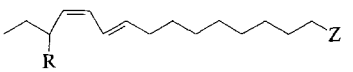
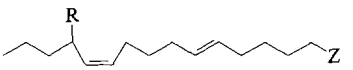
When pheromone molecules meet an insect's antenna, opening of ion channels is initiated in the dendritic membrane of nerve cells. The resulting flow of ions through the membrane alters the original rest potential. A receptor potential is set up which is electrotonically distributed over the membrane and later converted into action potentials, which if need be are further conducted via intermediary neurons into the central nervous system and processed there, possibly leading to a particular behavior. The mechanism of formation of the ion channels in the case of pheromones is still largely unknown. Recent investigations[1] suggest that second-messenger cascades are involved as in the case of the olfactory systems of vertebrates.[2] On the basis of structure–activity studies[3] one may assume that a functionally flexible interaction[4] between the signal molecules and a receptor occurs at the beginning of such a cascade, which can be determined by the stereochemistry of the pheromones to a greater or lesser extent.[5]

In the case of butterflies and moths (*Lepidoptera*), chemical communication generally takes place through a mixture of several different molecules which are present in a definite ratio.[3] In many cases the structures of the components of such a pheromone complex differ very slightly, often in the functional end group only. For each component there are receptor cells on the antenna of the respective species which specifically answer to pheromones or compounds derived therefrom, if the latter bear the correct functional end group. Thus, e.g., in the case of *Bombyx mori* one finds an alcohol and an aldehyde receptor for bombykol **1a** and bombykal **1b**,[6] and in the case of *Antheraea* species an acetate and an aldehyde receptor for (6*E*, 11*Z*)-6,11-hexadecadienyl acetate **3a** and the corresponding aldehyde **3b**.[7, 8] Further, often the same molecules are found as components of the pheromone complex in different species, e.g. bombykal **1b** in *Bombyx mori* and in *Manduca sexta*.[9]



1a, R = H, Z = CH_2OH; **1b**, R = H, Z = CHO
2a, R = Me, Z = CH_2OH; **2b**, R = Me, Z = CHO



3a, R = H, Z = CH_2O_2CMe; **3b**, R = H, Z = CHO
4a, R = Me, Z = CH_2O_2CMe; **4b**, R = Me, Z = CHO

There now arise the fundamental questions of whether 1) the receptors on the antenna of different species, which should take up the same signal molecules, have the same structure, and whether 2) receptors in the same species, which must receive very similar molecules with only different terminal groups (e.g. **1a** and **1b** or **3a** and **3b**), differ only in the complementary part for the functional end group or also in other parts of the molecule.[10]

To answer these questions we have enlisted the electrophysiological measurement of chiral pheromone derivatives. In earlier studies intended to show whether receptors for achiral signal molecules can differentiate chiral derivatives,[11] we used the electroantennogram technique.[12] In our present experiments single-cell recording has been used,[13] since only this enables accurate statements concerning the above questions. Our investigations led to the following results (cf. Table 1):

Question 1: The "aldehyde receptor" of *Bombyx mori* scarcely differentiates between the enantiomers of 14-methylbombykal **2b**. **2b** is fiftyfold less active than bombykal **1b**. The aldehyde receptor of *Manduca sexta*, on the other hand, differentiates between the two enantiomers of **2b**

[**] Pheromones, Part 85. This work was supported by the Deutsche Forschungsgemeinschaft and the Volkswagen-Stiftung. – Part 84: H. J. Bestmann, F. Kern, A. Mineif, H. Platz, O. Vostrowsky, *Z. Naturforsch. C*, in press.

by a factor of 100 with $R > S$. The (*R*)-enantiomer, however, is only ten times less active than the pheromone **1b**.

From these observations it can be concluded that the structures of the two bombykal receptors are different, since a) they differentiate the same chiral derivative to widely different extents, and b) the differences between the activity of the particular pheromone and **2b** differ largely.

Question 2: (*R*)-**2a** interacts with the "alcohol receptor" of *Bombyx mori* three times better than the (*S*)-isomer. It is ten times less active than the pheromone **1a**.

In summarizing all these data it may be concluded that the alcohol and aldehyde receptors in *Bombyx mori* differ not only in the structure of the part necessary for recognition of the functional end group.

Table 1. Results of electrophysiological measurements (single-cell recordings) with optically active pheromone derivatives.

Species	Substance [a]	Comparison	Factor	*n* [b]
Bombyx mori	**2a**	$R > S$	3	20
	1a/(*R*)-**2a**	**1a** > (*R*)-**2a**	10	12
	2b	$R \geq S$	–	20
	1b/(*R*)-**2b**	**1b** > (*R*)-**2b**	50	17
Manduca sexta	**2b**	$S > R$	100	24
	1b/(*R*)-**2b**	**1b** > (*R*)-**2b**	10	11
Antheraea pernyi	**4a**	$S > R$	3	24
	4b	$R > S$	10	22
	3a/(*S*)-**4a**	**3a** > (*S*)-**4a**	100	22
	3b/(*R*)-**4b**	**3b** > (*R*)-**4b**	400	18
Antheraea polyphemus	**4a**	$S > R$	3	20
	4b	$R > S$	50	20
	3a/(*S*)-**4a**	**3a** > (*S*)-**4a**	400	18
	3b/(*R*)-**4b**	**3b** > (*R*)-**4b**	10	12

[a] **2a**: (14 *R*)- and (14 *S*)-enantiomer; **2b**: (14 *R*)- and (14 *S*)-enaniomer; **4a**: (13 *R*)- and (13 *S*)-enantiomer; **4b**: (13 *R*)- and (13 *S*)-enantiomer. [b] *n* = number of measurements.

This is much more evident in the case of *Antheraea pernyi*. The acetate receptor differentiates between the enantiomers of **4a**[14] by a factor of 3, with $S > R$. The (*S*)-enantiomer is less active than the pheromone **3a** by a factor of 100. In the same animal species, the cell specific for the aldehyde differentiates between the enantiomers of **4b** by a factor of 10; but now $R > S$, i.e. the reverse of that in the case of the acetate. (*R*)-**4b** acts three times more weakly than the pheromone **3b**.

In the case of the related species *Antheraea polyphemus* we have the following picture: The enantiomers of the acetate **4a** are differentiated by a factor of 3 with $S > R$, whereby the activity of (*S*)-**4a** decreases by a factor of 400 compared to the pheromone **3a**. In the same species the aldehyde receptor differentiates (*S*)- and (*R*)-**4b** with a factor of 50, and again with $R > S$. (*R*)-**4b** is ten times less active than the pheromone **3b** of the species.

Since, in the two *Antheraea* species, the acetate receptor prefers the (*S*)-enantiomer while the aldehyde receptor prefers the (*R*)-enantiomer, one may conclude that the two receptors must differ in their structure, not only in the region corresponding to the functional end groups of the signal molecule but also at least in the part which intercalates the terminal alkyl group of the pheromone. Also the difference in the decrease of activity between the more active enantiomers of **4a** and **4b** compared to the acetate pheromone **3a** and the aldehyde pheromone **3b** suggests that the receptors have different structures.

In the case of the closely related species *A. pernyi* and *A. polyphemus* the differences between the respective acetate and aldehyde receptors are, however, not so pronounced as in the case of *Bombyx mori* and *Manduca sexta*.

We have suggested that the interaction between pheromone and receptor should be a flexible dynamic process.[3, 4, 11] Upon intercalation the conformations of signal molecule and receptor synchronously change until both are in a definite conformation, bound to each other by noncovalent interactions ("induced fit").[15] It is postulated that the "biologically active" conformation of the signal molecule of the receptor is the most stable.[16] However, as shown here, if for the same molecule in different insect species and for molecules which differ in the functional end group in the same species, receptors with different structure are available, one may assume that the intercalated conformations are also not the same but differ.[17] This means that the biologically active conformation in a few cases only is the thermodynamically most stable and that nature makes use of the many conformations in which signal molecules can occur.

[9] The complete pheromone of *Manduca sexta* was first elucidated only recently: J. H. Tumlinson, M. M. Brennan, R. E. Doolittle, E. R. Mitchell, A. Brabham, B. E. Mazomemos, A. H. Baumhover, D. M. Jackson, *Arch. Insect Biochem. Physiol.* **1989**, *10*, 255.

[10] Studies on brown algae show differences in behavioral responses to the same compounds in various species, D. G. Müller, W. Boland, L. Jaenicke, G. Gassmann, *Z. Naturforsch. C.* **1985**, *40*, 457. Brown algae are quite simple organisms in which one could possibly conclude the presence of different receptor structures on the basis of differing behavioral responses. In more highly developed organisms such as lepidoptera this is permitted only in rare cases or not at all. Behavioral responses are the result of signal processing in the *central nervous system*. The questions posed here by us do not however concern the primary interaction between signal molecule and its receptor in the denditric membrane, which finally initiate the opening of the ionic channels.

The results obtained deviate from those of electrophysiological measurements (Ref. [11]).

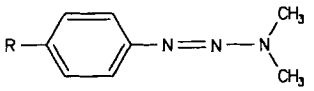
Electrochemical Oxidation of 1-(*p*-Dimethylaminophenyl)-3,3-dimethyltriazene—Cyclic Voltammetric Detection of a Triazene Radical Cation and Dication**

By *Bernhard Gollas* and *Bernd Speiser**

Dedicated to Professor Anton Rieker on the occasion of his 60th birthday

Stable or persistent radical cations have frequently been found as primary products in the oxidation of amines[1] and hydrazines.[2] In the case of triazenes, i.e. compounds with *three* linearly connected nitrogen atoms, apparently no example has hitherto been reported in which the one-electron oxidation product has a lifetime sufficiently long enough for experimental detection. Insights into hypothetical triazene radical cations, however, are of particular interest, since, on the one hand, they are possibly the first intermediates which also occur in the oxidative metabolism of the carcinogenic triazenes in biochemical systems and, on the other, since 1-aryl-3,3-dimethyltriazenes are used against malignant melanoma.[3] Reactions at an electrode can often be regarded as model reactions for biochemical processes.[4] Nevertheless, only few studies have been carried out concerning the anodic oxidation of triazenes.[5, 6] A triazene radical cation has been formulated as unstable intermediate but was not detected experimentally.[5]

For the generation and mechanistic study of the reactivity of triazene radical cations we have oxidized 1-aryl-3,3-dimethyltriazenes **1** at a Pt-anode in anhydrous acetonitrile with nBu$_4$NPF$_6$ as supporting electrolyte.[7] We report here on the one-electron oxidation of the compound **1a** to the radical cation **1a**$^{\bullet+}$, on its further oxidation to the dication **1a**$^{2+}$, and on the decomposition reactions of **1**$^{\bullet+}$ and **1a**$^{2+}$. The reaction mechanism of the triazenes **1b**–**1h** is more complicated and will be discussed elsewhere.



1a R = $(CH_3)_2N$ **1b** R = OC_2H_5
1c R = OCH_3 **1d** R = CH_3
1e R = H **1f** R = Br
1g R = CF_3 **1h** R = NO_2

Figure 1 shows cyclic voltammograms of **1a** at a scan rate of $v = 0.1$ Vs^{-1} in the potential ranges -0.9 to $+1.7$ and -0.4 to $+0.8$ V. The peaks I and II fulfill all criteria required for the pair of peaks of a reversible *one*-electron transfer: the peak current ratio i_p^{II}/i_p^{I} is close to 1 at sufficiently high scan rates ($v \geq 0.2$ Vs^{-1}) and a switching potential $E_\lambda = +0.4$ V; i_p^{I} is proportional to $\sqrt{v}$; the peak potentials E_p^{I} and E_p^{II} are independent of v (formal potential $E^\circ = +0.091 \pm 0.001$ V). The peak potential difference, ΔE_p (0.067 V), is increased only slightly compared to the value for a reversible one-electron transfer. Consistent with this, coulometric measurements gave a value of $n = 1.0$. The potentials do not vary with the concentration of the triazene. From the peak current i_p^{I}, a diffusion coefficient of $D = (2.2 \pm 0.2) \times 10^{-5}$ cm s^{-1} was calculated for **1a** in acetonitrile. For slower scan rates the ratio of the peak currents i_p^{II} and i_p^{I} becomes smaller ($E_\lambda = +0.4$ V; $v = 0.1$ Vs^{-1}: $i_p^{II}/i_p^{I} = 0.96$; $v = 0.01$ Vs^{-1}: $i_p^{II}/i_p^{I} = 0.82$). The initially formed triazene radical cation **1a**$^{\bullet+}$ undergoes further chemical reaction.

[**] Electrochemistry of Triazenes, Part 1. – This work was supported by the Deutsche Forschungsgemeinschaft.

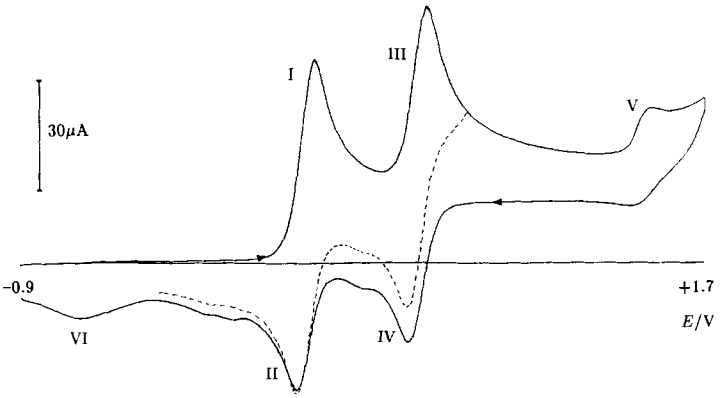

Fig. 1. Cyclic voltammograms of the triazene **1a** in CH_3CN/0.1 M nBu$_4$NPF$_6$ at a Pt electrode ($v = 0.1$ Vs^{-1}, $c = 2.16 \times 10^{-3}$ M) in the potential ranges -0.9 to $+1.7$ V (—), and -0.4 to $+0.4$ V (– – –).

Voltammograms in the region of the first electron transfer from **1a** were analyzed as a function of v using the computer program system EASIEST (*e*lectro*a*nalytical *si*mulation and parameter *est*imation).[8] The rate constant for the reaction of the radical cation determined from the peak potentials and peak current ratios on the basis of the EC model (reversible electron transfer with subsequent irreversible reaction) was found to be $k = 0.01$ s^{-1}. Simulation of the voltammograms with the reaction parameters thus obtained for various values of v confirmed the analysis. Figure 2 shows the agreement between experimental and simulated voltammograms for the fastest and slowest scan rates used.

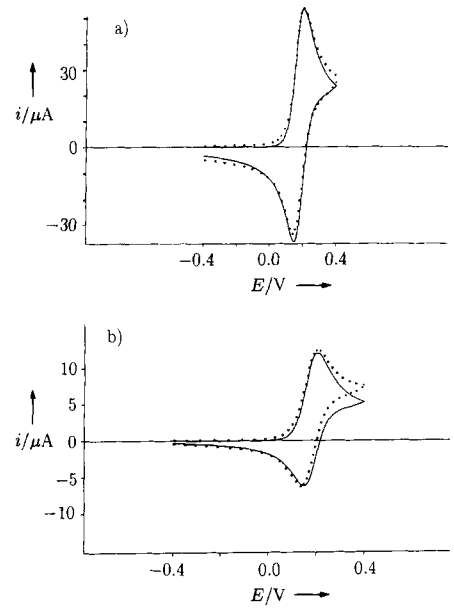

Fig. 2. Experimental (broken) and simulated (solid curve; simulation parameters see text) cyclic voltammograms of the triazene **1a** in the region of the first oxidation; a) $v = 0.2$ Vs^{-1}, b) $v = 0.01$ Vs^{-1}.

The deviations in the upper potential region, especially at $v = 0.01$ Vs^{-1}, are in part explained by the fact that the background current is not taken into account in the simulation. The second electron transfer leading to the dication as well as the electrode reaction leading to follow-up products also contribute quite clearly to the experimental total current in this region.

The electrolysis of **1a** in an ESR spectrometer at room temperature yielded a solution which showed the spectrum of the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine radical cation (Wursters Blue, $\mathbf{2}^{\bullet+}$) (Fig. 3a). Chemical oxidation with $I_2/AgClO_4$ also led to the spectrum of $\mathbf{2}^{\bullet+}$ (*blue* solution). After several successive cycles the cyclic voltammograms of **1a** show small peaks, which, by comparison can be assigned to the two-step oxidation of *N,N,N',N'*-*p*-phenylenediamine **2** to its dication.[9] Products of the preparative electrolysis of **1a** were investigated with the help of CAD mass spectrometry. Here too, the formation of **2** from **1a** was observed. Thus, the reaction of $\mathbf{1a}^{\bullet+}$ is so rapid on the time scale of these experiments that only the product of the decomposition is detected.

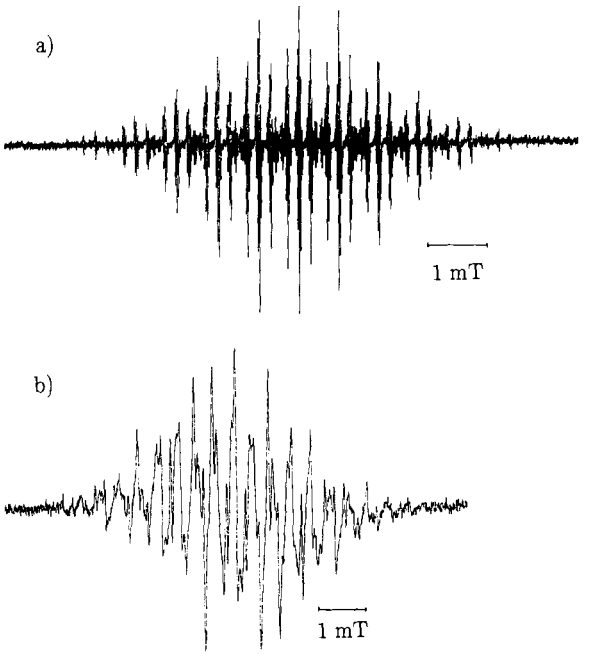

Fig. 3. ESR spectra after the oxidation of **1a** with $I_2/AgClO_4$ in acetonitrile; a) at room temperature, b) at −40 °C.

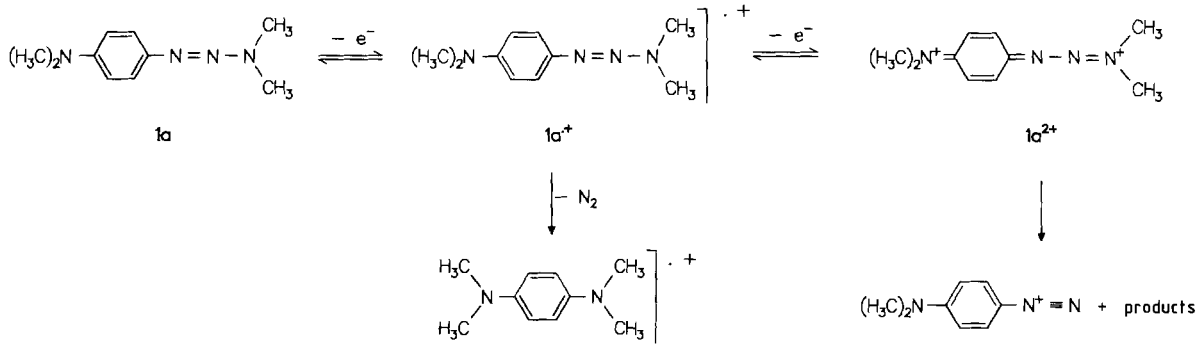
When the chemical oxidation of **1a** and the ESR investigation were carried out at −40 °C, the now blue-*green* solution gave a spectrum which differed from that of the radical cation $\mathbf{2}^{\bullet+}$ (Fig. 3b). The increased line width possibly arises from exchange phenomena between radical cations and non-oxidized molecules. This second spectrum is also observed upon electrolysis of **1a** at −40 °C and +0.25 V, albeit with poor resolution. In both cases a superposition with the spectrum of $\mathbf{2}^{\bullet+}$ cannot be ruled out. Upon warming the solutions to room temperature after the low-temperature experiments the spectrum of Wursters Blue was obtained, which then—even upon renewed cooling—remained unchanged. Thus, at −40 °C the ESR spectrum of a new species is recorded which converts into $\mathbf{2}^{\bullet+}$; the changes in the spectrum do not represent a temperature effect.

The reaction mechanism for the one-electron oxidation of **1a** is shown in Scheme 1 (left). A similar elimination of N_2 has already been observed in the *thermolysis* of a 1-vinylazopyrazole.[10] Possibly the reaction is initiated by splitting of $\mathbf{1a}^{\bullet+}$ into the corresponding diazenyl radical and the dimethylnitrenium ion. The diazenyl radical would then decompose to N_2 and the dimethylamino-substituted phenyl radical, which in turn would afford $\mathbf{2}^{\bullet+}$ by recombination with the nitrenium ion. On the basis of the measurements presented here, parallel reactions of $\mathbf{1a}^{\bullet+}$ to give non-electroactive and non-paramagnetic products cannot be ruled out.

A value of $n = 0.9$ was measured coulometrically for the second electron transfer (Peaks III/IV); $E^\circ = +0.516 \pm 0.004$ V). Accordingly, this is also a one-electron oxidation, which is consistent with the peak potential difference ($\Delta E_p = 0.069$ V).

The resulting triazene dication $\mathbf{1a}^{2+}$ decomposes more rapidly than $\mathbf{1a}^{\bullet+}$. Whereas the reduction Peak IV strongly decreases with decreasing scan rates, Peak V ($E_p^{ox} = 1.417 \pm 0.008$ V) grows significantly. Thus, the latter can be assigned to a product of the follow-up reaction of the dication. Peak VI ($E_p^{red} = -0.751 \pm 0.009$ V) is only to be observed in the reductive part of the voltammogram when **1a** is previously oxidized to at least the dication stage, but not when only oxidized to the radical cation. Accordingly, a decomposition product of $\mathbf{1a}^{2+}$ is reduced here. Both from a comparison of measurements on *p*-dimethylaminobenzenediazonium tetrafluoroborate **3** as well as from experiments with addition of **3** to the solution of the triazene, we conclude that the Peaks V and VI correspond to the oxidation and reduction of **3**, respectively. In both cases rapid irreversible follow-up reactions occur.

On the other hand, for the decomposition reaction of $\mathbf{1a}^{2+}$, which has already been formulated with a quinone imine structure,[5] splitting into **3** and the dimethylnitrenium ion would be conceivable, whereby the latter reacts to give follow-up products. On the other hand, **3** could be formed from a monocation after deprotonation of $\mathbf{1a}^{2+}$. The cleavage of the N–N bond and the occurrence of the diazonium ion **3** are not, however, to be attributed to the liberation of protons. The latter was postulated by Matřka et al.[5] In the present work, the oxidation of **3** was observed in peak V even



Scheme 1. The electrochemical oxidation of **1a**.

with a tenfold excess of the base 2,6-lutidine. The oxidation to the dication $\mathbf{1a}^{2+}$ is outlined in Scheme 1 (right).

In contrast to the electrochemical oxidation of amines,[11] the primary products of the one- and two-electron oxidation of the triazene **1a** initially decompose with cleavage of an N–N bond and not via solvolysis of an *N*-alkyl group. Compared to the bonding in the radical cations of tetraalkylhydrazines[2] this bond appears in the triazene cations to be labile. Regarding the bonding and the reactivity, the open-shell species $\mathbf{1a}^{\bullet+}$ and the dication $\mathbf{1a}^{2+}$ rather resemble triazenes protonated at N(3).[12]

$[SbCl([15]Crown-5)](SbCl_6)_2$ and $[BiCl([18]Crown-6)(CH_3CN)_2](SbCl_6)_2$: Salts with Antimony(III) and Bismuth(III) Dications

By *Michael Schäfer, Gerlinde Frenzen, Bernhard Neumüller*, and *Kurt Dehnicke**

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

In antimony–crown ether complexes $[SbX_3([15]crown-5)]$ (X = F,Cl (**1**), Br, I) the antimony atom is eightfold coordinated in a sandwich-like fashion by the five O atoms of the crown ether and the three halogen atoms.[1–3] The lone pair on the antimony atom is oriented towards the cavity formed by the crown ether, and according to ^{121}Sb Mössbauer spectroscopic findings contains a high s-part.

By exploiting the steric activity of the lone pair we were able, for the first time, not only to prepare a dication of antimony(III) but also one of bismuth(III), using the same synthetic strategy. In the case of bismuth(III) only the dicationic thiourea complex $[Bi(NO_3)\{SC(NH_2)_2\}_5]^{2+}$ has thus far been reported; it has an octahedral structure, and the lone pair shows no stereochemical activity.[4]

[*] Prof. Dr. K. Dehnicke, Dr. M. Schäfer, Dr. G. Frenzen, Dr. B. Neumüller
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-W-3550 Marburg (FRG)

The dication of antimony(III) is formed as colorless crystals upon reaction of **1** with excess antimony pentachloride in acetonitrile [Eq. (a)].

$$\underset{\mathbf{1}}{[SbCl_3([15]crown\text{-}5)]} + 2\,SbCl_5 \longrightarrow \underset{\mathbf{2}}{[SbCl([15]crown\text{-}5)](SbCl_6)_2} \quad (a)$$

According to the crystal structure analysis[5] the molecular structure contains two symmetry-independent cations which are almost identical; Figure 1 shows the crystal structure of one of them. The antimony atom is surrounded in an almost pentagonal-planar construction by the five O atoms of the crown ether and an axially oriented Cl atom, thus resulting in a structure with almost C_{5v} symmetry. The Sb

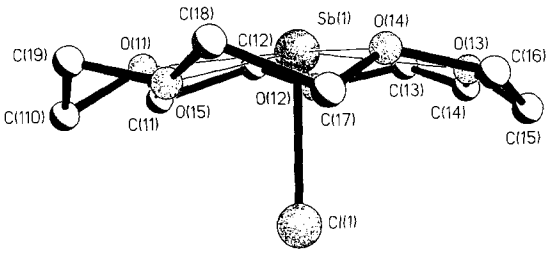

Fig. 1. The crystal structure of one of the two symmetry independent $[SbCl([15]crown\text{-}5)]^{2+}$ ions of **2**. Bond lengths and angles see text.

atom is located only 26 pm (dication **1**) or 17 pm (dication **2**) above the best plane through the five O atoms; it is thus shifted approximately in the direction of the lone pair. The Sb–Cl distances are shortened only slightly, on average from 241.7 pm to 236.5 pm (mean value of both dications), during conversion of the half-sandwich arrangement in **1**[1] into the dication of **2**, whereas the Sb–O distances are shortened drastically from 290 to 232 pm. Thus, they already fall in the range of bond lengths of covalent Sb–O bonds, as are found, for example, for the Sb–O axial distances in SbOF with a fivefold coordinated antimony atom (222 and 230 pm, respectively[6]).

The two resonance signals in the ^{121}Sb Mössbauer spectrum of **2** (Fig. 2) with contributions to the isomeric shift of $-16.8\ mm\,s^{-1}$ and $-3.0\ mm\,s^{-1}$ can be assigned to the an-

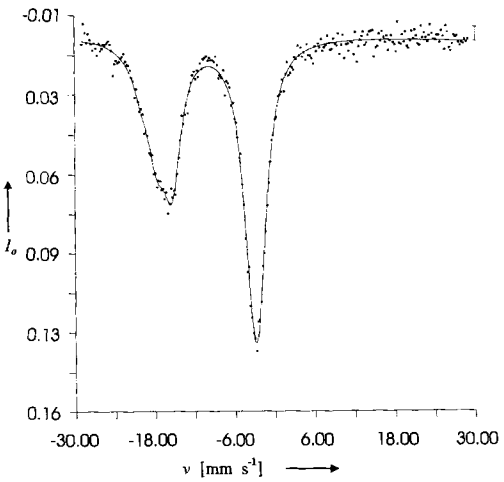

Fig. 2. ^{121}Sb Mössbauer spectrum of **2** at 4.2 K. I_o = resonance absorption, v = isomeric shift.

timony sites of cation and anion, respectively.[7] In the case of the $SbCl_6^-$ ion, whose symmetry deviates only little from O_h, the small electric field gradient leads to a quadrupole splitting ΔE_Q of only 5.1 mm s^{-1}, whereas in the case of the cation of **2** a ΔE_Q value of 16.0 mm s^{-1} is measured. The almost unchanged isomeric shift of **2** in comparison to **1** ($v = 17.0$ mm s^{-1} [2]) is indicative of a comparatively large s-part of the lone pair in both complexes. In contrast, the increase in the quadrupole splitting from 10.2 mm s^{-1} in **1** to 16.0 mm s^{-1} in **2** reflects the relatively large p_x–p_y bonding parts of the five Sb–O bonds of the equatorially arranged crown ether, which correlates well with the short Sb–O distances. Structure and ^{119}Sn Mössbauer investigations on tin–crown ether complexes [SnCl([18]crown-6)]X (X = ClO_4^-, $SnCl_3^-$) led to similar findings.[8, 9]

Reaction of bismuth trichloride with antimony pentachloride in the presence of [15]crown-5 analogously to Equation (a) leads to formation of only the monocation **3** [Eq. (b)].

$$BiCl_3 + [15]\text{crown-5} + SbCl_5 \xrightarrow{CH_3CN} [BiCl_2([15]\text{crown-5})(CH_3CN)]SbCl_6 \quad \textbf{3} \qquad (b)$$

As the crystal structure analysis shows[10] (Fig. 3), the cavity of the crown ether is obviously too small to accommodate the bismuth atom. Actually, the dication **4** is formed,

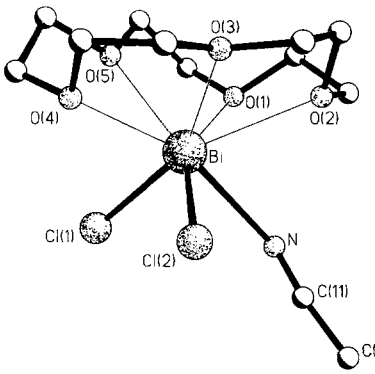

Fig. 3. The crystal structure of the $[BiCl_2([15]\text{crown-5})(CH_3CN)]^+$ ion of **3**. Selected bond lengths [pm] and angles [°]: Bi-Cl(1) 251.5(7), Bi-Cl(2) 248.9, Bi-N 265(3); Cl(1)-Bi-Cl(2) 93.6(3), Cl(1)-Bi-N 82.6(7), Cl(2)-Bi-N 79.7(6).

but only upon using the larger crown ether [18]crown-6 [Eq. (c)]. It should be pointed out that the formation of the dication in **4** is not only dependent on the size of the crown ether but is also determined by the Lewis acidity of the antimony pentachloride, since the corresponding reaction with bismuth trichloride as Lewis acid leads to $[BiCl_2([18]\text{crown-6})]_2^{2+}[Bi_2Cl_8]^{2-}$,[11] i.e. only to the monocation $[BiCl_2([18]\text{crown-6})]^+$. The Bi–Cl and Bi–O bond lengths in this monocation are quite similar to those in **3**.

$$BiCl_3 + [18]\text{crown-6} + 2\,SbCl_5 \xrightarrow{CH_3CN} [BiCl([18]\text{crown-6})(CH_3CN)_2](SbCl_6)_2 \quad \textbf{4} \qquad (c)$$

According to the crystal structure analysis of **4**[12] the cavity of the crown ether is obviously too large to facilitate

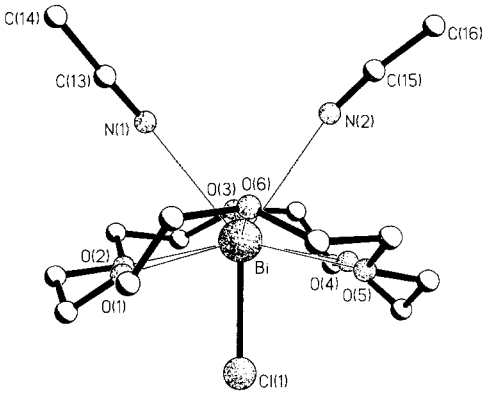

Fig. 4. The crystal structure of the $[BiCl([18]\text{crown-6})(CH_3CN)_2]^{2+}$ ion of **4**. Selected bond lengths [pm] and angles [°]: Bi-Cl(1) 247.9(6), Bi-N(1) 282(2), Bi-N(2) 286(3); Cl(1)-Bi-N(1) 141.0(6), Cl(1)-Bi-N(2) 144.8(5), N(1)-Bi-N(2) 74.1(7).

a coplanar arrangement of the Bi atom with the six O atoms (Fig. 4). Instead, the Bi atom is surrounded by the O atoms of the crown ether in a distorted prismatic fashion and the Cl atoms and the N atoms of the acetonitrile ligands each occupy a prism face. Hence, it is understandable why the acetonitrile ligands cannot coordinate to the side of the molecule away from the crown ether, as in **3**. A conceivable steric activity of the lone pair on the Bi atom cannot be established with certainty, as is usually the case with Bi^{III} compounds.[13] Nevertheless, a possible preferred direction of the lone pair along the Cl–Bi axis cannot be ruled out.

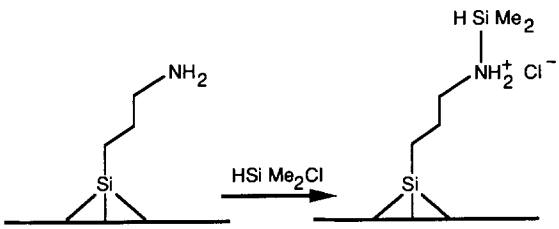
Quantification of the Reactivity of 3-Aminopropyltriethoxysilane Monolayers with the Quartz-Crystal Microbalance**

By *Dirk G. Kurth* and *Thomas Bein**

Surface reactions have been utilized to construct well-ordered, three-dimensional structures on surfaces and to study surface phenomena in self-assembled films.[1] An important question in surface chemistry is to what extent known reactions from the highly developed fields of synthetic organic and inorganic chemistry can be utilized on surfaces. One aspect is the chemical yield of a reaction conducted according to conventional procedures compared to that of a reaction conducted on a surface. Due to their high mass-sensitivity, piezoelectric devices, that is instruments employing oscillating crystals, have found application in studies of surface phenomena.[2] The method is based on measuring the shift in the resonance frequency of the crystal upon the deposit of mass on the electrode surfaces. For low masses the mass–frequency relationship is linear and obeys the Sauerbrey equation.[3] Although in situ electrochemical reactions on electrode surfaces[4] and the adsorption kinetics of thiols on gold[5] have been studied with piezoelectric devices, the use of quartz-crystal microbalances (QCMs) in quantifying sequential reactions confined to a surface has not been explored.

In this communication, we demonstrate that a reaction confined to a surface can be followed with a QCM. If 3-aminopropyltriethoxysilane (APS) is immobilized on an oxidized aluminium substrate and then allowed to react with chlorodimethylsilane, a surface-immobilized dimethylsilane–ammonium salt forms (Scheme 1). In contrast to the spontaneous organization of some molecular assemblies[6] APS does not form well-ordered, crystalline monolayers.[7] However, we have found that monomolecular layers of APS may be formed by gas-phase adsorption on the substrate.



Scheme 1. Schematic representation of the reaction of immobilized APS with chlorodimethylsilane.

In addition to the QCM we have also used reflection absorption IR spectroscopy (RAIR) spectroscopy, ellipsometry, and contact-angle measurements to elucidate the presence and the organization of the reactants and the products on the surface. In our experiments the precleaned substrate (glass slides with a layer of oxidized aluminium)[8] were placed in specially designed glass dishes at room temperature under dried nitrogen and were then exposed to APS vapor for several minutes to several hours. After evacuation of the chamber, the modified slides were exposed to chlorodimethylsilane vapors for 15 minutes. The samples were evacuated and handled under nitrogen until all measurements had been completed.

Figure 1 shows the RAIR spectrum of an APS monolayer on oxidized aluminium.[9] The thickness of the sample was determined by optical ellipsometry to be 6 ± 1 Å.[10] The contact-angle θ_a of this sample was $52 \pm 2°$. The RAIR spectrum shows two peaks at 1610 and 1583 cm^{-1} that are assigned to associated and free amino groups. The amine can undergo hydrogen bonding with the ethoxy, silanol, or surface hydroxy groups, which increases the frequency of the N–H deformation mode.[11] The hydrogen bonding is expected to force the amine group towards the surface, reducing the overall film thickness.

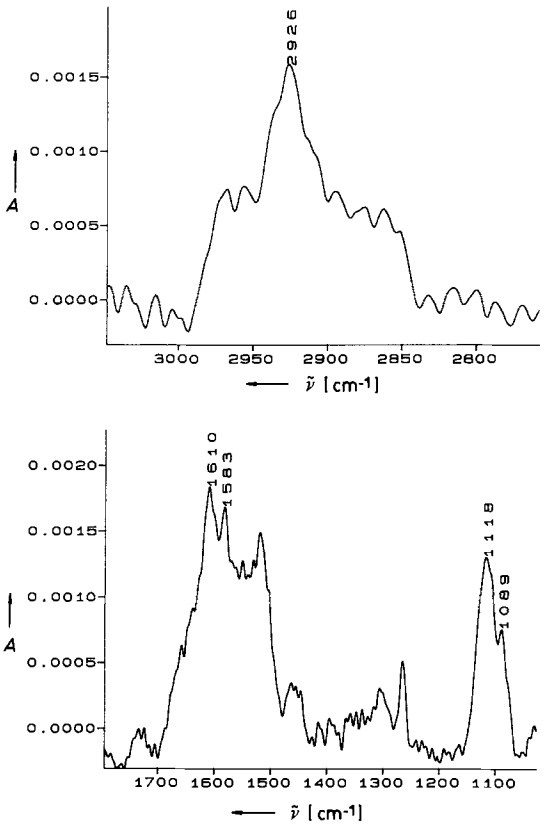


Fig. 1. RAIR spectrum of an APS monolayer on oxidized aluminum. *A*: absorbance (arbitrary units).

Figure 2 shows the QCM response for the adsorption of APS under rigorously dry conditions.[12] Upon exposure to the APS vapor a steady increase in the frequency shift was observed. To remove physisorbed material the reactor was evacuated and rinsed with nitrogen several times. According to the QCM results, the remaining mass is due to chemisorption of a monolayer of APS; the frequency reading of the QCM after evacuation was stable for several days. The frequency change ΔF, measured in several experiments, averages to 48 ± 2 Hz, which is equivalent to 5.2 ± 0.2 APS molecules per nm^2, assuming the attachment of $H_2N(CH_2)_3Si(OEt)$ species on the surface.[13] At this extent of coverage, each APS molecule occupies an average of 1.9 nm^2.[14] The

We are also grateful to Alfonso Torres for his help.

data are consistent with the attachment of about one monolayer of APS to the aluminium surface by gas-phase adsorption.

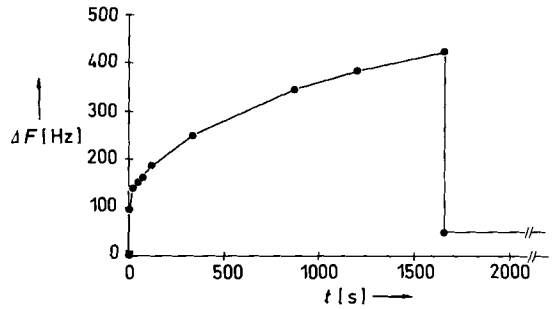

Fig. 2. QCM response for the adsorption of APS under rigorously dry conditions. After evacuation only one monolayer remains on the electrode surface of the QCM.

We conducted subsequent reactions on the APS monolayer with chlorodimethylsilane vapor by placing the slides in a reactor under nitrogen filled with 0.5 mL of the silane, and exposed the slides to the vapors for 15 minutes at room temperature. After this treatment the film thickness had increased by 5 ± 1 Å. The RAIR spectrum is shown in Figure 3. The

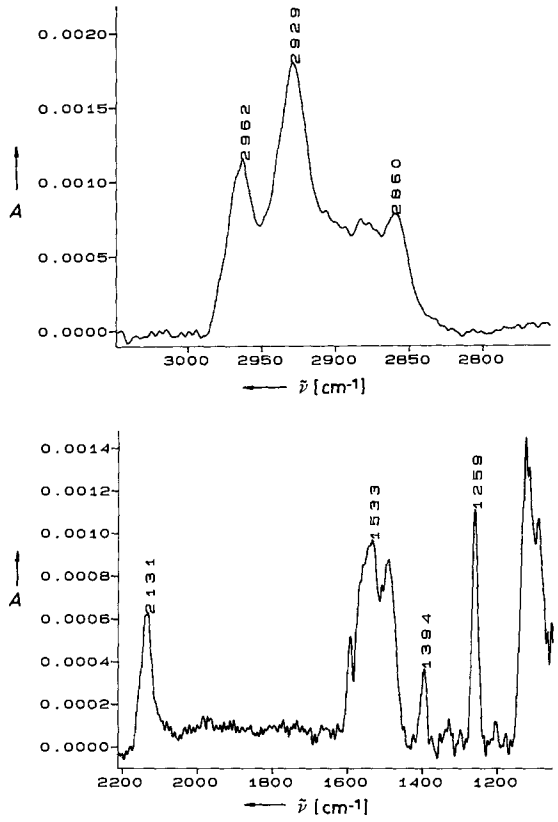

Fig. 3. RAIR spectrum after the reaction of the APS monolayer with chlorodimethylsilane. *A*: absorbance (arbitrary units).

strong bands at 2962, 2860, and 1259 cm^{-1} are assigned to the C–H stretching and deformation modes of the newly attached dimethylsilyl group. The band at 2860 cm^{-1} overlaps with the CH_2 stretching vibration of the propyl group from APS. The band at 2131 cm^{-1} is characteristic for the Si–H stretch. This band is shifted approximately 40 cm^{-1} compared to the comparable band of liquid chlorodimethylsilane (2175 cm^{-1}, transmission spectrum). This shift is attributed to the changed electronic environment after exchange of the chlorine atom.[15] The band at 1394 cm^{-1} is strongly enhanced after the reaction and assigned to the deformation mode of the CH_2 group next to the NH_2^+ group; the band at 1533 cm^{-1} is assigned to the deformation mode of the NH_2^+ group. The contact-angle decreases from $52 \pm 2°$ for the APS film to $41 \pm 3°$ after the reaction. The enhanced wettability of the sample after the reaction is consistent with the formation of an ammonium salt, as indicated by the RAIR data. Apparently, the newly formed overlayer composed of dimethylsilane is disordered and allows penetration of water into the film. This is in agreement with other reports that short-chain *n*-alkylthiols do not form well-ordered monolayers.[16]

The frequency shift in the QCM experiment averaged over several experiments is 33 ± 2 Hz, which is equivalent to 5.3 ± 0.2 additional HMe_2SiCl molecules per nm^2. The data indicate that within the experimental accuracy, all the immobilized amino groups reacted with chlorodimethylsilane from the gas phase. In contrast to reactions with dense self-assembled monolayers, this reaction is quantitative because the APS film is not highly organized.

[8] Ultraclean aluminum (99.999%) was evaporated onto glass slides at a base pressure of 10^{-6} Torr. The aluminum slides were cleaned in a nitrogen or oxygen plasma and exposed to water vapor. An amorphous aluminum oxide–hydroxide layer thus formed had a thickness of 50 Å to 100 Å, as indicated by optical ellipsometry (P. Thiel, T. E. Madey, *Surf. Sci. Rep.* **1987**, *7*, 211 and literature cited therein). Slides prepared this way were completely wetted by water (M. E. Schrader, *Surf.* **1979**, *2*, 541; *Contam. Genesis Detect. Control, Proc. Symp.* **1978**.

[9] RAIR spectra were obtained on a Mattson Polaris FTIR spectrometer with a Harrick attachment and an MCT detector at an angle of incidence of 86°. 1000 scans were collected. The sample spectra were compared to those obtained from precleaned gold reference slides. The spectra were electronically corrected in the baseline with two or three base points at a higher and lower frequencies.

[10] Ellipsometric measurements were made using a Rudolf Research Ellipsometer (43603-200E) with a He–Ne laser at a 70° angle of incidence and a 45°/135° azimuth of the compensator. Film thicknesses were calculated using the complex refractive index of the substrate, determined prior to derivatization, and the bulk refractive index of the film with an algorithm developed at Sandia National Labs (H. L. Tardy, *Ellipse User's Manual and Program Reference*; Report No. 89-0008; Sandia National Laboratories, Albuquerque, NM, USA, **1989**).

[11] K. Nakanishi, P. H. Solomon, *Infrared Absorption Spectroscopy*, 2nd ed., Holden-Day, San Francisco, **1977**.
[12] The QCM measurements were made on polished, AT-cut crystals (AT: orientation of the cut relative to the crystal axes) with aluminum electrodes operated at a frequency of 9 MHz. A surface roughness of 15%, as measured by nitrogen adsorption isotherms, was taken into account.
[13] The bands at 2975, 2888, and 1390 cm^{-1} in the RAIR spectrum reveal the presence of ethoxy groups within the surface-attached APS moiety. The bands at 1089 and 1118 cm^{-1} are characteristic for siloxane oligomers, indicating the loss of ethoxy groups and partial cross-linking on the surface.

Synthesis of the Calicheamicin Aryltetrasaccharide Domain Bearing a Reducing Terminus: Coupling of Fully Synthetic Aglycone and Carbohydrate Domains by the Schmidt Reaction**

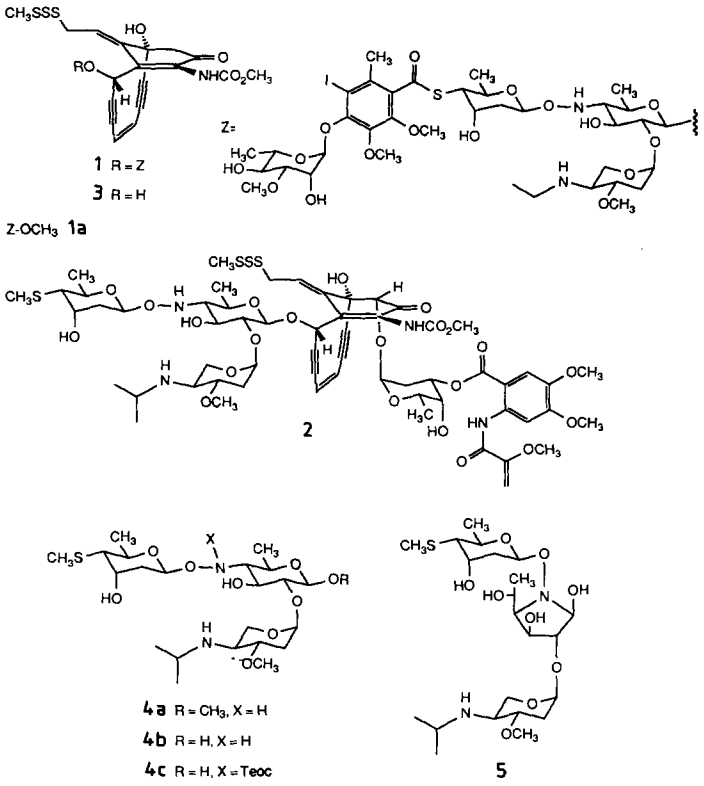
By *Randall L. Halcomb, Serge H. Boyer,* and *Samuel J. Danishefsky**

The identification of the mechanistically novel, highly potent antitumor agents calicheamicin (**1**)[1a,b] and esperamicin (**2**)[1c,d] as well as neocarzinostatin[2a] and dynemycin[2b] has spurred a variety of initiatives in synthesis,[3] biosimulation,[4] and computation.[5,6] An ultimate goal of the creative interactivity of such efforts is the development of more accessible compounds which manifest higher therapeutic indices than do the natural products.[7]

The aglycone sector of **1** is recognized as the source of the cytoxic diradical effector species.[8] Our laboratory has completed the synthesis of the fully functionalized aglycone, calicheamicinone (**3**).[9] Experiments conducted with the synthetic racemate,[10] showed it to retain the DNA-cleaving properties of the drug **1** though with significantly reduced potency. Suitably activated aglycone retains some of the remarkable capacity for direct hydrogen abstraction from C–H bonds of oligonucleotide constructs[11a,b] however, it lacks any significant sequence selectivity in DNA cleavage of the type manifested by calicheamicin.[12,13]

Recently, enzymatic resolution of intermediates en route to **3** and the descarbamoyl version thereof has been achieved.[14a,b] This advance provides access to enantiomerically pure "late" intermediates in the synthetic sequence. Of course the use of aglycone intermediates of unambiguous absolute configuration obviates the structural ambiguities arising from the employment of a racemate as a coupling component.

The carbohydrate domain is presumed[15,16] to provide the sensitivity to structural nuance responsible for the sequence selectivity manifested by the drug in its cleavage of various oligonucleotide targets. An important synthetic goal was achieved by Nicolaou et al. in their synthesis of the methylglycoside corresponding to the aryltetrasaccharide domain of calicheamicin.[17] Our efforts focussed on the related trisaccharide sector of esperamicin.[18,19] Those studies led to the synthesis of trisaccharide methylglycoside **4a**. Furthermore, it was demonstrated by inference that the fully deprotected system, **4b**, undergoes extremely rapid rearrangement to the azafuranose **5**.[20] Maintenance of the free reducing end was shown to be possible by protecting the nitrogen atom of the hydroxylamino linkage as a Teoc carbamate (see **4c**, Teoc = $Me_3SiCH_2CH_2O_2C$).[18]



We describe here a) the first synthesis of the aryltetrasaccharide sector of calicheamicin which bears a free reducing terminus and b) the first demonstration that a properly activated aryltetrasaccharide system will indeed function as a glycosyl donor toward enantiomerically pure advanced aglycone intermediates en route to **3**.

Ferrier rearrangement[21] of commercially available diacetyl-L-rhamnal affords **6**,[23] which upon exchange of protecting groups, osmylation, and selective monomethylation,[22] provided a 72% yield of **7** (Scheme 1).[23] The free axial OH group in **7** was acetylated, and the anomeric hydroxyl group was liberated by debenzylation. Compound **8**,[23] thus produced, was converted to the trichloroacetimidate **9**.[24,25] Upon treatment of **9** with $BF_3 \cdot Et_2O$ and phenol **10**,[26] the aryl glycoside **11**[23,27] was obtained in 83% yield. This compound was converted to the axial silyl ether **12**[23] under standard conditions in 91% yield. Selective methoxycarbonylation *para* to the glycosyloxy function[28] gave ester **13**[23] albeit in only 45% yield.

All attempts to convert **13** to **15** by dealkylation, hydrolysis, or other acyl-transfer methods were unsuccessful.[29] However, the desired acid **15**[23] could be obtained by reduction of **13** with diisobutylaluminium hydride followed by

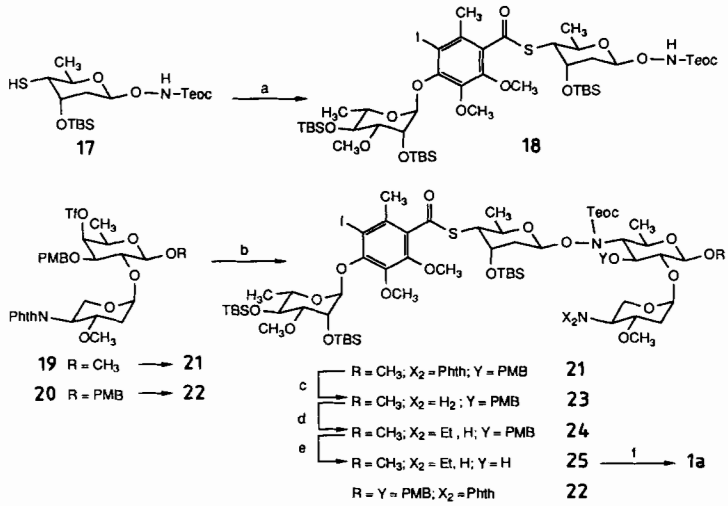
two-step oxidation[30a,b] of the resulting alcohol **14**. Compound **15** was converted to acid chloride **16** for subsequent reactions.

Under mediation by DMAP and Et_3N, **16** acylated the previously reported **17**[18] to afford **18**[23] in 85% yield (Scheme 2). The aryltetrasaccharide domain now could readily be assembled. Alkylation of the nitrogen atom[31] of the Teoc carbamate with the previously reported triflates **19** and **20**[18] provided the aryltetrasaccharides **21**[23] and **22**[23] respectively in yields of approximately 80%.

Hydrazinolysis of the phthalimide group of **21** followed by reductive alkylation[32] of **23**[23] afforded **24** in 98% yield. Cleavage of the *para*-methoxybenzyl (PMB) blocking group was accomplished (75%) using a standard protocol.[33]



Scheme 2. a) **16**, Et_3N, DMAP, CH_2Cl_2, 0 °C (85% from **15**). b) 1. NaH, **18**, dimethylformamide (DMF), 0 °C → RT; 2. **19** or **20**, DMF, 0 °C (80%). c) H_2NNH_2, EtOH, Δ (91%). d) CH_3CHO, $NaCNBH_3$, $MgSO_4$, MeOH (98%). e) dichlorodicyano-*para*-benzoquinone (DDQ), CH_2Cl_2, H_2O (75%). f) Bu_4NF, THF, 0 °C (60%).

Compound **25**[23] thus obtained was fully desilylated to afford the free methylglycoside **1a** Z-OCH_3.[23] The binding properties of **1a** with various oligonucleotide sequences are currently being evaluated.[34]

The two PMB groups of **22** were simultaneously cleaved[33] to give a 79% yield of **26**.[23] Compound **26** was

converted to trichloroacetimidate **27**[35] in the usual manner[25] (Scheme 3). As the aglycone coupling partner we selected an enantiomerically pure version of the previously reported **28**.[14b] In the event, reaction of **27** with **28** under standard Schmidt conditions[25] afforded **29**. Although the yield is modest (15%),[36] this is the first example of the use of the aryltetrasaccharide domain corresponding to calicheamicin as a glycosyl donor.

Now that the feasibility of such a reaction has been demonstrated, many exciting questions present themselves. These are subjects of active pursuit in our laboratory.

[35] A mixture of α and β imidates was produced in a 3:1 ratio and was easily separated. Only the α anomer was used in the glycosylation reaction.

[36] An equal amount of the α anomer was also produced. Higher anomeric ratios have been obtained using other optically active aglycone intermediates as coupling partners. These results will be published in due course.

Total Synthesis of Calicheamicin–Dynemicin Hybrid Molecules**

By *K. C. Nicolaou,* Erwin P. Schreiner, Yoshiharu Iwabuchi,* and *Toshio Suzuki*

The discovery of the novel and highly potent anticancer antibiotics of the enediyne class such as calicheamicin γ_1^I

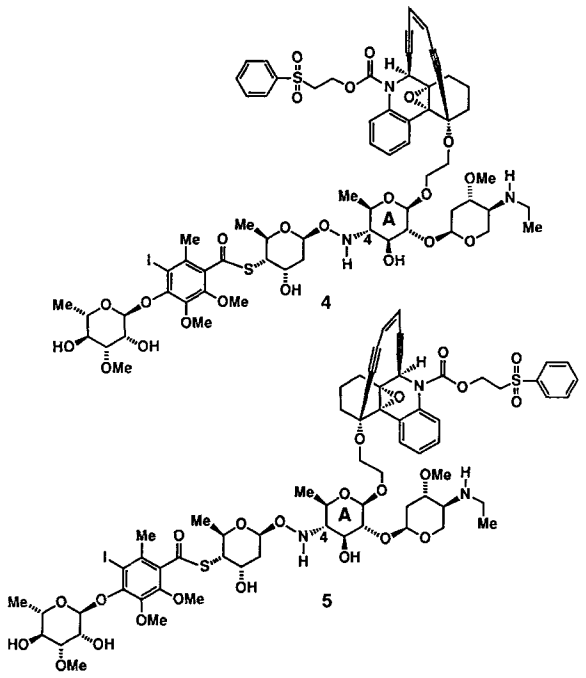
[**] This work was supported by the National Institutes of Health (USA) and the Scripps Research Institute.



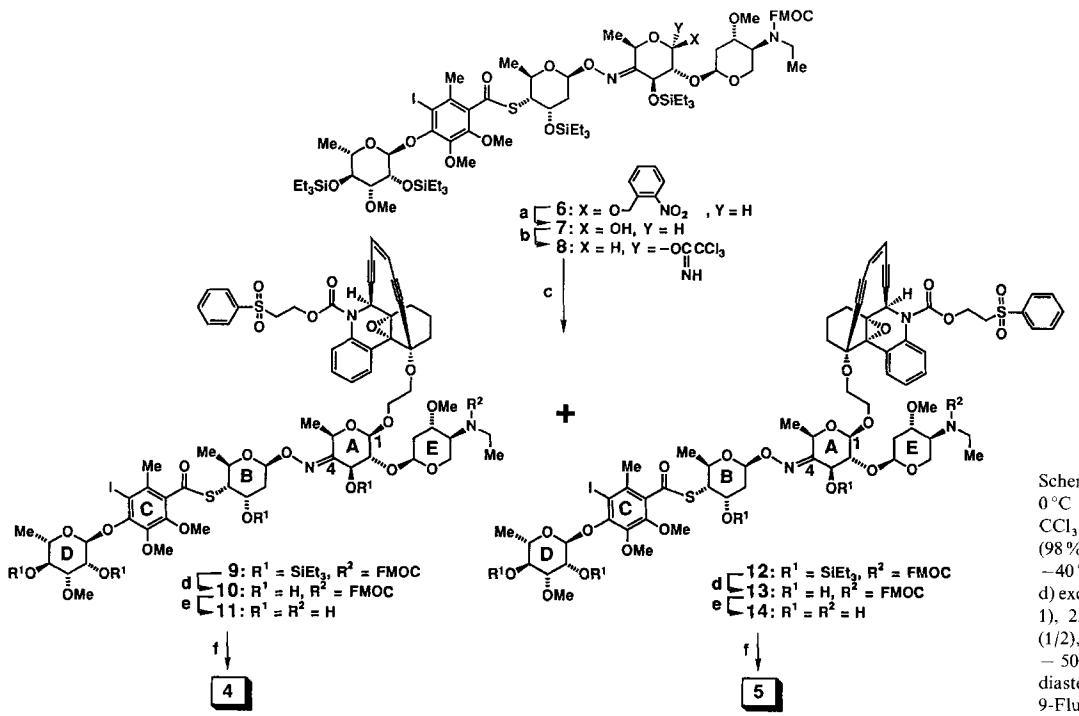
(**1**)[1] and dynemicin A (**2**)[2] generated a great deal of excitement in the chemical, biological, and medical communities.[3] Undoubtedly one of the prime challenges in the field is the design and synthesis of molecules that mimic, combine, or even outperform the biological actions of the natural products.[4] Several reports relating to this subject have already appeared.[3-5] In this communication we report the total synthesis of a series of hybrid molecules that combine the intact oligosaccharide fragment of calicheamicin γ_1^I (**1**) with the "warhead", dynemicin A (**3**), and a triggering device.

Hybrid structures **4** and **5** and their A-4 epimers were constructed according to Scheme 1. Thus the oligosaccharide **6** (Table 1) capped at the anomeric position of ring A with the photoremovable *ortho*-nitrobenzyl ether protecting group was synthesized following modifications of our recently published procedure.[6] Deprotection of **6** by photolysis furnished the free lactol **7** (95% yield), which was then converted into the trichloroacetimidate **8** with catalytic amounts of NaH and excess CCl_3CN in methylene chloride[7] (98% yield).

Coupling of **8** with (±)-**3**[8] under the influence of boron trifluoride–ether led to a mixture of four compounds (70%, ca. 5:5:1:1 ratio) which were separated by high pressure liquid chromatography (silica gel, heptane: diethyl ether, 3:7 → heptane:ethyl acetate, 7:3, gradient). Based on ^{1}H NMR and optical rotation data,[9] the four isomers were tentatively assigned structures **9** (major), A-1 anomer of **9** (minor), **12** (major), and A-1 anomer of **12** (minor).

The two major compounds (β-anomers) **9** and **12** were then taken through the sequence indicated in Scheme 1 to the four final products **4**, **5**, A-4 epimer of **4**, and A-4 epimer of **5** as follows: The triethylsilyl ethers were removed by exposure to HF–pyridine complex to afford compounds **10** (85%) and **13** (85%). The secondary amine was then liberated under carefully controlled conditions (Et_2NH, 0 °C) affording precursors **11** and **14**, respectively, in 68% yield in each case. Finally, reduction of the oxime double bond with sodium cyanoborohydride/boron trifluoride–ether at low temperatures led to a 1:1 mixture of A-4 epimers in 80% total yield for each case. Pure hybrid structures **4**, **5** (Table 1) and their A-4 epimers were obtained by preparative thin-layer chromatography (silica gel, 10% methanol in ethyl acetate). The A-4 stereochemistry was assigned based on ^{1}H NMR data [the A-4 protons for compounds **4** and **5** appear as a pseudotriplet at $\delta = 2.34$ ($J = 10.0, 10.0$ Hz) and 2.27 ($J = 10.0, 10.0$ Hz), respectively, revealing the equatorial orientation of the nitrogen].[6]

Preliminary biological results revealed significant anticancer activity with only two of these agents, namely compounds **4** and **5** which, interestingly, possess the correct stereochemistry for calicheamicin γ_1^I (**1**) at all stereocen-



Scheme 1. a) *hv*, THF/H_2O (9/1), 0 °C (95%); b) NaH (cat.), CCl_3CN/CH_2Cl_2 (1/12), 25 °C (98%); c) **3**, CH_2Cl_2, −60 → −40 °C (70%, $\beta:\alpha = 5:1$ ratio); d) excess HF. pyr, CH_2Cl_2/THF (7/1), 25 °C (85%); e) Et_2NH-THF (1/2), 0 °C (68%); f) $NaCNBH_3$, −50 °C (80%, 1:1 mixture of the diastereomers at A-4). FMOC = 9-Fluorenylmethyl carbonate.

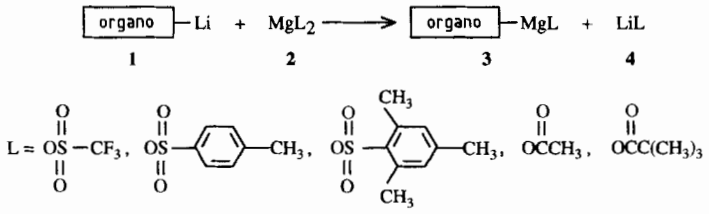
Ligand Effects in Grignard Additions**

By *Manfred T. Reetz*,* *Nicholas Harmat*, and *Rainer Mahrwald*

Dedicated to Professor Günther Maier on the occasion of his 60th birthday

An important method for controlling chemo- and stereoselectivity of "carbanions" consists in titanation with reagents of the type $ClTiL_3$ (L = Cl,OR,NR_2, etc.).[1] Since the sense and extent of selectivity in carbonyl addition reactions depends to a great extent on the nature of the ligands L, such a transmetalation makes possible, inter alia, the exploitation of ligand effects in carbanion chemistry. Although in recent



Scheme 1. Magnesiation of carbanions as a means to control chemo- and stereoselectivity (organo = CH_3,nC_4H_9,iC_3H_7, PhC≡C,C_6H_5).

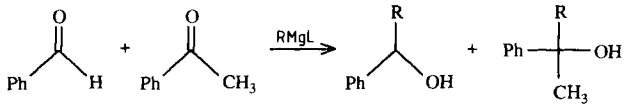
times other metals have been tested along similar lines (e.g., cerium,[2] iron,[3] and ytterbium[4] salts), the potential effects of ligands on selectivity have not been explored to date. This also applies to classical Grignard reagents.[5] We report here the first systematic studies on ligand effects in carbonyl addition reactions of organomagnesium reagents. In order to prepare the new Grignard reagents **3**, organolithium compounds **1** were transmetalated with magnesium salts MgL_2 (**2**). Since we have not yet studied the structure or the Schlenk equilibrium, the diagram for **3** is simply a formal description.[6]

The reagents **3** prepared by this route add to carbonyl compounds as smoothly as the traditional Grignard reagents RMgX (X = Cl, Br, I). At least in the case of the alkyl- and arylmagnesium carboxylates RMgOC(O)R this is not necessarily self-evident, because carboxylate salts have some electrophilic character and could react in the sense of a Gilman ketone synthesis.[7] The first indication of synthetically meaningful ligand effects came about in a simple study regarding chemoselectivity. Upon reacting 1:1 mixtures of an aldehyde (e.g. **5**) and a ketone (e.g. **6**) with one equivalent of the reagents RMgL in competition experiments, the aldehyde reacts essentially exclusively to form adducts **7**. In contrast, classical alkylmagnesium halides lead to about 2:1 mixtures of carbonyl adducts **7** and **8**. Selectivity for aldehydes is also high in the reactions of organotitanium reagents $RTiL_3$; this behavior results from steric effects originating from the bulky ligands L at titanium.[1, 8]



Scheme 2. Product ratio **7**:**8** (depending on RMgL): 55:45 (CH_3MgBr), 95:5 (CH_3MgOTs), 99:1 ($CH_3MgOC(O)C(CH_3)_3$), 60:40 (*n*BuMgBr), 99:1 (*n*BuMgOTs).

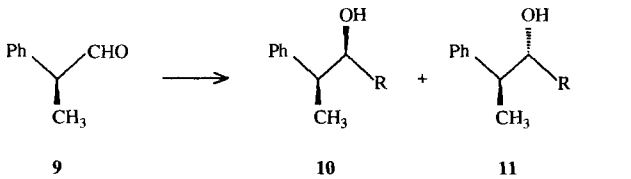


Table 1. Stereoselective Grignard additions to aldehyde **9**.

Reagent	Yield [%]	**10**:**11**

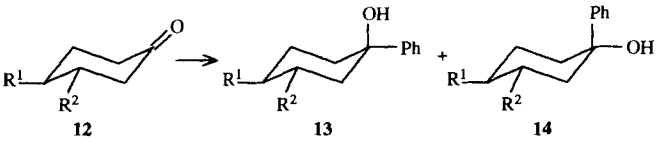
PhMgOTf	74	88:12
PhMgOTs	67	93: 7

[a] Tf = triflate. [b] Ts = tosyl.

In spite of considerable progress, the Cram/anti-Cram problem in addition reactions of α-chiral aldehydes of the type **9** has, in general, still not been solved.[9-12] Table 1 shows that for these aldehydes ligand effects in Grignard additions are also beneficial. The observed Cram selectivity is comparable or higher than in the analogous reactions of organotitanium[10] or other selective organometallic reagents.[11] Furthermore, branched alkyl groups such as isopropyl add readily, which is not possible when using organotitanium reagents due to undesired reduction (e.g., β-hydride elimination.[1]

Another challenge in synthesis is the stereoselective addition of arylmetal reagents to substituted cyclohexanone derivatives, because such "flat" reagents afford 1:1 or 2:1 mixtures of alcohols with axial and equatorial OH groups.[13] In the case of reactions of 4-*tert*-butylcyclohexanone (**12a**), remarkable ligand effects are obtained with the reagents described above (Table 2). Whereas the conventional reagent PhMgBr (and PhLi as well) leads to a 1:1 mixture of **13a** and **14a**, the bulky analog $PhMgOSO_2C_6H_2(CH_3)_3$ gives rise to a diastereoselectivity of 90% in favor of **13a**.[14] In the case of 3-methylcyclohexanone **12b**, axial attack is favored to the extent of 95%!

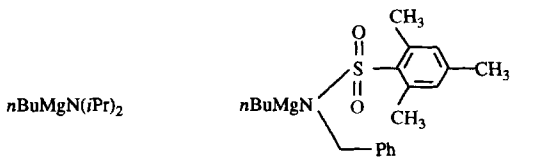


Scheme 3. **12**–**14**: R^1 = *t*Bu, R^2 = H (**a**); R^1 = H, R^2 = CH_3 (**b**).

Table 2. Additions to the cyclohexanone derivatives **12**.

Ketone	Reagent	Yield [%]	**13**:**14**
12a	PhMgBr	94	49:51[13]
12a	PhMgOTf	87	73:27
12a	PhMgOTs	90	85:15
12a	$PhMgOSO_2C_6H_2(CH_3)_3$	82	90:10
12b	PhMgBr	54	59:41[13]
12b	PhMgOTf	85	70:30
12b	PhMgOTs	83	79:21
12b	$PhMgOSO_2C_6H_2(CH_3)_3$	75	95: 5

Finally, nitrogen-based ligands were also tested. For example, reagents **15**[15] and **16**[16] add to 2-phenylpropanal **9** with essentially complete Cram selectivity affording **10** (R = *n*Bu) (*ds* = 97% for **15** and >98% for **16**) in yields of 76% and 69%, respectively. In the usual chemoselectivity test with the aldehyde/ketone pair **5**/**6**, **15** exclusively formed the aldehyde adduct **7** (R = *n*Bu).



The reactions described herein show that ligand effects in chemo- and stereoselective Grignard reactions can be use-

ful.[17] It remains to be seen whether ligand effects also play a role in aldol additions of magnesium enolates or in Ni- and Pd-catalyzed coupling reactions and Cu-catalyzed conjugate additions of organomagnesium reagents RMgL.

Experimental Procedure

A solution of a magnesium carboxylate $Mg[OC(O)R]_2$ (1.55 mmol) in dry THF (10 mL) was treated with an alkyl- or aryllithium reagent at −78 °C. The temperature was allowed to rise to 0 °C, whereupon the stirred solution was cooled once more to −78 °C. To the homogeneous solution was added a carbonyl compound, and the mixture was stirred at −78 °C for about 0.5 h. After allowing the temperature to reach 0 °C, the mixture was treated with a NH_4Cl solution and worked up analogously to traditional Grignard reactions. Reagents with tosylate ligands are sometimes insoluble. A racemate of aldehyde **9** was used.

[6] Since lithium salts **4** are formed in this reaction, complex magnesium- and lithium-containing reagents need to be considered, for example, ate complexes.

[7] In fact, no carbonyl addition reactions were observed with methylmagnesium trifluoroacetate $CH_3MgOC(O)CF_3$ prepared in situ; presumably the more electrophilic C-atom of the carboxylate is attacked by the nucleophile, so that the reagent does not survive or is never formed.

[15] Prepared from diisopropylamine and salt-free $(n\text{Bu})_2\text{Mg}$. The degree of diastereoselectivity in the addition of **15** to aldehyde **9** is not influenced by the presence of Li salts.

[16] Prepared by the reaction of the corresponding sulfonamide with $(n\text{Bu})_2\text{Mg}$ (in situ from *n*BuMgCl and *n*BuLi).

[17] Salt effects can also play a role (cf. [6.15]).

Two Stereoisomeric [4.5.5.5]Fenestranes Formed by Intramolecular [2 + 2] Cycloaddition**

By *Reinhart Keese**

Structural modification in the periphery of fenestranes of type **1** leads to the opening of two opposite bond angles ρ and σ at the quaternary central C atom.[1] Whereas the bond angles ρ and σ in all-*cis*-[5.5.5.5]fenestrane (**2a**) are 115°,[2] they are 128.3° and 129.2°, respectively, in a derivative of [4.4.4.5]fenestrane.[3] For all-*cis*-[4.4.4.4]fenestrane **4**, bond angles of 130° have been calculated.[4] The fenestranes of the all-*cis* series hitherto prepared have bond angles between those of **2** and **4**.[1] Stereoisomeric fenestranes that differ from the all-*cis* series by the presence of at least one *trans*-fused bicyclo[x.y.0]octane unit are 'inverted' at the appropri-

[**] This work was supported by the Swiss National Science Foundation. I gratefully acknowledge the skillful experimentation of B. Herzog and thank Priv.-Doz. Dr. P. Bigler and Dr. C. Müller for NMR measurements. Part of these results was presented at the Int. Chem. Congr. of Pacific Basin Chemical Societies, Honolulu, December 1989; cf. *Nachr. Chem. Techn. Lab.* **1990**, *38*, 322.

ate bridgehead. According to our MNDO calculations, these fenestranes have two opposite bond angles at the quaternary C atom that are larger than 109.47°. For example, in *cis-cis-cis-trans*-[5.5.5.5]fenestrane **5** they are 122° and 127.4°.[1a]

Reports on syntheses of stereoisomeric fenestranes are scarce. The mechanistic interpretation of one of the products obtained in the photolysis of 1-[but-3-enyl]-7-methoxyindane implies the formation of the [4.5.5.6]fenestradiene **6**, which contains a *trans*-fused bicyclo[3.2.0]heptane substructure.[5] More recently, P. Grieco et al. reported the synthesis of a derivative of **7a** through Claisen rearrangement in H_2O.[6] Smits and Caple et al. reported the formation of two derivatives of the oxafenestrane **7b**.[7] We describe here the synthesis of the stereoisomeric [4.5.5.5]fenestranes **12** and **13**. The latter compound contains a *trans*-fused bicyclo[3.3.0]-octane unit. The key step of our synthesis is the photochemically induced intramolecular [2 + 2] cycloaddition, which has previously been used only for preparation of all-*cis*-fenestranes.[8]

After double deprotonation with NaH-*n*BuLi, alkylation of ethyl 2-oxocyclopentanoate in the 3-position with 4-bromobutene gave **8**. Annulation of **8** with bromide **9**[9] gave a mixture of **10** and **11**, which could be separated by chromatography.[10] As expected, irradiation of **10** in hexane with a 125 W low-pressure lamp in a quartz vessel gave the fenestrane **12** in 89% yield.

Surprisingly, the endo isomer **11** is also photoreactive and gave in a yield of 86% a single product, which according to detailed NMR studies (2D, NOE and hetero-NOE analysis) is the stereoisomeric *cis-trans-cis-cis*-(4.5.5.5)fenestrane **13** (cf. Table 1).[11] This is the first example of a photochemically induced, intramolecular [2 + 2] cycloaddition at the *endo* side of a bicyclo[3.3.0]oct-1-en-3-one with concomitant formation of a *trans*-fused bicyclo[3.3.0]octane framework. For the parent hydrocarbons of **12** and **13** opposite bond angles (ρ and σ) of 120.8 and 133°, respectively, for ρ and 120° and 126°, respectively, for σ are calculated.[13] At present, the compounds **13**, **3**, **7a**, and the O-containing **7b** are the sole hydrocarbons with $C(C)_4$ subunits that according to MNDO calculations contain two opposite bond angles with an average value of as large as 129°.[13]

Conformational Preference of the Torand Ligand in Its Complexes with Potassium and Rubidium Picrate**

By *Thomas W. Bell,** *Peter J. Cragg, Michael G. B. Drew, Albert Firestone* and *Daw-Iong A. Kwok**

Torands[1, 2] are unusual host compounds for cationic guests and small hydrogen-bond donors. Among known host families, including crown ethers,[3] cryptands,[4] and spherands,[5] torands are unique in that their macrocyclic perimeters are defined by smaller, completely fused rings. Torand **1**[1] is an unusually planar, highly preorganized system that binds alkali metals rapidly to form 1 : 1 complexes of exceptional stability[1a] when compared with complexes of other nonencapsulating ligands. Despite its binding

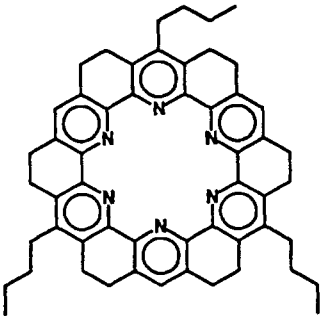
strength and preorganization, torand **1** displays weak size-selectivity toward alkali metals. Detailed structural and thermodynamic studies are required to understand these apparent contradictions fully. Described herein are the first X-ray crystal structures of torand complexes; they verify the relative planarity of **1** and reveal its preference for a staggered conformation.



1

Torand **1** forms 1:1 complexes with Li^+, Na^+, K^+, Rb^+, and Cs^+, all of which have been characterized as their picrate salts.[1a,c] Crystal structure analyses of the potassium picrate complex (**1** · K^+)(picrate$^-$) and the rubidium picrate complex (**1** · Rb^+)(picrate$^-$) are reported in this communication. The following article[14] describes the structure of the lithium picrate complex, which crystallizes in 2:2 stoichiometry. Key points of interest regarding these structures are the exact coordination environment of the cation and the conformation of the macrocyclic ligand. Since the perfectly planar conformation of **1** would be destabilized by eclipsed H-C-C-H torsional interactions in the six ethylene fragments, a twist is induced between each pair of pyridine rings. The resulting conformations can be described by eight possible combinations[6] of the six N-C-C-N torsion angles of the central 18-membered ring: (+ + + + + +), (+ + + + + −), (+ + + + − −), (+ + + − + −), (+ + − + + −), (+ + + − − −), (+ + − + − −) and (+ − + − + −). The X-ray structural analyses of both **1** · K^+ and **1** · Rb^+ reveal that **1** adopts the same overall conformation (+ − + − + −), in which the six nitrogen atoms are staggered above and below the best plane of the macrocycle.

Model studies on torands[7] indicated that metal ions having radii in the range of 1.4 to 1.5 Å should match the cavity size when binding in the best plane of **1**. Potassium was expected to fit most exactly because its radius ranges from 1.38 to 1.55 Å for coordination numbers 6 to 9.[8] The X-ray crystal structure of **1** · K^+ depicted in Figure 1[9] shows the K ion lying only 0.21 Å out of the best plane of the six nitrogen atoms, to which it binds approximately equally (K–N distances 2.73–2.85 Å, mean 2.77 Å). The seventh contact is to one of the nitro oxygen atoms of the picrate anion (2.85 Å). The phenoxide oxygen atom is disordered between positions O90A and O90B (Fig. 1) in the ratio of 61:39. In position O90A this oxygen forms the next shortest contact to the potassium ion (3.40 Å); a nitro oxygen atom of a neighboring picrate ion forms the shortest intermolecular K–O contact (3.72 Å). The absolute values of the six N-C-C-N torsional angles in **1** · K^+ range from 14 to 18°. The central 18-membered ring thus deviates from the D_{3d} symmetry observed in many crystalline 18-crown-6 complexes.[3d] This lowering of symmetry is possibly caused by axial coordination to the picrate ion, which is 3.29 Å from the nearest pyridine ring (N13 ··· N91). The angle between the picrate phenyl ring and the pyridine ring is 22.2°.

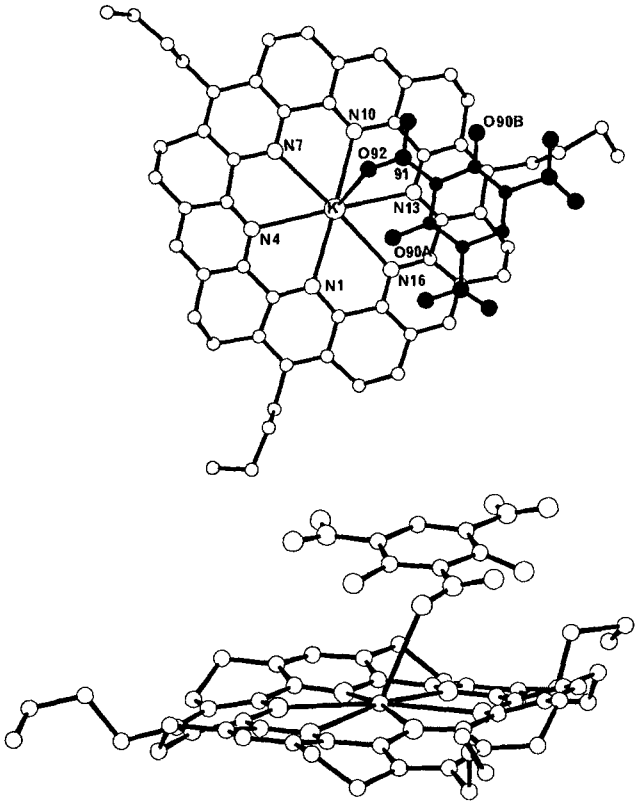


Fig. 1. Structure of **1** · K^+(picrate$^-$) in the solid state (hydrogen atoms omitted, picrate ions shown in black). Top: View perpendicular to the best plane of **1**. Bottom: Side view. Bond lengths [Å] and angles [°] of interest: K-N1 2.728(5), K-N4 2.850(5), K-N7 2.753(7), K-N10 2.738(5), K-N13 2.781(6), K-N16 2.792(6), K-O90A 3.469(9), K-O92 2.836(6), N1-K-N4 59.7(2), N4-K-N7 58.4(2), N7-K-N10 61.0(2), N10-K-N13 61.1(2), N13-K-N16 59.0(2), N16-K-N1 59.9(2), O92-K-N10 71.8(2), O92-K-N13 75.8(2); N1-C-C-N4 16(1), N4-C-C-N7 −14(1), N7-C-C-N10 17(1), N10-C-C-N13 −18(1), N13-C-C-N16 18(1), N16-C-C-N1 −17(1).

The structure of **1** · Rb^+ depicted in Figure 2[9] is similar to that of **1** · K^+ except that the Rb ion is 8-coordinate and is displaced by 1.06 Å from the best plane of the six nitrogen atoms. The six Rb–N distances range from 2.93 to 3.06 Å (mean 2.98 Å); in these complexes, Rb^+ appears to be 0.21 Å larger than K^+, in approximate agreement with Shannon's ionic radii (1.46 Å for 7-coordinate K^+ and 1.61 Å for 8-coordinate Rb^+).[8] The picrate ion in **1** · Rb^+ is bidentate with Rb–O contacts that are 0.21–0.24 Å longer than the K–O contact in **1** · K^+. In keeping with a larger metal-ion radius, torand torsional angles in **1** · Rb^+ (18–22°) are larger than in **1** · K^+. The longer oxygen contacts also allow an increase in the distance between the picrate ion and the nearest pyridine ring (smallest distance: C83 ··· C40, 3.49 Å; angle between picrate phenyl ring and pyridine ring, 4.6°).

The displacement of the metal ion from the torand plane and the larger torsional angles in **1** · Rb^+ produce an alternation of pyridine orientations with respect to the metal ion. Rubidium lies approximately within the planes of three pyridine rings (*para*-C-N-Rb^+ angle 172°) and is significantly displaced from the planes of the other three (*para*-C-N-Rb^+ angle 145°). Interactions between ligands and alkali metal ions are predominantly electrostatic,[10] and this alternation of the alignments of pyridine dipoles should weaken three of the six contacts. Despite the change in metal–macrocycle coordination from hexagonal planar in **1** · K^+ to hexagonal pyramidal in **1** · Rb^+, the torand conformations are remarkably similar. On the average, the N-C-C-N tor-

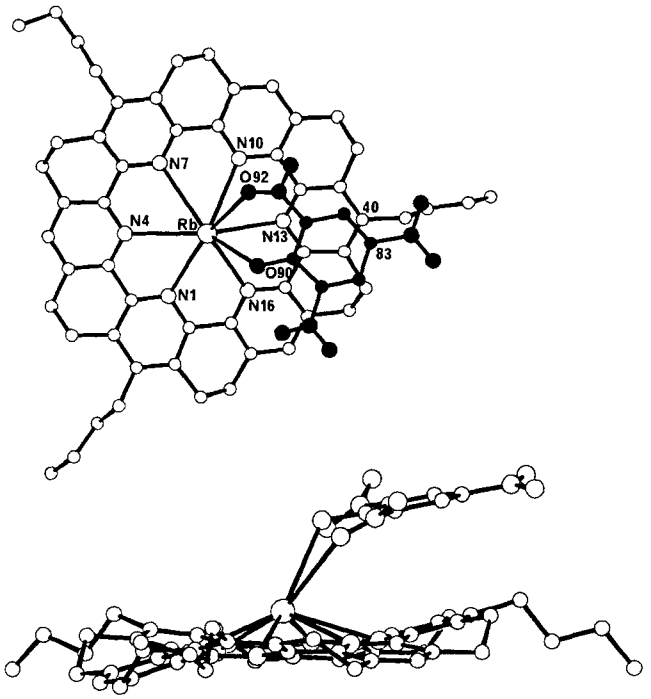

Fig. 2. Structure of **1** · Rb^+(picrate$^-$) in the solid state (hydrogen atoms omitted, picrate ions shown in black). Top: View perpendicular to the best plane of **1**. Bottom: Side view. Bond lengths [Å] and angles [°] of interest: Rb-N1 3.009(8), Rb-N4 3.006(8), Rb-N7 3.061(8), Rb-N10 2.954(8), Rb-N13 2.948(7), Rb-N16 2.926(8), Rb-O90 3.06(1), Rb-O92 3.09(1), N1-Rb-N4 55.0(2), N4-Rb-N7 55.1(2), N7-Rb-N10 55.0(2), N10-Rb-N13 56.1(2), N13-Rb-N16 57.0(2), N16-Rb-N1 56.1(2), O90-Rb-N13 80.0(2), O90-Rb-N16 80.1(2); O92-Rb-N10 62.9(2), O92-Rb-N13 78.6(2), N1-C-C-N4 −22(1), N4-C-C-N7 21(1), N7-C-C-N10 −18(1), N10-C-C-N13 19(1), N13-C-C-N16 −19(1), N16-C-C-N1 22(1).

sional angles decrease by only 4°. This suggests that the (+ − + − + −) conformation is preferred. Preliminary results of molecular mechanics calculations support this conclusion. Although the average O-C-C-O torsional angles in ([18]crown-6) · KNCS[11] and ([18]crown-6)$_2$ · $(RbNCS)_2$[11a,12] also vary by only 4°, more extreme conformational changes are observed in (dibenzo[18]crown-6) · KNCS and (dibenzo[18]crown-6) · RbNCS.[13] The coordination numbers and geometries of potassium and rubidium ions are apparently forced to adjust to the spatial requirements of torand **1**, although the conformations of macrocyclic ligands usually adjust to the bonding demands of metals. Even spherands, which dictate the coordination numbers of alkali metals, adjust their conformation in complexes.[5] On the other hand, axial coordination is not controlled in torands and in other planar macrocyclic ligands; this can lead to considerable variation in structures of complexes, as illustrated in the accompanying article.[14]

Experimental Procedure

1 · K^+(picrate$^-$): A solution of torand **1** [1a] (37 mg, 0.047 mmol) in $CHCl_3$ (3 mL) was washed with 15 mL of an aqueous solution of potassium picrate (40 mg, 0.15 mmol) and of K_2CO_3 (40 mg, 0.29 mmol). The aqueous layer was extracted with CH_2Cl_2 (10 mL), and the combined organic solutions were evaporated to dryness. The residue was recrystallized from n-butyronitrile (8 mL), and the resulting yellow-orange crystals were dried at room temperature (0.1 torr) for 12 hours. Yield: 31 mg (64%).

^{1}H NMR: (10^{-3} M in D_2O-saturated $CDCl_3$, 300 MHz) δ = 8.380 (s, 2H; picrate), 7.503 (s, 3H; pyridine-H), 3.031 (s, 24H; $ArCH_2CH_2Ar$), 2.784 (t, 6H; CH_2Pr), 1.5–1.6 (m, 12H; CH_2CH_2Me), 1.027 (t, J = 7 Hz, 9H; CH_3). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3080(w), 2940(m), 2920(m), 2840(m), 1630(s), 1600(w), 1540(s), 1485(m), 1445(m), 1425(w), 1370(m), 1350(m), 1320(s), 1290(s), 1270(m), 1250(s), 1210(s), 1180(w), 1150(m), 1095(w), 1060(m), 1030(w), 985(w), 960(m), 930(m), 920(w), 900(m), 775(m), 720(m), 710(m), 700(m). Correct C, H, N analyses. Recrystallization from a CH_2Cl_2 solution layered with CH_3CN gave clear, yellow rectangular crystals. The crystal used for X-ray diffraction studies measured 0.4 × 0.2 × 0.1 mm.

1 · Rb^+(picrate$^-$): A solution of **1** (30.4 mg, 0.039 mmol) in $CHCl_3$ (3 mL) was washed with 25 mL of an aqueous solution of rubidium picrate (32 mg, 0.10 mmol) and 0.2 mL of triethylamine. The $CHCl_3$ solution was evaporated to dryness, and the residue was recrystallized by slow evaporation of the solvent of a solution in ethyl acetate/CH_2Cl_2. The resulting yellow powder was dried for 12 hours at room temperature (0.1 torr). Yield, 33.4 mg (76%).

^{1}H NMR: (D_2O-saturated $CDCl_3$, 300 MHz, δ = 8.387 (s, 2H; picrate), 7.452 (s, 3H; pyridine-H), 2.986 (s, 24H; $ArCH_2CH_2Ar$), 2.751 (t, 6H; CH_2Pr), 1.5–1.6 (m, 12H; CH_2CH_2Me), 1.025 (t, J = 7 Hz, 9H, CH_3). A Supramolecular Assembly of Two Torands, Two Lithium Ions, and Three Water Molecules **

By *Thomas W. Bell,* Peter J. Cragg, Michael G. B. Drew, Albert Firestone,* and *Daw-Iong A. Kwok**

The preceding article describes structures of crystalline 1:1 complexes between a torand (**1**) and the picrate salts of potassium and rubidium. The sodium and potassium complexes are remarkably stable in chloroform,[1] and the crystal structure of the potassium complex shows axial coordination to picrate. Lithium also forms stable 1:1 complexes with **1**,[2] despite its small size compared with the cavity formed by the central 18-membered ring of **1**. The X-ray structural analysis reported here shows that **1** · Li aggregates in the solid state form a stacked torand dimer threaded by a hydrated chain of two lithium ions.

Torand **1** was treated with an aqueous solution of lithium picrate and lithium hydroxide to give **1** · Li^+(picrate$^-$) · $(H_2O)_{1.5}$, which was crystallized from a mixture of organic solvents. The crystal structure[3] depicted in Figures 1 and 2 shows the aggregation of two molecules of the 1:1 complex with three molecules of water, one of which bridges between the two lithium ions. Figure 1 shows the triclinic unit cell containing two symmetry-related molecules of the 2:2 complex as well as a view of the complex along the axis perpendicular to the torand rings. The picrate ions are not coordinated to lithium, hydrogen-bonded to water, or linked by π stacking to torands. Each molecule of the 2:2 complex is a discrete entity in which the two torands are coaxially stacked, as shown in Figure 1 (bottom). This diagram also shows that the torands are rotated with respect to each other by approximately 30° about the perpendicular axis, producing a pseudo-S_{12} axis. The three water molecules lie nearly on this axis, whereas the two lithium ions are offset, binding unsymmetrically to the torand cavities.

Both lithium ions have approximately tetrahedral coordination geometries, and Li–O bonds to a terminal water molecule and to the bridging water molecule. Each lithium ion is coordinated to a bipyridine fragment through one short Li–N bond (2.04, 2.09 Å), and one longer Li–N bond (2.30, 2.35 Å). For each the next shortest contact is to a third nitrogen atom (both 2.61 Å), suggesting that the torand acts partly as a terpyridyl ligand. The Li–O distances fall in the range 1.86–1.96 Å and are shorter than usually observed for hydrated lithium (1.91–2.34 Å).[4] It is clear, however, that the coordinated oxygen atoms belong to water molecules rather than hydroxide ions because the C–O bond lengths in the picrate ions (1.22, 1.26 Å) are consistent with those observed for a picrate anion (1.22–1.25 Å)[5] rather than picric acid (1.31–1.35 Å).[6]

The two torands in $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ are clearly in van der Waals contact since the angle between the best planes of the six nitrogen atoms of each is only 3°, and the distances between N_6 centroids is 3.64 Å. On the other hand, the torands are not completely planar and are complementarily folded. The six N-C-C-N torsion angles for each of the central 18-membered rings are given in Figure 2 and show that this folding produces an approximate mirror plane, neglecting the hydrated dilithium chain. The folding plane bisects

torand A through opposite pyridine rings containing N7A and N16A. The six torsional angles fit a $(+--/++-)$ pattern where the position of the mirror plane is indicated by the symbol/. The 30° rotation of torand B with respect to A requires that this folding plane falls between pyridine rings; thus it bisects the CC bonds for N1B-C-C-N4B and N10B-C-C-N13B. These are the smallest torsional angles (−3, −7°), and the remaining torsions nicely fit a $(+-/+-)$ pattern.

The conformations of the torands in $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ differ significantly from the staggered $(+--+--)$ conformation observed in $\mathbf{1} \cdot K^+$(picrate$^-$) and $\mathbf{1} \cdot Rb^+$(picrate$^-$). This difference is apparently due to the complementary folding observed in the dimer, but why does $\mathbf{1} \cdot Li^+$ crystallize as a 2:2 complex, whereas $\mathbf{1} \cdot K^+$ and $\mathbf{1} \cdot Rb^+$ crystallize as 1:1 complexes with axial coordination by the picrate ion? The answer may be that this supramolecular assembly is stabilized by a hydrogen bonding network. An obvious difference between $\mathbf{1} \cdot Li^+$ and $\mathbf{1} \cdot K^+$ or $\mathbf{1} \cdot Rb^+$ is that the lithium ion does not fill the cavity of **1**, leaving the potential for hydrogen bonding by uncoordinated pyridine-N atoms. Lithium also possesses a larger hydration energy than potassium or rubidium.[7] Coordination to lithium should enhance the ability of water to donate hydrogen bonds, so the structure of $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ was carefully examined for evidence of OH···N hydrogen bonding.

Both terminal water molecules lie within 3.0 Å of several uncoordinated pyridine-N atoms, but only two of these pyridine rings are oriented with their lone pairs on N directed towards the O atoms. Thus N16A may be hydrogen-bonded to O1 (2.94 Å), and N7B to O2 (2.96 Å). It appears more likely that the bridging water molecule is hydrogen-bonded to inward-directed pyridine-N atoms N1A and N4B. Although these O–N distances are somewhat long (3.07 and 3.08 Å respectively), these nitrogen atoms and the lithium ions are located approximately tetrahedrally around O3 (Li1-O3-N1A 89°, Li1-O3-N4B 109°, Li2-O3-Ni1A 125°, Li2-O3-N4B 90°, N1A-O3-N4B 105°). The combination of weak hydrogen bonds to O3 and van der Waals interactions between the torands can explain the formation of the observed supramolecular assembly as well as the relatively short Li–O bridging distances in the complex.

Among the known crystal structures of lithium complexes,[4, 8–11] the structure of $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ is unusual in that lithium is unsymmetrically associated with three nitrogen atoms of the macrocycle. In two complexes of planar 15-membered macrocycles containing five sp^2 nitrogen donors,[9] lithium binds symmetrically with Li–N distances ranging from 2.15 to 2.27 Å. While this ligand contains a terpyridyl fragment, the distance between terminal nitrogens in this smaller macrocycle is only 4.13 Å, compared to an average of 4.81 Å in $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$. Average Li–N bond distances are 2.08 Å in complexes with N-containing arene ligands[4] and 2.13 Å in the bipyridine complex of lithium picrate,[8] indicating that lithium is too small to bind symmetrically to a terpyridyl fragment of **1**.

A range of structures has been observed for lithium complexes of crown ethers,[4, 10] and $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ bears some resemblence to the 1:2 complexes between lithium salts and [12]crown-4. The Li([12]crown-4)$_2^+$ ion is useful for characterizing free anionic species in the solid state.[10a] Again $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ breaks the rule: lithium normally coordinates to picrate in complexes.[4, 8] Also of relevance are the structures of Li_2([18]crown-6)$(H_2O)_4X_2$ (X = Cl or Br).[10b] One of the two lithium ions in these structures forms three contacts of unequal length to consecutive oxygens of the crown ether. In the 1:2 complex of 18,18′-spirobi([19]crown-6) with $LiI(H_2O)_2$ the metal ion is also coordinated unsymmetrically to three consecutive oxygens of the crown.[10c]

Lithium salts show a pronounced tendency to form hydrated aggregates; key examples are the complexes of [18]crown-6 already mentioned[10b, c] and $[Li_2(H_2O)_6]^{2+}$.[11] In both cases the environments of the lithium ions are approximately tetrahedral, and two lithium and two oxygen atoms form four-membered rings. The linear $Li_2(H_2O)_3$ chain observed in the torand complex is apparently unique, although linear chains of hydrated sodium ions are known.[12] These observations suggest that the design of lithium-selective hosts might profitably accommodate part of the lithium hydration shell. Moreover, the structure of $[\mathbf{1}_2 \cdot Li_2(H_2O)_3]^{2+}$ suggests that longer linear chains of torands might be produced by decreasing the ratio of bridging ligand to metal, paving the way to polymeric materials with potential for ion and electron conductivity.

Experimental Procedure

A solution of torand **1**[1,2] (30 mg, 0.039 mmol) in $CHCl_3$ (3 mL) was washed with 7 mL of an aqueous solution of lithium picrate (30 mg, 0.11 mmol) and of $LiOH \cdot H_2O$ (35 mg, 0.83 mmol). The $CHCl_3$ solution was evaporated to dryness, and the residue was dissolved in ethyl acetate/CH_2Cl_2. Slow evaporation of the solvent yielded yellow needles of $[\mathbf{1}_2 \cdot Li_2(H_2O)_3(picrate)_2]$, which were dried for 12 hours at room temperature (0.1 torr). Yield 32 mg (71%).

^{1}H NMR (10^{-3} M in D_2O-saturated $CDCl_3$, 300 MHz): δ = 8.312 (s, 2H; (picrate), 7.515 (s, 3H; pyridine), 3.044 (s, 24H; $ArCH_2CH_2Ar$), 2.777 (t, 6H; CH_2Pr), 1.5–1.6 (m, 12H; CH_2CH_2Me), 1.020 (t, J = 7 Hz, 9H; CH_3). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3400(br), 3080(w), 2940(m), 2840(m), 1630(s), 1600(m), 1540(s), 1510(m), 1485(m), 1450(m), 1430(m), 1375(m), 1350(m), 1320(m), 1290(s), 1270(m), 1250(s), 1210(m), 1150(m), 1095(w), 1060(m), 1030(w), 960(m), 910(m), 900(w), 780(m), 720(m), 700(m). Correct C,H,N analyses. The crystal used for X-ray structural analysis (0.6 × 0.3 × 0.05 mm) was grown from a CH_2Cl_2 solution layered with 10:1 (v/v) ethyl acetate/hexane.

Idealized Pentagonal-Planar Coordination for Indium in $[(\mu_5\text{-In})\{Mn(CO)_4\}_5]^{2-}$

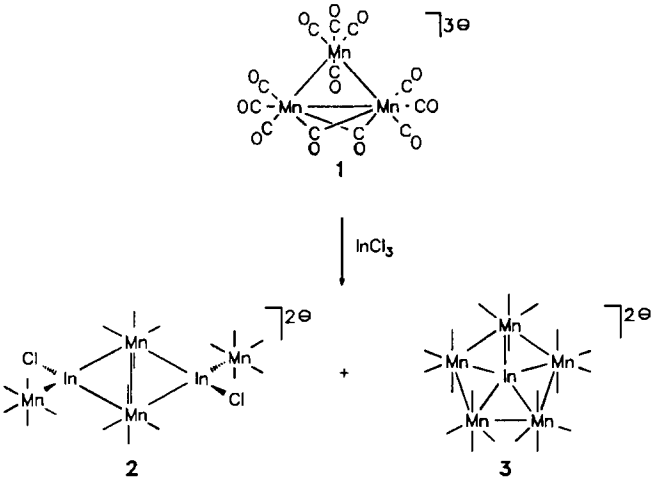
By *Martin Schollenberger, Bernhard Nuber,* and *Manfred L. Ziegler**

The possible geometries for a pentacoordinated central atom are so similar that they are easily interconvertible.[1] The idealized coordination polyhedrons, the trigonal bipyramid and the square pyramid, occur only very rarely in nature in undistorted form.[2] In almost all cases, however, these two coordination geometries are energetically considerably more favorable than a pentagonal-planar structure. Pentagonal-planar coordination has thus been observed only when interpretation as a virtual pentagonal bipyramid is possible.[3–6] We report here on the anionic complex $[(\mu_5\text{-In})\{Mn(CO)_4\}_5]^{2-}$ (**3**), in which the indium atom is found in the center of a five-membered ring constructed from five $[Mn(CO)_4]$ units. Although this ring is not strictly planar but is distorted towards an envelope conformation, the coordination environment of indium in the center of the ring can best be described as idealized pentagonal planar. This unusual coordination form is forced on the indium exclusively by the steric requirements of its position in the center of a rigid five-membered ring.

Metathesis reactions aimed at constructing carbonylmanganese compounds usually proceed from easily accessible $[Mn(CO)_5]$ derivatives. Because of the high inherent stability of the $[Mn(CO)_5]$ unit, the products as a rule also include the $[Mn(CO)_5]$ fragments. For instance, $InCl_3$ reacts with $Na[Mn(CO)_5]$ by stepwise substitution to form $[\{Mn(CO)_5\}_nInCl_{(3-n)}]$ $(n=1-3)$.[7] We have shown that in metathesis reactions, anionic clusters constructed from three $[Mn(CO)_4]$ moieties afford derivatives in which the $[Mn_3(CO)_{12}]$ unit generally remains intact. Thus $[(\mu\text{-H})Mn_3(\mu\text{-CO})_2(CO)_{10}]^{2-}$ reacts with $InCl_3$ to form $[In\{(\mu\text{-H})Mn_3(CO)_{12}\}_2]^-$ and $[InCl\{(\mu\text{-H})Mn_3(CO)_{12}\}\{Mn(CO)_5\}]^-$.[8]

In contrast, the completely deprotonated form of $K_2[(\mu\text{-H})Mn_3(\mu\text{-CO})_2(CO)_{10}]$, $K_3[Mn_3(\mu\text{-CO})_2(CO)_{10}]$ (**1**),[8,9] affords predominantly the tetranuclear product **2** with excess of $InCl_3$ (Scheme 1).[10–12] In **2** two $[Mn(CO)_4]$ units joined by Mn–Mn bonds are bridged by $[\{Mn(CO)_5\}InCl]^-$ groups. In a broad sense these bridging ligands, which are derivatives of the type R_2In^-, are isoelectronic with bridging methylene ligands R_2C and their homologues R_2Si and R_2Sn.[13–15] The Mn centers are in an idealized octahedral geometry, because the bridging ligands and the equatorial CO groups are approximately coaxially bound. Thus the Mn atoms, the indium centers, and the equatorial CO groups are coplanar. The center of gravity of the molecular ion **2** lies on the crystallographic inversion center, the substituents on the bridging ligands are *trans* to one another, and the Mn–Mn bond in **2** (316.4(2) pm) results in a comparatively small Mn-In-Mn bond angle (72.6(1)°).

Complex **3** is formed as a side product in the synthesis of **2** (Scheme 1).[10,11] It has a very unusual structure (Fig. 1) in which the five $[Mn(CO)_4]$ units are joined to form a five-membered ring of metal atoms; the indium center in the middle of this ring forms bonding interactions with all five manganese atoms.



Scheme 1. The reaction of **1** with $InCl_3$. The lines at the manganese atoms of **2** and **3** represent terminal CO ligands.

The conformation of the cyclic $[Mn_5(CO)_{20}]$ building block (isolobal to C_5H_5!) is a flattened envelope (torsion angles [°]: Mn5-Mn1-Mn2-Mn3 −7.0; Mn2-Mn1-Mn5-Mn4 33.1). The Mn3-Mn4-Mn5 plane lies at an angle of 45° to the best plane containing Mn3-Mn2-Mn1-Mn5. The manganese atoms are in an idealized octahedral environment; with respect to the five-membered ring two CO groups are equatorial and two CO ligands are axial at each Mn

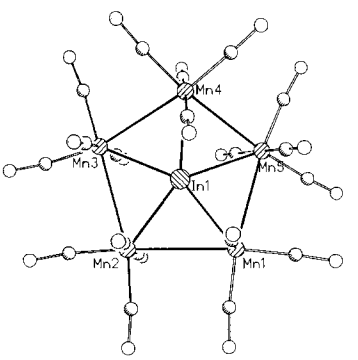


Fig. 1. Structure of **3** in the solid state. Selected distances [pm] and angles [°]: In1-Mn1 265.0(2), In1-Mn2 261.8(3), In1-Mn3 264.6(2), In1-Mn4 265.1(2), In1-Mn5 265.7(2), Mn1-Mn2 320.8(3), Mn1-Mn5 314.2(3), Mn2-Mn3 323.5(3), Mn3-Mn4 317.8(3), Mn4-Mn5 309.5(3); Mn1-In1-Mn2 75.0(1), Mn1-In1-Mn5 72.6(1), Mn2-In1-Mn3 75.8(1), Mn3-In1-Mn4 73.7(1), Mn4-In1-Mn5 71.3(2).

atom. The indium lies almost at the center of gravity of the ring spanned by the five manganese atoms (distance 8.5 pm; deviation from the best plane 4.6 pm). Its coordination is approximately pentagonal planar. This unusual coordination form in **3** is exclusively due to the sterically rigid $[Mn_5(CO)_{20}]$ "ligand".

Experimental Procedure

All manipulations were conducted under an inert atmosphere (argon) in the absence of moisture and air. All glass apparatus was evacuated several times on an oil vacuum line and flushed with argon before use. The solvents were dried under argon and freshly distilled.

1: Prepared by published methods [8, 9], this compound contains 30% KOH. For the preparation of **2** and **3**, **1** was freed of KOH by dissolution in acetone and filtration, followed by evaporation of the acetone. KOH-free **1** is pyrophoric.

2 and **3**: THF (8.5 mL) was added to a mixture of **1** (0.58 g, 0.94 mmol) and dry $InCl_3$ (0.87 g, 4.10 mmol). The color changed immediately from green to blue. The solution was stirred for 5 min, methanol (1.5 mL) was added, and the mixture was separated on a chromatography column (MPLC column 46 × 2.6 cm, silica gel 40–63 μ, eluent THF/methanol 10/1). A yellow and a blue fraction that have not yet been able to be characterized were eluted first in low yields. The third violet fraction was treated with $AsPh_4Cl$ monohydrate (100 mg, 0.229 mmol), the solvent removed at 10^{-1} mbar, and the residue taken up in a mixture of *n*-hexane, ethyl acetate, and acetone (5:20:15 mL). The violet mother liquor was filtered off through a G3 Schlenk filter; at +4 °C **2**-$(AsPh_4)_2 \cdot (CH_3)_2CO$ precipitates as red-brown crystals. They are separated from the mother liquor by decantation, washed three times with diethyl ether, and dried in vacuum. Yield: 90 mg (8%, calculated on initial amount of **1**), correct elemental analyses.

The fourth, brown fraction was treated with $AsPh_4Cl$ monohydrate (50 mg, 0.115 mmol), the solvent removed at 10^{-1} mbar, and the residue taken up in ethyl acetate. Excess $AsPh_4Cl$ and KCl remained undissolved. The brown mother liquor was filtered through a G-3 Schlenk filter. At +4 °C, **3**-$(AsPh_4)_2$ precipitated in the form of dark brown crystals, which were separated by decantation from the mother liquor, washed three times with diethyl ether, and dried at 10^{-1} mbar. Yield: 15 mg (2%, calculated on initial amount of **1**), correct elemental analyses. A light brown residue which cannot be eluted remains on the column.

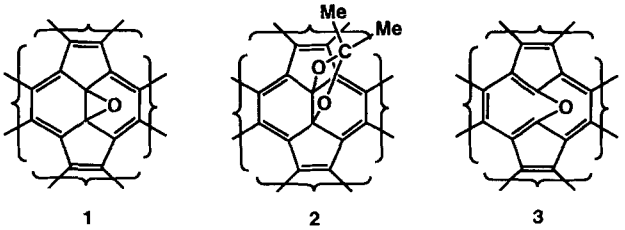
Reaction of C_{60} with Dimethyldioxirane—Formation of an Epoxide and a 1,3-Dioxolane Derivative**

By *Yiannis Elemes, Scott K. Silverman, Chimin Sheu, Michelle Kao, Christopher S. Foote,* Marcos M. Alvarez,* and *Robert L. Whetten**

Since their discovery,[1] the fullerenes have attracted much attention.[2–4] Although gram quantities of C_{60} and C_{70} can now be produced,[5, 6] the chemical reactivity of these new compounds is just beginning to be explored, and few products have been completely characterized. Among these are adducts to C_{60} of OsO_4,[7, 8] other metal-complex fragments,[9–11] and diphenylcarbene.[12]

Although C_{60} is easy to reduce and reacts readily with nucleophiles, it is very difficult to oxidize.[13–17] Dioxiranes have been used to make epoxides that are difficult to prepare by other routes.[18–26] We now report that C_{60} reacts with dimethyldioxirane to give an epoxide $C_{60}O$ and a 1,3-dioxolane derivative.



1 **2** **3**

C_{60} reacts with dimethyldioxirane to give two products, **1** and **2**, which in the solid state are stable dark crystals. Solutions of **2** in toluene are yellow, those of **1**, purple (similar to solutions of C_{60}). The UV/VIS spectra of **1** and **2** are shown in Figures 1a and 1b. The FTIR spectrum of **1** is shown in Figure 2a. The ^{13}C NMR spectrum of **1** (Fig. 3a) consists of 17 signals, of which four correspond to two carbon atoms and

thirteen correspond to four carbon atoms. This is the correct number and ratio of peak intensities for a C_{60} adduct of C_{2v} symmetry. The osmium-tetraoxide adduct, of which a detailed NMR study has recently appeared,[27] has the same symmetry.

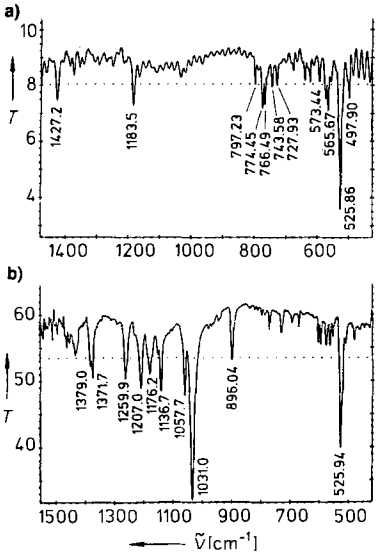

Fig. 2. FTIR spectra (KBr pellets) of a) $C_{60}O$ **1** and b) C_{60}-1,3-dioxolane **2**.

The LD-TOF mass spectrum (laser desorption time-of-flight)[28, 29] of **1** displays a peak for $C_{60}O$ (m/z 736 ± 2, M^+) as well as for C_{60}, which arises from loss of one oxygen atom. The FAB mass spectrum (not shown) shows a weak peak at m/z 736, but the loss of an oxygen atom is much more pronounced here. There is no $C_{60}O$ in the starting material, as shown by the LD-TOF spectrum, and the isolated **1** is not contaminated by C_{60} according to HPLC. Based on the above data, **1** is a monoepoxide of C_{60} with the oxygen bridging the bond connecting two six-membered rings, a bonding situation also found in other C_{60} adducts.[27]

After much of this work had been completed, we received a manuscript from chemists at Exxon and the University of Pennsylvania reporting the preparation of $C_{60}O$ by a photochemical route and by isolation from soot.[30] The properties of their material are in excellent agreement with those reported above. The infrared bands differ slightly in relative intensities, which we attribute to the difference in medium (KBr pellet vs. film). The ^{13}C NMR shifts are quite similar, although the solvents used are different (CS_2 vs. C_6D_6). Both $C_{60}O$ and $C_{70}O$ have also been detected in the gas phase.[31] An oxide of C_{70} is formed in the soot with other fullerenes and has been characterized only by mass and UV/VIS spectrometry.[6] Recent electrochemical studies reported that the dianion of C_{60} reacts with O_2 to form a series of C_{60} oxides which were detected by FAB mass spectrometry but were not otherwise characterized.[32]

Our product is clearly the epoxide **1** rather than the annulene[33] **3**, as shown by the ^{13}C NMR signal at $\delta = 90.92$; an sp^2 C–O should give rise to a signal below $\delta = 140$.[34, 35] Substituted epoxide carbons typically resonate at $\delta = 52$–70.[36] Although the resonance at $\delta = 90.92$ is at low field for epoxide carbons, the downfield shift is probably caused by the anisotropy of the partially broken fullerene, which was also reported in the diphenylcarbene adduct.[12] The similarity of the UV/VIS spectrum of the diphenylcarbene adduct to that of C_{60} was taken as indirect evidence for the open annulene structure, which is clearly implied by the long C–C bond.[37] The UV/VIS spectra of **1** and C_{60} are also quite similar, but the NMR spectrum of **1** provides definitive proof of its epoxide character.

Based on spectral data we identify the second product of the reaction of dimethyldioxirane and C_{60} as 1,3-dioxolane **2**. The FTIR spectrum of compound **2** (Fig. 2b) shows a very strong sp^3 C–O absorption band at 1031 cm^{-1} and a C–H absorption band at 2900 cm^{-1}. The LD-TOF mass spectrum has a molecular ion (m/z 795, M^+, corresponding to C_{60} + dimethyldioxirane) and signals of greater intensity for fragmentation to $C_{60}O$ (loss of acetone) and to C_{60}. The exact molecular mass of M^+ (794) was obtained from the FAB mass spectrum but here, as with **1**, the signal of the C_{60} ion is dominant. The ^{13}C NMR spectrum of **2** (Fig. 3b) also has 17 signals for the C_{60} skeleton, of which 13 correspond to four carbon atoms, and four correspond to two carbon atoms. The resonance at $\delta = 96$ (at lower field than the related signal in **1**) is assigned to the O-bound carbon atoms. The signals at $\delta = 113.04$ (1 C) and 28.92 (2 C) are assigned to the

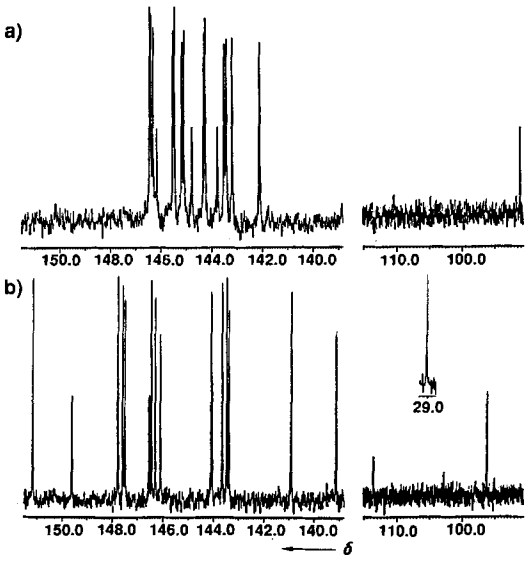

Fig. 3. ^{13}C NMR spectra of a) $C_{60}O$ **1** and b) C_{60}-1,3-dioxolane **2** in CS_2 with [D_6]acetone as internal lock and [Cr(acac)$_3$] as relaxation agent.

ketal and methyl C atoms, respectively. In the ^{1}H NMR spectrum (in CS_2) the methyl hydrogens give rise to a sharp singlet at $\delta = 1.56$.

The 1,3-dioxolane structure can be deduced from the number of signals in the ^{13}C NMR spectrum; the 1,2-isomer would have only a single mirror plane. The same reasons advanced in favor of the epoxide structure for **1** lead us to conclude that adduct **2** also has the closed structure. The fullerene regions of the ^{13}C NMR spectra of the OsO_4 adduct of C_{60} [27] and of **2** are strikingly similar (Fig. 3b), confirming their structural similarity. Hydrolysis of this ketal and oxidation of the resulting diol may offer an attractive and specific route to ring-opened fullerenes.

The determination of the mechanism for the formation of **1** and **2** will require further study. It is particularly surprising that the O–O bond of the dimethyldioxirane opens. To our knowledge, this is the first reported dimethyldioxirane adduct of this type. Small amounts of a 1,3-dioxolane were formed during the epoxidation of *cis*-3-hexene,[38] but this resulted from addition of acetone to the epoxide under the acidic conditions used. When a solution of **1** in acetone/toluene was stirred at 50 °C for 12 h, no change was observed (HPLC). Solutions of **1** in toluene heated at 110 °C for 24 h showed gradual decomposition of **1** to C_{60}. The 1:1 dimethyldioxirane–C_{60} adduct **2** could give epoxide **1** by loss of acetone, or **1** and **2** could be formed in competitive reactions. But no change was observed (HPLC) for solutions of **2** in toluene after they had been heated at 110 °C for 24 h. Thus, the two compounds do not interconvert under more extreme conditions than those required for their formation (and isolation), and the competitive pathway seems likely.

Addition of dimethyldioxirane to C_{60} could proceed by either homolytic or heterolytic cleavage of the O–O bond. Although Wudl et al. report reactions of C_{60} with 1,3-dipoles,[12] the path via diradicals seems more likely in our case.

Experimental Procedure

A solution of C_{60} (200 mg, 0.28 mmol) [39] in toluene (400 mL) was treated with 2.5 mL of a solution of dimethyldioxirane [19] in acetone (0.11 M) at room temperature. After 12 h a brown insoluble material was removed by filtration. The elemental analysis (C 84.97, H 0.94, O 14.09) corresponds to $C_{60}H_{9\ldots10}O_{7\ldots8}$; FTIR (KBr): ν[cm^{-1}] = 527, 1041 (s), 1208, 1174, 2940 (w), 2989 (w). The products were separated by preparative HPLC (C_{18} reverse-phase, acetonitrile/toluene, 55:45 (v:v), detection at 340 nm, 9.5 mL min^{-1}). Baseline peak separation allowed isolation of 12 mg of **2**, 8 mg of **1**, and 66 mg of unreacted C_{60}. Chromatography on alumina also led to separation of **1** and **2**. UV/VIS (*n*-hexane): **1**: λ_{max} [nm] = 228, 249, 319 (s), 405, 416 (w), 478 (br., w); **2**: λ_{max} [nm] = 253, 313 (s), 412, 444, 471 (vw). FTIR (KBr): **1**: $\tilde{\nu}$[cm^{-1}] = 1427, 1184, 774, 766, 566, 526, and others; **2**: three weak bands at 2900 cm^{-1}, others at 1379, 1207, 1176, 1138, 1058, 1031 (s), 896, 526 (s). ^{13}C NMR (125 MHz, CS_2, [D$_6$]acetone as internal lock, [Cr(acac)$_3$] as relaxation agent, 42000 scans, 25 °C): **1**: δ(number of carbon atoms) = 146.32(4), 146.29(4), 146.20(4), 146.04(2), 145.40(4), 145.34(4), 145.05(4), 144.97(4), 144.64(2), 144.18(4), 144.14(4), 143.64(2), 143.38(4), 143.30(4), 143.07(4), 141.99(4), 90.92(2); **2** (same conditions as for **1** except 38000 scans): δ = 151.04(4), 149.47(2), 147.64(4), 147.45(4), 147.36(4), 146.40(2), 146.31(4), 146.17(4), 145.96(4), 143.96(4), 143.93(2), 143.53(4), 143.35(4), 143.26(4), 140.79(4), 139.02(4), 113.04(1), 96.15(2), 28.92(2).

Ab Initio Investigations of Structure and Stability of $[R_3SiAl]_4$, R = H, Me, *t*Bu**

By *Uwe Schneider, Reinhart Ahlrichs,* Hans Horn,* and *Ansgar Schäfer*

The synthesis of metastable Al^I compounds, for example, AlCl in toluene/ether by Schnöckel et al.,[1] opened new routes in aluminium chemistry.[2] Thus, $Cp^*_4Al_4$,

[*] Prof. Dr. R. Ahlrichs, Dipl.-Chem. U. Schneider, Dr. H. Horn, Dipl.-Chem. A. Schäfer
Institut für Physikalische Chemie und Elektrochemie der Universität Kaiserstrasse 12, D-W-7500 Karlsruhe (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. H. Schnöckel for very helpful discussions and the communication of unpublished results.

$Cp^* = C_5Me_5$, could be synthesized and structurally characterized.[3] The compound shows a central Al_4 tetrahedron, as known from the analogous boron compounds (e.g. B_4Cl_4[4, 5]). Recently, by the reaction of the sodium silane tBu$_3$SiNa with AlCl, the successful synthesis of tBu$_3$SiAl was achieved, which, according to evidence from mass spectrometry, also exists as a tetramer.[6] A structure determination has not been possible up to now because no suitable crystals could be obtained. Herein, we report the results of ab initio calculations on tBu$_3$SiAl and its tetramer, from which statements can be made concerning the structure (Fig. 1) and the relative stability of these compounds.

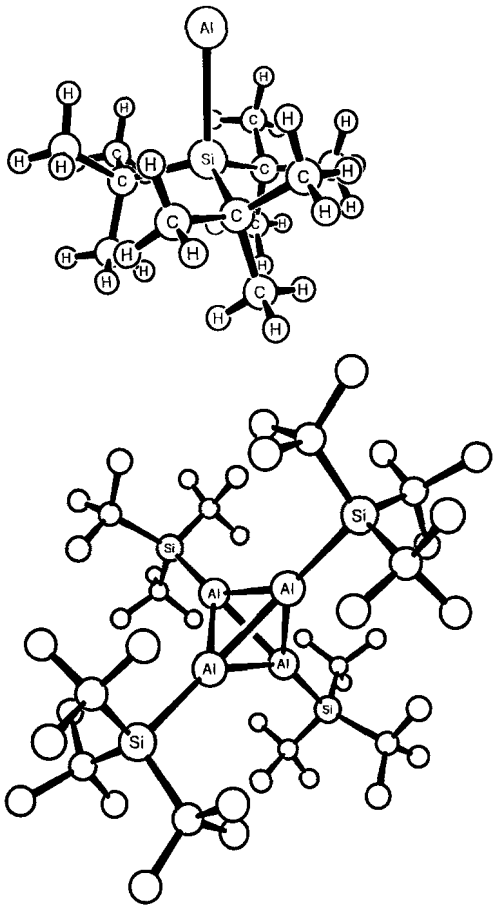

Fig. 1. Calculated structures of tBu$_3$SiAl with C_3 symmetry (top) and [tBu$_3$SiAl]$_4$ with T symmetry (bottom, H atoms are not drawn).

B^I and Al^I compounds have a tendency to form tetramers and higher oligomers, for example, B_9Cl_9.[7] The molecules B_4R_4 (R = Cl, F, H), like the analogous Al_4R_4 species, have already been theoretically intensively investigated.[5, 8, 9] The four lone pairs n(M) of the MR-building blocks are available for bonding in the central M_4 tetrahedron of M_4R_4 (M = B, Al) (Fig. 2). From these in (the local) T_d symmetry, a_1 (bonding) and t_2 (antibonding) MOs are formed by linear combination. The t_2 MOs are stabilized by admixing of contributions of vacant AOs π(M) (e in C_{3v}) of the monomer MR (Fig. 2). This effect is crucial for the stability of M_4R_4 relative to 4 MR.[9] In an alternative view each tetrahedral face can be assigned an electron pair, which occupies a bonding three-center MO.[8, 10]

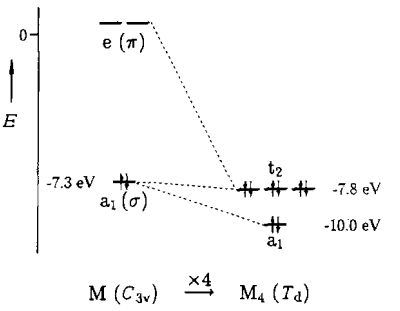

Fig. 2. Qualitative MO diagram of the M_4 tetrahedron in M_4X_4 (T_d). The energies are valid for M = Al, X = $SiMe_3$. For the other molecules the relationships are similar.

The π(M) stabilization competes with a posssible stabilizing π delocalization π(R) → π(M) in the monomers. This explains the decreasing stability of M_4R_4 relative to 4 MR in the series R = H, Cl, F for M = B and R = H, Cl, F, Cp for M = Al, because the π-delocalization in the monomers increases in this order. According to Wade's rules,[11] a stable dianion $M_4R_4^{2-}$ would be expected. Since with the two additional electrons a degenerate level of type t_1, t_2 or e (other MOs are not at disposal in the valence region) would have to be partially occupied, Wade's rules seem to fail for the tetramer.[8]

The ab initio calculations[12] were carried out on IBM RISC 6000 workstations using the TURBOMOLE program[13] within the framework of the SCF approximation partially supplemented by MP2 calculations.[14] With gradient calculations all structural parameters were optimized for each given molecular symmetry.[15] For the molecules H_3SiAl, $[H_3SiAl]_4$, Me_3SiAl and tBu$_3$SiAl force field calculations (analytical second derivatives of the SCF energy with respect to the nuclear coordinates in the corresponding basis) confirmed that the symmetries C_{3v}, T_d, C_{3v}, and C_3, respectively,[16] each lead to a local minimum on the SCF potential energy surface (all calculated vibration frequencies are real).

The important results of the calculations are collected in Table 1. The calculated Al–Al distances in the tetramers vary very little (261.1–263.8 pm). They are similar to the distance in Al_4H_4 (261.7 pm[9]) and are somewhat shorter than a typical Al–Al single bond of 266 pm.[17] The Si–Al distances for $[H_3SiAl]_n$ and $[Me_3SiAl]_n$ decrease from the monomer to the tetramer by approximately 12 pm. The lone pair n(Al) in the monomer is weakly Si–Al antibonding; in

Table 1. Calculated structures and energies of $[R_3SiAl]_n$, $n = 1,4$ [distances in pm, energies in E_{SCF} and E_{MP2} in Hartree, ΔE_{tet} in kJ mol^{-1}, see Eq. (a)].

R	n	Symmetry	Al-Al	Si-Al	Si-R	E_{SCF}	E_{MP2}	ΔE_{tet} (SCF/MP2)
H	1	C_{3v}	–	260.8	149.2	– 532.505179	– 0.125022	–
H	4	T_d	261.6	249.1	148.5	– 2130.172013	– 0.578834	– 397/–604
Me	1	C_{3v}	–	261.3	189.1	– 649.473263	– 0.391149	–
Me	4	T_d	261.1	249.5	188.1	– 2598.055776	– 1.651537	– 427/–655
tBu	1	C_3	–	260.3	197.1	– 1000.443891	–	–
tBu	4	T	263.8	259.4	197.4	– 4001.939364	–	– 430/–

the tetramer this effect is reduced through cage bonding.[9] For [*t*BuSiAl] an almost identical Si–Al distance (ca. 260 pm) was found in the monomer and tetramer, which can be seen as a result of a low steric repulsion between the tBu$_3$Si groups in the tetramer. The Si–Al bond has a relatively small force constant[18] and therefore reacts sensitively to disturbances.

The reaction energy ΔE_{tetr} for the tetramerization of tBu$_3$SiAl is obtained from the SCF approximation as shown in (a). For H_3SiAl and Me_3SiAl, the very similar values

$$\Delta E_{tetr}([t\mathrm{Bu_3SiAl}]_4) = E([t\mathrm{Bu_3SiAl}]_4) - 4E(t\mathrm{Bu_3SiAl}) = -430\ \mathrm{kJ\,mol^{-1}} \quad \text{(a)}$$

-397 and -427 kJ mol^{-1}, respectively, were obtained. The SCF approximation underestimates the tetramerization energy. This is shown by MP2 calculations, which for H_3SiAl showed an addditional contribution of -207 kJ mol^{-1} and for Me_3SiAl of -228 kJ mol^{-1}, which is in agreement with the results for the tetramerization of AlR (R = H, F, Cl,), $\Delta\Delta E \approx -200$ kJ mol^{-1}.[9] If a similar effect is assumed also for tBu$_3$SiAl, then a tetramerization energy of ca. -600 kJ mol^{-1} can be expected.[19] This value corresponds to a bond energy of 150 kJ mol^{-1} per electron pair or tetrahedral face or 100 kJ mol^{-1} per Al–Al pair or tetrahedral edge.

The comparison of [tBu$_3$SiAl]$_4$ with Al_4R_4 (R = H, Cl, F, Cp)[9] shows a consistent picture. Since no π delocalization $\pi(t\mathrm{Bu_3Si}) \rightarrow \pi(\mathrm{Al})$ is expected for tBu$_3$SiAl, the the metal atoms of the tetramer are as strongly bound as in Al_4H_4 (-571 kJ mol^{-1}[9]), in agreement with the calculated distances.

In particular, the bonds in Cp_4Al_4 are significantly weaker than those in [tBu$_3$SiAl]$_4$: in the Cp compound, the Al–Al distance of 276.9 pm (exp.;[3] calc. 279.6 pm[9]) is relatively long, and the tetramerization energy (-160 kJ mol^{-1}, with MP2) is relatively low. These results are in agreement with those found experimentally: [tBu$_3$SiAl]$_4$ can be sublimed at 180 °C, whereas $Cp^*_4Al_4$ in the solid form decomposes at 70 °C.[20]

The compound [tBu$_3$SiAl]$_4$ (see Fig. 1, bottom) is a molecule with a completely nonpolar (hydrophobic) surface. Therefore, it is to be expected that crystals are highly disordered or even show plastic phases. This could be an explanation for the above mentioned difficulties for the structure determination.

According to our calculations, [tBu$_3$SiAl]$_4$ holds a special position among the Al$^{\mathrm{I}}$ compounds: the Al_4 tetrahedron shows optimal stabilization (lacking competition of a π delocalization in the monomer) and is shielded without larger steric hindrance or strains by the substituents.

[14] C. Møller, M. S. Plesset, *Phys. Rev.* **1934**, *46*, 618; MP2 denotes the treatment of electron correlation in the second order of perturbation theory, starting from the Hartree-Fock ground state. In our calculations, we only included the correlation of the valence electrons.
[15] Examples of investigations of AlH and Al_4H_4 with more precise methods (MP2-gradient, coupled cluster (CCSD(T))) showed that correlation effects reduce the Al–Al distance only by 2 pm. The bond energy of the tetramer is underestimated in the MP2 approximation by approximately 50 kJ mol^{-1}. Analogous relationships are also to be expected for the compounds examined here (J. Gauss, personal communication).
[16] tBu$_3$SiAl does not have the highest possible symmetry C_{3v}, because in this case imaginary wave numbers of 99 icm^{-1} and 27 icm^{-1} were obtained for two normal modes. The lowering of symmetry from C_{3v} to C_3, which is caused by steric hindrance of the *tert*-butyl groups, leads to an energy reduction of 20 kJ mol^{-1}. For $[Me_3SiAl]_4$ and [tBu$_3$SiAl]$_4$, for which force field calculations were not possible, T_d and T symmetry respectively were assumed on the basis of these results.
[17] W. Uhl, *Z. Naturforsch. B* **1987**, *42*, 557.
[18] In the framework of the SCF approximation the force constant of the Al–Si bond is 100 N m^{-1} in tBu$_3$SiAl, 94 N m^{-1} in H_3SiAl, 133 N m^{-1} in $[H_3SiAl]_4$.
[19] A MP2 calculation for [tBu$_3$SiAl]$_4$ was unfortunately not possible.
[20] On the basis of its low decomposition temperature (around -60 °C), Cp_4Al_4 could not be investigated in a crystalline form; C. Dohmeier, H. Schnöckel, unpublished.

Chemiluminescence Oscillations Driven by a Flow-through Reactor in the $[Ru(bpy)_3]^{2+}$ Catalyzed Belousov–Zhabotinskii Reaction

By *Harry R. Weigt**

The Belousov–Zhabotinskii (BZ) reaction[1]—in the strict sense the metal-ion-catalyzed oxidation of malonic acid by bromate/sulfuric acid—is already considered a classical model system for the formation of dissipative structures.[2] On exceeding certain critical parameters and for suitable reaction procedures far from the equilibrium, sustained concentration oscillations occur, for example, or even spatially and spatial/temporally organized reaction states.[3] The extremely complicated underlying mechanism has not nearly been elucidated.[4]

An interesting extension of conventional methods is the involvement of electronically excited species on the basis of oscillating chemiluminescence (OCL) arising spontaneously in many BZ systems.[5] The measurement of the OCL has proved to be a convenient, very sensitive technique, which appears to be most highly developed for $[Ru(bpy)_3]^{2+}$ catalyzed BZ systems (bpy = 2,2′-bipyridine).[6] Some of the reasons for this are the remarkable photophysical and photochemical properties of the metal complex,[7] including its CL potential through the excited charge-transfer state.[8] In the

[*] Dr. H. R. Weigt
Fachbereich Physik der Universität
Am Neuen Palais 10, D-O-1571 Potsdam (FRG)

past without exception, however, batch experiments were conducted. As this process is limited fundamentally to transient states and structures, the interpretation in particular of the sometimes very complicated temporal CL behavior appeared problematic. For instance, for a system with the concentrations given in the legend of Figure 1 under batch conditions (i.e., on the way to equilibrium), we found an oscillator lifetime of only 30 min which had a extremely variable oscillation form almost impossible to interpret.

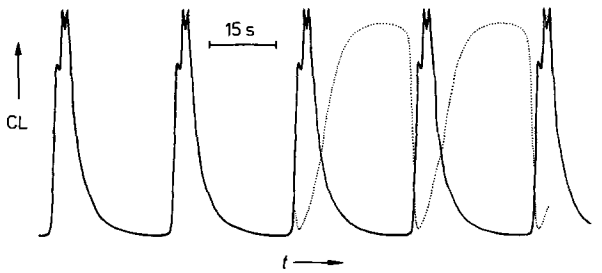

Fig. 1. CSTR-stabilized OCL in $[Ru(bpy)_3]^{2+}$ catalyzed BZ system. Operating parameters: initial concentrations $[mol\,L^{-1}] = 0.053(BrO_3^-)$; 0.35 $(CH_2(COOH)_2)$; 1×10^{-4} $([Ru(bpy)_3]^{2+})$; 1.0 (H_2SO_4); reactor volume = 26 cm^3; $T = 299\,K$; $\dot{V} = 2.2\,mL\,min^{-1}$. CL measurement: $\lambda_{em} = 610$ nm; redox potential (dotted line): potential difference (peak-to-peak) = 40 mV.

Stabilization of the various, only momentarily existing system states over a longer period was achieved with a (stirred) flow-through reactor (CSTR = Continuous-flow Stirred Tank Reactor).[9] This provides a thermodynamically open system through a constant flux of starting materials and simultaneous removal of products. Among the freely variable operating parameters are the flux concentrations, the average residence time of the reactive material (as quotient of the reactor volume and total flow rate) and the reactor temperature. Figure 1 shows the behavior of the system for the chosen set of parameters under flow conditions. Represented are the time-resolved CL intensity[10a] and the simultaneously recorded redox potential.[10b] The OCL is characterized by significantly more features in its oscillogram than in that of the potential. For each oscillation three clearly distinguishable emission peaks are reproduced in a basic pattern. The periodic steep onset of the luminescence corresponds to the beginning of the autocatalytic part of the process (recognized by the drop in the redox potential). The signal shape of the electrode's (integrated) display does, however, not correspond to the characteristic CL peak pattern for this set of parameters.

Even on variation of only the total flow rate $\dot{V}$, a number of OCL modes can be generated. As example Figure 2 shows the behavior for a stepwise decrease of $\dot{V}$. The essential part of a cycle for each $\dot{V}$ is represented. Between the individual stabilized cycles (corresponding to the limit cycle behavior) in this experiment is a period of nonstationary transition behavior lasting of the order of 1 h. The oscillation pictures resulting from the chosen $\dot{V}$ are obtained independent of the operating mode of the reactor and the direction of $\dot{V}$ change. Hysteresis effects, which are conceivable, were not observed. At high flow rates (above $12\,mL\,min^{-1}$) the time-resolved CL structure is characterized by a pronounced side peak (similar to that found for batch experiments a short time after the start[6]), which is deformed to a shoulder as $\dot{V}$ decreases. At $\dot{V} = 3.0\,mL\,min^{-1}$ a second side peak following the first in time is seen, which becomes a needlelike signal. Concomitant with this change is a decrease of the major peak. Below $\dot{V} = 1.0\,mL\,min^{-1}$ the curve shape is markedly

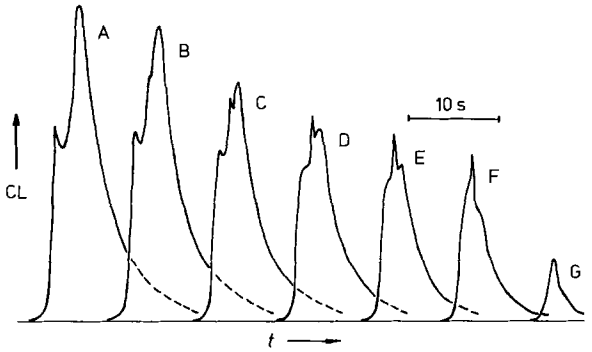

Fig. 2. Dependence of OCL structure on the total volume flow $\dot{V}$. Operating parameters: $\dot{V}\,[mL\,min^{-1}] = 4.0$ (**A**); 3.0 (**B**); 2.5 (**C**); 2.0 (**D**); 1.5 (**E**); 1.0 (**F**); 0.3 (**G**); remaining conditions and CL measurement as in Figure 1.

smoothed; at $0.3\,mL\,min^{-1}$ (corresponding to a relatively large average residence time for the reactants) only a weak kink may be seen in the relatively weak CL signal.

In contrast to the hardly changing curve shape of the potential (for redox as well as Br^--sensitive electrodes), the OCL is apparently a selective indicator representing specific but still coded responses of the system to the variation of the operating parameters. The controlled development of the CL structure will thus be able to contribute supplementary information to that obtained from conventional methods in the discussion on relevant elementary processes.

The CSTR-stabilized OCL also appears interesting in connection with newer investigations on the oxygen effect on BZ oscillators.[12,13] We could confirm the results of Saigusa[13]—extrapolated to flow conditions—to a large extent. When the reaction mixture is enriched with additional oxygen, a transition to an "O_2-induced state"[13] is observed (Fig. 3).[14] This transition is characterized by a noticeably

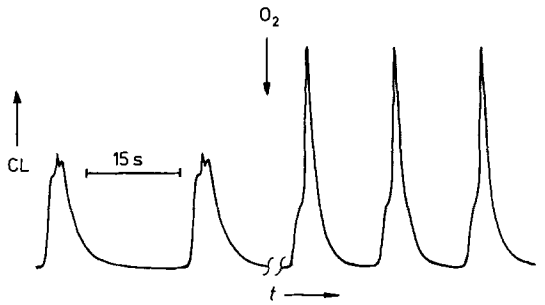

Fig. 3. Oxygen-induced OCL regime in flow experiment [14]. Operating parameters: $\dot{V} = 2.0\,mL\,min^{-1}$; O_2 flow rate = $0.12\,L\,min^{-1}$; remaining conditions and CL measurement as in Figure 1.

different period, CL-amplitude, and oscillation shape. The OCL here undoubtedly points to a phase change. In contrast to Saigusa[13] our system returned to the original undisturbed state after switching off the oxygen flow. This reversibility naturally occurs only in the flow experiment.

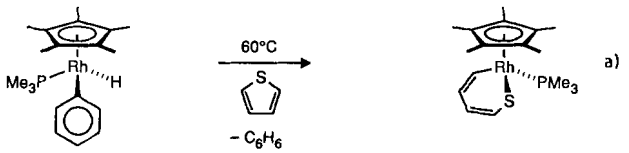
Dimerization of Thiophene to Give a Linear $S(CH)_8S$ Fragment with $[(C_5Me_5)Rh(C_2H_4)_2]$**

By *Robert M. Chin* and *William D. Jones**

Reactions of thiophenes with transition metals as models for studying the hydrodesulfurization of petroleum have aroused increased interest over the past few years.[1] A variety of coordination modes of thiophene have been found,[2] and reactions in which the ring has been cleaved have been reported.[3] The simple insertion of an unsaturated rhodium[4] or iridium[5] metal center into the thiophene C–S bond has also been examined [Eq. (a)], and we report here an example in which C–C bond formation occurs concomitant with the C–S cleavage.

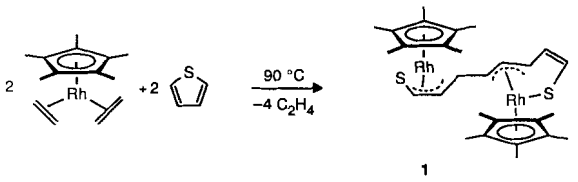


a)

Heating a solution of $[(C_5Me_5)Rh(C_2H_4)_2]$ with a 20-fold excess of thiophene in benzene solution at 90 °C for 15 h was followed by removal of solvent and extraction of the residue with hexane. Upon cooling a red-black precipitate forms. The product is identified as **1** on the basis of NMR and analytical data.[6]

$[(C_5Me_5)Rh]_2[\mu^2\text{-}1,2,3,4,\eta^4\text{-}5,6,7,10\text{-}\eta^4\text{-}S(CH)_8S]$ **1**

The ^1H NMR spectrum shows eight distinct multiplets for the eight methine groups; a COSY spectrum (COSY = *co*rrelated *s*pectroscop*y*) indicates that these groups are attached in a linear array. Two distinct C_5Me_5 resonances are also observed. The ^{13}C NMR spectrum shows two downfield singlet and six upfield doublet resonances, suggesting that six carbons in the chain are attached to metal centers. A $^{13}C/^1H$ HETCOR spectrum (HECTOR = *het*eronuclear *cor*relation) shows that these six carbons are adjacent to each other at an end of the $(CH)_8$ chain. These data led to the formulation of **1** as indicated in Equation (b). Use of α-deu-



b)

1

teriothiophene in the reaction leads to a product in which the resonances at $\delta = 6.503$, 6.009, 4.165, and 3.245 are diminished in intensity by half, indicating that the $S(CH)_8S$ fragment arises by the coupling of two α thiophene carbons after C–S cleavage.

Confirmation of the structure deduced from NMR results was obtained from a single-crystal X-ray diffraction study.[7] Since the compound proved difficult to crystallize, a preliminary data set was obtained on a small crystal (Fig. 1). A

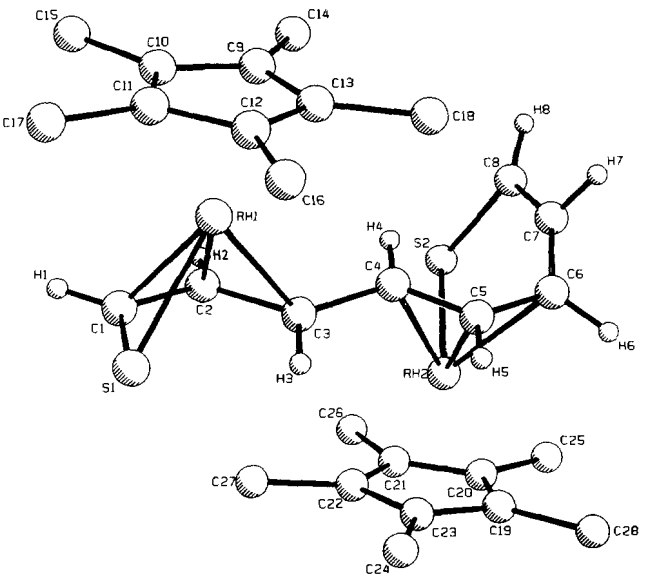


Fig. 1. PLUTO drawing of the structure of **1** in the solid state. Selected distances: Rh(1)-S(1), 2.38(2); Rh(1)-C(1), 2.11(7); Rh(1)-C(2), 2.15(7); Rh(1)-C(3), 2.30(7); Rh(2)-S(2), 2.36(2); Rh(2)-C(4), 2.19(6); Rh(2)-C(5), 2.11(7); Rh(2)-C(6), 2.31(7); S(1)-C(1), 1.65(8); S(2)-C(8), 1.80(7); C(1)-C(2), 1.5(1); C(2)-C(3), 1.54(9); C(3)-C(4), 1.5(1); C(4)-C(5), 1.33(8); C(5)-C(6), 1.4(1); C(6)-C(7), 1.5(1); C(7)-C(8), 1.4(1)

more symmetric molecule with the $S(CH)_8S$ unit bound in a $1,2,3,4\text{-}\eta^4\text{-}7,8,9,10\text{-}\eta^4$ fashion is not observed, despite the fact that $[(C_5Me_5)Rh(\text{polyolefin})]$ complexes are expected to be labile at 100 °C,[8] leading to the conclusion that the structure observed for **1** is thermodynamically preferred.

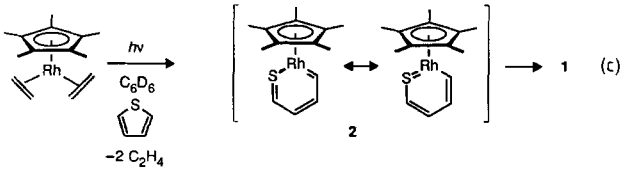
Department of Chemistry University of Rochester, Rochester, NY 14627 (USA)

[**] This work was supported by the National Science Foundation grant CHE-9102318.

Irradiation (310–380 nm, 25 °C) of a 0.034 M solution of $[(C_5Me_5)Rh(C_2H_4)_2]$ in [D_6]benzene containing a ninefold excess of thiophene shows the formation of both a small amount of **1** and another material displaying four low-field resonances in the ^1H NMR spectrum. In addition to a C_5Me_5 resonance at $\delta = 1.504$, multiplets are seen at $\delta =$ 11.843 (ddd, $J = 9.2$, 6.3, 1.6 Hz; 1 H), 9,082 (dd, $J = 8.7$, 6.8 Hz, 1 H), 8.256 (ddd, $J = 9.4$, 7.1, 1.3 Hz, 1 H), and 7.575 (ddd, $J = 9.0$, 7.1, 1.3 Hz, 1 H), suggesting the presence of aldehydic and/or carbenoid hydrogens. This intermediate is tentatively assigned structure **2** [Eq. (c)], and reacts thermal-



ly to form dimer **1**. A methyl-substituted iridium analogue of **2** which also displays low field resonances for the metallacycle hydrogens, has been isolated as a stable species.[5] Further mechanistic details are under investigation.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Liquid Crystallinity in Polymers. Principles and Fundamental Properties. Edited by *A. Ciferri*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. x, 438 pp., hardcover DM 155.00.—ISBN 0-89573-771-X/3-527-28922-9

The field of liquid crystalline polymers, which has undergone rapid development during the last few years, has already given rise to several multi-author books. The book reviewed here belongs to this category. However, whereas most publications of this kind are collections of articles covering a broad range of topics, an attempt has been made here to make the contributions more closely related to each other. The editors have also imposed a system of priorities with regard to topics, which clearly sets the book in a class apart from previous publications.

The book "Liquid Crystallinity in Polymers" aims to describe the various theoretical approaches towards an understanding of liquid crystalline (LC) polymers, and to compare their predictions with experimental data. LC polymers of both thermotropic and lyotropic types are considered. The book is divided into four parts. Part 1, consisting of two articles, deals with the conformations of LC polymers. First N. Lauprêtre and C. Noel report on the conformational analysis of mesogenic groups in polymers, then G. L. Brelsford and W. R. Krigbaum discuss the theory of persistence lengths in LC polymer chains and the experimental methods used to determine them. Part 2 consists of three articles on theories that attempt to explain liquid crystalline behavior in terms of molecular properties. A. Khoklov reports on theories based on the Onsager equation. A. Abe and M. Ballauff describe the Flory lattice model, then G. Ronca and A. Ten Bosch discuss other theoretical approaches. In Part 3 we at last come to three contributions dealing with the dependence of phase properties on many different variables of the system. Here the editor, A. Ciferri, gives an overview of the phase behavior of rigid and semirigid mesogens, A. Sirigu contributes a discussion of the phase behavior of flexible main-chain polymers, and H. Finkelmann discusses polymers with liquid crystalline side-chains. The fourth and last part of the book is devoted to physics. S. D. Lee and R. B. Meyer discuss the viscosity and elastic properties of liquid crystalline polymers. M. Kleman considers questions and defects and texture, and the final contribution by G. Marrucci is devoted to the rheology of nematic polymers.

All the articles are written by leading experts in their special fields, and together they ensure that the book impressively achieves its purpose of explaining different theoretical approaches and comparing them with experimental results. In addition the numerous literature references at the end of each contribution (typically between 100 and 200 per article) provide a good basis for further reading on each topic. However, concentrating on the specific objective described above has meant that some other equally important aspects of liquid crystalline polymers have had to be left out or only briefly touched on. For example, theoretical models are developed only for the nematic phase, so that smectic phases are assigned only a minor role which understates their importance in liquid crystalline polymers. Other aspects given scant attention include some that are of particular interest to the chemist: relationships between structure and properties, chemical synthesis, and matters relating to technology and applications. Also the strongly theoretical bias means that readers without considerable previous knowledge of solid state physics will find the book difficult to understand, except for Part 3, where the discussions are more understandable for the non-specialist reader and are less narrowly defined in subject matter. For these reasons the book can be recommended primarily for theoretically orientated chemists, technologists and physicists.

In summary, "Liquid Crystallinity in Polymers" achieves its stated purpose very well; however, it is essentially a more specialized work than its rather generally worded title suggests.

