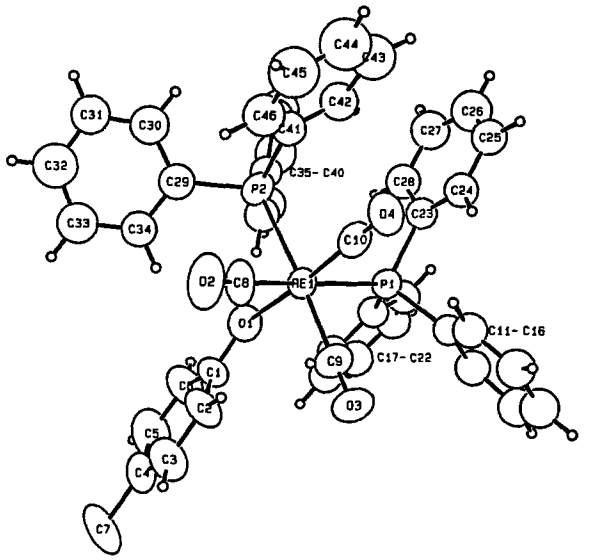

Fig. 1. Crystal structure of **2a**. Important bond lengths [Å] and angles [°]: Re-O1 2.143(9), O1-C1 1.341(20), Re-C8 1.963(12), Re-C9 1.954 (16), Re-C10 1.913(15); Re-O1-C1 131.5(11), O1-Re-C10 175.5(4), O1-Re-C9 94.6, P1-Re-P2 96.9.

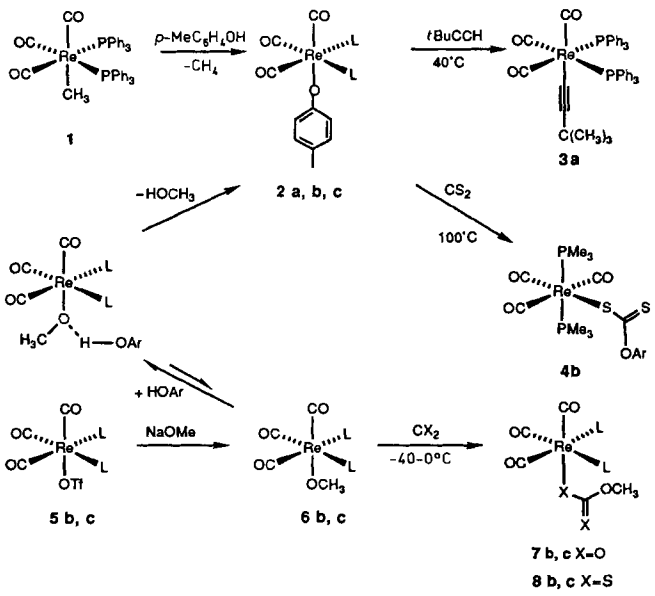
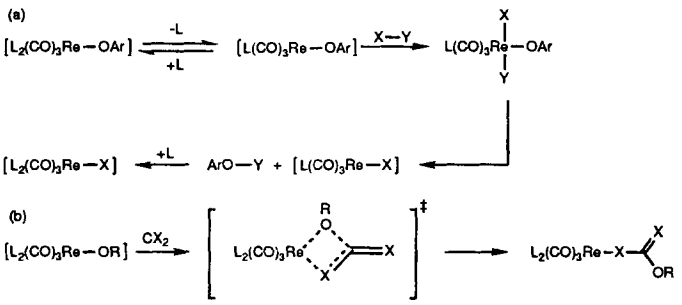
Treatment of *fac,cis*-$[Re(CH_3)(CO)_3(PPh_3)_2]$ **1** with 1.5 equivalents of *p*-cresol in benzene at 45 °C affords the cresolato complex **2a** (74% yield, Fig. 1[12]) and methane (Scheme 1). The triphenylphosphine ligands of **2a** may be readily displaced by sterically less demanding ligands such as PMe_3 or *o*-phenylenebis(dimethylarsine) (diars). This approach cannot be employed for the synthesis of the corresponding alkoxido complexes; complex **1** reacts with alcohols (including trifluoroethanol) to give complicated mixtures of products (analysis by $^{31}P\{^1H\}$ NMR spectroscopy). However, the alkoxido complexes **6** may be prepared in 75–86% yield by treatment of the trifluoromethanesulfonato complexes **5** with an excess of sodium methoxide in a mixed benzene/methanol solvent system.[13] Attempts to use this method to prepare alkoxido complexes without chelating ligands failed except for the case of the bis(trimethylphosphine) complex **6b**. The *fac,cis* geometries of these complexes were established by their characteristic infrared and ^1H and ^{13}C NMR spectra.



Scheme 1. **a**: L = PPh_3; **b**: L = PMe_3; **c**: L,L = diars. OTf = O_3SCF_3.

The cresolato and alkoxido complexes show similar behavior in protonolysis reactions. The metal–oxygen bonds may be cleaved by strong electrophiles such as HCl and acetyl chloride to yield the corresponding metal chloride and the free or acetylated alcohol. Alcohol exchange reactions also occur quite readily, but here the observed behavior is more sensitive to the nature of the complex, and leads to the following observations: a) Treatment of **6a** with 1.5 equivalents of isopropanol in benzene leads rapidly to a (presumably equilibrium) mixture of **6c** and the corresponding isopropoxido complex. b) In contrast, treatment of **6b** or **6c** with *p*-cresol in $[D_6]$benzene leads to the formation of hydrogen-bonded complexes which are temporarily stable in this medium.[14] Heating these complexes to 45 °C releases methanol and the exchanged aryloxido complexes **2b** or **2c** (observed by NMR spectroscopy). c) Product **2c** may be recovered unchanged after dissolving in methanol, establishing that the **2c**/**6c** equilibrium lies strongly on the side of the aryloxido complex.

Despite the fact that in some of these experiments hydrogen-bound species are directly observed, and in some they are not, it seems likely that all the reactions proceed by initial hydrogen-bonding. However, in order for these intermediates to be stabilized and characterized, the metal-bound alkoxido ligand apparently must be relatively basic (e.g., methoxide) and the proton donor relatively acidic (e.g., *p*-cresol).



Scheme 2.

Other reactions of the aryloxido complexes proceed more slowly. For example, the PMe_3 and diars complexes **2b** and **2c** do not react readily with terminal alkynes such as $tBuC{\equiv}CH$. The bis(triphenylphosphine) complex **2a** reacts at 40 °C to form the σ-acetylide complex **3a** and *p*-cresol. Under pseudo-first-order conditions with respect to **2a** saturation kinetics are observed: a plot of $1/k_{obs}$ versus $[tBuC{\equiv}CH]/[PPh_3]$ is linear. This kinetic behavior is consistent with reversible loss of phosphine, followed by alkyne C-H activation, and then O-H reductive elimination (mechanism (a) in Scheme 2).[15, 6] A similar reaction of **2a** with trimethylsilane is observed, yielding the hydride complex

$[Re(CO)_3(H)(PPh_3)_2]$ and the silylated cresol. None of the cresolato complexes inserts CO_2. Carbon disulfide insertion occurs only very slowly with **2b** (7 d at 100 °C) to afford the *trans* product **4b** in 52% yield. Although the mechanism of this insertion reaction has not been investigated, the vigorous reaction conditions required and formation of the isomerized product strongly suggest that ligand loss is again required to initiate the transformation.[7]

Table 1. Spectroscopic and analytical data for representative compounds **2b**, **6b**, **7b**, and **8b** [a].

2b: ^{1}H NMR ($CDCl_3$): $\delta = 7.15$ (d, $J = 8.39$ Hz, 2H; $OC_6H_4CH_3$), 6.01 (d, $J = 8.39$ Hz, 2H; $OC_6H_4CH_3$), 2.29 (s, 3H; $OC_6H_4CH_3$), 1.22 ($A_9A_9'XX'$, "J" = 8.22 Hz, 18H; PMe_3); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): $\delta = 197.4$ (br, Re(-CO)$_3$), 168.9 (t, $J = 2.74$ Hz, $OC_6H_4CH_3$(*ipso*-C), 130.2 (s, $OC_6H_4CH_3$), 122.5 (s, $OC_6H_4CH_3$(*ipso*-C), 119.6 (s, $OC_6H_4CH_3$), 20.65 (s, $OC_6H_4CH_3$), 15.77 (AXX', "J" = 30.09 Hz; PMe_3). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2010, 1921, 1888 (ν, CO). – Correct C,H-analysis.

6b: ^{1}H NMR (C_7D_8, −70 °C): $\delta = 4.60$ (s, 1H; $ReOCH_3$), 0.90 ($A_9A_9'XX'$, "J" = 8.06 Hz; PMe_3); $^{13}C\{^1H\}$-NMR (C_7D_8, −70 °C): $\delta = 193.8$ (br, Re(-CO)$_3$), 69.7 (t, $J = 4.90$ Hz; $ReOCH_3$), 16.6 (AXX', "J" = 30.63 Hz; PMe_3). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2012, 1921, 1876 (ν CO). – The instability of this complex in solution precluded attempts at recrystallization and further purification.

7b: ^{1}H NMR ($CDCl_3$): $\delta = 3.57$ (s, 1H; $ReO(CO)CH_3$), 1.58 ($A_9A_9'XX'$, "J" = 7.43 Hz, 6H; PMe_3); $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 193.8$ (t, $J = 7.12$ Hz; CO *trans* to $O(CO)OCH_3$), 191.6 (AXX', "J" = 51.7 Hz; CO *cis* to $O(CO)OCH_3$), 159.8 (t, $J = 2.75$ Hz; $ReO(CO)OCH_3$), 53.9 (s, $O(CO)CH_3$), 17.11 (AXX', "J" = 31.9 Hz; PMe_3). IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2027, 1979, 1905 (ν CO), 1670 (ν C = O). – Correct C,H-analysis.

8b: ^{1}H NMR (C_6D_6): $\delta = 4.04$ (s, 1H; $ReS(CS)CH_3$), 0.90 ($A_9A_9'XX'$, "J" = 8.06 Hz, 6H; PMe_3); $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = 223.2$ (t, $J = 6.0$ Hz; $ReS(CS)OCH_3$), 192.1 (br. CO *trans* to $S(CS)OCH_3$), 191.7 (br, CO *cis* to $S(CS)OCH_3$), 59.6 (s, $S(CS)OCH_3$), 17.18 (AXX', "J" = 33.03; PME_3). IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2019, 1950, 1894 (ν CO), 1425 (ν CS). – Correct C,H-analysis.

[a] The ^{1}H NMR spectra were recorded at 400 MHz; the $^{13}C\{^1H\}$ NMR spectra, at 100 MHz.

In striking contrast, the corresponding methoxido complexes **6b** and **6c** react with both CO_2 and CS_2 to form the insertion products **7b**, **c** and **8b**, **c**, which exhibit C–O and C–S stretching absorptions at 1665 and 1417 cm^{-1}, respectively.[8] These reactions all occur very rapidly: In a sealed NMR tube, a 0.0244 M solution of **6c** reacts with 10 equivalents of CO_2 at −40 °C in less than 5 min. At higher dilution, the reaction of **6c** with CS_2 could be monitored by UV/VIS spectroscopy.[9] The rate of the reaction at 0 °C was found to be proportional to the concentration of CS_2. This suggests a simple bimolecular mechanism such as pathway (b) in Scheme 2, but the observation could also result from the failure to reach a limiting rate corresponding to saturation. This situation could arise from an initial rapidly reversible unimolecular reaction of **6c**, such as ionization of the methoxido ligand followed by slower attack of MeO^- on CS_2, or rapidly reversible loss of one of the other ligands.[10] An ionization mechanism should exhibit a large solvent effect, but the rate constant for the reaction varied only slightly: $k_2 = 8.0 \times 10^{-2}$ M^{-1}s^{-1} in THF, 6.3×10^{-2} M^{-1}s^{-1} in acetonitrile, and 2.4×10^{-2} M^{-1}s^{-1} in toluene.[11] Activation parameters of $\Delta H^{\neq} = 8.9$ kcal mol^{-1} and $\Delta S^{\neq} = -31$ cal K^{-1} mol^{-1} obtained for the insertion reaction in THF are characteristic of a bimolecular reaction. Loss of another ligand to provide an open coordination site was discounted by our failure to observe incorporation of $[D_9]PMe_3$ or ^{13}CO into **6b** (the instability of this compound precluded a full kinetic study). These observations and the activation parameters suggest that ligand dissociation is substantially slower than insertion.[12]

The lack of reactivity of the cresolato complex stands in marked contrast to Darensbourg's anionic aryloxido and fluoroalkoxido complexes which readily insert CO_2.[1b] We conclude that the actual insertion of CO_2 between the oxygen atom of the alkoxido ligand and the metal is a rapid bimolecular reaction, and that two factors are capable of promoting this process: a) negative charge on the complex, and b) the presence of a relatively electron-donating alkyl group attached to oxygen. Unfluorinated anionic alkoxido complexes, if they could be made, would combine these factors and should have exceptionally high reactivity toward carbon dioxide and other electrophilic species.

[2] X-ray structure of **2a** ($C_{46}H_{37}O_4P_2Re$): $M_r = 902.0$; clear crystals (0.15 × 0.33 × 0.44 mm); space group $Pbc2_1$ (No. 29); $a = 19.0169(16)$, $b = 20.6117(25)$, $c = 20.4698(22)$ Å, $\alpha = 90.0°$, $\beta = 90.0°$, $\gamma = 90°$; $V = 8023.6(25)$ Å^3; $Z = 8$; $\varrho_{calcd} = 1.49$ g cm^{-1}; $\mu_{calcd} = 31.9$ cm^{-1}. The structure was solved by Patterson methods and refined by standard least-squares and Fourier techniques. Because there were too few data to refine all atoms with anisotropic thermal parameters, only the Re, P, and the atoms of the carbonyl and cresol ligands refined anisotropically. Hydrogen atoms were included (except for those of the cresol methyl group) in idealized locations (values of B_{iso} were approximately 1.2 times the B_{eqv} of the atoms to which they were attached). Hydrogen atoms were included in the structure calculations but not refined. The final residuals for 494 variables refined against the 4286 reflections for which $F_2 > 3\sigma(F^2)$ were $R = 0.0307$, $R_w = 0.0355$, and GOF = 1.57. The R value for all 5417 reflections was $R = 0.0680$. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

[3] Typical experimental procedure: In an inert-atmosphere box, a Schlenk flask was charged with 50 mg of freshly cut sodium metal, stoppered, and removed from the box. Benzene (10 mL) and methanol (4 mL) were added via syringe. The resulting mixture was allowed to stir until effervescence had stopped. This solution was transferred via cannula to a rapidly stirred slurry of trifluoromethanesulfonate **5c** (625 mg, 0.877 mmol) in benzene (20 mL). The resulting mixture was allowed to stir under Ar for 12 h, after which time it was homogeneous. After this time the solvents were removed in vacuo and the resulting residue extracted with toluene (2 × 20 mL). The solvent was removed in vacuo to yield **6c** as a pale yellow powder (381 mg, 76%).

[4] Hydrogen bonds have been shown to form between metal-bound alkoxido ligands and free alcohols, for example: a) S. E. Kegley, C. J. Schaverien, J. H. Freudenberger, R. G. Bergman, S. P. Nolan, C. D. Hoff, *J. Am. Chem. Soc.* **1987**, *109*, 6563; b) C. Di Bugno, M. Pasquali, P. Leoni, P. Sabatino, D. Braga, *Inorg. Chem.* **1989**, *28*, 1390; c) Y.-J. Kim, K. Osakada, A. Takenaka, A. Yamamoto, *J. Am. Chem. Soc.* **1990**, *112*, 1096; d) K. Osakada, K. Ohshiro, A. Yamamoto, *Organometallics* **1991**, *10*, 404.

[5] The complexes $[(CH_3)Pt(dppe)(OCH_3)]$ and $[Ru(C_5Me_5)(OH)(PMe_3)_2]$ react with terminal alkynes to form σ-acetylide complexes without loss of ligands: a) H. E. Bryndza, L. K. Fong, R. A. Paciello, W. Tam, J. E. Bercaw, *J. Am. Chem. Soc.* **1987**, *109*, 1444; b) T. G. Appleton, M. A. Bennett, *J. Organomet. Chem.* **1973**, *55*, C88.

[6] An analogous reaction has been shown to occur with alkylrhenium complexes: J. G. Stack, R. D. Simpson, F. J. Hollander, R. G. Bergman, C. H. Heathcock, *J. Am. Chem. Soc.* **1990**, *112*, 2716.

[7] The complex **2a** also reacts with CS_2 at 45 °C, liberating triphenylphosphine and leading to a complex which was too insoluble to be characterized. Presumably this material is a dimer or higher oligomer. Complex **2c** does not react with CS_2.

[8] Experimental Procedure: In an inert-atmosphere box a glass vessel fitted with a Kontes vacuum-stopcock was charged with 50 mg (0.085 mmol) of **6c** and 3 mL of benzene, and transferred to a vacuum line. The vessel was frozen in liquid nitrogen and 0.255 mmol CO_2 was condensed into the vessel. As the reaction mixture thawed, the pale yellow solution quickly became colorless. After 1 h at room temperature the benzene was removed in vacuo to yield a white powder. This was returned to the inert-atmosphere box and washed with hexane (3 × 5 ml). The product was dissolved in CH_2Cl_2, hexane was layered on top of the solution, and the recrystallization mixture was cooled to −40 °C for 3 d. Complex **7c** was obtained as white crystals, 51 mg (98%).

A New Fullerene Synthesis**

By *Gregor Peters* and *Martin Jansen**

The fullerenes,[1] pure carbon molecules C_n with $n = 28–94$,[2] are a third allotropic form of carbon, or rather a family of allotropes, after graphite and diamond.[3] They offer fascinating perspectives for basic as well as applied research. Potential topics range from application in unaltered forms as materials or catalysts, to investigations of their solid-state reactions with metals and nonmetals, conversions to three-dimensional porous materials, and the numerous imaginable electrocyclic reactions of the olefinlike fullerene system.[4] Until now progress in this research has been hampered by the poor availability of the fullerenes.

The laser vaporization technique developed by Smalley and Kroto[1a,5] and the isolation of fullerenes from the soot produced by optimized flames[6] are not useful methods for the preparation of significant amounts of fullerenes. Both methods have been outstripped by the process developed by Krätschmer and Huffman in which graphite is evaporated in an electric arc by resistive heating.[7] The conditions necessary for the spontaneous formation of fullerenes are for the most part not known. Important parameters include the composition of the gas phase with respect to the type and pressure of the cooling gas as well as the temperature, which reaches up to 6000 °C in the arc. In our search for other methods of production (continuous if possible) with an optimizable space–time yield we first considered the thermal evaporation of carbon at significantly lower temperatures.

Cylindrical bodies made of carbon of various quality (isotactically pressed purest graphite, pyrolytic graphite, and glassy carbon containing residual hydrogen obtained from polymeric precursors) were heated inductively and evaporated. The apparatus employed is sketched in Figure 1. Graphite evaporates noticeably at temperatures above 2500 °C[8] under a helium atmosphere (150 hPa).[9] But the soot collected on the cooled quartz surface of the reaction tube is still free of fullerenes at vaporization temperatures between 2500 and 2600 °C. If the vaporization is conducted at 2700 °C, however, good yields of fullerenes can be obtained from the collected soot. The surprisingly low temperature of formation and the possibility of adapting this method for continuous production (by moving the graphite cylinder or the inductor) could be options in the production of larger amounts of fullerenes.

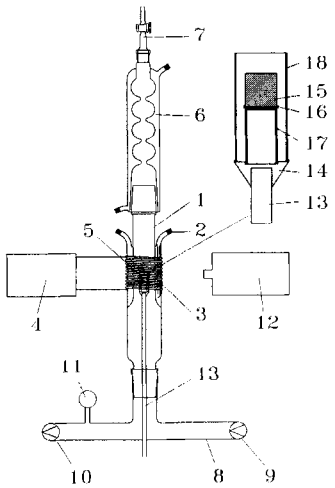

Fig. 1. Cross section of the high-frequency apparatus for the preparation of fullerenes (actual dimensions of the quartz tube: 70 mm diameter, 500 mm height). Quartz tube (1) with water jacket (2), inductor (3), HF generator (4), inductive heating zone (5), condensor (6) with vent (7), T-joint (8), gas-inlet valve (9), valve to vacuum pump (10), manometer (11), pyrometer (12), water-cooled copper tube (13), copper block (14), carbon body (15), graphite or boron nitride platform (16), boron nitride platform support (17), boron nitride insulation tube (18).

The fullerene content of the toluene extracts was determined by mass spectrometry.[10] We found that the percentage of fullerenes of higher molecular-weight (> 720 includ-

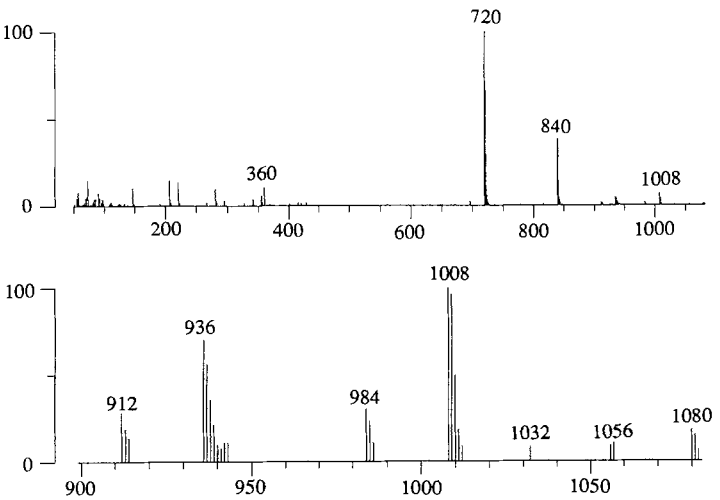

Fig. 2. Mass spectrum (above) of the toluene extract of the soot and an enlargement (below) of one portion. The relative frequency in % is plotted against m/z.

ing C_{60}) is greater here than that observed in the crude fullerene mixture obtained from the electric arc.[7] A typical mass spectrum is shown in Figure 2. This indicates a fullerene composition (in decreasing amounts) of C_{60} (m/z 720), C_{70} (840), C_{84} (1008), C_{78} (936), C_{82} (984), C_{76} (912), C_{90} (1080), C_{88} (1056), C_{86} (1032).

Experimental Procedure

In the evaporation of graphite in a high-frequency furnace (Hüttinger IG 15/400, high-resistance version of a Hartley switch, 15 kW terminal power, 500 kHz) the following parameters were varied: a) graphite quality: purest graphite (EK 966, Ringsdorff, Bonn), pyrolytic graphite (Ringsdorff, Bonn), glassy carbon (Sigri, Meitingen); b) shape of the graphite bodies: tubes, cylinders, some slitted or laminated, some with cone-shaped cavities; c) thermal isolation by one or two additional boron nitride tubes between the graphite body and the water-cooled glass tube; d) water-cooling and inductor; e) type of cooling gas (Ar, He) and the pressure of the cooling gas.
These investigations led to the following optimized procedure: The apparatus (Fig. 1) was evacuated (10^{-3} hPa) and flushed a number of times and finally heated in vacuum and then under a stream of inert gas (each heating lasted 20 min). The graphite body was heated quickly (over several min) to 2700 °C and evaporated at this temperature under a weak helium stream (150 hPa). The soot deposited on the inside of the PBN insulation tube never contained fullerenes. Most of the soot collected on the wall of the quartz tube and had a large proportion of fullerene products. This soot was removed from the quartz tube with a brush. The fullerenes were extracted from the soot with toluene yielding a deep-red solution. The evaporation of 1 g of graphite in 10 min provided 80–120 mg of crude fullerenes.

[8] The temperature could be measured pyrometrically on the graphite surface until soot formation started. Then the temperature was determined by extrapolation based on the power data of the generator.
[9] The necessary inert conditions can be best obtained by the use of a water-cooled quartz reaction tube, which is connected by a ground metal joint to a gas-inlet valve and a valve to a vacuum pump. A balance must be made between the power supplied to the inductor of the HF generator and the power lost by the cooling water. The heat loss can be reduced substantially by the use of a single- or double-walled insulation tube made of pyrolytic boron nitride (PBN) which increases the temperature at the location of the graphite body and reduces the temperature of the quartz surface. An additional effect of the PBN tube is seen in the creation of a larger hot reaction zone (possible gas-phase deposition of fullerene on soot particles) and in a chimney effect.
[10] The mass spectra were recorded with a Concept 1H spectrometer (Kratos, Manchester). Ionization method: EI.

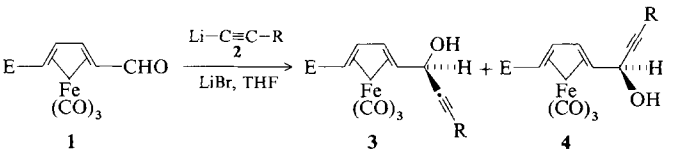
New Route to α-[(1*E*,3*E*)-dienyl]allenes via Butadiene-tricarbonyliron Complexes**

By *Kurt Nunn, Paul Mosset, René Grée,* Rolf W. Saalfrank,* Karl Peters,* and *Hans Georg von Schnering*

Allenes are readily accessible from propargyl derivatives through reactions with organocopper(I) reagents.[1] The stereochemistry of this transformation results from an SN2′ process, which usually favors *anti*-configurated products.[1m, 1n, 2, 3] Organocopper(I) reagents of the type [RCuX)M] (X = halogen, M = Li, MgX) are preferable in this reaction since diorganocuprates [R_2Cu)M] are known to racemize chiral allenes.[4, 1k, 1n]

Here, we report on our successful synthesis of acyclic α-dienylallenes **7**, starting from complex **1**.[5] The introduction of planar chirality by the $Fe(CO)_3$-organometallic moiety enables us to verify the stereochemical course of the propargyl–allene transformation, since a partial epimerization of the allene part would generate two easily distinguishable diastereoisomeric α-(allenylbutadiene)tricarbonyliron complexes.

Reaction of butadienetricarbonyliron complex **1**[5] with 1-lithioalkynes **2** in the presence of lithium bromide (THF, −78 °C, 3 h) afforded ψ-*exo* and ψ-*endo* alcohols **3** and **4**[6] in 73–82 and 10–18% yield, respectively, after easy separation by chromatography on silica gel (Scheme 1). Due to the



Scheme 1. E = CO_2Me. Reaction at −78 °C for 3 h.

stereoelectronic effects of the $Fe(CO)_3$ moiety of **3**, the choice of an appropriate nucleofugal group was rather difficult. Among numerous experiments, treatment of the alcohols **3** with phenyl chloroformate in the presence of pyridine in THF, and in situ[7] reaction of the resulting crude carbonates with six equivalents of (EtCuBr)MgBr · LiBr or (*t*Bu-

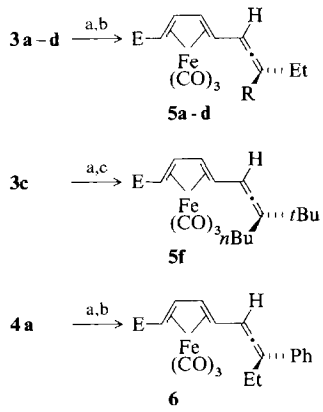

Scheme 2. E = CO_2Me. a) $ClCO_2Ph$, pyridine, THF, 25 °C, 10 min; b) (EtCuBr)MgBr · LiBr, ether, −65 °C, 15 min; c) (*t*BuCuBr)MgBr · LiBr.

CuBr)MgBr · LiBr gave the highest yields for the α-(allenylbutadiene)tricarbonyliron complexes **5a–c** or **5f** (81, 75, 55, and 77%)[8] (Scheme 2). Each of the allenes was formed as a single isomer as judged by NMR ($ds \geq 95\%$).

Starting from **3a** or **4a**, respectively, and (EtCuBr)MgBr · LiBr, the α-allenylbutadienetricarbonyliron complexes **5a** and **6** are formed (81 and 61%, Scheme 2). Complexes **5a** and **6** are clearly different by NMR. The relative stereochemistry of the allene and organometallic moieties was unequivocally established by X-ray crystallography (Fig. 1).[9]

These results strongly support a formal 1,3-*anti*-substitution mechanism for the formation of acyclic allenes from propargylic esters and organocopper(I) reagents.[1n]

Table 2. Physical data for **5a**, **6**, and **7a**.

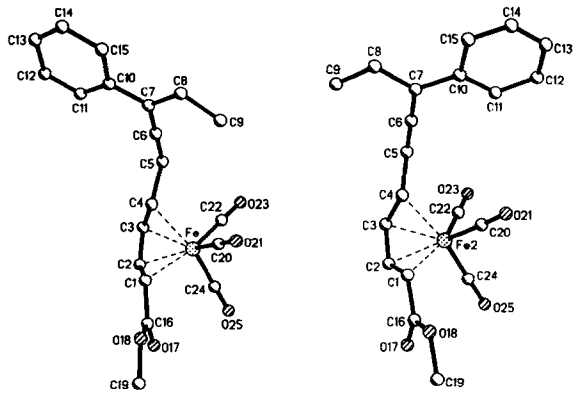

Fig. 1. Molecular structures of **5a** (left) and **6** (right) in the solid state.

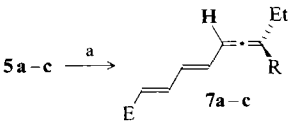
Decomplexation of **5a–c** with ceric ammonium nitrate removed the organometallic moiety to afford the air-sensitive colorless α-dienylallenes **7a–c** (Scheme 3). The *E,E* stereochemistry of the diene unit was established by ^1H NMR ($J_{2,3}$ = 15.3 Hz, $J_{4,5}$ = 14.8–15.0 Hz). Starting from enantiomerically pure **5a–c** should lead to chiral non-racemic α-dienylallenes **7a–c** provided that the decomplexation step is accomplished without racemization.



Scheme 3. E = CO_2Me. a) 3.5 equiv ceric ammonium nitrate, MeOH, 0 °C

To the best of our knowledge, this is the first example where allenes are obtained in the presence of a butadienetricarbonyliron organometallic moiety. The excellent reactivity of the carbonate leaving group compared to that of acetates and benzoates must be emphasized. Furthermore, these α-dienylallenes may be good substrates for sigmatropic rearrangements as shown by some studies in the retinoid field[1j, 10] or provide an entry to natural products[11] such as the antibiotic mycomicin[12] and its analogues.

Experimental Procedure

5a: To a solution of $LiCuBr_2$ cooled at −65° [6 equiv; prepared from lithium bromide (410 mg, 4.7 mmol) and cuprous bromide (680 mg, 4.7 mmol)] in THF (10 mL) was added an solution (8 mL) of ethylmagnesium bromide in ether [prepared from magnesium turnings (125 mg, 5.1 mmol) and bromoethane (0.35 mL, 4.7 mmol)]. After 30 min at −65 °C, a solution of propargylic carbonate was added. This was prepared by sequential addition of pyridine (0.165 mL, 2.05 mmol, 2.6 equiv) and phenyl chloroformate (0.13 mL, 1.01 mmol, 1.3 equiv) to a stirred THF solution (5 mL) of propargylic alcohol **3a** (300 mg, 0.78 mmol) followed by 10 min reaction at room temperature. After 15 min reaction at −65 °C between the carbonate and (EtCuBr)MgBr · LiBr, the reaction mixture was poured onto 25% aqueous ammonium chloride (100 mL) containing sodium cyanide (3 g). The resulting mixture was extracted twice with ether, and the combined organic extracts were dried with $MgSO_4$ and concentrated. Flash-chromatography of the remaining oily residue on silica gel (45 g) with ether/petroleum ether (1:19) as eluent afforded the allene **5a** as an orange oil which solidified on cooling.

7a: To a solution of complex **5a** (93 mg, 0.24 mmol) cooled to 0 °C in anhydrous methanol (5 mL) was added portionswise over 15 min ceric ammonium nitrate (448 mg, 0.82 mmol, 3.5 equiv). After stirring for a further 10 minutes at 0 °C, the reaction mixture was diluted with ether and water. The aqueous phase was extracted with ether and combined organic extracts were washed with brine. Drying ($MgSO_4$), concentration, and flash-chromatography of the remaining residue with ether/petroleum ether (1:9 and then 1:4) as eluents yielded **7a** (53 mg, 88%) as a white solid which gradually turned yellow upon exposure to air.

The physical data of compounds **5a**, **6**, and **7a** are listed in Table 2.

Ion-Spray Mass Spectrometry of Lipopeptide Vaccines**

By *Jörg W. Metzger, Werner Beck,* and *Günther Jung**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Ion spray (IS) is a soft ionization method in which a solution of the analyte is sprayed with compressed air through a capillary that is held at several kilovolts.[1] The high electric field and nebulization causes the formation of highly charged droplets from which predissolved ions are emitted directly into the gas phase. Two models for the mechanism of ion production from charged droplets are at present under discussion: ion evaporation[2] and Rayleigh disintegration.[3] The pneumatic nebulization assists droplet formation effecting a more stable ion current and therefore allows higher flow rates[1] than the closely related electrospray[4] technique. IS ionization takes place at atmospheric pressure (atmospheric pressure ionization mass spectrometry, API–MS). After ejection from the liquid the ions are sampled through a small orifice into the mass spectrometer. As no heat is applied, ion spray mass spectrometry (IS–MS) provides a highly sensitive method for molecular mass determination of thermolabile molecules like peptides and proteins.[5]

For routine analysis of a polypeptide or a protein the sample is dissolved and continuously introduced into the IS source at flow rates up to 200 μL min^{-1}. Sensitivity increases with decreasing flow rate. IS mass spectra of peptides or a protein consist of a series of peaks arising from singly and multiply charged, protonated molecular ions $[M + n\mathrm{H}]^{n+}$. For most peptides and proteins the multiplicity is related to the number of basic lysine, arginine, and histidine residues in addition to the *N*-terminal α-amino group.[5, 6] Each peak in the spectrum constitutes an independent measure of the mass of the parent species; from each pair of adjacent peaks the molecular mass can be calculated.[7] Therefore mass assignment can be made with greater precision and more confidence than is possible with singly charged ions. The effective mass range of any analyzer is increased by a factor equal to the number of charges on an ion. This opens the intriguing possibility to determine molecular masses of biomolecules in the kD range with quadrupole analyzers.

The increasing importance of synthetic lipopeptide vaccines for immunological screening[8] and the lack of a simple and reliable routine method for the characterization of these compounds were the reasons for this study. The synthetic vaccines investigated consist of the three-chain lipoamino acid *N*-palmitoyl-*S*-[2,3-bis(palmitoyloxy)-propyl]-(*R*)-cysteine (tripalmitoyl-*S*-glycerylcysteine, Pam_3Cys-OH; molecular mass 910.5 u)[9] and selected partial sequences (B- and T-cell epitopes containing 15–25 amino acids) of viral proteins.[8] We found IS–MS to be an extremely valuable tool for characterizing these compounds and their precursors. As common aqueous solvent mixtures cannot be used for the analysis of these highly lipophilic, water-insoluble compounds, we evaluated the possibility of using organic solvent mixtures for IS–MS.[10] Smaller lipopeptides of this kind, for example, the amphiphilic lipohexapeptide Pam_3Cys-Ser-$(Lys)_4$[11] or related lipoids[12] we could analyze by field-desorption mass spectrometry and plasma desorption mass spectrometry. Matrix-assisted laser desorption[13] has also be proven to be a powerful method for the mass determination of large lipophilic compounds.

Lipopeptide vaccines[8] are usually built up by solid-phase peptide synthesis (Merrifield synthesis). The lipoamino acid Pam_3Cys-OH is attached to the antigenic determinant either *N*-terminally in the last coupling step[8] or *C*-terminally beginning the synthesis with Pam_3Cys-Lys(Fmoc)-OH (Fmoc = 9-fluorenylmethoxycarbonyl) as a resin-bound building block.[14] A third possibility is to introduce *O,O'*-dipalmitoyl-*S*-glyceryl-cysteine within a peptide chain using an N_α-Fmoc protected derivative.[15] Thus, the partial sequence 135–154 of O_1K foot-and-mouth disease virus VP1[8], an icosapeptide, was built up on an acid-labile resin using Fmoc/*t*Bu strategy. This epitope contains three arginine residues, which were introduced by using Fmoc-Ar-

g(Mtr)-OH (Mtr = 4-methoxy-2,3,5-trimethylbenzenesulfonyl). Especially in longer sequences the quantitative removal of Mtr with trifluoroacetic acid can be problematic, even with elevated temperatures and prolonged reaction times. For controlling the synthesis of this epitope a small amount of the synthesized resin-bound peptide (the antigenic determinant) was split off the resin prior to the coupling of lipoamino acid Pam_3Cys-OH. The resultant crude peptide VP1 (135–154) was investigated by IS-MS. The mass spectrum showed the doubly, triply, and quadruply charged quasimolecular ions of three different peptides: the expected free peptide VP1 (135–154) (molecular mass 2325.7 u) and two partially deprotected peptides containing one and two Mtr protecting groups at the arginyl side chain (molecular masses 2537.9 and 2750.2 u; Fig. 1a). Optimized coupling and deprotection conditions afforded pure VP1 (135–154) (Fig. 1b).

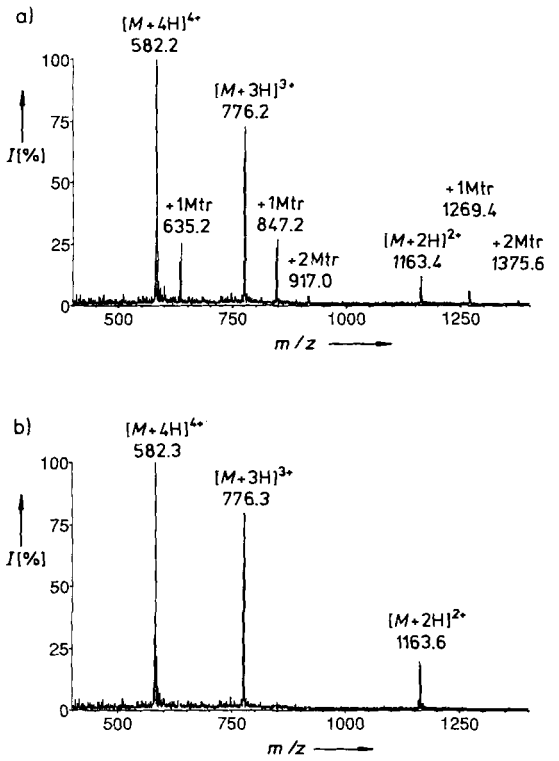

Fig. 1. a) IS mass spectrum of a peptide mixture obtained by solid phase peptide synthesis of the icosapeptide VP1 (135–154). Three series of doubly, triply, and quadruply charged ions indicate the presence of the free peptide (calculated molecular mass 2325.7) and two partially deprotected peptides (calculated molecular masses 2537.9 and 2750.2). b) the icosapeptide VP1 (135–154) (molecular mass 2325.7) obtained after optimizing coupling and cleavage conditions. The mass values annotated above the (not centroided) peaks correspond to the observed peak apices.

N-terminal coupling of the lipoamino acid Pam_3Cys-OH to the resin-bound peptide and subsequent cleavage from the resin with trifluoroacetic acid resulted in a conjugate,[8] which was only sparingly soluble in water or water/methanol mixtures.

We tried different mixtures of organic solvents including chloroform, dichloromethane, dimethylformamide, methanol, acetonitrile, 2-propanol, and *tert*-butyl alcohol for investigating such lipopeptides. Optimal results were obtained when the synthetic vaccine was pre-dissolved in chloroform (two parts by volume) followed by addition of methanol (three parts by volume) and 10% aqueous formic acid or 1% ammonium acetate (one part by volume). Chloroform/methanol mixtures not containing any acid or salt, which have been reported to give good ion yields with the atmospheric pressure spray method,[16] did not lead to satisfying results with the IS technique. The solution was introduced into the IS source at a flow rate of 5 $\mu L\,min^{-1}$. The IS mass spectra of Pam_3Cys-Ser-Ser-[VP1 (135–154)] (calcd. 3392 u; Fig. 2a) and Pam_3Cys-Lys([VP1 (135–154)])-Ala (calcd. 3417 u; Fig. 2b), a conjugate where the lipoamino acid was

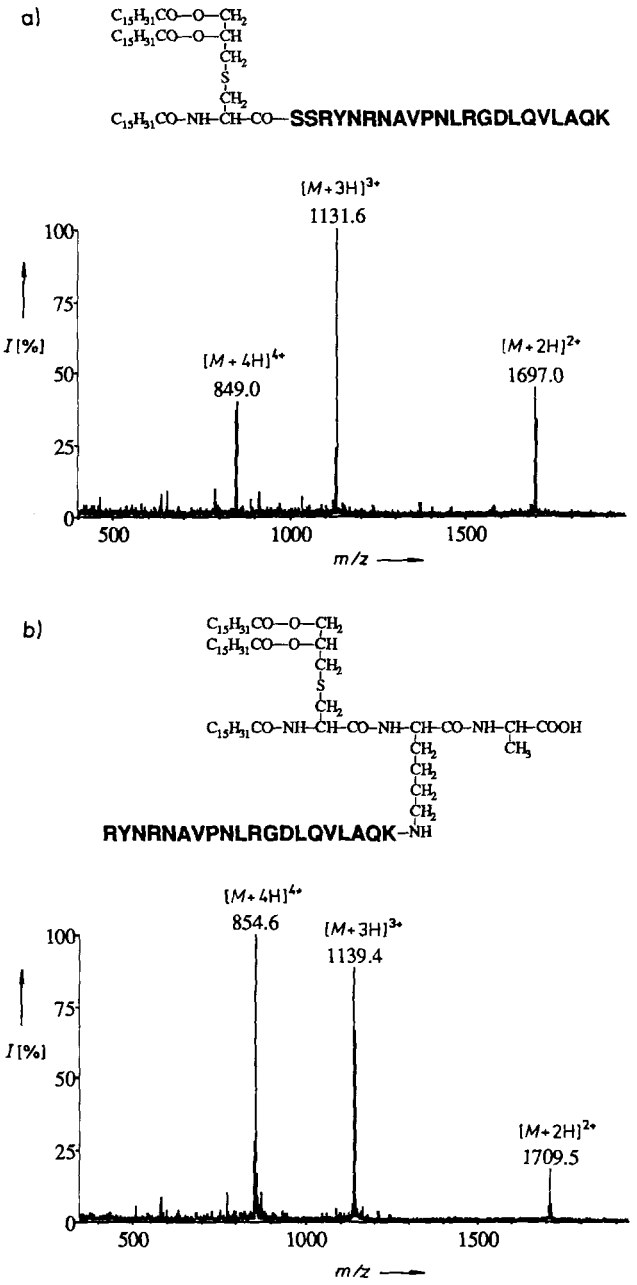

Fig. 2. Structural formulas and IS mass spectra of the lipopeptide vaccines. a) Pam_3Cys-Ser-Ser-[VP1 (135–154)] with *N*-terminally attached Pam_3Cys (calculated molecular mass 3392.3 u) and b) Pam_3Cys-Lys[VP1 (135–154)]-Ala with *C*-terminally attached Pam_3Cys (calculated molecular mass 3417.4 u).

placed at the *C*-terminus of the partial sequence, showed the doubly, triply, and quadruply charged quasi-molecular ions from which the molecular mass was determined with an ac-

curacy of ±1 u. Optimized cleavage conditions afforded pure and fully deprotected lipopeptides according to the IS mass spectra. The IS mass spectra showed the quasi-molecular peaks in high abundance; fragment peaks above 400 u were not found (Fig. 1 and 2). However, fragments can usually be observed together with solvent signals below 400 u (data not shown). The degree of fragmentation during IS ionization is influenced by the applied orifice potential and is also dependent on the structure of the lipopeptide; in the ion-spray mass spectrum of a lipopeptide constituting the synthetic *N*-terminus of the cytochrome subunit from a bacterial photoreaction center, for example, we observed two fragment peaks in high abundance, which resulted from cleavages at proline residues in the peptide chain during ionization.[17]

IS–MS proved to be a convenient method for the characterization of lipopeptide vaccines: it is fast and sensitive, and the sample preparation is very simple. Accuracies of better than ±1 u were achieved routinely for mass determinations up to 6000. The use of solvent mixtures containing chloroform in IS–MS not only allowed investigation of lipopeptides, but also of other lipophilic compound classes such as modified cyclodextrins.[18]

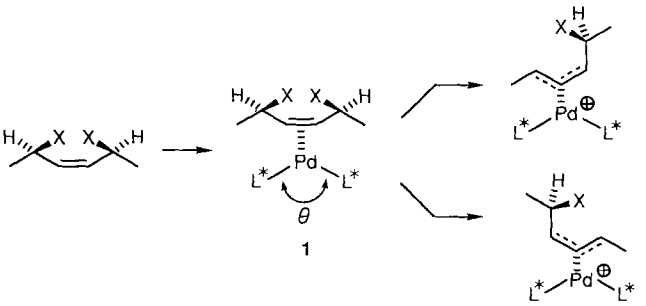
Asymmetric Ligands for Transition-Metal-Catalyzed Reactions: 2-Diphenylphosphinobenzoyl Derivatives of C_2-Symmetric Diols and Diamines**

By *Barry M. Trost** and *David L. Van Vranken*

The realization of transition-metal-catalyzed asymmetric hydrogenation[1, 2] and oxidation[1, 3] stimulates the search for chiral ligands for other types of transition-metal-catalyzed reactions. Allylic alkylation catalyzed by palladium complexes has proved to be particularly recalcitrant in responding to asymmetric induction, since both bond breaking and bond making occur on the face opposite palladium and its attendant ligands.[4–7] Of the various scenarios for asymmetric induction in allylic alkylation, differentiating between prochiral leaving groups as formulated in Equation (a) represents a generally useful strategy and coincides with our program directed towards the synthesis of glycosidase inhibitors.[8] We took the transformation of the diol **2** to the oxazolidinone **3** as our model reaction [Eq. (b)] for the general problem. This cyclization seemed to be a stringent test because a rather low enantiomeric excess (*ee*) was observed using BINAPO,[9] an asymmetric ligand that has proven to be rather successful in a related case.[7, 8]



In designing ligands, ease of accessibility is a major criterion. The ready availability of 2-diphenylphosphinobenzoic acid (**4**) by Wurtz coupling of sodium 2-chlorobenzoate and sodium diphenylphosphide (from sodium and triphenylphosphane)[10] and of chiral alcohols and amides makes the

corresponding esters and amines attractive potential ligands. Furthermore, by varying the length of the tether in bidentate-type ligands, the "bite angle" θ in **1** [Eq. (a)] can be modified. Opening this angle pushes the chiral environment of the ligands towards the reacting allyl system and could enhance asymmetric induction.[7]

The importance of ligands possessing C_2 symmetry for many asymmetric reactions[11] led to the synthesis of a series of potential bidentate diesters from C_2-symmetric diols. Diamides from C_2-symmetric diamines were also particularly desirable as ligands because the amide linkage makes them more rigid than esters. The availability of the corresponding diols and diamines in enantiomerically pure form provided

ready access to ligands **5**–**11** and **12c**[12] by dicyclohexylcarbodiimide (DCC) coupling (catalytic amounts of 4-dimethylaminopyridine (DMAP), THF, room temperature) with the acid **4**. We performed our selected reaction [Eq. (b)] with this diverse array of chiral ligands and $[(dba)_3Pd_2]\cdot CHCl_3$ (dba = dibenzylideneacetonate) (see Table 1). Several noteworthy trends appear. The good to excellent *ee*'s contrast with *ee*'s of 5–15% obtained with monodentate and non-C_2-symmetric polydentate ligands. Curiously, changing

Table 1. Catalysis using chiral 2-(diphenylphosphino)benzoyl esters and amides as ligands[a].

Ligand	t [h]	T [°C]	Yield [%]	$[\alpha]_D$	c (CH_2Cl_2)	*ee* [b] [%]
5	1	0	100	+ 83.9 (±.3)	3.90	60
6	8	0 to 20	98	+ 86.2 (±.3)	2.40	61

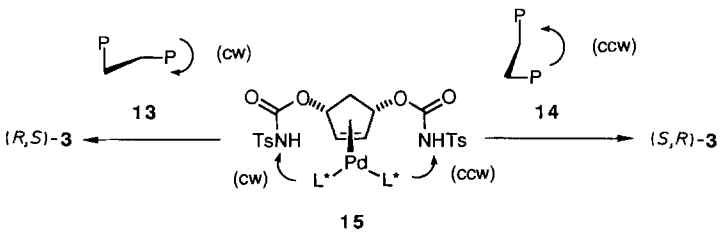
12c	0.33	0	94	−124.2 (±.1)	3.41	88

[a] All reactions were run with 0.05 equiv Pd(0) in THF. [b] $[\alpha]_D$ = **141** (c = 2.52, CH_2Cl_2) for enantiomerically pure oxazolidinone; *ee* determined by ^1H NMR of the (+)-*O*-methylmandelate esters of the hydrolyzed product.

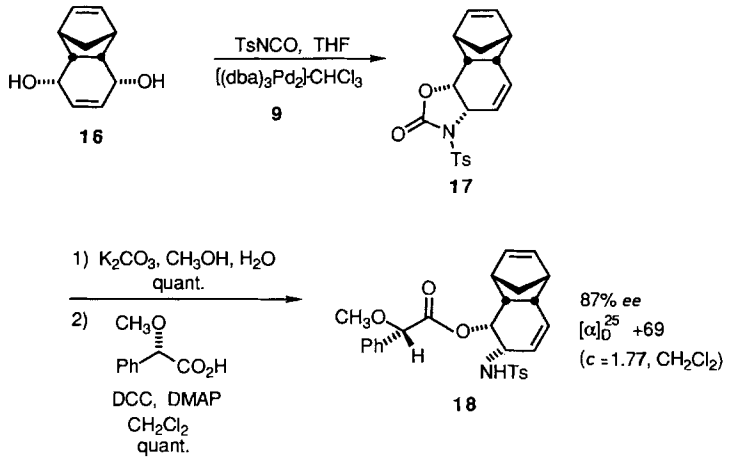
the distance between the two esters by modifying the precursors from a 1,2 (**7**) to a 1,4 (**6**) or a 1,5 diol (**5**) showed little variation in *ee*. On the other hand, increasing conformational rigidity by going to the flat tartrimide **11** or the less flexible amides **8** and **9** provides excellent yields of oxazolidin-2-one with high asymmetric induction at reasonable operating temperatures. Part of the increased *ee* observed with the tartrimide **11** may derive from increasing θ in **1** by an enlarged dihedral angle between the acyloxy substituents imposed by the flat ring.

Applying these arguments on the influence of conformation to the amides, which offer higher rigidity, led to the design of the bisamide **12c**. It is synthesized by the standard acylation of optically pure diamine **12b** which, in turn, derives from a Curtius rearrangement[13] of the known optically active diacid **12a**.[14] Indeed, cyclization proceeded in excellent yield with the highest *ee* obtained so far in this cyclization.

The absolute configuration of the product was determined from the *O*-methylmandelate ester[15] of the hydrolyzed hydroxytosylamide, as was the enantiomeric purity. The configurations were established as (*R,S*) for the levorotatory isomer of **3** and (*S,R*) for the dextrorotatory isomer. Ligands **5**–**9** all produced (*S,R*)-**3** and ligands **10**–**12** all produced (*R,S*)-**3**. If one views the ligands along the principal axis between the two stereogenic centers as drawn, the phosphine substituents are arranged in a clockwise (CW) helical sense as in **13** for ligands **10**–**12** and in a counterclockwise (CCW) helical sense for ligands **5**–**9**. The clockwise arrangement of the ligand induces ionization of the prochiral leaving group by a clockwise rotation of the palladium in **15** and vice versa.



15



The high asymmetric induction observed with these new classes of ligands appears to be more general. The conversion of the diol **16**[16] to its oxazolidin-2-one **17** using diamide **9** provides 87% *ee* of the enantiomer depicted (determined by conversion to the mandelate **22**). The high *ee* observed here compared to that of the cyclization of **2** with the same ligand may arise because a six-membered ring is more inflexible than a five membered ring.

The strategy described herein offers wide scope in the design of asymmetric ligands for transition-metal-catalyzed reactions. In palladium-catalyzed allylic alkylation, a reaction in which asymmetric induction previously proved difficult to achieve, these ligands are highly effective. Many questions remain—the most prominent is whether these ligands are serving as chelating ligands. Two facts support a bidentate coordination. Firstly, a high *ee* is obtained when virtually equimolar quantities of ligand and palladium are used. Secondly, a C_2-symmetric ligand from isomannide which for steric reasons can act as a bidentate ligand only with difficulty effects cyclization with only low ee. An advantage of these ligands is the versatility for rational modification in the chiral scaffold independent of the phosphine substituents. Indeed, the ethanoanthracene ligand **16** was developed after identification of some of the structural parameters that appeared important for asymmetric induction in our allylic alkylations.

Spontaneous Self-Assembly of a Dinickel(II) Double Helicate Containing a 1,3-Benzenediyl Spacer Group

By *Edwin C. Constable,* Michael J. Hannon,* and *Derek A. Tocher*

Molecular species exhibiting a double-helical topology attract the chemist because of their inherent beauty and the synthetic challenge of controlling the twisting of the component strands.[1] There has been considerable recent interest in the utilization of the specific coordination requirements of metal ions to control the assembly of such species.[1-3] Simply mixing suitable ligands with compatible metal ions results in the spontaneous self-assembly of polynuclear double-helical arrays. A helicating ligand must contain two or more separate polydentate metal-binding sites which are either directly linked or are connected by a suitable spacer group.[3] We have been particularly interested in developing ligands in which the twisting of molecular threads occurs about interannular C–C bonds between aromatic rings (Scheme 1).[4] We now describe a new class of helicating ligand (**1**) containing a 1,3-benzenediyl spacer group.

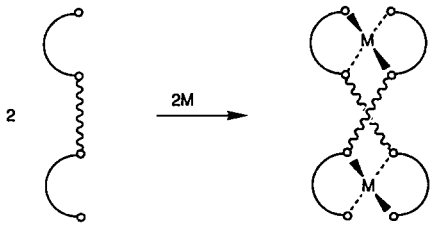
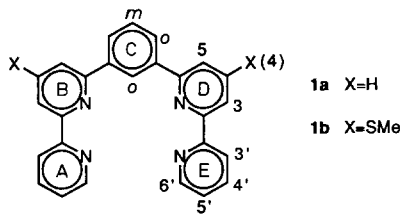


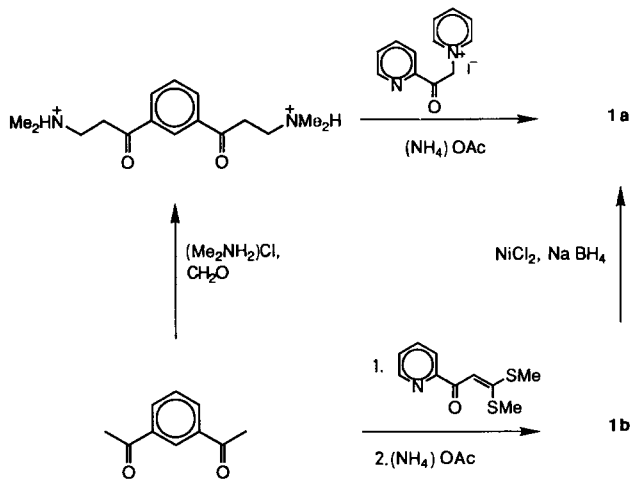
Scheme 1. Formation of a double-helical complex. The ligand has two bidentate coordination sites separated by a spacer group.

The new ligands are readily prepared as off-white solids[5] by routes involving the synthesis of rings B and D (Scheme 2). Compound **1a** is obtained in low and variable



Scheme 2. The new ligands for the synthesis of double helical complexes, showing the ring designations used in the text.

yield from a Kröhnke synthesis[6] or 60% yield from the dethiomethylation of **1b** with $NiCl_2$/Na[BH_4].[7] The derivatized compound **1b** was prepared in 60% yield from a double Potts reaction.[7, 8]



Scheme 3. Synthesis of the ligands **1a** and **1b**.

The reaction of **1a** or **1b** with solutions of either [Cu(MeCN)$_4$](BF$_4$) or [Cu(MeCN)$_4$](PF$_6$) in acetonitrile, or [{Cu(OAc)$_2$(H$_2$O)}$_2$] in methanol followed by the addition of methanolic $(NH_4)PF_6$ or $NaBF_4$, resulted in the formation of red-brown solutions from which deep red crystals of $[Cu_2L_2]X_2$ (L = **1a**,**1b**; X = PF_6,BF_4) separated.[9] Molecular modeling studies suggested that strain would make the formation of 1:1 complexes impossible and that binuclear double-helical complexes should result. Direct evidence for this comes from the FAB mass spectra. Similar compounds of 2:2 stoichiometry, $[Ag_2L_2]X_2$ (L = **1a**,**1b**; X = PF_6,BF_4) are obtained as colorless crystals from the reactions of ligands **1** with silver(I) salts.[10] Although these silver(I) and copper(I) complexes give well-formed crystals, these are invariably twinned and none suitable for X-ray structural analysis were obtained.

The reaction of **1a** or **1b** with Ni(OAc)$_2 \cdot 4H_2O$ in methanolic solution results in the formation of deep emerald green solutions, from which well-formed crystals of the blue-green salts $[Ni_2(OAc)_2L_2](PF_6)_2$ (L = **1a**,**1b**) could be obtained directly from the reaction mixture by the addition of methanolic $(NH_4)PF_6$ solution. We have determined the

$[Ni_2(OAc)_2(\mathbf{1b})_2][PF_6]_2$ **2**

crystal and molecular structure of **2**[11] and the structure of one of the two enantiomers of the cation is shown in Figure 1a.

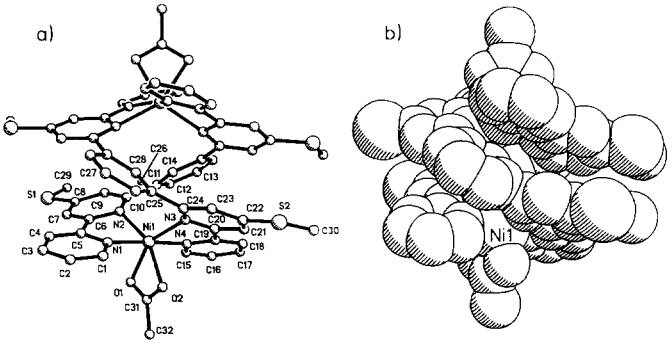


Fig. 1. The crystal structure of the $[Ni_2(\mathbf{1b})_2(OAc)_2]^{2+}$ cation in **2** showing the numbering scheme adopted. Important bond lengths [pm] and angles [°]: Ni1-N1 201.4(7), Ni1-N2 214.6(6), Ni1-N3 215.4(5), Ni1-N4 203.6(7), Ni1-O1 214.8(6), Ni1-O2 208.5(7), N1-Ni1-N2 78.9(3), N1-Ni1-N3 105.0(3), N2-Ni1-N3 116.8(2), N1-Ni1-N4 175.4(3), N2-Ni1-N4 100.2(3), N3-Ni1-N4 79.4(2), N1-Ni1-O1 86.8(3), N2-Ni1-O1 92.2(2), N3-Ni1-O1 150.0(2), N4-Ni1-O1 88.7(2), N1-Ni1-O2 91.6(3), N2-Ni1-O2 153.4(2), N3-Ni1-O2 89.6(2), N4-Ni1-O2 87.3(3)

The cation is double-helical with each nickel(II) center coordinated to a 2,2′-bipyridyl moiety from each of two **1b** ligands. Each nickel atom is in a distorted N_4O_2 octahedral environment with a bidentate acetate ligand completing the donor set. The Ni–N (2.014–2.154 Å) and Ni–O (2.085–2.148 Å) distances are unremarkable. Each 2,2′-bipyridyl–metal interaction is associated with a typical "bite-angle" of 79 ± 0.5°.[12] The helical structure is achieved by interannular twisting; the 2,2′-bipyridyl moieties are slightly nonplanar (13.9 and 14.9° interplanar angles for the two crystallographically unique 2,2′-bipyridyls) but the major twisting occurs between the 2,2′-bipyridyls and the 1,3-benzenediyl rings (38 and 35°). The two benzenediyl spacers are mutually skewed (62.8° with respect to one another).

Unlike other double helicates that we have studied, **2** does not exhibit any short face-to-face stacking interactions between near-coplanar aromatic rings.[4] A space-filling representation of **2** is shown in Figure 1b. The closest approaches between aromatic rings are those between the terminal pyridyl rings of one ligand and the central benzene spacer of the other (3.79 and 3.67 Å), although these rings are not coplanar (interplanar angles for the two crystallographically unique interactions, 28.1 and 24.7°). The two nickel(II) centers show no direct metal–metal bonding interactions and are 5.87(1) Å apart in the cation.

Experimental Procedure

1b: (3,3-bis(methylthio)-1-oxoprop-2-enyl)pyridine (14.0 g, 61.6 mmol) was added to a suspension of 1,3-diacetylbenzene (5.0 g, 30 mmol) and *t*BuDK (14.0 g, 126 mmol) in THF (200 mL) under an atmosphere of dinitrogen, and the mixture stirred at room temperature for 4 h. Then acetic acid (50 mL) and $(NH_4)OAc$ (10.0 g) were added, an air condensor fitted to the flask, and the suspension boiled for 3 h. After cooling, the reaction mixture was treated with H_2O (100 mL), and the solid precipitate recrystallized from EtOH/DMF in the presence of activated charcoal to yield relatively clean **1b** (8.6 g, 60%).

1a from **1b**: **1b** (2.17 g, 0.45 mmol) and $[Ni(H_2O)_6]Cl_2$ (21.61 g) were dissolved in EtOH (100 mL), and a solution of $NaBH_4$ (10.30 g) in 40% aqueous NaOH (100 mL) was added dropwise over 4 h while keeping the reaction mixture between 0° and 5 °C under an atmosphere of N_2. The reaction mixture was then heated at reflux for 24 h, filtered hot, and the filtrate evaporated to dryness and washed well with water to give an off-white residue. The precipitate was recrystallized from EtOH in the presence of activated charcoal to yield **1a** (1.03 g, 59%).

2: A solution of **1b** (0.05 g, 0.1 mmol) and $Ni(OAc)_2 \cdot 4H_2O$ (0.026 g, 0.1 mmol) in methanol (10 mL) was heated at reflux for 5 h to give a clear emerald-green solution. The solution was filtered hot, and the filtrate treated with methanolic $(NH_4)PF_6$ (0.1 g). On cooling, emerald-green crystals of $[Ni_2(OAc)_2(\mathbf{1b})_2](PF_6)_2$ separated. Yield 0.061 g, 79%; correct C, H, N analysis; FAB mass spectrum (3-nitrobenzyl alcohol matrix) *m/z* 535 [Ni(**1b**)], 593 [Ni(**1b**)(OAc)], 1191 $[Ni_2(\mathbf{1b})_2(OAc)_2]$, 1337 $]Ni_2(\mathbf{1b})_2(OAc)_2(PF_6)]$.

The Hydroxyl-Directed Hydrogenation of Vinylstannanes and Silanes: A Highly Diastereoselective Route to β-Stannyl and β-Silyl Alcohols

By *Mark Lautens,* ChunHao Zhang,* and *Cathleen M. Crudden*

Reactions in which an existing functional group directs a reagent to a nearby site represent an important strategy for the diastereo- and enantioselective construction of complex molecules. The directed hydrogenation of an olefin by an allylic or homoallylic alcohol in the presence of a soluble transition-metal catalyst is a powerful method for controlling the relative stereochemistry of alkyl and hydroxyl groups.[1, 2] All studies reported thus far have been limited to olefins bearing carbon substituents including alkyl, aryl, and acyl groups. We report a highly diastereoselective hydrogenation of olefins bearing silicon and tin substituents cata-

lyzed by the cationic rhodium complex **1**.[3] Prior to these studies, they were regarded as unreactive towards typical hydrogenation conditions.[4]

(dppb)Rh(nbd)BF_4 **1**

The vinylstannanes for this study were prepared by our hydrometalation–stannylation sequence.[5] Vinylsilanes were prepared by known routes.[6]

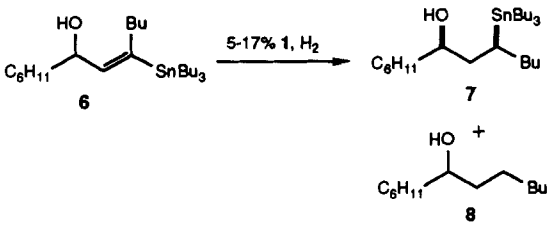
Table 1. Directed hydrogenation of Γ-hydroxyvinylstannanes. The substrate is treated with catalyst **1** in CH_2Cl_2 for 24–48 h.

Substrate	Reaction Conditions	Product	Yield [%] [a] (*syn*:*anti* ratio)
 **2**	[b]	 **3**	67 [c]
 **4**	[d]	 **5**	59
 **6**, R′ = *n*Bu	[b]	 **7**, R′ = *n*Bu	70 (>100:1) 85 (>100:1)
10, R′ = *i*Pr	[b]	**11**, R′ = *i*Pr	83 (>200:1)
12, R′ = *t*Bu	[d]	**13**, R′ = *t*Bu	70
 **14**	[b]	 **15**	95
 **16**	[e]	 **17**	51
 **18**	[f]	 **19**	

[a] Yield refers to pure product after flash chromatography. [b] 5 mol % of **1** at 103×10^5 Pa. [c] 17% of the starting material was recovered. [d] 17 mol % of **1** at 96×10^5 Pa. [e] 20 mol % at 103×10^5 Pa. [f] 5–20 mol % at 103×10^5 Pa.

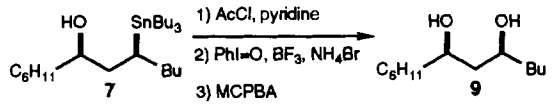
Hydrogenation of vinylstannanes **2** and **4** (Table 1) was examined first to determine the conditions necessary to achieve reaction without the additional complication of determining the diastereoselectivity. Treatment of **2** or **4** with 5 mol % of catalyst **1** in dichloromethane under ca. 1500 psi (103×10^5 Pa) of hydrogen for 24–36 h gave the saturated products **3** and **5** in 67% and 59% yields, respectively. The hydrogenation is therefore significantly more facile than destannylation by insertion into the C–Sn bond.[7]

The diastereofacial selectivity was probed by hydrogenation of vinylstannane **6**. By using 17 mol % of catalyst **1** at 1400 psi (96×10^5 Pa) for 36 h, alkylstannane **7** was isolated in 70% yield along with an additional product **8** in which hydrogenolysis of the vinylstannane and hydrogenation of the olefin had occurred [ca. 13%, Eq. (a)]. By reducing the amount of catalyst to 5 mol % and increasing the pressure to 103×10^5 Pa the yield of **7** improved to 85% and of **8** decreased to only 3%. The diastereoselectivity was found to be greater than 100:1 by HPLC following preparation of an authentic mixture of both diastereomers.



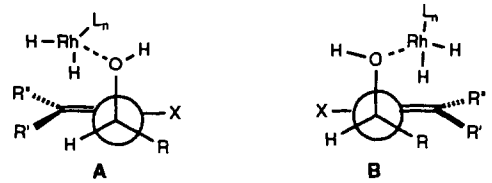
(a)

The relative stereochemistry of the hydroxyl and stannyl groups was determined to be *syn* by oxidation of the carbon–tin bond to a carbon–oxygen bond with retention of stereochemistry[8] and comparison with an authentic sample prepared by an independent route.



(b)

Selective formation of the 1,3-*syn* product is predicted by analysis of the Newman projections designated **A** and **B** (Scheme 1) representing the two most likely reactive conformers. The controlling element which determines the facial



Scheme 1. X = H

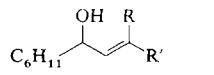
selectivity of the hydrogenation is the nonbonded steric interaction between R′ and R which disfavors conformer **B**; **A** leads to the observed product.[9] In accord with this analysis, substrates **10** and **12** (Table 1) bearing increasingly bulky substituents R′ also undergo facile and highly diastereoselective hydrogenation with catalyst **1**. The diastereoselectivity exceeded 200:1 for **11**, and only one isomer was detected for **13**. In contrast, Evans has shown that the hydrogenation of 1,1-disubstituted allylic alcohols (X = alkyl group and R′,R″ = H) leads to the 1,2-*anti* diastereomers, indicating that conformer **B** is favored over **A**.[1g]

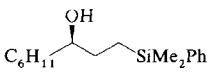
The stereochemistry of the vinylstannane and the size of R group on the carbon containing the hydroxy group were also found to play a significant role in determining the course of the reaction. Whereas the *E* and *Z* isomers **14** and **16** undergo hydrogenation to give the diastereomeric hydroxystannanes **15** and **17**, the *Z* isomer of **6** (**18**) led primarily to the destannylated alcohol **19**. Control experiments proved that destannylation precedes hydrogenation.

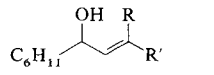
γ-Hydroxyvinylsilanes also undergo hydrogenation (Table 2). Treatment of **20a**, **b**, **22**, and **24** with catalyst **1** for

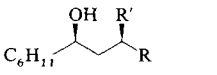
48 h gave the saturated silanes **21**, **23**, and **25** in greater than 90% yields. Exceptionally high diastereoselectivities (>500:1) were noted in all cases. No desilylation was observed under these conditions.

Table 2. Directed hydrogenation of γ-hydroxyvinylsilanes. The substrate was treated with 5 mol % of the catalyst **1** in CH_2Cl_2 for 24–48 h at 103×10^5 Pa.

Substrate	Product	Yield [%] [a] (*syn*:*anti* ratio)
		




20a, R = H, R′ = $PhMe_2Si$	**21**	99
b, R = $PhMe_2Si$, R′ = H		90
		




22a, R = Me, R′ = $PhMe_2Si$	**23a**, R = Me, R′ = $PhMe_2Si$	99 (>500:1)
24, R = $PhMe_2Si$, R′ = Me	**25**, R = $PhMe_2Si$, R′ = Me	95 (1:>500)

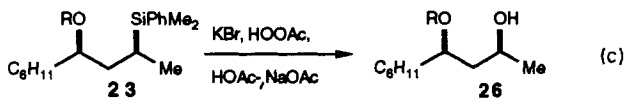
[a] Yield of pure product.

The significance of these results lies in the ease of conversion of a carbon–silicon σ bond to a carbon–oxygen bond under very mild conditions with retention of stereochemistry.[10] Oxidation of **23a** under the conditions described by Fleming gives the *syn* diol **26a** in 68% yield [Eq. (c)]. Differentially protected diols are readily prepared by protection of the hydroxyl group prior to the oxidation step. Thus treatment of **23b** gives **26b** in 71% yield as a single diastereomer.



23 **26** (c)

a, R = H; **b**, R = Me

Olefins bearing both tin and silicon moieties also undergo hydrogenation (Table 2). Thus compounds **27** and **29** were formed in good yield, the latter with 60:1 diastereoselectivity. The sense of diastereoselection was assumed to be identical to that previously observed for the silanes and stannanes.

In conclusion, we have shown that vinylsilanes and stannanes can be readily hydrogenated by a cationic rhodium catalyst, that the hydroxyl group directs the addition to one face of the olefin with very high diastereoselectivities, and that a subsequent oxidation provides a route to 1,3-diols. The reactivity of diastereomerically enriched 1,1-dimetalated compounds such as **30** is currently under investigation.