Similarity Models in Organic Chemistry, Biochemistry and Related Fields. (Series: Studies in Organic Chemistry, Vol. 42.) Edited by *R. I. Zalewski, T. M. Krygowski* and *J. Shorter*. Elsevier, Amsterdam, 1991. XV, 694 pp., hardcover, DFl 420.00.—ISBN 0-444-88161-1

Similarity studies of various kinds are currently very much in vogue in the chemical world. Of those scientists involved with such studies, a growing number occupy themselves with so-called similarity modeling. This is the latest name for a field that has steadily evolved from work dating back to the 1960s on the use of Hammett's equation in biological contexts through linear free-energy relationship (LFER) studies to correlation analysis in organic chemistry (CAOC). Today the field has expanded to embrace an overlapping network of methodologies concerned with such things as sophisticated data clustering techniques, a wide variety of quantitative structure–activity relationship (QSAR) procedures, and innovative pattern recognition methods. The motivation behind all the present activity is the possibility of designing chemical species optimally suited for a range of practical applications. The design process typically involves the characterization of the species by appropriate molecular descriptors followed by the clustering of these descriptors by means of similarity modeling. The whole procedure has now been honed to a fine instrument that can, in principle, be used to design molecules of any genre. In practice, however, it is used almost exclusively for the design of molecules that are biologically active such as pharmaceutical drugs.

Because of the potential value of this kind of research, the number of books dealing with similarity modeling has gradually begun to mount. Among notable recent examples, mention might be made of Willett's "Similarity and Clustering in Chemical Information Systems" and the compendium of Johnson and Maggiora (Eds) on "Concepts and Applications of Molecular Similarity". The volume reviewed here may be considered as the third part of a trilogy, each part of which has sought to bring its readers up-to-date on the latest developments in the broad area of molecular structure–property correlations. The first volume, Chapman and Shorter's (Eds.) "Advances in Linear Free Energy Relationships", came out in 1972, and the second volume from the same editors titled "Correlation Analysis in Chemistry: Recent Advances" appeared in 1978. All three volumes are associated with the veteran John Shorter who has been prominent in the field for over a quarter of a century. As was the case for its two predecessors, the third part reflects contemporary thinking in the chemometrics domain. Moreover, all of its eleven contributed chapters are written by important workers in the field. This means the reader has the advantage of several different approaches to and perspectives on state-of-the-art similarity modeling.

The drawbacks of having so many contributors are also clearly in evidence in the considerable amount of overlap in the topics covered. Thus, Chapters 1, 2, 4, 6, 8, and 10 discuss various aspects of the Hammett equation, and solvent effects are treated in Chapters 2, 5, 6, 8, and 9. In general authors have tended to focus on their own specialties to the exclusion of several of the newer trends and developments in similarity modeling. The coverage of the central theme is therefore somewhat patchy and certainly less than comprehensive. Whereas the statistical treatment of data and the role of steric effects are given a heavy emphasis, other equally important topics are dismissed with the briefest mention. Topics that have been short-changed include the burgeoning applications of topological indices, recent developments on molecular shape descriptors, quantitative approaches to the recognition of molecular similarity, and the use of ab initio quantum-chemical methods for the comparison of molecular similarity based on electron densities. The standard of writing of the various chapters is not uniformly high. The contributions from authors whose native language is not English are in most cases badly in need of language editing. In general there seems to be far too much stress in this volume on the more traditional approaches to structure–activity correlations and far too little on some of the more exciting new directions in which the field is now heading.

The breakdown by chapter is as follows: Chapter 1 (Krygowski and Wozniak) starts off with a fairly hefty dose of statistics. The principal discussion is devoted to the statistics of regression analysis and is comprehensive. A number of appropriate examples are provided. The inclusion of such a chapter is a good idea and will be welcomed by many of the practitioners of similarity modeling. It will be especially helpful now that sophisticated software packages such as SPSS offering a variety of statistical options have appeared on the market. In Chapter 2 (Shorter) the application and development of the Hammett equation are reviewed up to the present time. Shorter shows convincingly that the equation still has many important uses, particularly in its multiparametric forms, in spite of the fact that it was first put forward in 1937. Both Chapters 3 (Godfrey) and 4 (Häfelinger) deal with substituent effects, the former with the transmission of these effects in organic systems and the latter with the behavior of hydrogen as a substituent in organic π systems. The authors point out that current models oversimplify the chemistry involved and consequently interpretations based on field, inductive, or resonance effects alone are likely to be inadequate. Chapter 5 (Laurence) illustrates how-

the similarity principle has been applied in both infrared and ultraviolet spectroscopic data correlations with solvent and substituent effects. The principle is revealed as a powerful tool in the organization and analysis of a very large body of data. In Chapter 6 (Langhals) the rather vexing issue of solvent effects is addressed within the context of binary solvent systems. This chapter contains a number of useful tables of relevant parameters. Chapters 7 (Oszczapowicz), 8 (Jaworski and Kalinowski), and 9 (Zalewski) support the notion that similarity modeling is usually the most appropriate means of establishing structure–property relationships in the respective fields of gas chromatography, organic electrochemistry, and food chemistry. The former two make use of linear free-energy relationships whereas the latter applies a principal component analysis and also discusses the mathematical foundations of this type of approach. Chapter 10 (Livingstone) offers a general overview of quantitative structure–activity relationships and is one of the most readable chapters in the book. Not only does it serve as a valuable introduction to neophytes, but it also reports on a number of significant advances made since the late 1970s. This chapter includes a total of 513 references and an appendix listing software suppliers. The final Chapter 11 (Charton) treats the author's own approach to the quantitative description of steric effects. This chapter is also well-written and informative, containing among other things, several tables of atomic radii and two appendixes on the parameters used in regression equations. The index to the volume is adequate, though I would have preferred to have found more multiple entries in it.

As a whole this work is not comprehensive in its coverage; nor it is really suitable for use as an introductory text on the various applications of similarity modeling. Its appeal will be rather to those researchers and others currently engaged in the more conventional approaches to structure–activity relationships in chemistry.

Photochemical Technology. By *A. M. Braun, M.-T. Maurette* and *E. Oliveros*, Translated by *D. F. Ollis* and *N. Serpone*. Wiley, Chichester, 1991. XX, 559 pp., hardcover £ 95.00—ISBN 0-471-92652-3

This book on photochemistry (originally published as *Technologie Photochimique,* Presses Polytechniques Romandes, Lausanne, 1986) is the first to be concerned primarily with the technical aspects of such processes, especially in connection with organic photoconversions that have been and are being utilized in economically viable industrial processes. I have not previously encountered a book that gives so much valuable information on experimental procedures and apparatus used in both laboratory scale and pilot plant photochemical reactions. The first chapter is concerned with photochemical principles (e.g., absorption spectroscopy, photophysical decay processes of excited states, energy transfer, etc.). While entirely sufficient for the purpose of this book, this chapter is (appropriately) not as comprehensive as treatments in other well-known photochemistry texts. The chapter on radiometry and actinometry provides more detail on these subjects than I have previously seen in any book, supported by relevant theory, and many figures and tables. The next two chapters, concerned with light sources and filters and photochemical reactors, totaling almost one hundred pages, are remarkable. The information here is of enormous use to anyone planning to carry out photochemical reactions on any scale. Detailed schematic figures of lamps and reactors in ordinary and not so ordinary use are provided, along with extensive tables listing characteristics of various types of lamps, lasers, and filters. The extremely detailed figures, which cannot be found elsewhere, clearly required enormous care and effort to produce.

The rest of the book provides a wealth of information about a number of photochemical conversions that have found diverse industrial applications. Technological details regarding all stages of these processes are given, with abundant references to the patent literature. Again, this kind of information is not available in any other source, and must have taken great effort to compile. Specifically, these chapters cover photonitrosylation, photochlorination, photobromination, sulfochlorination and sulfoxidation, photochemical desulfonation and desulfonylation, photohydrodimerization, photooxidation, and vitamins. While the mechanistic aspects of these reactions are not the main focus, a significant amount of such discussion is included in each case. The economic aspects of these processes are discussed, along with safety considerations. The wealth of useful information is staggering. The authors have clearly shown, for the first time in my experience, the potential as well as the limitations of photochemistry on an industrial scale, and they put the lie to the common criticism that photochemistry is an arcane subject with no significant practical applications. The one important subject that the authors do not treat with the attention it deserves is solar energy conversion, which I hope they will address in a future book or future editions of this book.

In summary, "Photochemical Technology" is a wonderfully useful book which admirably fills an important gap in this field. It is highly recommended to anyone involved in the practice of photochemistry, from students to researchers to engineers. It is an indispensable compendium of easily accessible information, presented in a clear and lucid style that readers at all levels will appreciate. No one involved with photochemistry should fail to include this book in their personal as well as institutional libraries. The authors are to be congratulated for their remarkable achievement.

Handbook of Thin Layer Chromatography. (Chromatographic Science Series, Vol. 55). Edited by *J. Sherma* and *B. Fried*. Marcel Dekker, New York, 1991. viii, 1047 pp., hardcover $ 165.00 (US and Canada), $ 198.00 (all other countries).—ISBN 0-8247-8335-2

This book is divided into two parts: the first has 13 chapters devoted to theory and general practices of TLC, while the second has 18 chapters dealing with applications based on compound types such as amino acids, peptides, antibiotics, carbohydrates, lipids, natural pigments, inorganics and organometallics, pesticides, pharmaceuticals, steroids, synthetic dyes, and vitamins. There are also chapters on "TLC Coupled with MS", "Thin Layer Radiochromatography", "Applications of Flame Ionization Detectors in TLC", and "Photographic Documentation", in Part 1, and on the application side, on polymers, toxins, and enantiomer separations, as well as phenols, aromatic acids, and indoles

which can be considered as special features and are required to keep pace with the fast developing modern analytical methods vis-à-vis TLC. OPLC, a relatively young thin layer technique still gaining in improvement and popularity, gets proper treatment in the form of a chapter.

Chapter 1 is an introduction to basic techniques, materials, and apparatus involved or required for TLC. Though there are full chapters devoted to theory and mechanism of TLC, sorbents and layers, optimization, development, OPLC, and documentation, each of these, in addition to various other aspects of TLC, has been introduced briefly in Chapter 1, making the chapter a real introduction to present day TLC. Similarly, sample preparation and spotting methods have been sufficiently described.

Though each step in TLC can be optimized, it is far from simple due to the large number of variables involved. General optimization methods and specific strategies for solvent selection have been presented in detail; they can be used to enhance detection limits in post-chromatographic derivatization reactions or to obtain a better separation in the chromatographic development step.

Commonly used sorbents have been characterized in terms of their physical and chemical parameters and chromatographic properties. These include silica gels, aluminas, kieselguhrs, cellusoses, polyamides, and Sephadex®. A brief discussion on RP-plates, amino-, cyano-, and diol-modified precoated silica layers, AE-, CM-, and DEAE- cellulose with modified functional groups to be used for ion exchange TLC, impregnated layers, precoated layer with concentrated zones, and Chiralplates® makes the chapter more useful and suggests wider and versatile applications of TLC. It clearly establishes the advancement in the technique and methodology of TLC since Stahl's fundamental work in developing sorbent materials for TLC which culminated in the first standard handbook (Dünnschichtchromatographie—Ein Laboratoriums-Handbuch, Springer Verlag, Berlin, 1962). Trends and procedures in preparative layer chromatography (PLC) have been discussed and compared for classical PLC with the two forced-flow techniques of over-pressure-layer and rotation-planar chromatography, maintaining the importance of PLC as a successful method for the isolation of synthetic and natural products.

With due regard to the complexity of chromatographic processes, limitations of the existing semiempirical models, and the need to study and understand further the theory of chromatography, the chapter on "Theory and Mechanism of TLC" provides a good review of the basic knowledge about the physical phenomenon, main concepts about efficiency of separation, usefulness of partition and adsorption models used in everyday laboratory practice, and attempts to enhance performance of TLC. The chapter on "Photodocumentation of Thin Layer Chromatograms" views laboratory photography as a sophisticated methodology needed to complement the TLC and analytical process, and serves as a good, useful guide for photographic techniques, equipment and principles for instant photography, especially under UV light.

TLC, like other aspects of research chemistry, is rapidly becoming dominated by instrumentation and automation techniques. This includes areas such as sample application and dosage, chromatogram development, densitometric evaluation by absorbance or fluorescence (200–800 nm), data acquisition, peak location and optimization, spectra recording, multi-wavelength scanning, and integration and calibration, as well as the use of flame ionization detectors (though with applications limited to lipids and related substances), the application of MS with FAB or SIMS as detectors with unique and wider advantages, and the development of the imaging proportional counter (IPC) detector for in situ counting or radioscanning of materials labeled with isotopes without the need to remove labeled material from the TLC plate for scintillation counting. The rapid advances in instrumentation made over the past decade to provide fast, quantitative analysis, as noted above, have been described very well in the Handbook in different chapters. Unfortunately there is no reference to the instrumentation and operational costs, which seem to be high and mostly outweigh advantages due to automation and make TLC far from a simple and inexpensive method. An updated discussion on such aspects would be worthwhile in such a Handbook, indicating a steady period of refinement and growth in the area.

The chapters have been contributed by recognized experts, have a comprehensive, organized plan and present a thorough description and discussion on the topic. The references cited are largely recent ones but also include more significant older literature. A large number of tables and figures have been provided, presenting various suitable TLC methods that have been extensively tried and tested in various laboratories, mentioning detection limits, and minimizing the need to refer to original journals. There are no printing errors. A list of contents of individual chapters would have helped the reader to orientate himself more rapidly to a problem of interest within the multi-authored volume. The glossary and the directory of manufacturers provide useful additional information. The book is a valuable source of information for everybody (specialists and beginners) involved with separation studies in universities, industry, analytical laboratories, clinical analyses, and in the areas of organic synthesis, protein analysis, food and drug analysis, biosynthesis etc. Complete addresses of contributors, suitable for correspondence, would have probably been more meaningful, and a comparatively low price would have encouraged individuals to own a copy.

Carbohydrates as Organic Raw Materials. Edited by *F. W. Lichtenthaler*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. x, 367 pp., hardcover DM 148.00.—ISBN 3-527-28280-7/1-56081-131-5

This book is essentially a summary of the sixteen papers presented at the workshop-conference on "Progress and Prospects in the Use of Carbohydrates as Organic Raw Materials", which took place in Darmstadt in April 1990. It is intended mainly for research scientists in industry who need to be aware of the current state of knowledge on the technology of using carbohydrates as renewable raw materials. However, the editor limits the coverage mainly to mono- and disaccharides, and excludes starch and cellulose, which are also very important raw materials. The title of the book leads one to expect a more comprehensive treatment of the subject. In fact, only two of the chapters are concerned specifically with polysaccharides.

Each chapter is clearly set out, consisting of an abstract, which is useful for recapitulating after reading the chapter, followed by the main text, and lastly a bibliography, which is quite extensive in most cases. The subject index too seems to be comprehensive and clear. The frequent changes in the style of the formulas, sometimes within a single chapter, have a rather distracting effect. Synthetic chemists will find that in some cases not enough details of reactant quantities and yields are given.

Chapter 1 has been included in the book as an addition to the conference papers. This reviewer was unable to understand the colored "computer pictures" that are intended to represent hydrophobic and hydrophilic surfaces of sucrose, and they seem superfluous. The six chapters that follow are concerned with the disaccharide sucrose. The first of these describes the esterification and chloride substitution of different OH groups to produce nonionic surfactants and sweeteners. Here we come across the first errors. On page 39 the compound under discussion is D-*galacto*-sucrose, but the formula given is that of D-*gluco*-sucrose; on page 46 the formula shown is not that of the sweetener aspartam, as the caption claims. Chapter 3 describes, with the help of diagrams, the enzymic conversion of sucrose to isomaltulose and higher oligosaccharides using immobilized fructosyltransferases, then goes on to discuss the extraction and uses of 5-hydroxymethylfurfural and levoglucosan. Unfortunately some formula errors have also crept into this chapter (p. 75). In Chapter 4 the synthesis and applications of sucrose-methacrylate gels and sucrose-formaldehyde resins are discussed. One of the uses of these products is for immobilizing and stabilizing transition metal complexes and photoreactive components. It is also suggested that they could be used as drug carriers. In this chapter we also find (on p. 102) a pentavalent carbon atom! Chapter 5 gives a brief account of methods for synthesizing sucrose sulfates. Chapter 6 is a very instructive and competent description of the chemical and enzymic conversion of glucose to various 1-*O*-α-D-glycopyranosides for the production of surfactants and polymerizable vinylsaccharides. Chapter 7 is a clearly written account of the detailed process for the enzymic modification of sucrose.

Next Chapter 8 briefly discusses the microbiological production of polyfructose and its potential use as a carrier material for flavorings and colorants. Chapter 9 gives a detailed account of the history of the disaccharide leucrose, from its discovery and structure determination to its production by a microbiological process and its use as an odor additive in food products. In contrast, the description of methods for obtaining poly-, oligo-, and monosaccharides from sugar-beet pectin is of a very general nature.

In Chapter 11 attention is drawn to the potential uses of the cheaply available saccharides glucose, fructose, lactose, and isomaltulose for industrial-scale syntheses. The chapter contains a number of serious printing errors that need to be corrected. For example, on page 213 the acetylation of D-fructose and ring-opening with PCl_5 suddenly results in the appearance of a benzoylated fructose derivative. Moreover, the continuation from page 213 is found on page 215, and from here one goes to page 214 (confusing); also formula **17** on page 217 needs to be corrected. The chapter continues by describing the synthesis of natural products from carbohydrate precursors, with a few examples. The extensive bibliography to this chapter might also have included a reference to the article by A. Vasella in *Modern Synthetic Methods* **1980**.

The next three chapters are concerned with the use of hydrogen fluoride in carbohydrate chemistry and with a few newer methods for the selective oxidation of D-glucose and of poly- and oligosaccharides, e.g. cyclodextrins. Chapter 15 describes the synthesis of vinyl-substituted sugars and their polymerization to polyvinylsaccharides. The potential applications of these interesting polymers remain to be explored. Lastly, Chapter 16 discusses the possibility of using sucrose as a starting material for the manufacture of dyes, pigments, and carbohydrate-modified organic conductors.

Leaving aside some printing errors and mistakes in diagrams that could have been avoided, this book gives a good and informative account of the potential uses of sucrose, leucrose, and glucose as organic raw materials, more especially by virtue of the extensive bibliography provided. Also, by reading selected chapters, industrial chemists working in this area will find stimulating ideas for the increased exploitation of carbohydrates.

Short-Lived Molecules. By *M. J. Almond.* Ellis Horwood, New York, 1990. 194 pp., hardcover $ 59.95.—ISBN 0-13-798554-1

This book is intended for qualified chemists who do not have a detailed knowledge of the subject described by the title; the readership envisaged ranges from advanced chemistry students to chemists already engaged in research. In particular it is claimed to be of interest to materials scientists in industry, to readers whose work is concerned with catalysis and with photochemistry, and to those with interests in high-temperature processes.

The relatively small size of the book means that the treatment of the subject must be limited to a few examples, and the same also applies to the choice of material and the way in which it is treated. Thus the book claims to be no more than an introduction to the chemistry of short-lived molecules. The author has taken account of this by including a list of references at the end of each chapter, covering published work up to 1988. A noteworthy feature is a systematic compilation of the most important review articles published between 1978 and 1988; this fills in most of the gaps that the book itself has unavoidably had to leave.

After an introduction the author briefly describes most of the experimental techniques now commonly used for generating, detecting, and characterizing short-lived molecules (evaporation, sputtering, flames, shock waves, photolysis, flow systems, matrix isolation techniques, trapping experiments). The literature citations refer the reader on the one hand to fundamental papers on individual techniques, and on the other hand to published work breaking new ground at the forefront of developments in modern experimental methods.

The chapter on the photochemistry of metal carbonyl compounds is the longest in the book (35 pp., 41 references). As an especially important example the photosubstitution of ligands in complexes of the type $M(CO)_6$ (M = Cr, Mo, W) is described in considerable detail, and some problems arising with particular methods of investigation are also discussed. This is followed by an account of the knowledge that has been gained, mainly by matrix spectroscopy, about the short-lived carbonyl complexes that can be generated from various stable precursors ($Fe(CO)_3$, $Mo(CO)_3$, $Mo(CO)_4$, $Mo(CO)_5$ etc.) by splitting off one or more CO ligands. This chapter ends with some considerations regarding multinuclear complexes, and complexes containing CO-related ligands such as NO, ethene, and cyclopentadienyl. The rest of the chapters are concerned with the reactivity of free metal atoms, the chemistry of divalent silicon, aspects of organic photochemistry, high-temperature molecules, ions and radicals, routes to inorganic materials, and the chemistry of the atmosphere and interstellar space.

At first sight this choice of topics seems rather arbitrary, and probably reflects the personal preferences of the author as a guiding principle. However, one can accept this in view

of the aim set out in the introduction, which is to give a selective overview of the field. A similar situation is found with regard to the choice of material within each chapter. In every case one could have made a different choice which would have been at least equally good, and many topics are only touched on very briefly. For example, in the final chapter there is no mention of the buckminsterfullerenes (C_{60} and higher homologues),[*] as important forms of interstellar carbon and constituents of carbon black; however, the manuscript was in preparation at a time before the critical voices doubting this interpretation of the then available spectra had been completely silenced, and one can therefore understand the reasons for the omission.

Altogether the book contains such a wealth of stimulating ideas that the reader whose interest goes deeper is unlikely to be content with the text itself; the references provide easy access to material for more detailed study. Thus the book is a working guide rather than a textbook, and from this standpoint I found it enjoyable reading, and can therefore recommend it for the readership envisaged by the publishers. It would be useful for university and research institute libraries to have copies of the book so that it would also be easily accessible to students.

der Universität Erlangen-Nürnberg (FRG)

Frontiers in Supramolecular Organic Chemistry and Photochemistry. Edited by *H.-J. Schneider* and *H. Dürr*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. xii, 485 pp., hardcover DM 196.00.—ISBN 3-527-28016-2/0-89573-951-8

This book contains twenty articles which, except for the chapters written by the two editors, are based on papers presented at the Workshop on Supramolecular Organic Chemistry and Photochemistry which took place at the end of August 1989 in Saarbrücken, Germany. The main focus of interest here lies not in the individual molecules but in the association of molecules. The activities of the individual research groups in the area of supramolecular chemistry are aimed not only at gaining a deeper understanding of biological systems but also, most importantly, at developing new materials and technologies. In this book (p. 25) Lehn defines the goal as: "... strategies toward properties and functions rather than toward structures ...". The topics covered in this book are concerned with both aspects: they range from the design of ligands and their synthesis, and a description of the formation of complexes containing these ligands, through to the photochemistry of biological systems. The arrangement of the book's contents also essentially follows this pattern.

In the first chapter (pp. 1–28) Jean-Marie Lehn reviews the work of his group, from the start of their investigations of molecular recognition through studies of structures with electronic and ionic conductivity up to work on information and signal processing and molecular self-organization. This is followed by a series of chapters dealing with problems of host–guest interactions, as follows: selectivity and complementarity in molecular recognition, Schneider, pp. 29–56; receptors of the calixarene type, Ungaro, pp. 57–82; metallomacrocycles as host compounds for neutral guests, Reinhoudt, pp. 83–108; the design and synthesis of a biotin receptor, determination of association constants in host–guest complexes, Wilcox, pp. 123–144; azacyclophanes, Murakami, pp. 145–166. The main emphasis is also on synthesis in Stoddart's contribution (pp. 251–264); here, however, in catenanes and rotaxanes one is dealing with noncovalent bonding of a different kind.

Czarnik and Diederich describe some real applications. Czarnik (pp. 109–122) uses changes in the fluorescence properties as a method of analysis in the formation of chelates by anthracene derivatives, while Diederich (supramolecular catalysis, pp. 167–192) has not only used his cyclophanes for binding substrates but has also developed them into catalysts, e.g. for the condensation of benzoin or for the oxidation of aromatic aldehydes.

In the second part of the book the discussion of supramolecular systems is extended beyond host–guest complexes, which are made up of only a few molecules, to micelles, vesicles, membranes and various other systems, many of which have liquid crystalline properties. The topics dealt with are helical clathrates formed by inclusion in amylose (Hui, pp. 203–222), transport through channel-containing membranes (Menger, pp. 193–202), and self-organizing membranes (Fuhrhop, pp. 223–250).

The final part of the book deals with photochemistry in supramolecular structures, i.e. with those photochemical and photophysical properties that distinguish supramolecular structures from the individual molecules of which they are formed. The discussion is mainly concerned with fluorescence and electron transfer phenomena. The ultimate objectives of these studies, for example economically viable processes for the photochemical breakdown of water or the fixing of CO_2 or nitrogen in nonbiological systems, are still far from being attained. These contributions should therefore be regarded as more in the nature of progress reports.

In the area of photochemistry the systems discussed again include complexes made up of a small number of molecules, but also in addition liquid crystals, micelles and biological materials. Thus the topics covered include the photochemistry and photophysics of anthraceno-crown ethers (Bouas-Laurent, pp. 265–286) and of ion pairs and coordination compounds (Balzani, pp. 371–392). Schaffner discusses the photophysics and photochemistry of the biliprotein chromophore with regard to its protein matrix (pp. 421–452). Ringsdorf describes the photoinduced structural changes that occur in some organized supramolecular systems, most of which are liquid crystalline (pp. 311–336), and Willner deals with photoinduced electron transfer in systems of this type (pp. 337–370), whereas Braun discusses oxidation reactions in microheterogeneous media (pp. 393–420). De Schryver describes the use of fluorescence measurements for characterizing micelles. The photochemical part concludes with a chapter on supramolecular photosensitizers (based on ruthenium) for nonbiological photosynthesis (Dürr, pp. 453–476).

Altogether this book is an excellent collection of papers from the Saarbrücken Workshop, and it summarizes the latest developments in a number of different areas that come under the general heading of supramolecular chemistry. The layout of the text is clear and systematic, and there are plenty of figures, some of which are in color. Regrettably, however, the high price will be an obstacle to reaching a large readership.

Dienes in the Diels-Alder Reaction. By *F. Fringuelli* and *A. Taticchi*. Wiley, Chichester, 1990. xx, 348 pp., hardcover £ 55.15.—ISBN 0-471-85549-9

Within its 348 pages this book offers no fewer than 165 pages of tables and 63 pages of references. While this may be taken as evidence of the authors' great diligence, it does not make up for the fact that the presentation of the data leaves much to be desired. In their preface the authors indicate that the audience they have in mind includes undergraduate students. Such students should be warned, however, that this book, at the steep price of £ 55, is not a good investment, since only the first of its six chapters can be considered didactic. The first chapter does indeed contain a discussion of the fundamental principles of the Diels–Alder reaction, but since the treatment is somewhat superficial and is compressed into 40 pages, it would have been preferable to omit this chapter altogether and, by way of introducing the subject, to refer the reader to an appropriate and well-received textbook, such as that by W. Carruthers,[*] a recent text that also happens to be less expensive since it is available as a paperback (US $ 36.01 paperback, US $ 73.01 hardcover).

Probably most readers will lose interest in the book after the first chapter. That is where the enumeration begins of 1,3-dienes and their reactions with various dienophiles. The organization is conventional: open chain dienes (Chapter 2), exocyclic dienes (Chapter 3), compounds with one exocyclic and one endocyclic double bond (Chapter 4) and with two endocyclic double bonds, each in a different ring (Chapter 5), and finally, cyclic dienes (Chapter 6). Each of these classes of dienes is introduced by means of representative reactions and individual reactions are then described in extensive tables. In the tables the diene component is listed by structure, whereas each dienophile is described in two ways: firstly, either by full name or by an abbreviation, and secondly by a code classifying reactive centers and substituents. The purpose of this latter listing escapes me.

It is difficult for a reviewer to assess whether the collection of data presented in this volume is really comprehensive. In trying to do so I chose 20 relevant references between 1980 and 1986, which are known to me, but found only 12 of them referred to in the book. Older references cannot be traced here; it was made quite clear in the preface that the literature is covered only between 1978 and 1987. Nevertheless, the extensive tables which list reactants and yields may be useful to academic or industrial research chemists who wish to check their own literature surveys.

This volume is presumably based on an extensive search of Chemical Abstracts. Unfortunately, the references so collected were not placed in any systematic order whatever, alphabetic, numerical or chronological. Thus, Chapter 2 lists 500 references but its first section, 2.1 (1,3-butadienes), starts with reference 456. In Chapter 6 each of the three sections is referenced independently. The first section of this chapter, 6.1 (carbocyclic dienes) (453 references), starts with reference 413. All this is annoying, particularly since many cheap computer programs are available that can execute alphabetical or numerical sorting with ease. With reference to computer software, apparently several different programs of varying quality were employed to draw the formulas in this book: in some cases double bonds are not clearly drawn (e.g., pp. 152, 233, 237), and several drawings are smudged (e.g., the representations of face-selective Diels–Alder reactions, pp. 38 and 63).

What a pity: a great deal of work has gone into this volume, but not enough thought was given to its design and execution.

Sulfur Analogues of Polycyclic Aromatic Hydrocarbons (Thiaarenes). Environmental Occurrence, Chemical and Biological Properties. (Series: Cambridge Monographs on Cancer Research.) By *J. Jacob*. Cambridge University Press, Cambridge, 1990. XIV, 281 pp., hardcover £ 55.0. – ISBN 0-521-30120-3

This monograph provides chemists, biologists, and medical scientists with information on the sulfur analogues of polycyclic aromatic hydrocarbons, with special regard to their possible environmental effects, in particular their mutagenic and carcinogenic properties. It includes analytical and synthetic aspects, as well as the physical and biological data that are available up to now. As the information on these topics is widely scattered throughout the literature, the authors have performed a valuable service in bringing it together in an encyclopedic compilation, and in presenting, for the first time, comparisons with the corresponding non-sulfur polycyclic arenes that have been studied more thoroughly. Nevertheless, because there are still many gaps in our knowledge of these sulfur compounds, this cannot be more than a first crude attempt. Since many new sulfur-containing polycyclic arenes have recently been synthesized, one must hope that it will soon be possible to fill in the picture in more detail, and to find out whether the sulfur analogues are in fact less carcinogenic than the corresponding arenes.

The monograph is written in a concise and clearly understandable style. It begins with a general part (94 pp.) which gives information on the biological activities of this hitherto relatively little studied class of compounds, deals with questions of nomenclature, and discusses spectroscopic data (UV/VIS, fluorescence, phosphorescence, IR, NMR, mass spectrometry); in some cases these data are presented in the form of tables together with those for the corresponding non-sulfur arenes. This first part also includes general information on the synthesis of the compounds and their isolation, separation and identification, based on oxidations or reductions in combination with a wide variety of chromatographic methods. The picture is completed with information on natural occurrence and on mutagenic formation from the biomass. The biosynthetic building blocks are believed to be hydrogen sulfide from microbial processes, elemental sulfur, and sulfur-containing amino-acids. This explains the instances of occurrence in mineral oil and coal. A carefully compiled bibliography, including also metabolic aspects, is provided.

The second part (132 pp.) gives information on individual thiaarenes. The choice seems rather subjective, but has been determined by the relevance to biological activity. Unfortunately the monocyclic compound thiophene is not included. The compound-specific part begins with bicyclic and ends with nonacyclic compounds. There is a general preponderance of thiaarenes with the sulfur atom in the five-membered ring, i.e. thiophene derivatives. Only a few isolated examples of thiapyrans are included. One quickly gets used to the peculiar notation used for the partial structural formulas.

For example, C_4S–C_6 stands for benzothiophene, C_4S–C_6–C_6 for naphthothiophene, and so on. In any case, this is then followed by the structural formula, the name, and details of synthesis, occurrence, and properties. In each case the data are supported by the names of the authors and the year of publication. The full citation can be found in a special chapter containing nearly 1000 references, arranged alphabetically by authors. There is also an index containing about 900 keywords relating to the thiaarenes listed.

One might criticize by pointing out that, despite the wealth of material, only a modest amount of information on mutagenic and carcinogenic properties is given, and that the manuscript deadline was apparently as early as 1986. Nevertheless, the monograph is an essential first step, and it provides a sound basis for a deeper understanding of the possible environmental effects of sulfur-containing polycyclic arenes and an initial attempt at a comparative study. At the same time it also reveals the disturbing inadequacy of our knowledge of this specialized topic, but on the other hand it points the way to future work, including especially computer-aided molecular modeling studies. Although this is an unconventional book, it can be recommended for everyone interested in the subject.

Transition Metals in Total Synthesis. By *P. J. Harrington*. Wiley, Chichester, 1990. xvi, 484 pp., hardcover £ 47.50.—ISBN 0-471-61300-2

The very welcome aim of this book is to demonstrate the value of proven synthetic methods based on organotransition-metal chemistry, by exemplifying their application to key steps in total syntheses. The author states in the preface that it is intended for advanced students as well as experienced chemists.

The well-bound book, whose clean, well-set text contrasts to some extent with the rather unprofessional looking structural formulas, consists of 14 chapters and is provided with a subject index. Each chapter is linked to one or two structurally related target compounds and usually starts with an explanation of their origin and biological activity. This is always followed by a quite detailed description of a certain class of organotransition-metal compounds, covering methods of preparation and typical reactivities. The chapters conclude with a tersely presented ("synform-like") total synthesis of the target molecule(s) in which the previously discussed organometallic compounds are involved in key positions.

In this manner, the book describes a rather limited, but quite relevant selection of synthetically useful methods for C–C-bond formation, in all of which transition-metal complexes are used either as catalysts (e.g. Heck reaction, allylic alkylation, Stille coupling, Vollhardt cyclization), stoichiometric reagents (e.g. Pauson-Khand reaction, Tebbe-Grubbs reactions, Schwartz reaction) or building blocks (e.g. reactions at carbonyl π complexes of Cr, Fe or Co, or the Dötz reaction).

Upon first glance the book makes a favorable impression. It is at once evident that the author made an effort to give the reader a broad overview with the emphasis on the preparative scope of each method. In this he can be excused for occasionally resorting to mere lists, and not even flinching from including ten-page tables. However, in the likewise very detailed explanations of mechanisms it would have been desirable to put a greater emphasis on the basic and common principles of organotransition-metal reactions.

One ground for criticism is the rather frequent mistakes in structural formulas (for example, on page 210 alone, four of the twelve formulas contain a total of six errors); there are the contracted C-rings of two steroids (page 233), the apparently epimerized 17-β-estradiol (page 202), the inadvertently partially hydrogenated arene (page 212), and a product with a shifted methoxy group (page 331). Also the denotation of nonisolable intermediates by square brackets is not applied consistently, which leads to confusion, as too does the fact that in many of the formulas the (relative) stereochemistry is not fully indicated or (sometimes) not given at all.

Apropos stereochemistry: It is unfortunate that in this book little or no distinction is made between absolute and relative configuration. Even the target compounds (with biological activity) are usually introduced as racemates (e.g. (±)-estrone on page 200), and the chosen syntheses then lead likewise to racemic mixtures. Thus, readers who regard the control of absolute configuration as an important objective as well might not be completely convinced of the usefulness of organotransition-metal methods. The term "enantioselectivity" does in fact appear in one of the chapters, but not in the context of a synthesis, and characteristically, of the "chiral" ligands shown there (pp. 74–75) at least two are (according to the formula diagram) meso compounds. That stereochemistry is not exactly the author's favorite topic becomes especially apparent in Chapter 11, where arene tricarbonylchromium complexes are discussed. After convincing the reader that compounds of this type can be chiral, the author states (on page 337): "To illustrate, complexation of racemic 1-indanol can produce as many as four diastereomers. In fact, complexation occurs exclusively on the same face as the hydroxyl group. The pair of diastereoisomeric complexes are separable. Oxidation of the (S)-isomer affords a single complex of indanone". This statement is quite simply wrong at several points. It ought to read: "... as many as four stereoisomers (two diastereomeric pairs of enantiomers). In fact, complexation occurs diastereoselectivity on the same face as the hydroxyl group. The pair of enantiomeric complexes may be separated by classical resolution techniques (via diastereomer formation). Oxidation of the (1S)-isomer...".

There are also other errors that do not exactly inspire confidence, for example, the conversion of a ketone to an epoxide by using the dimsyl anion (p. 140), or the (improbable) occurrence of free cyclobutadiene as an intermediate in the preparation of its $Fe(CO)_3$ complex from 3,4-dichlorocyclobutene (p. 98).

The currentness of the book leaves something to be desired as well. Although there are a handful of literature references for 1987 (mostly to the author's own work) and 1988, the discussions are, on average, considerably less up-to-date than this. Had the author taken the trouble to research the more recent literature, it would have saved him several further embarrassments. For example, it is regrettable that in discussing the Semmelhack syntheses of (±)-acorenone and (±)-acorenone B (Chapter 11) he has failed to mention the work of Uemura et al., which was published in 1986. In stating that "stereospecific synthesis of (intermediates) A and B would improve both syntheses significantly" (p. 343) he reveals his ignorance, as exactly this problem has already been solved by Uemura. In another passage (pp. 318–319) he describes how complexes of benzene derivatives with $Cr(CO)_3$ can be prepared by transcomplexation at 200 °C; here we read: "Thus, the naphthalene complex should be most suitable for preparation of new arene complexes by arene

exchange". It is almost beyond belief that the method introduced several years ago by Kündig and since applied by others, which does in fact use the naphthalene complex as the reagent (at mild 70 °C), is not cited here.

Though the book's flaws are flagrant, its strengths should not be completely ignored. Many of the chapters are quite readable, interesting, and well written from a teaching standpoint. Doubts remain, however, that the author can convince a wider circle of readers of the usefulness of organotransition metal methods, since almost no comparisons with alternative methods of synthesis are made. And when the low cost of a starting material (e.g. 2-methylanisole) is put forward as a "selling point" for a particular synthesis, many readers will be annoyed to discover that the cost of the transition metal reagent required in stoichiometric quantities is many times greater, but not even mentioned. Instead, so many thoroughly sound arguments and good examples could have been put forward as impressive confirmation of the usefulness of transition metals for total syntheses—even for nonracemic target compounds.

To summarize, the author's intentions are entirely laudable, but the value of the book is considerably diminished by the many shortcomings as regards the quality and up-to-dateness of the discussions. Readers who use the book for casual browsing will certainly be able to derive some interesting ideas and insights from it. On the other hand, those looking for a good treatment of the applications of transition metals in organic synthesis, especially beginners in the field, would be better advised to go to other (and also cheaper) monographs, such as that by Collman, Hegedus, Norton, and Finke and/or to a selection of recent review articles on the individual topics. The gap in the market, which this book was intended to fill, remains open.

Multiple Peptide Synthesis Methods and Their Applications

New Synthetic Methods (87)

By Günther Jung* and Annette G. Beck-Sickinger

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

Rapid developments in the biotechnology of new proteins, as well as advances in immunology and the development of pharmaceuticals based on inhibitors and antagonists, have led to immense demands for synthetic peptides. Simultaneous preparation of 100–150 completely different peptides, having chain lengths of up to 20 amino acids can nowadays be achieved using multiple synthesis methods. The yields and qualities of the peptides so obtained are high enough to permit reliable in vivo and in vitro screening for biological activities. Moreover, it is possible to optimize synthetic conditions and to carry out comparative studies on the secondary structures and conformational mapping of proteins. Special multiple synthesis methods facilitate the epitope mapping of larger peptides for diagnostic purposes and for the development of vaccines based on a few hundreds of free or rod-bound peptides that are useful for immunoassays. Multiple methods of peptide synthesis also enable the preparation of so-called peptide libraries which could comprise hundreds of thousands of peptides, and by which new perspectives for the screening of lead structures will be opened up. Peptide synthesis using a combination of photolabile protecting groups and photolithographic procedures enables the assembling of peptide libraries on small plates for use in miniature immunoassays. Furthermore, lipopeptide-antigen conjugates allow both the preparation of peptide-specific and monoclonal antibodies as well as a complete screening of epitopes of B-, T-helper and T-killer cells. Applications in the areas of AIDS diagnosis, the development of vaccines, and screening for the hormone analogues, demonstrate just some of the possibilities that have been opened up by multiple peptide synthesis methods.

1. Peptide Synthesis Through the Ages

Peptide chemistry is currently witnessing a tremendous upswing in technological progress. The numerous possibilities for research using synthetic peptides in the solving of biological problems are becoming increasingly better recognized.[1–8] No other area of organic chemistry seems so dependent on interdisciplinary cooperation as peptide chemistry. The fields of research in modern peptide chemistry include synthesis and analysis, isolation and structure determination, conformational investigations, and molecular modeling. Project-oriented studies are being carried out in conjunction with research groups in pharmacology, physiology, immunology, biology, and biophysics. More and more peptides with unusual amino acids,[9–15] modified peptide bonds,[16–21] linker or spacer molecules,[22, 23] and peptide mimetics[14–26] are being prepared. Highlights of the medicinal chemistry of agonists and antagonists of biologically active peptides and inhibitors have recently been summarized by Hirschmann.[26a] Great progress has also been made in immunology at the molecular level regarding recognition mechanisms, using both synthetic peptides[27a, b] and vaccines.[27c–e] The peptide chemist is continually being con-

fronted with new challenges at ever shorter intervals.[28, 29] There is a greater demand for new strategies, faster syntheses,[28] better coupling reagents and protecting groups, and especially for methods for the simultaneous preparation and analysis of very large numbers of peptides in a short time.

We present here a survey of the latest developments in the area of multiple peptide synthesis (MPS) and address the possibilities of modern analysis for a large number of polypeptides (multiple peptide analysis, MPA). These methods will be illustrated by means of examples showing their characteristic applications.

1.1. Synthetic Partial Sequences of Proteins

In 1963 Anderer[30] prepared virus-neutralizing antibodies using the synthetic *C*-terminal hexapeptide of the protein of tobacco mosaic virus. Since then, the use of synthetic partial sequences of proteins has played a major role in the determination of antigenic determinants. Concomitant with the progress being made in gene technology research and the development of automatic protein sequencers, the number of sequenced proteins is increasing so rapidly that sequences can be ascertained and compared only by using special programs and data banks.[31] Despite the progress made in gene technology, the chemical synthesis of short proteins is presently one of the fastest methods for obtaining experimental information about binding-domains, active centers, and modifications.

Interestingly, Merrifield's decisive concept[32, 33] of an automated peptide synthesis on a solid support, appeared shortly after Anderer's investigations. The Merrifield synthesis[28, 33–36] was a prerequisite for the rapid synthesis of many peptides. Biosynthesis of the sequence analogues of biologically active peptides and proteins has been achieved by the use of side-chain mutagenesis; however, a specific modification by inserting non-proteinogenic amino acids is almost only possible by chemical methods. Owing to the large number of diagnostically and therapeutically interesting proteins, and to the increasing demand for proteins in biochemical research, it is no longer possible to prepare the required protein segments using conventional methods of fragment condensation within a reasonable time.[37–39]

1.2. Biologically Active, Low Molecular Weight Peptides

The number of highly biologically active peptides which can be used as a basis for the development of pharmaceuticals, or can be employed for therapy in the natural form, has increased drastically. Our bodies 'recognize' and react with many more peptides than was previously thought. Bombesin, endothelins, epidermal growth factor (EGF), magainin and neuropeptide Y are just a few examples of a large number of highly active peptides which have been the subject of chemical research in the last few years. Continuous activities are also aimed at modifying other significant peptides such as atrial natriuretic factor, renin, somatostatin, cholecystokinin, pepstatin, calcitonin, bradykinin, enkephalin, angiotensin, vasopressin and oxytocin.[1–8] Knowledge of the structure-activity relationships which disclose the correlation between amino acid sequence, peptide conformation and biological activity is important both for the elucidation of the underlying principles of signal recognition and information transfer, and for pharmacological applications. Furthermore, an understanding of the mechanisms of agonism and antagonism of peptide hormones can be gained only by a systematic modification of peptide and non-peptide analogues.

1.3. Analytical Procedures are Advancing

By improved methods of biological, biochemical and instrumental analysis, it is possible to have access to picomolar (or even less) amounts of novel biologically active materials. Fully automatic gas-phase sequencing according to the method of Edman[40, 41] requires less than 100 pmol of a protein. Furthermore, by using HPLC on-line coupling, the molecular masses of polypeptides over 10000 Da can be determined by ion-spray mass spectrometry;[40, 42] likewise in the lower picomolar range. For amino acid analysis even a few femtomol of peptide suffices in special cases.[40, 43] Consequently, it is more often possible to sequence naturally occurring peptides in the picomolar range, and then to study their biological activities using synthetic compounds and their analogues.[27, 44, 45]

Günther Jung, who was born in Tübingen in 1937, studied chemistry at the Universität Tübingen, where he gained his doctorate in 1967 under the supervision of E. Bayer. After his habilitation (1971) in the natural products area he became Professor of organic chemistry and biochemistry at the Universität Tübingen, after turning down numerous positions at other universities. He spent 1967/68 in the USA as an assistant professor at the Univeristy of Houston, Texas. In 1989 he was awarded the Max Bergmann Medal for his work on lantibiotics. His areas of research include the structural elucidation, mode of action and biosynthesis of larger polypeptide antibiotics and siderophores, structure-activity relationships of the neuropeptide Y, models for transmembrane channels, multiple peptide synthesis methods, B-, T-helper and T-killer cell epitope mapping, and the development of synthetic peptide vaccines.

Annette G. Beck-Sickinger, born 1960 in Aalen (Germany), studied chemistry (Diploma 1986) and biology (Diploma 1990) at the University of Tübingen. After a period of research work with R. A. Houghten at the Scripps Clinic & Research Foundation (La Jolla, California) she returned to Germany and gained her doctorate (1989) under the supervision of Professor G. Jung. From 1990 to 1991 she carried out research as a post-doctorate with Professor Carafoli at the ETH Zürich. She is presently at the University of Tübingen where she is working on her habilitation. Her research interests lie in the areas of peptide-protein interactions, photocrosslinking, and structure-activity relationships of neuropeptides.

2. Multiple Peptide Synthesis—the Logical Step

In order to respond to the rapidly growing demands for a large number of peptides with completely different sequences, several groups have, since 1985, been developing different concepts for a multiple peptide synthesis (Tables 1 and 2). The term multiple peptide synthesis (MPS), also known as simultaneous multiple peptide synthesis (SMPS), denotes the parallel synthesis of many peptides having various lengths and amino acid sequences. In principle, the various methods can be distinguished by the differences in the polymeric support employed, the number of peptides possible, and the amount of products obtained. Typically, if more, than 10 mg of product is obtained, not only the characterization but also a purification step can be carried out. Subsequent modification of the peptide then becomes possible.

The multiple synthesis methods are mostly applied in hormone and inhibitor research. For the identification of relevant side chains, every amino acid of a biologically active peptide can be systematically substituted, the chain lengths can be varied, and *N*- as well as *C*-termini can be modified (Fig. 1).[46] In the original solid-phase synthesis, the various *N*-terminal modifications such as acetylations, biotinylations, succinimidylations or couplings for preparing immunogens could be achieved by portioning the peptide–resin. By contrast, modifications within the peptide chain or at the *C*-terminal segment can only be achieved by multiple methods or by consecutive syntheses. Thus, in the multiple

Fig. 1. Top: Identification of amino acids of the hormone neuropeptide Y (NPY) which interacts with a receptor (rabbit kidney cortex). Using 48 analogues of the heptadecapeptide YPSK-Ahx-RHYINLITRQRY-NH_2 (Ahx = 6-aminohexanoic acid), prepared by the MPS method and by replacing one position each of the sequence by L-alanine, glycine or the corresponding D-amino acid, it was shown that the *C*-terminal tetrapeptide amide RQRY-NH_2 is essential for the interaction, since substitution at these four positions leads to a large decrease in the receptor affinity [57a]. The figure shows the order of the natural amino acid plotted on the x-axis. Receptor-binding data of the analogues are presented as -lg IC_{50} (pIC_{50}) (IC_{50} = concentration in [M] of the half-maximal inhibition of the binding of ^{125}I-NPY is shown by the bars). Bottom: Sequences of the analogues. Left-hand column: small letters symbolize the position substituted by the D-amino acid; center column: substitution by L-alanine A; right-hand column: substitution by glycine G.

Using the systematic scanning of a protein with anti-peptide or anti-protein antibodies, called epitope mapping, usually leads to the detection of sequential B-cell-epitopes. T-helper-cell epitopes (length of 12–17 amino acids) and T-killer-cell epitopes (length of 8–10 amino acids) can be identified with short peptides, which cover the whole sequence of the protein. In addition, conformational mapping, the investigation of the folding of a protein, is possible when overlapping segments (length of 15 to 20 amino acids) are synthesized and systematically investigated by experimental methods for the analysis of the conformation. These scans are more precise when greater numbers of defined peptides from the one protein are used.

In the sequential mapping of a protein for immunological and biochemical investigations, it is often sufficient to have a few milligrams of peptide, if overlapping sequences are used. The length of the sequences and width of the raster are then to be adjusted to the types of investigation and determine the number of peptides to be synthesized (Fig. 2).

If, e.g., the nef-protein of HIV-virus with 208 amino acids (AA) is going to be investigated by using hexapeptide segments and a raster of 1,[47] 203 peptides are required. For the number n of required peptides, the following is generally valid.

$$n = \frac{\text{no. of AAs of protein} - \text{no. of AAs of peptide segment}}{\text{raster number}} + 1 \qquad \text{(a)}$$

Such a fine scanning with overlapping partial sequences is carried out in particular in the determination of immunoglobulin binding-sites (Fig. 2). For investigation of the immunogenicity of protein segments, longer peptides are required but with a less dense raster. Thus, the P6-protein of *Haemophilus influenza Type b*, containing 134 amino acids, could be immunologically mapped using 28 peptides with a raster of 4 and a peptide segment containing 20 amino acids.[48]

3. Different Synthetic Concepts—One Goal

3.1. Peptide Synthesis in a 'Tea Bag'

Houghten's tea-bag method, although published for the first time in 1985,[49] already belongs to the oldest strategies of multiple peptide synthesis. This method is suitable for preparing up to 150 different peptides with a yield of up to 50 mg. Separation of the polymeric support is achieved by sealing it in polypropylene nets before the solid-phase synthesis is begun. For each peptide, such a labeled tea bag of noted solvent stability is filled with ca. 100 mg of polymeric support.[50] Generally polystyrene-divinylbenzene (1%) is used, but it is possible to employ other polymeric supports as long as the size of the smallest particle is larger than the pores of the net (Fig. 3, p. 372).

Deprotection of the α-amino group and washing are simultaneously carried out in a suitable polypropylene, screw-capped bottle, the size of which can be adjusted depending on the number of peptides and the washing volume. The washing volume per tea bag is typically 3–5 mL. For the coupling, tea bags are sorted according to the coupling amino acids and are allowed to react parallel with the activated amino acids in separate reaction vessels. Next, for removal of excess reagents, the tea bags are separately washed twice and then reunited for deprotection. In order to facilitate diffusion of reagents into the resin, washing and coupling steps are carried out with vigorous shaking.

In principle, the tea-bag method is not dependent on protection strategy or activation. Houghten developed this method for the *tert*-butoxycarbonyl (Boc)/benzyl (Bzl) strategy and *N,N'*-diisopropylcarbodiimide (DIC) activation.[49, 51] We employ the superior Fmoc/*t*Bu strategy and *O*-(benzotriazol-1-yl)-*N,N,N,N'*-tetramethyluronium tetrafluoroborate (TBTU) activation,[52] which leads to faster coupling cycles and avoids halogenated solvents.

In comparison to other parallel syntheses, the tea-bag method yields at least 30–50 mg of peptide with a chain

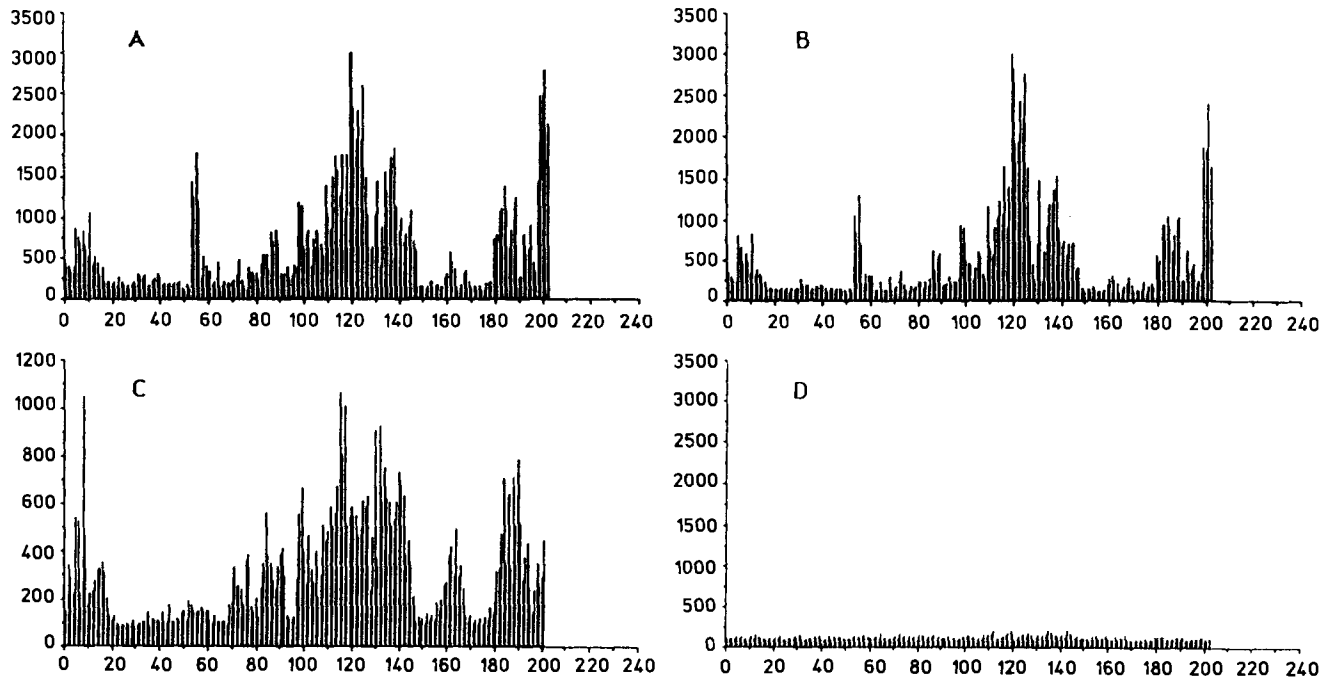

Fig. 2. Epitope screening of the HIV nef-protein by means of Pepscan-ELISA according to Gombert et al. (cf. Section 3.2.1) [47]. The intensity and accumulation of positive peaks in the ELISA indicate continuous (sequential) B-cell-epitopes in distinct sequences, which are recognized by anti-Nef-antibodies. A continuous B-cell-epitope consists of adjacent amino acids within the sequence of a protein. The specificity and affinity of antibodies against discontinuous epitopes, which contain several parts of a protein within different areas of the sequence, might be increased. However, ELISA-assays with peptide-antigens are frequently used with great success. The continuous B-cell epitope of the Nef-protein from three HIV isolates (SF2 (A), BRU (B) and MAL (C)) were determined by binding of antibodies (Fig. 5), which were directed against the Nef-protein, and obtained from HIV positive sera (dilution 1:1200). Serum D is a HIV negative control serum. The ELISA values (optical density × 1000 at 405 nm) were plotted versus the peptide numbers. By testing a representative number of HIV positive sera, several peptides of different length (cf. Fig. 6) showed a very clear limitation of the relevant epitope [47].

length of more than ten amino acids. This amount is sufficient for detailed analyses, spectroscopic investigations (including NMR studies), and a large number of biological tests.

The variability of this method is noteworthy: solvents, activation of amino acids, coupling schemes and further synthetic parameters can be altered from coupling to coupling, as well as during one coupling cycle. Therefore, this procedure is particularly suitable for methodological investigations.[53] Different bases for neutralization,[51] many coupling reagents[53a] and various reagents for the end-capping of non-coupled N^{α}-amino groups[53b] have thus been systematically investigated. From the syntheses of more than a hundred peptides, conclusions can be made concerning the amino acid- and position-dependent coupling efficiency.[54]

Information about the structure-activity relationships of fibrinogen,[55] magainin-2[56] and neuropeptide Y[46, 57] as well as elucidation of antigen-antibody interactions[58] could be obtained by the synthesis of many peptide analogues using the tea-bag method. Furthermore, the tea-bag method has also been used successfully for the conformational mapping of proteins.[59a] The flexibility of this method and the relatively large amounts of peptide obtained have proven advantageous (Fig. 4, p. 373).

Conformational predictions, based on the behavior of peptide sequences in HPLC-chromatography, have recently been published.[60] In this way, e.g., the change in behavior of amphiphilic helices following amino acid substitution has been investigated.[61] For statistically significant evaluations of such investigations, a large number of similar peptides is required. These can only be obtained by multiple synthesis methods. A further advantage of Houghten's MPS method is the low cost, as no investment for instruments is necessary. Since all the steps in this procedure (washing, sorting of the bags, etc.) have to be carried out manually, the method is laborious, which must be considered its major disadvantage. A computer-supported calculation of the synthetic cycles, especially in the sorting steps, becomes indispensible. Moreover, in practice, it becomes impossible to carry out a coupling control for a large number of peptides.[54b, c] However, this method is improved by our own procedure, i.e., the use of a combination of tea-bag synthesis and a semi-automatic synthesizer (Labortec-Bachem, Bubendorf, Switzerland), which allows automation of the washing steps[52] (Fig. 3c).

3.2. Peptide Synthesis without Visible Yields?

3.2.1. Peptide Synthesis on Rods

Peptide synthesis without visible amounts of peptides? – This concept was developed by Geysen et al.[62] Several hundred peptides can be simultaneously prepared using this procedure. The peptides remain permanently bound to the carrier, however, not only during but also following the synthesis. At the end of the synthesis only the protecting groups are removed. Amino-functionalized polyethylene rods (4 mm diameter, 40 mm length) are employed as support. 96 of these so-called 'pins' are fixed into a block con-

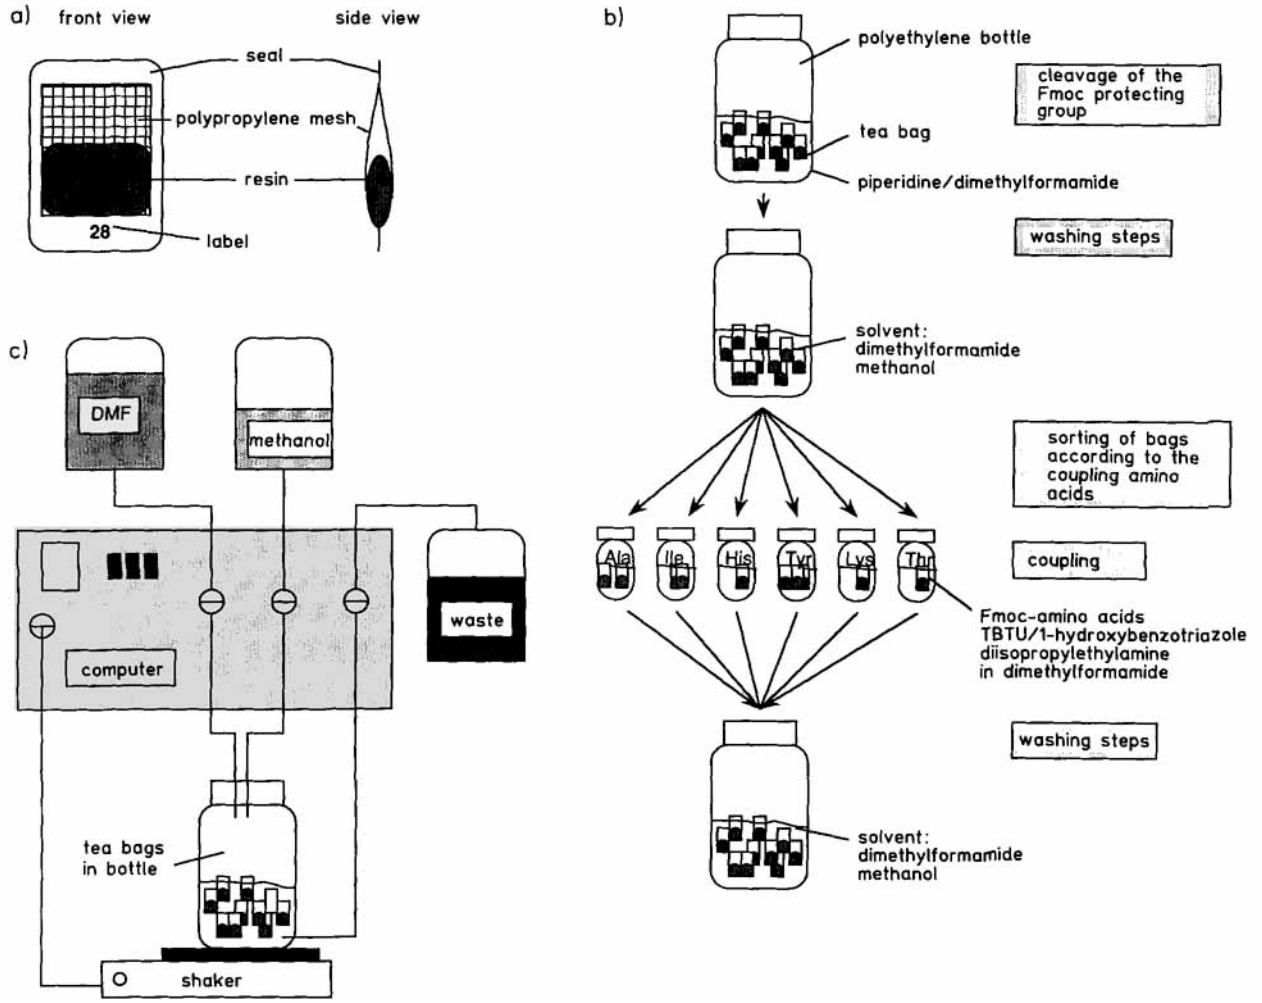

Fig. 3. Schematic representation (a) of a 'tea bag', (b) of the synthetic steps for a multiple peptide synthesis and (c) of the semi-automatic synthesizer [52]. a) Polypropylene net (pore size 64 μm) is labeled and sealed to prepare the bags (3 × 4 cm) [49]. After filling the bags with the polymeric support and sealing the last opening, the bags are tested for leaks and used for the synthesis. One peptide is obtained per bag. b) In a multiple synthesis, cleavage of the N^{α}-protecting group as well as all the washing steps are performed with all the tea bags in a common reaction vessel. For coupling, the bags are sorted for the different amino acids and treated with activated N^{α}-protected amino acids in different vessels. c) Washing of the bags is carried out automatically, whereby addition and removal of solvents by suction are effected by means of computer-controlled valves [52]. TBTU = *O*-(benzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium tetrafluoroborate, DMF = dimethylformamide, Fmoc = fluorenylmethoxycarbonyl.

taining 8 rows of 12 rods (Fig. 5). The pins are so arranged, that they fit exactly into the wells of the plates used for the *e*nzyme-*l*inked *i*mmuno*s*orbent *a*ssay (ELISA). Washing and deprotecting steps are carried out in large baths. The amount and distribution of the Fmoc-amino acids to be coupled are calculated by a computer program. We were able to make a substantial improvement here by using a computer-controlled stencil, which enabled rapid and accurate pipetting onto the dimethylformamide-stable ELISA plates. After activation, the blocks are placed on the plates and coupling can be carried out. Polyethylene rods cannot swell or shrink, and adsorbed molecules can only be removed with difficulty. Therefore, a thorough washing after each reaction step of the synthetic cycle is of utmost importance. In a new variant, detachable 'heads' and not the rods themselves are functionalized. The blocks themselves can be used several times.

The importance of the pin method lies in the immunoanalytical field.[63-65] Antibodies against large proteins can be tested using overlapping tetra- and nonapeptides in the so-called Pepscan.[65] Mono- or polyclonal sera are distributed in the ELISA-plates and are incubated with the rods. The corresponding specific antibodies in the antisera preferably bind only to the peptide rods having the sequence of a continuing B-cell epitope. Direct application of human sera necessitates some experience in order to suppress non-specific reactions. Since the synthetic peptides cover the entire protein, with only an amino acid shift in each peptide, very accurate analyses of the B-cell epitopes are obtained. In the case of monoclonal antibodies, the continuing binding site can be accurately determined, down to the amino acid (Fig. 6, p. 374).

The VPI-protein from the virus of foot-and-mouth disease,[62] FeLVgp70-protein,[66] the capsular protein of Epstein-Barr virus,[64] and various proteins of HIV-subtypes[47,67] are only a few examples of proteins which have so far been investigated with regard to their antibody binding sites.

If the primary sequence of a protein, against which a monoclonal antibody is directed, is not known, or if it concerns a discontinuous epitope, then this epitope can also be imitated by peptides which do not occur in the protein sequence. Such antibody-binding peptides are called *mimotopes*.[65]

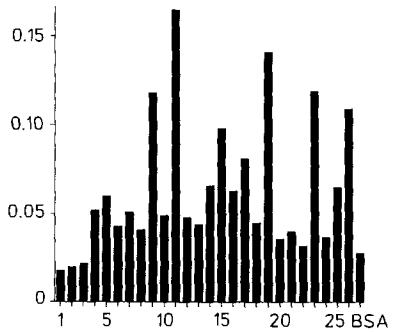

Fig. 4. Conformational analysis (top) and epitope mapping (bottom) of thymidine kinase (376 amino acid residues) from *Herpes simplex* virus [59a]. By using sequential peptides (15 to 17 amino acids) it was possible to refine the three-dimensional models obtained by the molecular dynamic simulation (middle) [59b]. 26 peptides were prepared by the tea bag method (cf. Fig. 3), analytically characterized, and investigated by circular dichroism (CD). Figure 4 (top) shows the calculated percentage of the different conformations for every peptide as derived from the CD spectra. Recognition of the peptides by a thymidine kinase antiserum is shown in Figure 4 (bottom). In the model, the parts on the surface area (B-cell epitope) are better recognized than the peptides from internal segments of the protein. x-Axis: peptide numbers. BSA = bovine serum albumin as negative control; y-axis: ELISA value, relative absorption value.

Such antibody-binding peptides are called *mimotopes*.[65] The mimotope is developed by means of combining D- and L-amino acids and is always controlled by the antibody binding tests (Pepscan-ELISA). However, a high specificity of the monoclonal antibody is required, since one normally begins with screening at the dipeptide level.[65] Carrier-bound mimotopes can be used, e.g., for the isolation of antibodies from antisera by means of affinity chromatography or for blocking an antibody binding site. They are also of interest for the screening of new lead structures.

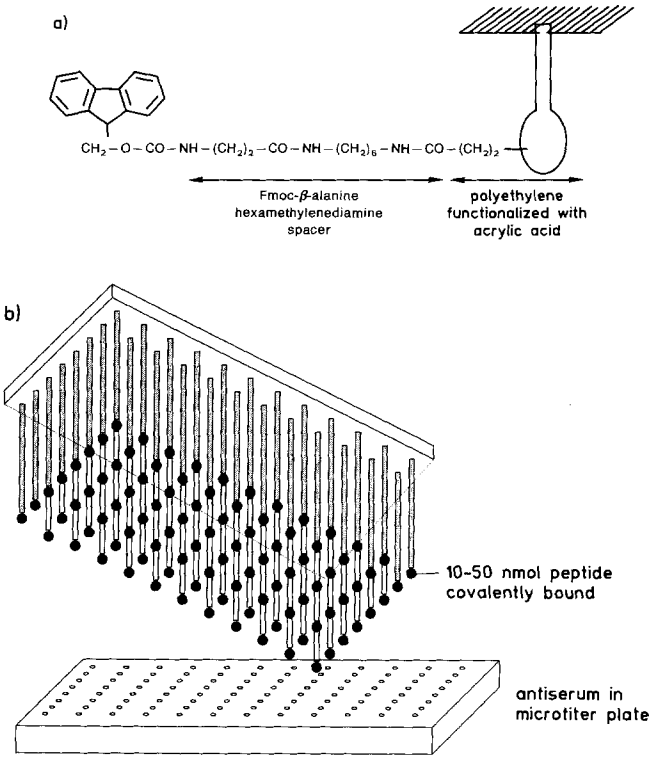

Fig. 5. Schematic representation (a) of a pin and (b) of the block for the pin synthesis. Polyethylene rods (4 × 40 cm) are functionalized with acrylic acid, and N^{β}-Fmoc-β-alanyl-1,6-diaminohexane is introduced as a spacer. Peptide synthesis is carried out on DMF-stable polyethylene microtiter plates. The test is performed by means of pepscan-ELISA, whereby the covalently linked pin-peptides in the usual microtiter plates are investigated for the binding capability of antibodies (cf. Fig. 2). After successful tests, the pins are washed with detergent and are ready to be used for new sera. Use of a single block for up to 50 tests is possible.

In order to obtain free peptides by the pin synthesis method, either an acid-labile anchor has to be inserted between the first amino acid and the polyethylene rods, or special enzymatic or acidolytic cleavage points must be *C*-terminally introduced. For this purpose, R. van der Zee et al.[68a, b] have proposed either Asp-Pro-Gly or Lys-Gly as the *C*-terminal cleavage sequence; the former can be cleaved with formic acid, the latter with trypsin. Neutral cleavage of a Lys-Pro polymer via diketopiperazine formation is another possibility; however, after this cleavage the diketopiperazine adduct is formed and not the free peptide acid.[68c] A better alternative is the use of extremely acid-labile anchors such as 4-(2′,4′-dimethoxyphenylhydroxymethyl)phenoxy and 2-methoxy-4-alkoxybenzyl, which have been fully investigated with regard to their cleavage reactivity.[69] This efficient syn-

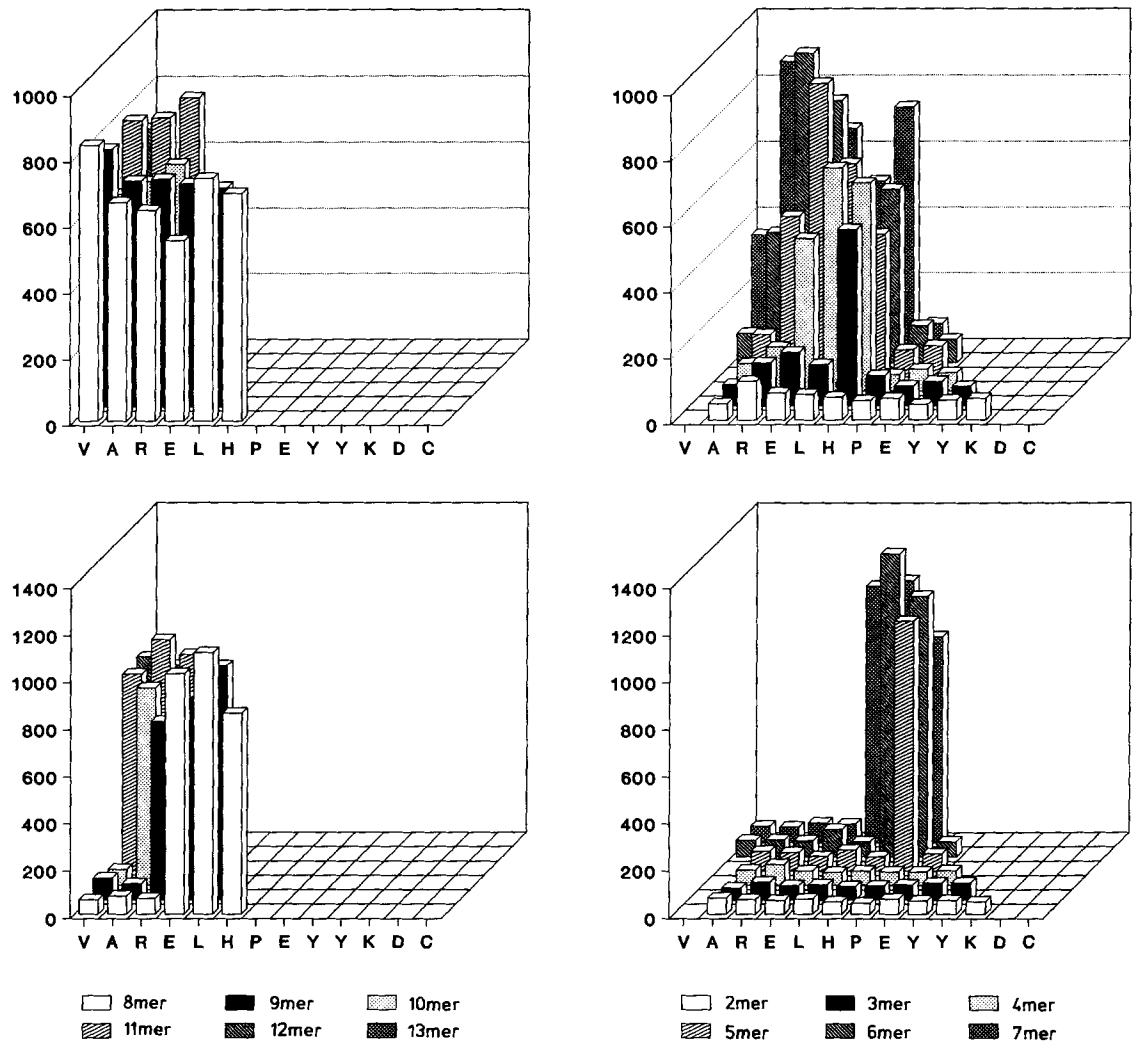

Fig. 6. Epitope fine-mapping, exemplified by two monoclonal antibodies against HIV 1 Nef-protein (Spohn, Universität Tübingen, private communication). The 2- to 13-peptides employed have been prepared by pin synthesis (cf. Fig. 5), and tested by Pepscan-ELISA. Sequences of the tested protein region are plotted on the x-axis (*C*-terminal consensus-sequence of the Nef-protein from various HIV 1-isolates relative to HIV-BRU 193–206). Each bar represents a peptide, whereby an assignment in the direction of the *N*-terminal amino acid takes place. The y-axis shows the absorption in ELISA in mOD at 405 nm, which is a criterion for the binding of antibody. Top: For the production of antibody (Dü6) a mouse was immunized with a lipopeptide immunogen (cf. [27b]) Pam_3Cys-VARELHPEYYKDC without further adjuvant or carrier. The monoclonal antibody obtained recognizes the Nef-protein, the smallest sequence is the tripeptide H-P-E. Bottom: The monoclonal antibody (Dü 106) was obtained by immunization with the Nef-protein. The shortest sequence is the pentapeptide P-E-Y-Y-K.

thetic method, on rods, is suitable for preparing peptides for immunological investigations. It is especially effective for the identification of epitopes which are recognized by monoclonal antibodies and polyclonal sera. Because of the different initial loading and lack of purity controls, however, no quantification should be attempted.[70] Since maximally 300 nmol of peptide can be synthesized per rod, peptide synthesis on rods is not suitable for the structure-activity investigations of hormone analogues.

3.2.2. Spot Synthesis

An inexpensive procedure for the preparation of polymer-bound peptides, used for the screening of sera, has recently been introduced by Frank et al.[71] The first amino acid was coupled to a sheet of cellulose paper (55 × 105 cm). For this purpose, 1 μL aliquots of the coupling reagent (0.3 M solution of Fmoc-amino acid HOBt-ester) were pipetted onto the paper at 49 points with a point separation of 1 cm. The entire sheet was then immersed into appropriate solutions for washing, acetylation, and deprotection. After the last step, an ethanol washing, the paper was dried. Coupling of the next amino acid was then carried out by distribution of the aliquots on the corresponding spots. This could be accomplished manually or by using a pipetting robot. The peptides were not removed from the paper under the cleavage conditions of the side-chain deprotection (20% trifluoroacetic acid, 1% triisobutylsilane); therefore, the sheets can be directly employed for immunological tests. The peptide-bound paper sheet can be subsequently treated and tested in a manner similar to the membranes of the western blot. Frank et al.[54] exemplified this by performing epitope analysis of the immunogen region of cytomegalovirus (hCMV), using 49 peptides, made simultaneously on paper sheets. If free peptides are to be prepared, a cleavage point is introduced

before the first amino acid,[68c] the spots are cut out and the peptides are cleaved separately.

3.3. Fully Automatic Synthesizers are Successful

The tediousness of the tea-bag and pin syntheses has so far prevented employment of these multiple methods in many laboratories. Since during multiple peptide synthesis (Tables 1 and 2), as in solid-phase synthesis,[32-36] deprotection, washing and coupling steps are repeated in every cycle, SMPS should also be automatable. In the meantime, two methods have been realized independently of each other. In both cases a commercially available pipetting robot has been modified and programmed for the requirements of peptide synthesis (Fig. 7).

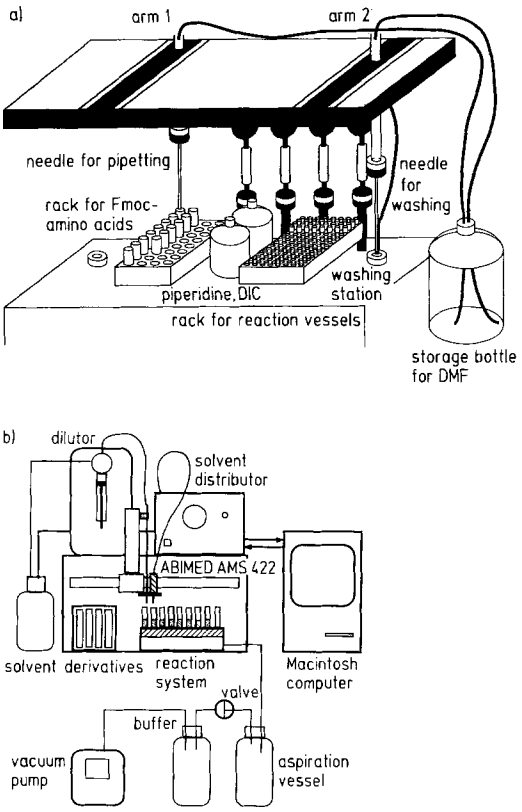

Fig. 7. Schematic representation of the fully automatic multiple peptide synthesizers based on PC-controlled pipetting robots: a) After Schnorrenberg [72]: The robot, with two arms moving in the x, y and z directions, pipettes reagents and derivatives according to the desired sequence. DMF serves as solvent. Suction is effected by two needles ('washing needles') which are equipped with a platinum sieve. b) After Gausepol [75]: Addition of reagents is likewise achieved by means of a pipetting needle. The synthesis takes place in a sintered-glass vessel; suction is achieved by connecting to a vaccum. (Thanks are due to Dr. H. Gausepohl from Abimed, for supplying this Figure).

Schnorrenberg et al.[72] employed a modified Tecan RSP 5052 (Zinsser SMPS 532), a robotic sample processor with two freely moving (in the *x*, *y* and *z* directions) needles attached to two arms. Needle 1 is used for addition of reagents, activated amino acids, and solvents. Needle 2 is equipped with a stainless steel sieve and is used for the removal (by suction) of solvents. Depending on the programming, any kind of glass vessels or Eppendorf tubes can be employed as reaction vessels. Furthermore, as in the tea-bag method, cross-linked polystyrene–divinylbenzene (1%) is used as the polymeric support, and amino acids are predissolved in dimethylformamide/1-hydroxybenzotriazole and activated by addition of *N,N'*-diisopropylcarbodiimide. The synthetic cycle and sequence-dependent amino acid distribution are controlled by a personal computer (Fig. 7a).

Many successful applications, such as investigation of the structure-activity relationships of endothelin[73a] and T-cell epitopes of influenza nucleoproteins,[73b,c] as well as the possible application of various activation methods for amino acids,[74] verify the suitability of this robot for multiple peptide synthesis. By using a device for simultaneous suction in the new synthesizer, version SMPS 532, the solvent consumption is lowered and the time for the synthesis of 48 decapeptides is reduced from three days to just one.

Alternatively, the multiple synthesizer developed by Gausepohl et al.[75] (Abimed AMS 422) is based on the Gilson M222 laboratory robot. The one-arm apparatus, controlled by a personal computer, is equipped with six extra needles for the distribution of reagents. These enable parallel distribution of the reagents and solvents into the $6 \times 8 = 48$ reaction vessels. The bottom of each reaction vessel consists of a sintered-glass filter, so that suction of solvents can be simultaneously carried out by means of a vacuum pump and control valves (Fig. 7b). Therefore, the duration of cycles can be substantially reduced. The use of up to 50 mg of polymeric support per reaction vessel and distribution of the Fmoc-amino acids and activation reagent for the synthesis of peptide-polypropylene pins has been described.[75b] Activation was formerly achieved using benzotriazol-1-yl-oxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP)/*N*-methylmorpholine; recently the less toxic benzotriazol-1-yl-oxy-tripyrrolidinophosphonium hexafluorophosphate (PyBOP) has been used.

So far, automated multiple peptide synthesis with the help of robotic sample processors is only possible using Fmoc strategy. Open vessels prohibit the use of trifluoroacetic acid which is required in every cycle of the Boc strategy. The parallel, fully automatic synthesis of eight peptides in the range of 5–400 μmol has recently been published by Nokihara et al.[77] The reaction vessels, reservoirs and amino acid derivatives have been supplied on eight tracks. Each track was used for the synthesis of a peptide and contained the complete set of reagents for a synthesis. An arm, on which eight needles are mounted, moves in the *x*-axis for the pipetting of solvents and reagents. The software can be varied with respect to different activation methods and the scale of peptides to be synthesized. This apparatus, however, allows the parallel synthesis of only eight peptides; an expansion is not possible.

Holm and Meldal[78] reduced the time required for the manual parallel synthesis by using a semi-automatic synthesizer. Addition of solutions and solvents into 96 vessels was simultaneously carried out via 96 connections; removal of the solvents was achieved by reduced pressure. Macrosorb-SPR (7 μm) was employed as the polymeric support, Fmoc-amino acid-Dhbt (Dhbt = 3-hydroxy-4-oxo-3,5-dihydro-1,2,3-benzotriazine) esters were used as the activated derivatives, and the colored material thus produced was spectroscopically monitored. This method was used for the

synthesis of 20 tetrapeptides; 100 mg of resin was used in each vessel.[78b]

Wolfe (1978) introduced a semi-automatic synthesizer R^{a}MPS (Dupont) for the parallel synthesis of 25 peptides, each on 50 mg of polystyrene.[79] Addition of the reagents was performed manually by pipetting; suction of the solvents was simultaneously carried out in all vessels by a vacuum pump. This was the first synthesizer with which the idea of multiple peptide synthesis was realized; however, it could not compete with newly developed ones with regard to the capacity, automation, and number of peptides to be synthesized. Nonetheless, it is a moderately priced machine and probably suitable for laboratories which maximally require 25 peptides at a time.

Krchňak et al. introduced a variant for multiple synthesis using the continuous flow procedure at low pressure.[80] Here, up to ten reactors were employed, each of which contained 40–500 mg of polystyrene-divinylbenzene (1%). The solvents used for washing were simutaneously introduced into the corresponding coupling vessels by means of valves and the whole system was operated under nitrogen pressure. Each of the amino acid/1-hydroxybenzotriazole active esters prepared in situ was manually added to the corresponding reactor. The use of Fmoc and Boc strategies for peptide synthesis by this method is described.[81]

3.4. Cellulose as Support in Multiple Syntheses

Functionalized paper is also used as a polymeric support in multiple peptide synthesis. Eichler et al.[82] employed paper strips (Whatman 540) loaded with 1–2 μmol/cm^2 of N^{α}-protected amino acids. Both Boc/Bzl and Fmoc/*t*Bu strategies can be employed in this way. The peptides synthesized can either be detached from the paper, or, after removal of the side-chain protection, they can remain attached to the paper and be employed for the antibody formation test by means of ELISA on paper (dot blot). Coupling cycles, applications and advantages are comparable to those of the tea-bag synthesis (cf. Section 3.1). Further advantages include the simple operation—cutting instead of sealing and filling (as in the tea bags)—as well as lower costs through both the use of cheaper materials and low consumption of washing solvents. However, up to now there is a lack of experience of working with cellulose as a support for peptide synthesis. Moreover, low mechanical stability of the support imposes certain limitations.

Frank et al.[83, 84] described simultaneous multiple peptide synthesis on labeled cellulose paper disks as solid supports (cf. Section 3.2.2.). A peptide is synthesized on each disk using a manually operated multicolumn continuous flow synthesizer. For each coupling the paper disks (diameter 1.55 cm, Whatman 3MM) must be sorted and tightly stacked in columns (1.5 × 10 cm glass tubes). As many as 100 disks can be reacted simultaneously with the same amino acid derivative in one reactor column, but several columns can be used in parallel. Therefore this method is expecially suitable for systematic sequence alteration. A computer program furnishes the correct compilation for a minimal number of cycles. The peptides can either be employed for immunological tests while on the cellulose support, or, after detachment, as free peptides, e.g., for structure-activity relationship studies.[85] Allylic anchor groups[86] have been used for the parallel preparation of protected fragments of parathyroid hormone.[87] A yield of only 8–10 mg of crude peptide somewhat limits the application of the paper disks; owing to the specificity of the column of the apparatus, the size of the disks cannot be varied indefinitely. As already described for other automatic methods, there is a limited flexibility with respect to the synthetic strategy and coupling reagents; savings in time and chemicals are, however, great.

Cotton, the purest form of cellulose, is mechanically much more stable than paper. Lebl et al. have previously used this support for both solid-phase synthesis and in continuous flow peptide synthesis (CPPS).[88] Cotton pieces (3 cm in diameter) have been used for the multiple synthesis of overlapping fragments of CRF (corticotropin releasing factor), whereby decapeptides with yields of 4–6 mg have been obtained.[89] The washing step in this method is interesting; removal of solvents is achieved by centrifugation, similarly to the procedure used in laundry machines. This efficient method of centrifugation for peptide-resins has already been employed by Birr[36] in his automatic centrifugal reactor for peptide synthesis.

3.5. Polystyrene–Polyethylene Film, a New Procedure?

With the use of polystyrene-grafted polyethylene film (PS-PE) as a support, a further variation of multiple peptide synthesis has been accomplished.[90] In this procedure, styrene is polymerized on a polyethylene film using γ-irradiation. Like the tea bags, small pieces of film (1.5 × 3 cm) can be washed and deblocked together, while couplings are carried out simultaneously in separate vessels. Because of the covalent bonding of polystyrene to polyethylene, there are no losses of resin support, and it is also not necessary to prepare polypropylene bags by sealing.

Peptide yields per gram of PS-PE film compare with those of the tea-bag synthesis; therefore, in principle, all the uses described in Section 3.1 are also applicable in this case. Structure-activity investigations of both melittin analogues[91] and parathyroid hormone (PTH)[92] have already been carried out using peptides prepared by this procedure.

4. Multiple Cleavage

With the existing numerous concepts for multiple peptide synthesis, the question of the multiple cleavage of peptides from polymeric supports has to be examined. No problems of this kind are encountered in the case of pin synthesis (Pepscan), since the peptides remain bound to the rods during most applications, and only the side-chain protecting groups are removed. In syntheses using the Fmoc strategy, deprotection is achieved with trifluoroacetic acid. The only commercially available 'multiple cleavage apparatus' has been developed for the tea-bag method and the Boc strategy. 24 peptide–resins can be simultaneously treated with hydro-

gen fluoride.[93] The important problem of multiple cleavage is not discussed in all the other published methods.

A substantial advantage of the Fmoc strategy over the Boc strategy lies in the use of trifluoroacetic acid instead of hydrogen fluoride. Consequently, during cleavage of peptides conventional glass and plastic apparatus can be employed. In our optimized multiple procedure, we pour a slurry of the peptide–resin in deprotecting solvent (trifluoroacetic acid containing scavenger) into Pasteur pipettes which are stopped with glass wool at the outlet; the peptide solution is then separated from the resin by simple filtration under pressure, just by pressing the suction balls of the pipettes. Finally, the peptide is precipitated, as usual, with ether. Owing to the large number of peptides, the centrifuges and lyophilizers employed should have large capacities.

5. Multiple Analysis—a Challenge

Ever since Merrifield developed the synthesis of peptides on polymeric supports, one question which has always arisen, is, 'how pure' are the synthetic products. The 'Merrifield synthesis' could achieve its ultimate goal only with the advent of HPLC and the purification possibilities it offers (cf. also Ref. [28a]). Besides requiring the highest possible separation performance in the chromatographic methods, multiple peptide analysis also calls for the treatment of a large number of samples in a short time.

Reversed-phase HPLC with automatic HPLC-sample distributor and on-line UV spectrometer[49, 94] is an absolute prerequisite. Similarly, fully automatic peptide hydrolysis with on-line amino acid analysis[40, 43, 95] is also required. Commercially available capillary zone electrophoresis (CZE) with an autosampler[96, 97] offers a new possibility for the fast, high-resolution analytical investigation of a large number of synthetic peptides.[98]

One of the best methods for on-line peptide analysis is the combination of LC (or CZE) and mass spectrometry; a combination which is rapidly becoming a routine procedure.[40, 42, 99] High sensitivity, mild ionization and detection of high molecular masses are achieved by electro- and ion-spray ionization. Hence, these methods are suitable for the analysis of peptide solutions (Fig. 8).[98, 100, 101] A microbore-HPLC unit is preferable as the HPLC component because of its low flow rate, since otherwise a solvent at a flow rate of more than 200 μL/min can no longer be removed by existing vacuum systems. A normal HPLC and a T-splitter can also be used; a combination whereby UV and mass spectra of all the peaks are simultaneously recorded. By using an automatic sample distributor without on-line HPLC, up to 60 peptide solutions can be consecutively analyzed by ion-spray mass spectrometry per hour.

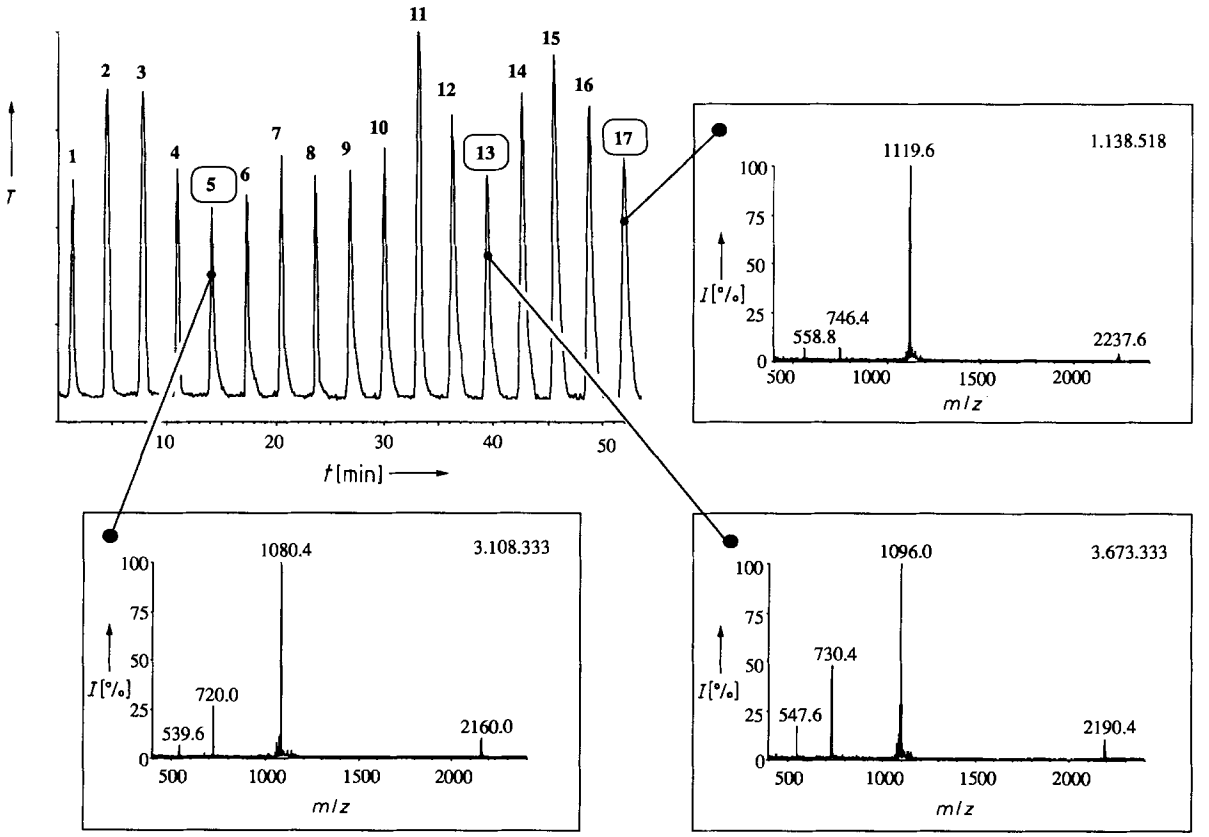

Fig. 8. Analysis of 17 peptide samples by ion-spray mass spectrometry within 55 min [100]. Injection of the dissolved peptides (50 pmol) is performed with an autosampler every 1–3 min. The total ion stream is captured in the spectrometer, and the individual peaks can be analyzed at the end of the run. This ionization method, which is especially suitable for peptides and proteins, produces multiply charged molecular ions. The following masses have been found: Peptide 5: 2159 at $(M + H)^{\oplus}$ 2160, $(M + 2H)^{2\oplus}$ 1080.4, $(M + 3H)^{3\oplus}$ 720.0, $(M + 4H)^{4\oplus}$ 539.6. Peptide 13: 2189.4 at $(M + H)^{\oplus}$ 2190.4, $(M + 2H)^{2\oplus}$ 1096.0, $(M + 3H)^{3\oplus}$ 730.4, $(M + 4H)^{4\oplus}$ 547.6. Peptide 17: 2236.6 at $(M + H)^{\oplus}$ 2237.6, $(M + 2H)^{2\oplus}$ 1119.6, $(M + 3H)^{3\oplus}$ 746.4, $(M + 4H)^{4\oplus}$ 558.8.

6. Peptide Libraries—or: How One Synthesizes Thousands of Peptides

Peptide libraries can consist of thousands of individual peptides which are synthesized as a mixture of peptides or as separate individual peptides. The review in Table 3 summarizes the studies published on this important subject so far. The pharmaceutical industry hopes to elucidate a large number of the novel lead structures by means of these peptide libraries.

parent peptide. Such a procedure can offer great advantages for the development of synthetic vaccines.

Multiple substitutions with conservation of the so-called anchor positions have also been used for the identification of octa- and nonapeptide motifs of the MHC-I molecule-bound peptides which are recognized by cytotoxic T-lymphocytes.[27a, 44]

The method of Houghten et al. for the construction of a peptide library[105] is based on the same principle and employed for the identification of a definite, biologically active

Table 3. Review of the methods for contructing peptide libraries containing more than 1000 peptides.

Methods	Light-controlled synthesis	Expression in phages	Separation methods	Library of free peptides	Mixotopes
Polymer	Aminated glass slides	pIII-protein of fusion-phages	Polymeric beads	PS-DVB	PS-DVB
Procedure	Photolabile N_α protecting group (Nvoc), removal by a process of photolithography, HOBt/DIC coupling	Randomly modified phages [$(NNK)_6$-insertion in pIII-protein] expression of hexapeptides	SPS with Fmoc or Boc strategy, any activation, separation of beads before the coupling, deprotection and washing steps are carried out together	Tea bag SPS, Fmoc or Boc strategy, any activation, coupling of amino acid mixtures at definite positions	SPS, Fmoc or Boc strategy, any activation, coupling of amino acid mixtures at definite positions
Screening	Fluorescence labeled antibodies are detected by fluorescence microscopy	Selection and subcloning of phages, recognition by antibody	Labeled antibodies catalyze a color-reaction and stain the polymeric beads after binding	Combination of biotest and the next synthetic cycle	Not necessary
Identification	Synthesis on localized spots, spatially addressable	DNA sequencing of the genome of phages	Protein sequencing from positively identified peptide-beads	Defined peptide sequences in the last bioassay	Defined synthetic mixtures
Application	Screening of antibodies or soluble receptors	Screening of antibodies or soluble receptors	Screening of antibodies or soluble receptors	Screening of antibodies or soluble receptors	Vaccination, or immunization

SPS = solid-phase peptide synthesis.

The first publications on parallel, non-separated peptide synthesis appeared in 1990.[102] Inspired by the 'mixed' synthesis of oligonucleotides,[103] mixtures of different amino acids—instead of a single amino acid derivative—have been activated and coupled at definite positions. The resulting analogues have been separated by preparative HPLC, analyzed and characterized; the parallel synthesis of six analogues has been described.[102] It seems that this method is very promising if small amounts ($<0.1-1$ mg) of analogues of a peptide are required. HPLC isolation of the components effects their purification at the same time. Problems are encountered with analogues having very similar structure and containing by-products which cannot be separated simply by RP-HPLC. This phenomenon is mostly unpredictable, especially when several positions are simultaneously substituted, and in the case of larger peptides when their chromatographic behavior is influenced by the formation of secondary structure. Moreover, a structurally dependent, non-uniform coupling of different amino acids leads to dissimilar product distribution.

Gras-Masse et al.[104] have synthesized 7.5×10^5 analogues of the HIV-gp120 sequence. Each peptide consists of 22 amino acids, the substituted positions reflect the variable amino acids of different HIV isolates, and the conserved positions are maintained. These so-called 'mixotopes'[104] are therefore not accidental sequences, but analogues of the sequence. For an oligopeptide having a certain length, the 'anchor amino acids', 'defined positions' and 'mix positions' are distinguished. 'Anchor amino acids' characterize the already known, essential positions of a sequence and are found in all peptides. The number of defined positions determines the number of peptide mixtures which were prepared by Houghten using the tea-bag synthesis.[49-51] For a defined position, 20 so-called 'sublibraries' are needed, each containing one of the 20 amino acids at this position. Consequently two defined positions lead to 400 and three to 8000 peptide mixtures. If amino acids other than the proteinogenic ones are also used, the number of resulting peptides increases rapidly. The remaining positions (mix positions) are coupled as a mixture of all derivatives. Therefore, in the case of 20 amino acids and n mix positions, each sublibrary contains a mixture of 20^n peptides.

Neither an analysis nor a separation is necessary for the identification of a biologically active peptide, only the biological test determines which sublibrary (i.e., which tea bag) contains the active peptide. The thus determined defined position becomes an extra new 'anchor amino acid' in the next synthetic cycle or 'peptide book' of the oligopeptide library. Consequently, a multiple peptide synthesis is necessary for each unknown amino acid position (Table 4).

The sensitivity of the biological test system is a limiting factor for the number of mix positions, which, among other

Table 4. Dependency of the number and content of individual peptides in a peptide mixture (for preparing peptide libraries) on the number of variable positions.

Number of variable positions	Six	Five	Four	Three	Two	One	None [a]
For 20 amino acids:							
Number of peptides in the mixture	64000000	3200000	160000	8000	400	20	
Amount of one peptide in 1 mg product with a mass of 660 amu (hexapeptide)	16 pg 25 fmol	300 pg 0.5 pmol	6 ng 9.4 pmol	125 ng 190 pmol	2.5 μg 4 nmol	50 μg 75 nmol	1 mg 1.5 μmol
Molarity of one peptide, 1 mg mL^{-1}	2.5×10^{-11}	5×10^{-10}	9×10^{-9}	1.9×10^{-7}	4×10^{-6}	8×10^{-5}	1.5×10^{-3}
For 40 amino acids (including D-amino acids):							
Number of peptides in the mixture	4096000000	102400000	2560000	64000	1600	40	
Amount of one peptide in 1 mg product with a mass of 660 amu (hexapeptide)	0.25 pg 0.4 fmol	10 pg 15 fmol	390 pg 590 fmol	16 ng 23 pmol	625 ng 1 nmol	25 μg 40 nmol	
Molarity of one peptide, 1 mg mL^{-1}	4×10^{-13}	1.5×10^{-11}	5.9×10^{-10}	2.3×10^{-8}	10^{-6}	4×10^{-5}	

[a] Normal synthesis.

things, is determined by the binding constants. Having, e.g., 5 mix positions, 1 mg of a peptide mixture contains only 300 pg of each individual peptide. In the case of hexapeptide mixtures in solutions of 1 mg per mL, this corresponds to a concentration of 5×10^{-10} mol L^{-1} (Table 4); therefore, a test is only meaningful in the case of receptor systems with very high affinity.

Well-sorted peptide libraries offer the possibility for discovering active analogues, ligands for receptors or antibodies, and for testing cross-reactivities. Also non-polymer-bound peptide mixtures make it possible to carry out investigations on membrane-bound proteins. If, however, protein segments are to be investigated, it becomes an immensely time-consuming procedure. Problems of the presence of different percentages of various analogues, which are due to the non-uniform couplings, also arise in this case.

In order to avoid these problems, Furka et al.[106] and, later, Lam et al.[107] separated the polymeric supports for the coupling of each of the 20 amino acid derivatives. Uniform couplings can, therefore, be achieved, since the competition between slow and fast couplings no longer exists. Subsequently, the polymer was again mixed, washed and the *N*-terminal protecting group was jointly removed. For the next coupling, the distribution of the polymer in each vessel containing the 20 amino acids is purely statistical. Initially, Furka et al.[106] demonstrated this proportional-mixing method for the synthesis, cleavage, and chromatographic separation of nine tetrapeptides which have been identified by sequencing. This method is suitable for the manual synthesis of a very large number of resin-bound oligopeptides within a relatively short time.

Lam et al.[107] likewise established a library of oligopeptides which remained bound to the polymeric support and were only freed from the side-chain protecting groups. A separation step is not necessary; only the biological activity of the analogues is important. If the polymer is used in the form of beads, only a defined peptide and its failure sequence, determined by the conditions of synthesis, are found on every bead. If, e.g., the peptide of this single bead is recognized by an antibody, the polymer-peptide-antibody complex can be stained by a second antibody carrying a fluorophore or an enzyme, and can hence be distinguished from the polymeric beads containing non-bound peptides. Under a microscope, the positively identified peptide-polymers are separated from the beads having non-bound peptide and the peptide sequence is determined by the Edman degradation. The method is highly efficient and practicable; it can be carried out in every peptide laboratory using standard methods and without the need for elaborate apparatus.

With respect to the scale of synthesis, one should be aware of the following limitations in the use of proportional-mixing methods. The usual loading of 0.5 mmol/g signifies about 200 pmol of peptide per polymeric bead. The number of polymeric beads should be at least ten times higher than the number of peptides, since the loading of each bead fluctuates and, practically, more than one bead is required for the detection and analysis. Assuming that each time only ten beads (200 mesh) are loaded with a defined peptide, and by using only 20 proteinogenic amino acids in several positions, one obtains almost 10 g of peptide–resin for a pentapeptide library, 150 g for the hexapeptide, 3 kg for the heptapeptide, and over 50–100 kg for the octapeptide libraries. If at the same time D-amino acids are also to be used in several positions, then for the large libraries tons of resin will be required. This unreasonable situation can be circumvented by the construction of sublibraries with firm and defined positions, as well as by the use of very small polymeric beads. These possibilities are limited by the sensitivity and capacity of the biological tests and instrumental analysis.

In the molecular biology laboratories of Scott and Smith,[108] and Delvin et al.[109] a completely different kind of epitope library has been developed. Fusion-phages in *E. coli* are transformed through – $(KKN)_{15}$ or $(KKN)_6$ –, where K corresponds to a mixture of all four deoxynucleotides and N to a mixture of guanidine and thymidine. Every triplet KKN can code for all of the 20 amino acids, but only for one stop-codon. The production takes place in p-III protein which is coded by phages and which is expressed at a defined position on the surface of the phages. Identification of the active peptide sequence is again achieved at the DNA level. Phages which bind to the biotin-labeled antibody are isolated over streptavidin (affinity purification), multiplied, and their DNA is isolated and sequenced. Since the pattern of the restriction enzymes of phages and the production site are known, sequencing is less elaborate than expected. This method can represent a simpler procedure for the gene technology laboratories in need of epitope libraries. To what extent interactions with the surface of phages, as well as

changes in the secondary structure of ligands in proteins can impair the desired recognition, however, must be further investigated.

The parallel synthesis of thousands of oligopeptides at defined sites and on the micromolar scale is possible by the method of Fodor et al.[110] In this recently reported novel concept,[111] photolabile nitroveratryloxycarbonyl is used for the amino protection. Irradiation and hence deprotection of a surface area of only 100×100 μm is possible by means of stencils; following this the coupling of the next amino acid is carried out. Suitable choice and the combination of stencils enables the synthesis of 100×100 peptides per cm^2. Since regulation of the mask is carried out analogously to the process of photolithography, it is possible to accurately assign the positions. Detection is achieved in a biological test system, e.g., by fluorescence microscopy using antibodies carrying a fluorescence label. The precision of the method, as well as the efficiency and the application of photolithographic techniques in peptide synthesis, are impressive. However, incompleteness of the photolytic removal of protecting groups in the synthesis of large peptides could pose a problem. Establishment of the method as routine, however, is simply not possible, since it involves large investments in both equipment and personnel. It can however be assumed that this microtechnique will bring advances in the area of biosensor research.

The methods for the construction of peptide libraries introduced in this section open up a new dimension in peptide synthesis. The selection ensues from the biological test systems. For this purpose, the peptides used are often bound to polymers, either *C*-terminally to the polymeric support, or to a protein from phages. This imposes two restrictions: firstly, blocking of the *C*-terminus must not be restrictive, secondly, the biological test system must be active in the soluble or solubilized form. Both prerequisites are often fulfilled for antigen–antibody interactions. All these methods have proven successful, especially in the screening and identification of binding sites of monoclonal antibodies.

Tests on membrane receptors or intact cells, however, require mixtures of free peptides, and these should contain the individual peptides, preferably in detectable amounts. So far, only Houghten's method[105] offers this possibility, but for this method a substantially greater elaboration is required.

7. Natural Peptide Libraries and the Future of Multiple Synthesis Methods

Peptide libraries have not been invented by the human. Nature impressively demonstrates the interaction of individual peptides from natural oligopeptide libraries with highly specifically differentiated proteins from the body's own and foreign sources. By isolation and so-called 'pool-sequencing' it was recently shown to be possible to determine the individual, specific sequence motifs of naturally processed self-peptides for a few defined MHC class I alleles.[27a] Thousands of these self-peptides appear continuously as degradation products of the body's own cellular proteins on the cell surface, bound to a cleft of the major histocompatibility complex (MHC) molecules. Membrane-bound proteins of MHC class I molecules present short peptides to the killer-cell receptors (cytotoxic T-lymphocytes, CTL). The MHC class II proteins present somewhat longer peptides to the T-helper cell receptors, by which the B-cells become prone to stimulation for differentiation and subsequent antibody production. The binding relationships in the cleft of MHC class I molecules are well established.[112] The sequence motifs of the highly complex, natural peptide mixtures show certain anchor amino acids (cf. Fig. 9) in constant positions of the octa- or nonapeptides. The amino acid side chains of the anchors fit into the allele-specific pockets of the MHC cleft, whilst among the other positions a large variability of the amino acids often occurs.[27a]

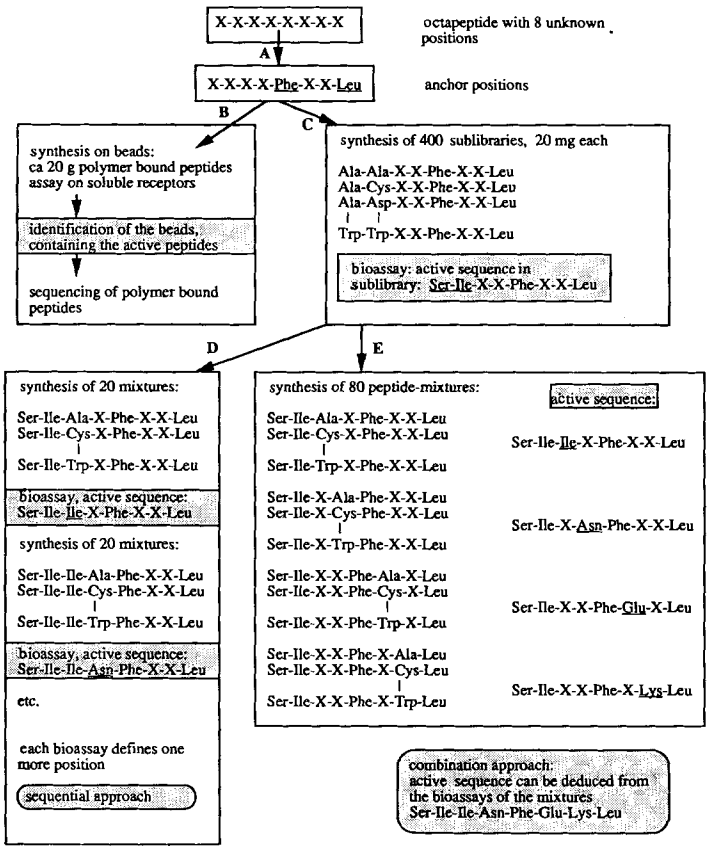

Fig. 9. Possible identification of active sequences exemplified by K^b-restricted CTL-epitope ovalbumin 258–267. Binding to MHC class I receptor of the killer cells serves as the bioassay. Positions 5 (Phe) and 8 (Leu) are known (from the literature) as the anchor positions for binding to the cleft of the MHC class I molecule (**A**) [27a]. Construction of a corresponding peptide library can be performed either by the proportionation method (**B**) or by means of free peptides in sublibraries (**C**). For this purpose 400 sublibraries have to be separated, each with two defined sequences and four variable positions (X). Identification of the variable positions can be achieved either sequentially (**D**) or by combination (**E**). In both cases, 80 further peptide mixtures will be necessary.

A selection could therefore be achieved with the help of two consecutive recognition processes from our body's extensive peptide libraries. First, the binding in the MHC cleft is specific for definite motifs in the peptide sequences, and second, by the cell–cell contact through the ternary interactions of MHC, peptide and T-cell receptor it will be decided whether the origin of presented peptide fragment is from the body itself or a foreign source. The cell which, e.g., carries a

foreign viral peptide is then lysed by the killer cells in the immune system, or it initiates a T-helper cell-mediated antibody reaction against a shell protein of the virus.

The peptide chemist assumes a decisive role in the interdisciplinary research projects discussed in the introductory sections. He has special experience and recognizes the possibilities for new variants of multiple synthesis methods and new analytical procedures. Therefore, he decides in most of the cases which kind of structural variations are to be carried out. The valuable 'tools' which the peptide chemists have so far put at the disposal of pharmacology, immunochemistry, molecular biology, physiology and biophysics have been tailored and have contributed to rapid development in these fields. The successful use of multiple synthesis methods will add new areas to these research fields, whose experimental feasibility seemed utopic until recently.

In this review, the largest fields for the application of products obtained by multiple peptide synthesis could only be briefly referred to; the following must also be mentioned. The development of vaccines can be performed on the molecular level, by investigation of the above-mentioned naturally processed and presented peptides from viral, bacterial and the body's own proteins.[27b,c] The results of bioassays of natural isolates and synthetic peptide mixtures can be compared. By systematic variation and substitution of amino acids the folding tendency of the larger peptides can be studied experimentally, rapidly and more exactly. Furthermore, rapid development of enzyme inhibitors may be achieved, and the screening of new enzymes and enzyme specificities can be carried out by the incorporation of backbone modifications and unusual amino acids.

Multiple synthesis methods will undoubtedly offer surprising new possibilities in many areas including biosensors, and above all, automation for the screening of lead structures in pharmaceutical research.

Thanks are due to the Bundesministerium für Forschung und Technologie, the Deutsche Forschungsgemeinschaft (SFB 323) and the Fonds der Chemischen Industrie for financial support of the project oriented research in multiple peptide synthesis. The multiple methods of peptide synthesis and analysis could not have been achieved in our laboratory without the engagement, substantial ideas and experimental contributions of K.-H. Wiesmüller, F. Gombert, R. Spohn, W. Tröger, H. Dürr, H. Drechsel, E. Hoffmann, J. Metzger, S. Stefanovic and W. Beck. A. G. Beck-Sickinger thanks the Deutsche Forschungsgemeinschaft for a research stipend.

Natural Products as Probes of Cellular Function: Studies of Immunophilins

By Michael K. Rosen and Stuart L. Schreiber*

One of the great mysteries of cell biology remains the mechanism of information transfer, or signaling, through the cytoplasm of the cell. Natural products that inhibit this process offer a unique window into fundamental aspects of cytoplasmic signal transduction, the means by which extracellular molecules influence intracellular events. Thus, natural products chemistry, including organic synthesis, conformational analysis, and methods of structure elucidation, is a powerful tool in the study of cell function. This article traces our understanding of a group of natural products from the finding that they inhibit cytoplasmic signaling to their current recognition as mediators of the interaction between widely distributed protein targets. The emphasis of the discussion is primarily structural. The interactions between the natural-product ligands and their protein receptors are analyzed at a molecular level in order to shed light on the molecular mechanisms of the biological functions of these compounds. In the process we hope to illustrate the power of chemical analysis as applied to biological systems. Through chemistry we can understand the molecular basis of biological phenomena.

1. Introduction

Signal transduction refers to the process by which extracellular molecules influence intracellular events. For example, the actions of the hormone insulin are initiated at the cell surface, when extracellular insulin binds to the membrane-bound insulin receptor. This binding triggers a series of membrane-associated events, followed by a cascade of poorly defined intracellular events that result in the transcription of genes that encode metabolic enzymes. Thus, a signal that originates outside the cell is transmitted through the cell membrane, along intermediate carriers in the cytoplasm, and into the nucleus, causing a change in the status of the cell. In recent years, much has been learned about the mechanisms of signal transduction at the membrane and in the nucleus of the cell. In contrast, very little is known about the mechanisms of signal transduction through the cytoplasm of the cell. Despite the importance of such processes, the detailed mechanisms of cytoplasmic signaling remain among the great mysteries of cell biology, a fact that has led the cytoplasm to be referred to as the "black box" of signal transduction.

Natural products chemistry has long played an important role in the elucidation of biological mechanisms. Pioneering synthetic and mechanistic studies of molecules such as steroids, prostaglandins, and porphyrins, to name only a few, have led to fundamental insights regarding the biological functions of these important classes of compounds. Certain natural products are also uniquely suited for the study of the mysterious processes of the cell, including cytoplasmic signaling, due to their interference with these processes. By studying inhibitory natural products bound to their biological receptors, we may gain a detailed understanding of the function of these receptors. Research in this area relies on a combination of the powerful, complementary tools of synthetic chemistry, molecular biology, cell biology, and methods of structure elucidation, including both NMR spectroscopy and X-ray crystallography. This review highlights recent advances in the structural and mechanistic understanding of cytoplasmic signaling that have arisen through application of these techniques to the study of the immunophilins, a family of cytosolic proteins that bind natural products. These advances have culminated in the identification and characterization of pentameric complexes composed of two normally noninteracting protein constituents and a natural product "glue" that binds the proteins together in a biologically significant manner. In the process, it has been discovered that a protein phosphatase is a key cytoplasmic component of a family of signal transduction pathways.

2. Background

FK506[1, 2] and cyclosporin A[3] (CsA) are fungal natural products (Fig. 1) that inhibit Ca^{2+}-dependent[**] signaling pathways in a variety of cell types.[4, 5] In T cells, both agents inhibit the transcription of a number of genes, including that encoding interleukin-2 (IL-2), which are normally activated by stimulation of (by binding of certain extracellular molecules to) the T cell receptor (TCR).[6] In mast cells they inhibit the exocytosis (i.e. movement to the cell surface and fusion with the cell membrane) of secretory vesicles that normally results from stimulation of the IgE receptor.[7] A variety of biochemical and biological data indicate that in both cases inhibition occurs within the cytoplasm and not at the cell surface or in the nucleus.

On a biochemical level FK506 and CsA are also quite similar. Through synthesis of radiolabeled and immobilized derivatives of these agents for use in protein purification, it was discovered that both bind with high affinity to soluble, cytoplasmic receptor proteins[8] (immunophilins;[8, 9] this term is used to denote immunosuppressant binding proteins, as both FK506 and CsA are immunosuppressive drugs[2, 10]). The FK506 receptor has been named FKBP,[11] and the CsA receptor has been named cyclophilin[12] (CyP). Both proteins catalyze the isomerization of *cis* and *trans* amide-bond rotamers of peptide and protein substrates.[11, 12]

[*] Prof. Dr. S. L. Schreiber, M. K. Rosen

Cambridge, MA 02138 (USA)

[**] The terms Ca^{2+}-dependent and -independent in this context refer to signaling pathways that are characterized by the presence or absence, respectively, of an immediate rise in the concentration of intracellular cytoplasmic Ca^{2+} following binding to the cell surface receptor.

The enzymatic activity of FKBP is potently inhibited by binding of FK506 (K_i = 0.4 nM), but not CsA,[11] and the activity of CyP is inhibited by CsA (K_i = 6 nM),[12] but not FK506.

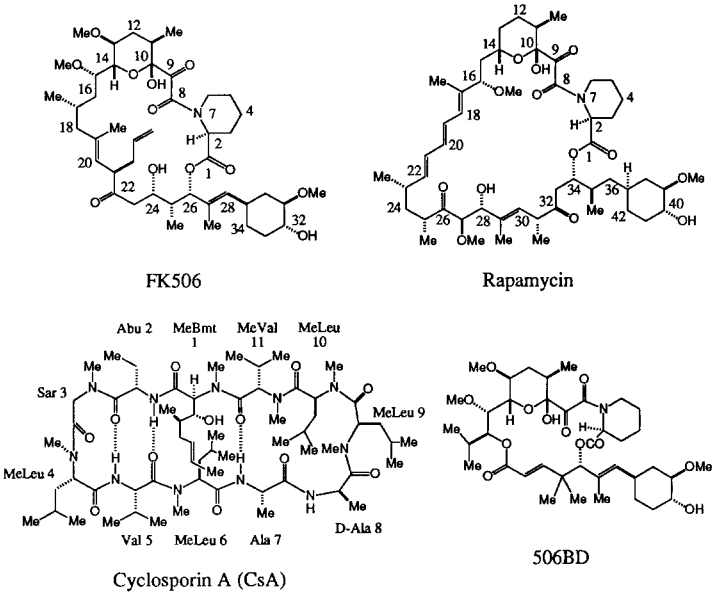

Fig. 1. Chemical formulas of the immunophilin ligands.

Although FK506 is approximately 100 times more effective than CsA in cellular assays, in virtually all other respects the two molecules behave identically in both T cells and mast cells. This similarity in biological function, coupled with the discovery that the molecules inhibit two distinct rotamase enzymes,[*] led to speculation that the biological effects of these agents were due to their rotamase inhibition. It was hypothesized that a necessary step in activation of unknown proteins required for IL-2 transcription in T cells was rotamase-catalyzed isomerization of a peptidyl–prolyl amide bond. Inhibition of this catalysis by FK506 or CsA would then result in inhibition of IL-2 transcription.[13]

Strong evidence against this "rotamase hypothesis" came from biochemical and biological studies of two structurally related molecules: rapamycin,[14, 15] an immunosuppressive fungal natural product and FKBP ligand, and 506BD,[16] a synthetic FKBP ligand (Fig. 1). Given the structural similarities between the three ligands, it is not surprising that, like FK506, rapamycin and 506BD also bind tightly to FKBP and inhibit the rotamase activity of the enzyme (K_i(rapamycin) = 0.2 nM; K_i(506BD) = 5 nM).[15, 16] In fact, NMR and crystallographic studies have demonstrated that FK506 and rapamycin interact with a common domain of FKBP through their common structural elements.[17] Fascinatingly, although FK506 and rapamycin both bind to FKBP and inhibit its rotamase activity, rapamycin does not inhibit the same TCR-mediated signaling pathway that is affected by FK506 and CsA. Rather, it blocks a later Ca^{2+}-independent pathway associated with T cell activation, which is mediated by the IL-2 receptor (IL-2R)[15, 18, 19] (Fig. 2). Even more striking is the fact that 506BD has no inhibitory effect on either of the signaling pathways inhibited by FK506 or rapamycin. Furthermore, it was shown that FK506, rapamycin, and 506BD can all block the actions of the others,

[*] The expression rotamase has the same meaning as PPIase (for peptidyl prolyl *cis–trans* isomerase) an acronym used by others for the description of proteins that catalyze the isomerization of *cis* and *trans* amide-bond rotamers of peptides and proteins.

Stuart L. Schreiber was born in 1956 and was raised in Virginia (USA). He studied as an undergraduate in Charlottsville, Virginia, where he obtained a B.A. in chemistry in 1977 at the University of Virginia. Following Ph.D studies under the direction of R. B. Woodward and Yoshito Kishi at Harvard University, he began his independent career in 1981 in the Department of Chemistry at Yale University. In 1988, he accepted a Professorship at the Department of Chemistry at Harvard. His group is engaged in the study of biological processes through the combined application of synthetic organic chemistry and molecular and structural biology.

Michael Rosen was born in 1965 in Philadelphia, Pennsylvania (USA). He received B.S. degrees in chemistry and chemical engineering from the University of Michigan in 1987. As a Winston Churchill Scholar during 1987–1988 he earned a C.P.G.S. in the Natural Sciences from the University of Cambridge (England) under the direction of Professor Alan R. Battersby. Since that time he has been a graduate student in the research group of Professor Stuart L. Schreiber at Harvard University. His primary interests lie in the structural analysis of proteins and protein–ligand complexes by NMR.

presumably through competitive binding to a common receptor, FKBP. In contrast, the actions of FK506 and rapamycin are unaffected by CsA, which does not bind FKBP; the actions of CsA are also unaffected by FK506, rapamycin, and 506BD, which do not bind CyP.[15, 16, 19, 20] If the biological properties of FK506 and rapamycin were simply due to inhibition of the rotamase activity of FKBP, then they should both interfere with the same pathways. 506BD should also inhibit these same pathways and thus be biologically active. Because this is not the case, it implies that FK506 and rapamycin do *not* act by *eliminating* a function of FKBP; rather they act by *adding* a function to the protein. In a sense, FK506 and rapamycin are prodrugs that are activated by binding to FKBP. CsA is similarly inactive until it binds CyP. This explanation of the immunophilin–ligand complexes as the species responsible for signal inhibition has been termed the "active complex" hypothesis.[8, 9, 15, 16, 21] Genetic studies have also provided strong support for this idea by demonstrating that FKBP is both necessary and sufficient to mediate the actions of rapamycin in yeast,[22, 23] and that CyP mediates the actions of CsA in this organism.[21, 24] Paradoxically, although FK506 and rapamycin are structurally similar and bind to a common protein, FKBP, their FKBP complexes have different biological actions. Furthermore, while CsA is structurally dissimilar to FK506 and binds to CyP, which is unrelated to FKBP, the biological actions of the CyP–CsA complex are indistinguishable from those of the FKBP–FK506 complex. It is interesting to speculate that upon binding to CyP a yet-to-be discovered CyP ligand may provide a complex that has properties indistinguishable from those of the FKBP–rapamycin complex.

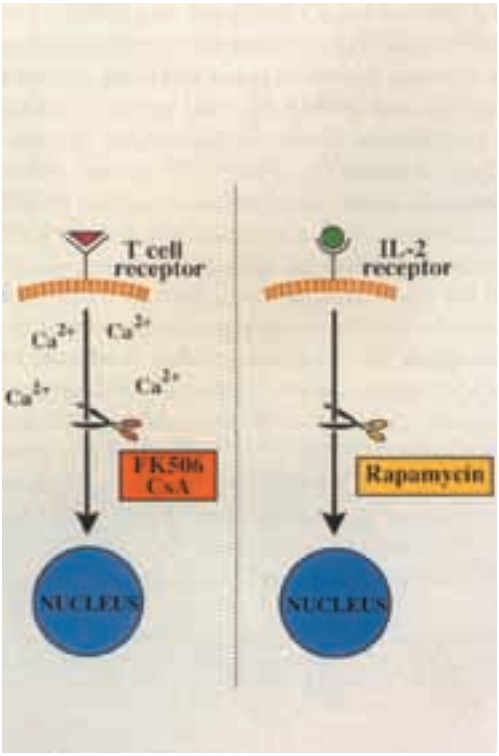

Fig. 2. FK506 and CsA inhibit Ca^{2+}-dependent signaling pathways, while rapamycin inhibits Ca^{2+}-independent pathways. These are illustrated in the T cell by the pathways emanating from the T cell receptor and the IL-2 receptor, respectively, but include signaling pathways in a variety of cell types, including mast cells and neurons.

One obvious, if seemingly unlikely prediction from the above biological data is that the structurally unrelated FKBP–FK506 and CyP–CsA complexes should act, either directly or indirectly (through other proteins), upon a common target molecule that is distinct from the target acted upon by the FKBP–rapamycin complex. The FKBP–FK506 and CyP–CsA target should be a component of Ca^{2+}-dependent signaling pathways such as TCR-mediated transcription in T cells and IgE receptor-mediated exocytosis in mast cells; the FKBP–rapamycin target molecule should be a component of Ca^{2+}-independent signaling pathways such as IL-2R-mediated proliferation in T cells. In both cases, the target should be unaffected by either protein or ligand alone, since only the immunophilin–ligand complexes are active inhibitors (Fig. 3 top).

In fact, we have recently demonstrated that calcineurin (CN), also referred to as protein phosphatase 2B, a calmodulin-dependent serine/threonine protein phosphatase,[25] possesses all the predicted biochemical properties of a target common to both FKBP–FK506 and CyP–CsA.[26] CN is a heterodimeric protein composed of two subunits, calcineurin A (CNA), which contains the calmodulin-binding and phos-

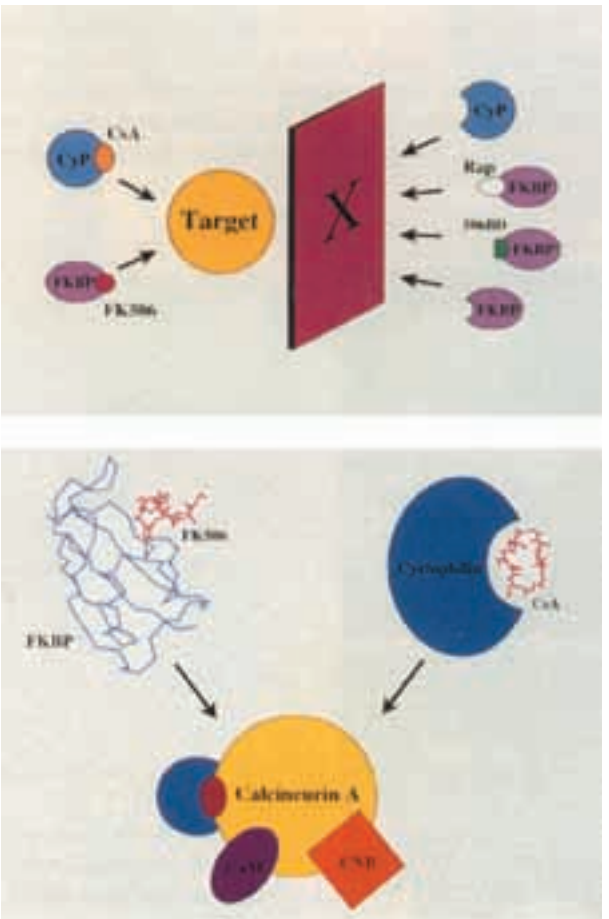

Fig. 3. Top: The CyP–CsA and FKBP–FK506 complexes act on a common target molecule that is not affected by FKBP or CyP alone, or by the FKBP–rapamycin or FKBP–506BD complexes. Bottom: Formation of the pentameric immunophilin-drug-CNA-CNB-calmodulin complex (see text).

phatase active sites, and calcineurin B (CNB), which is a Ca^{2+}-binding protein with, as yet, unknown function. The binding of calmodulin to CNA results in a tenfold increase in the phosphatase activity of the enzyme. In direct binding assays, CN binds to both the FKBP–FK506 and CyP–CsA complexes, but not to FKBP or CyP alone, or to the FKBP–rapamycin complex. In addition, the binding of CN to FKBP–FK506 is inhibited by CyP–CsA (but not by CyP or CsA alone), suggesting that the two complexes compete for the same, or two interacting binding sites. The phosphatase activity of calcineurin, when measured with a phosphopeptide substrate, is potently inhibited by the FKBP–FK506 and CyP–CsA complexes, but is unaffected by FKBP, CyP, FK506, rapamycin, 506BD, or the FKBP–rapamycin complex. Interestingly, it was recently reported that the translocation of a cytosolic component of the transcription factor NF-AT, which regulates IL-2 transcription and is sensitive to FK506, into the cell nucleus due to a rise in intracellular calcium levels is blocked by both FK506 and CsA.[27] The common dependence on intracellular calcium, location in the cytosol, and sensitivity to FK506 and CsA have led us and others to speculate that this component of NF-AT may be a substrate for CN, and that its location in the cell may be dependent on its phosphorylation state.[9, 28, 29] Thus, the inhibition of IL-2 transcription by FK506 and CsA may be the result of their indirect inhibition of the dephosphorylation of a component of NF-AT.

An important question arises from this body of data: How does the binding of FK506 and rapamycin to FKBP and of CsA to CyP change both the ligands and the receptors, enabling the complexes to perform functions the individual components are incapable of performing alone? The remainder of this review will focus on the aspects of ligand–receptor interactions most relevant to this question. In particular, we will discuss the structures of both the natural products and the proteins, and the changes that occur to each upon binding. The pentameric immunophilin-drug-CNA-CNB-calmodulin complexes (Fig. 3 bottom) will then be analyzed in light of the known biochemical data on the interactions between the immunophilin–ligand complexes and calcineurin.

3. Structural Studies of FKBP and its Complexes with FK506 and Rapamycin

3.1. Initial Work

Early structural studies of the FKBP–FK506 and CyP–CsA complexes centered on analysis of the interactions between ligand and receptor. These studies were motivated, in part, by two conflicting proposed mechanisms of rotamase catalysis, and hence of rotamase inhibition by the ligands[30] (Fig. 4). One mechanism involved initial formation of a tetrahedral enzyme–substrate adduct similar to that formed during the hydrolysis of the amide bond by serine or cysteine proteases. Rotation about the C–N bond in the adduct, followed by expulsion of the enzyme nucleophile would result in amide-bond isomerization. This mechanism was supported by studies of Fischer et al.,[12b] who showed that in CyP modification of a cysteine in the active site with *p*-hydroxymercuribenzoic acid eliminated the rotamase activity of the enzyme. Fischer et al.[31] also found an inverse secondary deuterium-isotope effect with substrates containing [α,α-^{2}H]Gly-Pro, indicating a change in hybridization ($sp^2 \rightarrow sp^3$) and thus formation of a covalent bond in the transition state of the reaction. These kinetic data were, however, disputed by Harrison and Stein,[32] who found a normal secondary deuterium-isotope effect using the same substrates. Site-directed mutagenesis studies further demonstrated that none of the cysteine residues in CyP are required for catalysis.[33] These results, coupled with measurement of thermodynamic activation parameters for CyP[32] and FKBP,[34, 35] led to an alternative mechanism of rotamase activity involving binding of a transition-state structure that contains a twisted, or distorted amide bond. In this view, the energy needed to overcome amide bond resonance and isomerize the C–N bond would come from favorable noncovalent interactions between the enzyme and a peptide substrate.

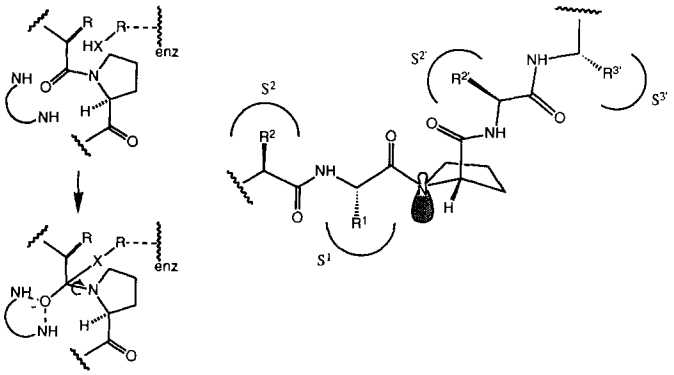

Fig. 4. Two proposed mechanisms of rotamase catalysis. Left: Initial formation of a tetrahedral intermediate. Right: Catalysis by stabilization of a twisted amide bond. enz = enzyme.

The mechanism involving a tetrahedral intermediate led to the consideration that FK506 and rapamycin might bind to FKBP through nucleophilic attack of a side chain of the enzyme on one of the two electrophilic carbonyl carbon atoms of the ligand, C8 or C9. ^{13}C NMR studies of the complex of fully synthetic [8,9-^{13}C]FK506[36] and recombinant human FKBP,[37] however, showed no evidence for formation of a tetrahedral adduct.[30] These studies also demonstrated that FK506 binds to FKBP in a single conformation, although the unbound ligand exists in organic solution as a 2:1 mixture of *cis* and *trans* amide-bond rotamers.

The finding that FK506 and, by inference, rapamycin do not bind covalently to FKBP suggested a possible explanation for the strong interaction between the ligands and their receptor. In the solid state, both FK506 and rapamycin possess a dihedral angle of approximately 90° about the C8–C9 bond. This conformation is also maintained in the complexes of both ligands with FKBP. A dihedral angle of 90° between C8 and C9 and a planar N7–C8 amide group place the keto carbonyl roughly perpendicular to the plane of the pipecolinyl ring (pipecoline = methylpiperidine). Because the pipecolinyl ring most probably mimics the proline ring in natural peptide substrates, the keto carbonyl of FK506 or rapamycin is in the same position as would be a twisted amide carbonyl group of a peptide undergoing rotamase catalysis (Fig. 5). Thus, the perpendicular keto carbonyl groups of FK506 and rapamycin allow the ligands to mimic

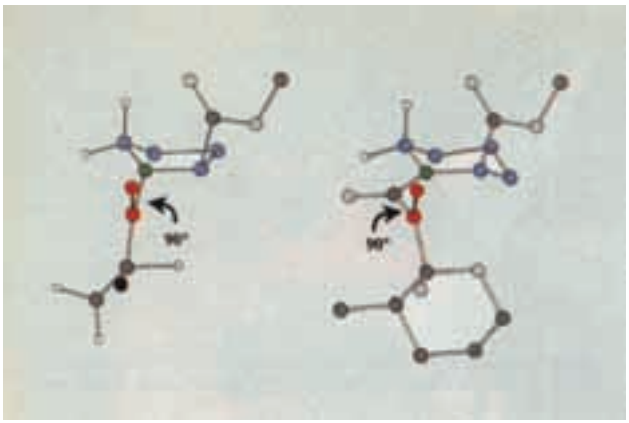

Fig. 5. FK506 and rapamycin may mimic a twisted peptido–prolyl amide bond in a peptide substrate. Left: Model of a twisted amide bond in a peptide substrate. Right: Portion of the crystal structure of free FK506. The analogous carbonyl groups in the two structures are colored red.

a transition-state structure involving a twisted amide bond.[30]

The view of FK506 and rapamycin as twisted amide peptidomimetics was further extended by studies of the substrate specificity of FKBP.[34] In the peptide series succinyl-Ala-Xaa-Pro-Phe-(*p*-nitro)anilide, it was found that peptides with branched hydrophobic amino acids Leu, Ile, and Val as Xaa were greatly favored (up to 1000-fold over peptides with Xaa amino acids with charged side chains as determined by measurement of $K_{cat}K_m^{-1}$ values) with Leu > Ile > Val. Analysis of the structures of FK506 and rapamycin suggested a possible rationale for these observations. Beginning with the pipecolinic acid moiety and proceeding in the "*N*-terminal" direction, both ligands possess a dicarbonyl group, a tertiary hydroxyl group, and a branched aliphatic chain. As illustrated in Figure 6, these can be mapped onto the amide carbonyl group, amide nitrogen atom, and the side chain of a branched aliphatic amino acid residue *N*-terminal to a proline. Thus, the binding of FK506 and rapamycin to FKBP was proposed to result from the ability of the ligands to mimic a Leu-Pro dipeptide with a twisted amide bond.[38]

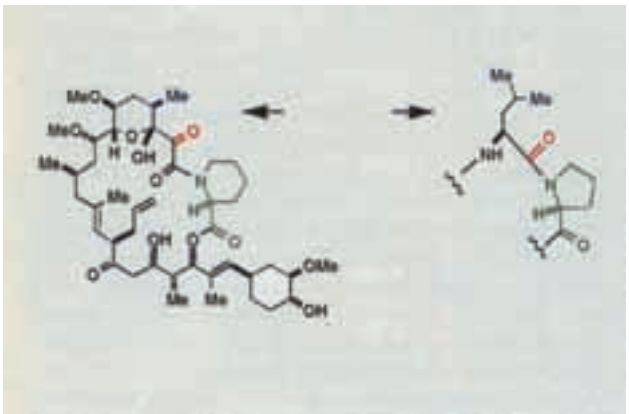

Fig. 6. FK506 (left) and rapamycin may mimic a leucine–proline substrate with a twisted amide bond (right). Analogous atoms are colored alike. Leu is the preferred P1 residue.

3.2. Three-Dimensional Structures

In order to further explain the enzymatic, ligand-binding and biological properties of the immunophilins, we undertook the structure determination of free human FKBP by NMR.[39–41] Our success in this effort was due significantly to the cooperative nature of FKBP, which proved to be soluble and stable, and gave beautiful NMR spectra. Structural studies of the human FKBP–ligand complexes were also undertaken in a fruitful collaboration with Professor Jon Clardy's group at Cornell University. This work resulted in high-resolution crystal structures of both the FKBP–FK506 and FKBP–rapamycin complexes.[42–44] Analyses of the three FKBP structures, showing both the bound and free forms of the protein, have yielded new insights into many aspects of immunophilin function.

3.2.1. Overview of the Structures

All three FKBP structures show the same fold of the protein (Fig. 7 left). The structure is characterized by a five-stranded antiparallel β sheet with a novel +3, +1, −3, +1 loop topology. The strands of the sheet, which run roughly

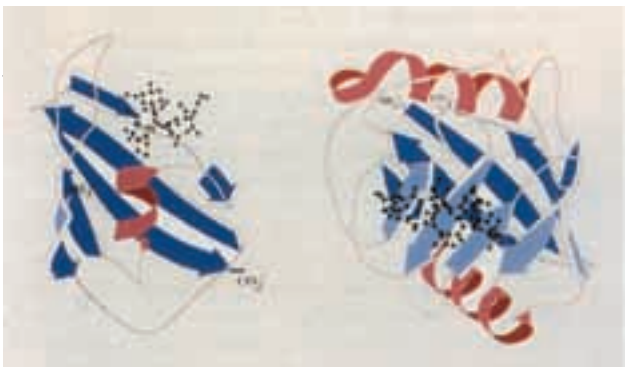

Fig. 7. Richardson diagrams of FKBP (left) and CyP (right). A ball-and-stick model of FK506 is positioned in the ligand-binding site of FKBP[42,44]. A similar model of CsA[69,70] is used to indicate *schematically* the location of the ligand-binding site in CyP[67,68]. We prepared an approximate model of the CyP–CsA complex by docking the structure of bound CsA[69] into the structure of free CyP[68] using reported intermolecular NOEs observed between MeLeu 9 of CsA and Trp 121 of CyP[73]. We thank Professor Ke for providing the CyP coordinates.

perpendicular to the long axis of the molecule, are composed of residues 2–8, 21–30, 35–38 with 46–49 (this strand is interrupted by a loop at residues 39–45), 71–76, and 97–106. A short amphipathic α helix containing residues 57–63 is aligned with the long axis of the protein and lies against the sheet, forming a tightly packed hydrophobic core. The core is composed entirely of aliphatic and aromatic residues, with all but one of the aromatic residues clustered at one end of the molecule. The conserved aromatic and aliphatic side chains of Tyr 26, Phe 36, Phe 46, Val 55, Ile 56, Trp 59, Tyr 82, and Phe 99 line a shallow cleft at the *N*-terminus of the α helix, forming the FK506 and rapamycin binding site. The side chains of these residues are well defined in both the

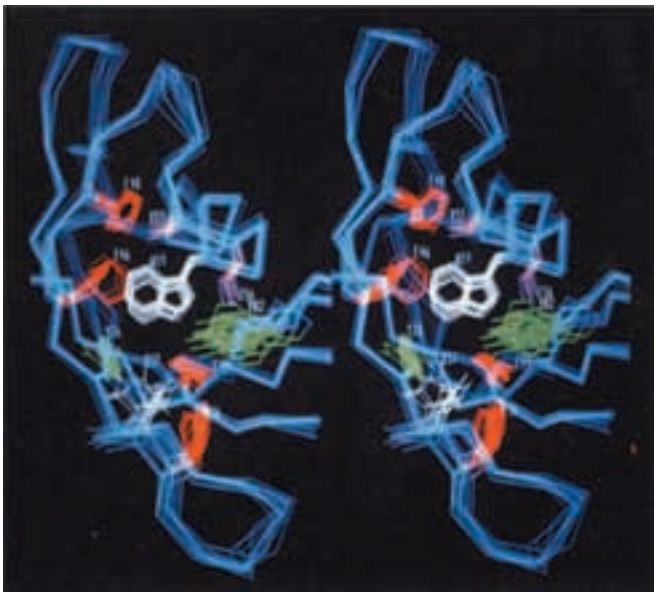

Fig. 8. Stereoview of selected residues in the ligand-binding pocket of FKBP. An overlay of 15 structures of the free protein generated by NOE-restrained molecular dynamics simulation is shown. The orientation is approximately perpendicular to that in Figure 7. (Note the α helix at the upper right and the β strands lining the lower left.) Residues are identified by the one-letter amino acid code. Side chains are colored as follows: Phe = red; Tyr = green; Arg, Asp, Trp = white; Ile, Val = purple. The loops Ser38–Pro45 and Gly83–His94 have been removed for clarity.

ligated and unligated forms of FKBP (Figs. 8 and 9). Both ligands fit tightly into the binding pocket and have a number of similar hydrophobic and hydrogen-bonding interactions with the protein. The FKBP-binding domain of FK506 extends from the C24 hydroxyl group, through the diketo pipecolinyl moiety and the pyranose ring, to the C15 methoxy group. This finding was anticipated on the basis of structural analyses of FK506 and rapamycin and on the biological properties of the two molecules, and led to the design of the FKBP ligand 506BD (see Fig. 1).[16] Most of the trisubstituted cyclohexyl ring (C26–C34) of FK506 and

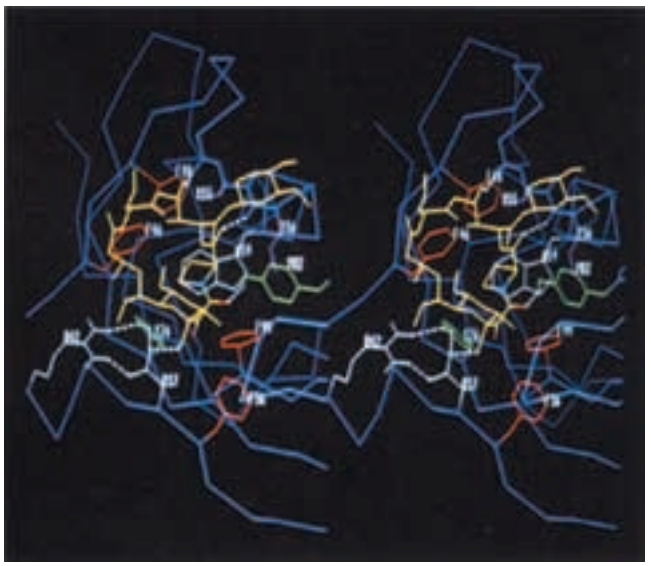

Fig. 9. Stereoview of selected residues in the binding pocket of the FKBP–FK506 complex. Orientation and colors of the side chains are the same as in Figure 8. Bound FK506 is yellow. Hydrogen bonds (see text) are white.

carbon atoms C18–C23 of its macrocycle, including the allyl group, do not contact FKBP and are exposed to solvent. Similarly, the binding domain of rapamycin consists of the region from the C28 hydroxyl group through the pyranose ring; carbon atoms C15–C27 are exposed to solvent. For rapamycin the orientation of the cyclohexyl ring (C34–C42) is different from that in FK506, and makes several contacts to FKBP. The pipecolinyl ring is the most deeply imbedded portion of both ligands (Fig. 9). This moiety is in van der Waals contact with the indole ring of Trp59 at the back of the binding pocket, and with the side chains of Tyr26, Phe46, Val55, Ile56, and Phe99 at the sides of the pocket. In the NMR spectra of the FKBP–FK506 complex the extremely high-field chemical shifts ($\delta = -2$ to 0) of the pipecolinyl methylene hydrogens, and several NOE cross-peaks in the aromatic region also reflect the proximity of this group to aromatic residues of the protein.[17] A number of additional hydrophobic contacts are made between the ligands and the protein. These include interactions between the pyranose ring and residues Tyr26, Asp37, Tyr82, His87, and Ile90, and between the region C24–C26 of FK506, and C28–C32 of rapamycin, and residues Phe46 and Glu54 of FKBP. Thus, the nanomolar binding constants of FK506 and rapamycin may be due, in part, to the complementary hydrophobic surface of FKBP.

The favorable van der Waals interactions between FKBP and both FK506 and rapamycin are complemented by similar arrays of intermolecular hydrogen bonds. Both ligands have identical hydrogen bonds from the C1 ester carbonyl group to Ile56 NH, the C8 amide carbonyl group to the Tyr82 phenolic OH group, and the C10 hemiketal OH group to the Asp37 carboxylate. Despite the differences between the C24–C26 region of FK506 and the C28–C33 region of rapamycin, both also make analogous hydrogen bonds to Glu54 CO, FK506 from the C24 hydroxyl group, and rapamycin from the C28 hydroxyl group. Rapamycin makes one additional hydrogen bond not seen in the FK506 complex, from the C40 hydroxyl group to Glu53 side chain CO group. The pattern of hydrogen bonds involving Ile56 NH, Glu54 CO, and Gln53 CO is reminiscent of the antiparallel β-sheet-like contacts often seen between proteins and peptide ligands. These hydrogen bonds then extend the portions of FK506 and rapamycin that may be described as peptidomimetic to include the region between the C1 ester carbonyl group and the C24 (C28 for rapamycin) hydroxyl group. The structural analogy between the ligands and a tetrapeptide is illustrated in Figure 10. The pipecolinyl ester carbonyl group acts as the proline amide carbonyl group in a Leu-Pro peptide fragment. The region from O1 to C25 (C29 for rapamycin), including the cyclohexyl ring, is roughly equivalent to an aromatic amino acid residue. The C24 hydroxyl group (C28-OH for rapamycin) then represents the amide NH group of the following residue in the chain. Thus, FK506 and rapamycin may bind to FKBP by acting as transition-state analogues of a Leu(or Val)-Pro-Xaa-Yaa peptide substrate. We are currently investigating this hypothesis through synthesis of peptides and peptide analogues designed based on the FKBP–FK506 and FKBP–rapamycin complex structures.[45] Biochemical analyses of these molecules, coupled with structural analysis of their complexes with FKBP (through X-ray crystallography and/or NMR

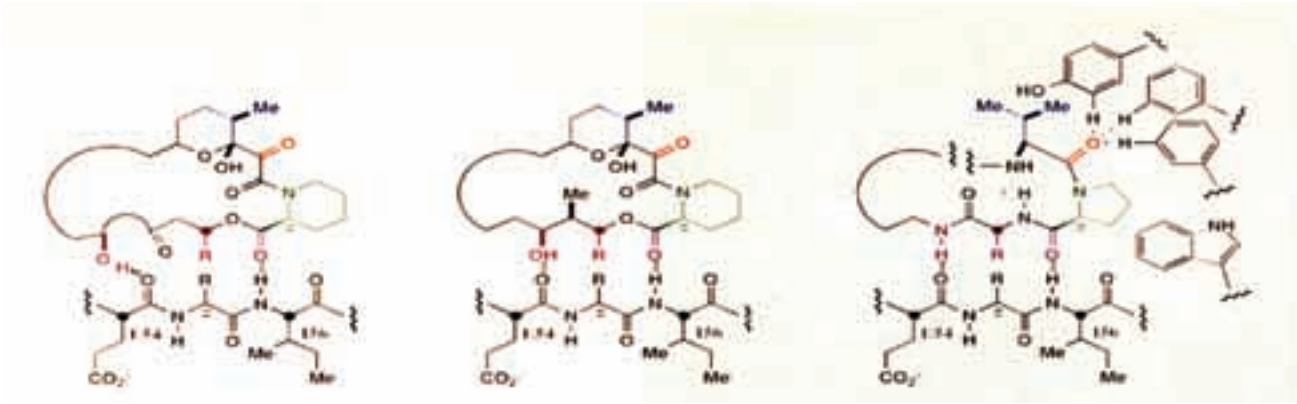

Fig. 10. Schematic illustration of the bonding between FKBP and the ligands rapamycin (left) and FK506 (middle) and a peptide (right). Analogous atoms have the same color.

spectroscopy) will probe the energetic contributions of the various receptor–ligand interactions.