Experimental Procedure

A high-pressure hydrogenation bomb (Parr instrument Co) containing a glass sleeve insert was charged with the substrate, the rhodium catalyst **1** (5 mol%), and dry, distilled, deaerated dichloromethane. The system was pressurized to 1500 psi (103×10^5 Pa), and the reaction stirred for 36–48 h. After the reaction was complete, the catalyst was precipitated by the addition of hexanes, the suspension was filtered through a plug of Na_2SO_4, and the volatiles removed in vacuo. Flash chromatography gave the pure product. ^1H NMR of **7**: (400 MHz, $CDCl_3$, 25 °C, TMS) δ = 3.4 (sb, 1H; *H*C-OH), 1.56–1.8 (m, 8H; HO-CH-CH_2, $(CH_2)_3$, Cy), 1.55 (m, 4H; -CH_2-CH-CH_2-), 1.4–1.45 (m, 7H; Sn-$(CH_2)_2$-CH_2-CH_3, O-*H*), 0.98–1.3 (m, 17H; Sn-CH_2-CH_2-CH_2-CH_3, Sn-*CH*-$(CH_2)_3$-CH_3, *CH*-CH-OH), 0.87, (t, ^3J(H,H) = 7.29 Hz., 9H; Sn-$(CH_2)_3$-CH_3), 0.79 (m, 6H; Sn-CH_2-$(CH_2)_2$-CH_3). ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C, TMS) δ = 74.3, 43.8, 37.3, 32.3; 32.1, 29.3, 26.4, 26.3; 26.1, 29.2, 27.4, 22.9, 22.2, 13.9, 13.5, 8.8. ^{119}Sn NMR (25 MHz, $CDCl_3$, 25 °C, Me_4Sn) δ = −5.2. IR (neat) $\tilde{\nu}$ [cm^{-1}] = 3631, 2926, 1464, 1457, 1451, 1376, 1101. Correct C,H analysis for $C_{25}H_{52}OSn$.

Nucleophilic Attack at the Central Carbon Atom of (π-Allyl)palladium Complexes: Formation of α-Cyclopropyl Esters**

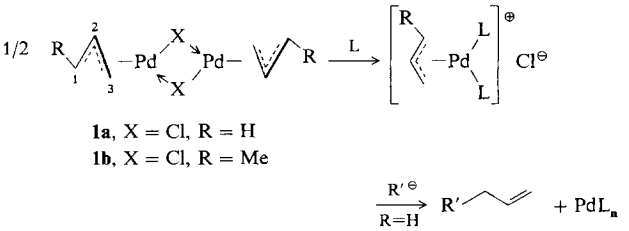
By *H. Martin R. Hoffmann*,* *Andreas R. Otte*, and *Andreas Wilde*

(π-Allyl)palladium complexes are key intermediates in organopalladium chemistry[1] and the structural formula of

[*] Prof. H. M. R. Hoffmann, A. R. Otte, A. Wilde
Institut für Organische Chemie der Universität
Schneiderberg 1B, D-W-3000 Hannover (FRG)

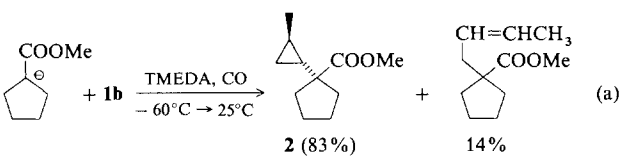
[**] This work was supported by the Fonds der Chemischen Industrie (PhD fellowship to A. Wilde) and Degussa AG (generous gift of palladium salts). We thank Dr. Victor Wray for kindly providing the 600 MHz NMR spectra.

the bridged dimer **1** has featured prominently as logo of a recent international symposium.[2] The reaction of (π-allyl)palladium complexes with various carbanions results in allylic alkylation (Tsuji–Trost reaction).[1] In these reactions, regiochemistry plays a decisive role. Although many studies have addressed the question of switching the site of terminal nucleophilic attack (C1 versus C3) for a given nucleophile,[1] only two isolated examples of C2 attack are known.[3, 4] More than a decade ago Hegedus and his coworkers observed attack at the central carbon (C2) of the allyl moiety with concomitant formation of a substituted cyclopropane ring.[3, 5] Recently, Santi reported that Pd complexes of bulky chelating phosphanes may catalyze the coupling of allyl acetates and ketene silyl acetates to produce cyclopropane derivatives in low yields.[4, 6]



1a, X = Cl, R = H
1b, X = Cl, R = Me

We now show that proper choice of the coordination environment affords functionalized cyclopropane in high yield. Specifically, addition of 1,2-bis(dimethylamino)ethane (TMEDA) followed by carbon monoxide to the (π-allyl)-palladium solution gave the cyclopropanation products in large excess as Equation (a) and Table 1 show.[8] Separation of **2** and **3** by column chromatography proved difficult. However, pure cyclopropane derivatives were obtained after treatment with OsO_4/H_2O_2 and chromatographic separation of the resulting diol.[7] The yields of allylic alkylation products were determined by NMR and GC analysis and the *trans* configuration of the cyclopropanation products **2** and **4** by difference NOE NMR measurements.



2 (83%) 14% (a)

In all cases the added ligand proved to be a crucial factor. TMEDA gave the highest yields, bis(dimethylamino)-methane and 1,3-bis(dimethylamino)-propane failed to deliver any cyclopropanation product, and sparteine provided moderate yields. According to calculations by Curtis and Eisenstein[9] published four years after the original paper by Hegedus,[3] the observed cyclopropanations should not be energetically accessible. As yet, theory has not dealt satisfactorily with these reactions.

Under the conditions we employed, lithium enolates of ketones and of less substituted esters (e.g., cyclohexanone, isobutyrophenone, methyl phenylacetate, and methyl 3,3-dimethylbutyrate) did not work. The scope and limitations of the reported transformations are under investigation.

Table 1. Cyclopropanes from (π-allyl)palladium complexes.

Entry	Nucleophile	π-Allylpalladium Complex	T [°C]	Added Ligand	Product	Yield [%]
1		**1a**	−60	TMEDA, CO	 **3**	72
2		**1b**	−60	TMEDA, CO	 **4**	70
3		**1a**	−60	TMEDA, CO	 **5**	60
4			−78	HMPA/ [a] Et_3N	 **6**	5
5		**1a**	−60	HMPA/ Et_3N		41
6			−60	TMEDA, CO		84 [b]

[a] HMPA = hexamethylphosphoric triamide. [b] Without CO the yield was smaller.

Experimental Procedure

Preparation of ester enolates: Diisopropyl amine (0.15 mL, 1.1 mmol) in dry THF (5 mL) was placed in an oven dried flask under N_2. After cooling the mixture to 0 °C, *n*BuLi (0.7 mL, 1.1 mmol, 1.6 M solution in hexane) was added. The solution was stirred for 5 min and cooled to −78 °C before the ester (1.1 mmol) was added. The reaction mixture was then stirred at 0 °C for 10 min, after which it was cooled to −78 °C and TMEDA (0.17 mL, 1.1 mmol) was added. The solution was stirred at −78 °C until required (about 30 min).

Cyclopropanation reaction: A dimeric (π-allyl)palladium chloride complex (0.275 mmol) in dry THF (5 mL) was placed in an oven dried flask under N_2. The solution was cooled to −78 °C and TMEDA (0.17 mL, 1.1 mmol) was added. After warming the mixture to −60 °C, the carbanion solution (see above) was added dropwise through a double tipped needle. Attachment of a CO balloon caused the reaction mixture to turn black and palladium to precipitate. After stirring for 1 h, the solvent was removed and ether (100 mL) was added. The mixture was filtered and the filtrate washed with water. The aqueous layer was back extracted with ether and the combined organic layers were washed with brine (20 mL), dried ($MgSO_4$), and concentrated. The resulting oil was purified by flash chromatography (silica gel, cyclohexane/ether, 10:1) to give the product as a colorless oil.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Atomic Spectroscopy. By *J. W. Robinson*. Marcel Dekker, New York, 1990. vi, 299 pp., hardcover $ 119.50.—ISBN 0-8247-8311-5

Atomic spectroscopy methods are nowadays the most important of the tools used in the analytical chemistry of the elements. Their great variety, which one can now barely keep track of, and the remarkably rapid pace of instrument developments in this field, already make it difficult for competent users to evaluate these with regard to such criteria as detection capability, reliability and value for money, so as to be able to solve analytical problems that are nowadays becoming ever more complicated.

The task of teaching young scientists the basic knowledge required is especially difficult. In principle, therefore, any attempt to make this easier by providing an up-to-date introduction to atomic spectroscopy, limited to the basic essentials, is appropriate and welcome.

The author of this book is an experienced spectroscopist and analyst who has been involved in the rapid developments that have occurred in this area of applied analysis since the 1950s, has made a name for himself through many original contributions, and now teaches analytical chemistry as a professor at the University of Louisiana, USA. He has previously written several monographs on the subject and chapters in handbooks, and is the editor of two specialist journals.

This monograph provides further evidence of his competence. He has set out to provide, in about 300 informative and richly illustrated pages, a picture of modern atomic spectroscopy, including the necessary basic physical background and the analytical capabilities and limitations of the methods.

A compressed introduction to such a broad subject obviously requires tight restrictions on the choice of methods and literature references. The textbook-style treatment is therefore limited to those methods of optical atomic spectroscopy that are currently most important and are in routine analytical use, such as atomic absorption, emission and fluorescence spectroscopies and their most important excitation sources, both classical and modern (radiofrequency plasmas).

However, this reviewer was disappointed at not finding at least some references to the most recent, highly interesting, developments in laser spectroscopy, which will revolutionize atomic spectroscopy in the future. Also there should have been some mention of microwave-induced plasmas (MIP) and glow discharges (GD), which are very powerful modern excitation sources for optical emission spectroscopy and mass spectrometry.

Unfortunately, too, not enough detail is given of the many different ways of reducing possible sources of error and improving detection capabilities by combining with appropriate chemical and physical methods of separation and enrichment, which are indispensable techniques in elemental trace analysis.

On the other hand, one could easily have done without the extensive tables of wavelengths (20 pages) used for the determination of elements by flame AAS, since practitioners already have access to adequate published tables, whereas newcomers to the field are unlikely to find them interesting. Also flame photometry is treated in too much detail in relation to its present importance.

Reading this book has again reminded the reviewer how difficult it is to give, in a limited space, a balanced treatment for teaching purposes of such an extensive and important field as atomic spectroscopy has now become in modern elemental analysis. Even more difficult is the undertaking of providing already practising analysts with anything more than just a condensed overview of the tools of the method and the basic physical principles on which they depend.

Just as providing a lump of marble, a hammer and a chisel does not at once result in a sculpture, so one finds that a description of the analytical techniques falls far short of enabling one to approach problems of analytical chemistry in the most effective way. To achieve this difficult task, which also involves teaching strategies, requires a more concentrated effort on the part of authors. Until that occurs we must be content with partial solutions; even this book has failed to achieve more than that.

With that reservation, however, I can recommend the book especially to students and analytical chemists wishing to make a start in atomic spectroscopy, provided that they

are not put off by its high price, which is not justifiable for a "textbook", despite the high standard of production and the clear and carefully prepared contents.

Houben-Weyl. Methods of Organic Chemistry. Additional and supplementary volumes to the 4th Edition. Vol. E12b. Organotellurium Compounds. Edited by *D. Klamann*. Thieme, Stuttgart, 1990, xli, 1004 pp., hardcover DM 1340.00—ISBN 3-13-219904-4.

The series "Methoden der Organischen Chemie" was established in 1909 by Theodor Weyl and continued in 1913 by Heinrich Houben. At that time, publishing a handbook in organic chemistry in German seemed most appropriate. Today, more than eighty years later, changing the "official" language of Houben-Weyl from German to English seems just as well motivated. I am sure the change will increase the international character of the series even more and I would like to congratulate the editors on their decision.

Organotellurium compounds were previously described by Houben-Weyl in 1955 (Vol IX), together with organosulfur and organoselenium compounds. At that time Rheinboldt used 292 pages for the description of the surprisingly old but little explored fields of organoselenium and organotellurium chemistry. A few years ago, organosulfur chemistry was updated in two volumes of Houben-Weyl, while the work with the organoselenium volume(s) is presently ongoing.

The last twenty-five years have seen a steady increase in the number of publications in the field of organotellurium chemistry. Recently, a number of useful organic transformations brought about by organotellurium reactions and reagents has focused the attention of synthetic organic chemists on the area. Thus, organotellurium chemistry, viewed by many as rather odd and peculiar, has now developed into an almost respectable field of research close to the mainstream of organic chemistry.

The author, Kurt Irgolic, was very well prepared for the gigantic work of putting together a volume of Houben-Weyl. In 1972 he summarized all previous work in the field in "The Organic Chemistry of Tellurium" which has since been frequently used as reference by all involved in organotellurium research. For many years thereafter he also published annual reports on the chemistry of organic tellurium compounds in the *Journal of Organometallic Chemistry*. Unfortunately, this work was disrupted in 1980. Since that time organotellurium chemistry has been treated in depth only in the Patai series, "The Chemistry of Organic Selenium and Tellurium Compounds", Vol. 1 1986; Vol. 2 1987. Due to the organization of the Patai series, which focuses attention on a number of diverse aspects of the field, these volumes are complementary to, rather than overlapping with, the Houben-Weyl volume.

The contents of the present volume are logically organized in a way similar to the one used by the author in his previous writing. Thus, the organic tellurium compounds are classified according to the number (1–6) of carbon–tellurium bonds in the molecule, and their reactions subdivided according to the traditional Houben-Weyl scheme of presentation (i.e., A. Preparation; B. Transformations). Polymeric tellurium compounds as well as heterocyclic (3–7-membered) organic tellurium compounds are treated in separate sections. In addition, a chapter (150 pages) is devoted to organic tellurium compounds without a carbon–tellurium bond in the molecule. Compounds described in this section include molecules where the organic moiety is separated from tellurium by another heteroatom such as oxygen, sulfur, selenium, silicon, or phosphorus. These compounds were traditionally not classified as organotellurium compounds but left in a no-man's-land between inorganic and organic chemistry.

The classification of chemical reactions as "Preparations" or "Transformations" in the treatment of various classes of compounds is not always consistent. For example, the reaction of a diorganyltellurium(II) species with a halogen, to give the corresponding diorganyltellurium(IV) dihalide is sometimes treated as a method of preparation, sometimes as a transformation of the class of diorganyltellurium(II) compounds. The latter treatment is the preferred one. The formation of complexes of organotellurium compounds with transition metals or electron-deficient organic molecules is usually found under "Preparations". However, in some cases these compounds are also treated under "Transformations". In my opinion the latter classification is more logical and should be used consistently.

A third category of classification is introduced for diorganotellurium dihalides on p. 577: "C. Diorganotellurium dihalides as synthetic intermediates". However, when the similar use of diorganotellurium compounds is discussed earlier on p. 480, the material is presented as a transformation.

The present supplementary volume of Houben-Weyl contains a respectable number of references and examples from the period (1840–1955) covered by volume IX. The old results are often presented in the light of new findings and contribute to a feeling of complete understanding and coverage of a certain class of compounds or reactions. In other cases the old material was too sparsely treated in the previous version and was in need of an expansion.

The overall impression of the present volume of Houben-Weyl is that of a complete coverage of the field. The number of papers not included can probably be counted on your fingers. This completeness will of course make the book invaluable for all involved in organotellurium research and those in other areas in need of information concerning organotellurium chemistry. However, the philosophy on which Houben-Weyl was established requires not only a complete description of preparative methods but also their critical evaluation. While going through the representative examples of the present volume, I sometimes got the impression that the author should have been more selective/critical in his choice. There are too many full-detail preparations where the yields do not exceed 10%. For example, nobody "skilled in the art" would ever consider trying to execute the 1% yield synthesis of diphenyl ditelluride described on p. 270, when there are so many better methods available. Similarly, on p. 2 the existence of tellurium(II) dihalides is discussed, and it is concluded that they probably do not exist as molecular entities in the solid state. Nevertheless, on p. 37 an example is presented where $TeCl_2$ is used as one of the reactants for the preparation of a ferrocene derivative. Likewise, on p. 841 TeI_2 appears in an example describing the synthesis of a heterocyclic tellurium compound.

An index of authors and a compound index is included at the end of the book. The compound index is very good if you are looking for a particular compound; however, it is of little help if you are searching for something else. I think a book of this size could afford also a subject index.

The number of printing errors is kept to a minimum throughout this volume of Houben-Weyl. Less than 50 errors (and only very few serious ones) were noted while going through the material. Except for p. XXXVII (where a terrible 20% of the references contain minor errors or are incomplete) the citation is comparable in quality with that found in the best journals.

In conclusion, the updated Houben-Weyl volume on organotellurium compounds is a masterpiece which will be enthusiastically received by all readers with an interest in tellurium chemistry.

Electrochemical Interfaces. Modern Techniques for in-situ Interface Characterization. Edited by *H. D. Abruna*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. xviii, 589 pp., hardcover DM 182.00.—ISBN 0-89573-715-9/3-527-27840-0

In seeking to describe and understand electrochemical processes that occur in the solid/liquid transition region, experimental data obtained by in-situ measurements are especially valuable. A classic example where this applies is the technique of cyclovoltammetry (CV). In this the flow of charge is recorded as a function of the potential, but the method is intrinsically incapable of yielding information of a highly specific kind. For this reason other techniques that can be used in combination with CV have recently been developed to complement it. Particularly interesting results can be obtained by carrying out in-situ measurements simultaneously with CV studies. This rapidly developing field is the subject of the specialist book edited by H. D. Abruna (Cornell University) which is reviewed here.

The book, with nearly 600 pages, contains ten chapters following an introduction by the editor, and there is a 22-page subject index at the end.

The individual chapters deal with X-ray absorption spectroscopy, surface X-ray scattering, X-ray standing waves, measurements of surface forces, surface-enhanced Raman scattering, nonlinear optical methods, surface infrared spectroscopy, in-situ Mössbauer spectroscopy, radioactive labeling, and measurements with vibrating quartz crystals. The contributions have been printed by the camera-ready method, and all except one are written by American authors.

Apart from the fact that several of the figures in Chapter 1 have been interchanged (see the comments of the editorial office), the contributions are impressively well prepared: they are logically set out, illustrated by clear figures, and packed with information. In each chapter the main emphasis is firmly on the description of the experimental techniques, but this is supported by informative examples of applications. In the description of the standing wave X-ray technique for characterizing the phase boundary region, it would have been desirable to have examples of a wider range of applications. Unfortunately the chapter on in-situ measurements with vibrating quartz crystals includes only two examples of applications, namely to coverages deposited in the under-potential range, and (in more detail) to studies of mass transport during redox processes in polymer films.

The selection of topics covered by the chapters is not exhaustive, nor can one expect it to be. However, it is noticeable that some important methods are not mentioned, for example UV/VIS reflectance spectroscopy, ellipsometry and photocurrent spectroscopy. It is also regrettable that in-situ topographic methods such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM), which give a microscopic image of the surface, in some cases with atomic resolution, are not included. Furthermore, there seems to be no logical connection between the individual chapters. The fact that articles on optically based techniques alternate with others on non-optical methods prevents a systematic presentation of the subject matter. Consequently it is hardly surprising that the book lacks a final summary linking the various methods and results and evaluating them.

The book has a binding of appropriately high quality. Considered as a whole it provides a good insight into the progress that has been made in the development of various in-situ techniques. However, one cannot overlook the shortcomings in the choice of topics and their relative emphasis, and the lack of a logical arrangement of subject matter, with the result that the reader fails to get a deeper understanding of the progress made. The book is unquestionably of considerable importance to scientists with interests in interfacial electrochemistry, and it should therefore be in every relevant library, especially since the price of DM 182.00 will prevent students from buying it.

Berlin (FRG)

Chemistry of Organosulfur Compounds. General Problems. (Ellis Horwood Series in Organic Chemistry). Edited by *L. I. Belen'kii*. Ellis Horwood, New York, 1990. 378 pp., hardcover $ 129.95.—ISBN 0-13-132051-3

Organosulfur chemistry traditionally occupies a position of considerable importance in Soviet research, and there is even a special scientific committee to promote it. The monograph reviewed here is based on a status report on work in this field that was prepared in 1986 by various authors, mainly from Moscow and Irkutsk. For this English version the Russian text has been rearranged and updated (but, as becomes apparent, only in parts). The 15 chapters of this version deal with the preparation of organosulfur compounds, their transformations, and the methods used to study them. Details of the chapters are as follows: Modern Principles of the Synthesis of Organosulfur Compounds (M. G. Voronkov et al., 14 pp., 25 references); Radical Reactions of Some Thiocarbonyl Derivatives in Solutions (R. Kh. Freidlina et al., 21 pp., 64 references); Thermal Reactions and High Temperature Syntheses of Organosulfur Compounds (M. G. Voronkov et al., 20 pp., 56 references); Photochemical Synthesis and Transformations of Organosulfur Compounds (N. N. Vlasova, 22 pp., 65 references); Radiochemical Synthesis and Transformations of Organosulfur Compounds (E. M. Nanobashvili, 8 pp., 11 references); Sulfur-stabilized Carbanions and their Synthetic Use (F. M. Stoyanovich, 43 pp., 267 references); Formation of C–C Bonds Using Sulfur-containing Electrophilic Reagents (W. A. Smit et al., 32 pp., 99 references); Catalytic Synthesis of Organosulfur Compounds (A. V. Mashkina, 20 pp., 40 references); Methods of Desulfurization and their Use in Organic Synthesis (L. I. Belen'kii, 36 pp., 189 references); Investigation of Organic Reactions by the Use of Radioactive Sulfur (V. M. Fedeseev, 15 pp., 49 references); Mass

Spectrometry of Organosulfur Compounds (A. A. Polyakova, 11 pp., 10 references); Electronic and Vibrational Spectroscopy of Organosulfur Compounds (Yu. L. Frolov, 11 pp., 30 references); ^{33}S NMR Spectroscopy (V. M. Bzhezovsky et al., 21 pp., 49 references); X-Ray Fluorescence Spectroscopy of Sulfur Compounds (G. N. Dolenko, 76 pp., 199 references); Quantum Chemical Calculations of Organosulfur Compounds (Yu. L. Frolov, 11 pp., 66 references).

The intention of the book is to concentrate on reporting the work of Soviet authors, and the high proportion of references to Soviet publications makes this clearly apparent. In contrast, published work in this field from the West is incompletely represented. Consequently, although the breadth and potency of organosulfur chemistry become clearly evident, some of the newer and particularly elegant synthetic applications of sulfur-containing functions, such as those introduced by Vedejs and by Warren, are dismissed too briefly or even omitted altogether. Also the usefuless of the book is reduced by the inadequacy of the rather meager subject index. For example, there is no entry for thioaldehydes, despite the fact that this class of compounds is mentioned at several places in the text. It therefore comes as welcome news to learn from the preface that a further monograph dealing with the most important classes of organosulfur compounds is planned.

The book is visually pleasing, thanks to the clear and attractive typography. The incidence of printing errors is as low as can reasonably be expected. There is an unfortunate mistake on page 84, where thiofenchone is shown instead of thiocamphor. The book fills a gap by reporting in detail on Soviet work in organosulfur chemistry, but for newcomers to this field it fails to provide a comprehensive critical overview.

Ernst Schaumann
Institut für Organische Chemie
der Technischen Universität Clausthal (FRG)

Chemical Kinetics. By *K. A. Connors*. VCH Publishers, Cambridge, New York/VCH Verlagsgesellschaft, Weinheim, 1990. xiii, 480 pp., hardcover DM 168.00.—ISBN 1-56081-006-8/3-527-28037-5

Spectacular successes were achieved during the sixties using the techniques of "fast kinetics", and this led to the publication of numerous monographs dealing with this important area of physical chemistry. As an example of these one may mention particularly the classic work "Fast Reactions in Solution" by E. F. Caldin. Since then these methods have become widely used in chemistry, and therefore the publication now of an up-to-date and comprehensive work on kinetics, which will make it easier for those interested in the topic to become involved, is greatly to be welcomed.

This book by K. A. Connors deals in eight chapters with the important field of kinetics in solutions, with an emphasis on the chemical aspects. Chapter 1 begins with a discussion of the significance of time as a variable in chemistry, followed by an explanation of fundamental concepts involved in kinetics, such as transition states, reaction intermediates and the rate of a reaction. The second chapter then deals with the integration of simple rate equations, the determination of the order of a reaction, and the calculation of the corresponding rate constants. The numerical problems associated with error limits are discussed in great detail at this stage. Chapter 3 deals with systems described by more complex equations, and here the application of Laplace transforms is introduced. Classical examples such as microreversibility and the condition for a stationary state are discussed, as well as more innovative methods such as Monte-Carlo simulations.

Following these discussions of basic principles, Chapter 4 is concerned specifically with fast kinetics. After dealing with diffusion-controlled reactions, the chapter goes on to consider periodic and aperiodic relaxation processes. Next some fundamental aspects of nuclear magnetic resonance spectroscopy as applied to kinetic studies are discussed. The chapter ends with descriptions of flow techniques, fluorescence quenching, and a brief reference to electrochemical methods.

Chapter 5 takes the discussion of fundamental kinetic theories a stage further. Starting from the Arrhenius equation, the author deals with simple collision theory, potential energy surfaces, and quantum-mechanical aspects of the reaction between H_2 and H and of the transition state based on partition functions. Next some examples from actual kinetic studies are described, and the relationship between free activation enthalpies and free reaction enthalpies is discussed. Here the Hammond, Brønsted, and Marcus representations are discussed. Chapter 6 describes examples of some important kinetic phenomena. In the catalytic field the influence of acids and bases on chemical reactions and the pH-dependence of rate constants are discussed. The chapter concludes with a discussion of isotope effects, which are very interesting from a mechanistic standpoint.

For organic chemists the most interesting part of the book is likely to be Chapter 7 on structure–reactivity relationships. The chapter begins with a discussion of linear free energy relationships, by which activation data are related to reaction parameters. As an example, these considerations are applied to substituent effects in arenes, including a detailed discussion of the Hammett equation and its limitations. Next the theory is extended to nonlinear phenomena, including electronegativity, polarizability and resonance effects. Substituent effects in aliphatic compounds are also treated and discussed in relation to the Taft constants for alkaline and acidic hydrolysis reactions; here steric effects are also taken into consideration. In addition the "hard–soft" concept and isokinetic relationships are discussed. It is pleasing to find that the potentially troublesome problem of propagation of errors in determining activation parameters is taken into account here, so as to avoid the risk that numerical errors could lead to wrong conclusions about isokinetic relationships.

The book ends with a chapter on the influence of the medium. It is shown that, in the determination of rate constants, differences as great as a factor of 10^{15} compared with the gas phase can arise. Theories of the effects of a dielectric continuum are discussed, including the early suggestions by Born and also the Hughes–Ingold theory. The effects of intermolecular interactions with solvents are discussed, including molar refraction, polarization, Coulomb potentials, charge transfer effects and hydrogen bonding. In this connection the empirical solvent scales based on thermodynamic and spectroscopic data, such as those proposed by Gutmann, Kosower, or Reichardt, are especially important.

The range of topics covered in this book extends considerably beyond the treatments of kinetics found in comprehensive textbooks of physical chemistry. The numerous examples give an excellent overview of the many different types of phenomena and reactions that have been studied. For the

practising chemist the details of the many methods that are described for determining rate constants are especially useful, since they give particular attention to considerations of error limits. The book is easy to read and should also be of great value to students; it can be recommended unreservedly.

Franz L. Dickert
Institut für Physikalische Chemie
der Universität Erlangen-Nürnberg (FRG)

Cycloaddition Reactions in Organic Synthesis. By *W. Carruthers*. Pergamon, Oxford, 1990. viii, 373 pp., paperback $ 30.00.—ISBN 0-08-034712-6

In this book, published as the eighth volume of the very successful "Tetrahedron Organic Chemistry Series", William Carruthers has set out to show why cycloaddition reactions are so important in organic synthesis. The author, who sadly died shortly after the completion of the manuscript, has succeeded very convincingly in this aim.

The first three of the seven chapters begin by dealing with general aspects of the Diels–Alder reaction and its applications in both its inter- and intramolecular forms. The most useful types of dienes and dienophiles for this reaction are described (including heterofunctionalized species), and the effects of aqueous solvent systems, high pressures, and the use of Lewis acids as catalysts are discussed, illustrated by examples taken mainly from recently published work. Regio- and stereochemical aspects, asymmetrical syntheses using chiral auxiliary groups, and the importance of the retroreaction are also discussed. A considerable amount of space is devoted to the analogous reactions of heterodienes and heterodienophiles, followed by general applications of Diels–Alder reactions to the synthesis of arenes and quinones. Lastly the author makes a special point of emphasizing the effectiveness of intramolecular Diels–Alder reactions for synthesizing terpenoids, alkaloids and other nitrogen-containing heterocycles, cannabinoids, steroids, and lignans.

Chapter 4 is concerned with other types of [4 + 2] cycloaddition reactions. Those described include reactions using allylic anions and cations, and also oxyallyl and pentadienyl cations. Palladium(0)-catalyzed reactions using trimethylenemethane, together with other related reactions, and cobalt-catalyzed acetylene trimerizations are also described. Chapter 5 treats various aspects of inter- and intramolecular ene-reactions. Here the main emphasis is on reactions involving heteroatom species, for example with carbonyl compounds as enophiles or with allylic Grignard reagents as metalloenes. Chapter 6 is concerned with 1,3-dipolar cycloadditions. Here the author introduces the azomethine ylides, the nitrile oxides and the nitrones as the most important 1,3-dipolar molecules for synthetic purposes. The preparation of these intermediates and their use for synthesizing a variety of classes of compounds are discussed with a thoroughness that befits their importance for preparative chemistry. The seventh and last chapter deals with [2 + 2] cycloadditions. Particular emphasis is placed on reactions of ketenes and keteniminium salts with olefins and imines, and on the de Mayo and Paternò–Büchi reactions.

In his treatment Carruthers places special importance on describing and illustrating the synthetic potential of the many different types of cycloadditions. Mechanistic details are included only where they are essential for understanding the synthesis under discussion or for clarifying the stereochemistry of the reaction stages. In this book, in contrast to student textbooks, considerations of the frontier orbitals involved in the reactions are avoided entirely. This policy is followed in all seven chapters, each of which is a self-contained article that can be read independently of the rest, and has its own detailed bibliography (extending up to 1988). A short explanation of the basic principles is followed in each case by an account emphasizing recent developments and applications to building up complex structures; occasionally certain types of reactions are overrepresented (for example, the use of electron-rich siloxydienes as developed by Danishefsky et al.). In some sections the discussion of asymmetric cycloadditions is too brief in relation to their importance, or is omitted entirely. Also it has not been possible to include the development of efficient chiral catalysts, e.g. for Diels–Alder reactions, which has only recently attained full maturity. Nevertheless, in every chapter the author has succeeded convincingly in summarizing the most important developments that have occurred in the area of cycloadditions during the last three decades. The presentations are always lucid and comprehensible, and the numerous reaction schemes are clearly drawn. This ensures that one can quickly extract the most important information, and can then go into topics in greater depth with the help of the detailed bibliographies.

Carruther's book succeeds well in its aims. It contains a wealth of elegant and well-chosen examples, which are very well-suited for illustrating lectures to advanced students. At the same time it provides the interested synthetic chemist, whether in a university or industry, with an excellent overview of the current state of research (up to 1988). Thus the monograph fits well into the scheme of the other volumes in this "Organic Chemistry" series. Since no other comparable work exists at present, and this volume is also very attractively priced, its purchase can be recommended unreservedly.

Herbert Waldmann
Institut für Organische Chemie
der Universität Mainz (FRG)

Polymer Solutions. By *H. Fujita*. (Series: Studies in Polymer Science, Vol. 9). Elsevier, Amsterdam, 1990. xviii, 370 pp., hardcover HFl 285.00.—ISBN 0-444-88339-8

It is always something of a special occasion when one of the great old men of polymer physics makes use of the well-deserved, but not always welcome, leisure of retirement to write a monograph or textbook. *Hirosha Fujita*'s book belongs to this category of works.

On the one hand the book discusses the progress achieved in the study of polymer solutions, while at the same time indicating, with an unusual degree of openness and clarity, the unanswered questions and unsolved problems that remain. It is a critical stocktaking, with the emphasis on *Fujita*'s life's work, which recurs as a central theme throughout the ten chapters of the book. The broad scope of *Fujita*'s research interests prevents the treatment of the subject from becoming too narrow.

The two parts of the book deal with the properties of dilute and concentrated solutions respectively, in the equilibrium state. Time-dependent nonequilibrium processes are not covered, apart from a few exceptions, and indeed to do so would certainly have exceeded the planned size of this book. *Fujita* begins by developing theoretical concepts, which he then compares critically with the relevant experimental observations. In the first part, on dilute solutions, the

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/0202-0240 $ 3.50+.25/0

important chain models for macromolecules are introduced, then different approaches to the problem of the excluded volume are described, the contributions of renormalization group theory to the understanding of solution properties are discussed, a separate chapter is devoted to the problems of describing semiflexible polymers, and a few selected topics of current research, such as computer simulations, coil collapse, dynamic light scattering, and polyelectrolytes, are described.

The second part, dealing with concentrated solutions, again begins with an introduction to the underlying theoretical concepts, which is then followed by a chapter on semidilute solutions. The dynamic properties of semiconcentrated solutions are discussed in detail from both theoretical and experimental standpoints, as also is the classical treatment of phase equilibria, although this is the only chapter that fails to mention some important new theoretical physics studies on the topic.

This book is certainly not intended as a textbook for students of macromolecular chemistry, although it contains extensive sections that could provide stimulating reading for advanced students. It is, on the other hand, a comprehensive evaluation of progress achieved in the understanding of polymer solutions, and is suitable for reading by researchers with interests in this field, whether in industry or academia.

Manfred Schmidt
Max-Planck-Institut für Polymerforschung
Mainz (FRG)

Cyclopropane Derived Reactive Intermediates. By *G. Boche* and *H. M. Walborsky*. Wiley, Chichester, 1990. V, 256 pp., hardcover £ 57.00.—ISBN 0-471-92748-1

As indicated on the front cover, this monograph is intended to be an updated version of the two volumes on cyclopropane derivatives that appeared in 1987 in the successful series *The Chemistry of Functional Groups*, by Patai and Rappoport. However, on the back cover it becomes apparent that the first chapter, "Cyclopropyl Radicals, Anion Radicals and Anions", is simply a reprint of the same authors' 1987 chapter with the same title. This at first strikes one as annoying, since after all, what reader wishes to pay a handsome price for something of which 45% (!) already exists on his or her bookshelf? The fact that it is almost an exact reprint is shown by the printing errors, all of which reappear, and are compounded by incorrect cross-references that were in the original and have not been put right. References to publications that were still in press in 1987 have, however, been given in full.

The subject matter of the first chapter has been augmented by an eight-page appendix with 22 references, which is introduced as Chapter 2. This is dominated by two X-ray structure analyses of cyclopropyllithium compounds carried out by one of the authors, and includes (on pages 114–115) a quite unnecessary speculation regarding the mechanism of an intramolecular nucleophilic substitution at a cyclopropane unit. The facts that the reactions reported by Seebach et al. that are cited here are stereospecific, that Bickelhaupt et al. observed an intramolecular substitution into a cyclopropane derivative with inversion, and that Banert has recently also described *intermolecular* substitutions with inversion, rule out any mechanism other than one of the S_N2 type.

Apart from these criticisms the contents of these first two chapters are of a very high quality. The criteria for deciding whether or not cyclopropyl radicals, anion radicals, and anions are likely to be formed as intermediates in any given reaction are clearly set out. This is especially valuable in view of the fact that the mechanistic situation is generally quite complicated. The task of reviewing the widely scattered results is one that only top-class experts in this field can undertake successfully.

Chapters 3–5 are entitled "Cyclopropyl Cations", "Cyclopropyl Carbenoids", and "Cyclopropyl Cation Radicals" respectively. There was a real need for a review of these topics, since the Patai–Rappoport series mentioned above does not contain chapters dealing specifically with these reactive intermediates, and consequently there are only a few isolated instances where such species are treated in adequate depth. Authoritative reports are now available which, although they do not cover the field comprehensively as this series aims to do, nevertheless deal with the main features in an appropriately concise way.

In the case of the cyclopropyl cations, the classification of substituent effects according to the nature of the leaving group and α- and β-substituents is sufficient to characterize some of the preconditions that determine whether a true three-membered ring cation or a partly ring-opened species is formed, or whether ring opening occurs immediately on departure of the leaving group.

Much space is devoted to the conversion of cyclopropyl carbenoids to allenes and insertion products. Explanations are offered as to why one or the other mode of reaction occurs preferentially in any given case, and why in bicyclic systems with more than seven atoms in the rings there is an overwhelming preference for the formation of cycloallenes, whereas with only seven ring atoms one obtains not 1,2-cycloheptadiene but predominantly tricyclo[4.1.0.$0^{2,7}$]-heptane. However, the discussion fails to mention that when the bicyclic system is further reduced in size, the preferred behavior alters yet again. Thus, the formation of 1,2-cyclohexadiene and its derivatives from 6-bicyclo[3.1.0]hexyl-carbenoids is not mentioned, even though these extremely short-lived cycloallenes are of preparative interest.

The chapter on cyclopropane cation radicals is especially topical. The conditions for the one-electron transfer process are now beginning to be understood, and it now seems likely that observations hitherto regarded as isolated curiosities can be fitted into an orderly scheme.

The relatively large frequency of printing errors is typical for these days, a situation that one has to get used to as time goes on. A possible cause of this is the time pressure under which the authors and those responsible for the final production have to work. Electronic information processing has not, in general, improved this unsatisfactory situation. On the contrary, one sometimes gets the impression that the number of mistakes is actually increased through trusting in the supposed infallibility of the computer.

A few examples: on page 65 the text belonging to the formula of *trans*-**145** is missing from above the bottom formula line; in formula **359** on page 98 and formula **101a** on page 145 substituents are missing; incorrect element or group symbols occur in the formulas of $Pb(OAc)_4$ on page 17, **357** on page 96, and **365** on page 98; double bonds are missing from formulas **46** on page 129 and **169** on page 159; the seven-membered rings in formulas **92** on page 143 and **55** on page 190 should be eight-membered rings; formula **67** on page 159 contains one CH_2 group too many, and formula **190** on page 165 contains an extra OH group; in Equation (10) on page 194 each of the formulas has an extra six-membered ring; reference 41b which appears on pages 228 and 233 is not in the bibliography; refer-

ence 207b on page 106 is incorrect; the name K. Rühlmann is spelt throughout with a "u" instead of "ü"; it was in fact possible to print the Umlaut, as is shown by the name L. Skattebøl, in which "ö" has consistently been used instead of "ø" to represent the Norwegian vowel sound œ; "ø" was actually available in the character set, as shown by the name Møller-Plesset on page 208; R. R. Squires has had a particularly raw deal, as his name only appears wrongly as Sguires (p. 68) or as Sguites (pp. 105, 248).

On the whole this monograph succeeds very well as regards its content. The properties of cyclopropane-derived reactive intermediates are treated collectively here in one convenient volume, which may well justify the reprinting of the first chapter. As considerable portions of the topic are not covered in any other comparable survey, this book will certainly be found to be indispensable for everyone concerned with cyclopropanes and their derived intermediates.

Manfred Christl

Electronic Aspects of Organic Photochemistry. By *J. Michl* and *V. Bonačić-Koutecký*. Wiley, Chichester, 1990. XIII, 475 pp., hardcover £ 51.30. – ISBN 0-471-89626-8

The key to understanding photochemical reactions lies in the analysis of the electronic states that are involved and their interactions with each other. Although an exact calculation of the total potential energy hypersurface for a multicomponent reaction is not (at present) possible, that is not necessary for an understanding of the nature and rates of the conversion processes occuring. These concepts have, of course, already become familiar even to those photochemists who have only a limited interest in the quantum-theoretical fundamentals. Up to now the main activation barrier in the way of getting to grips with the electronic fundamentals of organic photochemistry has been the highly mathematical nature of the available textbooks. That situation has been remedied in the book reviewed here.

Two authors of international repute (J. Michl, University of Texas, and V. Bonačić-Koutecký, Freie Universität Berlin) have achieved the trick of providing, even for the reader with only a rudimentary knowledge of quantum theory, a convincing and lively presentation of the theory of (mainly organic) photochemical reactions. To ease the path for beginners, the first chapter (50 pp.) contains a description of electronic states, potential energy hypersurfaces, and wave functions. Chapter 2 (59 pp.) on photophysical and photochemical processes seems to me especially successful. These processes (excitation, rapid and slow events) are described in terms of a complex potential energy hypersurface, in relation to which each of the processes in turn is discussed in detail. Here one becomes especially aware of the high standard of diagrammatic presentation that the authors maintain. Most of the figures are outstandingly well thought out, and in all their complexity they are also aesthetically pleasing. Of course, this expensive artwork further increases the price, and thus makes the book unaffordable for many students.

Part A ("Background") ends with a short chapter on minima, funnels, and barriers, and leads into the consideration of elementary photochemical processes. However, readers looking for a detailed description of reactions from the synthetic chemist's viewpoint will need to resort to other books, with which this work is not intended to compete.

Part B ("Elementary Photochemical Steps") begins by discussing the electronic structure of diradicals and diradicaloids, which often occur as reaction intermediates. This leads on to a description of the transition to chemical bonding. The effects of spin-orbit coupling and of C-pyramidalization on the probability of the transition to the closed-shell product are discussed in a very lucid and informative way. The following chapters 5–7 (192 pp.) are devoted to the theoretical description of a wide variety of organic photoreactions, including electrocyclic and sigmatropic reactions, cycloadditions and cycloreversions (Chapter 5), reactions involving the transfer of atoms, ions or charges (Chapter 6), and isomerizations, bond dissociations (Norrish type I reactions, peroxides, azo compounds), the Paternò–Büchi reaction, tautomerizations, Norrish type II reactions, three-membered ring-opening reaction, and fragmentations (Chapter 7). For most of these reaction types the authors compare simple MO correlation diagrams with the results of complex ab initio calculations. Such an extensive comparison of simple easily understood models with sophisticated quantum-chemical calculations is unique, and it provides an outstandingly useful source of information to help in understanding photochemical reactions.

These latter chapters are especially useful for those wishing to apply photochemical methods, as the analysis of elementary photochemical processes given here offers a rich source of ideas. For a book that is excellent in every respect the high price is justified, and it is to be hoped that it will not be kept in professors' offices to gather dust, but will instead be available also to students for frequent use.

The Biochemistry and Uses of Pesticides. Structure, Metabolism, Mode of Action and Uses in Crop Protection. 2nd Edition. By *K. A. Hassall*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1990. xviii, 536 pp., hardcover DM 128.00.—ISBN 3-527-28151-7/0-89573-976-3

This is a new edition of the book originally published in 1982 with the main title "The Chemistry of Pesticides". In the preface to this second edition, and also in the epilogue, the author emphasizes the enormous advances that have been made during the last ten years in the understanding of the modes of action of pesticides, a development that is reflected in the altered title "The Biochemistry and Uses of Pesticides". This second edition consists of 16 chapters, each ending with a short list of references. Three chapters of a general nature (general biological aspects, formulation and use, metabolism) are followed by six dealing with insecticides, three with fungicides, and four with herbicides. The greatest emphasis in this monograph is on insecticides, both as regards numbers of pages and of chapters. The author states that the book is intended for a wide range of readers involved in the science and practice of pesticides, and its purpose is to contribute to a greater understanding of the biochemistry of pesticides.

Nevertheless, it is not clear to these reviewers which group of readers the book is primarily aimed at. Does it set out to provide a background of science and theory for the pesticides practitioner, or is it mainly concerned with the biochemical aspects of pesticides, as the title of the second edition suggests? In fact, it does not meet either of these

objectives. For the technologist it would have been sensible to limit the treatment to the most important points and to elucidating the main principles, while on the other hand a book dealing generally with the biochemistry of pesticides would be expected to give a full and accurate account of the current state of knowledge. One would expect that a book published in 1990 should include an appropriate coverage of the literature on pesticide mechanisms and other recent developments, some aspects of which are treated in numerous publications, including some good reviews. This task has not been adequately addressed here.

Of the six chapters on insecticides the first three are devoted to organophosphates, carbamates and organochlorine compounds. These groups are dealt with clearly and comprehensively, with the emphasis on applications. Each of these chapters includes a list of compounds compiled with the practitioner in mind (although consisting only of selected examples); the lists for the organophosphates and carbamates are arranged according to the crop plants to be protected, whereas that for the organochlorine compounds concentrates on the harmful insect species (why the difference?). The next chapter is a detailed treatment of the pyrethroids. Whereas much space is devoted to the older classical insecticides, more recent developments are only treated marginally, even though some of these have already joined the "classical" category; it is exactly here that some sound information should have been provided for the novice practitioner. Whereas at least eight pages have been devoted to the benzoylphenylureas, the growth regulators are given only a single page. Thus, these sections, which appear under the title "Other Insecticides and Similar Compounds", are unsatisfactory as regards their content. The delta-endotoxin from *Bacillus thuringiensis* is only briefly mentioned in the epilogue, even though it is a chemical rather than a biological agent; even the author himself refers to this as "unfortunate". The chapters on insecticides conclude with a discussion of resistance. The current trend towards integrated pest management (IPM) would undoubtedly have justified being given a chapter to itself, especially since this monograph is intended also for newcomers to the area of modern insect control methods.

The three chapters on fungicides cover the subject in a very general way. The older products are over-represented at the expense of more recent ones. For example, mercury compounds are treated exhaustively, whereas the melanin biosynthesis inhibitors, which have the interesting property of preventing the fungal hypha from penetrating into the leaves, are omitted entirely. The information on the chemistry, metabolism, and mode of action of fungicides is well presented. In contrast the biological information is of such a general nature that there is a risk of misunderstandings. In Table 10.1, which lists the molds according to the manner in which they exist on the host plant, it is wrongly stated, for example, that true honeydew molds live under the leaf cuticle. In the same table the phenylamides are not listed against the *Oomycetes* in Group 1A. In the chapter on systemic fungicides the comments on resistance need to be treated with some caution, and should be qualified by noting that saturation treatments are not recommended as a way of overcoming resistance to fungicides, and that mixtures of phenylamides with carbendazim have no anti-resistance effect. The discussion of negatively correlated cross-resistance fails to mention the only example of commercial importance, namely the benzimidazoles and the phenylcarbamates, which are used to combat *Botrytis*.

In the part on herbicides the introductory chapter is concerned with definitions of relevant terms, such as uptake and transport in the plant, selectivity, persistence, methods of application, and herbicide mixtures. Some of the newer techniques, such as the use of herbicide safeners, should have been mentioned in this introductory chapter. In Table 13.1 the herbicides are classified from the standpoints of agronomy (for Group 1) and of biochemical mechanisms (for Groups 2 and 3). Here a uniform method of classification was desirable; this could have been achieved by integrating Table 14.1 with Table 13.1. The general biological aspects are treated comprehensively in three chapters, one on leaf herbicides and two on soil herbicides. The author also covers a few of the more recent developments from the applications standpoint, such as the introduction of the sulfonylureas. However, for many of the classes of herbicides the treatment of mechanisms is inadequate. For some products, such as photosynthesis inhibitors of the PS-II type (Fig. 14.2), the mode of action has now been clarified, and the basic principle should have been described in this book, also listing a few of the most important literature references. The mechanism of resistance to triazines (p. 454) is also known. It is also known that herbicide safeners (not "antidotes") essentially function by activating enzymes that metabolize the herbicides (pp. 468, 483). On page 395 the structure of phosphoenolpyruvate is shown incorrectly.

The literature citations are complete for the period up to about ten years ago. While it is true that some more recent original papers are also listed, the selection does not seem to be representative. Instead of citing original papers it would have been more useful to give references to recent review articles or more advanced reading, even to the extent of excluding all but these; this applies especially to students, who are regarded by the author as an important section of the potential readership.

Included as an appendix is a list of some of the pesticides mentioned in the book, including a few of their trade names. No claims are made regarding the completeness of the list. What is the use of a list that is incomplete in every respect? It is of equally little value to all types of readers, whether practitioners or academic researchers.

In summary, the book cannot be recommended in its present from. It is not a textbook, but neither is it an up-to-date review of the biochemistry of pesticides. The structure of the book is not systematic enough for students, and the material is not adequately presented from a teaching standpoint. It does not represent the current state of knowledge. Recent developments in the pesticides area receive too little attention, or are even omitted altogether.

Modern Pulsed and Continuous-Wave Electron Spin Resonance. Edited by *L. Kevan* and *M. K. Bowman*. Wiley, Chichester, 1990. 435 pp., hardcover £ 74.35.—ISBN 0-471-50274-X

The introduction of pulsed Fourier transform (FT) techniques, the trend towards using very high external magnetic fields, and the development of multidimensional methods (2D, 3D etc.) have brought about an enormous upsurge of activity in NMR spectroscopy during the past decade. Electron spin resonance (ESR) is a technique closely related to NMR, and it was evident from the start that its development must follow a similar course. However, it has taken a long time for this to happen, mainly due to problems of a techni-

cal nature. Nevertheless, Kevan and Schwartz edited an initial monograph on this theme as early as 1979 (*Time Domain Electron Spin Resonance*, Wiley). In recent years great strides have been made in this area, with regard to both instrumentation and technique. The most striking evidence of this is that since 1988 a commercial FT-ESR spectrometer has been on the market. Although several review articles dealing with this area have appeared, there has not until now been a monograph devoted especially to the techniques and instrumentation of pulsed ESR. The work reviewed here fills that gap.

The book contains six chapters dealing with particular aspects of pulsed ESR; a further three chapters are concerned with novel CW-ESR techniques, in which the microwave power is not pulsed (CW = continuous-wave). In the first chapter M. K. Bowman gives a good introduction to electron spin-echo (ESE) and FT-ESR spectroscopy and the historical development of these techniques. The resemblances to NMR and the differences are clearly pointed out, and the technical problems are discussed. As well as the instrumentation and data processing, some applications that are essentially inaccessible to CW-ESR are indicated. In Chapter 2 A. Schweiger reports on methodology and instrumentation of pulsed ESR, in particular with regard to the nuclear modulation effect observed in the electron spin-echo (ESEEM) for solids. An excellent introduction to the basic principles of this method is followed by an account of various special techniques for simplifying and interpreting spectra, most of which have been developed in the author's laboratory. A fairly long section is again devoted to the instrumentation, with a description of the important task of developing the probe-heads for pulsed ESR measurements. In Chapter 5 L. Kevan looks at the ESEEM effect from a different standpoint. He does not go into so much detail regarding the technique and instrumentation, emphasizing instead the methods for analyzing data in the time and frequency domains, and he draws attention to several new types of chemical applications. The two chapters devoted to ESEEM (Chapters 2 and 5) thus complement each other very nicely, and they show the importance of the method for measuring the electron-nuclear hyperfine couplings in solids, a technique which is complementary to the ENDOR (electron-nuclear double resonance) method. The latter method, which is already well-known from its use in CW spectroscopy, is the subject of Chapter 4, in which A. Grupp and M. Mehring give an excellent introduction to pulsed ENDOR (in which both the microwave and the radiofrequency power are pulsed). As well as the "classical" methods of Mims and Davies, some newer pulse sequences that have been developed by these authors or by Schweiger et al. are also described. Applications up to now have been confined to studies of solids. Chapter 3, by J. Gorcester, G. Millhauser, and J. Freed, is devoted to studies of molecular motions in condensed phases, especially in liquids, for which it appears that pulsed ESR is eminently suitable. The majority of the fascinating new methods described by these authors are two-dimensional ESE or FT-ESR techniques, some of which will already be familiar to the reader from NMR (e.g. spin–spin double resonance, COSY, SECSY etc.). Besides theory and the technique a considerable amount of space is also given (in an appendix) to the instrumentation needed to carry out such experiments and to the analysis of data. Chapter 6, by J. Allgeier et al., shows that pulsed ESR measurements are also now being carried out at high fields; here the authors describe their W-band spectrometer, which operates at a microwave frequency of 95 GHz, about ten times higher than that of a conventional X-band instrument (ca. 10 GHz). However, the evident advantages of this higher frequency band as regards spectral resolution and sensitivity are gained at the cost of more complex and expensive instrumentation.

A welcome feature of the book is that it also deals with those modern CW-ESR techniques that are related to the pulsed methods. Thus, in Chapter 7 K. McLauchlan reports on methods for detecting transient free radicals using CW-ESR. After a very good introduction to the theory and the experimental techniques the author discusses chemically induced dynamic electron spin polarization (CIDEP) and its application to studies of rate processes in solution, illustrated by various examples. In Chapter 8 Ya. Lebedev, one of the pioneers in the area of high-field ESR, describes CW-ESR techniques using microwave frequencies of 100 GHz and above. In addition to the physical principles he discusses technical aspects of all the high-field instruments of this kind that exist up to now. A considerable amount of space is devoted to chemical applications of such measurements, especially those that are inaccessible to ESR spectroscopy in the conventional frequency bands. In view of the great importance of imaging techniques in NMR one could hardly fail to include, in a book on modern ESR techniques, a contribution on ESR imaging. This topic is covered in Chapter 9 by S. and G. Eaton, who give a good survey of the current state of the art in this field. Here pulse techniques are beginning to play an increasingly important role. Applications to radiation chemistry, to polymer chemistry, and in the area of biological materials are described.

This book is intended for readers who wish to learn mainly about methods, techniques, instrumentation, and the sometimes difficult problems of data analysis in both pulsed and continuous-wave ESR. The reader must already have a solid background knowledge of magnetic resonance and of the analogous NMR techniques. Thus the book is addressed to the specialist rather than the novice. A recent review article by A. Schweiger[*] can be recommended as an introduction to the field of pulsed ESR.

Most of the authors in the book use application examples only to illustrate the techniques, and some of the chapters contain too little of this kind of material for my taste. One reason for this is that up to now very few applications-orientated research groups have adopted pulsed ESR methods, and consequently only a few systems of relevance to chemistry have been studied. In future these methods will become especially important in situations where they can yield information obtainable only with difficulty, if at all, by conventional ESR. Using pulsed ESR one can follow the time-dependent development of species such as photoinduced free radicals or triplet state molecules on time-scales from a few nanoseconds to milliseconds, so as to give information about the mechanisms of radical formation and conversion. For paramagnetic species with lifetimes longer than a few microseconds one can also use pulsed ENDOR to obtain valuable information about the electron distribution (via the hyperfine couplings). Time-resolved ESR techniques also make it possible to directly follow rate processes (by means of relaxation time measurements), thereby providing an insight into the motional processes of the molecules being studied. Certain CW and pulsed methods yield complementary information, for example ENDOR and ESEEM. For readers whose interests lie mainly in the biochemical and biological applications of the techniques discussed here, the recently published book *Advanced EPR—Applications in Biology and*

[*] *Angew. Chem.* **1991**, *103*, 223–251; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 265–292.

Biochemistry, edited by A. J. Hoff (Elsevier), can be recommended.

Pulsed ESR methods are now at the beginning of a development that could follow a course analogous to the enormous qualitative improvement of NMR techniques that has occurred in recent years. However, it remains to be seen whether microwave pulses will "exorcize the evil from ESR"—as has happened in the case of NMR—thereby opening a new "Golden Age" for ESR spectroscopy. Everyone who wishes to get to grips with these new and fascinating techniques, or who even foresees possible applications in his or her own research, is strongly recommended to read this book. Regrettably, however, the very high price—which has now become the rule rather than the exception for books of this sort—will limit the potential readership.

und Physikalische Chemie
der Technischen Universität Berlin (FRG)

One Dimensional and Two Dimensional NMR Spectra by Modern Pulse Techniques. Edited by *K. Nakanishi*. University Science Books, Mill Valley (USA), 1990. XII, 234 pp., paperback $ 29.95. – ISBN 0-935702-63-6

Yet another book on NMR methods has been published; in this the aim is to convey a knowledge of NMR by means of a catalogue of 92 experiments, rather than by a systematic form of presentation. In accordance with the book's title, the examples are arranged in two groups consisting of 31 one-dimensional (1D) and 61 two-dimensional (2D) experiments. Each experiment is described in about half a page of text with a few literature references (in which the name Bodenhausen has been wrongly spelled in nearly every case), together with a diagram showing the pulse sequence and the structural formula of the compound. The spectrum is reproduced on the opposite page, edited in a form which corresponds to the structural formula, so that the assignments are directly apparent. A set of parameter values is also shown alongside the spectrum in most cases, although unfortunately these are often too small to be read clearly and are insufficient to enable one to do further work on the problem; moreover, the accompanying text seldom includes experimental details.

The selection of experiments covers nearly all the standard types of problems nowadays encountered in organic chemistry. Thus the 1D part includes examples of techniques such as NOE difference measurements, SPT, DEPT, selective decoupling, and suppression of water signals, while in the 2D part one finds, in addition to the expected variants of COSY and NOESY, examples of HOHAHA, ROESY, and 2D-INADEQUATE experiments.

There are a few key molecules, such as β-ionone or strychnine, that are used again and again as examples in the book, thus enabling the reader to progress comfortably from simple types of spectra to more complicated types as applied to the same molecule; this is undoubtedly one of the book's main strengths. On the other hand the examples chosen are sometimes unnecessarily complicated, as in the cases of brevetoxin (No. 56), cyanoviridin (No. 84), or dictyotalide (No. 81), which tend to obscure the merits of the techniques under discussion rather than to clarify them. Nevertheless, the book as a whole offers a wealth of stimulating ideas taken from all the main research themes of organic chemistry, thus conveying to the reader some of the pleasure evoked by the power of modern NMR spectroscopy. The spectra that are reproduced, which are certainly the main substance of the book, are of better than average quality. However, there are a few criticisms that must be mentioned. For example: the convention of having the f_2 axis as the horizontal one is not applied consistently; for inversely recorded spectra (such as some of the examples of HMBC and HMQC experiments), the f_1 projection appears sometimes at the left-hand and sometimes at the right-hand border of the spectrum; too often some of the peaks of the projection are allowed to protrude into the 2D spectrum, which to me appears rather inelegant. Here it becomes evident that the book is not a unified whole but a collection of contributions from a number of spectroscopists using different spectrometers with different software.

There is a 40-page appendix entitled "Principles of FT-NMR", in which an attempt is made to explain the theory behind the experiments that are included. Everyone is likely to appreciate that a meaningful summary of the theory of modern 1D and 2D multipulse NMR spectroscopy is not possible within such a limited space, and consequently the reader is unlikely to derive anything useful from this account.

In summary it can be said that this book offers, at a reasonable price, a stimulating survey of the NMR methods nowadays used in organic chemistry. It can certainly be recommended for libraries and textbook collections, and for serious organic chemists who wish to learn what their NMR section should be capable of; it is less suitable for NMR specialists, who need a more detailed knowledge of the subject than can be conveyed within the space of this book.

Fachbereich Chemie
der Universität Marburg (FRG)

Modern Methods in Protein- and Nucleic Acid Research. Edited by *H. Tschesche*. de Gruyter, Berlin, 1990. ix, 446 pp., hardcover DM 330.00.—ISBN 3-11-012275-8

This book can be regarded as a continuation of the series "Modern Methods in Protein Chemistry", previous volumes of which appeared in 1983, 1985, and 1988. The latest developments in analytical and preparative methods are here described in 20 review articles by well-known authors belonging mostly to German research groups. This volume is the first to cover molecular biological methods. After a brief introduction to the techniques, the methods are described in turn using examples from each author's own field of research, sometimes including an experimental section giving practical details. Each article provides an up-to-date list of references, including review articles and monographs. The book is convenient to use and sturdily bound. However, the authors' typescripts have been directly reproduced, and the resulting lack of uniformity in type style and line spacing is rather distracting.

The first three articles are devoted to nucleic acids chemistry and molecular biology. H. Tschesche et al. describe the use of digoxigenin-11-dUTP as a realistic alternative to radioactive labeling. W. Kramer and H.-J. Fritz discuss the advantages and disadvantages of the various methods for preparing mutants using oligonucleotide techniques. B. S. Reckmann then describes new analytical procedures in DNA diagnostics. H. Wagner and J. Heinrich kindle interest in free flow electrophoresis, an elegant preparative electrophoretic method for purifying peptides, proteins, and whole cells. Other innovations in the purification and isolation of proteins

are the use of new types of polymers that give improved yields in ion-exchange chromatography (C. Jansen and W. Müller), and the use of immobilized nickel for affinity chromatography applied to poly-His fusion proteins (E. Hochuli). Problems of chain folding are addressed by R. Rudolph using in-vitro redox reactions, and by P. Flecker using activation chromatography; in the examples described here both methods give highly active proteins. Advances in *C*-terminal sequencing offer a method for the identification of biomolecules, which is here critically compared with *N*-terminal sequencing (B. Wittmann-Liebold et al.). The introduction of cyclodextrin phases for the enantioselective analysis of amino-acids by gas chromatography can greatly improve the separation achieved (W. A. König). New opportunities and capabilities in the use of mass spectrometry to investigate biomolecules are described by E. Bayer. Soft ion-spray mass spectrometry allows characterization of proteins up to 120000 Dalton and sequencing of segments at picomolar concentrations. The technique also has impressive capabilities when combined on-line with capillary zone electrophoresis or HPLC. Next W. Voelter et al. describe what can be achieved by immunological characterization. D. M. Doran gives an excellent review and comparison of current methods for predicting epitopes in proteins. Three articles deal with modifications of nucleic acids and proteins. In the first, R. I. Zhadanov reports on ESR studies of spin-labeled Ca-ATPase. H. Fasold et al. describe interactions of proteins with modified nucleotides. D. Brandenburg et al. give a thorough account of the use of photoaffinity-labeling in combination with radioactive or biotin labeling for isolating and characterizing receptors and for studying their interactions; this comprehensive chapter includes practical advice, information on typical reagents and their areas of application, and a list of common abbreviations. The last group of articles are concerned with methods for studying the structures of proteins. "How do you get large protein crystals?" is the title of the chapter by G. Wiegand, in which the crucial factors in the various crystallization techniques are discussed from a practical standpoint, illustrated by useful figures. J. Reed gives a good review of circular dichroism measurements, their areas of application, the types of information yielded, and the methods used to interpret the data. S. Suhai describes the theoretically orientated approach of molecular dynamics stimulation; unfortunately some of the diagrams in this chapter are illegible. H. Rüterjans et al. complete the treatment of protein structural studies by describing the application of 2D-NMR spectroscopy to ribonuclease-T_1.

It is certainly not possible to describe the whole of protein and nucleic acids research in 446 pages, but the editor has neither attempted nor claimed to do that. Instead the book is intended to give an insight into the latest developments. In this it has succeeded outstandingly well. The choice of topics represents the most significant trends in protein chemistry, the main emphasis throughout being on the techniques. The subject matter is logically arranged, and corresponds to the many stages that are needed to express, isolate, and characterize a protein. As it is not possible for a single research group to be completely knowledgeable in all these areas and equipped to carry out the experimental work needed, progress can only be achieved through the interdisciplinary collaboration of many specialists. This book helps to overcome trepidation about making the necessary contacts and to remove obstacles of technical language. Thus, for example, the molecular biologist is introduced to expressions such as NOESY and COSY, and the physical chemist learns to understand the problems of PCR methods. The book is of value to everyone who wishes to look out beyond the limited confines of his or her own research. Furthermore, it should help the reader to apply new methods without repeating familiar mistakes.

Benzene and Its Derivatives as Bridging Ligands in Transition-Metal Complexes

By Hubert Wadepohl*

Transition-metal complexes in which two or more metal atoms are bridged by one or more arene ligands led a shadowy existence in comparison to the extensive class of mononuclear arene complexes. Arene bridges can occur in a variety of coordination modes and with almost all of the transition-metal elements of the periodic table. Nowhere else are found so many forms of distorted and bent arene rings. The binuclear compounds can be divided into two classes: adducts which show relatively weak metal–arene bonding and complexes which show strong arene–metal interaction. Most of the adducts are in equilibrium with mononuclear complexes in solution or are only stable in the solid state (often as polymers). In both classes *syn* and *anti* coordination occurs; their geometries show a wide variation between the extreme cases of $\eta^1:\eta^1$-bridge and $\eta^6:\eta^6$-triple-decker structure. Metal surfaces with chemisorbed arenes can be seen as a form of multinuclear arene–metal complexes. On transition-metal surfaces, benzene can be bonded to one, two, or four surface atoms. Molecular clusters with face-capping arene ligands that are bonded to three metal atoms have until now mainly been limited to two classes. The arenes bound to $\{(CO)_3M\}_3$ (M = Ru, Os) or $(CpCo)_3$ clusters as μ_3-$\eta^2:\eta^2:\eta^2$ ligands show only a weak trigonal distortion towards a Kekulé structure. Detailed investigations of the molecular structure and ligand dynamics of $[(CpCo)_3(\mu_3\text{-arene})]$ complexes considerably help the understanding of the bonding of arenes to metal clusters and to metal surfaces.

1. Introduction

Metal–arene complexes[1] are true classics among the transition-metal complexes. As early as 1919 F. Hein[2] isolated his "phenyl–chromium compounds" from $CrCl_3$ and PhMgBr [Eq. (a)], which, however, were not identified until much later by H.H. Zeiss[3] as (η^6-benzene)(η^6-arene)-chromium(I) complex cations (**1**, arene = benzene, biphenyl).

The ability of Ag^+ ions to form complex compounds with arenes was also known in the 1920s. However, it was not until 1955 when E.O. Fischer and W. Hafner,[4] using the "reducing Friedel–Crafts method", found a rational synthesis for bis(η^6-benzene)chromium **2** [Eq. (b)] and with it laid the foundations for a rapidly expanding chemistry of bis(arene)metal complexes. These were soon joined by metal–arene carbonyls [5] and other "mixed" derivatives.

Today, a large number of arene complexes exists for almost all the transition metals.[6] Although the overwhelming

$$CrCl_3 + PhMgBr \xrightarrow[2.\ H_2O]{1.\ Et_2O} \underset{\mathbf{1}}{[Cr(\eta^6\text{-}C_6H_6)(\eta^6\text{-arene})]^+} \qquad (a)$$

$$3\ CrCl_3 + 6\ C_6H_6 + 2\ Al \xrightarrow[2.\ H_2O]{1.\ AlCl_3} 3\ [Cr(\eta^6\text{-}C_6H_6)_2]^+ + 2\ Al^{III} \xrightarrow[KOH]{Na_2S_2O_4} \underset{\mathbf{2}}{[Cr(\eta^6\text{-}C_6H_6)_2]} \qquad (b)$$

majority of these complexes have η^6-bonded arene ligands, examples are also known with η^1-, η^2-, η^3-, and η^4-bonded arenes. Until a few years ago, compounds in which two or more metal atoms are bonded to the same arene ring were overshadowed by the large class of mononuclear arene complexes. However, today we know of a considerable number of such multinuclear complexes. Some of the most interesting aspects of these complexes are:

- Arene bridges occur in a large variety of coordination modes (μ_2- and μ_3-bridges, *syn* and *anti* coordination geometry, varying hapticity of the μ-arene ligands).
- Nowhere else are found so many types of distorted and bent arene rings.
- Arene bridges are found in complexes with almost all of the transition metals of the periodic table. Although the majority of syntheses take different routes, the characteristic chemical properties of complexes with the different metals are reflected in the reactions forming these substances.
- Multinuclear arene complexes are important model compounds for intermediate steps in arene-exchange reactions and for adsorbates on metal surfaces.

2. Binuclear Complexes with Arene Bridges

Binuclear complexes with arene bridges can be roughly divided into two classes. In complexes of the first class, relatively weak bonds from the metal atoms to the bridging ligands are formed. These *adducts* are frequently in equilibrium with mononuclear complexes in solution or are only stable in the solid state (often as polymers). In the second class, there are molecular arene-bridged binuclear *complexes* with metal–ligand bonds which are as strong as those in mononuclear arene complexes. Between these two extremes intermediate forms exist, for example, complexes which only exist in the solid state and decompose in solution, but nevertheless show relatively strong bonds between the arene and metal atoms.

2.1. Adducts with Weak Metal–Arene Interactions

Adducts of arenes with Ag^I compounds have a long history. The composition and structure of such complexes is strongly dependent on the counterion. Already in the 1920s it was known that as a precipitate complex **3** is in equilibrium with the saturated solution of $AgClO_4$ in benzene and benzene/H_2O.[7] By 1950 R.E. Rundle had succeeded in proving the existence of benzene bridges between the silver atoms in crystals of **3**.[8]

$[Ag(C_6H_6)ClO_4]$ **3**

The X-ray structural analysis of this compound, which is only stable in a benzene atmosphere, shows infinite zigzag chains of [Ag-benzene-Ag-benzene]$_n$. These run along an axis of the orthorhombic unit cell and are linked to one another through weaker Ag–O interactions via perchlorate ions (Fig. 1).[8] The benzene ligand is *anti*-(μ-1,2-η^2:4,5-η^2)

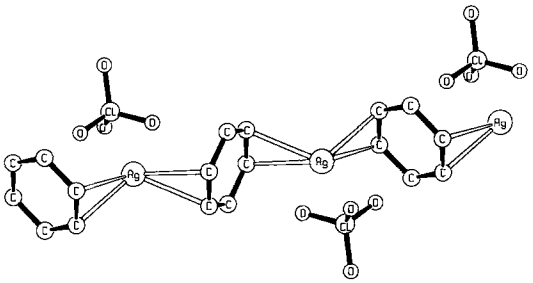

Fig. 1. Structure of [Ag(benzene)]$_n$ chains in a crystal of $[Ag(C_6H_6)]ClO_4$ (**3**).

coordinated. The silver atoms are bonded asymmetrically to the two opposite edges of the benzene rings [d_{Ag-C} = 2.496(6), 2.634(8) Å], so that the interaction of Ag with one carbon atom of each benzene ring predominates, as in the complex cations bridged only by anions, such as $[(arene)Ag]^+$ (arene = benzene,[9] for example) and $[(arene)_2Ag]^+$ (where (arene) = *m*-xylene[10a] or cyclohexylbenzene[10b] for instance). The metal-coordinated C–C bonds in the μ-benzene ligands are 1.354(17) Å, significantly shorter than the four other C–C bonds (1.427(10) Å). The results of solid-state ^1H NMR spectroscopic investigations[11] indicate that at 77 K the benzene molecules in **3** are rigidly held in the lattice whereas at 298 K they are more or less free to rotate about the sixfold axis. In contradiction of this assumption of a free or almost free rotation of the benzene rings at room temperature, the X-ray crystallographic

Hubert Wadepohl was born in 1954 and studied at first Chemistry and Mineralogy and then Chemistry from 1973–1980 at the University of Tübingen and in Bristol, England (1977/78). His research for his Diplom under F. G. A. Stone and J. A. K. Howard dealt with multinuclear platinum–alkyne complexes. In 1982 he obtained his doctorate with a thesis on double-, triple-, and quadruple-decker sandwich complexes of 1,3-diborolene. under W. Siebert in Marburg. He then spent a year and a half as post-doc with E. L. Muetterties at the University of California, Berkeley, initially as NATO Research Fellow and subsequently as Research Associate. From 1984 to 1990 he was Hochschulassistent at the Anorganisch-chemisches Institut der Universität Heidelberg where he habilitated in 1989 with a dissertation on cyclopentadienylcobalt fragments as building blocks for multinuclear complexes. He has been Privatdozent for inorganic chemistry and Heisenberg Fellow since 1990. His research interests include organometallic chemistry, multinuclear complexes containing bridging ligands, cluster complexes, and the structural chemistry of organometallic complexes in the solid and dissolved states.

electron-density synthesis has well-defined maxima and reveals distorted benzene rings.[12]

A further example of a silver complex with a bridging benzene ligand is **4**,[13] in which a *syn*-[Ag_2(benzene)] bridge

$[\{Ag(CF_3COO)\}_2(C_6H_6)]$ **4**

is observed. E.L. Amma et al. report only that a 1-η^1:4-η^1 coordinated benzene molecule is bonded to every second $Ag_2(\mu\text{-}CF_3COO)_2$ unit (Fig. 2). The Ag_2 units are part of polymeric chains bridged via the trifluoroacetate ions. Another benzene molecule is present per $Ag_2(CF_3COO)_2$ unit as solvent of crystallization. The distance of 2.851(3) Å between the silver atoms bridged by benzene was not considered to indicate Ag–Ag bonding.[13] Unfortunately no further information about the geometry of μ_2-benzene in **4** was given.

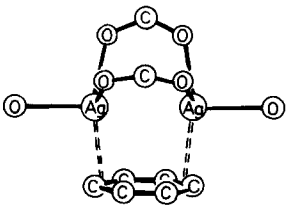

Fig. 2. Coordination of μ-benzene ligands on silver atoms in crystalline $[\{Ag(CF_3COO)\}_2(C_6H_6)]$ (**4**).

Apart from these complexes whose benzene bridges were established by structural analyses in the solid state, the existence of complexes such as $[(arene)Ag_n]^{n+}$ ($n = 1, 2$) have been proven by the measurement of the complex-formation constants in solution for several arenes.[14] As early as 1949 the (incorrect) [(η^6-arene)Ag]$^+$ half-sandwich structure for $n = 1$ was proposed. The dication $[(arene)Ag_2]^{2+}$, which for monocyclic arenes has a ten times smaller formation constant than the mononuclear complex, was assigned a symmetric triple-decker structure with a μ-η^6:η^6-arene bridge. Even though these proposed structures are incorrect, they were for this period—before the discovery of ferrocene!—a remarkable concept. The first triple-decker sandwich complexes $[Cp_3Fe_2]^+$ and $[Cp_3Ni_2]^+$ were observed by E. Schumacher und R. Taubenest[15] in 1964 when they examined the mass spectra of ferrocene and nickelocene. But it was not until 1972 that a triple-decker sandwich complex $[Cp_3Ni_2]^+$ was actually synthesized by H. Werner and A. Salzer.[16]

Benzene does not only bridge two silver(I) ions but also two cations of the lighter homologue, copper, in the solid state. The benzene bridges in polymeric **5**[17] show a less symmetrical *anti*-(μ-1,2-η^2:3,4-η^2) coordination than those in **3** or **4**. In **5**, infinite double chains of $Cu(CF_3SO_3)$ units are

$[\{Cu(CF_3SO_3)\}_2(C_6H_6)]_n$ **5**

bridged by the benzene molecules (Fig. 3). However, the structural analysis by M.B. Dines and P.H. Bird [17b] gave no precise information on the C–C bond lengths in the bridging ligands. The material, in contrast to the less stable silver complexes, liberates benzene under vacuum only above 120 °C.

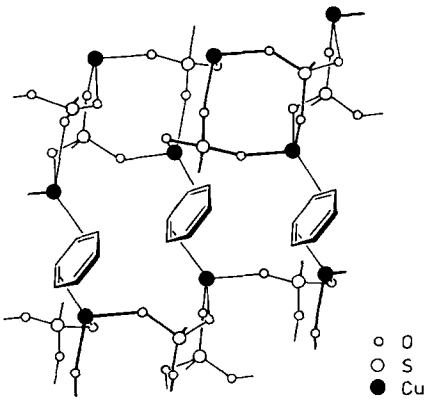

Fig. 3. Coordination of μ-benzene ligands on copper atoms in crystalline **5** (CF_3 groups are only shown as lines).

Through the exchange reaction of **5** with alkylbenzenes, the relative stability constants $K_{eq.}$ of the corresponding complexes were determined, yielding the series for $K_{eq.}$, benzene ≈ toluene ≈ *o*-xylene ≫ ethylbenzene ≈ *n*-butylbenzene ≈ isopropylbenzene ≈ mesitylene and *p*-xylene ≫ *o*-xylene > *m*-xylene. This sequence shows considerable shape selectivity, which cannot be correlated with the π basicity of the arenes.[17b]

The crystalline complex **6** reported by F.A. Cotton et al. can also be included among the coordination compounds with relatively weak bonding from benzene to two metal atoms.[18] In the crystal, $Cr_2(O_2CCPh_3)_4$ units are linked

$[Cr_2(O_2CCPh_3)_4(C_6H_6)]$ **6**

along the colinear Cr–Cr axes through benzene molecules to form infinite chains (Fig. 4). The benzene bridges are *anti*-(η^6:η^6) coordinated. From the Cr–benzene ring distance (3.299 Å) it follows that only a very loose bond exists in the $Cr_2 \cdots$ benzene $\cdots Cr_2$ "triple-decker" units. The μ-benzene ligands are trigonally distorted [alternating long (1.43(2) Å)

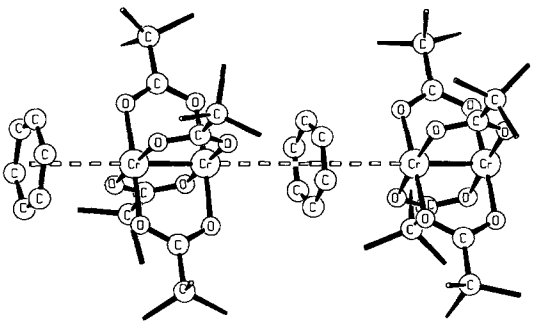

Fig. 4. Structure of $[Cr_2(O_2CCPh_3)_4(C_6H_6)]_n$ chains in crystalline **6** (of the phenyl rings only the *ipso*-C atoms are drawn).

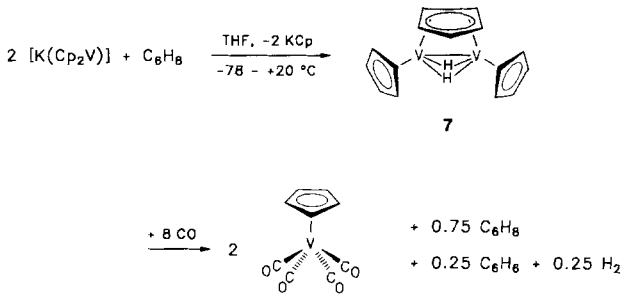
and short (1.35(2) Å) C–C distances). According to MO calculations on the model system (C_6H_6)-$[Cr_2(O_2CH)_4]$-(C_6H_6), benzene functions as a π donor to the Cr_2 unit and thereby weakens the π component of the Cr–Cr quadruple bond.[18]

2.2. Molecular Complexes with μ_2-*Arene Bridges*

In this section, μ-arene binuclear complexes that in the solid state and almost without exception in solution, contain discrete [(μ-arene)M_2] molecular units with strong bonding of the metal atoms to the briding ligand will be summarized. Here, as for the adducts described previously, many modes of coordination of the arene bridge are known.

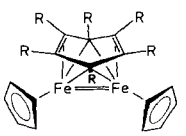
In general, it is possible to distinguish between *syn*-(μ-η^n:η^m)-arene and *anti*-(μ-η^n:η^m)-arene complexes. In both classes the hapticities η^n, η^m of the arene vary over a wide range. The *syn* bonding mode of two metal-complex fragments to an arene is always accompanied by a metal–metal bond which can be bridged by other ligands.

In each of the V_2 and Fe_2 complexes **7** [19,21] and **8**[20,21] (Cp = η^5-C_5H_5) described by K. Jonas et al., all the ring-carbon atoms of the arene are bonded to a M_2 unit. However, this is almost the only common feature of these two highly interesting complexes. In the synthesis of **7** from [K(Cp_2V)] and 1,3-cyclohexadiene, the "preformed" C_6 ring of the cyclohexadiene is dehydrogenated to benzene (Scheme 1). The



Scheme 1.

vanadium complex **7** reacts with CO to give [$CpV(CO)_4$]. In this reaction only a quarter of the expected amount of μ-benzene is eliminated intact, together with the equivalent amount of H_2. The dominant reaction pathway involves the migration of the hydridic H atoms to the benzene ring; in a sort of reversal of the formation reaction, cyclohexadiene is reformed (Scheme 1).[19] The hexaalkylbenzene in **8a** and **8b** is formed by the cyclotrimerization of 2-butyne and 3-hexyne, respectively. The mononuclear complex [CpFe(cod)] (cod = 1,5-cyclooctadiene), serving as a source for the CpFe fragments, reacts even at 0 °C with the alkynes affording **8** in approximately 90% yields.[20]

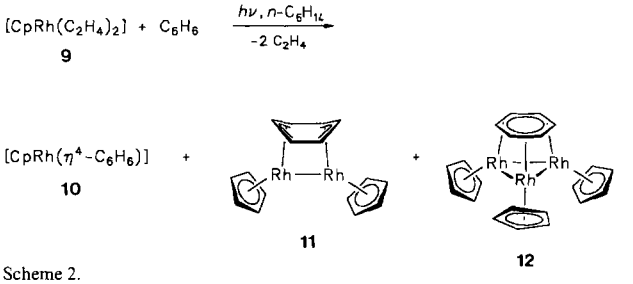


8a, R = CH_3
8b, R = C_2H_5

Complexes **7** and **8** have *syn*-(μ_2-1-4-η^4:4-6,1-η^4) coordinated arene bridges which are folded along the vectors C1···C4. In the divanadium complex **7** the fold-angle is approximately 20° and all the C–C distances within the benzene ring are equal (1.43(1) Å). In contrast, the folding of the hexamethylbenzene ligand in **8a** is much more pronounced (dihedral angle 43°). Both the C–C "double bonds" C2/5–C3/6, which are each coordinated to only one iron atom, are significantly shorter [1.38(1), 1.43(1) Å] than the other C–C bonds in the μ-hexamethylbenzene ligand (1.48(1) Å). For these reasons the notation with "aromatic" benzene was proposed for **7** and with a localized dienediyl structure for **8**. The assignment of valence electrons (VE) for these compounds is problematic; thus, **7** was formulated with a V–V single bond (corresponding to 16 VE per vanadium atom) in contrast to **8** which was formulated with a Fe–Fe double bond (18 VE on each iron atom). However, the authors pointed out that an assignment of the bond order from the lengths of bridged metal–metal bonds is problematic. The V–V bond order calculated from an ab initio CI–MO study[22] (CI = *c*onfiguration *i*nteraction) of **7** is 1.45; this relatively large value can be explained by the contribution of metal–metal bonding orbitals to the most stabilized ligand orbitals.

Complexes **7** and **8** are fluxional. A rotation of the arene rings above the M_2 units has been deduced from investigations by NMR spectroscopy. The dynamic process can be frozen on the NMR time scale at low temperatures. In addition, **8** shows an equilibrium between a diamagnetic low-temperature form and paramagnetic high-temperature form, which leads to antiferromagnetic behavior.

According to J. Müller et al.[23] the complexes **10**, **11**, and **12** were formed in 3, 5, and 1% yields following irradiation of a solution of **9** and benzene in hexane for 5 h (Scheme 2). On longer irradiation of the reaction mixture the concentrations of **10** and **11** decrease in favor of the trinuclear complex **12** (see Section 3).

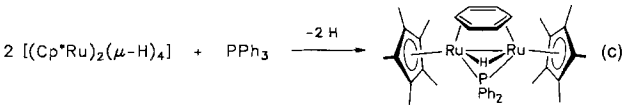


Scheme 2.

The *syn*-(1-3-η:4-6-η) bonded μ_2-benzene ligand in the crystal of the binuclear complex **11** can be described in a first approximation as a bis(enyl) ligand system showing a boat conformation. The angle between the two η^3-enyl planes ($\bar{d}_{C-C}$ = 1.42 Å), which indicates the extent of deviation of the benzene bridge from planarity to boat conformation is 125°. The ^1H NMR spectrum at room temperature shows a triplet (J_{RhH} = 1.1 Hz) for the μ_2-benzene ligands. Hence it can be supposed that the ligand can freely rotate above the metal framework in solution (identical coupling of the six

isochronous protons of the μ-benzene with both ^{103}Rh nuclei).

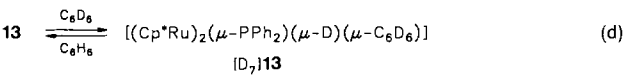
H. Suzuki et al.[24] investigated the reaction of triphenylphosphane with the tetrahydridodiruthenium complex $[(Cp^*Ru)_2(\mu\text{-}H)_4]$ ($Cp^* = \eta_5\text{-}C_5Me_5$) which affords the μ_2-benzene complex **13** [Eq. (c)]. A proposed mechanism for the formation is the oxidative addition of PPh_3 to a Ru center with breakage of a P–C bond (formation of μ_2-PPh_2 and σ phenyl units). Benzene can be reductively eliminated from the intermediate and then retained as a π bridging ligand in the complex.



(c)

13

The μ-benzene ligand in **13** is replaced slowly in solution (ca. 1 h at 60 °C) by the solvent toluene. With C_6D_6, [D$_7$]**13** is formed quantitively [Eq. (d)]. This arene/arene exchange occurs much more quickly than the exchange Ru_2H/Ru_2D, which possibly implies that the reaction **13** → [D$_7$]**13** occurs by C–H activation of the μ-benzene ligand.

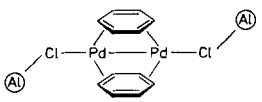


(d)

On the NMR time scale **13** is rigid up to 60 °C. The X-ray structural analysis[24] shows a *syn*-(μ-1,2-η^2:3,4-η^2) bonding mode of the nonplanar μ_2-benzene ligand. The C–C bond lengths in the metal-bonded planar "diene system" C1–C4 compare favorably with the values of olefin complexes despite the relatively large standard deviations. The benzene molecule is folded by 12° about C1 ··· C4, which causes the noncoordinated double bond C5–C6 (1.33(2) Å) to bend away from the Ru_2 unit.

Formally, the structure of the Ru_2 complex **13** can be related to that of the electronically unsaturated diiron complex **8** by oxidative addition of a secondary phosphane to the M_2 unit. After oxidation of the metal centers (formally Fe^I in **8**) the electronic situation in the Ru_2 complex is unambiguous; consequently the benzene now only uses four of its six π electrons for complex formation.

A similar coordination of benzene as in **13** was proven by G. Allegra et al.[25] from the X-ray structural analysis of the Pd_2 complex **14**. This and the analogous complex **15**[26] are products of the reaction of $PdCl_2$, $AlCl_3$, and Al in benzene. Both complexes are insoluble in hot benzene and decompose in polar solvents such as THF. Hence structural information was only obtainable for the crystalline solid. These were the first structurally characterized molecular complexes with bridging arenes. Despite their very similar composition, **14** and **15** show at first glance different coordination geometries for the μ-benzene ligands.



14, (Al) = $AlCl_3$
15, (Al) = Al_2Cl_6

The low-temperature X-ray structural analysis (−100 °C) of **15**[27] shows almost planar benzene ligands bound to the Pd_2 unit in a very unsymmetrical *syn*-(μ-1,2-η^2:3,4-η^2) coordination mode (Pd–C bond lengths 2.26(2)...2.63(2) Å). At room temperature the benzene rings are disordered.[25] In contrast, in **14** a more symmetrical *syn*-(1,2-η^2:3,4-η^2) coordination (d_{Pd-C} = 2.26(2), 2.37(2) Å) at room temperature was proven by X-ray crystallography (Fig. 5). In this case the arene rings are folded about C1 ··· C4 such that the uncoordinated formal double bond (1.37(4) Å) of each benzene ligand is bent towards the Pd_2 group (dihedral angle 7°). The observed C–C bond lengths in the μ_2-benzene ligands (1.37–1.45 Å in **14**, 1.36–1.49 Å in **15**) are difficult to interpret because of large standard deviations (0.04, 0.03 Å respectively) and systematic errors caused by the molecular dynamics in the solid.

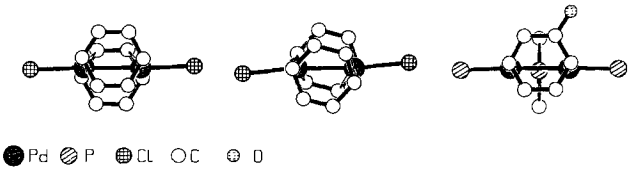


Fig. 5. Coordination geometry of the benzene ligands in **14** (left), **15** (center), and **16** (right).

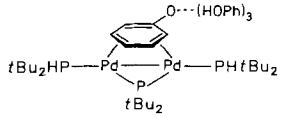
The results of the X-ray structural analyses and solid state ^{1}H NMR spectroscopy[28] indicate that the barriers to the rotation of the μ_2-arene ligands about the (pseudo)C_6 axis in the crystalline dipalladium complexes **14** and **15** are only very low. The upper limit for the activation energy of this process in **15** of approximately 2 kJ mol^{-1} was determined from the X-ray crystallographic results.[27] From the temperature dependence of the ^{1}H spin-lattice relaxation a value of 5.9 kJ mol^{-1} is found for **14**.[28]

Isoelectronic to **14** and **15** is the zwitterion **16** formed as a minor product from the photolysis of [Pd(tBu$_3$P)$_2$] **17a** in the presence of phenol.[29] Remarkable in the formation of **16** is the breaking of P–C bonds of the phosphane ligands in the starting material **17a**, which was not observed for [Pd(Cy$_3$P)$_2$] **17b** (Cy = cyclohexyl). The latter forms only the mononuclear hydrido complexes *trans*-[(Cy$_3$P)$_2$Pd(H)(OAr)] · ArOH.[30] Zwitterion **16** crystallizes as an adduct in which three phenol molecules are linked together by hydrogen bonds and the first is similarly linked with the oxygen atom of the phenolate ligand. The almost planar six-membered ring of the phenolate ligand is bonded through *syn*-μ-2,3-η^2:4,5-η^2 coordination to the Pd_2 unit. The Pd–C bonds to the outer C atoms of the Pd-coordinated "diene unit"



16

(2.3 Å) are shorter than those to the inner C atoms (2.5 Å) (Fig. 5). The distribution of C–C bond lengths (metal-coordinated C–C bonds 1.39(1) Å, free "double bond" 1.424(8) Å, others 1.41(1)–1.427(8) Å) in the μ-arene ligand indicates considerable bond delocalization. The ^{1}H NMR spectra of **16** point to a more symmetrical (dynamic?) structure, with respect to the NMR time scale in solution at $-50\,^{\circ}C$ (for the phenolate ligands only three signals occur for the five protons in the *ortho*, *meta*, and *para* positions relative to oxygen). Apparently at room temperature the complex-bound phenolate rapidly exchanges with the free phenol molecules (upfield shift for the signals of the ring protons on the phenolate ligand on decreasing the temperature).

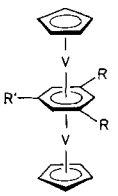
As a MO study[31] of the hypothetical complexes $[(LPd)_2(\mu\text{-}C_6H_6)(\mu\text{-}A)]$ ($L = Cl^-$, NH_3; $A = \eta\text{-}C_3H_5^-$, $\eta\text{-}C_4H_6$, $\eta^4\text{-}C_6H_6$) shows, the stability of the corresponding μ-benzene complexes is due to a donor/acceptor interaction between the HOMOs of the benzene and the Pd_2 unit. Since the $Pd_2(\mu\text{-}A)$ group has only two low-lying empty orbitals with suitable symmetry at its disposal, the benzene can only function as a four-electron donor. However, the experimentally observed bending of the arene in **14** cannot be satisfactorily explained from the calculations.

The catalytic properties of the binuclear Pd^I complexes **14** and **15** have been examined in some organic reactions. Under mild conditions, **14** and **15** catalyze the dimerization of ethene to butenes.[32] Some alkynes were cyclotrimerized to fulvenes or polymerized in the presence of **14** or **15**.[33]

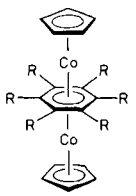
Binuclear complexes with *anti*-coordinated arene bridges include both "true" (that is, with (pseudo)axial symmetry) triple-decker sandwich complexes with $\mu\text{-}\eta^6\text{:}\eta^6$-coordination of the arene and less symmetrical molecules in which only some ring carbon atoms are bonded to the metals.

Among the many novel organovanadium compounds, which K. Jonas[34] showed to be either directly or indirectly accessible by the reductive disintegration of vanadocene, are also triple-decker complexes of the type $[L_nM(\mu\text{-}\eta^6\text{:}\eta^6\text{-arene})VCp]$. Thus, the complexes ***18a*** and ***18b*** are available from one-pot reactions of vanadocene, alkyllithium, and 1,3-cyclohexadiene.[35] The sandwich complex **18a** is still stable

18a, L = thf, n = 2
18b, L = tmeda, n = 1



20a, R, R' = H
20b, R = H, R' = CH_3
20c, R = H, R' = n-C_3H_7
20d, R = R' = CH_3



22, R = $COOCH_3$

in toluene at 100 °C. The triple-decker structure of **18b** is confirmed by a X-ray structural analysis.[35] The alcoholysis of **18** affords $[CpV(\eta^6\text{-}C_6H_6)]$, which reacts with Mg in THF to give the trinuclear complex **19**.[35] The structure of **19** is unknown; it is assumed that here too $\mu\text{-}\eta^6\text{:}\eta^6$-benzene bridges between vanadium and magnesium exist.[35]

$[(thf)_2Mg\{(C_6H_6)VCp\}_2]$ **19**

The reaction of $[CpV(allyl)_2]$ with 1,3-cyclohexadiene in n-heptane at 100 °C leads to a 50% yield of **20a**, the first triple-decker sandwich complex with complexed benzene as the "middle-deck" [Eq. (e)].[36] By-products of the reaction are **20c**, $[CpV(\mu\text{-}C_6H_6)]$, and H_2, besides aromatic and non-aromatic hydrocarbons. By heating **20a** in toluene or mesitylene it is converted into the toluene and mesitylene derivatives **20b** and **d**.[36] With lithium cyclopentadienide the VLi complex **18** is formed.[35]

$$[CpV(C_3H_5)_2] + 1,3\text{-}C_6H_8 \xrightarrow[100\,^{\circ}C]{n\text{-}C_7H_{16}} \underset{\textbf{20a}}{[(CpV)_2(\mu\text{-}C_6H_6)]} \quad \text{(e)}$$

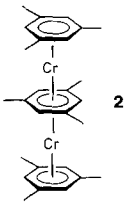
$$[(CpV)_2(\mu\text{-}C_6H_5nPr)] + [CpV(C_6H_5)] + \ldots$$
20c

The X-ray structural analyses of **20a** and **20d** show planar Cp and arene rings parallel to one another. The C–C bond lengths in the arene bridges are 1.439(8) (**20a**) and 1.443(5) Å (**20d**).[36] For **20a**, X–X and X–N electron density deformations have been determined which indicate an approximate octahedral distribution around the vanadium atoms.[37]

The paramagnetic complexes **20** with 26 valence electrons do not correspond to the 30/34 VE rule of R. Hoffmann et al. for triple-decker complexes.[38] In more recent theoretical investigations,[39,40] it was proven that this rule is actually not applicable for complexes of the electron-poor early transition metals.

The cocondensation of arenes with metal vapors is a successful method for the preparation of bis(arene)metal complexes.[41] In noble gas matrices half-sandwich complexes $[(\eta^6\text{-arene})M]$ were formed along with $[(\eta^6\text{-arene})_2M]$.[42] By increasing the metal atom concentrations in the matrix, G.A. Ozin et al. could prove the existence of the species $[(arene)_nM_2]$ (M = V, Cr, Mo; n probably 2) using kinetic and spectroscopic investigations.[43] Similar molecules can be produced in the gas phase in different ways (e.g. $[(arene)_2Cr_2]^+$, by the molecule–ion reaction during the disintegration of $[(arene)Cr(CO)_3]$ in the mass spectrometer;[44] $[(C_6H_6)VFe]^+$ and $[(C_6H_6)_2VFe]^+$ as products from the reaction of $[VFe]^+$ with cyclohexene;[45] $[(C_6H_6)_2Pt_n]$ ($n = 2$–6) from benzene and beams of Pt_n clusters[46]). Although the structures of such multinuclear complexes have not been completely verified, there are arguments for formulating them as arene-bridged $(metal)_n$ clusters.[43]

W. M. Lamanna[47] was able to isolate along with the well-known $[Cr(C_6H_3Me_3)_2]$, a binuclear complex $[Cr_2(C_6H_3Me_3)_3]$ (**21**) from the cocondensation product of



21

chromium vapor and mesitylene. The red, very air-sensitive complex has a triple-decker sandwich structure. In the solid the three planar mesitylene rings are parallel and eclipsed.[48] All three arene rings are expanded with respect to the free ligand, resulting in not significantly longer C–C bonds in the bridging ligand coordinated to both metals than in the terminal ligands (1.417(4) Å as opposed to 1.402(2) and 1.413(2) Å). The chromium–ligand distances are somewhat shorter for the terminal ligands (1.600(1) Å) than for the bridging ligand (1.669(1) Å).

As anticipated for a triple-decker complex with 30 VE, **21** is diamagnetic. In the ^{1}H NMR spectrum the ring protons of the bridging mesitylene ligands show a strong upfield shift ($\delta(^1H_{\text{bridging ring}}) = 2.9$, $\delta(^1H_{\text{terminal ring}}) = 3.4$).

Earlier, triple-decker sandwich complexes with an (η^6:η^6-arene)-bridge were postulated as intermediates in the exchange of arene ligands between mononuclear complexes such as $[(CO)_3Cr(\eta\text{-}C_6H_6)]$.[49] However, since the resulting "inversion" of the arene–metal bond could not be proven such an associative mechanism is rather unlikely.[50]

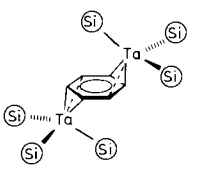
A triple-decker sandwich complex with 34 VE and a μ-η^6:η^6-arene ligand **22** was also prepared by the group of K. Jonas in Mülheim.[51] The diamagnetic compound is probably a stop-complex of the catalytic cyclotrimerization of dimethyl acetylenedicarboxylate with the bis(ethene) complex **23**. It melts without decomposition just under

$[(Cp(Co)_2\{\mu\text{-}C_6(COOMe)_6\}]$ **22** $[CpCo(C_2H_4)_2]$ **23**

200 °C. The highly symmetrical NMR spectra, even at −100 °C, practically exclude the alternative structures for **22** (e.g. with *syn* orientation of the CpCo groups).

A wide variety of structures are known for less symmetrical *anti*-(μ-arene) binuclear complexes, that is, complexes in which not all the ring-carbon atoms are simultaneously bonded to both metal atoms.

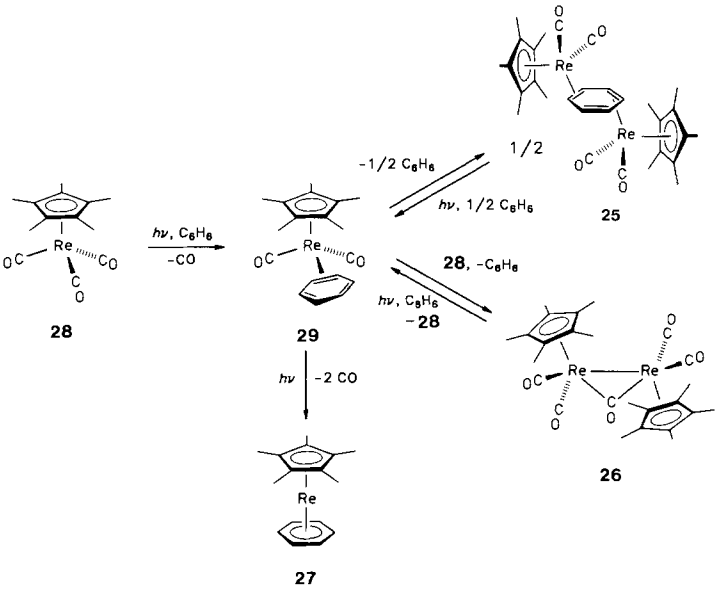
The sterically hindered strong Lewis acid $[Ta(silox)_3]$ (silox = $OSitBu_3$) reacts with pyridine affording the mononuclear complex $[Ta(silox)_3\{\eta^2\text{-(N,C)-pyridine}\}]$.[52] P. T. Wolczanski et al. obtained from a benzene solution of this compound after 10–14 days the crystalline diamagnetic Ta_2 complex **24** in 7% yield. The existence of the likely mononuclear precursor $[(silox)_3Ta(\eta^2\text{-}C_6H_6)]$ could not be proven.[52] Due to the bulky $Ta(silox)_3$ fragments, *anti*-(1,2-



24, Si = $OSitBu_3$

η^2:4,5-η^2) coordination of the bridging benzene is observed in the crystal. Each tantalum atom is bound very unsymmetrically to one C–C bond of the benzene ($d_{Ta-C} = 2.11(1)$, 2.33(1) Å). Since a weaker interaction ($d_{Ta-C} = 2.71(1)$ Å) exists between each Ta and another C atom, the coordination type can also be described as distorted (η^3-enyl) bonding. Unfortunately, the geometry of the μ-benzene ligand could not be precisely determined in the X-ray structural analysis.[52]

The alternative *anti*-(μ_2-1,2-η^2:3,4-η^2) coordination of the benzene ligand is observed in the binuclear Re complex **25** reported by P. Pasman et al.[53] It is formed in 5% yield along with **26** and **27** during the photolysis of **28** in benzene (Scheme 3). A key intermediate in the formation of **25** is the

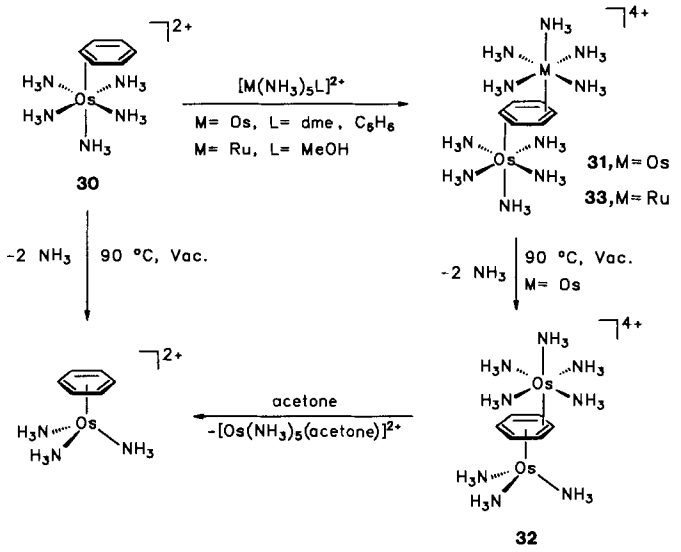


Scheme 3.

initially formed mononuclear complex **29**. This reacts in a dark reaction with the starting material **28** to give **26** or undergoes selfcondensation with the loss of a benzene ligand affording **25**. The complex **25** is photolabile and on longer irradiation reacts back to the η^2-benzene complex **29** which in turn forms the photolysis end product **27** with η^6-bound benzene through loss of CO (Scheme 3).

In the crystal, **25** has C_2 symmetry.[53] The planar bridging ligand can be well described as η^2:η^2-coordinated cyclohexatriene. The free C–C bond of 1.31(2) Å is considerably shorter than the C–C bonds (1.40(1) Å) which are coordinated to the rhenium atoms. The other C–C bond lengths are 1.46(1) and 1.47(2) Å, respectively. The NMR data (three ^{13}C NMR signals at δ = 40.9, 50.6, and 127.3) shows that in solution **25** had the same nonfluxional structure, at least at room temperature.

A series of binuclear complexes of benzene with $[Os(NH_3)_5]^{2+}$ and $[Ru(NH_3)_5]^{2+}$ metal-complex fragments was prepared by H. Taube et al.[54–56] In inert solvents the dication **30** loses benzene at room temperature and undergoes selfcondensation, affording the tetracation **31**.[54] This reaction also occurs in the presence of an excess of benzene. Cation **31** can also be prepared from **30** and $[Os(NH_3)_5(dme)]^{2+}$.[55] When **31** is heated in a vacuum to 90 °C, NH_3 is driven off and **32** is formed.[55] Tetracation **32** reacts with acetone to give the mononuclear complexes **30** and $[Os(NH_3)_5(\eta^2\text{-acetone})]^{2+}$ (Scheme 4).[55] The mixed-metal complex **33**, which is labile in solution, is accessible from **30** and $[Ru(NH_3)_5(MeOH)]^{2+}$.[56]



Scheme 4. dme = 1,2-dimethoxyethane, Vac. = vacuum.

The X-ray structural analysis[55] proves the *anti*-(μ-1,2-η^2:3,4-η^2) coordination of the benzene bridge for crystalline **31**-$(CF_3SO_3)_4$, which had been derived previously from the spectroscopic data of the salt in solution. The planar μ-benzene ligand has a similar ring geometry to that in **25**, within experimental error (lengths of the metal-coordinated C–C bonds 1.43(2), 1.49(2) Å, free double bond 1.32(2) Å, other C–C bonds 1.44(2) to 1.54(2) Å). Also the ^{13}C NMR shifts of the bridging ligands in **25** and **31** (δ = 49.6, 53.1, 127.6) are very similar despite the different charges of the complexes. The free C–C double bond in **31** is remarkably chemically inert. It is not attacked by $[Os(NH_3)_5]^{2+}$ fragments,[55] peroxo acids,[55] and H_2/Pd[57], probably due to steric effects.

Electrochemical oxidation of **31** furnishes the mixed-valent pentacation $[\{Os(NH_3)_5\}_2(\mu\text{-}C_6H_6)]^{5+}$, which has a delocalized electronic structure.[54] Based on the spectroscopic data the pyrolysis product **32** is assigned the very unusual *anti*-$[(NH_3)_5Os(\mu\text{-}\eta^2\text{:}\eta^6\text{-}C_6H_6)Os(NH_3)_3]^{4+}$ structure. Magnetization-transfer experiments show that the $[Os(NH_3)_5]^{2+}$ group bonded to only two ring carbon atoms moves slowly around the ring ($k \approx 1\ sec^{-1}$ at 20 °C). This tautomerization in **32** is approximately 10^4 times slower than in the mononuclear **30**.[55]

p-Xylene as a bis(enyl)-bound ligand is observed in the Co_2 complex **34a**. This complex prepared originally by K. Jonas et al.[20,21] is the "decomposition product" of the 1,4-dimethylcyclohexadienyl complex **35**, which is available via the hydrocobaltation of *p*-xylene with $[\{Cy_2P(CH_2)_2PCy_2\}$-Co(η-allyl)]/H_2 [Eq. (f)].

$$[\{Cy_2P(CH_2)_2PCy_2\}Co(\eta\text{-}C_3H_5)] + 2\,H_2 + p\text{-}(CH_3)_2C_6H_4 \longrightarrow$$

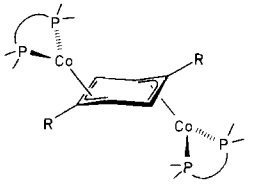
$$[\{Cy_2P(CH_2)_2PCy_2\}Co(1\text{-}5\text{-}\eta\text{-}(CH_3)_2C_6H_5)] + C_3H_8 \longrightarrow \quad \text{(f)}$$

35

$$1/2\ [\{(Cy_2P(CH_2)_2PCy_2)Co\}_2(\mu\text{-}1,4\text{-}(CH_3)_2C_6H_4)] + 1/2\ p\text{-}(CH_3)_2C_6H_4$$

34a

As in the starting complex $[\{Cy_2P(CH_2)_2PCy_2\}Co(\eta$-allyl)] each cobalt atom in **34** achieves only a 16 VE configuration (d^8-Co^I with pseudo-square-planar coordination) by bonding to three C atoms of the *p*-xylene. A symmetrical triple-decker structure (which would have 32 VE) is not formed. The structure containing a *syn*-(μ_2-η^4:η^4-arene) bridge and Co–Co multiple bond analogous to the isovalent $[(CpFe)_2(\mu\text{-}C_6R_6)]$ **8** would be improbable already on steric grounds. In the crystal the μ-(1-3-η^3:4-6-η^3-*p*-xylene) ligand shows a geometry typical for η^3-methallyl groups. Since the η^3-enyl planes are bent away from the planar xylene structure by 22.6°, the bridging ligand takes the form of a flattened chair. The same bonding situation as in **34a** was recently also proved for the benzene bridge in **34b** by X-ray crystallography.[21]



34a, P⌒P = $Cy_2P(CH_2)_2PCy_2$, R = CH_3

34b, P⌒P = $iPr_2P(CH_2)_2PiPr_2$, R = H

The major product (approximately 60%) of the reaction of hexafluorobut-2-yne with $[Ni(cod)_2]$ is the binuclear hexakis(trifluoromethyl)benzene complex **36a**, which can be converted into **36b** or **36c** with phosphites.[58] On the basis of ^{19}F and ^{31}P NMR data, F.G.A. Stone et al. had initially proposed dynamic structures with *syn*-(μ-η^3:η^3)-bound arene bridges for **36a–c**.[58] Later the same authors decided that an *anti*-$[(NiL_2)_2\{\mu\text{-}1,2\text{-}\eta^2\text{:}3\text{-}4\text{-}\eta^2\text{-}C_6(CF_3)_6\}]$ structure was more likely.[59]

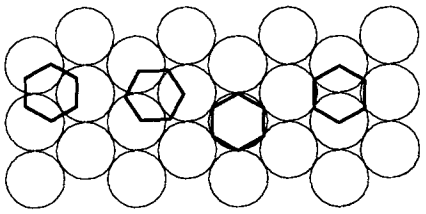
3. Chemisorbed Arenes on Metal Surfaces and Arene-Capped Cluster Compounds

From the point of view of the chemist, molecules chemisorbed on metal surfaces often do not greatly differ from the corresponding ligands in molecular metal complexes.[60] In many cases chemisorption can be described as being localized, that is, through a "cluster-like" bonding of the substrate to the surface.[61] In this respect, chemisorbed arenes on transition-metal surfaces are particularly interesting varieties of arene–metal multinuclear complexes.

The adsorption of benzene on transition-metal surfaces has been well studied.[62] Most investigations were carried out on single-crystal surfaces with low Miller indices. In almost all cases benzene is adsorbed as a molecule (i.e., no dissociation takes place). The plane of the adsorbed benzene ring lies parallel to the metal surface; nevertheless, different adsorption sites for different metals have been proposed. Benzene can be bonded to one or more surface atoms. For the simple case of benzene on a close packed, atomically flat metal surface (e.g., the (111) face of a metal with cubic closest packing) there are at least four different sites for the

chemisorbed benzene (Fig. 6): one with sixfold local symmetry (highest symmetry C_{6v}), e.g. Rh(111)/C_6H_6,[64] Pd(111)/C_6H_6[65]); with threefold local symmetry [$C_{3v}(\sigma_v)$ or $C_{3v}(\sigma_d)$, e.g. Os(0001)/C_6H_6,[66] Rh(111)/C_6H_6/Na,[67] Pd(111)/C_6H_6/2CO,[68] and Pt(111)/C_6H_6[69]]; and with twofold local symmetry (C_{2v}, e.g. Pt(111)/2C_6H_6/4CO[70]).



$C_{3v}(\sigma_d)$ $C_{3v}(\sigma_v)$ C_{6v} C_{2v}

Fig. 6. Adsorption sites of benzene on a densely packed transition-metal surface. The local symmetry at each site is given.

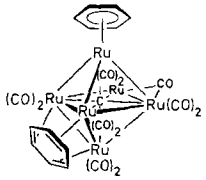
Once chemisorbed, benzene cannot be completely thermally desorbed from metal surfaces.[71] From all investigated metal/benzene adsorbates, both benzene and dihydrogen are desorbed by warming; the desorption:dehydrogenation ratio for benzene depends on the metal and the surface coverage.

Due to great experimental difficulties associated with the structural analysis of adsorbates on surfaces, only very little structural data is available for adsorbed arenes.[72] According to electron diffraction (*l*ow *e*nergy *e*lectron *d*iffraction, LEED) investigations by M.A. van Hove, G.A. Somorjai et al., the benzene rings in the Rh(111)/C_6H_6/CO coadsorbate[73] were found to be trigonally distorted (d_{C-C} = 1.33(15) and 1.81(15) Å for the alternating shorter C–C "double bonds" and the longer C–C "single bonds"). In Rh(111)/C_6H_6/2CO[70] and Pd(111)/C_6H_6/2CO[68] the distortion of the chemisorbed benzene is not significant (d_{C-C} = 1.46(15) and 1.58(15) Å, 1.40(10) and 1.46(10) Å, respectively). The same is true for benzene adsorbed at a C_{2v} site in Pt(111)/2C_6H_6/4CO[70] (two C–C bonds with d_{C-C} = 1.65(15) Å, four C–C bonds with d_{C-C} = 1.76(15) Å).

F.P. Netzer et al.[74] deduced from the angle-resolved photoelectron spectra (ARUPS, *a*ngle-*r*esolved *U*V *p*hotoemission *s*pectroscopy) C_{6v} symmetry for benzene in Rh(111)/C_6H_6/CO. This excludes a significant Kekulé distortion of the chemisorbed benzene. The obvious contradiction of the results from the electron diffraction studies has not yet been resolved.

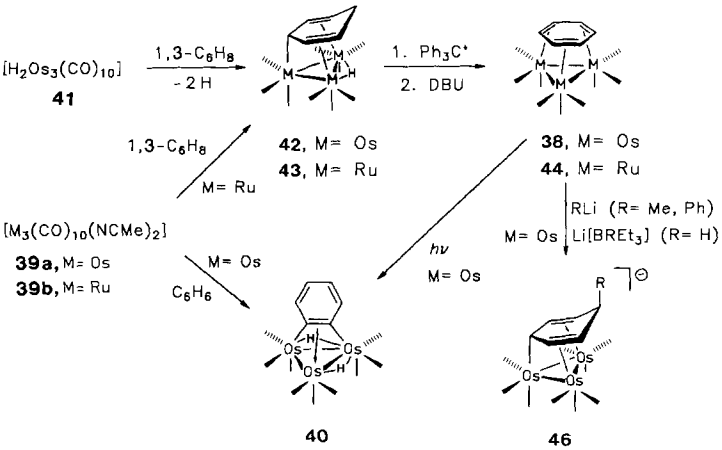
If alkyl benzenes are adsorbed with the plane of the arene ring parallel to the metal surface, the C–H bonds of the side chains are close to the surface atoms. This leads to dissociative adsorption with the cleavage of C–H bonds.[71] In the case of the adsorption of toluene on a Pt(111) surface, the product of such a selective dehydrogenation, a $(\pi + \sigma)$-bound η^7-benzyl species, could be observed by spectroscopy at 350 K.[75]

Molecular cluster complexes [{L_mM}$_n$(μ-arene)] with $n \geq 3$, in which an arene ligand is bonded to three or more metal atoms, are of some significance as possible model substances for the metal-surface/arene chemisorbates.[63] The first syntheses of such molecules were successfully carried out by J. Lewis et al. in 1985.[76] In the octahedral Ru_6 cluster compound **37**,[76] obtained from [$Ru_6C(CO)_{12}(\eta^6$-$C_6H_6)]^{2-}$ and [$(PhCN)_3Ru(\eta^6$-$C_6H_6)]^{2+}$, one of the benzene rings is bonded as an η^6 ligand to a ruthenium atom. The second benzene molecule takes a position parallel to a triangular face of the Ru_6 octahedron and interacts with three metal atoms.



37

For the synthesis of the Os_3 cluster **38**, [$Os_3(CO)_{12}$], or the more reactive [$Os_3(CO)_{10}(NCMe)_2$] (**39a**) cannot simply be treated with benzene. In such a reaction benzene oxidatively adds to the metal cluster forming **40**, a complex of dehydrobenzene.[77] The method used by J. Lewis et al. for the preparation of **38** starts with **41** and 1,3-cyclohexadiene which are converted into the μ_3-benzene on the metal complex via **42**,[78] an intermediate containing the μ_3-cyclohexadienyl ligand (Scheme 5). In a similar way **44**, the Ru_3 homologue of **38**, is prepared from **43**.[79] With Me_3NO/MeCN **38** reacts to form the activated **45a**, from which the further monosubstituted products **45b–e** and the disubstituted [$Os_3(CO)_7(C_2H_4)$(MeCN)(μ_3-η-$C_6H_6)$] are accessible.[80,81] The latter reacts with alkynes C_2R_2 to give [$Os_3(CO)_7(\eta^6$-$C_6H_6)(\mu_3$-η^1:η^2:η^1-$C_2R_2)$]. In this reaction the benzene is transferred from the Os_3-face-capping position into a η^6-coordination at only one osmium atom.[81]



Scheme 5. DBU = 1,8-diazobicyclo[5.4.0]undec-7-ene. The CO ligands in the formulas for **38**, **40**, **42–44**, and **45** are indicated by dashes.

a, L = MeCN; **b**, L = PPh_3; **c**, L = $P(OMe)_3$; **d**, L = C_2H_4; **e**, L = H_2C=CHPh)

Strong nucleophiles such as H^- and RLi (R = Me, Ph) add to the μ_3-arene ring of **38** in the *exo* position. The prod-

ucts are the anionic clusters **46** with substituted (μ_3-η^2:η^1:η^2-cyclohexadienyl) ligands.[82] In contrast, HBF_4 attacks **38** at the metal framework forming $[Os_3(CO)_9(\mu_2\text{-}H)(\mu_3\text{-}\eta^6\text{-}C_6H_6)]^+$[82]). On irradiation ($\lambda > 290$ nm) **38** isomerizes quantitatively by oxidative addition of the μ_3-benzene to the Os_3 cluster to form the μ-η^1:η^2:η^1-dehydrobenzene(dihydrido)cluster **40**.[83] In inert matrices at 12–20 K the photolysis probably occurs in two steps and without dissociation of CO.[83] The conversion of **38** into **40** is irreversible and can also be accomplished by prolonged heating of **38**. All these results indicate that **40** is the thermodynamically more stable isomer.

A few years ago a method of synthesis for tricobalt clusters with face-capping arene ligands $[(CpCo)_3(\mu_3\text{-arene})]$ **47–58** (Table 1) was developed in our research group.[63,84] Our method does not generate a benzene molecule on the metal cluster as in the case of the Os_3 clusters but a metal cluster is assembled on the arene. To achieve this, substituted

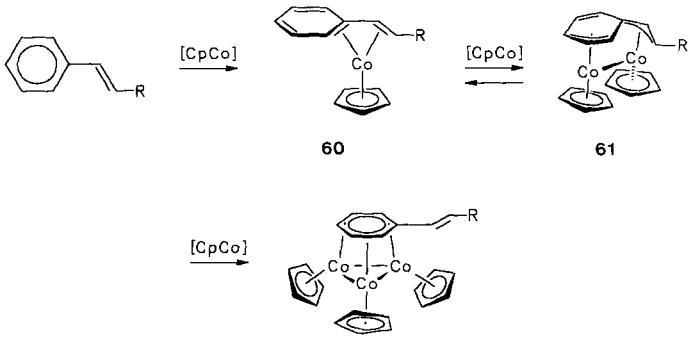
styrene derivatives are treated with Jonas reagent [CpCo(C_2H_4)$_2$] (**23**) or **59**, both excellent sources of CpCo complex fragments.[85] The yields of these one-pot reactions are

$[CpCo(\eta^6\text{-}C_6Me_6)]$ **59**

often very high, and are determined by the degree of substitution at the arene ring and at the side chain.[63] Allylarenes and 4-phenyl-1-butene can also be used. In these arenes, the double bond of the side chain is catalytically shifted into the α position to the arene ring in a preequilibrium.[63,84] Benzene and alkylarenes do not react.

The 1-alkenyl group on the arene ring serves as a "landing-strip" for the first complex fragment, which is probably initially coordinated to the double bond of the side chain, and then, aided by the chelate effect, attacks the aromatic π system (Scheme 6). The mononuclear primary product **60** is

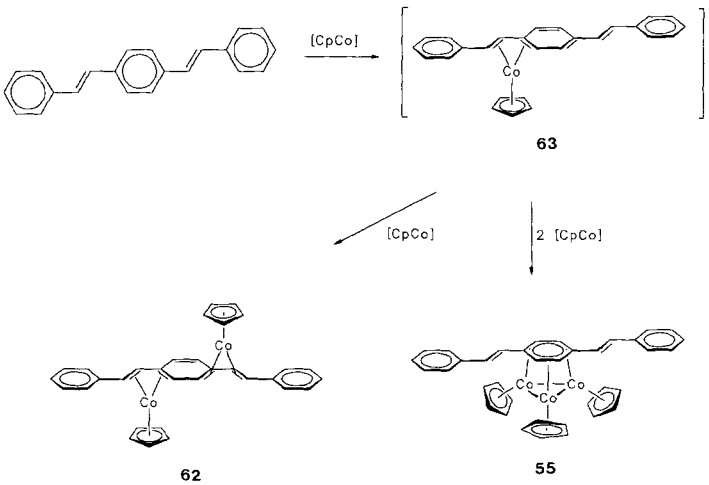


60 **61** **47–58**

Scheme 6.

activated for further reaction since the six π electrons of the arene are disturbed by the complexation of two carbon atoms. A Co_3 cluster can only be formed if further CpCo complex fragments attack in a *syn* position to the cobalt atom in **60**. Therefore, we proposed the complex **61** with a (β,α,1-η^3:2-4-η^3-alkenylbenzene) ligand as a binuclear intermediate[88] in which the cobalt atoms (each formally Co^{II}) are linked by a metal–metal bond and thus can be retained on the same side of the alkenylbenzene ligand. The third CpCo complex fragment can now be added to the uncoordinated C–C double bond in **61** to form the metal cluster. Simultaneously the alkenyl group is decomplexed. So far, however, there have only been indirect indications for the participation of such mono- and binuclear intermediates in the formation of the clusters **47–58**.

A good indication that complexes of the type **60** are intermediates is the formation of **62**, along with the μ_3-arene complex **55**, from *p*-distyrylbenzene and Jonas reagent **23** or **59** (Scheme 7).[86,87,89] In the mononuclear complex **63**, which has not yet been detected but is surely initially formed, the π system of the central arene ring is activated in comparison to the free ligand. The addition of two more CpCo com-

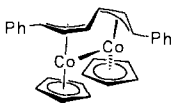


63 **62** **55**

Scheme 7.

plex fragments to the coordinated arene ring finally leads to the μ_3-arene cluster **55**. But the diene system formed from only two carbons of the inner six-membered ring and the second styryl group can also be coordinated. This forms the "trapped product" **62**. With *m*-distyrylbenzene as a ligand the binuclear complex analogous to **62** could be isolated.[87]

CpCo complexes with α- and β-vinylnaphthalene or α-styrylnaphthalene as ligands are the most similar to the postulated intermediates **60** containing β,α,1,2-η^4-alkenylarene ligands. In these crystalline solids, as in **60**, two carbon atoms of the aromatic ring and two of the 1-alkenyl side chain are bonded to the cobalt atom.[88,90] These substances are unstable already at room temperature and cannot be subjected to further reactions to form [$(CpCo)_3$(μ_3-alkenylnaphthalene)] clusters. A model compound for the binuclear intermediate **61** is **64**. The *syn*-(μ-η^3:η^3) coordination of a hexatriene unit postulated for **61** has been shown by X-ray crystallography[88] to occur in the (open-chain) 1,3,5-hexatriene ligand of **64**.



64

At this point attention should be drawn to the strikingly different reaction behavior of 1-alkenylbenzenes with the $(CO)_3Fe$ complex fragment, which is isolobal and isoelectronic with CpCo. Many stable complexes of the type [$(CO)_3$Fe(β,α,1,2-η-1-alkenylbenzene)] are known, which often react with further [$(CO)_3$Fe] affording binuclear complexes.[89] However, these have an *anti*-[{$(CO)_3Fe$}$_2$(β,α,1,2-η^4:3-6-η^4-1-alkenylbenzene)] structure, and they do not react any further to form the hypothetical clusters [{$(CO)_3Fe$}$_3$(μ_3-arene)].

As mentioned in Section 2.2, J. Müller et al.[23] recently obtained the trirhodium complex [$(CpRh)_3$(μ_3-η-C_6H_6)] (**12**) by the photolysis of [$CpRh(C_2H_4)_2$] (**9**) in the presence of benzene (Scheme 2). The complexes [$CpRh(\eta^4$-C_6H_6)] (**10**) and *syn*-[$(CpRh)_2$(μ-η^3:η^3-C_6H_6)] (**11**), isolable after several hours of irradiation, are probably direct precursors of **12**, since after longer reaction times only **12** is formed. Even a long reaction time affords **12** in very small quantities (approximately 2.5% yield after 7.5 h); this clearly illustrates the crucial role of the alkenyl substituents on the formation of the tricobalt cluster complexes [$(CpCo)_3$(μ_3-alkenylarene)], where in some cases an almost quantitative yield is obtained.[63]

In all the cluster compounds with arene bridges which have been structurally characterized so far, the (μ_3-η^2:η^2:η^2)-bonding mode of the arene ligand to an M_3 unit was found in the solid (Table 2). M_3-triangle and arene-hexagon are parallel to each other and adopt a staggered orientation. The μ_3-benzene ligands of the Ru and Os complexes **37** and **38** were at first described as M_3-face-capping cyclohexatrienes[76] because of the alternating long and short C–C bond lengths determined by X-ray crystallography. However, the X-ray structure analyses of five [$(CpCo)_3$-(μ_3-arene)] derivatives show that only a small (although crystallographically significant) alternation of the C–C bond lengths (average difference 0.03 Å) occurs, at least in the complexes of this type (Table 2).[63,84,92–94] The probability that this is also true for the previously mentioned (μ_3-benzene) clusters with metals of the 2nd and 3rd transition-metal series, for which the C–C distances show much larger experimental errors, is supported by the recently published structure of [$Ru_3(CO)_9$(μ_3-η-C_6H_6)] (**44**).[79] Although only small, the trigonal distortion of the μ_3-arenes towards a Kekulé structure is induced by a mixing of HOMO and LUMO of the arene, according to a theoretical MO analysis.[93] This occurs in such a way that the three C–C bonds which lie above the metal atoms are shortened, whereas the others are lengthened. This is made possible by the threefold symmetry enforced upon the arene by the M_3 cluster. There exists an interesting parallel to the mononuclear complexes [$(CO)_3M(\eta^6$-C_6H_6)] (M = Cr, Mo, W) which also show a weak alternation of the C–C bond lengths in the complex-bound benzene ligand.[95] The bending of the arene C–H bonds away from the metal cluster observed by crystallography can also be well understood from MO theory.[93]

Table 2. C–C bond lengths in several μ_3-η^2:η^2:η^2-arene ligands (standard deviations of single values in parentheses; for each complex, first line: the average value of the alternating long and short bonds [a], second line: difference between the longest and shortest single value).

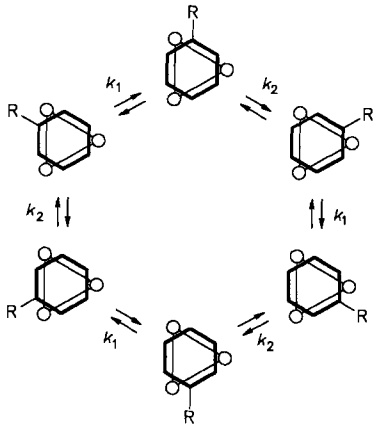
[a] Exception: **47a**$^+$ in which the order of shorter and longer C-C bonds is irregular.

In solution rotation of the M_3-triangle with respect to the arene ring is hindered. For the clusters **45d** and **45e**, this dynamic process is coupled with the rotation around its bonding axis of the alkene bound to one osmium atom. For this reason **45** was quite aptly named "organometallic helicopter".[80] In Rh_3 cluster **12** the ^{1}H NMR signal of the benzene protons at room temperature is a quartet (J_{RhH} = 0.7 Hz),[23] so that here, too, a rapid rotation of the arene can be assumed.

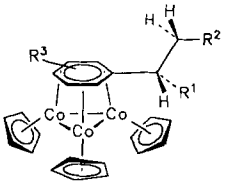
With 2D EXSY NMR spectroscopy (EXSY = *Ex*change *s*pectroscop*y*) successive [1,2]-shifts of the cobalt atoms at

the μ_3-arene (i.e. 60° rotation of the arene above the Co_3 cluster as the elementary step, Scheme 8) can be proven directly for the clusters $[(CpCo)_3(\mu_3\text{-}C_6H_5R)]$ (see below).[86] In the one-dimensional ^1H and ^{13}C NMR spectra the hindered ligand movement causes the singlet for the three CpCo groups (which at room temperature is often already broadened) to split into three separate signals at low temperature. The slow rotation has interesting stereochemical consequences.[86,89]



Scheme 8.

A cluster $[(CpCo)_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_5R)]$ with a monosubstituted arene (e.g. **65** and **66** in Table 3), which when rigid is asymmetrical, is converted by a 60° rotation of the μ_3-arene ligand into its enantiomer. However, in **65a**, if the arene rotation is slow the methyl groups of the prochiral isopropyl substituent become diastereotopic. Thus on lowering the temperature, the ^1H NMR spectrum does not only show three CpCo resonances but also two methyl doublets. The same effect makes all methylene protons in **66b** nonequivalent at low temperature.



65–67

Table 3. Complexes of the type $[(CpCo)_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-arene})]$ **65–67**.

Complex	R^1	R^2	R^3	Ref.
[(CpCo)$_3$(*iso*-propylbenzene)] **65a**	Me	H	H	[86]
[(CpCo)$_3$(*n*-propylbenzene)] **65b**	H	Me	H	[63]
[(CpCo)$_3$(1,1-diphenylethane)] **66a**	Ph	H	H	[86]
[(CpCo)$_3$(1,2-diphenylethane)] **66b**	H	Ph	H	[86]
[(CpCo)$_3$(*p*-diethylbenzene)] **67**	H	H	4-Et	[86]

In contrast, the arene rotation in **66a**, which has an asymmetrical C atom in α position to the μ_3-phenyl ring, converts the two chiral diastereomers **A** and **B** into each other (Fig. 7). At low temperature the equilibrium lies completely on one side: in solution at −70 °C only one diastereomer is observ-

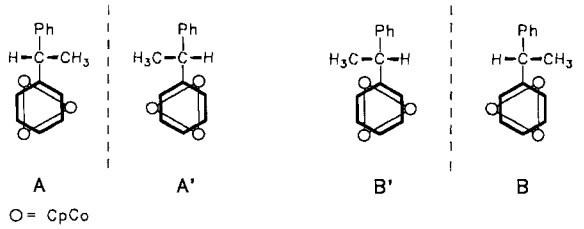


Fig. 7. Schematic representation of the diastereomeric pairs of enantiomers (**A**, **A'** and **B**, **B'**) of **66a**. In the crystal **A** and **A'** are observed.

able (three singlets in the region for Cp resonances in the ^1H (Fig. 8) and ^{13}C NMR spectra). Although not directly observable, the presence of the other diastereomer in the dynamic equilibrium becomes apparent in a characteristic way from temperature-dependent ^1H NMR spectra.[86,96] This can be particularly well observed from the signal for the methyl group ($\delta = 1.1$), which is sharp at high and low temperatures but is broadened at intermediate temperatures (Fig. 8). In the crystal also, only the two enantiomers of the

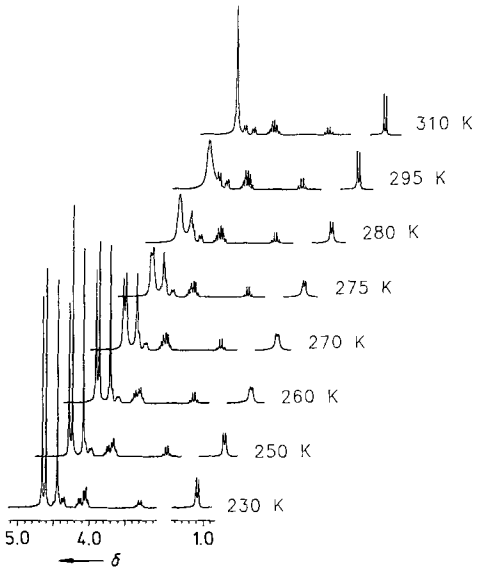

Fig. 8. Temperature-dependent ^1H NMR spectra of **66a** (200 MHz, in $[D_8]$toluene).

sterically more favorable diastereomer are observed.[92] A stereochemically similar situation exists for **51b**. However, in this case the two diastereomeric rotamers can be detected simultaneously at −90 °C in solution by NMR spectrocopy (two sets of three singlets each in the region for the Cp resonances, Fig. 9).[87]

A quantitative analysis of the temperature-dependent NMR spectra for the general case of a monosubstituted μ_3-arene ligand is difficult. In most cases only the Cp resonances can be analyzed. The mechanism of the arene rotation (60° rotation of μ_3-arene ligand and $(CpCo)_3$ cluster relative to one another) shown in Scheme 8 generates a complicated exchange matrix for the CpCo groups, since with each elementary step only two of the three chemical shifts are exchanged with one another (no simple cyclic permutation).[97] Furthermore, two different rotation barriers have to be con-

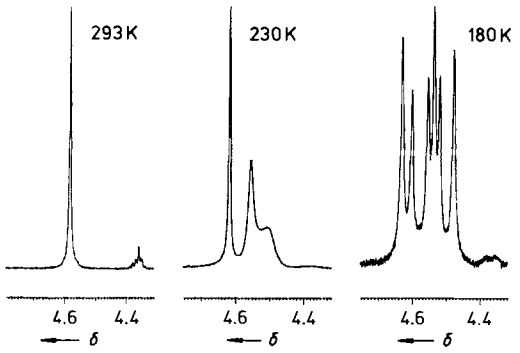

Fig. 9. Section of the temperature-dependent 200 MHz ^{1}H NMR spectrum of [(CpCo)$_3$(μ_3-(*m*-methyl)-β-methylstyrene)] **51b** (region of Cp signals). The spectrum at 180 K was folded with a Gaussian function. Signals at $\delta = 4.35$ stem from the protons on the μ_3-arene ring.

sidered a priori, depending on whether the substituent moves across a CpCo group (rate constant k_1) or between two such groups (k_2). Qualitatively it can easily be shown that the two activation barriers are indeed different. This is shown in Figure 10 with two ^{1}H EXSY NMR spectra of **47b** as illustration. With a short mixing time in the EXSY experiment[98] only the quicker exchange process is observed. In the 2D matrix, cross-signals occur between only two of the three Cp resonance signals (Fig. 10a). With longer mixing times the slower process also becomes apparent; now one of the Cp resonance signals is connected with *both* the others by cross-signals (Fig. 10b). This corresponds exactly with the mechanism of Scheme 8. Simulations of the exchange-broadened one-dimensional ^{1}H NMR spectra show the same result. Unfortunately neither method can be used to determine the activation barriers very precisely.

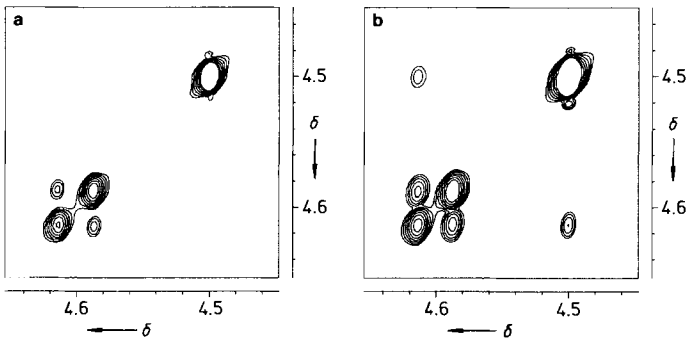

Fig. 10. Section of the 200 MHz ^{1}H EXSY NMR spectra of [(CpCo)$_3$(μ_3-β-methylstyrene)] **47b** at 230 K (region of the Cp resonance signals). Mixing times: 60 ms (a) and 150 ms (b); echo detection. In the phase sensitive 2D spectrum the diagonal and cross-signals have the same phase.

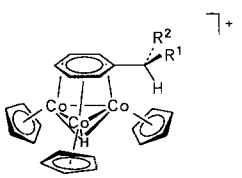
The temperature dependence of the methyl resonance signals in **65a** can be better analyzed (two exchanging doublets that are not coupled to each other in the ^{1}H NMR spectrum); however, it only gives the weighted mean of the two barriers ($\Delta G^{\neq}_{290K} = 57$ kJ mol^{-1}). Symmetrically *para*-disubstituted derivatives such as *p*-distyrylbenzene complex **55** or [(CpCo)$_3$(μ_3-*p*-diethylbenzene)] (**67**) offer better prospects. The latter is only accessible indirectly through the catalytic hydrogenation of the side chain in *p*-ethylstyrene complex **49**.[86] Complexes **55** and **67** have C_s symmetry and therefore only one rotation barrier. For both the ^{1}H resonance signal of the CpCo groups is split into two (ratio of intensities of 2:1) on lowering the temperature. Additionally, the methylene protons of the ethyl groups in **67** become diastereotopic, forming an exchanging spin system of the type $ABM_3 \rightleftarrows C_2M_3$. This now fulfils all the prerequisites for an iterative line shape analysis,[99] from which the values $\Delta H^{\neq} = 59 \pm 1$ kJ mol^{-1} and $\Delta S^{\neq} = 37 \pm 5$ J mol^{-1} K^{-1} can be obtained. From the coalescence of the Cp and μ-arene-CH signals, approximate values for $\Delta G^{\neq}_{235K} = 50$ kJ mol^{-1} and $\Delta G^{\neq}_{240K} = 49$ kJ mol^{-1} respectively, are obtained. These values are consistent with the free energies of activation calculated from $\Delta H^{\neq}$ and $\Delta S^{\neq}$. Taken together, all the data available up to now indicate that the energy barriers of the arene rotation ($\Delta G^{\neq}$) in clusters of the type [(CpCo)$_3$(μ_3-η-arene)], and the difference of the free energy (ΔG^0) of the diastereomeric conformers of **51b** and **66a** are due to steric hindrance by the substituents at the μ_3-arene rings and not by a localization of double and single bonds in the μ_3-arene rings.

Clusters of the type [(CpCo)$_3$(μ_3-arene)] are chemically more stable than the [(CO)$_3$Ru]$_3$ and [(CO)$_3$Os]$_3$ analogues.[63] The μ_3-arenes cannot be substituted by other arenes or two-electron ligands such as CO, PMe$_3$, and P(OMe)$_3$. Strong Lewis acids like AlCl$_3$ or BF$_3$, which could catalyze the arene exchange, lead to a decomposition of the substances. [(CpCo)$_3$(μ_3-stilbene)] (**53b**) catalyzes the cyclooligomerization of propargyl alcohol. The product mixture obtained after 5h at 114 °C consists of cyclotrimer and cyclotetramer in the approximate ratio 1:4.[100] Such a high proportion of the cyclotetramer is very unusual for cobalt catalysts (e.g. with [CpCo(C$_2$H$_4$)$_2$] (**23**) as catalyst under similar reaction conditions a typical product ratio of cyclotrimer:cyclotetramer $\approx$ 1:1 is obtained[100]).

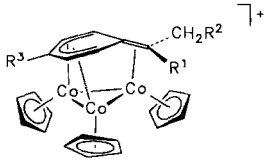
The 1-alkenyl side chains are apparently deactivated by the bonding of the arene to the metal cluster. In contrast to the free ligands, they no longer react with diazomethane or diazoethylacetate, for instance. A bromination at the allyl position with *N*-bromosuccinimide is also no longer possible. However, as mentioned above, the hydrogenation of the 1-alkenyl groups can be accomplished at room temperature and atmospheric pressure on a Pd/charcoal catalyst. In this way derivatives with saturated side chains are accessible (see Table 3). This reaction convincingly shows that the 1-alkenyl side chain, although a prerequisite for the formation of the complexes, has little significance for the stability of an already formed [(CpCo)$_3$(μ_3-arene)] cluster.

[(CpCo)$_3$(μ_3-arene)] clusters with alkyl or phenylalkyl side chains are protonated at the metal framework by strong Brønstedt acids. According to a X-ray structural analysis of crystalline **68**-(CF$_3$COO), a μ_3-hydrido ligand caps the face of the Co$_3$ triangle which is not hindered by the arene.[86,92] This structure is retained in solution.



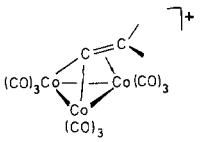
68, R^1 = CH$_3$, R^2 = Ph

If a C–C double bond is present in an α position to the μ_3-arene ring, a proton is added to the carbon atom in the β position on reaction with acid. The products **69** and **70**, which in the widest sense can be considered α-[$(CpCo)_3(\mu_3$-η-phenyl)]-substituted carbenium ions, are strongly stabilized by the interaction with the metal cluster. So far we have not



69a, $R^1 = CH_3$, $R^2 = R^3 = H$
69b, $R^1 = R^3 = H$, $R^2 = CH_3$
70, $R^1 = R^2 = H$, $R^3 = OCH_3$

been able to obtain these salts as single crystals. The temperature-independent ^1H and ^{13}C NMR spectra are consistent with a structure in which all the carbon atoms of the arene ring as well as the (formally positively charged) α-C atom of the side chain are bonded to the tricobalt cluster. Our proposed structure is similar to that of α-[(nonacarbonyltricobalt)carbynyl]-substituted carbenium ions **C**,[101,102] which show a similarly high stabilization.



C

4. Outlook

Multinuclear complexes with arene bridges are no longer exotic! On the contrary, benzene and its derivatives have proven to be very flexible ligands that are capable of adapting to the needs of different metal-complex fragments. However, almost all of the μ-arene complexes reported in this review have been obtained fortuitously, often only as by-products. A systematic approach to the synthesis of such complexes has been attempted only for a very few cases. Consequently most of these complexes have not been investigated beyond their synthesis and characterization, so that almost nothing is known about the reactivity of the μ-arenes. This is even more amazing when one considers the significance of mononuclear arene–metal complexes in organic synthetic chemisty.[105]

The analogy between chemisorbates on metal surfaces and molecular cluster complexes, propagated in particular by E.L. Muetterties[60c], has in the recent past proven useful, especially for the understanding of chemisorbates,[106] but is still under discussion.[107] Cluster compounds with face-capping arenes are the simplest model compounds for adsorption states of benzene on metal surfaces. The interpretation of the data obtained by a multitude of sophisticated surface-analytical methods still encounters many difficulties. The knowledge about the structure, dynamics, and reactivity of the arene bridges obtained from the molecular (μ-arene)–metal cluster complexes should be invaluable for the interpretation of these data. For example, the structures of the molecular systems show that the local threefold symmetry of the cluster does not necessarily enforce a large Kekulé distortion on the μ_3-arene.

The theoretician finds himself confronted by challenging problems concerning arene-bridged multinuclear complexes. The geometrical distortion and thus probably also the electronic structure of the μ-arenes are very different in complexes which appear to be similar—a problem not yet theoretically addressed. The field is open for the synthetic chemist, spectroscopist, crystallographer, and theoretician. What is certain is that also in the future much will be heard about the arene complexes that are already considered classical.

I would like to thank my graduate students for their enthusiasm and commitment; their names appear in the literature citations. I am especially grateful to Dr. Hans Pritzkow for many X-ray structural analyses and his never-failing willingness to discuss the work. I also thank Prof. Dr. Walter Siebert for his continual support. Further thanks go to my colleagues Prof. Dr. Jörn Müller, Prof. Dr. Piera Sabatino, and Doz. Dr. Dirk Walther for informing me of their unpublished results. Our research has been financially supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the companies BASF AG and Degussa AG (donations of chemicals); I would like to thank these institutions for their help. Furthermore, I thank the Deutsche Forschungsgemeinschaft for a Heisenberg scholarship.

[1] A. Kekulé defined aromatic compounds as derivatives of benzene. (A. Kekulé, *Liebigs Ann. Chem.* **1866**, *137*, 129–196.) Later this term was used for similar (e.g. polycylic) hydrocarbons (see for example, W. Hückel, *Theoretische Grundlagen der organischen Chemie*, *1. Band*, 6. Aufl., Akademische Verlagsgesellschaft, Leipzig, **1949**, 2. Buch, Chapter 9.) Following IUPAC rule A-12.4, arene is the generic name for mono- and polycylic hydrocarbons. In this review, the term arene is used in Kekuléan sense, i.e. as benzenoid arene. See also: D. Lloyd, D. R. Marshall, *Angew. Chem.* **1972**, *84*, 447–451, *Angew. Chem. Int. Ed. Engl.* **1972**, *11*, 404.