The hypothesis that FK506 and rapamycin are transition-state analogues of an FKBP substrate predicts that in addition to the interactions discussed above there should be significant contacts between the protein and the keto carbonyl groups of the ligands. These same contacts would then stabilize a twisted amide bond in the transition state for rotamase catalysis. Initially we had expected, based on the many known structures of protein–ligand complexes, that the keto carbonyl group (at C9) would be bound by a network of hydrogen bonds or typical electrostatic interactions with charged residues. However, the structures of the two receptor–ligand complexes clearly show that the keto carbonyl group does not make any hydrogen bonds to the protein, nor does it contact any charged residues of the protein. Instead, it is in close proximity to the $C^{\varepsilon}H$ atoms at the edges of three aromatic rings, Tyr26, Phe36, and Phe99 (Fig. 9). Such C–H···O interactions have been observed in small organic molecules[46] and proteins,[47] and it has been proposed that these contribute to the stability of such systems. Theoretical calculations, too, support the notion that C–H···O interactions can stabilize small molecules as well as proteins.[48] However, to our knowledge the FKBP complexes would be the first examples in which this type of interaction contributes significantly to the binding of a ligand to its receptor. It would also represent a novel mechanism of catalysis, wherein transition-state stabilization is achieved through arene–carbonyl interaction.

3.2.2. *Structural Consequences of Binding*

Since neither FKBP nor FK506 or rapamycin are able to bind to or inhibit the phosphatase activity of CN, it is important to analyze the differences between the free and bound forms of both protein and ligands in order to understand the biological actions of the two complexes. How does binding activate FKBP and its ligands, allowing FKBP–FK506 to recognize CN, and FKBP–rapamycin to recognize a different target protein? The existance of both free and bound structures of all components of these complexes now allows this question to be addressed.

3.2.2.1. Comparison of free and bound FKBP

Comparison of the structure of unbound FKBP with those of either of the FKBP–ligand complexes reveals that the majority of residues in the protein binding pocket are not greatly perturbed by ligand binding. In particular, the aromatic and aliphatic residues making direct contact to ligand (Tyr 26, Phe 46, Val 55, Ile 56, Trp 59, and Phe 99) show only small conformational differences between the bound and free structures (compare Figs. 8 and 9). In addition, regions of the protein that are not directly involved in binding (for example, the bulk of the α helix and the β sheet) are also not dramatically different in the bound and free structures. Subtle changes in these regions may prove to be significant, but as will be discussed later in Section 5, this seems unlikely. There are several loops in FKBP, however, that appear to undergo both structural and dynamic changes on ligand binding. Not surprisingly, these loops are located at the rim of the binding pocket. In the structure of free FKBP, the seven residue bulge, Ser 39 to Pro 45, that occurs in the middle of the fifth strand of the β sheet is only poorly characterized by the NMR data (Fig. 11). A lack of medium- and long-range NOEs in this loop, coupled with the relatively weak sequential and intraresidue NOEs further suggest that this region may be disordered, sampling a wide range of conformations. In the crystal structure of the FKBP–FK506 complex this loop is well defined by the electron density. This structure is stabilized by a large number of backbone/backbone and backbone/side-chain hydrogen bonds despite its rather unusual conformation. A similar set of hydrogen bonds is seen in the FKBP–rapamycin complex. However, the high thermal factors observed for residues 40 to 43 in this structure indicate greater mobility or disorder than in the

Fig. 11. α Carbon overlay of ten structures of free FKBP generated by NOE-restrained molecular dynamics simulation. The view is similar to that in Figures 8 and 9. The α helix is colored red (as in Fig. 7). The basic loop Ser39–Pro45 is blue. The loop Gly83–His94 is green.

FK506–FK506 complex. This difference probably reflects different numbers of intermolecular contacts in this region in the two crystal forms.[44] Many of the hydrogen bonds in the region appear to be facilitated by an Asp-Arg-Tyr triad[49] involving the side chains of Asp37, Arg42, and Tyr26 (Fig. 9). This interaction bends the backbone of the loop toward the body of the protein, enabling many hydrogen-bond donors and acceptors to come together. In free FKBP no evidence for these interactions with Arg42 has yet been observed in the NMR data. Further, preliminary NMR analyses of the FKBP–FK506 complex have shown that the chemical shifts of the amide hydrogens of several residues between Ser39 and Pro45 change substantially on binding. Thus, ligand-binding may increase the propensities of residues in this region to form hydrogen bonds, resulting in changes in conformation and/or mobility of the loop. Interestingly, the region from Lys34 to Lys44 is one of the most highly charged (seven of eleven residues are charged) and most basic (net charge +3) sequences of FKBP (see hFKBP12 sequence in Fig. 12). The proximity to the bound ligand, structural changes on ligand binding, and high charge density all suggest that this region may be important in contacting CN in the pentameric complex.

A second region of FKBP that appears to change significantly on ligand binding is the segment from Tyr82 to His94 (green in Fig. 11). This loop is poorly defined in free FKBP. Like the basic loop described above, this segment shows few

Fig. 12. Manual sequence alignments of known FKBPs. Only the homologous region of each protein is shown. Numbers at the ends of each row are the position of the nearest amino acid in the full protein. Gaps inserted in the sequences are represented by hyphens, *C*-termini are marked with stars, and uncertain assignments are in lowercase. Residues in boldface correspond to residues of hFKBP12 that contact FK506 in the X-ray structure of the complex[42,44]. Degrees of conservation are indicated by solid and open circles above the sequence as follows: •• completely conserved; •o strong preference for one amino acid (at least seven occurrences); • conservative substitutions; o mostly similar amino acids. Below the sequences, the secondary structure of hFKBP12 in the complex with FK506 is shown; α helix is marked with α, antiparallel β strand with β, and β turns with numbers corresponding to type beneath the second and third positions. The following sequences are included: human FKBP12[37], bovine FKBP12[57a], bovine FKBP12[57a], bovine FKBP25[57b], human FKBP13[56], NcFKBP (*Neurospora crassa*)[57c], ScFKBP (*Saccharomyces cerevisiae*)[57d], NmFKBP (*Neisseria meningitidis*)[57e], LpMIP (*Legionella pneumophila* macrophage infectivity potentiator)[57f], CtMIP (*Chlamydia trachomatis*)[57g], PaORF (open reading frame in the *Pseudomonas aeruginosa algR2* gene)[57h], and Mustrans2 (homologue of mouse transition protein 2)[57i].

long-range NOEs, and only weak sequential and intraresidue NOEs. In addition, TOCSY and NOESY NMR spectra provide evidence for two distinct conformations of this loop that interconvert slowly on the NMR time scale.[39] Although the exact nature of this interconversion has not yet been determined, chemical shift perturbations show that it affects several residues between Tyr 82 and His 87.[50] Thus, in the absence of ligand the loop Tyr 82 to His 94 appears to sample at least two, and possibly more, different conformations. In contrast, in both FKBP–ligand complexes this loop shows a single, well-defined conformation that is stabilized by several intraprotein hydrogen bonds and a number of van der Waals contacts to the ligand. In the free protein these contacts would be absent, allowing the loop greater flexibility. These changes suggest that this loop, like that from Ser 39 to Pro 45, may be involved in CN recognition. If this proves to be the case, then the CN binding site could span up to almost 20 Å, and contain regions of both high positive charge density (from the protein) and high hydrophobicity (from the effector domains of the ligands). Mutagenesis studies are currently underway to identify definitively the regions of FKBP that are important in the formation of the ternary complex with CN.

3.2.2.2. Comparison of Free and Bound FKBP Ligands

The differences between bound and free FK506 and rapamycin are also revealing. Free FK506 has been examined with a variety of techniques, including X-ray crystallography,[1] NMR spectroscopy,[51, 52] and theoretical calculations.[53] The structure of the molecule crystallized from organic solvent[1] is shown in Figure 13. In the crystal, FK506 exists in a single conformation with a *cis* amide bond. In contrast, in organic solution it exists as a 2:1 mixture of *cis*:*trans* amide-bond rotamers.[1, 51, 52] The structures of both rotamers were recently determined by NOE–restrained molecular dynamics calculations.[51, 52] Although similar to the crystal structure in some respects, both conformations are significantly different in others. In the FKBP binding domain, the *cis* structure in solution is quite similar to the solid-state structure. However, the two differ in the region surrounding C23, with large deviations in the torsion angles about C20-C21, C21-C22, C23-C24, C24-C25, C25-C26, and C26-C27. Most notably, the cyclohexyl residue extends away from the macrocycle in the solid state, while in solution it is wrapped under the macrocycle due to a C25-C26-C27-C28 dihedral angle of 91°. It is interesting that the *trans* conformer in solution differs from the crystal structure in the FKBP binding domain but is relatively similar in the remainder of the molecule. Other than changes to the torsion angles about C1-C2 and C9-C10, which compensate for the *trans* versus *cis* amide bond, the only other differences between the two structures are in the torsion angles from C16 to C19. An important common feature (see below) of all three unbound conformers is the orientation of the pyranose moiety outside of the macrocyclic ring. In this orientation, the pyranose ring does not make any intramolecular contacts.

Free FK506 has also been studied theoretically.[53] Calculations employing a Monte Carlo search of torsion angles in the macrocycle of the molecule have revealed the presence of

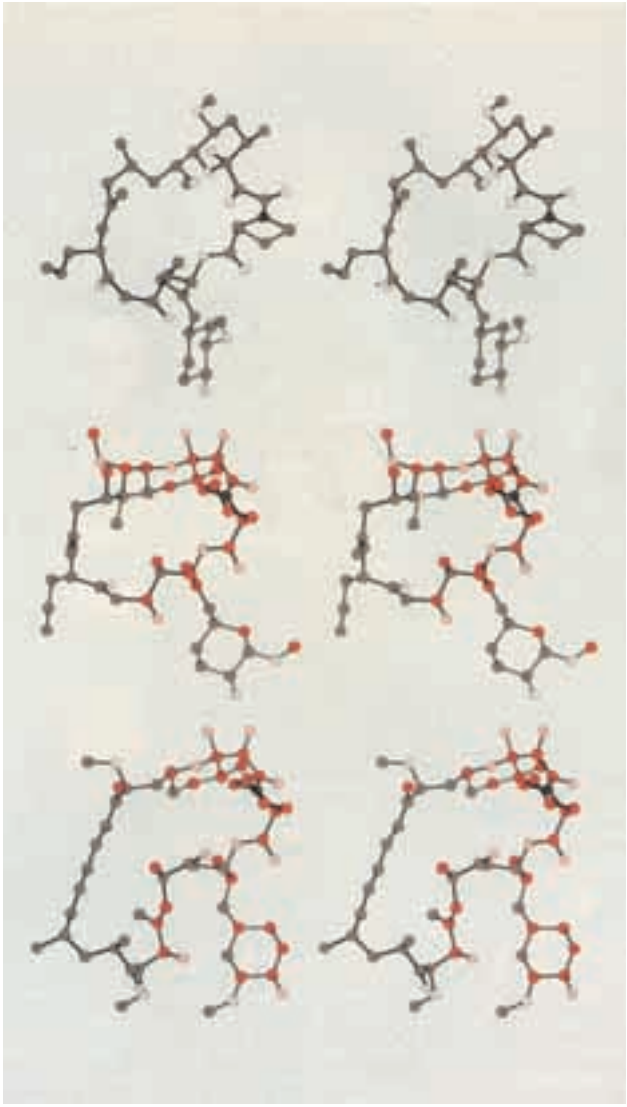

Fig. 13. Stereoviews of the structures of free FK506 (top), bound FK506 (middle), and bound rapamycin (bottom) in the solid state. In middle and bottom pictures, atoms in close contact (< 4 Å) with heavy atoms of FKBP12 are shaded red[42–44].

21 distinct low-energy conformations (within 12 kcal mol^{-1} of the lowest energy structure)[53] including both the *cis* and *trans* amide-bond isomers. Molecular dynamics simulations have also been used to study the structure and dynamics of FK506 in water[53] (the insolubility of the molecule in aqueous media has prevented direct structural analysis in this environment). Over the course of a simulation of 200 ps, beginning with the energy-minimized solid-state structure, FK506 adopted two stable conformations that differed primarily in the torsion angles about C17-C18 and C18-C19. Flexibility was also observed about the C1-C2 and C8-C9 torsions. In general, however, the structure did not deviate significantly from the solid-state conformation during the 200 ps.

The structure of bound FK506[42, 44, 54] (Fig. 13 middle) is dramatically different from the known structures of the free ligand[42, 44] (A necessary caveat at this point is that the structure of FK506 in aqueous solution has not yet been experimentally determined. Thus, the differences between the free and bound forms of the molecule described below do

not necessarily reflect effects of binding, and thus should only cautiously be interpreted as such). This is true of both the solution and solid-state conformations. The most notable change between the crystalline forms is that the amide bond of bound FK506 is *trans*, while in the crystal structure of the free molecule it is *cis*. This change is compensated for by large rotations about the C1–C2, C14–C15, C15–C16, and C16–C17 bonds. Significant changes are also seen in these same torsion angles when either of the free forms in solution is compared to the bound form. The differences in the torsion angles flanking the pyranose ring, C14-C15 and either the amide torsion angle (for the *cis* conformations) or C9-C10 (for the *trans* conformation), result in a rotation of this moiety under the macrocycle in the bound structure. This gives the binding domain a more compact shape and forms a hydrophobic core of the ligand. Overall, these changes result in only a 3 kcal mol^{-1} increase in energy due to unfavorable steric interactions on binding (comparing crystal structures in both the free and bound forms).[42] However, the approximately 150° rotation about the C14–C15, bond does result in steric interaction between the methyl substituents of the C13 and C15 methoxy groups. These groups are roughly *anti* to each other in all forms of the free ligand. But in the bound structure of FK506, the C15 methoxy group is rotated to the outer side of the macrocyclic ring and adopts a gauche + /gauche − orientation with respect to the C13 methoxy group. The energetic consequence of this interaction, which is not present in rapamycin, may be in part responsible for the ligand specificity observed in other FKBPs (see Section 6).

In contrast to FK506, the free and bound conformations of rapamycin are highly similar.[43, 44] The root-mean-square deviation (rmsd) between the bound and free structures is 0.48 Å. Like bound FK506, rapamycin has a *trans* amide bond in the solid state (in organic solution it exists as a 4:1 mixture of *trans*:*cis* amide-bond rotamers). It also has the pyranose ring folded under the macrocycle, and the cyclohexyl moiety extended outward from the body of the molecule. Interestingly, the conformation of the FKBP-binding domain of bound FK506 is virtually identical to that of rapamycin. The rmsd between the two bound ligands from C1 to C13 is 0.12 Å. Thus, the FKBP binding pocket interacts strongly with only one conformation of the two ligands. The fact that rapamycin's FKBP-affinity is twice that of FK506 may, in part, reflect its greater propensity to adopt this conformation.

Although the conformation of FK506 may be significantly altered by binding to FKBP, the same can probably not be said of rapamycin. This is true of both domains of the molecules. While ligation may serve to alter the conformation of FK506, better enabling it to contact CN in the pentameric complex, for rapamycin it appears that this may simply serve to surround the ligand with residues of the protein. Binding may also aid in the transfer of both molecules from the lipid membrane into the aqueous environment of the cytoplasm. It seems likely that since FK506 and rapamycin bind to the same site in FKBP, the selectivity of the two FKBP–ligand complexes arises from the different chemical compositions of the two ligands. These result in two different composite protein–ligand surfaces, enabling the complexes to bind two different targets.

3.3. 506BD

The synthetic FKBP ligand 506BD[16] has proven to be extremely useful in increasing our understanding of the structural basis for the biological actions of FK506 and rapamycin. This molecule contains the common FKBP-binding domain of FK506 and rapamycin, but lacks the effector domain of either ligand.[16] Instead, the geometry of the binding domain is maintained by a simple (both structurally and synthetically) *trans* enoate spacer. The ability of 506BD to bind FKBP and inhibit the biological actions of FK506 and rapamycin, coupled with the inability of the ligand to inhibit signal transmission pathways clearly defined the two-domain (binding and effector) nature of FK506 and rapamycin. In retrospect, however, the success of 506BD as an FKBP ligand was somewhat fortuitous, for the molecule was designed based on the crystal structure of unbound FK506. When 506DB was designed, the conformation of bound FK506 would not be known for almost two years. Because the free and bound structures of FK506 are very different, it is surprising that a linker designed to bridge two points in the free molecule would be able to bridge the same two points in the bound. This is in fact the case. The enoate spacer in 506BD was designed to connect from C16 to C25, a distance of 5.2 Å in unbound FK506.[1] A *trans* enoate was employed in order to accomodate both the *cis* and a possible *trans* amide-bond rotamer. The regions flanking the spacer were also designed to maintain the local conformational preferences seen in the C14–C26 region of FK506. Inspection of bound FK506 revealed that despite the many unanticipated changes detailed above, C16 and C25 are 4.2 Å apart in this conformation. Thus, the same *trans* enoate linker can join these points together without significantly perturbing the bound structure of the binding domain.[16]

3.4. Insights from Protein Sequence

FKBP is only one member of a growing family of FK506- and rapamycin-binding proteins. At least four other proteins that bind the two ligands have been observed and partially characterized in human T cells.[55, 56] In addition, a number of proteins with high homology to FKBP have been identified in various organisms, including other mammals, yeast, and bacteria.[57] Cyclophilins, too, have been identified in a variety of cell types and different organisms.[58] The known FKBPs range in molecular weight from 12 kDa for the archetypal protein (hereafter referred to as FKBP12) to 59 kDa for the phosphorylated FKBP59 found in T cells.[55] Despite their variations in size, all members of the FKBP family that have been sequenced to date (either directly through automated Edman degradation, or indirectly through cloning and sequencing of their complementary DNA (cDNA)) show a common FKBP12-like domain of approximately 12 kDa. An alignment of the sequences of some of these proteins is shown in Figure 12 (see Section 3.2.2.1.) Several features of this alignment are striking. First, although the number of conserved amino acids from approximately residue 25 through the *C*-terminus (residue numbers referenced relative to hFKBP12) is fairly high, the *N*-terminus shows very little homology among the various proteins.

Interestingly, in hFKBP12 residues 1 to 13 and 13 to 29 correspond to the first two of four exons in the genomic DNA encoding the protein.[59] These exons are separated from the remaining two exons, which encode residues 29 to 66 and 67 to 107, by a large intron of 16000 DNA bases. The other introns are much smaller and contain only 109 and 3300 bases. This gene structure suggests that the *N*-terminal regions of the FKBPs may have developed through the recruitment of unrelated exons by the large intron preceeding the common *C*-terminal domain. Thus, analysis of the FKBP12 gene provides an evolutionary explanation for the high variability seen in the *N*-terminal peptide of members of the FKBP family.[59]

Examination of the sequence alignment in light of the structures of unbound FKBP12 and of the two FKBP12–ligand complexes also provides insight into the requirements for stability, ligand binding, and rotamase catalysis of these proteins. A total of 13 residues are exactly conserved in all known FKBPs. Six of these, Gly 33, Gly 69, Gly 83, Gly 28, Leu 97, and Leu 103, are important to the structural integrity of the protein.[57b] The remaining seven, Tyr 26, Phe 36, Asp 37, Val 55, Ile 56, Tyr 82, and Phe 99, line the binding pocket or make important contacts to ligand. Trp 59, which also appears critical for maintaining the structure of the binding pocket is conserved in all but one sequence, where it is replaced by Phe. The high conservation of residues in the FKBP binding pocket suggests that all proteins in the family will bind ligands in a similar manner. In all cases, binding will involve a large number of van der Waals interactions with aromatic and aliphatic residues of the protein, plus several specific hydrogen bonds from the ligand to the protein. The sequence conservation coupled with a view of FK506 and rapamycin as transition-state analogues also suggests that these types of interactions may be necessary for rotamase catalysis. The conserved residues Tyr 26, Phe 36, and Phe 99 may be important for stabilizing the carbonyl group of a twisted amide in the rotamase transition state. The potential of the Tyr 82 phenolic hydroxyl group to form a hydrogen bond and the capacity of the Asp 37 carboxylate group to form a salt bridge may be important as well. Furthermore, it has been suggested that the hydrophobicity of the rotamase active sites of both FKBP and CyP may play a significant role in the enzymatic mechanism of the isomerization reaction.[35, 44, 60] Vapor pressure measurements have shown that peptide bonds are highly solvated in aqueous media.[61] Wolfenden and Radzicka[60] have argued that bound water molecules will inhibit isomerization of the amide bond since the presumably non-resonance-stabilized transition-state structure will be less polar than the starting or product structures. An enzyme that promotes desolvation by providing a hydrophobic binding site will then facilitate isomerization. In support of this hypothesis for catalysis by desolvation[62] are NMR data demonstrating that the isomerization of *N*,*N*-dimethylacetamide is significantly more rapid in methylene chloride than in water.[63] Kofron et al. have discussed a similar mechanism[35] on the basis of theoretical calculations indicating that interactions with water reduce the flexibility of amide bonds.[64] Finally, Van Duyne et al.[44] have noted calculations showing that the dipole along the C–N bond is decreased in a twisted amide relative to the planar species,[65] and that the stability of dipolar species is decreased in low-dielectric environments.[66] Thus, they postulate that the hydrophobic ligand-binding site of FKBP may promote isomerization by destabilizing the strongly dipolar amide bond in a peptide substrate.

4. Structural Studies of Cyclophilin (CyP) and its Complex with Cyclosporin A (CsA)

4.1. Cyclophilin (CyP)

Although the structure of the CyP–CsA complex remains unknown, Kallen et al. and Ke et al. have recently determined the structures of a CyP–tetrapeptide complex and unbound CyP by X-ray crystallography.[67, 68] In addition, Weber et al. and Fesik et al. have also determined the structure of CsA bound to CyP by isotope-edited NMR spectroscopy.[69, 70] The results of these studies provide many clues regarding the structure and biological function of the CyP–CsA complex. As can be seen in Figure 7, the structure of CyP bears no obvious resemblance to that of FKBP12. CyP is composed of an eight-stranded antiparallel β barrel capped at each end by an α helix. The topology of the β strands is $+1, -3, -1, -2, +1, -2, -3$, which results in an unusual loop crossing reminiscent of that seen in FKBP12. The eight-stranded β-barrel structure of CyP is related to the structures of several members of the β-protein family,[71] including bilin-binding protein,[72a] retinol-binding protein,[72b] β-lactoglobulin,[72c] and insecticyanin.[72d] Like CyP, these proteins also bind small hydrophobic ligands. The ligand-binding pocket of β-proteins is in a cleft between the two sheets forming the barrel.[71, 72] In CyP, however, intermolecular NOEs, chemical shift changes on binding, and overall geometry of the protein indicate that the CsA-binding pocket is not located inside the central β barrel.[67, 68] Rather, it is in a cleft at the protein surface formed by one sheet of the barrel and the loop from Lys 118 to His 126. Previous NMR studies indicated that bound CsA contacts the side chains of the single tryptophan residue of CyP, Trp 121, and an unidentified phenylalanine residue.[73] The CyP structure corroborates this data, since Trp 121 sits at one end of the binding pocket, and Phe 60 and Phe 113 are located at its base. The structure also provides an explanation of the inhibition of CyP rotamase activity and CsA binding by modification of cysteine residues with *p*-hydroxymercuribenzoic acid,[12b] as Cys 115 and Cys 62 are both located in the binding pocket. The roles of other residues in the binding cleft, including His 54, Arg 55, Ile 57, Met 61, Asn 102, Gln 111, Leu 122, and His 126 are still unclear. However, the generally high conservation of these residues in the various cyclophilins suggests that they make important contacts to the ligand, and may also be involved in rotamase catalysis. In this regard, it is curious that there are no obvious similarities between the active sites of FKBP12 and CyP.

4.2. Cyclosporin A (CsA)

In the absence of a complete structure of the CyP–CsA complex it is difficult to identify differences between bound and unbound CyP that may be important for interaction

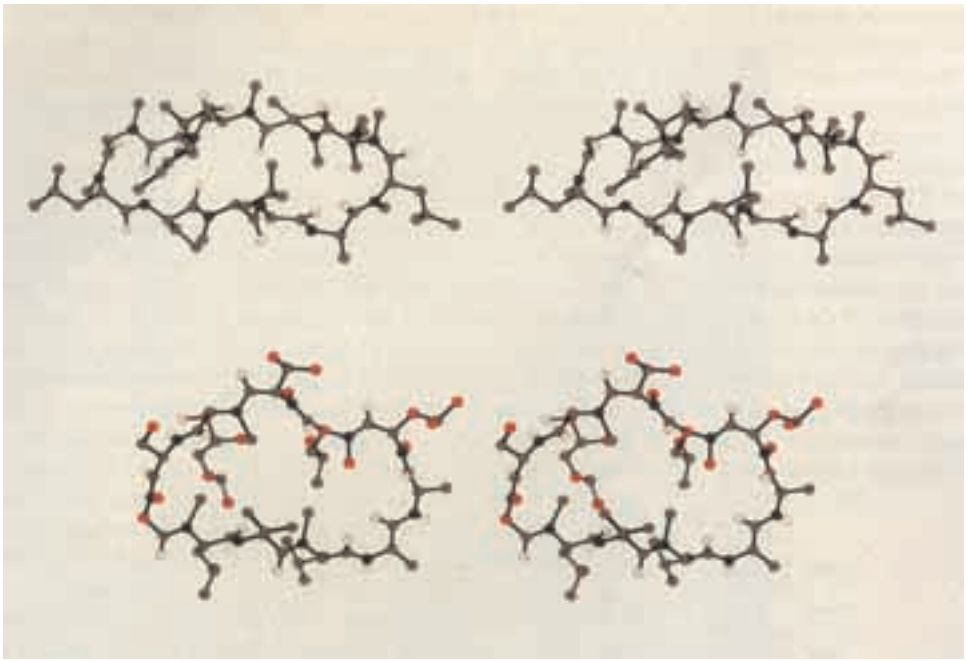

Fig. 14. Stereoviews of free (top) and bound (bottom) CsA. In the structure of bound CsA, atoms with attached hydrogens that show NOE crosspeaks to CyP in a NOESY spectrum (50 ms) of the CyP–CsA complex are shaded red[70].

with CN. However, the existance of both free[74] and bound[69, 70] CsA structures (Fig. 14) does allow such an analysis to be made for the ligand portion of the complex. The conformation of bound CsA is strikingly different from the conformation of the free ligand in the crystalline state and in organic solvents. (The crystal and solution structures of CsA in organic media, for example methylene chloride, are extremely similar, and hence will be referred to jointly as the conformation of the "free" ligand. The insolubility of CsA in aqueous media has prevented detailed structure determination in more biological environments (however, see Quesniaux et al.[75]). Thus, as with the FKBP ligands, comparisons between free and bound CyP ligands should be interpreted cautiously.) Free CsA can be divided into two overlapping domains. The first consists of residues 11–3 and 4–7, which form two strands of an antiparallel β sheet joined by a type β II′ turn at residues 3 and 4. There are hydrogen bonds between Abu 2 NH and Val 5 CO, Val 5 NH and Abu 2 CO, and Ala 7 NH and MeVal 11 CO stabilizing the structure. Notably, all the *N*-methyl groups in this region (11, 2, 4, 6) are directed outside the macrocyclic ring. The second domain consists of residues 7–11, which form an irregular loop stabilized by a hydrogen bond from D-Ala 8 NH to MeLeu 6 CO and a number of van der Waals contacts, including several to the *N*-methyl group of MeVal 11, which is directed into the center of the macrocycle. All amide bonds in the structure are *trans*, except that between MeLeu 9 and MeLeu 10, which is *cis*.

In contrast to free CSA, the bound molecule has no elements of regular secondary structure. In addition, there are no intramolecular hydrogen bonds. Of the seven *N*-methyl groups, only two, those of MeVal 11 and MeLeu 9, are exposed. The remainder are directed into the macrocycle and make a number of intramolecular van der Waals contacts. Correspondingly, all four amide NH groups and ten of eleven amide CO groups are at least partly exposed. On the basis of H/D-exchange rates it was proposed that one amide NH group, that of Abu 2, makes an intermolecular hydrogen bond to CyP. Strikingly, all amide bonds in the bound conformation are *trans*, indicating a high energy barrier to binding.

In addition to determining the structure of bound CsA, Weber et al. and Fesik et al. also identified a number of intermolecular NOEs between ligand and receptor.[69, 70] In particular, many NOEs were observed from aromatic and aliphatic residues of CyP, including the sole tryptophan, Trp 121. These NOEs indicate, as had been previously suggested,[76] that CsA binds in a hydrophobic pocket of the protein. The patterns and locations of protein–ligand NOEs also allowed both groups to determine the regions of CsA that contact CyP in the complex. As indicated in Figure 14 bottom, the amino acid residues 9 through 3 all show a number of intermolecular contacts. Hence, these residues constitute the binding domain of CsA. In contrast, residues 4 through 8 show only intramolecular NOEs, indicating they do not strongly interact with the protein. This suggests that these residues may constitute the region of CsA that is in contact with calcineurin (CN) when simultaneously bound to CyP.

An important tenet of the active complex hypothesis is that the only necessary requirement for signal inhibition by a drug is binding of the immunophilin–drug complex to its relevent biological target (CN in the case of FK506 and CsA). The tight binding of drug to immunophilin is not necessary per se, and as demonstrated with 506BD is also not sufficient to cause inhibition. With this in mind, the identification of distinct binding and possible effector domains of CsA allows explanation of the biochemical and biological data on a wide range of CsA analogues. In most but not all cases there is a direct correlation between CyP binding and inhibitory activity measured in T-cell activation assays.[77, 78] Not surprisingly, most of the analogues that do not bind CyP have been modified in the regions of the drug that contact the protein. For example, the following analogues all

have > 80% decrease in CyP binding and activity in T-cell activation assays relative to CsA: MeAla 9, MeAla 10, MeAla 11, MeLeu 11, α-amino-γ-fluorobutyrate 2.[77] A number of modifications of the MeBmt 1 side chain have similar effects. There are, however, several CsA analogues that do not show a correlation between CyP binding and signal inhibition. These can be divided into two categories: 1) those that do not bind CyP tightly, but are inhibitory and 2) those that do bind CyP, but are not inhibitory. The existence of such compounds has led to speculation that CyP may not be the relevant biological receptor of CsA (that is, not the receptor responsible for the biological actions of the drug).[78] The active complex hypothesis provides an interesting alternative explanation of this data. In the first category there is only one reported molecule, dimethyl-Bmt–CsA (Fig. 15). This compound binds CyP roughly a hundredth as

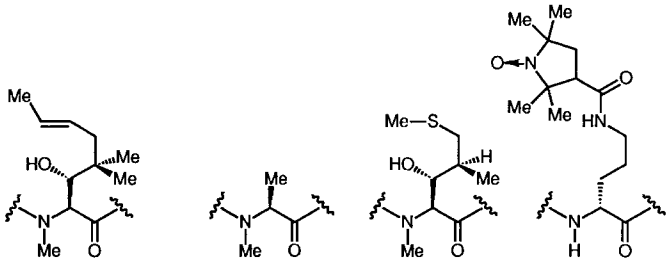

Fig. 15. Modified side chains of CsA analogues whose immunosuppressive activity does not correlate with affinity for CyP. Numbers refer to amino acid positions in CsA.

tightly as CsA, but retains 35% of the inhibitory activity of CsA in T-cell activation assays. It is possible that although dimethyl-Bmt–CsA binds CyP weakly on its own, its binding may be enhanced on binding of the ligand–receptor complex to CN. That is, the additional protein–protein and protein–ligand contacts in the ternary complex may be sufficient to overcome the energetic penalty incurred by the addition of a methyl group to CsA. Investigations of the CyP–dimethyl-Bmt–CsA complex support this possibility and indeed resolve the paradox surrounding this molecule.[79] The second category of CsA analogues consists of compounds with modifications to three residues: MeBmt 1, MeLeu 6, and D-Ala 8. These compounds include, among others, MeAla 6, Me-Thia-Bmt 1, and TPc-D-Orn 8 (Fig. 15). The properties of these molecules are reminiscent of those of 506BD, which binds FKBP but does not interfere with signal transduction in T cells or mast cells. By analogy with 506BD, these molecules contain the elements necessary to interact with CyP, but do not have the proper structure to enable their ligand–receptor complexes to bind to CN. This explanation is consistent with the location of residues 6 and 8 on the effector domain of CsA. In addition, the MeBmt 1 derivatives in the second category all possess modifications of the MeBmt side chain at locations near the side chain of MeLeu 6 on one face of the bound CsA macrocycle. Thus, MeBmt 1 may be important for contacting both CyP and CN in the pentameric complex. In support of these explanations of the various synthetic analogues, results in our laboratory illustrate that for a number of analogues of both FK506 and CsA, inhibition of signal transduction correlates exactly with the ability of complexes of these molecules with their cognate immunophilin receptors to inhibit the phosphatase activity of CN.[79]

The conformation of the CsA effector domain also suggests a possible mode of interaction of the CsA portion of the CyP–CsA complex with CN. The CsA backbone from the carbonyl group of Sar 3 through the amide NH group of Ala 7, with the exception of MeLeu 4, is reminiscent of one strand of a pleated β sheet. This suggests that the interactions between bound CsA and CN may resemble those observed between strands of a β sheet. The carbonyl groups of residues 3 and 5, and the NH group of residue 7 all lie in the plane of the CsA macrocycle, and are directed outward. The amide plane containing Val 5 NH and MeLeu 4 CO is angled relative to the plane of the macrocycle, although Val 5 NH could still be accessible for hydrogen-bonding interactions with CN. Note that the *N*-methyl groups of residues 4 and 6, which might interfere sterically with a regular pattern of hydrogen bonds, are directed into the macrocyclic ring and thus remain unobtrusive. Finally, the side chains of residues 4, 5, and 6 alternate above and below the plane of the CsA macrocycle in a fashion similar to that seen in β sheets. This enables the side chains of MeLeu 4 and MeLeu 6 to participate in stabilizing contacts with the side chains of MeLeu 10 and MeBmt 1 on one face of the macrocycle. These features together result in a regular, accessible surface composed of the side chains of 4, 5, and 6, and the backbone amide groups of residues 3 through 7 that would be able to make a number of hydrophobic and hydrogen-bonding contacts with CN. The structure of this surface suggests that the CsA portion of the CyP–CsA complex may interact with CN in a β-sheet-like structure.

5. Structures of the Pentameric Immunophilin-Drug-CNA-CNB-Calmodulin Complexes

5.1. Contacts between the Immunophilin–Ligand Complexes and CN

It interesting to speculate on which regions of the various immunophilin–ligand complexes are important for contacting their biological targets and which regions impart specificity to the complexes, allowing them to interact with different partners. Is it possible that only the ligand portions of the complexes contact the partner, and that the sole function of the protein is to correctly position the ligand and mold it into the proper conformation for binding? Or can it be that only the protein is important for binding, and that the function of the ligands is to induce or stabilize particular protein conformations that are then able to interact with different biological partners? Or is it possible that a composite surface formed by both ligand *and* receptor is required for binding, and that the ligands and receptors mold each other cooperatively? A variety of evidence suggests that, at least for the FKBP12–ligand complexes, the last possibility is the most likely. The free and bound structures of rapamycin are virtually identical. Thus, rapamycin does not need to interact with FKBP12

in order to take on its biologically active conformation. Yet it is inactive on its own.[22, 23] Comparison of the structure of free FKBP12 with those of its FK506 and rapamycin complexes reveals that regions of the protein that do not contact ligand are not changed significantly by complexation. Thus, the ligands do not exert large allosteric effects on the protein that might facilitate binding to target. This is not surprising, given the relatively small size of FKBP12. More significantly, comparison of the two complexes shows that even in the regions of the structure surrounding the ligands, the two proteins are extremely similar. (The differences observed in the region Gly28–Gly33 are most likely artifacts of crystal packing and therefore are probably not significant.[44]) Given the distinct biological effects of the complexes, it then seems unlikely that only the protein contacts the biological target molecules. This analysis suggests a ternary complex in which both immunophilin and ligand make contacts with the target.

5.2. Structure of the FKBP–FK506 and CyP–CsA Binding Site of Calcineurin

Phosphatase inhibition and binding data[26] on the immunophilin–ligand complexes provide insight into the structures of the pentameric complexes. The ability of CyP–CsA to displace calcineurin and calmodulin from an immobilized FKBP–FK506 reagent demonstrates that the two complexes share either a common binding site or two interacting binding sites on CN.[26] It is not apparent from the available structural data how the two complexes might interact with a common site. The resolution of this issue may require further information on the regions of the two proteins (FKBP12 and CyP) that are involved in CN recognition. The inability of calmodulin or the CNB subunit to bind immunophilin–drug complexes suggests that the binding site(s) probably resides in the CNA subunit.[79] The increased binding of FKBP–FK506 and CyP–CsA to CN in the presence of calmodulin also suggests that the calmodulin- and immunophilin–ligand-binding sites are not independent.[79] The interaction between these sites may be transmitted indirectly, through changes to CN, or more directly, through stabilizing interactions between calmodulin and the immunophilin–ligand complex when both are bound to CNA. A more detailed picture of the immunophilin–ligand binding site may be derived from the substrate-dependence of CN inhibition. The dephosphorylation of a 20-residue phosphopeptide by CN is strongly inhibited by both FKBP–FK506 and CyP–CsA (K_i = ca. 30 nM when measured with bovine CN and human immunophilins[79]). However, dephosphorylation of *p*-nitrophenyl phosphate is actually enhanced by approximately a factor of 3 at similar concentrations of the two immunophilin–drug complexes.[26] These data indicate that the binding site for the complex is not the enzyme active site, but the two sites are probably spatially close to each other. A similar relationship between binding and active sites is seen in the recently solved crystal structure of cyclic AMP-dependent protein kinase bound to a peptide inhibitor.[88] A schematic illustration of this description of the immunophilin–ligand binding site is presented in Figure 16. Thus, our current model of pentameric complex formation

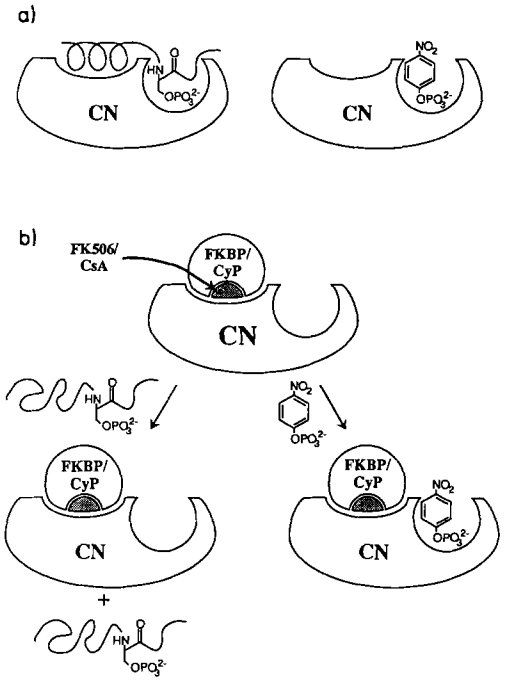

Fig. 16. Model of the binding site of CN in the immunophilin–ligand complex. a) Two different substrates, a phosphopeptide and *p*-nitrophenyl phosphate, are bound to CN. b) Immunophilin–ligand complexes, FKBP12–FK506 and CyP–CsA, affect the enzymatic activity of CN on the two substrates (phosphopeptide and *p*-nitrophenyl phosphate).

involves calmodulin-facilitated binding of FKBP–FK506 or CyP–CsA in a single or in two interacting hydrophobic binding sites that are adjacent to the phosphatase active site present on the A subunit of CN.

6. Additional Roles of the Immunophilins

A variety of data indicate that in addition to mediating the signal inhibition of FK506, rapamycin, and CsA, immunophilins may also have a number of other roles in the cell. For example, FKBP13 is a membrane-associated protein and the predominant FKBP in mast cells.[7, 55, 56] Although FKBP12 and FKBP13 share 43% amino acid sequence identity, and show exact identity for all residues lining the ligand-binding pocket, the two proteins are significantly different in the regions immediately surrounding the binding pocket. In particular, residues in the highly charged basic loop of FKBP12 (Arg40 to Lys44) have been replaced with much different, uncharged residues in FKBP13 (RDRNK → LPQNQ, using the one-letter amino acid code). If this loop is important for binding of the FKBP12–FK506 complex to CN, then these differences imply a different biological role for FKBP13. Indeed, the FKBP13–FK506 complex does not bind CN, although the structural basis for this has not yet been determined.[79] Clues to the biological role of FKBP13 also can be drawn from the protein sequence. Unlike all other known FKBPs, FKBP13 is initially synthesized with a signal peptide at its *N*-terminus that directs the protein into the endoplasmic reticulum (ER).[55, 80] In the ER the peptide is cleaved, leaving the soluble form of the molecule. At its extreme *C*-terminus FKBP13 also contains a possible ER-retention sequence,[81] Arg-Thr-Glu-Leu-CO_2^- (Fig. 12). This causes

the protein to be retained in the ER rather than secreted or directed to other parts of the cell. These two signal peptides indicate that FKBP13 is a resident protein of the ER, and suggest that it may play a role in regulating protein traffic in this organelle. Thus, FKBP13 may be similar in function to the heat-shock proteins[82] and protein disulfide isomerase,[82, 83] which stabilize nascent unfolded or improperly folded polypeptide chains in the ER, preventing their aggregation and precipitation. It is not unreasonable that FKBP13, too, may stabilize unfolded peptides through interactions with its hydrophobic pocket. It may also act as a protein foldase by facilitating the *cis–trans* isomerization of peptidyl–prolyl amide bonds, an event shown to be rate limiting in the in vitro folding of a number of proteins.[84]

Similar roles have also been postulated for two members of the cyclophilin family, CyP-B[58f, 58g] and the protein product of the ninaA gene.[58d, 85] Both these molecules reside in the ER, although CyP-B is a soluble protein whereas ninaA is bound to the membrane through a transmembrane *C*-terminal domain. The ninaA protein, which is located specifically in photoreceptor cells in the eye of *Drosophila melanogaster* is necessary for proper function of the visual pigment rhodopsin. *Drosophila* photoreceptor cells containing a mutant ninaA gene have dramatically reduced levels of rhodopsin, resulting in impaired visual function (the rhodopsin is trapped in the ER[86]). When the mutant gene is replaced with the wild type, rhodopsin function is restored along with normal vision. The actions of ninaA have also been shown to be substrate specific: Of the homologous rhodopsins Rh1, Rh2 (70% amino acid identity to Rh1), and Rh3 (35% amino acid identity to Rh1), only the levels of Rh1 and Rh2 are affected by ninaA mutations. These data suggest that the ninaA cyclophilin is required for the proper trafficking of rhodopsin from the ER to the plasma membrane of the eye.[58d, 85, 86]

Another interesting member of the FKBP family that was discovered using a synthetic rapamycin-based affinity matrix[55] is FKBP25.[57b] This protein consists of two clearly defined domains. The *C*-terminal region consisting of 114 residues is homologous to FKBP12 (42% sequence identity). But the *N*-terminal region consisting of 101 residues does not show significant homology to any known protein. Unlike FKBP12 and FKBP13, which bind FK506 and rapamycin with roughly equal affinity, FKBP25 shows almost 200-fold selectivity for rapamycin over FK506 (K_i(rapamycin) = 0.9 nM; K_i(FK506) = 160 nM). FKBP25 also possesses a possible nuclear localization sequence,[87] consisting of a Lys_4 tetrapeptide and one of two Lys_2 dipeptides. The apparent sequestering of FKBP25 in the nucleus suggests a different role for this protein than for FKBP12 and FKBP13. Rapamycin selectivity, and the presence of an *N*-terminal domain also point to this conclusion. Identification of the role of FKBP25 must wait, however, for a number of analyses. These include confirmation of its presence in the nucleus, determination of the function and structure of its *N*-terminal domain, and assessment of its ability to form inhibitory complexes with FK506 and rapamycin.

The body of data accumulated in the various immunophilins, including those described above, clearly suggest multiple roles for this family of proteins. They are found in virtually all organisms examined to date. They show tissue specificity. They are localized in the cell in compartments ranging from the cytoplasm to the nucleus. They exist in soluble and membrane-bound forms. Finally, nearly all proteins tested to date show rotamase activity, yet the substrate specificity varies from protein to protein. These data, while providing only hints as to the exact nature of the biological roles of this family, do indicate that there are many interesting aspects of immunophilin function that are still unexplored.

7. Summary and Outlook

In summary, a family of natural products was used to identify a new family of protein receptors, named immunophilins. Investigations of these proteins resulted in the understanding that they function as complexes with their cognate immunosuppressive ligands. This led to the use of immunophilin–ligand complexes as probes of cellular signal transduction pathways, allowing the discovery of a common target, calcineurin. Identification of substrates of CN may provide yet a further step in this pathway. In this manner, by beginning with inhibitory natural products, a signal transduction pathway can be investigated molecule by molecule through the black box of the cytoplasm.

It is not unusual for natural products from one organism to bind to proteins in another. Examples of this include many pharmacologically useful compounds including the opiates and antimitotic agents. It is also not unprecedented that ligands are able to enhance the interaction between two proteins. The uniqueness of the immunophilin story resides in the fact that the ligands FK506, CsA, and rapamycin possess both these properties. Not only do they bind to proteins in organisms other than those that produce them, but in binding they enhance the interactions between these proteins and others. Thus, all three of the known natural immunophilin ligands have evolved with two separate but related abilities. It seems difficult to believe that this dual function arose fortuitously, especially if one considers the complex relations between the three ligands described in the introduction of this review.

This quandary leads to a number of basic, and still unanswered questions regarding the function of these fascinating compounds and their biological receptors. To begin with, why do the immunosuppressants FK506, CsA, and rapamycin exist? What purpose does it serve fungi to make compounds with their complicated and interrelated spectrum of properties? Similarly, why do the immunophilins exist? Surely they did not evolve to bind molecules found only in microorganisms. If their purpose is to regulate signal transduction in cells, how are they activated? Are there endogenous molecules whose actions are mimicked by the various immunosuppressants? If so, can we identify these molecules and use their bound structures to design better signal transduction inhibitors? At a more detailed level there are still many questions. What is the physiological role of CN, and what are its natural substrates? Thus, how close are we to defining all of the molecules in the black box of the signal transduction pathway from cell surface receptors to the nucleus? (For a speculative proposal addressing this question see [89].) What is the target of the later acting FKBP–rapamycin complex? Is this molecule related to CN? Finally,

what is the structural basis for the formation of the different ternary immunophilin–ligand–target complexes? Can the structures of these complexes provide us with general knowledge about the mechanisms of molecular recognition? The resolution of these questions will depend, as have the studies that led us to them, on a variety of experimental methods and approaches. It is hoped that by applying the complementary tools of chemistry, biology, and structural analysis, we will be in a position to pose even more exciting questions in the future.

We would like to thank our many friends and colleagues who have been involved in the structural studies of the immunophilins. In particular, our continuing collaborations with Jon Clardy and his group at Cornell University have yielded a wealth of structural insights into the molecular basis of immunophilin function. Our success in determining the solution structure of unbound FKBP12 would also have been impossible without the patience, guidance, and efforts of Stephen Michnick, and the hard work and critical analysis of Tom Wandless and Professor Martin Karplus of the Harvard Chemistry Department. Thanks go out to Mark Albers and Tom Wandless for critiquing the manuscript, Robert Standaert for kindly providing Figure 12, and Dr. Hengming Ke of the University of North Carolina for providing coordinates of CyP (used to prepare Fig. 7) prior to publication. Finally, we owe a great debt to other members of the Schreiber group, including M. A., Jun Liu, Pat Martin, R. S., and T. W. whose commitment and enthusiasm have made the immunophilin project in this laboratory exciting and successful. M. K. R. would like to thank the American Chemical Society Division of Organic Chemistry and Merck, Sharp & Dohme for financial support in the form of a graduate fellowship. Immunophilins research in the S. L. S. laboratory is supported by grants from the National Institutes of General Medical Sciences (GM-38627 and GM-40660).

On the Influence of Heteroatoms in α- and β-Functionalized Alkyl Transition-Metal Compounds

By Dirk Steinborn*

Dedicated to Professor Rudolf Taube on the occasion of his 60th birthday

The first homoleptic trimethylsilylmethyl transition-metal complexes were synthesized about 20 years ago in the research groups of Wilkinson and Lappert, resulting in a significant advance in the understanding of the thermodynamic and kinetic stability of transition-metal–carbon σ bonds. The relatively high thermal stability of these bonds provides a dramatic contrast to the Köbrich lithium carbenoids XCH_2Li, known for about 30 years and famous for their extraordinarily high reactivity. Both compound classes illustrate that introduction of a heteroatom into an alkyl ligand can have a profound influence on the structure, stability, and reactivity of an alkylmetal compound, opening the possibility of entirely new reactions. Because of their simple and unambiguous structure, α- and β-heteroatom-substituted transition-metal compounds containing the unit [M–CH_2–Y] or [M–CH_2–CH_2–Y] (where Y is an element from the 4th–7th main groups or groups 14–17, not including C[**]) are particularly suitable for studying effects of the nature of a heteroatom center (neutral/cationic, coordinatively saturated/Lewis basic) on structure, stability, and reactivity as a function of the type of complex, the nature of M, and the number of methylene groups separating M and Y. The diversity of stabilizing and destabilizing influences emanating from the heteroatom center generally produces a broad spectrum of reactivity and stability. This is reflected in an impressive way in homogeneous catalysis, where functionalized alkylmetal compounds arise as intermediates, as well as in the electronic influences of functionalized alkyl ligands, which are determined largely by the nature of the heteroelement present.

1. Introduction

Main-group organometallic compounds have been the subject of intensive investigation since the beginning of this century. By contrast, the chemistry of transition-metal–organic complexes experienced its first dramatic development in the 1950s. One important stimulus was certainly the recognition that transition-metal organometallic compounds are capable of catalyzing a vast number of C–C bond-formation processes and functionalizing reactions of unsaturated hydrocarbons, which in turn opens entirely new possibilities in synthetic organic chemistry and has a profound significance in the context of biochemical phenomena as well.[1]

A growing body of knowledge about organometallic chemistry, together with improved preparative techniques and new approaches to the characterization of substances, have made it increasingly possible to study systems containing not only an M–C bond but also other centers of high reactivity. These include complexes with functionally substituted σ-organo ligands. Important prototypes for functionalized organometallic complexes are the ω-heteroatom-substituted alkylmetal compounds **1**, which can contain a neutral, coordinatively saturated heteroatom center ($YR_n = SiR_3$), a neutral, Lewis-basic heteroatom center ($YR_n = NR_2, PR_2, OR, SR, F, Cl, Br, I$), or a cationic heteroatom center ($^+YR_{n+1} = {}^+NR_3, {}^+PR_3, {}^+OR_2, {}^+SR_2$).

$[L_xM\text{-}(CH_2)_m\text{-}YR_n]$ **1a** $\quad [L_xM\text{-}(CH_2)_m\text{-}\overset{+}{Y}R_{n+1}]$ **1b**

R = alkyl, aryl, H; $m \geq 1$; M = metal

The interface between inorganic and organic chemistry is illustrated by **1**. These compounds represent a link between the "purely organic" doubly substituted hydrocarbons **2** and the binuclear organometallic compounds **3**.[2]

$R_nY\text{-}(CH_2)_m\text{-}YR_n$ **2** $\quad [L_xM\text{-}(CH_2)_m\text{-}ML_x]$ **3**

The unambiguous structure of the compounds **1** seems to predestine them for studies of the influence of metals and heteroatoms as a function of the length of the alkylene bridge. The effect of the heteroatom is complex; on one hand the electronic characteristics and the spatial demands of the organo ligand are modified, and reactions that are possible with analogous nonfunctionalized compounds can be suppressed; for example, β-hydride elimination is *not* possible with the α-functionalized alkyls $[L_xMCH_2YR_n]$ (R = alkyl, aryl), even though with the transition-metal alkyls $[L_xMCH_2CHR_2]$ this generally represents a decomposition pathway with low activation energy. On the other hand, heteroelements can also facilitate fundamentally new types of reactivity (Scheme 1).

As a result of manifold reaction pathways and a variety of stabilizing and destabilizing influences, heteroatom-substituted alkylmetal compounds are subject to a wide variation, as illustrated by the organometallic inner complexes (for instance **4**, the first well-characterized compound of type **1**[3]), the carbenoid **5** that decomposes at temperatures as low as −100 °C,[4] and the thermally relatively stable

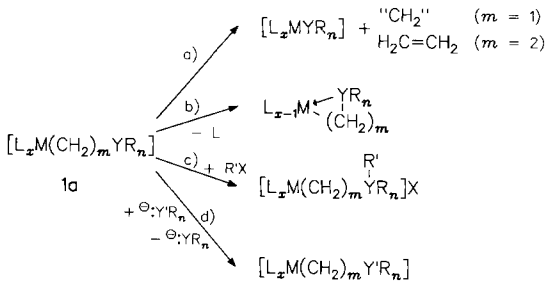
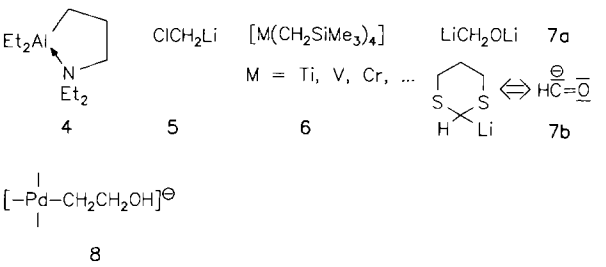
[**] Other abbreviations: Bz = benzyl; Cp = η^5-C_5H_5; Cp* = η^5-C_5Me_5; cy = cyclohexyl; H_2pc = phthalocyanine; tmeda = *N,N,N',N'*-tetramethylethylenediamine; X = halogen.



Scheme 1. Some characteristic reactions of **1a**: a) carbenoid reactions ($m = 1$) and fragmentation and β elimination reactions ($m = 2$); b) inner-complex formation; c) ylide ($m = 1$) and "onio" alkyl complex formation ($m \geq 2$); d) substitution of YR_n.

homoleptic[*] alkyl transition-metal compounds **6**.[5] With the synthesis and characterization of **6** the "long search for stable alkyl transition-metal compounds" (Wilkinson, Nobel Prize Lecture 1973[6]) was successfully concluded, leading to fundamental understanding of the stability and reactivity of metal–carbon σ bonds. The significance of the class of compounds **1** is underscored by the potential application of such systems as synthetic building blocks in organic chemistry and as catalysts for homogeneous catalysis, as illustrated by the reagent **7** with its "umpoled" reactivity,[7] as well as by **8**, which is a key intermediate in the Wacker process.[8]



This article provides an overview of the chemistry of the α- and β-functionalized organo-transition-metal compounds **1** ($m = 1, 2$). Several discussions have already appeared of compounds containing γ- and δ-functionalized alkyl ligands together with a Lewis-basic heteroatom (e.g. **4**).[9, 10] The reader is referred to other sources for reviews of the chemistry of α-heteroatom-substituted organo-alkali-metal compounds[11, 12] and metal complexes containing ylide ligands.[13–15]

[*] The term *homoleptic* is applied to σ-organometallic compounds that contain only σ-bonded organo residues. These might also be coordinated further by way of a heteroatom in the sense of intramolecular coordination (organometallic inner or chelate complex).

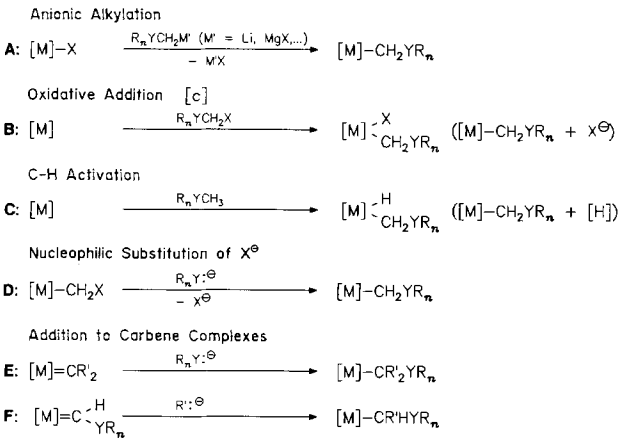
2. Heteroatom-Substituted Methylmetal Compounds

2.1. Silicon as Heteroatom

2.1.1. Synthesis and Reactivity

Table 1 summarizes broadly applicable synthetic principles relevant to α-functionalized alkylmetal compounds.

Table 1. Principles of synthesis for α-functionalized alkylmetal compounds [a,b].



[a] η^2 Coordination can also occur in place of the indicated η^1 coordination provided Y carries a nonbonding pair of electrons. [b] Here and in the following, square brackets around the metal are used to indicate those ligands in a complex that take no direct part in the reaction. The possibility of cleavage or addition of ligands has not been taken into account in the schematic equations, nor has charge balance. [c] Includes reactions that proceed as nucleophilic substitutions with loss of X^-.

Virtually all the metals form trimethylsilylmethyl complexes, and methods **A** and **B** are particularly useful for their synthesis. The isolable homoleptic transition-metal derivatives shown in Table 2 warrant special attention. Their synthesis by anionic alkylation is to some extent attributable to redox reactions (Scheme 2).

Bond strengths for M–CH_2SiMe_3 and M–C_{alkyl} tend to be comparable.[28] The relatively high thermal stability of homoleptic trimethylsilylmethyl complexes has a kinetic origin and is due largely to the absence of β-H atoms (no β-H elimination is possible), the great stability of the Si–C bond,

Dirk Steinborn, born in 1946 in Berlin, studied chemistry from 1965–1969 at the Humboldt-Universität in Berlin and moved in 1970 to the Technische Hochschule Leuna–Merseburg where he completed his doctoral work in 1974 under R. Taube. He then worked for three years in industry. In 1984 he was awarded the degree Dr. sc. nat. for work on nitrogen-substituted alkylmetal compounds and the electronic influence of organo ligands. This was followed in 1986 by a Facultas docendi, after which he was appointed (in 1987) to the faculty of the Technische Hochschule Merseburg. In the same year Steinborn was awarded the Friedrich Wöhler Prize of the Chemischen Gesellschaft. His areas of interest include coordination chemistry, organometallic chemistry and complex catalysis, and bioinorganic chemistry.

Coordinative interactions are not excluded between the lithium ion and the organic residue (e.g., through multicenter bonding with the σ-bonded C atoms or with the nonbonding electron pairs of Lewis-basic heteroatoms). [f] L = Et_2O, thf, 1/2 tmeda; Ln = Y, Er, Yb, Lu. [g] Regarding the existence of the neutral complex [$Sc\{CH_2SiMe_2(o\text{-}MeOC_6H_4)\}_3$] cf. [49]. [h] L = Et_2O, thf. [i] For L = thf at 273 K.

coordinative saturation of the Si atom, and the increased spatial requirement[29] of the trimethylsilylmethyl ligand (bimolecular decomposition reactions are hindered). In addition to homolytic bond cleavage, thermal decomposition has been shown to involve methylidene and methylidyne complex formation as a consequence of α-H eliminations. It may be that agostic α-CH–M interactions are also relevant, as has been demonstrated for the zirconium complex [$Zr(CH_2SiMe_3)_4\{Me_2P(CH_2)_2PMe_2\}$] (Zr–H = 248 pm, Zr–C = 221.5(9) pm).[30]

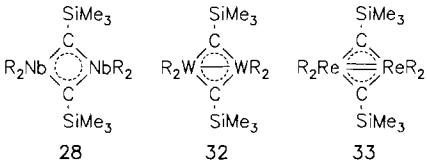
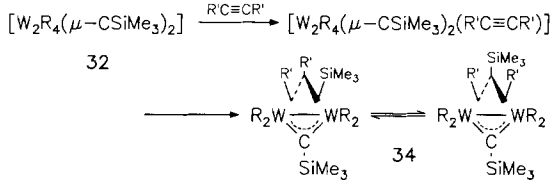
such as [$\{(CO)_3Co\}_3(\mu_3\text{-}CSiMe_3)$].[34] A quasi-aromatic planar dimetallacyclobutadiene structure is present in the binuclear complexes **28**, **29**, **32**, and **33**, in which, depending upon whether the interaction is d^0–d^0, d^1–d^1, or d^2–d^2, the two metal atoms exhibit no bonding, a single bond, or a double bond.[32, 35]



Scheme 3. The methylidyne complexes **28**, **32**, and **33**. The metal–metal distances are 289.7 (**28**), 253.5 (**32**), and 255.7 pm (**33**). R = Me_3SiCH_2.

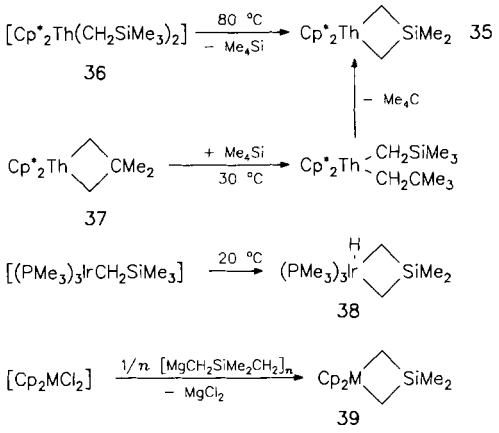
Compound **32** reacts with alkynes via a π-alkyne complex to give **34** by insertion into the μ_2-$CSiMe_3$ ligand–metal bond. The remarkable fluctuation in μ-allyl ligands probably occurs by way of a μ-cyclopropene complex as intermediate (Scheme 4).[35, 36]



Scheme 4. Reaction of the binuclear complex **32** with alkynes. R = Me_3SiCH_2.

2.1.2. C–H Activation

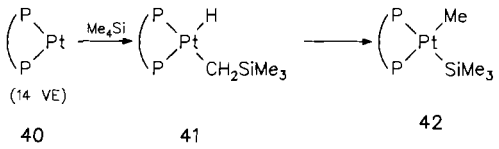
In the case of trimethylsilylmethyl complexes, intramolecular γ-C–H activation[37] leads to 3-sila-1-metallacyclobutanes[38] (Scheme 5). The M-C-Si-C ring in **39** is nearly planar, with fold angles along the C–C vector of up to 14.3°.[38c] Even the weakly reactive C–H bonds in Me_4Si can be acti-



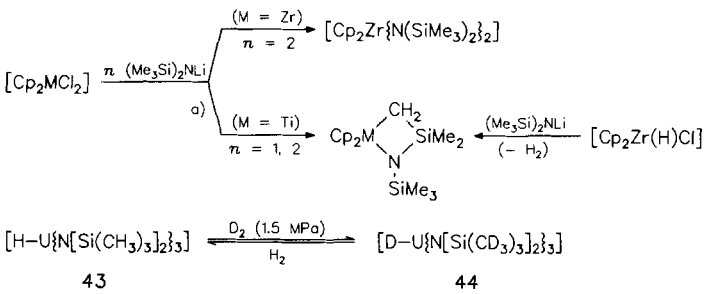
Scheme 5. Synthesis of 3-sila-1-metallacyclobutanes by C–H activation with and without elimination of Me_4Si, as well as by anionic alkylation. M = Ti, Zr, Nb, Mo.

vated intermolecularly! This is shown, for example by the formation of **35** from **37** and Me_4Si.[38d]

The 14 valence-electron (VE) complex fragment **40** ($\widehat{PP} = t\mathrm{Bu_2PCH_2P}t\mathrm{Bu_2}$), whose highly strained four-membered ring (P-Pt-P 74.7(1)° in $[(\widehat{PP})\mathrm{Pt(H)CH_2CMe_3}]$) is responsible for its exceptional reactivity, reacts with Me_4Si by oxidative addition of the C–Si bond to give **42**, a consequence of prior C–H activation.[39] In the case of $\widehat{PP} = \mathrm{cy_2PCH_2CH_2Pcy_2}$ the ring strain is lowered and the reaction ceases at the hydrido complex **41**.[40]



A γ-C–H activation in bis(trimethylsilyl)amide complexes—which can be induced thermally, photochemically, or by bases—leads to azasilametallacyclobutanes[41,42] (Scheme 6).

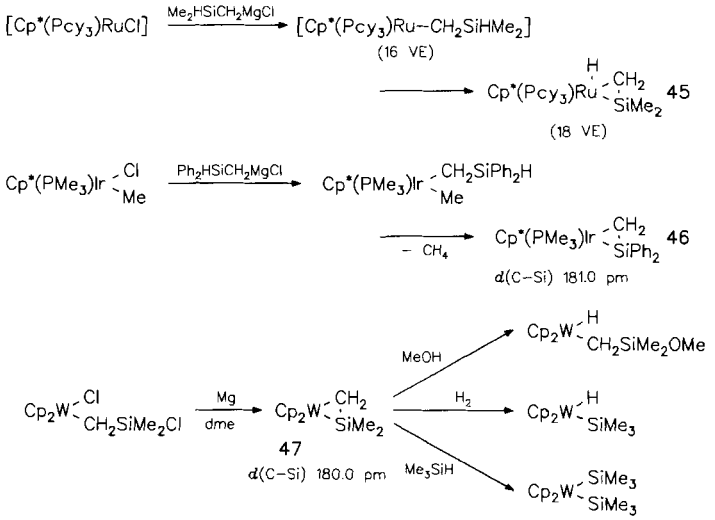


Scheme 6. Synthesis of azasilametallacyclobutanes, which occur as intermediates in the H–D exchange in **43**. a) γ-C–H activation also occurs with 2 equiv $(Me_3Si)_2NLi$ [41]. M = Ti, Zr.

Compounds of this type are key intermediates for the rapid H–D exchange observed in systems like **43**.[43]

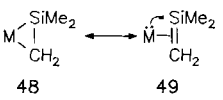
2.1.3. η^2-Silaethene Complexes

η^2-Silaethene complexes can be synthesized by Si–H activation or reductive dechlorination from H- or Cl-substituted silylmethyl ligands, respectively (Scheme 7).[44,45] Depending upon the extent of back donation, η^2-silaethene complexes can be characterized either as silametallacyclopropane **48** or π-silene complexes **49**. The experimentally determined Si–

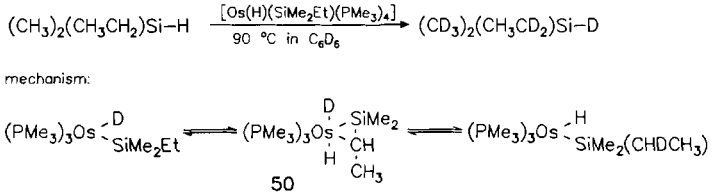


Scheme 7. Synthesis of η^2-silaethene complexes, and characteristic addition reactions involving cleavage of M–Si or M–C bonds.

C bond length of approximately 180 pm indicates partial double-bond character (Si–C ≈ 189 pm; Si=C ≈ 173 pm). The iridium complex **46** is actually quite stable, since no decomposition is observed even at 140 °C in the presence of PMe_3 or upon treatment with hydrogen or UV irradiation.[45] This distinguishes it significantly from comparable



olefin complexes.[46] η^2-Silaethene complexes such as **50** are also accessible by β-H elimination from silylmetal compounds. They are intermediates in the strictly regioselective metal-catalyzed H–D exchange of alkyl silanes (Scheme 8).[47]



Scheme 8. Metal-catalyzed H–D exchange in alkylsilanes showing the reaction mechanism.

2.1.4. Bis- and Tris(trimethylsilyl)methyl Complexes

The introduction of additional trimethylsilyl residues into trimethylsilylmethyl ligands leads to ligands with considerable spatial demands and a characteristic ability[48] to 1) stabilize metals in their lower coordination states (cf. the overview of homoleptic transition-metal complexes in

Table 4), and 2) produce subvalent main-group-metal alkyls in low oxidation states (cf. the higher homologues of carbenes and alkyl radicals $M[CH(SiMe_3)_2]_n$; M = Ge, Sn, Pb; $n = 2, 3$[54]).

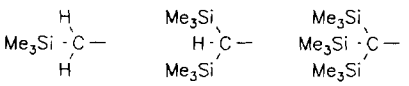


Table 4. Homoleptic bis- and tris(trimethylsilyl)methyl complexes of transition metals.

Compound	Color	$\mu_{eff.}$ [μ_B]	M.p. [°C] (B.p. [°C]; p [Torr])	Ref.

51 [LnR_3] (Ln = La, Sm) [a]				[49]
52 [TiR_3]	blue-green			[50]
53 [VR_3]	blue-green			[50]
54 [CrR_3]	green	3.8	80 [b]	[50]
55 [UR_3]	blue	3.0	60 [b]	[51]
56 [MnR_2]	pale yellow	5.5	8–10 (100–110; 0.5)	[52]
R = $(Me_3Si)_3C$				
57 [MnR_2]	pale yellow	5.1	290 (315 [b])	[53]

[a] An important factor in synthesis according to **A** is the introduction of a Ln alcoholate in place of $LnCl_3$ [49a]. [b] Decomposition temperature.

The structure of bis- and tris(trimethylsilyl)methyl complexes—similar to the case of the homoleptic norbornyl complexes[55]—is characterized in a striking way by the high spatial demands of the ligands and not by the electronic structure of the central atoms. Whereas Mn displays the coordination number 4 in the polymeric compound **17** (see Table 2), the complexes **56** and **57** are linear and monomeric. The coordination number 2 is characteristic for (monomeric) homoleptic tris(trimethylsilyl)methyl compounds: neutral complexes **58**[53, 56] and the anions in **59**[57] are isostructural and isoelectronic. All display strictly linear structures. The structure of **59a** is exceptional in that the compound is a lithate complex.

$[M\{C(SiMe_3)_3\}_2]$ **58**

58: M = Mg (a), Zn (b), Cd (c), Hg (d), Mn (e)

$[Li(thf)_4][M\{C(SiMe_3)_3\}_2]$ **59**

59: M = Li (a), Cu (b), Ag (c)

Compound **54** deviates significantly from planarity (C-Cr-C angle of 117.6°[50]); **51** and **55** are even pyramidal (C-M-C: for M = La, Sm, 110°;[49] for M = U, 107.7°[51]). This is not simply a result of steric factors, but rather is related to an increase in coordination number through agostic γ-methyl–metal interactions, which have also been demonstrated in other bis(trimethylsilyl)methyl complexes.[51, 58] In the case of crystalline $[\{(Me_3Si)_2CH\}_2Mg]_\infty$ there is even an intermolecular agostic interaction $Mg\cdots C'H_3$ (Mg–C' 253.5(4), Mg–H 233.3–251.6 pm, C-Mg-C 140.0(2)°), leading to the unusual coordination number of 3 for magnesium.[59]

The reactivity of bis- and tris(trimethylsilyl)methyl complexes is largely a function of spatial shielding of the central atom: **58b** is stable in boiling hydrochloric acid; it also does not react with bromine.[56a] The Cd and Hg compounds $M[C(SiMe_3)_2(SiMe_2CH{=}CH_2)]_2$ show a similar reactivity; in the case of the Hg compound the vinyl group can be substituted with trifluoroacetic acid at 60 °C without attack on the M–C bond.[60]

The unusually high decomposition temperatures of **58** and $[(Me_2PhSi)_3C–Hg–R]$ (R = CH_2Ph, Ph, Bu) (about 300 °C in the melt!) demonstrate that sterically demanding ligands can also result in stabilization relative to unimolecular radical dissociation, which has been considered in the context of the insufficiently investigated phenomenon of energy transport and energy transfer within a ligand and through a metal.[48, 61]

2.2. Lewis-Basic Heteroatoms

2.2.1. Synthesis of Homoleptic Transition-Metal Complexes

Anionic alkylation (synthesis **A** in Table 1) with $C_5H_{10}NCH_2Li$ has been used to prepare a complete series of homoleptic piperidinomethyl complexes of the 3d elements[62, 63] (Table 5). Treatment of $TiCl_4 \cdot 2thf$ with

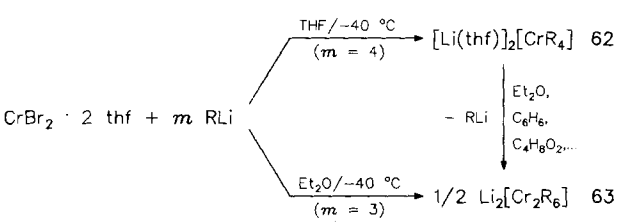
$C_5H_{10}NCH_2Li$ leads by α-elimination to the carbyne complex **60**, which probably has a dimeric structure analogous to the μ-trimethylsilylmethylidyne complex **28**. $VCl_3 \cdot 3thf$ can be converted with $C_5H_{10}NCH_2Li$ under redox disproportionation into **61**. $CrBr_2 \cdot 2thf$ reacts with $C_5H_{10}NCH_2Li$ in

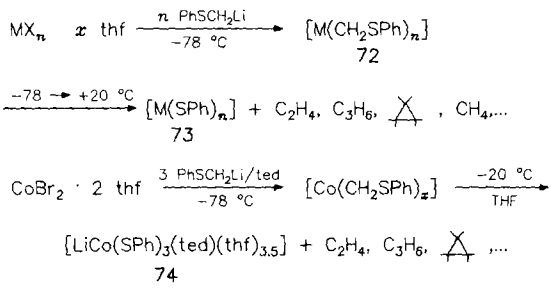


Scheme 9. Synthesis of piperidinomethylchromium(II) complexes. R = $C_5H_{10}NCH_2$.

THF as solvent to give **62**, a high-spin tetraalkylchromate(II) complex, and in ether to give **63** (Scheme 9).

The compounds **60–68** are extremely sensitive to hydrolysis and to air. Reaction with alcohols and $LiAlH_4$ leads, respectively, to protolytic and reductive cleavage of the ligand in the form of *N*-methylpiperidine. A remarkable feature of the homoleptic transition-metal alkyls is their high thermal stability ($T_{dec.} > 100\,^{\circ}C$). These are in every case more stable than the analogous methyl complexes. Apart from the stability of the ligand to β-elimination and its electronic influence, the decisive factor appears here to be a Li–N interaction in the "ate" complexes.

If the halides of the 3d elements from Ti to Ni are treated with thioanisolyllithium at $-78\,^{\circ}C$ and then warmed to room temperature, the result is release of the C_1 to C_3 hydrocarbons with formation of thiophenolate complexes[66] (Scheme 10). The reaction of $CoBr_2 \cdot 2thf$ has been examined in greater detail and shown to produce **74**. The homoleptic thioanisolyl compounds of the 3d elements **72** that are assumed to be intermediates are apparently characterized in general by a low degree of thermal stability due to facile cleavage of the methylene group. Only in the case of palladium has a homoleptic compound **71** (Table 5) been isolated, with μ-η^2-coordination of the thioanisolyl ligand.[65]

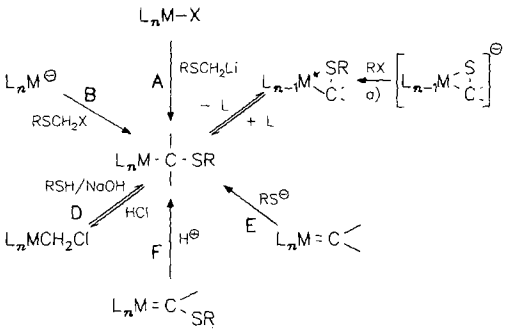


Scheme 10. Reaction of halides of the 3d elements with thioanisolyllithium. In parentheses: fraction of PhSH in sulfur-containing hydrolysis products as percentage. Fe^{II} (88) ≈ Co^{II} (83) > Ni^{II} (58) ≈ Mn^{II} (56) > V^{III} (44) ≈ Ti^{III} (40) > Ti^{IV} (31) ≫ Cr^{III} (9). ted = $N(CH_2CH_2)_3N$.

Reference is made in Table 5 to two stable homoleptic phosphinomethyl transition-metal complexes. The zirconium compounds $[Zr(CH_2YMe)_4]$ (Y = O, S) have been only partially characterized.[67]

2.2.2. Synthesis of Heteroleptic Transition-Metal Complexes

A wide range of heteroleptic transition-metal complexes with functionalized methyl ligands has been prepared; see as a representative example the syntheses of thiomethyl complexes in Scheme 11 and Table 6. The compounds R_nYCH_2M **75** ($R_nY = R_2N$, R_2P, RO, RS; M = Li, MgX) represent readily accessible and reasonably stable starting materials for anionic alkylation (**A**); only $ROCH_2Li$ and $ROCH_2MgX$ decompose as carbenoids at temperatures below $0\,^{\circ}C$.[11, 76] Halomethyl compounds[77] of lithium and magnesium are such thermolabile carbenoids (they decompose between -50 and $-100\,^{\circ}C$[4, 76]) that they are unsuitable for syntheses along route **A**. On the other hand, they can



Scheme 11. Synthesis of heteroleptic functionalized methyl transition-metal compounds as illustrated by the example of thiomethyl complexes. a) *S*-Alkylation of thioformaldehyde complexes.

be considerably stabilized by complex formation with transition-metal compounds such as $[Ti(OiPr)_4]$.[78]

An oxidative addition reaction **B** employing the iminium salts $[R_2N{=}CH_2]X$, $ROCH_2Cl$, $RSCH_2Cl$, or CH_2X_2 has been widely used in particular for the synthesis of CO-, Cp-, and PR_3-stabilized complexes. Oxidative addition of methylene halides may be preceded by formation of a CH_2Cl_2 complex.[79]

Table 6. Examples of syntheses according to reaction routes given in Scheme 11.

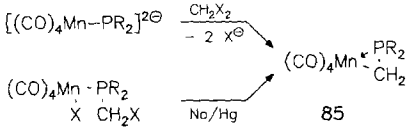
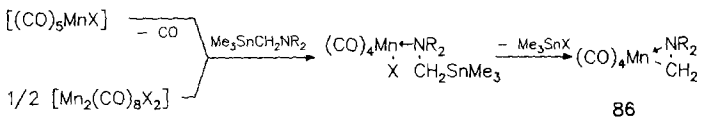
[a]	$[Cp_2(PMe_3)Ti(\eta^2\text{-}CH_2SMe)]^+$ **84**	[73]

[a] *S*-Alkylation of thioformaldehyde complexes affords thiomethyl compounds. See also [74]. [b] For the 1,2 shift of MeS from the carbanionic C atom according to the reverse reaction in **E**, see [71, 75].

η^2-Phosphinomethyl complexes such as **85** are accessible through oxidative addition/nucleophilic substitution of CH_2X_2 starting with phosphidometallates[80] and by reductive cycloelimination from chloromethyl–phosphane complexes.[81] The synthesis of **86** from aminomethyltin compounds apparently proceeds by way of similar intermediates.[82]





Remarkably mild reaction conditions suffice for C–H activation in the trimethylphosphane–metal(0) complexes of

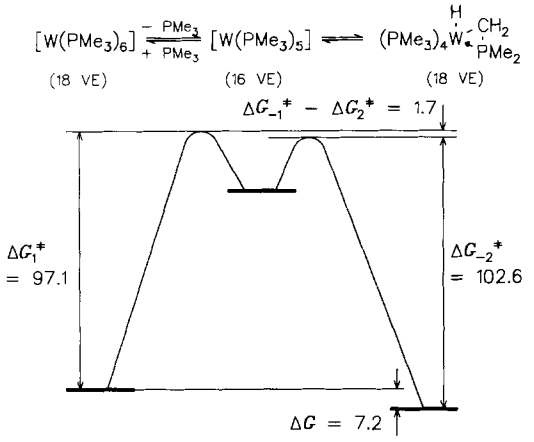


Fig 1. C–H Activation in $[W(PMe_3)_6]$ (data in kJ mol^{-1}). The rate-determining step is the dissociation of PMe_3. In the case of the 16-electron complex $[W(PMe_3)_5]$ oxidative C–H addition is favored over ligand association [83e].

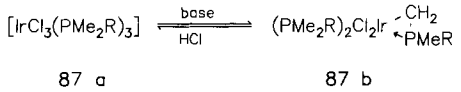
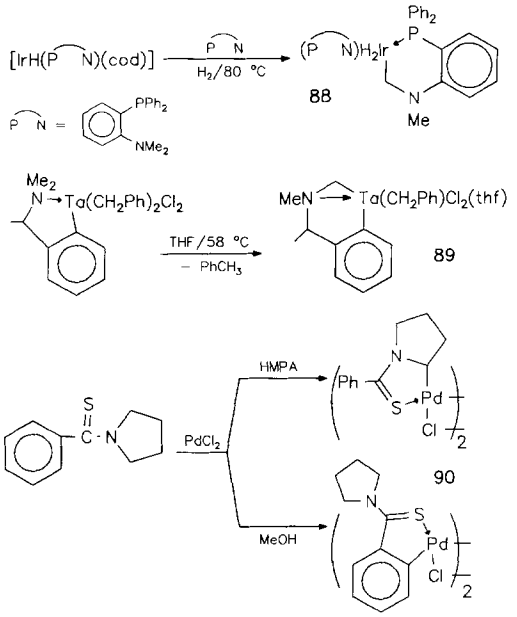
Mo, W, Fe, Ru, and Os, with the formation of hydrido-η^2-phosphinomethyl complexes[83] (cf. Fig. 1). This is a result of high electron density at the metal as a consequence of the powerful σ-donor and weak π-acceptor tendencies of trimethylphosphane. The reversible interconversion of phosphane complexes (**87a**) and η^2-phosphinomethyl complexes **87b** through deprotonation of the phosphane ligands facilitated by amides, organolithium compounds,[84a] or ylides, (cf. Schmidbaur et al.[84b]) or through protolytic cleavage of the M–C bond, illustrates that C–H activation in methylphosphane complexes can also proceed in the sense of an electrophilic substitution (supported by nucleophiles).



87 a 87 b

C–H bonds in *N*-bound methyl groups are accessible through intramolecular activation in the sense of oxidative addition (**88**) and electrophilic substitution (**89**), which may, given certain structural features and under particular reaction conditions—as in the case of **90**—compete with orthometallation (sp^3 C–H vs. sp^2 C–H activation)[85] (Scheme 12). It would appear that an *N*-methyl C–H activation is also responsible for the unusual isomerization at temperatures as low as 60 °C of a 2,6-bis(*N*,*N*-dimethylaminomethyl)phenyliridium(I) complex into the 2,4 analogue.[86]

Functionalized methylmetal complexes can be prepared from Fischer carbene and carbyne complexes according to **E** and **F** (see Table 1) by nucleophilic addition or migration of a nucleophile from a metal to a carbene carbon atom (Scheme 13).[87] The latter approach is applicable to protonation: with **93**, for example, the first step is protonation of the metal atom, followed by the reverse of an α elimination, in which hydride transfer occurs from the metal to the carbene.[87a, 88] The thermal transformation of the methyl phosphide iridium complex **94** is a result of intramolecular transfer of phosphide to a carbene, preceded by a spontaneous α-H elimination from a methyl ligand. The kinetic and thermodynamic products of the reaction are **95** and **96**, respec-



Scheme 12. Intramolecular C–H activation in *N*-methyl groups. HMPA = hexamethylphosphoric triamide.

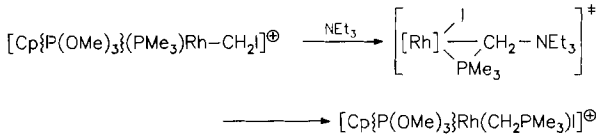
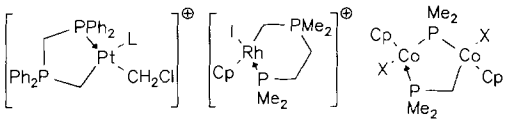


Scheme 15. Isomerization reaction.

tively. Photochemical reaction leads directly to the phosphane complex **96**.[89]

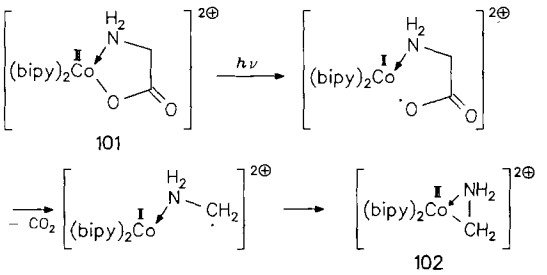
The halogen atom in halomethyl compounds can undergo nucleophilic substitution through a reaction similar to an S_N1 or S_N2 process according to **D** (see Table 1). Neutral nucleophiles lead to ylide complexes, and substitution of the ylide may follow as a competing reaction[70, 90, 91] (Scheme 14). Cleavage of halogen and addition of the nucleophile may occur in the sense of an intramolecular 1,2-shift, as is assumed in the case of the NEt_3-catalyzed isomerization of the Rh complex in Scheme 15.[92] Intramolecular substitutions **D** result in the formation of **98**–**100**[93] from the corresponding halomethyl phospane or phosphide complexes.



98 99 100

Transfer of a halide to a carbene is also the basis for synthesis of halomethyl complexes from metal halides and diazomethane.[94] Halomethylmetal compounds can also be prepared from formyl complexes,[95] as well as by decarbonylation of haloacetyl complexes.[96]

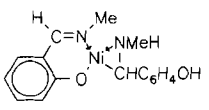
Photochemical decarboxylation of α-aminocarboxylate complexes **101** results in α-aminomethyl complexes **102** by way of radical intermediates.[97] An important factor in the smooth course of this reaction is the well-known facile elim-



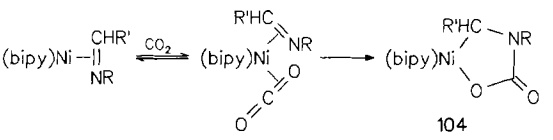
101 102

ination of CO_2 from RCO_2 radicals.

Azomethines can be transformed at nickel(0) centers into aminomethyl complexes, as illustrated by the formation of **103** from $[Ni(cod)_2]$ and *N*-methylsalicylaldimine.[98]



103

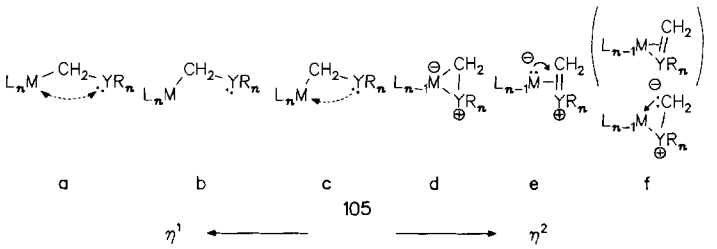


104

Oxidative coupling of the two hetero-π-systems to the five-membered ring heterocycles **104**[99] occurs in the presence of CO_2 under very mild reaction conditions ($T < 0\,^{\circ}C$; atmospheric pressure) with a wide variety of Ni^0 substrates. These and the corresponding reactions with isocyanates[100] demonstrate the ability of transition-metal complexes to accomplish the activation of CO_2.[101]

2.2.3. *Structure and Bonding*

Lewis-basic hetereoelements in functionalized methyl ligands are capable of entering into binding interaction with Lewis-acidic metallic centers, whereby the transition between η^1- and η^2-coordination is rather fluid (Scheme 16). Repulsive M–Y interactions (**105a**) as in $[Cp_2Zr(\eta^1\text{-}CH_2PPh_2)Cl]$ (Zr-C-P 130°)[102a] occur only in exceptional situations. Weak Fe–N interactions (**105c**) have been dis-



Scheme 16. Interactions between a Lewis-basic heteroatom and a Lewis-acidic metal center.

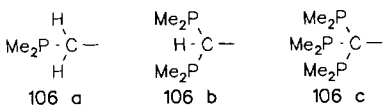
cussed in the case of $[Cp(CO)_2FeCH_2NMe_2]$.[102b] η^2-Complexes can be described as metallacyclopropanes **105d** ($H_2\overset{\ominus}{\ddot{C}}\text{–}\ddot{Y}R_n$ as ligand) or as heteroolefin complexes **105e** (with $H_2C{=}\overset{\oplus}{Y}R_n$ or $H_2C{=}\overset{\ominus}{\ddot{Y}}R_n$ as ligand), representing differing extents of electron-density transfer from the metal into the π* orbital of the C–Y double bond (cf. the Dewar–Chatt–Duncanson model). An ylide-like structure ("metal ylide", **105f**) involving more or less strong interaction between the ylidic C atom and the metal has been suggested when there is extremely strong M–Y interaction.[80d] In this way it becomes possible to invoke resonance structures corresponding to **105d**–**f** to describe the bonding relationships in η^2-complexes within the context of a valence-bond model.

As a consequence of the weak Lewis basicity of halogen and ether-oxygen atoms, stable η^2-halo complexes are unknown, and η^2-alkoxymethyl complexes are known only for strongly oxophilic central atoms like Zr^{IV}[103] and Mo^{II}.[88a]

η^1-Amino, η^1-phosphino-, and η^1-thiomethyl complexes also have the ability to enter into intermolecular complexation due to the strong Lewis basicity of the heteroatom, leading to $\mu\text{-}\eta^2$ coordination. Both homo- and heterobimetallic compounds have been described, including $[CpNi(\mu\text{-}\eta^2\text{-}$

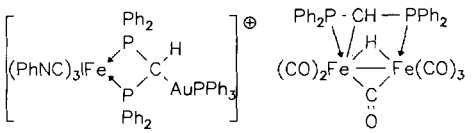
$CH_2PR_2)_2NiCp]$[81b] and $[Cp_2Zr(\mu\text{-}\eta^2\text{-}CH_2PR_2)_2ML_x]^{n+}$ (ML_x = Rh(cod), $n = 1$; ML_x = $Cr(CO)_4$, $n = 0$).[104]

Bis- and tris(dimethylphosphino)methyl ligands (**106b** and **106c**) show an increasing tendency toward phosphorus coordination. Ligand **106b** is an exceptionally ambident lig-

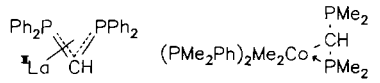


106 a 106 b 106 c

and with a wealth of possibilities for coordination[105] and the ability to stabilize main-group metals in low oxidation states.[106] *P,P*-Coordination dominates with transition metals, whereby the carbanion-like C atom is capable of either inter- or intramolecular coordination of complex fragments, as in **107** and **108**.[107] η^1-*C*-coordination has been demonstrated for $[Hg\{CH(PPh_2)_2\}_2]$.[108] A η^3- (i.e., π-allyl-like) coordination of the ligand is found in a homoleptic



107 108

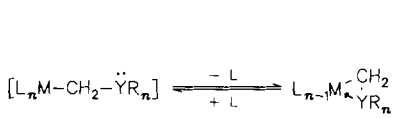


70 109

complex of La^{III} (**70**), a hard central atom with little tendency toward phosphorus coordination (Table 5).[64] Systems of this type, as well as the η^2-*P,C*-coordination found in **109**, apparently represent important intermediates through which ligand fluctuations (e.g., η^2-*P,P*-coordination $\rightleftharpoons$ η^1-*C*-coordination) and rearrangements (e.g., $[L_nM(H)(R_2PCHPR_2)] \rightarrow [L_nM(R_2PCH_2PR_2)]$) may pass.[64, 107c]

2.2.4. Reactivity

A reversible transformation from η^1 to η^2 coordination is generally associated with a thermally or photochemically induced ligand cleavage or addition (Scheme 17). If the α-hydrogen atoms in $[Cp_2Zr(\eta^1\text{-}CH_2PMe_2)Cl]$ are replaced by Me_3Si groups, *C*-nucleophilicity is reduced relative to *P*-nucleophilicity, producing a η^2 compound $[Cp_2Zr\{\eta^2\text{-}C(SiMe_3)_2PMe_2\}Cl]$.[109]

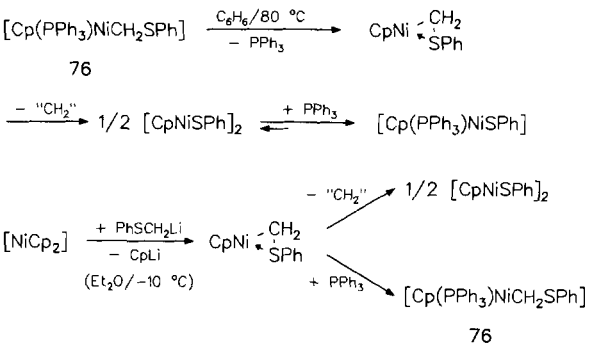


110 111

Scheme 17. Reversible transformation between η^1 and η^2 coordination.

Interactions between metal and heteroelement may influence the reactivity of a complex in a crucial way. It has been demonstrated with halomethyl compounds of Groups 1 and 12 that metal–halogen interaction is a significant factor in carbenoid reactivity (that is, cleavage of the CH_2 group from substituted methyl ligands).[110]

The carbenoid reactivity of thioanisolyl compounds has been closely investigated in the case of the nickel and titanium complexes **76** and **77**, which are transformed into thiophenolato complexes in boiling benzene (Table 7). During the decomposition of **77** small amounts of toluene have been detected as an insertion product of the solvent benzene and the CH_2 group that is cleaved. Norcarane is observed in the presence of cyclohexene. Methylene cleavage apparently proceeds via η^2-thioanisolyl complexes, as shown for **76** in Scheme 18. Because formation of a η^2-thioanisolyl structure



Scheme 18. Proposed mechanism of the thermal decomposition of **76**. The presumed intermediate $[CpNi(\eta^2\text{-}CH_2SPh)]$ can be trapped in high yield with PPh_3 as **76** in the reaction of $[Cp_2Ni]$ with $PhSCH_2Li$ [68].

is effectively prevented by the phthalocyanine ligand, thermal decomposition of **78** occurs in an entirely different way: at 150–170 °C in THF there is homolytic cleavage of the Fe–C bond without formation of a thiophenolato iron complex.[68] It remains an open question what the structural prerequisites for facile methylene cleavage in a η^2-thioanisolyl complex are.

Carbenoid reactivity has not been observed with any of the thioanisolylmercury or -zinc compounds **114**–**117** shown

Table 7. The transformation of thiomethyl complexes into thiolate complexes.

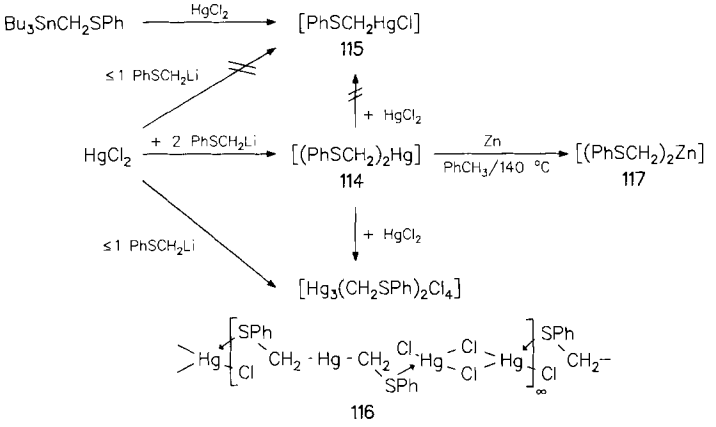
true for bis(phenylthio)methylmercury compounds.[117]

A β-sulfur-substituted 1,2-diphenylethylzirconium compound has been assumed to be an intermediate in the thermal decomposition of **112** (Table 7).[111] The thermally induced rearrangement of **113** (R = Ph) (Table 7) proceeds in an intramolecular way according to first-order kinetics ($\Delta H^{\neq}$ = 85.0 kJ mol^{-1} at 82 °C).[111] Based on an NMR spectroscopic investigation, the metallathiacyclopropane compound **119** is thought to be in rapid equilibrium with the carbene–mercaptide form **118**, a circumstance reflected in its reactions with



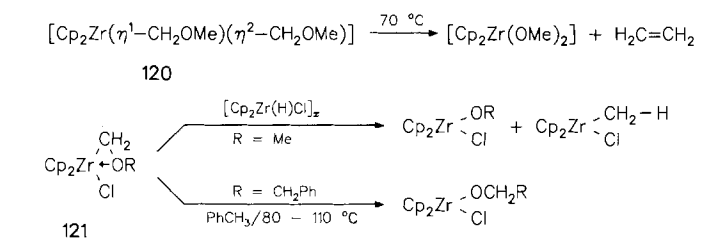
Scheme 19. Thioanisolyl compounds of mercury and zinc [112]. The strong tendency toward formation of **116**—from which $HgCl_2$ is not eliminated even in boiling acetone or THF—is due to mercury's high affinity for sulfur, which is also reflected in the crystal structure of **116** [113].

phosphanes and $[Me_3O]BF_4$, which involve cleavage of the C–S bond in the three-membered ring.[71]

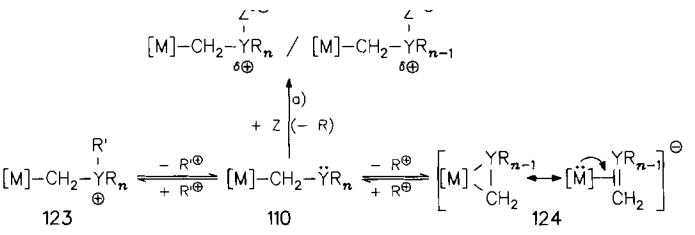
Compounds functionalized with oxygen such as **120** and **121** can also be converted into alkoxide complexes, with the

118 119

elimination of olefins.[115] The zirconium complex **121** is capable of transferring a CH_2 group under relatively mild conditions (40 °C) to the Schwartz reagent. At 80 °C, but only for R = CH_2Ph, it undergoes a Wittig rearrangement.[103, 116]

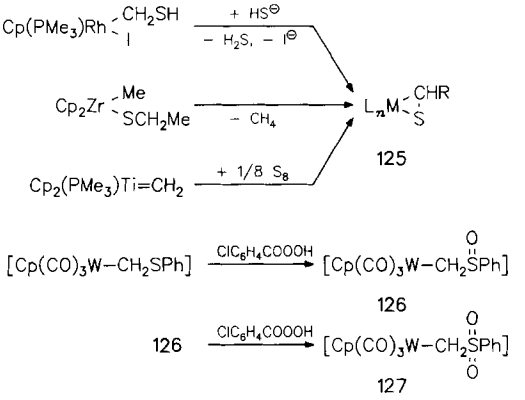


Functionalized methyl ligands support transformations like those shown in Scheme 20. Functionalized organo ligands with dipole stabilization as in complexes **122** have electronic characteristics between those of the ylide ligands **123** (see Section 2.3) and **110**. A wide variety of such systems has been described,[117] and they will not be treated here.



Scheme 20. a) Z represents a substituent that induces the positive end of a dipole at Y; for example, a substituent with a –M effect.

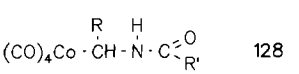
The complexes **124** can be regarded either as metallacyclopropanes or as π complexes [see, for example, the complexes with formaldehyde,[118, 119] thioformaldehyde,[74] imines,[98, 118a, 120] and methylenephosphanes (phosphaalkenes)[121]]. Representative of the reactions of these ligands, the formation of the thioformaldehyde complexes **125** is detailed in Scheme 21.[73, 74] Targeted oxidation of thiomethyl compounds leads to complexes like **126** and **127** with sulfinyl- and sulfonylmethyl ligands. Such ligands are regarded as dipole-stabilized.[122]



Scheme 21. Synthesis of thioformaldehyde complexes **125**, and oxidation of a thioanisolyl complex.

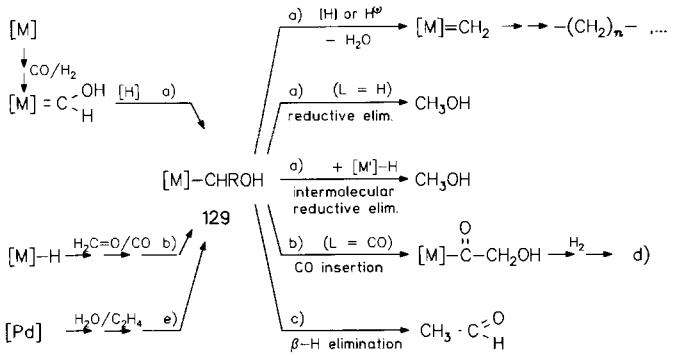
2.2.5. *Catalytic Aspects*

Aminomethyl complexes like **128** probably occur as intermediates in the synthesis of α-amino acids under the conditions of the "oxo" reaction, starting with aldehydes and acid amides. An aminoacetyl complex can arise from CO insertion into **128**, from which the amino acid is liberated by hydrolysis.[123]



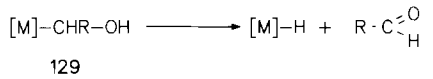
128

Metal-catalyzed hydrogenations of CO proceed to give a broad spectrum of hydrocarbons and oxygen-functionalized compounds depending upon the catalyst and reaction conditions. Such reactions occur by way of α-hydroxyalkyl compounds **129**, where R = H, alkyl (Scheme 22). Further re-



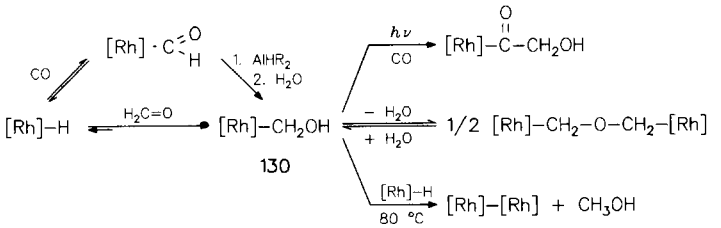
Scheme 22. α-Hydroxyalkyl complexes in catalysis. a) CO hydrogenation. b) Hydroformylation of formaldehyde. c) Wacker process (R = Me; otherwise, R = H). d) Reaction forming C_2 products like ethyleneglycol and glycol aldehyde. Certain ligands L from the coordination sphere of [M] are given above the reaction arrow.

duction or protonation with elimination of water leads to methylene complexes, which are important intermediates in the Fischer–Tropsch synthesis.[124] Reactions of hydrido hydroxymethyl complexes (**129**, L = H) and of **129** with metal hydrides can proceed by intra- or intermolecular reductive elimination to give methanol. CO insertion and subsequent reductive elimination of the acyl group from carbonyl hydroxymethyl complexes (**129**, L = CO) opens the way to C_2 products such as hydroxyacetaldehyde and ethylene glycol.[125]



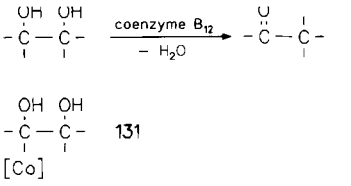
Scheme 23. Decomposition of α-hydroxyalkyl complexes **129** to hydrido complexes and aldehydes.

In general, α-hydroxyalkyl complexes are thermodynamically unstable and decompose to hydrido complexes and aldehydes (Scheme 23; for an exception see [126]). A reaction of this type is utilized in the Wacker process to liberate acetaldehyde.[8] The reverse reaction plays a role in metal-catalyzed formaldehyde hydroformylations and homologations.[125] Model reactions have been used to emulate important elementary steps in the catalytic processes (Scheme 24).[126]



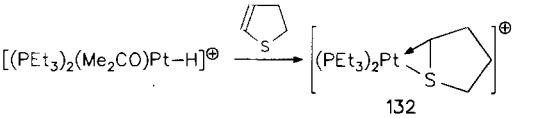
Scheme 24. Reactivity of the hydroxymethyl complexes **130**. [Rh] = octaethylporphyrinrhodium.

Coenzyme-B_{12}-dependent diol dehydratases catalyze the rearrangement of 1,2-diols to aldehydes or ketones. Probably an α,β-dihydroxyalkylcobalt compound[131] is formed first, and this species subsequently—perhaps via radical intermediates—causes isomerization and dehydration of the diol (Scheme 25).[127]



Scheme 25. Dehydration of 1,2-diols to aldehydes or ketones.

α-*S*-functionalized alkylmetal compounds are probably significant as intermediates in catalytic hydrodesulfurization (HDS), used for removing thiophene and other organosulfur compounds from crude petroleum fractions.[73, 128] For example, the hydrogenation of thiophene under HDS conditions may proceed by way of these intermediates, as documented in the formation of **132** through insertion of dihydrothiophene into a Pt–H bond.[128]

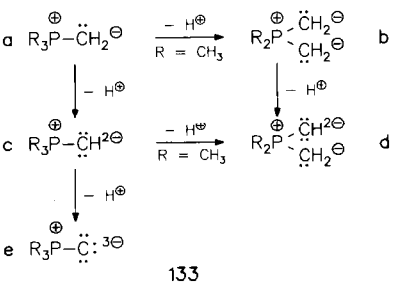


2.3. Ylide Complexes

Ylides must be regarded both as zwitterions and neutral ligands.[13–15] As a result of the neighboring positive charge on the heteroatom—and, in the case of Y = P, S a supplementary $p_\pi d_\pi$ contribution to bonding (Scheme 26)—the

Scheme 26. Resonance structures of ylides.

donor potential at carbon is considerably lower than that of the corresponding alkyl anion. This inhibits intramolecular electron transfer[129] and constitutes an important factor in the stability of ylide complexes. The positive charge on the heteroatom assures (especially with *P*- and *S*-ylides) facile activation of the neighboring C–H bonds, so that various coordination possibilities are present in addition to bonding as a simple σ-donor ligand (Scheme 27).



Scheme 27. Coordination possibilities for phosphorus ylides **133**. **a**, **c**, and **e** function as monodentate and b, d as bidentate ligands. **c**/**d** are carbene/alkylidene ligands, and **e** is a carbyne/alkylidyne ligand (R = Me).

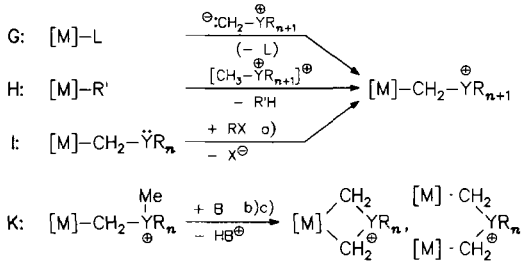
[a] Selection. In some cases additional compounds have been described with other organic residues on phosphorus. [b] Ln = Y, La, Nd, Gd, Er, Pr, Sm, Ho, Lu. [c] The appropriate phenyl-substituted compound is subject to orthometalation [132].

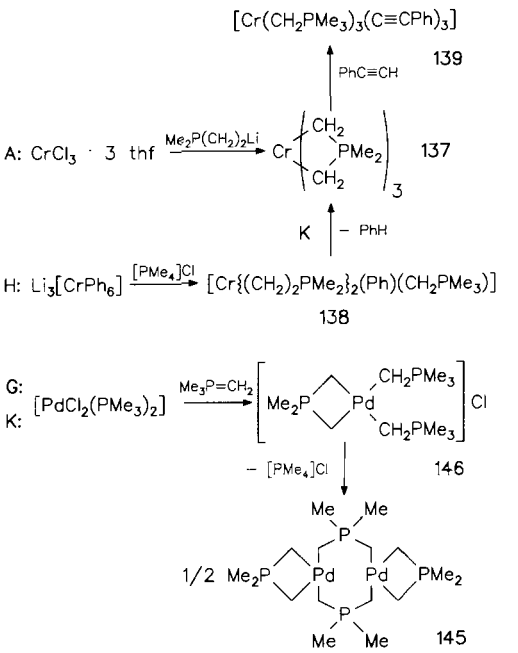
Apart from the methods **D**–**F** (Table 1), other broadly applicable approaches are available for the synthesis of η^1-ylide complexes (**G**–**I**, Scheme 28). Method **A** with $R_nY(CH_2)_2Li$ and method **K** are particularly valuable for the preparation of η^2 complexes. Many very thermally stable homoleptic phosphorus ylide complexes of transition metals have been prepared (Table 8); for examples of syntheses see Scheme 29.[132, 135]



Scheme 28. Synthetic principles for ylide complexes. a) Including R = H. b) B represents a base, which may be coordinated to M. c) Including "transylidation" reactions (B = ylide).

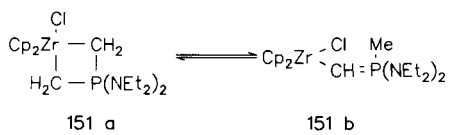
Ylide **133b** plays the role of a bridging ligand (μ-η^2 coordination). The two metal centers may also be subject to M–M bonding. The Group 6 metal complexes **136** and **140** belong to the chromium(II) acetate structural type (symmetry reduced to C_{4h} as a result of a nonplanar five-membered ring).[133] The fourfold bond between the metals leads to very short M–M distances of 189.5(3) pm in **136** and 208.2(2) pm in **140**.

Ligand **133c** is isomeric to **133b** (R = CH_3).[14, 137] The prototropic zirconium complexes **151a** and **b** exist in solution in equilibrium.[138] Complexes with **133c** as ligand can be characterized as (specially substituted) carbene complexes or as metal-substituted phosphorus ylides. Further deprotonation of **133c** leads to **133e**, which forms μ-methylidyne complexes containing M_2C_2 four-membered rings in the cases M = Zr (**135**)[131] and M = Ti.[14, 138]



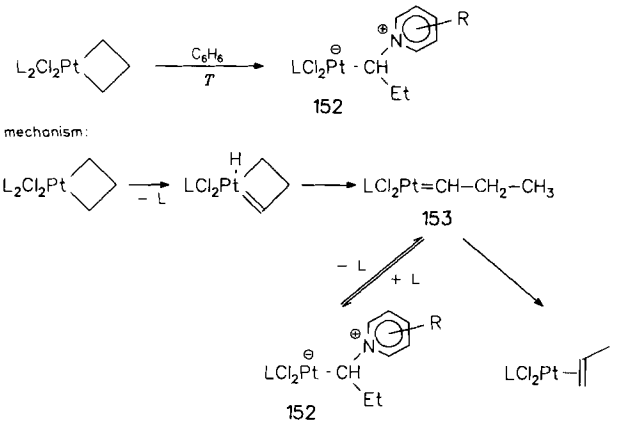
Scheme 29. Examples of the synthesis of homoleptic phosphorus–ylide complexes of transition metals.

Homoleptic palladium complexes **149** and **150** containing sulfur ylides (Table 8) have been described; homoleptic compounds of the main-group elements and metals of Groups 11 and 12 have long been known.[15, 139] The synthesis of **149** and **150** by treatment of $[PdCl_4]^{2-}$ with $(Me_3SO)I$ in aqueous (!) alkaline solution[136] is unusual, and may be relevant to biochemical processes. Of interest from a preparative standpoint is the synthesis of the organometallic com-



pounds $[Pd\{(CH_2)_2S(O)Me\}(PPh_3)_2]I$ and $[Pd\{(CH_2)_2S(O)Me\}(I)(PPh_3)]$ from the diphosphanepalladium halides and $(Me_3SO)I$ under phase-transfer conditions (CH_2Cl_2/NaOH; $(R_4N)I$ as phase-transfer catalyst).[140]

A great many heteroleptic *P*-, *S*-, and *N*-ylide complexes have been prepared by substitution reactions starting with halomethyl compounds (**D**), by addition of YR_{n+1} (HYR_n) to carbene complexes (**E**), and by alkylation, arylation, or protonation (**I**) (Table 1 and Scheme 28). Protonation is in principle reversible. Ylide addition or substitution reactions of type **G** are restricted to ylides displaying sufficient stability, hence this type of synthesis of *N*-ylide complexes is feasible only with such resonance-stabilized ylides as $R'C(O)-\overset{\ominus}{\underset{\cdot\cdot}{C}}H-\overset{\oplus}{N}R_3$. The *N*-ylide complexes **152** are accessible by isomerization of pyridine–platinacyclobutane complexes (Scheme 30).[141]



Scheme 30. *N*-Ylide complexes starting with platinacyclobutanes. One possible mechanism is indicated, involving α-H elimination, reductive elimination, and carbene addition. The competitive formation of propene might be explained by a 1,2 hydrogen shift starting with **153** [141b]. L = pyridine, substituted pyridine.

The reactivity of ylide complexes is largely determined by the characteristics of the leaving group YR_{n+1} (HYR_n). Low basicity of the leaving group is thus responsible for the carbenoid reactivity of *O*- and *S*-ylide complexes such as $[Cp(CO)_2FeCH_2ORH]^+$ (in situ) and $[Cp(CO)_2FeCH_2SR_2]^+$ (**154**).[142] Facile synthesis and control over carbenoid reactivity by variation of R are responsible for making **154** attractive as cyclopropanation reagents. This in turn permits one to invoke *O*- and *S*-ylide complexes in place of halomethyl compounds as precursors for substitution reactions corresponding to **D** (Table 1; see, for example, Schemes 11 and 14, as well as the formation of $[\{Cp(CO)_2FeCH_2\}_2NMe_2]^+$ and $[\{Cp^*(CO)_2FeCH_2\}_2SR]^+$ from the amino- and thiomethyliron complexes, respectively).[102b, 143]

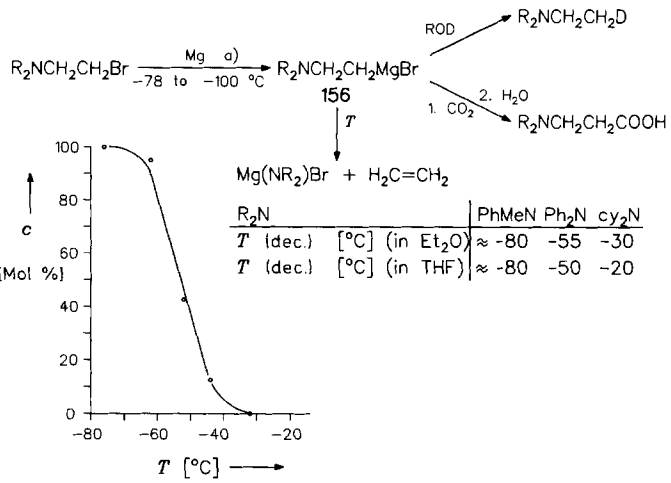
3. β-Heteroatom-Substituted Ethylmetal Compounds

3.1. Alkali-Metal and Alkaline-Earth Compounds

β-Substituted alkyllithium and Grignard reagents **155** containing a Lewis-basic heteroatom are unstable (Scheme 31).

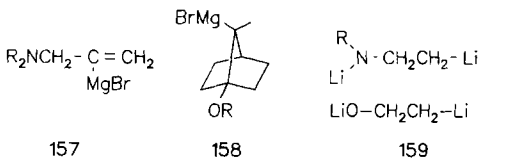
Scheme 31. M = Li, MgX; R_nY = R_2N, R_2P, RO, RS, X.

They have been assumed to arise as intermediates in reactions involving ethylene elimination,[144] and in the course of ether cleavages.[145] So far, the synthesis of **156** has only proven possible by reaction of β-bromoethylamines with highly active magnesium at temperatures between −78 °C and −100 °C. It could be shown that decomposition occurred with heterolytic fragmentation as a function of the residue R between −80 °C and −20 °C (Scheme 32).[146]



Scheme 32. Synthesis of β-aminoethylmagnesium bromides **156**. The illustration depicts the decomposition curve for $Ph_2NCH_2CH_2MgBr$ in THF as solvent [146]. a) Preparation of highly reactive Mg by reduction of $MgBr_2$ with K according to Rieke.

Stabilization of β-substituted ethyllithium and Grignard reagents can be achieved by suitable modification of the basic structure **155** (Scheme 33).[147] Crucial to increasing the stability are stereoelectronic considerations (**157**; **158**,



Scheme 33. Decomposition temperatures: **157**, greater than 20 °C; **158**, 130 °C; **159**, −60 °C.

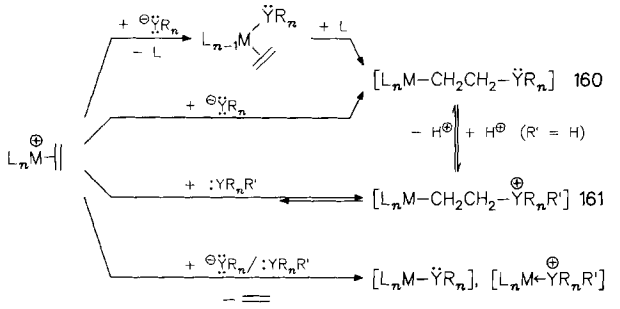
Bredt's rule), increased electronegativity at an sp^2-hybridized C atom (**157**), and, in the case of **159**, a dramatic increase in the basicity of the leaving group LiO^- vs. RO^- or $Li(R)N^-$ vs. R_2N^-.

3.2. Transition-Metal Compounds

Homoleptic transition-metal compounds are unknown, but a wide variety of heteroleptic β-functionalized ethyl tran-

sition-metal compounds has been prepared by oxidative addition of $R_nYCH_2CH_2X$.

The addition of anionic nucleophiles R_nY^- to olefin complexes, which can occur either as a one-step, intermolecular reaction or as an insertion subsequent to coordination of the nucleophile at the metal center, leads to the functionalized ethyl compounds **160** (Scheme 34). Neutral nucleophiles $R_nR'Y$ lead to the compounds **161** with a cationic center in the alkyl ligand ("onio"-ethyl complexes). Complexes **160** and **161** exist in a protonation/deprotonation equilibrium when R' = H.



Scheme 34. On the reactivity of nucleophiles toward olefin complexes. Kinetic and thermodynamic data for the conversion of $[Cp(CO)_2Fe(\eta H_2C{=}CH_2]^+$ (**162**) is summarized in Table 9.

Table 9. Kinetic and thermodynamic data for the reaction of $[Cp(CO)_2Fe(\mu^2\text{-}H_2{=}CH_2)]^+$ (**162**) with nucleophiles according to Scheme 34 [148] [a].

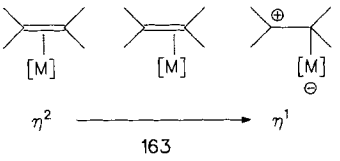
Rate of addition	$cyNH_2 > MeO^- > P(p\text{-}MeOC_6H_4)_3 > PPh_3 >$ py		
$\Delta H^{\neq}$ [kJ mol^{-1}]	52	30	31
$\Delta S^{\neq}$ [JK^{-1} mol^{-1}]	−15	−107	−108

[a] Kinetic studies on the rate of addition confirm that with MeO^- as nucleophile, desolvation makes the major contribution to $\Delta G^{\neq}$ [149]. [b] Addition to the analogous propene complex affords $[Cp(CO)_2FeCH_2CHMePPh_3]^+$, which is readily converted to $[Cp(CO)_2Fe(PPh_3)]^+$ upon cleavage of propene. [c] Dependent on the reaction conditions.

Nucleophilic addition competes with substitution of the olefin. A high degree of electrophilicity like that encountered in cationic olefin complexes favors nucleophilic addition.[150] The electron density at the olefin is also influenced crucially by the donor–acceptor characteristics of the *trans* ligand, which provides an opportunity for directing the addition/substitution competition.[151]

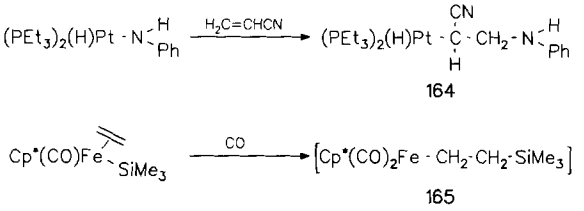
Stereochemical investigations have shown that intermolecular nucleophilic addition is a *trans* process.[152] MO calculations indicate that the LUMO of the olefin increases in energy as a result of symmetric η^2-olefin coordination to a metal-complex fragment. Moreover, activation with respect to ligand-addition reactions occurs only to the extent that the olefin is bound unsymmetrically, tending towards η^1 coordination (see **163**).[153] The insertion of an olefin is a concerted cyclic process. Model calculations on palladium complexes have shown that—consistent with experimental observations—the insertion can be regarded as an orbital-



163

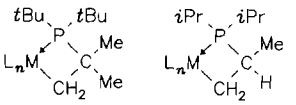
controlled reaction, whereas *trans* addition entails both orbital and charge control.[154]

In principle, olefins can also be inserted into $M–YR_n$ bonds, as demonstrated by the regioselective insertion of acrylonitrile as an olefin with an activated double bond to form Pt complex **164**,[155] as well as by the formation of **165**.[156]



164 165

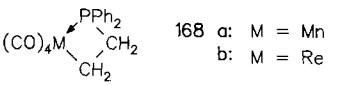
C–H activations are particularly easy to achieve in *tert*-butyl- and isopropylphosphane complexes in the form of electrophilic substitution or oxidative addition, leading to the formation of metallaphosphacyclobutanes[157] like **166** (M = Pd^{II}, Pt^{II}) and **167** (M = Ru^{II}, Os^{II}, Ir^{III}), containing



166 167

nonplanar four-membered rings.[158] The reaction is influenced fundamentally by the spatial demands of the phosphane.[159] In the case of $PtBu_2R$ complexes with long-chain R residues there is competition with a δ-C–H activation process (five-membered versus four-membered ring formation).[157b, 160]

The complex fragment $[Cp^*(PMe_3)Ir]$ reacts with *tert*-butyl amines and alcohols not through oxidative addition of the N–H or O–H bond, but rather of a C–H bond to give $[Cp^*(PMe_3)(H)Ir–CH_2CMe_2YR_n]$ (YR_n = NH_2, OH).[161]



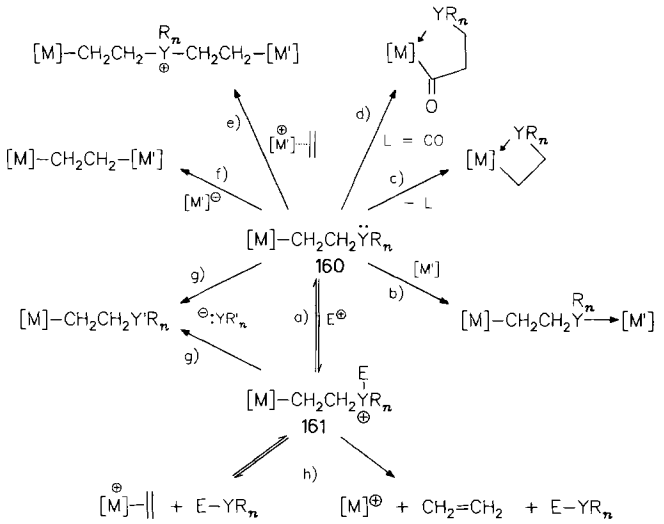
168 a: M = Mn
b: M = Re

Similarly to the formation of α-functionalized derivatives **85** and **86**, the metallaphosphacyclobutane compounds **168** can be prepared by reductive cycloelimination from β-chloroethylphosphane complexes,[81, 162] although the analogous synthesis of $[CpNiCH_2CH_2PR_2]$ proved unsuccessful.[81b] The highly strained four-membered rings in **168a** and **168b** react with SO_2 (and, in the case of **168a**, with CO and CO_2) to cause ring expansion.[163] Not only α-

aminocarboxylates (cf. **101**) but also the β-aminocarboxylates of Co(III) undergo photochemical decarboxylation with the formation of azacobaltacyclobutanes.[97]

3.3. Reactivity

β-Functionalized ethylmetal complexes **160** display in addition to a σ M–C bond with the Lewis-basic heteroelement yet another reactive center. They are accessible through the reactions in Scheme 35.



Scheme 35. Reactions of complexes **160**. a) Addition of electrophiles; b)–d) inter- and intramolecular complex formation; c) addition to olefin complexes; f) formation of binuclear complexes by oxidative addition/nucleophilic substitution; g) nucleophilic substitution; h) β-elimination of EYR_n and heterolytic fragmentation.

Reaction route a) represents the addition of electrophiles to $\ddot{Y}R_n$. Particularly important are protonation (reversible!) and alkylation of Y to "onio"-ethyl complexes.

Syntheses b)–d) involve inter- and intramolecular complexation of $-\ddot{Y}R_n$. As a result of ring expansion through insertion (of CO, for example) into the M–C bond the strain in the four-membered ring is reduced. Organometallic inner complex formation decreases the tendency toward β elimination, since the latter requires a coplanar M-C-C-H arrangement.

Route e) is the addition of **160** to metal–olefin complexes. As a result of this reaction the synthesis of **160**/**161** by addition of HYR_n to metal–olefin complexes may become difficult or impossible. Thus, $[L_nPt(C_2H_4)]ClO_4$ reacts with Et_2NH, $EtNH_2$, and NH_3 to give $[(L_nPtCH_2CH_2)_2NEt_2]ClO_4$, $[(L_nPtCH_2CH_2)_3NEt]ClO_4$, and $[(L_nPtCH_2CH_2)_4N]ClO_4$ [L_n = (tmeda)Cl].[164]

In reaction path f) oxidative addition of $X–CH_2CH_2–X$ to metal complexes give ethylene-bridged bimetallic compounds via $[M]–CH_2CH_2–X$ intermediates (example: $[Cp(CO)_2Ru–CH_2CH_2–Ru(CO)_2Cp]$).[2]

Reaction route g) is a nucleophilic substitution of ^-YR_n ($E–YR_n$), especially with $^-Y'R_n$ = Cl, Br, OR, and E–YR = HOR.

β-Elimination of $E–YR_n$ with formation of a metal–olefin complex [route h)] either involves the reverse of the reaction for synthesizing **161** in accord with Scheme 34, or heterolytic fragmentation.

Depending upon the structure of the compound there can be considerable differences in thermal stability, as illustrated by the example of the aminoethyl complexes in Table 10. The

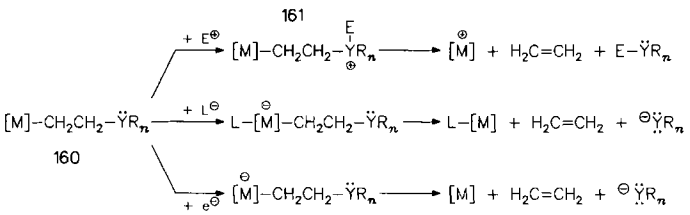
Table 10. On the thermal stability of selected β-aminoethyl complexes.

Compound	Synthesis principle	T (dec.) [°C] $-NPh_2$	$-NPhMe$	$-NC_5H_{10}$	Ref.
169 $Na[pcFeCH_2CH_2NR_2]\cdot x$ thf [a]	**B**	>100	>100	>100	[165a]
170a $[pcFeCH_2CH_2NR_2]\cdot 1/4$ thf	[b]	181	142	114	[165b]
170b $[pcCoCH_2CH_2NR_2]$	**B**	212	180		[165c]
156 $R_2NCH_2CH_2MgBr$	[c]	−50 [d]	−80 [d]	−20 [d, e]	[146]

[a] x = 3–5. [b] Oxidation of **169** with trityl chloride. [c] Cf. Scheme 32. [d] In THF as solvent. [e] R_2N = cy_2N.

exceptionally high stability of the phthalocyanine complexes **169** and **170** can be attributed to strong M–N bonds in the complex, which block all the coordination positions in the vicinity of the M–C bond. Thus, H elimination and bimolecular reactions are effectively ruled out as decomposition processes with low energies of activation. Comparison of the phthalocyanine derivatives **169** and **170** with the Grignard reagents **156** clearly reveals the influential role of the nature of the M–C bond on stability.

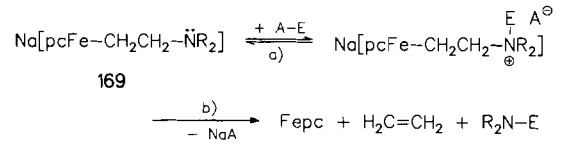
Heterolytic fragmentation can be induced in three ways (Scheme 36), namely, 1) by increasing the positive charge on the heteroatom Y through protonation, alkylation, or reaction with other electrophiles;[165, 166] 2) by introduction of a



Scheme 36. Fragmentation reactions of the ethyl complexes **160**.

ligand with a strong *trans* effect (e.g., OH^-, CN^-) in a position *trans* to the alkyl ligand;[167] or 3) by reductive M–C bond cleavage.[168] Thus, the tendency toward elimination of, in the case of 1), the nucleofugal group and in the case of 2) and 3), the electrofugal group, as a result of weakening the M–C bonding, is increased.

ROH and R_2NH have been particularly thoroughly investigated as nucleofugal leaving groups, and cobaloximes, cobalamines, and metallophthalocyanines as electrofugal leaving groups. Thus, the exceptionally stable β-aminoethyl(phthalocyanine)iron(II) complexes **168** undergo heterolytic fragmentation upon treatment with electrophiles (Scheme 37). The rate of decomposition is a function both of the position of equilibrium a) and of the nature of the actual fragmentation reaction b). It increases with increasing elec-



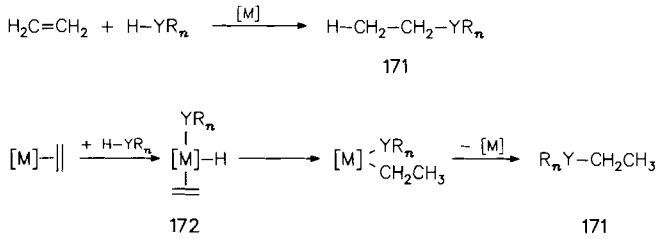
Scheme 37. Heterolytic fragmentation of the phthalocyanine complexes **169**. The reaction rate depends on the electrophile A–E (MeI < MeOH ≈ MeC(O)Cl < $C_7H_7SO_3H$) and on the amino group $-NR_2$ (NPh_2 ≪ NPhMe < NC_5H_{10}).

trophilicity of the attacking agent and with increasingly high nucleophilicity or basicity at the nitrogen of the aminoethyl ligand.[165a] The Fe^{III} and Co^{III} compounds **170** react analogously.[165b, c]

A technique for removal under mild conditions of *C*- and *N*-terminal protecting groups in peptide synthesis is based on the reductive cleavage of M–C bonds in *β-O*-functionalized ethyl(phthalocyanine)cobalt(III).[168a, 169] Reductive cleavage can also be accomplished electrochemically by the use of catalytic amounts of cobalt phthalocyanine.[168b]

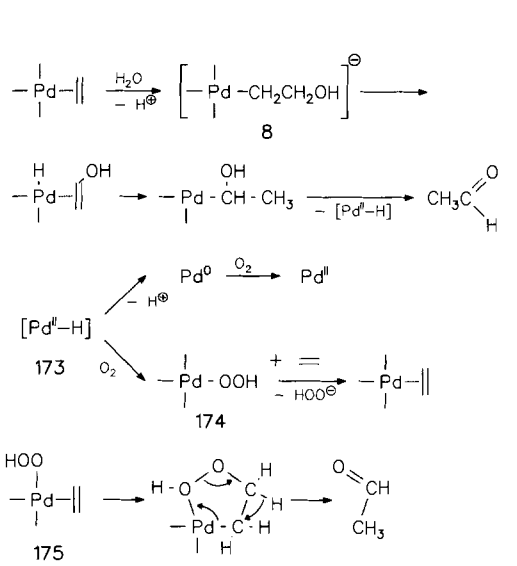
3.4. Catalytic Aspects

In the present understanding of the mechanisms of metal-complex-catalyzed functionalization reactions of unsaturated olefins (Scheme 38, top), three principle routes need to be considered: 1) intermolecular addition of HYR_n to an olefin activated by complex formation (cf. Scheme 34), 2) insertion of an olefin into an M–YR_n bond (cf. Scheme 34), and 3) a sequential insertion–elimination (Scheme 34, bottom). The intermediates in mechanisms 1) and 2) are *β*-functionalized alkyl complexes.



Scheme 38. Functionalization reactions of olefins, illustrated with the example of ethene.

Palladium-catalyzed oxidative functionalization of ethylene with H_2O or HOAc for the synthesis of acetaldehyde and vinyl acetate, respectively, proceeds by way of *β-O*-functionalized alkylpalladium compounds. Results of kinetic and stereochemical investigations of the Wacker process are consistent with an intermolecular addition of H_2O to an ethenepalladium complex with the formation of **8** as an intermediate (Scheme 39). It is not yet certain to what extent the palladium hydride **173** formed by elimination of acetaldehyde then decomposes to Pd^0, to be subsequently reoxidized, or forms the palladium hydroperoxide complex **174** by O_2 insertion.[8] In principle, closure of the C–O bond might also occur through **175**, a suggestion supported by investigations with radioactively labeled oxygen.[8b]

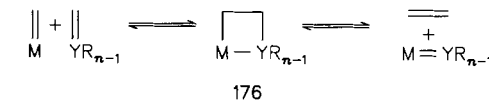


Scheme 39. On the mechanism of the Wacker process.

The mechanism of transition-metal-catalyzed olefin amination (Scheme 38 top: H–YR_n = H–NR_2)[170] and aminomethylation (Scheme 38 top: H–YR_n = H–CH_2NR_2)[171] has not been established (cf. the review in [172]). Intermolecular amine addition with the formation of *β*-amino- or *β*-ammonioethyl complexes is a possibility in the case of rhodium-catalyzed amination, as already demonstrated for the stoichiometric (!) amine additions to olefin complexes of Pt and Pd. In principle Ir complexes are also capable of undergoing N–H addition[173] and olefin insertion into an Ir–amide bond,[155] so an insertion/elimination mechanism cannot be ruled out.

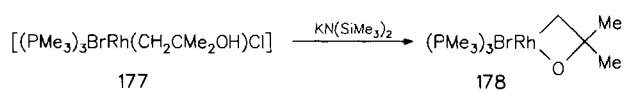
Both insertion/elimination and insertion mechanisms have been discussed for hydrosilylation (Scheme 38 top: H–YR_n = H–SiR_3), corresponding to C–Si bond formation by reductive elimination of Et–SiR_3 from an ethylsilylmetal complex or insertion of ethene into an M–Si bond.[174]

Metathesis reactions might proceed as [2 + 2] cycloadditions by way of metallacyclobutane intermediates such as



176 (YR_{n-1} = O, NR, CR_2). This has been clearly demonstrated in the case of olefin metathesis (YR_{n-1} = CR_2).[175] Metallaoxetanes (YR_{n-1} = O) have been assumed to be intermediates in metal-assisted or metal-catalyzed oxidations and oxygen-transfer reactions,[176] processes that are extremely important not only in organic synthesis (e.g., oxygenation of olefins according to Sharpless and the Tebbe–Grubbs procedure for deoxygenation of carbonyl compounds) but also in biochemistry (e.g., oxidations catalyzed by cytochrome P-450).

Metallaoxetanes are accessible from metal alcoholates through C–H activation,[177] or from *β*-hydroxyalkyl com-

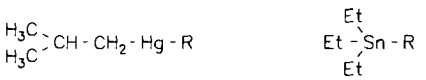


pounds via O–H activation, (**177** → **178**).[178] The four-membered ring in **178** is planar. The relatively short bond lengths for Rh–C (206.9(10) pm in **178** and 213.1(8) in **177**) and C–O (141.6(12) pm in **178** and 145.2(9) in **177**) suggest polarization in the direction metal carbene complex/ketone (see **179**).[178]

179 a 179 b

4. Electronic Characteristics of Functionalized Alkyl Ligands

Important electronic characteristics of ligands are reflected in their electronic influences. This applies specifically to the ability of a ligand L in a complex LML'_x to influence via the central atom other metal–ligand bonds M–L' or the other ligands L' themselves (in their ground state![179]). Such effects have direct consequences for the chemical, physical, and spectroscopic properties of complexes. They also play a significant role in complex-chemical activation or stabilization of ligands, and in ligand-dependent control over reactions catalyzed by metal complexes.[180–182]



180 181

The electronic influence of L is primarily a feature of L itself, but it also depends upon a number of other very complex and diverse factors. Neglecting all differences related to the types of complexes investigated and to the experimental methods enables a universal parameter P_{trans} for characterizing the *trans* influence to be derived.[183] This points to the potentially very considerable electronic influence of σ-organo ligands that results from the low electronegativity of carbon.

The electronic influence of the σ-organo ligand R on the isobutylmercury and triethyltin compounds **180** and **181** has been characterized by NMR spectroscopy on the basis of $^1J(^{199}Hg,^{13}C_{iBu})$ and $^1J(^{119}Sn,^{13}C_{Et})$ in a consistent and theoretically well-founded way.[184] Here the magnitude of the coupling constant is a measure of the s character of the metal hybrid orbital directed toward the indicator ligand (Me_2CHCH_2 or Et). According to Bent's rule[186] the s character of this orbital decreases with increasing donor character of R. This in turn reduces the coupling constant, so that the latter indeed reflects the electronic influence of R. The accuracy of such predictions in the case of the compound types investigated (for an analysis of other metal alkyls cf. Steinborn et al.[187]) is demonstrated by the validity of Equation (a).[184]

$$1/n \sum_{i=1}^{n} J^i/J^i_s = 1 \qquad (a)$$

$J^i = {}^1J(M,{}^{13}C)$ in **180** and **181**; $J^i_s = {}^1J(M,{}^{13}C)$ in the corresponding symmetrically substituted compounds $[R_2Hg]/[iBu_2Hg]$ and $[R_4Sn]/[Et_4Sn]$; M = ^{199}Hg, $n = 2$; M = ^{119}Sn, $n = 4$. For **180** these conclusions are also supported by pseudopotential ab initio calculations on the compounds [Me–Hg–R].[188]

Figure 2 depicts series of electronic influences for ligands R that have been established according to this theoretically sound procedure.[184] Both series provide as a crude classification of the ligand influence the sequence alkyl > alkenyl ≈

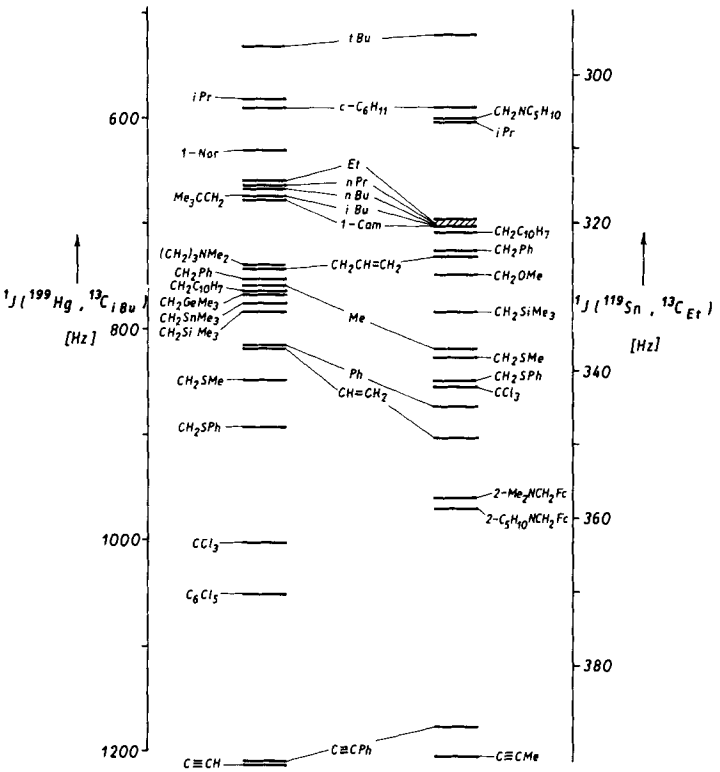


Fig. 2. Electronic influence of R in **180** (scale on the left) and **181** (scale on the right) based on the coupling constants $^1J(^{199}Hg,^{13}C_{iBu})$ and $^1J(^{119}Sn,^{13}C_{Et})$, respectively [184a,c,e, 185]. 1-Nor = 1-norbornyl; 1-Cam = 1-camphenyl; $CH_2C_{10}H_7$ = α-naphthylmethyl; 2-R_2NCH_2Fc = 2-(aminomethyl)ferrocenyl.

aryl > alkynyl, that is, $sp^3 > sp^2 > sp$, though this sequence is subject to some modification as a consequence of secondary effects. Certain calculated and experimental quantities for σ-organo residues are observed to follow similar trends,[1d] including the s character of the valence-hybrid orbitals, the electron affinities of the corresponding radicals, the ionization potentials of the anions, the electronegativities of R, and the acidities of RH, but in none of these cases is there a rigorous correlation over the complete range of investigated organo ligands. This is due to the specificity of metal–ligand bonding and the variation in donor–acceptor characteristics of the metal-complex fragments ML'_x to which R is bonded.

The relationship between the tin compounds **181** and the group electronegativity χ is shown in Figure 3.[182] This is an especially important model quantity, and it can be interpreted as a measure of σ-donor strength. Within the confines of the parent systems (Et, $CH{=}CH_2$, Ph, C≡CH) and the simple alkyl residues (Me, Et, *n*Pr, *i*Pr, *n*Bu, *t*Bu) there is a consistent, but inverse, correlation. Deviations point to peculiarities in bonding characteristics that are also apparent in

a comparison of the electronic ligand influences of R in **180** and **181**.[182]

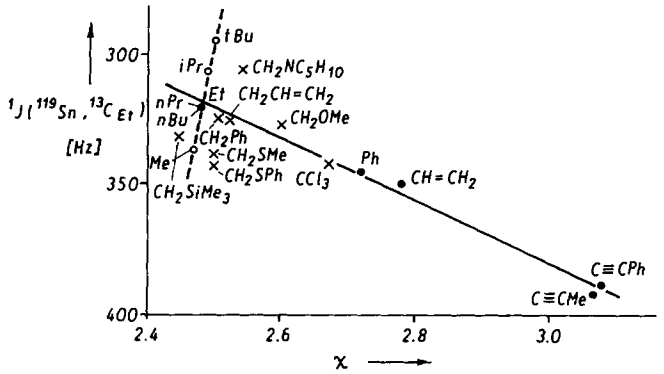

Fig. 3. Dependence of the coupling constant $^1J(^{119}Sn,^{13}C_{Et})$ as a measure of the electronic influence of ligand R in **181** on the electronegativity χ (based on Inamoto) of R [182].

Inconsistencies are particularly striking in the case of the allyl and benzyl ligands, as well as with functionalized methyl ligands whose π or n electrons are capable of entering into conjugative interaction with electrons from the M–C bond (conjugation of the σ–π or σ–n type, or negative hyperconjugation[189]). This is underscored by quantum-chemical calculations, according to which methyl anions are significantly less stabilized by elements of the first complete row (NH_2, OH, F) than by elements of the second row (SiH_3, PH_2, Cl) (see Figure 4).[190] Such results are due largely to

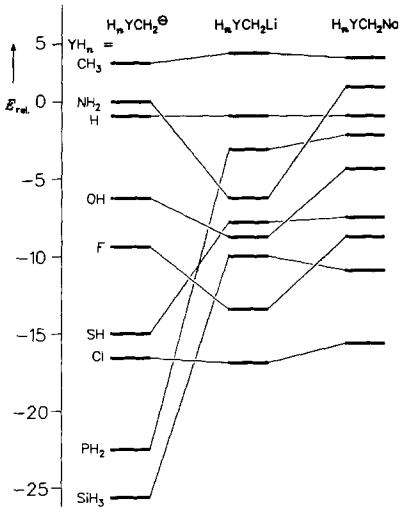

Fig. 4. Comparison of the stabilization energies $E_{rel.}$ of functionalized methyl anions with the corresponding functionalized methyllithium and methylsodium compounds [190].

greater polarization and more strongly developed negative hyperconjugation, and not to a d-orbital contribution. Moving to lithium compounds effectively reduces this additional stabilization. Stabilization of organo alkali-metal-compounds is largely a consequence of the formation of bridged structures (η^2-coordination), which are more prevalent for M = Li than for M = Na. The influence of the heteroatom is also reflected in the thermodynamic stability of lithium compounds, as indicated by investigations into variously substituted alkoxymethyllithium compounds.[191]

The two series of electronic influences shown in Figure 2, which are among the most extensive of their type, facilitate meaningful classification and characterization of a large number of σ-organo ligands in terms of their electronic influences on the basis of a theoretically grounded physical parameter. Such results provide an important foundation for judging structural and bonding effects in organometallic compounds generally.

5. Future Prospects

A geminal or vicinal arrangement of carbanion-like species and heteroatom centers in structural units such as M–CH_2–Y or M–CH_2–CH_2–Y leads to unusual bonding and stability relationships as well as to new types of reactions for complexes.

By contrast, the inductive effect of a heteroatom on the M–C bond is small in the case of the homologous γ- and δ-functionalized alkylmetal compounds. At the same time, 1,ω-eliminations with the formation of cyclopropane/propene or cyclobutane/butene[192] make way for the classical decomposition pathways of alkylmetal compounds.[1] When Y is coordinated to M the result is a five- or six-membered chelate ring, which generally leads to stabilization, permitting, for example, the synthesis of homoleptic γ-aminopropyl transition-metal complexes of Zr, Cr, Mn, and Co[193] as well as advantageous application of γ-aminopropylgallium and -indium compounds in MOVPE processes (MOVPE = *m*etal *o*rganic *v*apor *p*hase *e*pitaxy).[194]

There still remain a great many white (and gray) areas on the "topographic map" of alkylmetal compounds. Complexes with heavier heteroatoms, for example, have been investigated only to a limited extent. These might well prove to be a source of new aspects of reactivity, due in the case of α-stannylmethyl compounds to relatively facile electrophilic cleavage of the Sn–C bond. For example, R_3SnCH_2Li—in contrast to R_3SiCH_2Li—behaves as the equivalent of CH_2^{2-}.[195]

Completion of systematization with increasing reference to more complex systems, more thorough elucidation of the relationships linking structure with reactivity, and a more sophisticated theoretical foundation particularly for the electronic influences of the heteroatom on the M–C bond are certain to bring to light much that is new in this important and interesting area of organometallic chemistry.

[179] The electronic influence is more narrowly specified as a *trans* (*cis*) influence in the case of a mutual *trans* (*cis*) arrangement of the influencing and affected ligands. This is to be distinguished from the electronic effect (*trans*/*cis* effect), which describes the impact of L on the reaction rate of a ligand-substitution reaction of the type L–[M]–L′ + L″ → L–[M]–L″ + L′. With the electronic effect, the impact of L is thus reflected in both the ground state *and* the transition state [180,181].

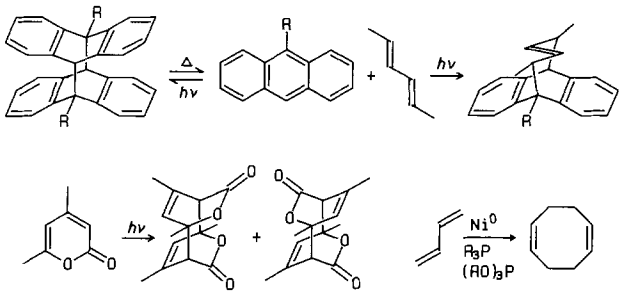
[4 + 4]-Cycloaddition Reactions in the Total Synthesis of Naturally Occurring Eight-Membered Ring Compounds

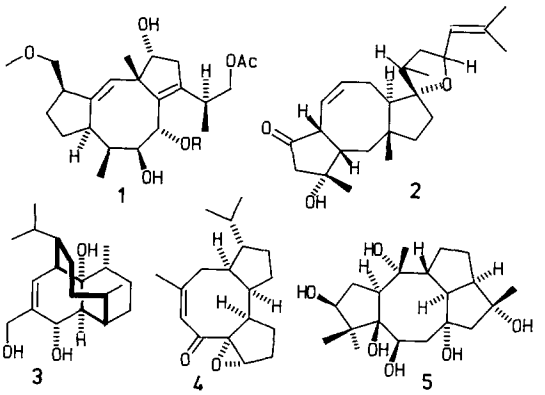
By *Gerd Kaupp**

Eight-membered rings can be obtained by [4 + 4]-cycloadditions of 1,3-dienes[1] via diradicals or other intermediates. Synthesis of such compounds has been achieved by thermal,[2] photochemical,[3] and by metal-catalyzed[4] processes: these reactions have been the subject of extensive mechanistic studies.[5] The thermal version has generated little interest, except in the case of cycloreversion; the Cope rearrangement of 1,2-divinylcyclobutanes[3] is more commonly used. [4 + 4]-Cycloadditions are also used with 1,3-dipoles or mesoionic heterocycles for the synthesis of six- and seven-membered rings, and also for [6 + 4]-cycloadditions.[2b] Good yields can be obtained with the photolytic reaction when the 1,3-diene is fixed in the *s-cis* configuration. Such is the case for, amongst others, condensed arenes, α-pyrones, and 2-pyridones. Two coupled, linear [4 + 4]-cycloadditions lead to ten-membered rings.[2e] Catalysis by Ni^0 is the obvious method of choice for open-chain 1,3-dienes, favorable coordination (template effect) apparently solving the difficult problem of bringing the terminal groups of the bis-1,3-diene into contact. The choice of typical examples given in Scheme 1 shows that one, two, or four eight-membered rings, which are not connected by zero bridges, can be formed by [4 + 4]-cycloadditions.