High Resolution Spectroscopy below the Doppler Width

By Hans Jürgen Neusser* and Edward William Schlag

Microscopic insights into elementary molecular processes are only feasible through the observation of unique quantum states and the study of their couplings and time-dependent behavior. In the case of larger chemically relevant molecules, the corresponding transitions lie so close that they mostly overlap and lead to band structures. For example, electronic band spectra of large molecules cannot be resolved into single lines even by high resolution UV-spectrometers. The reason for this is the Doppler broadening, arising from the random velocity of the molecules in the gas phase. In this article, we want to demonstrate that modern laser spectroscopic methods make it possible to overcome this "Doppler barrier" and to resolve the line structure in band spectra. The selective excitation of unique quantum states yields precise information on the mechanisms responsible for energy redistribution in molecules. Energy redistribution processes represent a crucial first step preceding chemical reactions, which they influence decisively. Very high resolution spectroscopy elucidates the influence of molecular rotation on the energy redistribution. Through Coriolis forces in rotating molecules, vibrations can couple, causing a flow of energy from the selectively excited vibrations to the many other vibrational degrees of freedom. Weak interactions, namely van der Waals interactions and hydrogen bonding, determine the structure of large molecules (biomolecules) and supermolecular systems. Weak intermolecular interactions, given their selectively resolved quantum states, can be analyzed and understood at the microscopic level. "Doppler-free spectroscopy" with its resulting line spectra furnishes information on the structure, including bond lengths, of van der Waals complexes. With this information, Doppler-free spectroscopy provides the model parameters indispensable for the quantitative description of complex systems.

1. Introduction

The general goal of chemical spectroscopy is the investigation of the positions of the quantum states of microscopic systems, such as atoms or molecules. On the one hand, the exact energetic position of these states when collated with predictions of theoretical models pins down the electronic arrangement, the bond strengths, and the structure of the nuclear frame in molecules. On the other hand, the line widths of the transitions yield information on the lifetimes of the excited states and thus about dynamical processes in the molecule. In this way spectroscopy has, up to now provided the key information for an understanding of the physical and chemical properties and the reactivity of elements and compounds.

In ultraviolet spectroscopy the absorbed photons excite electrons of the molecule. Typically, this electronic excitation proceeds according to the Franck-Condon principle, exciting, in addition, vibrations of the molecule. Furthermore, before the excitation, the molecules are in various rotational and vibrational states, as given by the Boltzmann distribution at the appropriate gas temperature. This rotational state distribution is preserved or changed insignificantly in the excitation. Unambiguous spectroscopic information can be expected only if unique quantum states can be excited, i.e. states for which all of the quantum numbers are fixed. This means that along with the electronic and the vibrational quantum number, the rotational quantum number must also be distinctly defined.

In the case of large polyatomic molecules, single rotational lines in electronic or vibrational-electronic transitions (vibronic transitions) are so densely packed that they can no longer be resolved by conventional spectroscopic methods. This explains the broad band spectra with no line structure typically reported for large molecules. The culprit is the Doppler broadening of the transition, caused by the random velocity of the molecules in the gas phase. A typical value for the Doppler width of a molecule of the rough size of benzene (C_6H_6) is in the case of the $S_1 \leftarrow S_0$ transition at about 40000 cm^{-1}, 1.7 GHz or 0.05 cm^{-1} at room temperature.

Before discussing the possible methods of overcoming the Doppler barrier in order to achieve line structure in spectra, we enter briefly into the chemically relevant problems whose clarifications demand the separation of single rotational transitions in electronic or vibronic spectra. These are namely inquiries of the precise structure of molecules and extremely unstable weakly-bound van der Waals complexes (treated in the second half of this article). Using Doppler-free spectroscopy, quantities such as van der Waals bond lengths and potential parameters can be experimentally obtained which lead to a quantitative understanding of the weak intermolecular interactions inherent in complex systems.

Essential for an understanding of elementary chemical reactions are insights into the reaction dynamics, or the study of the course of reactions at the microscopic level. The study of reaction mechanisms is not only essential for an understanding of chemical processes, but could have a tremendous practical use if successfully applied to block, accelerate, or initiate selective chemical reactions.

For an understanding of the reactions of polyatomic molecules at the microscopic level, statistical theories, in particular the Rice-Ramsperger-Kassel-Marcus (RRKM) theory[1]

or Quasi-Equilibriums theory,[2] are at present very popular and useful. For many chemical reactions occurring along bound potential curves, these theories are able to explain the observed reaction course and its rate constant. The crucial assumption of these theoretical models is that the total energy of the molecule before the reaction is statistically distributed over all of the degrees of freedom of the molecule. In many cases a good agreement with experimental results is achieved with this hypothesis. Consequently, over the last decade and at present, the focus of studies in reaction dynamics is: How does a statistical distribution of energy in a molecule come about? Is the distribution complete or limited to certain vibrational states?

The process responsible for the redistribution of energy is the intramolecular vibrational redistribution (IVR) occurring within a molecule.[3] Precise information on the IVR process can only be obtained if distinct quantum states of the molecule are prepared and the intramolecular vibrational redistribution observed.

The states of polyatomic molecules lie so dense that state-selective excitation demands Doppler-free studies. Initiating such studies, the dye laser[4] with its very sharp frequency width, can be finely tuned over the molecular transitions. This in turn has led in the last decade to the development of various experimental methods such as saturation spectroscopy, optical double-resonance spectroscopy and two-photon absorption spectroscopy, which in principle serve to reduce or to eliminate the Doppler width of an optical transition.[5] These methods therefore hurdle a natural barrier to the spectral resolution. The use of collimated atomic or molecular beams should be included here, as this technique also reduces the Doppler width, in this case through geometric selection of molecules of the same velocity. However, application of the molecular beam technique for high resolution spectroscopy first became possible through the use of extremely narrow-band tunable lasers; examples of high resolution UV-spectroscopy on van der Waals complexes is presented in the second half of this article.

The various methods mentioned above were mainly developed for studying fine structure in atomic spectra. Extension to large molecules is not possible for every one of these methods. In a series of studies, our group has established that two-photon spectroscopy represents a practical method of obtaining Doppler-free high resolution spectra of large molecules.[6, 7]

2. Doppler-free Two-Photon Spectroscopy of Molecules and Intramolecular Energy Redistribution

2.1. Concepts of Doppler-free Two-Photon Absorption

At the microscopic level, energy is transferred to atoms and molecules in the smallest energy units, called photons. As early as 1930, Maria Göppert-Mayer postulated that not only one photon could be transferred, but rather that two photons could also participate in one elementary absorption step.[8] Not until 1960, through the discovery of the laser with its very high light intensity, could two-photon absorption be experimentally proved.[9] In two-photon absorption, absorption of two photons excites the molecule to a state whose energy is given by the summed photon energy. In this manner, it is possible for example to excite UV absorption bands of benzene with visible blue light. Moreover, as the selection rules for one- and two-photon absorption differ,[10] spectroscopic information on previously unknown vibrational[11, 12] and electronic states[13] is collected.[14] These selection rules complement each other in a way analogous to those of infrared and Raman spectroscopy, both of which

Edward W. Schlag was born in 1932 in Los Angeles. He studied chemistry at the Occidental College, Los Angeles. He gained his doctorate at the University of Washington in Seattle in 1958 under the supervision of Professor B. S. Rabinovitch for work on the unimolecular isomerization of cyclopropanes. Since 1971 Edward Schlag has held a professorial chair for Physical Chemistry at the Technical University of Munich. Several honors have been conferred on him for his diverse research activities, which have been reported on in more than 250 original papers and books: Since 1978 Schlag has been a full member of the Bavarian Academy of Sciences, and since 1984 a fellow of the American Physical Society. In 1988 he was made an honorary Doctor of the Hebrew University in Jerusalem. His main interests currently focus on the investigation of the structure and dynamics of molecules and molecular complexes using high-resolution spectroscopic methods.

Hans Jürgen Neusser was born in 1943 in Troppau (Czechoslovakia). He studied physics at the Technical University (TU) in Munich, where he was awarded his doctorate in 1971 for work with Professor W. Kaiser. Subsequently, he worked for seven years with W. E. Schlag and gained his habilitation in Physical Chemistry for work on the two-photon spectroscopy of molecules in the gas phase. In 1979 Neusser was appointed Professor of Physical Chemistry at the TU Munich. In 1983 he was awarded the Chemistry Prize of the Academy of Sciences, Göttingen, for his work in the field of Two-Photon Spectroscopy, Multiphoton Ionization and Doppler-free High-Resolution Molecular Spectroscopy. At present his main interests focus on the laser spectroscopy of molecules and molecular complexes, intramolecular dynamics, and the kinetics of ionic decomposition.

supplement spectroscopic information on the electronic ground state.

If both absorbed photons stem from one light bundle or from two different light bundles traveling in the same direction, then the spectral resolution of the two-photon absorption is limited, as that in one-photon absorption, by the Doppler broadening. The Doppler width of a specific transition arises from the individual molecular absorption lines from molecules with differing velocities; the shifts of their absorption frequencies, depending on their speed and velocity vector, vary in accordance with the first order Doppler effect. In the above absorption case, the resultant shift is the sum of that from light frequencies ν_1 and ν_2. The averaging over the differing Doppler shifts yields an inhomogenously-broadened Gaussian-shaped absorption line, as illustrated in Figure 1 (top).

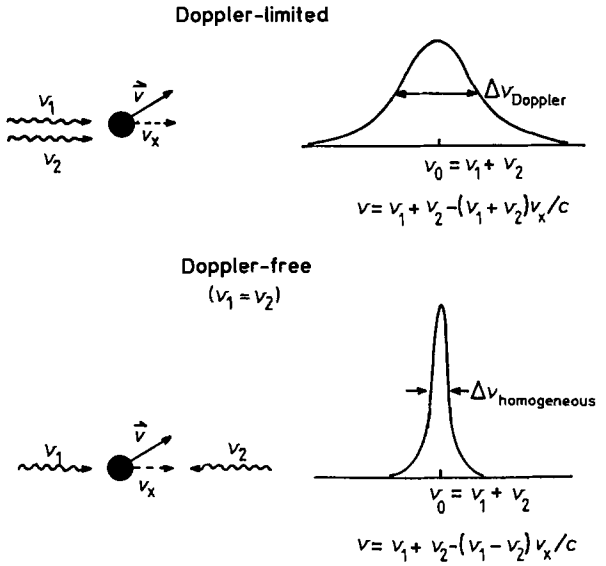

Fig. 1. Schematic representation of Doppler-limited (above) and Doppler-free (below) two-photon absorption processes. If both photons approach the absorbing molecule from the same direction, their Doppler shifts are added, resulting in a broadened transition with a Gaussian line shape. If, however, the two photons approach the absorbing molecule from opposite directions, the Doppler shifts are subtracted and thus compensate each other; this eliminates the Doppler broadening and reveals the sharp homogeneous line shape of the transition (after [14]).

In 1970, Chebotayev et al.[15] suggested the application of two-photon absorption of two antiparallel light bundles of an extreme monochromatic laser to avoid Doppler broadening. The principle of this method is illustrated schematically in Figure 1 (bottom). Note that now the Doppler shifts of the two light frequencies are subtracted. Whereas the light wave approaching from the left experiences a red shift, the frequency of the light wave approaching from the right is blue-shifted. If the two antiparallel light bundles have the same frequency, the two shifts compensate each other exactly, eliminating the Doppler shift for each and every velocity component, so that the transition is free from any Doppler broadening. Naturally, the transition frequency can then be determined with considerably higher accuracy, and transitions which were perhaps concealed under the Doppler broadening can be resolved. Furthermore, it is now possible to observe a transition's homogeneous line width. As we will see later, the homogeneous line width is of special significance in studies of intramolecular relaxation processes, as it supplies very important additional information on the dynamic behavior of the molecule. To summarize, Doppler-free two-photon absorption should enable, even for large molecules with very densely packed absorption lines, the excitation of unique rotational states in vibronic quantum states (unique rovibronic states), and consequently the precise monitoring of relaxation processes.

2.2. The Experimental Technique of Doppler-free Two-Photon Absorption

Doppler-free two-photon absorption was first realized in 1974 on atoms.[16] Attempts at extending this technique to large polyatomic molecules faced nontrivial experimental difficulties. Firstly, in molecules the oscillator strength of the two-photon transition is divided among many vibronic transitions. Secondly, about 10^3–10^4 rotational states are populated, as if having to work with an effective low molecular number density. And, in addition to these difficulties, two-photon absorption is inherently a weak higher order effect, whose observation requires high light intensities.[14]

A possible experimental setup to achieve sufficient signal strengths to observe the weak two-photon absorption is illustrated in Figure 2.[17] A continuous-wave single-mode

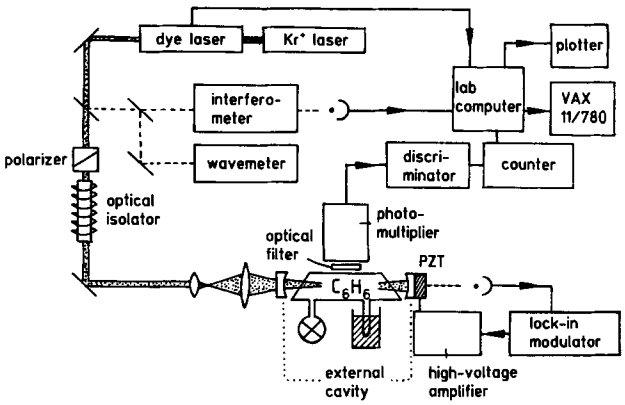

Fig. 2. Schematic diagram of the experimental setup for measurement of Doppler-free molecular spectra with high resolution. Elimination of the Doppler broadening proceeds by absorption of two photons, traveling in opposite directions, from the narrow-band standing light waves in the external resonator. PZT is a piezoelectric transducer.

ring dye laser, pumped by a Kr^+ laser, supplies very narrrow-band light ($\Delta\nu = 1$ MHz $= 3 \times 10^{-5}$ cm^{-1}). A "wavemeter" measures the absolute laser frequency, while an interferometer records very precisely the relative frequency. The molecular gas under study is contained in a fluorescence cell at the low pressure of less than 1 Torr so as to avoid molecular interactions through collisions. This cell is placed in an external resonator, so that the Doppler-free two-photon absorption occurs through a standing light wave composed of two antiparallel light bundles. If now a molecule absorbs one photon from each of the oppositely-traveling light bundles, the Doppler shift of the transition frequency for each mole-

cule, regardless of its velocity, will be compensated, and a Doppler-free spectrum at the sum of the two photons' energies will be observed. The use of the external resonator is crucial, as this can immensely amplify the light intensity, which in turn increases the two-photon signal intensity with its quadratic dependence on the light intensity by several orders of magnitude.

The resulting two-photon absorption is detected through the emitted UV fluorescence with the help of a photomultiplier tube. Scanning the laser light frequency requires synchronous fine tuning of the external resonator using a piezoelectric transducer (PZT); this ensures that the resonance conditions in the external cavity for the particular wavelength in question are constantly fulfilled. A data processing system facilitates the signal storage and the plotting of the Doppler-free two-photon spectrum on the desired scale.

2.3. Doppler-free Two-Photon Spectra of Benzene

To illustrate the potential of Doppler-free spectroscopy, Figure 3 displays a part of the $S_1 \leftarrow S_0$ spectrum of benzene at various spectral resolutions. The topmost trace shows the

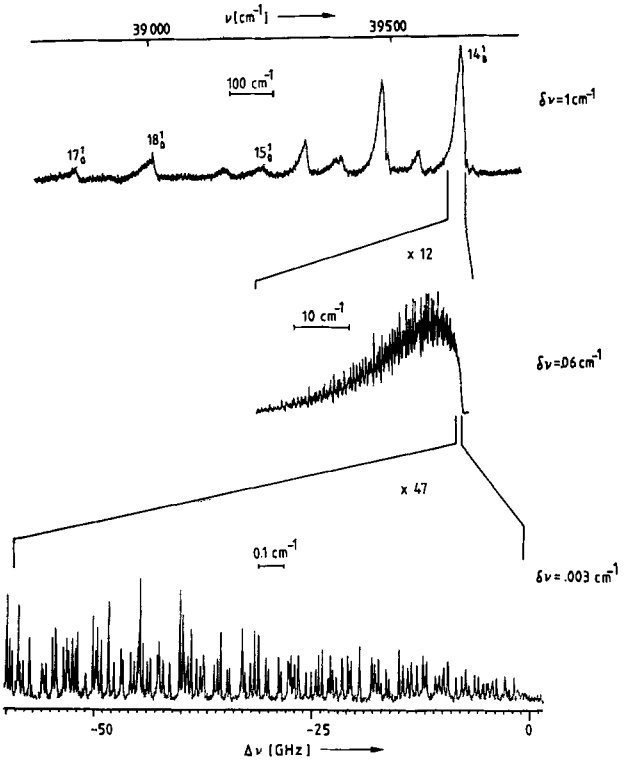

Fig. 3. The two-photon spectrum of the electronic $S_1 \leftarrow S_0$ transition in benzene at various spectral resolutions (after [14]). Top: Vibrational structure of the $S_1 \leftarrow S_0$ transition. Center: Q-branch of the strongest (14^1_0) band at Doppler-limited resolution. Bottom: After elimination of the Doppler broadening, single rotational lines appear which were hiding under the Doppler width. $\delta\nu$ gives the resolution.

two-photon spectrum at a spectral resolution of 1 cm^{-1}. (The structure of the one-photon spectrum of benzene is in principle similar, although due to the differing selection rules, different vibrational bands are observed.) The middle spectrum shows the central portion of the strongest vibrational band (14^1_0)[*] at a resolution limited by the Doppler broadening. This represents the highest resolution achievable through conventional one-photon spectroscopy, even with the help of a high-resolution spectrometer. The observed structure represents the overlapping of many rotational lines. The individual rotational lines become visible only after the introduction of a technique of elimination of the Doppler broadening and an increase in the resolution by a factor of 50. The lowermost spectrum, recorded using Doppler-free two-photon spectroscopy, displays single rotational lines. The frequency scale is now given in GHz instead of cm^{-1}, since the interferometer which measures the exact relative frequency is calibrated in GHz (1 $cm^{-1} \approx 30$ GHz). This spectrum represents the blue edge and thus only a small fraction of the complete vibrational band. Evidently thousands of rotational lines, hidden under the Doppler broadened vibrational band, first manifest themselves after elimination of the Doppler broadening.

The resulting rotational line spectrum can be unambiguously analyzed to yield extremely precise rotational and centrifugal distortion constants of the molecule in its electronic ground state (S_0) and in its electronic excited state (S_1). The accuracy is a factor of 100 larger than in conventional high-resolution (Doppler-limited) UV spectroscopy. A typical result for the rotational constants of the S_1 state with accompanying excitement of one quantum of C-C ring vibration ν_{14} of b_{2u} symmetry is[18] $B'_{14} = 0.181284$ and $C'_{14} = 0.090711$ cm^{-1}, accurate to 10^{-6} cm^{-1}. The rotational constants B and C are given by the rotational energy level formula for an oblate symmetric top molecule [Eq. (a)].[19]

$$E_{Rot} = BJ(J+1) - (B - C)K^2 \qquad (a)$$

J is here the quantum number of the total rotational angular momentum. K is also a good quantum number for a symmetric top molecule and describes the projection of the total angular momentum on the spinning top axis.

The accurately determined rotational constants and measurements on isotopomers (e.g. C_6D_6) allow exact determination of the bond lengths in the molecule and the changes in bond length upon electronic excitation. For benzene in its electronic ground state, an average C–C bond length of 1.397 Å and an average C–H bond length of 1.079 Å are determined. In the S_1 excited electronic state, the C–C bond length increases to 1.432 Å, whereas the C–H bond length decreases slightly to 1.075 Å. As anticipated, promotion of a π electron to an antibonding π^* state is accompanied by a decrease in binding energy, evoking an expansion of the benzene ring.

The accurately determined rotational and centrifugal distortion constants suffice to reproduce the measured rotational line structure with respect to the line positions and heights. A good agreement between the reproduced and measured line positions implies in this case that the excited rovibronic states are not coupled to other vibrational states, so that no energy transfer to other vibrational modes can take place.

[*] The superscript denotes the number of excited quanta of a particular vibration (here No. 14) in the final state of the transition (here S_1 state), while the subscript denotes the number of quanta of this vibration in the initial state (here S_0 state).

2.4. The Model of Intramolecular Energy Redistribution: a Primer

Before evidence of intramolecular energy redistribution in a Doppler-free spectrum is discussed, an introduction to the theoretical model of this process should be presented.

In the description of molecules, one assumes that electronic, vibrational, and rotational states can be considered as separated in the Born-Oppenheimer approximation. Theory designates such states as zeroth-order states. In reality, zeroth-order states are not isolated from each other, but are often coupled to other zeroth-order states of the molecule. This coupling can occur, e.g., between states of the same or differing multiplicities, resulting in internal conversion (IC) or intersystem crossing (ISC), two well-known processes of radiationless decay. In the case of intramolecular energy redistribution preceding a chemical reaction, the pertinent coupling is between different vibrational states of the same electronic potential (intramolecular vibrational redistribution, IVR).

A more precise formulation of intramolecular coupling is possible with the help of the theory of nonradiative processes.[20] The two limiting cases depicted in Figures 4 and 5 are the most intuitively clear. Figure 4 shows the situation

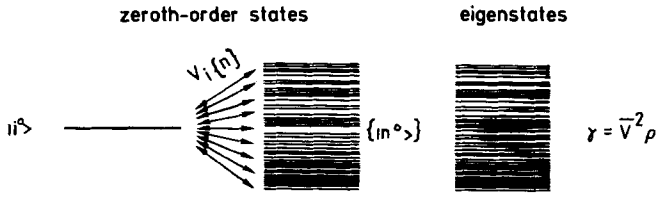

Fig. 4. Schematic representation of a nonradiative process at the statistical limit. The coupling of a molecular state $|i^0\rangle$ to a quasicontinuum of densely-packed states $\{|n^0\rangle\}$ leads to a broadened Lorentzian-shaped line.

present at the "statistical limit." Here a large number of states $|n^0\rangle$ lie within the width of the coupling matrix element $V_{i\{n\}}$ of a zeroth-order state $|i^0\rangle$. The manifold of states $\{|n^0\rangle\}$ form a quasicontinuum to which the zeroth-order state $|i^0\rangle$ is coupled. The case of coupling to a continuum is of course well-known for ionization and dissociation processes, but can also arise as a limiting case for the process of intramolecular vibrational redistribution in large molecules, due to the strongly increasing density ρ of vibrational states with increasing excess energy in the electronic state. In the simplest case, only state $|i^0\rangle$ carries oscillator strength and therefore can be optically populated or is, in spectroscopy jargon, "light", whereas the manifold of states $\{|n^0\rangle\}$ is "dark". If we now carry out an experiment with a low coherence width (such as with continuous-wave narrow-band laser light), we can expect for this coupling limit, a Lorentzian-broadened line shape of width $\gamma = \bar{V}^2\,\rho$, arising from the projection of the fragmented oscillator strengths or "light"

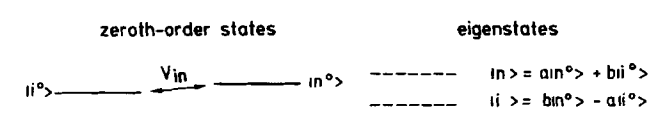

Fig. 5. Schematic representation of the coupling of two zeroth-order states, $|i^0\rangle$ and $|n^0\rangle$, yielding a mixing and repulsion of the eigenstates $|i\rangle$ and $|n\rangle$.

fractions on the eigenstates. On the other hand, using a large coherence width, such as short-time pulsed laser excitation, it is feasible to excite the "light" zeroth-order state $|i^0\rangle$, which due to the high state density evolves exponentially and irreversibly with time. Under these conditions, we are dealing with what we call "dynamics".

The situation is entirely different when the density of states is so low that the only coupling is between the two zeroth-order states $|i^0\rangle$ and $|n^0\rangle$ (Fig. 5). This is the natural case for small molecules or for very low excess energies in the electronic states of large molecules. As is well known in spectroscopy, such a coupling leads to repulsion of the states and mixing of the wave functions of the two states. The repulsion of the zeroth-order states leads to an "avoided crossing" of the energy level curves of the eigenstates, which is observable in the spectrum (static perturbation).

This short introduction to the theoretical description of nonradiative processes demonstrates that the intramolecular dynamics can reduce to the case of static coupling well known in spectroscopy at the low density of states typical for low excess energies. Unresolved questions and thus topics of current research are the following points:

- When does the statistical limit begin? What is the nature of the transitional region from static perturbations to dynamics at the statistical limit?
- Which coupling mechanisms are responsible for IVR? Are only the anharmonic couplings between the vibrational states of importance, or does the molecule's rotation in the form of rotational-vibrational coupling also play a role?
- Is the coupling selective? Does the redistribution occur only within a particular group of states?

With the example benzene, we are able to study a molecule at increasing total excitation energy and so to analyze diverse regions of the spectrum exhibiting strongly differing densities of vibrational states: as will be demonstrated below, the benzene molecule with its 30 vibrational degrees of freedom is especially suitable. Both limiting cases described above can be reached if, on the one hand, one excites a low excess energy up to 2000 cm^{-1}, and on the other, the excess energy within the optically-accessible region of the S_1 state is increased to about 4000 cm^{-1}; additionally, the excitation of unique states can be guaranteed by the Doppler-free two-photon spectroscopy. Concrete studies of the 14_0^1 vibrational band and the $14_0^1 1_0^1$ and $14_0^1 1_0^2$ progressions of this band at higher excess energies were carried out. These vibrational bands correspond to totally symmetric two-photon transitions originating in the ground state,[21] with one quantum each of the ν_{14} (b_{2u}) vibration with 1570 cm^{-1} of energy excited in the S_1 state. The progressions arise from addition of quanta of the totally symmetric C-C stretching vibration ν_1 (a_{1g}) amounting to excess energies of 2492 ($14^1 1^1$) and 3412 cm^{-1} ($14^1 1^2$). With regards to Figures 4 and 5, the final states of these three transitions correspond to "light" zeroth-order states in the S_1 state. The density of zeroth-order states increases from 1.2 (14^1) to 17 ($14^1 1^1$) to 165 ($14^1 1^2$) per cm^{-1}. These background states are not, however, directly visible in the spectrum, as they carry negligible oscillator strength for the two-photon transition. Nevertheless, through their interaction with the 14^1, $14^1 1^1$ and $14^1 1^2$ excited states, they have a characteristic influence on the spectrum as described below. Around 3000 cm^{-1}, the electronic

relaxation behavior of the molecule changes, as concluded by early measurements from the abrupt drop in the fluorescence quantum yield.[22] The cause of this behavior was tentatively attributed to a fast nonradiative relaxation channel ("Channel Three") whose origin was at the time unknown.

Using several selected examples, we shall explain in the following section the spectral effects of a strongly increasing density of background states with increasing excess energy and how these observations fit into the theory of intramolecular vibrational redistribution. With such information, a clarification of the mechanism of "Channel Three" is possible.

2.5. Information on the Mechanism of Intramolecular Energy Redistribution

A careful examination of the spectrum of Figure 3 (bottom) at higher rotational energies reveals irregular, seemingly unsystematic deviations between the measured and predicted (using the experimentally determined rotational constants) rotational structure, which cannot be consistently clarified by a new set of rotational or centrifugal distortion constants.[18, 23] This is a signature of perturbations in the spectrum, denoting interaction with a "dark" background state.

Figure 6 demonstrates such isolated perturbations in two sections of the spectrum. Below are two calculated sections of the spectrum of the 14_0^1 band: above, for collation, are the corresponding measured spectral sections. A collation of the calculated and measured spectra for each section yields good agreement for the majority of rotational lines. Nevertheless, there are lines (marked by an arrow) in the experimental

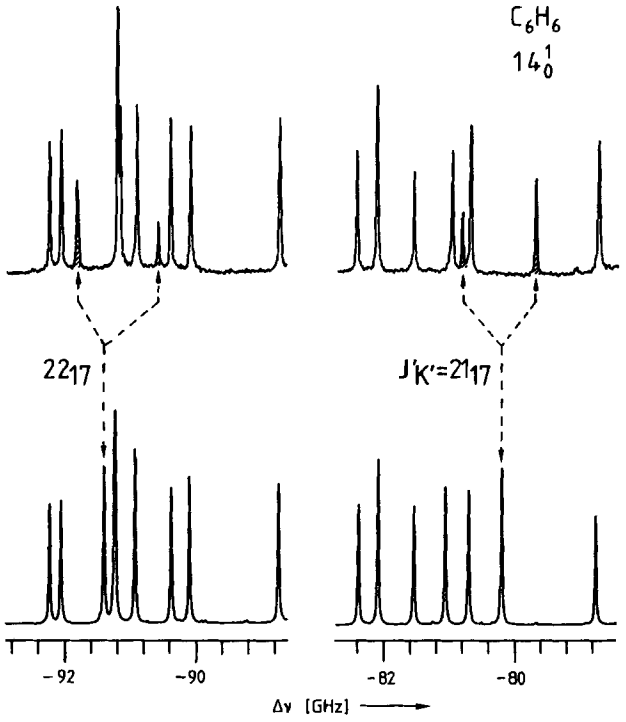

Fig. 6. Comparison of a section of the experimental (above) and calculated (below) spectrum of the 14_0^1 vibrational band; low excess energy in the S_1 electronic state of benzene. The lines tagged in the theoretical spectrum are absent in the experimental spectrum: instead, two nearly symmetrically shifted lines appear, analogous to the coupling case described in Figure 5 (after [23]).

spectrum with no direct match in the calculated spectrum and vice versa. Instead two smaller lines appear in the experimental spectrum which are nearly symmetrically shifted about the calculated line position. We are obviously witnessing here the coupling case described by Figure 5, namely the coupling of two states, leading to a repulsion of the two resulting eigenstates and to a mixing of the two coupled zeroth-order states. This coupling is selective since an energy resonance between a "light" and a "dark" state is rare with the low density of states of 1.2 states/cm^{-1} at the excess energy of 1570 cm^{-1}. The mixing of states results in two observable eigenstates (rather than the one anticipated "light" state) which share the oscillator strength of the one "light" state. These eigenstates are direct proof of the coupling of two normal vibrational states, which finally leads to an energy redistribution in the molecule.

A closer analysis of such perturbations in the spectrum indicates a value of the coupling matrix element of the order of a few 100 MHz. Moreover, a dependence of the coupling matrix element on the rotational quantum numbers J and K is found. This result can in no way be clarified through an anharmonic interaction of the coupled vibrations, rather it must follow that Coriolis coupling plays a crucial role. Coriolis forces appear in rotating molecules and can cause the coupling of vibrational states through the rotation of the molecule.

This result, fundamental to the understanding of intramolecular energy redistribution, was obtained for the spectral region of low excess energy, but can just as well be confirmed at high excess energies. The region of high excess energy is particularly interesting since the reactive region of the potential of an electronic state is in general first reached at high energies. Figure 7 displays results from the high resolution spectroscopy of the $14_0^1 1_0^2$ vibrational band at an excess energy of 3412 cm^{-1}. Here the line shapes (under extremely high resolution) of the three rotational lines $J_K = 2_0$, 6_0, and 14_0 of the $14_0^1 1_0^2$ vibrational band are presented.[24] For clarification, we emphasize that this spectral structure lies well below the Doppler width; the Doppler width of the transition in Figure 7 is namely 1.6 GHz or four times larger than the complete frequency range displayed in Figure 7. It is obvious here that the measured line width increases strongly with J, namely from 12.7 to 53.2 MHz as J increases from 2 to 14. In addition, the measured line shape corresponds with high accuracy to a Lorentzian line. (The solid lines represent Lorentzian lines fitted to the data points.) In contrast to the results at low excess energies, here the line widths rather than the positions depend strongly on the molecule's rotation. This rotational dependence cannot be attributed to an electronic relaxation process but rather must arise from coupling within S_1. The Lorentzian shape of the lines indicates moreover an irreversible vibrational relaxation at the statistical limit as given in Figure 4. A quantitative analysis of these results[24] establishes that even at these high excess energies, or even in the "Channel Three" region, Coriolis coupling produces an interaction of vibrational states within S_1 and decisively influences the IVR process. the rotationally-dependent line broadening directly demonstrates that Coriolis coupling to particular "dark" vibrational states represents the primary process of "Channel Three". These results, with respect to the intramolecular en-

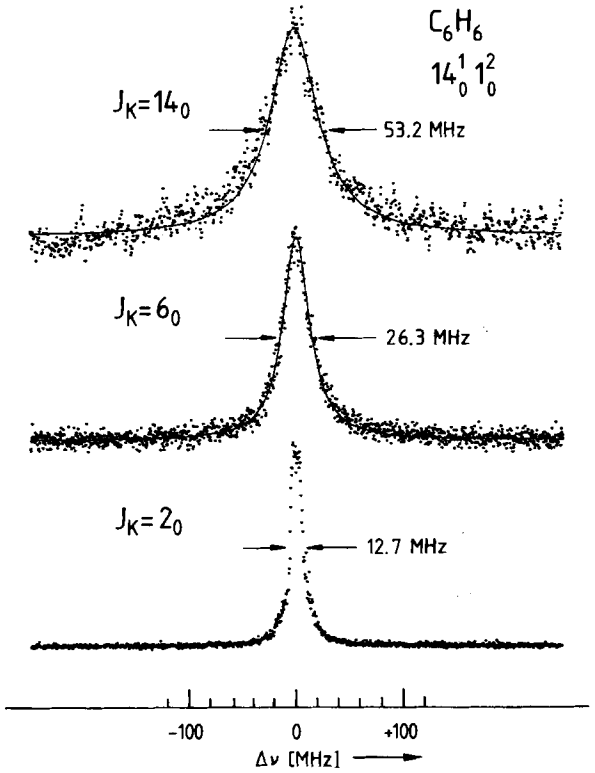

Fig. 7. Three rotational lines from the $14^1_0 1^2_0$ vibrational band; high excess energy in the S_1 electronic state of benzene. The Lorentzian line shapes and the strong increase in line width with increasing rotational quantum number J indicate that the rotation of the molecule plays a crucial role in the intramolecular vibrational relaxation via Coriolis coupling (after [24]).

ergy redistribution and the coupling mechanism, should in principle be transferable to the electronic ground state, since the S_1 and S_0 states behave similarly with respect to couplings and density of states.

Using selected examples from the spectrum of benzene, we have shown in this section that Doppler-free spectroscopy enables the excitation of uniquely defined quantum states even for large molecules with densely-lying transitions. Line splittings and homogeneous line widths present below the Doppler width have proven that rotation plays a decisive role in the energy redistribution in molecules. Couplings between individual normal vibrations of a molecule are not only generated through anharmonicities, but also through Coriolis forces in a rotating molecule. Selection rules apply to this coupling which determine the nature and symmetry of the coupled "dark" state. In such a way, we have gained an understanding of microscopic physical processes fundamental to energy redistribution. In conclusion, the basic mechanics of the energy redistribution process in a chemically relevant molecule has been presented for the first time.

3. Doppler-free Ultraviolet Spectroscopy of Weakly Bound van der Waals Complexes

3.1. Introduction

Interest in the spectroscopy of weakly-bound complexes has grown immensely in the last ten years. Such complexes or clusters result from clustering of molecules or atoms, made possible by long-range, but weak electrostatic forces, such as dipole-dipole interaction or induced dipole-dipole interaction.[25] With weak binding energies of the order of a few kJ/mol, these complexes are generally unstable at room temperature. The increasing number of cluster studies can be attributed to the convenient method of producing isolated gas phase atomic and molecular clusters in cooled supersonic beams.[26] The general goal of these studies is the quantitative microscopic understanding of van der Waals bonding, intrinsic to solvation processes and the structure and properties of the liquid phase and thus critically influencing chemical processes in the liquid phase. This goal in turn necessitates investigation of the exact structure of the complex, its binding energy, the shape of the van der Waals potential, and its dynamic behavior, i.e. the examination of its energy redistribution and its dissociation.

For complexes involving large organic molecules, the discussion of the previous section on polyatomics molecules applies to an even larger extent: the desired information can first be obtained when the spectral resolution is high enough to resolve individual rotational lines within the Doppler width. Particularly instructive are studies on complexes involving spectroscopically well-studied molecules. It is therefore natural to produce complexes containing the benzene molecule. Moreover, with the distinct planar ring structure of benzene, one expects a complexation behavior typical for the large class of aromatic molecules, thus acquiring important basic information for the description of solvation processes at the microscopic level. In the simplest case, noble gas atoms or small molecules are complexed with benzene. Here we can expect relatively minor changes in the well-known spectrum of benzene as the complexation entails no new chemical bonds, thus minimally influencing the molecular electronic structure.

This section presents results of the Doppler-free spectroscopy of complexes of benzene with noble gas atoms or small molecules such as N_2. As in the case of benzene itself, Doppler-free spectroscopy provides a resolution of the rotational structure below the Doppler width, enabling precise statements to be made on the structures and dynamic behavior of these clusters.

3.2. Experimental Techniques for the Preparation and Spectroscopy of van der Waals Complexes

Due to their small binding energies, isolated van der Waals complexes are not stable at room temperature. Such complexes are thus frequently prepared in cooled supersonic molecular beams.[26] Hereby a gas at a high pressure of a few atmospheres is expanded into a vacuum through a small orifice.[27] During the expansion process, the thermal energy of the gas particles is converted into translational expansion energy, resulting in a gas beam with a highly directed velocity and a low temperature of translational, rotational and vibrational degrees of freedom. In the cooling process, condensation of the gas can occur, leading to formation of van der Waals complexes of various sizes.

Figure 8 shows the experimental setup for the high resolution spectroscopy of van der Waals complexes. The core of the setup is the cooled molecular beam. Benzene at its natu-

rally-occurring vapor pressure of about 60 mTorr is mixed with a noble gas (e.g. Ar) at the high pressure of about 5 atm and then expanded through a small orifice ca. 0.3 mm in diameter into the first vacuum chamber. The gas throughput is limited by the short pulsed opening of a valve, which proceeds synchronously with the arrival of the laser light pulses. Due to the cooling upon expansion, various homo- and heteroclusters of benzene and Ar are formed. A conical-shaped skimmer peels away the outer shell of the molecular beam, enabling the expansion of the central part into a second vacuum chamber with a lower background pressure where the interaction with the light occurs. The skimmer contributes substantially to the realization of a Doppler-free spectrum, as its small opening selects exactly the molecules that have the smallest velocity components perpendicular to the direction of propagation of the molecular beam. Thereby the Doppler broadening amounting to ca. 0.05 cm^{-1} in a bulk gas is reduced to 0.001 cm^{-1}. This suffices for the resolution of rotational lines in the UV spectrum, so that the method of Doppler-free two-photon spectroscopy becomes superfluous here and, moreover, would not lead to a better resolution due to the limiting frequency width (ca. 0.0025 cm^{-1}) of the exciting laser light.

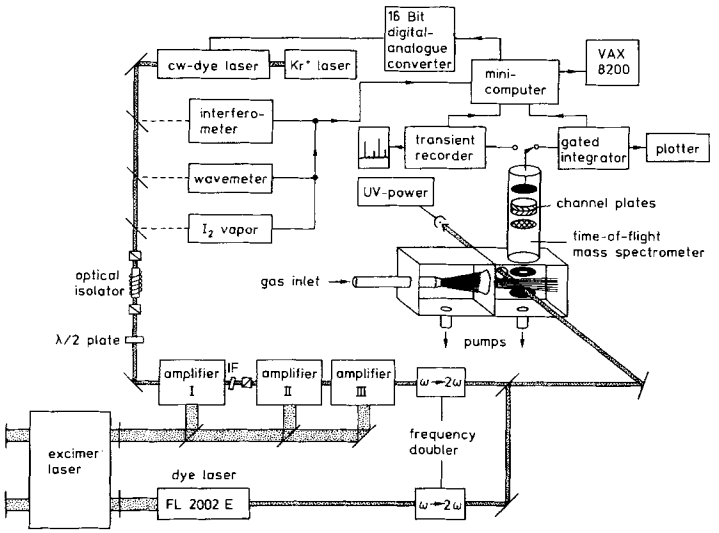

Fig. 8. Schematic diagram of the experimental setup for obtaining high resolution Doppler-free UV spectra of van der Waals complexes (after [31]). Van der Waals complexes of benzene and Ar are produced by expanding a gaseous mixture of benzene and Ar at high pressure through an orifice into vacuum. After a skimmer selects the central portion of the molecular beam, reducing the Doppler broadening, the complexes are excited to the S_1 state by a pulsed, narrow-band laser light and finally ionized by a second pulsed laser. The nascent ions are mass-analyzed in a time-of-flight mass spectrometer. To obtain spectra of the particular complex, free from obscuring overlaps with spectra of other species, only the current from ions of a selected mass is observed and integrated.

In the present experiments, the narrow-band light of the single-mode ring dye laser already described in Section 2.2 is pulsed-amplified to a high peak power in a three-stage excimer-laser-pumped amplifier setup. The generated visible blue-green light pulses have for their pulse length of 10 ns the best possible frequency sharpness of 80 MHz. In this case, the pulse length and the frequency width are linked to each other by a Fourier transform. The amplification and the use of pulsed laser light with its high peak intensities enable

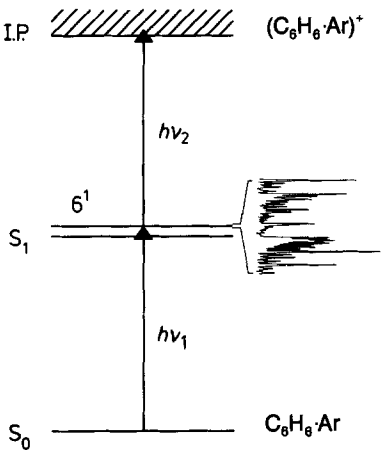

Fig. 9. Energy level scheme for resonance-enhanced two-photon ionization of molecules or van der Waals complexes. The efficiency of the ionization process is extremely enhanced when the energy of the first photon is resonant with a rovibronic transition in the complex (resonance-enhancement). As the frequency ν_1 of the narrow-band laser light is continuously scanned, the signal (ion current) is modulated due to the spectrum of the intermediate state. In this manner, Doppler-free rotationally-resolved spectra of mass-selected van der Waals complexes can be measured. I.P. = ionization potential.

frequency-doubling of the blue-green light into the ultraviolet spectral region, which in turn allows excitation of the $S_1 \leftarrow S_0$ transitions in the benzene-containing van der Waals complex through the absorption of one photon of energy $h\nu_1$ as depicted in the energy scheme of Figure 9. The subsequent absorption of a further UV photon ($h\nu_2$) stemming from a relatively broad-band dye laser, simultaneously pumped by the excimer laser, brings the excited (to S_1 state) complexes into the ionization continuum. The total excitation process corresponds to a two-photon ionization which is enhanced by the resonant state at the energy of the first absorbed narrow-band photon $h\nu_1$: each time the energy of the narrow-band photon agrees with a rovibronic transition of the cluster, the probability of a two-photon ionization is drastically enhanced. If the frequency of the narrow-band light $h\nu_1$ is tuned while monitoring the ion current, this will be modulated according to the spectrum of the intermediate state and consequently reflects this spectrum. The principal advantage of resonant two-photon ionization is that the created ions can be registered separately according to their mass in a mass spectrometer. This property of resonance-enhanced two-photon ionization was recognized at an early date[28] and is quite essential to the spectroscopy of van der Waals complexes. This was first demonstrated in several experiments with relatively low resolution just sufficient to resolve the vibrational structure in the spectra,[29] and is also essential for the high-resolution spectroscopy of the van der Waals complexes described here. Namely, a mixture of complexes of different composition and size whose spectra often overlap is produced in a cooled supersonic beam, as mentioned above. The mass-selective recording of the spectra facilitates the measurement of the spectrum of a selected complex in the mixture without interference by the presence of complexes of a different mass. In the experiment the mass separation proceeds in a simple time-of-flight mass spectrometer in which all cluster ions are accelerated to the same kinetic energy and subsequently separated in time in a field-free flight tube due to their mass-dependent flight times. Channel plates at the

end of the flight tube serve as the ion detector, delivering an ion current each time an ion bundle of the chosen mass arrives. The remaining units of the experimental setup facilitate the monitoring of the exact frequency of the exciting laser light and the recording and processing of the ion signal.

3.3. Structure and van der Waals Bond Lengths of Benzene–Noble Gas Dimers

Using the experimental method described in the previous section, the rotational lines of vibronic transitions in benzene–noble gas dimers were successfully resolved. In this section, we will show that analysis of the high-resolution spectrum allows the determination of the structure and van der Waals bond length to a high precision. The vibrational structure of the transition in benzene is only minimally perturbed by the weakly-bound Ar atom. Accordingly, the 6_0^1 band of the benzene–Ar complex is shifted by only 21 cm^{-1} to longer wavelength relative to the corresponding band in pure benzene.[30] This red shift denotes that the complex is more strongly bound in the S_1 state than in its electronic ground state. Whereas the vibrational structure of the $S_1 \leftarrow S_0$ transition changes negligibly through complexation, the rotational structures of the 6_0^1 band of benzene and the benzene–Ar complex, which were resolved by Doppler-free spectroscopy, no longer show any similarities. This can be traced back to the fact that two inertial moments of the system are altered by the addition of a noble gas atom. Figure 10 unequivocally demonstrates the high sensitivity of the rotational line positions to changes in the mass and structure. The high-resolution spectrum of the 6_0^1 band of the benzene–Ar complex is here contrasted with the corresponding band of benzene.[31] The spectral analysis proves that the complex, despite its completely altered moments of inertia, is to high accuracy, like benzene itself, a symmetric top. Moreover a temperature distribution of the rotational degrees of freedom of ca. 1.5 K can be derived and the rotational constants can be determined (by a procedure similiar to that described in Section 2.3) to the hitherto unattainable high accuracy of 10^{-5} cm^{-1}.

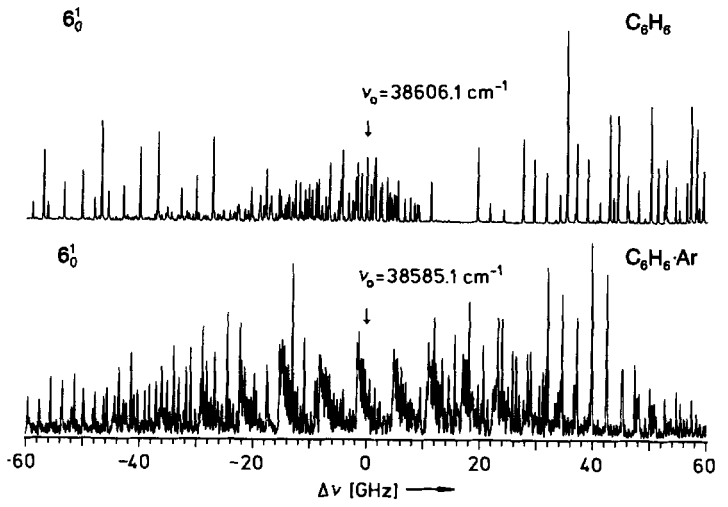

Fig. 10. Measured rotational structure of the 6_0^1 vibronic bands in the UV spectrum of benzene (above) and the benzene–Ar complex (below). The arrangement of the rotational lines differs completely, and indeed allows a precise determination of the structure of the complex by means of its inertial moments [31].

This spectral information is transposable into structural information. From the fact that the observed spectrum is that of a symmetric top, it follows that the sixfold rotational axis of the benzene is preserved even after complexation; consequently the Ar atom must sit on this axis (see Fig. 11).

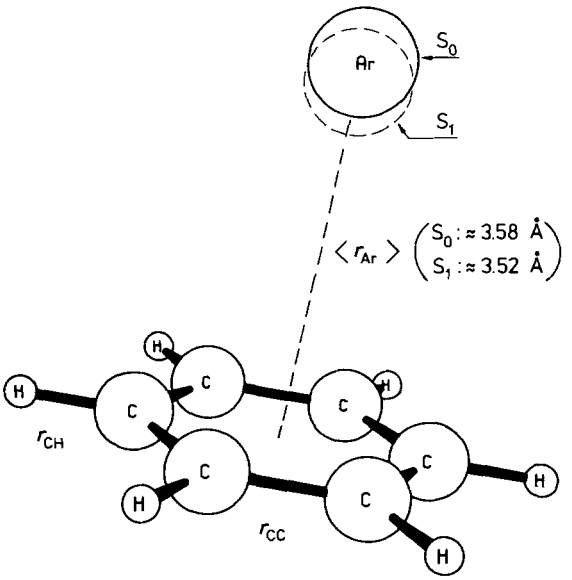

Fig. 11. The average structure of the benzene–Ar complex resulting from the high-resolution spectrum displayed in Figure 10. The Ar atom sits on the sixfold axis of benzene at a distance of 3.58 Å from the benzene ring. This distance decreases to 3.52 Å when the benzene is excited to the S_1 state (see text) [31].

The average van der Waals distance (Ar from the benzene plane) follows from the rotational constants. It is 3.58 Å in the ground state and *decreases* by 60 mÅ upon electronic excitation to the S_1 state. This behavior, in contrast to normal chemical bonds which typically expand upon electronic excitation, is thereby characteristic for van der Waals bonding. Since benzene and obviously the Ar atom as well have no permanent dipole moment, the induced dipole moments and hence the polarizabilities of each unit constitute the attractive van der Waals forces. The electron cloud expansion, in particular that of the π-orbital of benzene after an electronic excitation into the S_1 ($\pi\pi^*$) state, increases the polarizability and thus the attractive forces. The resulting decrease in the van der Waals bond distance is in addition supported by the expansion of the benzene ring accompanying electronic excitation (see Section 2.3); owing to the stronger attractive forces, the Ar atom can approach the expanded benzene ring more closely before the repulsion through overlap of the electron clouds dominates.

Similar results have been found for other benzene–noble gas complexes[32]: the van der Waals bond distance in the electronic ground state for the Ne atom complexed with benzene is 3.46 Å and increases gradually from Ar (3.58 Å) to Kr (3.68 Å) to Xe (3.81 Å). This moderate increase in the van der Waals bond distance is caused by the increase in atomic radius with increasing mass number along the row of noble gases. This effect, responsible for the repulsive part of the potential, is partially compensated by the strong increase in polarizability and hence attractive interaction from Ne to

Xe. Experimental values of comparable accuracy on the benzene–He complex have not yet been obtained, as the complexation process is so inefficient that, for example, no detectable concentration of complexes is observed in the present experiment. Values for the van der Waals bond distance of benzene–He are at present only known from experiments with lower spectral resolution,[33] and, due to their lower accuracy, cannot be instructively compared with the data presented in this work.

3.4. The Structure of a Larger Benzene–Noble Gas Cluster

After the exact position of the first clustered noble gas atom is known, a natural question concerns the subsequent complexation behavior, i.e. at which positions do further noble gas atoms attach. With the help of the technique described in Section 3.2 it is also possible to mass-selectively measure the spectra of such larger complexes, despite their lower concentrations and hence reduced signal strengths. In addition, however, the moments of inertia become larger and consequently the rotational lines in the spectrum become denser, making their resolution more difficult. Furthermore, it is not definite that further noble gas atoms are strongly enough bound to exclude isomerization processes, i.e. fast migration of the Ar atom about the benzene ring, at the vibrational temperature achieved in the cooled supersonic beam.

The first actual experiments yielded a rotationally resolved spectrum at mass 158 a.m.u., i.e. for the C_6H_6–Ar_2 complex.[34] Analysis of this spectrum yields a structure in which the Ar atoms are located on the sixfold axis, one on each side of the benzene ring (see Fig.12). From the precise experimental rotational constants, a bond distance of 3.58 Å is derived, exactly that in the benzene–Ar complex (with one Ar atom). This implies that the benzene ring completely screens any possible van der Waals interactions between the two Ar atoms. Such a behavior is typical for complexation processes in planar aromatic molecules.

At this point we must ask if the structure in Figure 12 is the only existing structure or do other stable structures of the benzene–Ar_2 complex also exist. Recent experiments with lower resolution[35] point to the stability of at least one additional structural isomer in which both Ar atoms lie on the same side of the benzene ring. Only the rotationally resolved Doppler-free spectrum can provide an unambiguous clarification of this problem. Such experiments will be possible in the near future.

3.5. Benzene–Molecule Complexes

The two previous sections were concerned with complexes formed by the absorption of noble gas atoms with isotropic polarizabilities to the benzene molecule. The next step is the absorption of simple diatomic molecules with anisotropic polarizabilites to the benzene surface. The benzene–N_2 complex has been studied by Doppler-free spectroscopy.[36]. The rotationally resolved spectrum yields the structure shown in Figure 13, in which the N_2 molecule is adsorbed parallel to the benzene surface. Besides the transitions which correspond to a symmetric rotor structure, there appear lines which can only be accounted for in terms of the internal rotation of the N_2 molecule about the C_6 axis of benzene. The distance of the center of mass of the N_2 molecule from the benzene plane is 3.50 Å and decreases by 45 mÅ upon electronic excitation of the benzene to the S_1 state. Despite the spectroscopic complexity presented by the internal rotation of the N_2 molecule, this phenomenon is nevertheless of particular interest for future studies. Namely, this internal rotation serves as a probe of the anisotropy and wavelike

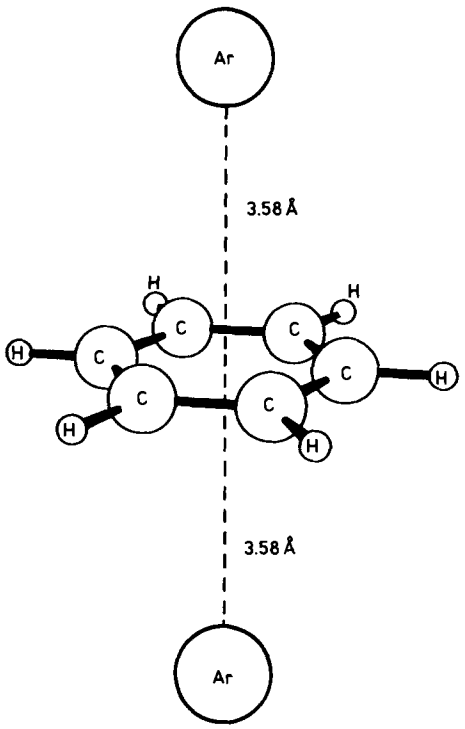

Fig. 12. The experimentally determined structure of the benzene–Ar_2 complex. The Ar atoms sit 3.58 Å from the benzene plane; a distance identical with that found for benzene–Ar (see Fig. 11). This signifies that the benzene ring effectively screens the long-range van der Waals interactions between the two Ar atoms.

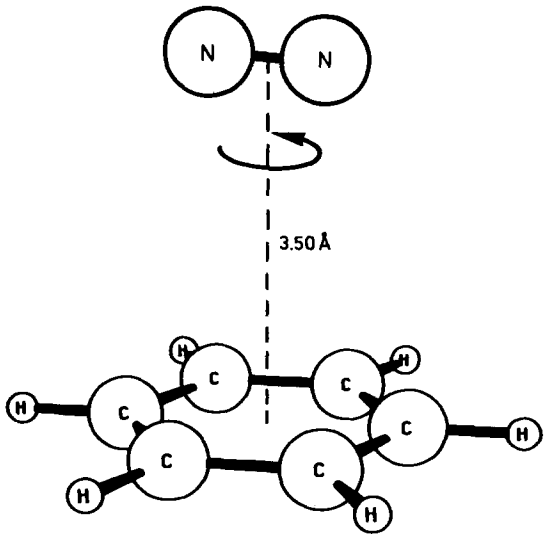

Fig. 13. The experimentally determined structure of the benzene–N_2 complex. Lying in the plane parallel to the benzene ring at a distance of 3.50 Å, the nitrogen molecule internally rotates about the sixfold rotational axis of the benzene.

curvature of the van der Waals binding potential with respect to rotation about the sixfold axis, which is caused by the periodic change in electron density along the benzene ring.

4. Summary and Outlook

Through the rapid development of new methods in laser spectroscopy it is possible, even for large molecular systems, to observe spectroscopic fine structures which are hidden by Doppler broadening in conventional high resolution spectroscopy. Elimination of the Doppler broadening allows the spectroscopic study of such systems with a precision previously possible only for atoms or small molecules; thus, access is provided to the domain of high resolution spectroscopy within the Doppler width. In this manner, more and more chemically relevant issues which are typical for large systems can be addressed.

Intramolecular energy redistribution, as the primary process preceding chemical reactions, is of fundamental importance in reaction kinetics. With a detailed understanding of this process, the influence or even control of chemical reactions should be possible. For this reason it is understandable that there has been substantial activity in the last two decades in the field of intramolecular vibrational redistribution. Whereas a general theoretical understanding of intramolecular vibrational redistribution through the theory of radiationless processes is available, precise experimental results to serve as critical tests of the theoretical models are seemingly scarce. In this article, using a test molecule we have proven the power of high resolution spectroscopy in this respect. Resolution of the band structure of the benzene spectrum into many individual rotational lines enables monitoring of the development of vibrational redistribution from the situation typical for small molecules to that for large molecules with their high level densities. Analysis of these initial results furnishes the surprising new finding that not only anharmonic coupling must be considered as the coupling mechanism, but rather that rotational-vibrational interaction in the form of Coriolis coupling also plays an essential role. The results thus obtained also permit a quantitative comparison with theoretical models and give a deeper insight into the coupling mechanisms.

The second part of this article demonstrated that Doppler-free spectroscopy furnishes detailed spectroscopic information on the large field of weakly-bound van der Waals complexes. The rotational line spectrum of selected complexes in the mixture of many clusters produced in the cooled molecular beam can be measured by the combination of Doppler-free excitation with mass-selective two-photon ionization. Initial experiments have yielded the structures and precise van der Waals bond distances for benzene–noble gas dimers and trimers and complexes of benzene with small molecules. These results demonstrate the precision and unambiguity of the statements regarding structure made possible by Doppler-free spectroscopy.

Doppler-free spectroscopy of van der Waals complexes is a very young field of research. For this reason Doppler-free spectra currently exist for only a few prototype systems. These few examples nevertheless outline the full scope of applications of this new spectroscopic method. Studies of larger and differently bound complexes will lead in the near future to a deeper understanding (at the microscopic level) of intermolecular bonds, such as the hydrogen bond, and of complexation and solvation processes integral to chemical and biological processes in the liquid phase.

The authors would like to thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support of this research. We thank Drs. Riedle, Schubert, Sieber and Weber for invaluable collaboration with the experiments and interpretation of the results. We also wish to thank Dr. Alice M. Smith for the English translation of this article.

Alkynyl- and Alkenyl(phenyl)iodonium Compounds

New Synthetic Methods (86)

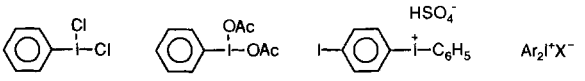
By Peter J. Stang*

Compounds with highly coordinated, polyvalent main-group elements represent an interesting alternative to the many well-known transition-metal complexes. Among the oldest and best known stable examples of such organic molecules are the iodine(III) compounds. Diaryliodonium species, Ar_2IX, for example, have been known for over a hundred years and play an important role in lithography. Likewise, acetylenes and olefins are among the oldest, most important, and most valuable compounds in chemistry. Besides simple hydrocarbon alkenes and alkynes, numerous functionalized derivatives are also known and widely employed in organic chemistry. Despite the ubiquity and prominance of both I^{III} species and olefins and acetylenes, the combination of these two types of functional groups in a single molecular unit, namely compounds with polyvalent iodine and at least one alkyne or olefin residue, was unknown until recently. The successful preparations of simple alkynyl- and alkenyl(phenyl)iodonium species during the 1980s has resulted in a renaissance in both acetylene and I^{III} chemistry. These alkynyliodonium compounds readily undergo nucleophilic substitution on the alkyne moiety (S_N-A reactions) which are difficult with other substrates. The application of a wide variety of nucleophiles in this reaction resulted in diverse functionalized alkynes including previously unknown acetylenic carboxylates, sulfonates, and phosphates. These are excellent substrates for cycloaddition reactions as well as numerous other interesting chemical transformations.

1. Introduction

Iodine was discovered in 1811, and although it is relatively uncommon in nature it plays an important role in biological organisms, including humans, for whom it is essential for the proper functioning of the thyroid gland. It is found most often as monovalent compounds and forms relatively weak bonds with first-row elements including carbon. However, because it is the most polarizable and largest element among the common halogens, it is also capable of forming stable polycoordinate, multivalent compounds.

Just over a hundred years ago, in 1886, the German chemist C. Willgerodt reported the preparation of (dichloroiodo)-benzene (**1**), the first compound with tricoordinate iodine(III) and at least one carbon substituent, by the simple chlorination of iodobenzene.[1] This was rapidly followed by the preparation of (diacetoxyiodo)benzene (**2**),[2] diaryliodonium bisulfate (**3**),[3] the first iodonium salt, and numerous other organic compounds with tri- and multicoordinate iodine. In 1914 when Willgerodt published his comprehensive treatise on these types of compounds[4] nearly 500 were known; the most intensely studied representatives were the diaryliodonium salts **4**.



1 **2** **3** **4**

In the century since the publication of Willgerodt's synthesis of **1**, interest in organic tri- and multicoordinate iodine species waxed and waned until the 1980s.[5] Since the early 1980s the chemistry of organic compounds with multicoordinate (hypervalent) iodine has undergone a renaissance.[6] This rebirth of interest is generally attributed to several factors:[7] First, the recognition of the similarities (ligand exchange, reductive elimination, etc.) between compounds with I^{III} and other polyvalent main-group and transition-metal coordination compounds.[8] Second, the chemical behavior and reactivity of iodine(III) species are similar to those of compounds with Hg^{II}, Tl^{III}, and Pb^{IV}, but without the toxic and concomitant environmental problems of these heavy-metal analogues. Third, attention was focused on these unique compounds by the publication of a number of surveys[6] including two outstanding *comprehensive* reviews by G. F. Koser.[9, 10] Finally, numerous iodine(III) compounds such as **1**, **2**, PhIO (**16**), and $PhI(O_2CCF_3)_2$ (**9**) have become useful, commercially available, organic reagents.[11]

Despite this long and distinguished history and considerable current interest in iodine(III) compounds, alkynyl- and simple alkenyliodonium species **5** and **6** were conspicuously absent until recently from the family of compounds with tricoordinate iodine with at least one carbon substituent.

5 **6**

Such compounds are of interest from the perspective of tricoordinate iodine as well as from the aspect of acetylene[12] and olefin chemistry,[13] since they represent a new, unusual class of iodine(III) species with carbon ligands and are also uniquely functionalized alkynes and olefins. Hence, it is the purpose of this article to provide a comprehensive and critical review of the preparation, characterization, and chemistry of these two relatively new classes of organic iodine(III) species, with emphasis on the more recent and widely used alkynyl species.

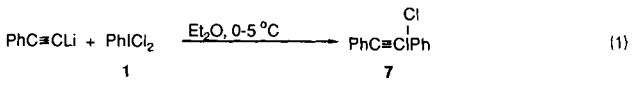
2. Synthesis of Organic Iodine(III) Compounds

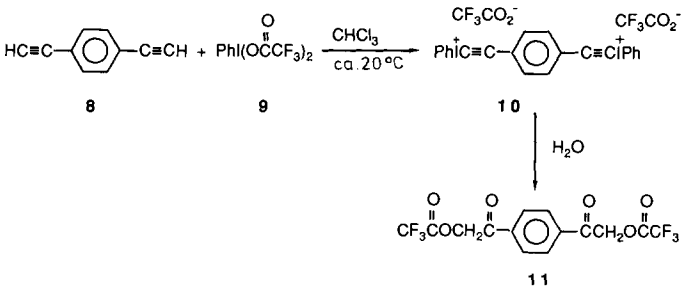
2.1. Preparation of Alkynyl(phenyl)iodonium Compounds

The first preparation of an acetylenic iodonium species involved the reaction of phenylacetylide and Willgerodt's (dichloroiodo)benzene **1** [Eq. (1)] as reported by Beringer and Galton in 1965.[14] However, the yield of phenyl(β-

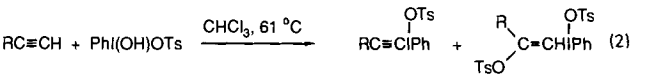


1 7 (1)

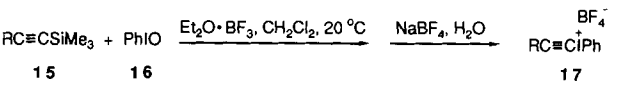
phenylethynyl)iodonium chloride (**7**) was only 12–20%. Moreover, **7** decomposed to chlorophenylacetylene and iodobenzene in a 1:1 ratio after a few hours at room temperature. As we shall see, this decomposition could be expected, at least in retrospect, since alkynyliodonium compounds are salts and must have a nonnucleophic counterion in order to be stable. The next reported synthesis of an alkynyliodonium species from the interaction of *para*-diethynylbenzene (**8**) with **9** in chloroform was reported by Merkushev and coworkers.[15] Iodonium salt **10** was isolated in 64% yield as a crystalline compound but was characterized only by IR spectroscopy and its ready "hydrolysis" to the bis(ketoester) **11**.



A more general approach to stable alkynyl(phenyl)-iodonium compounds as tosylates was developed by Koser et al. in the early 1980s.[16] According to this method terminal acetylenes are allowed to react with (hydroxy(tosyloxy)-iodo)benzene (**12**)[17,18] in refluxing chloroform [Eq. (2)]. Unfortunately, the product mixture consists of the desired iodonium species **13** and the related vinyl species **14**, resulting in purification problems and greatly diminished yields.

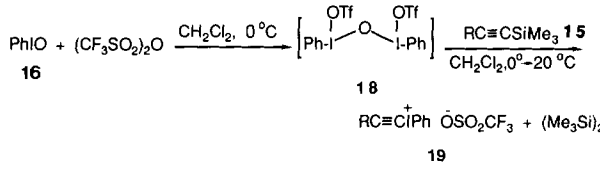


Nevertheless, the discovery of this relatively simple procedure, by Koser et al. was an impetus for the subsequent rapid developments in the synthesis and chemistry of this new class of phenyliodonium species. A number of modifications and improvements for the ready preparation of alkynyl(phenyl)-iodonium tosylates **13**[19,20] were developed by my group, such that these compounds are now routinely available in pure form in 60–90% yield. Parallel to our work Fujita et al.[21] synthesized a variety of alkynyl(phenyl)iodonium tetrafluoroborates **17** in 50–85% yield by the reaction of trimethylsilylacetylenes **15** with iodosobenzene **16** and $Et_2O \cdot BF_3$ in dichloromethane, followed by treatment with aqueous $NaBF_4$.

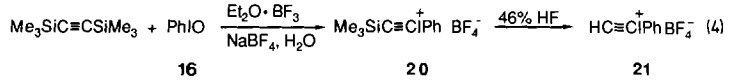


Most recently we developed two new efficient methods for the preparation of alkynyl(phenyl)iodonium trifluoromethanesulfonates (triflates). In the first procedure a trimethylsilyl- or stannylalkyne is treated with Zefirov's reagent **18** generated in situ[22,23] [Eq. (3)]. A variety of alkynyliodonium triflates **19** are obtained in good to excellent yields (45–95%) as stable, microcrystalline solids.[24]

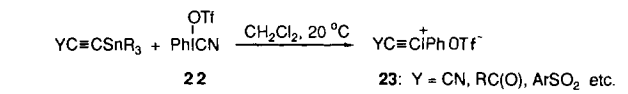
Peter J. Stang was born in November 1941, in Nürnberg, Germany and raised in Hungary until 1956. He received a B. S. in Chemistry in 1963 from DePaul University, Chicago and a Ph.D. in 1966 from U. C. Berkeley under the direction of A. Streitwieser, Jr. After postdoctoral experience with P. von R. Schleyer and a year as instructor at Princeton University, he joined the faculty at the University of Utah in 1969, where he is currently Professor and Chairman of the Department of Chemistry. In 1977 he received a Senior US Scientist Award from the Alexander von Humboldt Stiftung and spent a year in Tübingen, Germany. Subsequent honors abroad included visits to Japan in 1985, the Technion in Haifa in 1986, Zagreb, Yugoslavia in 1988, and the Soviet Union in 1989. In 1992 he is in Kaiserslautern, Germany as a BASF Visiting Professor. He was elected a Fellow of the American Association for the Advancement of Science in 1986 and since 1982 has been an associate editor for the Journal of the American Chemical Society. In February 1992 he was awarded an honorary Doctorate of Science by the Russian Academy of Sciences and Moscow State University. His main research interests are reactive intermediates (vinyl cations and unsaturated carbenes), organometallic chemistry (mechanism of cross-coupling reactions between unsaturated compounds), alkynyliodonium and alkynyl ester chemistry, and strained ring compounds (alkylidenecycloproparenes). He has published over 200 papers and coauthored a text on the spectroscopy of organic compounds and a monograph on vinyl cations.



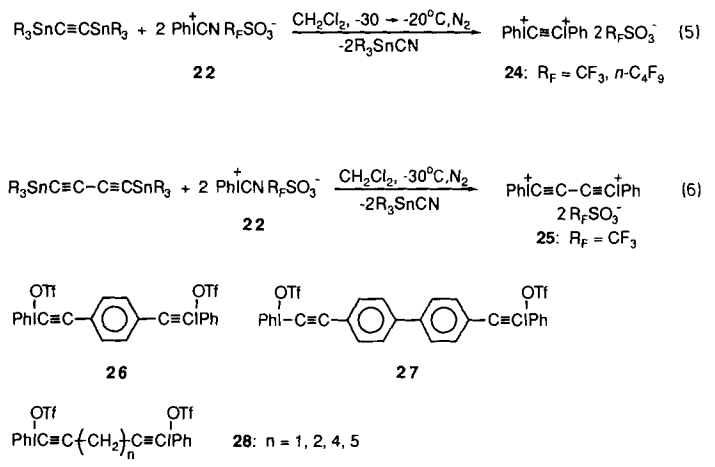
If a stannyl instead of a silyl substituent is used to stabilize[25] the intermediate vinyl cation (vide infra), this procedure even affords the parent ethynyl(phenyl)iodonium triflate in 56% isolated yield (see Section 3.3).[26] The analogous tetrafluoroborate **21** has been prepared by desilylation of **20** with HF/H_2O [Eq. (4)].[27]



The second method involves the use of stannylalkynes and iodonium triflate **22**[28] for the preparation of a wide variety of β-alkyl- and β-arylethynyl(phenyl)iodonium triflates **19**. The previously inaccessible β-functionalized ethynyl(phenyl)iodonium triflates **23** may also be synthesized in this way.[29]

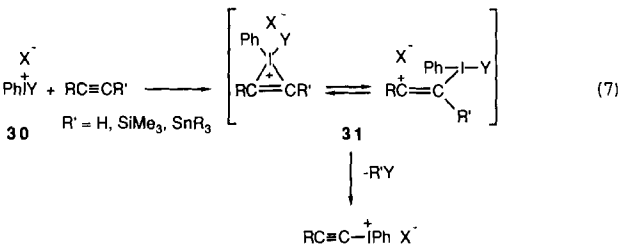


Likewise this procedure allowed us to prepare[30] the novel bis(iodonium)acetylenes **24** [Eq. (5)], diynes **25** [Eq. (6)], and related bis(iodonium) compounds **26**–**28**.[31] This reaction of **22**, an iodonium transfer, is the most general and simplest method to date for the preparation of alkynyliodonium species.[29, 30] This method can also be used for the syntheses of buta-1,3-diynyl(phenyl)iodonium triflates **29**.[32]



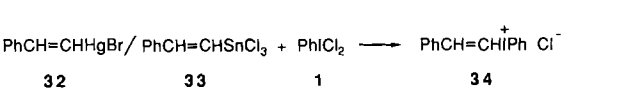
It is evident from the foregoing discussion that alkynyl(phenyl)iodonium species have become readily available in the past few years[20, 21, 24, 26, 29, 30] and represent a new member of the family of compounds with polycoordinate iodine and carbon substituents.

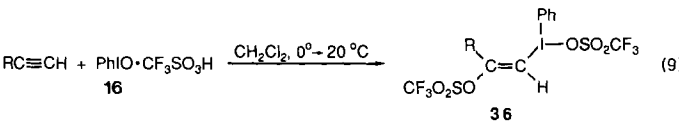
Although little direct mechanistic work has been reported concerning the formation of these alkynyliodonium species, indirect evidence provides a reasonable hypothesis. With the exception of Beringer's synthesis of **7** all methods employ some type of an electrophilic iodonium reagent such as **9**, **12**, **18**, and **22**. Hence, in the first step an iodonium species **30** must add electrophilically to an alkyne with formation of a vinyl cation[33] and/or cyclic iodonium species **31**. Subsequent loss of R'Y results in the alkynyl(phenyl)iodonium species [Eq. (7)]. In support of this mechanism[20] is the observed acceleration of the reaction in polar solvents, the regiochemistry of addition, and above all the stabilization of carbocations, particularly vinyl cations,[34, 35] by β-silyl and β-stannyl substituents.[25, 34]



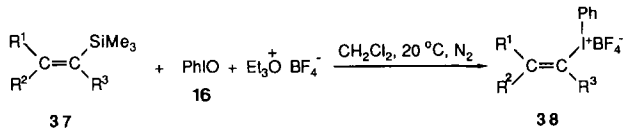
2.2. Preparation of Alkenyl(phenyl)iodonium Compounds

Although a few β-halogenvinyliodonium species have been reported[4, 5, 9] since the days of Willgerodt, their methods of preparation were rather inefficient and limited. More recent procedures[36] afford β-substituted alkenyl(phenyl)iodonium compounds **34** in low yields (5–10%) from the reaction of the related alkenylmercuric bromides **32** or alkenylstannanes **33** with Willgerodt's (dichloroiodo)benzene (**1**). A more general, simpler procedure[16] provides phenyl(β-tosyloxyalkenyl)iodonium tosylates **35** in yields of 40–60% from the reaction of alkynes with the iodonium compound **12** [Eq. (8)]. In a similar fashion the highly stereoselective electrophilic *anti* addition of PhIO CF_3SO_3H to acetylene derivatives furnishes ((*E*)-β-trifluoromethanesulfonyloxyalkenyl)iodonium triflates **36** in yields of 87–100% [Eq. (9)].[37]





The best and most general procedure for the preparation of alkenyliodonium compounds was developed by Fujita, Ochiai et al.[38] Here readily available alkenylsilanes **37**[39] react stereospecifically with PhIO and $Et_3O^+BF_4^-$ with retention of olefin geometry. A wide variety of acyclic as well as cyclic alkenyl(phenyl)iodonium tetrafluoroborates **38**



37 38

were obtained in 60–94% yields, [38] thereby encouraging the exploration and application of these alkenyl I^{III} reagents.

3. Characterization and Properties of Iodine(III) Compounds

3.1. Physical Properties

The great majority of alkynyl- and alkenyl(phenyl)-iodonium compounds are microcrystalline solids. Their stability depends both upon the substituents on the alkyne or alkene and on the counterion. The less nucleophilic the counterion, the more stable the resulting iodonium species. Hence, the most commonly used counterions are BF_4^- and $CF_3SO_3^-$ and to a lesser extent ClO_4^-. Tosylates, *p*-$CH_3C_6H_4SO_3^-$, and mesylates, $CH_3SO_3^-$, may also be stable but are usually less stable than those species previously mentioned. In general, the simple alkyl-substituted alkynyl-(phenyl)iodonium compounds such as **13**, **17**, and **19** (with R = alkyl or H) are indefinitely stable as solids when refrigerated. Substituted compounds such as **23** and the bis(iodonium) species **24** and **25** tend to be somewhat less stable.

Although explosions have been reported[40] with both $(Ph^+I{-}O{-}^+IPh)2BF_4^-$ [41] and the perchlorate analogue of **40** we have not experienced any problems with either alkynyl(phenyl)iodonium triflates or tosylates. Nevertheless, it is prudent to exercise caution in the handling of all iodonium species.

3.2. Spectral Properties

Both alkynyl- and alkenyl(phenyl)iodonium compounds have highly characteristic spectral properties. Their Fast Atom Bombardment (FAB) mass spectra generally show abundant peaks for the intact cations, $RC{\equiv}C^+IPh$ and $(M{-}OTf)^+$, and $R_2C{=}CR^+IPh$ and $(M{-}BF_4)^+$, respectively. These peaks are quite useful for the identification of the individual salts.

The infrared spectra display strong absorptions characteristic of the anions: for BF_4^-, intense broad bands between 1000–1100 cm^{-1} and for $CF_3SO_3^-$, two strong signals around 1270 and 1000 cm^{-1}. Moreover, the C≡C absorption of the alkynyl compounds, although generally weak, is usually discernible between 2120 and 2190 cm^{-1}.

Most diagnostic are the ^1H and ^{13}C NMR spectra. All alkynyl- and alkenyl(phenyl)iodonium species have ^1H NMR spectra with three signals between $\delta = 7.50$ and 8.25 in a 2:1:2 ratio for the hydrogens of the phenyl group (Fig. 1). The relatively low-field position of these signals is in accord with the strong electron-withdrawing effect of the iodonium moiety and its deshielding. The σ_I of ICl_2, for example, is 1.17 and for $I(OAc)_2$, 0.85 compared to only 0.45 for iodine itself.[42] Likewise, in alkenyl(phenyl)iodonium species **38** both H_α and H_β are considerably deshielded with $\delta = 6.8$–7.8.[38]

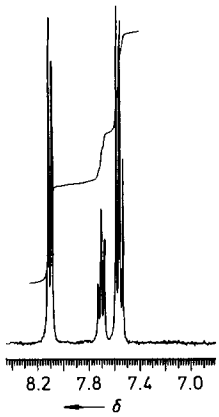


Fig. 1. Characteristic pattern in the aromatic region of the ^1H NMR spectra of alkynyl- and alkenyl(phenyl) iodonium compounds.

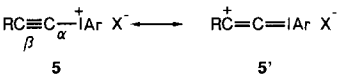
The most characteristic features of the ^{13}C NMR spectra of the alkynyl and alkenyl species **5** and **6** are the signals of the acetylenic and olefinic carbon atoms. The C_α and C_β signals in **5** are generally found at $\delta = 20$–40 and 110–120, respectively. The low-field resonance of the β carbon is due to the contribution of resonance from **5'**, the electronic distribution in the alkynyliodonium compound, and spin-orbital effects of the iodine atom.[43] For example, the β carbon in parent compound **39** resonates at $\delta = 98.3$ and C_α, at $\delta = 27.3$, whereas the signal for acetylene itself is at $\delta = 71.9$.[26] Interestingly, the ^{13}C NMR signal of **24** ($R_F = CF_3$) is found at $\delta = 51.8$, between the C_α and C_β signals of **5** and *upfield* from the ^{13}C NMR signal of acetylene.[30] For alkynyl(phenyl)iodonium triflates there is



5 5'

a further signal generally centered at $\delta = 121$ (q, $J_{F,C} \approx 319$ Hz) arising from the triflate group. The alkenyliodonium species **6** display similar spectra. The C_α signal is found between $\delta = 75$–118, that of C_β at $\delta = 146$–159.[38] Finally, both iodonium triflates and tetrafluoroborates display highly characteristic signals in their ^{19}F NMR spectra: for $CF_3SO_3^-$ at $\delta = -77.5$ to -79.0 and for BF_4^- at $\delta \approx -150$.

3.3. X-Ray Structural Analyses

To date X-ray structural analyses have been reported for three alkynyl(phenyl)iodonium species: **39**,[26] **40**,[19b] and **41**.[44] The ORTEP representation and relevant structural

39 40 41

data of the simplest species, ethynyl(phenyl)iodonium triflate (**39**), are shown in Figure 2.

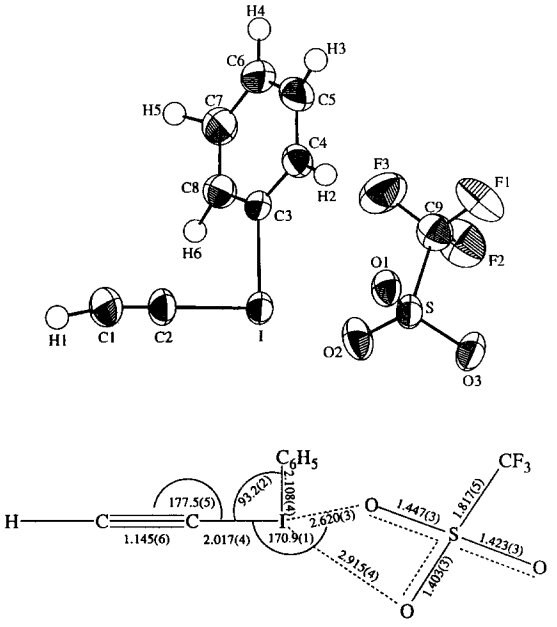


Fig. 2. Top: Crystal structure of **39** (ORTEP). Bottom: Important bond lengths [Å] and angles [°].

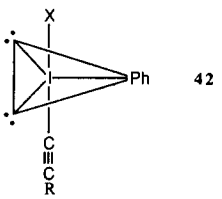
In all three compounds the geometry about the iodine can be described as distorted trigonal pseudobipyramidal or T-shaped (**42**). This is in accord with the hypervalent nature of these salts (10-I-3).[8a] In other words the central atom,

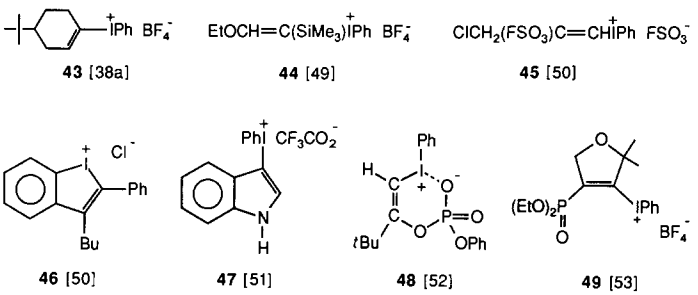


42

iodine, is surrounded by three ligands and has ten electrons in its valence shell. The equatorial positions are occupied by the phenyl group and two sets of lone-pair electrons; the axial positions are taken up by the alkyne and the anion. As expected the most electronegative groups occupy axial positions, and the least electronegative phenyl group resides in an equatorial position. Similar structures are observed for the related (10-I-3) iodine compounds $PhICl_2$,[45] PhI(OH)OTs (**12**),[46] and $PhI(OAc)_2$ (**2**).[47]

The most noteworthy features of the structure of **39** (and also of **40** and **41**) are the I–O distances of 2.620 and 2.915 Å, well outside both the sum of the theoretical covalent radii of I and O and the I–O single-bond length of 1.99 Å. This along with the three nearly identical S–O bond lengths of 1.424 ± 0.023 Å clearly indicate the ionic nature of these species, even in the solid state. These structural effects are in accord with the results of recent theoretical calculations on the nature of the bonding, and in particular the dominance of ionic bonding and negative hyperconjugation over d-orbital participation in hypervalent molecules.[48]

X-ray structural determinations have been carried out on the alkenyl(phenyl)iodonium species **43**–**49** to date. Again the common structural feature for all these iodonium compounds is a trigonal bipyramidal geometry analogous to that of **42**. The phenyl group occupies an equatorial position and



43 [38a] **44** [49] **45** [50]

46 [50] **47** [51] **48** [52] **49** [53]

the alkene and anion, the axial positions. Secondary interactions and geometries distorted from trigonal bipyramidal are observed in many I^{III} species including **5** and **6**. A typical

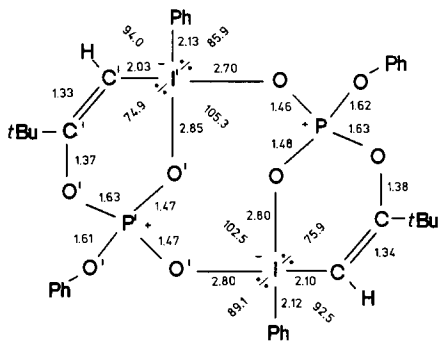


Fig. 3. Important bond lengths (Å) and structural features of the (12-I-4)-alkenyliodonium dimer $(\mathbf{48})_2$.

example is the novel zwitterionic alkenyl species **48** that is actually dimeric in the solid state (Fig. 3).[52]

4. Chemistry of the Iodine(III) Compounds

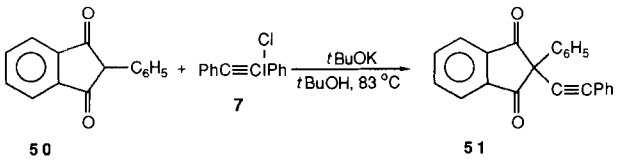
4.1. Chemistry of Alkynyl(phenyl)iodonium Compounds

Nucleophilic acetylenic substitutions (S_N-A), although known, are generally unfavorable.[54] However, iodonium groups are excellent leaving groups,[55] and loss of neutral iodobenzene from phenyliodonium salts, analogous to the loss of neutral nitrogen from diazonium salts, should facilitate S_N-A processes. Furthermore, alkynyl(phenyl)-iodonium species **5** may serve formally as masked alkynyl cations $RC{\equiv}C^+$. This amounts to an umpolung of the normal acetylene reactivity. Reactions with nucleophiles are possible in contrast to the better known reaction of acetylides $RC{\equiv}C^-$ with electrophiles. Hence, at least in principle, it is possible to think in terms of "alkynylations"

using **5** as the alkynylating agent, in analogy to the well-established alkylation reactions using saturated substrates RX.

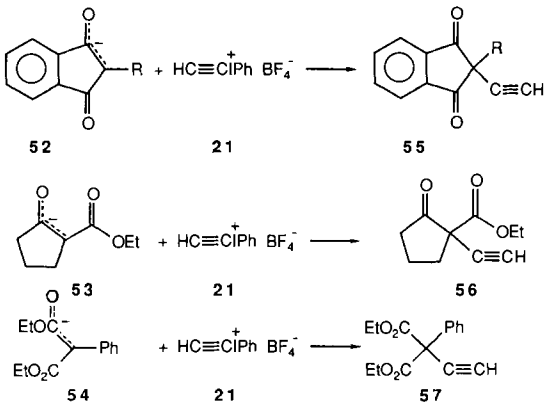
4.1.1. Alkynylations

The first alkynylation reaction with an alkynyliodonium species was reported by Beringer and Galton.[14] Reaction of iodonium salt **7** with the anion of indandione **50** in refluxing *t*BuOH gave phenylethynylindandione **51** in 73% isolated



50 **7** **51**

yield. Ochiai et al.[27] demonstrated that **21** reacts with a variety of β-dicarbonyl enolates **52**–**54** resulting in the corresponding ethynyl products **55**–**57**. Similarly, Bachi, Stang

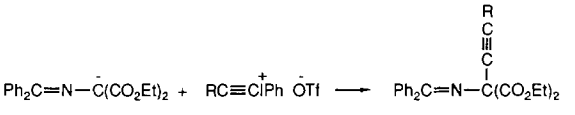


52 **21** **55**

53 **21** **56**

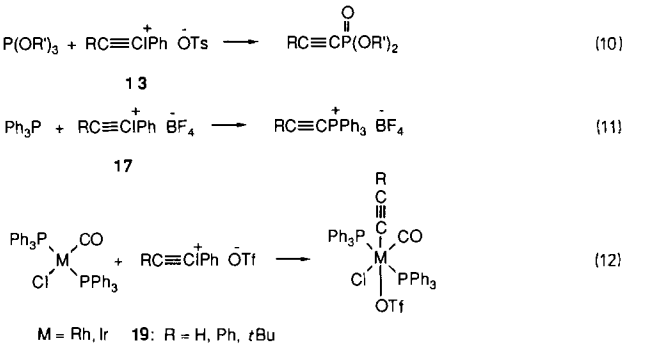
54 **21** **57**

et al.[24] established that alkynyl(phenyl)iodonium triflates **19** react with aminomalonate **58** providing the corresponding alkynylmalonates **59** in 30–95% yield. Unfortunately, this reaction only works with soft nucleophiles such as the anions of dicarbonyl compounds just mentioned. Alkynylation of simple enolates does *not* occur.

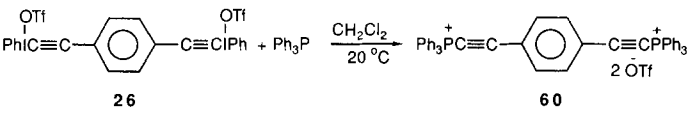


58 **19**: R = Ph, *n*Bu, *t*Bu, Me_3Si **59**

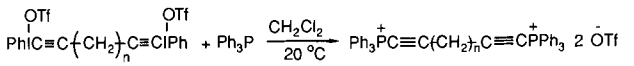
However, alkynylation is possible for soft inorganic nucleophiles such as trialkyl phosphites[56] [Eq. (10)], Ph_3P[57] [Eq. (11)], and even organometallic nucleophiles[58] [Eq. (12)]. Reaction (12) amounts to an oxidative addition to a metal center and is one of the best ways of introducing a terminal σ acetylide ligand into a metal complex.[58]



Similarly, the bis(iodonium) species **26** and **28** react with excess Ph_3P to furnish the corresponding bis(phosphonium)salts **60** and **61** in excellent yields.[31]



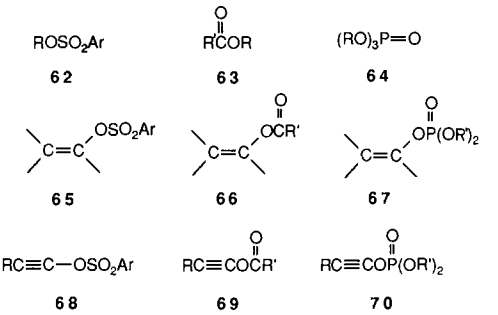
26 **60**



28 **61**

4.1.2. Acetylenic Ester Formation

Esters of all types, sulfonates **62**, carboxylates **63**, and phosphates **64**, are ubiquitous and play important roles in organic as well as biochemistry.[59] Likewise, their unsaturated congeners, enol esters **65**–**67**, are well known and widely used. The corresponding acetylenic esters **68**–**70**, on the other hand, were unknown until recently. This is all the more surprising, since a large number of functionalized acetylenes with diverse substituents are known to be generally stable.[12]



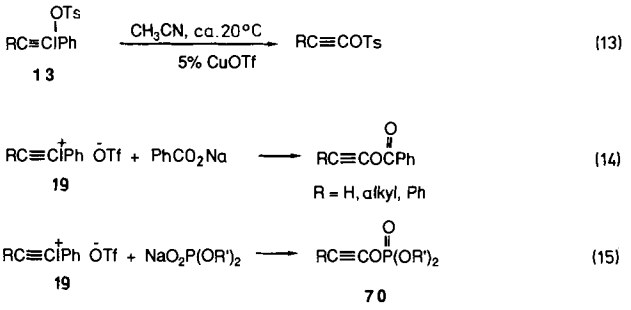
62 **63** **64**

65 **66** **67**

68 **69** **70**

Conventional methods of either ester or acetylene synthesis did not work for the preparation of these novel alkynyl esters **68**–**70**, which combine two of the most common and useful organic functional groups in a single molecule.[19b] The problem was solved by the use of alkynyl(phenyl)-iodonium species as progenitors. Treatment of alkynyl-(phenyl)iodonium sulfonates **13** with CuOTf in CH_3CN yielded the hitherto unknown but stable alkynyl sul-

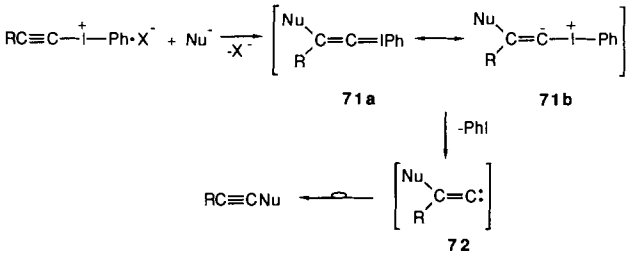
fonates **68** [Eq. (13)]. (The reaction may also be conducted with the mesyl rather than tosyl derivative.) Likewise, treatment of **19** or related compounds with polyvalent iodine with $PhCO_2Na$ gave the corresponding alkynyl benzoates[60] [Eq. (14)]. The reaction of either **13** or **19** with $NaO_2P(OR')_2$ gave the corresponding alkynyl dialkyl phosphates **70**[61] [Eq. (15)]. These alkynyl esters derived from alkynyl-



(phenyl)iodonium compounds have been the subject of numerous interesting studies[66] including the generation of ynolates,[62] novel hydrolyses,[63] enzyme inhibition,[64] and cycloadditions.[65]

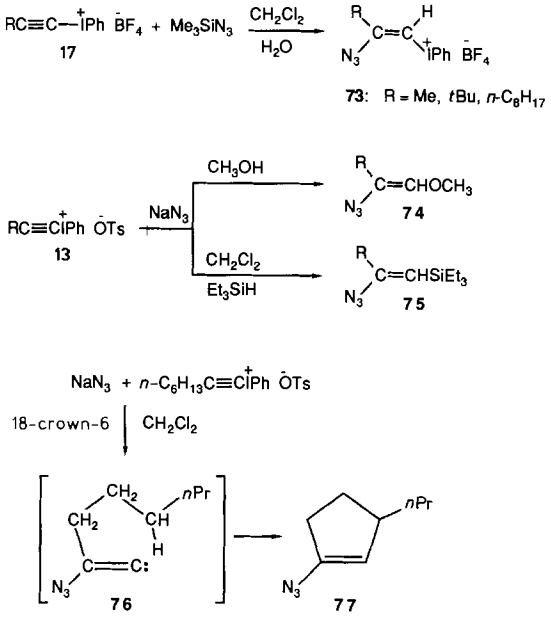
4.1.3. Mechanism of the S_N-A Reaction

Formally both the alkynylations discussed in Section 4.1.1. and the acetylenic ester formations (Section 4.1.2.) are S_N-A processes. However, the actual reaction mechanism is more complex. There is increasing evidence that these reactions occur by Michael addition, formation of an unsaturated carbene, and rearrangement to the alkyne (Scheme 1). Specifically, Michael addition of the nucleophile to the alkynyl(phenyl)iodonium species results in ylide **71**.

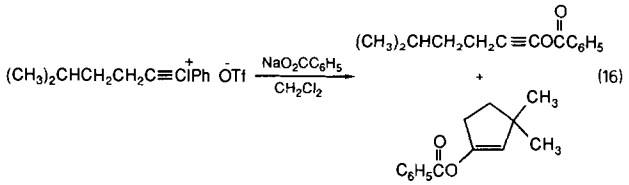


Scheme 1. Mechanism of the S_N-A reaction of alkynyl(phenyl)iodonium compounds.

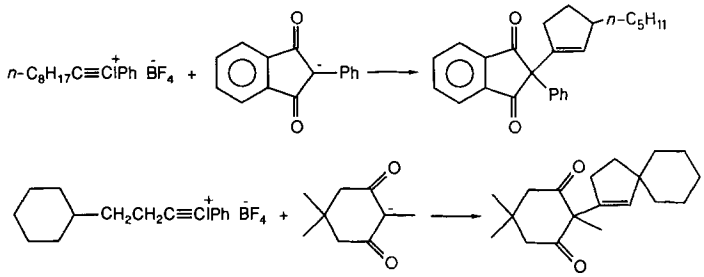
Loss of iodobenzene from **71** gives the known unsaturated carbene **72**,[67] which in the absence of external traps rearranges to the alkyne. Evidence for this process includes the following: When **17** is treated with Me_3SiN_3 in *wet* CH_2Cl_2, (β-azidoalkenyl)phenyliodonium tetrafluoroborates **73** are isolated in yields of 50–90%.[68] This is the result of ylide **71b** being trapped by protons from water. If the reaction is carried out with NaN_3 in CH_3OH or in the presence of Et_3SiH, products **74** and **75** are obtained;[69] These result from the well-known insertion of unsaturated carbenes (**72**, Nu = N_3) into the CH_3O–H and Et_3Si–H bonds, respectively.[67] Moreover, carbene **72** (Nu = N_3) may also be trapped intramolecularly by insertion into a C–H bond;[69] intermediate **76** then gives the cyclic alkenyl azide **77**.



More recently we have isolated both the rearranged alkyne (major product) and the trapped product (a cyclopentene derivative) from the same reaction [Eq. (16)].[70] In fact, Ochi-

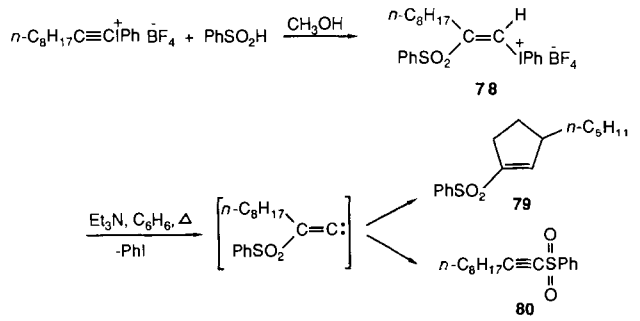


ai et al.[71] have taken advantage of these tandem Michael carbene-insertion reactions of alkynyliodonium compounds in an elegant, very efficient synthesis of cyclopentene derivatives



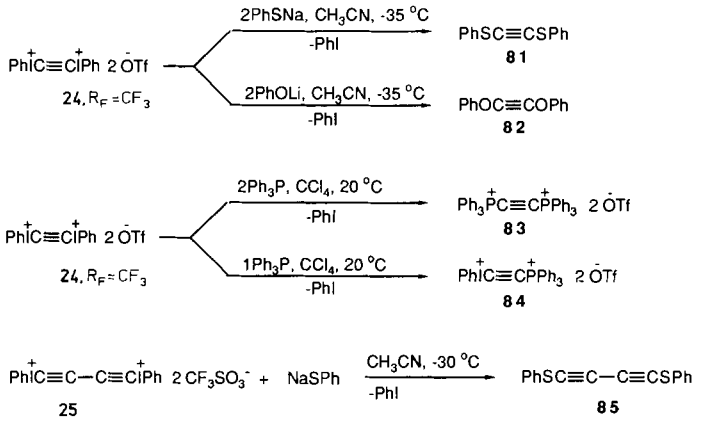
Scheme 2. Cyclopentene synthesis with alkynyliodonium compounds.

(Scheme 2). Likewise, addition of $PhSO_2H$ to alkynyliodonium compounds furnishes the β-(phenylsulfonyl)alkenyliodonium species **78**.[72] Treatment of **78** with Et_3N gives a mixture of the cyclopentene **79** (major product) and alkyne **80**.



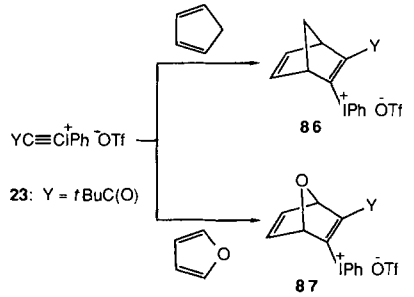
4.1.4. C_2- and C_4-Transfer Reactions

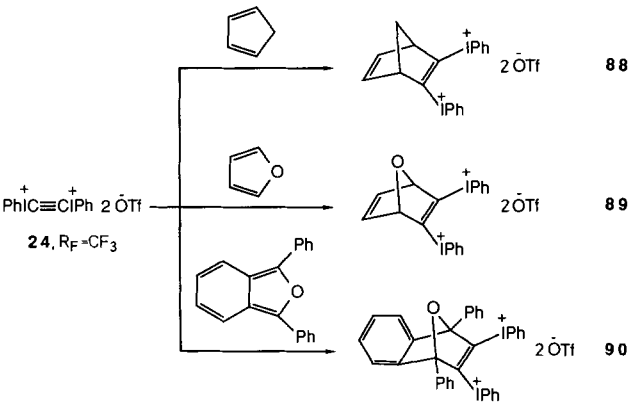
Interaction of **24**, $R_F = CF_3$, with a variety of nucleophiles results in novel difunctionalized acetylenes **81**–**84**. This corresponds formally to a C_2-transfer.[30] Analogously, **25** reacts with NaSPh by a C_4-transfer to give **85**.[30] Compounds **26**–**28** react with excess Ph_3P, as well as with other nucleophiles, resulting in the corresponding diphosphonium salts (analogous to **83**) and difunctionalized alkadiynes, respectively.[31]



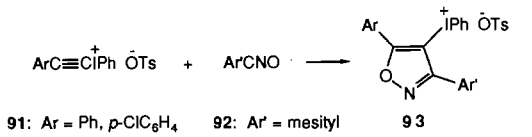
4.1.5. Cycloadditions

As highly electron-deficient acetylenes, alkynyliodonium compounds should be excellent cycloaddition partners. Indeed **19** and in particular the substituted systems **23** readily react with cyclopentadiene and furan resulting in cycloadducts **86** and **87**, $R_F = CF_3$.[73] Similarly, **24**, $R_F = CF_3$, reacts with a variety of dienes under very mild conditions providing the cycloadducts **88**–**90** in good yields.[30b] These adducts are versatile cyclic products suitable for further synthetic elaboration by virtue of the remaining iodonium functionality.



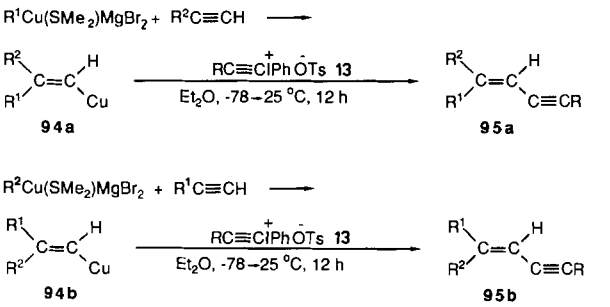


Alkynyliodonium salts have also been reported to react as 1,3-dipolarophiles towards nitrile oxides.[74] Thus reaction of **91** and **92** gave the isoxazole iodonium compound **93** as product. If **91** had Ar = *p*-$CH_3OC_6H_4$, a different regioisomer was formed.[74]



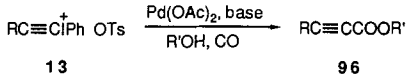
4.1.6. Other Reactions

Conjugated enynes **95** were obtained in 40–60% yield from the coupling of alkynyl(phenyl)iodonium tosylates **13** with vinylcopper reagents **94**.[75] In this reaction the configuration of the C–C double bond can be controlled by simply changing the order of the substituents in the individual components (Scheme 3). The method very nicely complements the recent Pd-catalyzed processes[76] for the formation of these useful aliphatic compounds.



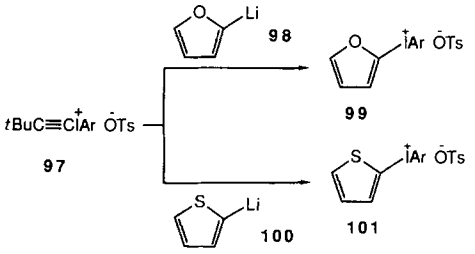
Scheme 3. Coupling reactions of alkynyliodonium compounds with vinylcopper reagents.

Pd-catalyzed carbonylation of **13** gave alkyne carboxylates **96** in 60–80% yield.[77] Reaction of **97** with 2-lithiofuran (**98**) gave the corresponding aryl(2-furyl)iodonium



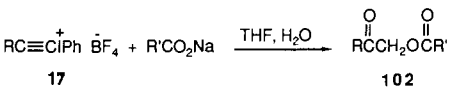
13 96

tosylates **99** by an exchange of carbon ligands.[78] In a similar reaction 2-lithiothiophene **100** gave the corresponding 2-thionyliodonium species **101**. Alkynyl(phenyl)iodonium compounds have been employed in the conversion of α-hydroxyketo groups to α-γ-dihydroxy-β-keto groups,[79] and alkynyl(phenyl)iodonium tosylates **13** have been used in the oxidative rearrangement of alkynes to carboxylic acid esters.[80]



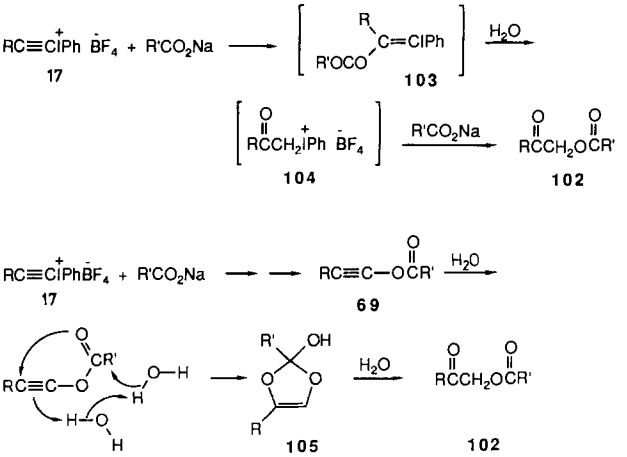
97 98 99 100 101

Finally, the reaction of **17** with sodium carboxylates in the presence of H_2O affords β-(oxoalkyl)carboxylates **102**.[81]



17 102

A mechanism involving a β-(alkoxycarbonyloxy)vinyliodonium intermediate **103** and a β-(oxoalkyl)iodonium species **104** has been invoked to explain these results (Scheme 4 top).[81] However, in light of the ready hydrolyses of alkynyl carboxylates **69** to (oxoalkyl)carboxylates via the cyclic



Scheme 4. Two possible mechanisms for the formation of **102**.

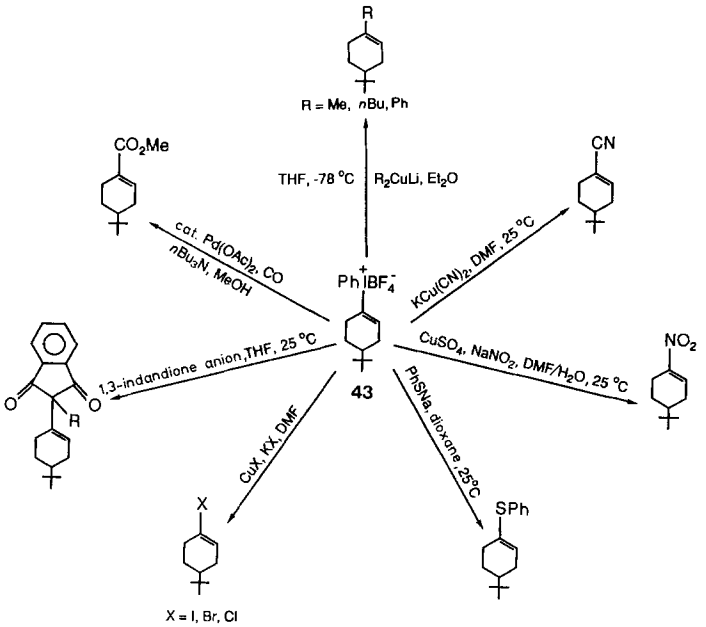
intermediate **105**,[63] another equally or more likely mechanism may be invoked for the formation of **102** (Scheme 4 bottom).

4.2. Chemistry of Alkenyl(phenyl)iodonium Compounds

Just as the alkynyl(aryl)iodonium species **5** serve as highly reactive functionalized acetylene derivatives, the analogous alkenyl species **6** serve as highly reactive functionalized alkenes. More specifically, alkenyl(phenyl)iodonium compounds **6** may be considered masked vinyl cations[33] and highly reactive substrates for nucleophilic vinylic substitutions (S_N-V).[82] The few reactions reported for the previously known alkenyl(phenyl)iodonium salts have been reviewed.[9] The modern chemistry of these species may be placed in three categories: substitution reactions, alkylidenecarbene formation, and other reactions.

4.2.1. Substitution Reactions

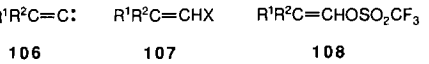
The many useful substitution reactions of alkenyl(phenyl)iodonium species, elegantly carried out by Ochiai, Fujita et al.,[38] are best summarized and illustrated by the examples in Scheme 5.



Scheme 5. Substitution reactions with alkenyl(phenyl)iodonium compounds. DMF = dimethylformamide.

4.2.2. Alkylidenecarbene Formation

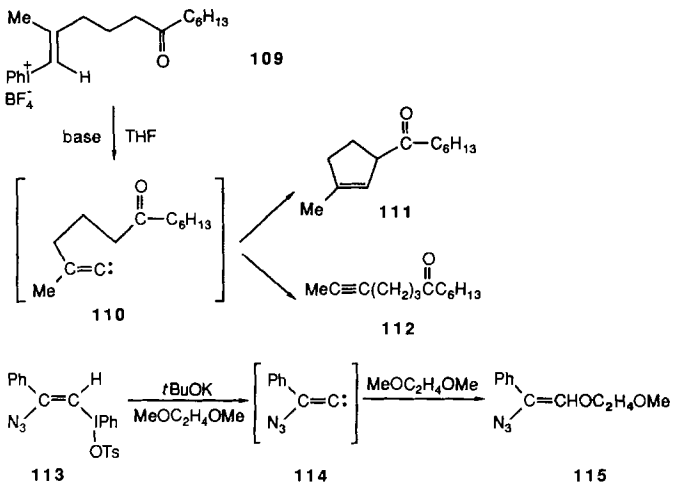
Alkylidenecarbenes **106** are well-established reactive intermediates,[67] which were previously most often generated from alkenyl halides **107** and triflates **108** by base-initated α-eliminations. More recently, 1-alkenyl(phenyl)iodonium species have been employed as progenitors for **106**.



106 107 108

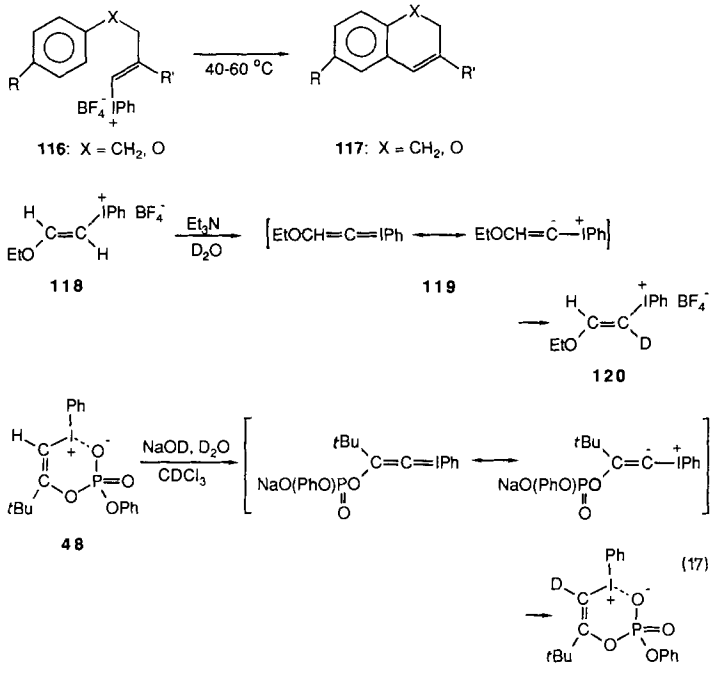
Ochiai et al.[83] have demonstrated that reaction of 1-alkenyl(phenyl)iodonium tetrafluoroborates such as **109**

with bases like *t*BuOK or Et_3N in THF gives **110**, which may undergo insertion to **111** and rearrangement to **112**. The related reaction of the β-sulfonylalkenyliodonium salt **78** to **79** and **80** has already been discussed in Section 4.1.3. Treatment of **113** with *t*BuOK in dimethoxyethane provides **115** via the carbene intermediate **114**.[69]

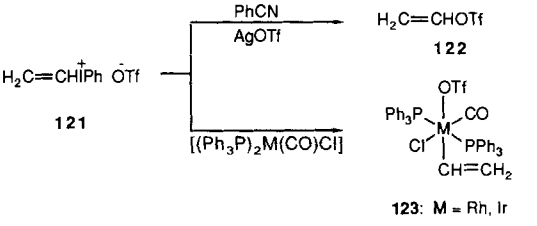


4.2.3. Other Reactions

(Arylalkenyl)phenyliodonium species **116** underwent intramolecular cyclization to **117** upon heating in various solvents between 40–60 °C.[84] Treatment of **118** with D_2O in THF gave the deuterated product **120** presumably via the ylide **119**.[49] A similar iodonium ylide was proposed as an intermediate in the H/D exchange of **48** [Eq. (17)].[52]



Finally, ethenyl(phenyl)iodonium triflate **121** is an excellent vinyl cation equivalent and precursor to the hitherto unknown parent vinyl triflate **122**.[85] In addition, **121** can vinylate organometallic complexes providing compounds like **123**.[86]



5. Conclusions and Prognostications

This review shows that a wide variety of both alkynyl- and alkenyl(phenyl)iodonium compounds are now readily available by simple, general, preparative procedures in good to excellent isolated yields. They are stable crystalline solids, which—with a few exceptions—can be easily stored for long periods. These newest members of the family of compounds with polyvalent iodine are revitalizing and revolutionizing the chemistry of alkynes and alkenes. They serve as highly reactive substrates for nucleophilic acetylenic, S_N-A, and vinylic, S_N-V, substitution reactions and allow the synthesis of hitherto unknown or not readily available functionalized acetylenes and olefins. Moreover, these compounds, as masked alkynyl and alkenyl cations or in other words through their *electrophilic* rather than nucleophilic character, allow an umpolung of the chemistry of the alkynes and, to a lesser extent, the alkenes. To date they have served, for example, as novel alkynylating and vinylating agents. Alkynyl(phenyl)iodonium compounds in particular have been used in the synthesis of previously unknown alkynyl esters, as novel C_2- and C_4-transfer agents, and as cycloaddition partners.

This is just the beginning of the many potential applications of these I^{III}-functionalized alkynes (and alkenes) since their first successful preparation only a decado ago. Considering the rich chemistry of the much longer and better known diaryliodonium compounds **4** and that of related species like **1**, **2**, **16**, etc., one may expect many more new developments in the chemistry of **5** and **6**. New synthetic procedures using **5** and **6**, polymers based upon or related to **5** or **6**, potential applications in biochemistry, and unique materials such as $[L_nMC{\equiv}CML_n]$ derived from alkynyl(phenyl)iodonium species are just a few examples of the nearly limitless possibilities opened up by these new I^{III} species. Moreover, such obvious congeners as **124** and **125** are yet to be discovered and reported.

We thank the National Cancer Institute of the National Institutes of Health for the support of our own work described here (Grant number ROCA16903).

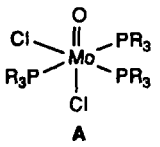
Bond-Stretch Isomers: Fact or Artifact?

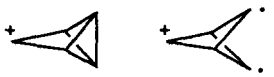
By *James M. Mayer**

Isomerism—the idea that a set of atoms can have more than one stable structure—is a fundamental concept in chemistry. The observation of isomers spurred the study of stereochemistry in both inorganic and organic chemistry well before the advent of modern tools for structure elucidation. Isomers can be broadly classified as constitutional isomers, with different connectivity between the atoms (e.g., 1-butene vs. 2-butene) or configurational (or conformational) isomers, with the same connectivity but different shape (*cis*- vs. *trans*-2-butene). In the early 1970s, a new kind of isomerism was independently proposed by Chatt et al.[1] and by Hoffmann et al.,[2] in which the isomers differ only in their bond lengths.

Chatt et al. performed X-ray structural studies of blue and green forms of the molybdenum oxo complexes $[Mo(O)Cl_2(PR_3)_3]$ ($PR_3 = PMe_2Ph$, PEt_2Ph) and found that both adopted a *cis-mer* arrangement of the ligands (**A**) but appeared to have very different molybdenum–oxygen bond lengths: 167.6(7) pm in the blue form (a normal length for Mo=O[3]) but 180.1(9) pm in the green form.[1] They termed these compounds "distortional isomers". Stohrer and Hoffmann proposed the more precise term "bond-stretch isomers" in their theoretical study of possible isomers of $(CH)_5^+$ (**B**) and related species.[2]

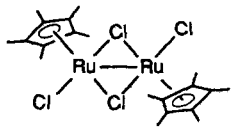


A

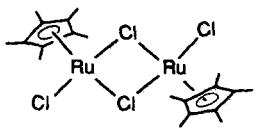


B

Bond-stretch isomers are defined theoretically by the presence of a double minimum in the potential energy surface along the coordinate of a vibrational bond stretch with enough of a barrier between the minima to allow observation of the isomers. In 1988 Jean, Lledos, Burdett, and Hoffmann examined Chatt's compounds using extended Hückel calculations[4] and proposed that bond-stretch isomerism could arise from electronic mechanisms described as Jahn–Teller distortions, which can be described in this case as the competition between the chloro and oxo ligands for π bonding to the metal. But Jahn–Teller minima typically have very small barriers between them, and observed structures are thought to be strongly affected by crystal-packing forces.[5] Two minima are more commonly found when two different potential energy surfaces are involved. There are a number of examples of transition-metal complexes with different spin states, for instance iron(III) tris(dithiocarbamate) complexes with high spin/low spin equilibria.[6] Kölle has recently reported an interesting example in this journal: The dimeric ruthenium complex $[\{Cp^*RuCl(\mu\text{-}Cl)\}_2]$ ($Cp^* = \eta\text{-}C_5Me_5$) appears to have two isomers, one diamagnetic with a metal–metal bond (Ru–Ru = 293.0(1) pm) (**C**) and the other paramagnetic without strong Ru–Ru bonding (375.2(1) pm) (**D**).[7] Kölle has also given a brief discussion of such bistable systems in a recent Highlight in this journal.[8]



C



D

But bond-stretch isomers have the same bonding arrangement and yet two minima on the same energy surface. If unequivocally proven this would be an important new kind of isomerism.

However, the conclusion that there are isomeric forms of Chatt's molybdenum complex **A** has been recently shown to be in error. Yoon, Parkin, and Rheingold have re-examined $[Mo(O)Cl_2(PR_3)_3]$ ($PR_3 = PMe_3$, PMe_2Ph) by X-ray crystallography and found a variety of Mo="O" bond lengths, from 167.5(3) pm to more than 200 pm, depending on the specific crystal chosen.[9] Elemental analysis and spectroscopic investigation of the crystals, particularly by NMR, showed that the green crystals with the long Mo="O" bonds are actually solid solutions (mixtures) of $[Mo(O)Cl_2(PR_3)_3]$ (**1**) and $[MoCl_3(PR_3)_3]$ (**2**). Similar conclusions have been reached by Enemark et al. using a number of spectroscopic and analytical techniques.[10]

The critical feature is that **1** and **2** co-crystallize, because the crystal packing is determined by the bulky phosphine ligands. Therefore in the X-ray experiment one "sees" a mixture of O and Cl in the position of the oxygen atom, and measures a distance between the true M=O and Mo–Cl distances of 167.5(3) and 240.0(1) pm. In Yoon, Parkin and Rheingold's study each crystal had a different ratio of oxygen to chlorine and exhibited a different Mo–"O" distance. This crystallographic disorder had not been previously noticed, because the structures with Mo–O/Cl distances up to 187.1(3) pm were refined quite nicely as containing simply an oxygen atom (although at this distance the thermal ellipsoid of the "oxygen" atom begins to look a little elongated).[9b] Remarkably, the crystal that showed an apparent bond length of 187.1(3) pm, 20 pm longer than the true Mo=O distance, was obtained from a sample of composition 96% **1** and only 4% **2**. A small amount of **2** can cause a large change in the apparent bond length because the heavier chlorine atom scatters X-rays much more effectively than oxygen does.

Since the original report by Chatt, a dozen or more metal complexes have been suggested to be distortional or bond-stretch isomers.[11] Given that Chatt's compounds are not isomers, these claims must be called into question as well. Many of them appear to fit Parkin's explanation, that the

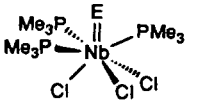
"isomer" with the long bond is actually a mixture, in which the site in question may be occupied by either O or Cl (typically). For instance, Wieghardt now believes that the green "isomer" of $[(Me_3tacn)W(O)Cl_2]^+$ with the long W–O bond is likely a mixture of this type, with $[(Me_3tacn)W(O)_2Cl]^+$ as the impurity (Me_3tacn = *N*,*N*′,*N*″-trimethyltriazacyclononane).[12] In addition, recent ab initio calculations by Hall et al.[13] on the molybdenum–oxo complexes and related systems have failed to provide any evidence for bond-stretch isomers. This calls into question the earlier theoretical study based on more approximate calculational methods.

New reports of bond-stretch isomers thus bear a heavy burden to prove that the apparent isomers are not mixtures. A recent report in this journal by Bashall, Gibson, McPartlin, et al.[14] provides a good example. Yellow and green bond-stretch isomers of the niobium–oxo complex $[Nb(O)Cl_3(PMe_3)_3]$ (**3a, b**) and orange and green isomers of the thio analogue, $[Nb(S)Cl_3(PMe_3)_3]$ (**4a, b**), were proposed; the green forms in each case are reported to have unusually long M–E multiple bonds (E = O, S). If this case resembles that of **1** and **2**, the green isomers would contain $[NbCl_4(PMe_3)_3]$ (**5**), a known material[15] which is green and essentially isostructural with **3** and **4**. Indeed, the crystal of the green



3: E = O; **3a**, *d*(Nb=O) = 178.1 (6) pm; **3b**, *d*(Nb=O) = 192.9 (6) pm

4: E = S; **4a**, *d*(Nb=S) = 219.6 (2) pm; **4b**, *d*(Nb=S) = 229.6 (2) pm

oxo complex **3b** was found to contain ca. 20% **5** by X-ray crystallography.[14] The fact that complex **5** is an impurity in this system can be explained easily, because PMe_3 is a good reducing agent and Nb^V is somewhat oxidizing—**3a** converts to **3b** on standing in toluene. According to Yoon, Parkin, and Rheingold,[9] as little as a few percent of **5** in a crystal of **3b** would be sufficient to increase the Nb="O" bond length by 14 pm. Bashall, Gibson, McPartlin et al. claim to have successfully modeled the compositional disorder in their crystal of **3b**, although the Nb–Cl bond length they obtain for the $NbCl_4(PMe_3)_3$ impurity in **3b** is 8 pm longer than the distance in crystals of pure **5** (see note 12 in ref. [14]). It is also troubling that while the X-ray data show 20% of paramagnetic (d^1) **5** in the crystals of **3b**, magnetic measurements show **3b** to be diamagnetic (note 11 in ref. [14]). Clearly, it is important in these cases that all measurements be done on samples from the same batch of material, preferably on the same crystal.

It is more difficult to prove that the green thio complex **4b** is a mixture. Sulfur and chlorine are next to each other in the periodic table and therefore have very similar X-ray scattering power. Thus a much higher level of impurity would be required for the observed bond lengths to be obtained. Assuming the same scattering from S and Cl, this argument would suggest that **4b** is a mixture of about 55% **4a** and 45% **5** based on the Nb="S" bond length of 229.6(2) pm, roughly halfway between the Nb=S and Nb–Cl bond lengths of **4a** and **5** (219.6(2) and 240.9(4) pm).

It is not clear that Gibson and McPartlin's results can be explained simply by the assumption that the green isomers are mixtures. The most difficult observation to explain are the different Nb=O and Nb=S stretching frequencies in the isomers, particularly in the case of the thio complex, for which different $\nu_{Nb=S}$ bands could be observed in IR spectra of solutions. (Although it is strange that **4b** has a *longer* Nb–S bond and a *higher* stretching frequency.) But given that there are no clear examples of bond-stretch isomers, more work is required—and more studies will certainly follow their brief and interesting communication—to demonstrate that these materials are truly isomers. One approach would be to show that there is very little **5** in both the single crystals and bulk samples of the green materials by EPR or optical spectroscopy, magnetic susceptibility measurements, elemental analysis for Cl, electrochemistry, or some other combination of techniques. Comparison of the properties of the green isomers with intentionally made mixtures of **3a** or **4a** with **5** in defined proportions could also be informative. Perhaps the most definitive results would be obtained from other X-ray structures. Parkin and Rheingold found that each batch of crystals had a different composition and therefore showed a different apparent bond length. If a number of structural analyses all yielded the bond lengths found for the **a** and **b** isomers, this would be good (though not conclusive) evidence for two discrete isomers.

The possible existence of bond-stretch isomers will likely continue to fascinate chemists for some time. However, because the early reports of bond-stretch isomers have been shown to be incorrect, there are now no established examples. Thus in new reports of bond-stretch isomers, chemists would be prudent to take the approach that they are proving a new, and challenging, form of isomerism.

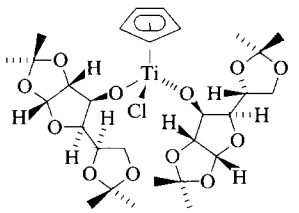
Sugars as Chiral Auxiliaries for the Synthesis of Enantiomerically Pure Compounds

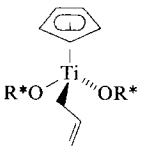
By *Hans-Ulrich Reissig**

Practical solutions for the preparation of enantiomerically pure compounds by asymmetric synthesis have been found for most important reactions. An often recurring feature is the use of derivatives of amino acids or terpenes as inducing auxiliaries. Although economical and available in a large structural variety, sugar derivatives play a far smaller role in this respect, which is certainly attributable to their large number of functional groups that makes the interpretation of the reaction path difficult. This complexity apparently frightens off most chemists. But the rapidly increasing number of publications proves that the use of sugar derivatives can achieve an impressive asymmetric induction in many reactions.

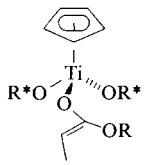
As several papers by Duthaler et al.[1] show, the organotitanium compounds **2** and **3** may be prepared from [Cp-Ti(OR*)$_2$Cl] (**1**), which is easily accessible from "diacetoneglucose" and cyclopentadienyltitanium trichloride. These organotitanium complexes transfer their nucleophilic allyl or enolate component to aldehydes with high enantioselectivity. The resulting alcohols and aldol adducts are formed usually in more than 90% *ee*.



1



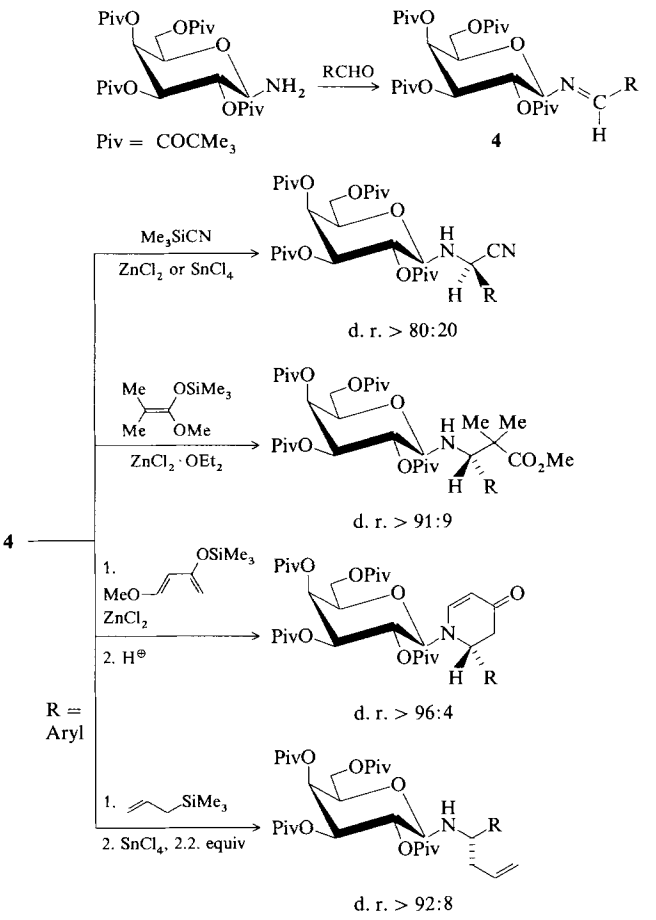
2



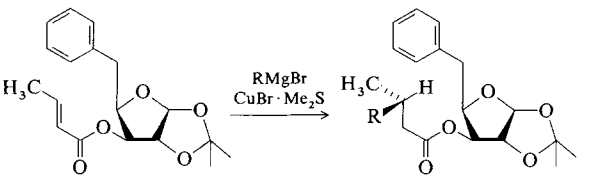
3, R = Alkyl, Aryl

As electrophilic reagents one can employ imines **4**, derived from D-galactosylamine. They react—mostly supported by Lewis acids—with several nucleophiles to form amines. The research group of Kunz, which studies the potential of carbohydrates as chiral matrixes, discovered that D-α-amino acids may be prepared in this way in a Strecker synthesis.[2] Although the asymmetric induction is seldom complete, the primary addition product may be obtained diastereomerically pure by simple recrystallization. They hydrolyze to the enantiomerically pure D-amino acids and tetra-*O*-pivaloyl-D-galactose, which can be converted back to imines.

The β-amino acids[3] are obtained analogously from mono-*O*-silylated ketene acetals, Mannich bases[4] (which may be cyclized to form piperidones) from 1-methoxy-3-trimethylsiloxybutadiene, and finally homoallylamines in high optical yields[5] from allyltrimethylsilane. No mechanistic interpretations of these reactions will be discussed because as yet they remain speculative. L-Fucose is a quasi-enantiomer to D-galactose and therefore the imines derived therefrom should undergo similar reactions to yield the antipodes of the above-mentioned compounds. This was verified for the homoallylamines at least.[6] Asymmetric 1,4-additions of cuprates to enones with a carbohydrate auxiliary have



also been described recently.[7] Cuprates generated from Grignard reagents attack the D-xylofuranose derivative **5** with a strong preference for the front side and yield the corresponding adducts in a diastereomeric ratio of mostly more than 95:5.



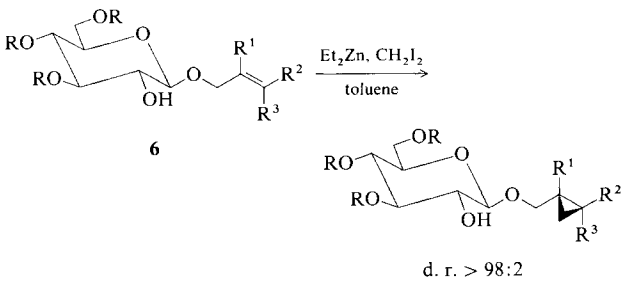
5

d. r. > 94:6

Certainly, sugar derivatives were also employed as auxiliaries for cycloaddition reactions. Often the selectivity may be improved by fixing the conformation of the carbohydrate component with Lewis acid catalysts or reagents like those in the examples already described. This is clearly fulfilled in the asymmetric cyclopropanation of allyl ethers of type **6**, which are easily accessible as pure β-anomers from tri-*O*-benzyl-D-glucal and allyl alcohols. Their reaction with an excess of diethylzinc/diiodomethane proceeds with diastereoselectivities of greater than 50:1 in favor of the front-side attack, effectively directed by a prior complexation of the carbenoid

[*] Prof. Dr. H.-U. Reissig
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-W-6100 Darmstadt (FRG)

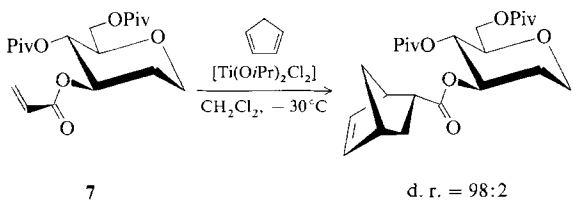
at the free hydroxyl group (Scheme 1).[8] Without the free 2-hydroxyl group, the preorientation of the reagent is very much less effective, and the selectivity falls to 2–3.5:1. The amount of cyclopropanation reagent (more than 2 equiv) is also crucial for success.

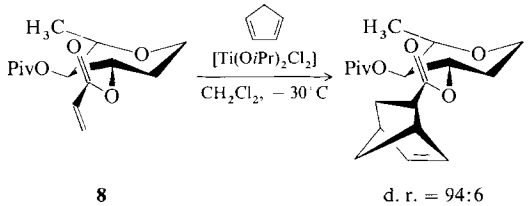


Scheme 1. R = $CH_2C_6H_5$; R^1 = H, alkyl; R^2 = alkyl, C_6H_5; R^3 = H, alkyl.

In this way several optically active, functionalized cyclopropane derivatives are available in high enantiomeric purity after the removal of the sugar auxilary. Interestingly, the use of the α anomer induces the opposite configuration at the cyclopropane ring! Thus, both enantiomers of a cyclopropane derivative are accessible through one auxiliary.

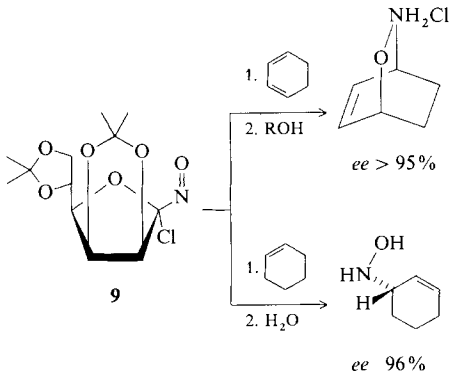
Kunz et al.[9] also thoroughly investigated Diels–Alder reactions of acrylates with carbohydrate auxiliaries. By correct choice of Lewis acids [4 + 2] cycloadditions are possible with many 1,3-dienes with excellent diastereoselectivities. The reactions of acrylates **7** and **8**, synthesized from D-glucose and L-rhamnose, respectively, with cyclopentadiene, which lead to stereochemically complementary cycloadducts, serve as representative examples.



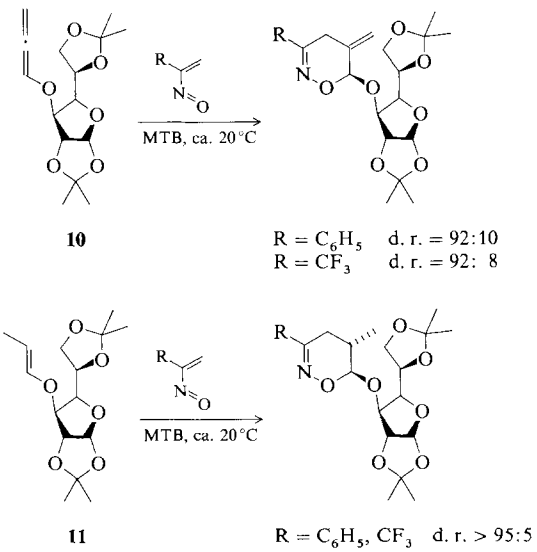


In addition, 1,3-dienes[10] and nitrones[11] with carbohydrate auxiliaries have already been employed in cycloadditions but with varied success. In these reactions the conformational fixation by metal-complex fragments is lacking, and the asymmetric induction is not always high. Kresze et al.[12] performed hetero-Diels–Alder and ene reactions with the nitroso compound **9** and obtained interesting hydroxylamine derivatives in high enantiomeric purity.

Moreover, for Diels–Alder reactions with inverse electronic demand, enol ethers with diacetoneglucose as inducing chiral auxiliary have proved to be quite effective



dienophiles.[13] Allene **10** or (*E*)-enol ether **11** react with nitrosoalkenes generated in situ to form 1,2-oxazines with high diastereoselectivities (Scheme 2). In particular the rapid and economical synthesis of diacetoneglucose distinguishes this auxiliary from others. The examples quoted emphasize that chelate effects for fixing conformations are not a prerequisite for successful asymmetric syntheses with sugar derivatives if suitable auxiliaries are chosen.



Scheme 2. MTB = *tert*-butyl methyl ether.

The intention of this (incomplete) summary is to demonstrate that carbohydrates are also securing their place as optically active chiral auxiliaries in organic synthesis, and that in this hitherto little explored area further successes can be anticipated.[14] These inexpensive compounds can be harnessed as willing workhorses for asymmetric syntheses. This method should stand beside with the more or less elegant dissection of carbohydrates, which makes use of only the stereochemically required fragment as building block for enantiomerically pure compounds.[15]

Structures, Structures, and Structures

By *Rudolf Janoschek**

The production of new compounds has always been the main concern of chemistry. But what has changed in the course of time is the documentation of the corresponding molecules. For a long time the representation of empirical formulae was seen as sufficient. The phenomenon of isomerism then forced the chemist to write molecules in such a way that their atom connectivity could be seen. This notation not only made it possible to write two chemically different compounds also in a different way, but furthermore, made it possible that today for a given empirical formula using a topological algorithm the complete set of all possible constitutional isomers can be written down from which it can be realized just how few of all the possible compounds are known up to now. For example, there are 217 constitution isomers for the empirical formula C_6H_6, of which up to now only a small fraction is known.

However, the atom connectivity, too, from today's viewpoint is only an insufficient fact file. The times in which methane was drawn as a planar cross and benzene as an elongated hexagon have long since passed. This was the result of the arrival of new methods in chemistry for the determination of molecular structures. Here, above all, X-ray diffraction should be mentioned which led to bond lengths, bond angles, and dihedral angles now being seen as binding numerical data. The sign of recognition of a molecule today is a ball-and-stick model shown in perspective. For further details concerning the development of the chemical symbol terminology see an amusing essay of R. Hoffmann and P. Laszlo.[1]

As useful and successful as X-ray diffraction is to determine *the* structure for *one* molecule, it might nevertheless keep something significant from us. Apart from constitutional isomerism there are also other forms of isomerism as well, among them one for which the isomers do not differ in the atom connectivity, hardly differ in bond lengths and angles, however, they do differ in the dihedral angles. These isomers are called conformers. One example is the chair- and boat-forms of cyclohexane. Isomers which only differ in dihedral angles generally are energetically very similar. Of course, only those isomers which actually exist can be investigated by X-ray crystallography. In contrast, there are no limits for the quantum chemical structure determination if, on the basis of the energy hypersurface, it wants to break structurally new ground.

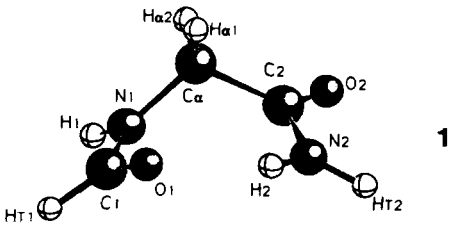
The concept of a calculated structure determination led to the realization that for a chemical compound one should no longer ask for *the* structure but should expect structures about structures. Quantum chemistry provides a precise differential geometric definition for the structure term: A structure corresponds to a point on the energy hypersurface at which the first derivatives of the energy to all inner degrees of freedom are zero (stationarity) and all second derivatives (force constants) are positive. The reader might be surprised to find such banalities under the heading "highlights". However, he is referred to last year's editions of some chemical journals to see how many declared structures have never been adequately identified as minima. This rebuke is not only directed at the authors. Where the calculated structures were correctly characterized by first and second derivatives of the energy, the author usually liked to point out that an interesting goal for the synthesis had been calculated. However, such prognoses, too, are premature because in the differential geometric structure definition the kinetic stability necessary for an experimentally relevant structure is not taken into consideration. For this a deterring example is described below.

The molecule of elemental phosphorus is the tetrahedral P_4; an N_4 homologue to this has so far not been proven. The study of the electronic structure of the calculated N_4 did not provide any indications concerning instability. There are sufficient bonding orbitals as for P_4. Thus, naive chemical bond theory in its innermost core shows a fatal inability, which

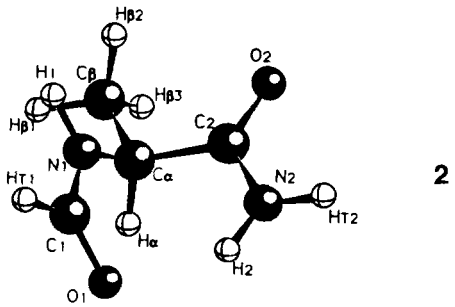
[*] Prof. Dr. R. Janoschek
Institut für Theoretische Chemie der Universität
Mozartgasse 14, A-8010 Graz (Austria)

manifests itself when the attempt is made to derive statements on stability from molecular orbitals. The reason for the instability of N_4 has to be searched for somewhere completely different: Tetrahedral N_4 corresponds to a minimum on the energy hypersurface but the activation energy for the decomposition of N_4 into $2\,N_2$ is only 1 kcal mol^{-1}. Not only that, on the other side of the transition structure an extreme energetic drop of 230 kcal mol^{-1} takes place to $2\,N_2$ (according to semiempirical PM3 calculations). Thus, it is the particular stability of N_2 which makes N_4 so unstable. It seems that a minimum on the energy hypersurface is only a necessary condition for an experimentally relevant structure. Additionally, it has to be made sure that all activation "barriers" which are directly reachable from this minimum have a certain energetic minimum height.

After this self-examination, we now want to turn to the "highlight". The authors T. Head-Gordon, M. Head-Gordon, M. J. Frisch, C. L. Brooks, and J. A. Pople had made it their objective to calculate all the conformers relative to the dihedral angles ϕ = C1-N1-C_α-C2 and ψ = N1-C_α-C2-N2 for two model compounds—the analogues **1** and **2** of glycinedipeptide and alaninedipeptide respectively—by ab initio methods.[2]



1



2

They proceeded as follows. At first an energy point-lattice was produced via the definition area of the dihedral angle pair. For each lattice point all remaining inner degrees of freedom were optimized. All in all, a total of 576 optimizations were carried out per molecule. From the energy point-lattice the approximate localization of all stationary points can be read off. In a second step these were numerically precisely recorded through total optimizations. In a third step the stationary points were characterized via the second derivatives of the energy. Apart from the structures of the conformers (minima) all transition structures between them could be recorded. The latter, too, correspond to stationary points but to those with one negative force constant. For **1** two minima and three transition structures were found, for **2** six minima and ten transition structures.

Figure 1 shows the (ϕ, ψ)-surface for **1**, which is symmetrical relative to the inversion center $\phi = \psi = 0°$. If improved calculations (HF/6-31+G*) for the stationary points are carried out, then the minimum 3 and the transition structures 4, 7, and 8 disappear. Via the saddle point 5 (activation

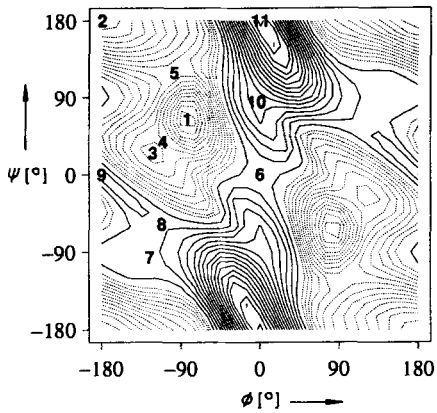


Fig. 1. The (ϕ,ψ)-surface of **1**, calculated at the HF/3-21G level. The zero of energy lies in the minimum 1 (the corresponding structure is **1**). The dashed energy contours are drawn every 0.5 kcal mol^{-1}, the solid contours every 1 kcal mol^{-1}, and the stationary points are numbered in ascending order of energy. (From [2])

energy 1.8 kcal mol^{-1}) the minimum 2 (1 kcal mol^{-1}) is thermally easily reached from the most stable minimum 1 (0 kcal mol^{-1}), whereas a transition via 6 (9.1 kcal mol^{-1}) is less favorable. The most stable minimum 1 corresponds to the NHO-bridged structure **1**. From this it can be concluded that the secondary structure of longer protein chains in solution, which is due to intermolecular H bridges, is most likely caused by interactions with solvent molecules and not by intramolecular interactions within the dipeptide unit. Thus, earlier traditional explanations for the formation of the secondary structure are disproved.[3]

Figure 2 shows the (ϕ, ψ)-surface for **2** which as a result of a lack of symmetry looks rather more complicated than that for **1**. Here, improved calculations (HF/6-31+G*) cause the minimum 7 and the transition structures 11 and 19 to disappear. Structure **2** corresponds to the most stable minimum 1

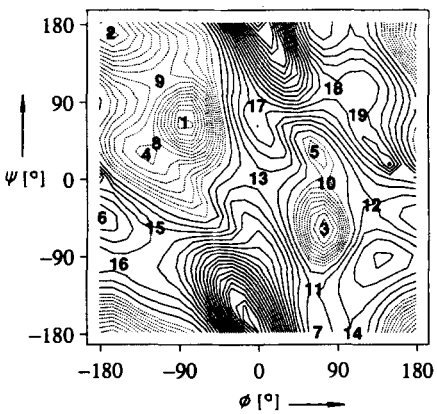

Fig. 2. The (ϕ,ψ)-surface of **2**, calculated at the HF/3-21G level (from [2]). For further annotations see Figure 1.