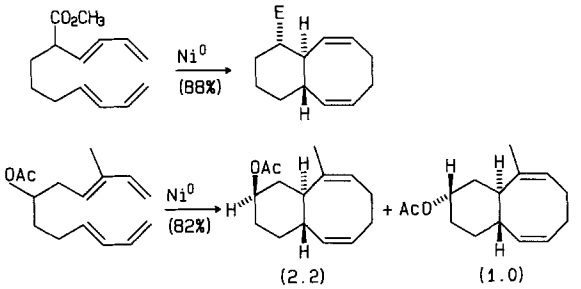


Scheme 1.

Cyclooctanoids (eight-membered ring compounds) can also be found among biologically active natural products such as sesqui-, di-, and sesterterpenes, as well as non-terpenoids. The total synthesis of such compounds has been a challenge for many research groups for years. In spite of intensive efforts, the total synthesis of the chemotherapeutic taxol **13** has not yet been achieved. Less highly functionalized analogues of taxol, which also inhibit the depolymerization of tubulin,[6] are now being prepared. In addition to taxol **13**, some of the best known naturally occurring cyclooctanoids include fusicoccin A (**1**), ophiobolin A (**2**), vinigrol (**3**), epoxybasmenone (**4**), kalmanol (**5**), (+)-asteriscanolide (**8**), crispolide, vulgar olide, cotylenin, variecolin, pleuromutilin, taxusin, and others.



Strategies have been developed for the synthesis of these compounds, in some cases successfully, that do not depend on [4 + 4]-cycloaddition for formation of the eight-membered ring. The concern, unjustly, was that the control of the regio- and stereoselectivity would not be possible and that cross-dimerization with substituted 1,3-dienes would lead to poor yields. Original German work was apparently not so



Scheme 2.

accessible in the United States, so that exchange of information concerning cycloaddition strategies in the synthesis of natural products containing eight-membered rings was very slow. It was not until 1986 that Wender et al. at Stanford showed[7] that it was possible to conduct stereoinduced Ni^0-catalyzed [4 + 4]-cycloadditions, even in the presence of oxygen-containing substituents (Scheme 2). Thereafter, the same group achieved the enantioselective synthesis of the cyclooctanoid **8**, a sesquiterpene.[8] With this approach they also plan on exploring further possibilities for the synthesis of cyclooctanoid diterpenes of the taxane series, such as **13**.[9] The key step in the synthesis of **8** was the Ni^0-catalyzed intramolecular [4 + 4]-cycloaddition of **6** (accessible in 11% yield from acrolein in nine steps) to give **7** in 67% yield (leading to a 36% yield of **8** in three further steps): a satisfyingly short and elegant total synthesis.

[*] Prof. Dr. G. Kaupp
Fachbereich 9 – Organische Chemie I – der Universität

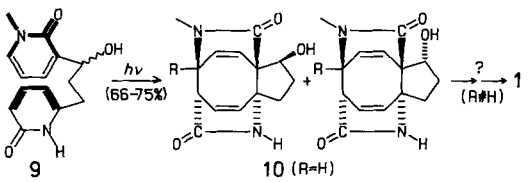
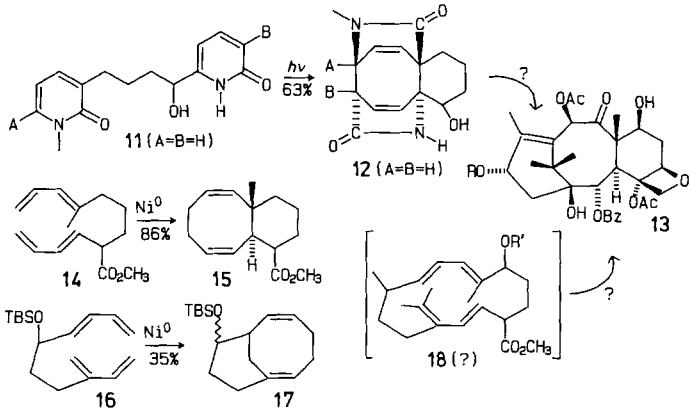
Presumably stimulated by the success of template-controlled syntheses, Sieburth et al. in Stony Brook hoisted the flag for photochemical metal-catalyzed stereoselective [4 + 4]-cycloadditions.[10] This case requires, of course, that two *s-cis*-constrained dienes are connected to each other. The choice thus fell on 2-pyridones. Target molecules are fusicoccin **1** and the cancer chemotherapeutic agent taxol **13** (cf. ref. [6]). The 3,6-bis(2-pyridone) **9**, used as the racemate but undoubtedly separable into the enantiomers, provides favorable prerequisites for the [4 + 4]-photocycloaddition. The nitrogen atoms, the carbonyl groups, and the double bonds are so arranged that further reaction to give **1** by standard methods appears to be possible. Indeed, the epimers **10** were formed by photolysis in good yield (66 and 75%). Moreover, suitable choice of solvent (protic or aprotic) even allowed preferential formation of one of the epimers. What is unfortunately still lacking is a suitable substituent R that can be employed for formation of the other 5-membered ring in **1**, without impeding the photoreaction: an interesting interim result.



Sieburth et al. also photolyzed the racemic 3,6-bis(2-pyridone) **11**, in which the two rings are connected by a four-membered chain, obtaining both epimers of the secondary alcohol **12** (2:3, 63%). A certain resemblance to taxol **13** is clearly present, but there is still a long way to go. For example, a hydroxyl group is required at the other end of the bridging chain, B should be preferably a methyl group, and a suitable substituent A must be found that allows cyclization to the additional six-membered ring in **13**. Alternatively, it would be better if the methoxymethyl-substituted five-membered ring was already present on the *N*-methylpyridone ring. This interim result must be compared with that from Stanford in 1987, in which the [4 + 4]-cycloaddition was catalyzed with Ni^0.[9] Using conversion of **14** to **15** and **16** to **17** as model reactions allows the eight-membered ring and each of the two six-membered rings to be constructed, although not simultaneously (Scheme 3). A starting compound such as **18**, in which both possibilities are combined, and from which conversion to **13** is feasible with standard reactions after treatment with Ni^0, is not yet known. (A starting material similar to compound **16** was used in work recently published.[11] This starting compound, however, contains a methyl group at C4 and the *tert*-butyldimethylsiloxy group has been shifted from C5 to C7. This could, in connection with the [4 + 4]-cycloaddition (74%), possibly lead to crispolide, but neither this "model" nor **16** is suitable for synthesis of taxol **13**).



Scheme 3. TBSO = *tert*-butyldimethylsiloxy.

Although Sieburth et al. have not yet reached their goal, their results have nevertheless provided vital new impetus for the total synthesis of naturally occurring cyclooctanoids. The most suitable cycloaddition strategy in each case stands or falls with the accessibility of the bis-diene required. It should always be attempted, by means of stereoselective cycloaddition, to save steps in a total synthesis. The foundation for the application of [4 + 4]-cycloaddition for the most varied experimental conditions already exists. One should also not forget, that *cyclovinylogous* additions[5b] contain still further ideas for saving synthetic steps. For example, eight-membered rings can also be constructed by [2 + 2]-cycloaddition of cyclobutenes or of alkynes to (hetero)cyclohexenes or arenes followed by further ring expansion.[3a, 12] Diels–Alder reactions between components connected by a bridging group with six carbon atoms lead to cyclooctanone-annelated cyclohexenes.[13] Further perspectives for the synthesis of natural products are opened up by the cyclovinylogous [6 + 4]-[2b, 5b] (for ten-membered rings, see **3**, **13**, pleuromutilin), [6 + 6]-[14] and [4 + 4 + 4]-additions[4] (twelve-membered rings, see **5**), are often investigated in parallel with the [4 + 4]-additions. Thus, synthesis strategies aimed at the largest ring present containing no zero bridges should definitely also be considered. The work of Wender[7–9] and Sieburth[10] appears to illustrate a renaissance of cycloaddition reactions of polyenes, with very promising potential.

[Ni(P*t*Bu)$_6$]—a Strain on the 18 Electron Rule? **

By *Kurt Dehnicke**

The 18e rule already established in 1927 by Sidgwick has proved to be extremely successful for the understanding of the constitution, structure, and chemical reactions of simple, especially organometallic complexes and has contributed considerably to the development of organoelement chemistry. In the 18e rule the valence electrons of the central atom and the sum of the electrons participating in the bonds of the ligands to the central atom are added together. If the total is 18 electrons, then the compound has achieved the electron configuration of the next noble gas atom and at the same time is diamagnetic. The stability maximum connected with this can be understood from MO theory: All 18 electrons are placed either in bonding or in the most unfavorable case also in nonbonding molecular orbitals. Examples for this are the tetrahedral complexes nickel tetracarbonyl (**1**), the trifluorophosphane derivative (**2**) which is accessible from **1** by ligand exchange, and **3** only recently prepared from the reaction of bis(cyclooctadiene)nickel with phosphabenzene.[1] The total of 18 electrons in these complexes results from the 10d electrons of the nickel atom and a total of eight electrons from the four ligands.

$[Ni(CO)_4]$ **1** $[Ni(PF_3)_4]$ **2** $[Ni(PC_5H_5)_4]$ **3**

However, exceptions to the 18e rule soon became known, such as the V complex **4** with 17e, the Co complex **5** with 19e, and the Ni sandwich complex **6** with 20e constructed analogously to **5**.

$[V(CO)_6]$ **4** $[Co(C_5H_5)_2]$ **5** $[Ni(C_5H_5)_2]$ **6**

[*] Prof. Dr. K. Dehnicke
Fachbereich Chemie der Universität Marburg
Hans Meerwein-Strasse, D-W-3550 Marburg (FRG)

All these complexes (**4**–**6**) are paramagnetic and show a strong tendency to achieve 18 valence electrons: **4** gains an electron to form the $[V(CO)_6]^-$ ion and **5** loses an electron to give the very stable cobaltocenium ion $[Co(C_5H_5)_2]^+$.[2] Complex **5** is also used preparatively as a reducing agent.[3] The decamethyl-substituted derivative of **6** can be oxidized under certain conditions to the dication with 18 valence electrons.[4]

Based on the 18e rule, Wade[5] and Mingos[6] later established the counting rules for cluster molecules. These proved particularly successful for the understanding of the electronic and framework structures of boranes and carboranes and made predictions concerning the *closo* (closed), *nido* (nest), and *arachno* (spider) structures possible.

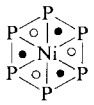
None of these well-tried rules can be applied to the very recently synthesized nickel complex **7**.[7] According to the

$[Ni(PtBu)_6]$ **7**

crystal structure analysis, the nickel atom of **7** sits in the middle of a near-planar P_6 ring in which the *tert*-butyl groups almost envelop the Ni atom above and below the $[NiP_6]$ plane. Compound **7** is stable at room temperature, diamagnetic, and slowly decomposes in solution to Ni and $(PtBu)_4$. A simple count leads to 22 valence electrons. The results of a standard ab initio calculation[7] carried out very carefully are in excellent agreement with the data from the crystal structure analysis. The P–P distances in the P_6 ring are approximately 8 pm longer than in noncomplexed phosphacycles; also the Ni–P distances are somewhat longer than expected.[8] This fits well to the relatively large spatial requirement of the Ni^0 atom. Furthermore, the Ni atom is in close contact with the six P–P σ bonds of the "P_6 life bouy" and contributes to the extension of the P–P bond through the back bonding from the d_{xy} and $d_{x^2-y^2}$ atomic orbitals into the antibonding e* molecular orbitals of the P_6 ring. How-

ever, the effects of the electron correlation are especially important for the stability of **7**. Apart from the $3d^{10}$ electrons of the Ni atom and the electrons in the six σ P–P molecular orbitals it is the six free electron pairs of the phosphorus atoms (sometimes adding up to a total of 34e!), which participate in the "strong-correlated motion". The influence of the *tert*-butyl groups planarizing the P_6 ring which prepares the ring for the inclusion of the Ni atom is also important. $(PtBu)_6$ in the free state is unknown. According to the ab initio calculation $(PtBu)_6$ should have a near-planar P_6 ring due to the spatial requirement of the *t*Bu groups. The calculations for $(PMe)_6$ showed a strongly puckered P_6 ring with a chair conformation.[7] The spatial requirement of the *tert*-butyl groups can be fulfilled more easily for $(PtBu)_4$ than for $(PtBu)_6$. According to a crystal structure analysis,[9] which is in good agreement with the ab initio calculation,[7] $(PtBu)_4$ contains a nonplanar P_4 ring. This explains why **7** does not decompose to Ni and $(PtBu)_6$ but instead to the tetramer. It has to be noted that the planarizing effect of the *t*Bu groups still has an effect on the structure of $(PtBu)_4$, which among the six known cyclotetraphosphanes shows the smallest P–P torsion angle of 24.5°. [9]

The contribution, which the *t*Bu groups enveloping the Ni atom are able to provide for the stability of **7** towards the decomposition (with the loss of metallic Ni (428 kJ mol^{-1})), can be understood if it is assumed that three H atoms each of the three Me groups of the six *t*Bu moieties above and below the $[NiP_6]$ plane in alternating sequence point at the $[NiP_3]$ segments (Scheme 1). Thus the nickel atom in **7** is coordinated analogously to the cubic close packing of metallic Ni so that it can "feel at home".



Scheme 1. Schematic representation of the Ni complex **7**. The filled and empty circles show the position of the H atoms of *t*Bu groups above and below the P_6 ring, respectively.

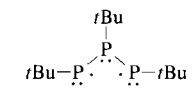
The structure and bonding of **7** are unusual and the method of its synthesis was also unexpected. Apparently due to a labeling mistake the ampule that was thought to contain $PtBu_3$ and was to be used for the peripheral protection in the construction of the nickel clusters[10] actually contained $(PtBu)_3$! Thus, **7** was formed according to Equation (a) in a

$$NiCl_2 + 2(PtBu)_3 \xrightarrow[-ClSiMe_3]{P(SiMe_3)_3} \underset{\mathbf{7}}{[Ni(PtBu)_6]} \qquad (a)$$

redox reaction with the ring opening of the P_3 ring. The product corresponds to a template reaction of Ni^0.

A further product of the ring opening of the P_3 ring of $(PtBu)_3$ could be obtained by the reaction with **1**, which led to the nickel cluster **8**. Besides three :P*t*Bu groups (4e donor) which bridge the nickel atoms, this also contains the open-chain ligand group **9** (8e donor) as a bridging ligand.[6]

$[Ni_5(CO)_5(PtBu)_3(P_3tBu_3)]$ **8**



9

A dimerization of **9** in the presence of naked Ni atoms makes the formation of **7** easy to understand. Since it is known that **1** is not a good precursor for Ni atoms, $[Ni(cod)_2]$ would have been a better partner for the synthesis of **7**!

What consequences could that have for the 18e rule? Well, on closer inspection it proves to be very durable. If it is assumed that the four additional electrons in **7** occupy the antibonding doubly degenerate HOMO of the NiP_6 group, then this would partially compensate for the bonding effect of the highest occupied HOMO of the same symmetry. The result is then only a weakening of the Ni–P bonds which is alleviated by the described correlation effect and by the shielding effect of the *t*Bu groups.

The hopes remain that soon the higher homologue of **7**, namely $[Pd(AstBu)_6]$, will be synthesized.

Spectral Hole Burning at Room Temperature and with a Single Molecule: Two New Perspectives**

By *Christoph Bräuchle,**

Although the first experiments concerning spectral hole burning were conducted almost 20 years ago, this field still surprises with new and fascinating results and developments. This may be due to the deep insights into the electronic structure of molecules in solids that can be gained by the high spectral resolution, and the ready application of these fundamental scientific findings in high technology areas such as optical storage. The two phenomena which are discussed in this contribution, namely spectral hole burning at room temperature and spectral hole burning with a single molecule, show this dual significance and were presented at an international conference entitled "Persistent Spectral Hole Burning: Science and Applications" in September 1991 in Monterey, California.

The principle of spectral hole burning is represented schematically in Figure 1.[1] Dye molecules embedded in a solid matrix (crystal or amorphous solids such as polymers and glasses) have different environments, and therefore different local fields. This leads to a distribution of the absorption

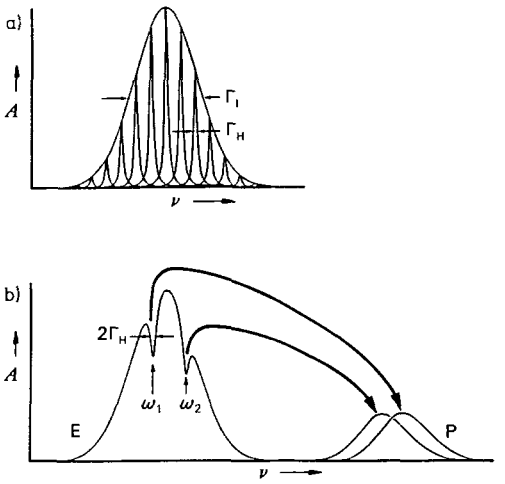

Fig 1. Principle of spectral hole burning. Absorption band a) before the burning, b) after the burning with the frequencies ω_1 and ω_2. A: absorption; ν: frequency; E: starting material; P: product; Γ: line width.

frequencies for the dye molecules, in which the various frequency packets are characterized by their homogeneous line widths Γ_H. The envelope of all frequency packets observable in the experiment is the inhomogeneous broadened absorption band of width Γ_I. At liquid helium temperatures ($T \leq 4.2$ K) the homogeneous line width Γ_H of zero phonon transitions (pure electronic transitions of the molecules without the participation of the phonons of the surrounding solid) becomes very small (10^{-4}–10^{-1} cm^{-1}), whereas the inhomogeneous line width Γ_I remains large (100–1000 cm^{-1}) and many (10^3–10^6) frequency packets are hidden beneath the inhomogeneous absorption band.

The most interesting spectroscopic information about the molecules is contained in the homogeneous absorption bands (their position, width, and form). Thus, for instance, the effective relaxation time T_2 can be obtained directly from Γ_H, which consists of the lifetime of the excited state T_1 and the pure phase relaxation time T_2^* in accordance with $\Gamma_H = 1/(\pi T_2) = 1/(2\pi T_1) + 1/(\pi T_2^*)$. Based on the assumption that spectral diffusion (structural relaxation processes between the burning of the hole and its detection, see discussion below) does not lead to an additional broadening of the hole, the homogeneous absorption band can be obtained from a hole burning experiment. For this, the probe is irradiated with an extremely narrow-band laser ($\Delta\omega \ll \Gamma_H$), so that only one frequency packet absorbs photons. The excited molecules can undergo photochemical reactions (e.g. proton tautomerism in the case of the free base of phthalocyanine dyes), in which their absorption frequency changes. Due to the transition of these molecules from starting materials to products, a spectral hole occurs by the recording of a new absorption spectrum. This is a "negative" of the corresponding absorption band of the frequency packet (Fig. 1b).

However, the burning of a spectral hole does not necessarily require a photochemical reaction, but is also possible photophysically, for example by a change of the state of a so-called *T*wo-*L*evel *S*ystem (TLS). A TLS may correspond to the motion of a segment of a polymer chain or the breaking and forming of a hydrogen bond. Both of these can be characterized by the two energy levels of a double-well potential. There is a large distribution of TLS with different energies and transition probabilities as a result of the many different degrees of freedom especially in an amorphous solid. When embedded molecules interact with such TLS and if these change their state as a result of irradiation, then the absorption frequency of the molecules is shifted, and a spectral hole is detected in the original position. The process can also be considered as a reorientation in the environment of the molecules, without the molecules themselves being changed photochemically.

From this description it becomes clear that spectral hole burning provides information not only about the molecules themselves but also in particular about their environments. Thus, the molecules are probes with which the surrounding solid can be scanned. This becomes especially fascinating when the hole burning is achieved with a single probe molecule. This aspect is the topic of the second part of this contribution. First the application-oriented side of spectral hole burning shall be discussed.

Already in 1978 a high-density optical storage device was proposed on the basis of the permanent spectral hole burning as "Frequency Domain Optical Storage" (FDOS).[1, 2] An overview of the optical and magnetic storage methods and the corresponding storage densities in bit per cm^2 and bit per cm^3, respectively, is given in Figure 2. From this it can be seen that data pit memories already on the market and

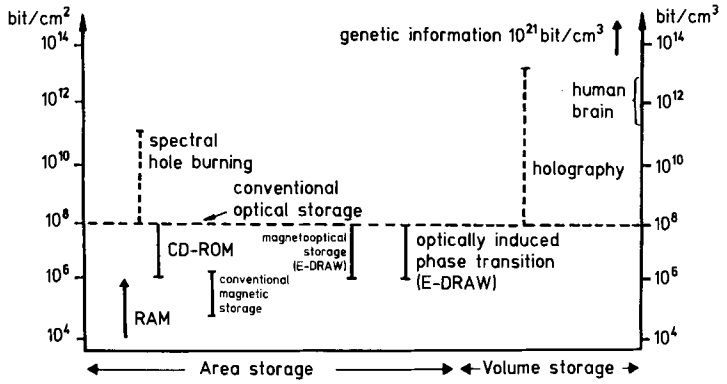

Fig. 2. Overview of the storage methods and their corresponding storage densities. Left axis for area storage, right axis for volume storage.

conventionally referred to as optical, CD-ROM (*C*ompact *D*isk *R*ead *O*nly *M*emory) and the reversible magnetooptical E-DRAW memory (*E*rase *D*irect *R*ead *A*fter *W*rite), have storage densities limited to 10^8 bit per cm^2. This limiting value has physical causes (diffraction limit for the focused laser spot) and can only be improved by a factor of 4 by the use of a frequency-doubled semiconductor laser. So far, for optical data pit storage the laser is only used to give a point-like heating of the material in the focus of the laser; that is, the characteristic properties of laser light, namely its monochromacity and coherence, are not used. However, if the monochromacity of laser light is used, then with the help of the spectral hole burning (FDOS), the storage on the area (two dimensions) can be extended by the storage on the frequency axis as the third dimension, and the storage density can be raised to 10^{11} bit per cm^2 by the writing of typically 1000 spectral holes at each laser-focused spot. If the coherence of laser light is used, information can be stored in the depth of the medium as the third dimension with the help of holography and thus provide a volume storage with a theoretical storage density of 10^{13} bit per cm^3. By the skillful use of holographic methods not only the storage but also the optical processing of information is possible.[3]

In the meantime the storage density of the FDOS memory has been increased further by the utilization of the electric field (Stark effect) as the fourth storage dimension and the combination with holographic detection methods. The resulting storage of 100 holograms in the frequency range of only 1 cm^{-1} has already been demonstrated.[4] It could also be shown here that the application of holographic methods made additional logical connections between the stored information possible and thus opened one way to the optical computer.

Although the methodic possibilities of the FDOS memory have thus been extended considerably, the development of materials suitable for the storage remains a difficult and unresolved problem. This is a result of the various requirements,[1] of which the most important are reversibility, rapid writing, thresholding, and high-temperature hole burning. Reversibility,[1] rapid writing,[1, 5] and thresholding in the form of two-color writing[1, 6, 7] have already been demonstrated on a series of different systems. Thus, in principle, concepts for a corresponding material design have been achieved. However, spectral hole burning is extremely difficult at temperatures greater than 10–20 K. This is mainly a result of the decrease of the zero phonon band relative to the phonon side-band and manifests itself in a very large broadening of the spectral hole with increasing temperature. As a result, at $T > 20$ K either no spectral hole or one which is almost as wide as the total inhomogeneous absorption band is detected.

So far, this situation has been avoided by the use of dye molecules such as porphyrins and phthalocyanines,[8, 9] which only show a weak coupling of the pure electronic transition to the phonons of the solid. Thus, during the electronic transition in the molecule "fewer" phonons in the solid are produced. However, these attempts did not succeed in meeting a further requirement for high-temperature hole burning: the shift of the phonon spectrum of the matrix to higher frequencies. In this way phonon states could be occupied in considerable number only at higher temperature. To increase the rigidity of the polymer matrix and thus raise the phonon frequencies, the polymer matrix was cross-linked.[8] The maximum of the phonon frequency distribution, however, was still at $\omega_0 \leq 25\ cm^{-1}$. Nevertheless, in systems of porphyrins or phthalocyanines in polymers, spectral holes with a hole width of approximately $\Gamma_L \leq 15\ cm^{-1}$ could be burned at liquid nitrogen temperatures and at up to $T \leq 120$ K. Due to the narrow inhomogeneous line width of the systems used, only a multiplexing factor $M = \Gamma_i/\Gamma_L$ of roughly 50 was achieved; that is, 50 holes or bits can be stored in the frequency axis as the third storage dimension in addition to the area.[8] This already shows that compromises must be made with regard to the overall properties of a system. Thus, though hole burning may be conducted at higher temperatures, the resulting storage density is not increased to the extent possible for the hole burning at low temperatures.

Recently, in another approach dye molecules were adsorbed on surfaces.[10] For a system in which quinizarine (1,4-dihydroxyanthraquinone) was adsorbed on γ-Al_2O_3, the coupling of the pure electronic transition to the phonons was significantly lower and ω_0 with 50 cm^{-1} significantly higher than for the same dye in ethanolic glass or polymer matrices. As a result of the greater inhomogeneous line width Γ_i of this system, the multiplexing factor was 70–100 for $T = 80$ K. Since similar effects were also observed for other adsorbate/substrate systems,[10] a new material concept was demonstrated. However, the ultimate aim of hole burning at room temperature has not yet been realized in these studies.

Recently, room-temperature hole burning was achieved with a completely different system, namely substitutionally disordered microcrystals of $SrFCl_{0.5}Br_{0.5}$[11] and $Mg_{0.5}Sr_{0.5}FCl_{0.5}Br_{0.5}$[12] doped with 1 atom% Sm^{2+} ions. The basic strategy for the development of this system[13] is exactly opposite to the one previously described. In the experiments mentioned up to this point the attempt was made to retain the intensity of the zero phonon band also at higher temperatures, and a wide inhomogeneous absorption band could be assumed. In contrast, for the Sm^{2+}-doped systems a wide inhomogeneous absorption band must first be produced, but an intense zero phonon band can be assumed even at room temperature. This is due to the strong shielding of all the inner 4f electron transitions of Sm^{2+} which are used for the spectral hole burning in these systems. For a wide inhomogeneous absorption band of the 4f transitions a

strong disturbance in the environment of the Sm^{2+} ions is necessary. This is produced by the substitutional disorder in $BaFCl_{0.5}Br_{0.5}:Sm^{2+}$ during the statistical exchange of Cl^- or Br^-, relative to $BaFCl:Sm^{2+}$ and $BaFBr:Sm^{2+}$, respectively.[13] The broadening can be further increased by additional statistical variation of the cation, for example in $Mg_{0.5}Sr_{0.5}FCl_{0.5}Br_{0.5}:Sm^{2+}$.[13]

The ratios for the $^5D_0-^7F_0$ transition of the 4f electrons of Sm^{2+} in $SrFCl_{0.5}Br_{0.5}:Sm^{2+}$ at room temperature are illustrated in Figure 3.[11] The calculated multiplexing factor is

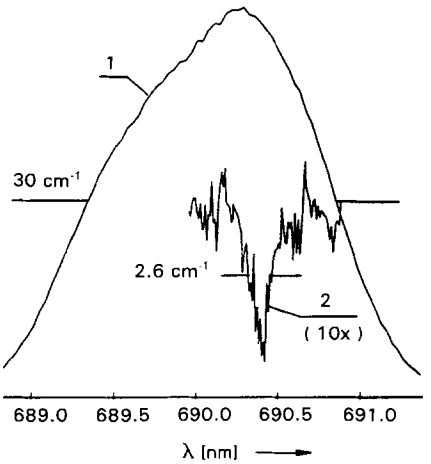

Fig. 3. Inhomogeneous absorption band of the $^5D_0-^7F_0$ transition in microcrystals of $SrFCl_{0.5}Br_{0.5}:Sm^{2+}$ (1) and the spectral hole at room temperature (2).

roughly 10, much smaller than the values obtained at liquid He temperatures. But experiments with the Sm^{2+}-doped systems, even though these are not ideal FDOS meterials, are important nevertheless, since they have shown a new strategy which makes hole burning at room temperature possible and which yields spectral holes of sufficient thermal stability. Interestingly, the Sm^{2+} systems also show reversibility,[11] and two-color writing[6, 11] is possible. The latter means that two different wavelengths for the associated photochemistry are used to write the information, so that on reading at only one wavelength the written information cannot be destroyed (threshold requirement).

A further approach should also be mentioned which uses small particles of variable diameter with dye molecules on their surfaces.[14] Spectral hole burning is possible in such systems, because the resonance absorption varies with the particle size, and the dye molecules are photochemically transformed on particles which fulfill the resonance condition for the wavelength used for the burning. Since temperature dependence does not arise here, spectral hole burning at room temperature is a priori possible. However, it has been shown that the particles must be above a minimum size due to both the resonance requirement and the formation of satellite bands. Thus, the gain of storage density in the frequency dimension is overcompensated by the loss of storage density in the area. So far it remains unclear whether this disadvantage can be overcome.

In all optical storage systems the storage of a bit on a molecule would be the absolute upper limit of a memory on a molecular basis. Almost a year ago a "Highlight" in this journal[15] discussed the first spectroscopic observations by W. E. Moerner et al.[16] and M. Orrit et al.[17] of single pentacene molecules embedded in a *para*-terphenyl crystal. The fascinating results were made possible by high dilution, extremely small sample volume (ca. 200 μm^3), and spectral separation by highly sensitive detection of fluorescence excitation. Despite many unsuccessful attempts to extend the technique to other molecule/matrix systems, pentacene in the *para*-terphenyl crystal seemed to be the only object of study. Thus, in their outlook the authors[15] pointed out that the extension of this experiment to the even more interesting amorphous dye/matrix systems, such as dye molecules in polymers and glasses, remained a significant experimental challenge.

In a post-deadline paper for the Monterey conference, T. Basché and W. E. Moerner[18] were the first to describe the spectroscopic detection of single perylene molecules in an amorphous polyethylene matrix. Figure 4 shows the absorption of single perylene molecules dependent on the laser frequency and the probe location in one dimension. The extension of the method to these new classes of systems, the detailed study of the amorphous state of polymers and other solids possible as a result, and the novel observation of spectral hole burning with a single molecule are of great interest.

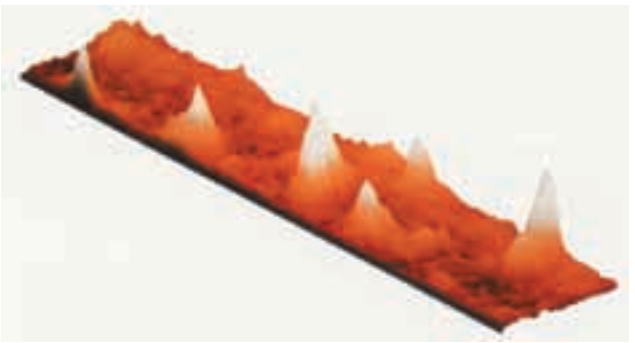

Fig. 4. Fluorescence signals of six single perylene molecules in a polymer film. Each increase corresponds to the fluorescence of one molecule. The frequency of the scanning laser is varied (6.1 GHz), and the laser is moved over the surface of the sample (23 μm) in one dimension. The emission intensities are different because the positions of the molecules relative to the laser focus differ. In some signals the form is changed due to a small amount of spectral diffusion during the scans.

Figure 5 shows such a hole burning experiment.[18] The fluorescence excitation spectrum of a single perylene molecule in a perylene/polyethylene film system (mass ratio $9.5 \times 10^{-7}:1$) was recorded by a laser scan with ± 1 GHz for the center at 448.021 nm. Here a frequency-stable molecule that showed no spectral diffusion was chosen. The latter can be recognized by a sudden stochastic frequency jump of the total absorption band caused by the phonon-induced change of state in a TLS in the environment of the molecule. Since the absorption band of the molecule remained constant in the three laser scans carried out successively a–c in Figure 5 (and five further laser scans before spectrum a was recorded), this molecule can be classified as frequency stable in the sense of the above. After spectrum c was recorded, the laser frequency was altered such that it agreed with the absorption frequency of the molecule. As spectrum d shows, the absorption of the molecule disappeared within 30 s. Surprisingly, after a few minutes the absorption of the molecule returned

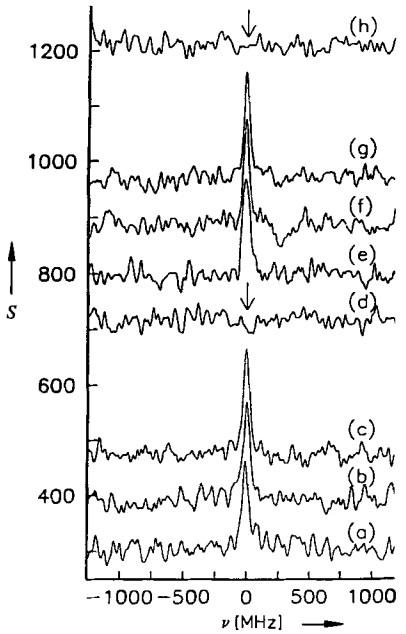

Fig. 5. Spectral hole burning with a single perylene molecule in polyethylene at $T = 1.5\,K$. The meaning of the laser scans a–h is described in the text. ν: laser frequency, S: fluorescence excitation signal in the number of occurences per 100 ms.

to the same location within ± 10 MHz in a frequency-stable form (spectra e to g). After that, a further hole could be burned (spectrum h), and the whole process could be repeated several times. To confirm that a spectral hole had actually been burned, that is that a single molecule had been manipulated by light, Basché and Moerner repeated the reaction at different burning powers of 4.5 to 27 nW. They observed an unequivocal decrease of the average burning time with increasing laser power, whereas the return time was completely stochastic and independent of the power of the laser. Thus it is confirmed that the spectra in Figure 5 reflect spectral hole burning with a single molecule.

The process can be interpreted as follows: A transition in a nearby TLS is activated by the irradiation, and in a quantum jump the absorption frequency of the molecule is shifted to that of the "product state". This lies outside the frequency window of Figure 5, and therefore could not be identified so far. The recurrence of the molecular absorption shows the stochastic return of the TLS into the original state and serves as a clear indication that only a single TLS participates in the process. (Of course, there were also molecules whose absorption frequency did not return to the original value after the burning.)

As a result of their experiments Basché and Moerner were able to prove a hierarchy of the TLS with which the dopant molecule interacts. TLS which are distant from the dopant molecule produce very rapid and small frequency changes. These changes are the main reason for the dephasing and thus for the homogeneous line width Γ_H. Here the interaction of the molecule is averaged over many TLS so that the homogeneous line width should be of the same size for all single molecules. TLS which are closer to the dopant molecule produce much larger and less frequent frequency changes. These TLS are responsible for the sudden frequency jumps, which are observable within the frequency window of the experiment and cause the spectral diffusion. Here each single molecule sees its own local environment, which with these experiments can be observed for the first time. Finally, there are TLS which are the "direct neighbors" of the dopant molecule, which can only be activated by spectral hole burning and cause the largest frequency changes. Some of these TLS return spontaneously to their original state others do not.

Apart from these highly interesting scientific results, Basché and Moerner have also demonstrated the first optical switch or the first optical storage element based on a single molecule in their spectral hole burning with a single molecule. Thus they have reached the absolute limit of optical storage on a molecular basis. In such molecular storage the existence or nonexistence of the molecular absorption at its original frequency position is assigned with a "1" or a "0", respectively. Initial considerations show that storage densities of 10^{14} bit per cm^2 should be possible, taking into account the dilution of the donation molecules. This density would be six orders of magnitude greater than those of commercially available optical storage devices. The application of subdiffraction-limited light with a cross section similar to the absorption cross section of the molecules is of great interest. Thus, the signal-to-noise ratio would also increase greatly, and a more reliable and very rapid detection of the hole burning process or the molecular switch process would be possible.

Apart from the hole burning described here the specific manipulation of a single molecule is only feasible with the help of the tunnel microscope.[19] Both procedures are unique in that they allow us from our macroscopic world to directly address *specific single* molecules or atoms in the microscopic domain, and to manipulate them and receive signals from this domain. Thus, the way to molecular electronics in its true sense, in which information is specifically stored, passed on, and switched by single molecules, has become more feasible.

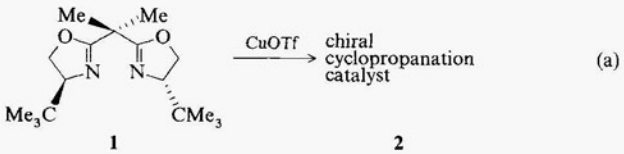
'Bis(oxazolines)' as Ligands for Self-Assembling Chiral Coordination Polymers— Structure of a Copper(I) Catalyst for the Enantioselective Cyclopropanation of Olefins**

By *David A. Evans,* Keith A. Woerpel,* and *Michael J. Scott*

We recently reported that the 1:1 complex of copper(I) trifluoromethanesulfonate (Cu^{I}-triflate, CuOTf) and the chiral 'bis(oxazoline)' **1**[***] forms an effective catalyst for the enantioselective cyclopropanation of olefins with diazoacetic acid esters.[1] This reaction proceeds in 97 to >99% *ee*, and, with the proper choice of ester, disubstituted cyclopropanes can be formed with high *trans* selectivity. Although oxazolines have been previously employed as chiral ligands,[2] bis(oxazolines) have recently shown their utility not only in cyclopropanations,[3, 4] but in other reactions as well.[1, 4, 5] To gain better insights into the coordination chemistry of this versatile C_2-symmetric ligand[6] and to probe the origin of the high enantioselectivity, we attempted to isolate the active catalyst. We report here the X-ray crystal structure of the bis(oxazoline)–CuOTf complex **2**, which forms an unusual chiral, non-racemic, helical coordination polymer. Furthermore, we report on the use of this complex in the highly enantioselective cyclopropanation of olefins and on the determination of the absolute configuration of the products, and we show how our results compare with those reported by other groups.[3, 4]



(a)

1 **2**

Bis(oxazoline)[7] **1** and CuOTf·0.5 C_6H_6[8] form a complex in dichloromethane, which was isolated as a white solid [Eq. (a)]. The X-ray crystal structure, shown in Figure 1,[9] shows a single-stranded helical polymer with threefold symmetry where the bis(oxazoline) ligand occupies a bridging position between two nearly linear, two-coordinate copper(I) ions. The structure further reveals that the triflate counterion is dissociated from the metal center. The ligand adopts a conformation wherein the large *tert*-butyl group is directed away from the center of the helix. Accordingly, the bis(oxazoline) **1**, by virtue of its chirality, directs both the assembly of the polymer and the sense of helicity. To date, only one other example of a chiral, non-racemic helical coordination polymer has been reported.[10] Unlike this and other coordination polymers and oligomers which involve multidentate ligands,[11] the structure of complex **2** demonstrates that bidentate ligands are also capable of enforcing macromolecular organization. The complex **2** is also noteworthy since it is one of the few oxazoline–metal complexes characterized by X-ray crystallography.[6b–d] With regard to the metal–ligand bond distances, the Cu–N bond lengths (1.88 Å) are typical for two-coordinate copper(I) and are the same as those of a recently reported two-coordinate CuOTf–bis(imine) complex.[12] Finally, despite the extreme oxygen sensitivity of solutions of copper(I) complex **2**, the solid complex can be stored for months in air without deterioration. Inspection of the crystal structure reveals that the copper(I) atoms are sterically protected from oxidation by the *tert*-butyl groups.

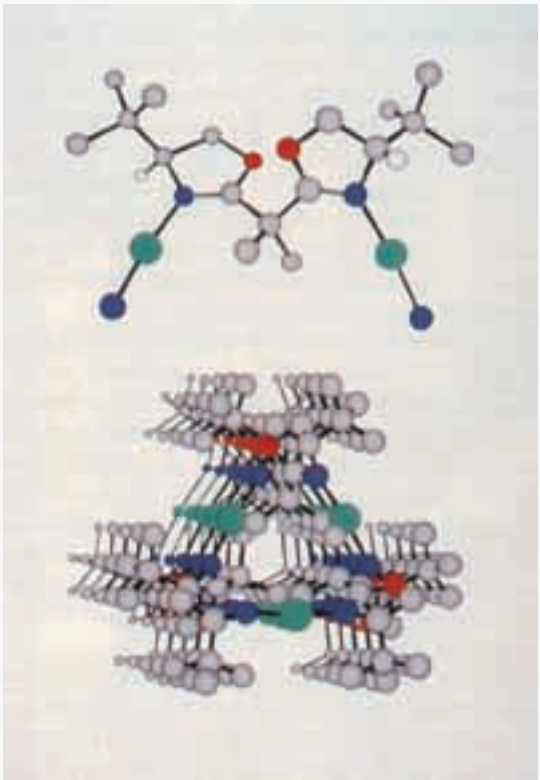


Fig. 1. Top: View of the repeating unit of the cation of **2** in the crystal. Cu–N 1.88(1) Å; N–Cu–N 171.6(4)°. Bottom: The helical cation of **2** as viewed along the three-fold screw axis.

With the knowledge that complex **2** is polymeric in the solid state, we studied its structure in solution using several spectroscopic techniques. Sharp resonances were observed in the ^1H and ^{13}C NMR spectra of **2** at 25 °C ($CDCl_3$), indicating that the complex is not paramagnetic. These spectra also

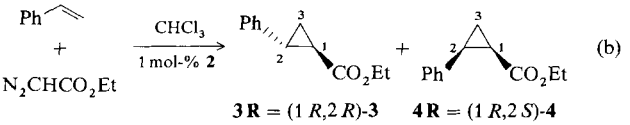
[***] According to IUPAC rules of nomenclature, compound 1 is a bis(dihydrooxazolyl)propane.

revealed the presence of only *one* oxazoline moiety, demonstrating equivalence of the two heterocycles caused either by symmetry or fluctionality. Incremental addition of excess ligand **1** (from 0 to >2 equiv) to solutions of **2** led to spectra which again showed a single set of sharp resonances different from those observed for either **1** or **2**. We therefore conclude that rapid ligand redistribution is occurring and that the polymeric structure is disrupted in solution. This was confirmed by variable temperature NMR experiments, since spectra of **2** acquired between −50 and 0 °C lacked symmetry. An IR spectrum of a $CHCl_3$ solution of **2** showed that the C–N double bond absorbance had shifted to longer wavelengths upon coordination. The IR spectrum also showed a strong absorbance at 1280 cm^{-1}, which is indicative of a noncoordinated triflate in $CHCl_3$ solution.[13] Fast-atom bombardment mass spectrometry confirmed that **2** was a complex of **1** and CuOTf, displaying major ions at *m/z* 357, 651, and 506, which correspond to **1**-$^{63}Cu^+$, $(\mathbf{1})_2$-$^{63}Cu^+$, and **1**-$^{63}CuOTf^+$. Attempts to ascertain the molecular weight of the dissolved compound by vapor-pressure methods failed. Regarding the structure in solution, the only conclusions we can make at this time are that the ligand **1** is coordinated to the copper atom and is undergoing rapid ligand redistribution, and that the triflate is fully dissociated from the metal center.

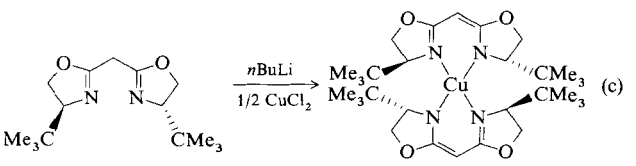
Complex **2** was found to be an effective catalyst for the enantioselective cyclopropanation of olefins by ethyl diazoacetate. A sample of **2** (1 mol%) was employed as the catalyst for the cyclopropanation of styrene by ethyl diazoacetate. The ethyl cyclopropanecarboxylates **3R** and **4R**[14] were isolated in a 73:27 ratio in 75% isolated yield [Eq. (b)]. The enantioselection was found to be 98% *ee* for each isomer, as determined by capillary GLC analysis of the amides obtained by amidation with (*R*)-1-phenylethylamine. These results are similar to those obtained when the catalyst from CuOTf and **1** was prepared in situ.[1]



(b)

3R = (1*R*,2*R*)-**3** **4R** = (1*R*,2*S*)-**4**

The absolute configurations of the products **3** and **4** derived from chiral bis(oxazoline) catalysts have been the subject of some confusion.[1, 3a, 4] The sense of asymmetric induction for the major diastereomeric product **3** observed in this study is in agreement with the independent studies of Masamune et al. and Pfaltz et al. employing the pre-catalyst **8** derived from the ligand **7** [Eq. (c)]. However, the absolute configuration of the minor product **4** was not the same in the three reports. In order to resolve this issue, we employed the pre-catalyst **8** in reaction (b) and obtained **3R** (88% *ee*) and **4R** (83% *ee*), which are the same products observed employing catalyst **2**, but **4** was observed to be of the opposite configuration to that reported.[3a] Furthermore, we have also established that the catalyst obtained from **7** and CuOTf also leads to the same products **3R** (98% *ee*) and

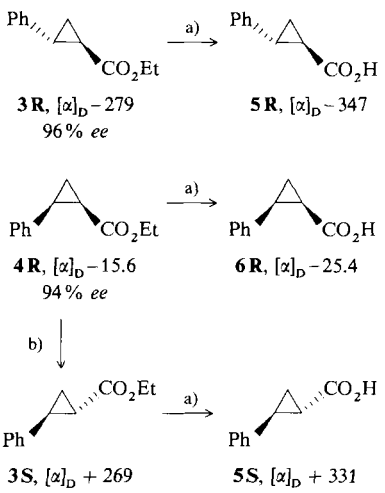


(c)

7 **8**

4R (93% *ee*).[1] To clarify these ambiguities, we investigated the stereochemical relationship between products **3** and **4**.

The esters **3R** (96% *ee*) and **4R** (94% *ee*) were hydrolyzed separately to the corresponding acids **5R** and **6R**. Comparison of the optical rotations of these four compounds with the literature values suggests that the configuration is as shown (Scheme 1).[15] To demonstrate that the *cis*- and *trans*-products have the same configuration at C-1, the *cis* product **4R** was epimerized with potassium bis(trimethylsilyl)amide, which resulted in a mixture of *trans*- and *cis*-esters in a ratio of >100:1 (capillary GLC). The product was found to be the *trans* ester **3S** with a rotation of opposite sign to that of the cyclopropanation product **3R**. Hydrolysis of **3S** afforded



Scheme 1. a) NaOH, $MeOH/H_2O$. b) $KN(SiMe_3)_2$, THF, −78° → 0 °C.

the *trans* acid **5S**, again of opposite optical rotation to the product **5R** obtained from the cyclopropanation product **3R**. We therefore conclude that the reaction products differ in configuration at C-2, the carbon which bears the phenyl group, but both are of the (*R*) configuration at C-1. Finally, we have obtained an X-ray crystal structure of the amide obtained by reaction of **3S** with (*R*)-1-phenylethylamine which confirms that the product is indeed the (*1S,2S*)-isomer. This result, along with the chemical correlation, unambiguously established the stereochemical relationship between the 2-phenylcyclopropanecarboxylate isomers. Thus, we conclude that the Masamune/Pfaltz catalyst derived from **8** and complex **2** effect the same sense of enantioselection.

Synthesis and Structure of the First Trinuclear, Half-Sandwich Carboranegadolinium(III) Cluster **

By *Aderemi R. Oki, Hongming Zhang,* and *Narayan S. Hosmane* *

The cyclopentadienyl ligand and a number of its *C*-substituted derivatives have been widely utilized in organometallic chemistry.[1] Although almost all of the s-, p-, d-, and f-elements have been complexed with these ligands, only a limited number of cyclopentadienyl gadolinium complexes have been structurally characterized.[2] Moreover, no known examples of trinuclear π-organogadolinium complex systems could be found in the literature.[3] However, the first carborane complex of an f-element is the uranium complex $[\{Li^+(thf)_4\}_2\{commo\text{-}3,3'\text{-}UCl_2(3,1,2\text{-}UC_2B_9H_{11})_2\}^{2-}]$, whose bent sandwich structure was determined by X-ray diffraction.[4] Since then, a number of *closo* (half-sandwich), and *commo* (sandwich) lanthanide complexes with *nido*-C_2B_9 and *nido*-C_2B_{10}-carborane ligands have been reported.[5] To date, there have been no reports on any of the carborane gadolinium complexes. Here, we report the synthesis and X-ray structure analysis of the first *closo*-carboranegadolinium(III) cluster complex. To our knowledge, complex **1** also represents the first trinuclear, μ_3-oxygen-bridged, half-sandwich, Gd(III) π-complex of any ligand system known to date.

$[\{\eta^5\text{-}1\text{-}Gd\text{-}2,3\text{-}(SiMe_3)_2\text{-}2,3\text{-}C_2B_4H_4\}_3\{\mu_2\text{-}1\text{-}Li\text{-}2,3\text{-}(SiMe_3)_2\text{-}2,3\text{-}C_2B_4H_4\}_3(\mu_3\text{-}OMe)\{\mu_2\text{-}Li(C_4H_8O)\}_3(\mu_3\text{-}O)]$ **1**

Treatment of the THF-solvated $Li_2[2,3\text{-}(SiMe_3)_2C_2B_4H_4]$ salt **2**[6] with anhydrous $GdCl_3$ in a molar ratio of 2:1 in dry benzene, followed by extraction and crystallization of the product from a solution containing 95% dry *n*-hexane and 5% dry THF resulted in the isolation of light yellow, transparent, and extremely air- and moisture-sensitive crystals of **1** in 58% yield. The paramagnetism of **1** precluded obtaining useful NMR data. However, the solution IR spectrum of **1** exhibits three terminal B–H stretches, presumably due to their interactions with the metals. Fine structures of this kind have been previously observed in the IR spectra of *closo*-$[1,1,1,1\text{-}(thf)_4\text{-}1,2,3\text{-}LnC_2B_9H_{11}]$ ($Ln = Sm^{II}$, Yb^{II}).[5c] The structure of the title compound could be determined unequivocally by X-ray diffraction analysis.[7]

The crystal structure reveals that **1** is a cluster complex consisting of six carborane cages, three THF molecules, three Gd atoms and six Li atoms, and possessing approximately a threefold symmetry-axis that passes through O(100) and O(120) atoms (Fig. 1). The metal atoms construct a tri-

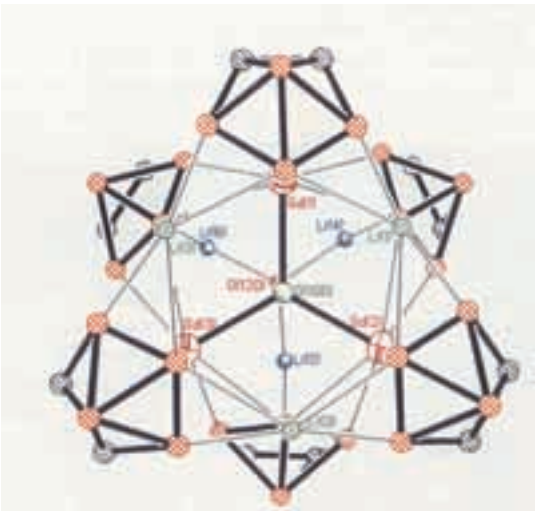

Fig. 1. Perspective view (from above) showing the C_2B_4-carborane cages and the equilateral triangles of Gd and Li atoms in **1**.

capped trigonal prism with gadolinium atoms in the capping positions. While the upper and lower Li-triangular planes [Li(1), Li(2), and Li(3) and Li(4), Li(5) and Li(6), respectively], are parallel (dihedral angle of 1.1°) their dihedral angles to the central Gd_3-triangular plane [Gd(1), Gd(2), and Gd(3)] are 1.0 and 1.4°, respectively. The central μ_3-bridged oxygen atom [O(100)] is located only 0.22 Å above the Gd_3-triangular plane. On the other hand, the methoxy oxygen [O(120)] links the apical Li atoms of three *closo*-lithiacarboranes in a tetrahedral fashion and is located 0.72 Å below the lower Li-plane. The distances of 4.04(3), 4.10(3) and 4.11(3) Å between the cage-bridged and THF-solvated Li metals are considerably longer than the distances in the central Gd_3-triangular plane [3.772(2), 3.778(2) and 3.786(2) Å] and the lower Li_3-plane [2.92(3), 2.96(3) and 2.94(3) Å] consisting of three *closo*-lithiacarborane units. Although Li-triangles eclipse one another, their presence, in staggered conformations, above and below the central plane of three apical Gd atoms is particularly noteworthy (Figs. 1 and 2).

The gadolinium metal atom in each *closo*-gadolinacarborane unit is η^5-bonded to the cage atoms, with Gd–carborane face and Gd–centroid distances ranging from 2.71(2) to 2.80(2) Å and 2.38 to 2.4 Å, respectively. The metal–centroid distances in **1** are slightly shorter than those in the structures of $[(\eta^5\text{-}C_5H_5)_3Gd(thf)]$,[8] $[\{\eta^5\text{-}C_5H_5\}_2Gd(Br)\}_2]$,[9] $[\{\eta^5\text{-}C_5H_5)Gd\}_5(\mu_2\text{-}OMe)_4(\mu_3\text{-}OMe)_4(\mu_5\text{-}O)]$ (**3**),[3] and in the

polymeric complex $[(\eta^5\text{-}C_5H_5)_2Gd(Br)]_\infty$.[9] The *closo*-gadolinacarboranes are also bridged by $[Li^+(thf)]$ moieties with Li–B distances of 2.24(3)–2.40(2) Å. The average Gd–O(100) distance of 2.193(7) Å, observed for **1**, is quite reasonable for a triply-bridged O atom when compared to the Gd–(μ_5-O) distances of 2.42(1) Å in the structure of **3**.[3]

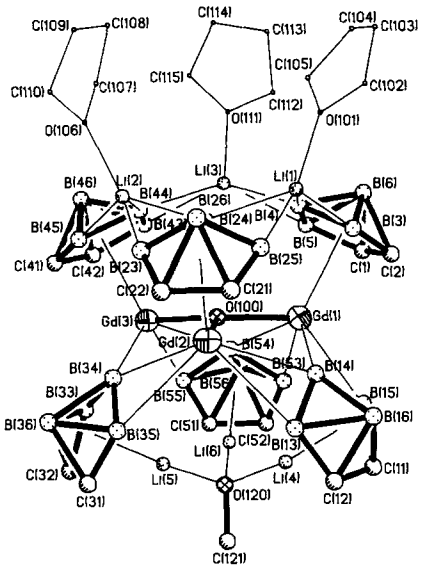

Fig. 2. A side view of **1** showing the atom numbering scheme. The $C_{(cage)}$-$SiMe_3$ groups are omitted for clarity. Selected distances [Å] and angles [°]: Gd(1)-center 1 [C(1) to B(5)]2.379, Gd(2)-center 3 [C(21) to B(25)] 2.386, Gd(3)-center 5 [C(41) to B(45)] 2.399, Gd(1)-O(100) 2.196(7), Gd(2)-O(100) 2.196(7), Gd(3)-O(100) 2.186(7), Li(4)-center 2 [C(11) to B(15)] 1.83, Li(5)-center 4 [C(31) to B(35)] 1.89, Li(6)-center 6 [C(51) to B(55)] 1.82, Li(4)-O(120) 1.87(3), Li(5)-O(120) 1.80(3), Li(6)-O(120) 1.87(2), O(120)-C(121) 1.43(3), Gd(1)-B(Li-carborane) 2.69(2)–2.87(2), Gd(2)-B(Li-carborane) 2.66(1)–2.91(2), Gd(3)-B(Li-carborane) 2.69(2)–2.87(2), Li(1)-B(Gd-carborane) 2.24(3)–2.38(3), Li(2)-B(Gd-carborane) 2.33(3)–2.39(3), Li(3)-B(Gd-carborane) 2.33(3)–2.40(2); center(1)-Gd(1)-O(100) 115.9, center(3)-Gd(2)-O(100) 115.9, center(5)-Gd(3)-O(100) 116.4, Gd(1)-O(100)-Gd(2) 118.4(3), Gd(1)-O(100)-Gd(3) 119.2(3), Gd(2)-O(100)-Gd(3) 119.6(3), center(2)-Li(4)-O(120) 169, center(4)-Li(5)-O(120) 173, center(6)-Li(6)-O(120) 168, Li(4)-O(120)Li(5) 105(1), Li(4)-O(120)-Li(6) 105(1), Li(5)-O(120)-Li(6) 107(1), Li(4)-O(120)-C(121) 114(1), Li(5)-O(120)-C(121) 116(1), Li(6)-O(120)-C(121) 109(1).

As can be seen in Figures 1 and 2, each lithiacarborane complex bridges the two Gd atoms of the central plane with the Gd–B distances ranging from 2.66(1) to 2.91(2) Å. The bonding of the lithium atom to the C_2B_3 face of the carborane units, below the Gd-triangular plane, is pentahapto with the Li-centroid distances ranging from 1.82 to 1.89 Å. However, the average Li–C distance [2.17(3) Å] is significantly shorter than the average Li–B distance of 2.36(3) Å. Slippage of this kind, although more pronounced in the present case, has already been found in the structures of lithium complexes of 1,2-diboratabenzene and 2-boratanaphthalenide.[10] Since each of the six carborane ligands is doubly negatively charged and three Gd^{III} and six Li^I metals are present, for charge compensation an additional $(MeO)^-$ moiety is bound to the apical lithium atoms of the lower triangle of *closo*-lithiacarboranes [average Li–O(120) = 1.85(3) Å] in a tetrahedral fashion (the average Li–O(120)–Li and Li–O(120)–C(121) angles are 106(1) and 113(1)°, respectively) and an O^{2-} unit, that is almost coplanar with the central Gd-plane, is triply-bridged to three Gd atoms in a trigonal-planar geometry with an average Gd–O(100)–Gd angle of 119.1(3)°. The recent report on trinuclear lanthanide complexes of the type $[Ln_3(\mu\text{-}pzMe_2)_6(\eta^2\text{-}pzMe_2)_3\{(\mu_3\text{-}O)Na_2(solv)_2\}]$ (Ln = Yb, solv = THF; Ln = Ho, solv = $pzMe_2$, pz = pyrazolyl) suggests that complexes containing lanthanides other than Gd^{III}, incorporating trinuclear units of the type $[(\mu_3\text{-}O)Ln_3]^{n+}$ with trigonal-planar geometry, can be synthesized.[11] Nonetheless, the exact source of the μ_3-OMe ligand and the μ_3-O ion in **1** is still unknown. Since the methoxide ion could be generated slowly at room temperature from the cleavage of THF by organoalkali metal compounds,[12] a similar reaction could occur between THF and *tert*-BuLi as a side-reaction during the formation of **2**. In any case, we have not only reproduced the yield and the formation of cluster complex **1** but also synthesized the samarium analogue whose molecular geometry is identical with that of **1** as determined by single crystal X-ray diffraction analysis.[13]

The presence of reactive lithiacarborane units suggest that **1** could react with three further equivalents of MX_2 (M = p, d, or f-metal in the oxidation state +II, X = halogen) to give a series of novel, mixed metal, and stacked trinuclear cluster systems in which a new triangle of metal atoms could be bent-sandwiched by two gadolinium cluster complexes. Such an endeavor is currently underway in our laboratories.

Experimental Procedure

1: **2** (6.4 mmol) [6] was allowed to react with anhydrous $GdCl_3$ (0.84 g, 3.18 mmol) in dry benzene (25 mL) at 0 °C for 24 h, during which time the color of the solution turned to yellow. At this point, the heterogeneous product mixture was filtered through a frit in vacuo and the solvent was removed from the filtrate, leaving a pale-yellow solid. This solid was then dissolved in a solvent mixture of hexane (95%) and THF (5%) and filtered in vacuo. After slow removal of the solvents from the second filtrate, a light yellow, highly air and moisture sensitive crystalline solid, identified as **1**, was obtained in 58% yield (1.3 g, 0.61 mmol; moderately soluble in polar and nonpolar organic solvents; m.p. 100–103 °C). Reproducible microanalytical data for the same sample of **1** could not be obtained, as it is extremely sensitive to air and moisture. IR (C_6D_6): $\tilde{\nu}$ [cm^{-1}] = 2500 (sh), 2360 (vs, br), 2250 (s, br) (B–H).

[7] Crystal data for **1**: $C_{61}H_{203}O_5B_{24}Si_{12}Gd_3Li_6$, M = 2127.1, triclinic, $P\bar{1}$, a = 16.035(7), b = 16.883(6), c = 23.903(9) Å, α = 89.04(3), β = 88.87(3), γ = 67.95(3)°; V = 5996(4) Å^3, Z = 2, ϱ_{calcd} = 1.178 g cm^{-3}, μ = 1.844 mm^{-1}. Of 10077 data collected on Nicolet *R3m/V* diffractometer ($Mo_{K\alpha}$, 2θ = 3.5–38°, 230 K) 9563 reflections were unique and 8103 reflections were observed [$I > 3.0\sigma(I)$]. Data were corrected for Lorentz, polarization, and absorption effects. The structure was solved by heavy-atom methods and refined by block-diagonal least-squares techniques using SHELXTL-Plus (G. M. Sheldrick, *Structure Determination Software Program Package*, Siemens Analytical X-ray Instruments, Inc., Madison, WI, USA, 1990). All non-H atoms, except for the disordered THF [O(101),

C(102) to C(105)] were refined anisotropically. Bonds of the disordered THF were constrained during refinements. No attempts were made to locate the H atoms. The final refinement of **1** converged at $R = 0.053$, $wR = 0.081$, and $GOF = 2.78$ for observed reflections. The maximum and minimum residual electron densities are 0.94 and -0.85 e/Å^3, respectively. The polymer dissolves in toluene/dichloroethane under carefully controlled conditions and acid catalysis with formation of oligolides at 100 °C; the triolide is the major component and can be distilled (after the removal of acidic impurities by washing with sodium carbonate solution) to give colorless crystals (mp = 110.0–110.5 °C) in about 50% yield.[8] Crystal structure analysis of the triolide (Fig. 1) shows that the three nearly parallel carbonyl groups point in the same direction and are in effect ready to complex an ion.[9]

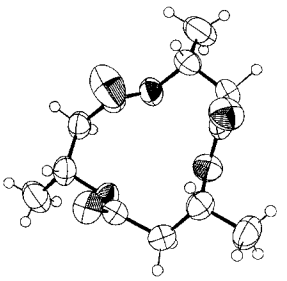

Fig. 1. ORTEP plot [13] of the crystal structure of **1** [14]. The ellipsoids of the thermal vibrations of the atoms correspond to a 50% probability. The radii of the hydrogen atoms are chosen arbitrarily.

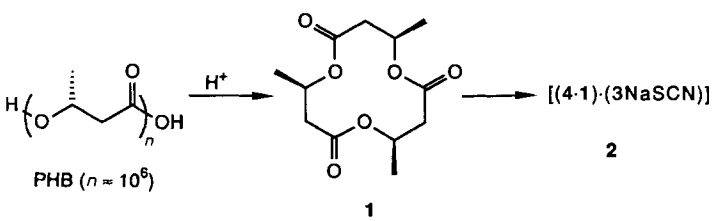
The Triolide of (*R*)-3-Hydroxybutyric acid—Direct Preparation from Polyhydroxybutyrate and Formation of a Crown Estercarbonyl Complex with Na Ions

By *Dieter Seebach,* Hans-Martin Müller, H. Michael Bürger,* and *Dietmar A. Plattner*

Besides polypeptides, polynucleotides, and polysaccharides, the polyhydroxyalkanoates (PHA) are a class of biopolymers whose importance in biochemistry and medicine has been recognized only recently.[1, 2] The longest known representative of this class of compounds, poly-(*R*)-3-hydroxybutanoate (PHB),[3] has made its way into the newspapers as a component of the biodegradable plastic BIOPOL.[4] Mixtures of oligolides of 3-hydroxybutanoic acid (HB) were obtained by macrolactonization by the methods of Yamaguchi and Shanzer, and it was possible to isolate pure compounds containing three to ten HB units, albeit in low yield, by chromatographic separation.[5] These oligolides may provide exact structural data relevant to the PHB polyester backbone and should serve as models for testing the hypothesis according to which PHB is involved in the formation of ion channels through cell membranes and even in the passage of DNA into genetically competent bacteria, for example in cloning.[6]

We have now found a remarkably simple way of preparing the triolide **1** ((*R,R,R*)-4,8,12-trimethyl-1,5,9-trioxadodeca-2,6,10-trione) on a 20 g scale directly from the cheap PHB.[7]



Indeed, crystallizations from acetonitrile solutions containing the triolide and alkali-metal salts yield complexes of a variety of compositions. From a solution of NaSCN and **1** we were able to isolate single crystals of the complex **2** suitable for X-ray structure determination.

The section of the structure shown in Figure 2 reveals the presence of crownlike complexes with one sodium ion coordinated to the three carbonyl oxygen atoms of the triolide (Na–O distances 2.44, 2.50, and 2.53 Å). Comparison of the conformations of the ligand with and without the sodium ion (Fig. 2, bottom) shows that it "adjusts" to the ion by the oxygen atoms moving closer together in the direction of the sodium ion (ion–dipole interaction).

Although numerous structures are known in which keto or amide carbonyl oxygen atoms act as ligands for alkali-metal ions,[10] or in which ether and carbonyl oxygen atoms cooperate in the complexation,[11] or in which only ester carbonyl oxygen atoms are involved in the complexation with other functional groups present in the ring (compare the complexation of alkali-metal ions with depsipeptides, especially with valinomycin[12]), we do not know of any alkali-metal complexes with cyclic ligands containing only ester functionalities such as in **2**. However, in the Ca-polyphosphate-PHB ion-channel proposed by Reusch Ca ions are complexed by ester carbonyl groups.[6]

Experimental Procedure

A mixture of PHB (36 g) and toluene-4-sulfonic-acid monohydrate (15.5 g, 81.5 mmol) in 750 mL of toluene/dichloroethane (4:1) was heated and stirred at reflux for 20 h. The water was removed azeotropically with a Dean-Stark trap (15 h). The clear brown solution was cooled to room temperature, washed with a half-saturated solution of Na_2CO_3 and with saturated NaCl solution, dried over $MgSO_4$, filtered, and evaporated to dryness. The semisolid residue was distilled (100 °C/0.05 Torr). Yield: 15–19 g (42–53%) colorless solid. Mp = 110.0–110.5 °C; $[\alpha]_D^{RT} = -33.9$ ($c = 1.005$, $CHCl_3$); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2995w, 1745vs, 1725s, 1375s, 1305s, 1295s, 1260m, 1190vs, 1130s, 1110s, 1045s; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 1.30$ (d, $^3J = 6.4$ Hz, 9H; CH_3); $\nu_a = 2.39$, $\nu_b = 2.46$ (ABX, $^3J_{AX} = 2.1$ Hz, $^3J_{BX} = 11.3$ Hz, $^3J_{AB} = 13.5$ Hz, 6H; CH_2); 5.31–5.39 (m, 3H; HC-O); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 20.76$ (CH_3), 42.15 (CH_2), 68.86 (CH), 170.02 (CO); SIMS-

Caro's Acid: Molecular Structure and Association in the Solid State at −130 °C

By *Walter Frank** and *Birgit Bertsch-Frank**

Caro's acid (trioxoperoxosulfuric acid H_2SO_5),[1] one of the best known named compounds in inorganic chemistry, is representative of the class of inorganic peroxoacids. Its high oxidation potential and its instability—which can also result in spontaneous, explosive degradation[2]—complicates the preparation and study of the pure acid. Since the crystallization of the extremely hygroscopic and low-melting compound (m.p. = 47 °C) is also difficult to control, the possibility of obtaining a single crystal for structural analysis was considered doubtful.[3]

Pure H_2SO_5 (**1**) was first prepared by D'Ans and Friedrich, not without danger, by reacting H_2O_2 with HSO_3Cl.[4] If H_2O_2 is treated with SO_3, a reaction which formally yields the desired compound directly, substantial amounts of side products and degradation products are formed.[5] Much simpler is the preparation of defined H_2SO_4/H_2SO_5 mixtures, which when cooled under moisture-free conditions are storable indefinitely, and from which we could crystallize the peroxoacid **1** at low temperature without danger. Methods that have proved useful in the study of thermolabile crystals were employed for the further treatment of the crystalline material.[6]

From the vibration spectra[7, 8] a molecular structure with an intramolecular O-H···O hyrogen bond, in which the hydrogen atom of the peroxo group is close to an oxo oxygen atom, was postulated for crystalline **1**. The actual molecular structure in the solid at −130 ± 3 °C, however, shows that no intramolecular hydrogen bond is present (Fig. 1).[9] The

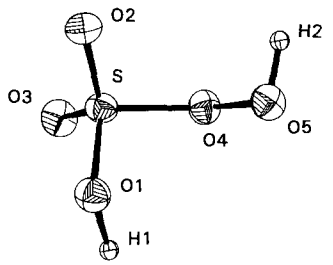

Fig. 1. The molecular structure of Caro's acid in the solid state at −130 °C. The ellipsoids of the thermal movement correspond to a residence probability of 50%; the radius of the hydrogen atoms was chosen arbitrarily. Bond lengths [pm] and angles [°]: O4-O5 146.4(3) (in H_2O_2 145.8(4) [10]), S-O1 152.4(2), S-O2 141.8(2), S-O3 143.2(2) (in H_2SO_4 S-OH 153(2), S-O 142(2) [11]), S-O4 160.2 (in $S_2O_8^{2-}$ anion 164.4(5) [12]), O1-H1 94(4), O5-H2 95(4); O1-S-O2 106.8(1), O1-S-O3 112.9(1), O1-S-O4 104.0(1), O2-S-O3 121.4(2), O2-S-O4 109.3(1), O3-S-O4 101.0(1), S-O4-O5 108.7(2), H1-O1-S 112(2), H2-O5-O4 98(3).

O–O bond length does not differ notably from that of solid hydrogen peroxide,[10] and the S–O distances also lie within the expected range.[13] From them, using simple empirical relationships,[14] we estimated a bond order of about 1 for the bond from S to the peroxo group, about 4/3 for the bond to the OH group, and about 5/3 each for the bonds to the oxo oxygen atoms. Thus, in contrast to H_2SO_4 ($2 \times 7/4$ and $2 \times 5/4$),[11] in H_2SO_5 the character of only three of the S–O bonds is intermediate between that of double and single bonds.

The shape of the molecule (point group symmetry 1) is determined by the conformation of the H1–O1–S–O4–O5–H2 chain and the torsion angles H1-O1-S-O4 (− 68 °), O1-S-O4-O5 (− 59.4 °), and S-O4-O5-H2. The value for the latter of −104° lies between that for the potential minimum for rotation in gaseous H_2O_2 (120 °)[15] and that in solid H_2O_2 enforced by the molecular association (90.2 °). It also gives an impression of the structure modifying forces of the solid state association for **1**.

The molecules in the crystal of **1** are linked in layers parallel to the *a,b* plane by a system of unsymmetric, almost linear O–H···O hydrogen bonds. If the O···O distance (265.6 and 272.1 pm) is used as criterium, the hydrogen bonds are strong.[16] There are only slight differences between these distances and those between the oxygen atoms involved in hydrogen bonding in H_2SO_4 and H_2O_2 [263(2) and 276.1(5) pm, respectively], which explains the relationship between the two halves of the molecule **1** with the parent compounds, the different acidity of the OH and OOH functions, and indirectly the monobasic character of the acid. Further details of the linkage of the associated molecules and layered structure may be seen in Figure 2. Viewed in an

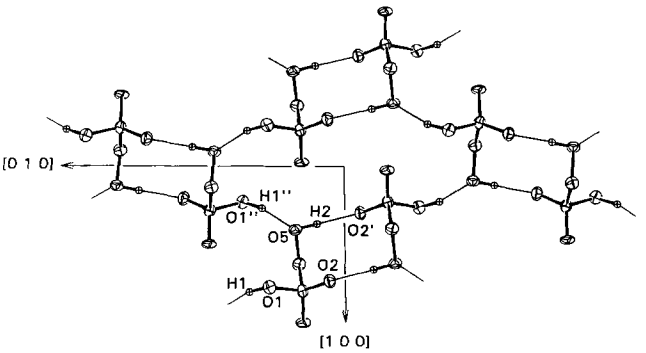

Fig. 2. Hydrogen-bond system and layer structure. Section of a layer of O–H–O linked H_2SO_5 molecules. (Distances [pm]: O1''···O5 265.6(4), H1''···O5 173(5), O5···O2' 272.1(4), H2···O2' 178(5); angles [°]: O5···H1''-O1'' 173(10), O2'···H2-O5 172(10); symmetry coding: ': 1-x, -y, 1-z, '': −0.5 + x, 0.5-y, 1-z).

abstract way[17] a layer may be seen as a (8.4^2) network with the S and O5 atoms as knots or as a (4.4) network of (H_2SO_5) enantiomeric pairs. Only van der Waals forces hold the layers together.

Experimental Procedure

Oleum (65%, 33.1 mL; i.e., 42.9 g (0.535 mol) SO_3) was added to an 87.3% hydrogen peroxide solution (14.3 mL; 17.2 g (0.505 mol) H_2O_2) over a period of 1 h at 0–10 °C. Half an hour thereafter the iodometric and cerimetric analysis of the viscose liquid revealed 62.9% H_2SO_5 and 0.5% unreacted H_2O_2. After many attempts, crystals suitable for a single-crystal X-ray analysis were obtained by slow cooling to −20 °C over 24 h. They were selected and transferred to a glass capillary at low temperature and freed of adhered mother liquor in a stream of argon. All apparatus for the preparation and the structural analysis was of glass and was treated with concentrated H_2SO_4, rinsed with distilled water, and dried in a dust-free environment.

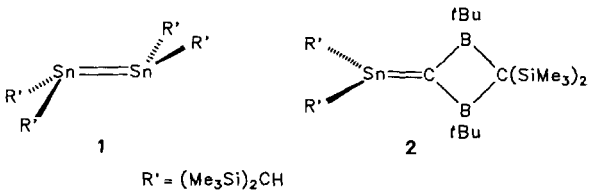
Investigations of the Structure and Reactivity of a Stannaketenimine**

By *Hansjörg Grützmacher,* Stefanie Freitag, Regine Herbst-Irmer,** and *George S. Sheldrick*

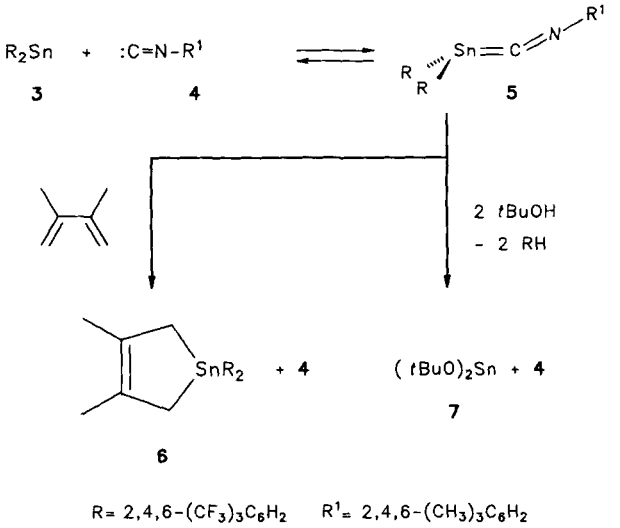
Dedicated to Professor Hans-Friedrich Grützmacher on the occasion of his 60th birthday

Investigations of the existence or nonexistence of systems with multiple bonds to elements of the higher periods have long entertained experimental and theoretical chemists.[1] In this context compounds with tin–element multiple bonds are interesting; of these only the distannene **1**[2] from Lappert et al. and the stannaethene **2**[3] from Berndt et al. have been characterized by X-ray structural analyses. A number of groups have reported experimental evidence of stannaethenes and stannanimines.[4] Quantum chemical calculations of the tin–carbon and tin–tin "double bond" have also been conducted.[5]

We report here the synthesis and molecular structure of the adduct of diarylstannandiyl **3**[6] and mesitylisocyanide **4**,



compound **5**, which is formally a stannaketenimine and thus comparable to the silaketenimine $tBu_2Si{=}C{=}NR$ (R = Ph, Mesityl, 2,4,6-$tBu_3C_6H_2$)[7] postulated by Weidenbruch et al. as an intermediate.



R= 2,4,6-$(CF_3)_3C_6H_2$ R^1= 2,4,6-$(CH_3)_3C_6H_2$

A solution of equimolar amounts of **3** and **4** cooled to −78 °C provided pale yellow crystals of **5**.[8] Crystals suitable for X-ray structural analysis were obtained by sublimation at 40 °C/0.01 Torr. The structure of stannaketenimine **5** shows atoms C11(C20), Sn1, C1, and N1 to have a very bent orientation (Fig. 1). In an idealized ketenimine these atoms

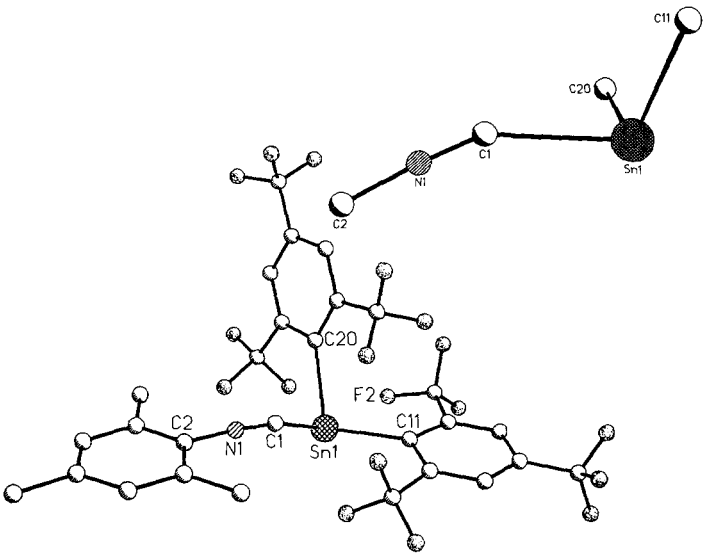


Fig. 1. Structure of **5** in the crystal. Selected bond lengths [Å] and angles [°]: Sn1-C1 2.397(3), Sn1-C11 2.306(2), Sn1-C20 2.314(3), C1-N1 1.158(3), N1-C2 1.405(3), Sn1-F2 2.72; C20-Sn1-C11 102.6(1), C1-Sn1-C11 104.9(1), C1-Sn1-C20 83.4(1), Sn1-C1-N1 153.9(2), C1-N1-C2 175.0(3). The stannaketenimine frame without substituents is shown in the upper right.

would lie in one plane. The comparison of the C11-Sn1-C1 and C20-Sn1-C1 bond angles (104.9(1) and 83.4(1)°, respectively) points out the distortion of the pyramidal coordination geometry of the tin atom; this arises from the relatively short Sn1–F2 contact (2.72 Å).[6] The Sn1–C1 distance of 2.397(3) Å is significantly greater than the distances between Sn1 and the *ipso* carbon atoms C11 and C20 in the aryl rings,

which correspond to the lengths of single bonds in sterically encumbered tin compounds (2.22–2.30 Å).[10] The C1–N1 bond length (1.158(3) Å) is typical for isocyanides.[11] In the IR spectrum of **5** the C–N stretching vibration (2166 cm^{-1}; KBr) is shifted to higher wave numbers relative to that of **4** (2118 cm^{-1}; KBr), as is also found for isocyanide–transition-metal complexes.

The bent molecular structure of **5** was predicted by the model of Malrieu and Trinquier, which correlates the geometry of a system with (cumulated) double bonds with the singlet–triplet energy difference of the molecular fragments.[13] According to this model the silaketene $H_2Si{=}C{=}O$, which can be described as a silandiyl–carbon monoxide complex, also has a bent structure.[14] The Sn1-C1-N1 angle in **5** deviates 26° from that of the linear Sn1-C1-N1 frame of a pure donor(isocyanide)–acceptor(stannandiyl). This is an indication that the Sn1–C1 interaction in **5** may be described as a "double" π donor–acceptor interaction, similar to that in **1** (Scheme 1). This is weaker than the interaction which is

2 5

Scheme 1. Qualitative MO description of the bonding systems in **2** and **5**.

equivalent to a tin–carbon single bond. Measurement of the temperature-dependence of the ^{119}Sn NMR chemical shifts (Fig. 2) allowed the determination of the dissociation enthalpy $\Delta H^\circ = 29.6 \pm 0.4$ kJ mol^{-1} and the dissociation entropy $\Delta S^\circ = 90 \pm 1$ J $K^{-1} mol^{-1}$ for the dissociation of **5** to **3** and **4**. Not unexpectedly the reaction of adduct **5** with 2,3-dimethylbutadiene and *tert*-butylalcohol affords exclusively reaction products **6** and **7**, which are the products of the reaction of **3** with these reagents.[15]

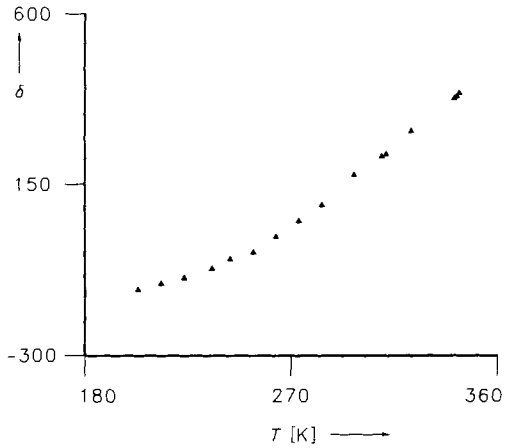

Fig. 2. ^{119}Sn NMR chemical shift of **5** as a function of temperature. The spectra were measured at temperature intervals between −80 to +70 °C in a 10 mm NMR tube with 0.3 g **5** in 0.5 mL C_6D_6 and 2 mL toluene. The ^{119}Sn NMR chemical shift of **3** is known ($\delta \approx 678$)[6], that of **5** was extrapolated to $\delta = -150$. The experimental ^{119}Sn NMR data collected at a number of temperatures was used in the calculation of the dissociation enthalpy and entropy. (Parameter correlation ln*K* vs. 1/T: 0.9935).

Stannaethene **2** with trigonal-planar coordination and the shorter tin–carbon bond (2.025 Å) is formally an adduct of the stannandiyl as Lewis base and the extremely electrophilic carbene $:C(BtBu)_2C(SiMe_3)_2$, which does not exist in this form.[16] In **5**, on the other hand, the stannandiyl is the Lewis acid. In this respect the two bonding systems **2** and **5** are complementary to each other and delineate the range of bonding in the stannaethenes.

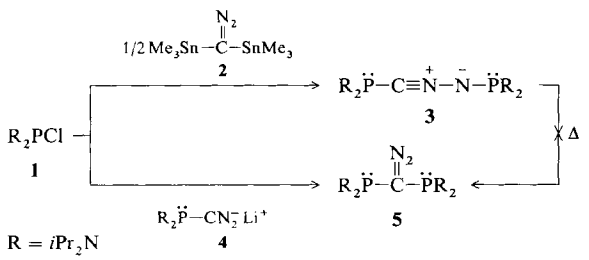
A Straightforward Synthesis of Nitrilimines; X-Ray Crystal Structure of a Nitrilimine Stabilized by Non-Heteroatom Substituents**

By *Régis Réau, Guilaine Veneziani, Françoise Dahan,* and *Guy Bertrand**

Dedicated to Professor Hans-Friedrich Grützmacher on the occasion of his 60th birthday

Recently, the use of heteroatoms has allowed the preparation of stable species that were believed to be only transient intermediates. The most striking example is the synthesis of stable carbenes[1] bearing either a silicon and a phosphorus atom,[2] or two nitrogen atoms.[3] So far, the only known nitrilimines stable at room temperature bear heteroatom substituents (B, Si, P), both at the carbon and nitrogen ends.[4] They were obtained from the reaction of lithiated diazo compounds with electrophiles, a reaction assumed for a long time to give only diazo compounds.[5] Since nitrilimines can rearrange into the more thermodynamically stable diazo compounds,[6] and the concomitant formation of both isomers has never been observed, we believed that nitrilimines were the products of the kinetically controlled reaction, and that they were only isolable because of the stabilizing effect of the heteroatoms.[4c] The primary formation of nitrilimines from the lithiated diazo compounds could imply that the lithium atom is bound to the nitrogen end rather than to the carbon end. Here we report that tin diazo compounds are powerful precursors of nitrilimines as exemplified by the synthesis of the first stable nitrilimine with non-heteroatom substituents. We also demonstrate that the formation of nitrilimines and diazo compounds from lithiated diazo compounds results from competitive attack at either the nitrogen or carbon atom.

The structure of tin diazo compounds is well established in contrast to that of lithium diazo compounds; in the former, the metal is bound to the carbon atom.[7] However, in THF at room temperature, bis(trimethylstannyl)diazomethane (**2**)[8] readily reacts with chloro[bis(diisopropylamino)]-phosphane (**1**) to give quantitatively *C*-[bis(diisopropylamino)phosphino]-*N*-[bis(diisopropylamino)phosphino]-nitrilimine (**3**).[9] In contrast, the reaction of lithiated bis(diisopropylamino)phosphinodiazomethane **4** with chlorophosphane **1** provides the isomeric bis(phosphino)-diazomethane **5**.[10] Nitrilimine did not thermally isomerize



to **5**, clearly demonstrating that **3** is not the product of the kinetically controlled reaction of lithium compound **4** and phosphane **1**; in other words, the electrophilic attack on the carbon and nitrogen ends are two competitive processes.

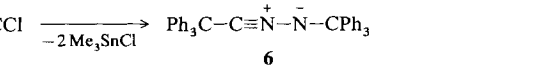
[**] This work was supported by the Centre National de la Recherche Scientifique (CNRS).

Since **3** was the first stable nitrilimine bearing two electron-donating substituents, the importance of the electronic effects in stabilization was considered. Indeed, the reaction of tin diazo compound **2** with triphenylmethylchloride in acetonitrile at −30 °C gave rise to nitrilimine **6**, which was isolated as surprisingly air-stable, pale yellow crystals (60 °C decomp., 90% yield). The identification of **6** as a nitrilimine



was supported by ^{14}N NMR [$\delta = -182$ (C*N*N)][11] and ^{13}C NMR data [$\delta = 60.71, 76.26$ (Ph_3C), 85.5 (CNN)], and by a strong, broad absorption band in the IR spectrum at 2052 cm^{-1}. The structure of **6** was confirmed by an X-ray structure analysis[12] (Fig. 1). Nitrilimine **6** has a structure

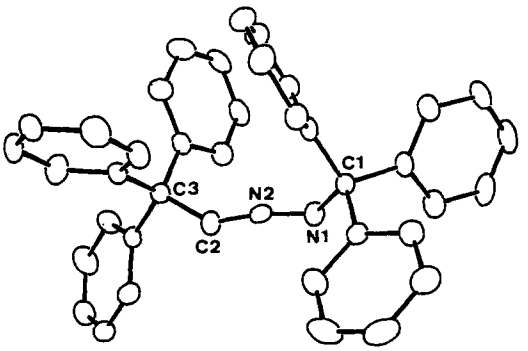


Fig. 1. Molecular structure of **6** in the crystal (ORTEP, ellipsoids at the 35% probability level). Selected bond lengths [Å] and angles [°]: C1-N1 1.530(2), N1-N2 1.262(2), N2-C2 1.173(3), C2-C3 1.503(3), C1-N1-N2 115.2(2), N1-N2-C2 169.4(2), N2 C2-C3 137.3(2), C1-N1-N2-C2 135.7, N1-N2-C2-C3 134.0

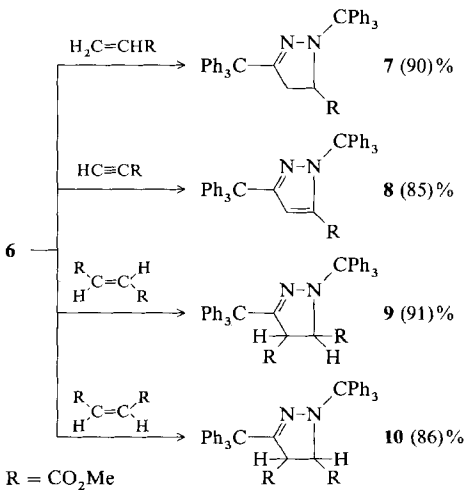
similar to the bent allenyl model predicted by theory,[13] and interestingly resembles the previously reported *C*-thiophosphoranyl-*N*-phosphinonitrilimine.[4d] The stability of **6** can only be explained in terms of steric effects, because the triphenylmethyl groups have no apparent electronic interaction with the CNN skeleton. In spite of its bulky substituents, nitrilimine **6** undergoes typical 1,3-dipolar reactions:[14] Compound **6** underwent regio- and stereospecific [2 + 3] cycloaddition with methyl acrylate, methyl propiolate, dimethyl fumarate, and dimethyl maleate, leading to the respective five-membered heterocycles **7**–**10**[9] in high yields.



The formation of bis(phosphino)nitrilimine **3** demonstrates the potential of tin diazo compounds as nitrilimines precursors and allows a clarification of the mechanism of the reaction of electrophiles with lithium diazo compounds. The first experimental evidence of an organic nitrilimine and its isolation were separated by 30 years. The crucial step was the stabilization of these 1,3-dipoles by heteroatom substituents.

Experimental Procedure

6: An acetonitrile solution (4 mL) of bis(trimethylstannyl)diazomethane (**2**) (278 mg, 0.757 mmol) was added dropwise to 2 equivalents of triphenylmethylchloride (421 mg, 1.51 mmol) in acetonitrile (6 mL) at $-30\,^{\circ}C$. The solution was stirred for 1 h at $-30\,^{\circ}C$, and **6** precipitated as a pale yellow solid which was washed several times with acetonitrile. Trimethylchlorostannane was removed under vacuum (ca. 15 h) at room temperature. Nitrilimine **6** was recrystallized from THF/Et_2O (358 mg, 90%). Nitrilimine **6** is air stable in the solid state but slowly decomposes in solution above $-20\,^{\circ}C$.

Cycloaddition reactions: A solution of the dipolarophile in THF was added to the stoichiometric amount of nitrilimine **6** in THF at $-30\,^{\circ}C$. The mixture was allowed to warm to room temperature, and the solvent was then removed at 10^{-2} Torr. The solids **7**–**10** were washed several times with pentane and dried in vacuo.

Preparation, Ligand Exchange Reactions, and Structure of a Diene(aqua)ruthenium Complex $[(cod)Ru(H_2O)_4](OTs)_2$**

By *Ulrich Kölle,* Gabriele Flunkert, Ralf Görissen, Martin U. Schmidt,* and *Ulli Englert*

Metal ions which together with water are complexed to arenes or olefins, contradict the Jørgensen rule[1] for transition metal complexes (either hard, hard or soft, soft!) and therefore are expected to have special properties. Apart from the well characterized dicationic benzene(aqua)Ru- and Os complexes[2, 3] as well as the recently described tetramethylthiophene-Ru analogue,[4] a series of dicationic cyclopentadienyl(aqua)–metal complexes, some of them less well characterized, of the type $[Cp^{(*)}M(H_2O)_3]^{2+}$ ($Cp^* = \eta^5$-C_5Me_5) is known; $[CpCr(H_2O)_3]^{2+}$,[5] $[Cp^*Co(H_2O)_3]^{2+}$,[6, 7] $[Cp^*Rh(H_2O)_3]^{2+}$,[7, 8] $[Cp^*Ru(H_2O)_3]^{2+}$.[7] These complexes are of differing stabilities. Most recently also a number of olefin(aqua) complexes was prepared.

The dication **1** of the title compound proved to be a surprisingly robust organometallic aqua complex which was prepared in the way shown in Scheme 1 and is the first structurally characterized diene(aqua)–metal complex.

$$RuCl_3 \cdot nH_2O \xrightarrow[EtOH]{C_6H_8} [\{(C_6H_6)RuCl_2\}_2] \xrightarrow[-AgCl]{Ag^+,\,H_2O} [(C_6H_6)Ru(H_2O)_3]^{2+}$$

$$\xrightarrow[H_2O,\,10\,^{\circ}C]{h\nu} [Ru(H_2O)_6]^{2+} \quad (\mathbf{2}) \xrightarrow{cod,\ EtOH} [(cod)Ru(H_2O)_4]^{2+} \quad (\mathbf{1})$$

Scheme 1. Counterions of the dicationic complexes: p-$CH_3C_6H_4SO_3^-$ (OTs) or SO_4^{2-}. cod = 1,5-cyclooctadiene.

The photochemical route convenient for the preparation of $[Ru(H_2O)_6]^{2+}$ (**2**),[7, 10] avoids the somewhat involved reduction of aqueous ruthenic acid by activated lead[11] and makes smaller scale preparations of the hexaaqua-metal ion easier. In contrast to the reaction of **2**-$(OTs)_2$ with 1,3-cyclooctadiene which gave a (η^5-cyclooctadienyl)(η^6-arene) complex,[12] we found that in ethanol with cod only a complexation to the dicationic complex **1** with one cod and four aqua ligands occurred (yields and physical data for this and

the other newly prepared compounds see Table 1). This is, dependent on the anion, soluble in polar organic solvents and particularly soluble in water. In contrast to **2**, the solutions are not air sensitive and also do not decompose or disproportionate when warmed.[13]

Table 1. Yields and selected physical data of the compounds **1**-$(OTs)_2$, **3**, **4**, **5a**–**5c** (as PF_6 salt), and **6**-$(OTs)_2$.

1-$(OTs)_2$: ^{1}H NMR (80 MHz, D_2O, H_2O (δ = 4.65) as standard): δ = 4.4 (br s, 4H; =CH), 2.3 (br s, 8H; CH_2); ^{13}C NMR (D_2O): δ = 28.86 (t, J(C, H) = 132.6 Hz), 89.90 (d, J(C, H) = 161.6 Hz); IR(KBr) $\tilde{\nu}$ [cm^{-1}] = 3271 (br, H_2O), 2960, 2930, 2880 (CH_2, CH_3), 1635 (C=C), 1446 (δ CH_2) 682 (δ HC=CH); correct C,H-analysis

3: Yield 80%; ^{1}H NMR (300 MHz, C_6D_6): δ = 1.75, 2.01 (s, each 3H; CH_3), 5.25 (s, 2H; CH), 1.83, 2.44 (m, each 2H), 2.16 (m, 4H; CH_2), 4.23, 4.57 (m, each 2H; =CH); ^{13}C{^{1}H} NMR (60.2 MHz, C_6D_6): δ = 27.38, 28.12 (CH_3), 98.77 (CH), 186.67, 186.75 (C–O), 28.86, 30.78 (CH_2), 88.99, 92.08 (=CH) [a]

4: ^{1}H NMR (80 MHz, CD_3OD): δ = 3.95 (s, 4H; CH_2), 6.9, 7.2 (m, 8H; arom.), 8.44 (2H=CH), ca. 2 (br m, 8H; CH_2), ca. 5.6 (br m, 4H; =CH)

5a-PF_6: Yield quantitative; ^{1}H NMR (80 MHz, $CDCl_3$): δ = 5.03 (s, 5H; Cp), ca. 4 (br m, 12H, OCH_2; 4H, CH), 3.06 (br s, 2H; H_2O), ca. 2.1 (m, 8H; CH_2), 1.22, 1.27, 1.28 (t, J = 7.1 Hz, each 3H; CH_3); IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 1280 s (P=O), 1112, 1037 s (δ POEt), 839 vs (PF_6^-)

5b-PF_6: from **5a** and NaN_3, yield 70%; ^{1}H NMR (80 MHz, CD_3OD): δ = 4.15 (s, 5H; Cp), ca. 4.1 (br m, 12H, OCH_2; 4H, CH), ca. 2.14 (m, 8H; CH_2), 1.32 (t, J = 7 Hz, 6H; CH_3), 1.27 (t, J = 7 Hz, 3H; CH_3); IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2060 s (N_3), 1112, 1140 s (δ P(O)OEt)

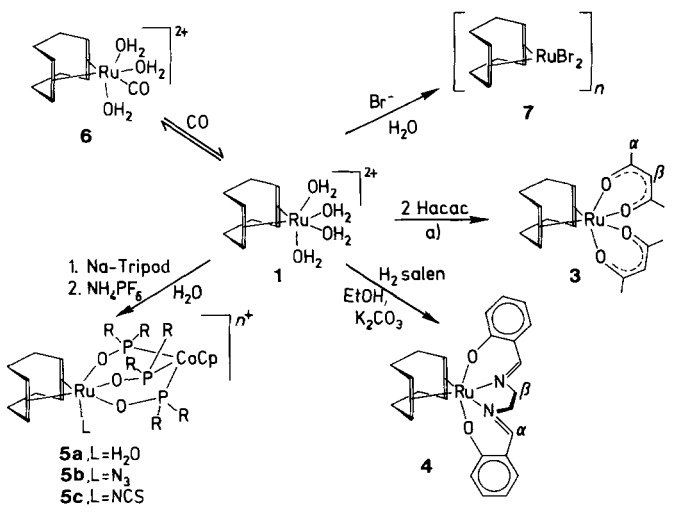
5c-PF_6 from **5a**-PF_6 and KSCN; ^{1}H NMR almost like **5b**-PF_6; IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2126, 2077 s (SCN), 1113, 1040 s (δ P(O)OEt)

6-$(OTs)_2$: from **1**-$(OTs)_2$ with 2 bar CO, 20 h, roomtemp., H_2O; ^{1}H NMR (80 MHz, D_2O): δ = 4.40 (br s, 4H; =CH), 2.08 (s, 8H; CH_2), 2.31 (s, 6H; CH_3OTs), 7.68, 7.57, 7.33, 7.23 (m, 8H; arom.); ^{13}C NMR (CD_3OD): δ = 197.5 (br s, CO), 94 (m, =CH), ca. 30 (m, CH_2); IR (KBr) $\tilde{\nu}$[cm^{-1}] = 1984 cm^{-1} (CO)

[a] See also P. Powell, *J. Organomet. Chem.* **1974**, *65*, 89 [6].

In the cyclic voltammogram in dimethylformamide, within the limits +1.9 to ca. −1.2 V (saturated calomel electrode), no electon transfer is observed.

Compound **1** was chemically characterized by ligand exchange reactions, which led to the complexes **3**–**7** (Scheme 2). During these reactions, depending on the ligand, one to four aqua ligands were exchanged. The tripod ligand served as a model for a triaqua ligand moiety.[14] The coordination shown in **5**, to a metal complex fragment with twofold symmetry (see Fig. 3), causes the methyl signals of the OEt groups of the tripod ligand to split into three triplets of equal intensity. The remaining aqua ligand can be easily exchanged for other ligands to form a variety of further complexes **5**.



Scheme 2. R = OEt. Hacac = acetylacetone, H_2salen = bis(salicylidene)ethylenediamine. a): EtOH, K_2CO_3, 40 °C, 2 h.

According to the NMR spectra, the salene in **4** coordinates in a similar way to acac in **3** such that a molecule with C_2 symmetry results. Particularly noteworthy is the exchange of an aqua ligand for CO under a mild CO pressure. This reaction corresponds to the recently found carbonylation of **2**-$(OTs)_2$ which afforded the monocarbonyl(aqua) complex.[15] Here, too, the splitting of the cod signals, especially in the ^{13}C NMR spectrum, indicates an unsymmetrical molecular unit and thus, together with the single CO absorption in the IR spectrum, a monocarbonyl complex. With halide ions, for example Br^-, the polymeric dihalide $[(cod)RuBr_2]_x$ immediately precipitates from water. Neither this, nor the analogous chloride could be used, for example with Ag^+ ions in water, to form **1**.

Crystals of **1**-$(OTs)_2$ suitable for a structure determination were obtained by slow evaporation of an aqueous acetone solution. The molecular structure of **1** is shown in Figure 1, and a packing diagram of **1**-$(OTs)_2$ in Figure 2. The complex

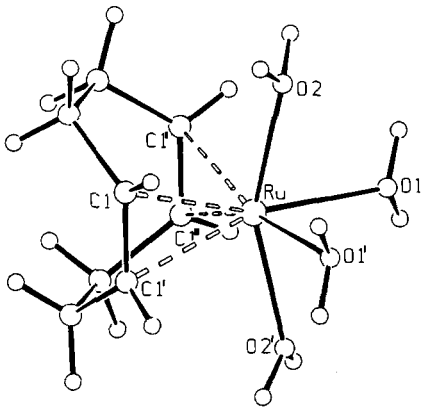


Fig. 1. Crystal structure of **1** (SCHAKAL). Distances [Å]: Ru-O1 2.158(1), Ru-O2 2.095(2), Ru-C1 2.178(1), C1-C1' 1.367(3); Angles [°]: O1-Ru-O1' 86.14(9), O2-Ru-O2' 154.8(1), (middle C1-C1')-Ru-*cis*-O1 93.82, (middle C1-C1')-Ru-*trans*-O1 180, (middle C1-C1')-Ru-O2 99.15, (middle C1-C1')-Ru-(middle C1''-C1''') 86.22.

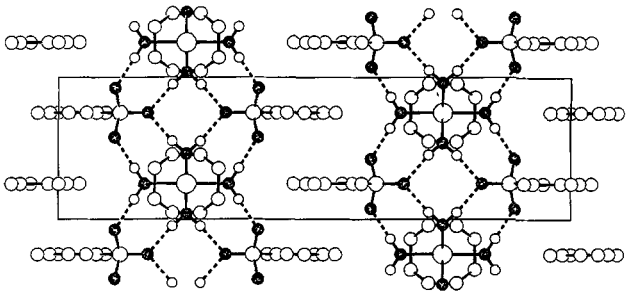

Fig. 2. Packing diagram of **1**-$(OTs)_2$. Oxygen atoms dark. The strands of $[(cod)Ru(H_2O)_4]^{2+}$ ions, each twice H-bonded via tosylate ions, lie along the *c* axis, distance RuO···H···OS 2.746(2), 2.683(2) Å.

contains one (cod)Ru unit, to which are symmetrically coordinated four aqua ligands to yield a highly distorted octahedral arrangement. Two crystallographic mirror planes of the space group *Pmmn* through the Ru, interconvert the two aqua ligand sets as well as the cod halves. Of the aqua lig-

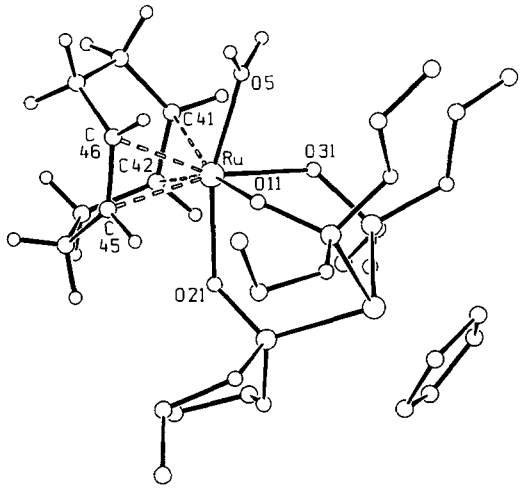

Fig. 3. Crystal structure of **5a**-ClO_4 (SCHAKAL). Distances [Å]: Ru-O11 2.10(2), Ru-O21 2.09(2), Ru-O31 2.10(3), Ru-O5 2.10(2), Ru-C41 2.17(2), Ru-C42 2.17(2), Ru-C45 2.17(3), Ru-C46 2.19(4), C41–C42 1.38(1), C45–C46 1.385(9); Angles [°]: O5-Ru-O11 81.2(6), O5-Ru-O21 162(2), O5-Ru-O31 81.3(7), (middle C41–C42)-Ru-O21 95, (middle C45–C46)-Ru-O5 95.

ands, two are *trans* to an olefin double bond (O1), and two are approximately *trans* to each other (O2) with a O–Ru–O angle for the latter of 155°. Note that the Ru–O1 distances of 2.158(2) Å are significantly longer than those of Ru–O2 (2.095(2) Å. Since all of the water-H atoms are hydrogen-bonded to the sulfonate groups of the anions, as illustrated in Figure 2, whereby the crystalline salt forms a chain structure, this difference has to be attributed to a real *trans* effect of the double bonds. Thus, in **1**, for the first time the influence of the organic ligand on the metal–water bond is structurally evident. The effect could not be derived from the structure of $[(C_6H_6)Ru(H_2O)_3]^{2+}$, the only other compound comparable with $[Ru(H_2O)_6]^{2+}$, because the lack of a threefold crystallographic axis and the different H bonding of the water protons makes the Ru–O distances unequal.

In Figure 3 the cation of the perchlorate **5a**-ClO_4[17] is shown. Of the two possible orientations, the tripod ligand adopts the one that substitutes the O1 and O1′ and O2. Here, the Ru distances to the tripod O atom (2.10(2), and 2.09(2) Å, respectively) are as long as those to the remaining aqua ligand, and correspond to the Ru–O2 distance in **1**-(OTs), i.e. the rigid tripod ligand does not reflect the observed *trans*-effect in the aqua complex. Two oxygen atoms of the disordered ClO_4^- ion connect the cations via H bonds to form dimeric units. The Ru–cod distances as well as the relatively short C=C distances of the coordinated cod double bond, which classify the aqua-Ru complex as a poor back bonding fragment, are the same in the two complexes within the limits of error.

The few measurements carried out so far concerning the kinetics of water exchange in organometallic aqua- and closely related complexes[18] all show a rate of exchange increased by a factor of 10^3–10^5 towards the hexaaqua–metal ions of the same electron configuration. Evidently this kinetic lability is related to the longer metal–water bond. A corresponding relationship was noted for the Ru^{II} acetonitrile complexes $[Ru(CH_3CN)_6]^{2+}$, $[(C_6H_6)Ru(CH_3CN)_3]^{2+}$, and $[(C_5H_5)Ru(CH_3CN)_3]^{+}$, with an increasing exchange rate of the acetonitrile in this order.[19] The kinetic lability together with the thermal stability of the dicationic complex **1**, and the possibility of a reversible CO addition (Scheme 2), hopefully mean that diene(aqua) complexes can also act as effective catalysts.

Experimental Procedure

A solution of $[Ru(H_2O)_6](OTs)_2$ (0.3 g, 0.48 mmol) and cod (1.5 mL) in ethanol (30 mL) was stirred for 4 h at room temperature under an inert atmosphere. This resulted in a color change from red-violet to yellow. The solvent was removed under vacuum, and the residue was taken up in water (5 mL) and extracted three times with hexane (5 mL) to remove the excess cod. A yellow oil remained after the removal of water under vacuum. This was dissolved in acetone/ethanol (4:1), and cooled to −10 °, whereby the salt was obtained in the form of orange-yellow needles. Yield ca. 70–85%.

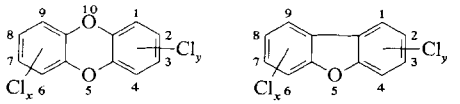
The Beilstein Test: An Unintentional Dioxin Source in Analytical and Research Laboratories

By *Barbara M. Scholz-Böttcher, Müfit Bahadir,** and *Henning Hopf*

In 1872 F. Beilstein introduced his now classical experiment as an easy proof for halides in organic materials.[1] In this flame test on copper wire, the volatile copper halides are detected by the green color of the flame. Even if there are doubts about its specifity,[2] the Beilstein test is a routine and quick screening test, mainly for chloride, up to the present day.

The combustion of chlorinated organic materials is suspected to generate polychlorinated dibenzo-*p*-dioxins (PCDD) and -furans (PCDF).[3] Main reasons for their formation are the preformed structures in precursor substances as well as a catalyzed de novo synthesis during the combustion. By now it is a well-known fact that even traces of copper(II) chloride have a high catalytic activity on the formation of PCDD and PCDF during thermal treatment. This has been confirmed in model experiments with synthetic matrices as well as fly ash from municipal waste incineration plants.[4-6] The optimal temperature for the formation of PCDD or PCDF is 300 °C.



Scheme 1. Structures of polychlorinated dibenzo-*para*-dioxins (PCDD) and dibenzofurans (PCDF). $x = 1-4$, $y = 0-4$.

Aromatic systems arising from a partial, incomplete combustion process are subject to chlorination reactions. Radical mechanisms and chlorination by free halogen, both generated in the presence of $CuCl_2$, have been proposed. Chlorine is released from $CuCl_2$ by thermal activation. In the presence of oxygen, Cu(II) chloride may also act as a catalyst as demonstrated by the Deacon reaction for chlorine generation.[4]

The conditions of the Beilstein test thus provide all prerequisites for PCDD and PCDF formation: appropriate combustion temperatures, chlorinated organic compounds, oxygen, and copper. To prove this assumption, seven chlorinated compounds have been investigated: 2,4-dichloro- (2,4-DCP), 2,4,6-trichloro- (2,4,6-TCP) and pentachlorophenol (PCP) as well as monochlorobenzene (MCB), known to be PCDD and PDCF precursors,[3, 7] and triphenylmethylchloride (Trityl), trichloroethylene (TRI), and polyvinylchloride (PVC), from which PCDD or PDCF generation is only possible from de novo synthesis during the test.[3]

Around 100 mg MCB and TRI were burned in a total of ten tests after dipping the copper wire into the substances and collecting the combustion gases on glass wool and polyurethane foam (PU). About 10 mg of the chlorinated phenols were tested in the same manner. The exact quantities used were calculated by reweighing. In case of PVC 100 mg of polymer was cut into small pieces and burned in five portions; here glass wool was the only adsorbent. The adsorbents were extracted for 8 h with toluene in a soxhlet apparatus. After introducing ^{13}C-labeled 2,3,7,8-substituted PCDD or PCDF isomers that contain between four and eight chloro substituents the sample cleanup was carried out with alkaline alumina according to Hagenmaier et al.[8] The final solution in 100 µL of isooctane octane was analyzed with GC-MS in selected ion monitoring (SIM) mode. Tetrachloro- to octachloro-substituted PCDD or PCDF compounds were quantified by comparison with corresponding ^{13}C-labeled internal standards (isotope dilution technique), whereas monochloro- to trichloro-substituted PCDD or PCDF compounds were calculated from the response factors of tetrachlorinated dioxins and furans (TeCDD and TeCDF).[9]

The main intention of our experiments was to examine whether PCDD and PCDF are formed under the conditions of the Beilstein test, which are typical for combustion in general. It is almost impossible to reproduce exactly the complex reactions under the test conditions. Variations in the temperature gradient depending on the flame position of the copper wire, in the induction periods for each compound and in the amounts used all play a significant role. Since many modifications of the Beilstein test exist, our results may represent just an order of magnitude of PCDD and PCDF generation.

The temperature inside the glass wool reached a maximum at between 300° and 500 °C (Fig. 1) depending on the duration of one single test (10–30 s) and drops immediately after the burner was removed. The temperature of the PU foam never exceed 40 °C; that of the moderate flame lay between 700 °C and 900 °C. Although catalytic effects of PCDD or PCDF formation on the surface of the glass wool or other solid inorganic adsorbents cannot be excluded, this type of sampling for the following GC-MS analysis is the state of the art for the generation and analytical characterization of gaseous combustion products.[10-12]

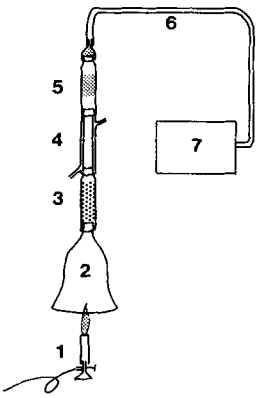


Fig. 1. Apparatus used for the Beilstein test. Bunsen burner (1), funnel (2), tube filled with glass wool (3), water-cooled condensor (4), tube filled with polyurethane foam (5), PVC tubing (6), pump (7).

The Beilstein test led to the formation of PCDD/F for all investigated compounds (Table 1). The toxicity equivalencies (TEQ) relative to 2,3,7,8-TeCDD were calculated using the toxicity factors recommended by the German Federal Health Agency.

Chlorinated phenols are well-known precursors for PCDD and PDCF. In case of PCP and 2,4,6-TCP the direct condensation products, OcCDD and TeCDD, respectively, predominated. 2,3,7,8-TeCDD, however, was not detectable in either case. A chlorine content in PCDD and PCDF higher than expected from the structures of the precursors 2,4,6-TCP and 2,4-DCP was observed, which indicates catalytic effects

of copper. In the case of 2,4-DCP little direct condensation product, but large amounts of OcCDD were detected. The adsorption efficiency of the filters for less chlorinated PCDD or PCDFs might have been insufficient because of their relatively high vapor pressures.[7] All isomers except MoCDD or MoCDF and DiCDD were generated from MCB. The amounts formed were one order of magnitude less than those of the chlorophenols, because of the necessity of an additional incorporation of oxygen into the molecule. Mainly PCDF isomers were formed by the de novo synthesis in case of Trityl, TRI, and PVC. The direct condensation product of three trichloroethylene molecules is hexachlorobenzene. This might be the reason, why the higher chlorinated PCDD and PCDFs predominated in the Beilstein test.

The generation of PCDD and PCDF during incineration of PVC is still controversial. While on the one hand the influence of PVC on the concentration of PCDD and PCDF in combustion processes is denied,[13] on the other it could be shown that the combustion of PVC in an oxidative atmosphere generates these compounds by interactions of organics with HCl, both of which are generated during the combustion of PVC.[14] In the Beilstein test, PVC serves as a source of organic compounds and chlorine simultaneously, and the copper-catalyzed formation of PCDD and PCDF does occur.

In conclusion, our experiments show that formation of PCDD and PCDF under the conditions of the Beilstein test must be expected. Their generation is due to preformed structures of the starting materials and partly by de novo synthesis. Absolute amounts of 0.4–340 μg PCDD and PCDF and 5–915 ng TEQ per gram of tested compound were obtained. In no case could we detect 2,3,7,8-TCDD itself. This phenomenon is mainly attributed to the substitution pattern of the compounds investigated. The application of 2,4,5-TCP, for example, would very likely have led to a high yield of 2,3,7,8-TeCDD and correspondingly high TEQ, which we tried to avoid in our laboratory.

Based on today's knowledge, the national ADI values (acceptable daily intake) of 2,3,7,8-TeCDD TEQ are set at 1–10 pg per kg body weight, amounting to 70–700 pg for an adult. Depending on the copper target used (e.g., a piece of copper wire or a German Pfennig) between 1 and 5 mg of an unknown compound are usually applied for one Beilstein test. While testing 5 mg 2,4,6-TCP, more than 4500 pg 2,3,7,8-TeCDD TEQ are released. This calculation demonstrates that, depending on the chlorinated compound used, a single Beilstein test can easily exceed the daily tolerance. A long term accumulation, for example, on dust particles, in research and teaching laboratories is likely to occur.

As a conclusion we propose that the Beilstein test for halides should be substituted in a laboratory's daily practice[15] or if a substitution is not practicable, Beilstein tests should be only carried out under a fume hood equipped with a charcoal filter and a UV lamp for decontamination purposes.

Molecular Machines: Molecular Structure of $[(p\text{-Tol}_3P)_{10}Au_{13}Ag_{12}Cl_8](PF_6)$—a Cluster with a Biicosahedral Rotorlike Metal Core and an Unusual Arrangement of Bridging Ligands**

By *Boon K. Teo** and *Hong Zhang*

Further miniaturization poses a major challenge in the development of microelectronics.[1] Progress must rely on the fabrication of components on the nanometer scale ("nanotechnology", molecular machines, molecular computers, etc.[2, 3]). Two approaches for building such devices can be distinguished: the "scaling down" of state-of-the-art microelectronics technology ("top-down" method)[1] and the construction of molecular or supramolecular assemblies with specific functions and properties from smaller building blocks ("bottom-up" method).[4–7] These organized and functional supramolecules and -complexes,[4] constructed either by direct synthesis or by self-assembly, are prototypes of more sophisticated molecular devices.[5] In this regard, the "cluster of clusters" concept proposed by us[8–10] for building large cluster aggregates from smaller clusters is also useful in the design and synthesis of "supraclusters" which may ultimately serve as models for molecular machines of well-defined structures. The driving force for such spontaneous cluster assemblage is the "self-organization self-similarity" principle (fractal) often observed in nature.[8, 11, 12] In this paper, we report a new 25-metal-atom cluster which, along with two recently reported clusters of the series, can be visualized as a molecular rotor with two metal icosahedra sharing a vertex. Hence, this supracluster assemblage may also be termed a "biicosahedral rotor". The ellipsoidal (prolate) metal core measures approximately $1 \times 1 \times 1.5\ nm^3$, suggesting that this series of clusters can be envisaged as a prototype for nanomechanical rotary devices.

Our recent work in the synthesis and structural characterization of a series of phosphine Au–Ag halide clusters gave rise to a new sequence of cluster structures which can be described as vertex-sharing polyicosahedra.[8–10] In these structures, the basic building block is an icosahedron composed of 13 metal atoms (Au_7Ag_6), and the design rule (mode of construction) is vertex-sharing.[8, 9] The first member of this series is the cationic 25-metal-atom cluster **1** (isolated as the PF_6^- salt), which can be considered as two Au-centered Au_7Ag_6 icosahedra sharing one Au atom (nuclearity = $2 \times 13 - 1 = 25$).[10b] The adjacent metal pentagons in **1** are staggered (*s*) with respect to one another, giving rise to three icosahedral (or bicapped pentagonal antiprismatic) cages (*sss* conformation). More recently, the SbF_6^- salt of the cluster cation **2** was shown to have a novel staggered/eclipsed/staggered (*ses*) conformation.[10c] Here, the two middle Ag_5 pentagons are eclipsed (*e*), resulting in a central bicapped pentagonal prismatic cage. The title cluster cation $[(p\text{-Tol}_3P)_{10}Au_{13}Ag_{12}Cl_8]^+$ (**3**), has a new conformation nearly halfway between those observed in **1** and **2**, and an unusual arrangement of the bridging ligands which is distinct from that of **1** or **2**. Larger clusters in this series include the 37-metal-atom dication $[(p\text{-Tol}_3P)_{12}Au_{18}Ag_{19}Br_{11}]^{2+}$[10e] and the 38-metal atom cluster $[(p\text{-Tol}_3P)_{12}Au_{18}Ag_{20}Cl_{14}]$[10f, g] and the 46-metal atom cluster $[(Ph_3P)_{12}Au_{24}Ag_{22}Cl_{10}]$.[10h] In these latter structures, the icosahedral units are linked by (interpenetrating) bicapped pentagonal prisms (as in the *ses* configuration), instead of (interpenetrating) icosahedra (as in the *sss* conformation).[8, 9, 10c] Clusters based on other building blocks and different modes of construction can be found in the literature.[13–19]

$[(p\text{-Tol}_3P)_{10}Au_{13}Ag_{12}Br_8]^+$ **1**

$[(Ph_3P)_{10}Au_{13}Ag_{12}Br_8]^+$ **2**

$[(p\text{-Tol}_3P)_{10}Au_{13}Ag_{12}Cl_8]^+$ **3**

The PF_6^--salt of cluster cation **3** was prepared by the reduction of a mixture of $(p\text{-Tol})_3P$, $HAuCl_4$ and $AgNO_3$, (Au:Ag = 1:1) with $NaBH_4$ in absolute ethanol, followed by the addition of excess NH_4PF_6 in ethanol. The dark red precipitate was filtered and purified by recrystallization from ethanol/hexane. Crystals suitable for X-ray diffraction study were obtained by evaporation of an ethanol/hexane solution of the recrystallized product.[20, 21]

In Figure 1a and b the metal core and the $[P_{10}Au_{13}Ag_{12}Cl_8]$ framework of **3** are depicted. The cluster has ten tri(*p*-tolyl)phosphine and eight chloride ligands. The ten phosphine ligands coordinate to ten peripheral Au atoms

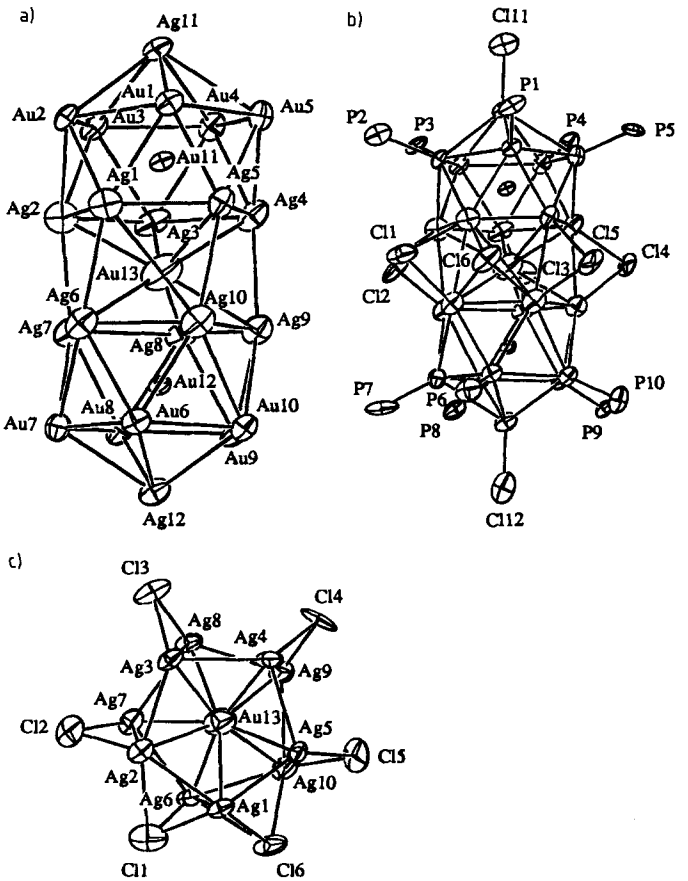

Fig. 1. Crystal structure of **3** (PF_6^- salt). a) Biicosahedral framework of the $Au_{13}Ag_{12}$ core; b) metal–ligand framework ($P_{10}Au_{13}Ag_{12}Cl_8$); c) projection of the two Ag_5 pentagons onto the approximate plane of the six doubly bridging chloride ligands. The cluster has an idealized C_5 axis passing through Ag11, Au11, Au13, Au12, and Ag12. Important distances [Å]: (n = 1–5, m = 6–10): Au11-Au(n) 2.718(av), Au11-Ag(n) 2.804(av), Au11-Ag11 2.86(1), Au11-Au13 2.791(9), Au12-Au(m) 2.719(av), Au12-Ag(m) 2.874(av), Au12-Ag12 2.69(1), Au12-Au13 2.847(9), Au13-Ag(n) 2.91(av), Au13-Ag(m) 2.86(av), Au-P 2.32(av), Ag11-Cl11 2.33(5), Ag12-Cl12, 2.36(5), doubly bridging chloride ligands Cl2-Cl5, Cl-Ag 2.47(av), triply bridging chloride ligands, Cl1-Ag1 2.62(6), Cl1-Ag2 2.93(5), Cl1-Ag6 2.51(5), Cl6-Ag1 2.48(4), Cl6-Ag6 3.07(5), Cl6-Ag10 2.78(5). The six chloride ligands form a distorted hexagon with "nonbonding" (crystallographically independent) distances of Cl6···Cl1 3.66, Cl6···Cl5 3.78, Cl1···Cl2 4.01, Cl2···Cl3 4.93, Cl3···Cl4 5.03, Cl4···Cl5 4.31.

in a radial fashion. As for the eight chloride ligands, two are terminal (Cl11 and Cl12), while the remaining six are bridging (Cl1-Cl6) (Fig. 1c).

The most interesting feature of the structure of **3** is that the metal framework has neither an *ses* nor an *sss* conformation (cf. Fig. 1c). In fact, it is nearly halfway between these two extremes. As a result, the metal framework has an idealized D_5 symmetry (instead of D_{5d} for *sss* as in **1**, or D_{5h} for *ses* as in **2**). The projection of the four pentagons of metal atoms (two outer Au_5 rings and two inner Ag_5 rings) onto the plane of the bridging ligands gives rise to a ring of 20 metal atoms more or less evenly distributed around the circle (Fig. 2). It is conceivable that in solution, the two metal icosahedra are relatively free to rotate about the shared vertex (Au13),[22] and that the observed solid-state structure is a snapshot of one of many energy minima.

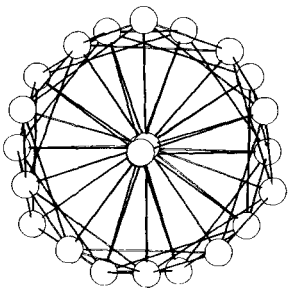

Fig. 2. The projection of the four pentagons of metal atoms in **3** (see Fig. 1a) onto the plane of the bridging ligands.

The arrangement of the six bridging chloride ligands (Cl1–Cl6) which connect the two Ag_5 pentagons (Ag1–Ag5 and Ag6–Ag10) is also rather unusual. Since pentagonal symmetry is incommensurate with the hexagonal net, we expect significant distortions in the arrangement of the bridging ligands. Indeed, as shown in Figure 1c the six bridging ligands can be categorized into two groups: four doubly bridging (Cl2–Cl5) and two triply bridging (Cl1, Cl6) ligands. The coordination of the doubly bridging ligands is more or less symmetrical whereas that of the triply bridging ligands is highly asymmetrical. For example, Cl1 has one long (2.93(5) Å) and two short (2.51(5) and 2.62(6) Å) Cl–Ag distances. The opposite is true for Cl6, which has one short (2.48(4) Å) and two long (2.78(5) and 3.07(5) Å) Cl–Ag distances.

There are several empirical rules for the Au–Ag superclusters that we have structurally characterized: 1. The interstitial or "bulk" atoms in the icosahedral cages are gold atoms; 2. The shared vertices (bicapped pentagonal prismatic cages) are also gold atoms; 3. The phosphine ligands are attached to surface gold atoms; 4. The halide ligands are bonded to silver atoms. These observations can be explained by the fact that gold is substantially more electronegative than silver (2.54 for Au, 1.93 for Ag). This disparity in electronegativity is related to relativistic effects.[23] The more electronegative gold atoms tend to prefer sites of high electron density, including the centers of the icosahedra or the shared vertices (which are centers of the bicapped pentagonal prisms). The more electron-donating phosphine ligands prefer more electronegative Au atoms, whereas the more electron-withdrawing halide ligands prefer the more electropositive Ag atoms.

This metal framework with a conformation halfway between *ses* and *sss* provides strong evidence for the concept of a "cluster of clusters" as applied to this series of vertex-sharing icosahedral Au–Ag superclusters. Further structural evidence comes from the separations between the pentagons: the intraicosahedra Au(1–5)–Ag(1–5) and Au(6–10)–Ag(6–10) interplanar distances of 2.40 Å and 2.52 Å are 0.5 Å shorter than the intericosahedra (inner) Ag(1–5)–Ag(6–10) interplanar distance of 2.91 Å. Moreover, the average intraicosahedral metal–metal distances of 2.772 Å (Au11-centered) and of 2.792 Å (Au12-centered) in **3** are significantly shorter (ca. 0.1 Å) than the average intericosahedral distances of 2.872 Å (Au13-centered). These observations suggest that intraicosahedral bondings are stronger than intericosahedral bonding, thereby reinforcing the cluster of clusters concept in which the individual icosahedron serves as a building block.

[20] Single crystal X-ray diffraction data were collected with an Enraf-Nonius diffractometer ($Mo_{K\alpha}$ radiation). $[(p\text{-}Tol_3P)_{10}Au_{13}Ag_{12}Cl_8](PF_6)\cdot n$EtOH: monoclinic $P2_1$, $a = 20.410(1)$, $b = 20.767(3)$, $c = 28.182(3)$ Å, $\gamma = 91.71(4)$; $V = 11939.9(4)$ Å^3, $Z = 2$. The tolyl groups and the PF_6^- anion were refined as rigid bodies (see [10g] for details). Anisotropic (heavy atoms)-isotropic (carbon atoms) refinement gave $R_1 = 0.112$ for 6706 independent reflections ($2\theta \leq 46°$) with $I > 3\sigma$.

[21] Further details of the crystal structure are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH in D-W-7514 Eggenstein-Leopoldshafen 2, on quoting the following number CSD-56021, the names of the authors, and the journal citation.

[22] It is interesting to note that the isotropic thermal parameters of all the gold atoms (Au1–Au12) fall within the narrow range of $B = 2$–3 Å^2, with the exception of the shared vertex (Au13) which has a B value of 6.6(2) Å^2. This latter value may signify a greater thermal motion and/or site disorder (split peaks) of the shared vertex. For comparation, the B values of the silver atoms fall within the range of 3–5 Å^2.

Tris(cyclopentanolato)oxovanadium(v): a Model for the Transition State of Enzymatic Phosphoester Cleavage**

By *Frank Hillerns, Falk Olbrich, Ulrich Behrens,* and *Dieter Rehder**

Dedicated to Professor Reinhard Nast on the occasion of his 80th birthday

(Alkoxo)oxovanadium complexes ("vanadate esters") have come under general scrutiny lately, on one hand because of their potential in generating thin metal-oxide and -carbide layers by gas-phase deposition,[1] and on the other because of the biological importance of vanadium ester compounds. The ester-like bond in vanadate(v) ($H_2VO_4^-$) is discussed, for example, in connection with the vanadate-dependent haloperoxidases from brown marine algae[2] and with the interaction of vanadate with phosphate-metabolizing enzymes and their substrates.[3] Some of these enzymes are inhibited by vanadium—the inhibition of ribonuclease A[4] and T_1,[5] for example, have been well studied. The cleavage (or formation) of the phosphoester bond in RNA proceeds via a pentavalent, trigonal-bipyramidal intermediate.[6] Enzymes take up vanadate esters as substrate in competition to phosphate esters,[3] and their function is thereby blocked. Such vanadate–enzyme complexes, which are stable analogues of the transition state of the phosphorylation reaction, were detected in systematic ^{51}V NMR investigations,[7] but could not be isolated. We have thus conducted model studies with cyclopentanol[8] in order to characterize them better. We show that vanadate esters, unlike phosphate esters, can be pentacoordinate.

In aqueous medium vanadate(v) forms esters with cyclopentanol (ROH) that can be identified by ^{51}V NMR spectroscopy. At physiological pH, the major component of the products is an ester which has the composition $[HVO_3(OR)]^-$ and a formation constant of $K = 0.13(2)$ M^{-1}.[9]

In nonaqueous systems in which the competitive condensation reaction of monovanadate to form oligovanadates does not take place, the formation tendency for vanadate esters is clearly more pronounced than that of the analogous phosphate esters. The ester **1** formed from $VOCl_3$ and *cyclo*-C_5H_9OH[10] shows one signal in the ^{51}V NMR spectrum at concentrations over 100 mM ($\delta = -616$); at lower concentra-

$[VO(cyclo\text{-}C_5H_9O)_3]$ **1**

tions a second signal appears ($\delta = -623$), which increases in intensity as the total concentration decreases (Fig. 1). We

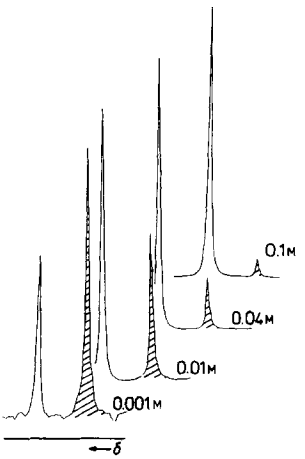

Fig. 1. ^{51}V NMR spectra (94.7 MHz) of $[VO(cyclo\text{-}C_5H_9O)_3]$ (**1**) in $CDCl_3$, showing the position of the equilibrium described in Equation (a) for four concentrations c. The signal at high magnetic field ($\delta(^{51}V) = -623$, hatched) corresponds to the monomer, that at $\delta = -616$ to the dimer. A 2D EXSY (*ex*change *s*pectroscop*y*) experiment shows that the chemical exchange formulated in Equation (a) actually takes place.

have already observed concentration and temperature dependence of $\delta(^{51}V)$ for other vanadyl esters and concluded that at least two species participate in an exchange equilibrium [Eq. (a)].[8b, 11] When R = *cyclo*-C_5H_9 the exchange is so slow even at room temperature that monomer and oligomer can be detected simultaneously.[11] In the concentration

$$n[VO(OR)_3] \rightleftharpoons [\{VO(OR)_3\}_n] \quad \text{(a)}$$

range c of 0.001 to 0.08 M for the vanadyl ester **1**, $n \approx 2$ [Eq. (a)], and the dimerization constant $K = [\text{dimer}]/[\text{monomer}]^2 = 870(50)$ M^{-1}. An X-ray structure analysis of the dimer of **1** showed how the dimerization took place. $[\{VO(cyclo\text{-}C_5H_9O)_3\}_2]$[12] comprises two monomeric units bridged by two alkoxide oxygen atoms (Fig. 2). In each of these units vanadium is in the center of a distorted trigonal bipyramid. The oxo ligand and the bridging alkoxo oxygen atom of the adjacent unit form the apexes. The vanadium atom lies 35 pm above the plane spanned by the three oxygen atoms of the alkoxo ligands (all-*cis* configuration). The distance from the V atom to the bridging O atom (O2) of 183.5(4) pm is distinctly longer than the distances to O3 and O4 [176.2(3) and 176.3(6) pm]. Even longer [229.6(3) pm] is the distance from O2 to the symmetry-related VA of the second monomeric unit of the dimer, which is only a little shorter than these bond lengths in multinuclear oxo–vanadi-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

um compounds with unsymmetric oxygen bridges.[13] The dimer of **1** has C_2 symmetry in the solid state, but C_{2h} symmetry in solution, as deduced from ^1H and ^{13}C NMR spectra of concentrated solutions that only contain the dimer.[14] The mirror plane passes through V, O2, VA, and O2A.

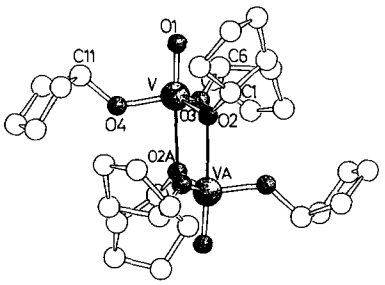

Fig. 2. SCHAKAL representation of $[\{VO(cyclo\text{-}C_5H_9O)_3\}_2]$. Selected bond lengths [pm] and angles [°]: V-O1 159.5(3), V-O2 183.5(4), V-O3 176.2(3), V-O4 176.3(6), V-O2A 229.6(3), O2-C1 142.0(7), O3-C6 143.7(6), O4-C11 144.5(7), V···VA 335.3(2); O1-V-O2 101.0(2), O1-V-O3 101.3(2), O1-V-O4 101.5(2), O1-V-O2A 172.9(2), O2-V-O3 117.5(2), O2-V-O4 118.3(2), O3-V-O4 113.1(2), O2-V-O2A 71.9(2), V-O2-C1 131.5(3), V-O3-C6 130.4(3), V-O4-C11 129.7(4), V-O2-VA 108.0(2).

The following aspects are interesting with reference to the model character of $[\{VO(cyclo\text{-}C_5H_9O)_3\}_2]$ for biological systems with vanadium as coordination center. 1) The short V–O distances [176.3(6) and 176.2(3) pm] are comparable with those found for V–O (apart from the usual single-bond lengths of about 195 pm) in vanadate-dependent peroxidase (172 pm),[2a] suggesting that for the binding of vanadium to this enzyme, serine possibly plays a role. 2) V^V strives for a trigonal bipyramidal coordination sphere in the presence of alkoxo ligands, as discussed for the transition state for the enzymatic phosphoester cleavage; (alkoxo)oxovanadium compounds are therefore analogues of this transition state. 3) This impression is supported by the two different V–OR bond lengths in our model (176.3 and 183.5 pm); a similar asymmetry is also found in the complexes formed from ribonuclease A and uridine and vanadate, in which the V–O distances to the oxygen functions of ribose in the 2′- and 3′-position are given as 170 and 189 pm .[15] 4) The distinct tendency—also in solution—to dimerization is relevant in connection with more recent observations that not only monovanadate but also divanadate (among others) can inhibit phosphorylation enzymes.[16]

Oligo(9,10-anthrylenes), Organic Compounds with Stable High-Spin States**

By *Martin Baumgarten, Uwe Müller, Angelika Bohnen,* and *Klaus Müllen**

Stable high-spin states play a central role in the search for organic solids possessing ferromagnetic properties.[1] The "uncoupling" of individual spins has usually been sought in π-conjugated compounds with so-called non-Kekulé structures.[2] The ionic derivatives of oligo(9,10-anthrylenes) **1**[3] ought to be able to form high-spin states, if only because of the almost orthogonal configuration of their individual anthracene components. By theoretical studies, we have been able to show that ferromagnetic coupling is possible in the triplet dianion of 9,9′-bianthryl **2**.[4, 5]

Although the chemical and physical properties of **2** have been thoroughly described,[5, 6] higher oligoanthrylenes **1**, $m > 0$, have not previously been studied. Here we report the

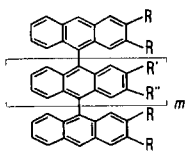
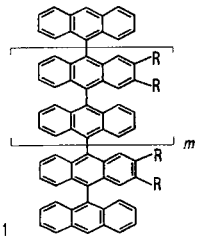
[**] This study was supported by the Federal Ministry for Research and Technology.

synthesis of defined, soluble oligomers up to the heptamer (**3a**, **3b**, **4**, **5**). Cyclovoltammetric and ESR characterization of the title compounds provides evidence for their extreme redox activity and, above all, for the possibility of forming high-spin states.



1: R = R' = R'' = H
2: R = R' = R'' = H, $m = 0$
3a: R = R'' = H, R' = $C(CH_3)_2CH_2CH_3$, $m = 1$
3b: R = H, R' = R'' = n-C_6H_{13}, $m = 1$
4: R = n-C_6H_{13}, R' = R'' = H, $m = 2$



5: R = n-C_6H_{13}, $m = 2$

The starting materials of the trimers **3a**, **b**, are the anthraquinones **6a** or **6b**, alkyl-substituted in the 2- or the 2- and 3-positions, which can easily be prepared by standard procedures.[7, 8] **6a** and **6b** react with 9-lithioanthracene **8a** (2 equiv. diethyl ether, room temperature, 24h) to yield the coupling products **7a** and **7b** respectively. These are then treated with hydrogen iodide and hypophosphorous acid (glacial acetic acid, reflux, 3h), to afford the trianthrylenes **3a** (50%) and **3b** (60%) respectively, after chromatography over silica gel (Table 1). The tetramer **4** is formed by reaction of the 10,10'-bianthronylidene **9** with the lithium compound **8b**[9] (diethyl ether, room temperature, 24h), followed by aromatization with hydrogen iodide/hypophosphorous acid and chromatographic purification (31% yield; Table 1). In contrast to the coupling method described, the palladium-catalyzed reaction of arylboronic acids with arylhalogenides,[10] which is often useful for direct aryl-aryl couplings, yields only dimeric products in this case.

[a] All NMR spectra were measured in $C_2D_2Cl_4$ at 200 MHz and room temperature. Numbering of the anthracene rings follows IUPAC nomenclature rules.

opens a simple route to higher homologues of **1**. Thus, **3c** can be quantitatively converted to the lithio derivative **3e**, and then coupled to **6b** to yield the heptamer **5**, in a reaction sequence analogous to the trimer syntheses. Compound **5** can be isolated by volume exclusion chromatography (18%).

The unusual redox properties of the oligo(9,10-anthrylenes) are demonstrated by cyclovoltammetric studies (Table 2). **3a** can be reversibly converted both into the

mono-, di-, and tricationic forms, and into the mono-, di-, and trianions. For **3b** a tetracation can also be obtained, and for **4** a reversible redox sequence can be detected which proceeds in eleven successive steps from the pentaanion to the hexacation (Fig. 1). All of the first reduction and oxidation potentials are virtually independent of the number of replications, thus excluding the possibility of significant conjugative interactions between the individual subunits. The minor differences between the first reduction potentials of **3a** and **3b** can be explained by the different number of alkyl substituents, which serve to solubilize the molecule and stabilize the cations.

Reduction of oligoanthrylenes with alkali metals permits ESR and ENDOR characterization of the resulting para-

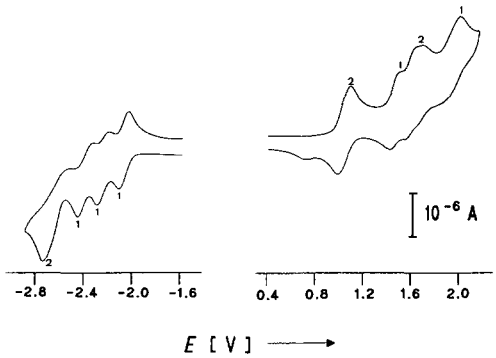

Fig. 1. Cyclic voltammagram of the oxidation and reduction of **4**. Each individual oxidation or reduction step is marked as a one or two electron transition.

magnetic ions in solution. The spin density distribution in the monoradicals is of particular interest here; i.e., the spin localization or delocalization with respect to the individual anthracene units, and the presence of triplet states in the dianions or higher spin multiplicities in the more highly charged forms. The hyperfine coupling constants of the ring protons of the radical monoanion **3b** (K^+/methyltetrahydrofuran (MTHF)) (Table 3) are very similar to those of the anthracene radical anion,[13] and the reduction in symmetry is indicated by the nonequivalence of the 1,4-, and 2,3-protons. This finding is consistent only with a localization of the electron spin on a terminal anthracene residue of $\mathbf{3b}^{\bullet-}/K^+$. The electronic absorption spectra of the monoanions of **2**, **3b** and **4** also demonstrate that in each case one anthracene unit is charged: the respective λ_{max} values are virtually independent of the chain length[14] and reveal the anthracene units to be independent electrophores.

[a] ENDOR/ESR measurements were carried out at 200 K, solvent: MTHF. Assignment of the hyperfine coupling constants by correlation with Hückel-MO charge densities.

Successive further reduction of $\mathbf{3b}^{\bullet-}$ in frozen solution (T = 150 K) yields an ESR signal which must be assigned to a triplet state of $\mathbf{3b}^{2-}$ (D = 3.85 mT)[5, 15], a quartet state of $\mathbf{3b}^{3-}$ (D = 11.5 mT)[16] and a triplet state of $\mathbf{3b}^{4-}$ (D = 15.2 mT) (Fig. 2A). Analogously, stepwise reduction of **4** affords ESR signals which confirm the initial formation of a triplet state of the dianion $\mathbf{4}^{2-}$ (D = 3.6 mT), and later that of a quartet state of $\mathbf{4}^{3-}$ (D = 11.4 mT); this is transformed into a quintet state of $\mathbf{4}^{4-}$ (D = 8.9 mT)[17] and finally into a triplet state (D = 14.5 mT) of an even more highly charged derivative of **4** (Fig. 2B). Interestingly, for dianions $\mathbf{3b}^{2-}$ and $\mathbf{4}^{2-}$ no $\Delta m_s = 2$ transition could be found, while for the more highly charged derivatives of **3b** and **4** and for $\mathbf{2}^{2-}$ a $\Delta m_s = 2$ transition can be observed at half resonance field. Transitions with $\Delta m_s = 3$ or 4 have not yet been detected, and studies in the L-band are planned.[16, 17]

For diradicals, the characteristic zero field parameters D allow an estimation of the mean distance between the interacting spins by the point-dipole approach[18]. In the case of species $\mathbf{3b}^{2-}$ and $\mathbf{4}^{2-}$ this indicates the charge on each of the

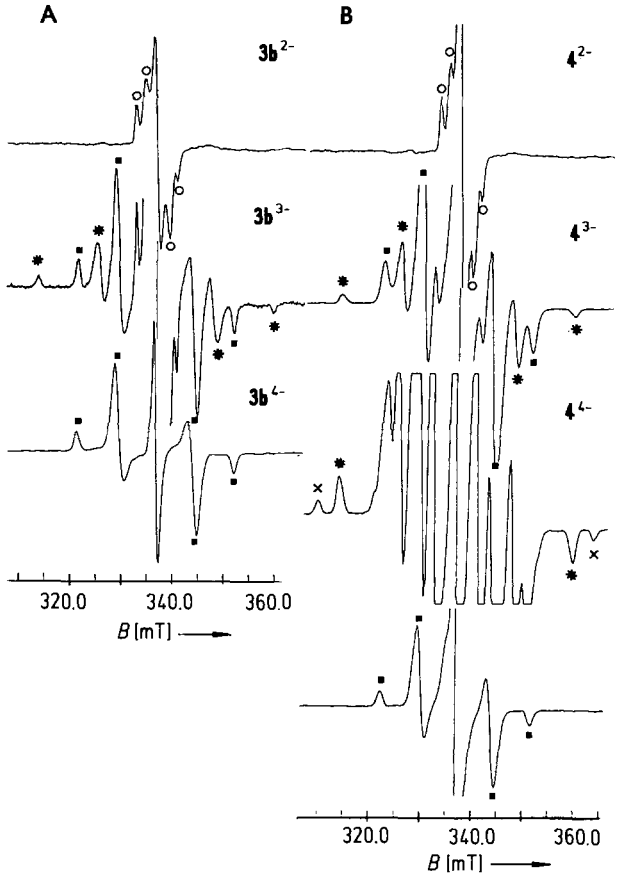

Fig. 2. ESR spectra of the anthrylene radical anions of **3** and **4** (MTHF/K^+/150 K). A: ESR spectra for three reduction steps of **3**, B: ESR spectra for various reduction steps of **4**. In each case, the largest spin state splitting (S = 1, 3/2, 2) is marked. o diradical (small D), * triradical, ■ diradical (large D), × tetraradical. terminal electrophores ($\mathbf{3b}^{2-}$: R = 0.89 nm, $\mathbf{4}^{2-}$: R = 0.92 nm).

Since the high-spin systems carry charges, they ought to tend less to coupling reactions than do the well-studied neutral radicals, and should therefore be chemically more stable. Further studies, such as the measurement of the magnetic susceptibilities and the ESR spectra at low temperatures (4–300K) are in progress. The prerequisite for these is the selective generation of definite redox states.

Bismuth Alkoxide Dimer Complexes Containing Planar $Bi_2(\mu\text{-}OR)_2$ Cores: Syntheses and Structures of $[\{Bi[OCH(CF_3)_2]_3(thf)\}_2]$ and $[\{Bi(OC_6F_5)_3(C_7H_8)\}_2] \cdot 2C_7H_8$**

By *Carolyn M. Jones, Michael D. Burkart,* and *Kenton H. Whitmire**

Recently, metal alkoxide compounds have been receiving attention as precursors to high-temperature superconductors via sol–gel or vapor deposition processes. Current precursors incorporate bulky ligands in order to achieve desirable volatility or solubility. However, more controlled syntheses might be achieved by the use of smaller ligands in order to form complex alkoxide oligomers and clusters with more than one metal constituent. To this end we explored the synthesis of soluble bismuth alkoxides containing nonsterically demanding ligands. Bismuth is an important component in many superconductors with a high transition temperature such as $[Bi_2Sr_2CaCu_2O_8]$ [1a] and $[Sr_2Bi_2Cu_2O_{7+d}]$.[1b] Unfortunately, relatively few bismuth alkoxides have been structurally characterized.[2] We report here the syntheses and structures of two bismuth alkoxide dimer complexes which act as Lewis acceptors.

The reaction of bismuth trichloride with three equivalents of $Na[OCH(CF_3)_2]$ in THF results in the formation of the tris(alkoxide) complex **1** as a THF solvate [Eq. (a)]. The analogous reaction with $NaOC_6F_5$ does not yield a tris(alkoxide) compound;[3] however, refluxing triphenylbismuth with HOC_6F_5 in toluene resulted in the desired product as a toluene solvate [Eq. (b)]. It was previously reported in the literature that trialkylbismuth compounds do not react with alcohols.[4] However, we have found this reaction to be facile for phenols; the reaction of triethylbismuth with HOC_6F_5 or HOC_6H_5 produces a monosubstituted phenoxy-bridged chain polymer.[5]

$$BiCl_3 + 3\,Na[OCH(CF_3)_2] \xrightarrow[-3\,NaCl]{THF} \underset{\mathbf{1}}{[\{Bi[OCH(CF_3)_2]_3(thf)\}_2]} \quad (a)$$

$$BiPh_3 + 3\,HOC_6F_5 \xrightarrow[-3\,C_6H_6]{C_6H_5CH_3} \underset{\mathbf{2}}{[\{Bi(OC_6F_5)_3(C_6H_5CH_3)\}_2]} \quad (b)$$

Compounds **1** and **2** are structurally similar in the solid state; each forms a loose dimer with a planar $[Bi_2(\mu\text{-}OR)_2]$ ring structure (Figs. 1 and 2). The bismuth centers show a distorted octahedral coordination geometry in which two of the sites are occupied by asymmetric bridging alkoxide ligands (for **1**: Bi(1)–O(1), 2.188(7); Bi(1)–O(1A), 2.688(7) Å; for **2**: Bi(2)–O(2), 2.210(8); Bi(2)–O(2A), 2.571(7) Å). A THF molecule (in **1**) or toluene (in **2**) is coordinated in the site *trans* to the shorter bismuth–oxygen bond of the $[Bi_2(\mu\text{-}OR)_2]$ unit. A stereoactive lone pair of electrons occupies one of the octahedral sites *cis* to the bridging alkoxide ligands. Two additional alkoxide ligands complete the octahedron. Compound **2** contains additional lattice toluene.