(0 kcal mol^{-1}). Via the saddle point 9 (activation energy 1.8 kcal mol^{-1}) the minimum 2 (1 kcal mol^{-1}) is, quite similar to that for compound **1**, thermally easily achieved. The other transition structures 13 (9.7 kcal mol^{-1}), 15 (8.0 kcal mol^{-1}), and 17 (9.3 kcal mol^{-1}) which all border onto the minimum 1 lie energetically significantly higher. The inclusion of the electron correlation via MP2/6-31 + G** single-point calculations on all found stationary points only changed the relative energies by 1 kcal mol^{-1} at most.

These results exceed earlier representations, in which the mere energetic arrangement of the conformers was deemed sufficient. The energetic positions of the transition structures make an alternative arrangement of more static to more dynamic structures possible. Complete conformer dynamics takes place in an energy interval of ca. 10 kcal mol^{-1}. The described procedure of the authors stands out because the information contained in the energy hypersurface is completely evaluated which creates a basis for the structure dynamics.

Does the Naked Fluoride Ion Exist?

By *Konrad Seppelt**

Of course the naked fluoride ion does not exist in a chemical environment, just as no free proton is stable in a chemical environment. The potential usefulness of a naked fluoride ion is apparent: whereas H^+ or the closest to it, the magic acids, are extremely acidic, F^- would be extremely basic with immense catalytic properties.

To approximate a naked fluoride ion, CsF is often used. The "cesium effect" is here a result of the inverse (in the sense of ionic size) NaCl structure, that is, the F^- ion strives to increase its coordination number. However, in aprotic solvents the reactions take place on the surface of solid CsF only. Crown ethers or phase-transfer reagents can partly remove this difficulty.

A better approximation of the naked F^- would be achieved if, for example, tetrabutylammoniumfluoride could be prepared solvent-free. The commercially available material is always a hydrate. The solvent molecule strongly diminishes the fluoride activity. Attempts at complete thermal dehydration result in decomposition by Hofmann degradation. In THF solutions of $(C_4H_9)_4N^+F^-$ the water can at least be partly removed by reaction with $(CH_3)_3SiSi(CH_3)_3$.[1] The resulting F^- solution is substantially more reactive, but unstable, and the exact nature of the "active principle" is still unknown.

Only a short time ago two florides that can easily be prepared in every laboratory became accessible. Even more important, the chemical properties of the cations of these fluorides are complementary. K. O. Christie et al. published a detailed description of the preparation of pure $(CH_3)_4N^+F^-$ [Eq. (a)].[2] The synthesis of this compound in pure state has often been attempted in the past. Without doubt the methyl groups can no longer undergo Hofmann degradation, making this fluoride stable to about 150 °C. The cation is still rather small for a naked fluoride ion, resulting in unsatisfactory solubility. The most suitable solvent is acetonitrile, which is, however, itself slowly decomposed by F^- to its dimer. But the striking advantage of the tetramethylammonium ion is its stability against oxidative attack. One must assume that the positive charge is distributed over twelve hydrogen ions, which protects them to a large extent from oxidative attack.[3] It is thus not surprising that inorganic fluoro anions such as $[XeF_5]^-$, $[ClF_6]^-$, $[BrF_6]^-$, $[IF_6]^-$, $[IF_8]^-$, $[IOF_6]^-$, and $[TeF_7]^-$ could be synthesized with this fluoride, in some cases from extremely oxidizing fluorides.[4] This sparked off a renaissance in studies on coordination numbers larger than six, which is still only in its initial stages. A second disadvantage should, however, be mentioned: the high symmetry of the cation often results in strongly disordered crystals in compounds with almost spherical anions. A nonuniformly substituted tetraalkylammonium fluoride would be the ideal solution, but an essential feature must still be the lack of β hydrogen atoms.

$$(CH_3)_4N^+OH^- + HF \xrightarrow{H_2O} (CH_3)_4N^+F^- \cdot xH_2O \qquad \text{(a)}$$

$$\xrightarrow[2.\ 150\,^\circ C,\ \text{vacuum}]{1.\ \text{recryst. } (CH_3)_2CHOH} (CH_3)_4N^+F^-$$

1

The cation–anion distance of about 420 pm in $(CH_3)_4N^+F^-$ is not at all large when compared with that in cesium fluoride. Therefore a much higher reactivity is anticipated for the phosphazenium fluoride **2** of R. Schwesinger et al., which has a cation–anion distance of 630 pm.[5] Even though **2** is probably not as stable as **1** toward oxidation, it is just as readily accessible [Eq. (b)]—and anhydrous! Since **2** is al-

$$3PCl_5 + NH_4Cl \xrightarrow[CH_3NO_2]{-4HCl} [Cl_3P{=}\overset{+}{N}{=}PCl_3]PCl_6^- \xrightarrow[2)\ Na^+BF_4]{1)\ (CH_3)_2NH}$$

$$\longrightarrow [\{(CH_3)_2N\}_3P{=}\overset{+}{N}{=}P\{N(CH_3)_2\}_3]BF_4^- \xrightarrow[2)\ 120\,^\circ C,\ \text{vacuum}]{1)\ KF,\ CH_3OH} \qquad \text{(b)}$$

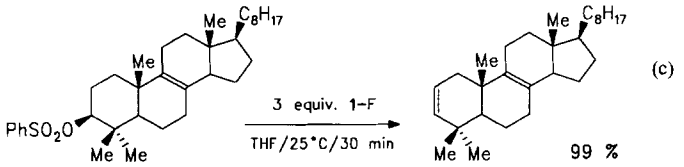
ready soluble in THF, it is ideal for use in organic chemistry. Elimination and halogen-exchange reactions have already been observed under the mildest of conditions;[5] Equation (c) gives an example.



(c)

The field is now wide open—studies on C–C bond formation, formation of carbanions, elimination and condensation reactions, silylation and desilylation, and cyclization, each with stoichiometric or catalytic amounts of F^-, is possible.[6] Finally it must be noted that many physicochemical properties of F^- need to be redetermined, since without doubt the almost naked F^- ion differs substantially from the hydrated F^- ion.

C_{60}-Fullerene—A Playground for Chemical Manipulations on Curved Surfaces and in Cavities**

By *Helmut Schwarz**

Fullerenes are currently sparking the imaginations of not only journalists[1] and managers,[2] interest in this third allotrope of carbon is also reflected in the rapidly increasing number of reviews,[3] highlights,[4] semiscientific articles,[5] and the almost unbelievable rate of manuscript submission of one or two per day.[6] This boom was sparked by Krätschmer's and Huffman's[7] ingenious method, which has been improved on since then[8] by several other research groups,[8,9] allowing almost anyone to produce C_{60} and its fullerene analogues in macroscopic quantities.[10] As a result, C_{60}-fullerene is structurally and spectroscopically probably one of the best characterized molecules.[3,7] The disturbing discrepancies in the calculated values of the enthalpy of formation ΔH_f^0 (from 286 to 973 kcal mol^{-1}) were recently resolved by Rüchardt et al.[11] by their combustion studies of highly pure C_{60} which provided $\Delta H_f^0 = 545$ kcal mol^{-1}.

This article gives a summary of the many facets of the chemistry of C_{60}. A critical review of the current understanding of the fullerenes will appear shortly.[3h]

1. Organometallic Derivatives of C_{60}: The goal of the first attempts at derivatizing C_{60} was to break the I_h symmetry of the fullerene and provide ordered crystals. The successful preparation of crystalline $[C_{60}(OsO_4)(4\text{-}tert\text{-butylpyridine})_2]$ by Hawkins et al.[12] revealed new interesting questions: For example, are the electronic differences in the two types of C–C bonds in C_{60} reflected in its reactions with transition metals as predicted by theory?[13] Does C_{60} act as an electron-poor ligand as suggested by MO calculations?[14] Can C_{60} undergo multiple additions of organometallic fragments, and if so, are there geometrical preferences? Satisfying answers to these questions have been found in the last few months,[12,15] and the following generalizations may be drawn:

1) Only the six-ring/six-ring double bonds are attacked in η^2 coordination. Reactions on the longer six-ring/five-ring double bonds do not occur. This is also true for the complex $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPh_3)_2]$.[16]

2) The ready complexation with electron-rich Pt and Ir fragments and the structural analyses of the resulting C_{60} adducts indicate that C_{60} functions as an electron-poor olefin. The electron distribution in these complexes is similar to that in $[O_2Ir(CO)Cl(PPh_3)_2]$, and it is assumed[15b] that transition-metal complexes which bind O_2 relatively easily also react with C_{60}.

3) The recently described[15d] sixfold platinum-substituted derivative $[\{(Et_3P)_2Pt\}_6C_{60}]$ (Fig. 1) is remarkable in a number of respects: a) Its indisputable structural characterization is the first for multiply substituted fullerenes. b) The X-ray structural analysis proves that the six platinum complex fragments are added to C_{60} in an octahedral fashion; this results in the rare point group T_h. c) Again the complexation occurs exclusively on the six-ring/six-ring double bonds. Because there are 30 such bonds in C_{60}, and a com-

Strasse des 17. Juni 135, D-W-1000 Berlin 12 (FRG)

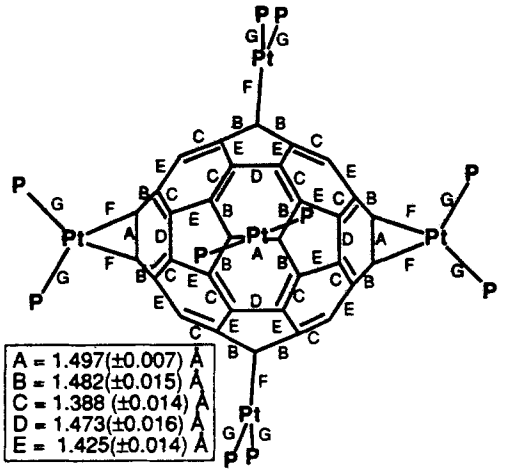

Fig. 1. Crystal structure of the complex $[\{(Et_3P)_2Pt\}_6C_{60}]$ (from [15d]).

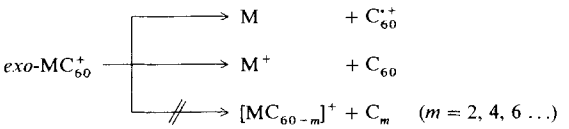
plexed $(Et_3P)_2Pt$ fragment blocks the four adjacent C=C bonds, a maximum of six such fragments may add to C_{60}.

"Naked" transition-metal ions M^+ (M = Fe, Co, Ni, Cu, Cu, Rh, La, VO) were "glued" on the outer skin of C_{60} by Freiser et al. recently.[17] In gas-phase experiments M^+ was induced to react with C_{60} at thermal energies, and the resulting complex MC_{60}^+ was characterized by mass spectrometry. For M = Ni the preparation of a complex analogous to the metallocenes, $[Ni(C_{60})_2]^+$, was possible.[17c] As is expected for exohedral complexes (see Section 3), the excitation of MC_{60}^+ results in the loss of the metal; the C_{60} cluster itself remains intact (Scheme 1).



Scheme 1. Fragmentation of an exohedral complex MC_{60}^+ in the mass spectrometer.

2. Organic Chemistry on the Surface of C_{60}: The classification of the reactions of C_{60} as either redox or addition reactions is reasonable, although mechanistically these alternatives are not always clearly differentiated. As was already mentioned, C_{60} is electron-poor, that is its electron affinity (EA) is high,[14] and ab initio calculations predict that both $C_{60}^{\bullet-}$ and C_{60}^{2-} correspond to bonding states.[14] In fact Marshall et al. were able to prepare both ions by addition of electrons to C_{60} in the gas phase.[18]

This result is remarkable since *free* dianions (i.e. without stabilizing interactions with counterions) rarely have a finite lifetime. Stabilization is usually achieved either by "anchoring" the two charges to functional groups which are held a certain distance apart, or by solvation effects, which help reduce the intrinsic instability related to the loss of an electron $M^{2-} \rightarrow M^{\bullet-} + e^-$. C_{60}^{2-} does not need these tricks, because even with the additional electrons in the C_{60} framework the molecule has an overall bonding character. For C_{60}^{3-}, however, the Coulombic repulsions are great enough to cause the loss of an electron.[14d] In solution the environmental effects expected for ions play a role. Thus it is hardly surprising that the complete series of polyanions up to C_{60}^{5-} was generated by cyclic voltammetry.[19] A crystalline (tpp)-chromium(III) complex (tpp = tetraphenylporphyrinato) with $C_{60}^{\bullet-}$ as counterion was also reported recently.[20] It is worth mentioning that the position of the equilibrium in this system can be influenced dramatically by the solvent [Eq. (a)].

$$Cr^{II}(tpp) + C_{60} \underset{\text{toluene}}{\overset{\text{THF}}{\rightleftharpoons}} Cr^{III}(tpp)^+ C_{60}^{\bullet-} \quad \text{(a)}$$

Initial spectroscopic data indicate that $Al^{III}(tpp^{\bullet-})$ also reacts with C_{60} by electron transfer, producing $C_{60}^{\bullet-}$. Furthermore, investigations have shown that $C_{60}^{\bullet-}$ appears to be an extremely weakly coordinating counterion.[20]

Investigations on the reactivity of $C_{60}^{\bullet-}$ in the gas phase[21] have demonstrated that *no* proton transfer takes place in its reactions with H_2O, Me_2CHOH, CF_3CH_2OH, $EtCO_2H$, and CF_3CO_2H [Eq. (b)]. This means that $C_{60}H$ is either an

$$C_{60}^{\bullet-} + RH \not\longrightarrow C_{60}H^{\bullet} + R^- \quad \text{(b)}$$

extraordinarily strong acid ($\Delta G_{acid} \leq 317\ kcal\,mol^{-1}$) or that proton transfer is hampered by a large kinetic barrier. Both explanations are consistent with the notion that the charge in $C_{60}^{\bullet-}$ is highly delocalized.

On the other hand, $C_{60}^{\bullet-}$ reacts with NO_2 by association [Eq. (c)]. The fact that the addition of a second molecule of

$$C_{60}^{\bullet-} \xrightarrow[\text{fast}]{NO_2} C_{60}NO_2^- \xrightarrow[\text{slow}]{NO_2} C_{60}(NO_2)_2^{\bullet-} \quad \text{(c)}$$

NO_2 is three orders of magnitude slower than that of the first could be related to the doublet character of $C_{60}^{\bullet-}$. This spin argument may not necessarily hold, because even the association of the first molecule of O_2 or NO proceeds too slowly to be followed.

Because no electron transfer from $C_{60}^{\bullet-}$ takes place in Reaction (c), $EA(C_{60}) > EA(NO_2) = 2.27$ eV. This result agrees qualitatively with that obtained by PE spectroscopy ($EA(C_{60}) = 2.6-2.8$ eV).[22]

The reduction of C_{60} with Li/THF/ultrasound provides diamagnetic polyanions whose ^{13}C NMR signals are shifted 14 ppm *down*field—an unusual finding for carbanions.[23] Methylation of the C_{60} polyanions with an excess of MeI gave polymethylated C_{60}-fullerenes [Eq. (d)], which contained up to 24 methyl groups and were dominated by products with even numbers of methyl groups. The reaction of the

$$C_{60} \xrightarrow[\text{2) MeI}]{\text{1) Li/THF}} C_{60}Me_n\ (n \leq 24) \quad \text{(d)}$$

polyanions with Me_3SiCl succeeded, but quenching with D_2O did not.[23]

One of the first derivatizations of C_{60} was achieved with the Birch reduction,[8b] which furnished colorless $C_{60}H_{36}$. Because oxidation of this hydrogenation product with dichlorodicyanoquinone (DDQ) regenerates C_{60} [Eq. (e)], the reduction is assumed to proceed without structural

changes in the C_{60} cluster. The authors offer a simple explanation of the incorporation of up to 36 hydrogen atoms based primarily on the general experience that only conju-

$$C_{60} \underset{DDQ}{\overset{Li/NH_3/tBuOH}{\rightleftharpoons}} C_{60}H_{36} \qquad (e)$$

gated double bonds are attacked in the Birch reduction. The hydrogenation product $C_{60}H_{36}$ must therefore contain twelve isolated double bonds (one per five-membered ring), that is at most $(60 - 2 \times 12) = 36$ C atoms of C_{60} are hydrogenated.

The calculations of the stability of the dodecahedrane analogue, $C_{60}H_{60}$, carried out by Saunders[24] still await experimental verification. According to MM3 calculations, the stereoisomer with 60 *exo* hydrogen atoms is extremely strained (strain energy (SE) = 836(!) kcal mol^{-1}). The isomeric $C_{60}H_{60}$ with just *one endo* hydrogen atom is 53 kcal mol^{-1} more stable, and the global minimum correlates to a C_1 symmetric structure in which ten hydrogen atoms occupy *inner* positions. No doubt the "cage builders" among the organic chemists will be challenged to provide explanations and macroscopic amounts of samples.

Two groups have reported successful fluorination experiments. Selig et al.[25] produced partially fluorinated fullerenes $C_{60}F_n$ $(30 < n < 50)$ with a maximum for $n = 36$. In an experiment on a 10 mg scale Taylor et al.[26] obtained $C_{60}F_{60}$ after reaction over twelve days. The fact that the ^{19}F NMR spectrum of $C_{60}F_{60}$ consists of one single line does not necessarily prove the product to be I_h symmetric. The equivalence of the 60 fluorine and carbon atoms would also be retained in the less symmetric *I* structure, with the consequence, however, that such a $C_{60}F_{60}$ would be a chiral molecule.[27]

The chlorination and bromination of fullerenes combined with the nucleophilic methoxylation and an $AlCl_3$-mediated Friedel–Crafts reaction of the polychlorofullerenes were recently described by Olah et al.[28] The reaction of C_{60} with Br_2 at intermediate temperatures furnishes $C_{60}Br_2$ and $C_{60}Br_4$, which both lose the halogen quantitatively at 150 °C. Chlorination, however, affords fullerenes containing an average of 24 chlorine atoms. Complete dehalogenation of these chlorinated products could be achieved at temperatures greater than 400 °C and under mass spectrometric conditions. Remarkably, in the reaction of the polychlorofullerenes $C_{60}Cl_n$ with MeOH/KOH (in excess) at reflux, all of the chlorine atoms were replaced by methoxy groups. According to the FAB mass spectrum, the product mixture contains compounds with up to 26 MeO groups. Because methoxy groups do not add to C_{60} under the same conditions,[46] it appears that this Cl → OMe exchange occurs by a front-side substitution on the surface of the cluster. Of

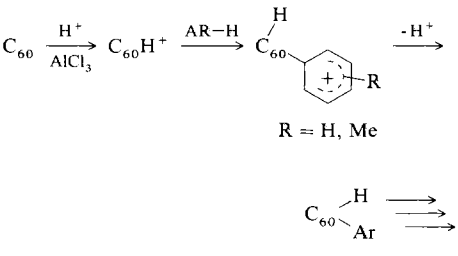
$$C_{60}Cl_n \xrightarrow[\Delta]{MeOH/KOH} C_{60}(OMe)_n \xleftarrow[\Delta]{MeOH/KOH} C_{60} \qquad (f)$$
$$n \leq 26$$

course this need not be the unprecedented S_N2 reaction proceeding with retention, since an addition/elimination mechanism would easily explain the observation.

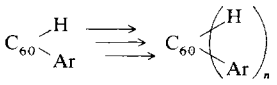
Polychlorofullerenes also undergo Friedel–Crafts ractions [Eq. (g)]. Thus $C_{60}Cl_n$ reacts with benzene or toluene in the presence of trace amounts of $AlCl_3$ providing polyarylfullerenes.

$$C_{60}Cl_n \xrightarrow[AlCl_3]{ArH} C_{60}(Ar)_n + n\,HCl \qquad (g)$$

The acid-catalyzed addition of fullerenes to arenes (fullerination) is also possible.[29] In the presence of $AlCl_3$, C_{60} reacts with benzene to give $C_{60}(HC_6H_5)_{12}$ as the major product and with toluene to the *para*-substituted C_{60}-$(HC_6H_4CH_3)_{12}$-fullerene. Whether this reaction proceeds by an SET mechanism or better yet by the electrophilic fullerination to arenes as illustrated in Equation (h) remains open. The fact that mixtures of C_{60}/C_{70} and polystyrene react with $AlCl_3$ in CS_2 to form highly cross-linked polymers may excite some materials scientists.



(h)

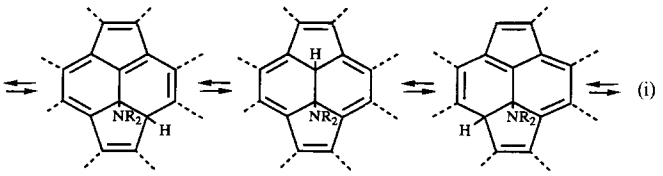


Electrophilic additions to C_{60} were also studied in the gas phase.[30] The proton affinity (PA) of C_{60} was found to be unusually high for an "arene" with a value of 204–207 kcal mol^{-1}. The ease with which $C_{60}H^+$ forms and the considerable resistance of $C_{60}H^+$ to charge transfer and fragmentation lend credence to the suggestion made by Kroto et al.[3c] that the diffuse absorption bands in interstellar space[3a] could be caused by this species.

Reactions of C_{60} with electrophiles E^+ (E = Me, Et, Bu) proceed readily in the gas phase.[30] One interesting observation is that in single-collision experiments on the adduct $C_{60}(t\text{-}C_4H_9)^+$, C_4H_8 is the main cleavage product. This could indicate that in the formation of the adduct no C–C bonds are formed, and that the adduct $C_{60}(t\text{-}C_4H_9)^+$ is better described as a proton-bound complex of the type $C_{60} \cdots H^+ \cdots C_4H_8$. Since it is true that $PA(C_{60}) > PA(C_4H_8)$, it is not surprising that the proton stays with the C_{60} cluster in the fragmentation caused by collisional excitation.

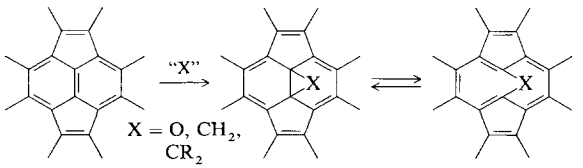
The addition of anions to C_{60} provides water-soluble fullerenes. The reaction of C_{60} with morpholine leads (presumably induced by an SET step) to the product $C_{60}H_6(N(CH_2CH_2)_2O)_6$.[31] ^1H NMR analysis of the adduct gives evidence of a reversible, rapid H-migration ($\Delta H^{\neq} \leq 10$ kcal mol^{-1}), and the degenerate [1,5]-sigmatropic rearrangement causes the H atoms to be "globe trotters" on the outer surface of the fullerene [Eq. (i)].

The fact that radicals and carbenes are also added to C_{60} does not justify the statement that C_{60} is not "choosy" in its choice of partners. Rather this completes the picture of the



(i)

very stable molecule which is also capable of unusual reactions. For example, Krusic et al.[32] report the addition of up to 15 photochemically generated benzyl radicals to C_{60}. ESR investigations of derivatives with three or five benzyl groups indicate that the radical centers on the C_{60} surface are primarily localized within the substituted five-membered rings. O and CH_2 adducts of C_{60} were identified by Cooks et al. by mass spectrometry.[33a] Presumably these are formed in the course of photochemical processes. According to mass spectrometry, both the O atom and the CH_2 group can be cleaved from these adducts only at considerable energies, implying that these units are covalently bound. The speculation that these compounds and $C_{70}O$ described by Diederich et al.[34] are fullerene analogues of Vogel's oxa- and methano[10]-annulenes [Eq. (j)] is quite tempting. Preparation of a C_{60}

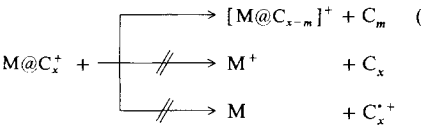


(j)

epoxide photochemically[33b] and by reaction of C_{60} with dimethyldioxirane have both been described.[33c] In the reaction with dimethyldioxirane the adduct C_{60}(1.3-dioxolane) was also isolated and identified.[33c] As proof of the insertion of a C_1 unit into the C_{60} framework, Wudl et al.[35] obtained X-ray data for the product of the reaction of C_{60} with diphenyldiazomethane. The product is assigned as Ph_2C_{61} and not as the diphenylcarbene adduct, Ph_2CC_{60}.

3. Endohedral C_{60} complexes: The perfect emptiness of the cavity of C_{60} (approximately 7 Å across) inevitably provokes questions, for example, if something could be placed inside and if fullerenes in general could serve as molecular containers and thereby offer the potential of endohedral chemistry[36]—chemistry inside of the cage. In the realization of these types of compounds two fundamentally differing concepts were applied: 1) Atoms M coincidentally present on the "inner" surface could be enclosed during the process of the formation of the fullerene clusters by "evaporation" of graphite. 2) Atoms M could penetrate the fullerene envelope in a bimolecular high-energy collision. Once the atoms are physically encaged they would be prevented from leaving their prison by high barriers. Both concepts were translated into reality, and a few examples serve to emphasize the fascinating aspects of endohedral fullerene complexes, for which the symbol $M@C_x$ has been suggested.[37c]

Smalley et al.[37] were able to prepare metal-containing fullerenes MC_{60} (M = La, Ni, Na, K, Rb, Cs) and LaC_x (x = 60, 70, 74, 82) by laser vaporization of doped graphite. The cluster ions MC_x^+ do not react with O_2, NH_3, or H_2O—the metal atom is protected from reactions by the carbon shell. Excitation with intense laser-light causes fragmentation. Unlike the typical fragmentation of the exohedral complexes (Scheme 1), the metal in the endohedral complex is not cleaved, but rather the cage shrinks with the loss of C_2 or several units of C_2 (Scheme 2). The complete destruction of the cluster occurs upon further excitation when the enclosed metal does not have enough room inside the cage.



Scheme 2. Fragmentation of an endohedral complex $M@C_x^+$ in the mass spectrometer.

Recently macroscopic amounts of endohedral metal–fullerenes were produced and used in subsequent experiments.[37c,d] The results for $La@C_{82}$ are worth mentioning: According to investigations with X-ray photoelectron spectroscopy, the central La atom has a formal charge of +3 (two electrons are donated to the C_{82} cage in the formation of C_{82}^{2-}, which is presumed to be especially stable; the third electron is delocalized inside the cavity). The compound could be extracted with boiling toluene, and the carbon cluster defied decomposition in the humid August climate in Houston. Similar results were reported for the yttrium complex. A doubly doped $Y_2@C_{82}$ cluster as well as a soluble La_2C_{80}[37e] have also been made. Do these molecules point the way to superconducting metallofullerenes? Who knows; this hope is certainly harbored by the authors.[37d]

The second variation, the penetration of an intact fullerene, was first carried out at the Technische Universität in Berlin[38] and later in other laboratories.[39] It could be shown that noble-gas atoms He and Ne could be incorporated into $C_{60}^{\bullet+}$, if highly accelerated $C_{60}^{\bullet+}$ ions were shot through a stationary noble-gas atmosphere in a molecular-beam experiment.[40] The resulting $MC_{60}^{\bullet+}$ complexes (M = He, Ne) disintegrate upon further excitation giving the fragmentation pattern typical for endohedral compounds with retention of M and elimination of C_m (Scheme 2).

Definitive proof that the noble gas is physically trapped inside the cavity of C_{60} was recently provided;[41] $HeC_{60}^{\bullet+}$ was reduced, and the resulting neutral compound was shown to have a finite lifetime of >90 μs. $He@C_{60}$ is the first "noble gas–carbon compound", and the proof that such inclusion compounds exist substantiates earlier speculations and experiments based on the premise that carbon clusters (without further specified structure) could function as containers for noble gases—presumably in interstellar space as well.[42]

Two research groups recently reported inverse endohedral C_{60} complexes: O. Wennerström from Göteborg prepared a water-soluble C_{60} supermolecule, in which C_{60} is enclosed in γ-cyclodextrin. The (current) highlight in this area is the synthesis and structural characterization of a 3:1 complex of hydroquinone and C_{60} reported by O. Ermer in Cologne.[44] In this case, a C_{60} molecule is enclosed in a net made of the three hydroquinone molecules stabilized by hydrogen bonds. Although charge-transfer interactions between host and guest occur, the orientation of the C_{60}-fullerene remains disordered. The complex is one of those rare cases in which the

guest throws his weight around more than the host: C_{60} is 2.2 times heavier than the three hydroquinone molecules together and takes up 50% of the crystal volume.

Admittedly, we are still miles away from fulfilling the promises pinned to the "wonder molecule" by the popular- and pseudoscientific media.[1, 2, 5] But the potential and uniqueness of C_{60} illustrated in this report may have whetted the appetite of some readers. Unfortunately, indigestion may result, since in the normal daylight C_{60} is one of the most efficient producers of singlet oxygen.[4, 5]

German version: *Angew. Chem.* **1992**, *104*, 301

[1] For example see *Der Spiegel* **1991**, *48*, 284, in which an article entitled "Ships in the Bottle" credits the fullerenes with a "totally new chemistry".

[2] In *Capital* **1991**, *91*, 247 C_{60} is declared to be "the material of materials". The authors venture that this molecule could change the world as much as nuclear fission did.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼″ and 3½″ diskettes.

The price of the index is DM 98.00, $ 64.00 or £ 37.00. Please order by telephone or in writing to VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.

Communications may be submitted in English *or* in German. Further details regarding the submission of communications can be found in the "Notice to Authors" reproduced in the January issue of the journal. Copies thereof may be obtained from the editorial office upon request.

Diprotonated Tetra(2-pyridyl)pyrazine and its Chemical Mimesis*** due to Different Hydrogen Bridges**

By *Hans Bock,* Thorsten Vaupel, Christian Näther, Klaus Ruppert*, and *Zdenek Havlas*

Dedicated to Professor Gerhard Quinkert on the occasion of his 65th birthday

Tetra(2-pyridyl)pyrazine, according to cyclovoltammetric measurements,[1] exhibits proton-sponge[2, 3] properties. This is of interest because the title compound contains four pyridine rings connected to a central pyrazine ring by four C–C axes; therefore, the altogether 132 degrees of freedom in the 40 center molecule $C_{24}H_{16}N_6$ are predominantly reduced to four rotations. Motivated by this dynamic aspect, we have determined the solid-state structures of the neutral compound[4] (Fig. 1 top) as well as of its diprotonated salts with either the "naked" or the "hydrocarbon-surrounded" counteranions Cl^-[5] (Fig. 1 middle) and $(C_6H_5)_4B^-$[6] (Fig. 1 bottom), respectively.

In the solid-state structure of tetra(2-pyridyl)pyrazine[4] (Fig. 1 top), the two pyridine rings on either side of the central pyrazine ring are twisted out of its plane by 50° either up or down. For this inversion-symmetric molecule with adjacent pyridine rings twisted in opposite directions an N ··· N distance of 324 pm results; this value exceeds the sum of two N-interference radii of 155 pm[7b] each and, therefore the repulsive nitrogen lone-pair interactions are reduced.

In the reaction of the title compound with HCl two diagonally opposing pyridine rings are protonated; hydrogen bridges N^+–H ··· Cl^- are formed to the two electron-rich

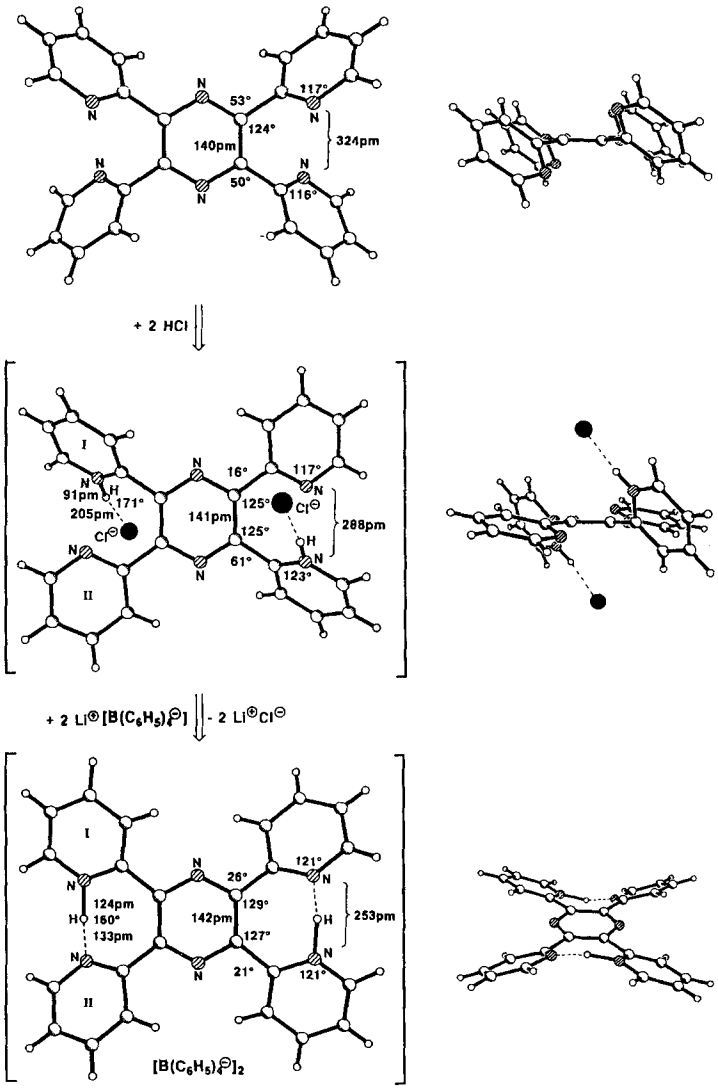

Fig. 1. Structures of tetra(2-pyridyl)pyrazine (top) and its diprotonated salts with chloride (middle) and tetraphenylborate anions (bottom). All six-membered ring skeletons exhibit inversion centers. Essential bond lengths [pm] (±1 pm) and angles [°] (±1°) are given; for further structural details see [4–6].

chloride anions (r_{Cl^-} = 180 pm),[7a] and distances between proton-donor and proton-acceptor centers of 295 pm are exhibited. Simultaneously, the unprotonated pyridine rings rotate into planarity with the pyrazine ring ($\varphi = 50° \rightarrow 16°$) causing the (H)$N^+$ ··· N distances to shorten to 288 pm, a distance less than the sum of two N interference radii (310 pm)[5] (Fig. 1 middle). The N^+–H bond lengths of 91 pm as determined by X-ray structural analysis must be corrected to about 104 pm, based on neutron-diffraction structural data. Concomitantly and in agreement with literature data,[7b] the distances H^+ ··· Cl^- must be corrected to about 185 to 190 pm. However, the angles $\sphericalangle N^+HCl^- = 171°$ can presumably be accepted without any correction.[7c]

Exchange of the electron-rich and therefore, preferred proton-acceptor center chloride ion for the phenyl surrounded one, tetraphenylborate, which under the reaction conditions is not protonated, can be achieved by anion exchange of tetra(2-pyridine)pyrazine dihydrochloride in acetonitrile

with $Li[B(C_6H_5)_4]$, on addition of which a yellow color is observed.[6] Structure determination of the yellow crystals proves drastic changes (Fig. 1 bottom). Thus, the torsion angles of the pyridine rings relative to the pyrazine ring are reduced to 21° and 26°, yielding a flattened molecular skeleton, which allows a rationalization of the color. This is essentially due to the formation of two intramolecular hydrogen bridges N^+–H···N between the N centers of adjacent pyridine rings, which are only 253 pm apart. The uncorrected distances N^+–H = 124 pm and H···N = 133 pm on both sides of the bending angle $\sphericalangle$ N^+-H-N = 160° differ by only 9 pm. These intramolecular N^+–H···N bridges are rather short even for proton sponges (N^+–(H)···N = 265–254 pm[3]) as well as almost symmetrical ($\Delta(N^+$–H/H···N) = 16–17 pm[3]) and change, in addition, other structural parameters of tetra(2-pyridyl)pyrazine (Fig. 1 top). Thus the external C-C-C angles of the pyrazine ring are expanded to 129°(!) and the differing pyridine *ipso* angles of 123° and 117° in the dihydrochloride (Fig. 1 middle) expectedly[2] equalize at 121°.

Additional information on the problem of different hydrogen bridges in one compound[7e,f] is provided by extensive quantum chemical calculations:[8]

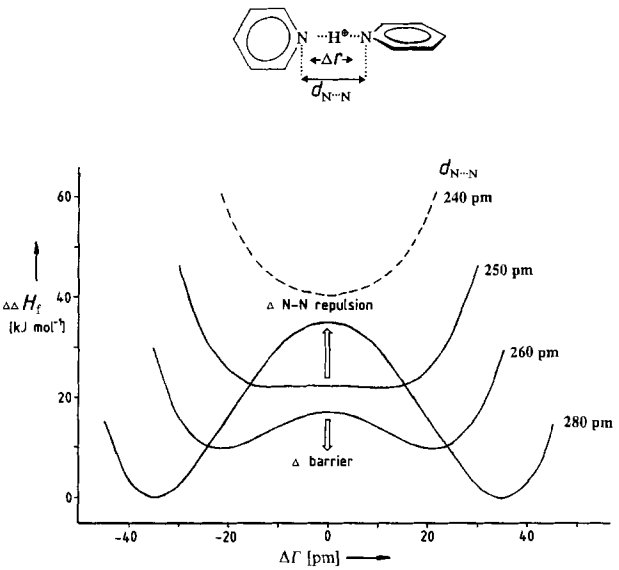
1) The preferred conformation of tetra(2-pyridyl)pyrazine in the crystal (Fig. 1 top) is reproduced by a complete AM1 geometry optimization starting from standard structural parameters.[8a] The alternative arrangement, which would contain triazachelate pincers and could be constructed by rotation of all pyridine rings, proves to be energetically less favorable, presumably due to the resulting N···N distances of about 290 pm, which are less then the sum of interference radii.

2) For the diprotonation and the conversion of the two external H^+ bridges to intramolecular ones, enthalpy of formation contributions of +91 kJ mol^{-1} and +443 kJ mol^{-1} are predicted.[8b] However, these gas-phase values must be corrected for the unknown solvation and lattice energies.

3) The AM1 charge distributions for tetra(2-pyridyl)-pyrazine *M* and for its different diprotonation products $[MH_2^+Cl_2^-]$ and $[MH_2^+]$ calculated from the crystal structure data, exhibit significant differences: Thus for the H^+ bridge centers, residual charges of +0.33 ($[MH_2^+Cl_2^-]$) and of +0.38 ($[MH_2^+]$) are estimated as well as −0.82 for the chloride anion. The partial charges at the pyridine N centers change from −0.12 (*M*) to −0.05 and −0.16 ($[MH_2^+Cl_2^-]$) and to −0.16 and −0.19 ($[MH_2^+]$), predicting $\Delta q_N = 0.11$ for the dichloride with one-sided NH^+ bridges and only $\Delta q_N = 0.03$ for the bis(tetraphenylborate) with almost symmetrical intramolecular bridges. As expected, the positive charges introduced by diprotonation are partially distributed to the peripheral pyridine hydrogens.

4) For a simulation of the H^+ bridge potentials, which depend strongly on the N···N distance,[8c] the structure of the 4-aminopyridine semiperchlorate provides an appropriate starting point (Scheme 1).[9] This structure has been determined by neutron diffraction and shows an N···N distance of 270 pm between the two perpendicular pyridine rings as well as an unsymmetrical hydrogen bridge (N^+–H 117 pm, H···N 152 pm). Variation of the distance $d_{N\cdots N}$ between 280 pm and 240 pm and stepwise movement of the bridge proton along the N–N axis by Δr yield different potential curves after each total geometry optimization of the pyridine rings (Scheme 1).

Double minima are calculated for structures with N···N distances between 280 pm and 250 pm; the height of the barrier decreases from 35 to 2 kJ mol^{-1}, and the difference in the N–H bond lengths is reduced from 70 pm to 22 pm. For



Scheme 1. Potential curves for pyridinium pyridine [8c] (see text).

the optimum N···N distance of about 270 pm, an N^+–H···N bond energy of 54 kJ mol^{-1} results. On shortening the N···N distance from 260 pm to 250 pm, the AM1 calculations predict an increase in energy due to increasing N–N repulsion, and for $d_{N\cdots N}$ = 245 pm a single minimum with equal distances N–H^+ of 122.5 pm is found. All other calculated properties exhibit only small changes: The pyridine *ipso* angles vary between 118° (H···N 197 pm) and 120° (N^+–H 103 pm) and the charges q_{H^+}, between +0.34 (N···N 280 pm) and +0.36 (N···N 250 pm).

5) In the diprotonated tetra(2-pyridyl)pyrazine containing two intramolecular hydrogen bridges (Fig. 1 bottom), the proton movement might be coupled to a "flip-flop" molecular dynamics: The adjacent pyridine rings are twisted by 26° and 21° out of the pyrazine plane. If their differing twisting angles are not caused by the crystal packing, the transition from one into the other double minimum should cause a change of ±5°. Therefore, in additional AM1 model calculations[8d] the proton was shifted in ten steps with Δd_{NH} = 9 pm along the experimentally determined structure with $d_{N\cdots N}$ = 253 pm. The following data are obtained for the barrier of the double minimum: height $\Delta\Delta H_f$ = 4 kJ mol^{-1}, d_{N-H^+} = 128 pm, bonding angle $\sphericalangle$ N(H^+)N = 170°, pyridine *ipso* angles of 121°, and a proton charge q_{H^+} = +0.38.

According to the approximate quantum chemical calculations, both tetra(2-pyridyl)pyrazine dihydrochloride and bis(tetraphenylborate) also differ in the type of their hydrogen bridge: With the electron-rich chloride ion as the proton acceptor, due to the rather long N···N distance of 288 pm, a simple potential minimum is approximated, in which the energetically favorably located proton vibrates only around its equilibrium position. The N^+–H···N bridges in the "naked" dication, on the other hand, are among the shortest known[3, 7, 19] with the smallest difference in the bond lengths N^+–H and H···N.[3, 7, 9, 10] Their formation causes the N···N distance to shorten by 35 pm (!) (Fig. 1 middle and 1 bottom), corresponding to a structure represented by a shallow double-minimum with a low barrier. The movement of the proton coupled with molecular dynamics, however, seems to be largely frozen in the crystal at 100 K[6] according to the center of inversion formed.

The mimetic behavior observed for tetra(2-pyridyl)-pyrazine upon exchange of the anions of the dichloride in

acetonitrile by addition of lithium tetraphenylborate presumably occurs in other protonatable nitrogen bases as well and is potentially of biological importance. In ongoing investigations the preparation of single crystals of metal-cation chelate complexes[11] of tetra(2'-pyridyl)pyrazine will be attempted.

[4] Tetra(2-pyridyl)pyrazine (Alpha): 100 mg were recrystallized from 3 mL dry $HCCl_3$ under an atmosphere of *n*-hexane. Colorless plates; for the crystal structure analysis we are grateful to Dr. J. W. Bats (Universität Frankfurt); see T. Vaupel, *Diplomarbeit*, Universität Frankfurt, **1992**. The molecule is arranged around a crystallographic inversion center. Angle sum of all six-membered rings 720°, bond lengths C–N 134 pm, C–C (ring) 138–139 pm, C–C 149 pm.

[5] Tetra(2-pyridyl)pyrazine dihydrochloride: 520 mg (1.3 mmol) tetra(2-pyridyl)pyrazine were stirred in 60 mL aqueous 1 *N* HCl at room temperature for 2 h. The water was then removed under reduced pressure and the dried residue recrystallized from 200 mL acetonitrile. Single crystals: 70 mg were dissolved in 100 mL boiling acetonitrile and slowly cooled to room temperature; after 2 d colorless polyhedra had grown. Crystal structure analysis: $C_{24}H_{18}Cl_2N_6$ (461.23) $a = 940.5(2)$, $b = 771.8(2)$, $c = 1563.2(6)$ pm, $\beta = 105.13(3)°$, $V = 1095.3 \times 10^6$ pm^3 (100 K), $Z = 2$, $\rho_{calc.} = 1.399$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.32$ mm^{-1}, monoclinic, space group $P2_1/n$, Siemens-AED II four-circle diffractometer, 6843 measured reflections $3° \le 2\theta \le 60°$, of which 2493 are independent with $I > 2\sigma(I)$. Structure resolution by direct methods and difference Fourier techniques (SHELXTL-Plus), N = 2943, NP = 182, $R = 0.033$, $R_w = 0.037$, $w = 1/\sigma^2(F) + 0.00008\,F^2$, GOOF = 2.864, Shift/Err ≤ 0.001, residual electron density +0.43/−0.30 e$_o$Å^{-3}. Empirical absorption correction, extinction correction, all C, N, and Cl atoms were anisotropically refined; H atoms (from difference Fourier analysis) isotropically refined. The dihydrochloride is arranged around a crystallographic inversion center. Angle sums of all rings 720°, bond lengths C–N 134 pm, C–C (ring) 139 pm, C–C 149 pm. b) Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2, on quoting the deposit number CSD-56020, the authors, and the literature citation.

[6] Tetraphenylborate salt of diprotonated tetra(2-pyridyl)pyrazine: A suspension of 200 mg (0.04 mmol) dihydrochloride in 20 mL acetonitrile was dissolved in methanol. On addition of 800 mg (2.5 mmol) lithium tetraphenylborate in 5 mL acetonitrile a yellow color appeared; after 3 h yellow cubes had grown. Crystal structure analysis: $C_{72}H_{58}B_2N_6$ (1028.7); $a = 11.082(6)$, $b = 11.160(7)$, $c = 12.366(6)$ pm; $\alpha = 80.98(5)$, $\beta = 84.87(4)$, $\gamma = 63.68(4)°$, $V = 1353 \times 46\ 10^6$ pm^3 (100 K), $Z = 1$, $\rho_{calc.} = 1.263$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.07$ mm^{-1}, triclinic, space group $P\bar{1}$, Siemens-AED-II four-circle diffractometer, 5461 measured reflections between $3° \le 2\theta \le 55°$, of which 3833 are independent with $I > 1\sigma(I)$. Structure resolution by direct methods and difference Fourier technique (SHELXTL-Plus), N = 3833, NP = 478, $R = 0.054$, $R_w = 0.040$, $w = 1/\sigma^2(F) + 0.0002\,F^2$, GOOF = 1.3660, Shift/Err ≤ 0.001, residual electron density +0.40/−0.26 e$_o$Å^{-3}. Empirical absorption correction, extinction correction, B, C, and N atoms were anisotropically refined; H atoms (from difference Fourier analysis), isotropically refined. The dication is arranged around a crystallographic inversion center. Angle sums of all rings 720°, bond lengths C–N 134 pm, C–C (ring) 139 pm, C–C 150 pm. For further details of the crystal structure see [5b].

[7] Selected reviews on hydrogen-bridge bonds: a) A. F. Wells, *Structural Inorganic Chemistry*, 5th ed., Clarendon Press, Oxford, **1987**, pp. 355–376; b) J. Elmsley, *Chem. Soc. Rev.* **1980**, *9*, 91–24; c) R. Taylor, O. Kennard, *Acc. Chem. Res.* **1984**, *17*, 320; d) G. R. Desiraju, *Acc. Chem. Res.* **1991**, *24*, 290. e) Among the examples for different hydrogen bridges within one compound, the yellow and white polymorphic modifications of 3,6-dichloro-2,5-dihydroxyterephthalic acid dimethyl ester which have different intramolecular bridges O–H···O and O–H···Cl, are pointed out (Q.-C. Yang, M. F. Richardson, J. D. Dunitz, *Acta Crystallogr. Sect. B*, **1988**, *45*, 312). f) For mono- and diprotonation see for example R. Schwesinger, M. Missfeldt, K. Peters, H. G. von Schnering, *Angew. Chem.* **1987**, *99*, 210; *Angew. Chem. Int. Ed. Engl.* **1987**, *26*, 1165.

[8] All quantum chemical calculations were performed at the AM1 level (M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc.* **1985**, *107*, 3902; program version SCAMP 4.0, T. Clark, Universität Erlangen). a) For the neutral molecule, a complete geometry optimization starting from standard structural parameters yields $\Delta H_f = 984$ kJ mol^{-1}, C–N 135 pm, C–C (ring) 140 pm, C–C 149 pm, *ipso* angle in pyridine 117°, twisting angle 54°, nonbonding distance N···N 320 pm; $\varepsilon_1 = 9.06$ eV (exp. $IE_1^V = 8.1$ eV; T. Vaupel, *Diplomarbeit*, Universität Frankfurt, **1992**). b) The calculations for the diprotonated compounds were based on the crystal structure data. Dichloride N^+–H distance corrected according to [7c] to 104 pm): $\Delta H_f = 1132$ kJ mol^{-1} ($[MH_2^+Cl_2^-]$) and 2314 kJ mol^{-1} (MH_2^+) as well as bis(tetraphenylborate) $\Delta H_f = 2411$ kJ mol^{-1} ($[MH_2^+]$). c) For the model calculations of $H_5C_5N^+$–H···NC_5H_5, the starting point was the structure determined by neutron diffraction [9] with the six-membered rings perpendicular to each other and the N···N distance varied between 280 pm and 240 pm. For the individual potential curves $\Delta\Delta H_f/\Delta r$ (Scheme 1), the bridge proton is moved in 5 pm steps along the N–N axis and the geometry of the complete system including both pyridine rings was optimized. Additional calculations for coplanar pyridine rings yield similar potential curves, the $\Delta\Delta H_f$ values of which are higher by 2–3 kJ mol^{-1}. It has been pointed out that semiempirical calculation procedures often exaggerate N/N repulsion relative to the H^+-bridge attraction due to insufficient N^+–H···N parametrization. d) For the calculations of diprotonated tetra(2-pyridyl)pyrazine with two intramolecular H^+ bridges, the simulation of the "flip-flop" molecular dynamics started with the cartesian coordinates of the experimental structure (Fig. 1 bottom), transforming the latter structure in ten equally weighted steps into that of its mirror image. In the fifth step the enthalpy of formation increased from 2410 kJ mol^{-1} to 2414 kJ mol^{-1}. The structural parameters given correspond to interpolation values.

Crystalline Nitrogen Oxides—Crystal Structure of N_2O_3 and a Remark Concerning the Crystal Structure of N_2O_5

By *Arndt Simon,* Jörg Horakh, Axel Obermeyer,* and *Horst Borrmann*

Our knowledge of the crystal structures of nitrogen oxides, N_2O, N_2O_2, N_2O_3, N_2O_4, and N_2O_5, is still rather incomplete. The structure determinations of N_2O[1] and N_2O_2[2] were complicated by the static disorder of the molecules. Raman spectra[3] contradict the linearity of the NO_2^+ ion in $NO_2^+NO_3^-$ as determined in the crystal structure of N_2O_5.[4] In the course of a structure determination of N_2O_3 only a possible unit cell could be proposed.[5]

Our results on the structure of the stable cubic and the metastable monoclinic forms of N_2O_4 have already been published.[6] Here we report on phase transformations in crystalline N_2O_3/N_2O_4 samples, a single-crystal structure determination of N_2O_3, and indications of the existence of

[*] Prof. Dr. A. Simon, J. Horakh, A. Obermeyer, H. Borrmann
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-W-7000 Stuttgart 80 (FRG)

hitherto unknown nitrogen oxides. In addition, we describe preliminary results, which prove that the crystal structure of N_2O_5 needs to be revised.

Indigo-blue N_2O_3 exists in its pure form only in the solid state, melting at about $-100\,^{\circ}C$.[7] Reed and Lipscomb discovered that single crystals become polycrystalline due to a phase transformation when cooled below $-125\,^{\circ}C$.[5] Therefore we first performed extensive powder diffraction experiments, using the modified Guinier technique,[8] in order to optimize conditions for crystal growth. The samples, prepared from NO_2 and NO,[9] showed a very complex behavior (Fig. 1). Depending on temperature and thermal treatment we were able to identify six different diffraction patterns besides those of N_2O_4.[10]

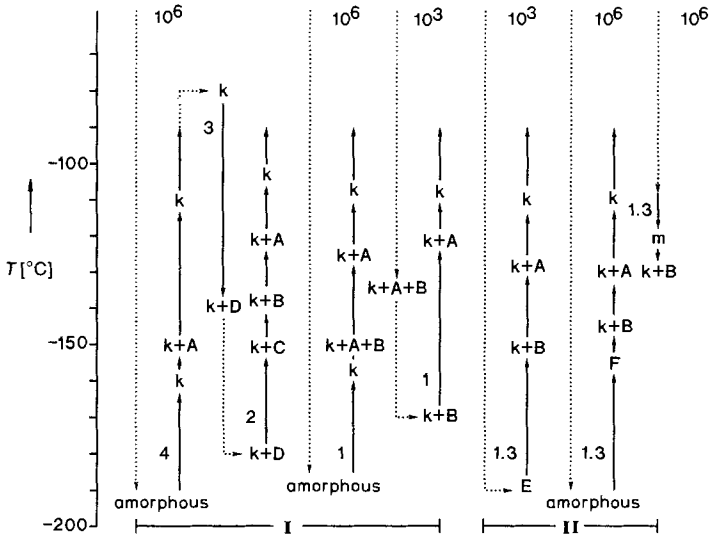

Fig. 1. Results of the investigation with the modified Guinier technique [8] of samples of N_2O_3 which were sealed in X-ray capillaries under vacuum (**I**) and 1 bar NO (**II**), respectively [9]. Arrows indicate directions of temperature changes (values in [$^{\circ}C\,h^{-1}$], dotted lines for temperature changes without X-ray observations, full lines for temperature changes with simultaneous X-ray diffraction). Cooling always began at room temperature with cooling rates of approximately 10^6 or $10^3\,^{\circ}C\,h^{-1}$. The diagrams of cubic and monoclinic N_2O_4 are denoted with k and m, respectively. Diagrams A through D were observed together with those of N_2O_4 in contrast to diagrams E and F[10].

Above approximately $-150\,^{\circ}C$ the intense lines of the cubic diagram k of N_2O_4 are observed with all samples. After being shock-cooled to $-190\,^{\circ}C$ the amorphous sample **I** was slowly heated up; at $-160\,^{\circ}C$ diagram k was observed first. At slightly higher temperature, diagram A of N_2O_3 was also observed. Obviously, N_2O_4 crystallizes more readily than N_2O_3. Therefore it is very surprising that after crystallization of the amorphous phase from either a shock-cooled or a slowly cooled sample **II**, the diagrams E and F did not show any lines for N_2O_4. At $-150\,^{\circ}C$ in both cases the cubic line pattern of N_2O_4 together with diagram B of N_2O_3 developed. These results are best explained with the existence of at least one new oxide below $-150\,^{\circ}C$, the composition of which must be between N_2O_3 and N_2O_4. We believe that diagrams A through D belong to distinctly different modifications of N_2O_3.

A single crystal of N_2O_3 was grown after the compound had been enriched locally in the sample by zone melting. Probably this is the reason why a crystal of phase B grew, in spite of the fact that in powder diagrams phase A was reproducibly observed in the same temperature range.[11, 12] Figure 2 shows a projection of the structure onto (100) of the orthorhombic unit cell.[13] As was proposed in 1920[14] and supported later by IR,[15] Raman,[16] and NMR experiments,[17] N_2O_3 must be described as a "nitroso-nitro" compound. There are only slight changes in geometric details

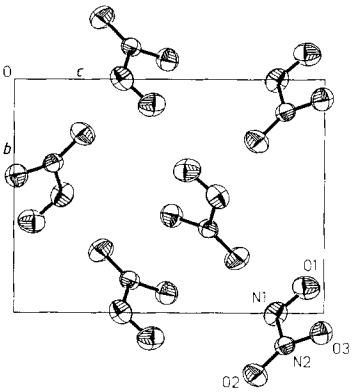

Fig. 2. Projection of the orthorhombic unit cell of N_2O_3 (phase B). The distances [pm] and angles [°] are: N1-N2 189.06(6), N1-O1 111.96(6), N2-O2 120.87(6), N2-O3 120.57(5); O1-N1-N2 105.12(4), O2-N2-O3 128.61(5), O2-N2-N1 119.55(4), O3-N2-N1 111.84(3).

determined in the solid state compared to the molecular shape as revealed from microwave spectra in the gas phase.[18] Especially the very long N–N distance (189.1 pm) is rather close to the value (186.4 pm) in the gas phase and represents a Pauling bond-order of about 0.2. A formal description as nitrosyl nitrite is also supported by the N–O distances and the O-N-O angle (N1–O1 112 pm compared to 115 pm in NO[19] and 106.5 pm in NO^+,[20] N2-O $\approx$ 121 pm and O-N-O 128.6° in comparison with 118 pm and 134.3° in N_2O_4[6] or 124 pm and 115° in NO_2^-[21]). The N_2O_3 molecule is almost planar; on the average the atoms deviate only 1.5 pm from the least-squares plane. However, because the angles around N2 add up to exactly 360.0°, this deviation is mainly due to the position of O1, which lies 7.8 pm above the plane through N1, N2, O2, and O3 (mean deviation 0.3 pm). The nitrosyl group and the nitrite unit are therefore twisted 3.7° about the N–N bond. The planarity of N_2O_4 was explained as a consequence of bonding interaction between the a_1 orbitals of the NO_2 fragments. These orbitals have significant oxygen character.[22] A similar explanation seems also reasonable for N_2O_3, since the O–O distance in N_2O_3 is even shorter than that in N_2O_4, despite the longer N–N distance. This particular geometry is also reflected in the smaller N1-N2-O3 angle relative to that of N1-N2-O2 and in the small O1-N1-N2 angle. Recently published ab initio calculations of the electronic structure of N_2O_3 were obviously performed only for the planar geometry without further explanation.[23] The calculated N–N distances are 10–15% shorter than the experimental value for all basis sets tested.

The redetermination of the structure of N_2O_5[4] from diffractometer data [24, 25] led to a surprising result. The (pseudo-)hexagonal structure was confirmed in the first instance, and the refinement converged at $R = 0.028$. The N–O distance in the NO_2^+ ion is 3.6 pm shorter and in the NO_3^- ion 1.5 pm longer than the values obtained from the earlier structure refinement. Refinements with data sets collected at different temperatures between 0 °C and $-168\,^{\circ}C$ did not give any hint for disorder or an erroneous description of the structure. However, a careful inspection of Guinier photo-

graphs showed very slight but systematic line splittings. Therefore the symmetry needs to be reduced from hexagonal to orthorhombic,[26] resulting in a very small deviation of 0.3% from the ideal $a:b$ ratio of the (ortho-)hexagonal system ($1:\sqrt{3}$). The structural consequences of this result are under investigation.

[9] **I**: N_2O_4 was condensed at $-78\,^{\circ}C$ and allowed to react with gaseous NO by slowly raising the temperature. At approximately $-50\,^{\circ}C$ a deep blue liquid separated from the N_2O_4. An X-ray capillary ($\varnothing = 0.2$ mm) was filled to a height of 2 cm, cooled to roughly $-100\,^{\circ}C$ (ethanol/N_2(liq)), evacuated, and sealed. **II**: A gaseous mixture of NO_2 and NO was condensed into an X-ray capillary at $-78\,^{\circ}C$. The NO pressure in the apparatus was kept at about 1 bar to maximize the amount of N_2O_3 in the reaction product. After "annealing" at $-50\,^{\circ}C$ for several hours with intermittant warming to room temperature, the sample had changed color from greenish blue to dark blue. The capillary was sealed at approximately $-100\,^{\circ}C$ under 1 bar NO.
[10] The different powder diagrams in Figure 1 are characterized by the following d values [pm]: A ($-110\,^{\circ}C$): 557, 406, 401, 360, 349, 299, 290, 286, 281, 272, 258, 257, 236, 235, 198.1, 194.1, 185.2. B ($-130\,^{\circ}C$): 523, 440, 402, 362, 331, 295, 275, 262, 261, 255, 252, 238, 235, 233, 209, 182.6. C ($-145\,^{\circ}C$): 599, 461, 351, 336, 280, 269. D ($-180\,^{\circ}C$): 420, 378, 347, 322, 297, 286, 274, 273, 258, 251, 249, 242, 231, 226, 213, 211, 197.6, 189.1, 178.5, 173.5. E ($-155\,^{\circ}C$): 511, 479, 408, 349, 348, 312, 282, 277, 264, 257, 256, 242, 229, 225, 193.1. F ($-150\,^{\circ}C$): 600, 426, 407, 404, 369, 353, 348, 300, 275, 256, 254. k ($-170\,^{\circ}C$): 548.3, 387.7, 316.6, 245.2, 207.3, 182.8, 173.4, 152.1, 133.0, 129.2. m ($-112\,^{\circ}C$): 517, 362, 351, 322, 285, 266, 259, 244, 235, 217, 194.7, 192.6, 181.5, 149.7, 148.0, 131.0.
[11] From the structure factors given by Reed and Lipscomb [5] a powder diagram can be calculated which is very similar to diagram A.
[12] Sample **II** completely crystallized at $-115\,^{\circ}C$ to form a light blue solid. A small part of the sample was kept solid and the rest was melted. At $-106\,^{\circ}C$ a crystal started growing from the solid and became deeper in color as was observed with the microscope. Rotation photographs showed the crystal to be mainly cubic N_2O_4. At the end of the solid column a separated section (0.5 mm length) remained; this was very dark blue and solidified at $-108\,^{\circ}C$. It was almost completely melted at $-104.5\,^{\circ}C$ and recrystallized when cooled at a rate of $1\,^{\circ}C$ per h. According to rotation and oscillation photographs, few crystallites of different sizes formed at $-106.5\,^{\circ}C$. During the two days measurements of a data set, a perfect single crystal formed which could be cooled to $-160\,^{\circ}C$ without destruction. [13]
[13] a) Crystal data of N_2O_3: $a = 506.86(4)$, $b = 647.96(5)$, $c = 863.26(6)$ pm at $-160\,^{\circ}C$; $\rho_{X\text{-}ray} = 1.781\ g\,cm^{-3}$, $Z = 4$, space group $P\,2_12_12_1$ (No. 19), $R = 0.022$ and $wR = 0.021$ for 1352 reflections and 47 refined parameters. b) Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-55934, the names of the authors, and the journal citation.

[24] NO_2 was purified by repeated sublimation of (colorless) N_2O_4, diluted with argon, and allowed to react with ozone (approx. 20% O_3 in O_2) in an apparatus based on the principle of Daniell's burner. The ratio was such that the gas phase was colorless. The product, N_2O_5, was condensed at $-78\,^{\circ}C$ in a trap and further purified by sublimation in ozone containing O_2. The X-ray capillary was filled at $-78\,^{\circ}C$ and sealed under vacuum. At $-25\,^{\circ}C$ the sample slowly recrystallized, and at slightly higher temperature one of the crystallites grew to a size sufficient for measurement.
[25] Crystal structure of N_2O_5: Measurements and calculations were performed based on the (pseudo-)hexagonal cell (see text). $a = b = 540.19(9)$, $c = 652.68(13)$ pm at $-168\,^{\circ}C$, $\rho_{X\ ray} = 2.175\ g\,cm^{-3}$, $Z = 2$, space group $P\,6_3/m\,m\,c$ (No. 194), 3674 measured reflections averaged to 189 independent ones ($R_{int.} = 0.042$), $R = 0.028$ and $wR = 0.029$ for all 189 reflections and 12 refined parameters [13b].
[26] Least-squares refinement with 34 reflections of the completely indexed diagram leads to the lattice constants ($-179\,^{\circ}C$) $a = 541.07(6)$, $b = 934.20(8)$ and $c = 653.22(8)$ pm.

Regioselectivity Control in the Palladium-Catalyzed Copolymerization of Propylene with Carbon Monoxide**

By *Antonio Batistini, Giambattista Consiglio,** and *Ulrich W. Suter*

The control of regioselectivity is exceedingly important in the carbonylation of olefins.[1, 2] The archetype of this reaction is the hydroformylation of propylene. Even 50 years after the discovery of the reaction, the control of regioselectivity is still a problem.[3] Better results have been obtained in the carbonylation of aromatic or functionalized olefinic substrates.[4–8] For instance in the hydroalkoxycarbonylation of styrene catalyzed by L_2PdCl_2[9] the use of monophosphine or chelating diphosphine ligands results in a very good control of the regioselectivity, yielding the branched or the straight-chain ester.[4–7] For aliphatic olefins such as propylene such regiochemical control has never been achieved.

In the copolymerization of olefins with carbon monoxide control of the regioselectivity is even more important. The regioselective linkage of the olefinic monomer is a general prerequisite for the production of stereoregular polymers.[10] The copolymerization of styrene with carbon monoxide catalyzed by $[Pd(p\text{-}CH_3C_6H_4SO_3)_2(phen)]$ (phen = 1,10-phenanthroline) provides poly(1-oxo-2-phenyltrimethylene)[11–13] with considerable stereochemical control: The content of racemic dyads is higher than 90%, and the stereochemistry is probably controlled by the end of the growing chain. The related catalyst precursor $[Pd(CF_3COO)_2(dppp)]$ (dppp = 1,3-propanediylbis(diphenylphosphine)) is able to promote not only the strictly alternating copolymerization of ethylene but also that of aliphatic α-olefins like propylene.[14–16] However, a sample of the propylene–carbon monoxide copolymer prepared under conditions similar to those reported in the patent literature[14, 15] and recovered by precipitation with methanol shows poor constitutional regularity. In fact, the ^{13}C NMR spectrum of the recovered material exhibits three broad groups of signals in the carbonyl region ($\delta = 217–207$) which are centered at about $\delta = 215.5$, 212.0, and 207.8 and have an intensity ratio of

[**] We thank Prof. Dr. D. Milstein (The Weizman Institute of Science, Rehovot, Israel) for the ligand 1,3-propanediylbis(diisopropylphosphine) as well as for suggestions related to its synthesis.

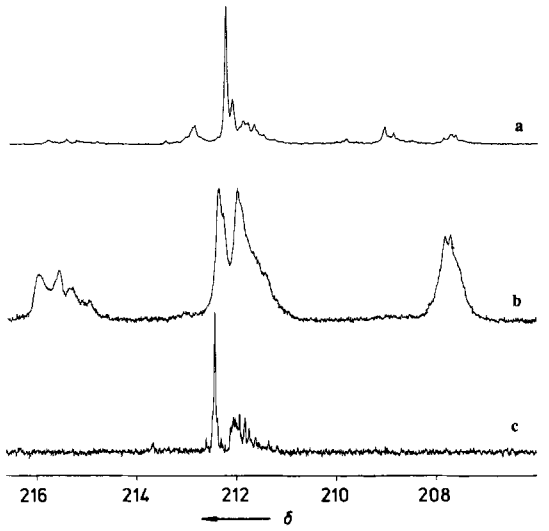

Fig. 1. The carbonyl region of the ^{13}C NMR spectra (125.8 MHz, $CDCl_3$) of propylene–carbon monoxide copolymers obtained with palladium catalysts modified by various ligands (bdpp (a), dppp (b), and dippp (c)).

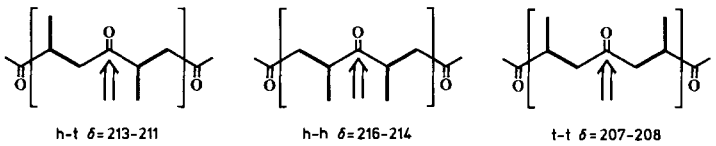
roughly 1:2.4:1 (Fig. 1, spectrum b). On the basis of the chemical shifts[17] and comparisons with model compounds, the signals can be assigned to carbonyl groups with different types of linkage to the neighboring propylene units (Scheme 1). From the relative intensities of the signals it can be deduced that the ratio of the two insertion modes is about 77:23. No apparent control of the stereoselectivity can be recognized from this spectrum. The lack of a melting point is consistent with the irregular structure of this material ($T_g = 22\,^{\circ}C$).



Scheme 1. Possible arrangements of the C_3 unit (regiosequences) in a propylene–carbon monoxide copolymer and the ^{13}C NMR chemical shifts for the inner carbonyl groups. h = head, t = tail.

In principle there are two possible approaches to improve the regularity of the polymer: 1. The use of chiral ligands, for example [(2,2-dimethyl-1,3-dioxolane-4,5-diyl)bis(methylene)]bis(diphenylphosphine),[18] to bring about enantiofacial selectivity,[19] thereby influencing the stereochemistry of the copolymer. 2. The use of ligands having different steric and electronic requirements, for example 1,3-propanediylbis(di-*n*-butylphosphine),[20, 21] to increase the amount of regular head-to-tail linkage. Regioselectivities over 90%[20] were obtained for a copolymer (melting point of 165 °C) defined as regio- and stereoregular.[18]

Following the same type of reasoning but emphasizing steric factors in the regulation of regioselectivity, we were able to obtain a considerable improvement in the stereoregularity of this copolymer and synthesized the first regioregular poly(1-oxo-2-methyltrimethylene). Figure 1 shows region of the ^{13}C NMR spectra of the most "regular" copolymers produced according to the two aforementioned approaches. The first copolymer (Fig. 1, spectrum a) was obtained with the modified catalytic system with (*R,R*)-2,4-pentanediylbis(diphenylphosphine) (bdpp)[22] under the same reactions conditions used for system with the achiral dppe ligand. The ^{13}C NMR spectrum reveals a remarkable improvement of both regio- and stereoselectivity. The intensity ratio of the signals centered at $\delta = 215.5$, 212.0, and 207.8 is about 1:9.9:1 in this case. The origin of the new signals at $\delta \approx 209$ and 213 is not yet clear. The high regularity of this material is reflected by the presence of (at least) two thermal transitions (at 130 and 200 °C), the higher of which is probably the melting point. The modification of the catalytic system with 1,3-propanediylbis(diisopropylphosphine) (dippp)[23] gives a polymer whose ^{13}C NMR spectrum (Fig. 1, spectrum c) gives evidence of the complete regioselectivity and good stereoselectivity of the polymerization. The same characteristics of regioregularity were observed for the polymer fraction which remained in solution after the addition of methanol. The less soluble material shows thermal transitions at 95 and 260 °C. The improved stereochemical control is also apparent from the narrow linewidth of the signals in the methyl region (Fig. 2). However, the ligands used to increase constitutional and configurational regularity caused a decrease in the molecular weight: $M_n = 25100$ (dppp), 4420 (bdpp), 2100 (dippp); the higher concentrations of terminal methyl groups are probably responsible for the signals at $\delta \approx 13$.

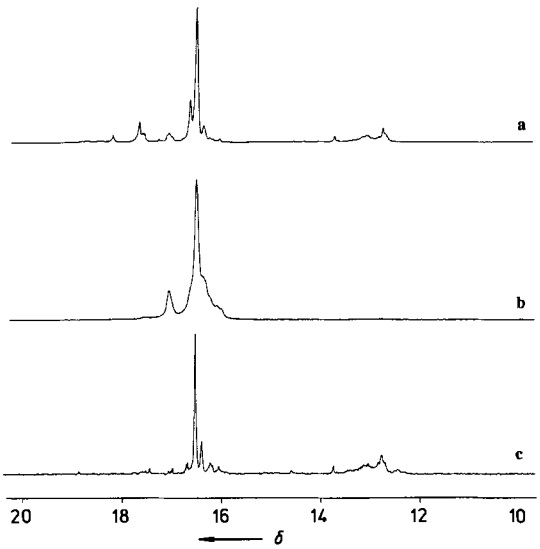


Fig. 2. The methyl region of the ^{13}C NMR spectra (125.8 MHz, $CDCl_3$) of propylene–carbon monoxide copolymers obtained with palladium catalysts modified by various ligands (bdpp (a), dppp (b), and dippp (c)).

These results clearly show the interconnection between enantiofacial selection and regioselectivity which was discussed previously for other addition reactions to olefins.[24] The regioselectivity can be, in fact, different on the two faces in reactions with enantiofacial discrimination. But complete regioselectivity can make the chain-end control of the entering olefin unit more effective. These results suggest possible ways to improve further the microstructure of this and related copolymers with other α-olefins.

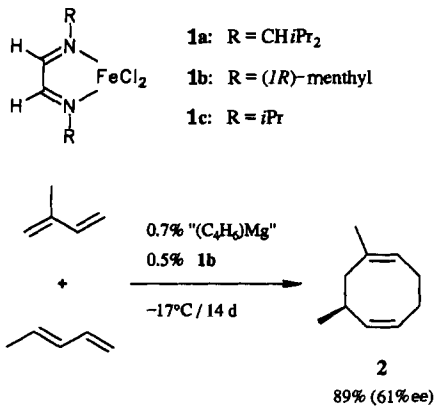
Enantioselective Syntheses of Cyclopentanoid Compounds from Isoprene and *trans*-1,3-Pentadiene**

By *Kai.-U. Baldenius, Heindirk tom Dieck,* Wilfried A. König, Detlef Icheln,* and *Torsten Runge*

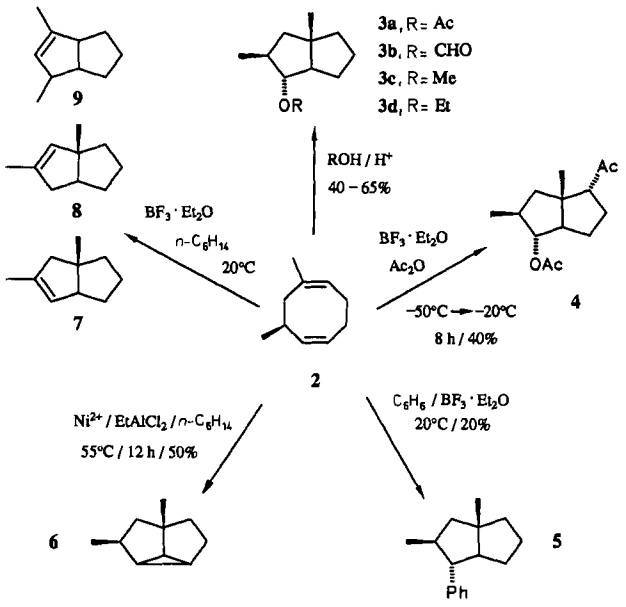
Dedicated to Professor Carl Heinrich Krauch on the occasion of his 60th birthday

Iron complexes with 1,4-diaza-1,3-diene (DAD) ligands catalyze the cyclodimerization of simples dienes.[1] A 1:1 mixture of *trans*-1,3-pentadiene and isoprene, for example, can be dimerized by **1a** activated with organomagnesium compounds[2] providing racemic 1,7-dimethyl-1,5-cyclooctadiene **2** in 88% yield (Scheme 1). We have found that reactions with precatalyst **1b** obtained from the C_2 symmetric (1*R*)-menthyl-DAD[3] deliver optically active (−)-1,7-dimethyl-1,5-cyclooctadiene (−)-**2** in 89% yield with up to 61% *ee*.



Scheme 1. Enantioselective codimerization of isoprene and *trans*-1,3-pentadiene.

Dimethylcyclooctadiene (DMCOD) **2** isomerizes readily under acidic conditions to derivatives of bicyclo[3.3.0]octane (Scheme 2). The cationic intermediate may be captured stereoselectively by a nucleophile resulting in the *endo* product (**3**–**5**). Alternatively, elimination or rearrangement/elimination may provide olefins like **7**–**9**. This elimination is always a side reaction and the cause for lowered yields of the addition product. Inspection of molecular models suggests that the cationic intermediate has a saddle conformation, in which the methyl group on the sp^3 C atom has a stereodirecting effect due to its preference for the *exo* position. Diastereomeric side products and racemization do not occur. In the reaction of **2** with acetic anhydride/$BF_3 \cdot Et_2O$, the electrophilic action of the acylium ion leads selectively to the *endo*-acetyl-*endo*-acetoxy product **4**.



Scheme 2. Acid-catalyzed reactions of **2**.

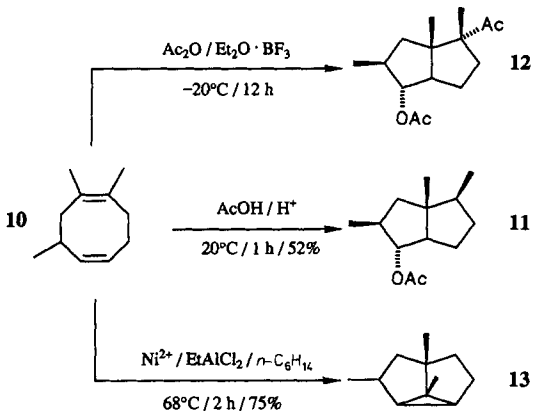
[**] This research was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. We thank Hoechst AG for their gift of chemicals.

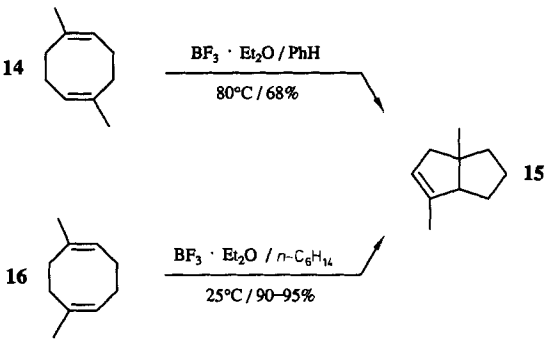
The reaction of (−)-**2** (61% *ee*) with $EtAlCl_2$ (20 mol%) in the presence of bis(2-ethylhexanoato)nickel (1.5 mol%) in hexane at 60 °C furnishes (−)-**6** in 50% yield (Scheme 2). Nickel plays a different role in this isomerization than that which we had originally assumed:[1b] The electron-rich Ni species present under these reaction conditions probably acts as a nucleophile; an alkylnickel compound is formed which undergoes a sterically favorable γ elimination leading to the tricyclic product.

1,2,4-Trimethyl-1,5-cyclooctadiene (**10**), in analogy to **2**, is converted to **11** by treatment with acetic acid/cat. H_2SO_4/20 °C and to **12** with acetic anhydride (Scheme 3); but in contrast to **2** its reaction with catalytic $Ni^{2+}/EtAlCl_2$ leads to C–C bond cleavage and product **13**. A Wagner–Meerwein



Scheme 3. Isomerizations of 1,2,4-trimethyl-1,5-cyclooctadiene (**10**).

rearrangement could precede the addition of the Ni nucleophile present in relatively low concentration here, as well in the reaction to **6**. A similar mechanism dependent on the presence of a nucleophile was formulated by Whitesell et al.[4] and Haufe et al.[5a] for the acid-catalyzed isomerization of 1,5-DMCOD **14**. The product of the rearrangement/elimination described by Whitesell et al. (**15**, Scheme 4) is also accessible from 1,6-DMCOD **16** and in better yields. Diene **16**, in turn, may be obtained with high selectivity from the dimerization of isoprene with DAD–iron catalysis.[1a]



Scheme 4. Acid-catalyzed isomerizations of **14** and **16**.

The very simple approach to differently functionalized optically active bicyclo[3.3.0]octanes described here should provide new impetus for the synthesis of cyclopentanoid compounds. Mehta et al.[6] and Pattenden et al.[7] have already pointed out the importance 1,5-DMCOD **14** and its derivatives could have in the synthesis of several naturally occurring triquinanes. Closer examination of the substructures of some of these synthetic targets as well as biologically interesting compounds with intact eight-membered rings make 1,7-DMCOD **2** appear to be an attractive starting material with an already respectable enantiomeric excess.[8] Other COD derivatives, some demonstrating fascinating isomerizations, are accessible by iron catalysis.[9, 10]

In addition our results emphasize the value of derivatized cyclodextrins (CDs) as stationary GC phases for the analytical control of asymmetric syntheses.[11, 12] All the chiral reaction products in this report could be separated completely into their enantiomers on selectively *O*-alkylated β- and γ-CD derivatives[13] in glass or fused silica capillaries.

Experimental Procedure

(−)-**2**: Isoprene and *trans*-1,3-pentadiene (dried over $LiAlH_4$ and distilled under N_2; 11.2 g, 165 mmol of each) were cooled to −40 °C under N_2. Butadienemagnesium-bis(tetrahydrofuran) (260 mg, 1.2 mmol) was then added followed by **1b** (380 mg, 0.8 mmol). The reaction mixture was stirred at least 2 h at −20 °C. The deep red-brown solution was held at −17 °C for 14 d. The product mixture was distilled off at room temperature (RT) under vacuum (≤ 0.05 Torr): 22.1 g condensate contained (GC): 90% 1,7-DMCOD **2**, <2% 1,4-DMCOD. <1% **14** and **16**. Product **2** was purified by spinning-band distillation to >95%. $[\alpha]_D$ − 4 (c = 4.5, $CHCl_3$), *ee* = 61%. Higher reaction temperatures accelerate the reaction but with resulting loss in *ee*.

(−)-**3a**: Acetic acid (8 mL) was allowed to react with conc. sulfuric acid (0.1 mL) and (−)-**2** (1.55 g, 95% purity, 11 mmol, 56% *ee*). The reaction mixture was stirred 15 h at RT, then taken up in 2 M NaOH, extracted with hexane, and dried over sodium sulfate. After the solvent was removed, the product was distilled (ca. 0.08 Torr, 42 °C). Yield: 1.3 g colorless liquid (6.6 mmol, 61%, 54% *ee*. $[\alpha]_D$ − 82 (c = 1.6, $CDCl_3$)). According to GC, four isomeric side products were also present (each less than 2%). The preparations of **3b–d** and **11** proceeded analogously. Treatment with formic acid did not require additional catalysis. Reactions with alcohols require higher temperatures (55 °C) and yield products of lower purity.

(−)-**4**: A solution of (−)-**2** (0.87 g, 90% purity, 5.7 mmol, 56% *ee*) in acetic anhydride (7 mL) at −50 °C was stirred vigorously and $BF_3 \cdot Et_2O$ (7.7 mmol) was added. The reaction mixture was allowed to stand 10 h at −20 °C before workup with hexane/$NaHCO_3$. Chromatography (silica gel, hexane/ethyl acetate) provided 0.55 g colorless oil (40%, $[\alpha]_D$ − 30 (c = 1.7, $CDCl_3$)). The preparation of **12** proceeded analogously.

[10] The iron catalysts employed are as sensitive as they are selective and usually do not tolerate dienes with heteroatom substituents. Other products than the desired ones with eight-membered rings are often produced due to steric reasons. For example, the reaction of 1-vinylcyclopentene with an excess of isoprene and **1c** does not lead to the anticipated bicyclo[6.3.0]undecadiene but rather to 4-(1-cyclopentenyl)-2-methylcyclohexene.

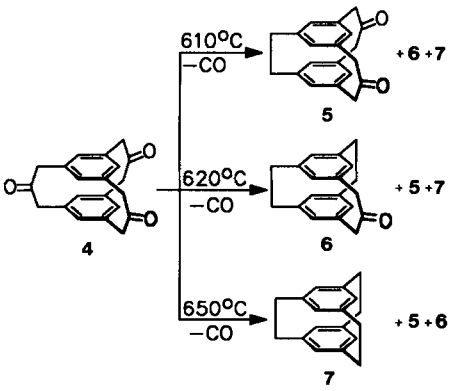
Selective Ketone Pyrolysis: New Synthetic Method for Mono- and Polycyclic Hydrocarbons**

By *Jörg Breitenbach, Frank Ott,* and *Fritz Vögtle**

The interest in polycyclic almost spherical molecular frameworks has increased, not least, through the results from the dodecahedrane[1] and fullerene area.[2] Our goals are large-cavity cage compounds, which could be isomerized and dehydrogenated to fullerene-like polycycles and those which retain guest molecules indefinitely.[3] In this context, we searched for synthetic methods for the preparation of macropolycyclic hydrocarbons. These can be obtained from the corresponding cyclic sulfones via the loss of sulfur dioxide.[4] However, sparing solubility, high melting points, and the insufficient volatility of sulfones as well as the sensitivity of some thiols and sulfides provide difficulties. Also the elimination of heteroatoms from aza-[5] and selenocyclophanes[6] does not occur readily. We have now found that cyclic ketones, via CO loss and C–C bond formation, can be preparatively ring contracted. As substrates for the development of the synthetic method, we chose cyclophanes which permit comparisons with the sulfone pyrolysis. The simple experimental design used there (horizontal, evacuated quartz tube, two tubular furnaces) also proved to be suitable here.

Optimization of the pyrolysis of the 12-membered ring diketone **1**[7] showed that the conditions (heat and pyrolysis temperature, vacuum) can be set to obtain the desired product (monoketone **2**, 23% yield; hydrocarbon **3**, 22% yield from **1**[8]).[9] Also [3.3.3]cyclophanetrione **4**, synthesized here for the first time, could be transformed selectively into the hitherto unknown ketones **5** (25% yield) and **6** (20% yield from **4**)[10] and then finally into the hydrocarbon **7** (31% yield in relation to **4**).[11]



In the paracyclophane series this pyrolysis, which only requires a few minutes, was achieved as before without problems: the [2.2]paracyclophane was obtained from [3.3]paracyclophane-2,12-dione[12] at 625 °C in 30% yield; the intermediate monoketone ([3.2]paracyclophane-2-one) could be obtained in 32% yield at 614 °C.[13]

Table 1. Physical and spectroscopic data as well as yields of the new compounds **2**–**6** and **8**. NMR spectra at 250 MHz (^{1}H) and 50.3 MHz (^{13}C) measured in $CDCl_3$.

2: Yield 23% [8]; m.p. = 115–116 °C; ^{1}H NMR: δ = 1.32 (s, 18H; CH_3), 2.20 (AA′, 2H; CH_2), 3.04 (XX′, 2H; CH_2), 3.39–3.55 [$(AB)_2$, 4H; CH_2], 4.98 (s, 2H; CH_{arom}), 7.10 (s, 4H; CH_{arom}); MS (70 eV): *m/z* 348.2447 [M^+], calc. 348.2453.

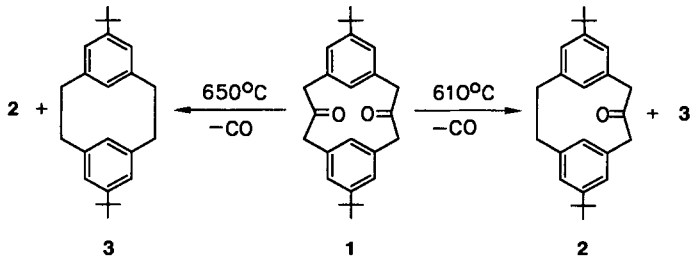
3: Yield 22% [8]; m.p. = 176–178 °C; ^{1}H NMR: δ = 1.35 (s, 18H; CH_3), 2.09 (AA′; 4H; CH_2), 3.05 (XX′, 4H; CH_2), 4.08 (s, 2H; CH_{arom}), 7.05 (s, 4H; CH_{arom}); MS (70 eV): *m/z* 320.2510 [M^+], calc. 320.2504.

4: Yield 7%; FP = 289–291 °C; ^{1}H NMR: δ = 3.77 (s, 12H; CH_2), 6.87 (s, 6H; CH_{arom}); MS (70 eV): *m/z* 318.1256 [M^+], calc. 318.1386.

5: Yield 25% [10]; m.p. = 261 °C; ^{1}H NMR: δ = 3.11 (s, 4H; CH_2), 3.68 (s, 8H; CH_2), 6.39 (s, br, 4H; CH_{arom}), 7.00 (s, br, 2H; CH_{arom}); MS (70 eV): *m/z* 290.1308 [M^+], calc. 290.1310.

6: Yield 20% [10]; m.p. = 210 °C; ^{1}H NMR: δ = 2.88–3.08 (AA′BB′, 8H; CH_2), 3.54 (s, 4H; CH_2), 5.61 (s, br, 2H; CH_{arom}), 6.51 (s, br, 4H; CH_{arom}); MS (70 eV): *m/z* 262.1351 [M^+], calc. 262.1357.

8: Yield 10%; m.p. = > 250 °C (decomp.); ^{1}H NMR: δ = 3.82 (s, 12H; CH_2), 6.90 (AA′, 12H; CH_{arom}), 7.08 (BB′, 12H; CH_{arom}), 7.29 (s, 6H; CH_{arom}); MS (FAB$^+$): *m/z* 775.3 [M^+ + H].



Thus, the ketone pyrolysis offers, besides a method for the production of the hydrocarbons, the possibility to obtain hitherto unknown, not easily accessible macrocyclic ketones. From the available examples, we conclude that the bond formation, as with the sulfone pyrolysis, occurs to a large extent intramolecularly. Even though the pyrolysis is a consecutive reaction, in which the intermediate products do not arise separately, the preferred formation of one of the products can nevertheless be achieved by the selection of the temperature.

For the preparation of the ketones, the TosMIC cyclization proved advantageous:[12,14] apart from the good accessibility of the building blocks, the simple procedure, and the good yields, the ketones obtained can be isolated without problems and are readily soluble. Starting from the tris(bromomethyl) compounds **9**[15] and **10**,[16] and toluene-4-sul-

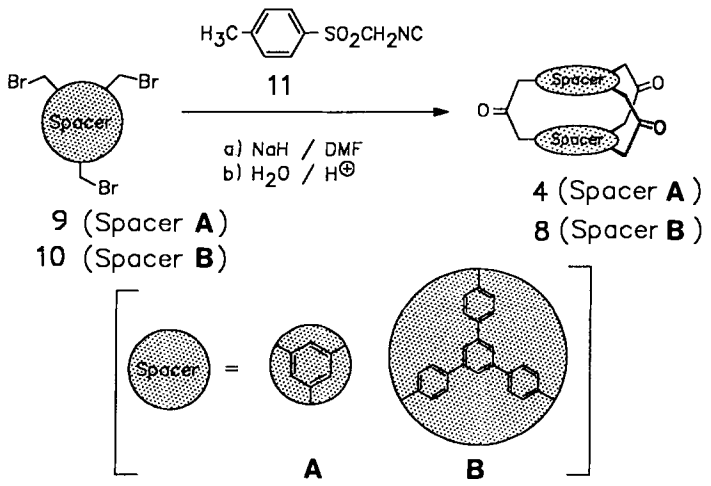
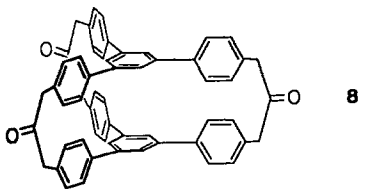
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 334).



fonylmethyl isocyanide (TosMIC) **11**,[17] we obtained the cyclophanes **4** and **8** in one step in yields of 7% and 10%, respectively.

In contrast to the previously reported cyclizations with TosMIC **11** under dilute conditions[19] and in solvent mixtures,[20] we carried out the cyclizations in dimethylformamide (DMF). The amount of solvent can thus be reduced so that the concentration of the reactants favors the selective formation of the desired macrocycles.[21]



8

Investigations showed that, as with the sulfone pyrolysis, also non-benzylic and alicyclic ketones[22] can be preparatively ring contracted by this method. Even benzophenones afford biphenyls under analogous conditions.[23] The selectivity of the method as a function of the pyrolysis temperature and reaction time, therefore, brings new synthetic goals in many fields within reach. With this method, in contrast to the sulfone pyrolysis, oxidizable groups are not limiting factors.

Experimental Procedure

Ketone pyrolysis: With the help of a tubular furnace **4** (20 mg, 0.06 mmol) was evaporated at 10^{-5} Torr in a quartz tube filled with quartz wool and sealed at one end (diameter 0.3 cm, length 22 cm) . The tube had been preheated to 610-650 °C in the region of the quartz wool (pyrolysis zone) with a second tubular furnace along a length of 10 cm. After withdrawal from the pyrolysis zone, the product condensed in the quartz tube as a yellow solid. From the pyrolysate, the compounds **5** ($R_f = 0.58$, pyrolysis temperature 610 °C), **6** ($R_f = 0.84$, pyrolysis temperature 620 °C), and **7** ($R_f = 1.0$, pyrolysis temperature 650 °C) were obtained through preparative thick-layer chromatography with dichloromethane/methanol (100:1, v/v). Reactions using up to 100 mg were conducted analogously.

Preparation of oligoketones with TosMIC (e.g. **4** and **8**): To a solution of the trisbromide **9** or **10** respectively (26.35 mmol) and TosMIC **11** (39.52 mmol) in DMF (200 mL, dried over molecular sieves (4 Å)), a suspension of sodium hydride (2.84 g, 118 mmol) in dry DMF (50 mL) was added over a 45 min period. The reaction mixture was stirred at room temperature for 5 h, then hydrolyzed by the addition of ice (200 g), and the organic phase was separated off by the addition of dichloromethane (100 mL). After the organic phase was concentrated to approximately 30 mL, concentrated HCl (15 mL) was added and the mixture was stirred for 15 min. Again, the organic phase was separated, washed with water (50 mL), dried over magnesium sulfate, concentrated, and chromatographed on silica gel (60-100 μm) [gradient elution, dichloromethane, dichloromethane/methanol (20:1, v/v)]. Compounds **4** (281 mg, 7%) and **8** (1.07 g, 10%) were obtained respectively.

[23] From the pyrolysis of cyclododecanone at 600 °C, we could isolate cycloundecane (9% yield); from the pyrolysis of benzophenone at 700 °C, biphenyl (9% yield) was isolated; see also G. R. Newkome, H. C. R. Taylor, *J. Org. Chem.* **1979**, *44*, 1362-1363. Also from these reactions unused starting material can be reclaimed whereby yields of 40 and 35% are achieved.

A Donor Cage with Two Tetrathiafulvene Units**

By *Martin Adam, Volker Enkelmann, Hans-Joachim Räder, Jörg Röhrich*, and *Klaus Müllen**

The treatment of the bis-1,3-dithiol-2-thione derivative **1** with phosphoric acid esters affords the tetrathiafulvalene (TTF) cage molecule **2** (Scheme 1).[1] As a result of the strong bending within the TTF unit, **2** shows a significantly different behavior from planar tetrathiafulvalenes in charge-transfer reactions. We have now determined that a surprising metathesis-like dimerization with the formation of the "expanded" cyclophane **3** results from the anodic oxidation of **2**. The cage of the easily accessible macrocycle **3** consists of two hydroquinone, and two TTF units, and thus is formed from four good donors.

S

The crystal structure by no means excludes conformations in solution, which can allow the inclusion of guest molecules.

The cyclic voltammetric investigation of **3**[12] shows three ideal reversible oxidations at $E^1_{1/2} = 0.36$ V (2e), $E^2_{1/2} = 1.01$ V (1e), and $E^3_{1/2} = 1.06$ V (1e). The first oxidation corresponds to a simultaneous loss of electrons from both TFF units, whereas the following oxidation waves correspond to the third and fourth charge. The electronic interaction of both donor units is apparently low because between the first and second oxidation no peak separation, and between the third and fourth oxidation only a very weak peak separation of 0.05 V is observed.

In the cyclic voltammogram of the monomeric cage **2** (Fig. 2), an irreversible oxidation wave at 0.93 V is observed, immediately followed by the oxidation waves corresponding to the formation of the tri- and tetracations of **3**. The first oxidation wave of **3** in the second scan of the cyclic voltammogram of **2** is observed even when the first scan is only carried out up to 0.93 V. Both results show that the

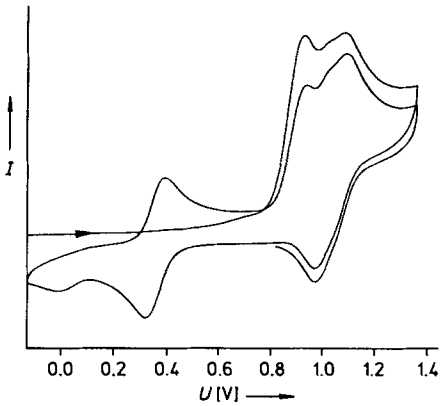

Fig. 2. Cyclic voltammogram of **2a** (potentials vs. SCE, dichloromethane, tetrabutylammonium hexafluorophosphate, 0 °C, 100 mVs^{-1}).

formation of **3** is already complete at a potential of 0.93 V. Therefore, the structure of the bisradical cation of **3** is attributed to the paramagnetic product of the preparative electrolysis of **2**, which as a result of the significantly higher concentrations, in contrast to the cyclic voltammetric experiment, is precipitated as the hexafluorophosphate salt.[13] Thus, the formation of **3** during the dissolution of the electrolysis product in dimethyl sulfoxide can be understood as a reverse reduction of the bisradical cationic salt to the neutral compound. The decomposition of charge-transfer (CT) complexes in solution via reformation of the neutral starting components has also been observed previously.[14]

The breakdown of ring strain during the transformation of **2** to **3** can be considered as the driving force for the ring-enlarging dimerization. So far, it is still unclear at which level of charge of **2** (radical-monocation or -dication) the primary C–C bond formation occurs and how the subsequent bond rearrangement within the four-center system of the fulvalene carbons takes place.

The macrocycle **3** forms CT complexes with iodine, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), and 2,3,5,6-tetrafluorotetracyanoquinodimethane ($TCNQF_4$). No such CT complexes were observed with tetracyanoquinodimethane (TCNQ) or tetracyanoethylene (TCNE). The powder conductivity at room temperature of $\mathbf{3a}(I_3)_{1.8}$ is $\sigma_{RT} = 6.1 \times 10^{-4}$ Scm^{-1} and $\sigma_{RT} = 1.2 \times 10^{-3}$ Scm^{-1} for $\mathbf{3a}(PF_6)_{1.7}$.[15] The requirement for the existence of electronic conductivity in TTF radical cationic salts is the formation of short S–S contacts in donor stacks or two-dimensional networks. Therefore, the measured σ-values show that in radical cationic salts of **3** both short intra- and intermolecular TTF contacts are possible. Attempts to obtain single-crystal charge-transfer complexes of **3** are in progress.

[2] Potential given vs. SCE; electrolysis time: 30 minutes, temperature: 20 °C, supporting electrolyte: tetrabutylammonium hexafluorophosphate.

[3] Spectrum of a solution in dimethylacetamide (line width 1.1 Gauss). In the solid-state spectrum, a drastic line broadening to 19.0 Gauss is observed.

[4] F. Wudl, G. M. Smith, E. J. Hufnagel, *J. Chem. Soc. Chem. Commun.* **1970**, 1453–1454.

[5] No ^{13}C NMR spectra could be obtained due to the low solubility of **3a–c**. Nevertheless, the recording of a ^1H NMR spectrum of **3c** was successfully achieved (400 MHz, [D_3]1,2,4-trichlorobenzene, 60 °C): $\delta = 1.16$ (t, 12H, $OCH_2CH_2CH_2CH_2CH_2CH_3$), 1.55 (m, 16H, $OCH_2CH_2CH_2CH_2CH_2CH_3$), 1.73 (m, 8H, $OCH_2CH_2CH_2CH_2CH_2CH_3$), 2.06 (m, 8H, $OCH_2CH_2CH_2CH_2CH_2CH_3$), 4.43 (t, 8H, $OCH_2CH_2CH_2CH_2CH_2CH_3$), 4.45 (s, 16H, SCH_2).

[6] Indications of oligomeric or polymeric condensation products of **2** are not present. As by-products compounds of low molecular weight are found whose formation can be explained by the opening of the 1,4-dithiacyclooctane rings.

[7] Correct elemental analyses have been obtained for **3a** and **3b**. A high-resolution mass spectroscopic determination with peak matching under FAB-ionization conditions confirms the expected elemental consistency of **3c** (found: $m/z = 1316.058401$, calc.: $m/z = 1316.064910$).

[8] The preparation of **4** is achieved analogous to the synthesis of bisxylylene-dithio-tetrathiafulvalene (L. M. Gol'denberg, R. N. Lyubovskaya, *Khim. Geterotsikl. Soedin.* **1986**, *6*, 855-856) starting from 2,3-bisbromomethyl-1,4-bishexyloxybenzene, which is accessible by Williamson etherification of 2,3-dimethyl-*p*-hydroquinone and subsequent NBS bromination.

[9] The growth of single crystals suitable for crystallographic analysis was achieved via the crystallization of **3b** in 1,2-dichlorobenzene on slow cooling (rate of cooling: 2 °C/h; starting temperature 180 °C). The crystals contain a molecule of 1,2-dichlorobenzene per molecule of **3**. Enraf-Nonius-CAD-4 diffractometer ($Cu_{K\alpha}$ radiation, $\lambda = 1.5404$ Å, graphite monochromator). $C_{50}H_{48}Cl_2O_4S_{16}$, monoclinic, space group $P2_1/n$; $a = 12.840$, $b = 13.816$, $c = 18.748$ Å, $\beta = 107.35°$, $V = 3174.5$ Å^3, $Z = 2$, $\rho_{calc} = 1.35$ gcm^{-3}, $\mu = 61.175$ cm^{-1}, 3766 reflections of which 2585 were observed ($I > 3\sigma(I)$; $F_0 > 4$). On cooling to temperatures below 0 °C the crystals experience irreversible damage due to a phase transition. Therefore, data collection was carried out at room temperature. The solution of the structure was achieved by Patterson search methods with the help of the donor fragment in its known bonding geometry. The 1,2-dichlorobenzene disordered in the crystal was "rigid body" refined. One of the two butyl side groups also shows a disorder due to two statistically equivalently occupied orientations. In Figure 1, only one of the two disorders is shown to allow a better overview of the structure. In the final refinement cycle the calculated H atoms in the "riding mode" were assigned isotropic temperature coefficients and C, Cl, O, and S with anisotropic temperature coefficients ($R = 0.066$, $R_w = 0.069$ and $w = 1$ for 346 parameters). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-55737, the names of the authors, and the journal citation.

A New Structure–Magnetism Relationship for Face-Sharing Transition-Metal Complexes with d^3–d^3 Electronic Configuration**

By *Andrea Niemann, Ursula Bossek, Karl Wieghardt,* Christian Butzlaff, Alfred X. Trautwein,* and *Bernhard Nuber*

In dinuclear transition-metal complexes the connection of the coordination polyhedra of two metal ions with octahedral geometry by face-sharing is a commonly observed structural feature. Metal $\cdots$ metal distances can range from 2.3 to 4.0 Å depending on the type of the three bridging ligands, which are often composed of one atom or coordinate only with one atom, for example O^{2-}, OH^-, RO^-, Cl^-, Br^-, and I^- (Table 1). If both metal ions possess unpaired electrons

Table 1. Metal–metal distances and spin exchange coupling constants for dinuclear face-sharing octahedral complexes with d^3-d^3 electronic configuration [9].

Compound number	Formula	M $\cdots$ M, [Å]	$-2J$ [cm^{-1}]
1	$[L_2Mn_2^{IV}(\mu\text{-}O)_3](PF_6)_2 \cdot H_2O$ [a]	2.296(2)	780

16	$(NEt_4)_3[Cr_2^{III}(\mu\text{-}Br)_3Br_6]$	4.00	0

[a] L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane. [b] L' = 1,5,9-triazacyclododecane. $H_2B(pz)_2^-$ = dihydrobis(1-pyrazolyl)borate. [c] Corrected value [10].

then intramolecular spin-exchange interactions and ferromagnetic or antiferromagnetic coupling results. This exchange interaction can be satisfactorily described for metals of the first transition-series by the isotropic Heisenberg–Dirac–van Vleck model with the spin-Hamiltonion operator $\boldsymbol{H} = -2J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$; here $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$ are the total spins on ions 1 and 2, and J is the spin-exchange coupling constant in cm^{-1}.[11] The value of J can be obtained from the temperature-dependence of the magnetic susceptibility of a complex. Antiferromagnetic coupling arises for homodinuclear complexes in which the two metals have d^3–d^3 electronic configurations; at low temperatures these complexes are diamagnetic ($\boldsymbol{S} = 0$, ground state). The energy difference between the singlet state ($\boldsymbol{S} = 0$) and the first excited triplet-state ($\boldsymbol{S} = 1$) is expressed by $2J$.

[+] X-ray structure analysis

[**] This research was supported by the Fonds der Chemischen Industrie and Deutsche Forschungsgemeinschaft under the auspices of the Schwerpunktsprogramm "Bioanorganische Chemie".

Although many face-sharing d^3–d^3 dinuclear complexes have been structurally characterized, and temperature-dependent susceptibility measurements have been carried out, no correlation has been found to date between structural parameters and the magnitude of J.[1c] We demonstrate here that the only relevant structural parameter that correlates with the value of J is the distance between the two metal ions.

We obtained **2** by protonation of an oxo bridge in **1**[2] (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane) with conc.

$[L_2Mn_2^{IV}(\mu\text{-}O)_3](PF_6)_2 \cdot H_2O$ **1** $[L_2Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}OH)](ClO_4)_3$ **2**

$HClO_4$. The X-ray structure determination (Fig. 1, top)[3] shows the $Mn^{IV} \cdots Mn^{IV}$ distance in **2** to be 0.11 Å longer than in **1** (Table 1). Measurements of the temperature-dependent magnetic susceptibility of **2** in the range of 4–298 K[4] (Fig. 2) provides a J value of $-256\ cm^{-1}$ ($\boldsymbol{H} = -2J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$; $\boldsymbol{S}_1 = \boldsymbol{S}_2 = 3/2$; $g = 1.98$), which points to a markedly smaller antiferromagnetic coupling in **2** than in **1** ($J = -390\ cm^{-1}$).

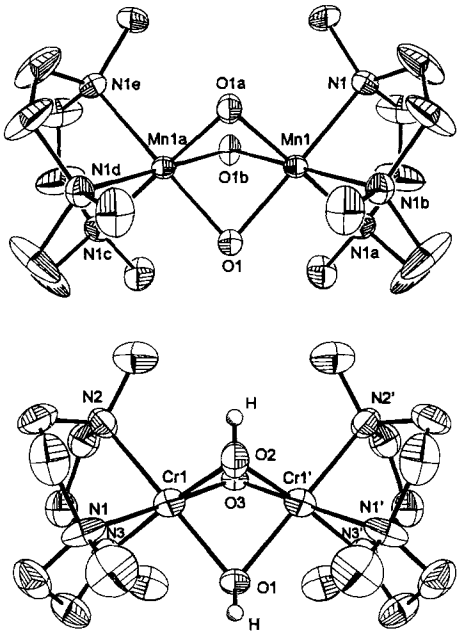

Fig. 1. Above: Structure of the trication in crystals of **2**. Important distances [Å] and angles [°]: Mn1-O1 1.858(7), Mn1-N1 2.086(8), Mn1 $\cdots$ Mn1a 2.408(5); Mn1-O1-Mn1a 80.7(4), O1-Mn1-O1a 82.6(1), N1-Mn1-N1a 84.3(3), O1-Mn1-N1 96.5. Below: Structure of the dication in crystals of **3**. Important distances [Å] and angles [°]: Cr1-Cr1' 2.518(5), Cr1-O1 1.983(8), Cr1-O2 1.961(10), Cr1-O3 1.869(8), Cr1-N1 2.148(11), Cr1-N2 2.085(10), Cr1-N3 2.093(12), Cr1-O1-Cr1' 78.8(4), Cr1-O2-Cr1' 79.9(5), Cr1-O3-Cr1' 84.7(5).

Complex **6**[5] can be deprotonated in alkaline[6, 7] solution to **3**. The Cr $\cdots$ Cr distance in **3** is shown by X-ray structure analysis (Fig. 1, bottom) to be 0.14 Å shorter than that in **6**.

$[L_2Cr_2^{III}(\mu\text{-}O)(\mu\text{-}OH)_2](ClO_4)_2 \cdot 2H_2O$ **3** $[L_2Cr_2^{III}(\mu\text{-}OH)_3](ClO_4)_3 \cdot 3H_2O$ **6**

A J value of $-125\ cm^{-1}$ was obtained from the temperature-dependent susceptibility measurements of complex **3**

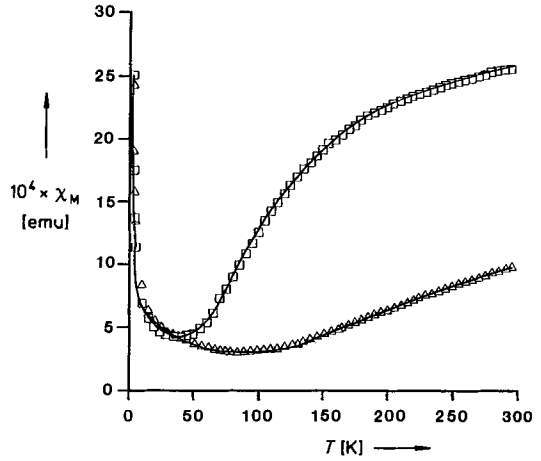

Fig. 2. Plot of χ_M versus temperature for complexes **2** (△) and **3** (□). The solid lines resulted from a fit of the data using the equation $\boldsymbol{H} = -2J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$; $\boldsymbol{S}_1 = \boldsymbol{S}_2 = 3/2$.

($\boldsymbol{H} = -2J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$; $\boldsymbol{S}_1 = \boldsymbol{S}_2 = 3/2$, $g = 2.00$); this value is roughly twice that of the value obtained for **6**, $-66\ cm^{-1}$.[5b]

Fifteen dinuclear octahedral face-sharing complexes whose structure and J values have been determined are listed in Table 1.[9] Complexes **1–8** each possess three oxygen atoms as O^{2-}, OH^-, or EtO^- bridging ligands; the central atoms are $Mn^{IV}(d^3)$ or $Cr^{III}(d^3)$. As is evident in Figure 3, the plot of $\ln|-2J|$ versus the metal–metal distance is linear. In complexes **9–12** and **15**, two metal ions, $Cr^{III}(d^3)$ or $V^{II}(d^3)$ are linked by three chloro bridges in each case. Remarkably

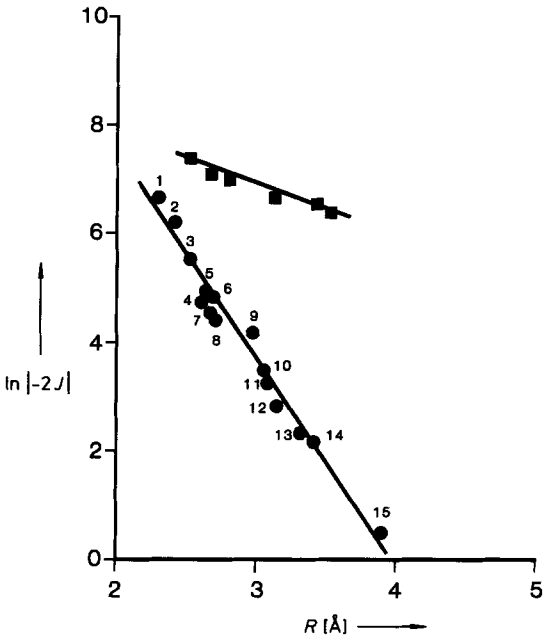

Fig. 3. Plot of $\ln|-2J|$ versus the metal–metal distance R for complexes **1–15** (●) and for complexes of the type $A_3[X_3Mo^{III}(\mu\text{-}X)_3Mo^{III}X_3]$ (A = K^+, Cs^+, NMe_4^+, NEt_4^+; X = Cl, Br) (■) [15].

the J values correlate with the M···M distances in the same way. Previous attempts at drawing correlation relationships for complexes **10–15** failed because of the application of the wrong J values.[9, 13] The values of the analogous tri-μ-bromodichromium(III) and tri-μ-iododichromium(III) complexes **13** and **14** also fit on the line in Figure 3. The correlation coefficient, 0.9935, shows how amazingly well this empirical correlation applies to so many different complexes. The plot of $\lg|-2J|$ versus $\lg|M\cdots M|$ is also linear[15] and with an equally good correlation coefficient (0.994). It is not possible to differentiate experimentally between the two relationships (a) and (b). The numerical values of the constant **A** is 7.52×10^6 with $n = 11.2$; of **B**, 7.50×10^6 with $\varepsilon = 4.0$ if J is given in cm^{-1} and the metal–metal distance R, in Å.

$$J = A R^{-n} \quad (a)$$

$$J = B\exp(-\varepsilon R) \quad (b)$$

Equation (b) is preferred,[11–13] because the spin-exchange interaction correlates with the extent of overlap of the magnetically relevant orbitals. The resonance integral β_{ii} (Hückel theory[12]) decreases *exponentially* with the increase in the distance between the two atoms. The antiferromagnetic coupling constant J^{AF} is dependent on β_{ii}, as shown in Equation (c).[12] The energy necessary for the transfer of one electron from metal 1 to metal 2 is described by U.

$$J_{ii}^{AF} = -4\beta_{ii}^2/U \quad (c)$$

The most important result is the observation that the spin-exchange interaction in face-sharing dinuclear complexes is *independent* of the type of a) bridging ligands and—amazingly—b) the metal centers,[13] as long as the electronic configuration is d^3–d^3. The metal–metal distance is the only relevant structural parameter. Thus it must be concluded that in face-sharing octahedral complexes with d^3–d^3 configurations *no* magnetic superexchange occurs through the bridging ligands, but rather a *direct* metal–metal interaction takes place. This can also be expressed as the existence of a very weak metal–metal bond. These results are in good agreement with the results of Extended-Hückel MO calculations conducted by Leuenberger and Güdel[14] for $[Cr_2X_9]^{3-}$ complexes (X = Cl, Br, I), which show that the main contribution to the exchange interaction arises from the interaction of the a_1 orbitals. On the other hand, in edge-sharing octahedral complexes with $Cr_2(\mu\text{-}OH)_2$ structural elements, the contribution to the exchange interaction through the bridging ligands is well documented (Glerup–Hodgson–Pederson model).[1c]

Equation (b) and the numerical values for the constants B and ε given here predict that no intramolecular antiferromagnetic coupling ($J \approx 0$) should be observed in complexes with metal–metal distances >4.0 Å. This is experimentally confirmed by complex **16**, which shows Curie paramagnetism (temperature-independent magnetic moment of 3.89 μ_B/Cr).[9]

Grey and Smith[15] found a similar structure–magnetism relationship for six complexes of type $A_3[X_3Mo^{III}(\mu\text{-}X)_3Mo^{III}X_3]$ (A = K^+, Cs^+, NMe_4^+, NEt_4^+; X = Cl, Br) (Fig. 3). The constants $B = 1.33 \times 10^4$ and $\varepsilon = 0.88$ [Eq.(b)] were determined when the Mo–Mo distance was expressed in Å and J, in cm^{-1} (correlation coefficient: 0.985). Because 4d valence orbitals are larger and more diffuse than 3d orbitals, the direct d–d orbital overlap is more effective than in 3d transition metals. Thus the exponential decrease in metal–metal interaction with increasing distance is not as dramatic. It remains to be seen if any, and if so what, physical meaning is related to the empirical terms B and ε in Equation (b).

Experimental Procedure

2: Complex **1** [2] (0.70 g) was dissolved in 60% $HClO_4$ solution (30 mL). Within a few days red-brown hexagonal crystals of **2** precipitated (yield: 0.52 g, 65%).

3: Solid NaOH (1.0 g) was added to an aqueous solution (30 mL) of **6** [5a] (0.80 g), and the color of the solution changed from red-orange to violet. After several days violet **3** precipitated (yield: 0.49 g, 70%). Both complexes provided correct elemental analyses (C,H,N,Cl).

[10] The J value for complex **9** in ref. [9] was calculated too large by a factor of 2, because the formula given there for the calculation does not hold for χ_M but for χ/V. The J value for **15** reported by Earnshaw and Lewis [9] is miscalculated. A new evaluation of the published χ_M data for **15** [9] and also our new susceptibility measurements provided $J = -1.67$ cm^{-1}.

[13] The fact that the data of the face-sharing Mn_2^{IV}, Cr_2^{III}, and V_2^{II} complexes correlate well with Equation (b) implies that two opposing factors compensate for each other: the 3d metal-orbitals of Mn^{IV} ions are more strongly contracted than those of the Cr^{III} and V^{II} ions; thus the Mn–X bonds are shorter than the analogous Cr–X and V–X bonds (X = bridging atom). In analogous $M(\mu\text{-}X)_3M$ compounds ($M = Mn^{IV}$, Cr^{III}, V^{II}) this leads to $M\cdots M$ distances $Mn_2^{IV} > Cr_2^{III} > V_2^{II}$, which compensates for the contraction effect.

Allylation of Quinones with Allylsilane in the Presence of Lithium Perchlorate in Ether**

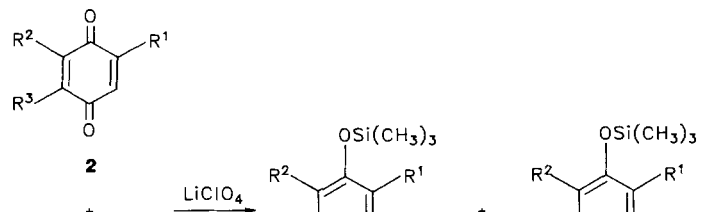
By *Junes Ipaktschi** and *Akbar Heydari*

Dedicated to Professor Günther Maier on the occasion of his 60th birthday

A recent publication[1,2] concerning the dramatic acceleration of a Diels–Alder reaction by a 5 M solution of lithium perchlorate in diethyl ether (LPDE) has revived a great interest in this reaction medium which often has been compared to a molten salt.[2c] Apart from the internal pressure of the 5 M LPDE solution,[1a] the Lewis acidity of the lithium ions has also been given as the reason for the increase in the reactivity.[3] The LPDE solution is preparatively very useful, for example, it can be shown that in this medium allyl vinyl ether undergoes a smooth [1,3] sigmatropic shift.[4]

A surprising reaction of *p*-benzoquinone with furan in an LPDE solution which led to 2-furyl-*p*-benzoquinone (**1**)[5,6] caused us to investigate the allylation of quinones with allyltrimethylsilane (**3**) also in this medium. The allylation of quinones is an important reaction for the preparation of biologically active isoprenoid quinones such as vitamin E,[7] vitamin K,[8] coenzyme Q_1,[9] and plastoquinones,[10] for which a series of synthetic methods already exists.[11]

We have now found that the reaction of **2a**–**d** with allyltrimethylsilane (**3**) in a 5 M LPDE solution leads to the allylhydroquinones **4a**–**e**. If **2a** is warmed with **3** in a 5 M LPDE solution for 15 hours at 40 °C, the allylhydroquinone **4a** is obtained in 73% yield, together with the non-allylated hydroquinone **5a** (12%).



Scheme 1. **a**: $R^1 = R^2 = R^3 = H$; **b**: $R^1 = R^3 = H$, $R^2 = CH_3$; **c**: $R^1 = CH_3$, $R^2 = R^3 = OCH_3$; **d**: $R^1 = H$, $R^2R^3 = -CH{=}CH{-}CH{=}CH-$; **e**: $R^1 = R^2 = H$, $R^3 = CH_3$; **f**: $R^1 = R^3 = C(CH_3)_3$, $R^2 = H$.

The reaction of **2b** with **3** showed no selectivity. Here, **4e** (41%) and **4b** (20%) were formed together with **5b** (10%). From the very slow reaction (10 days) of coenzyme Q_0 (**2c**) was obtained **4c** (22%), **5c** (18%), and interestingly, the indane derivative **6** (10%). The reaction of naphthoquinone **2d** produces a substantial amount of the reduction product; thus, in addition to the allylation product **4d** (44%), 42% of **5d** was also formed. Analogously, the allylation of **2a** with the allylsilane **7** afforded **8** (75%). Here, the reduction product **5a** (12.5%) was also obtained as a by-product.

Obviously the Lewis acidity and the very high polarity of the LPDE solution facilitate the formation of the polar com-

plex **B** and the ion pair **C** by an electron-transfer step from the quinone/allylsilane charge-transfer complex **A** (Scheme 2).[12] The subsequent C–C bond formation reaction and silylation of the resulting hydroquinone derivative with a further molecule of **3** then leads to the products **4** and **8**, respectively. Examples for the formation of **6** by the Sakurai reaction are already known.[13]

A **B** **C**

Scheme 2. D = donor, A = acceptor.

If the C–C bond formation step is prevented by a bulky substituent such as in 2,5-di-*tert*-butylbenzoquinone (**2f**), then in the presence of **3** as an electron donor in the step of **B** or **C**, the rearrangement to benzofuran **9** (45%) takes place, catalyzed by an electron-transfer reaction.

Experimental Procedure

4a: To a solution of **2a** (0.270 g, 2.5 mmol) in a 5 M solution of $LiClO_4$ (5 mL) in absolute diethyl ether, **3** (1.2 mL, 7.5 mmol) was added. The mixture was stirred for 15 h at 40 °C and subsequently diluted with pentane and washed with water. The GC analysis of the crude product showed that an almost quantitative reaction took place affording **4a** (73%) and **5a** (12%). Analytically pure **4a** and **5a** were isolated by fractional sublimation or gas chromatography

Large Hyperconjugative and Inductive Effects on C-C-X Bond Angles (X = Main-Group Element): The Crystal Structure of Triethylborane and Ab Initio Investigations**

By *Roland Boese,* Dieter Bläser, Norbert Niederprüm, Markus Nüsse, Waldemar A. Brett, Paul von Ragué Schleyer,* Michael Bühl,* and *Nicolaas J. R. van Eikema Hommes*

Remarkable deviations from expected geometries are found in seemingly simple compounds. Several structure determinations of molecules with tricoordinate boron and the structural element CH_3CH_2B revealed abnormally large C-

[**] This work was supported by the Fonds der Chemischen Industrie, at Erlangen by the Deutsche Forschungsgemeinschaft, and the Convex Computer Corporation. N. J. R. van E. H. was a recipient of an Alexander von Humboldt Foundation Fellowship, and M. B. received a fellowship from the Studienstiftung des Deutschen Volkes.

C-B angles of up to 120.2(5)°.[1] Such large expansions of the tetrahedral angle (109.47°) are not likely to be due to repulsive intramolecular[2] or intermolecular[3] interactions. Although the C-C-B angle is 118.3(1)° in the high-temperature phase of triethylboroxine (**1**),[3] no strongly repulsive interactions are apparent. (The shortest intermolecular nonbonded H···H distances are 2.39 Å).

Is hyperconjugation responsible for the large C-C-B bond angles? To answer this question, we compare the X-ray structure of Et_3B (**2**),[4] which has formally a vacant boron p orbital, with that of the sodium salt of Et_4B^- (**3**),[6] in which no hyperconjugation is possible. We also have carried out ab initio geometry optimizations with the MP2/6-31G* basis set[7] on **2** and **3**, as well as on ethylborane (in various conformations), $CH_3CH_2BH_3^-$, and the whole set of compounds of the type CH_3CH_2X with elements of the second (X = Li, BeH, BH_2, CH_3, NH_2, OH, F) and third periods (Na, MgH, AlH_2, SiH_3, PH_2, SH, Cl). This data allows our findings with the boron compounds to be interpreted in a general framework.

The molecular structure of **2** (Fig. 1 left) is only slightly distorted from the expected C_{3h} symmetry. The B–C distances are 1.573(1) Å (mean value). The shortest nonbonded H···H separations, are 2.50 Å (intramolecular, between the ethyl groups) and 2.44 Å (intermolecular, see packing diagram, Fig. 2) and are not expected to have more than a minor influence on the molecular geometry. The mean C-C-B angle in **2**, 118.9(2)°, is nearly as large as that in triethylboroxine (**1**). The MP2/6-31G* geometry of **2**, computed in C_{3h} symmetry, has the same C-C-B bond angle (118.4°).

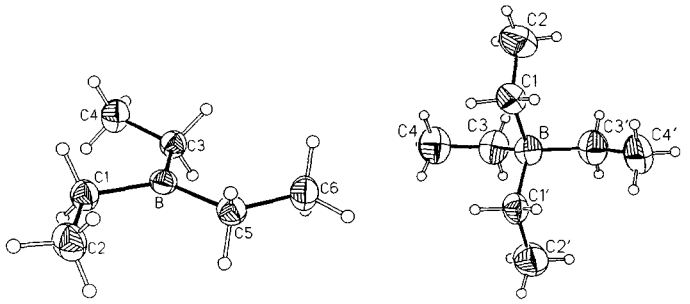

Fig. 1. Left: Structure of **2** in the crystal, the thermal ellipsoids are drawn at the 50% level. Bond lengths [Å] and angles [°], standard deviations 0.001 Å and 0.1°: B-C1 1.575, B-C3 1.573, B-C5 1.572, C1-C2 1.533, C3-C4 1.525, C5-C6 1.530; C1-B-C3 120.2, C1-B-C5 120.0, C3-B-C5 119.7, B-C1-C2 118.7, B-C3-C4 118.7, B-C5-C6 119.3; C2-C1-B-C3 178.4, C2-C1-B-C5 −0.9, C4-C3-B-C1 6.5, C4-C3-B-C5 −174.2, C6-C5-B-C1 −177.1, C6-C5-B-C3 3.7. Right: Structure of **3** in the crystal, the thermal ellipsoids are drawn at the 50% level. The cation and three surrounding dioxane molecules are omitted. Bond lengths [Å] and angles [°]: B-C1 1.643(5), B-C3 1.649(6), C1-C2 1.540(6), C3-C4 1.519(7); C1-B-C1' 107.4(4), C1-B-C3 109.6(2), C1-B-C3' 110.8(3), C3-B-C3' 108.6(4), B-C1-C2 116.4(3), B-C3-C4 116.3(3).

The crystallographic symmetry of **3** is C_2 (Fig. 1 right). The B–C distances (1.646(4) Å, mean value) are greater (by 0.06–0.10 Å) than those in **2** and in tetracoordinated mono- and diethylboron compounds[8] (1.599 Å, mean value). The C-C-B angles in **3**, 116.4(2)°, are in the same range as in related compounds[8] (115.6°, mean value), and only slightly smaller than in **1** and **2**. The shortest intramolecular nonbonded H···H distances between different ethyl groups (2.35 Å) and the shortest intermolecular distances (2.41 Å) should not affect the C-C-B angles to any appreciable extent. Hence, inductive, rather than steric or hyperconjugative effects, must be responsible for the large C-C-B angles in **3**. This is confirmed by both the C-C-B angle of 113.1° which

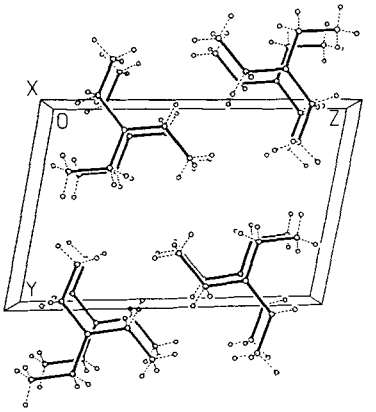

Fig. 2. Packing in **2** in the unit cell, intermolecular H···H separations between the stacks of molecules are 2.44 Å.

we compute for the small parent compound, the anion $CH_3CH_2BH_3^-$, in which steric repulsions are absent, and by the value for **3** in D_{2d} symmetry (116.1°; MP2/6-31G*).

As summarized in Figure 3, the C-C-X angles (ab initio, MP2/6-31G* basis set) in the whole set of compounds of the type CH_3CH_2X (X = Li–F, Na–Cl) range from approximately 105° for X = BH_2 to 118° for X = Li. (A search with the Cambridge Structural Database also reveals that greatly expanded C-C-X angles are common; Table 1.[9]) The general tendency of the C-C-X angles to correlate with the electronegativies (according to Allred–Rochow) of X[12] (element and group electronegativities are very similar) is apparent in Figure 3 (dotted line).

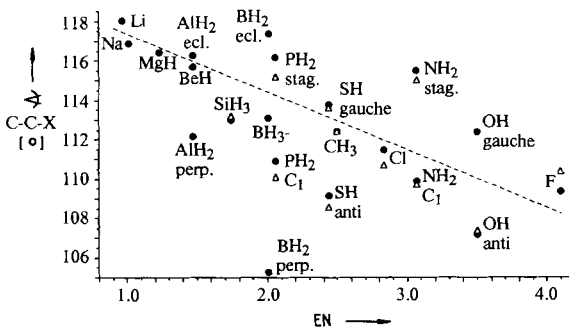

Fig. 3. Electronegativity EN (according to Allred–Rochow) and the C-C-X angles (MP2/6-31G*) of ethyl–main-group element compounds (black dots). Experimental data taken from "*Landolt-Börnstein*", *II*, Vol. 15, Springer, Berlin, **1987**, are included for comparison (triangles). The dotted line indicates the general trend to smaller angles with increasing electronegativity of the substituent (inductive effect). Deviations are due primarily to hyperconjugative effects (see text). Note the large angle differences when two conformations are possible. ecl = eclipsed, stag. = staggered, perp. = perpendicular. For more details see text.

The compounds with the more electronegative substituents have smaller C-C-X angles. This mimics the situation expected for carbocation/anion ion-pairs: more electropositive X substituents lead to the larger angles of the strongly pyramidalized carbanions (for example, in polar organometallic compounds). Thus, the expanded C-C-B angles, $\measuredangle$CCB = 113.1° in $CH_3CH_2BH_3^-$ (MP2/6-31G*) and in EtB_4^-, $\measuredangle$CCB = 116.4° in the X-ray crystal structure and 116.1° in the MP2/6-31G* structure, are primarily the consequence of the sigma (inductive) effect of boron in the absence of a vacant p orbital.

Deviations from such regular behavior (i.e., the points not on the dotted line in Fig. 3) are due primarily to hyperconju-

Table 1. Bond angles α ($\triangleq$ C-C-X, X = main-group element) determined by X-ray crystallography for compounds with the structure element Et-X.

X	n [a]	$\alpha \pm \sigma$[°]	α_{min}[°]	α_{max}[°]

S	245	112.69 ± 3.99	88.83	139.53

[a] n = Number of structures examined [9].

gation effects. Specifically, in the *perpendicular* conformation of CH_3CH_2–BH_2, the empty boron p orbital lies in the C-C-B plane (perp. in Fig. 3). Thus the resulting hyperconjugation with the C–C bond results in a considerable reduction in the C-C-B angle to 105.3°.

In the *eclipsed* conformation, in which the empty boron p orbital is *perpendicular* to the C-C-B plane, the C-C-B angle is influenced indirectly. Hyperconjugation with the vacant p orbital now involves the two equivalent α CH bonds (which have roughly 30° dihedral angles). Electrons are withdrawn from the CH_2 orbital with π symmetry. Hence, the antibonding interactions between the hydrogen atoms are reduced and the orbital which has H···H character has a greater influence. The result is that the H-C-H angle decreases to 103.1° in Et_3B (MP2/6-31G*). The C-C-B angle expands (to 117.4°) as a consequence (the Thorpe–Ingold hypothesis).[13]

When the X group is a π-donor rather than a π-acceptor, negative hyperconjugation with a lone pair results in a wider C-C-X angle. For example, for X = NH_2 in the *staggered* conformation with the N lone pair *anti* to the C-C bond the C-C-X angle is 115.5°. In the *trans* conformations of C_2H_5OH and C_2H_5SH, for example, the smaller C-C-X angles (ca. 107.2°) arise indirectly as summarized in Scheme 1.

Scheme 1. Orientations of the ethyl group relative to the p orbital of the main-group element X. Left, perpendicular conformation **A**; right, eclipsed conformation **B**. When the p orbital in **A** is empty, the C-C-X angle decreases; when occupied, the angle increases. When the p orbital in **B** is empty, the H-C-H angle decreases and the C-C-X angle increases; when occupied, the H-C-H angle increases and the C-C-X angle decreases.

Idealized "sp^3" bond angles of 109.47° require tetrahedral symmetry and thus cannot be expected generally. "The regular tetrahedral angle is the exception rather than the rule in organic chemistry."[14] Figure 3 and Table 1 emphasize the variety of molecular geometries and that many bond angles in simple organic compounds do not fit the widely accepted generalizations.

An Arsanylidensilane ("Arsasilene") and its Derivatization with Tellurium and Benzophenone**

By *Matthias Driess** and *Hans Pritzkow*

Organosilicon compounds with low-coordinated Si atoms and multiple bonds to silicon were of great importance for the recent development of silicon chemistry. In the last ten years the use of, for example, disilenes, silaalkenes, and

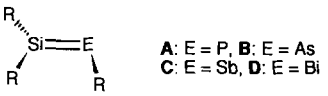
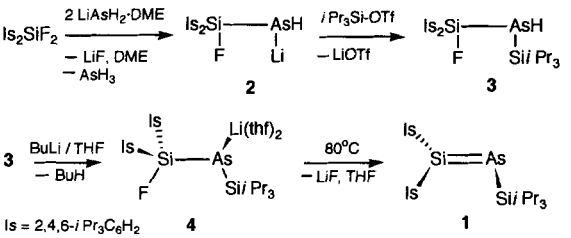
silanimines for the preparation of new classes of organosilicon compounds have proved to be extremely profitable.[1] For investigations into the structure and reactivity of compounds with low-coordinated Si atoms, the synthesis of unsaturated Si compounds of the type $R_2Si{=}E$ with new combinations of element–silicon $(p\text{-}p)_\pi$ bonds and λ^4, σ^3 coordinated Si atoms plays a key role. Therefore, we search for efficient ways to isolate compounds with π bonds between silicon and the heavy homologues of Group 15, i.e. phosphorus, arsenic, antimony, and bismuth. Whereas compounds with a P–Si π bond ("phosphasilenes") **A**[2] are already known, there are so far no examples for the homologous systems **B**–**D**.



A: E = P, **B**: E = As
C: E = Sb, **D**: E = Bi

Recently we have achieved, starting from Is_2SiF_2 (Is = 2,4,6-iPr$_3$C$_6$H$_2$) and $LiPH_2 \cdot DME$ (DME = dimethoxyethane), in a multiple-step reaction, a simple synthesis of thermally stable and at the same time activated phosphanylidensilanes ("phosphasilenes").[3] It has been shown that this simple synthetic route surprisingly is also suitable for the preparation of **1**, the first arsasilene. Thus, the reaction of Is_2SiF_2 with two equivalents of $LiAsH_2 \cdot DME$ in THF at 20 °C leads quantitatively to the lithiated coupling product **2**, which is stable in THF for several days.



Compound **2**, which is not isolated, can be directly transformed into the disilylarsane **3** (Table 1) with triisopropylsilyl trifluoromethanesulfonate. Lithiation of **3** with one equivalent of nBuLi in a hexane/THF mixture leads to the lithoarsane **4** (Table 1), which is isolated in the form of colorless, extremely air- and moisture-sensitive crystals. The ^{1}H NMR spectrum and an elemental analysis prove that the Li atom in **4**, solvated with two THF molecules, is only threefold coordinated. This result was confirmed by a crystal structure analysis of **4** (Fig. 1).[4]

In contrast to $LiAs(SiMe_3)_2 \cdot DME$,[5] which up to now is the only lithium disilylarsane complex structurally confirmed, and which both in solution and also in the solid state is dimeric, **4** is monomeric in the solid state. The Li atom is distorted trigonal planar, the As atom pyramidal, and the fluoro-substituted Si atom as a result of steric overloading has a highly distorted tetrahedral coordination. In contrast to that, the iPr substituted Si atom is tetrahedrally surrounded. Noteworthy is the short Li–As bond (2.46 Å). The As–Si bond lengths of 2.29 Å (FSi–As) and 2.32 Å (iPrSi–As) are shorter than As–Si single bonds (2.33–2.40 Å) and not significantly different from the value in the dimeric $LiAs(SiMe_3)_2 \cdot DME$ (2.30 Å).[5]

The thermal elimination of LiF and THF from **4** in toluene at ca. 90 °C leads to an intensely red solution of **1**,

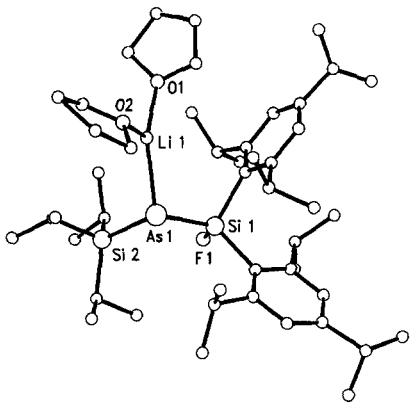


Fig. 1. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: As1-Si1 2.296(4), As1-Si2 2.320(4), Si1-F1 1.631(8), Li-As1 2.46(3), Li-O1 1.91(3), Li-O2 1.92(4); Si1-As1-Si2 106.4(1), Si1-As1-Li 110.2(7), Si2-As1-Li 109.5(7), As1-Li-O1 143.9(16), As1-Li-O2 114.0(15), O1-Li-O2 101.9(16).

which can be isolated as a spectroscopically pure (^{1}H NMR and mass spectra), deep-red oil (Table 1). In the ^{29}Si NMR spectrum, for the λ^4, σ^3 coordinated Si atom, similar to the analogous phosphasilene,[3] a signal at very low field ($\delta = 179.1$) is observed. The ^{29}Si nuclei of the SiiPr$_3$ group result in a singlet at $\delta = 28.0$. The ^{29}Si chemical shifts of **1**, as with the analogous phosphasilene[3] and other compounds of this type,[2] are noticeably temperature dependent [$\delta(^{29}Si)$ for Si=As at 80 °C: 177.2, for As–SiiPr$_3$: 27.9]; however, they are only slightly influenced by the donor ability of the solvent in contrast to silanimines. Therefore, the

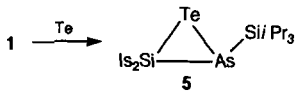
^{29}Si NMR spectrum proves that in **1** there is a As–Si π bond with similar polarity relations as is in the P–Si π system.

The high kinetic stability of **1** allowed investigations into the reactivity of this compound. Thus, the oxidation of **1** with elemental tellurium (toluene, 25 °C, 1 d) leads to the yellow, crystalline three-membered ring compound **5**. The structure of the AsSiTe three-membered ring is confirmed by mass spectrometry and ^{29}Si as well as ^{125}Te NMR spectra (Table 1), especially since the ^{29}Si and ^{125}Te chemical shifts are very similar to those of the homologous PSiTe three-membered ring.[6]



5

Since kinetically stabilized silanimines react with ketones in a metathetical process to give azomethine derivatives ($R_2C{=}NR$) and trimeric cyclosilanones $(R_2SiO)_3$,[7] we investigated whether analogous methylenarsanes "arsaalkenes" are obtained from **1** and ketones $R_2C{=}O$ (R = Ph, *t*Bu). Whereas benzophenone reacts with **1** to give **6** already at 0 °C, with $tBu_2C{=}O$ even at 90 °C for 8 h no reaction is achieved. The composition and structure of **6** are confirmed by mass spectrometry, and NMR spectroscopy, respectively (Table 1). In the mass spectrometer, as a retro reaction of **6** only the fragmentation to $\mathbf{1}^+$ and $Ph_2C{=}O$ is observed.

The crystal structure analysis[8] of **6** shows that as a result of the bulky substituents unusual bonding situations exist (Fig. 2). The SiOCAs four-membered ring is slightly bent

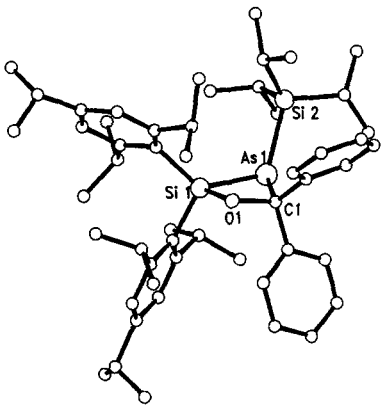


Fig. 2. Molecular structure of **6**. Selected averaged bond lengths [Å] and angles [°]: As1-Si1 2.382(2), As1-Si2 2.393(2), As1-C1 2.057(7), Si1-O1 1.688(4), C1-O1 1.450(8); Si1-As1-C1 68.6(2), As1-Si1-O1 82.5(1), Si1-O1-C1 105.8(3), O1-C1-As1 101.0(4).

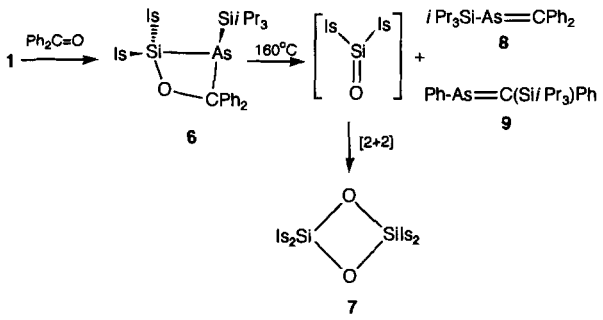
(along the As–O axis 11.7° and relative to Si1–C1 16.2°), the Si–As, Si–O, and C–O bond lengths correspond to extended single bonds, and the As atom is tetrahedrally coordinated (sum of angles 299.4°). Of particular note is the long As–C distance (2.060(7) Å), which is 0.1 Å longer than the average single bond (ca. 1.95 Å); this is probably caused by the bulky substituents. The inert behavior of $tBu_2C{=}O$ towards **1** is probably due to steric hindrance.

Under drastic conditions (160 °C, 10 h) **6** actually decomposes into $Is_2Si{=}O$, which immediately *dimerizes* to **7** (in contrast to less bulky silanones, which usually *trimerize*), and the arsaalkenes **8** and **9**.[9] This presents a new way to arsaalkenes[10] via arsasilenes by means of a pseudo Wittig reaction.



Experimental Procedure

4: A solution of Is_2SiF_2 (5.4 g, 11.44 mmol) in THF (40 mL) was added to $LiAsH_2 \cdot$ DME (3.98 g, 22.88 mmol) and was stirred for 3 h at 0 °C then 16 h at 25 °C. To the orange-yellow solution of **2**, $iPr_3SiOSO_2CF_3$ (3.5 g, 11.44 mmol) was added at −50 °C and then this was stirred for 30 min at 25 °C. Finally, all volatiles were removed at 10^{-2} Torr and the dark brown crude product was taken up in hexane (50 mL) and filtered over a G3 frit. Compound **3** could be crystallized from a concentrated solution. For the further processing to **4** this was not absolutely necessary. Therefore, the filtrate was diluted with THF (10 mL), cooled to −78 °C, and treated with *n*BuLi (11.44 mmol, 2.5 M solution in hexane, Aldrich). The clear orange solution was slowly warmed to 25 °C, the solvent removed in vacuum, and the solid residue recrystallized twice from hexane at −30 °C. Yield: 5.13 g (6.13 mmol, 53.7%), colorless crystals.

1: **4** (912 mg, 1.09 mmol) was dissolved in toluene (5 mL) and heated to 80–90 °C for 14 h. The red solution was completely evaporated and taken up in hexane (5 mL). Me_3SiCl (1 mL) was added and the solution was stirred for 1 d at 25 °C to separate the LiF. The LiCl was filtered off and the filtrate was concentrated in vacuum to give **1** as a deep-red, viscous oil. Yield: 660 mg (0.99 mmol, 91%).

5: **1** (420 mg, 0.63 mmol) was dissolved in toluene (10 mL) and stirred with Te powder (excess) for 1 d at 25 °C. The excess Te was filtered off and the red filtrate was concentrated to ca. 2 mL and left at 10 °C so that after two crystallizations yellow crystals of **5** precipitated. Yield: 199 mg (0.25 mmol, 39.8%), mp = 164 °C.

6: 1 (583 mg, 0.88 mmol) was dissolved in toluene (10 mL) and added to benzophenone (160 mg) dissolved in toluene (5 mL) at ca. 0 °C. The initial deep red color of the solution disappeared immediately. All volatiles were removed at 10^{-2} Torr, and the residue was recrystallized twice from hexane (2 mL) at 25 °. Yield: 621 mg (0.73 mmol, 83.3%), colorless crystals, mp = 135 °C.

Cyclodextrin Derivatives as Chiral Selectors—Investigation of the Interaction with (*R*,*S*)-Methyl-2-chloropropionate by Enantioselective Gas Chromatography, NMR Spectroscopy, and Molecular Dynamics Simulation**

By *Jutta E. H. Köhler, Manfred Hohla, Martina Richters,* and *Wilfried A. König**

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

Enantiomeric substrates form energetically and structurally distinguishable host–guest complexes with cyclodextrins and their derivatives. This is shown, for example, in the investigation of chiral substrates in the presence of cyclodextrins by enantioselective chromatography,[1] NMR spectroscopy,[2] and X-ray structure analysis.[3] To understand the host–guest interaction and thereby, the "chiral recognition" it would be very useful to obtain information concerning the spatial relationship between host and guest molecules in molecular complexes.

The model we investigated involves (*R*,*S*)-methyl-2-chloropropionate **1** complexed with heptakis(3-*O*-acetyl-2,6-di-*O*-pentyl)-β-CD (Lipodex D, **2**).[4] On capillary columns coated with **2**, the enantiomers of **1** are resolved with an unusually large separation factor ($\alpha = 2.02$, on a 25 m "fused-silica capillary" at 333 K $\Delta\Delta G^0_{R,S} = 2$ kJ mol^{-1}).

The ^{1}H NMR spectrum of a solution of **1** and **2** in a nonpolar solvent ([D_{12}]cyclohexane, [D_{14}]hexane) shows significantly different signals for (*R*)-**1** and (*S*)-**1**. All signals of the (*S*) enantiomer are shifted to lower field by up to $\Delta\delta = 0.5$ in comparison to the (*R*) enantiomer (Fig. 1). Futhermore,

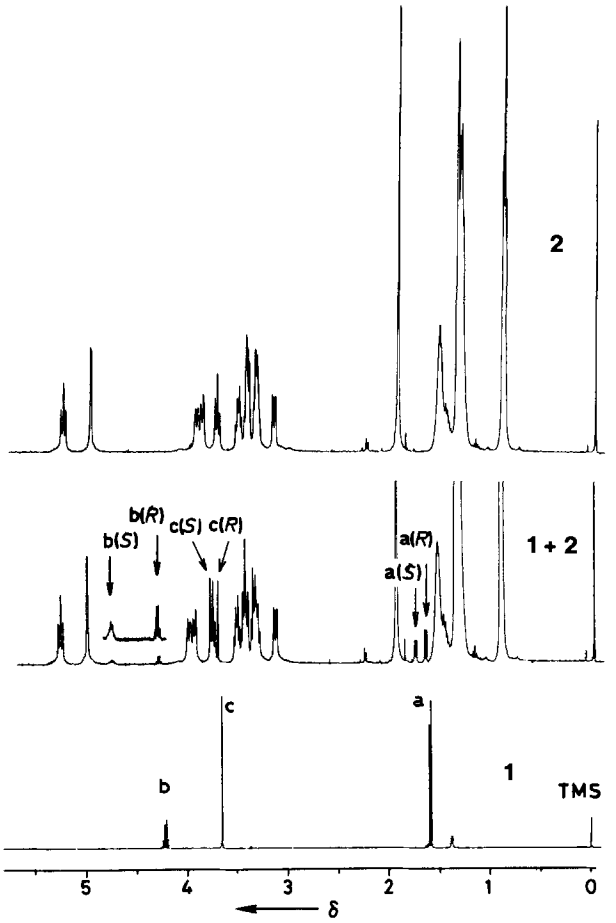

Fig. 1. 400 MHz ^{1}H NMR spectra of (*R*,*S*)-**1** (below) with the signals of the methyl (a), methine (b), and methoxy groups (c), of (*R*,*S*)-**1** and **2** in mol ratio 1:2.25 (middle; the resonance signals a, b, and c show different chemical shifts for the enantiomers) and of **2** (above). All spectra were recorded in [D_{12}]cyclohexane.

the methine proton of (*S*)-**1** does not show a quartet, but a signal of higher order (Fig. 2). This could indicate a nonequivalence of the coupling CH_3 protons as a result of a specific interaction with the chiral host molecule in the inclusion complex.

The differences in the chemical shift values decrease on raising the temperature and also on increasing the host–guest ratio. Similar, though less pronounced effects appeared in the ^{1}H NMR spectra of solutions of **2** and either (*R*,*S*)-methyl-2-bromopropionate, (*R*,*S*)-methyllactate, or (*R*,*S*)-methylmandelate. In every case, the protons of the enantiomer retained more strongly on the GC column also absorb at lower field. Thus, in principle, cyclodextrin derivatives are suitable as chiral shift reagents. A similar example of discrimination for the enantioselective inclusion of enantiomers was reported by A. Collet et al.[5] for bromochlorofluoromethane and a synthetic cryptophane.

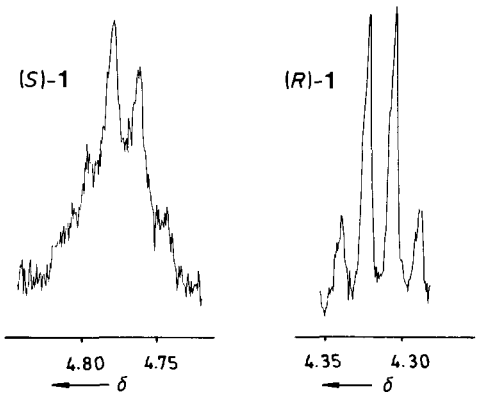

Fig. 2. Resonance signal of the methine proton of (*R*)-**1** (right) and (*S*)-**1** (le Recording conditions as for Figure 1.

To investigate why (*S*)-**1** complexes more effectively wi **2**, a total of four models for molecular dynamics (MD) sir ulations[6] was applied (Fig. 3).

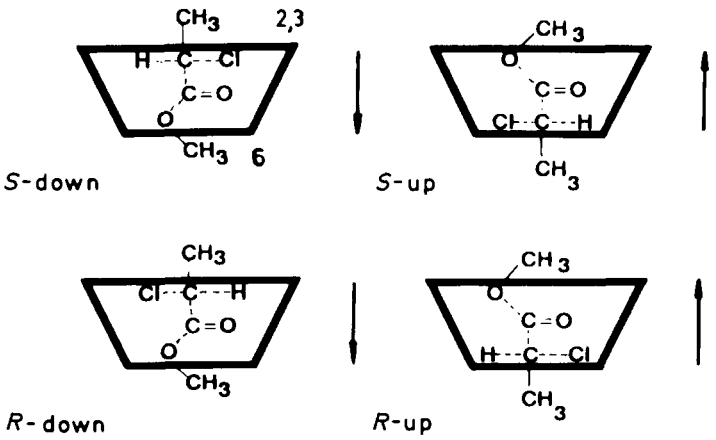

Fig. 3. Molecular dynamic models of complexes from **1** and **2**. The numbers 2, 3, and 6 (in the upper left picture) indicate the position of the substituents at C-2, C-3, and C-6, respectively, of the glucose units of **2**. This position is the same in all four models.

Based on the known X-ray structure data of β-CD,[7] the side chains of **2** were fixed in the 2, 3, and 6 positions of the glucose units, in such a way that they were oriented as evenly as possible vertically upwards (wider opening of the cavity, substituents at C-2 and C-3, see Fig. 3) and downwards (substituents at C-6). The substrates (*S*)-**1** and (*R*)-**1** were placed vertically in both orientations (Fig. 3) in the cavity of **2**.

Following this, the energy was minimized (under vacuum at 0 K) and then an MD simulation using the Discover program (version 2.6) over five picoseconds (ps) was carried out.[8] During the first picosecond the simulation proceeded at a temperature of 3 K, in order to carefully relax the possibly existing large strains of the energy-minimized structures. In the course of the second to fifth picosecond the temperature was 300 K. Both the "*S*-down" and the "*R*-down" complexes proved to be unstable. Already, after the third picosecond, the guest molecule has left the cavity of **2** (Fig. 4a, b). After 5 ps, the host and guest are completely separated. A return is not likely as a result of the high speed of the substrate.

The "*S*-up" complex proved to be the most stable. After the fifth picosecond, the substrate is still found in the cavity of **2** (Fig. 4c). For the "*R*-up" complex, after this time, the guest molecule is outside the cavity but still in the active region of the hydrophobic side-chains (Fig. 4d).

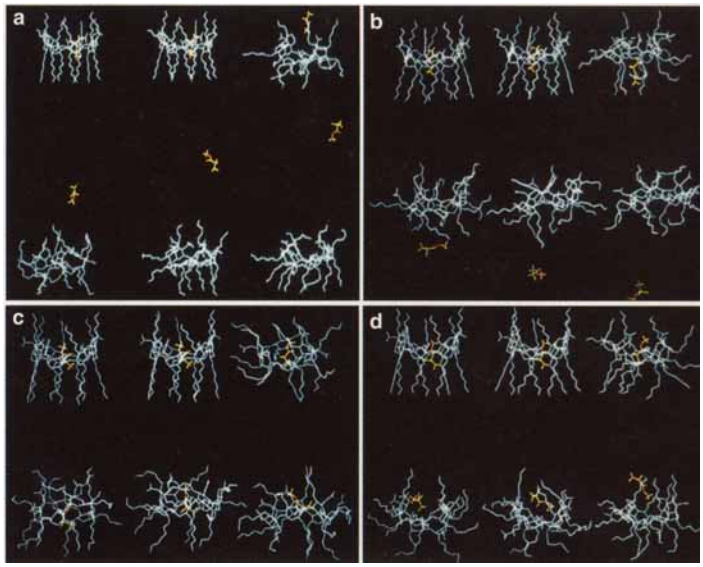

Fig. 4. Molecular dynamic trajectories over 5 ps for the complexes "S-down" (a), "R-down" (b), "S-up" (c), and "R-up" (d) from **1** (yellow and orange) and **2** (blue). The upper left picture shows the starting structure of each, next to which are shown the simulated structures obtained after 1 and 2 ps, and in the second row, those occurring after 3, 4, and 5 ps. Further explanations see text.

These results are in agreement with the GC and NMR results, which show that (*S*)-**1** forms the more stable complex with **2**. Furthermore, NOE measurements on the (*S*)-**1**/**2** and (*R*)-**1**/**2** systems showed that the methoxy group is, in agreement with the "up" orientation of the substrate, in the vicinity of the C-3 proton of the glucose units. A detailed spatial assignment has hitherto not been possible due to the complexity of the NMR spectra.

It should be noted, that a period of 5 ps is not sufficient for an unequivocal result, in the sense of statistical mechanics and with regard to the molecular dynamics. We will continue these studies with the aim to obtain information about the interactions existing for the complexation between host and guest molecules, from the trajectories obtained via simulations over considerably longer periods.

New Intermediate Steps in the Synthesis of Larger Nickel Clusters**

By *Dieter Fenske,** *Harald Krautscheid,* and *Michael Müller*

Phosphane complexes of electron-rich transition metal halides react in organic solvents with silyl derivatives of the elements P, As, Sb, S, Se, and Te with the loss of $SiMe_3Hal$, affording metal-rich clusters.[1] Thus, for example, nickel clusters with 3 to 34 nickel atoms can be isolated from the reaction of $[NiCl_2(PPh_3)_2]$ with $Se(SiMe_3)_2$.[1, 2] These reactions always result in a mixture of cluster complexes, whose structures are influenced by the solvent, the stoichiometric ratio of the starting materials, and the nature of the tertiary phosphanes. To investigate these influences we treated $Se(SiMe_3)_2$ with $[NiCl_2(PR_2R')_2]$ (R = *i*Pr, Phe (Phe = C_2H_4Ph), Et; R' = *i*Pr, Me, Ph) in THF.[3] In addition to the previously discussed cluster complexes we have now been able to isolate and structurally characterize the compounds **1**–**6**.[4, 5]

$[Ni_4Se_3(PPhe_3)_5]$ **1**

$Se(SiMe_3)_2$ → $[NiCl_2(PPhe_3)_2]$ → **3** $[Ni_7Se_5(PiPr_3)_6]$ + $[Ni_8Se_6(PiPr_3)_4]$ **4**

$Se(SiMe_3)_2$ $\xrightarrow{[NiCl_2(PEt_2Me)_2]}$ $[Ni_5Se_4Cl_2(PEt_2Me)_6]$ **2**

$Se(SiMe_3)_2$ → $[NiCl_2(PiPr_3)_2]$ → $[Ni_8Se_6(PEt_2Ph)_6]$ **5** + $[Ni_{21}Se_{14}(PEt_2Ph)_{12}]$ **6**

The cluster complexes **1**–**6** form black crystals whose IR and NMR spectra are not very informative. Following the cluster formation by ^{31}P NMR spectroscopy it can be seen that a) the reactions are only complete after 15–20 days; b) the phosphane selenide $R_2R'PSe$ is always formed as a by-product; c) in the reaction solution, together with other compounds, complexes of the formula $[Ni_3Se_2X_2(PR_2R')_4]$ (X = Cl, $SeSiMe_3$) **7** are always formed.

Complex **7** contains a Ni_3 cluster capped by two μ_3-Se ligands, in which PR_2R' groups and Cl^- or $SeSiMe_3$ ligands are additionally bonded to the Ni centers. It appears that **7** is an important intermediate in the synthesis of metal-rich clusters. The formation of **1** and **2** can be explained as resulting from the reaction of $Se(SiMe_3)_2$ with $[NiCl_2(PPhe_3)_2]$ or $[NiCl_2(PEt_2Me)_2]$ with the reactive Ni–X bonds of **7**.

The structure of **1** (Fig. 1, top) contains a severely distorted Ni_4 tetrahedron (Ni–Ni: 239.3–288.9 pm), in which, as a result of the steric protection from the $PPhe_3$ ligands, only two (of four) faces of the tetrahedron are capped by μ_3-Se (Se1, Se2) ligands. Additionally, Se3 acts as a μ_2-bridge. Due to the phosphanes coordinated to Ni, only Ni3 and Ni4 have similar chemical environments. Ni2 is trigonal-planar, bonded to P2, Se1, and Se2, and Ni1 is tetrahedrally coordinated. Although complex **1** with its 60 VE (valence electrons) fulfills the 18-electron rule for tetrahedral clusters, the Ni_4 cluster is, as mentioned previously, severely distorted.

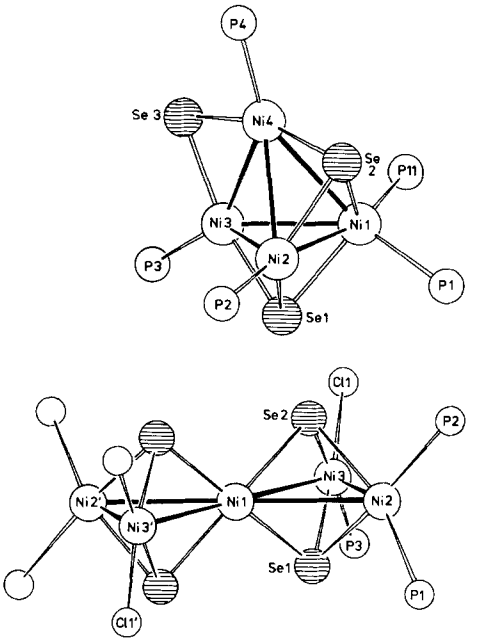

Fig. 1. Molecular structures of **1** (top) and **2** (bottom) (C atoms omitted for clarity). Important distances (± 0.3 pm) and angles (± 0.1°): **1**: Ni1-Ni2 239.3, Ni1-Ni3 283.3, Ni1-Ni4 279.5, Ni2-Ni3 288.9, Ni2-Ni4 288.3, Ni3-Ni4 265.8 (μ_3-Se)-Ni 223.0–238.6, (μ_2-Se)-Ni 221.9–223.4; Ni3-Se3-Ni4 73.3, Ni-(μ_3-Se)-Ni 61.4–79.2, Ni-Ni-Ni 49.4–67.0. **2**: Ni1-Ni2 294.2, Ni1-Ni3 322.8, Ni2-Ni3 298.3, (μ_3-Se)-Ni 229.2–234.5, Ni3-Cl1 223.3; Ni-Se-Ni 78.5–89.2, Ni2-Ni1-Ni3 57.6, Ni1-Ni3-Ni2 56.4, Ni1-Ni2-Ni3 66.0, Ni2-Ni1-Ni2' 180.0, Ni2-Ni1-Ni3' 122.4.

Complex **2** (Fig. 1, bottom) consists of a planar spirocyclic Ni_5 cluster with $\bar{1}$ symmetry which is formed from two vertex-sharing Ni_3 units, both of which are capped by two μ_3-Se ligands. The structural similarity of **2** and **7** is clearly shown by the fact that in **2**, a Ni atom (Ni2) is also bonded to two PEt_2Me ligands, and Ni3 to Cl^- and PEt_2Me ligands. This results in all the Ni atoms exhibiting a slightly distorted square-planar coordination geometry. The structure of **2** is similar to those of $[Pd_5Se_4Cl_2(PPh_3)_6]$, $[NiPd_4S_4Cl_2(PPh_3)_6]$, and a spirocyclic $HgNi_4$ cluster complex recently reported by Kubiak et al.[7] Based on the Ni–Ni distances in **2** (294.2–322.8 pm), it can no longer be assumed that bonding interactions exist between the metal atoms, each of which, after the 80 VE contained in **2** have been formally divided, have 16 VE per Ni center.

Figure 2 shows the structure of **3**, characteristic of which is a mirror plane through the atoms Se1, Se2, Se4, Ni1, Ni2, and Ni5. The structure can be described as consisting of two vertex-sharing tetrahedra. In accordance with the principle for the condensation of clusters this (previously unknown) cluster type contains 102 VE.[15] In the tetrahedron Ni1, Ni3, Ni3', and Ni5 the Ni–Ni distances range from 258.3–280 pm. The shorter bonds connect to Ni5 which is also bonded to the Ni atoms of the second tetrahedron (Ni2, Ni4, and Ni4') which has much shorter Ni–Ni distances (233–234 pm). Similar short Ni–Ni bonds have only previously been found in binuclear complexes such as $[Cp_2Ni_2X_2]$ (X = MeCN, Ph_2C_2, CO).[8] The distances between Ni2, Ni4, and Ni4' of 330 pm are greater than those reported for Ni–Ni bonding.

The polyhedral faces of the bitetrahedra are capped by one μ_3-SeH ligand and four μ_4-Se (Se1, Se2, Se3, Se3') ligands. A topological relationship between the structures of **3**, **7**, and **1** appears to exist. **3** shows an obvious relationship to previously isolated compounds, for example $[Ni_8S_5(PPh_3)_7]$,

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

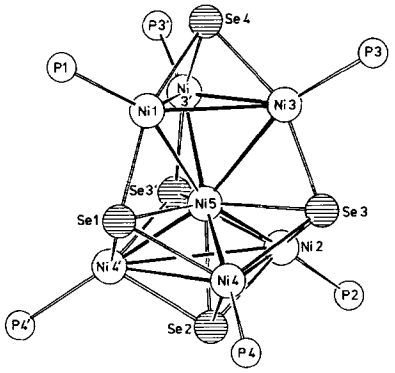

Fig. 2. Molecular structure of **3** (C atoms omitted for clarity). Important distances (± 0.3 pm) and angles (± 0.1°): Ni1-Ni3 274.4, Ni1-Ni5 258.3, Ni2-Ni5 233.0, Ni3-Ni5 259.4, Ni3-Ni3' 280.0, Ni4-Ni5 234.0, Se4-Ni 227.1 und 228.1 (μ_4-Se)-Ni 227.4–251.2, Ni-P 214.3–218.9; Ni1-Se4-Ni3 74.1, Ni2-Se2-Ni5 56.9, Ni2-Se2-Ni4 95.1, Ni2-Se3-Ni4 88.9, Ni3-Se3-Ni4 105.0, Ni2-Ni5-Ni4 96.3, Ni2-Ni5-Ni3 96.5, Ni1-Ni5-Ni2 156.4, Ni1-Ni5-Ni3 64.0, Ni1-Ni3-Ni5 57.8, Ni3-Ni1-Ni5 58.2.

which contains two edge-sharing Ni_5 bipyramids, and $[Ni_9E_9(PPh_3)_6]$ (E = S, Se), consisting of a Ni_9 cluster formed from two face-sharing Ni_6 octahedra.[1, 9] **3** is a probable intermediate on the way to clusters with *trans* face-sharing octahedra of the formula $[Ni_{3n+3}E_{3n+3}(PR_3)_6]$.

The synthesis of **4** (Fig. 3, top) clearly illustrates that other clusters can be formed under the same conditions. Complex **4** consists of a central, almost regular tetrahedron Ni5–Ni8 (indicated by dashed lines in Fig. 3) onto whose tetrahedral faces a further four Ni atoms (Ni1–Ni4) are bonded. The Ni–Ni bonds in the inner tetrahedron (281.1–284.6 pm) are considerably longer than those to the peripheral Ni atoms (247.6–250.1 pm). Alternatively, the eight Ni centers may be considered as being the vertices of a cube, which as a result of strong interactions along the face-diagonals, has been distorted into a dodecahedron consisting of irregular triangles. This distortion is a result of the varying coordination of the Ni atoms.

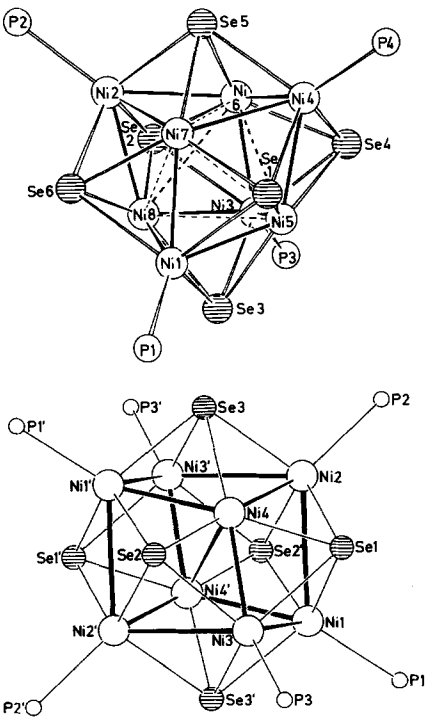

Fig. 3. Molecular structures of **4** (top) and **5** (bottom) (C atoms omitted for clarity). Important distances (± 0.4 pm) and angles (± 0.1°): **4**: Ni-Ni 247.6–250.1 und 281.1–284.6, Ni-Se 227.5–230.1 und 242.2–245.6, Ni-P 218.7–220.0; Ni1-Se1-Ni5 63.7, Ni1-Se1-Ni4 110.9, Ni5-Se1-Ni7 76.6, Ni5-Ni1-Ni7 69.4, Ni1-Ni5-Ni3 107.8, Ni1-Ni5-Ni7 55.1, Ni1-Ni5-Ni6 104.0, Ni6-Ni5-Ni7 60.3. **5**: Ni-Ni4 238.3, Ni4-Ni4' 266.7, Ni1-Ni2 277.9, Ni1-Ni3 274.7, Ni2-Ni3' 273.5, (μ_4-Se)-Ni 225.3–226.3 und 239.9–247.2, Ni-P 221.0–221.6; Ni1-Ni2-Ni3' 92.4, Ni2-Ni1-Ni3 93.5, Ni2'-Ni3-Ni1 93.7, Ni4-Ni2-Ni1 73.3, Ni2-Ni4-Ni3 115.2, Ni2-Ni4-Ni1' 114.2, Ni1'-Ni4-Ni3 113.2, Ni4'-Ni4-Ni3 75.2, Ni2-Ni4-Ni4' 76.8.

Whereas Ni5–Ni8 are each bonded to three Se ligands, Ni1–Ni4 are coordinated to three Se and one $PiPr_3$ ligands. The differing coordination of the Ni atoms probably arises from the large steric demands of the $PiPr_3$ groups.[10] This is shown in the space-filling model for the structure of **4**, in which further coordination of ligands is not possible, since the free coordination sites at Ni5–Ni8 are effectively protected by the *i*Pr groups.

Complex **4** has 112 VE and therefore fits the series of known cubic Ni_8 clusters. A shortening of the Ni–Ni bonds and a distortion of the Ni_8 cube is observed with an increasing deviation from the expected valence electron number (120 VE).[11] The ratio r of the length of the face-diagonal to the length of the edge of the cube can be used as a measure of the distortion. In clusters with 120 VE, for example $[Ni_8S_6(PPh_3)_8]$ or $[Ni_8Se_6(PnBu_3)_8]$, regular Ni_8 cubes (Ni–Ni: 270 pm) are found with $r = 1.41$.[11] In contrast, for $[Ni_8(PPh)_6(PPh_3)_4]$ (Ni–Ni: 251.7–254.1; Ni···Ni: 323–325 pm) containing 112 VE r = 1.28, and in **4** this value is further reduced to 1.14.[12] The differing bonding situations of the Ni centers also have an influence influence on the Ni–Se bond lengths, which for the Ni atoms with the coordination number three (Ni5–Ni8) of 227.5–230.1 pm are about 15 pm shorter than those for the Ni atoms with the coordination number four (Ni1–Ni4) (242.2–245.6 pm).

The controlling influence of the ligands on the cluster structure is clearly illustrated by the molecular structure of **5**. As in **4**, a distorted cube ($\bar{1}$ symmetry) exists, whose cubic faces are capped by μ_4-Se ligands. Six Ni atoms show the coordination number four and are bonded to three Se and one PEt_2Ph ligand (Ni1, Ni2, Ni3, Ni1', Ni2', Ni3'), whereas Ni4 and Ni4'are bonded only to three Se ligands. This coordination deficiency leads to a distortion of the Ni_8 cube along the solid-diagonal (Ni4–Ni4' 266.7 pm). The bonds from Ni4 to Ni1', Ni2, and Ni3 of 238.3 pm are considerably shorter than the other Ni–Ni distances (266.7–277.9 pm). In **5**, as in **4**, the Ni–Se bonds (225.3–226.3 pm) to the Ni centers with the coordination number three are approximately 14–21 pm shorter than those to the Ni centers with the coordination number four. Complex **5** contains 116 VE, four electrons fewer than would be expected for a cubic cluster.

The metal-rich cluster complex **6** can be isolated—depending on the reaction time—from the reaction of $[NiCl_2(PEt_2Ph)_2]$ with $Se(SiMe_3)_2$. Its structure ($\bar{1}$ symmetry) consists of a central Ni_{13} cuboctahedron (Ni5–Ni11 and the inversion-related Ni atoms) of which two Ni_4 faces (Ni5–Ni8, Ni5'–Ni8') are bonded to Ni1–Ni4 forming two cubes (Fig. 4). All Ni–Ni distances lie in the range 257.6–280.0 pm and correspond to the values observed in other selenium-capped Ni clusters.[1] The central, slightly distorted cuboctahedron represents a section of a face-centered cubic packing. Previously reported compounds containing this structure fragment include; $[Pt_6Ni_{38}(CO)_{48}H_2]^{4-}$, $[Pd_{38}(CO)_{28}(PEt_3)_{12}]$ and $[Pd_{23}(CO)_{22}(PEt_3)_{10}]$.[13]

The structure of the Ni_{21} framework can be regarded as an intermediate step to a series of "super clusters", in which a central M_{13} cuboctahedron is surrounded by n shells which contain $(10n^2 + 2)$ metal atoms ($n \geq 2$). This principle proposed by G. Schmid is illustrated by $[M_{55}Cl_6(PPh_3)_{12}]$ (M = Rh, Au).[14] In **6**, Ni1–Ni4 and Ni1'–Ni4' can be con-

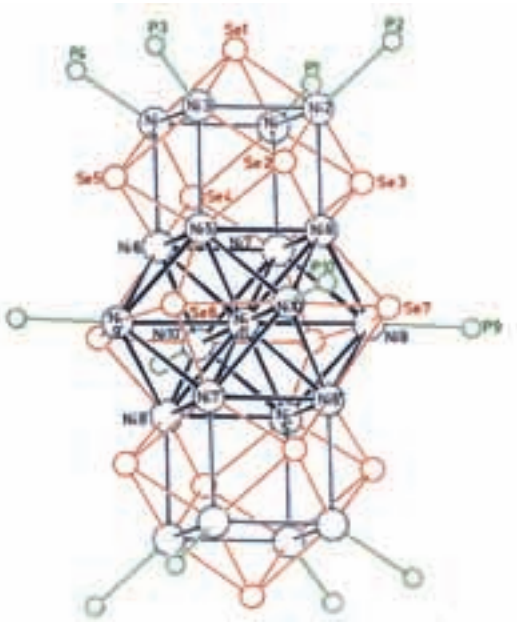

Fig. 4. Molecular structure of **6** (C atoms omitted for clarity). Ni: blue, Se: red, P: green. Important distances (± 0.2 pm) and angles (± 0.1°): In the cuboctahedron: Ni-Ni 260.6–272.4, Ni11-Ni 257.6–280.0; in den Ni_8-Kuben: Ni1-Ni2 263.8, Ni2-Ni3 265.7, Ni3-Ni4 265.1, Ni1-Ni7 262.1, Ni2-Ni8 259.3, Ni3-Ni5 261.4, Ni4-Ni6 262.3, (μ_4-Se)-Ni 231.0–241.9, Ni-P 219.4–225.8; Ni2-Ni1-Ni7 91.1, Ni1-Ni4-Ni3 90.3, Ni6-Ni11-Ni7 61.1, Ni8'-Ni11-Ni5 62.0, Ni7-Ni11-Ni9' 121.4, Ni7-Ni11-Ni9 58.5.

sidered as being part of a second shell, which could contain a maximum of 42 Ni atoms.

The metal framework is stabilized by 14 μ_4-Se capping ligands (Ni–Se 231.0–241.9 pm). Additionally, the Ni periphery (Ni1–Ni4, Ni9, Ni10, and the inversion-related Ni atoms) is bonded to 12 PEt_2Ph groups which provide full protection of the $Ni_{21}Se_{14}$ core. Complex **6** contains 290 VE, which is 16 electrons more than is predicted by the 18-electron rule if all Ni–Ni bonds shown in Figure 4 are considered as two-center two-electron bonds. The principle for condensation of clusters from D.M.P. Mingos affords a valence electron number of 286 which is in good agreement with the valence electron number of **6**.[15]

Synthesis and Structure of $[Ni(PtBu_6)]$ and $[Ni_5(PtBu)_6(CO)_5]$ and Calculations on the Electronic Structure of $[Ni(PtBu)_6]$ and $(PR)_6$, R = tBu, Me**

By *Reinhart Ahlrichs*,* *Dieter Fenske*,* *Hannes Oesen*, and *Uwe Schneider*

Cyclic phosphanes $(PR)_n$ (R = organic group, $n = 3–6$) have already been the subject of numerous studies,[1] and

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

they can be used as ligands in transition-metal complexes.[2, 3] For example, upon reaction of $(PR)_n$ with metal carbonyl compounds either derivatives with cyclic phosphane ligands or complexes with PR chains as ligands are obtained. In some cases a ring expansion of the cyclophosphane has also been observed. Thus, the mononuclear complex $[Mo(CO)_4(PEt)_5]$ is obtained upon reaction of $(PEt)_4$ with $[Mo(CO)_6]$.[4] We have now found a simple method for the synthesis of $[Ni(PtBu)_6]$ (**1**).

$NiCl_2$ was allowed to react with $P(SiMe_3)_3$ and $(PtBu)_3$ in THF affording a black solution, from which yellow crystals of **1** could be isolated in about 30% yield. Apparently **1** is formed as a result of a redox reaction of $NiCl_2$ and a ring expansion of the P_3 ring to a P_6 ring. Compound **1** is diamagnetic and decomposes slowly in solution with formation of nickel and $(PtBu)_4$.[5] In the ^{31}P NMR spectrum of **1** a resonance signal is observed at $\delta = -183$ (121.5 MHz, C_6D_6, 25 °C, H_3PO_4 ext. standard), and in the mass spectrum the molecular ion is found with the expected isotopic distribution.

$$NiCl_2 + 2(PtBu)_3 \xrightarrow[-Me_3SiCl]{P(SiMe_3)_3} [Ni(PtBu)_6] \quad \mathbf{1}$$

According to a crystal structure analysis,[6] **1** contains a P_6 ring at the center of which a Ni atom is located (Fig. 1).

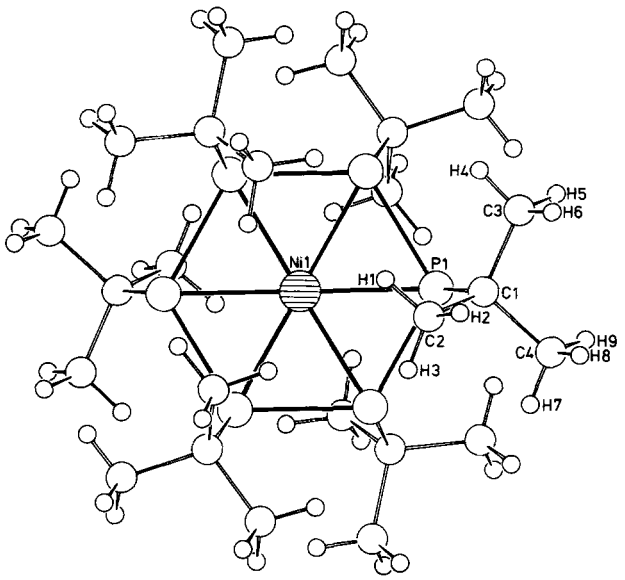

Fig. 1. Crystal structure of **1**. Important bond lengths [pm] and angles [°]: Ni-P 229.0(1), P-C 191.6(1), C-C 151.9–153.1(3), P-P 229.1(7); P-Ni-P 60.0(0), 120.0(0), 180.0(0), Ni-P-C 114.7(1), P-P-C 100.4, 104.5.

The maximum deviation of the atoms from the NiP_6 plane is ±1.1 pm. Three P atoms lie above, while the other three P atoms lie below this plane. The Ni–P distance (229.0(1) pm) is relatively large.[7] For example, in $[(PtBu)_2Ni(PtBu)_4]$ (**2**), a structural isomer of **1**, values of 215–226 pm are found for the Ni–P bond lengths.[8] A further remarkable feature are the unusually long P–P distances (229.1(1) pm) in **1**, which are about 6–12 pm longer than in free $(PPh)_6$ (223.7(5) pm), in **2** (219.6–223.7(4) pm), and in $(PtBu)_3$ (218.5–221.8 pm).[8–10]

The synthesis of **1** is remarkable, since apparently it has not hitherto been possible to isolate free $(PtBu)_6$ or to prepare complexes of this type. As illustrated in Figure 2, the Ni

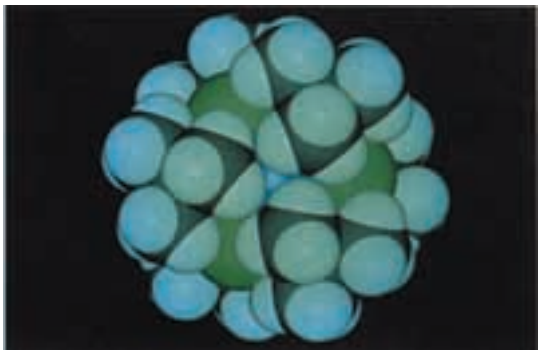

Fig. 2. Space-filling model of **1** (Ni blue, P green, H white).

atom located at the center of the P_6 ring of **1** is, however, so effectively shielded by the *t*Bu groups that this can be regarded as the reason for its stability.

The bonding situation in **1** could be described in terms of the Ni being present in the zero oxidation state. We have therefore attempted to prepare **1** by direct reaction of $(PtBu)_3$ with $[Ni(CO)_4]$ in diethyl ether. Rapid evolution of CO and concomitant formation of a dark solution was observed. After removal of the solvent by distillation, and recrystallization of the residue from pentane, black crystals of **3** were obtained. In the IR spectrum of **3** the ν(CO) vibration can be observed at 1967 cm^{-1}, and in the ^{31}P NMR spectrum four multiplets appear at $\delta = 137$, 253, 727, and 795 (121.5 MHz, C_6D_6, 25 °C, H_3PO_4 ext. standard).

$$(PtBu)_3 \xrightarrow{[Ni(CO)_4]} [Ni_5(PtBu)_3(P_3tBu_3)(CO)_5] \quad \mathbf{3}$$

3 (Fig. 3) can be regarded as an intermediate in the formation of a cluster analogous to $[Ni_8(PPh)_6(CO)_8]$ in which only three Ni atoms are missing for the construction of the

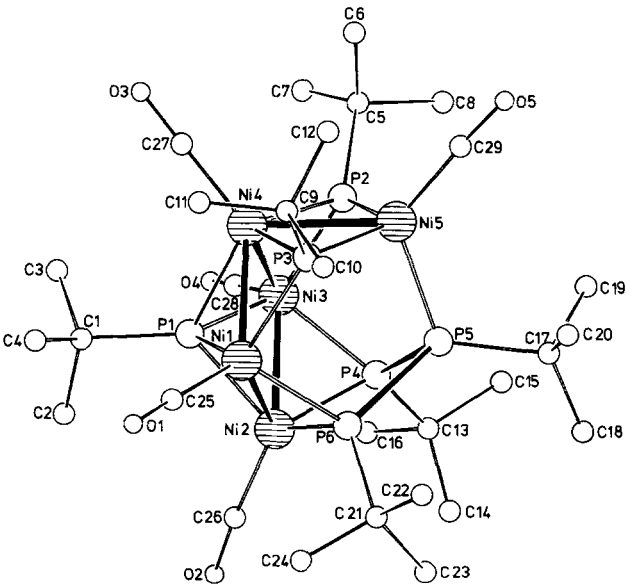

Fig. 3. Crystal structure of **3** (H atoms omitted). Important bond lengths (±0.2 pm) and angles (±0.1°): Ni1-Ni2 259.2, Ni1-Ni4 261.4, Ni2-Ni3 260.1, Ni3-Ni4 259.7, Ni4-Ni5 258.6, Ni-P1 219.5–223.3, Ni-P2 215.1–220.0, Ni-P3 214.8–220.5, Ni-P4 216.9–217.7, Ni5-P5 221.0, Ni-P6 217.0–218.4, P4-P5 225.2, P5-P6 226.2; Ni2-Ni1-Ni4 88.5, Ni1-Ni2-Ni3 91.6, Ni2-Ni3-Ni4 88.7, Ni1-Ni4-Ni3 91.2, Ni1-Ni4-Ni5 87.6, P6-P5-P4 79.7.

Ni_8 cube.[7, 11] This assumption is supported by the geometry of the Ni_5 cluster (Ni–Ni–Ni 87.6–91.6°, Ni–Ni 258.6–261.4 pm). The Ni atoms are each bound in a distorted tetrahedral fashion to a terminal CO ligand and to three P*t*Bu ligands. Different types of phosphane bridges are formed thereby. P1 acts as μ_4-bridging ligand while P2 and P3 act as μ_3-bridging ligands (Ni–P 214.8–223.3). The atoms P4–P6, on the other hand, form a P_3 chain, which is bound as a $\mu_4(\eta^2,\eta^{1'},\eta^{2''}$-ligand to Ni1, Ni2, Ni3, and Ni5 (Ni–P 216.9–220.5 pm). Apparently it is a P_3tBu_3 ligand formed by ring-opening of $(PtBu)_3$. Compound **3** fulfills the 18e-rule (80 VE) if the μ_3- and μ_4-P*t*Bu bridges are considered as 4e donors and the P_3tBu ligand as 8e donor.

To gain insights into the bonding situation and its correlation with the structure and stability of **1**, ab initio calculations[12] were carried out for **1**, $(PtBu)_6$ (**4**), $(PtBu)_4$, and the corresponding methyl compounds. MP2 calculations were also carried out, in so far as the size of the molecules allowed, in an attempt to describe approximately the electron correlation. Starting from the point group D_3, the structure of $(PtBu)_6$ (**4**) converges to a D_{3d} structure (Fig. 4). A lowering of symmetry ($D_{3d} \rightarrow D_3$) by rotation of the *t*Bu groups about the P–C axis by 9° increases the energy only slightly, by 8 kJ mol^{-1}. Within the limits of accuracy of the calculation, however, a D_3 structure cannot be ruled out.

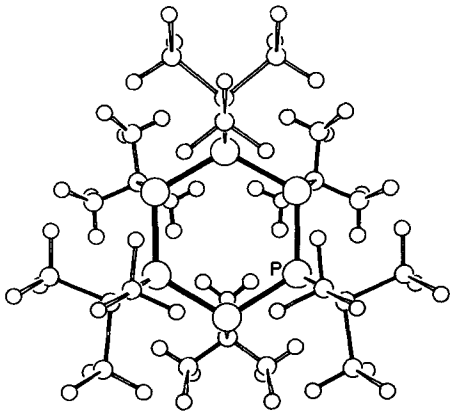

Fig. 4. Calculated molecular structure of $(PtBu)_6$ (**4**).

The P_6 ring has a slightly puckered chair form (deviation of 5.6 pm from the mean plane) with normal P–P distance.[8–10] Apparently the almost planar P_6 ring results from the steric requirement of the *t*Bu group, which is also reflected in the rather long P–C distance. In the case of $(PMe)_6$ (D_{3d}), on the other hand, a deviation from the plane of 32.3 pm and a P–C distance of 187.5 pm (4.1 pm shorter than in **4**) were obtained.

The SCF calculation of $(PtBu)_4$ yielded the structural parameters listed in Table 1. Accordingly, the SCF energy of one and a half molecules of $(PtBu)_4$ is 15 kJ mol^{-1} lower than that of **4**, even though P_4 rings are generally not very stable (as is also reflected in the P–P distance, which is elongated by 1.3 pm compared to that in the P_6 ring). The steric requirement of the *t*Bu group in $(PtBu)_4$ is easier to satisfy than in **4**. It is understandable, therefore, that **1** (in an unknown way) reacts with formation of $(PtBu)_4$. In the calculations for **1**, a closed-shell atomic wave function ($^1A_{1g}$ in D_{3d} and $^1A_1$ in D_3) was used, since **1** is diamagnetic. Subsequent calculations of triplet states always led to higher energy: **4** has no unoccupied low-lying MOs which could accept an electron from Ni. Optimization of the structure led to D_3 symmetry; the energy, however, is only 1.6 kJ mol^{-1} lower than for D_{3d} symmetry.

Table 1. Structure parameters of $(PtBu)_4$, **1**, and **4** calculated by SCF methods [12].

	$(PtBu)_4$	**1**	**4**
Point group	D_{2d}	D_3	D_{3d}
Distances [pm]

center-P-C	–	–	119.9
E_{SCF} [au]	−1989.07488	−4490.20551	−2983.60672

A comparison of the calculated structure parameters of **1** (Table 1) with those of the crystal structure analysis shows agreement within 3 pm/3°. This is remarkable, since larger errors were to be expected in the case of the calculation. Noticeable features in comparison with **4** are the longer (by 8 pm) P–P distance and a further planarization of the P_6 ring (deviation of the P atoms of 0.2 pm from the plane). The stability of **1** is obviously not due to cage effects, since **1** is considerably more stable than Ni + **4**.[13]

Population analyses[14] show that Ni is present in the zero oxidation state. The two methods of analysis gave net charges (over all atoms) of less than 0.2e.

The analysis according to Mulliken is particularly informative regarding the bonding situation. It furnishes the following valence populations: **4**: P $3s^{1.67}3p^{3.24}3d^{0.14}$; **1**: P $3s^{1.75}3p^{3.21}3d^{0.15}$, Ni $3d^{9.51}4s^{0.27}4p^{0.05}$. To a first approximation, Ni is present in the electronic configuration $3d^{10}$. The electron transfer in the Ni-4s AO is compensated by back bonding from the Ni-d_{xy}, and Ni-$d_{x^2-y^2}$ AOs (occupation in each case 1.78) to P–P antibonding e* MOs of the ring. This is seen in the strong interaction of these Ni AOs with the MOs of the P_6 ring, which is also reflected in the expansion of the ring. The electronic structure of **1** cannot be described in terms of the 18e rule. Electron correlation effects[13] are decisive for the stability of **1**, as is also the case for other Ni^0 compounds.[15]

Experimental Procedure

1: A suspension of anhydrous $NiCl_2$ (0.8 g, 6.2 mmol) in THF (50 mL) was treated with tri-*tert*-butylcyclotriphosphane (3.26 g, 12.4 mmol) and $P(SiMe_3)_3$ (1.0 g, 4.0 mmol). After a short time the $NiCl_2$ dissolved to give a black solution, from which a yellow oil separated. The solvent was removed by distillation, and the resulting residue was dissolved in pentane (40 mL). After filtration from the insoluble residue, large yellow crystals of **1** crystallized from the filtrate. Yield: 1.08 g (30%).

3: A solution of $(PtBu)_3$ (1 g, 3.8 mmol) in THF (20 mL) was treated at 20 °C with $[Ni(CO)_4]$ (1.29 g, 7.6 mmol). The solution darkened with concomitant evolution of CO. After 2 h the solvent was removed in a vacuum and the residue was recrystallized from pentane. Compound **3** crystalllized in the form of *black crystals*. Yield: 1.45 g (80%).

[12] The calculations were carried out with a Workstation IBM 6000/320 and the program system TURBOMOLE (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, 162, 165). The following basis sets were used: Ni, a Wachters basis of type (14s,11p,6d)/[8s,7p,4d] extended by (2p,1d) (A. J. H. Wachters, *J. Chem. Phys.* **1970**, *52*, 1034); P, (11s,7p,1d)/[6s,4p,1d]. C(P-bound): (8s,4p)/[4s,2p], from: S. Huzinaga, *Approximate Atomic Wavefunctions*, Department of Chemistry Report, University of Alberta, Edmonton, Alberta, Canada, **1971**; remaining C,H: minimum basis (9s,3p)/[2s,1p], and (3s)/[1s], respectively, which were completely energy-optimized for neopentane.
[13] The reaction Ni($3d^{10}$) + **4** → **1** is 168 kJ mol^{-1} exothermic in the SCF approximation. MP2 calculations for the corresponding Me-compounds gave a further stabilization of ca. 613 kJ mol^{-1} by correlation effects, which should also apply in the case of the *t*Bu compound. Since the $^3F(3d^8\,4s^2)$ ground state of Ni is 1.83 eV (176 kJ mol^{-1}) more stable than the $^1S(3d^{10})$ state (A. A. Radzig, B. N. Smirnow: *Reference Data on Atoms, Molecules and Ions*, Springer, Berlin **1985**, p. 157) the stability of **1** can be estimated to a very rough approximation to be 600 kJ mol^{-1}.

Dynamic Forcing, a Method for Evaluating Activity and Selectivity Profiles of RGD (Arg-Gly-Asp) Peptides

By *Gerhard Müller, Marion Gurrath, Horst Kessler,** and *Rupert Timpl*

A detailed knowledge of the receptor-bound conformation of substrate molecules and of the complementary receptor surface is of primary importance for rational drug design. Provided that the three-dimensional structure of a receptor or of the receptor–substrate complex are unknown, investigations of conformationally restricted model peptides containing biologically relevant recognition sequences offer a straightforward approach to characterize the requirements for binding.[1]

The tripeptide sequence RGD (Arg-Gly-Asp) was identified as a universal cell-recognition sequence within several extracellular matrix proteins. These proteins bind to transmembrane cell surface-receptors, the so-called integrins, and are involved in a variety of physiologically important processes like cell differentiation, platelet aggregation, and tumor metastasis.[2, 3]

We have synthesized several cyclic RGD peptides to study the conformational influence of the RGD sequence on the specificity of different integrin–RGD peptide interactions. In all peptides the same lead sequence was fixed in different conformations by variation of the chirality of selected residues. The peptides show a wide variety of biological activities in inhibition assays of tumor cell **adhesion**.[4] Of primary interest are the cyclic pentapeptides *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) = c(RGD*F*V) (**1**) and *cyclo*(-Arg-Gly-Asp-Phe-D-Val-) = c(RGDF*V*) (**2**). Compared to the prototype linear standard peptide GRGDS and the linear parent sequence of **2**, both peptides inhibit tumor cell adhesion, mediated by the laminin fragment P1, with activities which are two orders of magnitude higher (Fig. 1).

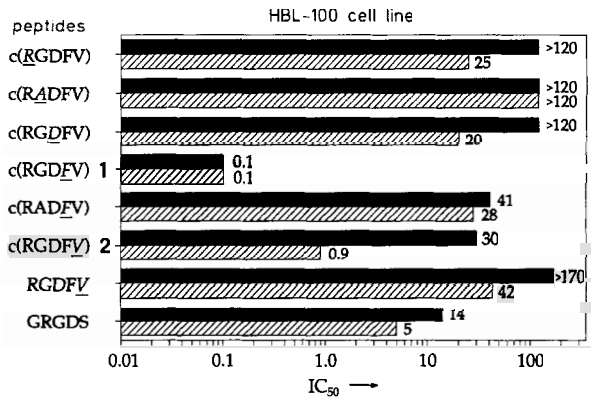

Fig. 1. IC_{50} [10^{-6} M] values of pentapeptides against laminin P1 (hatched) and vitronectin (filled) mediated tumor-cell adhesion. The D amino acid is printed in italics and underlined.

The conformation of the RGD sequence within the cyclic peptides is therefore closely related to the structure in the receptor-bound state. The increased activity of the cyclic peptide **2** compared to the linear precursor peptide RGDFV is due to a smaller loss of conformational entropy of cyclic compounds during binding.

Peptide **1** also inhibits vitronectin-mediated tumor-cell adhesion in a submicromolar range, but **2** is less active there. This demonstrates for the first time that enhanced selectivity can be achieved by conformational restriction of RGD peptides. In the following discussion, this biological observation will be correlated with structural features of the peptides by using molecular dynamics (MD) techniques.

The analysis of the conformations of peptides **1** and **2** results in identical structures for the common βII'γ turn motif. However, the position of the RGD sequences within the underlying structural templates is different in these two compounds. In peptide **1** the RGD sequence forms a tight γ turn with Gly in the central position. The Arg and Asp side chains

[**] This investigation was supported by the Fonds der Chemischen Industrie (doctoral fellowship for GM), the Studienstiftung des deutschen Volkes (doctoral fellowship for MG), and the Deutsche Forschungsgemeinschaft.

are oriented almost parallel to one another on the same side of the peptide ring. As expected the D residue (Phe) occupies the i + 1 position of the βII′ turn. In contrast the essential Arg and Asp side chains point in opposite directions in peptide **2**, so that the guanidino and carboxy functionalities are separated by a larger distance (Fig. 2).

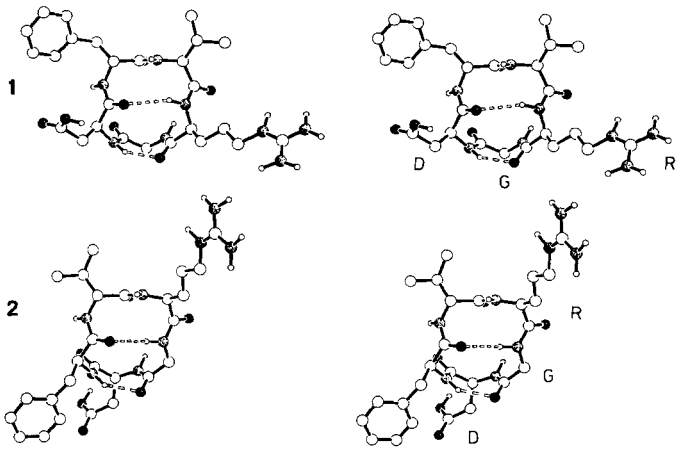

Fig. 2. Stereoplot of the NMR-derived conformations of c(RGDFV) **1** (above) and c(RGDFV) **2** (below). Oxygen atoms are filled, nitrogen atoms are shaded, and carbon atoms are shown as open spheres. Only hydrogen atoms of polar atom groups are shown explicitly. Both conformations are oriented so that the βII′ turn is located in the upper part of the molecule. The hydrogen bonds are indicated as dotted lines.

Based on the results of the inhibition experiments we propose the structure of **2** as the bioactive conformation for the laminin P1 receptor. The significantly different conformation of **1** is thought to be related to the receptor-bound conformation for the vitronectin receptor. This is sufficient to explain the interaction of the c(RGDFV)–laminin P1 receptor and the c(RGDFV)–vitronectin receptor, but not the nonselective binding of the more active peptide **1** to the laminin P1 receptor.

Valuable information was obtained for solving this contradiction from careful examination of the MD simulations. For **1** an unexpected hydrogen-bond pattern results from a 70 ps trajectory of a MD simulation in a dimethyl sulfoxide (DMSO) solvent box.[5] Peptide **1** forms the predicted hydrogen bonds between Arg^1NH and Asp^3CO and between Asp^3NH and Arg^1CO, and surprisingly an additional pair which is similar to that determined for peptide **2** (Table 1).

Table 1. Analysis of hydrogen-bond patterns over the last 70 ps of the 100 ps MD simulations of c(RGDFV) **1** and of c(RGDFV) **2**. r_{DA} = donor-acceptor distance, θ_{DHA} = donor-proton-acceptor angle.

	Donor	Acceptor	r_{DA} [pm]	θ_{DHA} [°]	Population [%]	Turn
1	Arg^1NH	Asp^3CO	341	160	41	βII
	Asp^3NH	Arg^1CO	294	139	85	γ
	Gly^2NH	Phe^4CO	348	135	20	βI *shift*
	Phe^4NH	Gly^2CO	321	134	37	γ_i *shift*
2	Gly^2NH	Phe^4CO	313	161	98	βII′
	Phe^4NH	Gly^2CO	283	142	95	γ

This fact indicates a second accessible conformation for peptide **1**, a finding which could not be extracted from any experimental data.

To verify this assumed receptor-specific transition we employed the method of *dynamic forcing*.[6] Dynamic forcing is a restrained molecular mechanics technique, in which a dihedral restraining is superimposed onto molecular dynamics simulations by extending the force field with an additional harmonic potential function that forces selected torsions into defined target values. For the simulation of **1** the main-chain dihedral angles of peptide **2** served as target values. Peptide **2** was forced to change its conformation to a structure related to that of **1**. By evaluating energetic parameters and by scaling the restraining force constant, dynamic forcing gives an impression of possible transition pathways.

Peptide **1** changes its conformation to the desired target structure of **2** during the initial phase of the 30 ps simulation (Fig. 3, center). The structural analysis of the trajectory

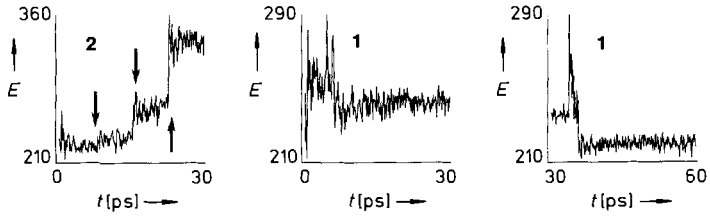

Fig. 3. Analysis of simulations with dynamic forcing for c(RGDFV) **2** (increase of the force constant is marked by arrows) and c(RGDFV) **1** of 0–30 ps as well as for **1** of 30–60 ps. E in kcal mol^{-1}.

shows stable intermediates as "snapshots" of the transition (Fig. 4). The peptide reaches a $\beta II'\gamma_i$ structure via the already populated shifted $\beta I\gamma_i$ conformation. The inverse γ turn (γ_i) then changes into a regular γ turn, so that the βII′γ target conformation, identical to that determined for **2** (Fig. 2, bottom) is adopted. The interconversion of the γ_i into the γ turn is a sterically hindered process as indicated by the energy barrier around 5–7 ps (Fig. 3, center).

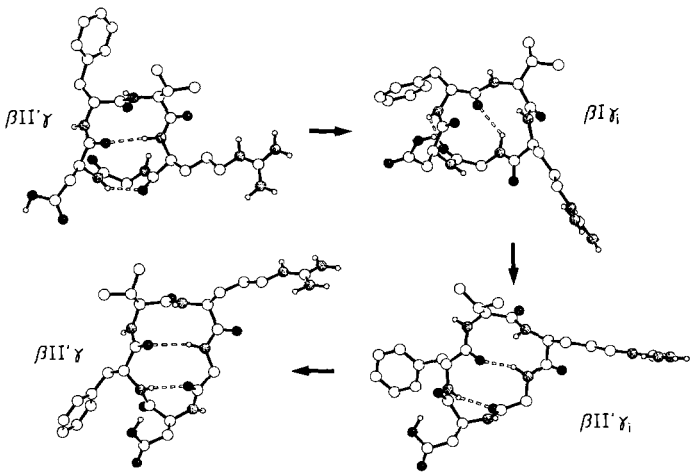

Fig. 4. Monitored intermediates of **1** with stable turn structures during the simulated conformational transition.

Peptide **2** is not able to adopt the target conformation under the same simulation conditions, although the force constant for the restraining term was increased. This is the reason for the stepwise increase in the potential energy profile for **2** in Figure 3 (left). Only energetically unfavorable conformations were observed.

We have extended the simulation of peptide **1** to 60 ps, changing the applied target torsion values after the first 30 ps

in such a way that the peptide is forced back into its initial, NMR-derived conformation. Again the peptide changes to the target structure in the initial phase of the simulation (6 ps) (Fig. 3, right). It is obvious that the NMR-derived conformation is the energetically favored structure, but the conformational transition induced by the laminin P1 receptor is easy to perform.

The positioning of the essential RGD sequence in conformationally restricted molecules that are defined by a rational design principle led to highly active and selective compounds. The combination of biological data and conformational characteristics allows the definition of conformation–activity relationships and furthermore implies a dynamic model of receptor–substrate interactions. Hence, from these computer simulation techniques it was possible to explain the biological profile of RGD peptides.

From the recently published conformational analysis of two native RGD-containing proteins, kistrin[7] and echistatin,[8] members of the disintegrin family, it was not possible to derive a bioactive RGD conformation, because the RGD sequence is located in both proteins in exposed and highly *flexible* loop regions. Our study of conformation–activity relationships with an underlying dynamic aspect demonstrates the importance of taking into account conformational changes of substrate molecules during receptor binding. The receptor exerts a *conformational pressure* on a substrate, enabling different substrate conformations to be induced, depending on the receptor environment.

Experimental Procedure

For structure refinement MD simulations were performed with the GROMOS force field [9] and NMR-derived interproton distances as constraints. The initial structure was built up manually so that no secondary structure elements were preformed. After energy minimization the structure was simulated by MD for 2 ps at 1000 K, 3 ps at 500 K, and further 5 ps at 300 K in vacuum with a distance-restraining force constant of 4000 kJ mol^{-1} nm^{-2}. The obtained conformation served as the initial structure for a 150 ps solvent simulation in a DMSO solvent box [5] with a box length of approximately 3.5 nm containing about 150–180 DMSO molecules. After the first 70 ps MD the distance restraining force constant was reduced from 1000 kJ mol^{-1} nm^{-2} to 500 kJ mol^{-1} nm^{-2} for further 30 ps. The last 50 ps of the 150 ps trajectory were simulated without any restraint to make sure that the obtained conformation after 100 ps restrained MD was a low-energy structure.

For the simulation of the conformational transitions of **1** and **2** the CVFF (*C*onsistent *V*alence *F*orce *F*ield) was employed which is implemented in the DISCOVER (BIOSYM) program package [10]. The force field was extended by a harmonic potential function for the dihedral-angle restraints. These simulations were performed in vacuum over 30 ps. The dihedral-angle restraining force constant was set for the first 7.5 ps at 1 kcal rad^{-2} and was increased in 7.5 ps steps to 2.5 kcal rad^{-2}, 5 kcal rad^{-2}, and 10 kcal rad^{-2}.

Selective Inhibition of Trypanosomal Triosephosphate Isomerase by a Thiopeptide**

By *Horst Kessler,* Hans Matter, Armin Geyer, Hans-Jürgen Diehl, Matthias Köck, Guido Kurz, Fred. R. Opperdoes, Mia Callens,* and *Rik K. Wierenga*

Dedicated to Professor Gerhard Quinkert on the occasion of his 65th birthday

Although much effort has been invested in the study of sleeping sickness its control has not yet been achieved.[1] The germs causing this tropical disease (*Trypanosoma brucei brucei*) obtain their energy exclusively from glycolysis. Thus, the synthesis of selective inhibitors of glycosomal enzymes of the pathogen is a promising approach.[2] In our investigations of the inhibition of trypanosomal *t*riosephosphate *iso*merase (TIM), EC 5.3.1.1), a key enzyme in this process,[3] we have developed several cyclic hexapeptides which have shown remarkable effectiveness and selectivity.[4] Several determinations of the crystal structure of TIM are known,[5] but the binding site of peptide inhibitors has not been localized until now.

Here we report the improvement of biological activity of a cyclic peptide, which was achieved by conformational changes in the peptide backbone. All side-chain functionalities were unmodified. The selective introduction of a thiocarbonyl group into the cyclic hexapeptide *cyclo*(Gly^1-Pro^2-Phe^3-Val^4-Phe^5-Phe^6) induces a drastic change in the backbone conformation,[6] resulting in a remarkable enhancement in the selective inhibition of trypanosomal TIM. The O/S exchange (*thionylation*) within conformationally restricted peptides can take place with high regioselectivity.[6, 7]

The introduction of a thiocarbonyl group as a modification of a peptide bond is an isosteric replacement of a carbonyl group. The local geometry in the vicinity of this fragment is scarcely influenced.[7] However, by the selective exchange of a CO-NH unit by its sulfur analogue the formation of transannular hydrogen bonds within the peptide can be influenced. The C=S fragment exhibits weaker acceptor properties, and due to its enhanced acidity the neighboring amide proton is a better donor than the oxo analogue. In addition, the larger van der Waals radius of the sulfur and the longer C=S bond limit the $\{\varphi, \psi\}$ conformational space in a characteristic manner: The thiocarbonyl fragment can be positioned at the i + 1 and i + 2 positions of a βI turn but only at the i + 2 position of a βII turn. The unfavorable steric interaction of the sulfur with the side chain of the L-amino acid in the i + 2 position prohibits the adoption of the βII turn.[8]

The thionylation of the peptide described here causes a remarkable increase of its inhibitory effect on trypanosomal TIM. Although the cyclic oxopeptide *cyclo*(Gly^1-Pro^2-Phe^3-Val^4-Phe^5-Phe^6) has only weak biological activity (Table 1), the analogous thiopeptide *cyclo*(Gly^1-Pro^2-Phe^3-Val^4-

Table 1. Inhibition of TIM by cyclic hexapeptides.

Peptide	IC_{50} [a] [μM] gTIM	R-TIM
cyclo(G-P-F-V-FΨ[CS-NH]F)	6	>100
cyclo(G-P-F-V-F-F)	150	>500
cyclo(P-F-F-K(Z)-W-F) F3-008	3	>125 [b]
cyclo(P-F-T-K(Z)-W-F) 008	7	>125 [b]

[a] Inhibition constants (amount required to inhibit the activity by 50%) for the inhibition of the glycosomal TIM of trypanosomes (gTIM) and the isoenzyme from rabbit muscle (R-TIM). [b] No significant inhibition is found for the isoenzymes from dog muscle, yeast, and *E. coli*.

Phe^{5}Ψ[CS-NH]Phe^6) is one of the most potent inhibitors. For comparison we list the biological activities of the best inhibitors examined so far (Table 1). These inhibitors show high selectivity for the trypanosomal TIM; the isoenzymes from dog or rabbit muscle, yeast, and *E. coli* are not inhibited.

This modification of biological activity by thionylation is induced by the change of the spatial structure. The conformation of both peptides was determined by a combination of NMR spectroscopy and molecular dynamics (MD) simulations. In Figure 1 we show the structures averaged over 80 ps of MD simulations in dimethyl sulfoxide (DMSO).[9] Both peptides exist in solution as two slowly exchanging isomers identified by two separate sets of signals in the NMR spectrum. In both cases the isomers differ in the configuration about the Gly^1-Pro^2 amide bond (*cis*/*trans*). The patterns of the *intra*molecular hydrogen bonding in the two peptides exhibit distinct differences. The oxopeptide contains a βI turn with a hydrogen bond from Gly^1 NH to Val^{4}C=O and a slightly distorted βI turn without the expected hydrogen bonds between Pro^2 and Phe^3 in the i + 1 and i + 2 positions. The *cis*/*trans* isomerization of the Gly^1-Pro^2 amide bond has only a small influence on the overall conformation of the peptide. The spatial structure next to the *cis* peptide bond of the less populated conformer exhibits a turn structure not yet described in cyclic hexapeptides.[10] A βII′ turn is found on the opposite side of this conformation.

The pattern of the hydrogen bonding within the thiopeptide[6] is shifted by one residue in the amino acid sequence relative to the pattern in the oxopeptide. The conformational influence of the thiocarbonyl group forces proline into the i + 2 position of a βII′ turn (*trans* isomer) or a βVIa turn [11] (*cis* isomer; see Scheme 1). Both isomers form hydrogen bonds between Phe^{3}NH and Phe^{6}C=O and between Phe^{6}NH and Phe^{3}C=O, the latter resulting from the altered donor properties of the Phe^{6}NH hydrogen next to the thiocarbonyl fragment. Steric effects have a minor influence on the conformational changes within the βI turn. Both isomers of the thiopeptide have been shown to be very flexible in MD simulations and in experimental relaxation studies.[6]

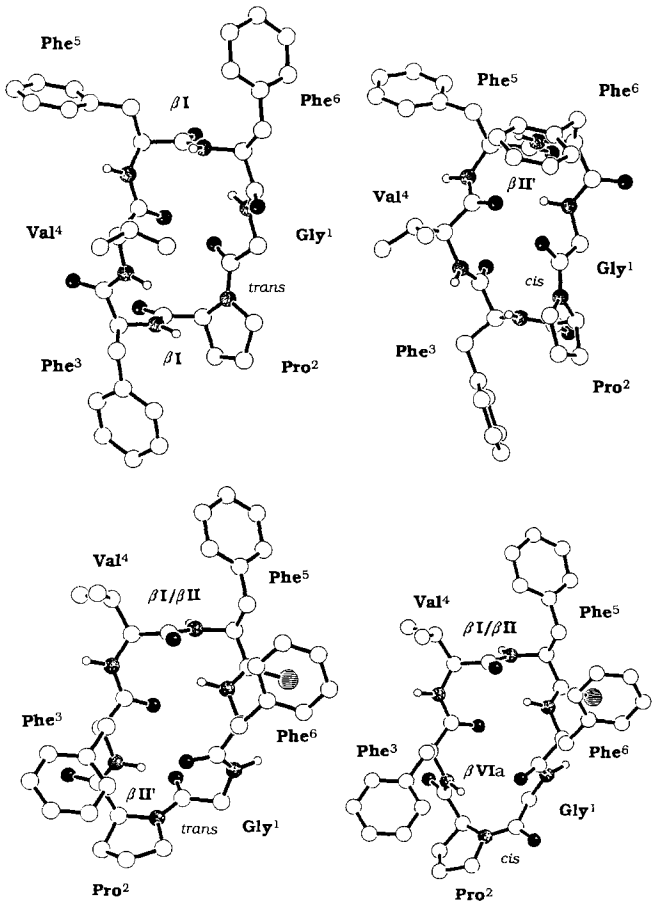

Fig. 1. Conformation of *cyclo*(Gly^1-Pro^2-Phe^3-Val^4-Phe^5-Phe^6) (above) and *cyclo*(Gly^1-Pro^2-Phe^3-Val^4-Phe^{5}Ψ[CS-NH]Phe^6) (below). The *trans* and *cis* isomers about the Gly^1-Pro^2 amide bond are shown on the right and left, respectively. The structures were obtained from 80 ps of MD simulation in DMSO with the GROMOS program [14]. Experimental data from 500 MHz and 600 MHz NOESY and ROESY measurements were used as distance restraints in the calculations. Side-chain conformations (except for Phe^6 in the *cis* isomer of the oxopeptide, upper right) were fixed in the most populated rotamers determined by coupling constants. It was impossible to ascertain the side-chain conformations of Phe^6 in the *cis* isomer of the oxopeptide because of the chemical-shift degeneracy of both diastereotopic C_β hydrogens [15]. The thiopeptide exhibited larger mobility during the MD simulation; here we show only one conformation with the βII turn in the flexible region.

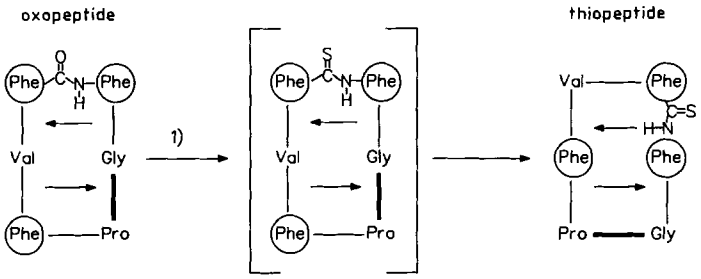

Scheme 1. Change in hydrogen-bonding patterns caused by selective thionylation of a cyclic hexapeptide. The bond in boldface between Gly^1 and Pro^2 in both peptides shows *cis*/*trans* isomerism. Thionylation exclusively at the Phe^5-Phe^6 amide bond was observed under the given conditions. 1) Yokoyama's reagent, 20 equiv, 16 h, room temperature.

Until now conformational control in cyclic hexapeptides has been achieved by the introduction of a D amino acid.[12, 13] A similar role might be conceded to thiocarbamide bonds in the future design of biologically active substances. The structure–activity relationships of the compounds examined so far show that a favorable arrangement of amino acids with aromatic side-chains is important for biological activity. Since the spatial structure of the peptide/TIM complex is not yet known, it is too early to speculate about the interactions leading to the observed biological effects.

Experimental Procedure

100 mg (0.15 mmol) of *cyclo*(Gly-Pro-Phe-Val-Phe-Phe) was suspended in 15 mL of absolute THF and homogenized in an ultrasound bath. 60 mg (15 mmol) of Yokoyama's reagent [6b] was then added, and the mixture was

stirred 16 h at room temperature. Isolation and purification were achieved by flash chromatography (chloroform/methanol 19/1). Yield: 27 mg (26%) *cyclo*-(Gly-Pro-Phe-Val-PheΨ[CS-NH]Phe). For further details see ref. [6].

[10] Because of the *cis* peptide bond between the i + 1 and i + 2 positions, we use the term *pseudo* βI turn since the Φ and Ψ angles correspond to a βI turn.

[15] The conformation shown has the Phe^6 side-chain with $\chi_1 = 60°$ which is usually unfavored in peptides.

Do Pheromone Receptors that Receive the Same or Similar Signal Molecules Have the Same or Similar Structure?**

By *Hans Jürgen Bestmann,** *Wu Caihong, Claudia Rehefeld, Friedrich Kern,* and *Barbara Leinemann*

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday