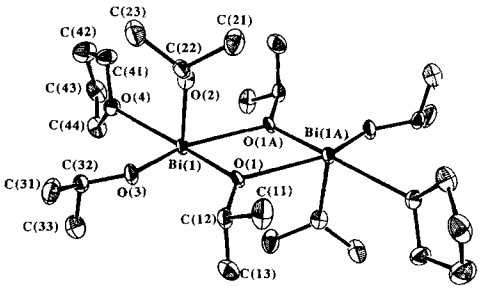

Fig. 1. ORTEP diagram of $[\{Bi[OCH(CF_3)_2]_3(thf)\}_2]$ (1) with thermal ellipsoids drawn at 40% probability level. Fluorine and hydrogen atoms were omitted for clarity. Selected bond distances [Å] and angles [°] not mentioned in text: Bi(1)–O(2), 2.064(8); Bi(1)–O(3), 2.116(7); Bi(1)–O(4), 2.575(7); Bi(1)–O(1)–Bi(1A) 109.1(3); O(1)–Bi(1)–O(1A) 70.9(3); O(1)–Bi(1)–O(2), 90.6(3); O(1)–Bi(1)–O(3), 81.8(3); O(1)–Bi(1)–O(4), 165.8(3); O(2)–Bi(1)–O(1A) 84.1(3); O(2)–Bi(1)–O(3), 90.6(3); O(2)–Bi(1)–O(4), 81.6(3); O(3)–Bi(1)–O(1A) 152.1(2); O(3)–Bi(1)–O(4), 86.4(3); O(4)–Bi(1)–O(1A) 119.7(2).

The NMR spectra of compounds **1** and **2** in C_6D_6 or $[D_8]$toluene suggest that these are not rigid structures in solution as only a single signal is observed for the alkoxy (in **1**) or phenoxy (in **2**) ligands at room temperature. A second signal appears in the ^{19}F NMR spectrum of **1** in $[D_8]$toluene as the temperature is lowered and is the predominant signal at −65 °C. The temperature-dependent NMR spectra may reflect monomer–dimer interconversion; the dimer is the predominant species at low temperature.

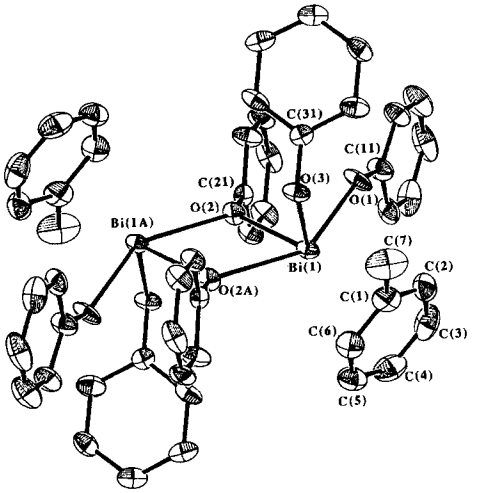

Fig. 2. ORTEP diagram of $[\{Bi(OC_6F_5)_3(C_7H_8)\}_2]\cdot 2C_7H_8$ (**2**) with thermal ellipsoids drawn at 40% probability level. Fluorine atoms on pentafluorophenoxide ligands, hydrogen atoms, and lattice toluene have been omitted for clarity. The carbons of the pentafluorophenoxide rings are numbered sequentially from the *ipso* carbon. Selected bond distances [Å] and angles [°] not mentioned in text: Bi(1)–O(1), 2.147(8); Bi(1)–O(3), 2.088(9); Bi(1)–O(2)–Bi(1A) 112.3(3); O(1)–Bi(1)–O(2), 86.5(3); O(1)–Bi(1)–O(2A), 145.4(3); O(1)-Bi(1)-O(3), 82.7(3); O(2)–Bi(1)–O(2A), 67.7(3); O(2)–Bi(1)–O(3), 92.6(3); O(2A)–Bi(1)–O(3), 76.1(3).

Compound **2** is particularly interesting in that it is a rare example of a bismuth–arene π complex and the first such bismuth alkoxide. The first examples of structurally characterized bismuth–arene complexes were the bismuth trichloride adducts, $[\{1,3,5\text{-}(CH_3)_3C_6H_3\}(BiCl_3)]$ and $[\{(CH_3)_6C_6\}(BiCl_3)]$, described by Schmidbaur.[6a] Two aluminum trichloride adducts of bismuth chloride arene complexes have also been structurally characterized.[6b]. In **2** the distance between the bismuth atom and the toluene ring centroid is slightly shorter than in the bismuth trichloride mesitylene complex (2.96(4) vs. 3.07(2) Å) and is close enough to be considered a real (albeit weak) interaction. The angle between the ring normal and the metal to ring center vector in **2** is 5.7° (vs. 2.1–7.3° for the bismuth trichloride adducts) indicating an η^6-bound toluene molecule.

The bismuth center appears to prefer a "hypervalent" electron configuration in tris(alkoxide) compounds and readily functions as a Lewis acid to alkoxide ligands on other bismuth atoms and to solvent molecules. Steric bulk on the alkoxide ligands can prevent further coordination as in the case of $[Bi\{2,5\text{-}Me_2C_6H_3O\}_3]$.[2a] The bismuth centers in the phenoxy-bridged chain polymers $[BiEt_2(\mu\text{-}OR)]_\infty$ mentioned earlier are four coordinate. The compound $[Bi(OC_2H_4OMe)_3]$ oligomerizes to make each bismuth(III) center five coordinate with a stereoactive lone pair of electrons.[2b] Compound **1** can be thought of as having four electrons in excess of the filled octet while **2** has eight more than needed. A similar situation exists for the bismuth atoms in the bismuth trichloride adducts of Schmidbaur et al. where the lone pairs are *not* stereoactive.[6a] The use of non-sterically demanding alkoxide ligands in **1** and **2** readily allows oligomerization which, together with the Lewis-acceptor properties of the bismuth center, raises the possibility of incorporation of other metal centers to form mixed-metal alkoxide oligomers.

Experimental Procedure

Compound **1**: Bismuth trichloride dissolved in THF was added to a THF solution containing three equivalents of $Na[OCH(CH_3)_2]$ formed in situ by the reaction of the alcohol with excess sodium hydride. A white precipitate resulted immediately Removal of the THF in vacuo was followed by extraction with hot toluene and filtration through Celite. Cooling to room temperature and reduction of volume afforded large colorless crystals of **1**. Compound **1** has been characterized spectroscopically and by single-crystal X-ray diffraction: ^{1}H NMR (C_6D_6): $\delta = 5.58$ (s), 3.39 (m), 1.26 (m); ^{19}F NMR (C_6D_6, 297 K, CF_3COOH): $\delta = 0.34$ (d, $J = 4$ Hz); ([D_8]toluene, 242 K) 0.172 (d, $J = 4$ Hz); IR (nujol) $\tilde{\nu}$ [cm^{-1}] = 1294 (s), 1284 (s), 1258 (s), 1188 (s), 1165 (m), 1138 (s), 1095 (s), 1022 (m), 926 (w), 889 (m), 859 (s), 850 (m), 831 (w), 744 (s), 690 (s), 684 (s). Crystal data for **1**: monoclinic space group $P2_1/n$ (no. 14), $T = -80$ °C, $a = 13.738(7)$, $b = 10.936(7)$, $c = 14.389(8)$ Å, $\beta = 94.53(4)$°, $R = 0.0427$, $R_w = 0.0471$, $S = 1.766$. For 326 parameters, 2786 observed reflections with $I \geq 3\sigma(I)$. Repeated attempts to obtain analytical data were unsuccessful because of fractional loss of THF from analytical samples.

Compound **2**: Triphenylbismuth was refluxed with three equivalents of HOC_6F_5 in toluene for 12 h followed by filtration. A clear yellow solution resulted from which yellow crystals of **2** grew at −20 °C. Compound **2** was characterized spectroscopically and by single-crystal X-ray diffraction: ^{19}F NMR (C_6D_6, CF_3COOH): $\delta = -87.74$ (d), −89.10 (t, $J = 19$ Hz), −94.44 (m); IR (nujol) $\tilde{\nu}$ [cm^{-1}] = 1307 (m), 1162 (m), 1021 (s), 795 (s), 751 (m). Crystal data for **2**: triclinic space group $P\bar{1}$ (no. 2), $T = -80$ °C, $a = 11.086(6)$, $b = 13.378(8)$, $c = 10.771(9)$ Å, $\alpha = 98.58(7)$, $\beta = 95.58(5)$, $\gamma = 95.22(5)$°, $R = 0.0591$, $R_w = 0.0581$, $S = 1.691$ for 411 parameters, 4019 observed reflections with $I \geq 3\sigma(I)$. Several attempts to obtain analytical data were unsuccessful due to fractional loss of toluene from analytical samples. Further details of the crystal structure investigators are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.

A Nonaromatic Expanded Porphyrin Derived from Anthracene—A Macrocycle which Unexpectedly Binds Anions**

By *Jonathan L. Sessler,* Tarak D. Mody, Debra A. Ford,* and *Vincent Lynch*

Dedicated to Professor James P. Collman on the occasion of his 60th birthday

Porphyrins are among the most versatile ligands, forming complexes with almost every metal cation in the periodic table.[1] However, little record of these species as anion-binding agents[2] has appeared in the literature.[3–5] One reason, perhaps, is that protonated porphyrins, with a core diameter

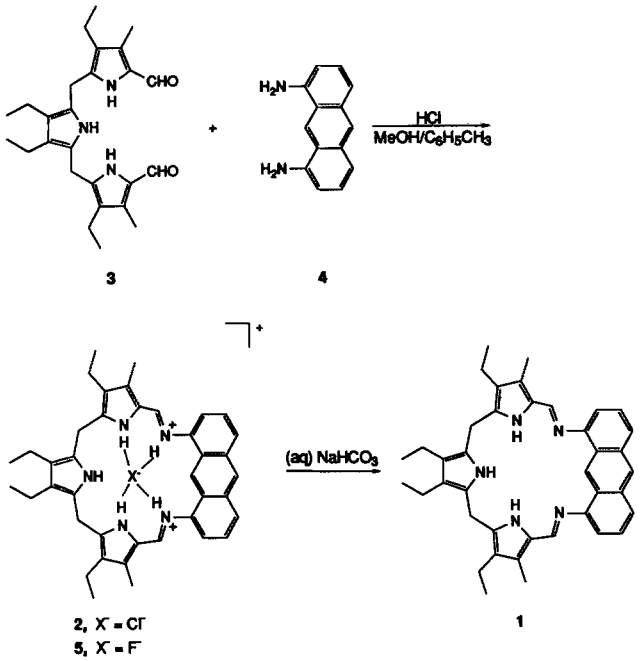
F. is grateful to the United States Navy for allowing an academic leave and for providing M. S. thesis support.

of approximately 4 Å, are too small to bind anions within the macrocyclic cavity.[2] Quite recently, we have found that certain aromatic "expanded porphyrins" including, sapphyrin[6] and rubyrin[7] are capable of serving both as anion receptors in the solid state[6, 7] and as anion carriers under certain solution-phase conditions.[8] Here, we wish to report the synthesis and crystallographic characterization of a novel, nonaromatic, anthracene-derived Schiff base, the expanded porphyrin **1**. As an X-ray structure analysis shows, the diprotonated form of **1** effectively binds chloride ions.[9, 10] In addition, we present the results of liquid-membrane transport experiments which are consistent with the binding of chloride and fluoride ions in solution.

The synthesis of macrocycle **2**-Cl and its neutral parent **1** is shown in Scheme 1. The critical step is the acid-catalyzed 1:1 condensation of 1,8-diaminoanthracene (**4**)[11] and the diformyl tripyrrane **3**.[12] X-ray quality crystals of the diprotonated macrocycle as its mixed chloride tetrafluoroborate salt, **2**-BF_4, were obtained by slow diffusion of diethyl ether into a solution of dichloromethane/methanol (2:1 v/v) containing **2**-Cl and a small excess of ethereal tetrafluoroboric acid.[10]



Scheme 1. Synthesis of **1**.

From the X-ray structure analysis,[10] the core of the macrocycle is found to contain a near mirror plane, and the two pyrrole rings A and C of the tripyrrane and the anthracene moiety lie in essentially the same plane (Fig. 1). The

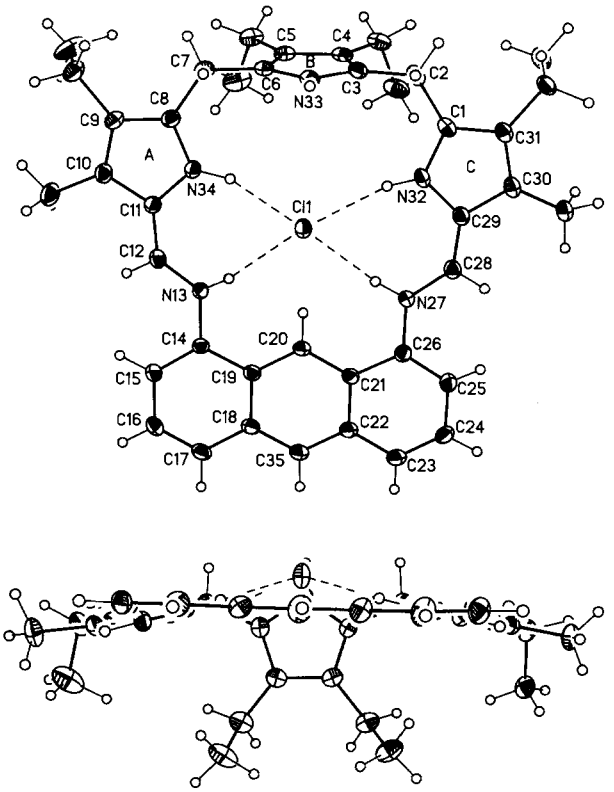


Fig. 1. Structure of **2**-BF_4 in the crystal (thermal ellipsoids at the 30% probability level, H atoms with arbitrary radii). The interactions of the Cl^- ion with the hydrogen atoms of the macrocycle are indicated by dashed lines. Not shown is an H-bonded BF_4^- counterion with an H–F distance of 2.02(3) Å which is nearly directly above N33 of pyrrole ring B. Top: View perpendicular to the plane through the nitrogen atoms. Bottom: Side view showing the nearly perpendicular orientation of the two planar subunits of the macrocycle and the partial encapsulation of the chloride counterion.

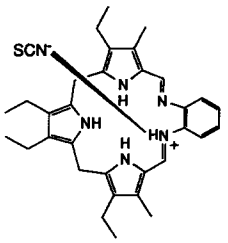
[a] HRMS = high-resolution mass spectroscopy.

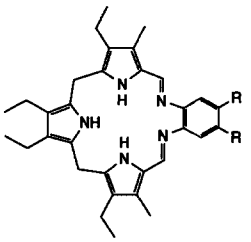
central pyrrole ring B is almost perpendicular to this plane; the dihedral angle formed is 79.3°. The chloride anion is bound in pseudo square-planar geometry 0.795 Å above the planar portion of the macrocycle with the four inner hydrogen atoms (H13, H27, H32, H34) pointing towards it. The H–Cl distances range from 2.21(4) to 2.41(4) Å. The N–Cl bond lengths are between 3.11 and 3.25 Å, which is consistent with strong hydrogen bonding.[2d] There is also a hydrogen-bonding interaction between F4 of the BF_4^- and H33 N33 of the central pyrrole unit. In this case the H–F distance is 2.02(3) Å.

The structure of the chloride-containing salt **2**-BF_4 differs from that of the HSCN salt **6** of the nonaromatic texaphyrin-type macrocycle **7**, which we reported previously.[12] For instance, **6** is clearly protonated at only one of the azomethine nitrogens, whereas **2**-BF_4 is clearly quite stable as a diprotonated salt. This may simply reflect effective differences in the basicity of the nitrogen atoms in these two con-

methine(N)–azomethine(N) distances (5.024(1) and 2.60(1) Å for **2**-BF_4 and **6**, respectively). In particular, we suggest that two protons can be accommodated in the cavity macrocycle **1**, whereas in **7** geometric and/or electrostatic repulsions would preclude such a double accommodation.[13] Certain-

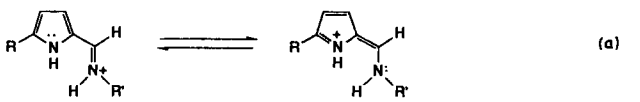


6



7, R = H
8, R = OCH_3

ly, in **2**-BF_4 the short bonds C11–C12 and C28–C29 (1.373 and 1.386 Å, respectively) are consistent with a model wherein the positive charges on the azomethine centers N13 and N27 are delocalized into the adjacent pyrrole rings A and B (Scheme 2).



(a)

Scheme 2.

In contrast to other comparable expanded porphyrin–anion adducts like **6**, for **2**-BF_4 the core chloride complex of cation **2** was detected in both the low-resolution and high-resolution FAB (fast atom bombardment) mass spectra. These data lead us to suggest that the chloride anion is bound tightly in **2**-BF_4, at least in the gas phase.

Further insight into the anion-binding properties of macrocycle **1** and its protonated derivatives[14] was obtained from preliminary solution-phase transport experiments using a three-phase model membrane system [AqI]-[CH_2Cl_2]-[AqII] (Aq = aqueous;[15] AqI = 0.5 M HF, adjusted to pH 3.2 with NaOH,[17] and AqII = NaOH (pH 12)). In a first set of experiments compound **1**, via the presumed intermediacy of **5**, was found to accelerate the transport of fluoride ions through the CH_2Cl_2 phase with an initial flux value Φ_{F^-} of 5.03 ± 0.16 μmol h^{-1} under conditions where the nonaromatic texaphyrin-type system **8**[18] proved much less effective as a carrier ($\Phi_{F^-} = 1.60 \pm 0.10$ μmol h^{-1}) and simple passive diffusion in the absence of any added carrier was negligible ($\Phi_{F^-} \leq 0.01$ μmol h^{-1}) (Fig. 2). Under these conditions roughly 13 hours were required in the case of **1** for the transport of 10 mol% of the fluoride ions from AqI through CH_2Cl_2 to AqII. During this time the carrier **1** appeared to be completely stable (no evidence of decomposition or hydrolysis of the macrocycle was found in the UV/VIS spectra and thin-layer chromatograms of the recovered material).[19] However, as expected, a steady decrease in the pH of AqII from 12 to 5 was observed during this monitoring period. This is consistent with fluoride ion transport by the so-called symport mechanism,[20] in which anions and protons are complexed and transported together by the macrocyclic carrier. Mechanistically, therefore, carrier **1** appears to function as a fluoride ion carrier in a manner similar to that of the under identical experimental conditions this new, nonaromatic expanded porphyrin is roughly six times more efficient (per mole) than sapphyrin as a fluoride ion carrier.

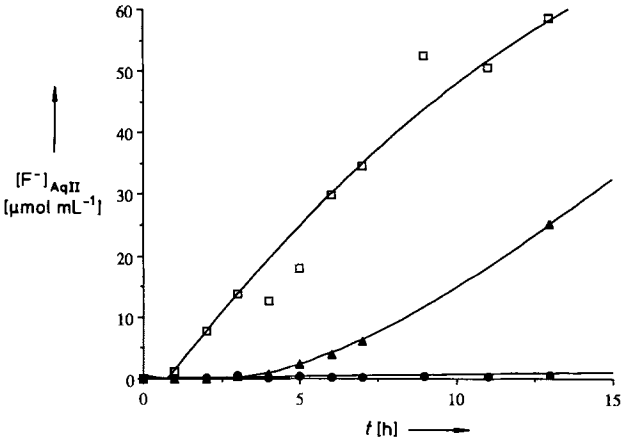


Fig. 2. Course of fluoride transport with macrocycles **1** and **8** with time. Transport experiments were performed with a glass U-tube at 28 °C. Conditions: AqI (1 mL): 0.5 M HF, adjusted to pH 3.2 with NaOH. Membrane; carrier: 1.0 mM, 10 mL CH_2Cl_2. AqII (1 mL): NaOH (pH 12). The release of fluoride ion into the receiving phase, AqII, was monitored at various times by a fluoride combination electrode (Orion). In all cases, the control experiment was performed in the absence of carrier. For anthraphyrin **1** (□) $\Phi_{F^-} = 5.03 \pm 0.16$ μmol h^{-1}. For the nonaromatic texaphyrin **8** (▲) $\Phi_{F^-} = 1.60 \pm 0.10$ μmol h^{-1} and for the control (●), recorded in the absence of carrier, $\Phi_{F^-} \leq 0.01$ μmol h^{-1}.

The transport of fluoride ions was found to be strongly inhibited by chloride ions. For instance, when the transport experiment was repeated with AqI = 0.5 M HF + 0.5 M NaCl (pH 3.2) and AqII = NaOH, (pH 12), Φ_{F^-} was 1.02 ± 0.10 μmol h^{-1}. This strong inhibition could reflect the fact that fluoride ion transport is limited by the formation and/or break-up of a strong, kinetically nonlabile chloride complex. Consistent with this supposition are the following findings: 1) Macrocycle **1** is a relatively ineffective chloride ion carrier and only nominally better than **8** ($\Phi_{Cl^-} = 1.56 \pm 0.16$ μmol h^{-1} and 1.13 ± 0.16 μmol h^{-1} for **1** and **8**, respectively; AqI = 0.1 M HCl + 0.4 M NaCl (pH 1.2); AqII = NaOH (pH 12)). 2) In CH_2Cl_2, chloride ions are bound roughly 14 times more effectively than fluoride ions by the diprotonated macrocycle **1** ($K_{S[Cl^-]} = 2.0 \times 10^5$ M^{-1}, $K_{S[F^-]} = 1.4 \times 10^4$ M^{-1}).[21] These results thus lead us to suggest that this new expanded porphyrin can serve not only as an effective anion carrier but also as an anion-specific receptor.

Experimental Procedure

4: This diamine was obtained by treating 1,8-diaminoanthraquinone [23] (2.00 g, 8.4 mmol, 88% purity) with sodium borohydride (4.0 g, 106 mmol) for 48 h in 100 mL isopropyl alcohol at reflux. The cooled suspension was poured into 250 mL ice water, and the red precipitate was filtered and washed with water several times. The red-brown solid so obtained was then dried under vacuum for 24 h. This solid was then dissolved in chloroform and purified by column chromatography. Initial elution with pure $CHCl_3$ was followed by a gradient elution with CH_3OH in $CHCl_3$ (0–3%). The last fraction, a bright fluorescent yellow solution, was collected and concentrated to dryness to afford a green solid. This solid was recrystallized from dichloromethane and *n*-hexane to yield 0.500 g (33% yield) 1,8-diaminoanthracene (**4**) as bright yellow needles.

2-Cl: This macrocycle was prepared in >90% yield from the acid-catalyzed reaction of **4** and **3**[12] according to the procedure reported earlier for the preparation of the non-aromatic texaphyrin **7**.[12] The red solid isolated was recrystallized from a solution of CH_2Cl_2 and CH_3OH layered with diethyl ether. Single crystals of the diprotonated chloride tetrafluoroborate salt **2**-BF_4 were obtained by slow diffusion of diethyl ether into a dichloromethane/

methanol solution (2:1 v/v) containing **2**-Cl and a small excess of ethereal tetrafluoroboric acid.

1: The neutral form of the macrocycle was obtained in essentially quantitative yield by dissolving **2**-Cl in dichloromethane and stirring vigorously with aqueous sodium bicarbonate for 15 min. The organic layer was then washed with water and brine (2 × each), dried over anhydrous sodium sulfate, and concentrated to dryness. The reddish-brown solid was recrystallized from CH_2Cl_2/CH_3OH to afford **1** as shiny brown needles.

[9] The systematic name for macrocycle **1** is: 4,5,9,31-tetraethyl-10,30-dimethyl-13,27,32,33,34-pentaazaheptacyclo[27.2.1.$1^{3,6}$.$1^{8,11}$.$1^{18,22}$.$0^{14,19}$.$0^{21,26}$]pentatriaconta-3,5,8,10,12,14,16,18,20,22(35),23,25,27,29,31-pentadecaene. We suggest the trivial name, anthraphyrin, for this compound.

[10] X-ray crystal analysis: $(C_{40}H_{45}N_5)^{2+}(Cl^-)(BF_4^-)$; triclinic, $P\bar{1}$ (No. 2), $Z = 2$, $a = 10.695(3)$, $b = 12.048(3)$, $c = 14.774(4)$ Å, $\alpha = 81.35(2)$, $\beta = 74.36(2)$, $\gamma = 88.75(2)°$, $V = 1811.8(9)$ Å^3, $\rho_{calc} = 1.32$ g cm^{-3} (198 K), $F(000) = 756$. Data collected at 198 K on a Nicolet R3 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator ($\lambda = 0.7107$ Å), ω-scans to 50° in 2θ; 6418 unique reflections, 4269 with $F_0^2 > 3\sigma(F_0^2)$. The structure was solved by direct methods and refined by full-matrix least-squares (SHELXTL-Plus, Siemens Analytical X-ray Instruments, Inc., Madison, WI, USA) with anisotropic thermal parameters for the non-hydrogen atoms. The positions of the hydrogen atoms were obtained from a ΔF map and refined isotropically. $R = 0.0465$, $wR = 0.0560$, GOF = 1.840 for 640 parameters. The minimum and maximum residual electron density were -0.26 and 0.31 e$^-$ Å^{-3}, respectively. Further details of the crystal structure are available on request from the Director of the Cambrdige Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.

[11] Satisfactory spectroscopic and mass spectrometric data were obtained for all new compounds (see Table 1).

[13] The structure of **2**-BF_4 also differs from that of tetrapyridyl porphyrin dihydrochloride. This latter system binds one chloride ion above and one below the macrocyclic plane (see ref. [2b]).

[14] The pK_a values of the diprotonated anthraphyrin, pK_{a_1} and pK_{a_2} are 4.0 and 8.5, respectively.

[15] Transport experiments were carried out at 28 °C with the glass U-tube set-up described earlier [8, 16]. The base of the U-tube cell (1.0 cm, i.d.; coated with Sigmacote™ to prevent etching of the glass by HF) was filled with a solution of the carrier (1.0 mM) in CH_2Cl_2 (10 mL). In the arms of the U-tube, the two aqueous phases, AqI and AqII (1.0 mL each), were layered on the CH_2Cl_2 phase. Initial flux values, Φ_{X^-} were calculated from the amount (μmol) of Cl^- and/or F^- transported per hour during the regime of linear dependence at the start and were found to be reproducible within the error ranges quoted in the text. In all cases, the control experiments were performed in the absence of carrier. We are grateful to Dr. Hiroyuki Furuta for his assistance.

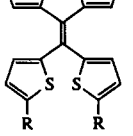
[23] We would like to thank Takashi Morishima and Mitsubishi Kasei Co. for kindly providing us with the requisite starting 1,8-diaminoanthraquinone. We are also grateful to Ken Lancaster for synthetic assistance.

Tetrathienylethylenes, a New Class of Electron Donors—Dications Twisted by 90° Stabilized by Formation of Polymethine Units**

By *Takanori Suzuki, Hiroaki Shiohara, Masayuki Monobe, Tomoo Sakimura, Shoji Tanaka, Yoshiro Yamashita,* and *Tsutomu Miyashi**

Recently much attention has been focused on multistage redox systems[1] because of their special properties such as conductivity and organic ferromagnetism. Although thiophene units have been frequently used in thienoquinoid[2] or condensed[3] forms in the design of new molecular skeletons, they have not been used as the end groups of redox systems. In view of the stabilization of a carbenium ion by thiophene units,[4] we have now prepared very simple yet hitherto unknown tetrakis(2-thienyl)ethylenes **1** and found that they are strong two-electron donors whose dications are stabilized by the formation of two polymethine subunits.

Unsubstituted **1a**[5] was prepared in 41% yield by a reductive coupling of bis(2-thienyl)ketone[6] using $TiCl_4/Zn$[7]



1a: R = H
1b: R = Me
1c: R = SMe

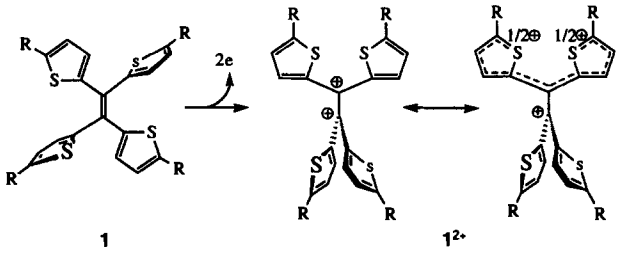
[**] We thank Dr. Kimio Akiyama and Prof. Dr. Yusaku Ikegami, Institute for Chemical Reaction Science, Tohoku University, for the measurement and evaluation of the ESR spectrum.

in refluxing THF. Reactions of **1a** with excess *n*BuLi in THF at −40 °C followed by treatment with iodomethane or dimethyl disulfide afforded tetrasubstituted derivatives **1b** (R = Me)[5] and **1c** (R = SMe)[5] in 71% and 48% yields, respectively.



1 1^{2+}

Scheme 1. The conformations of **1** and 1^{2+} according to the X-ray structure analyses of **1c** and $\mathbf{1c}^{2+}$.

The cyclic voltammogram of **1a** shows an irreversible wave similar to that of tetraphenylethylene, but the oxidation potential E^{ox}[8] of the former (+0.91 V) is much lower than that of the latter (+1.36 V). Derivatives **1b** and **1c** substituted at the reactive α position of thiophene undergo reversible one-wave two-electron oxidation (E^{ox} = +0.70 and +0.55 V, respectively). The oxidation potential of **1c** is nearly the same as that of the well-known electron donor dibenzotetrathiafulvalene (E^{ox} = +0.57 V). The blue dication $\mathbf{1c}^{2+}$ generated by electrochemical oxidation in CH_2Cl_2 was isolated as a stable ClO_4^- salt.[5]

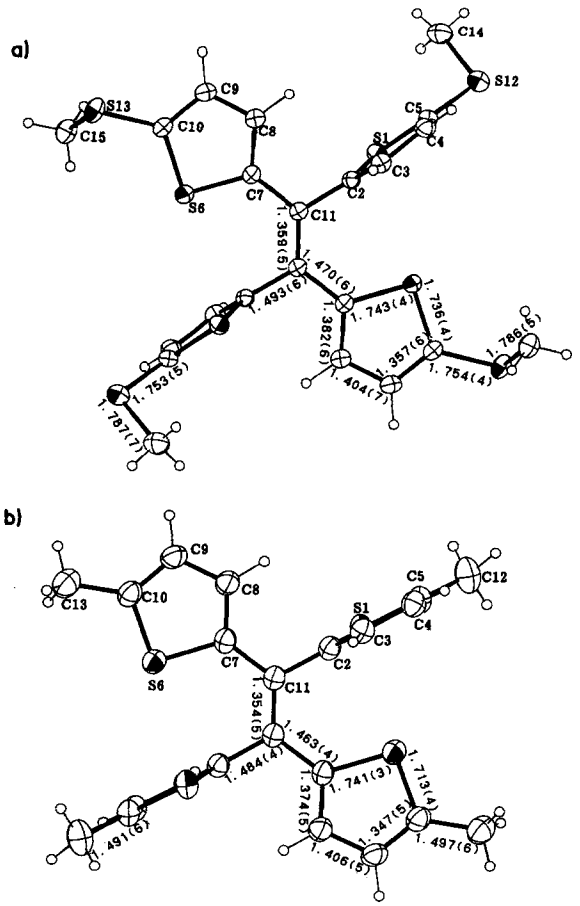


Fig. 1. X-ray crystal structures of the neutral molecules **1c** (a) and **1b** (b). The two halves of each molecule are related by an inversion center. The bond lengths are in Å. Additional bond lengths: S1–C2, S1–C5, C2–C3, C3–C4 and C4–C5 1.728(4), 1.730(5), 1.353(6), 1.418(7), and 1.360(7) for **1c**, and 1.725(3), 1.728(4), 1.360(4), 1.417(5) and 1.351(5) for **1b**, respectively.

The X-ray structural analyses[9] of **1c** and the $\mathbf{1c}^{2+}$ salt revealed that the molecular geometry is drastically changed upon oxidation (Scheme 1). Neutral **1c** possesses a planar *trans*-dithienylethylene structure substituted with two thiophene rings which are orthogonal to the molecular plane (Fig. 1a). In contrast, in $\mathbf{1c}^{2+}$ the two halves of the molecule are twisted around the central C–C bond (Fig. 2). Because $\mathbf{1c}^{2+}$ is penetrated by a crystallographic $\bar{4}$ axis, the rotation angle (90°) is the largest of the reported values for dicationic ethylene derivatives.[10–12] The dithienylcarbenium moiety itself is nearly planar with the largest deviation of 0.44 Å at thiophene S atoms,[13] indicating the delocalization of each positive charge over one half of the molecule. The dihedral angle between two thiophene rings is 35.8°, smaller than that between the two aryl groups in the dication of tetrakis(*p*-methoxyphenyl)ethylene (50.9°).[11]

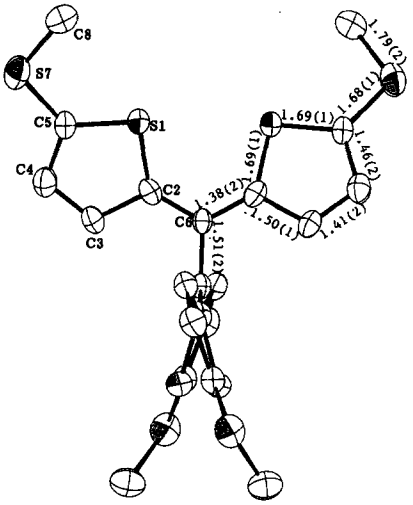

Fig. 2. X-ray crystal structure of the twisted dication in $\mathbf{1c}^{2+} \cdot 2ClO_4^- \cdot CH_2Cl_2$. The central C–C bond lies on a $\bar{4}$ axis, so only one-fourth of $\mathbf{1c}^{2+}$ is crystallographically independent. The bond lengths are given in Å.

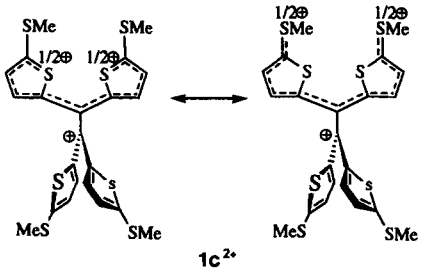
Stabilization of cations by delocalization over the polymethine unit[14] was proved recently to be unexpectedly large, even greater than an aromatic [4n + 2]π stabilization.[15] The structural features of $\mathbf{1c}^{2+}$ indicate a conjugated polymethine framework[16] for 1^{2+} ions with 12 electrons distributed over 11 atoms (Scheme 1). Evidence of the formation of the polymethine structure in $\mathbf{1c}^{2+}$ is also provided by the strong UV/VIS absorption[17] at 662 nm (lg ε = 5.16 in CF_3CO_2H) and the alternation of π-electron density as deduced from the ^{13}C NMR chemical shifts (Table 1). In contrast to trithienylcarbenium ions,[4] the largest positive charge is found on C_5 ($\Delta\delta$ = 47.04), not on $C_{ethylene}$ ($\Delta\delta$ = 19.82). The short bond length between S7 and C5 (1.68(1) Å) as well as the small torsion angles C8-S7-C5-S1 (9.3°) and

Table 1. ^{13}C NMR chemical shifts of **1c** and $\mathbf{1c}^{2+}$ [a].

	$C_{ethylene}$	C2	C3	C4	C5	CH3
1c	126.71	144.83	130.60	129.56	140.51	21.64
$\mathbf{1c}^{2+}$	146.53	140.72	149.14	133.61	187.55	20.38
$\Delta\delta$ [b]	19.82	−4.11	18.54	4.05	47.04	−1.26

[a] In $CDCl_3$ (**1c**) and CF_3CO_2D ($\mathbf{1c}^{2+}$). The chemical shifts were assigned on the basis of ^{13}C-^1H coupling and COSY spectra. [b] $\delta(\mathbf{1c}^{2+}) - \delta(\mathbf{1c})$.

C8-S7-C5-C4 (12.8°) indicate that not only the thiophene sulfur atoms but also the thiomethyl sulfur atoms act as end groups of the polymethine units in $\mathbf{1c}^{2+}$ (Scheme 2).



Scheme 2. Participation of the S atoms in the polymethine stabilization in $\mathbf{1c}^{2+}$.

Electrolysis of **1c** in CH_2Cl_2 gave rise to a radical cation which was detected by ESR. Its spectrum indicates that the unpaired electron of $\mathbf{1c}^{+\cdot}$ is delocalized over four equivalent thiophene rings.[18]

The quite similar molecular geometries (Fig. 1b) and redox properties of **1b** and **1c** indicate that $\mathbf{1b}^{2+}$ is also stabilized by the formation of polymethine units. In the electrochemical oxidation of **1b** and in its oxidation with excess $NOBF_4$ in CH_2Cl_2, a deep violet color developed due to $\mathbf{1b}^{2+}$ ($\lambda_{max} = 520$ nm, lg $\varepsilon > 4.65$ at -78 °C). However, attempts to isolate $\mathbf{1b}^{2+}$ as a salt have been unsuccessful; only a brown resin has been obtained.

The dithienylmethylene unit exhibits a strong donating property which may be exploited in new redox systems.[19] Absence of the interactions between *ortho* hydrogen atoms as observed in diarylcarbenium ions[11] makes it possible for dithienylcarbenium units to adopt a nearly planar arrangement, allowing the effective delocalization of positive charge over a polymethine subunit.

Experimental Procedure

1a: To a suspension of low-valent Ti prepared from $TiCl_4$ (5.88 g, 31.0 mmol) and zinc (4.37 g, 66.8 mmol) in 100 mL of dry THF under nitrogen were added dropwise pyridine (2.5 mL, 33.2 mmol) and a dry solution of bis(2-thienyl)ketone (5.76 g, 29.6 mmol) in 15 mL THF. The mixture was heated at reflux for 19 h, then poured into 600 mL of 10% K_2CO_3, and extracted with CH_2Cl_2. The extract was washed with brine and dried over Na_2SO_4. The solvent was evaporated, and the residue was washed with benzene to give pale orange crystals, which were purified by gradient sublimation (185 °C, 4×10^{-2} Torr). 2.16 g of **1a** were obtained in 41% yield.

1b: To a dry THF solution (15 mL) of **1a** (84.0 mg, 0.236 mmol) was added dropwise a solution of *n*BuLi in *n*-hexane (3.2 mL, 1.3 mol dm^{-3}, 4.16 mmol) at -78 °C under nitrogen. The mixture was stirred for 18 h at -40 °C, then iodomethane (3.41 g, 24.0 mmol) was added. The temperature was increased over 1 h to 20 °C, and the mixture was poured into 100 mL of water and extracted with CH_2Cl_2. The extract was washed with brine and dried over Na_2SO_4. Evaporation of the solvent gave an orange solid which was purified by chromatography on SiO_2 (CH_2Cl_2: *n*-hexane, 1:4), giving 69 mg of **1b** in 71% yield.

1c: Following a procedure analogous to that described for **1b**, **1a** (1.07 g, 3.00 mmol) was allowed to react with *n*BuLi in *n*-hexane (32 mL, 1.3 mol dm^{-3}, 41.6 mmol) for 6.5 h at -40 °C; dimethyl disulfide (10.5 g, 111 mmol) was then added. Corresponding workup and chromatographic separation on SiO_2 (CH_2Cl_2: *n*-hexane, 1:9) gave 780 mg of **1c** in 48% yield. The tris(methylthio) derivative **2** was also obtained as yellow crystals (320 mg) in 22% yield.

[8] All the potential values in the text are in Volt vs. the standard calomel electrode and were measured by cyclic voltammetry under the same conditions (0.1 mol dm^{-3} Et_4NClO_4 in MeCN, Pt-wire electrode, scan rate 100 mV s^{-1}, E^{ox}(of ferrocene = + 0.38 V). Oxidation number of **1b** was determined from the concentration dependence of peak currents with tetrathiafulvalene as an external standard. In the case of irreversible waves, E^{ox} was calculated as E_{pa} (anodic peak potential) -0.03 V.
[9] **1c**: $C_{22}H_{20}S_8$, M = 540.86, triclinic, space group $P\bar{1}$, $a = 9.581(2)$, $b = 10.887(1)$, $c = 6.031(1)$ Å, $\alpha = 93.39(1)$, $\beta = 93.78(2)$, $\gamma = 81.14(1)$°, $V = 619.5(2)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.450$ g cm^{-3}. A total of 3039 unique data was collected ($Mo_{K\alpha}$, $\lambda = 0.71049$ Å, $\mu = 7.018$ cm^{-1}, $2\theta < 58$°), of which 2867 non-zero reflections were used for structure refinement. $\mathbf{1c}^{2+} \cdot 2ClO_4^- \cdot CH_2Cl_2$: $C_{23}H_{22}S_8O_8Cl_4$, $M = 824.69$, tetragonal, space group $P4/n$, $a = b = 10.819(2)$, $c = 14.202(2)$ Å, $V = 1662.5(5)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.647$ g cm^{-3}. A total of 1916 unique data was collected ($Mo_{K\alpha}$, $\lambda = 0.71049$ Å, $\mu = 8.835$ cm^{-1}, $2\theta < 55$°), of which 936 had $F > 3\sigma(F)$ and were used for structure refinement. **1b**: $C_{22}H_{20}S_4$, M = 412.64, monoclinic, space group $P2_1/c$, $a = 9.578(4)$, $b = 8.496(1)$, $c = 13.178(3)$ Å, $\beta = 101.73(3)$°, $V = 1050.0(6)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.305$ g cm^{-3}. A total of 1811 unique data was collected ($Cu_{K\alpha}$, $\lambda = 1.5418$ Å, $\mu = 41.09$ cm^{-1}, $2\theta < 126$°), of which 1490 had $F > 3\sigma(F)$ and were used for structure refinement. These data sets were collected on an AFC-5R diffractometer at 286 K. Absorption correction was applied for **1b** (Ψ-scan-method). Block-diagonal least-squares refinement gave $R = 0.0460$ for **1c**, 0.1211 for $\mathbf{1c}^{2+} \cdot 2ClO_4^- \cdot CH_2Cl_2$ and 0.0387 for **1b**. Because of the disorder of solvent and a counteranion, the R value of $\mathbf{1c}^{2+} \cdot 2ClO_4^- \cdot CH_2Cl_2$ is very large and the large esds prevent the comparisons of bond lengths. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55915, the names of the authors, and the journal citation.

One-Pot Multifunctionalization of Polymethyl Hydrocarbon π Ligands. Maximum Space Occupancy by Double Branching and Formation of Arboroles**

By *Françoise Moulines, Bruno Gloaguen,* and *Didier Astruc**

De Gennes and Hervet successfully predicted[1] that the dendrimer strategy,[2–6] an idea pioneered by Vögtle,[2] leads to space saturation on the outer sphere surface after a few generations. We now show how the maximum number of functional branches in arboroles can be achieved in a one-pot reaction. For this purpose, the acidity enhancement of methyl substituents in polymethyl hydrocarbon ligands by complexation to cationic organo-transition metal fragments[7] is exploited in combination with allylation and benzylation reactions. This polysequential strategy is only limited by steric demand in the products when an excess of reagents is used.

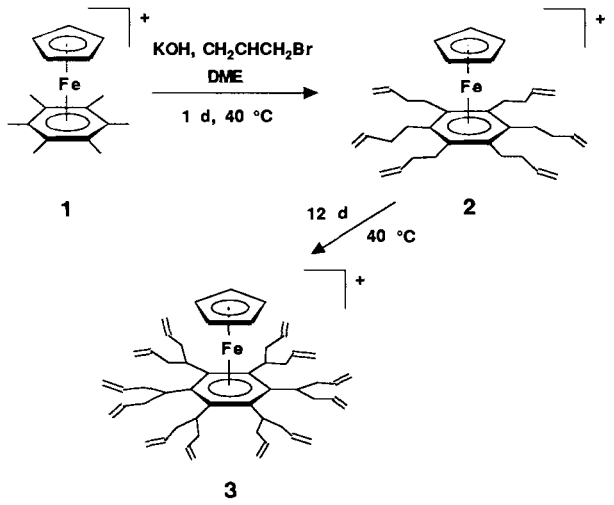
Up to now we had concentrated our attention on the hexafunctionalization of hexamethylbenzene leading to discoid molecules[8] [Eq. (a)].

$$[FeCp(C_6Me_6)]^+ \xrightarrow[R'X]{KOR} [FeCp\{C_6(CH_2R')_6\}]^+ \qquad (a)$$

R = H or *t*Bu; R′ = Me, CH_2Ph, CH_2CHCH_2; X = Br or I.

The deprotonation-allylation sequences of Equation (a) rapidly lead to the replacement of one H in each Me substituent by an allyl group.[8a]. We could now show that continuation of this reaction is possible and leads to the slower introduction of a second allyl group on each benzylic carbon. Thus, using a 20-fold excess of allyl bromide and KOH in dimethoxyethane (DME) at 40 °C, the twelve allyl branches are attached in about 12 days (KOH is replaced several times). Formation of **3**, the first hexaisoalkylbenzene-transition metal complex, via **2** results from 24 reactions starting from the proton reservoir complex **1** (12 deprotonations and 12 alkylations). The overall yield of **3** is only 17.5%, since the growing steric demand induces extensive decomplexation of the $CpFe^+$ fragment.

The structure of **3** is secured by the correct C, H, Fe analyses and by the ^1H and ^{13}C NMR spectra.[9] In particular, the slow, second branching is easily monitored by the new Cp peaks appearing in the ^1H NMR spectra of the reaction samples and by the integration ratio. The Cp peak position is shifted all the more downfield as the number of allyl arms increases from six (δ = 4.65, CD_3CN) to twelve (δ = 5) due to the deshielding effect of the *endo* allyl chains. The allyl group is the only one leading to double branching; alkyl and benzyl halides give only single branching[8c, d] [Eq. (a)] even under drastic conditions.



The slow formation and the decomplexation of the dodecafunctional complex **3** show how rapidly spatial crowding is reached. Starting from the durene complex **4** (Scheme 1), we are not confronted with such problems, and double branching proceeds more rapidly at room temperature giving **5** with-

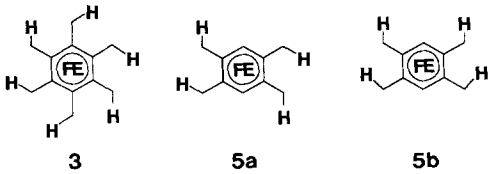
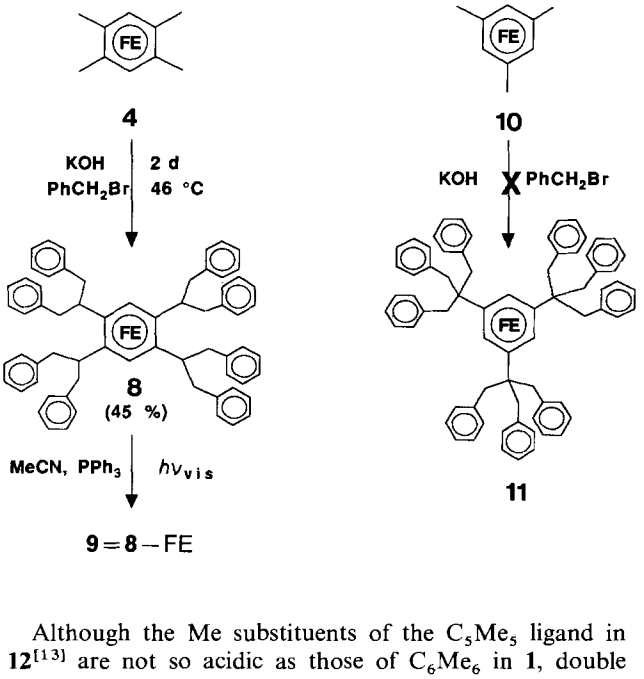
out decomplexation. The octafunctional ligand **6** of **5** can be readily removed by photolysis with visible light.[10] A convenient synthesis of the octol **7** is achieved by hydroboration with subsequent alkaline oxidation[11] (Scheme 1).

The NMR spectra of **3** and **5**–**7** show the directionalities[12a] of the geared, branched substituents. Whereas **3** has a single, blocked directionality, **5** and **7** have independent directionalities (Scheme 2) on the two sides with distinct *endo*- and *exo*-allyl branches on the NMR time scale up to 100 °C.[9] On the other hand, the geared rotation of the branches is faster than the NMR time scale in the free aromatic compound **6** (only one allyl type according to the ^{1}H NMR spectrum up to 500 MHz).

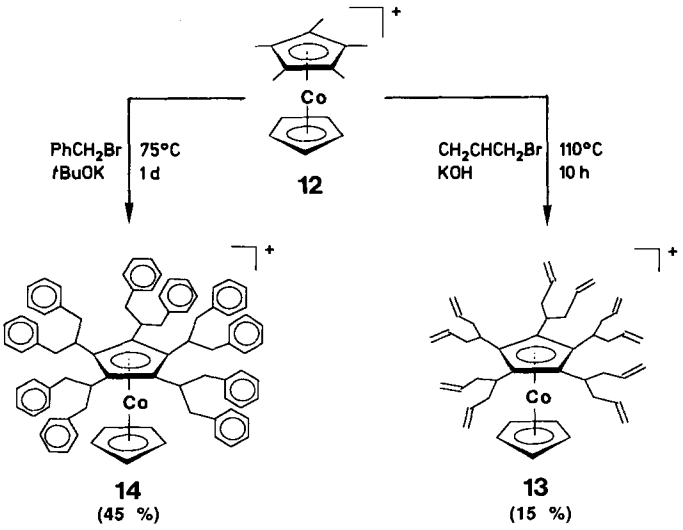


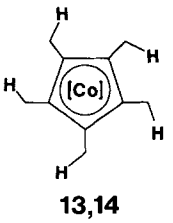
Scheme 2. Orientation of the arms in **3** and **5**. In the case of **5** two orientations are possible (**a** and **b**). The allyl groups are omitted for clarity.

Reaction of **4** with benzyl bromide and KOH in DME at 46 °C afforded pure **8**,[9] and photolysis with visible light, as for **5**, furnished the free ligand **9**. An attempted threefold branching of **10** to give **11** did not give any pure compound even under drastic conditions; the maximum number of benzyl branches achieved being between seven and eight.[12b] This indicates that the steric limit is attained before the third benzylation of the three benzylic carbons (the unusual reaction of **10** with allyl bromide will be described later[12b]).



Although the Me substituents of the C_5Me_5 ligand in **12**[13] are not so acidic as those of C_6Me_6 in **1**, double branching is easier because the C–centroid–C angle is larger in C_5Me_5 (72°) than in C_6Me_6 (60°).[14] Thus, decaallylation and decabenzylation of **12** furnish **13** and **14**, respectively.[9] As for **1**, the combination of reduced reactivity and bulk-induced decomplexation limits the yields, and the single directionality (Scheme 3) is blocked on the NMR time scale up to above 100 °C.





Scheme 3. Orientation of the arms in **13** and **14**; view from above. The allyl and benzyl groups, respectively, are omitted for clarity. [Co] = (η^5-Cp)Co$^+$.

Summarizing, one-pot octa-, deca- and dodecafunctionalization of π ligands can be performed by an activation process which uses cationic transition-metal fragments CpM^+ (M = Fe, Co). This double branching, multiple functionalization approaches the steric limit, as indicated by the low reaction rates, decomplexations, and impossible introduction of three benzyl groups on the three benzylic carbons of **10**. The new molecules have specific topologies and could be used in the future to encapsulate guest substrates (time-selective drug delivery), attach multiple redox centers, and serve as synthons in supramolecular[15, 16] organometallic chemistry.

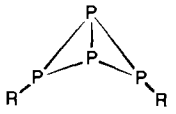
$(H_2Si)_2E_2$ and $(Mes(t\mathrm{Bu})Si)_2E_2$ (E = As, P): Incommensurable Systems of Different Stability with Unusually Long E–E Bonds**

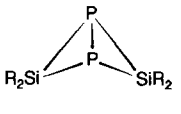
By *Matthias Driess,* Rudolf Janoschek,* and *Hans Pritzkow*

In memoriam Manfred L. Ziegler

We are interested in the influence of silicon as a framework atom on the ring strain and the isomerization ratio (*exo,endo*; *exo,exo*) in phosphabicyclo[1.1.0]butanes.[1] It is already known that the substitution of the two peripheral organophosphandiyl fragments R–P: in tetraphosphabicyclo[1.1.0]butanes **A** by isovalent electronic diorganosilandiyls R_2Si: **B** results in a drastic change of the character of the P–P bridgehead bond. Hence, the P–P bridgehead bond in **A** is ca.0.10 Å *shorter* than in normal diphosphanes with λ^3,σ^3-P atoms (2.20–2.23 Å), whereas derivatives of type **B** show an inverse behavior, i.e. have approximately 0.15 Å *longer* P–P bonds.[2] The relatively short central P–P bond in **A** is attributed to partial π character.[3]

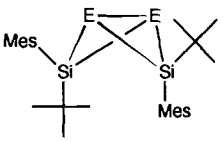


A

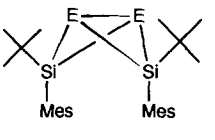


B

The longer bridgehead bond in the P_2Si_2 system **B** can also be explained qualitatively as the silicon in the peripheral position causes a high Baeyer's angle strain. A further characteristic of silicon atoms in the P_2Si_2 system **B** is their ability to avoid very unfavorable steric interactions in the *endo* position by *exo,endo* → *exo,exo* rearrangement (Si inversion).[1, 2] Such an isomerization of 1,3-diphosha-2,4-disilabicyclo[1.1.0]butanes **B** was first observed for the derivatives **1a** and **1b**, in which *tert*-butyl and mesityl groups are substituted at the silicon. In order to understand this new rearrangement at silicon comparative experimental and theoretical investigations are necessary. To learn how the size of the bridgehead atoms influences the length of the central bond and the relative stability of the *exo,endo* and *exo,exo* isomers, we have synthesized the compounds **2**, homologues of **1a** and **1b**, which in the bridgehead positions have arsenic atoms instead of phosphorus.



1a, E = P
2a, E = As



1b, E = P
2b, E = As

Compound **2a** was prepared analogous to **1a** by intramolecular As–As bond formation. The precursors **3** and **4** are also the first known 1,3,2,4-diarsadisiletanes. Compound **3** is formed by the cyclic condensation of Mes-(tBu)$SiCl_2$ (Mes = 2,4,6-trimethylphenyl) and $[LiAsH_2(dme)]$ (dme = dimethoxyethane) in the molar ratio of 1:2. Remarkably, only that isomer of **3** was formed in which the *tert*-butyl groups are in *trans* configuration. The constitution of **3** was confirmed by NMR spectroscopy[4] and an X-ray structure analysis (Fig. 1a).[5]

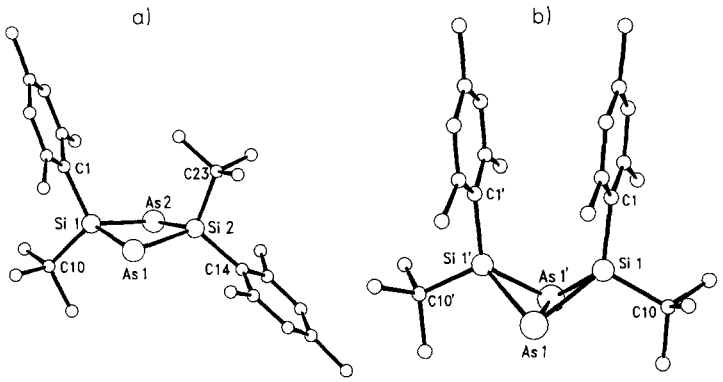

Fig. 1. a) Molecular structure of **3**. Selected bond lengths [Å] and angles [°]: Si-As 2.382-2.401(1), Si-C 1.900-1.914(6): Si-As-Si 83.6(1), As-Si-As 94.2, 94.9(1). b) Molecular structure of **2b**. Selected bond lengths [Å] and angles [°]: As1-As1' 2.602(3), As1-Si1 2.355(3), Si-C 1.904(6), 1.926(4); Si1-As1-Si1' 84.3(1), As1'-As1-Si1 56.5(1), As1-Si1-As1' 67.1(1).

The ^{1}H NMR spectra of **3**[4] are temperature dependent. This can be explained by dynamic effects at the arsenic centers (As inversion, *cis*, *trans* isomerism of the H atoms at the arsenic) analogous to those of the corresponding P_2Si_2 cyclobutanes. The heterocycle in **3** is nonplanar (As1–Si1–As2/As1–Si2–As2 21.5°), and the bond lengths and angles are in the expected range. The nonbonding As–As distance is 3.51 Å.

Double deprotonation of **3** with two equivalents of BuLi and subsequent mercurization with *t*BuHgCl leads to the 1,3-dimercurio derivative **4**,[6] in which according to ^{1}H and ^{29}Si NMR spectra, the *t*BuHg groups are *trans* to one another.

Photolysis of a colorless solution of **4** (0.025 M) in benzene with a 150 Watt light bulb yielded a yellow solution of **2a**, elemental Hg, isobutene, and H_2 after 24 hours. In contrast to **1a**, which under the same reaction conditions rapidly rearranges to **1b** (*exo,exo* isomer),[1] **2a** (*exo,endo* isomer) can be isolated in a pure form.[7] The *exo,endo* configuration of the Si *tert*-butyl groups in **2a** is proved unequivocally by the ^{1}H and ^{29}Si NMR spectra[7] (two types of *t*Bu and Mes groups each; two chemically inequivalent ^{29}Si nuclei).

If a solution of **2a** in hexane is stored for several weeks at 25 °C or irradiated for a longer period (ca. one week), the gradual formation of a small amount of the *exo,exo* isomer **2b** is observed spectroscopically (^{1}H and ^{29}Si NMR)[8] as the only product. At higher temperature or upon irradiation with UV light mainly uncharacterized products result. The compound **2b** was isolated in 8% yield in the form of orange-yellow crystals which were only slightly air sensitive. A crystal structure analysis[9] of **2b** (Fig. 1b) confirms the *exo,exo* configuration.

The fold angle As1–Si1–As1'/As1–Si1'–As1' is 72.8° and therefore differs only slightly from that in **1b** (71.7°).[1] The As–Si bond length (2.355(3) Å) is significantly shorter than that in **3** (average 2.391(1) Å), but nevertheless lies in the characteristic range for As–Si single bonds.[10] The most notable feature of the structure of **2b** is the extremely long As–As bond length of 2.602(3) Å. In contrast, in isostructural molecules with a As–As bridgehead bond,[11] the bond lengths *are shorter* than normal As–As single bonds [d(As–As) ≈ 2.44 Å]. The long As–As bond in **2b** is only comparable with that in realgar As_4S_4 (2.59 Å)[12] and thus very unusual for an As_2 group in a small ring system. To sum up, it can be established that the substitution of phosphorus atoms with arsenic atoms in the bridgehead position considerably increases the stability of the *exo,endo* isomer. In contrast, the change from a P_2 to an As_2 bridge in the bicyclo[1.1.0]butane framework hardly alters the length of the bridgehead bond relative to the single bond. The central As–As bond in the rearranged *exo,exo* product **2b** as well as the P–P bond in the analogous **1b** are ca. 6% longer than a normal single bond.

How can the Si inversion and different stability of *exo,endo* and *exo,exo* isomers be interpreted? For energetic reasons it can be assumed and calculations show that the Si inversion does not occur by homolytic cleavage, but via a transition structure with C_s symmetry (Fig. 2), i.e. for the inversion a SiR_2 unit should rotate 180° about the line that bisects the R–Si–R angle. However, if an ab initio calculation[13] (SCF/6-31G*) under C_s symmetry restriction is carried out for the parent compound $(H_2Si)_2P_2$, this does not result in the required energy minimum for the postulated transition structure (cf. Fig. 2). The energy is higher than the dissociation energy for $(H_2Si)_2P_2 \rightarrow SiH_2 + P_2(SiH_2)$ (SCF: 62.5 kcal mol^{-1}; MP2: 71.0 kcal mol^{-1})

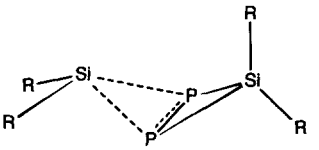

Fig. 2. C_s symmetrical transition structure of the Si inversion in 1,3-diphospha-2,4-disilabicyclo[1.1.0]butane.

Furthermore, the calculations reveal that by a coupling with the ring inversion (D_{2h}) no Si inversion is possible without dissociation. Tetrasilabicyclo[1.1.0]butane shows bond-extension isomerism,[14] which is in agreement with the rapid inversion of the folded bicycle at room temperature, whereas for $(H_2Si)_2P_2$ a relatively high barrier to ring inversion of 52.0 (SCF) and 51.0 kcal mol^{-1} (MP2), respectively, is observed. A second energy minimum for a structure with a longer P–P bridgehead bond could not be found. Possible diradical character of $(H_2Si)_2P_2$, with such long P–P distances as those in the folded equilibrium structure (C_{2v}, 2.360 Å) and the planar transition structure of the ring inversion (D_{2h} 2.667 Å), can be definitely rejected on the basis of the calculation of the multiconfiguration wave functions (MCSCF).[15] A CAS-MCSCF/6-31G* calculation of the wave function[16] with the active orbitals π, π*, and σ* (important for the P–P interaction) afforded as occupation numbers 1.992, 1.899, and 0.109, respectively. These disprove a diradical character (that would have occupation numbers of approximately 1, 1, and 2, respectively) and instead suggest an ionic donor–acceptor representation (Fig. 3).

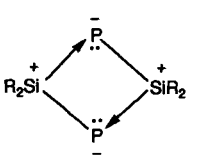

Fig. 3. Valence formula describing the P–P interaction in 1,3-diphospha-2,4-disilabicyclo[1.1.0]butanes.

Similar results were obtained for the folded structure. The atomic charges of −0.483 (on P) and +0.675 (on Si) as well as the high relative energy of the triplet state of 88.4 kcal mol^{-1} (UMP2) are in agreement with this interpretation of the electronic structure. The reliability of the ab

initio calculation of $(H_2Si)_2P_2$ is reflected in the good agreement of the calculated and experimental (substituted system) distances and angles. For the equilibrium structure (C_{2v}) a longer P–P distance of 2.360 Å was calculated, which is only 0.02 Å shorter than the experimental value for **1b**.[1] The negative results of the ab initio calculations regarding the Si inversion suggest that this process in **1a** is only forced to occur by the presence of bulky substituents. Hence, this is no characteristic of the folded P_2Si_2 bicycle. The incomparability of the parent compound and the derivative with bulky substituents is probably also true for diarsadisilabicyclo[1.1.0]butanes. The greater stability of the *exo,endo* isomer **2a** in comparison to **1a** is probably due to unfavorable As–As interactions in the transition state of the Si inversion.

Experimental Procedure

3: To a solution of Mes(*t*Bu)$SiCl_2$ (4 g, 14.54 mmol) in THF (30 mL) at −78 °C, a solution of [$LiAsH_2$(dme)] (5.06 g, 29.08 mmol) in THF (30 mL) was added. This mixture was warmed to −30 °C over a 2 h period, stirred for a further 2 h at this temperature, and then slowly warmed to 28 °C. After 8 h at 28 °C all volatiles were removed at 10^{-2} Torr. The residue was taken up in benzene (30 mL) and filtered. Concentration of the pale yellow, clear filtrate to ca. 5 mL afforded trapezoid-shaped, colorless crystals after 2 d at 28 °C. Yield 2.52 g (4.50 mmol, 62%). Mp = 188–190 °C.

4: To a solution of **3** (1 g, 1.78 mmol) in THF (20 mL), BuLi (227.8 mg, 3.56 mmol, 2.5 M solution in hexane) was added at −78 °C. The initial colorless solution immediately changed to an intense orange-yellow. After 30 min at −40 °C a solution of *t*BuHgCl (1.046 g, 3.56 mmol) in THF was added slowly which resulted in a colorless solution. Following this the solvent was removed, the residue was taken up in hexane (10 mL), filtered, and crystallized at −78 °C. Compound **4** was isolated as colorless, light-sensitive crystals. Yield 1.859 g (1.58 mmol, 89%). Mp = 176 °C (decomp.).

2a: A vigorously stirred benzene solution of **4** (100 mL, 0.025 M) was exposed to light (150 Watt light bulb) for 24 h. The yellow suspension formed was filtered several times over dry silica gel to remove Hg. Any remaining Hg was later removed under vacuum (10^{-3} Torr). Concentration of the intense yellow solution afforded spectroscopically (^{1}H and ^{29}Si) pure **2**. Yield 1.353 g (2.42 mmol, 97%).

2b: A hexane solution of **2a** (60 mL, 0.017 M) was irradiated analogously to that for the preparation of **2a** for 1 week at 25 °C. The solution was concentrated to ca. 1 mL, and within 2 weeks **2b** crystallized out completely (^{1}H NMR control, 45.6 mg, 8%).

New Routes to Alkylidyne-Bridged Ditungsten Compounds Supported by Alkoxide or Siloxide Ligands by the Activation of Ethylene**

By *Stephanie T. Chacon, Malcolm H. Chisholm,* Cindy M. Cook, Mark J. Hampden-Smith,* and *William E. Streib*

Dedicated to Professor E. O. Fischer

Following Fischer's[1] discovery of the carbyne ligand (now more commonly called alkylidyne) numerous other examples emerged with rich and interesting reactivity. The most common synthetic routes to carbyne complexes involve reactions of carbonyl ligands, α-hydrogen atom transfer from alkyl and/or alkylidene ligands, and C–C scission of coordinated alkynes.[2] We describe here two new reactions leading to carbyne-bridged ditungsten compounds, together with the results of labeling studies that reveal potential insight into the reaction pathways involved in these remarkably facile reactions.

The ethyne adduct $[W_2(\mu\text{-}C_2H_2)\{OSi(t\text{Bu})Me_2\}_6(py)]$[3] and ethylene (≥ 1 equiv) react in hexane at −20 °C to give the blue crystalline compound **1**.

$[W_2(H)(\mu\text{-}CCH{=}CHCH_3)\{OSi(t\text{Bu})Me_2\}_6]$ **1**

Compound **1** is also formed if the reaction is carried out at room temperature; however, a competitive reaction leading

to the previously characterized compound $[W_2(\mu\text{-}CCH)\{OSi(t\text{Bu})Me_2\}_5]$[3] is observed. The latter compound does not react with ethylene to give **1** as determined from a separate experiment. The structure of **1** has been determined from an X-ray crystallographic study and is shown in Figure 1.[4] The NMR data obtained for **1** in $[D_8]$toluene at

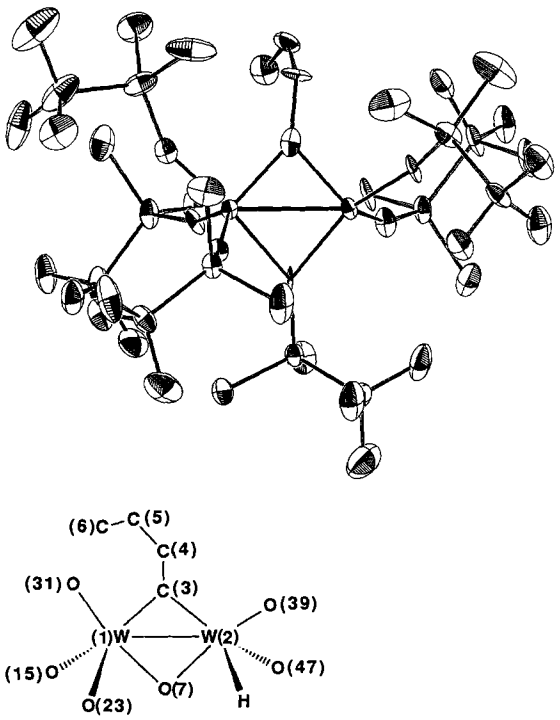

Fig. 1. Top: ORTEP drawing of $[W_2(H)(\mu\text{-}CCH{=}CHCH_3)\{OSi(t\text{Bu})Me_2\}_6]$ (**1**). Hydrogen atoms have been omitted for clarity. Pertinent distances [Å] are W(1)-W(2) 2.658(1), W(1)-O(7) 2.10(1), W(1)-O(15) 1.89(1), W(1)-O(23) 1.86(1), W(1)-O(31) 1.94(1), W(1)-C(3) 1.98(1), W(2)-C(3) 1.92(1), W(2)-O(7) 2.05(1), W(2)-O(39) 1.87(1), W(2)-O(47) 1.92(1). Bottom: The proposed position of the hydride ligand is indicated in the stick drawing.

$-70\,^{\circ}C$ are consistent with the structure found in the solid state (i.e., all siloxy ligands are chemically inequivalent) and, in particular, confirm the presence of the hydride and bridging 2-butenylidyne ligands. At $-70\,^{\circ}C$ the hydride signal shows a coupling to ^{183}W ($I = 1/2$, 14.5% natural abundance) of 145 Hz, while at 22 °C the magnitude of this coupling is only 83 Hz. The relative satellite intensity due to coupling to ^{183}W is notably larger in the room temperature spectrum. This, together with the low-temperature NMR behavior of the $OSi(t\text{Bu})Me_2$ signals, leads us to believe that in the structure of **1**, the hydride ligand occupies a terminal position on W2, which is otherwise only four coordinate. It is evident, however, that a fluxional process involving terminal-bridge interchange of both siloxide and hydride ligands is rapid on the NMR time scale at room temperature.

The compound $[W_2(\mu\text{-}CMe)(OCH_2t\text{Bu})_6(Ot\text{Bu})]$ (**2**), was first discovered as a minor product in the reaction between $[W_2(OCH_2t\text{Bu})_6]$ and ethylene (2 equiv).[5] The origin of the OtBu ligand can reliably be traced to the presence of adventitious tBuOH that was present in the solution as a residual impurity from the preparation of $[W_2(OCH_2t\text{Bu})_6]$ by alcoholysis of $[W_2(Ot\text{Bu})_6]$. The reaction shown in Equation (a)

$$[W_2(OCH_2t\text{Bu})_6(C_2H_4)_2] + t\text{BuOH} \longrightarrow [W_2(\mu\text{-}CMe)(OCH_2t\text{Bu})_6(Ot\text{Bu})] + C_2H_6 \quad (a)$$

2

provides a synthesis of **2** in ca. 50% isolated yields starting from $[W_2(OCH_2t\text{Bu})_6(C_2H_4)_2]$.[6]

The structure of the μ-ethylidyne complex **2**[4] is shown in Figure 2 and the NMR data are consistent with the solid-state structure.

Insight into the reaction pathways leading to the facile formation of compounds **1** and **2** may be gleaned from the following observations involving the use of labeled C_2 compounds: 1) The reaction between $[W_2(\mu\text{-}^{13}C_2H_2)\{OSi(t\text{Bu})Me_2\}_6(py)]$ and C_2H_4 in hexane at $-20\,^{\circ}C$ yields the isotopomer of **1** $[W_2(H)(\mu\text{-}^{13}C^{13}CH{=}CHCH_3)\{OSi(t\text{Bu})Me_2\}_6]$ while the reaction between $[W_2(\mu\text{-}C_2D_2)\{OSi(t\text{Bu})Me_2\}_6(py)]$ and C_2H_4 gives $[W_2(D)(\mu\text{-}CCD{=}CHCH_3)\{OSi(t\text{Bu})Me_2\}_6]$. 2) The reaction between $[W_2(OCH_2t\text{Bu})_6(C_2D_4)_2]$ and tBuOH in hexane yields $[W_2(\mu\text{-}CCD_3)(OCH_2t\text{Bu})_6(Ot\text{Bu})]$ and C_2D_5H as deduced from NMR studies.

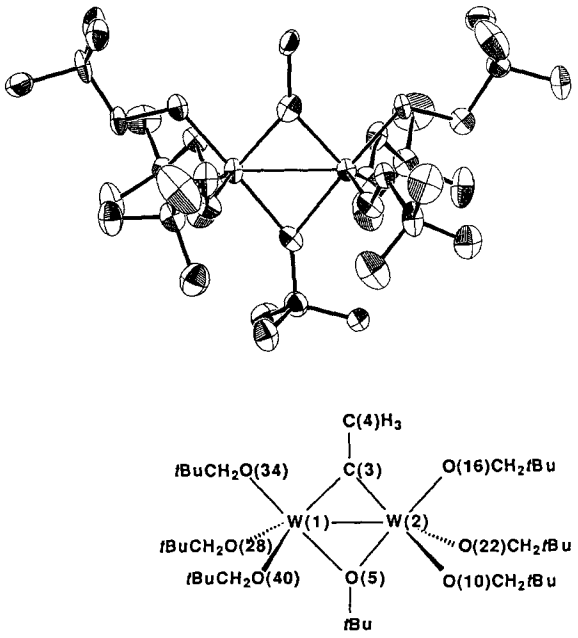

Fig. 2. Top: ORTEP drawing of $[W_2(\mu\text{-}CMe)(OCH_2t\text{Bu})_6(Ot\text{Bu})]$ (**2**). Hydrogen atoms have been omitted for clarity. Pertinent distances are W(1)-W(2) 2.644(1), W(1)-O(5) 2.05(1), W(1)-O(28) 1.90(1), W(1)-O(34) 1.94(1), W(1)-O(40) 1.91(1), W(1)-C(3) 1.94(1), W(2)-O(5) 2.03(1), W(2)-O(10) 1.90(1), W(2)-O(16) 1.94(1), W(2)-O(22) 1.90(1), W(2)-C(3) 1.94(1). Bottom: Stick drawing of **2**.

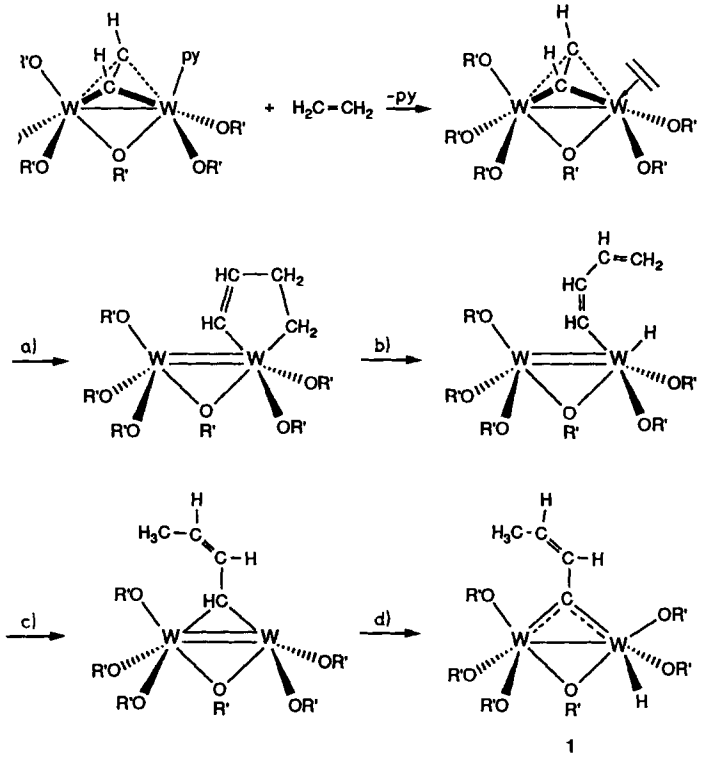
The stereospecific transfer of H/D atoms and the stereochemistry about the C–C double bond in **1** lead us to suggest that the alkylidyne ligand is formed by initial C–C bond formation to generate a metallacyclopentenyl moiety[7] followed by β-H elimination and reinsertion to generate an alkenyl ligand. By subsequent α-CH activation the hydride and alkenylidyne ligands are formed (see Scheme 1).

The formation of the isotopomer of **2** containing the $[W_2(\mu\text{-}CCD_3)]$ moiety indicates that the ethylidyne H/D atoms arise exclusively from those on ethylene and as such parallels the reaction of ethylene on a Pt^{III} surface that generates the μ_3-ethylidyne ligand.[8]

In conclusion, we have discovered two facile reactions leading to alkylidyne-bridged ditungsten compounds supported by alkoxide or siloxide ligands from ethylene. It seems quite plausible that these are merely the first examples in the reactions of ditungsten alkoxides/siloxides and alkenes.



Scheme 1. A possible reaction pathway leading to the formation of **1** from $[W_2(\mu\text{-}C_2H_2)\{OSi(t\text{Bu})Me_2\}_6(py)]$ and ethylene. R′ = Si(*t*Bu)Me_2. a) C–C coupling, b) β-H elimination, c) insertion, d) α-H elimination.

Experimental Procedure

$[W_2(H_a)(C_aC_bH_b{=}C_cH_cC_dH_{3d})\{OSi(t\text{Bu})Me_2\}_6]$ (**1**): A 50 mL Kontes flask charged with black $[W_2(\mu\text{-}C_2H_2)\{OSi(t\text{Bu})Me_2\}_6(py)]$ crystalline solid (330 mg, 0.26 mmol) and a stir bar was placed in a CO_2(s)/ethanol cold bath at −72 °C. Toluene (10 mL) was then added. The heterogeneous mixture was immediately frozen at −196 °C, evacuated, and C_2H_4 (1.31 mmol) introduced through a calibrated vacuum manifold. The flask was immediately placed in a cold bath at −72 °C for 30 min, during which time the mixture became homogeneous, and the brown solution gained a blue tint. The solution was placed at −20 °C for 12 h. Reduction of the volume to ca. 5 mL, and crystallization at −20 °C led to the isolation of deep blue-black crystals of **1**. Combined crystallizations gave **1** in 45% isolated yield.

^{1}H NMR (300 MHz, 22 °C, C_6D_6): δ = 15.76 (s, $J_{W,H}$ = 83 Hz, I = 32%, H_a); 8.22 (dq, $^3J_{Hb,Hc}$ = 11 Hz, $^4J_{Hb,Hd}$ = 1 Hz, H_b); 5.64 (dq, $^3J_{Hc,Hb}$ = 11 Hz, $^3J_{Hc,Hd}$ = 6 Hz, H_c); 1.88 (dd, $^3J_{Hd,Hc}$ = 6 Hz, $^4J_{Hd,Hb}$ = 1 Hz, H_d); 1.10 (s, br, OSi(*t*Bu)Me_2); 0.34 (s, br, OSi(*t*Bu)Me_2).

^{1}H NMR (300 MHz, −70 °C, C_7D_8): δ = 15.56 (s, $J_{W,H}$ = 145 Hz, I = 22%, H_a); 8.22 (dq, H_b); 5.64 (dq, H_c); 1.88 (dd, H_d); (OSi(*t*Bu)Me_2): 1.35, 1.24, 1.14, 1.12, 1.06, 1.02 (s with intensity ratio 1:1:1:1:1:1); (OSi(*t*Bu)Me_2): 0.70, 0.66, 0.48, 0.47, 0.32, 0.30, 0.29, 0.26, 0.21, 0.17, 0.16 (s with intensity ratio 1:1:1:1:1:1:2:1:1:1. The signal of intensity 2 is apparently due to accidental degeneracy).

^{13}C{^{1}H} NMR (75 MHz, 22 °C, C_6D_6): $^{13}C_a{}^{13}C_bH_b{=}{}^{13}C_cH_c{}^{13}C_dH_{3d}$ ligand only; δ = 313.8 (d, $^1J_{Ca,Cb}$ = 45 Hz, $^1J_{C,W}$ = 142 Hz, I = 22%, C_a); 152.0 (dd, $^1J_{Cb,Cc}$ = 70 Hz, $^1J_{Cb,Ca}$ = 45 Hz, C_b); 127.1 (dd, $^1J_{Cc,Cb}$ = 70 Hz, $^1J_{Cc,Cd}$ = 43 Hz, C_c); 16.7 (d, $^1J_{Cd,Cc}$ = 43 Hz, C_d). Chemical shifts and coupling constants are invariant at low temperatures (−70 °C).

^{13}C NMR (gated decoupled) (75 MHz, 22 °C, C_6D_6): δ = 313.8 (dd, $^1J_{Ca,Cb}$ = 45 Hz, $^2J_{Ca,Hb}$ = 10 Hz, C_a); 152.0 (dddd, $^1J_{Cb,Hb}$ = 154 Hz, $^1J_{Cb,Cc}$ = 70 Hz, $^1J_{Cb,Ca}$ = 45 Hz, $^2J_{Cb,Hc}$ = 4 Hz, C_b); 127.1 (dddq, $^1J_{Cc,Hc}$ = 157 Hz, $^1J_{Cc,Cb}$ = 70 Hz, $^1J_{Cc,Cd}$ = 43 Hz, $^2J_{Cc,Hd}$ = 7 Hz, C_c); 16.7 (dq of virtual triplets, $^1J_{Cd,Hd}$ = 126 Hz, $^1J_{Cd,Cc}$ = 43 Hz, $^2J_{Cd,Hb} \approx {}^4J_{Cd,Ha(trans)} \approx$ 11 Hz, C_d giving rise to second-order fine coupling which appears as virtual triplets).

$[W_2(\mu\text{-}CMe)(OCH_2t\text{Bu})_6(Ot\text{Bu})]$ (**2**): $[W_2(OCH_2t\text{Bu})_6(C_2H_4)_2]$ [6] (389 mg, 0.411 mmol) was placed in a 30 mL Schlenk flask equipped with a Teflon-coated stir bar and 10 mL of hexane was added at 0 °C. 100 μL of a 4.4 M *t*BuOH solution in toluene was added by syringe. The solution was allowed to stir for four days and then cooled to −20 °C. Three batches of 30, 48, and 148 mg of crystals were isolated for a total yield of 55% (226 mg, 0.228 mmol).

^{1}H NMR (300 MHz, −40 °C, C_7D_8): δ = 4.54 (s, 3H, CCH_3), $OCH_2C(CH_3)_3$: 4.67 (s, 4H), 3.60 (d, 4H, $^2J_{H,H}$ = 10 Hz), 3.34 (d, 4H, $^2J_{H,H}$ = 10 Hz); 1.97 (s, 9H, $OC(CH_3)_3$; $OCH_2C(CH_3)_3$: 1.35 (s, 18H), 0.86 (s, 36H).

$[W_2(OCH_2t\text{Bu})_6(Ot\text{Bu})(\mu\text{-}{}^{13}C^{13}CH_3)]$: ^{1}H NMR (360 MHz, 22 °C, C_7D_8): δ = 4.47 (dd, 3H, $^1J_{H,C}$ = 130 Hz, $^2J_{H,C}$ = 7 Hz, $^{13}C^{13}CH_3$).

^{13}C{^{1}H} NMR (75 MHz, 22 °C, C_7D_8): δ = 34.4 (d, $^1J_{C,C}$ = 30 Hz, $^{13}C^{13}CH_3$); 297.3 (d, $^1J_{C,C}$ = 30 Hz, $^1J_{C,W}$ = 160 Hz, I = 26%, $^{13}C^{13}CH_3$).

$[(Ph_3PAu)_6Mn(CO)_3]^+$, a Cluster with Pentagonal-Bipyramidal Structure**

By *Jörg Mielcke*, and *Joachim Strähle**

Dedicated to Professor Ernst Bayer on the occasion of his 65th birthday

The cluster cations $[(Ph_3PAu)_xM(CO)_y]^+$ are obtained from the photolysis of $[Ph_3PAuN_3]$ in the presence of metal carbonyls.[1–6] The composition of the cations is determined by the electronic requirement of the transition metal M, which tries to achieve a stable noble-gas electron configuration (for a qualitative explanation of the bonding see [5]). In the series of cluster cations which we have so far structurally characterized with the metal center Au_xM (x = 4–7), we

[**] Cluster synthesis by the photolysis of $[R_3PAuN_3]$, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Degussa AG for tetrachloroauric acid.– Part 6:[6].

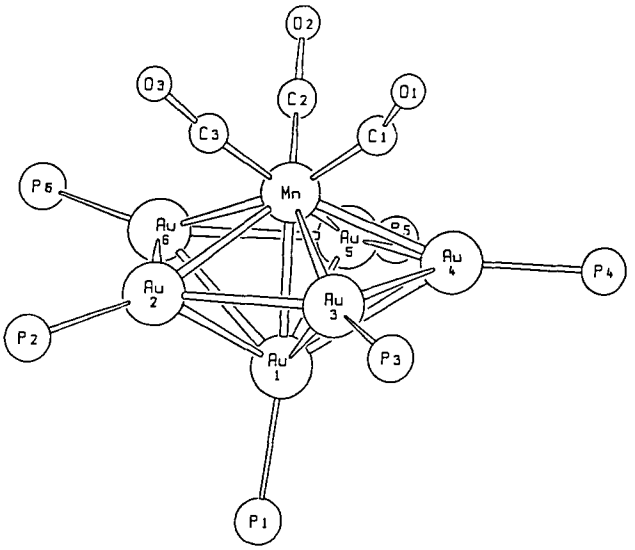

Fig. 1. Crystal structure of **2** (for the phosphane ligands only the P atoms are shown).[12] Important distances [Å] and angles [°]: Au1-Au2 2.812(1), Au1-Au3 2.864(1), Au1-Au4 2.951(1), Au1-Au5 2.802(1), Au1-Au6 2.917(1), Au2-Au3 2.826(1), Au2-Au6 2.948(1), Au3-Au4 2.861(1), Au4-Au5 2.792(1), Au5-Au6 2.920(1), Mn-Au1 2.618(1), Mn-Au2 2.718(1), Mn-Au3 2.671(2), Mn-Au4 2.649(1), Mn-Au5 2.723(2), Mn-Au6 2.622(2), Mn-C1 1.74(1), Mn-C2 1.78(1), Mn-C3 1.775(8), C1-O1 1.22(2), C2-O2 1.22(1), C3-O3 1.181(9), C1-Au4 2.44(1), C2-Au5 2.56(1); Mn-C1-O1 154(1), Mn-C2-O2 165.4(9), Mn-C3-O3 169.0(7).

have now prepared in addition to the Au_6M cluster $[(Ph_3PAu)_6V(CO)_4]^+$ (**1**)[6] also the cluster $[(Ph_3PAu)_6Mn(CO)_3]^+$ (**2**) of analogous formula. Interestingly, despite the same total number of electrons the clusters show different structures. The cluster framework of **1** can be described as a double-capped trigonal bipyramid with the vanadium atom in an equatorial position, whereas **2** forms a pentagonal bipyramid, in which the manganese atom is in an axial position (Fig. 1).

The Au_6Mn cluster **2** is formed in low yield together with $[(Ph_3PAu)_4Mn(CO)_4]^+$, on the photolysis of a solution of $[Ph_3PAuN_3]$ and $[Mn_2(CO)_{10}]$ in THF.[4] Better yields of **2** can be obtained starting from $[Ph_3PAuMn(CO)_5]$.[7] Compound **2** can be isolated after chromatographic separation as the PF_6 salt in the form of orange-red, air-stable, small plate-like crystals. The IR spectrum shows two bands for the $Mn(CO)_3$ group at 1894 and 1838 cm^{-1}. The crystal structure analysis[8] shows that **2** has a pentagonal-bipyramidal structure which is rare for metal clusters. The only other metal cluster known with this structure is $[(Ph_3PAu)_7]^+$.[9] In **2** strong Mn–Au bonds are found, which are between 2.618 and 2.723 Å long (comparable with the corresponding values in the cluster cation $[(Ph_3PAu)_4Mn(CO)_4]^+$ [4]). The Au–Au distances (2.792 to 2.951 Å) lie in the range of values which are found in the homonuclear gold clusters[10] between the peripheral gold atoms. Similar distances are also found in $[(Ph_3PAu)_7]^+$,[9] $[(Ph_3PAu)_4Mn(CO)_4]^+$,[4] and **1**.[6]

The Au_6 frameworks of **1** and **2**, like the metal frameworks Au_xM of other known cluster cations, can be interpreted as icosahedral fragments (Fig. 2).[5] The transition metal M is situated in the center of the incomplete icosahedron.

Compound **2** can be regarded as an analogue of the cyclopentadienyl complex $[CpMn(CO)_3]$, since the pentagonal-pyramidal $[(Ph_3PAu)_6]^+$ part of the framework is similar to the cyclopentadienyl ligand with respect to the structure and the bonding (Fig. 3) .

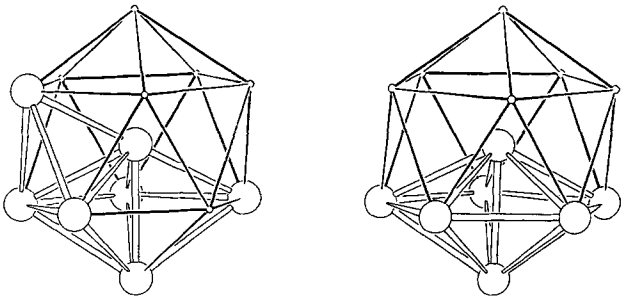

Fig. 2. Representation of the cluster frameworks Au_6M of **1** (left) and **2** (right) as centered icosahedral fragments.

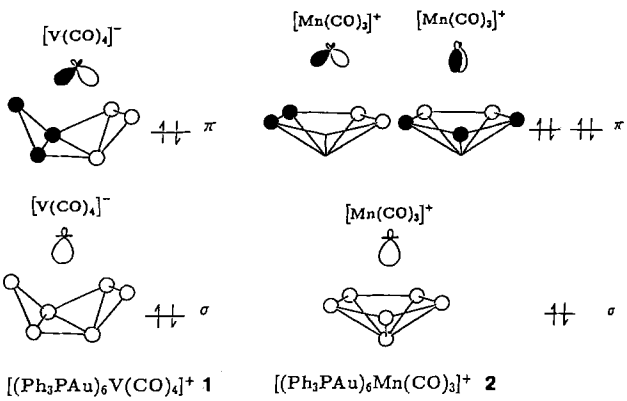

Fig. 3. Schematic representation of the cluster MOs in **1** [6] and **2**. The radial oriented sp-hybrid orbitals of the Ph_3PAu groups are symbolized by circles.

From our experience so far, the clusters $[(Ph_3PAu)_xM(CO)_y]^+$ [1–5] with the same number of valence electrons for the fragment $M(CO)_y$ form the same structure type as shown by the examples $[(Ph_3PAu)_4Co(CO)_3]^+$,[5] $[(Ph_3PAu)_4Mn(CO)_4]^+$,[4] $[(Ph_3PAu)_5Fe(CO)_3]^+$,[3] and $[(Ph_3PAu)_5Mo(CO)_4]^+$.[11] That this is not the case with **1** and **2** can be explained on the basis of the stereochemistry and the bonding. Hence, model studies show that the elliptical form of Au_6V in **1** results in a lower repulsion between the four CO groups and the $(Ph_3PAu)_6$ part of the framework than would be the case with a more spherical structure as exists for the Au_6Mn framework.

To interpret the bonding, the clusters **1** and **2** can be dismantled into the fragments $(Ph_3PAu)_6$, and $V(CO)_4$ or $Mn(CO)_3$, respectively. If the $M(CO)_y$ fragments allocate six electrons for the back bonding to the CO groups, then for **1** this results in a $[(Ph_3PAu)_6]^{2+}$ fragment with four valence electrons for the cluster bonding and a d^6 $[V(CO)_4]^-$ group with two vacant valence orbitals. For **2**, a $(Ph_3PAu)_6$ fragment with six valence electrons and a d^6 $[Mn(CO)_3]^+$ group with three empty orbitals remain. The latter can form a bonding cluster MO with σ symmetry as well as two MOs with π symmetry with the radial oriented sp-hybrid orbitals of the Ph_3PAu groups, whereas for **1** together with a cluster MO with σ symmetry only one MO with π symmetry results (Fig. 3). The structures of **1** and **2** are probably influenced by the π MOs. Since the two π MOs in **2** are arranged perpendicular to one another, a spherical cluster is preferred. In the case of only one π MO, as exists in **1**, the elliptical cluster structure obviously leads to a more effective overlap.

An alternative allocation of the valence electrons of **1** to one $(Ph_3PAu)_6$ fragment with six valence electrons and a d^4 $[V(CO)_4]^+$ group with four vacant valence orbitals could lead to a spherical structure analogous to $[CpV(CO)_4]$. How-

ever, from the explained reasons it is evidently less favored. The spherical structure for $[CpV(CO)_4]$ is determined by the rigid cyclopentadienyl ligand and tolerated due to its lower steric requirement. The more sterically demanding $(Ph_3PAu)_6$ framework is flexible because of the weak gold–gold interactions, and therefore able to adapt to its optimal structure.

Experimental Procedure

A mixture of $[Ph_3PAuMn(CO)_5]$[7] (300 mg, 0.458 mmol), $[Ph_3PAuNCO]$ (229.8 mg, 0.458 mmol), and $[Ph_3PAuN_3]$ (68.95 mg, 0.138 mmol) was irradiated in freshly distilled THF (70 mL) for 30 min using a high-pressure Hg lamp with a nitrogen purge. This produced a deep red-brown solution, which was filtered and evaporated to dryness under vacuum, then dissolved in a little CH_2Cl_2 and chromatographed on a Al_2O_3 column. An initial major fraction contained $[(Ph_3PAu)_4Mn(CO)_4]^+$. The compound **2** was eluted as a second fraction, and after the addition of KPF_6 was isolated as $\mathbf{2}\cdot PF_6$. Orange-red crystals were obtained after recrystallization from CH_2Cl_2/diisopropyl ether in 15% yield. IR: $\tilde{\nu}$ [cm^{-1}] = 1894 (C=O), 1838 (C=O); ^{31}P NMR: (CH_2Cl_2, 32.44 MHz): δ = 40.1; FAB MS: *m/z* 2893.5 ($[(Ph_3PAu)_6Mn(CO)_3]^+ - H$ = $(M-H)^+$), 2630.7 ($(M-PPh_3-2H)^+$), 1628.7 ($(M-2\ AuPPh_3-PPh_3-H)^+$).

The First Structural Characterization of a Metal–Enterobactin Complex: $[V(enterobactin)]^{2-}$ **

By *Timothy B. Karpishin* and *Kenneth N. Raymond**

Our appreciation of the significance of the siderophores[1]—microbial iron sequestering agents—has increased as their role in many diseases caused by pathogenic bacteria or fungi has become clearer. Iron supply, mediated by siderophores, is often the limiting factor in the growth of these organisms.[2] Of the approximately 200 siderophores now characterized, enterobactin (produced by enteric bacteria such as *E. coli* and discovered in 1970[3]) has been prominent and is the most powerful ferric ion chelator known (overall stability constant, $K_f \approx 10^{49}$).[4] The synthesis,[5] biosynthesis[6] and intracellular transport of enterobactin (Fig. 1) and its Fe^{III} complex[7] have all been studied. One

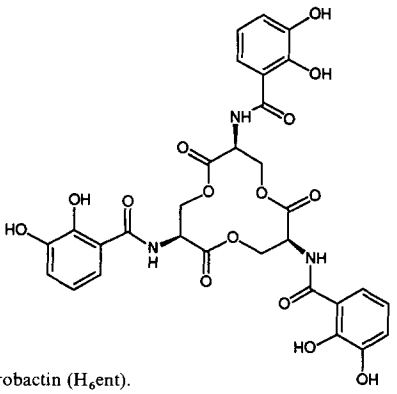

Fig. 1. The formula of enterobactin (H_6ent).

particular goal has been the explanation of the extraordinarily high stability of ferric enterobactin which is typically greater than that of simple model compounds by a factor of 10^6. Studies dealing with this issue have involved spectroscopic[8] and thermodynamic methods,[4] three-dimensional conformational analysis from NMR spectra of the diamagnetic Ga^{III} complex,[9] and molecular mechanics calculations of the free ligand and Fe^{III} complex.[10] The latter two analyses differ markedly in specific aspects of the predicted structure of the ferric enterobactin complex and how that structure affects the biological properties of the siderophore. Although enterobactin will bind many other metal ions in place of Fe^{III},[7b, 11] efforts in several laboratories over a number of years have failed to give crystals for a structure analysis. We report here the first structural characterization of a metal–enterobactin complex: $[V(enterobactin)]^{2-}$.

Reaction of protonated enterobactin, H_6ent,[12] with $VO(acetylacetonate)_2$ and two equivalents of KOH results in the displacement of the vanadyl oxygen[13] and formation of the vanadium(IV) complex, $[V(ent)]^{2-}$.[14] The complex anion is shown in Figure 2.[15] The molecule is a tris chelate complex (three catecholate groups) and has approximate C_3 molecular point symmetry. Since the backbone of enterobactin is based on three L-serine units, the introduction of chirality at the metal center (Δ or Λ) produces a diastereomeric complex ion. The chirality of the Fe^{III}, Cr^{III}, and Rh^{III} enterobactin complexes has been shown from CD spectra to be 100% Δ (a right-handed propeller).[11a, 16] As can be seen from a view down the approximate molecular threefold axis (Fig. 3), $[V(ent)]^{2-}$ also has Δ-configuration.[17]

The Δ configuration of $[Fe(ent)]^{3-}$ has important biological implications. Since the mirror image Λ-ferric enantioenterobactin (which consists of D-serine units) is not as efficient in growth promotion as the native Δ-$[Fe(ent)]^{3-}$,[7e] and since it is known that the tris(catechol) portion of the molecule is essential for recognition by the *E. coli* outer membrane protein,[7b] it has been suggested that it is the Δ chirality at the Fe center that is crucial in the recognition of $[Fe(ent)]^{3-}$. It is thus desirable to understand the interactions that stabilize the Δ isomer in metal–enterobactin complexes. Shanzer et al. have proposed that the preference for

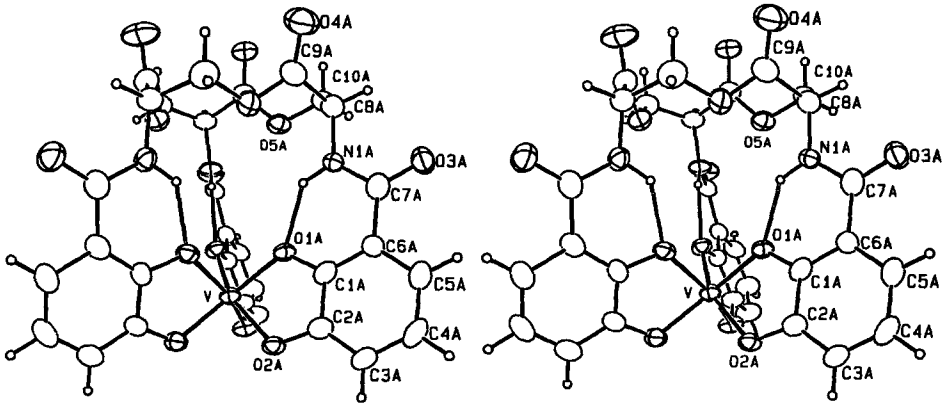

Fig. 2. Stereoview (ORTEP) of the structure of $[V(ent)]^{2-}$. The atoms in the structure are named A, B, and C to denote the threefold symmetry in the molecule. Average bond lengths and angles: V-O1 1.946(7) Å; V-O2 1.939(5) Å; O1-V-O2 79.8(6)°.

the Δ conformation of $[Fe(ent)]^{3-}$ is a result of hydrogen bonding between the amide protons and the ester oxygens of the serine backbone that occurs in the free ligand prior to iron binding.[10] This analysis suggested, however, that these bonds are broken once the ferric complex is formed. We

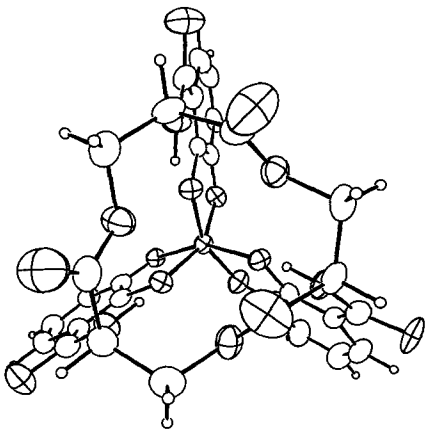

Fig. 3. Structure of $[V(ent)]^{2-}$; view down the approximate molecular threefold axis (ORTEP).

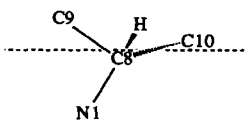
come to the conclusion that the preference for the Δ isomer in metal enterobactin complexes is a result of conformational constraints that exist within the twelve-membered ring, and this can be seen in our structure of $[V(ent)]^{2-}$. If a least-squares plane is defined by the twelve-membered ring atoms of the enterobactin molecule, six atoms (C9A, B, C; C10A, B, C) sit above the plane and six sit below (O5A, B, C; C8A, B, C). At the chiral center C8, the bonds within the twelve-membered ring (to C9 and C10) determine the tilt of the C8–N1 bond. Since each of the catecholamide arms remains planar (vide infra), the tilt of the C8–N1 bonds relative to the plane above sets the handedness of the propeller at the metal center. As a result of non-bonded interactions within the constraints of the twelve-membered ring, C9 sits on average 0.27(4) Å higher above the plane than C10 (Scheme 1). This in turn causes the three bonds from C8 to N1 to tilt as a right-handed propeller (when viewed down the threefold axis) to maintain normal tetrahedral angles at C8.



Scheme 1. Orientation of atoms around C8 (see text). The broken line shows the least squares plane.

Although molecular mechanics calculations on $[Fe(ent)]^{3-}$ have assumed ideal octahedral geometry around the iron center with a trigonal twist angle[18] of 60°, that angle in $[V(ent)]^{2-}$ is 28° and in $[Fe(ent)]^{3-}$ is likely to be ≈33°.[19] More accurate modeling of the structure of $[Fe(ent)]^{3-}$ will require incorporation of a coordination geometry intermediate between octahedral and trigonal prismatic.[20]

A very important feature in the structure of $[V(ent)]^{2-}$ is the hydrogen bonding between the amide protons (on N1) and the catechol oxygens (O1) (Fig. 2) forming stable six-membered rings and resulting in the planarity of the catecholamide arms. The average NH···O distance is 1.857(6) Å.[21] This hydrogen bonding between the amide protons and catechol oxygens of metal tris(catecholamide) complexes has been found in every such model compound crystallographically characterized.[22] Although this H-bonding was concluded not to be significant in the structure of $[Ga(ent)]^{3-}$ based on NMR studies,[9] the structures of $[V(ent)]^{2-}$ and the model compounds indicate that such hydrogen bonding plays a key role in the iron (III)–enterobactin complex.

Although the metal ion is somewhat smaller (V^{IV} = 0.58 Å; Fe^{III} = 0.65 Å[23]) the major features seen in this structure must apply also to the native $[Fe(ent)]^{3-}$ complex.[24] From Figure 2 it is clear that the twelve-membered ring is ideally suited as a base from which the three catecholamide binding groups arise. The average V–O1 bond length (1.946(7) Å) is essentially the same as the average V–O2 bond length (1.939(5) Å), indicating that the binding subunits are perfectly positioned by the ring above for coordination to a metal. In contrast, in the V^{III}[22a] and Fe^{III}[16] structures of trencam (a tripodal enterobactin analogue[25] whose Fe^{III} complex has an overall stability constant of $10^{43.6}$), the two M–O bond lengths differ by 0.022 Å and 0.038 Å respectively, indicative of the cap being too small to correctly position the three catecholate groups around the metal center. It is this feature in the design of enterobactin that we believe to be a major contributor to the high stability of the ferric complex relative to model compounds.

In summary, after much speculation regarding the detailed conformation and structure of ferric enterobactin, the major features of this important molecule are revealed by the $[V(ent)]^{2-}$ complex reported here. As the relationship between the structure of the ferric enterobactin complex and its mediation of iron transport into the cell is explored, these

results at last present a definitive answer regarding the key features of the molecular structure.

[15] Crystals of K_2[V(ent)] · 3 DMF were grown from a DMF solution of the complex by vapor diffusion of Et_2O over a period of six weeks: $K_2VC_{39}H_{42}N_6O_{18}$, $M_r = 1011.95$; monoclinic space group $P2_1$ (No. 4); $a = 13.164(3)$ Å, $b = 10.001(1)$ Å, $c = 16.600(2)$ Å; $\beta = 93.96(1)°$, $V = 2180(1)$ Å^3; $Z = 2$, $\rho_{calcd} = 1.54$ g cm^{-3}. The structure was solved by direct methods using SHELXS. Full matrix least-squares refinement (using the program MOLEN) yielded $R = 0.049$ and $R_w = 0.062$ for 600 parameters and 5551 absorption-corrected reflections with $I \geq 3\sigma(I)$. All non-hydrogen atoms in the complex anion were refined anisotropically. The data $(+h, +k, \pm l$ and Friedel pairs $-h, -k, \pm l)$ were collected on an Enraf-Nonius CAD-4 Diffractometer from $3 \leq 2\theta \leq 45$ using $Mo_{K\alpha}$ radiation. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-56008, the names of the authors, and the journal citation.

[17] The chirality of the three C8 atoms derived from L-serine (*S*) defines the correct enantiomorph in the crystal structure solution; nonetheless the enantiomorphic *R* structure was also refined as an internal check and yielded $R = 0.054$ and $R_w = 0.067$.
[18] The twist angle (θ) in tris chelate complexes is defined as the projection of the O-M-O angle onto a plane perpendicular to the idealized threefold axis; in O_h, $\theta = 60°$, in D_{3h}, $\theta = 0°$.
[19] The twist angle in Fe^{III} tris(catecholate) complexes is generally 4–6° greater than in V^{IV} complexes with the same ligands (cf. Refs. [22c,d, 24]). This is due to the smaller size of the V^{IV} metal ion [20].

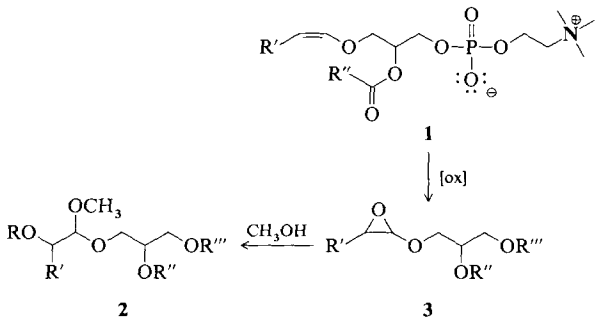
α-Hydroxyaldehyde Derivatives Arising from Oxidation of Plasmalogens**

By *Claudia Meyer*, *Arnulf Lutz*, and *Gerhard Spiteller**

Oxidized lipoproteins of low density (low density lipoproteins, LDL), which can bind to specific macrophage receptors, are known to play a significant role in the onset of atherosclerosis.[1] Polyunsaturated fatty acids of LDL phospholipids are believed to influence the oxidation of LDL,[1, 2] and the resulting aldehydes, like malondialdehyde (MDA) and 4-hydroxy-2-nonenal (4-HNE), react with the free amino groups of LDL proteins.[3] Until now, it was not considered that these aldehydes could also be formed either by hydrolysis or oxidation of plasmalogens such as **1**.[4–6] Plasmalogens make up a high percentage of the lipoprotein phospholipids (20–30% in the ethanolamine fraction).[7] Masked α-hydroxyaldehydes recently detected in tissue lipids are of similar reactivity as 4-HNE.[8–10] In this work we show that masked derivatives of α-hydroxyaldehydes result from oxidation of plasmalogens. These derivatives, once deprotected, could likewise participate in atherogenesis.

Lipids from bovine liver were extracted according to the method of Bligh and Dyer and reduced with lithium aluminum hydride.[9, 11–13] After separation of the fatty alcohols, the lysolipids were isolated by thin-layer chromatography (cyclohexane:ethyl acetate 1:2). The fraction with $R_f = 0.15–0.20$, which was silylated with *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide and analyzed by GC/MS, contained homologues of structure **2** where R′ = $C_{14}H_{29}$, $C_{16}H_{31}$, and



Scheme 1. Hypothesized origin of the mixed acetals **2** from plasmalogens **1**.

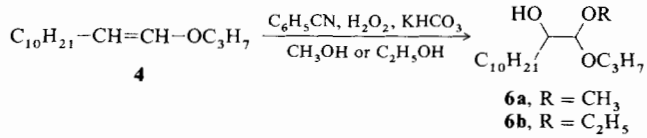
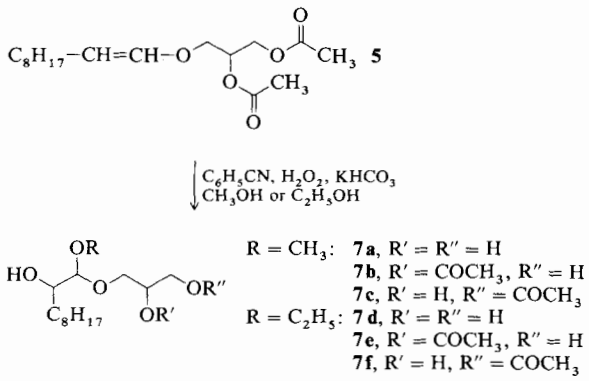
$C_{16}H_{33}$ [R = R″ = R‴ = $Si(CH_3)_3$]. These homologues are masked α-hydroxyaldehydes.

The presence of mixed acetals **2** is understandable if one postulates epoxides **3** as intermediates (Scheme 1). To test this possible pathway to **2**, we studied the plasmalogen model compounds dodec-1-enyl propyl ether (**4**) and 1-*O*-(dec-1-enyl)glycerol-2,3-diacetate (**5**). Vinyl ether **4** was prepared by the procedure of Gigg et al., and the synthesis of **5** was described previously.[9, 13, 14]

Payne epoxidation of **4** or **5** in methanol led to acetals **6a** and **7a–c** which are structurally analogous to **2**.[10, 15]. In ethanol, homologues **6b** and **7d–f** (Schemes 2 and 3) were

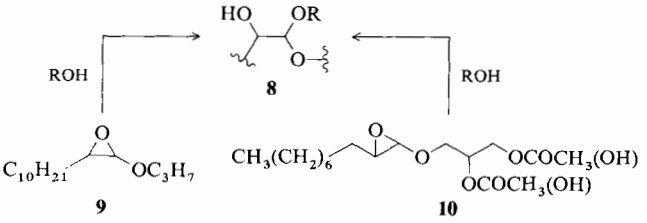


Scheme 2. Payne epoxidation of **4**.



Scheme 3. Payne epoxidation of **5**.

obtained. Compounds containing the α-hydroxyacetal group **8** arise from the attack of alcohols on epoxides **9** or **10** (Scheme 4; analogous to **3** → **2**).[16]



Scheme 4. Attack of alcohol on enol ether epoxides **9** and **10**.

Marmer et al. oxidized plasmalogen model compounds at 86 °C with air.[5] After 5 h, there was a decrease in the concentration of starting material, and the formation of aldehydes was observed. The authors reported that the addition of unsaturated fatty acids to the mixtures accelerated the reaction. In the present work, enol ether **4** was stirred with air in methanol at room temperature for 24 h to yield acetal **6a** plus aldehydes (C10–C12), carboxylic acids (C10–C12), and 1-hydroxy-2-dodecanone. The addition of methyl linoleate to the reaction mixture raised the yield of **6a** by about a factor of 10.

In conclusion, our studies showed that masked α-hydroxyaldehydes could be produced under very mild conditions and without the aid of enzymes. An analogous oxidation of plasmalogens to α-hydroxyaldehydes could also take place in vivo.

Experimental Procedure

2: Example: R′ = C_8H_{17}; TLC (cyclohexane:ethyl acetate 1:2): R_f = 0.14 (R = R″ = R‴ = H); GC (OV 101): RI = 2186/2206 [R = R″ = R‴ = $Si(CH_3)_3$]; MS (70 eV): *m/z* 103 (100%), 73 (76), 219 (76), 147 (32), 129 (28), 279 (12), 259 (8), 205 (2) [R = R″ = R‴ = $Si(CH_3)_3$].

4: Yield: ca. 10%; TLC (cyclohexane:ethyl acetate 10:1): R_f = 0.88; GC (OV 101): RI = 1553/1600 (*cis*/*trans*); MS (70 eV): *m/z* 57 (100%), 99 (44), 43 (40), 82 (26), 68 (14), 226 (M^+, 5); ^{1}H NMR (500 MHz, C_6D_6): *cis*: δ = 0.78 (t, *J* = 7.4 Hz, 3H), 0.90 (t, *J* = 7.0 Hz, 3H), 1.20–1.40 (m, 16H), 1.38–1.46 (m, 2H), 2.35 (dq, *J* = 7.3, 1.4 Hz, 2H), 3.37 (t, *J* = 6.5 Hz, 2H), 4.45 (dt, *J* = 7.3, 6.3 Hz, 1H), 5.85 (dt, *J* = 6.3, 1.4 Hz, 1H); *trans*: δ = 0.82 (t, *J* = 7.4 Hz, 3H), 0.91 (t, *J* = 7.0 Hz, 3H), 1.20–1.40 (m, 16H), 1.46–1.54 (m, 2H), 1.94 (dq, *J* = 7.3, 1.1 Hz, 2H), 3.40 (t, *J* = 6.5 Hz, 2H), 4.83 (dt, *J* = 12.6, 7.3 Hz, 1H), 6.32 (d, *J* = 12.6 Hz, 1H); ^{13}C NMR (500 MHz, C_6D_6): mixture of *cis* and *trans* isomers (ca. 1:3): δ = 10.4, 10.6, 14.3, 22.9, 23.1, 23.4, 24.6, 28.3, 29.5, 29.7, 29.8, 30.0, 30.0, 30.1, 30.4, 31.4, 32.3, 70.5, 73.5, 103.7, 106.8, 145.5, 147.0. In subsequent reactions a mixture of *cis and trans* isomers was employed.

5: Yield: 86%; TLC (cyclohexane:ethyl acetate 4:1): R_f = 0.47; GC (OV 101): RI = 1943/2013 (*cis*/*trans*); MS (70 eV): *m/z* 159 (100%), 43 (87), 57 (44), 99 (23); ^{1}H NMR (500 MHz, $CDCl_3$): *cis*: δ = 0.88 (t, *J* = 6.7 Hz, 3H), 1.21–1.56 (m, 12H), 2.0–2.06 (m, 2H), 2.07 (s, 3H), 2.09 (s, 3H), 3.84 (dd, *J* = 0.7, 5.3 Hz, 2H), 4.17 (dd, *J* = 6.0, 12.0 Hz, 1H), 4.34 (dd, *J* = 3.9, 12.0 Hz, 1H), 4.40 (dt, *J* = 6.1, 7.4 Hz, 1H), 5.19 (dt, *J* = 5.4, 6.1 Hz, 1H), 5.89 (dt, *J* = 1.4, 6.1 Hz, 1H); *trans*: δ = 0.88 (t, *J* = 6.7 Hz, 3H), 1.21–1.38 (m, 12H), 1.86–1.94 (m, 2H), 2.1 (s, 3H), 2.15 (s, 3H), 3.78 (d, *J* = 5.1 Hz, 2H), 4.18 (dd, *J* = 5.8, 12.0 Hz, 1H), 4.43 (dd, *J* = 3.9, 12.0 Hz, 1H), 4.79 (dt, *J* = 7.3, 12.6 Hz, 1H), 5.20–5.28 (m, 1H), 6.21 (dt, *J* = 2.7, 12.6 Hz, 1H).

6a: Yield (Payne epoxidation of **4** in CH_3OH): 22%; TLC (cyclohexane:ethyl acetate 10:1): R_f = 0.23; GC (OV 101): RI = 1835/1848; as trimethylsilyl (TMS) ether: RI = 1911/1924; MS (70 eV): *m/z* 103 (100%), 61 (94), 57 (32), 43 (32), 71 (20), 215 (4), 243 (2), 256 (0.5); as TMS ether: *m/z* 103 (100%), 61 (93), 73 (21), 43 (16), 243 (3), 257 (2), 287 (1), 314 (0.5).

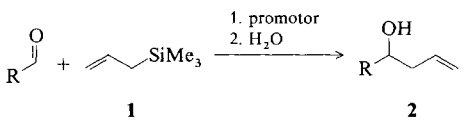
Catalysis of the Addition of Allyltrimethylsilane to Aldehydes by Silylating Agents. $Me_3SiB(OTf)_4$, a New, 'Supersilylating' Reagent**

By *Anthony P. Davis* and Marcel Jaspars*

The addition of allylsilanes such as **1** to aldehydes and ketones (Scheme 1)[1] can be induced by catalytic amounts of fluoride ion, stoichiometric amounts of Lewis acids or (as we ourselves showed recently) catalytic amounts of the superacid $H_2OTf^+B(OTf)_4^-$ (Tf = CF_3SO_2).[2] However, it is generally understood that it is not promoted by silylating agents, such as Me_3SiOTf[3,4] and Me_3SiI.[5–7] In the course

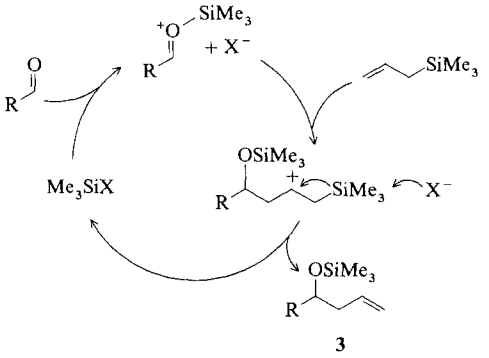


1 **2**

Scheme 1.

of an investigation into the mechanism of the superacid-catalyzed version of the reaction we have re-examined the question of catalysis by 'Me_3SiX', and have made two discoveries which we report herein. The first, perhaps of minor importance, is that Me_3SiOTf and (especially) Me_3SiI are considerably more active than previous reports have suggested. The second, of greater significance, is a new reagent which may fairly be described as a 'supersilylating' agent, is an excellent catalyst for allylations, and promises to have a variety of other applications in organic synthesis.

The results of some experiments involving Me_3SiOTf and Me_3SiI are presented in Entries 1–3 of Table 1. At room temperature and fairly high concentrations, both are capable of catalyzing the addition if given sufficient time. The most reasonable mechanism would appear to be as in Scheme 2; the initial adducts **3** are desilylated during work-up to give homoallyl alcohols **2**. A comparison of entries 2 and 3 in



3

Scheme 2.

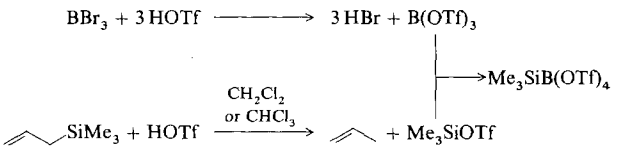
Table 1 indicates that Me_3SiI is considerably more active than Me_3SiOTf, and also gives a cleaner product. However, neither catalyst could be said to be preparatively useful. Yields are at best moderate, due to the formation of substantial amounts of nonpolar by-products.

Table 1. The addition of allyltrimethylsilane **1** to aldehydes RCHO, catalyzed by silylating agents Me_3SiX. [a]

No.	Aldehyde	Promoter [b]	Reaction time	Yield of **2** [%]
1	PhCHO	Me_3SiOTf (20)	21 h	61 [c, d]
2	$Ph(CH_2)_2CHO$	Me_3SiOTf (20)	23 h	27 [c]
3	$Ph(CH_2)_2CHO$	Me_3SiI (20)	45 min	65 [e]
4	PhCHO	$Me_3Si\,B(OTf)_4$ (1)	5 min	80
5	$Ph(CH_2)_2CHO$	$Me_3Si\,B(OTf)_4$ (0.2)	25 min	93 [f]
6	*n*-C_4H_9CHO	$Me_3Si\,B(OTf)_4$ (1)	20 min	80 [g]
7	*c*-$C_6H_{11}CHO$	$Me_3Si\,B(OTf)_4$ (1)	15 min	84

[a] Unless otherwise stated, the reactions were performed in CH_2Cl_2 at room temperature. [RCHO] = 0.5 M, [**1**] = 0.75 M. The initial adduct **3** was desilylated with MeOH/HCl (aq) and purified by flash chromatography. [b] Numerical values in brackets are amounts of the promoter in mol-%. [c] Desilylative work-up with $NaHCO_3$ (aq). [d] This experiment was mentioned briefly in Ref. [2]. [e] Desilylative work-up with $Na_2S_2O_3$ (aq). [f] Preparative scale experiment (see *Experimental*). [g] Desilylation with ether/HCl (aq) was only partially successful. Yield refers to a ca. 4:1 mixture of **2** and **3**.

In the reactions 4–7 in Table 1 the new 'supersilylating' reagent $Me_3SiB(OTf)_4$ was employed. It can be prepared as a solution in dichloromethane or chloroform simply by adding a solution of Me_3SiOTf to a freshly-prepared sample of $B(OTf)_3$[10] (Scheme 3). An exothermic reaction occurs, leading to a homogeneous, pale yellow solution.[11] The ^{11}B NMR spectrum (CH_2Cl_2, standard $BF_3{\cdot}OEt_2$) of one such solution showed a single resonance at $\delta = -3.17$ ($W_{1/2}$ = 28 Hz). Both the chemical shift and narrow line width are as expected for the 'spherically symmetrical' anion $B(OTf)_4^-$.[12]



Scheme 3.

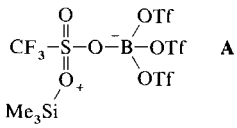
[**] This work was supported in part by the Science programme of the European Community. We are grateful to Dr. M. G. Orchard for helpful discussions.

The ^1H NMR spectrum (CD_2Cl_2, standard CH_2Cl_2) contained a single peak at $\delta = 0.58$ and the ^{13}C NMR spectrum (CH_2Cl_2, standard CH_2Cl_2) a single peak for *C*-Si at $\delta = 0.0$ ($^1J_{C,Si} = 54$ Hz) and a quartet for *C*-F at $\delta = 118$ ($^1J_{C,F} = 318$ Hz). The precise structure of the species in these solutions is still uncertain. Two possibilities (representing extremes of a continuum) are (a) an ion pair Me_3Si^+ $B(OTf)_4^-$ [13] and (b) a covalent structure **A** in which the Me_3Si group is exchanging rapidly between the sulfonyl oxygens (to maintain the apparent symmetry in the $B(OTf)_4$ unit). At present we are inclined to prefer the latter because of the unexceptional nature of the ^1H and ^{13}C NMR data.[14]



A

Irrespective of its structure, the relevant entries in Table 1 clearly suggest that $Me_3SiB(OTf)_4$ is a very powerful source of electrophilic silyl units. At room temperature it is able to catalyze the addition of allyltrimethylsilane to a variety of simple aldehydes with remarkable efficiency. The reactions are relatively clean, resulting in only trace amounts of the nonpolar by-products referred to above. Particular attention is drawn to the preparative-scale reaction (Entry 5 and *Experimental Procedure*) in which a 93% yield of product was obtained using only 0.2 mol % of catalyst. Despite its reactivity, this reagent is not especially difficult to handle. The dichloromethane solutions may be stored at $-10\,^\circ C$ under argon for several weeks without loss of activity. Considering the many applications which have been found for Me_3SiOTf[15] and Me_3SiI,[16] there is a high probability that $Me_3SiB(OTf)_4$ will prove to be a valuable addition to the synthetic chemists' armory.

Finally, as mentioned above, the original motivation for this work was our curiosity concerning the mechanism of our earlier variant of the addition of allylsilanes to aldehydes, catalyzed by the superacid H_2OTf^+ $B(OTf)_4^-$. Although it is still possible that our first proposal (catalysis by 'H^{++}')[2] is correct, the present work suggests a plausible alternative involving the reaction of the superacid with allyltrimethylsilane to form a supersilylating species within the reaction mixture.

Experimental Procedure

Me_3Si $B(OTf)_4$: Trifluoromethanesulfonic acid (531 μL, 6 mmol) was added to boron tribromide (distilled from Al powder; 190 μL, 2 mmol) at 0 °C. After evolution of HBr had ceased the flask was evacuated for 1 h to give $B(OTf)_3$ as a viscous yellow liquid [10]. In a separate flask, a solution of Me_3SiOTf was prepared by addition of trifluoromethanesulfonic acid (177 μL, 2 mmol) to a solution of allyltrimethylsilane (320 μL, 2 mmol) in CH_2Cl_2 (5 mL)[17], and leaving the resulting mixture to stand for ten minutes. Addition of this solution to the $B(OTf)_3$ at 0 °C resulted in the evolution of heat and formation of a pale yellow solution believed to contain Me_3Si $B(OTf)_4$ (for data, see text).

2: R = $Ph(CH_2)_2$: The above solution of Me_3Si $B(OTf)_4$ in CH_2Cl_2 (0.4 M, 25 μL, 0.01 mmol) was added to a solution of 3-phenylpropanal (665 μL, 5 mmol) and allyltrimethylsilane (112 mL, 7 mmol) in CH_2Cl_2 (10 mL). Analysis by TLC indicated that the aldehyde had been consumed after 25 min. MeOH (1 mL) and hydrochloric acid (36%, 12 drops) were added. Analysis by TLC indicated the desilylation to be complete in 40 min. The mixture was washed with $NaHCO_3$ aq. and extracted with CH_2Cl_2, and the extract was washed with NaCl aq. and dried ($MgSO_4$). Evaporation of the solvent followed by flash chromatography gave 1-phenyl-5-hexen-3-ol (824 mg, 93%) [D. Seebach, R. Imwinkelried, G. Stucky, *Helv. Chim. Acta* **1984**, *70*, 448], ^1H NMR (300 MHz, $CDCl_3$): $\delta = 1.70-2.05$ (m, 3H; O*H* + PhCH_2), 2.10–2.37 (m, 2H; CH_2CHOH), 2.62–2.87 (m, 2H; CH_2CH = CH_2), 3.60–3.72 (m, 1H; *H*COH) 5.05–5.20 (m, 2H; CH = CH_2), 5.70–5.95 (m, 1H; C*H* = CH_2), 7.08–7.29 (m, 5H; Ph). 36 mg of a less polar by-product was also isolated.

[6] References [3–5] make specific mention of failed attempts to catalyze the addition using the relevant silylating agents. These attempts are contrasted with other reactions which proceed more readily, such as that between allylsilanes and acetals.
[7] Silylating agents have been shown to be active in catalyzing the reactions of more nucleophilic species with aldehydes. For example, both Me_3SiOTf [8] and the combination $Me_3SiCl/SnCl_2$ [9] have been reported to catalyze the addition of silyl enol ethers to conjugated aldehydes, although in the former case only low conversions were achieved.

The Electronic Structure of $[(\eta^5\text{-}C_5H_5)_2Co_2]$: Comment on the Existence of a Complex with an Unsupported Co–Co Double Bond

By *Harmon B. Abrahamson, Gerald P. Niccolai, D. Michael Heinekey, Charles P. Casey,* and *Bruce E. Bursten**

Schneider et al. have recently reported the synthesis of a dinuclear cobalt complex **1**, formulated as $[Cp_2^*Co_2]$ ($Cp^* = \eta^5\text{-}C_5Me_5$), by the cocondensation of Co atoms and

Cp*H in a metal-atom reactor.[1] Crystallographic characterization of compound **1** indicates a very short (2.253 Å) Co–Co distance, which the authors state is consistent with the presence of an unsupported Co–Co double bond. This report of an unsupported Co–Co double bond almost coincides with the reports of two very different organodirhenium complexes, one that contains an unsupported d^2–d^2 double bond[2] and one that has a d^6–d^6 double bond supported only by two semibridging carbonyl ligands.[3]

If it is correctly formulated, **1** is the first compound to contain a "naked" Co–Co double bond. The high symmetry and paramagnetism of **1** also stimulated our interest in the metal–metal bonding in this complex, as we have previously rationalized the paramagnetism of a supported Fe–Fe double bond in a highly symmetrical environment.[4] We therefore report here nonempirical Fenske–Hall molecular orbital investigations of the bonding in the model complex $[Cp_2Co_2]$ (**2**; $Cp = \eta^5$-C_5H_5) and in the related hypothetical hydride complexes $[(CpCo)_2(\mu\text{-}H)_n]$ (**3**: $n = 1$; **4**: $n = 2$; **5**: $n = 3$; **6**: $n = 4$).[5] We believe that the results we present for **2**, when taken with the available physical and chemical data for **1**, mandate a closer examination of whether **1** truly possesses an unsupported Co–Co bond.

As shown in Figure 1 (left), the Cp–Co fragment exhibits the familiar "three-below-two" splitting pattern of the predominantly Co 3d orbitals.[6] With respect to bond formation along the fivefold axis of the Cp–Co fragment, the 3dσ orbital is part of the lower set of orbitals, while the doubly degenerate 3dπ orbitals form the upper set. Figure 1 (center) shows the result of interacting two Cp–Co fragments to form the MO's of **2**. The resultant orbital ordering is essentially the same as that derived by Lichtenberger et al. in their discussion of the bonding in $[(CpM)_2(\mu\text{-}L)_2]$ complexes,[7] and by us in our earlier study of $[(CpRu)_2(\mu\text{-}OMe)_2]$.[8] Even at the short Co–Co bond distance observed in **1**, the splitting induced by the Cp–Co interaction dominates that induced by Co–Co bond formation. As a result, the Co–Co σ* antibonding MO is lower in energy than the doubly degenerate Co–Co π bonding MO's, which are the highest occupied MO's in **2**. If we neglect the small contributions of the Co 4s orbitals to the σ* orbital, there is no net Co–Co σ bond in **2**; the molecule does indeed contain a Co–Co double bond, but both components of this bond have π symmetry.

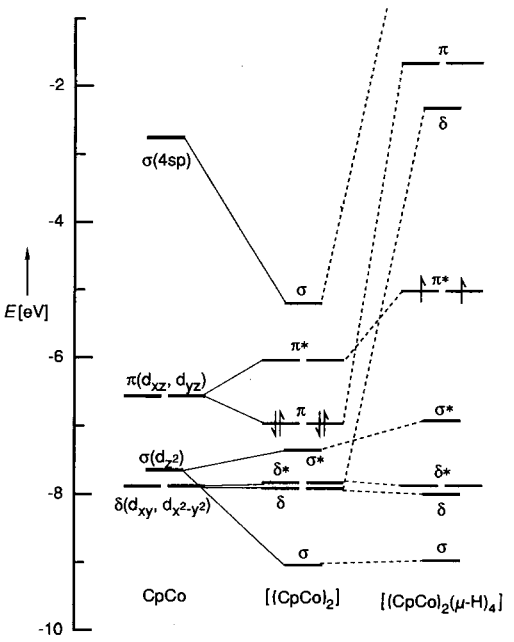

Fig. 1. Co 3d-based molecular orbitals of the Cp–Co fragment, their combination to form the molecular orbitals of $[Cp_2Co_2]$, and the correlation of these orbitals to those of $[Cp_2Co_2(\mu\text{-}H)_4]$.

This description of the bonding in the cyclopentadienyl dimer **2** causes us to question whether the pentomethylcyclopentadienyl dimer **1** has been formulated correctly. First, **1** has an exceptionally short Co–Co bond, yet it seems unlikely that the bond would be so short in the absence of a σ component. Second, ^{1}H NMR spectroscopy reveals a large paramagnetic shift for the Cp* methyl groups of **1** ($\delta = 61.3$ at 30 °C in $[D_8]$toluene).[1] A linear dependence between the paramagnetic shift and $1/T$ suggests that **1** has a high-spin ground state. By contrast, our calculations on **2** are consistent with a singlet ground state, although we observe a rather small (ca. 0.9 eV) splitting between the π HOMO's and the π* LUMO's of **2**. Thus, the lowest lying triplet state could be close enough in energy to the calculated singlet state to allow significant thermal population of the triplet state;[9] however, thermal population of a ππ* triplet state would significantly weaken the Co–Co bond, which is again inconsistent with the observed bond length in **1**. Third, **1** is apparently unreactive toward ethylene and CO,[1] which strikes us, and others,[10] as inconsistent with its electronic structure. The π orbitals of **2** are relatively high in energy for an occupied orbital, whereas the π* orbitals are rather low-lying unoccupied orbitals. Because the Co–Co bond is unsupported, both these sets of frontier orbitals should be spatially accessible to small reactant molecules. Thus, we would expect **1** to be quite reactive toward both electrophiles and nucleophiles. We are particularly surprised that **1** does not react with CO to form the well-known $[(Cp^*Co)_2(\mu\text{-}CO)_2]$ dimer (**7**)[11] or monomeric $[Cp^*Co(CO)_2]$,[12] which can be formed by the reaction of **7** with CO. The Co–Co distance in **7** (2.33–2.34 Å)[11] is consistent with a formal Co–Co double bond; that the bond length in **7** is so similar to that in **1** seems to indicate that CO addition to the unsupported Co–Co double bond would not significantly disrupt the metal–metal bonding. We also note that compound **1** was isolated by chromatography on Al_2O_3 that contained 5% H_2O.[1] That the molecule is unaffected by these manipulations is quite remarkable.

If the compound **1** prepared by Schneider et al. is not $[Cp^*_2Co_2]$, then what could it be? Because the authors have determined the crystal structure of **1**, it seems unlikely that additional second-row or heavier atoms are present. In the crystallographic details the authors point out that there is residual electron density (2.5 e Å^{-3}) located 1.8 Å from each Co atom on the crystallographic twofold axis, which bisects the Co–Co bond. Inasmuch as the magnitude of this electron density is not inconsistent with the presence of a bridging hydride ligand, and the characterization of **1** does not exclude this possibility,[13] we believe that one or more μ-H ligands may be present in the compound. To this end, we have also performed MO calculations on compounds **3**–**6**. Compounds **3** and **5** are formally mixed-valent complexes that are necessarily paramagnetic due to the presence of an odd number of electrons. However, it seems unlikely that the CpCo=CoCp fragment of the monohydride **3** would possess axial symmetry. Compound **4** would be the dihydride analogue of the Co(II) dimers $[(Cp^*Co)_2(\mu\text{-}X)(\mu\text{-}Y)]$ (**8**) prepared by Koelle et al.[14]

Compounds **8** exhibit longer Co–Co bonds than that observed for **1** (for example, Co–Co = 2.49 Å for X = Cl, Y = NMe_2) and are described as paramagnetic complexes with strong antiferromagnetic coupling. Our calculations on

4 indicate a HOMO–LUMO separation of 1.25 eV (slightly larger than that in **2**), so that at the short Co–Co separation a singlet ground state seems more likely than a triplet ground state. In **6**, the four hydride ligands interact strongly with one of the Co–Co δ and both Co–Co π orbitals, leading to significant destabilization of these metal-based orbitals, much as we saw for $[CpReH)_2(\mu\text{-}H)_4]$.[15] As a result of these interactions, the HOMO's of **6** are the half-filled, doubly degenerate Co–Co π* orbitals [Figure 1 (right)], and the molecule is expected to possess a triplet ground state.

Complex **6** has strong precedent in the literature. An analogous Group 8 complex, $[(Cp^*Ru)_2(\mu\text{-}H)_4]$ (**9**), which has two fewer valence electrons than **6** and is diamagnetic, possesses a Ru–Ru bond length of 2.463 Å consistent with its formulation as a hydride-supported metal–metal triple bond.[16] In addition, we have recently demonstrated that $[Cp^*_2Re_2(CO)_4]$ (**10**), which contains a Re–Re double bond supported by two semibridging carbonyls, reacts with H_2 at −80 °C to yield $[Cp^*_2Re_2(CO)_4(\mu\text{-}H)_2]$.[3] Compound **10** is more sterically congested than $[Cp^*_2Co_2]$, suggesting that the latter would also undergo facile addition of hydrogen (an expected by-product of the reaction of Co atoms with Cp*H) to the Co–Co bond.

In summary, we believe that the electronic structure of **2** together with the reactivity exhibited by **1** casts some doubt on whether the latter is truly $[Cp^*_2Co_2]$, and feel that there may be additional hydride ligands present in the observed structure. The presence of one, three, or four bridging hydride ligands could explain the observed magnetic behavior of **1**, and compounds with such supporting ligands would be less reactive than one containing an unsupported Co–Co double bond. We are currently undertaking higher level electronic structure calculations on compounds **2**–**6**, and we hope these comments stimulate further experimental studies of compound **1**.

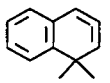
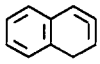
1,2,4-Cyclohexatriene, an Isobenzene, and Bicyclo[4.4.0]deca-1,3,5,7,8-pentaene, an Isonaphthalene: Generation and Trapping Reactions**

By *Manfred Christl*,* *Martin Braun*, and *Germar Müller*

After Miller and Shi[1] had generated the isomer **1** of dimethylnaphthalene by β elimination of HBr and had trapped it with potassium *tert*-butoxide as well as diphenylisobenzofuran, we asked ourselves whether the isonaphthalene **2** and the isobenzene **3** could also be prepared and subjected to trapping reactions. Two further isobenzenes, namely 1,2,3-cyclohexatriene and cyclohex-1-en-3-yne, were recently generated and intercepted.[2]



1



2

3

In connection with our work[3] concerning 1,2-cyclohexadiene and its derivatives,[4] we wanted to liberate **2** and **3** using the Doering–Moore–Skattebøl method. At first, the dibromocyclopropanes **13** and **14** were considered as unsuitable starting materials, since the addition of dibromocarbene, generated from bromoform and a base, to indene and cyclopentadiene only yields 2-bromonaphthalene[5] and bromobenzene, respectively, because of the rapid rearrangement of **13** and **14**.

Therefore, as previously for a precursor of 1-oxacyclohexa-2,3-diene,[6] we used the high energy of the C–F bond and added bromofluorocarbene ($CHBr_2F$, 50% NaOH, $PhCH_2NEt_3Cl$, CH_2Cl_2, ice bath) to indene and cyclopentadiene. We obtained **6**[7, 8] and **10**[7] in 16 and 20% yields,

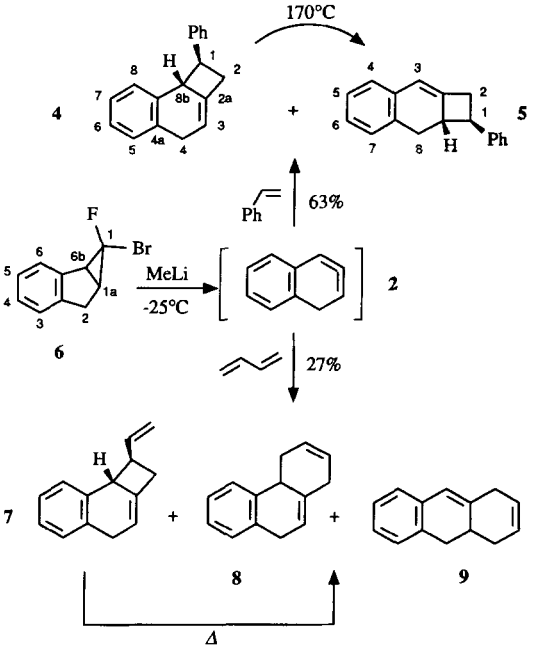
[**] Cycloallenes, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. L. Skattebøl, Oslo, for valuable suggestions and Prof. Dr. R. Janoschek, Graz, for the theoretical study of the isobenzene **3** (see following communication [11]).—Part 7: H. Jelinek-Fink, M. Christl, E.-M. Peters, K. Peters, H. G. von Schnering, *Chem. Ber.* **1991**, *124*, 2569-2575.

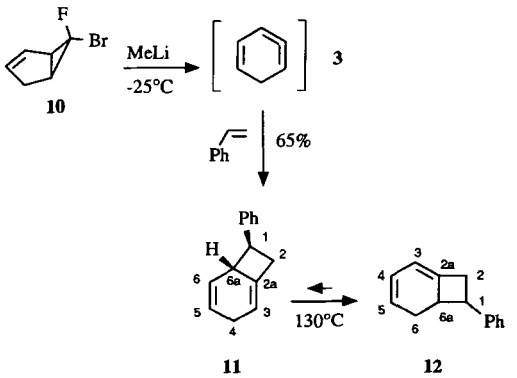
respectively. Only upon heating, the compounds **6** (130 °C, 3.5 h) and **10** (70 °C, 2 h) decompose to give 2-bromonaphthalene and bromobenzene, respectively.

As hoped, methyllithium causes the Br–Li exchange in **6** and **10**, followed by the loss of LiF. This leads, with ring expansion, to the cyclic allenes **2** and **3**, respectively, as the products of trapping reactions suggest.

Thus, a 14:1 mixture of the [2+2]cycloadducts **4**[7] and **5**[7] of the isonaphthalene **2** was formed by the reaction of **6** in styrene with MeLi in ether at −25 °C in 63% yield. Analogous products were obtained with α-methylstyrene. The use of butadiene as the trapping reagent afforded a 4:2:1 mixture of the [2+2]cycloadduct **7**,[7] and the [4+2]cycloadducts **8**[7] and **9**[7] in 27% yield. In the case of 2,3-dimethylbutadiene, the amount of the [2+2]cycloadduct was significantly larger than that of the [4+2]cycloadducts.

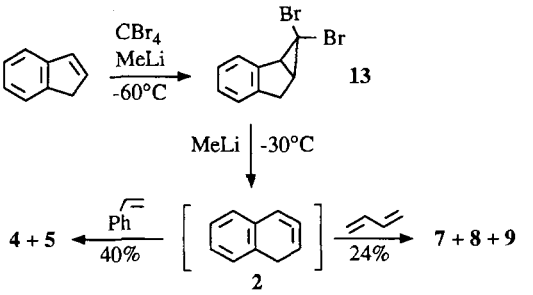


If **10** is allowed to react with MeLi in the presence of styrene, then the [2+2]cycloadduct **11**[7] of **3** and probably its diastereomer are obtained as a 19:1 mixture in 65% yield. The trapping reaction of **3** with α-methylstyrene proceeded analogously.

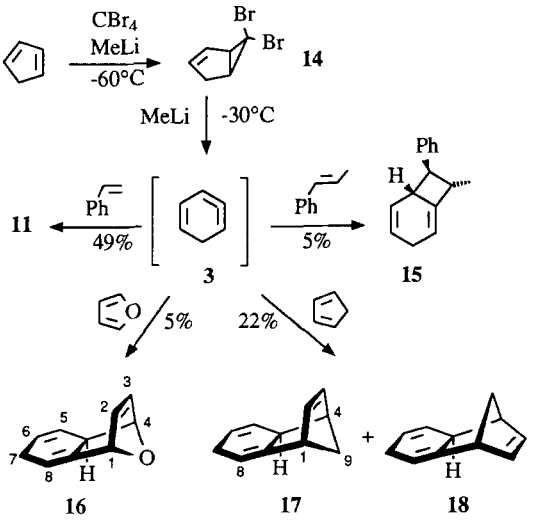


We then investigated whether the dibromocarbene adducts of indene and cyclopentadiene, namely **13** and **14**, respectively, were also stable enough for preparative purposes. Produced from indene and cyclopentadiene, respectively, and tetrabromomethane in ether with MeLi[9] at −60 °C, they are actually stable in solution up to 0 °C as proved by the ^{1}H NMR spectra. We have used these findings to synthesize the cycloadducts of **2** and **3** in one-pot reactions.

Treatment of **13**, prepared at −60 °C, with MeLi in the presence of styrene at −30 °C furnishes the same mixture of **4** and **5** as from the use of **6**. With butadiene instead of styrene, **7**–**9** were again formed. The yields based on indene were, with 40 and 24%, respectively, considerably higher than from the method via **6** (10 to 4%, respectively).

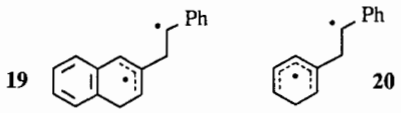


The cycloadducts **11** (49% compared with 13% via **10**), **17**[7] (14%) and **18**[7] (8%), **15**[7] (5%), and **16**[7] (5%), were formed analogously from cyclopentadiene, tetrabromomethane, MeLi, and the trapping reagents styrene and cyclopentadiene (see *Experimental Procedure*) as well as (*E*)-β-methylstyrene and furan, respectively. The 1,4-cyclohexadiene subunits of these compounds and their configurations are proved unequivocally by NMR spectroscopy (cf. Table 1).



Noteworthy are the reactivities of the different allene π bonds in **2** and **3**. The [4+2]cycloaddition of **2** with butadiene appears to lead, with little selectivity, to a 2:1 mixture of the tetrahydrophenanthrene **8** and the tetrahydroanthracene **9**. Due to the readily occurring thermal rearrangement of the [2+2]cycloadduct **7**, formed at the same time, into **8** and **9** in the ratio 2:1, this result must be confirmed by further investigations. The exclusive participation of the conjugated allene π bond in the [4+2]cycloadditions of **3** results in the

formation of **16**–**18**. We explain this by the more favorable frontier orbital energies in comparison to those of the nonconjugated allene π bond. This is based on the assumption of a one-step mechanism in the sense of the Diels–Alder reaction. In the [2+2]cycloadditions those allene π bonds react which are conjugated with the benzene unit in **2** and the ethylene unit in **3**, respectively. On the basis of previous results,[10] we assume that two-step processes occur with diradical intermediates such as **19** and **20** when styrene is used as the trapping reagent. Apparently, the ring closures of **19** and **20** yield **4** and **11**, respectively, with high selectivity under kinetic control. These are thermodynamically less stable than their conjugated isomers **5** and **12**, respectively.



19 **20**

The latter is supported by the thermolyses of **4** and **11**, which lead mainly to **5** (81%)[7] and a 1:3 mixture (64%) of **11** and **12**,[7] respectively. Here, the diradicals **19** and **20** should again be intermediates, because the ring closures **19** → **4** and **20** → **11** are probably reversible above 100 °C. The preferred pathways of **19** and **20** to the nonconjugated products **4** and **11**, respectively, are attributed to the absolute spin density maximum in the benzyl position of the allyl radical moiety of **19**, and in the center of the pentadienyl radical part of **20**, respectively. In the case of **20**, this is the result of a theoretical study, which also describes the nature of the isobenzene **3** (see following communication[11]).

Table 1. Selected physical data of **4**–**18**; ^{1}H NMR (200 or 400 MHz) and ^{13}C NMR (50 or 100 MHz) spectra measured in $CDCl_3$ if not stated otherwise.

4: Mp = 45–47 °C. ^{1}H NMR (C_6D_6): δ = 2.87 (m, 2H; H2), 3.09 (ddd, J(4,4) = 18.8, J(3,4) = 6.3, J(4,8b) = 2.3 Hz, 1H; H4), 3.25 (dm, J(3,4) = 2.9 Hz, 1H; H4), 3.27 (q, mean J(1,2) = J(1,8b) = 8.3 Hz; H1), 3.95 (m; H8b), 5.58 (ddq, mean J(2,3) = J(3,8b) = 1.9 Hz; H3), 6.90–7.90 (m, 9H; H-arene); ^{13}C NMR: δ = 30.6 (t; C4), 38.1 (t; C2), 46.9, 51.7 (each d; C1,8b), 113.7 (d; C3), 125.4, 126.0, 126.1, 126.4, 128.2 (each d; C5,6,7,8, *p*-C), 126.9 (d; *o*-C), 128.6 (d; *m*-C), 136.4, 139.1, 139.4 (each s; C2a,4a,8a), 144.2 (s; *ipso*-C)

[a] The assignment is based on decoupling and NOE experiments.

Experimental Procedure

11: To a stirred solution of 1,3-cyclopentadiene (2.25 g, 34.0 mmol) and tetrabromomethane (11.3 g, 34.1 mmol) in ether (50 mL), MeLi (34.0 mmol, 34 mL, 1.0 M in ether) was added dropwise at −60 °C under N_2 during 1 h. Then the mixture was warmed to −30 °C, and styrene (20 g, 192 mmol) was added. A further 34.0 mmol of MeLi was then added dropwise over 30 min. The mixture was stirred continually and allowed to warm to 0 °C over a 4 h period. Then water (30 mL) was added and the phases were separated. The aqueous phase was extracted with ether (3 × 30 mL). The combined ether layers were dried with Na_2SO_4, concentrated at 20 °C/20 torr, and the excess styrene was distilled off at 20 °C/0.1 torr. From the residue, colorless **11** (3.04 g, 49%) was distilled at 100 °C (kugelrohr)/0.1 torr, which probably contained ca. 5% of its diastereomer.

17 and **18**: As described above, to a solution of 1,3-cyclopentadiene (8.0 g, 121 mmol) and tetrabromomethane (4.14 g, 12.5 mmol) in ether (10 mL), MeLi (13.1 mmol and 14.6 mmol) was added at −60 and −30 °C, respectively. The final distillation at 60 °C (kugelrohr)/0.1 torr yielded a yellowish liquid (1.56 g). Purification by flash chromatography (SiO_2, pentane) afforded firstly dicyclopentadiene, then **18** (145 mg, 8%), and finally 307 mg of a 5.7:1.0 mixture of **17** (14%) and benzonorbornadiene (2%). Pure **17** was obtained by preparative gas chromatography (column length: 1.5 m, 20% ethylene glycol adipate (EGA) on Volaspher®, 100 °C). A mixture of **17** and **18** was dehydrogenated with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) which yielded benzonorbornadiene (38%).

1,2,4-Cyclohexatriene, an Isobenzene, and its [2+2] Cycloaddition with Styrene: A Theoretical Study**

By *Rudolf Janoschek**

Only a fraction of the 217 constitutional isomers with the general formula C_6H_6 are known. In the preceding communication Christl et al. describe their successful generation of the isobenzene 1,2,4-cyclohexatriene (**1**), which was proven by subsequent trapping reactions.[1] The identification of this interesting compound raises a number of questions. Where does isobenzene fit into the series of C_6H_6 isomers with regard to its heat of formation? What is its equilibrium geometry? Is this a chiral compound, and if so, how high is the barrier to racemization? What evidence is there for a possible diradical character of **1**? Questions arise concerning the chemoselectivity in its [2+2] cycloaddition with styrene. The amount of information in the respective answers can be increased by the comparison of this isobenzene with related known compounds, primarily with 1,2-cyclohexadiene (**2**) which has been investigated experimentally[2] and theoretically.[3]

Mozartgasse 14, A-8010 Graz (Austria)

[**] I wish to thank Prof. M. Christl, Würzburg for his initiative which sparked this work.

To answer these questions we employed the semiempirical AM1 method.[4] This computational method provides especially reliable results for hydrocarbons; another advantage is the speed with which answers for our list of complicated questions may be obtained. The calculations were conducted with the MOPAC6 program[5] on a STARDENT computer.[6] The bent and twisted allene fragments in **1** and **2** give rise to diradical character which requires a multiconfigurational wave function for its correct description.[7] The calculations were thus carried out with the configuration interaction (CI) formalism, in which all electronic configurations arising from the distribution of two electrons in two orbitals are taken into account. The restricted Hartree–Fock (RHF) open-shell orbitals served in the construction of the configurations. On the energy hypersurfaces numerous stationary points, discussed later in this communication, were characterized either as minima or saddle points (transition structures) by their complete sets of harmonic vibrational frequencies.

The calculated heat of formation of **1**, 93.7 kcal mol^{-1}, is considerably higher than that of benzene (22.0 kcal mol^{-1}). This increase in energy relative to benzene can be understood as arising from three contributions: loss of the stabilization of benzene, ring strain (bent allene), and rehybridization of the C6 center ($sp^2 \rightarrow sp^3$). The heat of formation of **1** correlates well with the values of the known C_6H_6 isomers like fulvene (62.6 kcal mol^{-1}) and Dewar benzene (116.7 kcal mol^{-1}).

A "planar or chiral allene fragment" are the two possible structural alternatives for **1**. Significant calculated structural data are listed in Table 1. The local energy minimum corresponds to a chiral structure with C_1 symmetry. The dihedral angles H-C1-C2-C3 and H-C3-C2-C1 with an average value of $-161°$ are characteristic ($-180°$ corresponds to a planar orientation). The C1-C2-C3 angle of 132.4° is indicative of considerable ring strain. Optical activity for the calculated chiral structure of **1** can be expected only if the energy barrier (activation enthalpy) to racemization is high enough. The corresponding transition structure has C_s symmetry and is only 2 kcal mol^{-1} higher in energy than the C_1 minimum (Fig. 1). The resulting high rate of racemization rules out the observation of optical activity. Isobenzene can thus be designated as dynamically chiral.

Table 1. Structural data for **1** and **2** (bond lengths in Å, angles in degrees), for the energy minima (C_1 and C_2), and for the transition structures (C_s) of the racemizations.

	1		**2**	
	C_1	C_s	C_2	C_s
C1-C2	1.334	1.335	1.329	1.347
C2-C3	1.348	1.377	1.329	1.347
C3-C4	1.456	1.424	1.497	1.488
C4-C5	1.354	1.364	1.538	1.526
C5-C6	1.502	1.486	1.538	1.526
C1-C6	1.493	1.488	1.497	1.488
C1-C2-C3	132.4	131.9	133.7	133.3
H-C1-C2-C3	−159.0	180.0	−154.3	−178.5
H-C3-C2-C1	−163.1	180.0	−154.3	178.5
C5-C4-C3-C2	−23.8	0.0	−29.8	−21.9
C4-C3-C2-C1	12.1	0.0	21.2	0.2

The predictive value of the calculated properties of the new compound **1** can be understood better if the related known 1,2-cyclohexadiene (**2**) is referred to. Significant structural data for both **1** and **2** are provided in Table 1. In the minimum energy structure of **2** (C_2 symmetry) the expanded dihedral angle H-C1-C2-C3 ($-154°$) relative to that

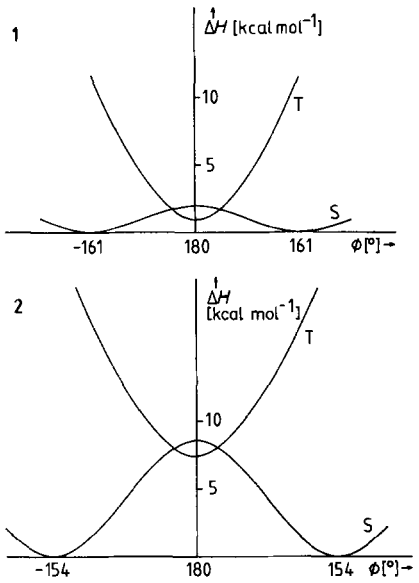

Fig. 1. Enthalpy profile for the racemizations of **1** and **2** over the dihedral angle ϕ = H-C1-C2-C3 = H-C3-C2-C1. These two angles are slightly different in **1** due to its C_1 symmetry (see Table 1); S: singlet, T: triplet.

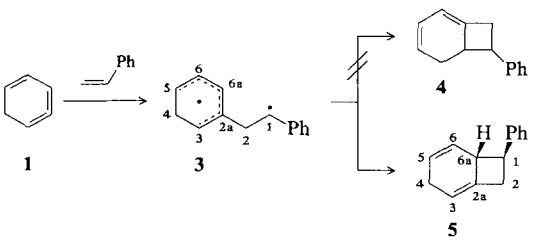
of **1** is an indication of the higher activation energy for racemization via the C_s transition structure, which with a value of 8.7 kcal mol^{-1} is actually the case. This value is in good agreement with the results of earlier calculations with semiempirical (MNDO-CI, 5.7 kcal mol^{-1}) as well as ab initio methods (MCSCF/3-21G level, 12.1 kcal mol^{-1}; the value given in ref.[3], 13.1 kcal mol^{-1}, was treated with a subsequent zero-point vibration correction). The calculations were supported by experimental evidence: When the generation of **2** and the trapping reaction were carried out at 80 °C, optical activity was lost.[8]

The expected diradical character of bent and almost planar allene fragments is apparent from the relative position of the triplet state. According to Figure 1 the diradical character of the transition structures of **1** and **2** is uncontested, since the triplet state lies about 1 kcal mol^{-1} lower than the singlet state in each case; in both molecules examined the triplet minima and the singlet transition structures have almost identical geometries. The vertical difference in energies between the triplet state and the singlet minima is also low, 11.6 kcal mol^{-1} for **1** and 23.8 kcal mol^{-1} for **2**.

Compound **2** was identified by IR spectroscopy on the basis of the intense asymmetric C=C stretching band of the allene fragment at 1886 cm^{-1}.[9] The calculations described here predict bands of high relative intensity at 1822 cm^{-1} for **1** and 1817 cm^{-1} for **2**.



Scheme 1. The [2+2] cycloaddition of isobenzene **1** with styrene via the reactive intermediate **3**. For comparative purposes the numbering scheme for **3** and **5** is the same.

In the context of a discussion of the reactivity of **1** in a [2+2] cycloaddition with styrene the following questions arise: Is there a diradical reactive intermediate **3**? Why is compound **5** formed in this reaction even though adduct **4** with conjugated double bonds is 1.8 kcal mol^{-1} lower in energy? A minimum could be localized for diradical **3**, in which a pentadienyl radical unit is evident in the six-membered ring as vouched for by the structural data in Table 2.

Table 2. Structural data for diradical **3** and adduct **5** (bond lengths in Å, angles in degrees).

	3	**5**
C2a-C6a	1.418	1.523
C2a-C3	1.367	1.328
C3-C4	1.478	1.495
C4-C5	1.478	1.495
C5-C6	1.363	1.342
C6-C6a	1.407	1.480
C2-C2a	1.492	1.500
C1-C2	1.471	1.569
C1-*ipso*-C-phenyl	1.408	1.478
C1-C6a	3.119	1.561
C1-C3	3.491	3.413
C1-C2-C2a-C6a	67.2	10.0
C5-C6-C6a-C2a	−0.1	31.5

A pentadienyl radical unit can be recognized by the nonequivalent bond lengths C2a–C6a and C2a–C3 as well as bonds of almost the same length, C2a–C6a, C6–C6a and C2a–C3, C5–C6. A delocalized description of the single electron in the six-membered ring in the sense of **3** is thus justified. The spin density is maximal on the C6a center, an analogous situation to that in the free pentadienyl radical. Furthermore, the C1-C2-C2a-C6a dihedral angle is markedly less than 90°, which causes the C1–C6a distance to be less than that of C1–C3. Thus the ring closure to **5** is sketched out in the reactive intermediate **3**. Structural data for adduct **5** are provided in Table 2. Both rings in **5** are puckered.

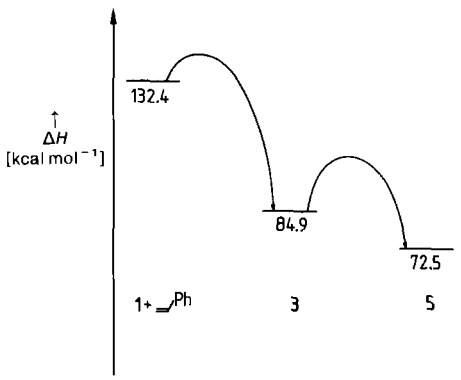


Fig. 2. The enthalpy diagram for the [2+2] cycloaddition reaction of **1** with styrene.

Finally the enthalpy diagram for the [2+2] cycloaddition reaction is sketched in Figure 2.

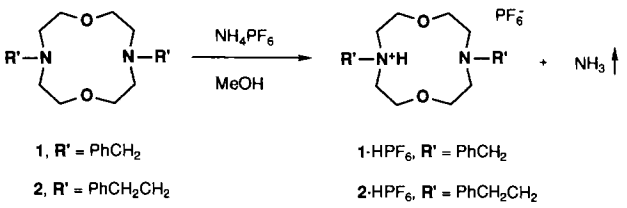
Designing Synthetic Cationic Molecular Receptors for Alcohols**

By *Luis Méndez, Raymond Singleton, Alexandra M. Z. Slawin, J. Fraser Stoddart,* David J. Williams,* and *M. Kevin Williams*

In the early days of supramolecular chemistry, the complexation[1] of cationic guests in apolar solvents was achieved largely using neutral hosts. In these instances, strong host–guest associations are a consequence of the electrostatic interactions between the charged guest and the dipoles centered on the heteroatoms within the host. The design of hosts that bind neutral guests successfully has proven to be much more taxing both intellectually and in practice. The principal intermolecular interactions that have been exploited in the complexation[2] of neutral guests by neutral hosts have been hydrogen bonding, π–π stacking interactions, and the hydrophobic effect. In most instances, the host–guest binding has relied upon the simultaneous and cooperative action of several such noncovalent bonding interactions.[3] Guests such as phenols,[4] ureas,[5] barbiturates,[6] and nucleotides[7] have been complexed strongly by sophisticated hosts by means of a combination of hydrogen bonds and/or π–π stacking interactions.

Monohydric alcohols of low molecular weight are particularly difficult to bind selectively with synthetic hosts because a) they possess only a single hydroxyl group, and b) they are soluble in a wide range of solvents. Although there have been a number of reports[8] of selective clathration and inclusion of short-chain alcohols in the solid state, no strong complexation of these relatively featureless substrates has been achieved[9] in solution. Recently, we described[10] the discovery of the complexation of MeOH by monoprotonated, disubstituted 1,7-diaza-12-crown-4 receptor units. Here, we report a) the preparation of some disubstituted 1,7-diaza-4,10-dioxacyclododecanes, b) the quantitative evaluation of their monoprotonated derivatives as hosts for binding short-chain alcohols in solution, and c) the solid-state structures[11] of both the free and complexed hosts.

Compounds **1** and **2** were prepared by reaction of 1,7-diaza-4,10-dioxacyclododecane[12] with benzyl bromide and 2-phenylethyl bromide, respectively, and protonated with one molar equivalent of NH_4PF_6 in MeOH. The formation of **1** · HPF_6 and **2** · HPF_6 is accompanied by the release of NH_3. These salts are highly soluble in CD_2Cl_2, a property which we exploited in ^{1}H NMR spectroscopic studies, in which their complexing ability towards MeOH, EtOH, *n*-PrOH, and *n*-BuOH, and—in some cases—the fully deuterated derivatives was quantitatively evaluated.



Interestingly, the signals for the OCH_2 protons in **1** · HPF_6 and **2** · HPF_6 are influenced most[13] on complexation with alcohols. The chemical shift dependence of the OCH_2 protons in **1** · HPF_6 and **2** · HPF_6 on the addition of these alcohols formed the basis for the titration method employed to establish 1:1 stoichiometries for the complexes, and used to provide data for a quantitative assessment of complexation strengths (Table 1). The 1:1 stoichiometry of the complex formed between **1** · HPF_6 and [D_4]MeOH was confirmed by the method of continous variations (Fig. 1).[14] The determinations of the association constants K_a were carried out by linearization (according to the Higuchi method[14, 15]) of the binding isotherm obtained from the ^{1}H NMR titrations. The importance of monoprotonation of the receptor is evident from a comparison of the K_a values for **2** and **2** · HPF_6 in Table 1; the K_a value of the protonated receptor is 40 times greater than that of the unprotonated receptor. The strength of complexation of alcohols is also dependent on the nature of the substituents ($PhCH_2$ in **1** and $PhCH_2CH_2$ in **2**). When the phenyl groups are more distant from the hydrogen-bond-

Table 1. The association constants K_a and derived free energies of complexation ΔG^0 for the neutral receptor **2** and the cationic receptors **1** · HPF_6 and **2** · HPF_6 with a range of short-chain alcohols [a] in CD_2Cl_2 at 20 °C.

Receptor	Alcohol	K_a [M^{-1}]	ΔG^0 [kJ mol^{-1}]
2	[D_4]methanol	1.1	−0.25
1 · HPF_6	[D_4]methanol	4.8	−3.81
1 · HPF_6	ethanol	1.6	−1.20
1 · HPF_6	*n*-propanol	2.2	−1.90
2 · HPF_6	[D_4]methanol	47	−9.37
2 · HPF_6	[D_6]ethanol	8.6	−5.23
2 · HPF_6	*n*-propanol	2.9	−2.60
2 · HPF_6	*n*-butanol	3.2	−2.84

[a] Deuterated alcohols were employed in some titration experiments in order to avoid masking the NMR resonances of the receptors.

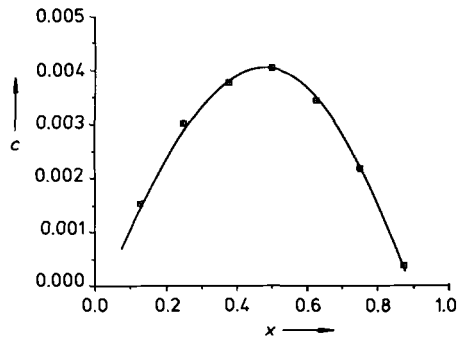

Fig. 1. The concentration c of $\mathbf{1} \cdot HPF_6 \cdot CD_3OD$ relative to CD_3OD versus the mole fraction x of $\mathbf{1} \cdot HPF_6$ in CD_2Cl_2 at 20 °C.

ing centers in the receptors, the complexes formed with MeOH, EtOH, and *n*-PrOH are all stronger.

The disubstituted 1,7-diaza-12-crown-4 derivatives are highly suitable receptors[16] for RNH_3^+ and $R_2NH_2^+$ ions, because they can form two $N \cdots H\text{–}N^+$ hydrogen bonds with the cationic substrates. When these same receptors are monoprotonated, it is possible for them to form simultaneously an $N \cdots H\text{–}O$ hydrogen bond and an $N^+\text{–}H \cdots O$ hydrogen bond with a neutral ROH substrate, because the lone electron-pair on the neutral nitrogen atom acts as a good hydrogen-bond acceptor and the protonated nitrogen atom is a strong hydrogen-bond donor. This two-point binding model (Fig. 2) has been confirmed by an organized sequence of structural investigations which have been carried out in the solid state on neutral and charged—free as well as complexed—disubstituted 1,7-diaza-12-crown-4 derivatives.

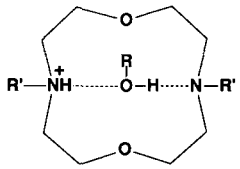

Fig. 2. The two-point binding model showing the hydrogen bonding of an alcohol (ROH) molecule to a monoprotonated disubstituted 1,7-diaza-12-crown-4 derivative.

The single-crystal X-ray structures[17–19] of **1**, $\mathbf{2} \cdot HPF_6$, and $\mathbf{1} \cdot HPF_6 \cdot MeOH$ are illustrated in Figures 3, 4, and 5, respectively. In the solid state, **1** (Fig. 3) possesses crystallographic C_i symmetry, the 12-membered ring adopts a [66] conformation,[20, 21] and the lone electron-pairs of the nitrogen atoms are on opposite faces of the macrocycle. In $\mathbf{2} \cdot HPF_6$ (Fig. 4), the cation assumes an asymmetric and folded geometry; the protonated and unprotonated nitrogen atoms are directed towards each other and form an almost linear hydrogen bond ([$N^+\text{–}H \cdots N$] distance 3.01 Å). The

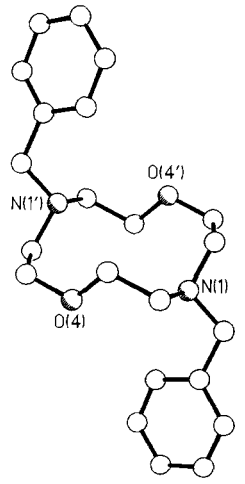

Fig. 3. The structure of **1** in the crystal. The transannular N–N and O–O distances are 4.37 and 4.35 Å, respectively.

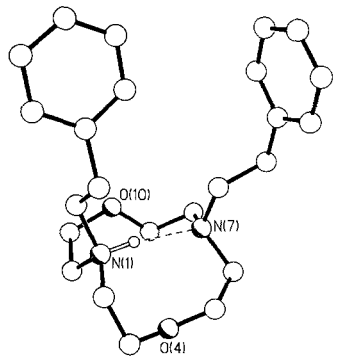

Fig. 4. The structure of $\mathbf{2} \cdot HPF_6$ in the crystal. The transannular N–N and O–O distances are 3.01 and 4.17 Å, respectively. The H-N(7) distance is 2.04 Å and the N(1)-H-N(7) angle is 169°.

solid-state structure of $\mathbf{1} \cdot HPF_6 \cdot MeOH$ (Fig. 5) has crystallographic C_s symmetry with the mirror plane passing through the two oxygen atoms in the monoprotonated disubstituted 1,7-diaza-12-crown-4 derivative. The MeOH molecule also lies in this mirror plane. The 12-membered ring

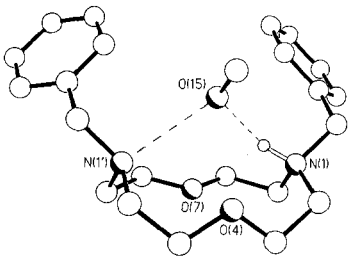

Fig. 5. The structure of $\mathbf{1} \cdot HPF_6 \cdot MeOH$ in the crystal. The transannular N–N and O–O distances are 4.53 and 3.06 Å, respectively. The H-O(15) distance is 1.87 Å and the N(1)-H-O(15) angle is 161°.

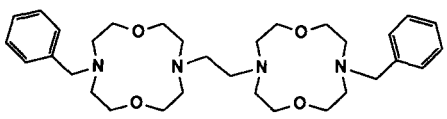
adopts a [48] conformation[20] in which both nitrogen atoms are oriented over one face of the macrocycle. The position of the ammonium proton was located from a difference electron-density map, though, of course, because of the crystallographic symmetry constraints, it must alternate between the two nitrogen sites throughout the crystal lattice. The position of the OH proton could not be located. But by inference with the geometry observed[10] in the MeOH complex of the diprotonated analogue $\mathbf{3} \cdot 2HPF_6$ we conclude



3

that the binding of the MeOH molecule to $\mathbf{1} \cdot HPF_6$ involves combination of $N^+\text{–}H \cdots O$ and $O\text{–}H \cdots N$ hydrogen bonds.[22] The $N^+ \cdots O$ and $O \cdots N$ distances are by symmetry both 2.81 Å.

The two-point binding model for the complexation of alcohols by monoprotonated disubstituted 1,7-diaza-12-crown-4 derivatives has been firmly established. The opportunity now exists to develop this type of complexation between cationic host and neutral guest for the design of receptors that will exhibit selectivity[23] within the homologous series of simple alcohols (CH_3OH, C_2H_5OH, C_3H_7OH) and the

constitutionally isomeric alcohols from C_3H_7OH upwards in molecular weight.

Experimental Procedure

1: 1,7-Diaza-4,10-dioxacyclododecane [12] (200 mg, 1.1 mmol) and Na_2CO_3 (0.61 g, 5.7 mmol) were suspended in dry MeCN (8 mL). Then, benzyl bromide (395 mg, 2.3 mmol) was added dropwise to the suspension under reflux. After 10 h the reaction mixture was cooled and filtered. Evaporation of the solvent from the filtrate under vacuum afforded a residue which was extracted with $CHCl_3$. Chromatography [SiO_2, 35%] NH_3/MeOH/Et_2O/$CHCl_3$ (0.2/10/30/80) afforded **1** [386 mg, 95%, mp = 89–90 °C, *m/z* (EIMS) = 354 (M^+); ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 2.77 (t, 8H, ^3J = 4.5 Hz), 3.61 (t, 8H, ^3J = 4.5 Hz), 3.70 (s, 4H), 7.20–7.45 (m, 10H)]. Single crystals suitable for X-ray crystallography were grown from *n*-hexane.

1 · HPF_6: A solution of **1** (1.0 g, 2.8 mmol) and NH_4PF_6 (0.46 g, 2.8 mmol) in MeOH (20 mL) was stirred under reflux for 8 h. When the reaction mixture cooled, colorless crystals formed, which were filtered and dried under vacuum during 36 h. They were characterized as **1** · HPF_6 [1.1 g, 78%, mp = 170 °C; ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 3.10 (t, 8H, ^3J = 4.8 Hz), 3.62 (t, 8H, ^3J = 4.8 Hz), 4.10 (s, 4H), 5.40 (br s, 1H), 7.36–7.47 (m, 10H)]. Single crystals of **1** · HPF_6 · MeOH suitable for X-ray crystallography were obtained by gradually cooling a saturated solution of **1** · HPF_6 in MeOH from 60 °C to 20 °C.

2: 1,7-Diaza-4,10-dioxacyclododecane [12] (300 mg, 1.7 mmol) and Na_2CO_3 (1.2 g, 11.3 mmol) were suspended in dry MeCN (40 mL). Then, a solution of 2-phenylethyl bromide (624 mg, 3.5 mmol) in MeCN (5 mL) was added dropwise to the stirred reaction mixture under reflux. After 24 h the reaction mixture was cooled and filtered. Evaporation of the solvent from the filtrate under vacuum afforded an oil which was extracted with boiling hexane. The hexane solution was concentrated under vacuum and cooled in an ice-box. Long colorless needles formed which were identified as **2** [244 mg, 37%, mp = 58–60 °C, *m/z* (EIMS) = 382 (M^+); ^{1}H NMR ($CDCl_3$, 250 MHz): δ = 2.70–2.80 (m, 16H), 3.61 (t, 8H, ^3J = 4.5 Hz), 7.15–7.31 (m, 10H)].

2 · HPF_6: A mixture of **2** (50 mg, 0.13 mmol) and NH_4PF_6 (21.3 mg, 0.13 mmol) in MeOH (2.4 mL) was stirred under reflux during 10 h. The solvent was removed under vacuum, affording an oil which crystallized on addition of Et_2O. After removal of the solvent, the crystals were dried under vacuum and characterized as **2** · HPF_6 [69 mg, 100%, mp = 155–160 °C; ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 2.89 (t, 4H, ^3J = 4.3 Hz), 3.10–3.18 (m, 12H), 3.74 (t, 8H, ^3J = 4.8 Hz), 5.38 (br s, 1H), 7.17–7.34 (m, 10H)]. Single crystals suitable for X-ray crystallography were grown by slow evaporation of a CH_2Cl_2 solution of **2** · HPF_6.

An Opinion on the Heterogeneous Photoreactions of N_2 with H_2O **

By *Jimmie G. Edwards,* Julian A. Davies, David L. Boucher,* and *Abdelkader Mennad*

Artificial photosynthesis of ammonia is an important research goal. In the course of other work,[1] we have reviewed

reported successful syntheses [2] and have attempted to reproduce, under a variety of conditions, reported ammonia yields by methods using iron-doped metal oxides as catalysts. We find such methods to be ineffective. Our most statistically significant results are presented here, and possible bases for previous reports are suggested. We argue that the likelihood of success with such methods is small and that further research in this direction should be undertaken only after careful consideration.

Schrauzer and Guth [3] first reported the reaction of N_2 with H_2O to make NH_3 by UV irradiation over TiO_2-based catalysts. Others [4–11] have confirmed and extended this photoassisted N_2-fixation (hereafter denoted by pNf) with a wide range of catalyst types. Solar energy was reported to drive pNf; [12] important contribution to the ammonia inventory of the earth by solar driven pNf with desert sands as catalysts was postulated. In one report [13] NH_3 was made at 2–18 mg h^{-1} in a solar reactor. This enticing reaction could be of immense practical importance, and its exploration and elucidation would seem to call for vigorous research activity.

Reported concentrations of ammonia from pNf were at the micromolar level or lower in most cases. The report by Lichtin and Vijayakumar [9] of molar concentrations was a typographical error; concentration units were μM.[14] Ammonia is ubiquitous in nature at micromolar levels.[15] For example, the ammonia concentration in water exposed to air in Antarctica gained 3 μM in 7 h; [16] up to 20 μmol h^{-1} of ammonia is exhaled in human breath.[17] It follows that contamination in artificial photosynthesis experiments must be a major concern. Further concern arises from the fact that ammonia is *oxidized* to NO_2^- by photocatalysis under the very conditions reported to promote *reduction* of N_2 to NH_3.[18–21] Confirmation of the reported pNf should, therefore, include ammonia synthesis and isolation in amounts well above background levels, or failing this, synthesis from isotopically labeled N_2 of equivalently labeled ammonia.

For the proposed stoichiometric reaction [Eq. (a)] [3, 4] a free energy of $\Delta G°(298\ K) = 658$ kJ per mol N_2 is calculated. This energy cannot come from just one photon per nitrogen molecule in the range 300–400 nm used in many reported experiments. Moreover, to avoid an unfavorable equilibrium, the product activity would need to be absurdly low. For example, at equilibrium at 298 K for reactants under standard conditions and an ammonia concentration of 1 μM, the oxygen partial pressure would be 10^{-70} atm. With a more reasonable oxygen activity of 10^{-10} atm, the ammonia concentration at equilibrium would be 6.3×10^{-51} M, which equates to one molecule of ammonia in a volume 240 times that of the earth. Organisms fix nitrogen as ammonia with hydrogen from water through multistep processes which ultimately are light-driven.[22] These naturally occurring reactions developed under evolutionary influences over eons. How remarkable it would be if a surface as common as that of iron-doped titanium dioxide could provide a template suitable for promoting such a complicated process.

$$N_2(g) + 3H_2O(l) \longrightarrow 2NH_3(aq) + 1.5O_2(g) \qquad (a)$$

Since the process involves more than one photon, if reversal of reaction (a) is to be slowed the proposed catalyst must have an almost inconceivably fortuitous set of thermal relaxation sites where photons, or resultant active sites or carriers can activate the system to the next levels. Each site must create through thermal equilibration an energy barrier to reversal as symbolized in Figure 1. Because such barriers must be present to impede the reverse reactions, a minimum of three photons per N_2 molecule would be needed, even in the unlikely case that each of the three steps involved about the same energy. Three 350 nm photons would supply the needed 658 kJ per mol N_2 and three barriers of 130 kJ mol^{-1}. If an electron/hole mechanism [23] is assumed, not three but six photons with energies greater than the band-gap energy of the photocatalyst would be required for the six-electron reduction of N_2 to $2NH_3$.

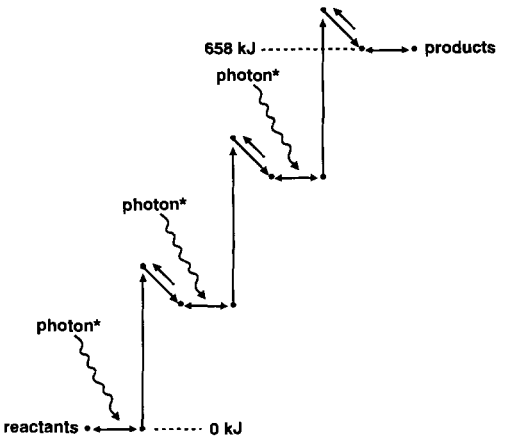

Fig. 1. Schematic, idealized, and generalized representation of a heterogeneous, photocatalytic mechanism requiring three photons with four adsorbed states of progressively higher energy, the higher three with reversal barriers arising from thermal equilibration. This diagram is not intended to represent any known steps in the photosynthesis of NH_3 or any states on the surface of oxide photocatalysts, because none in such a sequence has been established.

To elucidate this process, we did two types of experiments under conditions like those in the reported successful pNf experiments, but with $^{15}N_2$ as the nitrogen source.[24] Type 1: A prospective catalyst powder was saturated with water vapor, sealed in a reaction tube with either liquid water [25] or an atmosphere saturated with water vapor, and N_2(g) enriched to 99% with ^{15}N (hereafter called $^{15}N_2$), and irradiated; twelve irradiation experiments were done. The prospective catalyst powder was either coprecipitated or surface-loaded iron-doped titanium dioxide prepared with due regard to the cautionary notes [26] concerning photocatalyst syntheses. Type 2: A prospective catalyst powder was sealed in a reaction tube with liquid water and $^{15}N_2$ and irradiated. Twenty samples of prospective catalyst were used; all were single or binary oxide xerogels with components chosen from TiO_2, Fe_2O_3, NiO, Al_2O_3, and SiO_2. Twenty-five Type-2 experiments were done.

Both types of experiment used 45-mL quartz reaction tubes closed by quartz stopcocks with Teflon plugs. Stopcocks were covered by aluminium foil, and the tubes were irradiated in a circular rack in the center of which was a double-walled, water-cooled, quartz immersion well containing a 450-W Hanovia medium-pressure mercury lamp. A cylindrical steel reflector surrounded the rack. Reactant water was deionized to $\kappa_w > 19$ MΩcm and its background ammonia content was monitored by a specially developed method.[15] An isotope-ratio mass spectrometer (Europa Scientific Ltd.) was used to analyze for $^{14}N_2$: $^{14}N\,^{15}N$: $^{15}N_2$

ratios.[27] The sensitivity of the analysis was tested on 48 standards made of $^{15}NH_3$ and natural NH_3 such that excess ^{15}N over natural abundance ranged from 0.10 to 50.0 nmol in a sample of 7.14 μmol. The smallest enrichments were detected with a confidence exceeding 99%. One tenth nmol of $^{15}NH_3$ above natural levels was always detected at this confidence level. The samples were also analyzed for oxidized, fixed ^{15}N as NO_2^- and NO_3^- (hereafter denoted by NO_x^-).

In experiments of both types, and with all prospective catalyst powders, amounts of ammonia synthesized (here defined as that detected above natural abundance) varied around zero with a Gaussian distribution. The range in Type 1 was 0 ± 200 to 300 ± 150 pmol (average 15 ± 290 pmol). Amounts of synthesized NO_x^- were 40 ± 130 to 290 ± 750 pmol (average 100 ± 830 pmol). In the control experiments, the amount of synthesized ammonia in nonirradiated water was 100 ± 140 pmol and synthesized NO_x^- was 150 ± 140 pmol. In the control with water and no $^{15}N_2$, the total "fixed nitrogen" was 120 ± 150 pmol.

The amounts of synthesized ammonia from Type 2 were -80 ± 40 to 70 ± 50 pmol (average 1.5 ± 70 pmol), and of synthesized NO_x^- -0.2 to $+2.2$ nmol (average 0.32 ± 0.63 nmol). This outcome was skewed by four results of more than 1 nmol of $^{15}NO_x^-$ (21 experiments yielded 45 ± 180 pmol, 4 experiments 1.8 ± 0.6 nmol). In view of the not unfavorable free energy ($\Delta G°(298\ K) = 7\ kJ\ mol^{-1}$) of reaction (b) there remains some possibility that gaseous N_2

$$N_2(g) + 1.5O_2(g) + 2OH^-(aq) \longrightarrow 2NO_2^-(aq) + H_2O(aq) \qquad (b)$$

can be photooxidized either by O_2 or by an oxidizing prospective catalyst to aqueous NO_x^- in low concentrations. These results provide no evidence for reductive fixation of nitrogen in any of our cases.

In another set of experiments,[21, 28] the degradation of micromolar concentrations of aqueous ammonia under UV radiation in the presence of iron-doped TiO_2 was studied in atmospheres ranging from O_2 through air, N_2 and Ar, to H_2. Values of pH ranged from 1 to 12 and temperatures from 0 °C to 90 °C. In all cases ammonia was degraded in a few hours, and when oxygen was present NO_2^- or NO_3^- was formed. The degradation of ammonia under these conditions has been known for a long time.[18–20]

In this work we failed to fix nitrogen as ammonia under a variety of conditions with prospective catalysts of several types, some like those used in reports of successful pNf. Ammonia is degraded under the very conditions reported to produce it.

Ammonia is known to be pervasive in the background, and contamination from natural sources is an everpresent pitfall in artificial photosynthesis experiments.[16, 17] Known mechanisms for biological photosynthesis of ammonia from water and nitrogen are impressively complex and still not completely understood. Any simpler mechanism involving small molecules and heterogeneous catalysis on metal-oxide substrates would be subject to reversal or side reactions forming thermodynamically more favorable states.[18] There is well-founded interest in the surface chemistry and physics of doped ceramic oxides like TiO_2 under UV radiation,[4] but there is reason to doubt that ammonia can be photosynthesized on such surfaces. Further research on this enticing and fascinating nitrogen-fixation process should be undertaken only after due consideration. In particular, further work in this area should include identification and characterization of the favorable sites on the proposed catalyst which stabilize the necessary intermediate states in the suggested reaction.

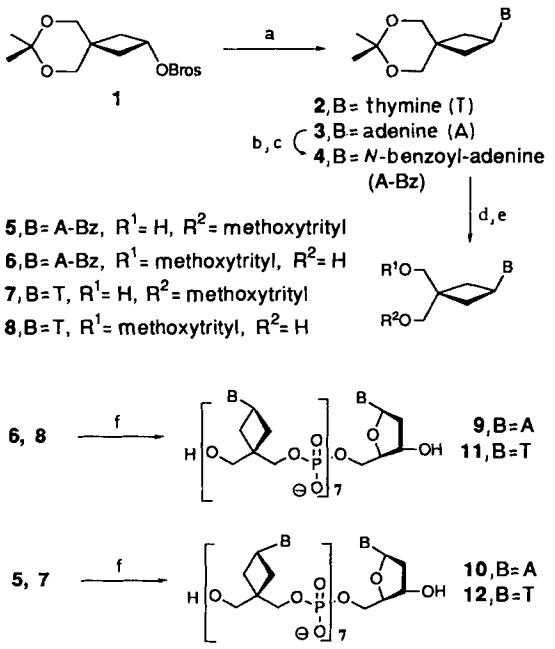
of our own work in this area. Several research groups have shown that the substitution of deoxyribose in nucleosides by oxetanes and cyclobutanes leads to biologically active compounds.[3] We are interested in the oligomeric phosphodiesters of such artificial nucleosides, especially for their ability to form double strands with ribo- and deoxyribonucleic acids i.e. to hybridize. Apart from the complementarity of the nucleic bases very little is known about the special conditions which two pairing strands and especially their phosphodiester backbone must satisfy. Herein, we report about adenyl and thyminyl derivatives of 1,1-cyclobutandimethanol.

Starting from 3-benzyloxy-1,1-cyclobutandimethanol,[4, 5] which was obtained in a slightly modified way, we synthesized the *O*-protected, sulfonated derivative **1** (Scheme 1) in three steps. Direct introduction of thymine with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in dimethyl sulfoxide (DMSO) at 80 °C afforded **2** (52%) together with the N^1,N^3-disubstituted product (34%). With adenine only **3** (90%) was obtained under the same conditions. The adenine group in **3** was protected by benzoyl chloride to give **4** whose subsequent monosubstitution with methoxytritylchloride (MeOTrCl) yielded the *trans*-substituted **5** and the *cis*-substituted **6** after chromatographic separation. In the thymine series we obtained the *trans* derivative **7** and the *cis* derivative **8**. The structures of these isomers were assigned from NOE



Scheme 1. Synthesis of cyclobutylcarbanucleosides and their octameric phosphodiesters. a) B (3 equiv)/DBU (3 equiv), DMSO, 24h, 80 °C B = A (90%) B = T (52%); b) PhCOCl/pyridine (95%); c) $NH_4OH/THF/H_2O$; d) HCl 2M/dioxane then Na_2CO_3 (70%); e) MeOTrCl/pyridine (**6** (9%) + **5** (27%), and **7** (35%) + **8** (42%), respectively); f) solid-phase synthesis [6,7] (80–87% per coupling step).

experiments. In **5** and **7** irradiation of $H_{1\alpha}$ produced a positive effect on $H_{2\alpha}$, $H_{4\alpha}$, and the methylene protons of the substituted hydroxymethyl group. In contrast in **6** and **8** this effect was observed on the unsubstituted hydroxymethyl group. The four compounds were converted by the phosphotriester method on a solid phase[6, 7] to give octameric phosphodiesters. The thymine-containing oligomers **11** and **12** have thymidine at the end, whereas the adenine-containing oligomers **9** and **10** have deoxyadenosine as the last nucleoside.[8]

The results of the pairing characteristics of the new oligonucleotides both towards ribo- and deoxyribonucleic acids and also towards the complementary homologous oligonucleotides are summarized in Table 1. Apart from the high T_m value[9] of the hybrids of **10** and poly-rU (55 °C), which cannot be explained at the moment, but perhaps indicates a triplex formation, three graded interactions between complementary oligomers can be identified. In contrast, strands with noncomplementary bases showed no cooperative melting properties (see Table 1, footnote [b]). As expected, the T_m values of the hybrids of cyclobutyl oligomers with the complementary DNAs (27 °C, 28 °C) are higher than the T_m values of their hybrids with the less adaptable RNAs (9 °C, 11 °C). The pseudo-α oligomers **10** and **12** lead to lower T_m values than the pseudo-β oligomers **9** and **11**. However, the most interesting result is the unequivocal interaction between the cyclobutyl-A oligomers **9** or **10** and the cyclobutyl-T oligomers **11** or **12** with intermediate T_m values of 18 °C and 20 °C. Hence, following Eschenmoser's example,[10] here is a further synthetic oligonucleotide system, which however, shows interactions with natural RNA and DNA in addition to those with itself.

Table 1. Melting temperatures T_m [°C] and hyperchromicity (in parentheses) of the octameric phosphodiesters [a].

	poly-rA	poly-dA	poly-rU	$(dT)_8$	**11**	**12**
9	[b]	[b]	9 (16%)	28 (25%)	20 (28%)	9 (14%)
10	[b]	[b]	55 (42%)	22 (27%)	18 (28%)	12 (16%)
11	11 (23%)	27 (24%)	[b]			
12		10 (10%)		[b]		
poly-rA				13 (35%)		

[a] All experiments were carried out in phosphate buffer pH = 7.0 and 1M sodium chloride; in physiological NaCl solution the T_m values are approximately 10 °C lower. [b] No determinable T_m value.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Non-Chromatographic Continuous Separation Techniques. By *M. Valcárel* and *M. D. Luque de Castro*. Royal Society of Chemistry, London, 1991. XII, 290 pp., hardcover £ 42.50.—ISBN 0-85186-986-6

The demands being made on the performance of analytical methods are becoming ever more exacting, not only with regard to the quality of the results but also from the standpoints of the speed and economy of the methods used. In recent years there have been great advances in methods of detection, in data processing, and in methods for the delivery of samples to the measuring instruments. The latest challenge presented is to incorporate the sample preparation into the automation of the analytical procedure, so that here too one can achieve higher efficiency and better reproducibility. Non-chromatographic separation techniques offer one approach to this problem, and form the subject of this book.

These techniques are dealt with under three sections. Based on the type of phase transition of the analyte used to achieve separation, the methods are classified as gas-to-liquid systems, liquid-to-liquid systems, and liquid-to-solid systems. Each of these sections is itself divided up in a very logical way, and this systematic treatment is an impressive feature of the book. However, the techniques of field flow fractionation and capillary electrophoresis do not fit into this scheme, and they are treated in a separate, but rather short, section.

Each chapter begins with an introduction to the nature of the problem, followed by a lucid and practically-orientated description of the principles on which the method is based. Next the various modules that make up the system are described, followed in many cases by details of actual instruments and of how the techniques are used. Applications to special types of problems are also described, with the help of clear block diagrams. These include some very original solutions, which reveal the deep knowledge of the subject possessed by the authors, who have themselves made considerable contributions to the development of the techniques.

There is a carefully compiled index, which includes advice on the use of the techniques, and information on the methods used to solve the special problems discussed in the book. There are about 600 literature references (extending up to 1991) giving access to more detailed information.

The book clearly explains the advantages that non-chromatographic separation techniques can offer with regard to precision, sample throughput rate, economy in reagents and reduction of analytical costs. On the other hand the limitations are also clearly explained, especially in the chapter on "leaching". The descriptions of the methods assume that one already has a sample in solution; techniques for handling solid samples are still at an early stage of development.

In their final summing-up the authors explain that their aim has been to familiarize people in the analytical world with these techniques, and so contribute to their becoming established; the book should succeed in this objective. This interesting and very readable monograph is suitable both for the newcomer to the field, seeking a general description of non-chromatographic separation methods, and for the specialist looking for a solution to a particular problem.

Modern NMR Techniques, and Their Applications in Chemistry. (Practical Spectroscopy Series, Vol. 11). Edited by *A. I. Popov* and *K. Hallenga*. Marcel Dekker, New York, 1991. x, 665 pp., hardcover $ 135.00 (USA and Canada), $ 162.00 (all other countries).—ISBN 0-8247-8332-8

The field of NMR spectroscopy is certainly not a branch of science suffering from a lack of literature; at all levels, from simple textbooks all the way through to sophisticated

specialized monographs, this market is fairly well catered for. Still, even for such a well-covered topic as NMR spectroscopy, there are areas in which one would like to see further books published. The book to be discussed here "Modern NMR Techniques and Their Application in Chemistry" is very timely as, for example, the title addresses one of the gaps in the NMR book market. It is certainly a very ambitious title, and since the price of the book is also substantial, high expectations are accordingly raised. Any evaluation will have to be guided by these expectations.

To be quite frank, I am a little disappointed with this book and I feel forced to attest a certain taste of a "misnomer" and at least some lack of "up-to-dateness". My reasons will be explained in greater detail in the following.

What does this book have to offer in its 665 pages? In ten chapters different authors address various aspects of the application of NMR spectroscopy in chemistry. Such a multi-author approach is perfectly acceptable in times of ever-increasing specialization.

Chapter 1, "NMR Properties of Nuclei" (52 pages), is somewhat out of place in a book such as this. This chapter contains the *very* basics of NMR spectroscopy which can be found in numerous variations in many textbooks written for a wide chemistry audience. Moreover, the potential readership of this book can be expected, nowadays, to have this basic knowledge.

Chapter 2, "Fourier Transform NMR: Theoretical and Practical Aspects" (72 pages), is much more useful in this respect. For a chemist, it is easily readable and the topic deserves its own chapter. Again, however, the contents can be found in several other NMR books.

The remaining eight chapters deal with the application of NMR in chemistry. It is very welcome that two chapters (208 pages) are devoted to solid state NMR spectroscopy. However, these two chapters are more likely to cement old prejudices rather than to generate appetite for application. For instance, the chapter "Solid State NMR of Spin-1/2 Nuclei" shows as application examples two figures (on pages 137, 160) from work by Pines et al. and by Herzfeld and Berger which can be considered as truly historical. Over the last ten years these two figures have appeared in a number of review articles and books. Further appetizing examples or an overview of the substantial achievements in this area of research in recent years are missing completely. Similarly the section of CP-MAS NMR spectroscopy is somewhat misleading. Examples given for this methodology are limited to ^{13}C measurements on coals and organic polymers. Fair enough, these *are* very important applications, but by no means do they alone represent what one would call "Modern NMR Techniques and Their Application in Chemistry".

Chapter 4, "Solid-State NMR: Quadrupolar Nuclei", presents a useful discussion of quadrupolar interactions and asymmetry parameters. In this chapter the selection of examples is much broader.

Chapter 5, "Quantitative Analysis by NMR" (46 pages), is again of mainly very basic character. It would have been appropriate for this chapter to address explicitly quantitation problems in solid-state NMR, as it is known that these problems are not quite the same for solutions and solids.

Perhaps it would have been better to combine Chapter 6 "Structural Determination of Organic Compounds" and Chapter 10 "Two-Dimensional NMR Studies of Biomacromolecules" into one chapter. The methodology used for these two topics shows many overlaps and parallels, the essential difference being just the molecular weight of the "objects" under investigation.

Chapter 7, "Structural Determination of Inorganic Compounds", does give a fairly broad overview, including inorganic and organometallic applications, as well as two-dimensional experiments in solution. Solid-state NMR spectroscopy comes off poorly in this chapter; only cement and zeolites are mentioned, and at that, very briefly. This is a real pity, especially since chapters 3 and 4 do not offer much in terms of inorganic applications either. A more detailed discussion, for example on the combined use of solid- *and* solution-state NMR, or on diffraction techniques plus NMR, would have been highly desirable.

Both Chapter 8 "Equilibria Studies in Solutions" and Chapter 9 "Reaction Kinetics and Exchange" are justified by the fact that these aspects of NMR spectroscopy are usually only dealt with very briefly in other textbooks.

To conclude, in my opinion another book on the same subject of modern NMR applications in chemistry approaches the ambitious goals of the refereed book much better. This alternative, edited by P. Granger and R. K. Harris and published in 1990, also uses the multi-author approach; it is quite comparable as regards size and price, and gives a much more up-to-date and broader overview ("Multinuclear Magnetic Resonance in Liquids and Solids—Chemical Applications", NATO ASI Series C, Vol. 322, Kluwer Academic Publishers, 1990, ISBN 0-7923-0986-3).

Preparative Polar Organometallic Chemistry 2. By *L. Brandsma*. Springer, Berlin, 1990. XII, 227 pp., paperback DM 86.00.—ISBN 3-540-52749-4

This second volume, in which preparations and reactions of lithium, sodium and potassium compounds that result from deprotonation at an sp_3-hybridized carbon atom are described, extends the scope beyond that of the first volume (published in 1987) by including also the most important examples of Li, Na and K compounds obtained by deprotonation at an sp_2-hybridized carbon. The care that is taken in the preparation of the "Brandsmas" is now almost legendary – to anyone acquainted with this author's love for experimental detail, especially in the organometallic field, that comes as no surprise. Following the developments during the 1980s that led to lithium, sodium and potassium compounds becoming some of the most important synthetic reagents in organic chemistry, it is extremely useful to now have access also to a wealth of carefully tested laboratory recipes for "sp_3 anions". Thus, this second volume, like the first, belongs in every organic chemistry laboratory!

The volume contains ten chapters as follows: 1. Reactivity of Polar Organometallic Intermediates; 2. Metallation of Aromatic and Olefinic Hydrocarbons; 3. Metallation of Saturated Sulfur Compounds; 4. α-Metallation of Derivatives of Toluene Containing Heterosubstituents; 5. Metallation of Heterosubstituted Allylic and Benzylic Compounds; 6. Metallation of Heterocyclic Compounds; 7. Metallation of Aldimines and Ketimines; 8. Metallation of Nitriles and Isonitriles; 9. Generation of Lithium Halocarbenoids; 10. Metallation of Carbonyl and Thiocarbonyl Compounds. The appendix contains first a very useful "Metallation–Functionalization" index, in the form of a table summariz-

ing the metallations and functionalizations with electrophiles that are described in Chapters 2–10. This is followed by a list of the starting compounds used in the preparations described in Volumes 1 and 2. Next there is an index to the contents of both volumes. Some typical reactions and special techniques are then described, with examples taken from both volumes. Lastly there is a section on the purification and storage of a few relevant reagents and solvents.

To summarize, I can only repeat what I wrote previously by emphatically recommending the second volume, like the first, for everyone concerned with the organometallic chemistry of lithium, sodium and potassium; this is likely to include a great many chemists.

The Chemistry of Polymers. (Royal Society of Chemistry Paperbacks Series). By *J. W. Nicholson*. The Royal Society of Chemistry, London, 1991. XII, 174 pp., paperback £ 14.50.—ISBN 0-85186-413-9

This little book is intended for advanced students, industrial chemists, and newcomers to the field of polymer chemistry, and provides a very brief introduction to the chemistry and physical properties of polymers. It is divided into ten chapters, each consisting of an introduction followed by 10–30 pages on a particular aspect of the subject; these include such varied topics as polymerization reactions, crosslinking, structure, mechanical properties, and decomposition.

Thus the book's title is repeated as a heading for the first chapter, which describes the structures and properties of the main polymers of industrial importance (polyethylene, polystyrene, nylon, etc.) and also several naturally occuring macromolecular substances such as starch and proteins. In the chapter on polymerization reactions special emphasis is put on classifying the reactions according to their kinetics into chain (addition) polymerizations and step (condensation) polymerizations. The basic principles of the reactions are discussed and illustrated by examples; the methods whereby these are scaled up into industrial processes are then described. The following chapter deals with the stereochemistry of polymers, including carbon atoms as chiral centers, and with crystallinity and thermal properties such as the glass transition temperature. Surprisingly, liquid crystalline polymers and their phase transformations are not discussed at this point; this topic is only briefly touched on later, in Chapter 9, which deals with special aspects of polymer chemistry.

In contrast, the various methods for crosslinking oligomers and polymers are described in detail, with particular emphasis on industrial-scale applications. The important chapter on methods for determining the molecular mass distribution of polymers is preceded by a discussion of their solution properties. The longest chapter in the book is that dealing with mechanical properties, including tensile properties and stretching behavior, rubber-like elasticity, and reinforced materials. Here (though not elsewhere) the reader is even referred to other literature for further study. Next the risks of polymers becoming degraded by heat and light are discussed, together with their combustion properties and fire resistance. In this context the use of the antimony-halogen synergistic effect to lower the flammability index of polymers is mentioned.

The idea of the final chapter, which aims to give a heightened awareness of environmental effects, is interesting and potentially valuable. However, it is mainly limited to general statements of an almost political kind about methods of waste disposal; biodegradable polymers are only very briefly mentioned.

In setting out to give an overview of the whole field of polymers, extending as far as their materials science and technology, J. W. Nicholson has had to keep the amount of detail down to a minimum, but unfortunately has not included recommendations for additional or more advanced reading. The book will be of interest and value mainly for newcomers to the field who expect to be involved in technological aspects of polymer chemistry. Detailed physicochemical and organic chemical aspects are not treated. The level of treatment is comparable with the introductory sections to be found in standard textbooks of organic and physical chemistry, but not with standard works on polymer chemistry such as those by Elias and Vollmert.

Transport and Fate of Organic Compounds in the Global Environment

By Karlheinz Ballschmiter*

Dedicated to Professor Heinz Harnisch on the occasion of his 65th birthday

The role of chemistry in our soon-to-be global industrial society requires a global perspective for the discussion of the uptake, transport, and conversion of chemical compounds in the environment. The fate of organic compounds in the volume flow of the atmosphere and hydrosphere can be categorized into transport pathways and adjustments of equilibria in the multiphase system atmosphere–oceans–land surface. The global volume flow in the atmosphere (wind, areas of high and low pressure) and in the hydrosphere (rivers, circulation of water in lakes, ocean currents) alone would account for the transport of organic compounds if they were stable and if all these compounds were molecularly distributed in these phases. However, this particular case is observed only for volatile chlorofluorocarbons and tetrachloromethane. For most organic compounds, complex adsorption/desorption processes on finely dispersed particle phases in the air and water as well as abiotic and biotic transformations determine the transport behavior.

The global fate of a compound includes its accumulation as well as its decomposition in defined environmental compartments. Both phenomenon may have long-term consequences in the affected areas; this is indicated by the accumulation of polychlorobiphenyls and analogous compounds in marine mammals and deep-sea fauna, and is evident in the decomposition of chlorofluorocarbons in the stratosphere. The accepted definition of the level of a risk, the product of the probability of an event and the potential amount of damage, takes on a new dimension when viewed from a global perspective—especially when one further connects the extent of the damage to the possible means of correction. It is the responsibility of scientists to point out the irreparable regional to global consequences directly and indirectly connected to the production of chemicals and to provide suggestions for prevention. Politicians can only react by applying their methods to limit the damage; however, they cannot generate any solutions based on science.

1. Introduction

An account of the pathways and mechanisms whereby organic compounds at low concentrations are transported in the atmosphere, the hydrosphere and the biosphere on a global scale must, within the confines of a review such as this, be limited to describing the basic processes that can occur and indicating their dimensions. The complexity arising from the mixing and separation processes that are possible, whose description involves geography, geophysics, meteorology and oceanography, is further compounded by the wide range of physicochemical and chemical properties of the many compounds that can be regarded as xenobiotics.[*] The list of compounds in the environment that result directly or indirectly from modern industrial civilization is extensive, including such widely varied examples as phosgene,[1] chlorofluoromethanes (F11 and F12),[2] benzene,[3] chlorinated biphenyls,[4] chlorinated dibenzo-*p*-dioxins and dibenzofurans,[5] and acetonitrile.[6]

[*] Prof. Dr. K. Ballschmiter
Analytische Chemie und Umweltchemie der Universität
Albert-Einstein-Allee 11, W-7900 Ulm (FRG)

[*] Greek xenos = foreign, bios = life; harmful chemicals in the environment.

Although attention is mainly focussed on those compounds that are produced and distributed through human activities when one is considering the question of their fate in the global environment, one must not overlook the fact that the observed atmospheric concentrations of some compounds, such as the solvent chloroform,[7] include a biogenic contribution. Likewise formaldehyde, whose occurrence as a pollutant has been much discussed, also has a natural background concentration in the atmosphere as an intermediate product during the 'cold' combustion of methane from sewage or marsh-gas (reaction with 'OH radicals). Both these compounds thus belong to natural evolutionary processes.

For many molecular species there are preferred transport pathways and consequently regions of the environment in which they mainly occur, while for others their occurrence is completely random.[8–15] Accumulation in a specific region can occur as a result of being introduced through use of a product or through being indirectly generated there, or it can arise through transport from another region.

The combined effects of transport and conversion processes can be envisaged as working like a sort of 'environmental chromatography' on a regional or global scale. Thus the global environment can be regarded as a complex chromatographic system in which gas chromatography and liquid chromatography are closely intertwined. The transport behavior of a compound is determined by its molecular properties and by the nature and structure of the transport medium in its various possible sub-phases (e.g. water present as clouds in the atmosphere, or particles and colloids in water).

In order to be able to describe the distribution processes that take place in the real environmental situation, regarding this as a sort of global laboratory, one must have access to the necessary analytical methods which meet the requirements of the task with regard to detection sensitivity, resolution, reliability, and truly representative sampling. The capability to analyze complex mixtures of organic compounds down to extreme trace concentrations forms the essential basis on which to develop a global environmental chemistry encompassing a very wide range of substances.

A knowledge of how xenobiotics (man-made chemicals) become distributed in the environment provides the basis for a discussion of the occurrence and fate of such chemicals, and thus forms part of a study of 'ecotoxicokinetics' that can ultimately be looked at on a global scale.

Toxicokinetics is a branch of toxicology, and describes the processes of resorption, distribution, transformation and elimination that are undergone by a biologically active (toxic) substance within an organism. If we extend the concept of an organism by giving it global dimensions, which are, however, decidedly finite, and we then consider not only direct biological interactions but also, quite generally, all types of interference with the global system of equilibria, such a global 'chemokinetics' is only slightly removed from the conventional approaches of toxicokinetics. The essential difference is that, in such a global 'ecotoxicology', experiments to study the effects are ruled out, or are only possible to a very limited extent; instead one must study events that have already occurred and from these develop strategies for preventing future damage.

A fact that is often overlooked is that the level of a risk is defined as the product of the probability of an event and the amount of damage caused. Where the potential damage is global, only an extremely low occurrence probability can result in a normal (acceptable) risk. Eventually a stage is reached where the occurrence probability must approach zero. Preventing environmental damage is not an entirely new human endeavor—forest plantings to prevent avalanches were essential to safeguard lives in the Alps, as also were dykes on coasts—but the general experience has been that visible local dangers prompt action far more effectively than possible scenarios involving global catastrophe.

Environmental chemicals, apart from a few exceptions, are 'got rid of' on a local or regional basis through emission or by dilution (e.g. via fume extractors, vehicle exhausts, chimneys and by wind, and for liquids through effluent outlets or drainage channels or by rivers); alternatively they are taken up by the environment in a more diffuse and more complex way in the course of or following their use. In principle, therefore, if the basic physicochemical properties (water solubility, vapor pressure, melting point, K_{OC}, K_{OW}, K_{GW}, Henry's constant) and chemical properties (reactivity, decomposition products) of a compound are either known or can be predicted, one can forecast the regional and global mass transport processes that a compound undergoes in the atmosphere[16–20] and hydrosphere,[16, 21–24] and hence the expected long-term consequences of its release into the environment and the subsequent dispersion processes.[25, 26]

The processes whereby organic compounds are transported in the environment can be classified as follows:

Karlheinz Ballschmiter, born 1937 in Petershagen (Pomerania), studied chemistry at the University of Mainz, where, in 1966, he also gained his doctorate and a prize for the best Doctorand in Rheinland-Pfalz. After a two-year spell doing research at the Argonne National Laboratory in Chicago, he habilitated in 1971 in Mainz. In 1973 he moved to the University of Ulm, where at present he is full professor of analytical chemistry and environmental chemistry. In 1982, Ballschmiter received the Merckle Research Prize from the University of Ulm, in 1990 the Philip-Morris Research Prize from the Philip-Morris Foundation, and in 1990 the Fresenius Prize from the German Chemical Society. He is actively engaged in a number of working groups, among them the Advisory Committee on Existing Chemicals of Environmental Relevance (BUA), of the German Chemical Society. His areas of research include the systematic and applications-oriented problems of organic trace analysis and environmental chemistry, as well as investigations of the global occurrence and migration of environmental chemicals and the correlation of chemical structure and final fate of the chemicals.

1. Transport in the technosphere from the site of production to the place of use.
2. Transport in the hydrosphere (surface water, groundwater, lakes, tides, oceans).
3. Transport in the atmosphere (troposphere 0–10 km, stratosphere 10–50 km).
4. Transport in the lithosphere (by groundwater).
5. Transport in the biosphere (migrations of animals etc., food chains, incorporation into eggs and milk, incorporation into the fetus).

There is a continual interchange between mechanisms 2–5, and the transport in the troposphere and that in the upper layers of the hydrosphere, especially in the oceans, can mutually reinforce each other. The phase transitions in each direction involve complex physicochemical processes, and attempts are being made to describe these using simplified models.[8, 9, 14]

In this discussion, transport in the lithosphere (the soil and groundwater) will not be examined in detail. The surface of land, including vegetation, does not have a direct transport function, but rather acts as a local or regional 'source' (e.g., following pesticide spraying), as an intermediate 'store' (e.g., by absorbing a substance deposited from the atmosphere), or as a 'sink' in which a substance is ultimately retained. Groundwater , on the other hand, has a long-term function as a transport medium for environmental chemicals on a local or regional scale.[13, 15]

In trying to assess whether or not a given compound is distributed via a particular transport pathway, the chemist's experience in the laboratory regarding properties such as its water solubility, volatility, volatility in steam, or stability can often be misleading. In particular, descriptions such as 'soluble in water' and 'involatile' need to the reinterpreted when one is concerned with regional and global processes.

A clear and unambiguous classification of the dimensions of transport pathways or of areas of distribution is essential for addressing many problems. The relevant distances or surface areas determine whether one is dealing with a point source (e.g., a town or city), a ribbon-shaped source (e.g., a highway), an extended source (such as an industrial zone), or a diffuse release over a very large area (e.g., Europe, Japan, the USA). On a local scale a chimney stack is a point source, and the same description can also apply to a city, whereas on a continental scale one might even regard the Ruhr region or the industrial belt around Birmingham (UK) as point sources. With regard to the question of a point of measurement, especially for measurements in the lower troposphere, one can only expect to get representative and meaningful results from sources of extended area if the measurements are carried out over a sufficiently long period and are supplemented by further data (time of year, weather conditions, cyclical pattern of work activity, variation through the day). Conclusions can then be drawn regarding, for example, the covariance of emissions of different substances, such as C_1 and C_2 organohalogen compounds in an industrial region, or regarding the intrusion of pollutants into a 'clean air zone'.[27]

A classification into distribution areas of different scales—local, regional or global—is also often applied, although one cannot define rigid distinctions between these. An attempt at such a differentiation is shown in Table 1. Here the term 'national' may take on a special practical significance when considering the spread of a pollutant in the environment. National boundaries are often identical to transitions between zones or patterns of use, and they therefore define sources, without, however, hindering the spread of a compound.

Table 1. Transport on different scales regarding distribution of environmental chemicals.

Description	Distances [km]	Description	Distances [km]
Point	0 to 0.05	National	200 to 1000
Local	0.05 to 10	Continental	1000 to 5000
Regional	10 to 200	Global	5000 to 40000

If one regards the global distribution and transformation behavior of a compound as an experiment, and defines its boundary conditions in terms of appropriate questions, then, assuming that one has suitable analytical methods for measuring the extremely low concentrations present in the unavoidably complex mixtures, it is possible to investigate global environmental chemistry in a retrospective manner.

The study of the chemistry of substances in the environment, 'environmental chemistry', has previously been mainly the domain of physicists and biologists rather than of chemists. However, the concept of the whole planet as a chemical reaction flask is already a reality. The processes that go on within it must now be treated as an integral part of the science that we call chemistry.

2. Global Parameters for Characterizing the Uptake of Chemicals into the Environment

For compounds that are direct products of the chemical industry, including oil processing, some indications of the quantities that one can expect to enter the environment may be obtained from national, regional and global production figures and patterns of use.[28] For some groups of compounds, such as the chlorofluorocarbons (CFCs), the C_1 and C_2 chlorinated solvents, or the BTEX arenes (benzene, toluene, ethylbenzene and xylene), one can easily arrive at such estimates. However, as soon as one moves to the chlorinated ethanes, ethylenes, cyclohexanes, benzenes and biphenyls, compounds that are becoming increasingly important as tracers for studying global distribution pathways, only crude estimates of annual world production, past and present, are available. Also one can only make crude estimates regarding what fraction of the material produced (e.g., the chlorinated benzenes and chlorinated biphenyls) has already entered the environment, or how much can do so in the future. Moreover, nothing is known about the extent to which chemical wastes are disposed of by improper, if not criminal, methods on a regional or global scale; the size of the problem may be considerable, and can only be guessed at.

Emissions of environmental chemicals, which are quite generally correlated with industrial production and thus with the standard of living (e.g., emissions of solvents, detergents, and plasticizers), can be estimated from the annual gross national product of each country, if one assumes that

Table 2. Countries with an annual gross national product (GNP) greater than $ 100000 M or a per head product greater than $ 5000 (1984). [29]

Country	GNP		CO_2 emissions (1986)
	Total $ M	Per head $	Tons per head per year
Federal Republic of Germany	678880	11090	11.7
France	542960	9860	7.0
United Kingdom	480680	8530	11.8
Italy	367040	6440	
Netherlands	135830	9430	
Switzerland	105060	15990	
Sweden	99060	11880	
Canada	330870	13140	
USA	3670490	15490	20.0
Mexico	158310	2060	
Saudi Arabia	116380	10740	
India	197210	260	0.7
China	318310	310	2.4
Japan	1248090	10390	7.6
Brazil	227280	1710	
Australia	184980	11890	15.5

the industrial structure is nearly the same in each case. Table 2 lists the countries that had a gross national product (GNP) of more than $ 100 million or a GNP per head of more than $ 5000 in 1984.[29] The regions where there is substantial industrial production or is likely to be in the future are mainly distributed within a narrow belt in the northern hemisphere, lying roughly within the range 30–55° N. However, China, with approximately 25% of the world's population, would need to increase its GNP per head by a factor of 20–30 to catch up with the present levels in Europe and Japan. Even if one assumes a severe reduction in the rate of world population growth—which is rather unrealistic—the efforts being made by all the political forces to raise the overall GNP per head to that already achieved in the leading industrial countries could alone lead to enormous emissions of pollutants on a global scale.[29] The question of what sort of industrial civilization should be aimed at worldwide, or indeed can have a long-term future, is a very practical one. Can the European-Japanese-US model have a future in the global sense?

GNP is not an appropriate parameter for those chemicals which, although produced in the industrially advanced countries or based on their science and technology, are specifically made for use in other regions of the world, for example in crop growing (rice, maize, cotton, etc.) or in cattle rearing (agents for controlling ectoparasites, tsetse fly, etc.). For these compounds one can arrive at estimates regarding sources on the basis of the structure of the economy and a knowledge of the pattern of use and the regions affected. For example, despite all the prohibitions on the use of 4,4'-DDT (dichlorodiphenyltrichloroethane) in the USA and Western Europe, there has been no significant reduction in the world total production of this insecticide and its use against malaria; the main reasons are its relative cheapness, low toxicity to humans, and the growth of resistance in the insect populations.[30] Up to 1984, 4,4'-DDT and other organochlorine insecticides continued to be produced in the former GDR.

The emissions from diffuse sources (consisting of a multitude of small sources dispersed over a large area) are often underestimated. For example, in Germany alone about 250 tons of material in the form of fine particles is generated each day by abrasion of vehicle tires, making a total of nearly 100000 tons per year. The emission of carbon particles from diesel vehicles now stands at about 60000 tons per year. According to the Federal Office of the Environment in Berlin, the quantity of fuel evaporated during 1988 from the tanks of the approximately 30 million motor vehicles in the then Federal Republic of Germany, when either stationary or traveling, was 362000 tons. A further 46000 tons was evaporated during the refueling of vehicles. Multiplying these figures to correspond to a total of 300 million vehicles gives some idea of the expected global emissions.

In cases where no figures for production and use are available from official statistics, indirect but nevertheless reliable estimates can be calculated from the accumulation of the compounds in non-migratory birds,[31] in non-migratory fish present in rivers, estuaries or in lakes that have no outflow,[32] or which can be found as deposits on foliage, mosses or conifer needles[33] or in lake sediments.[34] Data from the estuaries of large river systems such as the Rhine, Elbe, Rhône, Nile, Volga, Ob, Lena, Amur, Huangho, Congo, Amazon, Rio de la Plata[35] or Mississippi[36] are especially valuable for the information they give about releases into their catchment areas from industrial production, agriculture and aqueous effluents. Menhaden oil, extracted from a plankton-filtering fish that swims in shoals and is of industrial importance, provides an almost ideal means of studying the pollutants burden carried by the warm layer of the Gulf Stream.[32] Similarly, the pollutants burden found in fish from the Caspian Sea gives unequivocal information about the uptake of persistent chemicals carried by the Volga and Ural rivers from the large industrial regions of the former USSR.[37] In cases where the input of a compound or group of compounds from distant sources can be estimated, it is a simple matter to determine the local or regional contribution.[27]

If the rate of uptake of a chemical into the environment cannot be directly estimated, but it is known that this occurs exclusively in the northern hemisphere, or the proportion in the northern hemisphere can be estimated, and if it can also be assumed to be predominantly retained in the atmosphere, then the uptake in the northern hemisphere can be calculated from the concentration in the troposphere of the southern hemisphere, provided that one knows the mean partial lifetimes τ_{phys} (physical translocations) and τ_{chem} (chemical transformations). Such estimates have been made for 1,1,1.2-tetrachloroethane, hexachlorobutadiene and other trace pollutants.[38] Using data for the southern hemisphere ensures that one can assume global mixing to have occurred. These considerations are not valid for compounds whose chemical and physical lifetimes τ_{chem} and τ_{phys} in the atmosphere are short, i.e. on the order of days or weeks, since the time required for movement to the southern hemisphere is typically about one year.

3. The Chemical Stability of Chemicals under Environmental Conditions

How far xenobiotics are transported depends on their physical properties and their chemical stability. For trans-

port to occur requires time. If a compound disappears from the transporting media (air and water) within hours or days through being physically extracted ("translocation") or through a chemical transformation, this sets a limit on the distance over which it is dispersed. Conversely, a global distribution is possible only if there is chemical stability.

The lifetime τ of a compound in a particular compartment of the environment is defined as the reciprocal of the rate of disappearance; thus Equation (1) defines:

$$\text{rate of disappearance} = \tau^{-1} \tag{1}$$

The overall rate is made up of two components [Eq. (2)]:

$$\tau_{total}^{-1} = \tau_{chem}^{-1} + \tau_{phys}^{-1} \tag{2}$$

For the environmental compartment consisting of the atmosphere, τ_{chem}^{-1} (chemical transformation) and τ_{phys}^{-1} (translocation) can each be subdivided into several terms, resulting in Equation (3):

$$\tau_{total}^{-1} = [\tau_{OH}^{-1} + \tau_{O_3}^{-1} + \tau_{NO_2}^{-1} + \tau_{H_2O}^{-1} + \tau_{h\nu}^{-1} + \tau_{therm}^{-1}] + [\tau_D^{-1} + \tau_R^{-1} + \tau_W^{-1}] + \tau_T^{-1} \tag{3}$$

τ_{OH}, τ_{O_3}, τ_{NO_2} and τ_{H_2O} relate to the reactions of the compound in question with 'OH radicals, ozone, NO_2 and H_2O respectively. $\tau_{h\nu}$ and τ_{therm} relate to photolysis and thermal decomposition (as in PAN, (peroxyacetylnitrate) for example), τ_D^{-1} relates to extraction by dry deposition, τ_R^{-1} to extraction in rainfall after particles have acted as condensation nuclei for water droplets in clouds including 'in-cloud' and 'below-cloud' scavenging ("rain-out"), and τ_W^{-1} to absorption in rainfall in the manner of a gas-scrubbing process ("wash-out"). τ_T^{-1}, which relates to extraction through being carried by the wind out of a geographically defined environmental compartment ("transport"). It corresponds to an uptake into a different environmental compartment.

For many compounds the parameters of Equation (3) reduce to a simpler situation, for example as expressed in Equation (4).

$$\tau_{total}^{-1} = \tau_{OH}^{-1} + \tau_D^{-1} + \tau_R^{-1} + \tau_T^{-1} \tag{4}$$

Here the only processes that remain are reactions with 'OH radicals, extraction in the form of particles (deposition plus rain-out), and removal by wind. For a hemisphere one can instead have Equation (5), which includes only the reaction with 'OH radicals and extraction predominantly by wash-out.

$$\tau_{total}^{-1} = \tau_{OH}^{-1} + \tau_W^{-1} \tag{5}$$

3.1. Transformations in the Troposphere

This description refers specifically to the component of the reciprocal lifetime τ_{total}^{-1} that includes chemical reactions. The chemical lifetime τ_{chem} is defined as the time during which the initial concentration c_0 decays to $c_0 e^{-1}$ [Eq. (6)], i.e. to 38.6% of the initial concentration:

$$\tau_{(x)} \equiv c_{0(x)} \rightarrow c_{0(x)} e^{-1} \tag{6}$$

The sum of all transformation reactions in the atmosphere is given by Equation (7):

$$-\frac{dx}{dt} = (k_{OH} c_{OH} + k_{O_3} c_{O_3} + k_{NO_2} c_{NO_2} + k_{H_2O} c_{H_2O}) c_x \tag{7}$$

Normally one can assume $k_{OH} c_{OH} \gg k_{O_3} c_{O_3}$, $k_{NO_2} c_{NO_2}$, $k_{H_2O} c_{H_2O}$ so that the chemical lifetime is essentially determined by the reaction with 'OH radicals. Alkenes are an exception, as their reactions with ozone and with 'OH radicals have comparable rates, i.e. $k_{OH} c_{OH} \simeq k_{O_3} c_{O_3}$.

The product $k_{OH} c_{OH}$ is often written instead in the form K_{OH} as expressed in Equation (8).

$$\tau_{x(OH)} = (k_{OH} c_{OH})^{-1} = K_{OH}^{-1} \tag{8}$$

Hydroxy radicals, which are responsible for the cold combustion of organic substances in the atmosphere, are formed mainly through the action of intense solar radiation on moist air, in which oxygen atoms in the singlet state $O(^1D)$ react with water. Other important mechanisms forming 'OH radicals are the reactions of peroxy radicals ($HO_2^{\cdot}$) with NO or O_3. Table 3 summarizes yet more reactions whereby 'OH radicals are formed.[39] The concentration of 'OH radicals, c_{OH}, fluctuates according to the radiation intensity and the concentrations of the various precursor species. In measurements carried out at Schauinsland in the Black Forest in June 1984, the hydroxy radical concentration increased from 1×10^6 molecules cm^{-3} at 8.00 a.m. to 7×10^6 molecules cm^{-3} at midday.[40] In Washington State (46° N, 117° W) in October 1987 the measured concentrations varied from less than $(0.25 \pm 0.05) \times 10^6$ molecules cm^{-3} in the morning and evening to $(2.9 \pm 0.5) \times 10^6$ molecules cm^{-3} at midday. By contrast, in a city atmosphere the midday concentration rose

Table 3. Formation of 'OH radicals in the atmosphere.

Basic reactions [a]		Source reactions [b]	
Educts	Products	Educts	Products
$O(^1D) + H_2O$	$2\,^{\cdot}OH$	$O_2 + h\nu$ ($\lambda < 242$ nm)	$2O(^1D)$

to $(10.1 \pm 3.3) \times 10^5$ molecules cm^{-3}.[40] A new method of measuring 'OH radical concentrations based on the reaction with SO_2 gives time-scale resolutions in the order of minutes, and is expected to greatly improve the detection capabilities for this important atmospheric trace constituent.[41]

According to a photochemical model that takes account of 45 distinct reactions as well as the temperature, pressure and solar radiation intensity, one can expect a globally averaged daytime 'OH concentration of 1.6×10^6 molecules cm^{-3}, compared with a night-time value of 0.013×10^6 molecules cm^{-3}, i.e. about a factor of 100 smaller than the daytime value.[39] In contrast to work by other authors, this model predicts a higher average value for the northern than for the southern hemisphere (0.85×10^6 and 0.78×10^6 molecules cm^{-3} respectively).[39] The average value for the entire troposphere is 0.82×10^6 molecules cm^{-3}. As a global average for the concentration of 'OH radicals in the troposphere a value of $(0.5 \pm 0.1) \times 10^6$ molecules cm^{-3} is generally assumed.[42]

The most important scavenging reactions that remove 'OH radicals from the troposphere are the reactions with CH_4 (Table 4) and with CO. Global variations in the concentrations of these two trace gases in the troposphere are at present the main cause of differences in the average concentration of 'OH radicals.[42]

Table 4. Breakdown of methane by 'OH radicals in the atmosphere, giving formaldehyde, carbon monoxide, and finally CO_2.

Educts	Products	Educts	Products
Breakdown of CH_4:		*Breakdown of HCHO:*	
$CH_4 + {}^{\bullet}OH$	$CH_3^{\bullet} + H_2O$	$HCHO + {}^{\bullet}OH$	$CHO^{\bullet} + H_2O$
$CH_3^{\bullet} + O_2 + M$	$CH_3O_2^{\bullet} + M^*$	$CHO^{\bullet} + O_2$	$CO + {}^{\bullet}O_2H$
$CH_3O_2^{\bullet} + NO$	$CH_3O^{\bullet} + NO_2$	$CHO^{\bullet} + O_2$	$CO_2 + {}^{\bullet}OH$
$CH_3O^{\bullet} + O_2$	$HCHO + {}^{\bullet}O_2H$	$HCHO + h\nu$	$H^{\bullet} + HCO^{\bullet}$
$CH_3O^{\bullet} + NO_2$	CH_3ONO_2	$(\lambda \leq 330$ nm)	
Breakdown of CO:		*Chain scission [a]:*	
$CO + {}^{\bullet}OH$	$CO_2 + H^{\bullet}$	${}^{\bullet}O_2H + {}^{\bullet}O_2H$	$H_2O_2 + O_2$
$H^{\bullet} + O_2 + M$	${}^{\bullet}O_2H + M^*$	$CH_3O_2^{\bullet} + {}^{\bullet}O_2H$	$CH_3OOH + O_2$
${}^{\bullet}O_2H + NO$	${}^{\bullet}OH + NO_2$		

[a] Chain scission results when the concentration of NO is very much smaller than the concentration of $CH_3O_2^{\bullet}$ and $H_2O^{\bullet}$.

The reaction rate constant k_{OH} may be either determined experimentally or calculated approximately from molecular data.[43] The average lifetimes of CFCs in the troposphere, together with their relative ozone depletion potentials (ODP) and greenhouse effect potentials (GHEP), are listed in Table 5. This illustrates the fact that it is necessary to take into account both the occurrence of a compound and its conversion products under environmental conditions. The data show that the compounds that are envisaged as replacements for the older CFCs do not yet unequivocally meet all the environmental requirements.

In Table 6 the values of k_x and $k_x c_x \equiv K_x$ for X = OH, O_3 and NO_2 are compared for several environmental trace compounds.[44] For propene the rates of breakdown by 'OH radicals and by ozone are about the same, and this applies to all alkenes, including the large class of the terpenes. Biogenic terpenes ('pine fragrances') have half-lives varying from minutes to a maximum of 24 hours in the troposphere.[43] In

Table 5. Average lifetimes τ_{OH} in the troposphere, ozone depletion potentials (ODP) and greenhouse effect potentials (GHEP) for various chlorofluorocarbons (CFCs). The abbreviations of the compounds envisaged as successors to the older CFCs are italicized.

[a] Set at 1 as reference substance.

contrast, polychlorinated terpenes (e.g., polychlorocamphors, toxaphene) are capable of worldwide distribution, a fact demonstrated as long ago as 1979.[45] 500 kilotons of toxaphene were produced between 1947 and 1977.

Table 6. Relative contributions of the reactions with 'OH, O_3 and NO_2 to the lifetime τ_{chem} for some trace organic compounds in the atmosphere [a] [44].

Cpd.	k_{OH} [b]	K_{OH} [c] $[10^{-6}s^{-1}]$	k_{O_3} [b]	K_{O_3} [d] $[10^{-6}s^{-1}]$	k_{NO_2} [b]	K_{NO_2} [e] $[10^{-6}s^{-1}]$
Butane	2.5	1.3	$<10^{-11}$	$<10^{-5}$	3.5×10^{-5}	5×10^{-3}

[a] $\tau_{chem}^{-1} = \tau_{OH}^{-1} + \tau_{O_3}^{-1} + \tau_{NO_2}^{-1}$; $\tau_{chem} = (K_{OH} + K_{O_3} + K_{NO_2})^{-1}$. [b] $k_{OH}, k_{O_3}, k_{NO_2}$ in $[10^{-12}\,cm^3$ molecules$^{-1}s^{-1}]$. [c] $K_{OH} = 5 \times 10^5\, k_{OH}$. [d] $K_{O_3} = 10^{12}\, k_{O_3}$. [e] $K_{NO_2} = 1.3 \times 10^8\, k_{NO_2}$.

As an example of a typical sequence of reactions in the breakdown of a hydrocarbon by 'OH radicals, Table 4 shows the breakdown of methane. This does not differ fundamentally from the chemistry of the methane flame. For other hydrocarbons too there are many similarities between the chemistry of atmospheric processes and that of flames, since the reacting species are in many cases the same.[46]

The main photooxidants, i.e. reacting species and reaction products involved in the breakdown of organic compounds by 'OH, ozone and NO_x, can be listed on the basis of earlier and more recent studies as follows: 'OH, ${}^{\bullet}O_2H$, $RO_2^{\bullet}$ (R = any organic group, not confined to alkyl), ozone, NO_2, $NO_3^{\bullet}$, N_2O_5, organic nitrates, H_2O_2, methyl hydroperoxide, peroxyacetic acid, peroxyacetyl nitrate, peroxynitric acid, peroxynitrates. Complex reaction cycles can arise, especially under the action of solar radiation; although advances are being made in our knowledge of these, many unanswered questions remain regarding the reaction products (photochemical smog).[42, 43]

In Table 7 an attempt has been made to assign some of the organic compounds that are found in trace concentrations to

Table 7. Classification of organic compounds according to their reactivity with 'OH radicals. The reactivity classes are defined in terms of lifetime τ in days d, k_{OH} in cm^3 molecules$^{-1}s^{-1}$.

Reactivity class	τ [d]	k_{OH}	Compounds
6	5×10^4	$<10^{-16}$–10^{-15}	tetrachloromethane (F10); trichlorofluoromethane (F11); dichlorodifluoromethane (F12); chlorotrifluoromethane (F13); tetrafluoromethane (F14); hexachloroethane
5	5×10^3	10^{-15}–10^{-14}	methane; 1,1,2,2,-tetrachloroethane
4	5×10^2	10^{-14}–10^{-13}	chloromethane; bromomethane; 1,2-dichloroethane; 1,1,1,-trichloroethane; 1,2-epoxyethane; acetonitrile; 1,2-dichloronitrobenzene
3	50	10^{-13}–10^{-12}	dichloromethane; chloroform; 1,2-dibromoethane; tetrachloroethene; isobutyl nitrate; chlorobenzene; 1,2-dichlorobenzene; 1,4-dichlorobenzene; 1,2,4-trichlorobenzene; nitrobenzene
2	5	10^{-12}–10^{-11}	benzene; toluene; ethylbenzene; biphenyl; vinyl chloride; trichloroethene; ethane; methanol; pentyl nitrate; CS_2; *N*-nitrosodimethylamine (DMNA)
1	0.5	10^{-11}–10^{-10}	formaldehyde; acetaldehyde; benzaldehyde; phenanthrene; acenaphthene; cyclohexene; hexachlorocyclopentadiene; styrene; *N*-nitrosodiethylamine (DENA); diethyl ether; chlorotoluidine; morpholine; chloraniline

classes of different reactivities, so that their potential for global distribution can be estimated from the values of τ_{chem} ($\simeq \tau_{OH}$). Table 8 indicates the spread of values predicted for τ_{OH} at two different 'OH radical concentrations for a selection of chlorinated C_1 and C_2 compounds.

Table 8. τ_{OH} for chloromethanes, chloroethanes and chloroethenes in days as a function of the 'OH radical concentration.

Compound	k_{OH} [a]	c^1_{OH} [b] τ_{OH} [d]	c^2_{OH} [c] τ_{OH} [d]
CH_3Cl	0.42×10^{-13}	600	120
CH_2Cl_2	1.4×10^{-13}	170	34
$CHCl_3$	3×10^{-13}	120	24
CCl_4	0.0016×10^{-13}	1.5×10^5	0.3×10^5
CH_3-CCl_3	0.12×10^{-13}	1900	380
CH_2Cl-CH_2Cl	0.65×10^{-13}	400	80
$H_2C{=}CHCl$	68×10^{-13}	3	0.6
$HClC{=}CCl_2$	22×10^{-13}	11	2.2

[a] k_{OH} in cm^3 molecule$^{-1}s^{-1}$. [b] $c^1_{OH} = 0.5\times10^6$ [molecule cm^{-3}]. [c] $c^2_{OH} = 2.5\times10^6$ [molecule cm^{-3}]. [d] $\tau \equiv c_o \rightarrow c_o e^{-1} = c_o \times 2.72^{-1}$; τ_{OH} in days.

For the chlorofluorohydrocarbons (CFCs) especially, the long lifetimes in the troposphere, which result in a uniform distribution in the stratosphere and in direct photolysis occurring there, lead to the well-known problems of absorption of thermal radiation and ozone depletion. In the long term it will be necessary to replace the CFCs now in use by alternatives such as F123 ($CHCl_2$–CF_3) and F114b (CH_3–CCl_2F). Both these compounds have a low ozone depletion potential and greenhouse effect potential (Table 5) with long lifetimes in the troposphere, estimated as 1.6 and 7.8 years respectively. For these compounds one expects a uniform global distribution as for 1,1,1-trichloroethane. In refrigeration engineering F12 (CCl_2F_2) is now beginning to be replaced by the fluorocarbon F134a (CH_2F–CF_3). The predicted lifetime of this compound in the troposphere is 15.5 years.

3.2. Transformations in the Hydrosphere and Ecosphere

In the hydrosphere, and also in the ground, xenobiotics undergo conversion not only by reaction with water (hydrolysis) but also, to an important extent, by microbiological breakdown (the "self-cleaning" ability of rivers and seas, and the formation of humus in the soil). The biological transformation of xenobiotics occurs mainly through co-metabolization by non-specific enzymes such as the monooxygenases or hydrolases,[47] and can sometimes come to a stop at one of the subsequent stages (secondary or tertiary persistence, as in the example DDT → DDE (1,1-dichloro-2,2-bis(4-chlorophenyl)ethene)), or can form other xenobiotics of different compound classes (e.g., chlorobenzenes → chlorophenols → chlorocatechols,[48] or chlorobiphenyls → chlorobenzoic acids[49]). Classic examples of biotransformations giving a more toxic product are the hydrodechlorination of trichloro- and tetrachloroethylenes in groundwater to give vinyl chloride,[13] and the conversion of thiophosphoric acid esters into phosphoric acid esters which act as choline-esterase inhibitors. In contrast to this, for chlorinated biphenyls and dibenzo-*p*-dioxins, persistence (*para*-recalcitrance: persistence of Cl_xB compounds with 4,4'- or 2,5-substitution, and of Cl_xDD or Cl_xDF compounds with 2,3,7,8-substitution (chlorinated dibenzo-*p*-dioxines/dibenzofurans)) goes hand-in-hand with biological activity.[4, 50]

The fact that, despite the existence of so many different biological and non-biological mechanisms for the breakdown of pollutants, many compounds are already present on a global scale, clearly shows the severity of the demands now being placed on the ecosphere with regard to the breakdown of xenobiotics. For some time now there has been speculation as to whether microbial transformation does not begin until a threshold concentration is reached.

4. The Concept of Multiphase Equilibrium Distribution

Any system, whether it is the global system consisting of the atmosphere, oceans, biota (living organisms) and the earth's surface or a microsystem such as a garden pond, can be divided into the four basic phases of air, water, lifeforms (e.g., cells) and earth (humus, sediments, rocks). For a molecule these basic phases correspond to different states of aggregation, namely the gaseous state, a solution in water, a solution in fat, or adsorbed on carbon compounds or on silicates. The atmosphere as a compartment of the environment is itself a multiphase system consisting of oxygen and nitrogen, particles with a bimodal size distribution, and water in condensed or solid phases (clouds, mist, rain, hail, snow). Similarly the compartment consisting of the oceans is actually a suspension of particles and colloids together with a multitude of biological subphases ranging from plankton to whales.

In such a multiphase system each molecular species becomes distributed throughout the various phases in different concentrations, determined by the condition that it has the same chemical potential in each phase, depending on its physical and chemical properties (e.g., vapor pressure, water solubility, octanol/water partition coefficient K_{OW}, bioconcentration factor BCF, adsorption coefficient in sediments K_{OC}, Henry's constant $H = P_0 S_{H_2O}^{-1}$, or in the form $K_{GW} = a_{air} a_{H_2O}^{-1}$ for partition between gas and water, and the reduced Henry's constant H/K_{OW} for partition between gas and octanol) (Fig. 1).

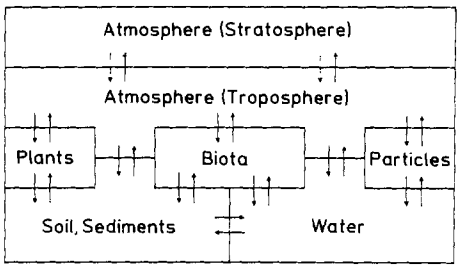

Fig. 1. Multiphase distribution of an environmental chemical in the environmental compartments ground, water, air and biota. The preference for a region is described as geo-, aquo-, aero- or bioaccumulation. For transport in the atmosphere and the hydrosphere, equilibria with the respective particulate phase play a central role.

For the basic phases air, water, ground (including sediments) and living organisms, compounds can be assigned, on the basis of their Henry's constants H, water solubilities, K_{OC} and K_{OW} values, to classes that have a preference for a particular phase and therefore accumulate in that region[51] (see Table 9). By applying multifactorial analysis it is found that for values of H greater than 22 $Pa\,m^3mol^{-1}$ the preferred environmetal compartment is the air for all values of K_{OW}. For $H < 2\ Pa\,m^3mol^{-1}$ either water or ground is the preferred phase, depending on the values of K_{OW}; there is a clear preference for water if $\lg K_{OW} < 4$, and for ground if $\lg K_{OW} > 5$.[52]

Table 9. Correlation between magnitude of physicochemical constants and preferential distribution of a compound between the four environmental compartments (air (H), water (S_{H_2O}), soil (K_{OC}), and biota (K_{OW}) [51].

Preferential concentration	Air H [$Pa\,m^3mol^{-1}$]	Water S_{H_2O} [$mol\,m^{-3}$]	Soil K_{OC}	Biota K_{OW}
low	$<10^{-3}$	10^{-3}	<1	$<10^3$
moderate	10^{-3}–1	10^{-3}–1	1–10^3	10^3–10^5
high	>1	>1	$>10^3$	$>10^5$

According to this concept of multiphase distribution, it is necessary to consider not only the processes of bioaccumulation and geoaccumulation but also aeroaccumulation (enrichment in the atmosphere) and aquoaccumulation (enrichment in the hydrosphere).

A knowledge of the mass fractions in a multiphase distribution, e.g., for a 1:1:1 system (Table 10), or for phase conditions approximating to those of the real world (the unit-world approach proposed by D. Mackay), provides important basic data with regard to the distribution in the environment.[53] Other authors have discussed similar models that are undergoing further refinement or have been applied to limited regions,[25, 26, 54] and models for the transport of xenobiotics to the arctic by air, snow and marine currents.[55]

Table 10. Equilibrium partition ratios of environmental chemicals between the environmental compartments air, water and solid phase according to Mackay level I [56].

Compound	Air [%]	Water [%]	Solid phase [%]	Preferred compartment
CCl_4	99.80	0.19	0.02	air
$CCl_2C{=}CCl_2$	99.45	0.40	0.15	air
hexachlorobutadiene	78.02	2.06	19.93	air, (solid phase)
pentachlorobenzene	48.10	2.10	49.81	air, solid phase
hexachlorobenzene	10.11	0.39	89.50	(air), solid phase
α-HCH [a]	0.28	50.67	49.05	water, solid phase
4,4'-DDT	0.40	0.42	99.18	solid phase
atrazine	0.01	93.15	6.84	water
nitrobenzene	30.49	68.04	1.47	air, water
3,4-dichloraniline	37.07	46.84	16.09	air, water, solid phase
phthalates:				
diethyl-	1.50	95.94	2.55	water
di-*n*butyl-	0.38	9.52	90.1	(water), solid phase
di(2-ethylhexyl)-[b]	1.62	4.74	93.65	solid phase

[a] HCH = hexachlorocyclohexane. [b] DEHP.

Mackay's unit-world model divides the world into 510×10^6 subunits.[53] An average static distribution among these subunits is then calculated, taking into account the phase volumes of atmosphere, biota and sediments (the oceanic system, with regard to its global share of the water phase, is not included), assuming that n moles of substance per year are released into the environment, and using an average value for the breakdown rate, so far as this is known. For example, if we assume that the global rate of release of DDT is 1.6×10^5 tons per year, this method predicts DDT concentrations of 6.2 $ng\,m^{-3}$ in the atmosphere, 5.5 $\mu g\,m^{-3}$ in water, and 0.25 $\mu g\,kg^{-1}$ in organisms. The values actually measured in the environment in air and water are less than these by about a factor of 10^3. The concentrations in fish living near the ocean surface are within about a factor of 10 of the predicted value, whereas for deep-sea fish the concentrations of 4,4'-DDT are greater by a factor of 10^4 (Table 11). These variations, even within the same basic phase, indicate that the unit-world theory gives only a partial description of the actual global distribution. At the same time the results listed in Table 11 illustrate that in practice there are wide differences between the patterns of distribution of individual compounds.[32, 57]

However, in developing theories of the global distribution of compounds one can assume values for their properties and calculate how these will affect the distribution between different environmental compartments. Nevertheless, such model calculations must always ignore the heterogeneity of the actual processes occuring in the atmosphere and oceans. The complexity and heterogeneity of environmental distribution processes can easily be appreciated if one considers an imaginary experiment in which water is regarded as a persistent environmental chemical. All molecules whose properties

are approximately the same as those of water will behave like it, whereas molecules that are unlike water will behave quite differently.

Table 11. Concentrations of organochlorine compounds in the liver of surface and deep-sea fish from the eastern part of the North Atlantic (Saõ Miguel (Azores) and Madeira). [58] All contents in micrograms per kg (ppb) based on fat.

Cpd.	Fresh water (rain) Lake Sete Cidades (Azores)		Salt water Coast (Azores)	Salt water Coast (Madeira)	Salt water Deep-sea (Madeira)

[e] ΣDDT = 4,4'-DDT + 4,4'-DDD + 4,4'-DDE + 4,4'-DDMU; 4,4'-DDD = 1,1-bis(4-chlorophenyl)-2,2-dichloroethane, DDMU = 2,2-di(4-chlorophenyl)-1-chloroethane. [f] Not quantified. Present (+) in the range 50–1000 $\mu g\,kg^{-1}$ (based on fat).

Figures 1 and 2 summarize in schematic form the phase equilibria, the different types of material transport and the physical and chemical removal of substances from the different compartments of the environment. This is a simplified model for the purposes of experimental studies; superimposed upon it in the real world are the climatic zones, the continents, the coasts and the currents flowing in the oceans and in the atmosphere. The approach that we have called the 'Ulm method' starts from observed data on the actual situation (compound distribution patterns and concentrations including their temporal and spatial changes) in representative regions within the global material flow, and sets out to understand these in terms of molecular properties and the basic geophysical processes. The guiding theme of our studies is to address the questions "which compounds?—how much?—where?—why?"[57]

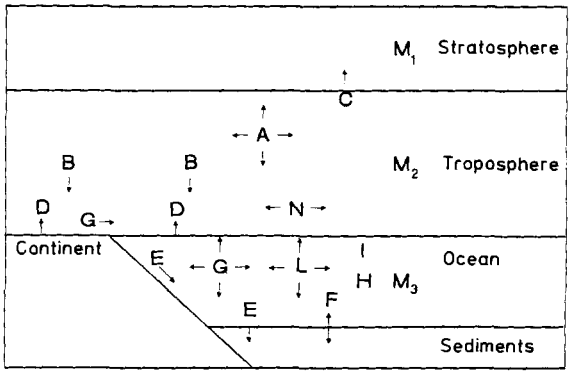

Fig. 2. Parameters of the global distribution of molecules. The following terms collate transport and transformation of an environmental chemical on a global scale: A = transport term (air) $\approx p_o$, K_{OH}^{-1}, $K_{h\nu}^{-1}$, K_{OW}^{-1}, $S_{H_2O}^{-1}$; B = deposition term (air) $\approx S_{H_2O}$, K_{OW}, K_{OC}, p_o^{-1}; C = extraction term stratosphere $\approx p_o$; D = evaporation term (water) $\approx p_o$, p_{H_2O}, K_{OW}^{-1}, $S_{H_2O}^{-1}$; E = sedimentation term $\approx K_{OW}$, K_{OC}, $S_{H_2O}^{-1}$; F = retention term sediment (geoaccumulation) $\approx K_{OC}$, K_{OW}; G = transport term (water) $\approx S_{H_2O}$; H = biotransformation term; I = retention term biophase (bioacccumulation) $\approx K_{OW}$; L = transport term biophase; M = transformation term (abiotic) $\approx K_{h\nu}$, K_{OH}, K_{O_3}, K_{NO_2}, K_{H_2O}, K_{therm}; M_1: stratosphere, M_2: troposphere, M_3: ocean; N = transport term, international commerce.

5. Global Dilution Volumes and Mass Transport

Substances that are released from the belt containing the industrial countries of the northern hemisphere, and become uniformly distributed throughout the world in accordance with their various partition constants Kp_i, have access to the following volumes and surface areas in which dilution and/or retention can take place (see Table 12).[18, 19, 21, 22]

Table 12. Areas, volumes and mass flows in the global context [21]. N = north, S = south; see also Table 13.

1. *Areas* [m^2]		2. *Volumes* [m^3]	
Surface area of the earth	510×10^{12}	Troposphere 0–11 km [a]	5.62×10^{18}
Land area	148×10^{12}	Segments: 0–30°N(S); 30–90°N(S) [b]	1.41×10^{18}
Total ocean surface area	362×10^{12}	Oceans (total)	1.350×10^{18}
Oceans in the northern Hemisphere	155×10^{12}	Pacific Ocean	0.696×10^{18}
		Atlantic Ocean	0.323×10^{18}
Oceans in southern Hemisphere	207×10^{12}	North sea	0.000054×10^{18}
		Baltic sea	0.000023×10^{18}
Pacific Ocean	166×10^{12}		
Atlantic Ocean	84×10^{12}		

3. *Annual evaporation and precipitation into the oceans* [$cm\,year^{-1}$] [63]

	Evaporation	Precipitation	Difference
Atlantic Ocean	104	78	−26
Indian Ocean	138	101	−37
Pacific Ocean	114	121	+7
Arctic Ocean	12	24	+12
All oceans (average)	125	112	−13

Volume evaporated from oceans	$440 \times 10^{12}\ m^3 year^{-1}$
Volume evaporated from land areas	$70 \times 10^{12}\ m^3 year^{-1}$
Total water in the troposphere (global)	$13 \times 10^{12}\ m^3$

[a] Normalized to STP $3.16 \times 10^{18}\ m^3$, weight 40×10^{20} g. [b] Normalized to STP $0.79 \times 10^{18}\ m^3$.

1) The atmosphere: The atmoshere close to the earth consists of the troposphere (0 to 10 km), with a volume of $5.62 \times 10^{18}\ m^3$, and the stratosphere, with a volume about four times greater, these two regions being separated by the tropopause (Fig. 3). The stratosphere extends to about

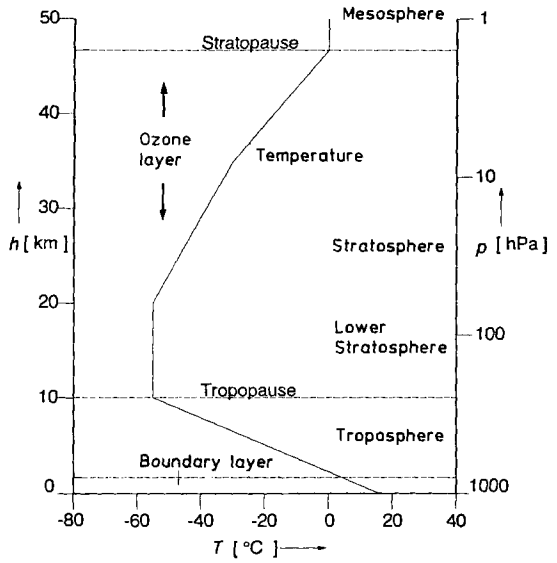

Fig. 3. Schematic representation of the vertical structure of the atmosphere. In the tropics the troposphere, as a region of rapid global mixing processes, reaches an altitude h of 14–16 km, at the Poles of 8–10 km. At middle latitudes (40–50°) it is changeable with diffuse transition to the stratosphere. The boundary layer between the two parts of the lower atmosphere (tropopause) is characterized by a temperature increase, the effect of which, corresponds to inversions in the neighborhood of the earth's surface. The ozone layer in the stratosphere at an altitude of 20–50 km, with a maximum ozone concentration on average at an altitude of 35 km, acts as UV filter. The absorption of radiation leads to an increasing temperature T at higher altitudes in the stratosphere.

50 km. If the volume of air in the troposphere is normalized to STP (standard temperature and pressure) one obtains a value of 3.16×10^{18} m^3. On the basis of the overall circulation consisting of the global wind system, the general circulation, it is useful to divide the troposphere into four roughly equal zones defined by the latitudes 0 to 30° N, 30 to 90° N, and the same in the southern hemisphere, containing circulating air masses that exchange with each other over well-defined time intervals (Fig. 4).

The stratosphere (10–50 km) is a space in which dilution occurs, and for most organic molecules it acts as a sink owing

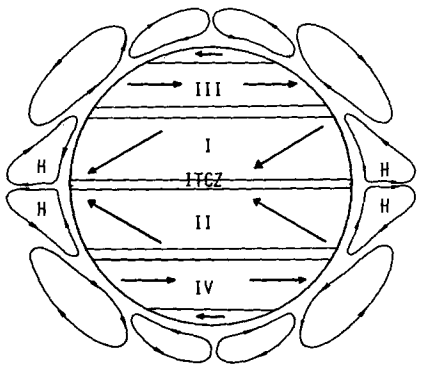

Fig. 4. Schematic representation of global circulation (general circulation) in the troposphere: I north-east tradewind, II south-east tradewind, III northern west-wind belt, IV southern west-wind belt. The climbing air in the intertropic convergence zone (ITCZ) forms, as a low-pressure channel, a distinct boundary layer between the northern and the southern hemisphere. The tradewind regions and the west-wind belt are separated by the so-called horse latitudes over the oceans; this boundary is wave-shaped. Thus, air pockets from the west-wind belt reach into the tradewind region. The indicated vertical movements of air round the circle which symbolizes the earth are here highly exaggerated. On scaling the globe down to a diameter of 1.2 m, the troposphere would form a layer of only ca. 1 mm thick.

to photolysis and reaction with triplet-state oxygen. Even for F12 (CF_2Cl_2) the quantity present on entering the stratosphere becomes reduced to 1% of this value after 40 km.[59] Only CF_4 is completely stable from 0 to a height of 34 km. The main source of CF_4 is aluminum production but it is also commericially available; from an environmental standpoint it is the most stable organic compound made by man.

2) The oceans: The total volume of the oceans is 1.35×10^{18} m^3, of which more than half is accounted for by the Pacific ocean (0.70×10^{18} m^3) The mean depth of the hydrosphere is 3790 m, that of the oceans alone is 4700 m. The volume of the oceans is about a quarter of that of the troposphere. 71% of the earth's surface is covered by sea. The portions of the ocean's surface in relation to the global wind system are: trade wind region 30%, west-wind belt 24%, horse latitudes 20%, intertropical convergence zone (ITCZ) (doldrums) 8%. All other regions sum up to 18%.

3) The ground: The earth's total land surface is 148×10^{12} m^2, of which 10% (14.8×10^{12} m^2) is used for agriculture. If one assumes that the depth to which penetration and exchange occurs is 50 cm, this gives a global dilution volume of 74×10^{12} m^3, of which 7.4×10^{12} m^3 is under cultivation.

For the ocean beds we may assume a penetration depth of 1 cm (since 1–4 mm of sedimentation occurs in 1000 years), giving a dilution volume of only 3.6×10^{12} m^3, which is virtually negligible; consequently one expects to find here the highest concentrations of those environmental chemicals with an affinity for soil that enter the oceans (see HCB, PCB and DDT in Table 11). The deep sea floor is no sink for organic chemicals as the benthic fauna reuses all available organic carbon compounds.

To a first approximation the volumes of the three main compartments available to environmental chemicals are in the ratio 10^6 (troposphere) to 0.25×10^6 (oceans) to 1 (ground). Particular environmental chemicals that show a nearly ideal global distribution as a result of their stability and volatility are the chlorofluorocarbons (CFCs)[60] and tetrachloromethane.[61] The quantities of these that have been released into the environment have become equally distributed between the northern and southern hemispheres ($C_{SH}/C_{NH} \simeq 1$), and the amounts present in the surface waters of the open sea correspond to the partition between the gas phase and the water phase that one expects from the value of K_{GW}.

Whenever the observed concentrations of a substance differ from the equilibrium values expected from the theoretical partition ratios (K_{GW}, K_{OW}, K_{OC}), this means that one phase is enriched and the other is depleted. Since these deviations must be regarded as resulting from globally integrated partition coefficients, they can give valuable information about the actual situation within the corresponding environmental compartments, and thus about real transport phenomena in the global mass flow and the presence of sources and sinks in the atmospheric and oceanic systems. For some halomethanes one finds a non-equilibrium distribution that does not correspond to that expected from the equilibrium partition constants K_{GW}, whereas for tetrachloromethane an equilibrium distribution is observed; this confirms that the upward convection currents off the coast of West Africa due to their increased primary production act as a source of these compounds, including chloroform.[7, 38]

The mass flows that take place during continental and global mixing processes in the atmosphere and hydrosphere are difficult to comprehend, and can only be expressed in terms of many powers of ten. Even for a regional air movement on a front that is 100 km wide and 1000 m high—nothing unusual in weather terms—100×10^9 m^3 of air, with a mass of 126 million tons, is moved for each kilometer of the path.

The mass of the troposphere (0–10 km) in one hemisphere is about 40×10^{14} tons, and the volume in the bottom 3000 m is 1530×10^{15} m^3. To produce in this a global concentration of 1 ng m^{-3} one would need only 1.53×10^3 tons of a substance. For many compounds a concentration of 1 ng m^{-3} can be measured without difficulty using modern analytical methods (optimizing enrichment and detection).

In 1976 alone, the total quantity of the chlorofluorocarbons $CFCl_3$, CF_2Cl_2 and CHF_2Cl (Freons) produced was 822×10^3 tons. These volatile and stable compounds become uniformly distributed throughout both hemispheres before being broken down by photolysis in the stratosphere, with all the consequences, much discussed in recent years, that this entails for the ozone layer there.[64] Because of the structure of our earth, there is nowhere else that CFCs can finally end up other than in the stratosphere. As an alternative sink for CFCs one might consider incorporating them into air used for high-temperature combustion processes (e.g., of coal, oil, petrol, diesel fuel, or incinerated wastes). In the long term such "anthropogenic" sinks could become important locally or regionally for removing stable CFCs that diffuse back from the stratosphere. A sink in the troposphere, whereby a substance is destroyed with the formation of decomposition products, can only be relevant for compounds whose lifetimes τ_{OH} in the troposphere are in the range 0.5 to 2 years as the upper limit (Table 5).

Table 13 summarizes the volumes transported by the most important ocean currents. These data are important when assessing the global flows of environmental chemicals. When one considers the global volumes available for dilution, which are in the ratio 4:1 for the atmosphere and the oceans, and also bears in mind that for many persistent and bioaccumulating environmental chemical (e.g. HCH, HCB, Cl_xB, DDE) the concentrations found are 1 in 100 or higher in volume terms, the importance of the flow of materials in the oceanic system becomes obvious. The time dimensions of the transport processes in the two compartments are different, but are of the same order of magnitude (Table 14).

Table 13. Transport of water by ocean currents [12]. N = north, S = south, W = west, E = east.

Current	Direction of flow	Flow rate [10^6 m^{3}s^{-1}]	Current	Direction of flow	Flow rate [10^6 m^{3}s^{-1}]
Gulf Stream (40° N)	NE	75–115	Peruvian current	N–NW	20
Canaries current	S	15	Pacific equatorial undercurrent	E	30–40
Kuroshio current (North Pacific)	NE	40–50	West wind drift (Antarctic current)	E	150–180
Eastern Australia current	S	30–45			

Table 14. Time-scales of various transport-processes in the atmosphere and the oceans.

Atmosphere	$\bar{v}$ [a]	t [b]	Hydrosphere (Oceans)	$\bar{v}$ [a]	t [b]
Storm	80 km h^{-1}	0.5 d	Surface currents	0.80 m s^{-1}	15 days
Moderate breeze	20 km h^{-1}	4 d	Deep currents	0.01 m s^{-1}	3 years
Depression or anticyclone	300 m h^{-1} (vertical)	–	Upward convection	3 m year^{-1}	–

[a] Average velocity. [b] Time required to travel 1000 km.

If the escape of xenobiotics into the global dilution space is impeded, either temporarily (e.g., by local or regional meteorological inversion conditions in the bottom layer of the troposphere) or permanently (as in inland seas such as the Baltic or Mediterranean), the increase of concentration in these environmental compartments proceeds at a time-lapse.

6. Transport from the Site of Production to the Place of Use

The movement of organic compounds by humans in the course of worldwide economic activities, an aspect of their introduction into the environment that belongs to the technosphere, can only be very crudely quantified; nevertheless, it makes an important contribution to the process of distribution into the environment. This form of transport can be superimposed on the natural distribution processes, as, for example, when the main regions in which 4,4′-DDT is used shift from the northern to the southern hemisphere, or when the use of a pesticide alters in response to long-term or temporary changes in the regional distribution of the target species (as in the case of Dieldrin for locust control), or when its population declines. Such changes shift the release point (or rather the release zone) from which the natural distribution processes start. Moreover, the transportation routes themselves have the potential to become point sources for release into the environment. The tanker accidents that appear so often in the news are just one example. Seasonal variations in the use of a compound or in its release to the environment can have significant effects on a global scale.

In many cases a knowledge of the agricultural land use (e.g., forestry, or a predominance of either crop-growing or cattle-rearing) or of the industrial structure of a region (e.g., coal-mining, oil or gas extraction, metals production, or the various types of chemical industries) can indicate the extent to which particular xenobiotics (solvents, plasticizers, raw materials, wastes, pesticides, etc.) are likely to be continuously transported in and eventually released into the environment.[65]

For the insecticide hexachlorocyclohexane (HCH) it is possible to verify such predictions, since the products used in the northern and southern hemispheres are of different constitution. In the northern hemisphere the product made and used in the largest quantities is the isomer mixture obtained by photochlorination of benzene (known as technical HCH or BHC, benzene hexachloride), of which γ-HCH (lindane) is the main insecticidal component and which contains about 60% α-HCH; pure γ-HCH is used to a lesser extent. On the other hand, in the southern hemisphere (Argentina, Aus-

tralia, New Zealand) only lindane is used in significant amounts. The exchange between the northern and southern hemispheres can be monitored relatively easily by measuring the ratio of the α/γ-HCH isomers in the atmosphere[66] and in the oceanic system (both water and fish).[67] Measurements in the lower troposphere at Réunion in the Indian ocean show that the transfer of α-HCH into the southern hemisphere only takes place very slowly. As similar results are found for hexachlorobenzene,[68] whose main source is definitely in the northern hemisphere, one must assume that for all semivolatile chlorohydrocarbons the interhemisphere exchange in the troposphere occurs only slowly.[66] The barrier responsible for this is the tropical rain belt (20° N to 20° S), where τ_R and τ_W reach their minimum values, so that their reciprocals, which determine the deposition rate, are at a maximum. For γ-HCH, as also for chlorinated biphenyls

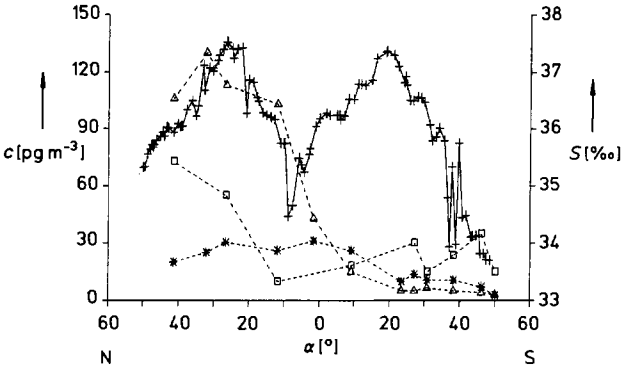

Fig. 5. North/South distribution of the concentration c of α- and γ-hexachlorocyclohexane (α-HCH: Δ, γ-HCH: *) and hexachlorobenzene (HCB: □) in the lower troposphere above the Atlantic Ocean (measurements by FS Polarstern-Ant. IX/1). The intertropic convergence zone (ITCZ) forms a distinct barrier to the entry of α-HCH and HCB in the southern hemisphere. Extraction from the troposphere takes place in the tradewind region over the North Atlantic following increased precipitation, which is indicated by the decrease in salinity (+) of the surface water. N = north, S = south, α = latitude, S = salinity.

(PCBs), there is a nearly uniform distribution in the troposphere above the Atlantic as a result of uptake into both hemispheres (Fig. 5).[68]

7. Molecular and Particle-Mediated Transport in the Atmosphere and Hydrosphere

For environmental chemicals that are equally stable the dimensions of their respective transport pathways are determined by the physics of the transport processes and the relevant removal mechanisms for the transport medium concerned (air or water), and thus by the distribution characteristics expressed by the physical lifetime τ_{phys}. If transport in the environment occurred solely in molecular-dispersed forms involving ideal gases and true solutions, it could be described in terms of the global volume flows in the atmosphere (general circulation and rainfall distribution) and hydrosphere (ocean currents) from a knowledge of the equilibrium partition constants Kp_i. However, for both transport compartments the organic compounds present in air and water undergo a constant exchange between molecular-dispersed forms and adsorption on particles or colloidal association (see Fig. 1). Compounds adsorbed on particles travel much shorter distances than when transported in molecular form in air or as solutions in water, due to both dry and wet deposition processes, both in the atmosphere and through sedimentation in the hydrosphere and bioincorporation as nutrients in the biosphere.

The fraction ϕ of a compound that exists in adsorbed form in water or air depends on the equilibrium partition coefficient Kp and on the volume fraction V_{part} of the particle phase as expressed by Equation (9):

$$\phi = Kp\,V_{part}(1 + Kp\,V_{part})^{-1} \quad (9)$$

Particle concentrations in the atmosphere above continents are typically in the range 10–100 $\mu g m^{-3}$, giving values for V_{part} of 5×10^{-12} to 50×10^{-12}. In clean marine air V_{part} is typically about 0.5×10^{-12} (Table 15). In the surface water of the open sea V_{part} can have values as high as 5×10^{-8}, corresponding to a particulate content of 100 $mg m^{-3}$ (Table 16).

Table 15. Particulate concentrations in the lower troposphere in marine [68, 80] and continental [81] locations.

Marine air [a]	Particulate concentration [$\mu g m^{-3}$]	Continental air	Particulate concentration [$\mu g m^{-3}$]
North Atlantic (middle)	6.71 ± 4.24	Swiss Alps (1550 m)	12.6 [b]
South Atlantic (middle)	9.06 ± 5.25	Rural air (940 m)	25.0 [c]
Pacific (28° N–40° S)	8.44 ± 5.14	Average for 46 cities [d]	79
Indian Ocean	3.52 ± 1.10		
Mediterranean	6.98 ± 2.92		

[a] Concentration of organic carbon (TOC) in marine aerosols (Bermuda) lies between 0.15 and 0.47 $\mu g m^{-3}$. [b] Majority of particles have a diameter less than 1 μm. The values for the measured particulate contents lie in the range 0.51–35.5. [c] Majority of particles have a diameter smaller than 1 μm. Measured values of particulate content lie in the range 5.2–74.4. [d] Measurements carried out in 1975.

In assuming Kp values for adsorption from the atmosphere it is unnecessary to a first approximation to make a correction for the nature of the particles, for example as regards their organic carbon content.[69] For adsorption on sediments, however, a correction is made for the organic carbon content OC, and thus $Kp = f(OC)$. On the other hand the enrichment of, for example, chlorinated biphenyls (Cl_xB) and of aromatic hydrocarbons with two to four rings on suspended particles in the water column follows the simple relationship $c_{part} = K'_p C_{solution}$.

The coefficients K'_p appear not to be correlated with K_{OW}.[70] The build-up of different chlorinated biphenyls on suspended particles was found to take place in the same proportions as their relative concentrations in solution. It was only when the sediments were analyzed that the expected enrichment in the more highly chlorinated PCBs, corresponding to the increase in the K_{OW} values ($K''_p = f(K_{OW})$), was observed.[70]

The extraction of compounds from the multiphase atmospheric system by particles (aerosols) and condensed and solid water phases (fog, spray, rain, hoar-frost, snow) has been very thoroughly studied.[55, 71–75]

The adsorption of gases in multimolecular films is described by the Brunauer–Emmett–Teller (BET) equation [Eq. (10)].

$$\frac{n}{n_\infty} = \frac{bp}{(p^0 - p)[1 + (b-1)p/p^0} \tag{10}$$

This contains the temperature dependence of the adsorption in the form of the vapor pressure p at the temperature T. However, differences in the aerosol surface area per unit volume are only taken into account indirectly via the ratio between the actual surface coverage n [$g\,cm^{-2}$] and the coverage n_∞ needed to give a monomolecular film (b is a numerical parameter).[76] The original BET equation as formulated in 1938 was subsequently put into a more convenient form by C. E. Junge.[69] By making certain simplifying assumptions he arrived at the following expression [Equation (11)] for the adsorbed fraction ϕ of a compound in the atmosphere as a function of the vapor pressure P^0 [Pa] and the available aerosol surface per unit volume θ [cm^2cm^{-3}]:

$$\phi_T = \frac{c\theta}{p^0 + c\theta} (T = \text{constant}) \tag{11}$$

The constant c is a function of the molecular mass, the heat of condensation, and a contribution to the adsorption interaction that is specific to the substance. For physisorption the latter term can be regarded as essentially constant for a wide range of compounds. An average value for c is about 17.2 Pa cm.

From experimental measurements of ϕ for several chlorinated biphenyls (Cl_xB) the specific surface area θ in $cm^2\,cm^{-3}$ can be calculated using the Junge equation [Eq. (11)]. Measurements of $\phi(Cl_xB)$ in the city environment of Ulm and in a forest area in the Schwäbische Alb gave values of $3-6\times10^{-6}$ cm^2cm^{-3} for city air and $1-4\times10^{-6}$ cm^2cm^{-3} for forest air.[77] These results are in agreement with the average values usually calculated for city and rural air from the quantities of aerosols present. For pure air regions the values found for θ are less than 1×10^{-6} cm^2cm^{-3}.[55, 69, 78] For $p^0 = c\theta$ the equation gives an equal partition between the gas and particle phases; the vapor pressure needed to achieve this in 'pure' air is about 1.7×10^{-5} Pa. Pankow and other authors have discussed the molecule-specific parameters of the Junge equation [Eq. (11)], and their findings support Junge's approach.[79]

For solids it has been shown experimentally that p^0 in Equation (11) is best expressed in terms of the vapor pressure p_L^0 existing above the supercooled melt.[72] p_S^0 and p_L^0 are related by Equation (12):

$$\ln(p_L^0 p_S^{0-1}) = S_F(T_m - T)/RT \tag{12}$$

Here T_m is the melting point and T is the temperature of the environment in Kelvin; S_F is the entropy of fusion; an average value of S_F/R is 6.79. For 2,3,7,9-tetrachlorodibenzodioxin (m.p. 305 °C) the vapor pressure p_L^0 above the supercooled melt is 745 times greater than the vapor pressure p_S^0 above the solid substance. Such differences are crucial in determining whether transport in the atmosphere is molecular or particle-mediated, and thus whether the scale of it is regional to continental or only local.[4]

If the ratio of the adsorbed fraction ϕ to the total amount is known, and it is assumed that an aerosol particle remains in the troposphere for an average period of a days, the physical lifetime τ_{D+R} is given by the simple expression in Equation (13), which takes into account the fall-out by both dry

$$\tau_{D+R} = a\phi^{-1} \tag{13}$$

and wet deposition. The average retention time of aerosol particles in the lower troposphere is 7 days, with a range of 2 to 20 days depending on the diameter.[69] For aerosols generated in the sea the average retention time is 1.5 days.[80]

The lower the vapor pressure of a compound and the greater the available aerosol surface, the greater will be the fraction adsorbed. For the insecticide 4,4′-DDT with a vapor pressure of only 4.5×10^{-6} Pa (at 20 °C) the adsorbed fraction for "pure" air is 20%, which means that 80% of the DDT is distributed as molecules in the gas phase. These values become meaningful when one compares the measured background burdens with the saturation concentrations. 4,4′-DDT has a saturation concentration of 1.9 $\mu g\,m^{-3}$ corresponding to the vapor pressure of the solid compound, compared with the experimentally observed concentrations of 1 to 10 $pg\,m^{-3}$ in the atmosphere. Thus the concentrations of 4,4′-DDT in the atmosphere only amount to about $1/10^5$ of the saturation concentration. If instead one takes the saturation concentration as that above the supercooled melt, corresponding to p_L^0, which is greater, the ratio of observed concentration to that at saturation is even smaller. For polychlorobiphenyls (PCBs, Cl_xB) the corresponding values for ϕ are around 0.01, which means that under clean air conditions 99% of the Cl_xB molecules in the multiphase system of the troposphere are in the gas phase. Even for city air that is heavily burdened with aerosols, the proportion of Cl_xB in the gas phase is still about 50%. These calculations apply for temperatures in the range 20–25 °C. However, when one takes into account the fact that the average temperature over the first 4000 m of the troposphere is −11 °C, the partition ratio is considerably shifted in favor of the adsorbed phase. Wet deposition (rain-out), which occurs when the particles act as condensation nuclei for water droplets which subsequently form rain, can then become an important extraction mechanism. As will be shown later, each raindrop is formed from about 10^6 cloud droplets, which means that at least 10^6 condensation nuclei loaded with absorbate are present in a single raindrop. Convection rainfall can also arise, for example from the melting of ice particles that have been formed by cooling to −25 to −50 °C at altitudes of 10–12 km.[82]

For any sufficiently complex mixture of compounds that belong to the same class and have vapor pressures and water solubilities differing over a range of several orders of magnitude, such as the chlorinated biphenyls (209 compounds), the chlorodibenzofurans (135 compounds), or the chlorodibenzodioxins (75 compounds), the Junge equation defines the range of properties that will lead to different partition ratios in the atmosphere. The condition $\phi \simeq 0$ corresponds to the fully molecular-dispersed state (the "all-off" state with negligible adsorption), whereas $\phi \simeq 1$ corresponds to the fully particle-dispersed state ("all-on"), with nearly complete adsorption). In the intermediate region, for related compounds

whose vapor pressures are sufficiently different (e.g., Cl_xB, Cl_xDF, Cl_xDD, $x = 1-2$, $7-8$) there can be a reversal of which of the two states (gas phase or adsorbed phase) predominates. This leads to differences in composition in the retained material (in the atmosphere) and in the fall-out (rain, fog, hoar-frost, snow). This effect has been demonstrated experimentally for polychlorinated biphenyls (Cl_xB) in city areas.[75, 83] In this environmental compartment the particle surface area per unit volume reaches 5×10^{-6} cm^2cm^{-3} or more, and at low temperatures (0–10 °C) this is sufficient to cause differences that result in a depletion of the less volatile chlorohomologues in the atmosphere. In clean marine air at sea level with a temperature of 28 °C (measured at Réunion in the Indian ocean) the distribution of PCBs in the atmosphere is typical of an "all-off" situation. The data listed in Table 15 for particle concentrations in the lower marine atmosphere show that in oceanic regions there are only small global variations. The results found at Réunion thus appear to be of general validity.

On a global scale one would expect that the numerous preferential transport processes, summarized in the global partition equation (Fig. 2), should result in a preponderance of the more volatile PCBs in the lower troposphere. If one assumes that the main source of PCBs is a belt extending from 40° N to 60° N, then as one moves from north to south across the Atlantic Ocean, with only a small change in the concentration in the lower atmosphere, no significant increase in the proportion of the more volatile trichloro- and tetrachlorobiphenyls (e.g., PCB 28 and PCB 52) is found in the more southerly latitudes (Fig. 6).[68] The expected enrichment in the less highly chlorinated compounds is only found when one compares the atmosphere above the Eastern Atlantic with that in central Europe (the Schwäbische Alb region in Germany), in samples in which the sum of the concentrations of all the PCBs is about the same. The concentrations of Cl_xB compounds for $x = 3$ to 7 in the lower atmosphere over the Atlantic show identical trends (Fig. 6).[68] However, their rise and fall is not directly correlated with the temperature of the surface water but with its particulate content, as

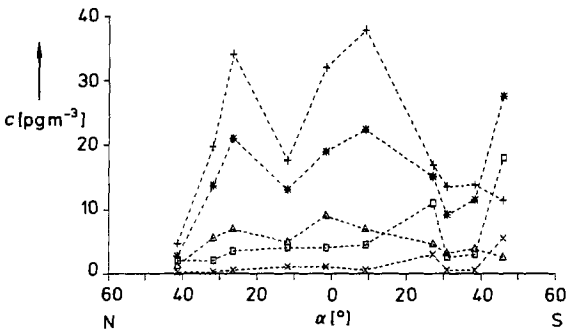

Fig. 6. North/South distribution of the concentration c of chlorinated biphenyls (Cl_xB) 2,4,4'-Cl_3B (PCB 28: Δ), 2,2',5,5'-Cl_4B (PCB 52: +), 2,2',4,5,5'-Cl_5B (PCB 101: *), 2,2',4,4',5,5'-Cl_6B (PCB 153: □) and 2,2',3,4,4',5,5'-Cl_7B (PCB 180: x) in the marine ground layer over the Atlantic ocean measured during a voyage of the FS Polarstern from Bremerhaven to Punta Arenas (Ant IX/1). The profile of the concentrations of PCB 28, 52 and 101 follows the salinity of the surface water. The increase in concentration of PCB 101, 153 and 180 at 48° South results from the extraction of such from the oil-producing areas of South Chile. The often postulated increase in concentration of readily volatile Cl_xB with increasing southern latitude could not be confirmed.

determined by the primary production processes, and with its salinity, as controlled by evaporation and precipitation.

The constancy of the marine PCBs distribution pattern makes it possible to obtain an indication of the amounts of PCBs released from industrial activities (mainly oil production) in the southern parts of Chile and Argentina. These releases are dominated by the more highly chlorinated PCBs with around 60% chlorine content (PCB 153 and PCB 180). Some indications regarding these regional inputs of highly chlorinated PCBs into the South Atlantic from industrial sources had already been obtained from the burdens found in the eggs of the various species of penguins that breed in the Falkland Islands and live at other times in a variety of habitats, including the open sea and the coastal regions of Patagonia.[84]

It is generally believed that in sea water the dissolved molecular fraction is the dominant form, even for compounds such as the PCBs, despite the fact that these are said to be "insoluble" in water by everyday standards. However, in the ocean the same sort of considerations apply as for the atmosphere. The 'particulates' content of sea water, which here includes not only dust and desert sand that enter the water, but also nanoplankton, crustacean shells and mud aggregates, determines how long a compound with limited water solubility remains in the water column. The particulates contents in the surface water of various oceans under open-sea conditions and for water columns in the open sea generally are listed in Table 16. As an approximate rule of

Table 16. Particulate concentrations in oligotrophic fresh-water lakes [70] and in oceans [85].

Surface waters	Particulate concentration [mgm^{-3}]	Water columns [b]	Particulate concentration [mgm^{-3}]
Great Lakes (USA–Canada)	100–500	Surface water (0–500 m)	110
North Atlantic (eastern side)	470	Middle depth (1000–3000 m)	5–20
South Atlantic (middle)	160	Bottom water (> 3000 m)	100
Indian Ocean (middle)	66		
North Atlantic (eastern side) [a]	(100)		
South Atlantic (middle) [a]	(25)		
Indian Ocean (middle) [a]	(10)		

[a] POC = particulate organic carbon content in surface waters. The total organic carbon content in oceanic surface water (TDC) is 0.3–1.0 gm^{-3} in the Sargossa Sea (Atlantic). [b] Average values are quoted.

thumb it can be assumed that 20–25% of the mass of the particulates consists of organic compounds (particulate organic carbon, POC).[85] When one gets to within several hundred meters of the ocean bed the particulates content begins to increase with depth due to resuspension.

The particulate content, including colloids (e.g., humic acids, saffrons), also influences the partition of less volatile and relatively insoluble compounds between surface water and the lowest layer of the troposphere, and this will be discussed later (Section 9).

Lifetimes in the surface waters of the oceans have been calculated for several groups of compounds by Japanese authors.[86] In the case of the hexachlorocyclohexanes they

found for α-HCH (water solubility 5.2×10^{-3} mol m^{-3}) values from 2 to 3.4 years, and for γ-HCH (solubility 2.1×10^{-2} mol m^{-3}) they found 5.1 to 10 years; in contrast, for PCBs with water solubilities ranging from 1.2×10^{-5} to 8×10^{-7} mol m^{-3} the corresponding retention times ranged from an average of 0.1 year (scatter: 0.07 to 0.12) to one of 0.57 year (scatter: 0.38 to 0.76). In each case the values apply for regions with high rates of primary production (150–250 g C m^{-2} a^{-1}) and for those with much lower rates (50–100 g C m^{-2} a^{-1}), which follow a trend reflecting the particulate content in the underlying water column. At a depth of 3200 m in the Sargasso sea in 1979/1980 an average particle-mediated flow of 1.6 μg m^{-2} year^{-1} of PCBs was measured.[87] The lifetimes for the *DDT* group of compounds are similar to those for the PCBs.

Considerably longer lifetimes of 3–5 years have been found for chlorinated biphenyls (Cl_xB) in the open sea surface waters of the Mediterranean.[88] Under deep-sea conditions the shortest lifetimes found were around 30 years.

Several different mechanisms must be distinguished, namely the adsorption on suspended particles, the exchange processes that take place during sedimentation, and the adsorption processes during the transformation of deposited particles (muds) into new sediments. The latter constitutes an entirely new phase whose composition is determined by chemical and biological activity. The early stages of diagenesis involve much chemical activity. Moreover, the solution/adsorbent (liquid/solid) ratio alters from one extreme to the other as the particulate/water system is transformed via the mud state into a new system consisting of a sediment with an interstitial solution.

Adsorption on and within the ground, which is the third important environmental compartment, is a complex process. The Langmuir isotherm equation is based on the assumption that the adsorbing surface is uniform. It was developed to describe the adsorption of gases, which was treated as a dynamic equilibrium.

The Freundlich isotherm was developed to describe adsorption from liquids. It assumes an adsorbing surface with a heterogeneous structure, and the adsorption is then a function of the concentration, as described empirically in Equations (14) and (15).

$$c_S = K c_{solution}^{1/n} \tag{14}$$

$$\lg c_S = n^{-1} \lg c_{solution} + \lg K \tag{15}$$

The Freundlich adsorption isotherm [Equation (15)] has been found to give a better description of the adsorption of organic compounds from dilute solutions and also in the ground,[89–91] since it contains the variable n which can be adjusted to fit the observed data. For very dilute solutions, n should have the value 1, and the simple Nernst distribution should then apply.

If the adsorption is related not to the mass of soil in grams but instead to the carbon content of the soil, the resulting adsorption constant K_{OC} is approximately independent of the nature of the soil as expressed in Equation (16):

$$K_{OC} = \frac{\text{μg of compound (\% org. carbon)}^{-1}}{\text{μg of compound (g of soil)}^{-1}} \tag{16}$$

Further, it has been shown that K_{OC} is only to a first approximation the same for different soils.[90] K_{OC} is directly related to K_{OW}. Both these quantities are often determined by regression analysis from the retention data obtained by C_{18}-RP liquid chromatography when compared with standard substances. However, it is better to calculate K_{OC} from data obtained by C_2-RP liquid chromatography.[91]

8. Transport in the Atmosphere

8.1. The General Circulation—The Global Wind System

The most rapid and effective horizontal and vertical mixing, extending to global dimensions, occurs in the lower 10 km of the atmosphere, i.e. the troposphere (see Fig. 3).[18,19] The transfer through the tropopause into the stratosphere (10–50 km) occurs only slowly, requiring about one year, while the theoretical return flow of organic substances that are photostable (for wavelengths $\lambda_{max} < 200$ nm) requires about four years.[92] Mixing in the stratosphere is much slower than that in the troposphere below.

The 'wind and weather' mass transport processes in the troposphere are associated with low-pressure areas (cyclones) containing upward air flows and high-pressure areas (anticyclones) with downward air flows. These cover a large area, and their time-scale can vary from hours, in regions where convection rainfall occurs, to the more usual periods of days to weeks within each hemisphere. An individual gas molecule or a particle with quasimolecular dynamic behavior ($d \leq 2$ μm) in the atmosphere of the temperate zone of westerly winds will take three to five weeks to travel around the world. With regard to mixing in the northern hemisphere, this means that the entire air mass above central Europe or that over Russia and Siberia travels around the world in an easterly direction about eight to ten times in a year. The contrary air movements that occur on a continental scale are only of regional importance, and can be analyzed in terms of "foreign" air masses that eventually become absorbed into the overall mixing process.

Even a very light breeze of only 4 km h^{-1}, one that can scarcely be felt, will move an air mass from Hamburg to the Alps in eight days. This enables one to easily appreciate the distances traveled by air masses in the average wind speed of 20 km h^{-1} that is generally assumed. Under these conditions it takes only ten days for air to travel from the east coast of the USA to central Europe, while a depression of storm strength would need only two to four days. The jet streams that occur in the tropopause of the tropics and middle latitudes can easily reach wind speeds of 200–500 km h^{-1}.

These global air movements take place in quite different directions in the two hemispheres, and thus affect different regions of distribution. In the middle latitudes (30° to 60° N or S) an easterly movement predominates, i.e. west winds prevail. Between the temperate latitudes and the equator the north-east trade winds and the south-east trade winds in the northern and southern hemispheres respectively converge towards each other, each with a strong east wind component, moving air towards the west (Fig. 7).[20] This convergence,

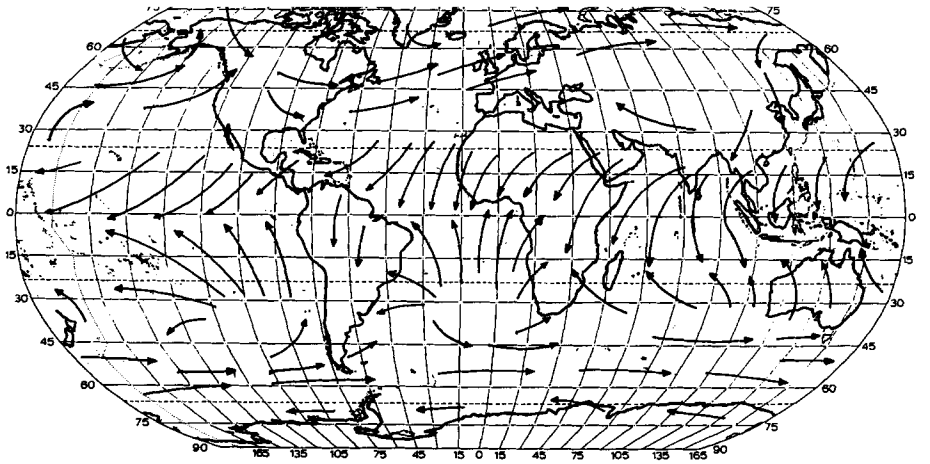

Fig. 7. Scheme of the prevailing winds in the lower troposphere (0–1000/2000 m) during the northern winter. In the northern summer, over the Indian Ocean, the south-east tradewind, as south-west monsoon, reaches out across the equator in a northerly direction as far as the Himalaya Region. The intertropic convergence zone (ITCZ) then shifts to ca. 30° North. Over the Atlantic and Pacific Oceans, the ITCZ shifts only slightly towards the south. The tradewind system remains essentially undisturbed. (See also Figs. 4 and 8.)

with an upward movement where the flows meet (the intertropical convergence zone, ITCZ, forming the so-called Hadley cells north and south of the equator) determines the time-scale for exchange between the hemispheres, which is about one year for gases (see also Fig. 4).[69]

In the continental regions this greatly simplified global "general circulation" is broken up into individual flows unique to their locations. Moreover, during the northern summer the north-east trade wind (north-east monsoon) swings around over the Indian Ocean to become the south-west monsoon, so that the south-east trade winds then extend across the equator towards the north. Thus, in the northern summer, air from the lower troposphere of the southern hemisphere pushes far to the north.[122]

Over the North Atlantic the permanent central Atlantic high (Azores high) results in a clockwise circulation of air which can carry Sahara dust as far as the Antilles (Caribbean) and Bermuda, while in Ireland it is possible to have fine dust carried over from the east coast of North America. The fact that dust from the Sahara is transported on a continental scale (giving reddish-yellow snow in the Alps, for example) vividly illustrates the potential for long-distance transport of substances. Similarly the global spread of radioactive particles from the Chernobyl disaster was a revealing, yet unwanted, experiment.

By carefully studying the weather map on a continental scale one can recognize preferred paths for the flow of air near ground level. Acid rain over Scandinavia (containing H_2SO_3 and H_2SO_4 extracted from the atmosphere) originates not only from central Europe (e.g., the Ruhr and the Saar region—Elsass-Lothringen) but also to a considerable extent from the industrial regions of the United Kingdom. Often the path taken by a typical 'low over the British Isles' is not over the central mountains of Germany towards Scandinavia but a more northerly route.[119]

Vertical air movements, familiar on a local scale as thermals or downward air currents, are manifested on a regional scale as the familiar "highs" (anticyclones) and "lows" (cyclones, depressions). Increased air pressure is caused by downward-moving air masses, and conversely a depression is characterized by rising air. The equatorial calm zones (the doldrums) are caused by regions of rising air masses with virtually no horizontal component of air-flow. The upward air movements in low pressure regions are an important factor in the mixing of the atmosphere, as they transport air that is near the ground, and therefore close to sources, up to higher altitudes.

Diffusion processes are of little importance for mixing in the troposphere, since the diffusion distances are quite insignificant owing to the very short mean free paths; even hydrogen has a mean free path of only 1.6×10^{-5} cm at 0 °C and 1 bar, compared with an average wind speed of 5.5 m s^{-1}. The potential rate of diffusion in the longitudinal direction for hydrogen at STP is only about 0.5 cm s^{-1}.

The planetary system of high- and low-pressure zones which builds up in the atmosphere well above the earth's surface (5–10 km) plays a very important role in global transport in the troposphere (Fig. 8). These circulating systems, whose influence extends far to the north and south, are best described in terms of the pressure relationships existing in the 500 mb region (corresponding to an altitude of about 5 km); they are responsible for the rapid exchange within the

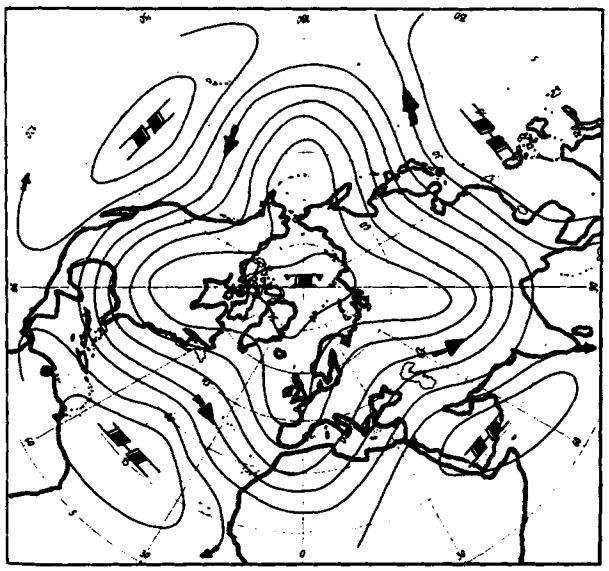

Fig. 8. Schematic representation of the planetary cyclone/anticyclone systems in the free atmosphere (ca. 5 km altitude) of the northern hemisphere. The air current follows the isobars, flowing in an easterly direction (west wind). Higher wave numbers can also occur (four bulges around the central low T). H = high.

equal distribution of trace substances between the two.[17, 18]

If the vertical exchange processes in a local area are slowed down or even halted by inversion layers (warm air lying above cool ground air), it is possible for pollutants such as SO_2, CO, nitrogen oxides, benzene or chlorinated solvents to accumulate in the cooler air near the ground, as their removel is then inhibited. Weather conditions such as these make one acutely aware, in an indirect way, of the 'normal' removal mechanisms in the lower troposphere.

In the stratosphere the temperature layers are such that there is a sort of permanent inversion (see Fig. 3), and the exchange processes are consequently much slower and less turbulent than in the troposphere. Return flows of air from the stratosphere to the troposphere can occasionally occur, usually where there are local disturbances in the tropopause at middle latitudes; these can, for example, act as sources of ozone from the stratosphere.

8.2. Extraction from the Atmosphere

Organic compounds can be removed from the troposphere in a number of ways, as follows:

1) by adsorption on large or very large aerosol particles (2–20 μm) which are then deposited;
2) through rain-out following adsorption on smaller aerosol particles which then act as condensation nuclei for cloud droplets and eventually form raindrops ('hydrometeorites');
3) by adsorption on particles which then collide with cloud droplets or raindrops and are captured;
4) through wash-out of molecules in the gas phase by raindrops, as in a gas scrubbing process;
5) by diffusion through the atmosphere/ocean interface;[16]
6) by moving out into the stratosphere.[92]

Which is the most effective process in a given case depends on the molecular properties (e.g., vapor pressure, polarity, water solubility) and the conditions in the troposphere (temperature, particulate surface area, amount of precipitation, type of rainfall (cyclonal or zenithal), stability of the tropopause, etc.).[58–60]

Relationships have been derived for some of the extraction mechanisms, as detailed below.[53–55, 71, 72]

1) Deposition as dry particles [Eq. (17)],

$$F = v_d c_{part} \tag{17}$$

where F = flow rate [$mol\,m^{-2}\,a^{-1}$] v_d = deposition velocity (for particles with diameters in the range 0.01 to 1 μm values of v_d from 0.02 to 0.5 $cm\,s^{-1}$ can be assumed, corresponding to the potential diffusion velocity of hydrogen in the longitudinal and slower directions), c_{part} = concentration of the compound existing in the adsorbed phase in air = ϕc_{total} [$mol\,m^{-3}$]; ϕ according to Equation (11).

2) Rain-out of particles that have acted as condensation nuclei for water droplets:

$$F = r c_{part} I_R \tag{18}$$

cient, c_{part} = concentration of the compound existing in the adsorbed phase in air = ϕc_{total} [$mol\,m^{-3}$], ϕ according to Equation (11), I_R = annual rainfall [$m\,a^{-1}$].

3) Wash-out of the gas-phase component by absorption [Eq. (19)]:

$$F = \frac{I_R c_{vap}}{H} \tag{19}$$

where F = flow rate [$mol\,m^{-2}\,a^{-1}$] I_R = annual rainfall [$m\,a^{-1}$], $c_{vap} = (1 - \phi)c_{total}$ [$mol\,m^{-3}$], ϕ according to Equation (11), H = Henry's constant = $p^0 S_{H_2O}^{-1} = c_{air}/c_{water}^{-1}\,RT$ [$Pa\,m^3\,mol^{-1}$]. The equilibrium between the gas phase and the raindrops becomes established after only about 10 m of fall.

The extraction by rainfall is also often expressed by the wash-out ratio W, defined by $W = c_{rain}/c_{air}$. W includes not only the extraction from the gas phase W_{vap} but also that from the adsorbed phase W_{part} [Eq. (20)], where W_{part} is the

$$W = W_{part} + W_{vap} \tag{20}$$

product of $c_{rain\,(part)}$ and $c_{air\,(part)}^{-1}$ and W_{vap} is the product of $c_{rain\,(solution)}$ and $c_{air\,(vapor)}^{-1}$, which is equal to RTH^{-1}.

The contributions of W_{part} and W_{vap} to W are determined by the fraction ϕ [Eq. (11)] of the compound that is adsorbed on particles [Eq. (21)]:

$$W = W_{part}\phi + W_{vap}(1 - \phi) \tag{21}$$

W_{part} can vary over a wide range.[72]

4) Extraction of organic compounds by diffusion at the interface atmosphere/ocean.[16] The exchange of molecules through the air/water interface is generally described by the Equation (22) developed by Liss and Slater,[93] which is based on Whitman's two-film model:

$$F = K_l(c_g H^{-1} RT - c_l) = K_g(c_g - HR^{-1}T^{-1}c_l) \tag{22}$$

in which K_l and K_g are the mass-transfer coefficients [$m\,h^{-1}$] in the liquid and gas phases respectively, c_l and c_g are the concentrations in the two phases [$mol\,m^{-3}$], and H is Henry's constant.

5) Extraction of organic compounds by their transport into the stratosphere.[92] In the various removal mechanisms the fraction ϕ [Eq. (11)] of a compound in the atmosphere that is adsorbed on particles evidently plays an important role. The fraction of adsorbed molecules is correlated with the vapor pressure and with the concentration of aerosol particles and/or the particle surface area per cm^3 [Eq. (11)]. Measurements and calculations show that in sea air at 20 °C as much as 90% of C_{24} alkanes[94] and a similar proportion of polychlorobiphenyls[84] remains in the gas phase. Values of ϕ for *n*-alkanes from C_{16} to C_{25} in city air (Barcelona) at an average temperature of 12 °C have been determined.[95] These measurements confirm the theoretically predicted dependence of ϕ on the aerosols specific surface area θ [$cm^2 cm^{-3}$] (Table 17).

The diameters of atmospheric particles show a bimodal distribution, with one maximum at 1.0 μm caused by the aggregation of Aitken particles ($d < 0.2$ μm) and another at

bons; ϕ = adsorbed fraction × (gas-phase fraction)$^{-1}$. (City air, Barcelona, 12 °C). [95]

alkanes	p [Pa] [a]	ϕ	alkanes	c (particles)	ϕ

10 μm consisting mainly of particles picked up by circular eddies from land and sea surfaces (dust, sandstorm seaspray). The distribution of organic compounds that characterizes their origin often follows the above particle size distribution. The majority of organic compounds are found on particles with diameters less than 2 μm, even though these constitute only 25% of the total particulate mass.[80, 81, 94] For particles collected from the atmosphere near London the burdens of polyaromatic hydrocarbons, PAH (phenanthrene to coronene), showed a clear maximum in the region $d = 0.2$ to 2 μm.[96] Moreover, aerosols with diameters less than 2 μm contain a large proportion of particles generated by combustion processes.[80, 95–97]

With regard to the regional distribution of organic trace substances in the troposphere, this marked preference for adsorption on particles with diameters less than 2 μm can necessitate treating the aerosols as a separate phase in the atmosphere and taking differences of particle size into account. For particles with diameters of 2 μm or less, dry deposition is, to a first approximation, negligible. Such particles behave like molecules, obeying gas dynamics. Their velocities of fall V_d are in the range 0.02 to 0.5 $cm\,s^{-1}$, or 0.7 to 18 $m\,h^{-1}$.[54] In contrast to this, average wind speeds are 20×10^3 $m\,h^{-1}$, and superimposed on these are the downward or upward air velocities in anticyclonic or cyclonic weather conditions respectively, which are of the order of 100 to 300 $m\,h^{-1}$, even if one ignores the thermals in the lowest layer (0–1000 m).

The Junge equation [Eq. (11)] can be extended to apply not only to aerosols but also to extraction by the surfaces of leaves and conifer needles. As well as taking into account the capture of aerosol particles by the fine structures of leaf surfaces, and the interception of rainfall before it reaches the ground (20–30% may fail to reach the ground as run-off from the foliage, branches and trunk), the leaf surfaces themselves can be treated in the same way as the surface of aerosols, with a value of θ [cm^2cm^{-3}] that is related to an average tree height of 10 m. In ecological studies one defines leaf area index (LAI) in m^2m^{-2} as the ratio of the total leaf area, assumed to be one-sided, to the ground area covered by forest or shrubs.[98, 99] For a leaf area index of 5 and an average tree height of 10 m, θ has a value of 10^{-2} cm^2cm^{-3}. For dust-laden city air the highest values of θ are around 4×10^{-6} cm^2cm^{-3}, and thus a typical value of θ for leaf surfaces is 10^3 to 10^4 times greater. In this case an adsorption of 50%, expressed by the value $\phi = 0.5$, would result for a vapor pressure in the range $(1.7 \text{ to } 17) \times 10^{-2}$ Pa. Thus leaf surfaces are of considerable importance for the extraction of substances from the troposphere near ground level.

These theoretical considerations are consistent with measurements of the soil burdens of Cl_xDD and Cl_xDF in different types of terrain in Germany, giving 1.5 ngiTE kg^{-1} for crop-growing land, 7.0 ngiTE kg^{-1} for grazing land, and 40.9 ngiTE kg^{-1} for forest leaf debris.[100] The leaf debris of a forest constitutes a sink which is analogous to ocean sediments.

The rates of fallout per m^2 resulting from deposition of aerosols have been determined for a number of organic compounds.[4] In Iceland in the summer of 1972 the rate of deposition of polychlorinated biphenyls (Cl_xB) by this mechanism was 1.1 $\mu g\,m^{-2}$ per month, whereas in winter the rate fell to 0.05 $\mu g\,m^{-2}$ per month. In the vicinity of Ulm in the Schwäbische Alb region in Germany in the winter of 1986, during a period dominated by high pressure, the rate of deposition of PCBs on the snow surface was 1.3 $\mu g\,m^{-2}$ per month. These rates of deposition are remarkably similar, if one excludes the winter figure for Iceland. This narrow range of deposition rates corresponds to a similarly narrow range of Cl_xB concentrations in the lower troposphere above the continents. In non-industrial regions of both central Europe (Schwäbische Alb (FRG))[66] and North America,[98] where there is very little direct uptake of these compounds, the concentration of Cl_xB in the lower troposphere was in the range 135–170 $pg\,m^{-3}$. In Réunion (Indian ocean) Cl_xB concentrations of about 125 $pg\,m^{-3}$ have been measured.[66]

There is considerable evidence that the Cl_xB concentration in the atmosphere above the oceans is determined by that in the surface water (Fig. 6). The quantity of Cl_xB present in the top 5 m of the ocean, assuming a concentration of 500–1000 $ng\,m^{-3}$,[86, 101, 102] is equal to that in the air column above it extending to a height of 10 km, if one assumes a concentration of 125–200 $pg\,m^{-3}$. The experimentally determined values for $K_{GW} = c_{gas}\,c_{water}^{-1}$ (dimensionless) for various compounds of the Cl_xB series range from 7.9×10^{-3} (for PCB 28, the 2,2′,4′ compound) to 0.4×10^{-3} (for PCB 180, the 2,2′,3,4,4′,5,5′ compound).[103] The concentrations measured in air and water at sea level give values for K_{GW} in the range from 4.1×10^{-3} to 0.1×10^{-3}. Thus the air contains much lower concentrations of Cl_xB than the equilibrium with water predicts. A more detailed comparison of the K_{GW} values found for individual PCBs in both continental and marine environments at ground level is given in Table 18.[77] These data confirm that under environmental conditions the concentrations of the PCBs investigated are lower in the atmosphere, and correspondingly greater in the water, by a factor of 2 to 6, when compared with the lowest

measured laboratory values for the gas/water partition constant K_{GW}.[103] A detailed study of the air/water and water/particulate distribution for chlorodibenzo-*p*-dioxins and chlorodibenzofurans in the Baltic similarly showed a higher fraction in the water phase than expected from laboratory results.[104]

The differences between the apparent environmental values of K_{GW} for an oligotrophic lake and for the open ocean are surprisingly small. According to Equation (30) and the results in Table 18 the proportion of Cl_xB present in unassociated solution form varies between 20 and 50%. It is not yet known why the trend of the fraction present in unassociated solution is opposite to that of the water solubilities of the different PCBs. Modeling studies of the uptake of persistent organochlorine compounds into the Arctic ocean gave ratios for hexachlorobenzene (HCB) that are similar to those given here for PCBs; for HCB too the calculations indicate a flow from the water into the atmosphere.[55]

Measurements of Cl_xB concentrations in the surface waters of the North Atlantic during the period 1973–1975 showed a maximum in the region between 5° N and 20° N, where the rainfall is greatest and also the North Equatorial Stream, a continuation of the Canaries Stream, flows.[99] For the corresponding region south of the equator (5° S to 20° S) the concentration of Cl_xB in the surface waters was found to be very much smaller. This region has a rainfall comparable to that in the corresponding northern latitudes, but here the surface water comes from the South Equatorial current and therefore from the South Atlantic. Both sets of results lead to the conclusion that if removal from the atmosphere occurs mainly through rainfall, as Harvey and Steinhauer have assumed, then the PCBs do not cross the intertropical convergence zone (ITCZ), and therefore the interhemisphere exchange in the troposphere must be greatly inhibited in the case of the PCBs. The same has also been found for hexachlorobenzene and α-hexachlorocyclohexane.[66] More recent measurements in the atmosphere at sea level over the Atlantic during two north–to–south and south–to–north crossings by the research ship "Polarstern" have confirmed these results (Fig. 5).[68] However, for PCBs the situation needs to be looked at in greater detail; here one must distinguish between regional and global transport, unless one assumes that the inputs of PCBs into the northern and southern hemispheres are equal (Fig. 6).

A research group has been set up under GESAMP (World Meteorological Organization) to bring together studies on the annual input of trace chemicals from the atmosphere into the global oceanic system.[105] Data are mapped in 10° squares and used to extrapolate. The inputs (in tons $year^{-1}$) and flow rates [$\mu g m^{-2}$ $year^{-1}$] for several chlorohydrocarbons are listed in Table 19. In assembling the data it became clear, not surprisingly, that the available information for the southern hemisphere, and also for organic compounds in general, is rather meager. There have, on the whole, been very few studies up to now of the distribution of trace organic compounds in the atmosphere. In this field, as in others, one detects the influence of the traditional emphasis on inorganic analytical chemistry in the education of chemists, and therefore also of those in related disciplines.

8.3. Transport Pathways in the Global Water Circulation

Rainfall has a key transport role (through rain-out and wash-out) in removing both polar and non-polar involatile organic compounds from the troposphere. Lakes that have no rivers running in or out receive their input of xenobiotics solely from rainfall, and therefore act as catchment basins for this fall-out, which accumulates in water, fish (see Table 11)[58] and sediments.[34]

The total volume of water present on the earth in liquid, vapor and solid forms is 1.384×10^9 km^3, of which 97.4% exists as brine in the oceans. The volume of water evaporated per year from the ocean surface is 440000 km^3, and of this about 400000 km^3 falls directly back into the oceans as rain (Table 12).[22, 63] The quantity of water falling onto land areas as rain is 110000 km^3 per year, of which 40000 km^3, about a third, originates from the oceans, while the rest comes from the continental or "minor" circulation. The total annual global rainfall is 510000 km^3, while the quantity of water present in the troposphere at any time is a mere 14000 km^3. The water in the troposphere undergoes 36 changes a year, i.e. once every 9–10 days, by falling back to the earth's surface as rain. In the tropics the annual rainfall in different latitude zones is 49000 km^3 for 20° N to 10° N, 82000 km^3 for 10° N to the equator, 64000 km^3 for 0 to 10° S, and 50000 km^3 for 10 to 20° S; the total of 245000 km^3 makes up nearly half the world's rainfall. Over the Atlantic and Pacific oceans there is a narrow but continuous belt in which the annual rainfall is as high as 300–400 cm (Fig. 9).[22]

The annual run-off from the continents in the form of rivers is 25000 km^3 in the northern hemisphere and 15000 km^3 in the southern hemisphere. The resulting north to south transport in the oceanic system is balanced by a transport of water vapor from south to north crossing the equator which takes place in the troposphere.

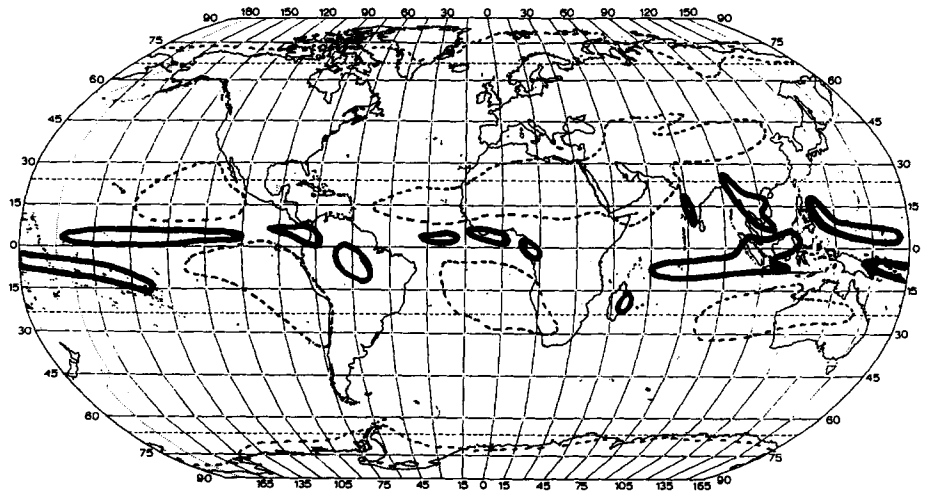

Fig. 9. Global distribution of the areas having the extremes of annual rainfall (areas marked by an unbroken line: annual rainfall > 2000 mm; areas marked by a broken line: annual rainfall < 250 mm). The well-known extremely dry areas on the continents stretch out to the high seas. As areas with high evaporation rates they also supply to the heavy precipitates formed in the ascending air masses in the intertropic convergence zone. These precipitates stemming from high clouds form a curtain of water between the northern and southern hemispheres, with all the consequences of the extraction of organic compounds by rain-out and wash-out.

With regard to the deposition of substances in rainfall, both in solution form and adsorbed on particles, it must be borne in mind that a quantity of rainfall equal to the entire water in the troposphere falls back to the earth's surface 36 times in the course of a year, while large areas are arid and take no significant part in this, and furthermore that about 71% of the earth's surface is occupied by the oceans. Consequently, at least 3/4 of the fall-out from the troposphere due to deposition, rain-out and wash-out reaches the surface of the oceans (Table 12).

Whereas for *ad*sorption processes an important quantity is the available particulate surface area per unit volume, the analogous quantity for *ab*sorption processes is the amount of the condensed water phase per unit total volume. Even in rain-clouds with a high water content, the mass of condensed water per unit volume seldom exceeds 1–4 $g\,m^{-3}$. Table 20 compares values for the ratio of the liquid water phase to the gas phase for haze, fog and clouds. If the water/air partition

Table 20. Phase ratios for water in the condensed phase and air.

[a] Average phase ratios water/air in $[m^3m^{-3}]$.

coefficient is known, one can estimate the maximum possible extraction by condensed water ('hydrometeorites'). Water drops of any size are called hydrometeorites. Water droplets in clouds cannot escape from the clouds other than by evaporation. Even for water droplets with a diameter of 200 μm the downward path in 90% saturated air is only 3 cm.[83] About 10^6 cloud droplets need to merge in order to form one average-sized raindrop, and accordingly there are about 10^6 condensation nuclei trapped in each raindrop.

For removal by solvation in the water phase (i.e. in raindrops) the Ostwald solubility α' (α' = solubility in water $[g\,L^{-1}]$/vapor density $[g\,L^{-1}]$) determines the rate at which a compound can be removed by wash-out. α' is the reciprocal of the more usual gas/water partition coefficient K_{GW} [Eq. (24)]:

$$K_{GW} = c_{air}\,c_{water}^{-1} \tag{24}$$

For transport calculations a useful quantity is the retention time or lifetime τ [years], defined, as previously [Eq. (1)], by $\tau = 1/(\text{removal rate})$ leading to:

$$\tau = \text{volume of air column} \times (\alpha' \times \text{rainfall volume})^{-1} \tag{25}$$

or, expressed in terms of K_{GW}:

$$\tau = K_{GW} \times \text{volume of air column} \times (\text{rainfall volume})^{-1} \tag{26}$$

For lindane, assuming a rainfall of 100 cm $year^{-1}$ from an 8000 m column of the atmosphere and a value of 0.2×10^{-4} for K_{GW}, the predicted retention time τ is 58 days. If the rainfall is increased to 300 cm $year^{-1}$, as in the tropics for example, the retention time for lindane is reduced to 19 days. For PCBs containing 60% chlorine (Arodor 1260, Chlorphen A 60), with a K_{GW} value of about 10^{-3},[103] the corresponding retention times for wash-out are about 8 and 2.7 years respectively. Furthermore, the removal of PCBs by wash-out is reduced by the phenomenon of water vapor distillation (similar to steam distillation), which also applies for raindrops.

From a knowledge of the ratio of the condensed water phase to the air volume (Table 20) and of K_{GW} values, one can make theoretical calculations of extraction rates for fog or rain. Measurements show that for semivolatile compounds there are always higher concentrations in rainfall than these calculations predict.[106, 107] Compounds with low solubilities in water are mainly removed with the rain on particles that act as condensation nuclei for fog and rain, at a rate determined by the partition ratio between the gas and absorbed phases. In this context one can regard the raindrops as dust particles that have become weighed down with water. Table 21 lists concentrations of organic compounds in rainwater, measured in a central European city (Hannover).[107]

Table 21. Concentrations of moderately volatile organic compounds in rainwater in Central Europe (Hannover, FRG) [107].

8.4. Variation of the Lifetimes τ_{OH}, τ_R and τ_W according to Latitude

On a global scale one needs to divide the atmosphere into at least three belts in each hemisphere, corresponding to the major climatic zones: 1) the polar regions (latitudes 90° to 60°; north pole, south pole), 2) the middle latitudes or west wind belts (60° to 30°; north-west and south-west passage), 3) the tropics (30° to 0°; northern and southern tropics). The two tropical belts are separated from each other by the relatively narrow but well-defined intertropic convergence zone (ITCZ) (see also Fig. 4).

The lifetime τ_{OH} of a compound in relation to its reaction with $^{\bullet}OH$ radicals is given by the reciprocal of the product of the rate constant k_{OH} and the concentration of $^{\bullet}OH$ radicals. For calculations relating to long time-scales it is sufficient to assume a global average figure of 0.5×10^6 molecules cm^{-3} for this concentration, but a realistic and more detailed consideration of the distribution behavior of compounds requires one to take into account the large variations of $^{\bullet}OH$ radical concentration with latitude (meridional variation). Whereas the reaction rate constant k_{OH} remains unchanged, the lifetime τ_{OH} decreases by a factor of 10 or more as one moves from the polar regions to the equator.[39, 42]

The concentration of $^{\bullet}OH$ radicals in the troposphere shows an approximate, and very important, correlation with the solar radiation intensity. Striking evidence of this is provided by the diurnal variations, by factors of as much as 100, in the concentrations of $^{\bullet}OH$ radicals.[39]

The lifetimes for rain-out (following adsorption on particles) and wash-out (absorption in raindrops), τ_R^{-1} and τ_W^{-1} respectively, take on a special significance in the regions immediately to the south and north of the ITCZ. The values of τ_{OH}, τ_R and τ_W have their global minima as one crosses the equator. In this connection it should be noted that a movement from the zone between 30° N and 60° N into the zone of larger area between 30° N and the equator is accompanied by streaming in a larger volume equivalent to a dilution which is further accentuated by the mixing-in of air descending from higher altitudes in the region of 30° N due to the trade winds.

If one assumes constant values for the gas/particle and gas/water partition coefficients, the lifetimes τ_R^{-1} and τ_W^{-1} for rain-out and wash-out respectively are influenced to different extents by the amount of rainfall and the average temperature. These latter two parameters also vary according to latitude. Furthermore, τ_R also depends on the average aerosol surface area per unit volume [$cm^2 cm^{-3}$]; for clean marine air this is constant throughout the world to a first approximation. With regard to the variation of temperature with latitude, the important variable is the average sea-level temperature. With increasing altitude the differences in average temperature disappear. The average temperature in each zone follows the annual cycle of solar radiation intensity, with extreme values in the polar regions.

With regard to the transport of organic compounds it is evident that the ITCZ forms an important physical and chemical barrier between the northern and southern hemispheres. Immediately to the north and south of the ITCZ one finds—as already mentioned—the global rainfall maxima, caused by cumulus clouds extending to heights of 10–12 km. The resulting high wash-out rate is accompanied by a marked increase in $^{\bullet}OH$ radical concentration, so that not only the physical but also the chemical lifetimes for compounds with high reactivities towards these radicals are significantly reduced in the tropics. The barrier effect of the ITCZ has been

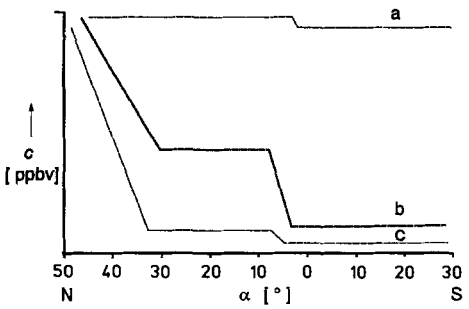

Fig. 10. Plot of the concentration c of tetrachloromethane (a), trichloroethene (c) and tetrachloroethene (b) in the tropospheric boundary layer of the Atlantic Ocean, recorded for a north-south traverse (Bremerhaven-Capetown). The intertropic convergence zone forms an effective barrier for chlorinated ethenes.

clearly demonstrated for a series of organohalogen compounds from C_1 to C_{12}, which have their main sources in the west wind region of the northern hemisphere (Fig. 10).[38] This barrier effect is further accentuated by the partial reversal of the flow direction that occurs in the rising air masses of the Hadley cells, returning a portion of this air back into the hemisphere from whence it has originated (see Fig. 4).

9. Transport from the Surface Waters of the Oceans into the Troposphere

The extent to which the oceans act not only as a "sink" by receiving rainfall but also as a 'source', returning chemicals into the troposphere by normal reverse diffusion, by the water vapor distillation effect, and by forming aerosols (sea spray) from the surface microlayer, is an unanswered question that one can only point to as a subject for future investigation. For nonvolatile compounds such as HBC, PCBs or DDT, our own recent measurements suggest that the concentrations in the upper levels of the ocean (0–50 m) determine those present in the column of the troposphere (0–12 km) above.[68]

Measurements of the concentrations of the hydrocarbons from decane ($C_{10}H_{22}$) to octaeicosane ($C_{28}H_{58}$) in the North Sea about 300 km to the north-west of Scotland gave values of 10 to 100 $\mu g\,m^{-3}$ in the sea and 0.1 to 10 $ng\,m^{-3}$ in the atmosphere above. The theory that the sea is the main source of biogenic alkanes in the marine atmosphere is further supported by the observation that the molecular mass distribution pattern of alkanes in the marine atmosphere, with a maximum at C_{15}, is considerably different from that in air above the continents, with a maximum at about C_{22}–C_{24}.[94, 105]

The basic theory of the exchange between air and water phases was derived in 1974 by Liss and Slater, who based their approach on the two-film theory of exchange at a gas/water interface [Eq. (22)], first described in 1923 by W. G. Whitman.[53, 93] The exchange taking place in the boundary layer between the two phases is determined by the sum of the transition barriers in the partial boundary layers of the gas phase and of the water phase. For substances with a small Henry's constant (p_L/S_L, where $p_L \ll S_L$) the exchange is controlled by the gas phase, whereas for substances with a large Henry's constant ($p_L \gg S_L$) it is controlled by the water phase.

Superimposed on the diffusion processes in the two partial boundary layers are the macroscopic motions occurring in the two phases (wind, disturbances of the water surface, currents). In natural waters (lakes and oceans) one must also take into account the surface microlayer (0–50 μm), which contains higher concentrations of organic substances and constitutes an important additional boundary in relation to molecular dimensions. The two-film theory can also be applied to the exchange between the gas phase and the condensed water phase in the atmosphere (clouds and rain). On the other hand, one needs to remember that the component in the water phase that is not present in free solution form does not take part in the diffusional exchange described by the two-film model.

Alongside the molecular exchange between the gas phase and the water phase we must also consider extraction from the water by sea spray and by the formation of droplets from the films around gas bubbles. The annual global uptake of organic substances into the lower troposphere by the latter mechanisms, thus contributing to the overall marine aerosol formation, is 50×10^6 tons, and this remains in the troposphere for periods determined by the lifetimes of the aerosols produced.[20] The types of compounds transported by these mechanisms, which mainly involve the surface microlayer, are those that tend to become concentrated in this layer, including not only those with surface-active properties but also organochlorine compounds that are relatively nonvolatile and sparingly soluble in water.[102]

The equilibrium distribution that exists in practice between the atmosphere and the warm water layer of the oceans (0–200 m) can be described, in analogy with the definition of Henry's constant, by the expression given in Equation (27).

$$H_{\text{environment}} = c_{\text{air}} RT c_{\text{water}}^{-1} \tag{27}$$

The total concentrations present in the atmosphere and in the water can each be divided into a molecular-dispersed fraction and a bound fraction (ϕ_A for air and ϕ_W for water).

$$H_{\text{environment}} = \frac{[c_{\text{air}}(1-\phi_A) + c_{\text{air}}\phi_A]\,RT}{c_{\text{water}}(1-\phi_W) + c_{\text{water}}\phi_W} \tag{28}$$

The molecular-dispersed fractions $(1-\phi)$ should be related to the true Henry's constant [Eq. (29)], whereby $R = 8.134$ [$Pa\,m^3mol^{-1}K^{-1}$] and $RT = 2.385 \times 10^3$ [$Pa\,m^3mol^{-1}$] at 293 K.

$$H_{\text{ideal}} = c_{\text{air}}(1-\phi_A)c_{\text{water}}^{-1}(1-\phi_W)^{-1}RT \tag{29}$$

If we make the reasonable assumption that the bound fraction in the atmosphere is adsorbed on particles, and that $\phi_A < 0.05$, Equation (29) can be simplified and rearranged to give Equation (30):

$$c_{\text{air}} = c_{\text{water}}(1-\phi_W)\,H_{\text{ideal}}(RT)^{-1} \tag{30}$$

or, after rearranging to give the bound fraction in water to Equation (31).

$$\phi_W = 1 - H_{\text{environment}} H_{\text{ideal}}^{-1} \tag{31}$$

Values of $H_{\text{environment}}$ have been estimated from experimental data for PCBs with different degrees of chlorination (Table 18). It should be possible to calculate H_{ideal} as $p_{(L)}/S_{H_2O(L)}$ using data for the supercooled melt. However, values calculated in this way are found to be 10 to 100 times greater than the values for PCBs determined by direct experiment, and any conclusions regarding ϕ_W based on such calculated values would therefore be invalid.[103] If instead the values from direct laboratory measurements[103] are inserted into Equation (30), it is found that the bound fraction ϕ_W in water for the various PCBs (Cl_xB) ranges from 0.5 to 0.9. However, this means that any calculations regarding thermodynamic equilibria must take into account a considerable correction factor for the difference between the measured concentration c_{analyt} and the effective concentration a. In the classical expression $a = fc_{\text{analyt}}$ the correction factor or activity coefficient includes interaction contributions that can only be crudely estimated at present.

In addition to the adsorption from water onto particulate matter (POM), all compounds with low water solubility are

affected to an equally important extent by various types of interaction (association, hydrophobic interactions) with substances loosely described as dissolved organic matter (DOM);[104a, 109, 110] these include humic acids and saffrons, mainly characterized by their UV absorption around 270 nm. Some compounds such as PCBs are found in laboratory measurements to have increased 'solubility' (better described as 'uptake') in water containing dissolved humic acids. This is of no direct importance in practice, even in the oceans, since the concentrations of these substances in the oceans are very low, but on the other hand the component that is bound in this way does not take part in the direct equilibrium between the atmosphere and the ocean, and is instead included in ϕ_w. In attempting to explain the reduction in the concentrations of PCBs at sea level in the atmosphere over the ocean, where there is increased primary production, these interactions need to be taken into account along with the adsorption on the surfaces of particulates. It is not yet possible to estimate the relative contributions of adsorption and association to ϕ_w.

10. Transport in the Hydrosphere

The importance of water as a transport medium and regional repository for xenobiotics has been strikingly demonstrated during the last few decades, through people's direct experience of the contamination of nearly all streams, rivers and coastal waters. Attempts that are being made at gradually restoring the conditions that existed a few decades ago are the first signs of an international concern over cleaning up the global environment.

10.1. Transport Processes in the Inland Hydrosphere of the Continents

In all parts of the world it is often regarded as an important precondition, when choosing an industrial production site, that one should be able to dispose of part or all of the wastes by having them carried away by surface water. Along with the release of wastes into the lower troposphere by wind, rivers are important disposal routes for all industrial civilizations; even if one does not have the benefit of an island location, they provide a direct outlet to the coast. However, the need to be able to use the surface waters in other ways, especially for drinking water, has given a great impetus to worldwide programs for cleaning up effluents and thus keeping rivers free of pollution.

In the northern hemisphere the volume of water returned annually into the oceans by river is 25000 km^3, while the figure for the southern hemisphere is 15000 km^3. Where a river that has an important function as a waste disposal route empties into an inland sea or a partly landlocked sea in which little exchange occurs, the problems caused by the input of pollutants become apparent more quickly than in the oceanic system. Examples of this are seen in the Caspian Sea, the Black Sea together with the Sea of Marmara, the Mediterranean, the Baltic, and even the North Sea, despite the fact that the water in the latter exchanges with the North Atlantic every three years.

The potential for transport of xenobiotics into and by the groundwater on a local or regional scale is less immediately obvious.[13, 15, 89] Depending on the geological conditions, rainwater seeps downward at a rate of 3 to 5 m per year (excluding limestone karst districts). Groundwater currents have velocities ranging from 10^{-4} to 10^{-6} ms^{-1}, giving transport pathways moving at about 4 km per year. Transport in groundwater resembles the slow sand filtration process used to purify drinking water, and thus the transport of xenobiotics is largely determined by their water solubility. Alongside the transport process there is a slow microbiological transformation caused by microorganisms, most of which generate methane. For trichloroethene and tetrachloroethene, two compounds that are often present as groundwater pollutants, the end-product of these transformations is vinyl chloride, which has a notoriously high biological activity.[13]

In inland seas in temperate zones the surface water and the water at greater depths are at nearly equal temperatures in spring and autumn, and therefore have similar densities. This, combined with the winds that are experienced at these times, usually results in a mixing process extending to considerable depths, known as the spring and autumn deep circulation (dimictic lakes or seas).[111] This circulation can extend to depths of 100 m or more. In summer, in lakes of appreciable depth (more than 20 m), a stable vertical temperature distribution becomes established, with the result that mixing can only occur in the top 6 to 10 m. Consequently, the input of substances through rain or dry deposition produces a concentration gradient. In polar and subpolar regions there is only one mixing process, which occurs in the summer (monomictic lakes or seas); for the rest of the year the "winter temperature distribution" prevails, with the water on the lake bed at $+4\,^{\circ}C$. In the tropics some lakes are monomictic while others are polymictic; here, depending on location and depth, a deep circulation process can take place in the winter as a result of the lower temperature of the surface water. However, more far-reaching circulation processes occur through wind action. An interesting example of this is found in the Caspian Sea, which is really a lake; this has a circulation which undergoes seasonal changes of direction according to the prevailing wind.

Such circulations not only regulate the transport of oxygen down to greater depths, but in a similar way other compounds that do not undergo transport on particulates are carried down to deeper regions.

10.2. Transport Processes in the Oceans

On a continental or global scale the surface currents of the oceans (Fig. 11) have transport functions that are second only to the mixing processes in the troposphere with regard to the quantities moved, the distances involved, and the transport velocities (Table 14). Typical average current velocities range from about 0.4 to 1.5 ms^{-1}, with peak values of about 2.0 ms^{-1}. For an average velocity of 0.8 ms^{-1} the distance traveled in a month is about 2000 km. However, the actual linear displacement can be greatly reduced by meanderings. The average rates of flow at great depths are about 0.01 to 0.02 ms^{-1},[112] so that a typical distance traveled in a year would be about 300 km. According to this, water that

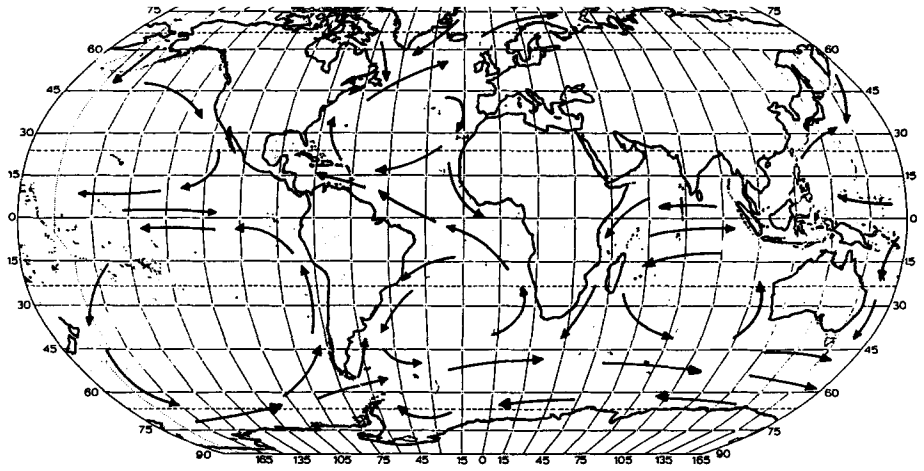

Fig. 11. Currents at the surface of the oceans. The global wind system and the necessities of mass/density balances shape the surface ocean currents. In the Atlantic the Southern equatorial current, which changes over into the Brazil current brings surface water northwards from the southern hemisphere. The surface currents flowing towards the west on the western side of the continent draw cold and nutrient-rich water from deeper layers to the surface. Surface water preferentially sinks at the poles.

sank to great depths in the Antarctic in 1950 should have traveled about 12000 km up to now. During this period deep-sea water should have traveled, in the South Atlantic bottom-water current, the distance of about 9000 km from the Antarctic to the equator.

The surface currents in all the oceans can be approximately represented as several global circulating currents,[24] which together preserve the world balance of mass and energy. In addition there is a further movement in the southern hemisphere, namely the west wind drift that circulates from west to east around the south pole in the Antarctic ocean, and extends to considerable depths. From this Antarctic west wind drift several cold currents branch northwards, on the western sides of South America (the Humboldt current), of South Africa (the Benguela current), and of Australia (the Western Australian current) (Fig. 11). As a result of these movements there is a constant exchange between the surface waters of the oceans. This inter-oceanic exchange at the surface is further reinforced by deep-sea currents that flow in a northerly direction and are also fed by the Antarctic west wind drift, which extends to depths of 4000 to 5000 m (Fig. 12).

A more detailed classification of the surface currents in the oceans reveals branch currents flowing across the equator. The South Equatorial current that flows in a westerly direction in the South Atlantic throws off the Guayana current towards the north, along the coast of the South American continent; this water subsequently flows through the Gulf of Mexico into the Gulf Stream. The upward currents on the western sides of the continents introduce bodies of water that have not previously, or at least not recently, been involved in the transport of xenobiotics.

Where two surface currents meet, their water masses are forced down to greater depths. These 'convergences' form relatively sharp boundaries in the classification of water masses in the world's oceans; in the case of the Antarctic convergence in the South Atlantic there is even a distinct boundary between different types of animals. The descending water masses carry down with them substances that have entered the ocean at the surface.

The descending surface waters at both poles form the oceanic deep currents, which extend well beyond the equator. In the southern hemisphere these ocean-bed currents, which are fed from the west wind drift circulating around the South Pole, flow towards the north (Fig. 12), whereas water from the North Polar Sea flows southwards (Fig. 13), eventually reaching the Indian and Pacific Oceans.[24, 112]

Where surface currents separate (divergences), they draw water upwards from deeper levels. This water is colder and richer in nutrients. There is then an increase in the rate of primary production, which is controlled by the light intensity

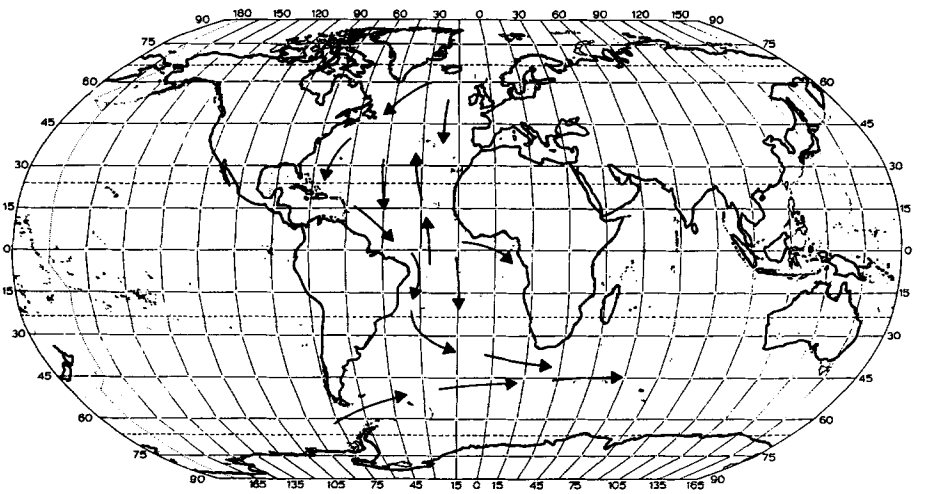

Fig. 12. Flow of Arctic and Antarctic bottom water currents at depths of over 4000 m. The circumpolar Antarctic west-wind drift reaching into the bottom water feeds water masses flowing northward which eventually reach a northerly latitude of 45° North.

and the phosphates content of the water, and corresponding increases occur in the trophic levels that follow.

The system of water layers in the ocean depths must be taken into account in an analysis of the global transport of xenobiotics, even though its effects are on a time-scale measured in decades. For example, it has been found that the distribution pattern of hexachlorocyclohexanes in the water column off Bermuda corresponds to that expected for the water layer in the southern hemisphere from whence it originates.[67, 102]

11. Transport in the Biosphere

The flow of matter in the biophase in the oceanic system, which can be treated to a first approximation as a separate mobile environmental compartment independent of water movements, is often overestimated. The average rate of primary production in the ocean is about 0.01 to 0.03 $kg\,m^{-2}\,year^{-1}$, whereas that on land is typically 50 to 200 times greater. Even in semi-desert regions used for nomadic grazing, a primary production rate of 1 $kg\,m^{-2}$ per year is generally assumed. In its progress down the various levels of the marine food chain, only 10–20% of the biologically generated material is retained at each level.[114]

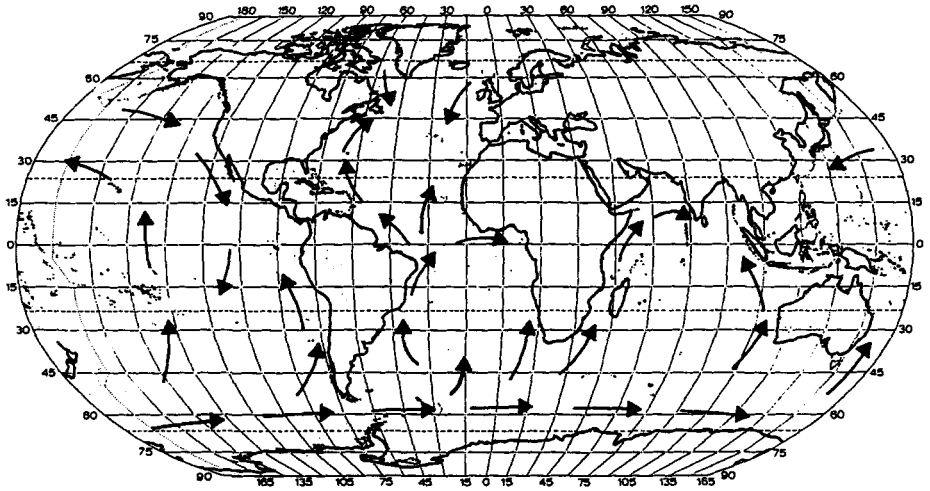

Fig. 13. Scheme of the flow of Arctic deep-water at a depth of ca. 2000 m in the Atlantic ocean. Water of Arctic origin penetrates as far as the southern regions of the Indian Ocean. Flow rates of 10–15 $cm\,s^{-1}$, corresponding to 60–90 $km\,d^{-1}$, are reached.

A model has recently been proposed to describe the delicate balance between the deep ocean currents and the surface currents that are largely determined by wind patterns and alter accordingly.[113] According to this, minor changes in the pattern of air movements caused by small climatic variations in the lower troposphere can have greatly magnified effects on the global oceanic system.

The transport of xenobiotics in the depths of the oceans takes place not only through the downward flows of water that occur mainly in the polar regions, but also by another mechanism, namely the fall-out of organic matter (detritus) in the oceans.[112] Excreted products from animal metabolism, exoskeletons and all kinds of dead organisms, from unicellular blue algae to whales, sink towards the ocean bed. Although many of these constitute food for other organisms, so that many biological cycles constantly interact with each other, the only significance of this for our present purpose is that it delays the transport to greater depths. However, it can also result locally in the accumulation of persistent compounds in trophic levels lower down the food chain.[114] This transport mechanism can be likened to the fall-out of particles from the atmosphere, and the interactions with xenobiotics are rather similar. Compared with transport by water it is quite rapid: the time needed to reach the ocean bed for a typical ocean depth of about 4000 m varies from a few days to several weeks. A rapid input of organic substances can occur when a surface blanket of algae dies and sinks.[114] The actual rate of sedimentation in the oceans, measured by the rate of deposition at the seabed, is about 1–4 mm per thousand years.

The total primary production of phytoplankton in the oceans is about 200×10^9 tons per year, corresponding to $(12-20) \times 10^9$ tons of biologically bound carbon, whereas only about $(10-20) \times 10^9$ tons of zooplankton are produced. These totals are very unevenly distributed in the oceans and there are great variations with time. Only $(0.2-1.5) \times 10^9$ tons per year of the primary production remains by the time we get down to the third and fourth trophic levels (i.e., fish). It is estimated that the maximum annual world fish catch that this can support indefinitely is 0.1×10^9 tons. The present annual fish catch total of 0.07×10^9 tons (Table 22) is already very near to this limit.

From the standpoint of the accumulation of persistent chemicals, the reduction in mass flow by a factor of 10 for each stage to the next trophic level means that there is a corresponding increase in concentration, since little or no

Table 22. Annual world deep-sea fish catches in 10^6 tons fresh weight [29] [a].

Year	Catch [10^6 t]	Year	Catch [10^6 t]
1950–54	24.7	1970–74	67.9
1955–59	32.3	1975–79	72.1
1960–64	46.2	1980–84	75.0
1965–69	59.5	1986	76.0

[a] Breakdown of uses (1982): fresh fish sales 18%, frozen fish 22%, canned fish 13%, dried or salted fish 14%, soaps, fish-meal, pharmaceuticals 33%.

breakdown of these compounds with a release of energy occurs. In certain cases this can result in the accumulation of large burdens of xenobiotics in non-migratory predators (e.g., perch, hawks) that feed on species which migrate large distances (pelagic fish, migratory birds), without the involvement of any other environmental transport mechanisms.

It is evident that transport in the biosphere plays a less important role in the global mass transport of xenobiotics than the flows in the atmosphere and hydrosphere described earlier. Its importance undoubtedly lies in the area of real or potential biological effects of environmental chemicals. The existence of food chains is a fundamental aspect of the biosphere, and the transport of xenobiotics can also have a connection with food chains, depending on the properties of the compounds. In the long term the bioaccumulation or biomagnification of stable (persistent) compounds in food chains must be regarded just as seriously from the environmental standpoint as acute toxic effects.[115] Algae that concentrate stable, strongly lipophilic compounds such as PCBs or the DDT group from the surrounding water pass these on through uptake by zooplankton and by plankton-filtering marine animals or fish. The phenomenon of marine food chains in which whole populations of species undergo a regular daily or nightly migration is another form of transport in and by the biosphere. Since the beginning of evolution deep-sea fauna, through their feeding activities, have been carrying organic compounds from higher to lower levels, and therefore the enormous concentration factors found for stable environmental chemicals in the biophase, e.g. in deep-sea fish (Table 11), are inevitable rather than surprising.[58] Similar effects are also found in marine mammals, which are at the end of the food chain.[115, 116]

The world's fisheries, which have harvested about 75 million tons of fish since 1980, are also a form of transport in the biophase. About 25 million tons of this total consists of 'industrial fish', which is processed rather than consumed directly (Table 22). Populations whose diet includes a high proportion of fish and marine mammals are exposed in a very direct way to the transport of chemicals in the biosphere.

Another transport process which, although it only applies to specific individuals, is nevertheless a basic phenomenon throughout the world and one for which there is no possibility of human intervention, is the partial transfer of persistent lipophilic xenobiotics from the mother to the fetus. This applies not only to humans but to marine mammals such as seals and dolphins.[117] Lipophilic compounds that can be transferred in this way during the gestation period in humans and other mammals include hexachlorobenzene, PCBs with substituents in the 2-, 4- and 5-positions, and the 17 compounds belonging to the 2,3,7,8-substituents of chlorinated dibenzo-*p*-dioxins and dibenzofurans.[50]

Similarly it has been found that persistent chemicals accumulated in the bodies of crustaceans and fish become transfered to their eggs or sperm.

The extent to which these effects can, over long periods, cause irreparable damage at one of the weakest points in the reproduction cycle, thereby threatening the survival of a species, can at present only be a matter for speculation, but the effects certainly cannot be dismissed as being of no significance. In this complex of questions the marine mammals are particularly affected, as nearly all of them are predators at the end of a long food chain. Marine mammals do not have the option of changing their diet or shortening the gestation period, whereas this is not fundamentally ruled out for humans, whether now or in the future.

12. Outlook

During the last 50 years the prediction that many man-made chemicals would reach every corner of the global environment has become a reality. Modern methods of organic trace analysis, used in conjunction with techniques for concentration, separation and detection at the very low concentrations in complex organic mixtures that need to be analyzed, have revealed this situation, but are not the cause of it, as is often naively claimed, even in discussions among chemists.

Bearing in mind the many different mechanisms of global transport that are possible in the atmosphere and in the oceans, it is virtually inevitable that certain compounds, which can be regarded as tracer chemicals in the environment, should be found to be present throughout the world, and should become concentrated in certain parts of the environment as a result of thermodynamic equilibria. This has occurred despite the fact that in many cases their use and distribution in the environment only began as recently as 40 years ago or less, despite limitations on their use in some regions, and despite the fact many of them, unlike pesticides, were not deliberately released into the environment.

It is now becoming apparent that even microbiological breakdown, which, as the converse of biosynthesis, has maintained the carbon cycle since the beginning of evolution, has a limit to its capabilities; otherwise it would not have been possible, within a few decades, for the world's oceans to accumulate easily detectable concentrations of a complex mixture of xenobiotics.

The chemical community has a duty to take note of the presence throughout the world of chemicals that it has produced, either directly or indirectly, and accordingly to reinforce the efforts now being made to develop products that are environmentally friendly in the long term. Biological evolution has avoided the introduction of chemical compounds that are not capable of being broken down again into basic building blocks such as H_2O, CO_2, H_2S, HCl or NH_3. All biosynthetic processes contain within them the mechnisms for biological breakdown of the compounds produced. Should not the chemist learn from nature in this respect? This happened in the past, and must now happen again. The chemist understands, and speaks, the language of molecules. Environmental chemistry is a new chapter in the chemistry of natural products; however, environmental chemistry also requires that we should ask ourselves whether that which is technologically possible and economically successful in a superficial sense can always be justified in a global and long-term context.[118]

[28] A readily accessible and very comprehensive review of world chemicals production is given every year in *Chemical and Engineering News* (American Chemical Society). Production figures for the last ten years are given for specific groups of chemicals and also for some individual compounds, including F11, F12, F22, 1,1,1-trichloroethane and tetrachloroethylene (*Chem. Eng. News,* 24 June 1991, pp. 28–81). For the Federal Republic of Germany the "Stoffberichte" published regularly by the Beratergremium für umweltrelevante Altstoffe (BUA) of the Gesellschaft Deutscher Chemiker include up-to-date figures for production and releases into the environment. These figures can be scaled up with a satisfactory degree of confidence to include production in other countries; however, the figures for environmental releases obtained in this way are likely to be too low, as few countries have more stringent environmental protection regulations than those in Germany. "Stoffberichte" for more than 80 compounds of environmental importance have been published by VCH, Weinheim, and this series of reports is continually being extended.

Reaction Dynamics of Aligned Molecules

By Franz Josef Comes

Dedicated to Professor Heinz Harnisch on the occasion of his 65th birthday

Photofragmentation—also termed 'half collision'—is a method to comprehend the complicated process of a chemical reaction (the 'full collision') better. The use of polarized light enabled the study of the spectroscopy of aligned molecules, yielding information about the photochemically produced intermediate state—the transition state. Even though stable reaction products were studied, the forces responsible for the motions of the fragments can be visualized. In this way a model can be constructed that represents the part of the potential hypersurface responsible for the observed motions. The application of this spectroscopic method to hydrogen peroxide H_2O_2 has become a classic example. The complex decomposition of hydrazoic acid, HN_3, represented a challenge, and its successful solution proves the general applicability of this method.

1. Introduction

The goal of reaction dynamics is to derive the mechanism of a chemical reaction from the microscopic properties of its atomic constituents. The summation of microscopic processes yields the macroscopically observed overall reaction. Until now, the situation was usually reversed: the observed reaction was used to deduce possible microscopic steps. The macroscopic reaction rate, however, is a parameter averaged over all microscopic reactant and product states of the involved particles and, hence, does not yield a direct insight into the microscopic events. While macroscopic rate laws yield very useful facts about the quantitative course of the reaction, they provide only limited information on important intra- and intermolecular motions that describe the course of the reaction on the microscopic level.

In order to deduce which forces disrupt some bonds and create others during the course of a reaction, it is necessary to extract information about the potential energy surface from experimental results. The desired forces are then simply the derivatives of this potential energy. This goal could in principle be reached with the help of quantum mechanics. It is well known, however, that real systems are suitable for exact quantum mechanical treatments only in rare cases.

To describe the course of a chemical reaction that is initiated by the collision of two reactants and ends (for simplicity's sake) in two products, the involved particles must be characterized not only by their energies, but also by their various momentums. When E_N^i and $\vec{p}_N$ represent the internal energy and the linear momentum, respectively, of particle N, this reaction is described by Scheme 1.

The goal of reaction dynamics, namely to understand the interactions between the particles involved in the reaction,

$A(E_A^i, \vec{p}_A) + BC(E_{BC}^i, \vec{p}_{BC})$	reactants
$\rightarrow (ABC)^*(E_{ABC}^i, \vec{p}_{ABC})$	transition state
$\rightarrow AB(E_{AB}^i, \vec{p}_{AB}) + C(E_C^i, \vec{p}_C)$	products

Scheme 1. Two reactants with specific internal energies and linear momenta react to form two products.

can be achieved by suitable preparation of the reactants. The use of molecular-beam and laser techniques has provided important advances for experimental studies of reaction dynamics. In the simplest case of a molecular-beam experiment, A particles in a beam are directed onto BC particles, which could also be within a beam. The scattering of the products AB and C as a result of the reaction is then observed. In these single collision experiments the particles are usually provided with a well-defined collision energy (translational energy). This makes it possible to study the scattering as a function of collision energy and impact direction ($\vec{p}$ is fixed).

Laser irradiation excites particles into specific states, thereby fixing their internal energy, E^i. In particular, it can be used to transform the molecule ABC directly, without a preceding collision, into an activated state $(ABC)^*$, which dissociates to form products AB + C. In this way a unimolecular reaction can be initiated through the conversion of internal energy. The decomposition of the activated molecule can also occur before any redistribution of internal energy in the complex $(ABC)^*$. In this process, also termed 'half collision', the fragmentation of $(ABC)^*$ into AB + C is of interest. It can be measured by observing the distribution of the internal energy with respect to angle, velocity, and state. The quantum state distribution of E^i can be measured with suitable methods such as chemiluminescence in the infrared or visible light range, laser-induced fluorescence (LIF), or resonance-enhanced multiphoton ionization (REMPI). The velocity distribution of the products can be measured with Doppler spectroscopy.

These state-selective chemical processes yield a detailed description of the chemical reaction and provide information about the events during the transformation of reactants to products. The investigation can either focus on the transient particle $(ABC)^*$ itself, for example, with real-time measurements in the pico- or even femtosecond range, or on the stable final products.[1] In the latter case, variables integrated over the entire course of the reaction are observed.

The method of Doppler and polarization spectroscopy belongs to the class of experiments that yield information from stable reaction products.[2] Nevertheless, from the vector properties of the fragments a detailed picture of the course of the reaction can be obtained.[3] These results there-

fore complement those from reactive scattering. The velocity or the angular momentum of the fragments yields information on the form of the potential surface near the transition state from which the translational or rotational energy arises. It is a fascinating idea to use these vector properties to determine the forces that cause them.

Doppler and polarization spectroscopy utilizes the ability to obtain spatially aligned molecules through the use of plane-polarized light.[3] The spatial asymmetry that occurs during the fragmentation of aligned molecules makes it possible, in conjunction with a narrow band laser, to perform a type of subdoppler spectroscopy that differs from its usual form with statistically distributed molecules. Both the width *and* the shape of the Doppler-broadened line become sources of information. From the vectorial properties of the fragments, for example, their velocity or angular momentum, conclusions can be drawn about the dynamics of the process. To do this, these quantities that are defined in the molecular frame are related to variables that caused the primary alignment in the external (laboratory) reference frame. The resulting vector correlations contain the information on dynamics in the form of details about the forces that led to the observed distribution of the vector quantities. Specifically, information can be deduced about the symmetry and lifetime of the transition state, as well as the shape of the potential surface, expressed in molecular coordinates relevant to the fragmentation.

Theory can contribute considerably to the understanding of the observed phenomena. Quantum mechanical calculations yield the shape of the multidimensional potential energy surface responsible for the nuclear motions during the reaction. Theory can also forecast the nuclear dynamics under selected initial conditions for the motions. Thus a direct comparison between experimental observations and theoretical predictions becomes possible. In addition, the detailed data furnished by modern spectroscopic techniques provide the opportunity to test theoretical approaches.

The following sections explain the spectroscopic method for obtaining the information described above. The method is illustrated by discussing the fragmentation reaction of hydrogen peroxide (H_2O_2), which has proven to be the classic example for the procedure. This molecule has a number of favorable properties for the application of the method and hence is the best studied molecule in this context. The knowledge gained from this investigation is then used to study another molecule, hydrazoic acid (HN_3). The fragmentation in this case is a complex process. Ab initio calculations of the potential surfaces show that these results are in full agreement with quantum mechanical predictions.

2. Doppler and Polarization Spectroscopy: the H_2O_2 Molecule as an Example

2.1. Background

The ability of molecules to absorb electromagnetic radiation is described by the absorption cross section σ. From energy considerations, the radiation required for fragmentation is, in general, UV light. The electric dipole approximation uses the transition moment $\vec{\mu}$ to describe the absorption-induced transition from initial to final states. $\vec{\mu}$ is a vector quantity and refers to molecular coordinates.

Light is characterized as an electromagnetic wave by the electric field vector $\vec{E}$. If this vector oscillates only in one plane, the light is called linearly or plane polarized. To maximize absorption at a given wavelength, $\vec{E}$ (defined by the polarization of the light in the laboratory frame) and $\vec{\mu}$ (defined in the molecular frame) must be parallel, since σ is defined according to (1) by the scalar product of $\vec{E}$ and $\vec{\mu}$. In the other extreme, when $\vec{E}$ and $\vec{\mu}$ are perpendicular the absorption cross section vanishes.

$$\sigma(\lambda) \approx (\vec{E}\vec{\mu})^2 \qquad (1)$$

The absorption of light correlates the two coordinate systems so that after absorption the excited molecules are a subgroup of aligned particles situated in an environment of statistically oriented, that is, disordered, particles. If the light was polarized in the z direction, the transition dipole moments point preferentially in the z direction. The distribution has a $\cos^2(\theta)$ dependence (1), with $\theta = \sphericalangle(\vec{E} = \vec{z}, \vec{\mu})$. The spatial intensity distribution has the same shape as the p_z orbital known from quantum mechanics.

The use of plane-polarized light makes it therefore possible to observe decomposition processes in which the excited and subsequently decomposing molecules have a certain alignment relative to the polarization direction of the excita-

Franz Josef Comes, born in 1928, obtained his Diplom in Physics in Mainz, and his doctorate at the Max-Planck-Institut für Chemie (Otto-Hahn-Institut) in Mainz working with Paneth on the study of meteorites by mass spectrometry. After this excursion into geophysics and cosmochemistry, he worked on the problems of molecular spectroscopy and reaction kinetics at the University of Bonn with Groth where he obtained his habilitation in 1964 and became Professor in 1969. In 1970 he was awarded the Fritz-Haber Prize of the Deutsche Bunsengesellschaft for fundamental work on photodissociation, photoionization, and molecular and photoelectron spectroscopy. After a guest professorship at the University of Southern California, Los Angeles, followed by a period as guest in the synchrotron group of Desy in Hamburg, he accepted the chair of Physical Chemistry at Frankfurt University in 1972. His interests include the application of lasers in chemistry, in particular in studies on reaction dynamics. Other fields of research are atmospheric chemistry and applications of the photovoltaic effect, in particular for the development of solar cells from amorphous silicon and germanium.

tion radiation and, hence, relative to a given spatial direction. This alignment of excited molecules does not stem from an application of an orienting force, but rather from the fact that only those molecules with $\vec{\mu}$ accidentally aligned parallel to the polarization direction are excited with maximum probability and induced to dissociate. The fragments to be observed stem exclusively from aligned reactant molecules. As the alignment of the molecules is correlated with their symmetry, the fragments' flight paths will, in general, display a spatial asymmetry caused by repulsive forces during the dissociation.

During photolysis, the fragments gain energy from the decomposition process. This energy is distributed among the degrees of freedom. The distribution is specific for each decomposition process. It is the goal of dynamics studies to analyze just this distribution. The different forms of energy of the products, for example, the kinetic energy E_{kin}, or the rotational energy E_{rot} (both scalar quantities), are related to vector quantities such as the velocity $\vec{v}$ or the angular momentum $\vec{J}$ of the fragments. To determine these variables, the analysis must leave the system undisturbed, that is, it must proceed without collisions, during the entire time interval from the beginning of molecular fragmentation to the identification of products. Only those spectroscopic observables are required that are associated with the *nascent* products of the fragmentation.

One method which fulfills these criteria for observing nascent species is based on fast spectroscopy with a time resolution in the nanosecond regime. This temporal resolution is sufficient, as the experiments are performed under reduced pressures, usually a few millitorr. Under these conditions the interval between two collisions falls in the microsecond time scale.

One possible experimental arrangement is to use a photolysis flash a few nanoseconds in duration to excite the reactant molecules. After a delay of at least the duration of one flash, a second flash, the probe flash, is employed to detect the products. This kind of experiment is called a pump-and-probe experiment and will be discussed in detail in Section 3.

An important initial piece of data for the application of Doppler and polarization spectroscopy is the energy content of the products, expressed by scalar quantities. For the photolysis of H_2O_2 with UV radiation [Eq. (2)] the two OH

$$H_2O_2 + h\nu \longrightarrow OH + OH \qquad (2)$$

product molecules exhibit an energy distribution that is very favorable for Doppler spectroscopy, since the energy is primarily translational in nature. According to Equation (3) the

$$E_{exc} = E_{h\nu} + E^i(H_2O_2) - E_{diss} \qquad (3)$$

absorbed light energy $E_{h\nu}$ together with the thermal energy $E^i(H_2O_2)$ from the experimental temperature T is shared between the two products after subtraction of the dissociation energy, E_{diss}. When the photolysis wavelength λ is 266 nm, about 90% of E_{exc} is kinetic energy and 10% is rotational energy. There is no measurable vibrational energy.[4] At this photolysis energy, the two OH product molecules acquire a velocity of about 3700 ms^{-1}, which is significantly faster than that of thermal particles. Therefore the OH fragments are, for all practical purposes, monoenergetic with respect to their velocity, which leads to extraordinarily sharp Doppler profiles.

2.2. Spatial Anisotropy; the $\langle\vec{\mu}\vec{v}\rangle$ Correlation

The simplest example of a fragmentation is the decomposition of a molecule AB into the fragments A and B, for which the transition dipole moment $\vec{\mu}$ is assumed to be perpendicular to the A–B axis, along which the dissociation will proceed. All molecules with their dissociation axes in a plane orthogonal to the direction of $\vec{\mu}$ have then the same probability for excitation.

Figure 1 shows two possible cases. Due to cylindrical symmetry, all directions in this plane are equivalent. If the fragments are to be observed by optical means (e.g. laser-induced fluorescence), the Doppler effect caused by the fragment velocity is the same for all directions in the plane. If, however, the observer is looking at the fragments down the direction of $\vec{\mu}$, perpendicular to the plane, no Doppler effect (i.e., no line broadening) will be registered. In this special case the velocity of the escaping fragments has no component in the direction of the observation. From the spatial asymmetry in the Doppler effect of the dissociation products, the linear momentum $\vec{p}$ of the fragments can be determined.

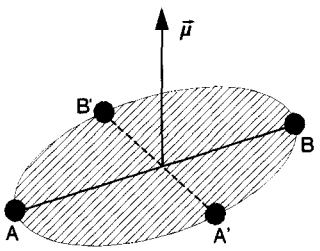

Fig. 1. After excitation of A–B by plane-polarized light, the transition dipole moments of the majority of excited molecules are aligned. All other orientations of the molecular axis (e.g. A'–B') in the plane perpendicular to $\vec{\mu}$ are equivalent and lead to the same alignment.

In reality, not only molecules with their transition moments $\vec{\mu}$ aligned with the electric field vector $\vec{E}$ are excited, but also those with a transition dipole moment at an angle to $\vec{E}$, that is, those that do have a finite component in the direction of $\vec{E}$. For an oblique position of $\vec{\mu}$ with respect to $\vec{E}$, the excitation probability simply follows a $\cos^2$ function [Eq. (1)]. Hence, molecules aligned parallel to $\vec{E}$ represent the largest contribution to the total excitation and, therefore, to the total fragmentation as well.

The H_2O_2 molecule in its electronic ground state exhibits only C_2 symmetry, which contains only the presentations A and B. The electronic singlet states can only be ^1A or ^1B. As the ground state is ^1A, the transitions $^1A \leftarrow {}^1A$ and $^1B \leftarrow {}^1A$ must be considered. For the first case, the corresponding transition dipole moment $\vec{\mu}$ must lie along the C_2 axis for symmetry reasons. It is therefore perpendicular to the O–O bond axis, as shown in Figure 2. Doppler spectroscopy (see later in this section) reveals that the first excited state of H_2O_2 is an ^1A state.[5, 6] At higher excitation energies, both ^1A and ^1B excited states are observed.[7] For the excitation

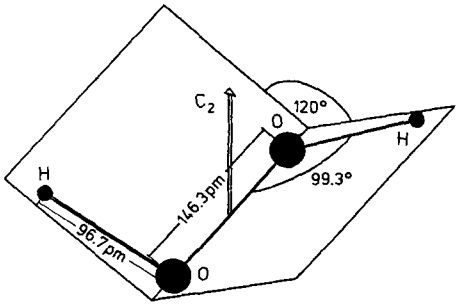

Fig. 2. Equilibrium configuration of H_2O_2, indicating the position of the C_2 axis. $\vec{\mu}$ is parallel to C_2 for the $^1A \leftarrow {}^1A$ transition.

to a ^1B state, $\vec{\mu}$ must lie, again for symmetry reasons, in a plane perpendicular to the C_2 axis, which therefore must contain the O–O bond axis. In addition, quantum mechanical calculations have shown that for excitation to the lowest lying ^1B state, the corresponding $\vec{\mu}$ is directed nearly exactly along the O–O axis.[8]

On irradiation with light of wavelength 266 nm, excitation of H_2O_2 leads solely to the ^1A state.[4, 5] When the polarization is in the z direction, the oxygen atoms of excited species will lie predominantly in the xy plane, due to the position of $\vec{\mu}$ perpendicular to the O–O bond [Eq. (1)]. If the excited molecule dissociates without a time delay, the two fragments will be expelled with the same high velocity $\vec{v}$ along the dissociation direction (the O–O axis). All directions in the xy plane are equivalent due to the cylindrical symmetry of the system.

If, as in Figure 3a and b, the fragments are observed by the probe laser along the x direction, OH fragments that

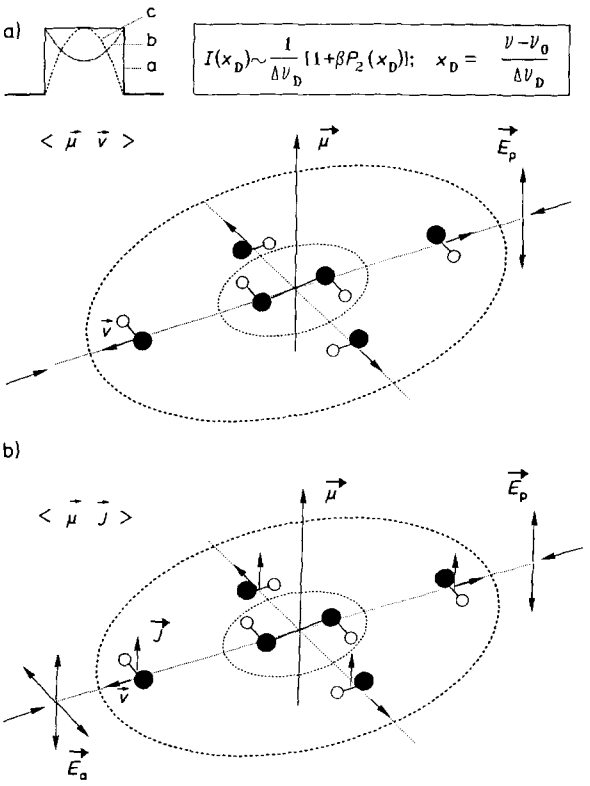

Fig. 3. Pictorial views of the vector correlations: a) $\langle \vec{\mu}\vec{v} \rangle$ correlation, b) $\langle \vec{\mu}\vec{J} \rangle$ correlation.

move directly towards or away from the detector in the x direction cause a maximum Doppler shift. Particles moving perpendicular to this direction (i.e., along the y or z axes) show no Doppler effect at all, because only the velocity component along the observation direction is Doppler active. There are no fragments with $\vec{v}$ along the z direction, a consequence of the spatial anisotropy in the distribution of the fragment velocities $\vec{v}$, which, in turn, results directly from the primary alignment of the reactant molecules.

For randomly (isotropically) aligned reactant molecules, the Doppler effect causes a rectangular pulse (Fig. 3a, curve a), if an infinite resolution (i.e., infinitesimal laser band width) and a monochromatic fragment velocity are assumed.

In the present example (the excitation to the ^1A state of H_2O_2 by z polarized light) no fragments with velocity vectors along the z direction will be formed. Such particles would not cause an observable Doppler effect along the x direction. As compared to the isotropic case, this leads to a lack of particles that show no Doppler effect. Therefore, the rectangular profile will experience a decrease in intensity at the center of the line, which is seen as a dip at the center (curve b in Figure 3a).

If the observation direction were along the z axis, profile c would result. Most of the fragments move in the xy plane and exhibit no Doppler effect along the z direction. From an experiment under the above conditions that results in profiles b and c one can conclude that, in the case of H_2O_2, the excited state has ^1A symmetry. The asymmetry of the velocity distribution determined from the Doppler effect yields information about the molecular symmetry of the excited state. The form of the velocity profiles is given by the equation shown in Figure 3a, where β represents the asymmetry parameter which contains the actual physical information. P_2 is the second Legendre polynomial for $\cos\theta$. In the isotropic case, $\theta = 0$. For the present example of H_2O_2, $\beta = -1$. For the excitation only to the lowest lying ^1B state ($\vec{\mu}$ aligned along the O–O axis) profiles b and c would be observed for the opposite detector orientations.

This example illustrates the correlation of $\vec{\mu}$ of the reactant molecule with the velocity vector $\vec{v}$ of its fragments (the $\langle \vec{\mu}\vec{v} \rangle$ correlation).

The discussion so far has shown Doppler profiles for given sets of conditions. The photolysis of H_2O_2 at 266 nm will now be used to illustrate actual experimental results (Fig. 4). An analysis of the profiles yields an asymmetry parameter of $\beta = -0.71$, rather different from -1,[5] which causes prediction and experimental results to differ. There are two conceivable reasons for this deviation. On one hand, the excitation at 266 nm may not exclusively yield the ^1A excited state, but a mixture of ^1A and ^1B states, thereby lowering the observed asymmetry. This would agree with the tendency of β to be as close to zero as possible, but can be excluded because measurements with different wavelengths, for example, 308 and 248 nm, yield the same results. On the other hand, the assumption of immediate dissociation of the excited molecule may not be justified.

In reality, a molecule requires a certain amount of time for fragmentation. During this interval, the molecule will, for instance, continue to rotate due to its thermal energy, leading to a rotation of the molecular coordinate system with respect to the laboratory frame. This rotation, in turn, causes

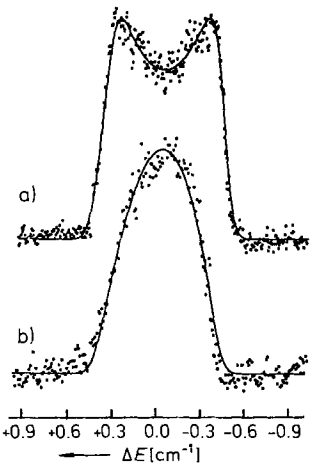

Fig. 4. Spectra of the $Q_1(4)$ transition (see also Section 2.3) of OH [5] for an arrangement of lasers where a) excitation and probe lasers are coaxial and polarized in parallel directions, b) pump and probe lasers are perpendicular to each other and polarization directions are as in a). A value of -0.71 is obtained for the asymmetry parameter β.

a lowering of the profile asymmetry, due to the change in the original alignment of the molecules. The observed value of β therefore decreases.

As has been shown by Bush and Wilson,[9] the average lifetime τ of the excited molecule can be calculated from the experimental value of β and the angular velocity of the reactant molecule. This velocity can be deduced from the rotational constants and the temperature of the molecules. From the experimentally determined β for H_2O_2 an average lifetime of $\tau = 60$ fs is obtained. As this is in the order of the period of one molecular vibration, we conclude that the H_2O_2 molecule decomposes along the fastest possible pathway after excitation. The potential surface of the excited state along the dissociation coordinate must therefore be purely repulsive. The application of Doppler spectroscopy yields, for the first time, information about the potential surface for the excited state that leads to fragmentation. One of the major goals of Doppler and polarization spectroscopy is to determine the shape of this potential surface; its gradients, in the proper coordinates, then describe the forces that cause the motion of the molecular fragments.

2.3. Rotational Asymmetry; $\langle \vec{\mu}\vec{J} \rangle$ Correlation

The fragmentation of H_2O_2 forms two diatomic OH molecules. In this section we are interested in the rotation of these fragments. The angular momentum $\vec{J}$ of diatomic molecules is perpendicular to the internuclear axis. For detection, the OH fragments are excited to the $^1\Sigma_g^+$ state. The J selection rules allow R, P, and Q transitions. For R and P transitions ($\Delta J = \pm 1$), the corresponding transition moment $\vec{\mu}_F$ of the OH fragment is perpendicular to $\vec{J}$. For Q transitions ($\Delta J = 0$), $\vec{\mu}_F$ is parallel to $\vec{J}$. If the output of the probe laser ($\vec{E}_p$) is also plane polarized, the alignment of the fragments relative to a given reference frame can be measured. For Q transitions, $\vec{\mu}_F$ parallel to $\vec{E}_p$ implies maximum excitation probability and means that $\vec{J}$ is parallel to $\vec{E}_p$ as well ($\vec{J} \parallel \vec{E}_p$). For R and P transitions, $\vec{\mu}_F$ is parallel to $\vec{E}_p$ when $\vec{J}$ is perpendicular to $\vec{E}_p$ ($\vec{J} \perp \vec{E}_p$).

At any given observation and polarization direction for the probe laser, the intensity ratios of bands stemming from R (or P) and Q transitions reflect the alignment of the angular momentum vector in space. One obtains a further vector correlation between the alignment of the reactant molecule, due to its transition dipole moment $\vec{\mu}$, and the fragment's angular momentum $\vec{J}$. This is generally referred to as alignment.

Figure 3b shows an expanded picture of the H_2O_2 fragmentation; the rotation of the fragments is now included. The present example is simplified as all $\vec{J}$ vectors are perpendicular to the xy plane. This, however, is irrelevant for the illustration of the $\langle \vec{\mu}\vec{J} \rangle$ correlation.

Both the $\langle \vec{\mu}\vec{J} \rangle$ and the $\langle \vec{\mu}\vec{v} \rangle$ vector correlations contain one piece of data each from the laboratory frame (the spatial alignment of $\vec{\mu}$ is determined by $\vec{E}$ of the excitation radiation) and the molecular coordinate system ($\vec{v}$ and $\vec{J}$ are determined by the molecular geometry).

2.4. The $\langle \vec{v}\vec{J} \rangle$ Correlation

The finite lifetime of the fragmenting molecules perturbs their original alignment in space. Therefore the $\langle \vec{\mu}\vec{v} \rangle$ and $\langle \vec{\mu}\vec{J} \rangle$ vector correlations are progressively lost with increasing lifetimes. However, the information on the dynamics of the molecular fragmentation is still present. If the fragment rotation is caused by a particular intramolecular motion, for instance, a bending oscillation, the velocity $\vec{v}$ and the angular momentum $\vec{J}$ of the fragments will always be preferentially perpendicular to each other (see later in this section). It is therefore necessary to eliminate the effects of the excited species' rotation before the fragmentation on the resulting observation, in order to recognize the correlation of $\vec{v}$ and $\vec{J}$ clearly. If $\vec{v}$ and $\vec{J}$ are correlated to $\vec{\mu}$, they must also be correlated to each other. However, this correlation, contrary to those discussed so far, is no longer connected to the laboratory frame, because both $\vec{v}$ and $\vec{J}$ are only associated with fragment motions. It is therefore necessary to find a transformation that identifies the correlation of $\vec{v}$ and $\vec{J}$. A formalism for this transformation has been developed by R. N. Dixon.[10] The $\langle \vec{v}\vec{J} \rangle$ correlation provides information that is independent of the lifetime of the excited reactant molecule, but contains the sought after results even if the molecule fragments, for example by predissociation, after a lifetime that is comparatively long for a dissociation process. For the case of fragmenting glyoxal (ethanedial), P. Houston et al. showed by analysis of CO fragments that the $\langle \vec{v}\vec{J} \rangle$ correlation is retained even after an excited-state lifetime of 1 μs (several thousand molecular vibrational periods), if the molecule was initially aligned.[11]

The $\langle \vec{v}\vec{J} \rangle$ correlation thus enables the elimination of effects of rotations of the parent molecule, even though these rotations cause a loss of the original molecule alignment. Even for molecules which decompose after a long lifetime, the full decay dynamics can be obtained by analyzing the $\langle \vec{v}\vec{J} \rangle$ correlation.

What kind of information does the $\langle \vec{v}\vec{J} \rangle$ correlation yield? Consider the decomposition of a planar molecule. If the fragmentation occurs from a motion within the molecular plane (Fig. 5a), the velocity vectors will also lie in this plane.

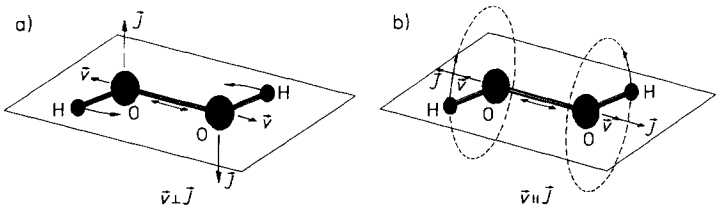

Fig. 5. Dependence of the orientation of $\vec{v}$ and $\vec{J}$ for H_2O_2 on the active mode of fragmentation. a) $\vec{v} \perp \vec{J}$; the active mode is a bending motion. b) $\vec{v} \parallel \vec{J}$; the active mode is a torsional motion.

A bending vibration in the plane causes a fragment rotation with an angular momentum vector perpendicular to the plane, leading to a perpendicular correlation between $\vec{v}$ and $\vec{J}$. More generally, any fragmentation stemming from a planar motion of the molecule yields a perpendicular correlation of $\vec{v}$ and $\vec{J}$. The value of the bipolar moment β_{vJ} described below is $-1/2$. If, however, the fragment rotation is caused by a torsional motion (Fig. 5b), $\vec{J}$ is parallel to $\vec{v}$ ($\beta_{vJ} = +1$).

Dixon has shown that the asymmetry parameter β can be expressed as the sum of bipolar moments $\beta_{\mu v}$, $\beta_{\mu J}$, β_{vJ}, and $\beta_{\mu vJ}$, which describe the correlation of the indicated fragment properties [Eq. (4)].[10]

$$\beta = \left[\frac{b_2\beta_{\mu v} + b_3\beta_{vJ} + b_4\beta_{\mu vJ}}{b_0 + b_1\beta_{\mu J}}\right] \quad (4)$$

Dixon also determined the numerical values of b_0 to b_4 for the various experimental geometries. This is done by observing R, P, and Q bands in different geometries.

The photolysis of H_2O_2 shows that the bipolar moments β_{vJ} are positive for the above described rotational states of the OH fragments. For an excitation wavelength of 193 nm, which was used for extensive experimental studies[12] as well as for dynamics calculations,[13] the value of β_{vJ} is close to $+1$, indicating that $\vec{v}$ and $\vec{J}$ of the fragments are nearly parallel. The intramolecular motion that causes the fragmentation is thus a torsional motion of the molecule.

This interesting result can have two origins. Torsional vibration, the lowest energy vibration of H_2O_2, is excited even at room temperature in the electronic ground state. It is possible that the fragment motions are caused by this torsional excitation. The more interesting case, however, is present when the observed OH torsion is a result of the shape of the excited state's potential surface. When the reactant molecules are strongly cooled, they lose internal energy. If the measured correlation still remains unchanged, the excited state must have caused the observed effect.

Experimentally, this is done by cooling the molecules in a molecular beam by adiabatic expansion to close to absolute zero. No significant change in the correlation was detected indicating that the source of the fragment torsion is to be found in the shape of the potential surface of the excited state.[7, 14]

2.5. The $\langle \vec{J}_A \vec{J}_B \rangle$ Correlation; Simultaneous Excitation of Several States

Doppler and polarization spectroscopy is potentially able to resolve further details of the molecular decay. For this to be feasible, the spectral resolution of the detector needs to be increased. For the experiments described so far, it was sufficient to resolve the absorption bands enough to determine the asymmetry parameter β. However, when viewed in detail, these bands are found to be composites of a number of bands. Further spectral resolution yields therefore added information about the fragmentation process.

The decomposition of a species containing four atoms into two diatomic products (e.g. $H_2O_2 \rightarrow OH(A) + OH(B)$) can lead to different values for the $\langle \vec{v}\vec{J} \rangle$ correlation. If $\beta_{vJ} = 1$, a torsional motion of the parent molecule is the driving force for fragmentation. The identical daughter fragments, OH(A) and OH(B), will have identical rotational energies, but opposite directions of rotation. This pair formation leads to another vector correlation, the $\langle \vec{J}_A \vec{J}_B \rangle$ correlation. OH(A) and OH(B) are formed in pairs, where $\vec{J}_A = -\vec{J}_B$. The ratio of the absolute values of $\vec{J}_A$ and $\vec{J}_B$ will be 1:1. Any deviation of the $\langle \vec{J}_A \vec{J}_B \rangle$ correlation from this ratio can be interpreted as a sign of additional motions within a plane of the parent molecule.

Thus a problem arises: how can one observe the two OH fragments which are created simultaneously from a single parent molecule? Experiments show that each molecule in the photolysis of H_2O_2 yields two OH fragments, but the rotational states of the fragments are differently populated. For a specific excitation energy, the parent molecule is apparently capable of reacting along different decay paths. According to Figure 6, the distribution of rotational states has a maximum at a particular rotational quantum number.

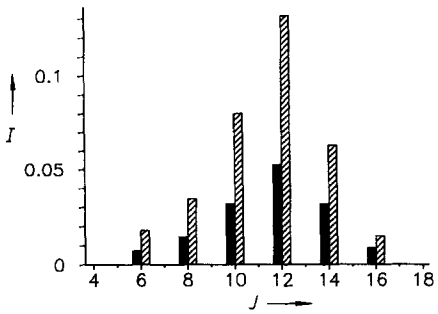

Fig. 6. Distribution of rotational states for the OH products after simultaneous excitation (193 nm) of cooled H_2O_2 into the $\tilde{A}\,^1A$ (▨) and $\tilde{B}\,^1B$ (■) states. For clarity, only data for even quantum numbers (J) are shown. I = population of the rotational level in arbitrary units.

However, it is in principle possible that OH fragments in lower rotational states are preferentially paired with those in higher states, which would depend only on the specific dynamics of the decomposition.

The different aspects of this method will be demonstrated on a simple example, for which three possible decomposition channels are assumed (Scheme 2).

$$H_2O_2 + h\nu \longrightarrow H_2O_2^*$$

$$H_2O_2^* \longrightarrow OH^{(A)}(J_i) + \begin{Bmatrix} OH^{(B)}(J_{i-1}) + \Delta E_{kin}(i, i-1) \\ OH^{(B)}(J_i) + \Delta E_{kin}(i, i) \\ OH^{(B)}(J_{i+1}) + \Delta E_{kin}(i, i+1) \end{Bmatrix}$$

Scheme 2. Decomposition channels for H_2O_2 as reason for the distribution of rotational states over the OH fragments.

Since in the decomposition of H_2O_2 the fragments have no vibrational energy, only rotational energy specified by its quantum number J, and kinetic energy, signified by ΔE_{kin}, are present. Each of the three paths exhibits a different combination of rotating fragments, differing in their kinetic energy according to the principle of conservation of energy. If we observe OH fragments in the J_i state, the processes of Scheme 2 contribute to the Doppler width of the measured rotation band. The corresponding kinetic energies are $\Delta E_{kin}(i,i-1)$, $\Delta E_{kin}(i,i)$, and $\Delta E_{kin}(i,i+1)$. The expected Doppler band is therefore in fact composed of three bands of different width, in accordance with the different amounts of kinetic energy that are released during the fragmentation (Fig. 7). The heights of the individual bands are proportional

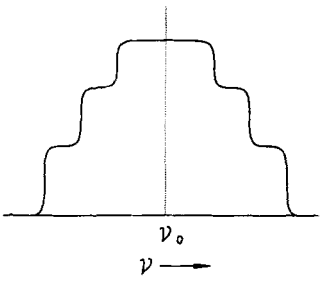

Fig. 7. Coincident pair formation. Schematic representation of a Doppler band for a case with three decay channels (see Scheme 2).

to the relative contribution of the corresponding decay channel. Hence, the desired information can be obtained from the wings of the band profiles. The spectral resolution of the analysis laser must be considerably increased to be able to reveal this information. High-resolution spectroscopy, that is, the analysis of the wings of a Doppler-broadened rotation band, makes it possible to examine simultaneously formed product pairs and to determine the so-called pair formation probabilities. This is exactly the $\langle \vec{J}\vec{J} \rangle$ correlation. This correlation expresses the probability of finding the counterpart of a fragment in the J_i state in the states J_{i+1}, J_i, and J_{i-1}.

2.6. Vector Correlations for the Simultaneous Excitation of Several Dissociation Continua

Both the ^1A and the ^1B states of H_2O_2 are excited simultaneously with light of wavelength 193 nm, because it contains sufficient energy, in contrast to a wavelength of 266 nm (Section 2.2). As described above, the transition dipole moment $\vec{\mu}$ of the lowest lying ^1A state lies along the C_2 axis, which is perpendicular to the O–O bond. Ab initio calculations for the ^1B state showed that the corresponding $\vec{\mu}$ lies nearly along the O–O axis. Therefore, if the excitation to the ^1A state causes a band shape similar to curve b in Figure 3a, the excitation to the ^1B state must lead to the complementary band shape, curve c, in Figure 3a (and vice versa). This is simply because those parent molecules excited to the ^1A state are preferentially aligned along an axis perpendicular to the O–O bond. For molecules excited to the ^1B state, the preferred alignment is in the perpendicular direction, along the O–O axis. When both states are excited simultaneously, the two band shapes overlap. For infinite detector resolution, the profile is square for approximately equal excitation probabilities for both states. The measured asymmetry parameter β_{obs} is composed of the weighted contributions of the two simultaneously initiated fragmentation processes [Eq. (5)].

$$\beta_{obs} = a\beta_A + (1-a)\beta_B \quad (5)$$

The variable a is wavelength dependent and indicates the fraction of the total excitation that is attributable to the ^1A state. The contribution of the ^1B state is $(1-a)$.

The analysis of vector correlations from a continuous absorption spectrum (a dissociation continuum) makes it possible to solve complicated problems such as the simultaneous participation of several excited states quantitatively.

From the vector correlations the contribution of each of the simultaneously excited states to the rotational excitation of the formed fragments can be calculated. In fact, the states ^1A and ^1B contribute about 65% and 35%, respectively, to the total absorption. The distribution of rotational states is nearly identical (Fig. 6).[6] The latter finding is in exact agreement with the decay dynamics computations performed by Staemmler et al. with ab initio techniques based on potential surfaces of the molecule in both excited states.[13, 15] These potential surfaces clearly show two things: the excited states are purely repulsive in nature (also found by using the $\langle \vec{\mu}\vec{v} \rangle$ correlation) and they are strongly repulsive with respect to the torsion coordinate (predicted by the $\langle \vec{v}\vec{J} \rangle$ correlation). The H_2O_2 molecule in its ^1A excited state exhibits a strong tendency to convert to the *trans*-planar conformation, whereas in the ^1B state the opposite motion towards the *cis*-planar conformation prevails. In both cases a torsional motion is excited. As the gradients of both potential surfaces are nearly equal in absolute value, the distributions of rotational states are also expected to be equal, as was shown experimentally (Fig. 6).

These specific details of the fragmentation reaction can be illustrated more clearly by choosing the isotopically substituted molecule D_2O_2 as example. In addition, the study of D_2O_2 can also serve to test these methods if the results are compared with predictions based on the experiments described above. Replacing the H atoms with heavier deuterium atoms moves the fragment's center of gravity closer to the deuterium position. Forces that repulse the two fragments therefore have more leverage, and a higher fraction of the total energy is expected to be in the form of rotational energy. This enhanced motion, which will manifest itself as planar motion, will shift the values for the $\langle \vec{v}\vec{J} \rangle$ correlation towards the negative as planar motions lead to negative correlations. The $\langle \vec{\mu}\vec{v} \rangle$ correlation will be even more negative than before.

The results of this experiment indicate an increase in the rotational energy of the OD fragments by 30% compared to OH. Both correlations were found to behave exactly as predicted: both $\langle \vec{v}\vec{J} \rangle$ and $\langle \vec{\mu}\vec{v} \rangle$ become slightly more negative.[16] This good agreement of experimental findings with theoretical predictions is an excellent proof for the power of this spectroscopic method.

3. Experimental Considerations

In Section 2, conditions for the successful application of Doppler and polarization spectroscopy were outlined. One

of these conditions was the absence of collisions involving the spectroscopically studied molecules. As also mentioned, a possible solution is to perform pump-and-probe experiments at reduced pressures while employing a temporal resolution in the nanosecond regime. This means that both pump and probe lasers must operate in the pulsed mode. To observe the spatial anisotropy of the fragment velocities, the Doppler profiles must be obtained in both coaxial and perpendicular beam directions. For the observation of the $\langle \vec{\mu}\vec{J} \rangle$ correlation is it necessary to polarize the two laser beams in mutually perpendicular directions. For the photolysis laser, it is sufficient to have available a number of fixed frequencies, so that the excitation of either a single absorption continuum or the simultaneous excitation of several continua is possible. The analysis laser must possess a narrow bandwidth and must be tunable in the UV range, so that different molecules can be studied. The last condition necessitates frequency doubling of the radiation.

In our experiments the probe laser is used according to the principles of laser-induced fluorescence. The molecule to be observed is excited by resonance absorption, and the resulting total fluorescence is measured without any prior spectral resolution. The spectrum obtained is called a fluorescence-excitation spectrum. This method is state-selective, which is absolutely necessary, and very sensitive, but usually requires a time delay of several pulse lengths between photolysis and probe pulses to reduce the effect of stray radiation caused by the stronger photolysis laser.

Figure 8 shows schematically a possible experimental setup that complies with the requirements described above.[17] The photolysis and probe beams pass through the sample chamber perpendicular to each other; the parallel arrangement of the probe laser is indicated by dashed lines. The observation direction along which the fluorescence is measured is perpendicular to both laser beams.

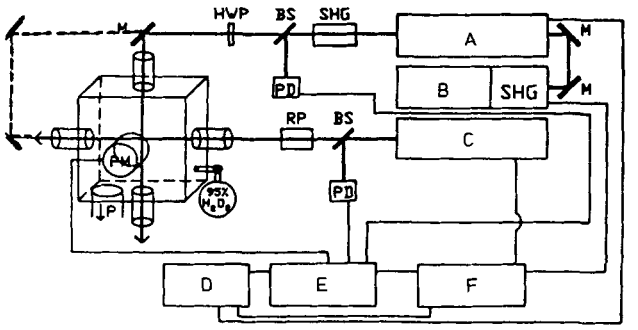

Fig. 8. Diagram of the apparatus for Doppler and polarization spectroscopy. M: mirror, BS: beam splitter, SHG: second harmonic generator (frequency doubler), PD: photodiode, RP: polarizer, PM: photomultiplier, P: pump, A: dye laser, B: Nd-YAG laser, C: ArF laser, D: computer, E: boxcar integrator, F: trigger.

The molecules to be studied are prepared either under quasi-static conditions or in a molecular beam. Quasi-static in this context means that the gas is under reduced pressure, but is kept flowing slowly, so that no secondary products can accumulate during the analysis. The molecular-beam experiment is performed in the form of an ultrasonic expansion to cause adiabatic cooling in order to permit the observation of particles at temperatures close to 0 K. These conditions yield molecules in their lowest energy states, thereby making it possible to neglect their internal energy in the analysis.

The $\langle \vec{J}\vec{J} \rangle$ correlation experiment requires a further increase in the spectral resolution. A diagram of the apparatus is not shown to conserve space, but it should be mentioned that a laser with high spectral resolution is necessary; for our H_2O_2 experiment, a continuous laser was employed. The output of this laser must be converted into intense light pulses, which is achieved by using a dye laser amplifier.[18] As follows from Equation (6), the pulse width Δt of this dye

$$\Delta\nu\Delta t \approx 1 \qquad (6)$$

laser must be chosen small enough to make the necessary frequency resolution possible (in the case of OH detection, $\Delta\nu \leq 100$ MHz). In order to convert this frequency resolution into the desired spectral resolution, the reactant molecules for the H_2O_2 experiment must be cooled by adiabatic expansion in the molecular beam.

4. Results of High-Resolution Doppler Spectroscopy: The Impact Parameter

Because of conservation of energy, the excess energy available to the fragments, E_{exc}, can be deduced from the photolysis energy, if the energy necessary for dissociation is taken into account [see Eq. (3)]. On application of the law of conservation of momentum, the internal energy of the fragments can be calculated. The conservation of angular momentum makes it possible to determine the impact parameter that affects the repulsion of the formed fragment pair. To apply this last principle the angular momentums involved must be analyzed in detail. The $\langle \vec{J}_A \vec{J}_B \rangle$ correlation is an important source of information, since its value indicates the distribution of angular momentum among simultaneously formed fragments. For H_2O_2 decomposition, the $\langle \vec{J}_A \vec{J}_B \rangle$ correlation indicates to what extent the fragments' rotational energy stems from a torsional motion of the parent H_2O_2 molecule. Particularly important, the fraction of the fragment's rotation due to other motions of the parent molecule can be deduced. This fraction should be directly related to the deviation of the $\langle \vec{J}_A \vec{J}_B \rangle$ correlation from a 1:1 ratio. The deviation, in turn, is dependent on the contribution of the orbital angular momentum to the total angular momentum of the fragments, from which the desired impact parameter can be calculated. If its value is vanishingly small, the repulsion of the two fragments can be treated like a central collision of the centers of gravity of the two fragments. Hence, the impact parameter yields information about the deviation of the collision from a central one.

The photolysis of H_2O_2 yields two chemically identical OH radicals as products. As discussed earlier, there are no fundamental reasons that prevent those two particles from being formed in different rotational quantum states. If the initial states of the two simultaneously formed species are completely uncorrelated, the probability of pair formation is the *product* of the formation probabilities of each separate species [Eq. (7)]. If the initial states are completely correlated, as would be the case had they been formed exclusively

from a torsional motion of the parent molecule, Equation (8) will hold. The determination of the probability matrix $P(J_A J_B)$ will yield information about possible correlations.

$$P(J_A J_B) = P(J_A)P(J_B) \tag{7}$$

$$P(J_A J_B) = \delta(J_A J_B)P(J_A)$$
$$\text{where } \delta(J_A J_B) = \begin{cases} 1 \text{ for } J_A = J_B \\ 0 \text{ for } J_A \neq J_B \end{cases} \tag{8}$$

Figure 9 shows the matrix elements as a function of J_A and J_B.[18] In general, the matrix elements on the diagonal are the largest. Therefore, the maximum probability process is the formation of fragments with equal rotational energy. However, the observed distribution of P shows a width at half height of about three rotational states.

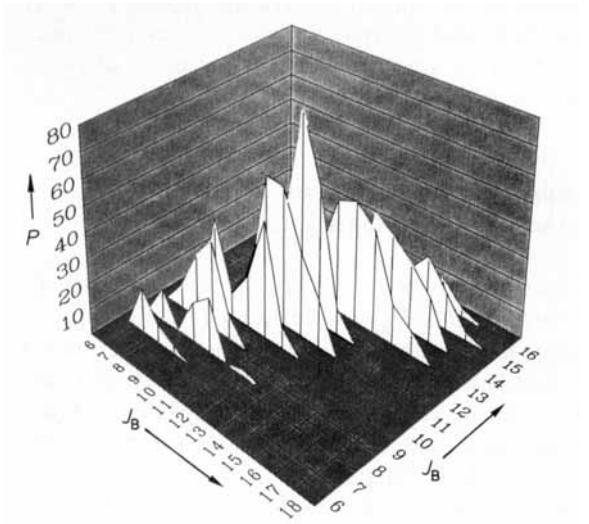

Fig. 9. Pair formation probability $P(J_A J_B)$ for the photofragmentation of H_2O_2 at 193 nm.

The primary result that can be gleaned from Figure 9 is that the 1:1 correlation of J_A and J_B could also be caused by a bending motion of the parent molecule. However, this would lead to a negative $\langle \vec{v}\vec{J} \rangle$ correlation. A strongly positive $\langle \vec{v}\vec{J} \rangle$ correlation is found instead, which must be due to a torsional motion. Therefore it is expected that $\vec{J}_A = -\vec{J}_B$. Deviations from this relationship are caused by additional bending motions of the rotamers. Studies at an excitation wavelength of 193 nm showed that the torsional contribution to the total rotation is 70%.[19]

As discussed earlier, the rotational motion of the fragments is governed by the law of conservation of angular momentum, which applies to the entire system. If the molecular beam contains cooled reactant molecules, their angular momentum will be close to zero. Therefore, if the angular momentum of the absorbed photon is ignored, the total angular momentum is composed of the angular momentums of the product molecules, $\vec{J}_A$ and $\vec{J}_B$, and any orbital angular momentum $\vec{L}_{AB}$. The law of conservation of angular momentum takes the form shown in Equation (9), and the limits of possible values for $\vec{L}_{AB}$ are given by Equation (10). The orbital angular momentum L_{AB} can be expressed as Equation (11) where μ represents the reduced mass of the system, v_{AB} represents the relative velocity, which can be determined accurately, and b is the impact parameter. The impact parameter acts as the lever that causes L_{AB}.

$$\vec{J}_A + \vec{J}_B + \vec{L}_{AB} = 0 \tag{9}$$

$$J_A + J_B \geq L_{AB} \geq |J_A - J_B| \tag{10}$$

$$L_{AB} = \mu b \, v_{AB} \tag{11}$$

According to the vector correlations, J_A and J_B are essentially oriented in an antiparallel manner. Therefore, the value of L is given by the difference ΔJ of J_A and J_B, yielding Equation (12) for b, where $\Delta\nu_D$ represents the Doppler line width and ν_0 the resonance frequency.

$$b = \frac{\Delta J \, \nu_0}{\Delta\nu_D \, c \, m_{OH}} \tag{12}$$

When the value of ΔJ found from Figure 9 is inserted, the impact parameter b is found to be (1.0 ± 0.3) pm.[18] This calculated impact parameter is smaller than the distance between the center of gravity of the OH group and the oxygen atom, which implies that the repulsive force does not act directly along the O–O bond, but rather along a line joining the two centers of gravity of the OH fragment pair. Therefore the simple picture of an oxygen–oxygen repulsion does not describe the dissociation of H_2O_2 in sufficient detail.

5. The Fragmentation of HN_3—a Complex Case

The study of the H_2O_2 decomposition by Doppler and polarization spectroscopy yielded a nearly complete characterization of this fragmentation. It indicated which forces are active during the dissociation and led to the observed energy distribution in the products. The fragmentation was shown to be a direct process, which occurs on a purely repulsive potential surface with a duration of only 60 fs. Now, as for all experimental methods, a question arises regarding general applicability, especially to more complex problems. The study of hydrazoic acid, HN_3, was chosen as example. The following discussion shows that its fragmentation could be studied in as much detail as that of H_2O_2.

HN_3 is a molecule containing four atoms, which absorbs UV radiation to decompose into two diatomic fragments. The first absorption continuum, which has its maximum absorption at 265 nm, yields the fragmentation reaction (13).[20, 21]

$$HN_3(^1A') + h\nu \longrightarrow HN_3(^1A'') \longrightarrow NH(a^1\Delta) + N_2(^1\Sigma_g^+) \tag{13}$$

The products of this reaction are NH, in a metastable excited electronic state, and N_2, in its electronic ground state. At first glance this molecule provides more favorable conditions for the study of the fragmentation reaction than H_2O_2: two different products are formed, which can be observed separately by spectroscopy. However, the potential surface proved to be significantly more complicated. In the following discussion, only the decay channel leading to the $v'' = 0$ vibrational state of $NH(^1\Delta)$ will be considered. The excited vibrational states that are also formed during the fragmentation will not be taken into account.[22]

At a photolysis wavelength of 193 nm, a second decay path yields hydrogen atoms, $H(^2S)$. These were identified by LIF employing the Ly_α radiation[17] of a frequency-tripled dye laser.[23] The other fragment is most probably the triatomic N_3, as expressed in Equation (14). N_3 was indeed observed. However, because this species could also be a product of (15), the mechanism of (14) has not yet been

$$HN_3 + h\nu \longrightarrow H(^2S) + N_3(\tilde{X}^2\Pi) \quad (14)$$

$$NH(^1\Delta) + HN_3 \longrightarrow NH_2 + N_3 \quad (15)$$

proved even though the experimental data indicate that N_3 is a primary product of the photolysis.[24] Since the decay channel described by (14) has not yet been examined with Doppler and polarization spectroscopy, this aspect of the fragmentation of HN_3 will not be discussed further.

The first important step of the analysis concerns the distribution of energy. From an argument analogous to that which led to Equation (3), an expression for the excess energy can be deduced [Eq. (16), where μ is the reduced mass of

$$E_{exc} = \langle E_{rot}(NH)\rangle + \langle E^i(N_2)\rangle + \tfrac{1}{2} m_{NH}^2 \langle v_{NH}\rangle^2/\mu \quad (16)$$

the system and $\langle v_{NH}\rangle$ the average velocity of the NH fragment]. This equation contains only the average rotational energy of the NH species, $\langle E_{rot}(NH)\rangle$, because in the present treatment there is *no* excitation of NH vibration.

All energy measurements, as well as the vector correlations discussed below, are performed exclusively on the NH fragment, which is identified by LIF through the measurement of the NH fluorescence stemming from the $c^1\Pi \rightarrow a^1\Delta$ transition produced by radiation from the probe laser. N_2 is more difficult to observe spectroscopically. Equation (17) is derived from Equation (16) to calculate the average internal energy of the N_2 fragment.

$$\langle E^i(N_2)\rangle = E_{exc} - \langle E_{rot}(NH)\rangle - \tfrac{1}{2} m_{NH}^2 \langle v_{NH}\rangle^2/\mu \quad (17)$$

From the beginning the distribution of this energy among the rotational and vibrational degrees of freedom is not determined. Of the excess energy, 51% is found as kinetic energy of the fragments; hence the contribution of the internal energy to the total is 49%. This internal energy is distributed in an extremely dissimilar way between the two fragments—the N_2 molecule receives 94% of it. Only 6% is present as rotational energy of the NH fragment. By using the laws of conservation of energy and momentum, the velocities of the two products are calculated to be 3320 ms^{-1} for NH and 1770 ms^{-1} for N_2.[22] The high NH velocity is the most significant result. High-resolution experiments, as used for the study of simultaneous pair formation, show that the N_2 velocity distribution is very narrow, indicating that, similar to the H_2O_2 case, sharp Doppler profiles can be expected.

Changing the photolysis wavelength from 280 nm to 266 nm, 283 nm, and 308 nm indicates the complex nature of the fragmentation, because the kinetic energy, and therefore the velocity of the particles, remains essentially unchanged. Moreover, the change in photon energy does *not* lead to a change in the NH rotation, which implies that the excess energy is exclusively utilized for excitation of N_2. This implication has very important consequences for the shape of the potential surface (Table 1).[25]

Table 1. Excess energies and energies of fragments [cm^{-1}] from the decomposition of HN_3 at different wavelengths.

	248 nm		266 nm		283 nm		308 nm	
	NH	N_2	NH	N_2	NH	N_2	NH	N_2
E_{exc}	21950		19210		~16970		14100	
E_{kin}	6800	3640	7040	3770	6430	3440	6950	3720
E_{rot}	700	10810	700	7700	~700	6400	690	2740

A further strong indication of the complexity of the HN_3 decomposition reaction comes from observations of the Λ states of the NH fragments. The study of the various Λ states of $NH(^1\Delta)$ and $ND(^1\Delta)$ at an excitation wavelength of 308 nm indicates equal population of the $^1\Delta(A')$ and $^1\Delta(A'')$ states but different vector correlations with evidence of a remarkable isotope effect. This suggests a distinctly nonplanar dissociation geometry of the fragmentation product in the $^1\Delta(A')$ state.[26]

In its ground state, HN_3 is planar.[27] The three nitrogen atoms form a nearly linear chain, while the H atom is at an angle of 71.2° to this chain. The absorption at 266 nm causes the transition $\tilde{A}^1A'' \leftarrow \tilde{X}^1A'$, which has its corresponding transition dipole moment $\vec{\mu}$ perpendicular to the plane of the molecule. The population of rotational states in NH has its maximum at $J = 5$ and shows a slight inversion in the lower quantum states.[22]

The experimental setup for the study of the HN_3 photolysis reaction is exactly the same as described in Section 3. The different photolysis wavelengths were generated by using the fourth harmonic of a Nd-YAG laser (266 nm), or the radiation of either a KrF (248 nm) or XeCl (308 nm) laser. The arrangement of the analysis laser remained unchanged.

Measurements of the asymmetry parameter of the R, P, and Q transitions in the occupied rotational states of the NH fragment were performed for the different experimental geometries mentioned earlier. They yield the bipolar moments $\beta_{\mu v}$, $\beta_{\mu J}$, and β_{vJ} [Eq. (4)] for each rotational state, which describe the vector correlations between the transition dipole moment $\vec{\mu}$ of the parent molecule and the velocity v or the angular momentum $\vec{J}$ of the NH fragment and between $\vec{v}$ and $\vec{J}$ of the NH fragment itself. The values of $\beta_{\mu v}$ deserve special attention. As shown in Figure 10a, the lowest energy NH rotation results in a value for $\beta_{\mu v}$ of -0.4, which is close to the absolute minimum for this quantity (-0.5), indicating an almost perpendicular alignment of $\vec{\mu}$ and $\vec{v}$. However, $\beta_{\mu v}$ increases with increasing rotational energy, finally becoming positive for $J > 9$.[22] This behavior for $\beta_{\mu v}$, which is observed for $\beta_{\mu J}$ as well, is also found at an excitation wavelength of 308 nm. Only minor differences are seen.[25]

Although $\beta_{\mu J}$ is very small and only slightly dependent on the NH rotation, it is always positive, indicating that $\vec{\mu}$ of the parent molecule and $\vec{J}$ of the NH products are oriented predominantly parallel to each other. The resulting β_{vJ} is positive and increases for the higher quantum states (Fig. 10b). This last result shows that a torsional motion of HN_3 is responsible for the fragment's rotation and that its influence increases with increasing rotational excitation of the NH species. The negative value for the $\langle \vec{\mu}\vec{v}\rangle$ correlation ($\beta_{\mu v}$ close to -0.5) is expected for a planar dissociation geome-

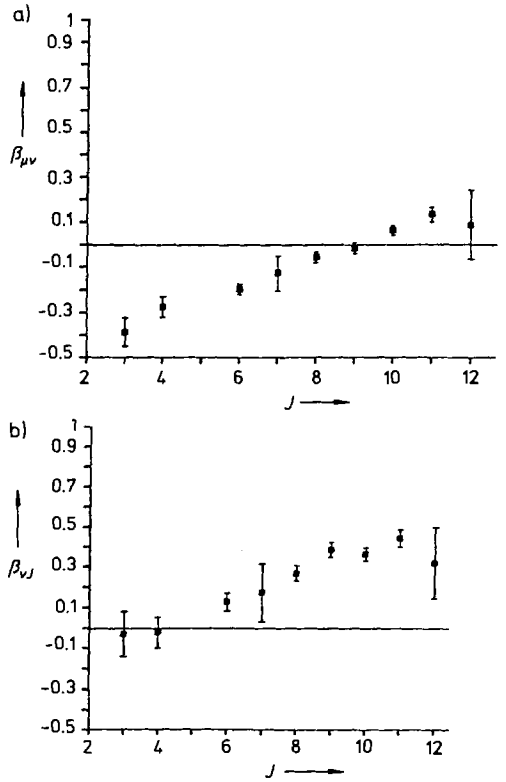

Fig. 10. Vector correlations expressed as the asymmetry parameter β for the NH fragment from the photofragmentation of HN_3 at 266 nm as a function of rotational quantum number of NH [22]. a) $\beta_{\mu\nu}$; b) $\beta_{\nu J}$.

try. When $\vec{\mu}$ and $\vec{v}$ become more parallel ($\beta_{\mu\nu}$ becomes more positive), the plane in which the NH fragment velocity is developed is tilted towards the direction of $\vec{\mu}$ leading simultaneously to a higher rotational excitation. Of all HN_3 vibrational modes, only the ν_6 (a″) mode satisfies this criterion. This is a bending vibration directed out of the original plane of the molecule. The excited state potential surface should therefore exhibit a large (negative) gradient with increasing angle between the three N atoms. The unequal distribution of the angular momenta is a direct result of such a geometry: the location of the centers of gravity of the fragments ensures that the N_2 species receives significantly more angular momentum than the NH fragment. For N_2, the center of gravity lies between the two N atoms, whereas for NH the center of gravity is nearly coincident with the nitrogen atom because the H atom is light. During the evolution of the fragment rotation from the bending motion of the parent molecule, the N_2 fragment is readily induced to rotate, while NH behaves nearly like a single atom and is provided primarily with orbital angular momentum.

Two experimental results support the above conclusion regarding the N_2 fragment. At a photolysis wavelength of 283 nm, REMPI spectroscopy showed that the produced N_2 is only rotationally excited, with an average rotational quantum number of 56. The distribution of the rotation is Gaussian, with a small half-height width of $\Delta J \approx 13$.[28] (An important consequence is the narrow velocity distribution, which is also determined by ΔJ.) The second confirmation stems from studies of simultaneous pair formation, which also show purely rotationally excited N_2 molecules for various photolysis energies. The rotational energy distribution in these cases is also narrow. For $\lambda = 248$ nm, the average rotational quantum number is 70.[29] The spectral resolution in the observation of pair formation by analysis of NH fragments is not sufficient to resolve the rotational states of N_2 by an LIF technique, because the difference in rotation constants of NH and N_2 is too large. Nevertheless, it can be said that the energy of N_2 is rather incompatible with vibrational excitation. If a Gaussian distribution is assumed, the maximum population of the rotational states of N_2 for an excitation at 248 nm occurs at $J = 70$, with a half-height width of $\Delta J = 18$.

Further information about the shape of the potential surface can be obtained from pair formation correlations. This correlation limits the possible motions of the system. According to Figure 11, maximum N_2 rotation occurs when NH rotation is at a minimum.[29] Furthermore, for high N_2

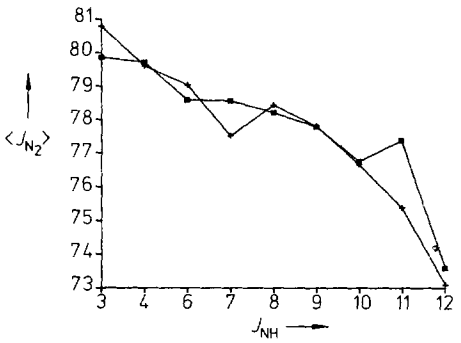

Fig. 11. Pair formation correlation for N_2 and NH for the photofragmentation of HN_3 at 248 nm [29]. $\langle J_{N_2} \rangle$ is the average rotational quantum number of the N_2 fragment. ■: photolysis under quasi-static conditions, +: molecular-beam experiment.

rotation $\langle \vec{\mu}\vec{J} \rangle$ is positive. This $\langle \vec{\mu}\vec{J} \rangle$ correlation is reduced to nearly zero with decreasing rotational excitation of N_2. A positive $\langle \vec{\mu}\vec{J} \rangle$ correlation for N_2 indicates that the rotation vectors of the fragments are more likely to be parallel to the transition dipole moment. For HN_3 this means that they are perpendicular to the original plane of the molecule, which leads to the conclusion that the high N_2 rotation is primarily caused by a motion of the parent molecule that lies *in* the molecular plane. This is the ν_5 bending motion. The potential surface gradient for this motion is therefore initially steeper. With decreasing N_2 and increasing NH rotation, the bending motion is increasingly out of this plane. From the $\langle \vec{\mu}\vec{v} \rangle$ correlation for NH it is known that, for higher NH rotations the bending motion perpendicular to the original plane (ν_6) becomes more important for the decomposition dynamics.

The vector correlations predict that the potential surface has large gradients for angle variations that occur in the original plane or perpendicular to it. These projections are fully confirmed by new ab initio calculations of this potential surface.[30] The theoretical predictions state that, in the vicinity of the N_2–NH equilibrium distance, the forces are directed much more strongly into the ν_5 rather than the ν_6 motion. Only with increasing N_2–NH distance, does the potential for the out-of-plane motion become steeper. This effect of changing from the ν_5 to the ν_6 mode during the process of decomposition influences the NH fragment rotation in such a way that a torsional motion is developed, which can be readily recognized by the positive $\langle \vec{v}\vec{J} \rangle$ correla-

tion. This correlation is very small for small NH rotations. These findings are in full agreement with the observation that small NH rotations are correlated with large N_2 rotations, which are caused by the ν_5 vibration in the original plane of the molecule.

As was discussed for the photodecomposition of H_2O_2, the product–pair correlations can be used in conjunction with the law of conservation of angular momentum to obtain information about the impact parameter. As the rotation of NH is small while that of N_2 is exceptionally large, the orbital angular momentum is determined primarily by the N_2 rotation. The orbital angular momentum can be determined by using Equations (10)–(12) developed for the H_2O_2 case [Eq. (18)].

$$L_{N_2-NH} = \mu_{N_2-NH} b v_{N_2-NH} \tag{18}$$

For the excitation at 266 nm, the most probable rotational quantum number is 70. Therefore, by using the experimentally observed fragment velocities, the impact parameter b is calculated to be approximately 0.9 Å.[22] This is somewhat larger than the equilibrium distance between the centers of gravity of the N_2 fragment and HN_3. The impact parameter decreases for lower excitation energies (283, 308 nm), which could indicate a smaller amplitude for the bending motion in these cases.

The preceding discussion demonstrates that Doppler and polarization spectroscopy is a powerful tool which yields an exact description of the forces that are acting during the decomposition of the transition state, not only for H_2O_2 but also for the more complex example, HN_3. It is possible to gain insight into the molecular motions of femtosecond duration occurring in chemical reactions. While conclusions are drawn from quantities that are integrated over the course of the reaction, the resulting information yields a complete description of the entire reaction path.

Conclusions

The studies of molecules with Doppler and polarization spectroscopy are performed with a spectral resolution that allows the exact determination of the band profile of an absorption line, which contains all necessary information. For this to be feasible, complete resolution of the rotational fine structure is essential. Further information from the spectrum is gleaned from the spin of the electron and the Λ splitting. Even nuclear spin effects can be observed. These subtle aspects of the spectral information have, with one exception, not been discussed here, in order not to exceed the limits of an introductory description of the potential of Doppler and polarization spectroscopy.

There is already a fairly large number of molecules that have been examined in several laboratories.[3] The analysis of pair formation, however, has so far only been applied to the two examples described in this review. This method renders possible a characterization of the fragmentation reaction that goes beyond the description given by the vector correlations between $\vec{\mu}$, $\vec{v}$, and $\vec{J}$. The examples were meant to show the potential of the method and the conclusions that can be drawn from it. The description of the photodecomposition process illustrates how a molecular system moves on the molecular level from an unstable excited state to a stable final state, providing insight into the nature of the reaction path of a chemical reaction and into how the molecules distribute the energy absorbed during a chemical process. As the motions of these products is a true image of the forces that cause them, it is possible to deduce the forces from properties of the products. Doppler and polarization spectroscopy, as well as time-resolved spectroscopy at extremely short lifetimes, are complementary methods for the investigation of important intramolecular events, which are of great importance to the understanding of reaction dynamics.

Experimental results cited herein were taken from several doctoral and master's (Diplom) theses. I am grateful to all collaborators for their enthusiastic efforts. I want to thank Dr. K.-H. Gericke, Prof. E. A. Reinsch and Prof. R. N. Dixon, whose collaboration and critical contributions were essential for the success of the investigations discussed in this review. The work was supported by the Deutsche Forschungsgemeinschaft.

Molecules with Large Cavities in Supramolecular Chemistry

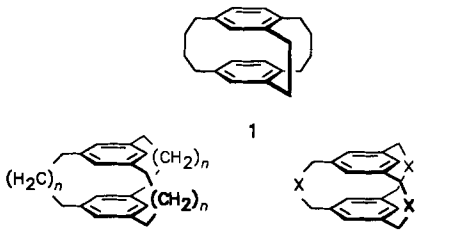
By Christian Seel and Fritz Vögtle*

Dedicated to Professor Heinz Harnisch on the occasion of his 65th birthday

Supramolecular chemistry is a new area of research that has rapidly developed from pure synthetic chemistry, and its novelty has led to interdisciplinary cooperation between organic and inorganic chemistry, biochemistry, physical and theoretical chemistry, and physics. Whereas *molecular chemistry* essentially deals with the covalent bonding of atoms, supramolecular chemistry is predominantly involved in the study of the weaker intermolecular interactions resulting in the association and self-organization of several components to form larger aggregates (supramolecules). The first crown ether discovered by the subsequent Nobel prizewinner Pedersen was more the fortuitous reaction product of an impurity, but nowadays, some twenty-five years later, chemists are able to tailor host molecules to special requirements. Host compounds having a cyclophane skeleton make an important contribution, since their aromatic structural units ensure the necessary rigidity of the molecular structures and thereby improve the preorganization of the coordination sites for the cooperative binding of the guests. During the course of the rapid development of supramolecular chemistry such a large number of synthetic hosts has been developed and their interaction with guests studied in such depth that we must restrict ourselves here to a discussion of a particular group of host compounds, namely cavity-supporting macrobicyclic and macrooligocyclic phanes, which bear a similar relation to open-chain and monocyclic hosts as the metal-complexing cryptands to the podands and crown ethers. The molecular architecture of these three-dimensionally bridged macrooligocycles is a challenge for synthetic chemistry. (Not only the size and shape of the intramolecular cavity, but also the provision of the latter with suitable coordination centers have to be included in the synthesis strategy.) The capacity for the envelopment of guests from all sides and the expedient *endo* functionalization often also produce a particularly strong binding of host and guest, outstanding selectivities with regards to molecular recognition, and special properties of the supramolecular complexes.

1. Introduction

The first triply bridged cyclophanes were the molecule **1**,[1] obtained by Cram in 1958 from a paracyclophane by intramolecular coupling (path E in Scheme 1), and the symmetrical [n.n.n]phanes **2**,[2] prepared by Dale and Hubert in 1965 by double cyclotrimerization of terminal diynes (path H in Scheme 1). A general route to such molecules was achieved with the synthesis of [3.3.3]phanes such as **3** (Tos = p-SO_2-C_6H_4Me) from two readily accessible trifunctionalized halves (paths A and D in Scheme 1) (Vögtle, 1970).[3] The



2: n = 5–7 **3**: X = S, SO_2, N-Tos

subsequent optimization of the cyclization reactions, the application of the dilution principle,[4] and chromatographic and analytic methods, and the discovery of the "cesium effect"[5] made it possible to transform polyfunctionalized starting compounds often in surprisingly high yields into macrocyclic three-dimensional compounds of comparably large molecular masses (well over 2000 Daltons) rather than into polycondensed products.

The development of synthetic host compounds, triggered by the crown ether chemistry founded by Pedersen, proceeded in parallel to this.[6] This research led to the realization that specifically directed complexing, molecular recognition, and ion transport through membranes can be achieved with synthetic ligands as well as with natural receptors. The "three-dimensional crowns" conceived by Lehn, namely the cryptands, illustrate the considerable influence that the three-dimensional envelopment of the guest by the host has on the complex stability and complexing selectivity.[7] With the inclusion of durene by a diphenylmethanophane, Koga (1980)[8] was one of the most successful pioneers in combining host–guest chemistry and cyclophane chemistry;[9] reports of other work in this field followed in quick succession.[10]

In the same year we attempted to imitate the inclusion properties of cyclodextrins with large-cavity benzocryptands.[11] The first efficient macrobicyclic hosts with a cyclophane framework were conceived at the beginning of the 1980s by Collet (1981, see Section 4.3.),[12] Diederich (1984, see Section 4.3.),[13] and us (1984, see Section 3.1.).[14]

In this review article we will discuss the qualitative and quantitative expansion of the studies of cyclophane-type macrooligocyclic hosts[15] in the more general field of supramolecular chemistry.[9d, 16] We will focus on their endoreceptor properties, that is, on the inclusion of guest components

in the cavity interior. In this discussion it will become evident that cavity-enclosing hosts with optimum preorganization[17] of their bonding centers often produce effects unobtainable with open-chain molecules.

2. Synthetic Strategies

A whole range of various strategies for synthesizing large, multiply bridged molecular skeletons is described in the literature. Common to all strategies is the stepwise assembly of easily accessible structural subunits according to a "molecular building-block principle"[15] (molecular LEGO[18]). Depending on the strategy, the starting compounds of the decisive cyclization step have completely different structures and functional groups. In the "simplest" case five components, namely two spacers and three bridge units are joined together by sixfold bond formation (path A in Scheme 1). Multistep reaction paths in which only two molecules are necessary in the final cyclization step (paths C and D) or in which ring closure occurs intramolecularly (paths E, F, G) are synthetically more time-consuming and complex, though in general more promising.

Cyclization to form triply bridged macrocycles proceeds most often through the formation of carbon–heteroatom bonds, especially through *N*-alkylations[19] and *N*-acylations. In general the yields are higher the fewer the bonds formed simultaneously. For example, from the one-pot reaction (path A in Scheme 1) of two equivalents of triamine **4** with three equivalents of diacid chloride **5**, we obtained the bicyclic compound **7** in only 1.5% yield (Scheme 2).[14] If on the other hand triacid chloride **6** is treated with **4** in a 1:1 cyclization (path D in Scheme 1), **7** is obtained in at least 13% yield. In the same way, a whole family of new macrobi-

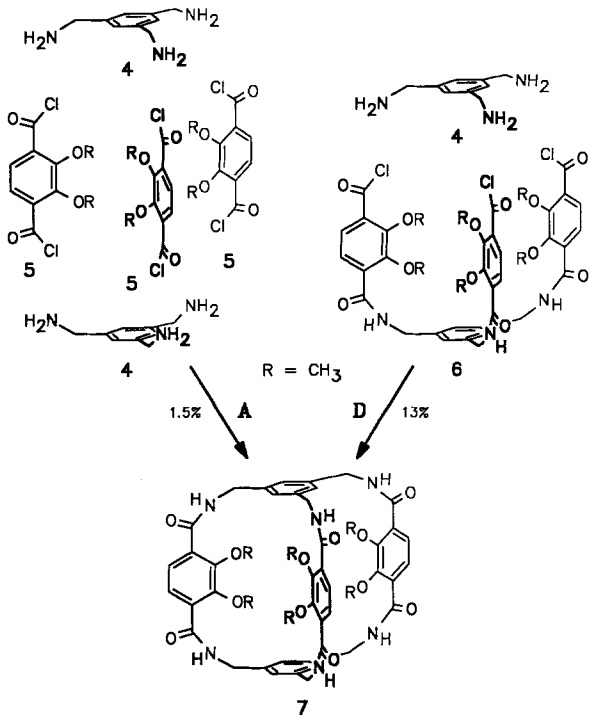
Fritz Vögtle, born in 1939 in Ehingen/Donau, studied chemistry in Freiburg as well as chemistry and medicine in Heidelberg. There he received his Ph.D. for research with H. A. Staab on the valence isomerization of double Schiff bases. After his habilitation on steric interactions inside cyclic compounds, he was H2/H3 professor in Würzburg from 1969 to 1975. He then accepted a position as director of the Institut für Organische Chemie und Biochemie in Bonn. He is interested in the field of supramolecular chemistry and molecular recognition and after working on topics concerning crown ethers, podands, and siderophores, he has concentrated on compounds with large intramolecular cavities, ligands for supramolecular photochemistry, concave dyes, molecular tweezers, and ball- and tube-shaped molecules. His further areas of research are deformed, strained, and chiral/helical molecules, cyclophanes, and compounds with appealing architecture.

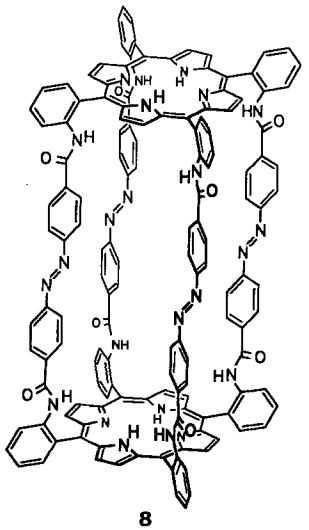
Christian Seel was born in 1963 in Bonn and studied chemistry there from 1983 to 1988. In his Diplomarbeit with F. Vögtle he synthesized macrobicyclic ligands for metal ions. In 1991 he received his Ph.D. in the same research group for his work on macrooligocyclic host compounds with large cavities for the complexation of organic guests.

cyclic hosts with three donor units (catechol, bipyridine, diaza crowns) or three hydrophobic structure elements (diphenylmethane, *o*-terphenyl) is now accessible.[15]

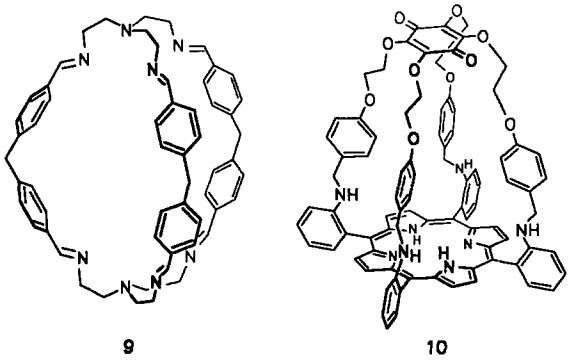


Scheme 2. Two pathways for forming the macrobicyclic tris(catechol) **7**.

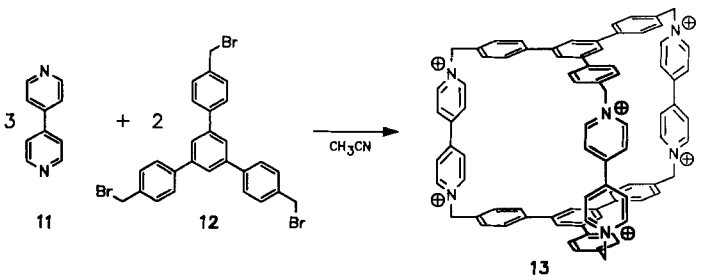
The efficiency of the cyclization by multiple lactam formation is also demonstrated by the synthesis of the tetraazo double-decker porphyrin **8**, obtained in 18% yield and involving a fourfold linkage.[20]



The simultaneous multiple condensation of aldehydes with amines to form Schiff bases leads to surprisingly good results in the formation of large, molecular cavities: With this method[21] Lehn et al. prepared the hexaimine cryptand **9** in 60% yield,[22] and Lindsey and Mauzerall obtained (after subsequent hydrogenation) the quadruply bridged porphyrin **10** in yields as high as 80–95%.[23]



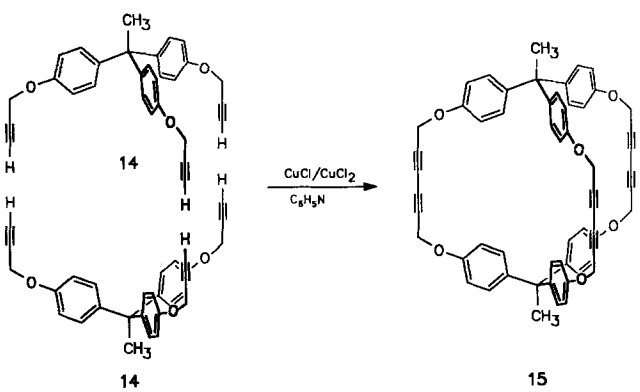
We successfully synthesized the tris(paraquat) cage **13** by sixfold quaternization of three 4,4'-bipyridine molecules (**11**) with two triphenylbenzene spacers **12** (Scheme 3).[24]



Scheme 3. Synthesis of the macrobicyclic tris(paraquat) **13**.

The ring closures by ether and sulfide linkages universally employed in crown ether and cyclophane chemistry have only rarely been used in the preparation of large molecular cavities. Examples include Cram's "carcerands", in which two bowl-shaped cavitands are linked by four sulfide or acetal bridges (see Section 4.5).

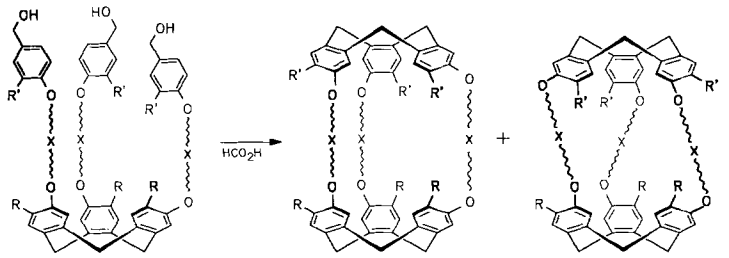
Last but not least, we must mention some cyclization methods in which not carbon–heteroatom bonds, but instead carbon–carbon bonds are formed.[25] An example is the alkyne coupling according to Eglinton; its application in the cyclodimerization of tris(propargyl ether) **14** to form the tris(diyne) **15** in 20–30% yields was described by Breslow



Scheme 4. Formation of the cage molecule **15** by triple alkyne coupling.

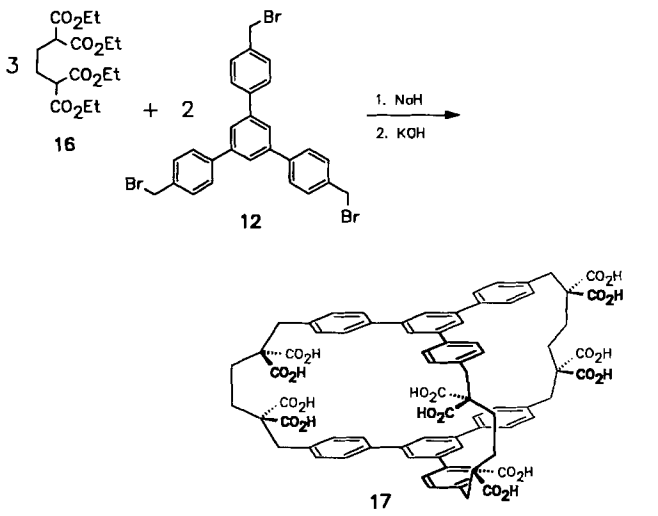
(Scheme 4, see also Section 4.3).[26] Bicyclic cage molecules are also accessible by intramolecular coupling of dialkynes and tetraalkynes (paths E and F in Scheme 1) (Whitlock, see Section 4.3, Lehn.[27]).

In the "cryptophane" host family developed by Collet et al. (see also Section 4.3),[28] the cyclotriveratrylene spacers (or their derivatives) are formed by intramolecular condensation of three veratrole units in the decisive step of the synthesis (path G in Scheme 1), thus simultaneously with the macrobicyclic skeleton (Scheme 5).



Scheme 5. Cryptophane synthesis by intramolecular condensation of a cyclotriveratrylene unit.

The first known purely carbo(bi)cyclic[29, 30] large cavity is found in the dodecacarboxylic acid **17**, which was obtained by sixfold malonic ester alkylation of three molecules of tetraester **16** with two trihalide units **12** (Scheme 6).[31]



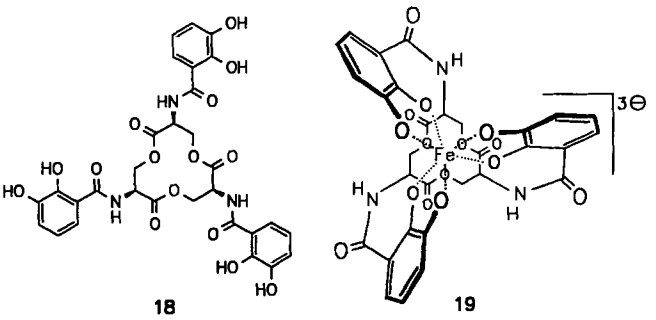
Scheme 6. Formation of the first molecule with an all-carbon framework containing a large cavity.

3. Metal Complex Formation—Large Cavities for Small Ions

3.1. Macrobicyclic Siderands

Siderophores (Greek: iron carriers) are defined as generally hexadentate chelate ligands of low molecular weight that are produced by microorganisms as growth factors for extracellular iron uptake by the complexation of Fe^{III}.[32] Iron plays an indispensable role in many oxidation and reduction processes in the cell. Iron(III) is not directly biologically available on account of its very low solubility at physiological pH values. By complexing with siderophores it is converted into a soluble, transportable form; the "sideroplexes" (iron complexes of the siderophores) can then be absorbed by membrane receptors on the cell surface.[33] The geometrical conditions and the chirality of the coordination center and of the anchor skeleton as well as the arrangement and nature of the peripheral functional groups are decisive in this connection. In recent years a large number of "siderands" (artificial siderophores) have been synthesized and investigated with regards to their complex-forming properties and biological activity. The intention was to elucidate the iron-transport phenomena, the structural requirements placed on the complexes and cell receptors, and the decomplexation mechanisms.[32]

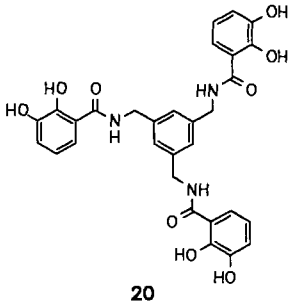
Many siderophores contain three catechol units, the six oxygen atoms of which in the deprotonated form can coordinate metal ions in an octahedral fashion. The prototype of the catechol siderophores is enterobactin (**18**).[34] In its Fe^{III} complex **19** the donor centers are wound in the form of a Δ-*cis* helix around the metal ion.[35] The formation constant K_{ass} for complex **19** is approximately 10^{52} M^{-1} and is the largest yet measured for a natural substance.[36] Numerous



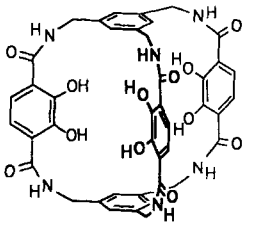
synthetic analogues of enterobactin have been developed in the last decade, in particular by Raymond et al.[32b] In these analogues the catechol units are fixed to freely movable sidearms of various linear, branched, or cyclic anchor skeletons. For example, in "MECAM" (**20**) the hydrolysis-sensitive cyclotriester of **18** is replaced by a benzene ring.[37] The formation constant of the Fe^{III} complex is 10^{46} M^{-1}.[38]

We prepared the macrobicyclic siderand **21** in 1984 with the aim of obtaining a chelate ligand with an optimally preorganized donor geometry.[14] In this case the catechol units are integrated in a large cage framework to restrict their conformational mobility. The skeleton is flexible enough, however, to permit an octahedral arrangement of the donor oxygen atoms in the complex. The spatial preorientation and three-dimensional "clamping" of the binding centers contributes decisively to the extremely strong bonding of the metal ion to **21** ("macrobicyclic effect").[39] This new type of ligand has the highest hitherto measured formation constant of an iron(III) complex: $K_{ass} \approx 10^{59}$ M^{-1}.[40] This complex is stable even at pH 3; **21** is found to be clearly superior to open-chain compounds in competition experiments.[41]

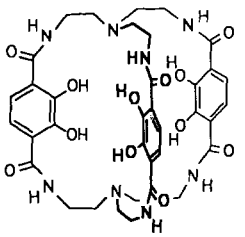
In 1987 Raymond et al. synthesized the related macrobicyclic ligand **22** ("bicapped TRENCAM").[42] The X-ray



20



21



22

structure analysis of its iron(III) complex revealed that the metal ion has a trigonal-prismatic coordination sphere previously unknown for such complexes, which is stabilized by six intramolecular hydrogen bonds between the amide protons and the adjacent catechol oxygen atoms (Fig. 1).[43]

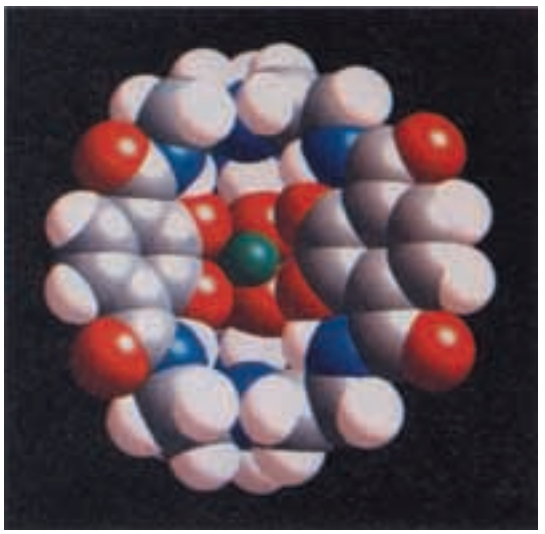


Fig. 1. Crystal structure of the Fe^{III} complex of siderand **22** with trigonal-prismatic coordination sphere of the cation. (All color diagrams were prepared on HP 825 SRX with MOLEK 9000, P. Bischof, ISKA, D-W-6140 Bensheim.)

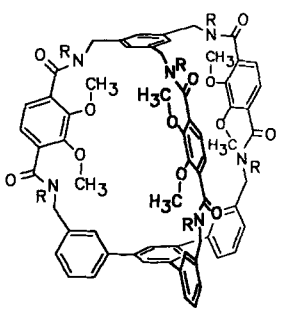
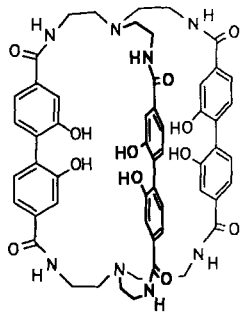
The volume of the cavity enclosed by the bicyclic molecular framework of **21** can be successively enlarged according to our building-block principle by incorporating larger spacers (1,3,5-triphenylbenzene and 1,1,1-triphenylethane units) instead of the central benzene rings.[44] Thus, the ligand **23** provides sufficient room for a convergent and cooperative arrangement of the six methoxy groups during the inclusion of a metal cation in the interior of the cavity.[45] This ligand forms alkali-metal complexes whose stabilities are comparable to those of complexes of crown ethers with alkali metals. Ligand **23** (R = benzyl) is size-selective; cesium ($\lg K_{ass}$ = 5.3 ± 0.5) is bound roughly six times more strongly than potassium.

Pierre et al. have just recently performed the template synthesis of the Fe^{III} complex of the macrobicyclic siderand **24**, whose donor centers are formed by *o,o'*-dihydroxybiphenyl instead of pyrocatechol units.[46, 47]



23

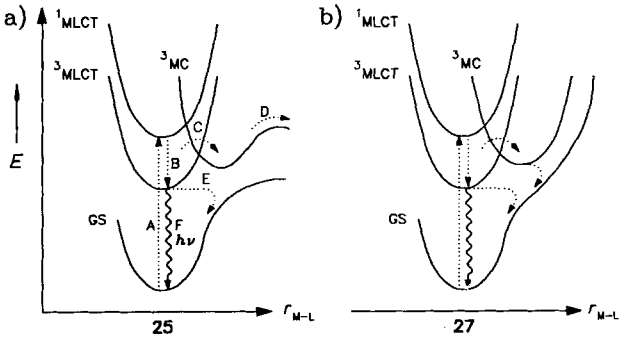


24

3.2. Cagelike Ligands with Three Bipyridine Units

For some years intensive efforts have been made to develop efficient molecular systems for photoinduced charge-separation, the first step in the photochemical utilization of solar energy.[48] Attention is focused in particular on supramolecular electron-transfer photosensitizers,[49] that is, molecules that are able to absorb light and consequently oxidize or reduce other molecules in reversible processes. Ruthenium(II)–bipyridine complexes are of particular interest because of their stability and special combination of lifetime, reactivity, redox potentials, and the chemoluminescence of their lowest excited state.[50]

The relatively rapid radiationless deactivation of the lowest excited state is problematical in complexes such as $[Ru(bpy)_3]^{2+}$ (**25**). This ^{3}MLCT state (MLCT = Metal-to-Ligand Charge-Transfer) is rapidly adopted after excitation to the first excited singlet state on account of the strong spin-orbit coupling of ruthenium (A and B in Scheme 7a) and is decisive for the luminescence properties and energy-transfer and electron-transfer processes of the system. A further disadvantage of this complex is its photodissociation (D in Scheme 7a), which proceeds by a (thermally excited) radiationless transition (C in Scheme 7a) to a distorted ^{3}MC

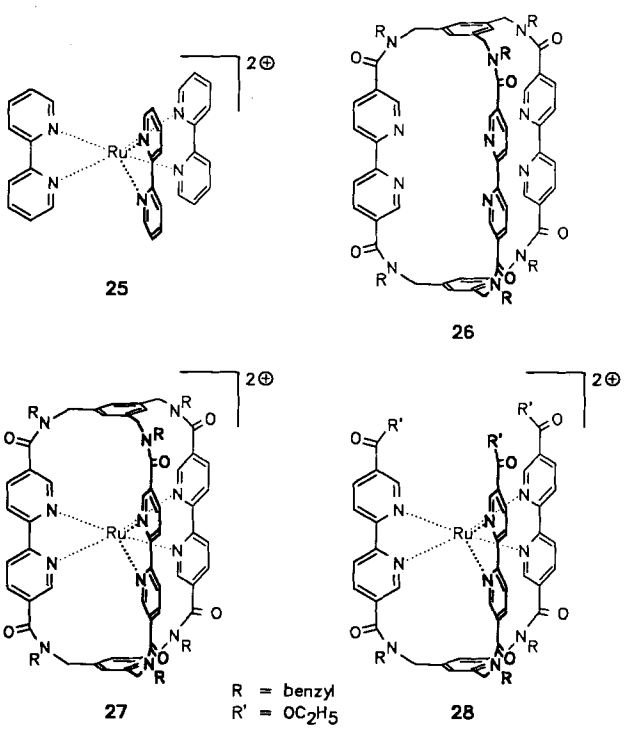


Scheme 7. Energy potentials of the ruthenium complexes **25** and **27** (LC: ligand-centered, MLCT: metal-to-ligand charge-transfer, MC: metal-centered, GS: ground state, r_{M-L}: metal–ligand distance). For A–F see text.

state (MC = Metal-Centered) with subsequent cleavage of one of the six ruthenium–nitrogen bonds.[48–50]

One possible way of improving the photostability is to increase the energy difference between the ^{3}MLCT and ^{3}MC states. Whereas the energy level of the latter cannot be increased, it is possible to reduce the ^{3}MLCT energy by suitable derivatization of the bipyridine units. This leads, however, to an enhanced (thermally independent) radiationless transition to the ground state (E in Scheme 7a) and thus to a drastic reduction of the lifetime of the ^{3}MLCT state and a lower photochemical quantum yield.

Alternatively, photodissociation can be prevented by clamping the bipyridine units in a bicyclic framework as in **26** (Scheme 7b). The photochemical properties of such complexes are hardly different than those of **25** as long as the first coordination sphere of the metal is not disturbed by steric effects. The rigidity of such a ligand furthermore reduces the rate of the thermally activated radiationless decomposition processes.[51]



Examination of Corey–Pauling–Koltun (CPK) models show that the tris(bipyridine) cage ligand **26**[52] is able to provide the strictly octahedral coordination sphere required by ruthenium(II). (In the schemes and figures the complexes are not depicted as octahedral for reasons of clarity.) In this case the host molecule together with its three chelate units is coiled in the form of a "triple helix" around the guest ion (Fig. 2). The electron-withdrawing amide groups in the cage complex should lower the energy level of the ^{3}MLCT state and thus reduce its lifetime. Since, however, the carbonyl groups are approximately vertical to the plane of the arene units as is evident in the model, their $-$M effect is weakened. This is demonstrated by the fact that in the absorption spectrum of the cage complex **27**[53] the d $\rightarrow \pi^*$ band (^{3}MLCT band) has a distinctly smaller red-shift compared to

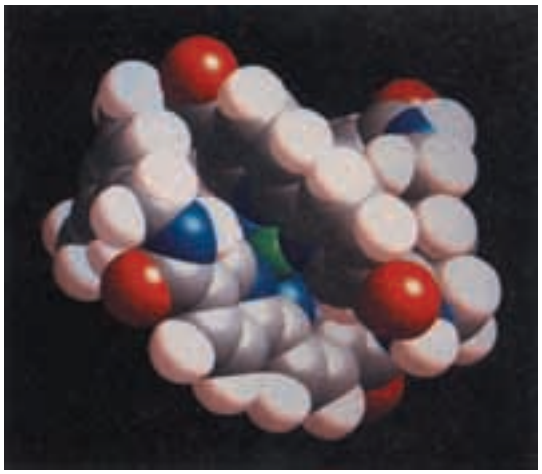


Fig. 2. Space-filling model of the cage complex **27** [according to MM2 calculations (MOLEK 9000 on HP 825 SRX) based on the crystal structure of **25**].

$[Ru(bpy)_3]^{2+}$ (**25**), than that in the case of the less rigid semicage complex **28**.[54, 55]

Similar effects are found in the luminescence band in the emission spectrum (90 K), which is attributed to the transition of the ^{3}MLCT state to the ground state (F in Scheme 7a). At 90 K the lifetime of the excited state is controlled by the energy difference relative to the ground state, and is 4.8 μs for both **25** and **27**. In contrast to this, however, the lifetime of the emission state of the cage complex at room temperature is twice as long as that of the bipyridine complex **25** (1.7:0.8 μs). At room temperature the lifetime is governed by the thermally activated transition from the ^{3}MLCT state to the geometrically distorted ^{3}MC state. The latter is sterically unfavorable for the cage complex, and accordingly the quantum yield of the photodissociation is at least four orders of magnitude less than in the reference complex **25**.

In **27** the shielding of the relevant orbitals of the metal ion from all sides causes the quenching of the ^{3}MLCT state by oxygen to be five times smaller than in $[Ru(bpy)_3]^{2+}$ (**25**). Table 1 provides a summary of the photophysical data of the complexes discussed.[51]

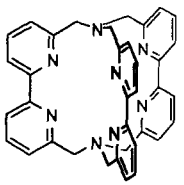
Table 1. Some photochemical data of the Ru^{II} complexes **25**, **27**, and **28**.

Complex	Absorption		Emission		Emission		Photodissociation
	298 K		298 K		90 K		298 K
	λ_{max} [nm]	ε	λ_{max} [nm]	τ [μs] [a]	λ_{max} [nm]	τ [μs] [a]	Φ_p [b]
25	452	13000	615	0.8	582	4.8	1.7×10^{-2}
27	455	10400	612	1.7	597	4.8	$<10^{-6}$
28	477	9500	640	0.45	620	1.9	$<10^{-5}$

[a] Lifetime of the ^{3}MLCT state. [b] Quantum yield of the photodissociation.

It is found that the photochemical properties of tris(bipyridine) complexes are substantially improved if the donor centers are integrated in tailor-made macrobicyclic molecular frameworks.[56] At similar absorption and emission behaviors, there is a greater photostability of the complexes as well as a substantially longer lifetime of the excited state responsible for the luminescence.

The cavity within the framework of ligand **26** is predestined for the octahedral coordination of transition-metal ions. This is also demonstrated by the fact that its Fe^{II} complex is stable even to powerful oxidizing agents such as hydrogen peroxide.[52] Hosts with insufficient conformational flexibility, such as the smaller cryptand **29**[57] synthesized from 6,6'-disubstituted bipyridine units, prove less favorable with regards to an octahedral coordination sphere.[58]



29

Lanthanide ions such as europium(III) and terbium(III) do not place such high demands on the orbital geometry of the ligand field as ruthenium(II). Lanthanide ions are of photochemical interest since their cryptates exhibit a distinct emission at room temperature, whereas their simple aqua complexes are not luminescent. This is attributed to the fact that the three-dimensional envelopment of the ions by the ligand impedes the radiationless deactivation by solvent molecules. The stable, photoactive cryptates of ligand **29** are effective molecular "A-ET-E luminophores" (A-ET-E = Absorption Energy-Transfer Emission), which reemit the UV light absorbed by the ligand (excitation at 320 nm), after intramolecular energy-transfer from $\pi \rightarrow \pi^*$ states to excited metal-states, as visible light (emission at 570–700 nm, Fig. 3). The

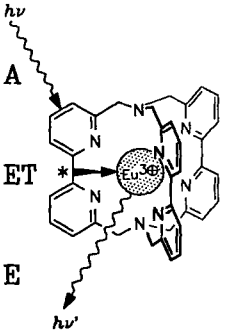


Fig. 3. A-ET-E light conversion processes of the europium(III) cryptate of **29**.

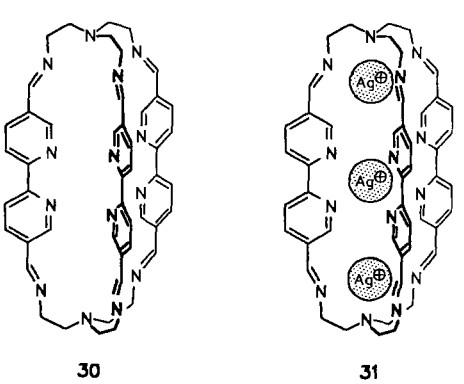
disadvantage of these cryptates is the low quantum-yield of these energy conversions, since in addition to emission, intensive ligand-internal, radiationless deactivation is always observed (Lehn, Balzani et al.).[59]

With the two "tren" caps (tren = tris(2-aminoethyl)amine), the macrobicyclic ligand **30** has two further metal-coordination centers in addition to the bipyridine units. The tritopic cryptand **30** forms trinuclear complexes such as **31**, which to our knowledge is the first trisilver cage complex. Figure 4 shows the structure resulting from the X-ray analysis of the tetrafluoroborate of **31**.[60]



30 **31**

Fig. 4. Crystal structure of the trisilver cage complex **31**.

4. Complexation of Organic Molecules with Cagelike Host Compounds

4.1. Binding Forces in Complexes with Organic Guests

In the complexation of organic guest molecules the intermolecular interactions that lead to binding are essentially weaker than those in the complexation of metal ions. The requirements in terms of the steric and functional complementarity and spatial preorganization of the host compounds are correspondingly high. In addition, suitable binding niches or cavities have to be considerably larger than in ligands for metal complexes, often calling for a greater synthetic effort.

In the molecular recognition of organic molecules with polar or protic functional groups, the formation of hydrogen bonds between the host and the guest is most often the driving force of the complex formation. For example, Rebek et al. have reported a whole family of niche-shaped hosts with different functional groups forming hydrogen bonds[61] and a self-replicating system based thereon.[62] A catalyst for nucleophilic condensations is also based on a network of hydrogen bonds (Kelly),[63] as are the supramolecular complexes of tris(melamine) compounds with cyanuric acid (Whitesides).[64] The molecular tweezers of Wilcox,[65] the urea ligand of Thummel[66] as well as Bell's torands[67] and Hamilton's diamidopyridine cycles[68] are further examples of hosts which bind guests by means of multiple hydrogen bonds.[69]

The binding forces that occur in the complexing of nonpolar organic molecules by nonpolar binding sites of corresponding host compounds are weaker; such binding forces include van der Waals interactions (London dispersion forces), arene stacking, cation–π interactions, dipole-induced-

dipole interactions and electron-donor–acceptor interactions. Last but not least the influence of solvent, which comes under the heading of the "hydrophobic effect", exerts a great influence in complexation.[70]

Recognizing that hydrophobic interactions decisively influence substrate binding in biological systems, Diederich et al.[71] investigated the solvent dependence of the binding strength in the complexation of aromatic guest molecules in studies involving water-soluble cyclophane hosts with hydrophobic cavities.[72] They showed that aromatic guests such as perylene or pyrene can be complexed even in a nonpolar solvent such as carbon disulfide and also in aromatic solvents (benzene). The complex formation constants are particularly large in water, as well as in trifluoroethanol and ethylene glycol. The constants decrease in the transition from polar protic solvents to dipolar aprotic solvents and are weakest in nonpolar solvents such as carbon disulfide. In this connection the free energy of binding shows a good correlation with the Dimroth–Reichardt parameter $E_T(30)$.[73, 74] This empirical parameter of solvent polarity is related to macroscopic properties such as the dielectric constant, dipole moment, cohesion, and polarizability. Since the shape of the host–guest complexes does not essentially alter when the solvent is changed,[75] the differences in the binding strength cannot be attributed to variable van der Waals interactions between the partners; they are instead related to solvation. If it is energetically favorable for a solvent to solvate the nonpolar surfaces of the host and guest, then association of the binding partners is promoted little or not at all. In the case of weak solvation, however, complex formation is supported correspondingly. The most important properties of the solvent that determine these influences are the cohesion interactions and the polarizability.[76] If the solvent molecules have strong cohesive interactions (like protic solvents, in particular water), the solvation of nonpolar molecular surfaces and cavities is unfavorable with respect to enthalpy. The solvent molecules on the surface can participate in fewer hydrogen bonds than those in the bulk and consequently are higher in energy. In the case of the association of two nonpolar surfaces, for example, in the inclusion of aromatic guests in molecular cavities, the surface solvent molecules are released into the bulk and their energy content is lowered, thereby promoting complex formation (enthalpic hydrophobic effect). At the same time a strongly positive entropy term comes into play: the ordered solvent cage enveloping the host and guest molecules is destroyed at the binding sites, and the molecules released are transformed into a less-ordered state (entropic hydrophobic effect).

The polarizability determines, in addition to the interatomic distances, the attractive potential of the London dispersion interactions. In weakly polarizable solvents such as alcohols and water (oxygen atoms and hydroxyl groups are substantially less polarizable than for example aliphatic and aromatic hydrocarbon groups), the dispersion forces between the solvent molecules and the nonpolar host and guest surfaces are weaker than those between the binding sites of the complex components. The situation is different in the case of easily polarizable solvents. Here the dispersive interactions between solvent, host, and guest are of comparable magnitude, and accordingly the driving force for complex formation exerted by the solvent is only weak or even completely absent.

Because of their favorable interactions with the binding sites of the host and guest, lipophilic solvent molecules such as chloroform or benzene may in fact be regarded as only weak competitors for the host receptor site. But due to their large excess, they effectively compete with the guest molecules. Water, in contrast, is the most favorable medium for the complexation of nonpolar compounds; however, it cannot promote complexation more strongly than can be expected because of its physical properties, namely the strong cohesive forces and low polarizability.[72]

The investigation of the complexation of imidazole with a macrobicyclic host shows furthermore that the size and shape of the solvent molecules may also influence the stability of host–guest complexes (Still and Chapman). Bulky solvent molecules, which cannot penetrate the cavity and solvate the binding sites as readily as smaller solvent molecules, give rise to higher binding constants.[77]

Cyclophane hosts can complex aromatic guest compounds even in nonpolar organic solvents,[72] which shows the importance of arene–arene interactions in the formation of corresponding supramolecules. These attractive forces between π systems are found, for example, in the packing of aromatic molecules in the crystal[78] and in phenomena such as vertical base-stacking, which stabilizes the double-helix structure of DNA, as well as the intercalation of drugs and other agents in the DNA strand.[79] An analysis of the crystal structures of a series of proteins shows the influence that the nonbonding interactions of aromatic side-chains have on the tertiary structure.[80, 81] Interacting arene pairs are defined as those in which the centers of the stacked rings are less than 700 pm apart.[80a] Arrangements in which a positively polarized hydrogen atom at the edge of one aromatic ring is directed toward the π-electron cloud of another ring are frequently observed (Fig. 5a).[82] A special case of these edge-to-face arrangements is the so-called T-stacking, in which the interplanar angle is approximately 90°, and the center of gravity of one ring is situated on the symmetry axis of the other ring.[83] The global minimum of the potential energy is also located

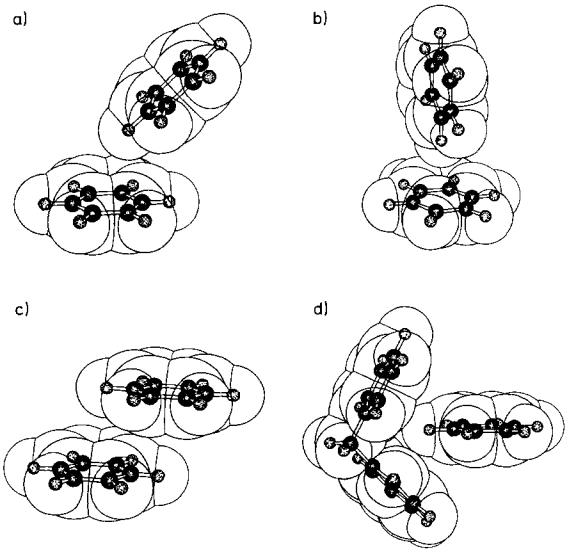


Fig. 5. Several arrangements of interacting benzene rings (π-stacking). a) Edge-to-face stacking. b) T-stacking. c) Offset face-to-face stacking. d) Edge-in-angle stacking (Software: SCHAKAL, E. Keller, Freiburg.)

here: for two benzene rings whose centers are 500 pm apart a potential energy of $E \approx -10.0\ \mathrm{kJ \times mol^{-1}}$ was calculated (Fig. 5b).[80b] A local minimum lies in an offset face-to-face stacking, in which one or two hydrogen atoms of both systems lie over the electron cloud of the partner molecule (Fig. 5c).[81] On the other hand frontal face-to-face stacking is unfavorable on account of the strong repulsion of the π-electron clouds. For inclusion in the niche of a diphenylmethane unit (a subunit often used in cyclophane hosts; see Section 4.3) the aromatic guest approaches the surfaces of the two phenylene rings with its edge. This double edge-to-face arrangement can be termed accordingly edge-in-angle stacking (Fig. 5d).

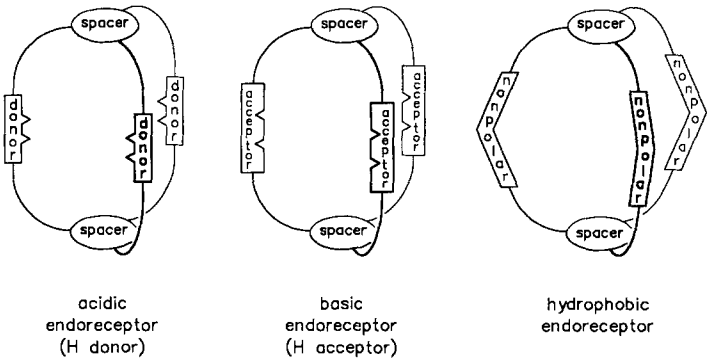
Hunter and Sanders developed a simple model to clarify the strict geometrical requirements for the interactions between aromatic systems.[84] In this model the σ frame and the π electrons are considered separately, and the charge distribution of the molecule is described by a set of point charges. The positive σ skeleton is sandwiched between two negative π-electron clouds. It is concluded that the arene–arene interaction does not involve, for example, an electronic attraction between the two π systems, but that the attractive π–σ interactions between the electron clouds and the positively polarized hydrogen atoms overcompensate for the unfavorable π–π repulsion.

Van der Waals interactions may have a considerable influence on the strength of arene pairing. Since this is proportional to the area of the π overlap, however, this influence cannot be dominating. This would necessarily involve a maximum overlap and thus favor a cofacial arrangement. Whereas electrostatic forces determine the geometry of the arrangement, van der Waals interactions and solvophobic interactions contribute only to the magnitude of the stacking energy.

Electron-donor–acceptor interactions are also important for the selective binding in host–guest complexes and in biological systems. For example, Diederich and Ferguson found that electron-rich host molecules (donors) and electron-poor guest compounds (acceptors) form particularly stable complexes; however, charge transfer was not observed in this connection.[85] Stoddart's template syntheses of catenanes constructed from electron-rich aromatic crown ethers and cyclic bis(paraquat) units,[86] as well as Hünig's preparation of macroheterocyclic, viologen-analogue onium host compounds by means of a phenanthrene template[87] are also based on effects of this type (and T-stacking effects). Electron-donor–acceptor interactions are also the driving force in the complex formation of "cyclo-bisintercalands" (Lehn)[88] and—in addition to hydrogen bonds—in tweezer molecules (Zimmerman,[89] Harmata[90]). Hamilton et al. demonstrated the influence that the distribution of the partial charges within the π-electron systems has on the orientation (face-to-face or edge-to-face) of a guest (additionally bound by hydrogen bonds) relative to the arene surfaces of the host.[91] Dougherty et al.[92] explained the strength of the complexation of quaternary ammonium salts by a cyclophane receptor by the occurrence of ion–dipole interactions,[93] whereby the positive charge of the guest is "solvated" by the electron-rich surface of the aromatic rings. This effect is also observed in the complexation of aromatic guests by azoniacyclophanes (Schneider[94]).[69]

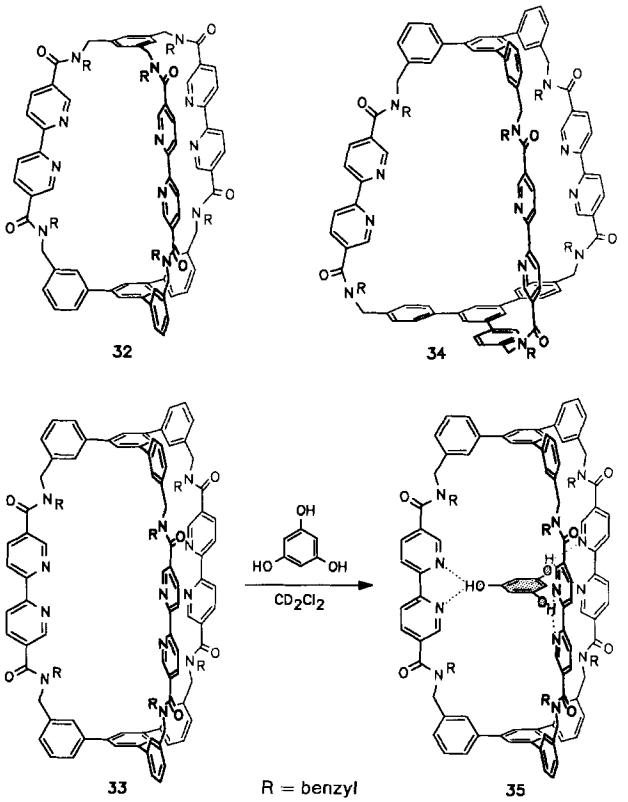
4.2. Molecular Recognition of Organic Molecules by Hydrogen Bonds and Ionic Interactions (Ion Bridges)

Following the donor–spacer concept[15] for the synthesis of macrobicyclic ligands, we prepared a series of hosts with increasingly larger intramolecular cavities by replacing the benzene anchor groups in ligands such as **21** and **26** by larger spacers, for example 3,3′,3″- or 4,4′,4″-trisubstituted triphenylbenzene units).[44,95] Varying the bridge building-blocks allows one to adapt the complexing properties of the macrobicyclic hosts to the binding character of many different types of guests. Using this principle we were able to prepare basic and acidic endoreceptors for the inclusion of respective hydrogen-bond donor and acceptor guests, and nonpolar endoreceptors for complexing hydrophobic molecules (Scheme 8).[15]



Scheme 8. Types of endoreceptors.

The internal walls of the tris(bipyridine) compounds **32**–**34** with the six basic heteroarenes are virtually lined with hydrogen-bond acceptors.[95] These hosts are thus tailor-made for



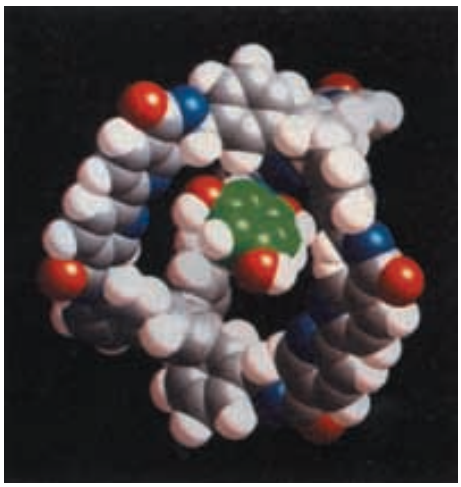


Fig. 6. Space-filling model of the phloroglucinol inclusion complex **35**. The *N*-benzyl groups are not shown; the carbon atoms of the guest are colored green.

encapsulating sterically and functionally complementary trihydroxybenzenes. Such guests, which are otherwise sparingly soluble in the organic phase (CH_2Cl_2), are solubilized by the hosts and bound by means of multiple hydrogen bonds in the cavity. The complexation can thus be detected not only by ^1H NMR spectroscopy (the spectra exhibit signals for both host and guest), but can also be followed macroscopically by the dissolution of the suspended guests. An association constant K_{ass} of $1.1 \times 10^4\ M^{-1}$ was determined (in CH_2Cl_2) for the phloroglucinol (1,3,5-trihydroxybenzene) complex **35** (Fig. 6); however, pyrogallol (1,2,3-trihydroxybenzene) and other compounds not complementary to the structure of the receptors are discriminated (Table 2).

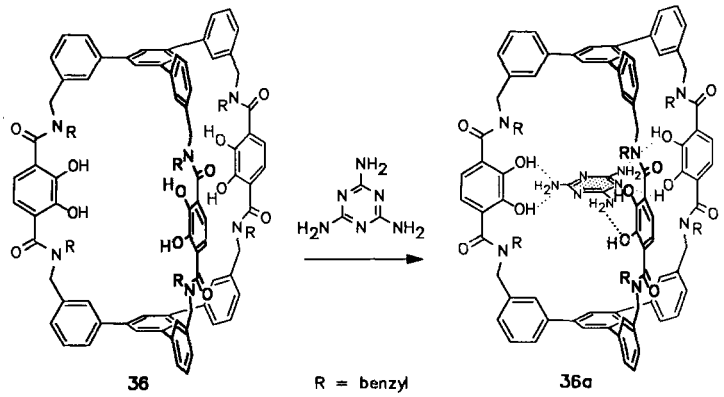
Table 2. Selective coupling of organic guests by tris(bipyridine) hosts in CD_2Cl_2 [a].

Guest	**32**	**33**	**34**
	+	+	−
	+	+	+
	−	−	−
	−	−	−

[a] (+ = complexation, − = no noticeable complexation.)

The hosts **32**–**34** also react sensitively to the introduction of methyl or ammonium groups into the guest molecules: 2,4,6-trihydroxytoluene or 2,4,6-trihydroxyaniline hydrochloride are not complexed. The more strongly acidic nitrophloroglucinol simply forms, like picric acid, 1:3 complexes.

In contrast to the tris(bipyridine) hosts, the macrobicyclic ligand **36** has pronounced proton-donor character (acidic endoreceptor, see Scheme 8) because of the six hydroxyl groups of the catechol units. As a consequence, it complexes organic molecules with basic functional groups as long as the pK_S and pK_B values are mutually compatible.[96] In experiments with strongly basic triamines, saltlike aggregates are formed as the result of an acid–base reaction. On the other hand, purine and pyrimidine bases and similar, less basic compounds can be solubilized by **36** in dichloromethane, *in* which they are otherwise only sparingly soluble. Host **36** is



clearly superior to open-chain catechol compounds on account of the better preorganization of its binding centers due to the clamping in the cage framework. Furthermore, in transport experiments based on solid–liquid–liquid extractions the rate of transport of the aforementioned guests through an organic phase and into an aqueous acidic solution is substantially increased by host **36**. Figure 7 shows the space-filling model of the adenine complex of **36**.

If three crown ether building-blocks are held in place by two spacers, then macropentacyclic structures are obtained whose cavities contain three coordination centers for metal ions or

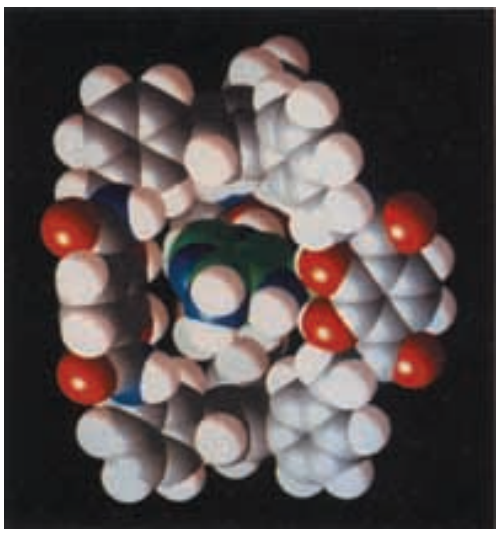


Fig. 7. Space-filling model of the adenine inclusion complex of the host **36**. The *N*-benzyl groups are not shown; the carbon atoms of the guest are colored green.

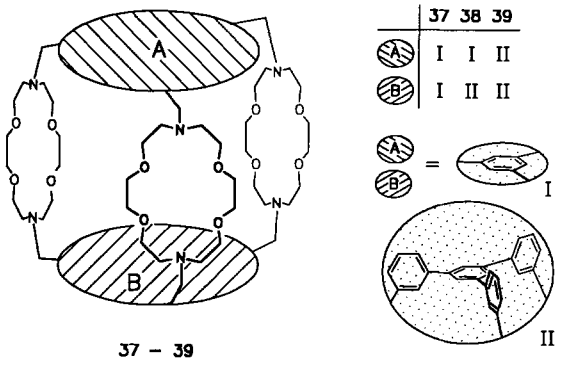
proton donors.[11] The water-soluble triscrowns **37**–**39** form 3:1 complexes with salts such as KSCN;[97] however, cooperative binding of cations was not observed. In addition, hosts **38** and **39** bind various naphthalenediols, whereas phenol as well as di- and trihydroxybenzenes and triammonium salts are not appreciably complexed.

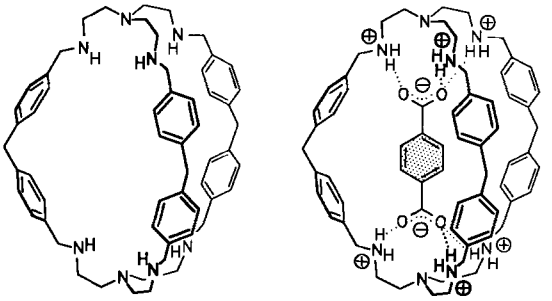


37 – 39

In the host compounds **40**, **42**, and **44** a cyclophanelike subunit is bridged with a crown ether building-block.[98] The crown ether part serves as a site for hydrogen bonds or ion bridges, whereas the cyclophane part offers lipophilic groups a nonpolar environment. The hosts are consequently ditopic receptors for organic guests, which in addition to hydrophobic subunits also contain polar protic or cationic structure elements. Thus, the basket-shaped[99] molecule **40** in $CDCl_3$ solubilizes for example ammonium *p*-nitrophenolate by the formation of the complex **41**.[100] Through the binding of the ammonium ion to the crown ether unit the phenolate is drawn into the host cavity and fixed by the ion bridge. The ionic centers are thus shielded from the lipophilic solvent by the host framework, while at the same time the arene ring of the guest is positioned between the naphthalene units.

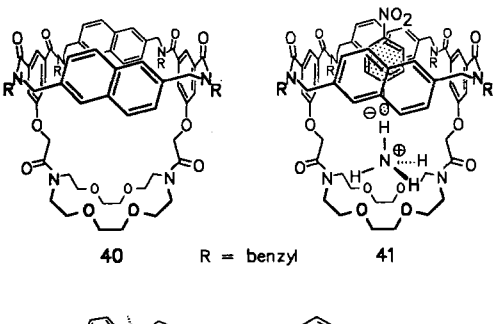
In a similar manner the cylindrical hosts **42** and **44** (Saigo[101] and Hamilton[102]) are able to incorporate various alkylammonium ions. The complexation of ω-phenylalkylammonium ions **43** by **42** proceeds with cooperative interaction if the guests are optimally adapted to the host in terms of their chain length. If the ammonium group docks on the crown, the terminal phenyl ring comes into contact with the nonpolar cyclophane unit when **43** has $(CH_2)_5$ or $(CH_2)_6$ chains. The resulting gain in stability is reflected in the association constants; with K_{ass} values of roughly $1.7 \times 10^3\ M^{-1}$, they are three to six times higher than those measured for guests with shorter or longer chains (determined by NMR spectroscopy in $CDCl_3/CD_3OD$ 4:1).[101]

Lehn et al. have reported on the molecular recognition of dicarboxylates[103] by the macrobicyclic receptor **45**.[104] In its protonated form this receptor forms inclusion complexes with the dianions of aliphatic α,ω-dicarboxylic acids. Adipate ($K_{ass} = 2.6 \times 10^3\ M^{-1}$) is the most complementary in terms of size and is more strongly bound than larger and smaller homologues. The terephthalate complex **46** ($K_{ass} = 2.5 \times 10^4\ M^{-1}$),

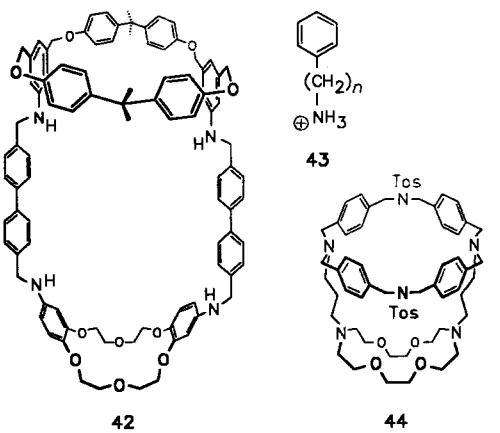


45 **46**

in which hydrophobic interactions as well as electrostatic interactions play a role, is one order of magnitude more stable. The X-ray structure analysis of **46** shows the envelopment of the guest by the host, and its fixation by the formation of three hydrogen bonds between each carboxyl group and the ammonium groups (Fig. 8).



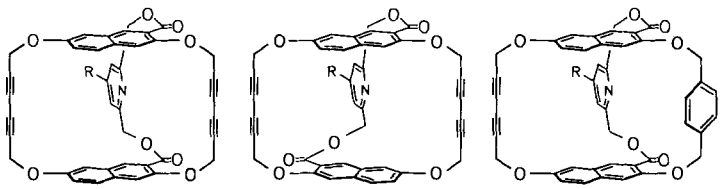
40 R = benzyl **41**



42 **44**

Fig. 8. Crystal structure of the terephthalate inclusion complex **46**. The hydrogen atoms are not shown; the carbon atoms of the guest are colored green.

Whitlock et al. have reported on a series of macrobicyclic host compounds **47**–**48** ("phenol sticky hosts"), which contain, in addition to rigid, hydrophobic naphthalene walls, a pyridine unit as "docking site".[105, 106] These polycycles bind phenols in nonpolar solvents with a high degree of efficiency and electronic and stereochemical specificity.



47a (*meso*) R = $N(CH_3)_2$ **47b** (±) **48a** : R = $N(CH_3)_2$ **48b** : R = H

The isomeric hosts **47a** (*meso*) and **47b** (±) are formed in the same cyclization reaction in a 2:1 ratio.[105] In the ligands **48a** and **48b** one of the two hexadiyne units of **47a** is replaced by a *p*-xylylene group. The distance between the naphthalene spacers is thereby reduced, with the result that the cavity is better adapted to the size of the guests.[106] Furthermore, as also demonstrated by the crystal structure, favorable edge-to-face interactions (T-stacking) occur between the guest and *p*-xylylene ring (Fig. 9). Accordingly, *p*-nitrophenol is four times more strongly bound by **48a** than by **47a** ($K_{ass} = 0.6 \times 10^4\ M^{-1}$ and $2.3 \times 10^4\ M^{-1}$). The (±) isomer **47b** binds even more weakly than the *meso* host **47a**, presumably due to its lesser conformational flexibility and the consequently larger steric barrier in complex formation. Here it is found that greater rigidity does not necessarily confer better ligand properties.

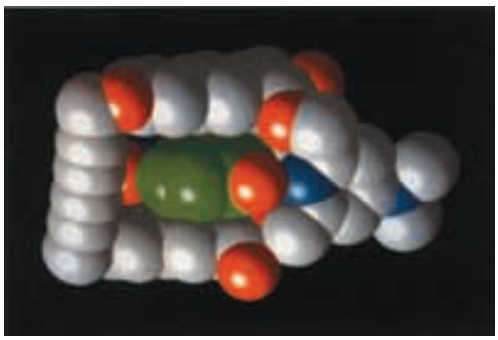


Fig. 9. Crystal structure of **48a** with intercalated *p*-nitrophenol. The hydrogen atoms are not shown; the carbon atoms of the guest are colored green.

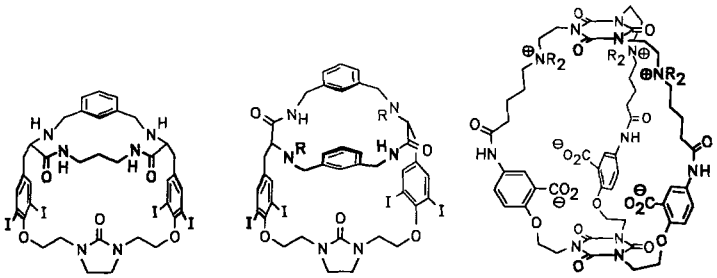
An important factor for molecular recognition by formation of hydrogen bonds is the optimum adjustment of the basicity of one component and the acidity of the other. For example **48b**, which is less basic due to the absence of the dimethylamino group, is a weaker host than **48a**. Complexation also does not occur if the guests are more acidic than *p*-nitrophenol, for instance 3,5-dinitrophenol or benzoic acids. In contrast to binding by hydrogen bonds, simple proton-transfer thus does not necessarily result in the formation of supramolecular structures (cf. the complexation properties of the hosts **32**–**36**).

The macrobicyclic hosts **49** and **50** of Still et al.[77] employ multiple hydrogen bonds to bind organic guests with donor and acceptor functionalities arranged in a manner complementary to the cyclourea units and amide groups of the molecular cavities.[107, 108] Various heteroarenes are thus incorporated. For example, the binding energy for the complex of 4-pyridone and **49** is approximately $-21\ kJ\,mol^{-1}$. Compounds such as pyridine or *N*-substituted imidazoles are discriminated, since they do not possess proton-donor properties.[107]

Host **50** complexes amides of primary amines. The binding results from interactions between the amide hydrogen atoms of the guest and the cyclourea unit of the host, as well as between the carbonyl group of the guest and the amide protons of the host. The molecular framework of **50** contains two asymmetric bridgehead carbon atoms with (*S*) configuration. In the case of amides with a center of chirality adjacent to the nitrogen atom, the (*S*) enantiomers are more tightly bound than the (*R*) enantiomers, since they are better adapted to the host geometry. Although the enantioselection is not high, it is nevertheless significant. For the two isomers of *N*-(1-phenylethyl)acetamide, for example, $\Delta\Delta G_{ass}$ is $1.7\ kJ\,mol^{-1}$ ($CDCl_3$) [$\Delta G = -12.7\ kJ\,mol^{-1}$ (*S*) enantiomer and $-11.0\ kJ\,mol^{-1}$ (*R*) enantiomer].[108]



49 **50** : R = benzyl **51**

The water-soluble bicyclic compound **51** (R = CH_3) is a ditopic host for zwitterionic amino acids (Askew).[109] The framework of the host contains three quaternary ammonium groups as well as three carboxylate groups, which in the case of inclusion of appropriate guests may be oriented towards the cavity.[110] The host binds γ-aminobutyric acid (GABA) with an association constant of $3.2 \times 10^3\ M^{-1}$ (D_2O). Glycine, which is too small, and 6-aminocaproic acid, which is too large, are only weakly bound.

Macrobicycles with chelate building-blocks integrated into the molecular skeleton are able to fix guests in the cavity by means of ionic interactions in addition to hydrogen bonds. The cage molecule **52**, with its convergently arranged phenanthroline bridges,[111] has three coordination sites for metal ions. The intramolecular cavity is essentially too large for 1:1 complexes of type **27** to be formed. Indeed, it offers so much space that three cations including three "guest ligands" can be accommodated (Fig. 10). In the hepternary complexes **52a** and **52b** three 2,9-disubstituted phenanthroline molecules are incorporated as copper(I) complexes. The 1:3:3 stoichiometry (*m/z* 2765 and 2307) and the *endo* conformation are unambiguously confirmed by spectroscopy. This stoichiometry is not observed for the complexes of

Fig. 10. Space-filling model of the hepternary supramolecular complex **52b**. The carbon atoms of the guest ligands are colored green.

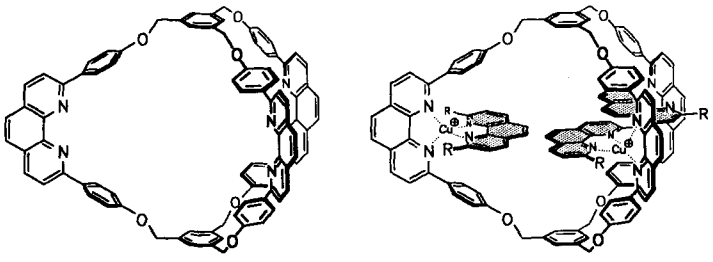
phenanthroline derivatives with space-filling substituents in the 4 and 7 positions.[112]



52

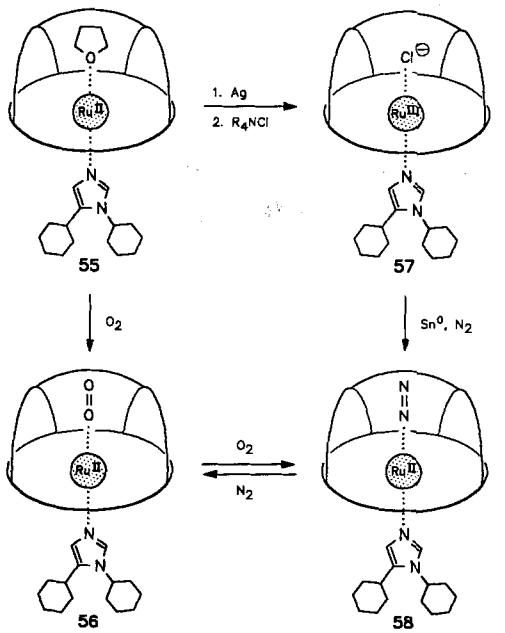
52a : R = *p*-tolyl
52b : R = CH_3

A series of multiply bridged porphyrins with intramolecular cavities is described in the literature.[113] The "capped porphyrins" (Baldwin,[114] Basolo,[115] Ibers,[116] Lindsey,[23]; for example **11**), the "pocket porphyrins" (Collman)[117] and the quadruply linked "double-decker porphyrins" ("stratibisporphyrins"; Kagan, Bruice,[118] Vögtle[20]; for example **8**) may be mentioned in this context. The porphyrinophanes developed by Collman et al. and termed "picnic basket porphyrins" (PBPs) because of their shape, will be illustrated with the example of **53**.[119] The rigid skeleton encloses a cavity that shields one face of the porphyrin unit, which (similarly to the crown ethers in the hosts **40**, **42**, and **44**) serves as binding sites for metal cations and additionally coordinated "guest ligands". PBPs are model compounds for the active center of cytochrome P-450 monooxygenases.[120]

Ru^{II} complexes of PBP **53** can be formed with $[Ru_3(CO)_{12}]$; the free, axial positions of the metal ions are then occupied by a CO ligand and a solvent molecule (pyridine (Py) or THF). The complexes exist in two regioisomeric forms: in one the CO ligand is located in the interior of the cavity, in the other outside the cavity. Equilibrium experiments have shown that the CO_{out}–Py_{in} complex is thermodynamically more stable than the CO_{in}–Py_{out} isomer **54** ($\Delta E \geq 8.2$ kJ mol^{-1}).[119a]

If sterically unprotected Ru^{II} porphyrins are exposed to molecular oxygen, the metal is irreversibly oxidized. This proceeds presumably via a μ-peroxo dimer, in which two porphyrin units are connected by an O_2 bridge.[119] In order to obtain more stable complexes, one must prevent this dimerization. In the PBPs one face of the porphyrin is shielded by the molecular skeleton. The other side can be blocked by tightly coordinating ligands. Such a ligand is 1,5-dicyclohexylimidazole (DCI), which is sterically too demanding to be able to occupy the cavity, with the result that complex **55** is formed regiospecifically. The weakly binding THF molecule can now easily be replaced by O_2 (complex **56**). The N_2 complex **58** may be obtained from **55** via the Ru^{III}-Cl-PBP complex **57** (Scheme 9).[119b]

Whereas the dioxygen complex **56** is only metastable in an O_2 atmosphere (half-life 90 min), the nitrogen complex **58** is



55 **57** **56** **58**

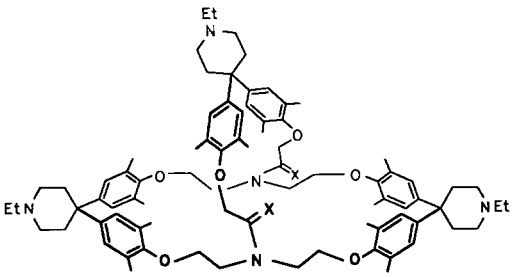
Scheme 9. Formation of the oxygen and nitrogen complexes of PBP by exchange of the *in* ligands.

stable for weeks under inert gas. The IR spectroscopic data of **56** indicate that molecular oxygen is reduced to the superoxide ion O_2^-, and **56** may be regarded as a Ru^{III}–O_2^- complex. Complex **56** is not paramagnetic, and consequently there are no unpaired electrons, which is why it is assumed that there is an additional bond between the metal and the directly coordinating oxygen atom.[119b]

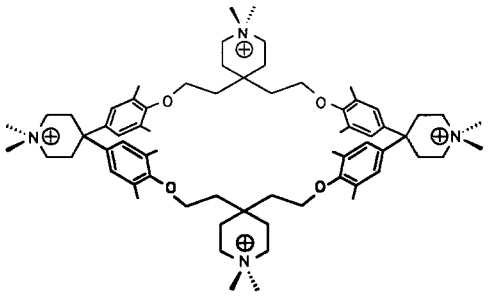
4.3. Complexation of Neutral Molecules by van der Waals Interactions

In 1955 Stetter and Roos were the first to become interested in large cyclophanes as potential inclusion hosts for small organic compounds.[121] The crystalline 1:1 complexes of their bis(benzidine) cycles with solvent molecules (benzene, dioxane) were subsequently shown, however, to be clathrates and not inclusion complexes.[122] At the beginning of the 1980s Koga led the way in the development of water-soluble host compounds for organic guests. In his tetraazacyclophanes two diphenylmethane units form hydrophobic niches and make the incorporation of nonpolar molecules in the aqueous phase and in the crystal possible.[8]

In 1984 Diederich and Dick synthesized the first macrobicyclic hosts **59a** and **59b** for complexing neutral molecules.[13] (The numerous monocyclic analogues cannot be



59a : X = O
59b : X = 2H

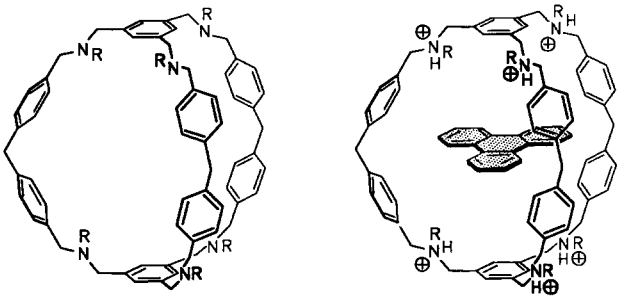


60

discussed individually within the scope of this article, but are described in detail elsewhere.[9d, 71]) The protonated piperidinium rings on the three diphenylmethane building-blocks confer water-solubility on the macrobicycles and their complexes. Due to the spiro linkage, the ionic centers are located on the periphery and thus do not interfere with the markedly nonpolar character of the cavity.

Host **59a** complexes flat aromatic guests in aqueous phase. The association constants are of a comparable order of magnitude to those of the monocyclic comparison compound **60**.[123] For the pyrene complex they were determined by liquid–liquid extraction to be $3.1 \times 10^6\ M^{-1}$ for **59a**[75] and $1.8 \times 10^6\ M^{-1}$ for **60**.[123] The envelopment of the guests by monocycle **60** is obviously very effective. In **59a** the hydrophobic character of the cavity is decreased by the solvation of the two polar amide groups. This unfavorable effect is obviously even more pronounced in the case of **59b**, which contains two protonated, highly solvated amine nitrogen atoms as bridgeheads, and its binding capacity for nonpolar guests in aqueous phase is clearly reduced. The situation is reversed in organic solvents (see Section 4.1): the solvation of the more polar amide groups is stronger than that of the (in this case non-protonated) amine functions. The extra energy expended in the desolvation in the complexing step reduces the binding strength. The association constants for the pyrene complexes in methanol were found to be $3.4 \times 10^4\ M^{-1}$ for **59b** and only $65\ M^{-1}$ for **59a** (UV titration).[75]

Another host with three diphenylmethane units is the macrobicyclic hexaamine **61**, which can be obtained from a relatively short synthesis (analogous to path A in Scheme 1).[124, 125] The six tertiary amino groups in the molecular framework of **61** not only impart solubility in aqueous HCl, but the resulting protonation prevents the collapse of the large discus-shaped cavity by means of the mutual repulsion of the positive charges. This host molecule exhibits a remarkable capacity for complexing various condensed arenes with complementary size and shape, such as triphenylene, perylene, or pyrene. The binding constant for the latter in methanol was found to be $10^{2.5}\ M^{-1}$. The com-



61 R = CH_3 **62**

plexation has drastic effects on the ^1H NMR signals. Not only are the proton signals of the guest shifted to higher field ($\Delta\delta \approx 1.5$), but also the otherwise broad signals of the host compound become sharper and resolve into multiplets; high-field and low-field shifts are also observed (see Fig. 11 for the triphenylene complex **62**). The conformational flexibility of the host framework is restricted by the inclusion of a guest, and the cavity shape is adapted to the guest ("induced fit").

Compounds that are too small, such as benzene and naphthalene, or too large, like coronene, are not appreciably complexed by the receptor model compound. Nor is anthracene bound appreciably, though phenanthrene is, a discrimination that has not hitherto been observed. Also, methyl-substituted and partially hydrogenated derivatives of arenes are not recognized as guests, even if the analogous parent com-

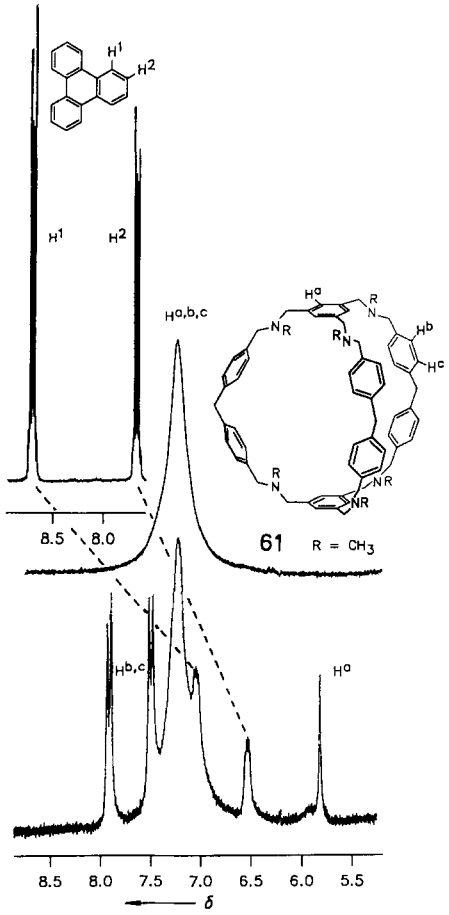


Fig. 11. Effect of complexation on ^{1}H NMR signals of the guest and host as illustrated by triphenylene and **61**. Top: guest triphenylene (CD_2Cl_2/D_3COD); center: host **61** (DCl/D_2O); bottom: host–guest complex **62** (DCl/D_2O).

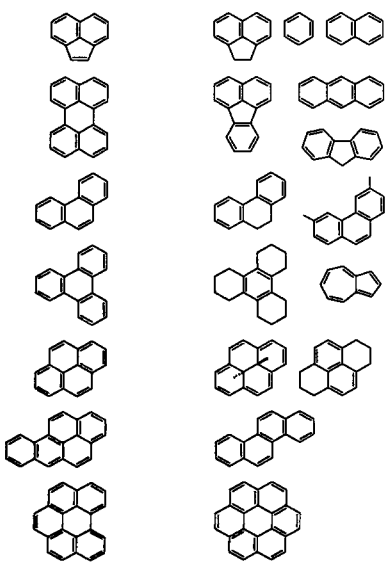
pounds are included. Aliphatic CH_2 and CH_3 groups obviously prevent a favorable inclusion in the niches of the diphenylmethane units, as is possible with the arene parent compounds. The attractive interactions with an edge-in-angle arrangement of two aromatic systems are exhibited in this case (see Section 4.1). Table 3 provides a summary of complexed and discriminated compounds. Fig. 12 shows the space-filling model of the triphenylene complex **62**. On account of selective complexation, pyrene for example could be separated from decahydropyrene, and triphenylene from dodecahydrotriphenylene in phase-transfer (liquid–liquid and solid–liquid) experiments.[124, 126] Phenanthrene can be successfully separated from a mixture with naphthalene in *n*-hexane by the U-tube method.[124]

Table 3. Selective complexation of condensed arenes by host **61** in aqueous solution.

Complexed	Not appreciably complexed
	



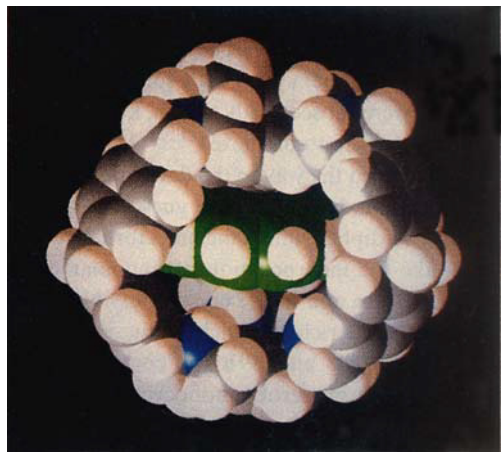


Fig. 12. Space-filling model of the triphenylene inclusion complex **62**. The carbon atoms of the guest are colored green.

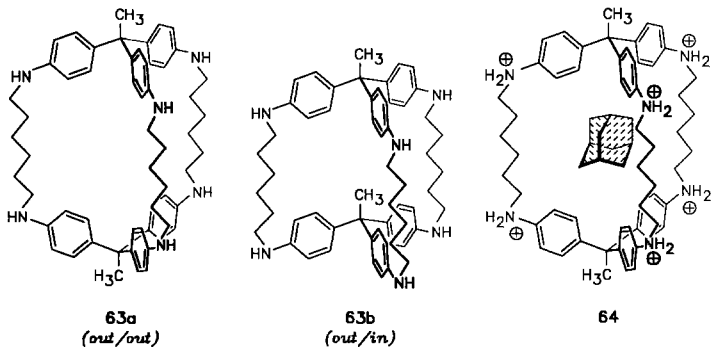
The two macrobicyclic hosts **63a** and **63b** illustrate an interesting case of configurational isomerism: the acid-soluble hexaamines are "*in/out* isomers", which cannot be interconverted by conformational changes. They are obtained in a ratio of about 1:1 in the cyclization.[127] The differing size of the molecular cavities resulting from the stereochemical differences has a drastic influence on the complexation behavior. Whereas naphthalene and 2,6- and 2,7-dihydroxynaphthalene are bound by both hosts in aqueous acidic solution, only the larger *out/out* isomer **63a** is able to incorporate adamantane and 1-adamantanethiol. To our knowledge this is the first time that the complexation of an alicyclic hydrocarbon has been successfully achieved (complex **64**).



Collet et al. developed a family of host molecules whose skeletons are constructed from two cyclotribenzyl units (e.g.

cyclotriveratrylene, CTV), which are linked to one another by three alkyldiether bridges. These cryptophanes exhibit an interesting behavior in their complexation of halomethanes.[128]

The inclusion of halomethanes is evident in the strong upfield shifts of the signals of the guests in the ^{1}H NMR spectra ($\Delta\delta > 4$). The crystal structure analyses of the CH_2Cl_2 complexes of the isomeric cryptophanes C (**65**) and D (**66**) demonstrate that the guests are incorporated in the cavity between the two bowl-shaped spacers.[128] Interestingly, only the CH_2Cl_2 complex of the (+) enantiomer crystallized from a racemic solution of (±)-cryptophane D (**66**) in CH_2Cl_2/acetone (enantiomer separation by crystallization, Fig. 13).[129]

The chirality of the host molecule **65** effects the enantioselective inclusion of the likewise asymmetric bromochlorofluoromethane.[130] Investigations with enriched CHBrClF and pure enantiomers of cryptophane C (**65**) showed that the complexes in which the host and guest have the same rotational direction (*p* complex) are more stable than in the other case (*n* complex, $\Delta\Delta G \approx 1.1$ kJ mol^{-1} in $CDCl_3$).

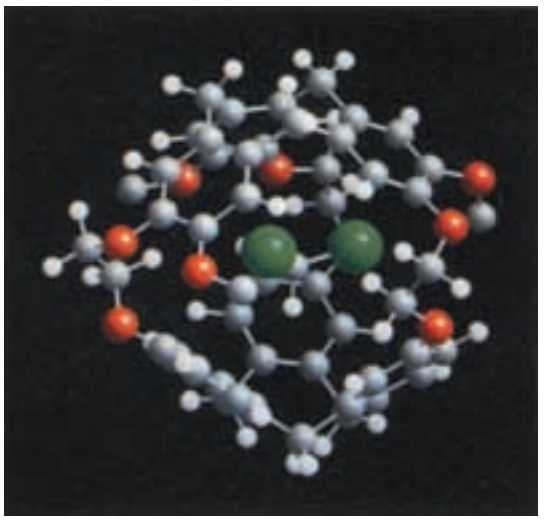


Fig. 13. Ball-and-stick model of the crystal structure of (+)-cryptophane D (**66**) with one CH_2Cl_2 molecule in the cavity (side view). The chlorine atoms of the guest are colored green.

The complex stabilities depend greatly on the size of the guest molecules (and of the solvent molecules[77]). In accord with Diederich's observations[71a, 131], it is found that the "best" guests are somewhat smaller than might be assumed from the CPK models. Cryptophane E (**67**) binds in (CD_2Cl_2)$_2$ a whole series of halomethanes, ranging in size from methyl iodide to carbon tetrachloride.[28, 132] The largest formation constant was found for the complex with the medium-sized chloroform ($K_{ass} = 470$ M^{-1}), whereas the smaller dichloromethane ($K_{ass} = 120$ M^{-1}) and the bulkier bromoform ($K_{ass} = 40$ M^{-1}) are bound substantially more weakly. Cryptophane A (**68**) on the other hand,[12] which has a smaller cavity and smaller portals, binds CH_2Cl_2 more strongly than $CHCl_3$ ($K_{ass} = 475$ M^{-1} and 230 M^{-1}, respectively).[133] A water-soluble derivative of **68**, the hexacarboxylic acid **69**, behaves in the opposite way. The stability constant K_{ass} of the complex with $CHCl_3$ is 7700 M^{-1}, but "only" 5000 M^{-1} with CH_2Cl_2. Probably because of the larger lipophilic surface and the resultant larger number of solvate molecules to be "stripped" in the complexing, the driving force of the hydrophobic effect is stronger for the binding of chloroform than of dichloromethane.[133]

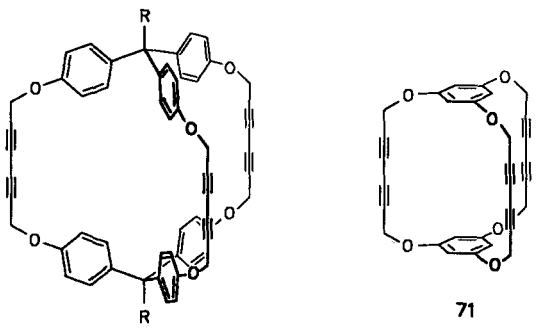
66 (+)-cryptophane D

67 (+)-cryptophane E

68 (-)-cryptophane A

69 R = CH_2CO_2H

Other macrobicyclic hosts with a predominantly nonpolar molecular framework include the tris(diyne) compounds **15**[26] and **70**.[134] The aromatic spacers as well as the diacetylene bridges impart a marked rigidity and prevent the frame from collapsing. The ether oxygen atoms acting as "hinges" enable the molecule to twist, however, and thus adapt to the size of the incorporated guests.[135]



15: R = CH_3
70: R = H

71

Crystals of **15** obtained from benzene strikingly illustrate this adaptation (Breslow et al.). The triphenylethane units are twisted helically so that a solvent molecule is rigidly clamped in the cavity interior between two oppositely situated phenylene rings of the host (Fig. 14). This is a typical example of

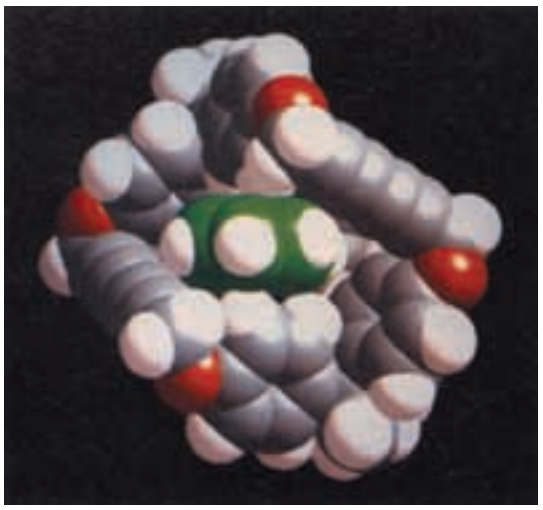


Fig. 14. Crystal structure of the macrobicyclic host **15** with intercalated benzene. The unit cell contains four further benzene molecules, two of which are also incorporated in the host framework. The carbon atoms of the guest are colored green.

a multiple edge-to-face interaction (T-stacking, see Section 4.1, Fig. 5).[26]

The inclusion complex of host **70** with acetonitrile is comparable.[134] The guest can take two alternative positions in the host cavity, one of which is illustrated in Figure 15. Through π-stacking and electron-donor–acceptor interactions, the two aromatic units of one of the three bridges of the macrobicyclic host are attracted to the interposed guest, and thus have a smaller interspacing than the remaining units. The IR spectrum of the complex exhibits a considerable shift of the nitrile band to smaller wavenumbers (2219 cm^{-1} compared to 2254 cm^{-1} in free acetonitrile), which could indicate a lengthening of the C–N bond on account of the intermolecular interactions.[134]

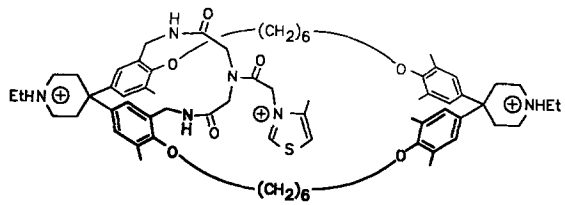
Fig. 15. Crystal structure of the acetonitrile inclusion complex of the host **70**. Only one of the two occurring orientations of the guest in the cavity is shown. The carbon atoms of the guest are colored green.

The smaller tris(diyne) **71** with two benzene spacers instead of triphenylmethane units also incorporates acetonitrile in the crystal. Here, too, the nitrile band is shifted 35 cm^{-1} in the IR spectrum. However, in contrast to **70**, in this case the methyl group of the guest is situated between the arene units of the host, and not the nitrile group. This arrangement can be interpreted as a consequence of a σ–π interaction between the acidic protons of the CH_3 group and the electron-rich (π-basic) tris(alkoxy)benzenes (Fig. 16).[136]

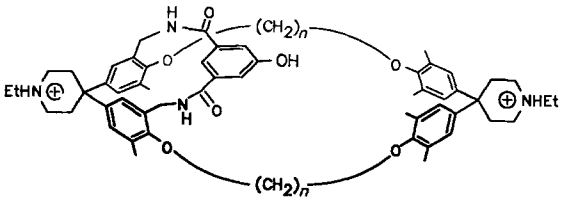
Fig. 16. Crystal structure of the acetonitrile inclusion complex of the host **71**. The carbon atoms of the guest are colored green.

4.4. Catalytically Active Host Compounds

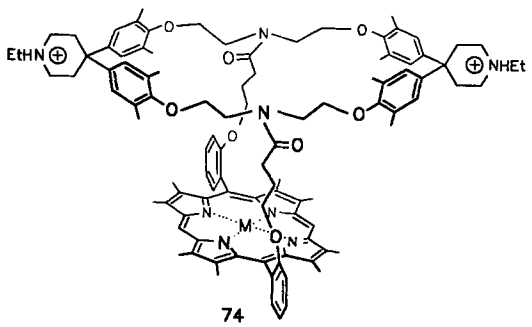
Starting from bis(diphenylmethano)cyclophanes, Diederich developed the supramolecular catalysts **72**–**74**. In the hosts **72** and **73** a thiazolium ring and a phenol ring, respectively, are arranged as catalytically acting groups above the molecular cavity, in other words above the binding site for aromatic guests. The thiazolium group is the active center in thiamine



72



73a: $n = 4$
73b: $n = 6$



74

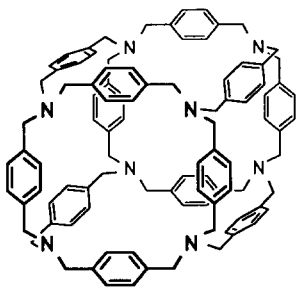
pyrophosphate (TPP), which serves as an important cofactor in many enzymes catalyzing C–C bond formation and cleavage.[137] The cavity of the enzyme model **72** provides sufficient space to accommodate two benzaldehyde molecules and fix them at a favorable distance relative to the thiazolium ring, with the result that benzoin is formed in high yield.[138]

The phenolic OH group of **73a** and **73b** is an effective nucleophile at physiological pH values,[137] and the two hosts thus act as synthetic esterases ("α-chymotrypsin mimics").[139] With 4-nitro-1-naphthyl acetate as substrate, significant differences are observed in the acceleration of the transacylation step: a factor of 178 in the case of **73a** compared to a factor of 14 in the case of **73b**. The cavity of **73a** is sufficiently large to permit an approach of the phenol and ester groups in the complex favorable for the reaction (productive complexing). The situation is different with the smaller host **73b**, which is also able to complex the aromatic residue readily, but only unproductively. The phenol residue of a second host molecule thus acts as catalytic center in this case.

The porphyrin-bridged cyclophane **74**[140] is a synthetic model compound for the natural cytochrome P-450 enzymes,[120] which as monooxygenases are involved in the catabolism of lipophilic substrates. They contain as an essential structural feature an iron(II) hemoporphyrin in the vicinity of a hydrophobic substrate binding site. In **74** the cyclophane part, which is linked by two bridges to the porphyrin ring, forms such a binding site. In trifluoroethanol the Fe^{III} complex of **74** incorporates acenaphthylene ($K_{ass} = 1.05 \times 10^3\ M^{-1}$) and oxidizes this guest selectively to acenaphthen-1-one, in the presence of iodosobenzene as oxygen carrier. Phenanthrene on the other hand, which is likewise strongly but unproductively bound ($K_{ass} = 1.33 \times 10^3\ M^{-1}$), inhibits catalysis competitively without being attacked itself.

4.5. Multiply Bridged Cage Host Compounds

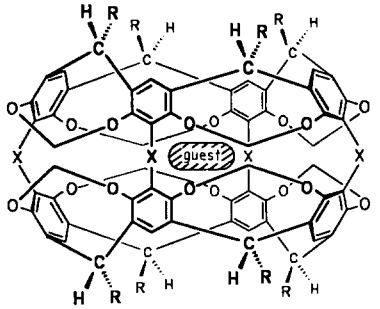
The macropentacyclic host molecule **75** has a rigid, cubic framework whose six sides are formed by tetraaza[3.3.3.3]-paracyclophane units (Murakami).[141] Because of its water-solubility in the protonated state, **75** is able to incorporate both neutral and anionic organic guests in its cavity by utilizing hydrophobic interactions.[142] The cavity in the octa-



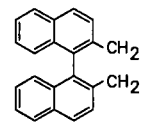
75

cation of **75** is no longer sufficiently lipophilic due to the strong solvation, and consequently no complex formation is observed.[143] In contrast the tetracation of **75** binds, for example, *N*-phenyl-1-naphthylamine with an association constant K_{ass} of $8.8 \times 10^4\ M^{-1}$ (pH 4). With the structurally related 8-anilinonaphthalene-1-sulfonate (ANS) electrostatic forces of attraction are also involved as driving forces: The binding of the guest ($K_{ass} = 1.6 \times 10^5\ M^{-1}$ at pH 4) is about twice as strong.[142]

Cram et al. designed a new family of molecular "container compounds": the carcerands **76a**[144] and **76b**,[145] which are constructed of two quadruply bridged "cavitand" subunits,[146] and have a virtually closed molecular surface. Once guests have been trapped in the cavity they can be released again only by destruction of the molecular framework. Inclusion complexes of all neutral molecules and ions present in the cyclization reaction have been detected: solvent molecules (THF, *N,N*-dimethylformamide, *N,N*-dimethylacetamide, and dimethyl sulfoxide), cesium ions of the auxiliary base, and even argon and freon from the inert-gas atmosphere. The complexes can be separated chromatographically, and there is consequently an exchange of information between the guest in the interior and the host environment. According to Cram these "carceplexes" provide a new phase of matter for the incorporated guests. The interior of the carceplexes is a definable mixture of free space and space-filling guests ("guest plus vacuum in varying proportions").[144]



76a : R = CH_3, X = CH_2SCH_2
76b : R = CH_2CH_2Ph, X = OCH_2O
76c : R = CH_2CH_2Ph, X = Y
76d : R = CH_2CH_2Ph, X = Z



If the cavitand halves are held in position with larger bridges (as in **76c**[147] and **76d**[148]) or with only three instead of four units,[149] the windows in the equator plane of the cage molecules are consequently widened and the shielding of the cavity is thus less complete. Consequently the "hemicarceplexes" can be decomplexed by heating in solvents consisting of bulky molecules. The free "hemicarcerands" can then form new inclusion complexes on treatment with other solvents or solutions of suitable guests. The steric barriers in these processes are relatively high and the complexes are correspondingly stable ("constrictive binding").

5. Future Outlook

Molecules with an aesthetic architecture reminiscent of macroscopic structures have always held a particular fasci-

nation for the synthetic chemist.[150] In this review article we have discussed the not insubstantial contribution made by large host molecules with intramolecular cavities and suitable endoreceptor properties in supramolecular chemistry and, in this context, particularly in the elucidation of the principle of molecular recognition. Despite much success in this field, by no means all the objectives have been achieved. For example the synthetic receptors for sugars,[151] steroids,[152] lipids, peptides, and nucleotides,[61a, 65, 68, 153] and the separation of enantiomers are certainly open to improvement.[154] One may also anticipate the insights provided by the investigations of dendrimers[155] (cascade molecules,[156] arborols[157]), which have recently been in the forefront of attention.

In the future, interest will extend over and above molecular recognition to desired functions. Biological systems with their outstanding properties often serve as examples in this connection. The first steps on the path to efficient and readily accessible bioorganic and bioinorganic catalysts that imitate highly specific enzymatic catalytic processes have already been taken, though many challenges still remain. Transport phenomena of all types are also worthwhile subjects for study, for example the transport of ions or molecules with mobile carriers[126] or transport by means of molecular channels or tubes through cell membranes.[158] From the medical aspect sequestering agents would be important in removing toxic and radioactive metals and other poisons from the body, or also as drug carriers for transporting drugs to targeted disease sites. Such complex-forming agents may also be imagined in fluorescence- or radiolabeling of antibodies[159] for early recognition of metastases (tumor imaging). Efforts will also continue in the transmission of information, such as occurs in nerve pathways, and in developing molecular wires, antennae, light converters, rectifiers, transistors, and systems for the photochemical splitting of water.[16]

With its multidisciplinary character, supramolecular chemistry offers a broad spectrum for scientists of all fields, and in the future will not only provide important incentives for basic research but also for innovative applications.

We wish to thank all co-workers who by their efforts and knowledge have contributed to the success of our research in the field of large molecular cavities. We also wish to thank W. Schmidt, Dr. A. Schröder, and in particular P.-M. Windscheif for preparing some of the diagrams for this review article. We are grateful to Professor A. von Zelewsky (Freiburg, Switzerland), Prof. V. Balzani (Bologna, Italy), and their co-workers for the fruitful cooperation in the field of supramolecular photochemistry. We also thank colleagues who have provided crystal structure data. Our work was supported by the Deutsche Forschungsgemeinschaft and the Bundesministerium für Forschung und Technologie.

Distorted Molecules: Perturbation Design, Preparation and Structures

By Hans Bock,* Klaus Ruppert, Christian Näther, Zdenek Havlas, Hans-Friedrich Herrmann, Claudia Arad, Ilka Göbel, Andreas John, Jochen Meuret, Sabine Nick, Andreas Rauschenbach, Wolfgang Seitz, Torsten Vaupel, and Bahman Solouki

Dedicated to Professor Heinz Harnisch occasion of his 65th birthday

The structure of a molecule can change considerably as its energy and thus its electron distribution within the time-domain of dynamic relaxation varies. Based on comparison of approriate measured data of related compounds and supported by quantum chemical calculations, therefore, charge-perturbed and/or sterically overcrowded molecules can be designed. Their preparation, handling, and structural characterization, frequently under extreme and especially largely aprotic conditions, provides some surprises. New structural principles become evident and old-fashioned ones are confirmed. Thus the contact-ion aggregates that form on ultrasonically supported reduction of unsaturated hydrocarbons with sodium metal partly contain dibenzene sodium sandwiches. Vicinal dimethylamino substituents or isoelectronic isopropyl groups cause steric overcrowding and facilitate oxidation to molecular cations by energetically favorable delocalization of the generated positive charge. Molecules and molecular ions in which an even number of π electrons are distributed over a σ skeleton containing an odd number of centers preferentially form cyanine subunits. This is demonstrated by the novel ethene dication and dianion salts with central C–C single bonds and molecular halves twisted relative to each other. Altogether in two years well over 50 structures have been determined. Much has been learned from them, especially about electron transfer and contact ion-pair formation in aprotic solvents. Nevertheless, we had to realize that answers to many questions, above all "what crystallizes, how, and why", are still out of reach.

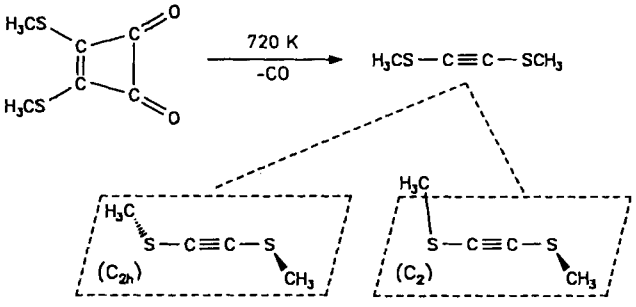
"Actually, everything is more complicated".
(Foreword from a Ph.D. thesis, Frankfurt University)

1. Starting Point: Structural Estimates from Measured Data and Approximate Energy Hypersurface Calculations

Even the predominantly preparative chemist profits considerably if he looks at his spectra from the additional point of view that these represent 'molecular state fingerprints'.[1] One example each from the gas phase and from solution will serve to illustrate both the approach and the gain of information.

1.1. The Structure of $H_3CS–C{\equiv}C–SCH_3$ in the Gas Phase

The gas-phase thermolysis of bis(methylthio)cyclobutene-1,2-dione at 720 K according to real-time gas analysis by photoelectron (PE) spectroscopy proceeds largely selectively by elimination of two energetically favorable leaving molecules of CO ($\Delta H^0_{f,273} = -110\,kJ\,mol^{-1}$) to form bis(methylthio)acetylene.[2] Two preferred conformations are conceivable for the latter in its ground state: the methylthio substituents are either coplanar or perpendicular to each other (Scheme 1). The possibilities can be evaluated from a



Scheme 1. Simulated synthesis of bis(methylthio)acetylene in the gas phase and its two preferred conformations.

calculation of an approximate one-dimensional MNDO energy hypersurface, in which only one of the total of $(3n - 6) = 30$ degrees freedom for the molecule containing $n = 12$ centers, namely the dihedral angle ω(C-SCCS-C) (Scheme 2), is considered.

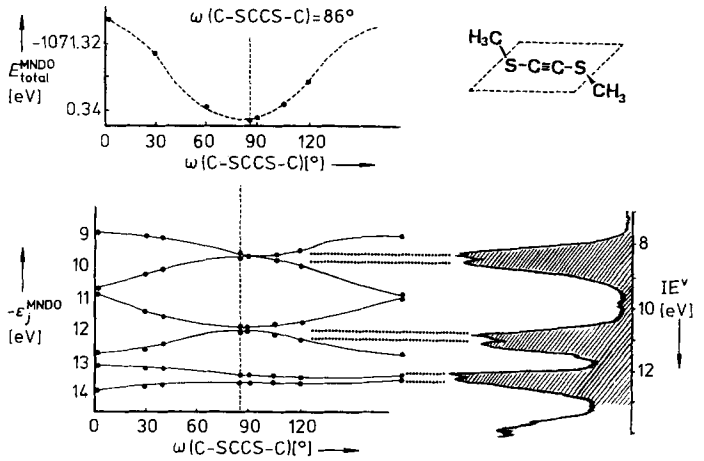
[**] Structure of Charge-Perturbed and Sterically Overcrowded Molecules, Part 20, and Molecular Properties and Models, Essay 24. Part 19: H. Bock, W. Seitz, Z. Havlas, J. W. Bats, unpublished; Essay 23: [34].

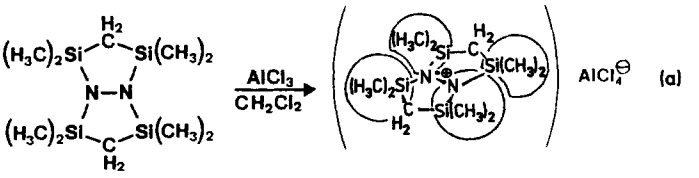


Scheme 2. Top: One-dimensional energy hypersurface for bis(methylthio)acetylene as a function of its dihedral angle ω(C-SCCS-C). Bottom: Koopmans's correlation of the eigenvalue pattern with the six lowest vertical ionization energies. IE^V, determined by PE spectroscopy. The intensity of the bands in the PE spectrum is given in counts per second (cps).

The MNDO potential minimum is found at a dihedral angle of 86°, and the MNDO eigenvalues calculated for the C_2 conformation reproduce via Koopmans's correlation, $-\varepsilon_j^{MNDO} = IE_n^V$, three double bands observed in the PE spectrum (Scheme 2). An independent structure determination of $H_3CS-C\equiv C-SCH_3$ by electron diffraction in the gas phase[3] confirms the preferred conformation deduced from the energy hypersurface minimum and by comparison of the measured vertical ionization energies with the calculated eigenvalue pattern. The dihedral angle is consistently determined to be 86°.[3]

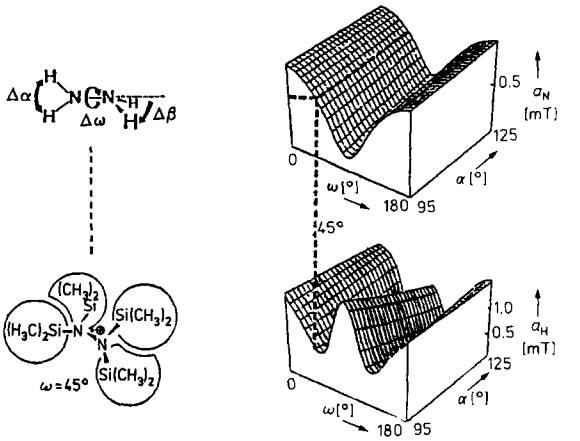
1.2. The Structures of Radical Cations $R_2NNR_2^{\bullet\oplus}$ in Solution

The oxidation of silyl-substituted hydrazine derivatives by the oxygen-free and selective one-electron-transfer oxidation reagent $AlCl_3/CH_2Cl_2$[4] yields their radial cations[1a, 4, 6] in their doublet ground states [Eq. (a)].



(a)

The high-resolution ESR spectrum including the ^{29}Si coupling (natural abundance 4.5%) of the planarized 1,5-diaza-2,4,6,8-tetrasilabicyclo[3.3.0]octane derivative can be simulated satisfactorily.[5] Problems, however, result on comparison with analogous silyl hydrazine radical cations such as $((H_3C)_3Si)_2N^{\bullet\oplus}$-$N(Si(CH_3)_3)_2$;[5] they can be resolved by reference to approximate quantum chemical calculations for the model compound $H_2N-NH_2^{\bullet\oplus}$, which reveal a

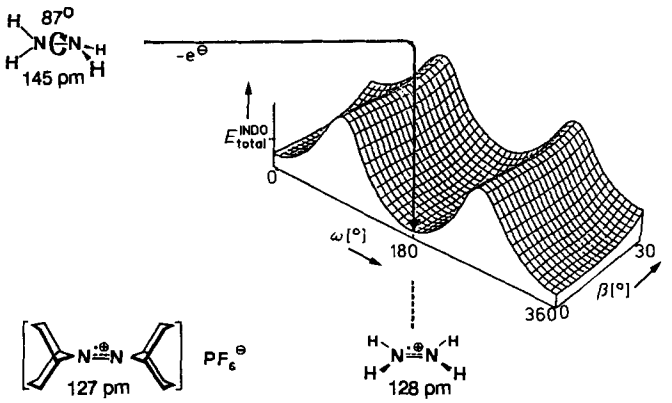


Scheme 3. INDO hypersurfaces for the dependence of the coupling constants a_N and a_H of $H_2N-NH_2^{\bullet\oplus}$ on angles ω and α, and estimated structure (---) for the sterically overcrowded tetrakis(trimethylsilyl)hydrazine radical cation in solution [5, 6].

Hans Bock obtained his Ph.D. in 1958 from the Ludwigs Maximilians University in Munich, submitting a thesis on reactions of the rocket-fuel hydrazine, and his habilitation in 1964 based on investigations concerning relations between color and constitution of azo compounds. In the following three years as a visiting fellow at the Federal Institute of Technology in Zurich, the three-volume book "The HMO Model and its Application" was compiled under the guidance of his mentor and friend Edgar Heilbronner and later translated into English, Japanese, and Chinese. In 1968 he received the Chemistry Award of the Academy of Science in Göttingen and the offer of an inorganic professorship at the Johann Wolfgang Goethe University of Frankfurt. Preparative nonmetal chemistry, in combination with physical measurements and quantum-chemical calculations has remained the trademark of his research group: Short-lived molecules, some of them found in interstellar space, are generated under nearly unimolecular conditions and identified by their PE-spectroscopic ionization fingerprints; radical ions and their ion pairs in aprotic solution are characterized by their ESR/ENDOR signal patterns and their respective molecular states; the accompanying structural changes are discussed based on calculated energy hypersurfaces. Professor Bock, a dedicated university teacher, has won numerous honors, among them the Frederic Stanley Kipping Award of the American Chemical Society and the Wilhelm Klemm Award of the German Chemical Society. The University of Hamburg bestowed an honorary Ph. D. degree on him in 1988. Since 1977 he has been an External Scientific Member of the Max Planck Society, and since 1981 an Adjunct Professor of The University of Michigan, Ann Arbor.

different angular dependence of the dominant couplings a_N and a_H[5, 6] (Scheme 3).

For the structure of tetrakis(trimethylsilyl)hydrazine radical cation in solution a twisting angle between the two molecular halves of 45° is deduced (Scheme 3), caused by the mutual repulsion of the four bulky $(H_3C)Si$ groups.[1a, 5] The corresponding INDO energy hypersurface for the unsubstituted hydrazine radical cation (Scheme 4) predicts a completely planar geometry about the N centers (symmetry D_{2h}) as well as an N–N distance shortened relative to that in H_2NNH_2 by 17 pm (!) to 128 pm due to the formation of a two-center/three-electron multiple bond.[5, 6]



Scheme 4. INDO energy hypersurface for $H_2N^{\cdot\oplus}NH_2$ and N–N bond length in the hexafluorophosphate salt of a tetraalkylhydrazine radical cation (cf. text).

Both predictions were confirmed shortly afterwards by the structure determination for the salt of a tetraalkylhydrazine radical cation, kinetically stabilized by steric wrapping. Accordingly, the radical cation is planar and exhibits an N–N distance of 127 pm.[7]

1.3. The Quintessence: The Structures of Molecules in Particular Molecular States

The examples selected from several investigations by PE spectroscopy in the gas phase[8] as well as ESR/ENDOR spectroscopy in solution[9] (Schemes 1 to 4) confirm that suitable correlations of experimental and quantum chemical molecular-state data together with approximate energy hypersurface calculations do indeed allow satisfactory estimates of the structures of short-lived, and therefore not isolable compounds.

Molecular states are—as documented for example by photochemical synthesis steps or by redox reactions—the real chemical 'building blocks'. They can be ordered with respect to both energy[1a, d] (Fig. 1) and time scales[10] (Fig. 2).

For closer elaboration of the abundant molecular-state data along of energy and time scales (Fig. 1 and 2),[1c, 8] PE and electron spin resonance (ESR/ENDOR)[9, 11] techniques are chosen as representative, because they proved to be useful in the planning of the structure investigations reported here. 'Vertical' ionization energy patterns, which are measured with a time resolution less than 10^{-15} s, can be correlated by applying Koopmans's theorem, $IE_n^v = -\varepsilon_j^{SCF}$ to the eigenvalues calculated for the neutral molecule[1, 8] (cf. Scheme 2). In contrast, ESR/ENDOR signal patterns are recorded with a considerably smaller time resolution of greater than 10^{-8} seconds, that is, long after the activation of molecular dynamics at about 10^{-13} seconds, and the spin populations ρ_μ detected for the individual radical ion centers μ can be rationalized, for example according to the McConnell relation, $\rho_\mu \propto c_{j\mu}^2$, by comparison with the squared orbital coefficients $c_{j\mu}^2$ calculated for them.[11] The measurement techniques complement each other, especially for radical cations, because of their different time resolution and together with approximate hypersurface calculations (Scheme 3 and 4) allow reliable estimates of structural changes of molecules M on adiabatic one-electron oxidations $M \rightarrow M^{\cdot\oplus} + e^{\ominus}$.

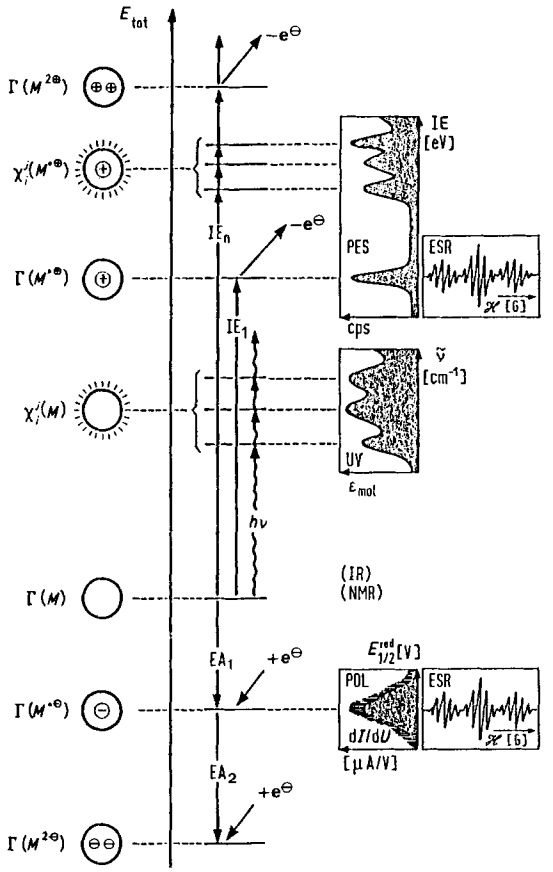


Fig. 1. A: Schematic energy scale for electronic ground (Γ) and excited (χ_i^j) states of a neutral molecule M and its radical cations $M^{\cdot\oplus}$ or dications $M^{2\oplus}$ generated by ionization or oxidation and its radical anions $M^{\cdot\ominus}$ and dianions $M^{2\ominus}$ resulting from electron insertion. B: Representative methods used in the reported investigations are UV, PE, ESR, and ENDOR spectroscopy as well as polarography (POL) or cyclic voltammetry (CV).

Many sets of molecular-state data (Fig. 1) can be advantageously discussed on the basis of a qualitative molecular-state model supported by quantum chemical calculations, which only considers the connection between the centers, their spacial arrangement, their effective nuclear potentials, and the resulting electron distribution[1] (Scheme 5). These rather drastic simplifications, however, accentuate that each

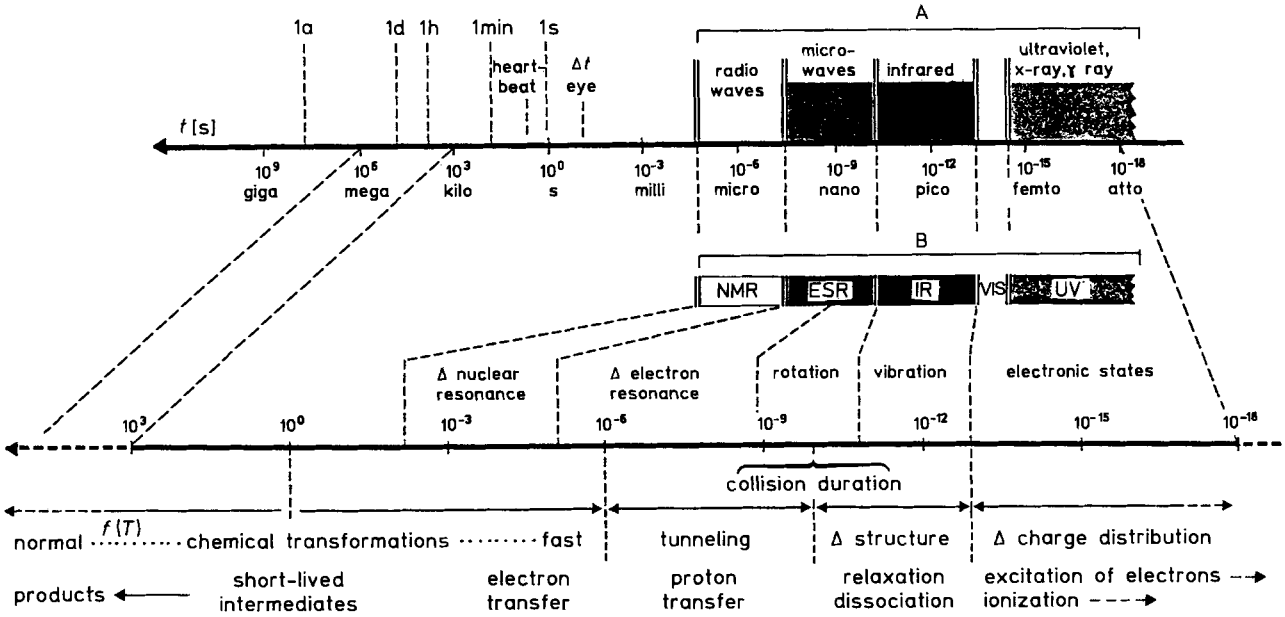

Fig. 2. Schematic time scale for molecular states and their changes (in seconds, the time unit intermediate between the duration of a human heart-beat and the transmission of stimuli by the eye) [10].

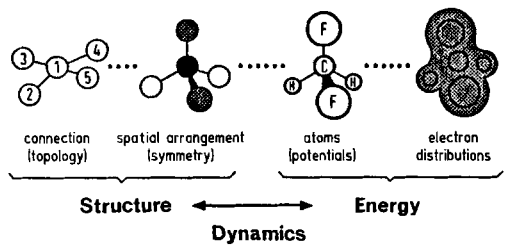
molecular state defined accordingly must possess an individual structure, and that changes in its energy and its charge distribution (Fig. 1) will always provoke structural changes through the inherent molecular dynamics (Fig. 2).



Scheme 5. Qualitative molecular-state model.

The following syntheses of charge-perturbed molecules, their growth as single crystals, and their structural characterization all started from considerations of the molecular states based on appropriate experimental data and supplementary quantum chemical calculations.

2. Organic Compounds of Alkali Metals Containing Inter- and Intramolecular Dibenzenesodium Sandwiches—Examples for the Usefulness of Quantum Chemical Structure Calculations

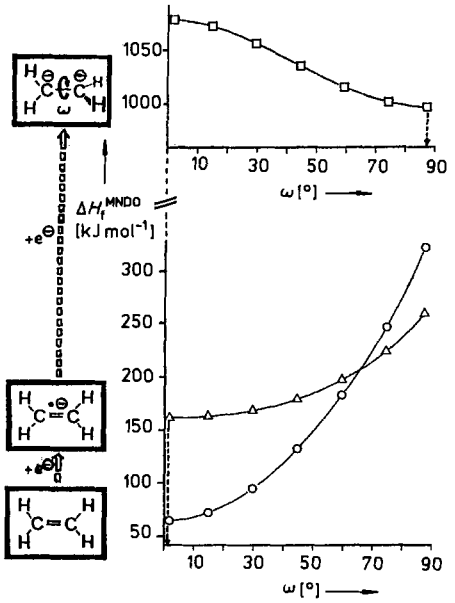
Perphenyl-substituted unsaturated hydrocarbons such as tetraphenylethene,[12, 13] tetraphenylallene,[14, 15] or tetraphenylbutadiene[16, 17] can be reduced at alkali-metal mirrors in aprotic conditions under argon; 1,1-diphenylethene forms a C–C bond to yield the tetraphenylbutane-1,4-diyl dianion.[18] In all the reduction products obtained as well as in many known[19] alkali metal–organic contact ion aggregates, the negative charge of the molecular anions and dianions is compensated by the alkali–metal cations, which are usually solvated and in some of the sodium compounds reported here are complexed in dibenzene sandwiches. In addition, the discussion of these novel molecular-anion salts demonstrates the usefulness of prior and subsequent chemical calculations.[14–18]

2.1. Tetraphenylethene

Ethene, the simplest monounsaturated hydrocarbon exhibits interesting molecular-state properties. On energy increase of 418 kJ mol^{-1} by $\pi \rightarrow \pi^*$ excitation, it switches from its ground state $\tilde{X}(^1A_g)$ of D_{2h} symmetry into its $\tilde{A}(^1B_{1u})$ state, for which after vibronic relaxation two perpendicular H_2C molecular halves are postulated.[20]

Stimulated by this spectroscopic result, we have estimated by approximate energy hypersurface calculations for varying dihedral angles ω which structural changes are to be expected for redox reactions of ethene.[12, 21] For the ground state of the neutral molecule, the well-established D_{2h} gas-phase structure is reproduced (Scheme 6, ○). For a fictive electron insertion that does not account for the stabilizing effects of countercations the calculated enthalpies of formation ΔH_f^{MNDO} predict an energy increase, and because of its shallower potential trough (Scheme 6: △) the structure of ethene radical anions might deviate slightly from planarity. The insertion of a second electron, enforced with rather crude quantum chemistry under an unrealistic energy increase, however, should twist the negatively charged molecular halves considerably relative to each other (Scheme 6, □).

Despite of considerable concern that the semiempirical results for the ethene dianion calculated without explicit account of the electron correlation are likely to be classified as 'se non e vero, e ben trovato',[23] we have chosen phenyl substituents for an improved charge delocalization and



Scheme 6. MNDO enthalpies of formation for ethene, its radical anion, and its dianion as a function of the dihedral angle $\omega(H_2C\text{-}CH_2)$.

treated tetraphenylethene[23] in aprotic diethylether ($c_{H\oplus} < 1$ ppm) under argon with a sodium metal mirror generated at 10^{-4} mbar (Fig. 3a). The stringlike structure determined for the isolated green and extremely air-sensitive crystals exhibiting a metallic luster in a cold (210 K) N_2 flow (Fig. 3b) may be described in stages (Fig. 3c to e) as follows: Twofold reduction of the unsaturated hydrocarbon to its dianion[24] elongates the C–C double bonds by 13 pm (!) to a C–C single bond. The molecular halves, in which the negative charge is energetically favorably delocalized as in a cyanine ($C_6 \cdots C^{\ominus} \cdots C_6$, cf. Section 6), are twisted by 56° (Fig. 3c). In the contact ion pair formed (Fig. 3d), the $Na^{\delta\oplus}$ counterion solvated by two ether molecules is coordinated to a chain of six carbon centers, which stretches from phenyl ring I over the central C–C bond to phenyl ring III. The contact ion-pair units are connected to form an infinite string by the dibenzenesodium sandwich links (Fig. 3b).

For the formation of the twofold reduction product of tetraphenylethene with the unexpected polymeric structure of the contact ion triples, the following speculations, which are partly supported by experiment, can be forwarded[12] (cf. Section 4): Tetraphenylethene shows a planar $C_2C{=}CC_2$ skeleton, around which the four phenyl groups are twisted by angles between 45° and 53°,[23] thereby largely covering the central π cloud of ethylene by their *ortho* hydrogens (Fig. 3a). On single-electron transfer the radical anion is formed. Since its structure remains similar to that of the sterically overcrowded neutral molecule, it presumably only forms solvent-separated radical ion pairs $M^{\bullet}_{solv}{}^{\ominus} \cdots Na^{\oplus}_{solv}$, and therefore preferentially disproportionates, especially in ether solution, according to $2\,M^{\bullet\ominus} \rightarrow M + M^{\ominus\ominus}$ yielding the dianion. Considerable structural changes that lay bare the central C–C bond (Fig. 3c) accompany the second electron transfer to generate the dianion, which can be stabilized by formation of contact ion pairs $[M^{2\ominus}Na^{\oplus}(OR_2)_2]^{\ominus}$ (Fig. 3d). Under the reaction conditions, a polymer chain linked by dibenzene sodium sandwiches (Fig. 3e) crystallizes (Fig. 3b).

2.2. Tetraphenylallene

Who would have possibly suspected that the twofold reduction of organic molecules—often formulated as the inadmissably simplified equation $M + 2e^{\ominus} \rightarrow M^{2\ominus}$—takes such a complicated pathway in the case of tetraphenylethene? The knowledge gained spurred us on to numerous investigations, for instance, into the analogous reduction of tetraphenylal-

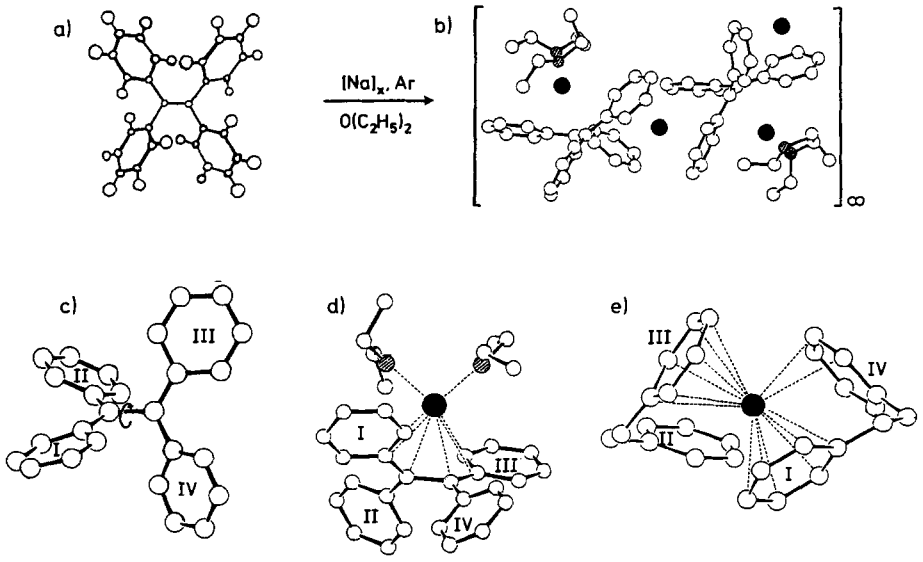


Fig. 3. Results of single crystal structure analyses of a) tetraphenylethene and b) its dianion salt, which is generated by a twofold reduction with sodium metal in diethyl ether and consists of a chain of contact ion pairs d) between $Na^{\delta\oplus}$ counterions solvated by two ether molecules and the dianion c). The chain is connected by dibenzenesodium sandwich links e) [12]. The following structural details are emphasized (●: Na, ◍: O; cf. also Scheme 13): In the tetraphenylethene dianion c) the negatively charged molecular halves are joined by a C–C single bond 149 pm long and twisted relative to each other by 56°. In the contact ion pair d), the sodium countercation solvated by two ether molecules is embedded in a cradle of six carbon centers, which extends from ring I across the central CC bond to ring II. The contact distances amount to 270–283 pm for $Na^{\delta\oplus} \cdots C$ and to an average of 232 pm for $Na^{\delta\oplus} \cdots O$. The contact ion-pair units d) are linked by 14-fold coordinated $Na^{\delta\oplus}$ centers e) at nine $Na^{\delta\oplus} \cdots C$ distances between 276 and 298 pm and five between 302 and 309 pm forming an infinite polymer chain.

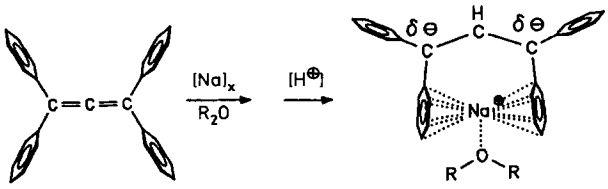
lene with sodium.[14] From the reaction mixture, crystals of a salt containing the anion can be grown, in which the $Na^{\delta\oplus}$ counterion surprisingly is embedded in an intramolecular dibenzene sandwich [Eq. (b)].

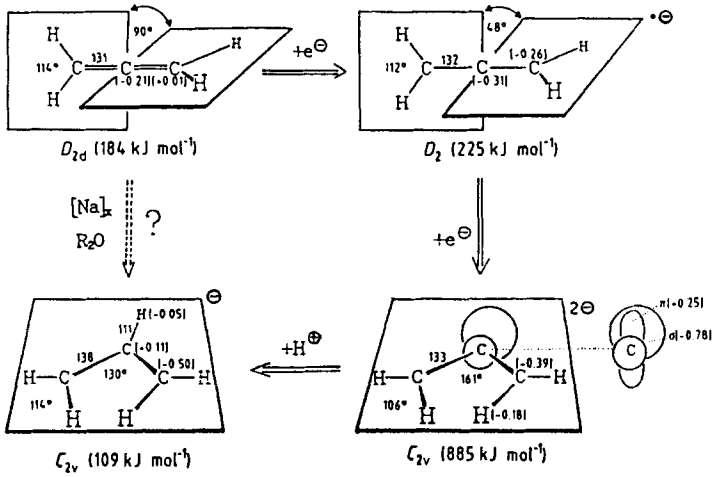


(b)

The course of the reaction had been suggested by comprehensive energy hypersurface calculations, each fully geometry-optimized, for the parent compound allene, chosen as model to save CPU-time[14] (Scheme 7). Clearly the gas phase structure of allene[27] is satisfactorily reproduced in the MNDO total energy minimum. Single-electron insertion to form the radical anion should reduce the dihedral angle $\omega(H_2C\cdots CH_2)$ to about half. For further reduction to the dianion, a considerable energy difference ($\Delta\Delta H_f^{MNDO}$ $(D_2 \rightarrow C_{2v}) \approx 660$ kJ mol^{-1}) is predicted, which must cause drastic structural deformations: Thus the molecular skeleton should be both planarized and bent ($\sphericalangle$ CCC $\approx 160°$). The resulting largely localized and accordingly extremely basic carbon σ lone pair ($q_u^{MNDO} = -0.78$) might be protonated, for example by the solvent, to form an allyl anion in which the negative charge would then be energetically far more favorably distributed over the two outer carbon centers ($\Delta\Delta H_f^{MNDO} \approx 780$ kJ mol^{-1}).

Well forecast? The structure of the extremely air-sensitive black crystals with a metallic luster, determined in a cold N_2 flow (200 K), confirms the quantum chemical planning of the experiment (Scheme 7) in detail: A tetraphenylallyl anion has been formed, exhibiting inter-carbon distances of 139 pm and a C-C-C bending angle of 130°. Unexpected and unique (according to a literature search[25, 26, 28]) therefore, is only the cage of the two phenyl rings opposite to each other containing the $Na^{\delta\oplus}$ counterion and closed by a coordinated diethyl ether molecule in W conformation as a solvent-plug.

To rationalize the surprising formation of the intramolecular dibenzenesodium sandwich, again extensive MNDO energy hypersurface calculations have been performed chosing for the sake of reduced CPU-time diphenylallylsodium diethyl ether as an appropriate model compound.[29] The



Scheme 7. Geometry-optimized MNDO energy hypersurface calculations for the course of the reduction allene → allyl anion (cf. text; bond lengths in pm, heats of formation in parentheses and charge orders in square brackets).

structure corresponding to the minimum of the MNDO total energy (Fig. 4b) reproduces all essential experimental observations (Fig. 4a) in a satisfactory approximation and suggests, in addition, the following plausible explanation for the formation of the intramolecular dibenzenesodium sandwich: In the energetically favorable C_2 structure of the diphenylallyl anion, the phenyl rings facing each other are twisted each by 41° out of the C-C-C allyl plane. A total negative charge of $\sum q_C = -0.47$ is calculated for their five outer ring-carbon centers, which exceeds the charge of a single terminal allyl-carbon center of $q_C = -0.36$ (Fig. 4c). If, therefore, the $Na^{\delta\oplus}$ counterion is fixed to one of the outer allyl-C centers, it moves along a barrier-free trough of the MNDO hypersurface between the two acute-angled phenyl rings into the center of the largest possible contact ion-pair interaction (Fig. 4b). The total charge at the $Na^{\delta\oplus}$ center is calculated to be +0.34 and in the isolated sodium salt containing the allyl anion, therefore, largely covalent complexation should prevail. The ether solvent-plug of the hydrocarbon cage reduces the MNDO enthalpy of formation considerably.

2.3. 1,1-Diphenylethene

A third example of the reductions of phenyl-substituted unsaturated hydrocarbons with alkali metals illustrates additional facets: If 1,1-diphenylethene is treated with either

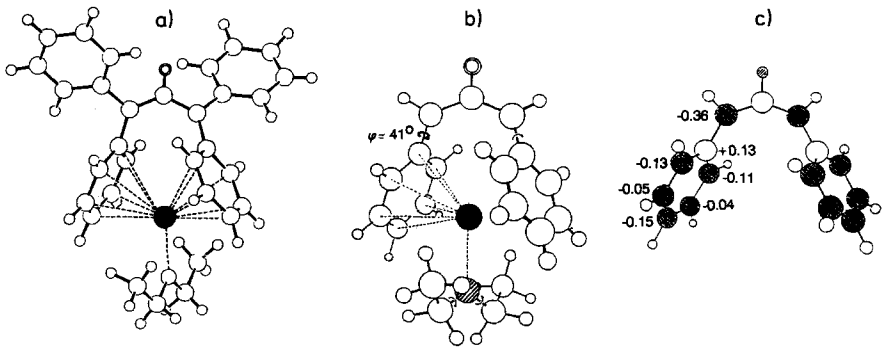


Fig. 4. a) Single crystal structure of tetraphenylallylsodium diethyl ether (●: Na, ◎: O, ○: H); b) MNDO geometry-optimized structure of the diphenyl derivative; c) charge distribution of the diphenyl derivative (cf. text). Selected bond lengths [pm] [14] and angles [°]: GH_{allyl} 99, $C\text{-}C_{phenyl}$ 146, φ(C-phenyl(Na)) 56, Na···C 272–310, Na···O 225. Calculated: φ(C-phenyl(Na)) 41, Na···C 260–273, Na···O 251.

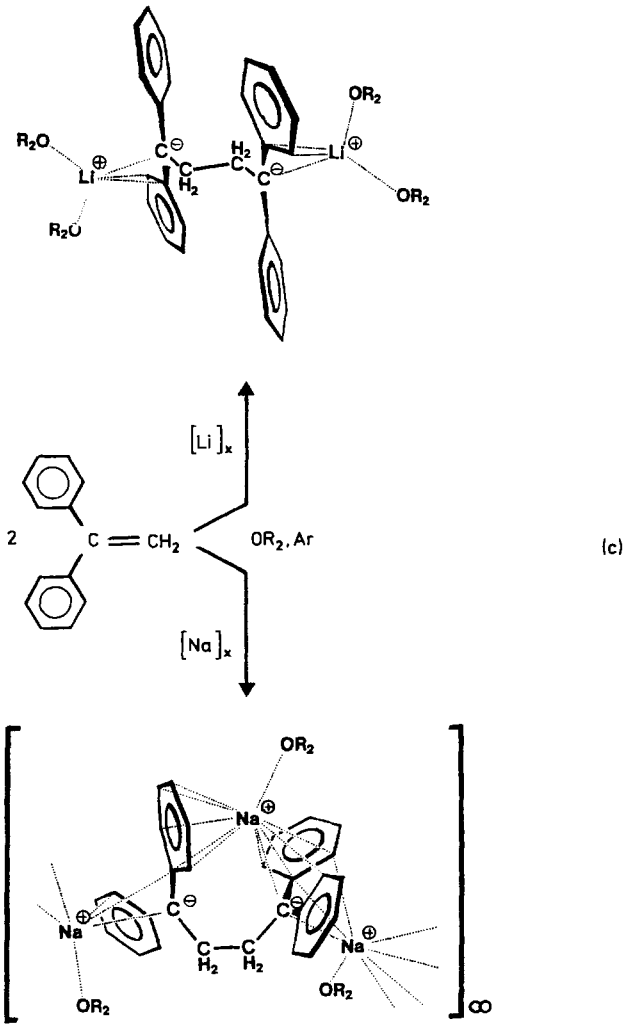
sodium or lithium in aprotic diethyl ether solution under argon, the salts of the 1,1,4,4-tetraphenylbutane-1,4-diyl dianion [Eq. (c)] result through C-C bond formation[30] as



(c)

hydrolysis-sensitive intermediates of a 1,1,4,4-tetraphenylbutane synthesis. This has been proven for both contact ion triples by their single crystal structures[18] (Fig. 5).

On two-electron reduction of 1,1-diphenylethylene with lithium or sodium, distinct types of contact ion triples thus result, the structures of which (Fig. 5) obviously depend on the differing cation solvation energies (see Scheme 9a) and

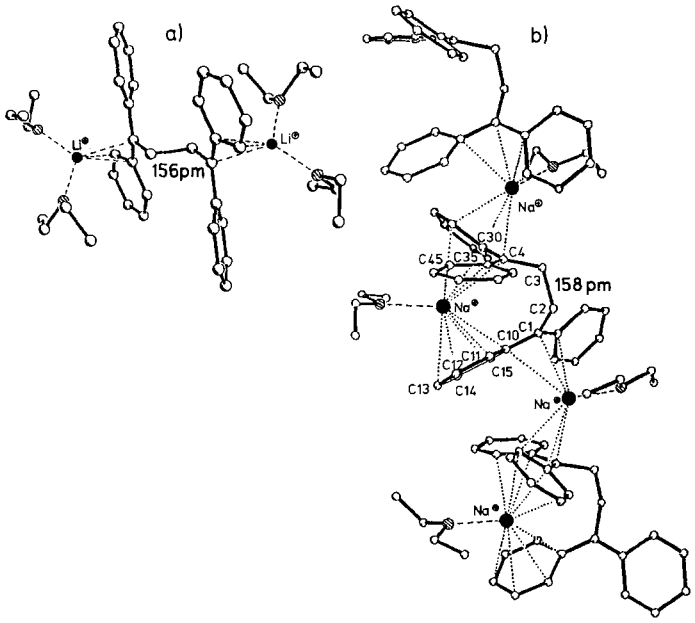


Fig. 5. Single crystal structures of a) 1,1,4,4-tetraphenylbutane-1,4-diyldilithium tetrakis(diethyl ether) and b) 1,1,4,4-tetraphenylbutane-1,4-diyldisodium bis(diethyl ether). The contact distances [pm] are: $Li^{\oplus}\cdots O$ 193, $Li^{\oplus}\cdots C$ 232 to 258, $Na^{\oplus}\cdots O$ 235 and $Na^{\oplus}\cdots C$ 273 to 305 (for further structural data see ref. [18] as well as Scheme 13).

may also be influenced by their different radii (see Scheme 9b). The monomeric dilithium compound solvated by four diethyl ether molecules exhibits an antiperiplanar ethane conformation ($^{\ominus}C$–H_2C–CH_2–$C^{\ominus}$). In contrast, the polymer string of the disodium aggregate solvated by only two diethyl ether molecules consists of contact ion pair anions $[M^{2\ominus}Na^{\oplus}OR_2]^{\ominus}$, which again contain intramolecular dibenzenesodium sandwich subunits. These are bridged by synclinal $^{\ominus}C$–CH_2–CH_2–$C^{\ominus}$ chains (Fig. 4a) and are connected by each η^3-coordinated, ether-solvated $Na^{\delta\oplus}(OR_2)$ cations. The negative charges on the two carbanion centers that are separated by an ethane bridge, are only partly delocalized into the phenyl rings. The resulting repulsive interaction stretches the central C–C single bond to 156 pm (Fig. 5a) and even to 158 pm (Fig. 5b).

Extensive quantum chemical calculations have been performed on the disodium salt of tetraphenylbutane-1,4-diyl dianion containing another intramolecular dibenzenesodium sandwich (cf. Section 2.2) aimed especially at detecting the effect of optimum charge distribution in the formation of

	$M^{2\ominus}$	$[M^{2\ominus}Na^{\oplus}(OH_2)]^{\ominus}$	$(Na^{\oplus}\cdots[\ ]\cdots Na^{\oplus})$

Scheme 8. MNDO model calculations for a hydrated link of the chain from a polymeric string of tetraphenylbutane-1,4-disodium (cf. Fig. 5b and text).

contact ion aggregates. The differences both in the heats of formation $\Delta\Delta H_f^{MNDO}$ and in the charge distribution q_μ^{MNDO} between the dianion $[M^{2\ominus}Na^{\oplus}(OH_2)]^{\ominus}$ and the corresponding chain subunit $Na^{\oplus}\cdots[M^{2\ominus}Na^{\oplus}(OH_2)]^{\ominus}\cdots Na^{\oplus}$ (Scheme 8) have been estimated by using the experimentally determined structure (Fig. 5b) as starting point.

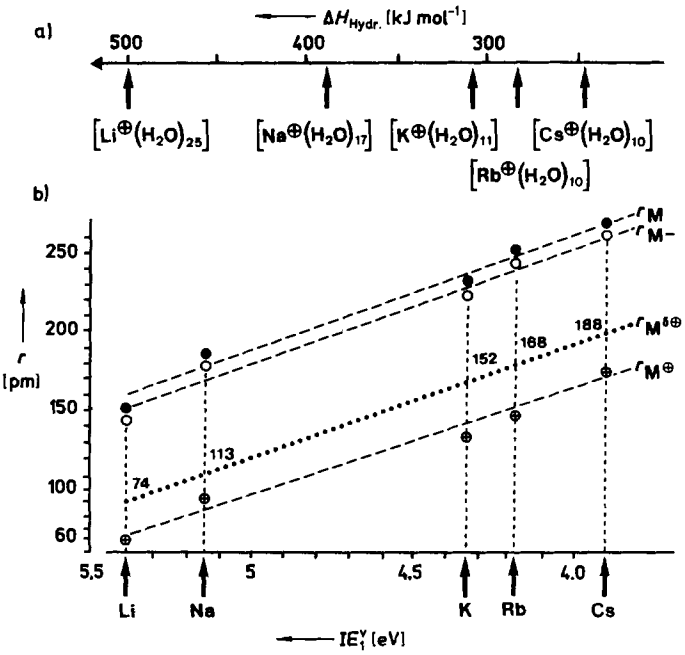
As expected, the MNDO model calculations (Scheme 8) demonstrate that in contact ion pairs the enthalpy of formation is drastically lowered. The charges $\sum q_\mu^{MNDO}$ of the various dianion phenyl rings drop considerably, especially for the chain structure subunit $(Na^{\oplus}\cdots[M^{\ominus\ominus}Na^{\oplus}(OH_2)]^{\ominus}\cdots Na^{\oplus})$ in which, however, the additional outer ligands have been neglected. On the other hand, the charges q_{C1} at the butane diyl centers remain approximately constant. In summary, the preferred formation of an intramolecular $Na^{\delta\oplus}(OR_2)$ sandwich is supported quantum chemically also in the case of the tetraphenylbutane-1,4-diyl dianion.[18]

2.4. Why Dibenzenesodium Sandwiches in Particular?

Altogether three novel "hydrocarbon oysters with solvated sodium pearls" have been presented so far: the polymeric string of the tetraphenylethylene dianion salt[12] (Fig. 3b) with an intermolecular dibenzenesodium subunit, and with intramolecular ones, the monomeric tetraphenylallyl anion complex[14] (Fig. 4a) and the polymeric tetraphenylbutane-1,4-diyl dianion aggregate[18] (Fig. 5b). They all form under the rather brutal conditions of sodium metal reduction in ether solution, add new facets to the fascinating world of alkali-metal–organic compounds,[19] and in addition, illustrate the usefulness of quantum chemical calculations for the prediction and rationalization of hitherto unknown structures.

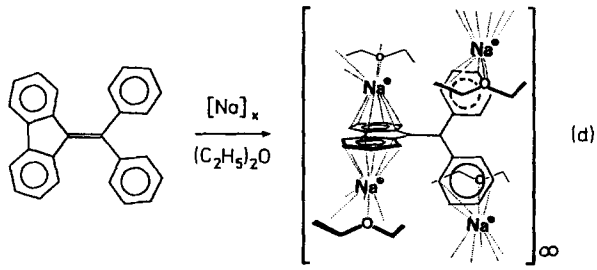
Nevertheless, many questions on the topic "what crystallizes, how, and why" (Section 8.2) remain unanswered. Let us begin with the formation of the inter- and intramolecular dibenzenesodium subunits possibly already in solution (Section 4). Analogous structural arrangements are also known in $Li^{\oplus}$ complexes[19, 25] and in salts of other phenyl-substituted hydrocarbon anions, but as half-sandwiches or with η^3-coordination.[19, 26]. There is hardly any doubt that competing solvation effects play an important and presumably essential role, because the enthalpies of hydration doubles from $[Cs^{\oplus}(H_2O)_{10}]$ (248 kJ mol^{-1}) to $[Li(H_2O)_{25}]$ (500 kJ mol^{-1})[31] (Scheme 9a). In addition, but with the necessary caution, the potential influence of the countercations' radii will be emphasized: Starting point is the correlation of first vertical ionization potentials of the alkali atoms as a measure of their effective nuclear charges (as defined according to Slater[32]) versus their atomic (r_{Met}), covalent (r_{Met-}), and ionic radii ($r_{Met\oplus}$) as well as their radii defined for 80% ionic character ($r_{Met^{\delta\oplus}}$)[19] (Scheme 9b).

The radius of the ring of maximum π electron density of benzene can be estimated at 120 pm by inserting the bond length $d_{CC} = 139$ pm into the formula for the inner circle radius of a regular hexagon, $r_{inner} = d\sqrt{3}/2$. If the radii ratios (Scheme 9b) do play some role, it would therefore be the $Na^{\delta\oplus}$ counterion which preferentially offers itself for six-membered ring sandwich formation.[18] Other single-crystal structures determined since then agree with this hypothesis.



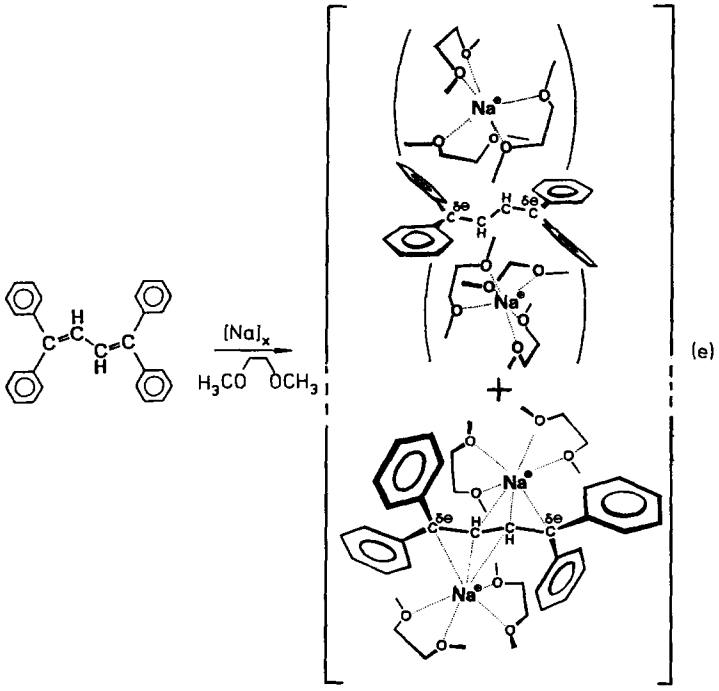
Scheme 9. a) Enthalpies of hydration for alkali-metal cations [31]; b) correlation of the atomic, covalent, and ionic radii (numbers given are for 80% ionic character [19]) with the first vertical ionization energies of alkali-metal atoms.

For instance, the sterically more rigid (biphenyl-2,2'-diyl) diphenylethenesodium diethyl ether[13] [Eq. (d)] contains within its complicated layer-lattice η^6-complexed six-membered fluorene rings exhibiting $Na^{\delta\oplus}$ contact distances between 281 and 298 pm. The other hemisphere of the tenfold coordinated $Na^{\delta\oplus}$ centers shows only a η^3-allylic bonding to the six-membered ring of the next-neighbor diphenylethene molecular half through contact distances of 269, 275, and 295 pm.[13]



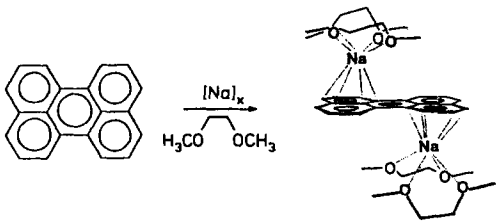
Counter examples, however, exist and should not be concealed. The most interesting one resulted from the numerous attempts to grow single crystals of the reduction products of tetraphenylbutadiene with sodium in the chelating solvent, dimethoxyethane(DME) (cf. Section 3.2): The structure obtained from our so far largest X-ray data set of 9000 registered reflexes proved that the unit cell of the almost black, dark-red crystals exhibiting a metallic luster contained one contact ion triple $[M^{2\ominus}(Na^{\oplus}dme_2)_2]$[33] and one dianion $[M^{2\ominus}]$ with two separated, octahedrally solvated counterions $[Na^{\oplus}(dme)_3]$[33] [Eq. (e)].

From this unexpected structure one may gather that the favorable charge delocalization along a butene-1,4-diyl chain leads to a preference for the η^3-allyl coordination over the η^6-sandwich complexation to the phenyl rings (Eq. (c)



and Fig. 5), and that the stronger solvation by the chelating solvent dimethoxyethane relative to diethyl ether is energetically comparable to the η^3-allyl coordination to the butene-1,4-diyl dianion.

As pointed in the foreword 'actually, everything is more complicated'. Thus on reduction of perylene with sodium in dimethoxyethane a contact ion triple results, in which the dianion again forms η^6-half-sandwich subunits with only doubly solvated $Na^{\delta\oplus}$ counterions[33] [Eq. (f)].



Within the context elaborated (Scheme 9 and Eq. (e)), the structure found may be rationalized at first glance by assuming that in competition between a η^6-sandwich coordination of the $Na^{\delta\oplus}$ counterions and threefold solvation by DME, here the former wins. Possibly, however, the stacking of the contact ion triples in the crystal provides a decisive contribution (Section 8.2).

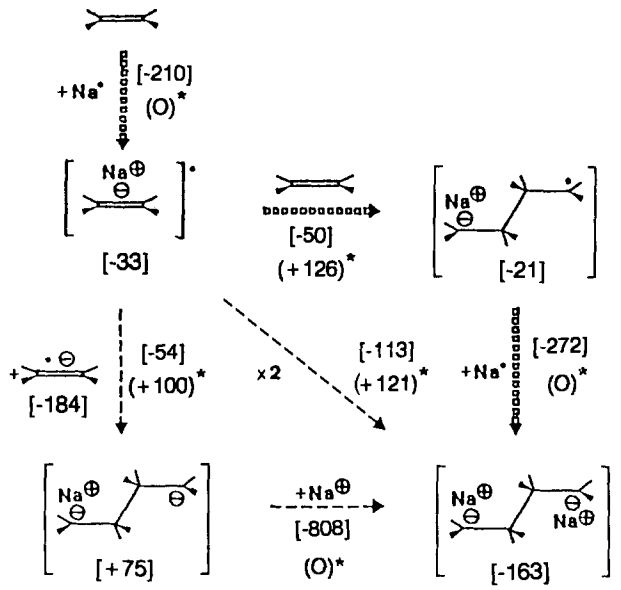
This section's question, 'why dibenzenesodium sandwiches in particular?', cannot be answered straightforwardly due to their multifaceted aspects. Additional experiments planned to reduce unsaturated hydrocarbons containing six-membered rings by varying both the alkali metal as well as the solvent will help to elucidate the origin of the obviously favorable benzenesodium sandwich formation and, above all, contribute to the interesting competition between countercation solvation and their π coordination to molecular anions of unsaturated hydrocarbons.

3. Structural Changes on Reduction of Unsaturated Hydrocarbons

According to molecular state considerations (Section 1.3), every redox reaction inevitably is accompanied by structural changes due to the changes in energy coupled to the uptake or removal of electrons. Atoms and ions change their radii, diatomic molecules their bond lengths, and larger molecules with more degrees of freedom often preferentially their bond angles.[1d, 34] Because a discussion of all the individual data for the present structures of the organic compounds of alkali metals and especially of their comparison with the many literature values[19] would exceed the scope of this review, three variations characteristic for the reduction of unsaturated hydrocarbons to their molecular anions have been selected for illustration.

3.1. C–C Bond Formation

1,1-Diphenylethene is reduced by lithium or sodium metal to dianion salts of tetraphenylbutane-1,4-diyl[18] (Eq. (c) and Fig. 5). Presumably, the C–C bond formation on dimerization is initiated by a heterogeneous surface reaction, but proceeds in the anionic polymerization of hydrocarbons such as the copolymerizations of styrene on technical scale within the liquid phase.[18] Because of their more general relevance, MNDO/CI energy hypersurface calculations[35] have been performed for the model system ethylene to obtain some insight into the pathway of the C–C bond formation for the intermediates of the reduction isolated as single crystals (Scheme 10).



Scheme 10. MNDO/CI calculations for C–C bond formation on reduction of ethene with sodium (enthalpy differences $\Delta\Delta_f^{MNDO}$ in square brackets and activation enthalpies in parentheses, each in kJ mol^{-1}).

The following tentative reduction pathway (Scheme 10: ⇒) is proposed:[18] At the sodium mirror the energetically preferred contact ion-pair radical $[H_2C{=}CH_2^{\bullet\ominus}Na^{\oplus}]$ forms and adds surplus ethylene to the $Na^{\oplus}$ butane-1-yl radical,

which is further reduced to the diamagnetic triple ion $[Na^{\oplus}H_2C^{\ominus}-CH_2-CH_2-CH_2^{\ominus}Na^{\oplus}]$. Phenyl substituents lower all enthalpy values.[35]

3.2. CC Double Bond Shift

On reduction of 1,1,4,4-tetraphenylbutadiene by sodium in dimethoxyethane as well as by potassium in diethyl ether, which again (cf. Fig. 5) yield contact ion aggregates of different structure[16] (Fig. 6), the alternation in the bond lengths of the C_4 chain is reversed.

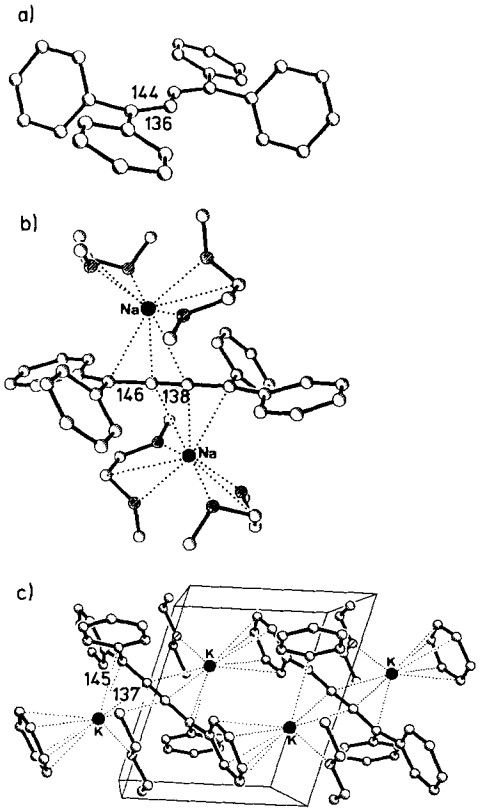


Fig. 6. Single crystal structures of a) 1,1,4,4-tetraphenylbutadiene and of its b) monomeric Na/DME and c) polymeric $K/O(C_2H_5)_2$ reduction products.

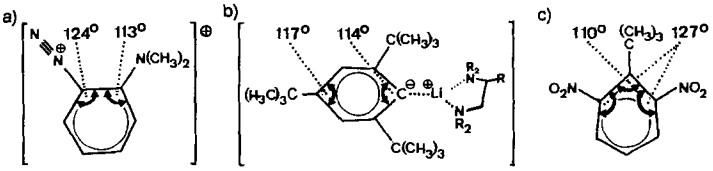
The reaction with sodium in the chelating dimethoxyethane solvent yields a monomeric contact ion triple, in which on each side of the central C_4 chain a doubly solvated $Na^{\oplus}$ counterion is coordinated in a η^3 fashion [Fig. 6b and Eq. (e)]. In contrast, the reduction with potassium in diethyl ether as a weaker solvating ligand produces crystals with a complex layer structure of infinite polymer chains (Fig. 6c), in which the tetraphenylbut-2-ene-1,4-diyl dianions are connected by altogether ninefold coordinated, but each only singly ether-solvated $K^{\oplus}$ counterions alternately in η^3- and η^4-modes. Despite these structural differences, caused by the decreasing solvation of the countercations and their increasing radii (Scheme 9), the two-electron reduction of tetraphenylbutadiene to its dianion[19] is accompanied in both of them by equally large eye-catching C=C bond shifts along the C_4 chain. The two outer, C–C double bonds (136 pm) are elongated by about 10 pm towards a C–C single bond, whereas the inner C···C partial π bond is shortened by 6 pm to 138 pm. The negative charges are predominantly located at the chain ends C_1 and C_4, and again (cf. Scheme 8) are only partly delocalized into the phenyl rings as can be gathered from their connecting CC bond lengths of 144 and 148 pm and their twist angles of 23° and 51°. Remarkable among the several structural changes that occur on two-electron reduction of 1,1,4,4-tetraphenylbutadiene,[16] are also the opened angles at the inner butene centers (129°), presumably due to the Coulomb repulsion between the outer carbanion centers, as well as the interior angles at the *ipso* carbon centers of the phenyl substituents ("*ipso*-angles") decreased to 114°. The changes at the *ipso* angles will be discussed subsequently in a general context.

3.3. Variation of *ipso* Angles in Six-Membered Rings of Benzene Derivatives

This rather frequent structural distortion in planar six-membered rings shall be illustrated here by three spectacular observations[36–38] (Scheme 11). In the 2-dimethylamino-

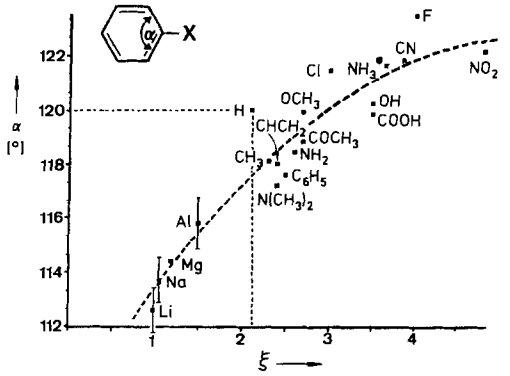


Scheme 11. Selected examples of *ipso* angles of benzene derivatives perturbed by substituents (R = CH_3).

benzenediazonium cation (Scheme 11a), the planar six-membered ring (interior angle sum of 720°) exhibits *ipso* angles widened to 124° at the (diazonium)acceptor-substituted center but closed to 113° at the (dimethylamino)donor-substituted center.[36] The (pentamethylethylenediamine)$Li^{\oplus}$ salt of the supermesityl carbanion (Scheme 11b) also contains a planar six-membered ring, which, however, is stretched along the $C^{\ominus}\cdots Li^{\oplus}$ axis, that is, the *ipso* angles at the $C^{\ominus}$ center and at the *para* carbon are reduced to 114° and 117°, respectively.[37] The structural data for 2-*tert*-butyl-1,3-dinitro-benzene (Scheme 11c) prove that even uncharged benzene derivatives can show considerable ring distortions and that steric effects (Section 7) may also play some role. The *ipso* angles at the (nitro)acceptor-substituted centers are enlarged to 127° (!), and that at the sterically overcrowded (*tert*-butyl)donor center is squeezed to 110° (!).

A generalization of changes in the *ipso* angles observed for six-membered rings, which are extensively documented and discussed in the literature,[37, 39] is achieved by a presumably nonlinear correlation with substituent perturbation parameters ξ[37] (Scheme 12). Accordingly, the corresponding angles for benzene (Scheme 12, X = H) are changed in different ways on substitution: donor substituents exert a strong angle-diminishing and acceptor groups a smaller angle-widening effect.

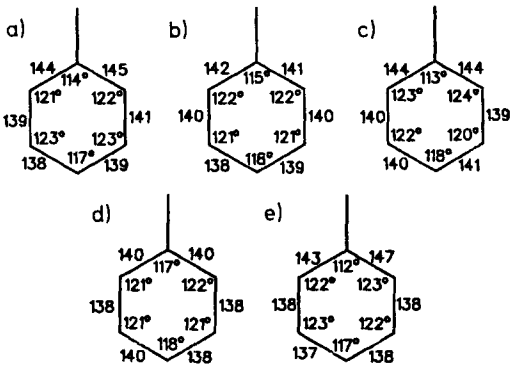
In the structures of the sodium salts of the phenyl-substituted hydrocarbon anions and dianions presented in Fig-



Scheme 12. Correlation of the *ipso* angles (α) of benzene derivatives with substituent electronegativities ξ [37].

ures 3 to 5, considerable distortions of the six-membered rings are observed (Scheme 13).

In the tetraphenylethene dianion, both the rings I and III (Scheme 13a and b) participate in the $Na^{\oplus}$ contact ion-pair from the front and in the dibenzenesodium sandwich subunit from the back. However, ring IV that does not exhibit any $Na^{\delta\oplus}$ contacts is more strongly perturbed (Scheme 13c). The *ipso* angle is reduced to 113° and its sub-



Scheme 13. Representative six-membered ring distortions in phenyl-substituted hydrocarbon anions (Fig. 4) and dianions (Fig. 3 and 5). a) Ring I, b) ring III, c) ring IV of Figure 3e; d) the sandwich-forming ring of Figure 4a; e) the sandwich-forming ring C10–C15 of Figure 5b.

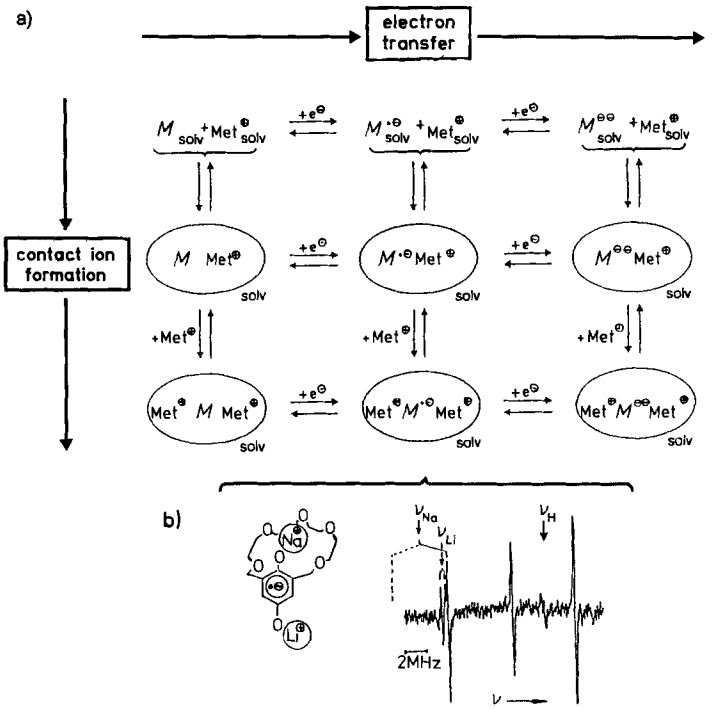
tending bonds are each increased to 144 pm by the negative charge at the carbon anionic center 146 pm away (Fig. 3 and Scheme 12). In contrast, in the six-membered rings forming the intramolecular dibenzenesodium sandwich in the tetraphenylallyl anion (Scheme 13d and Fig. 4a), the C–C bond lengths are balanced to a large extent due to the pronounced η^6 coordination, and the *ipso* angle is reduced only to 117° because of the rather small negative partial charge at the adjacent allylic carbon center. The strongest distortion in all the sodium salt structures investigated is found in the sandwich-forming phenyl ring of the butane-1,4-diyl dianion (Scheme 13e). It is caused by the considerable negative partial charge at the adjacent $C^{\ominus}$ center of the saturated C_4 chain (C_1 in Scheme 8): the *ipso* angle shrinks to 112° and the subtending bonds are as elongated as in ring IV of the tetraphenylethene dianion (Scheme 13c).

Summarizing, the *ipso* angle reductions in the phenyl-substituted contact ion aggregates, the skeletal twisting and bond lengthening observed (Section 2), and the C–C bond formation and C=C bond shift discussed in more detail in Sections 3.1 and 3.2 all illustrate the striking structural changes that can accompany the reduction of unsaturated hydrocarbons M to their anions $M^{\ominus}$ and dianions $M^{2\ominus}$.

4. Structures of Radical Anion Salts—The Tip of the Iceberg of Equilibria Networks in Solution?

4.1. Proof of Single-Electron Reduction Products in Solution and the Crystallization of Fluorenone–Sodium–Bis(dimethoxyethane)

The structures of alkali-metal salts of phenyl-substituted hydrocarbon anions presented so far exclusively concern diamagnetic end products of two-electron reductions by alkali metals at room temperature (Sections 2 and 3.2). In essence, they prove the surprising formation of inter- (Fig. 3) and intramolecular (Figs. 4 and 5) dibenzenesodium sandwich subunits, the C–C connection to dianions (Fig. 5) and their protonation (Fig. 4), as well as their crystallization partly to monomeric contact ion multiples (Figs. 4, 5a, and 6b) and partly to cation-bridged polymer chains (Figs. 3b, 5b, and 6c). Proposals for their formation have been forwarded repeatedly, based on additional experimental as well as quantum chemical information (see e.g. Fig. 4 or Schemes 7 and 10). However, despite an ocean of known organic compounds of alkali metals[19] exhibiting fascinating structures, both the effects of the countercations and their solvation on the crystallizing product (Section 2.4) and many other details of the redox processes involved (Scheme 14) remain sunk at unknown depths. To sound

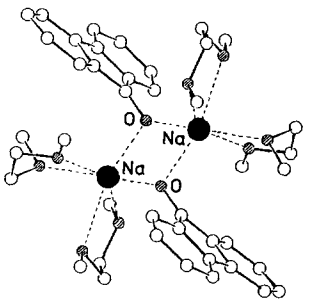


Scheme 14. a) A two-dimensional cut through the multidimensional network of equilibria in reduction reactions; M = molecule, Met = metal. b) ENDOR characterization of a radical cation consisting of a contact ion triple in aprotic THF solution ($c_{H^{\oplus}} < 1$ ppm) at 200 K [43a].

them out would be of interest also for the many chemical and biochemical reactions that are controlled by ion-pair interactions.[40] From a structural point of view especially, the question arises whether a single negative charge may already cause the drastic distortions observed in the single-electron oxidation of tetraalkylhydrazines (Section 1.2).

The study of these aspects remains a dream: reduction reactions in solution proceed by a multidimensional network of electron transfer, solvation, complex formation, and aggregation equilibria[41] (Scheme 14a), which often are decisively influenced by the reaction conditions as, for instance, negligible proton activities, the solvent chosen (solv), the concentrations of the reactants, or the temperature. Depending on the reaction conditions and the counterions $Met^{\oplus}$, a molecule M may pass through the network of equilibria by different routes.[42,43] Thus for the crystallization of tetraphenylethenedisodium bis(diethyl ether), a pathway via $\{M^{2\ominus} + Met^{\oplus}\}$ has been proposed, whereas the formation of the "shape-selective" radical cation triple formed by a macrocyclic polyether radical anion[43a] (Scheme 14b) should proceed via $\{M + Na^{\oplus}\}$ and $\{[M^{\bullet\ominus}Na^{\oplus}]^{\bullet} + Li^{\oplus}\}$. In general, although contact ion pairs of radical anions can be structurally characterized in solution at low temperatures by their ESR/ENDOR signal patterns,[11,43,44] they often decompose by disproportionation according to the equation $2M^{\bullet\ominus} \rightarrow M + M^{\ominus\ominus}$ on attempted isolation.

Fluorenone has been chosen as a suitable model compound for the planned preparation of a radical contact ion pair $[M^{\bullet\ominus}M^{\oplus}]$. The relatively large difference of $\Delta\varepsilon_{\frac{1}{2}}^{red} = -1.29 - (-1.95) = 0.66$ V[45a] for its two lowest and each reversible halfwave reduction potentials suggest that the fluorenone radical anion has a rather low tendency to disproportionate, and its radical contact ion-pairs have already been investigated at low temperature in tetrahydrofurane glasses.[45b] The ultrasonically activated stoichometric reaction of fluorenone in dimethoxyethane with sodium metal under Ar in aprotic conditions ($c_{H^{\oplus}} < 1$ ppm) at 260 K yields a dark red solution, from which on slow cooling to 230 K red needles with a greenish metallic luster crystallize.[46] The structure determination of the extremely air-, moisture- and temperature-sensitive crystals in a stream of nitrogen at 180 K proves that a contact ion pair-dimer has been formed (Scheme 15).



Scheme 15. Structure of the dimeric contact ion pair, fluorenonesodium bis(dimethoxyethane) [46].

The presumably first[46,47] single crystal structural analysis of a radical contact ion-pair dimer provides a wealth of information. The obviously preferred sixfold coordination of the doubly DME-solvated $Na^{\oplus}$ counterions enforces the formation of a $Na_2^{\oplus}O_2^{\delta\ominus}$ parallelogram with $d_{NaO} = 228$ and 240 pm. The structure depicts the aggregation of contact ion pairs[41] within the multidimensional equilibrium network (Scheme 14a) and agrees with the results of the solid state ENDOR measurement.[45b]. It should be kept in mind for speculations about the pathway of the reduction of organic carbonyl compounds by sodium metal to 1,2-diols HOR_2C-CR_2OH.[48] Each $Na^{\oplus}$ counterion is positioned 115 pm above the molecular plane of the fluorenone radical anion with which it interacts most strongly and 28 pm from the π_{CO} plane. This allows a direct spin transfer from the radical anion, which according to the frequently applied empirical Hirota rules[11,43,44] corresponds to the positive sign of the ^{23}Na ENDOR coupling[44] measured and thus provides structural evidence to substantiate them. In contrast, the interesting question from the structural point of view concerning the distortions due to one negative charge has a disappointing answer: On single-electron reduction of fluorenone, only small changes are observed because the charge is extensively delocalized over the 113 center molecular skeleton; for example, the C=O bond is only marginally lengthened from 122[49] to 128 pm.[46]

4.2. Solvent-Separated Radical Ion Pairs of Tetraphenylbutadiene and -Butatriene

The successful low-temperature reduction of fluorenone with sodium and the single-crystal growth of the contact ion-pair dimer $[fluorenone^{\bullet\ominus}Na^{\oplus}]_2$ in the joint solvent cage of four dimethoxyethane molecules stimulated an extensive literature search for further structure determinations of salts containing radical anions of unsaturated hydrocarbons. However, only solvent-separated[19] radical ion pairs were discovered such as $[biphenyl^{\bullet\ominus}][K^{\oplus}(tetraglyme)]$,[50a] $[terphenyl^{\bullet\ominus}][Na^{\oplus}(dme)_3]$,[50b] or $[TCNE^{\bullet\ominus}][Cp_2Fe^{\oplus}](H_3CCN)$ (TCNE = tetracyanoethene).[50c] Interesting facets are that TCNE also exhibits a rather large difference of 1 V between its first and second half-wave reduction potentials,[51] and that despite the presence of hydrocarbon radical anions, alkali-metal countercations can be completely solvated by polyethers (see [Eq. (e)], Section 2.4). Such structures prove in addition that here, other than in many known donor/acceptor molecular complexes,[52] the complete electron transfer to the hydrocarbon component under formation of the corresponding radical anion has taken place.

Extending the reduction of phenyl-substituted unsaturated hydrocarbons by alkali metals (Section 2 and 3), we have treated 1,1,4,4-tetraphenylbutadiene with lithium shavings[53] and tetraphenylbutatriene with a sodium mirror,[53] each 1:2 in the chelating solvent dimethoxyethane at room temperature. Unexpectedly, crystals of dark red $[tetraphenylbutadiene^{\bullet\ominus}][Li^{\oplus}(dme)_3]$ (Fig. 7a) and violet $[tetraphenylbutatriene^{\bullet\ominus}][Na^{\oplus}(dme)_3]$ (Fig. 7b) have been isolated.

The structural analyses prove that in both cases a threefold solvation of the cation by DME is preferred to π complexation by the hydrocarbon skeleton. The resulting "naked" radical anions enable a direct structural comparison (Scheme 16) with the neutral molecules M[16] (Fig. 6)[54]

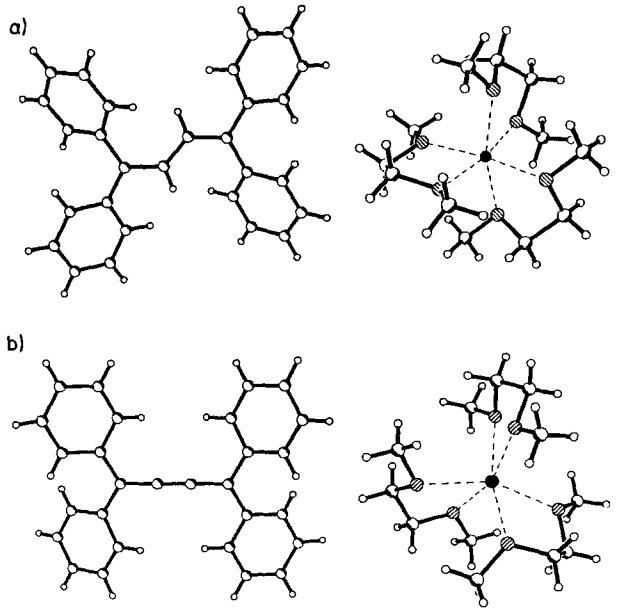


Fig. 7. Single crystal structures of the solvent-separated salts of radical anions a) 1,1,4,4-tetraphenylbutadienelithium tris(dimethoxyethane); b) tetraphenylbutatrienesodium tris(dimethoxyethane) (● = $Li^{\oplus}$, $Na^{\oplus}$; ◍ = O; for structural details see Scheme 16).

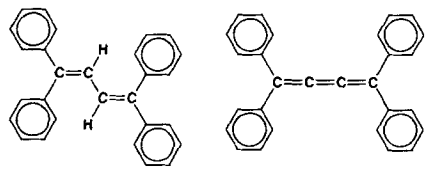
as well as with the likewise "naked" dianion $M^{2\ominus}$ of 1,1,4,4-tetraphenylbutadiene [Eq. (e)].

With increasing charge $M \rightarrow M^{\bullet\ominus} \rightarrow M^{\ominus\ominus}$, the length of the outer C–C bonds within the C_4 chain increases, while the central C–C bonds decrease in length (Scheme 16). These



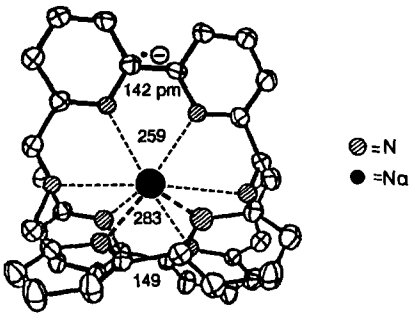
M	136	144	135	126
$M^{\bullet\ominus}$	142	139	139	124
$M^{\ominus\ominus}$	146	137		

Scheme 16. Comparison of CC bond lengths along the C_4 chains of tetraphenylbutadiene and -butatriene, and their dependence on the total charge.

structural changes are more pronounced for tetraphenylbutadiene, because of the Coulomb repulsion between the negative charges, which are predominantly localized at the ends of the chain. The synthesis of the unknown tetraphenylbutriene dianion, for which quantum chemical calculations predict a significant kink[54] in the C_4 chain, is presently being attempted by the deprotonation of 1,1,4,4-tetraphenylbut-2-yne.[53]

4.3. Staple and Spatial Lattice Structures of the Alkali-metal Salts of 2,3-Diphenylquinoxaline and Tetracyanoethene Radical Anions

Radical anion salts of the fluorenonesodium type (Scheme 15) exhibiting isolated contact ion pairs are still a rarity. Recently, the novel intramolecular sodiocryptatium **A**[55] has been added, in which one of the three α,α′-bipyridyl bridges of the cryptand has been recognizably reduced to its radical anion. The C–C bond between the two six-membered rings is shortened from 149 to 142 pm and, in addition, the two $Na^{\oplus} \cdots N^{\delta\ominus}$ contact distances of 259 pm are shorter than the others of 283 pm.



A

The radical anion salts of organic compounds, which are topical because of their magnetic properties,[56a] frequently crystallize in either separated stacks favored by flat molecular skeletons or, in case of more pronounced "salt character", spatial lattice structures. From the multitude of known compounds,[19a] the following ones are selected as being representative: [hexaazaoctadecahydrocoronene$^{\bullet\oplus}$][TCNE$^{\bullet\ominus}$],[56c] [tetracyano-*p*-quinodimethane$^{\bullet\ominus}$$Rb^{\oplus}$]$_{\infty}$,[56b] [chloranil$^{\bullet\ominus}$$K^{\oplus}$],[56c] and the also solvent-free [TCNE$^{\bullet\ominus}$$Cs^{\oplus}$]$_{\infty}$.[56d] We have also isolated single crystals of the cation-solvated radical anion salts [2,3-diphenylquinoxaline$^{\bullet\ominus}$$K^{\oplus}$(dme)]$_{\infty}$ (Fig. 8a),[57] [TCNE$^{\bullet\ominus}$$Na^{\oplus}$(dme)]$_{\infty}$ (Fig. 8b),[58] and [TCNE$^{\bullet\ominus}$$K^{\oplus}$(dme)] (Fig. 8c)[59] after reduction in the chelating solvent, dimethoxyethane.

To faciliate rationalization of their three-dimensional lattices, these structures (Fig. 8) are characterized as follows: [2,3-Diphenylquinoxaline$^{\bullet\ominus}$$K^{\oplus}$(dme)]$_{\infty}$ (Fig. 8a) crystallizes in layers of the radical anions, which stack in the perpendicular direction. The anions are alternately turned around the stacking axis,[57] presumably to achieve optimum packing (cf. Section 8.2). Between these stacks, the singly DME-solvated $K^{\oplus}$ counterions are found. Their eightfold coordination[57] illustrated in detail shows a clearly recognizable η^3 complexation to the quinoxaline nitrogen lone pair and two adjacent carbon centers of the phenyl rings, which are each twisted by 55° out of the molecular plane. The $C \cdots K^{\oplus}$ contact distances of 312 and 333 pm are considerably larger than the ones to the electron-rich O and N centers of 277 and 281 pm.[57] [TCNE$^{\bullet\ominus}$$Na^{\oplus}$(dme)]$_{\infty}$ and [TCNE$^{\bullet\ominus}$$K^{\oplus}$(dme)] (Figs. 8b and c) exhibit structural differences due to the size of the countercations: $Na^{\oplus}$ forms altogether six contacts to four TCNE$^{\bullet\ominus}$ and one DME molecule;[58] $K^{\oplus}$ formally seven to four TCNE$^{\bullet\ominus}$ and two DME molecules.[59] In the crystal lattice of the sodium salt,[58] the TCNE$^{\bullet\ominus}$ radical anions are arranged in parallel strings shifted relative to each other, and because they are connected by the singly DME-solvated $Na^{\oplus}$ counterions between them, they form "infinite tubes" (Fig. 8b). In the potassium salt, the TCNE$^{\bullet\ominus}$ subunits are packed in stacks; they form undulating parallel

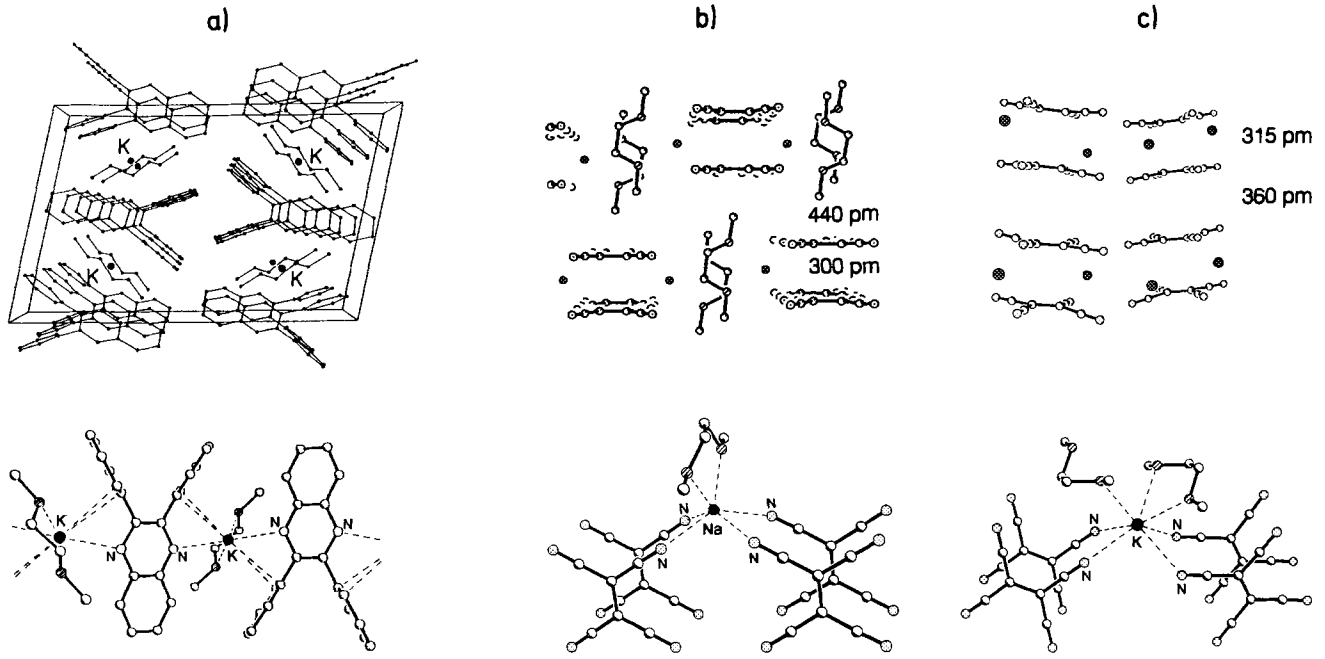


Fig. 8. Single crystal structures of radical anion salts containing solvated countercations. a) [2,3-diphenylquinoxaline$^{\cdot\ominus}$K$^{\oplus}$(dme)]$_\infty$: unit cell perpendicular to the radical-anion stacks (top) and details of the polymer string (bottom); b) [TCNE$^{\cdot\ominus}$Na$^{\oplus}$(dme)]$_\infty$: view along the 100 direction (top) and coordination sphere around the Na$^{\oplus}$ cations (bottom); c) [TCNE$^{\cdot\ominus}$K$^{\oplus}$(dme)]$_\infty$: layers viewed along the 010 direction (without dme) (top) and coordination sphere around the K$^{\oplus}$ cations (bottom). ● = counterions, ◍ = O, ◎ = N; see text and Scheme 18.

layers alternately 360 and 315 pm apart; the K$^{\oplus}$ counterions are interspersed in the smaller gap[59] (Fig. 8c).

The effect of a single negative charge on the molecular skeleton of the TCNE radical anion is of special interest, because its "naked" dianion in the complex salt [Cp$_2^*$Co$^{\oplus}$]$_2$[TCNE$^{2\ominus}$] comprises two molecular halves connected by a C–C single bond 149 pm long and twisted by 87° (!) relative to each other[24b, 56a] (Table 1). These fundamental structural changes can be rationalized analogously to those in the tetraphenylethene dianion (Fig. 3b), by the formation of two energetically favorable cyanine subunits (see Section 6.1) during the second reduction step $M^{\cdot\ominus} \rightarrow M^{\ominus\ominus}$, and can be reproduced quantum chemically (cf. Scheme 6). Similar although considerably smaller effects are expected and observed for the insertion of only a single electron $M \rightarrow M^{\cdot\ominus}$ (Table 1): The central C–C bond is elongated by 3 pm to 7 pm depending on the cation, and the molecular halves are twisted by 19°.

Table 1. Bond distances d_{CC} and $d_{CC(N)}$ [pm] and dihedral angles $\omega(C_2C\text{-}CC_2)$ [°] for tetracyanoethene TCNE, its radical anion [TCNE$^{\cdot\ominus}$] with different countercations, and its dianion salt [M$^{2\ominus}$] (average values in parentheses).

	TCNE	TCNE$^{\cdot\ominus}$				TCNE$^{2\ominus}$
		[Cp$_2^*$Fe$^{\oplus}$]	Na$^{\oplus}$ (dme)	K$^{\oplus}$ (dme)	Cs$^{\oplus}$	[Cp$_2^*$Co$^{\oplus}$]$_2$
	[59]	[50c]	[58]	[59]	[56d]	[50c]
d_{CC}	136	139	142	142	(143)	149
ω	0	0	8	12	18	87
$d_{CC(N)}$	143	142	142	142	(142)	139

The introductory question whether one negative charge can cause similarly drastic structural changes as a single positive charge in the special case of electron-rich molecules (Section 1.2), can therefore by affirmed according to the known structures of molecular anion salts only for the formation of intramolecular contact ion pairs (Section 2.2). The structural differences between the radical anions presented here (Scheme 15, Figs. 7 and 8) and to the neutral compounds are usually significantly smaller than those between them and the molecular dianions. This fact supports the proposals forwarded for their formation via solvent-separated radical ion pairs (Section 2.1).

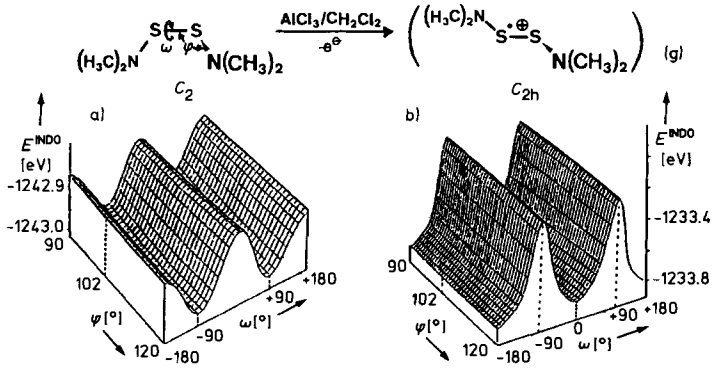
In general, the radical anions $M^{\cdot\ominus}$ that often decompose in solution are stabilized on insertion into a crystal lattice, as expected. In addition to the informative structure comparison with the corresponding neutral molecules M and their dianions $M^{2\ominus}$, however, the single-crystal structures of radical anion salts provide varied and interesting insights into the multidimensional network of electron transfer, solvation, contact ion complexation or aggregation equilibria (Scheme 14a), which determines for the particular molecule, counterion, solvent, and reaction conditions the isolated end products. Also in this respect their investigation deserves intensified effort.

5. Molecular Polycations and Their Design—Examples of the Usefulness of Suitable Data

5.1. Vertical Ionization in the Gas Phase and Adiabatic Oxidation in Solution

These electron removal processes take place at different points in the "chemical" time scale (Fig. 2). Vertical ionization occurs in less than 10^{-15} seconds, that is, faster than the vibrational processes which start at about 10^{-13} seconds.

The radical cation states (Fig. 1) observed in photoelectron spectra therefore exhibit the "frozen" structure of the neutral molecule. In contrast, the oxidation in solution at more than 10^{-8} seconds is slower and thus allows energetically favorable structural changes in the resulting radical cation through its $(3n-6)$ degrees of freedom. This time dependence of all molecular redox reactions in solution[34] will be illustrated by the example of the "electron-rich" bis-(dimethylamino)disulfide[9d] (Scheme 17).



Scheme 17. INDO energy surfaces for the model compound H_2NSSNH_2 used to rationalize the oxidation of the experimentally studied bis(dimethylamino)disulfide [Eq. (g)]: Dependence of the INDO energy for a) vertical ionization and b) adiabatic oxidation on the dihedral angle ω(NS-SN) and on the obtuse angle φ(S-S-N) of H_2NSSNH_2.

The vertical ionization of $(H_3C_2N\text{–}SS\text{–}N(CH_3)_2$ at 8.02 eV produces its radical cation ground state of unchanged C_2 symmetry (Scheme 17a), in which the positive charge generated is largely delocalized over the N and S lone pairs. The first adiabatic ionization energy is observed at 7.2 eV, that is, about 0.8 eV = 77 kJ mol^{-1} lower.[9d] Adiabatic one-electron oxidation with $AlCl_3$ in CH_2Cl_2[4] generates a planarized radical cation of C_{2h} symmetry (Scheme 17b) as proven by the ESR spectrum registered with a time resolution of greater than 10^{-8} s. Accompanying INDO closed- and open-shell energy hypersurface calculations for the model compound $H_2N\text{–}SS\text{–}NH_2$ (Scheme 17) support—as for $H_3CS\text{–}C{\equiv}C\text{–}SCH_3$ (Scheme 2) or $R_2N\text{–}NR_2^{\bullet\oplus}$ (Schemes 3 and 4)—the structures inferred from the experimental data and predict a dihedral angle ω(NS-SN) of 90° for the neutral compound (Scheme 17a) and 0° for its planarized radical cation (Scheme 17b).

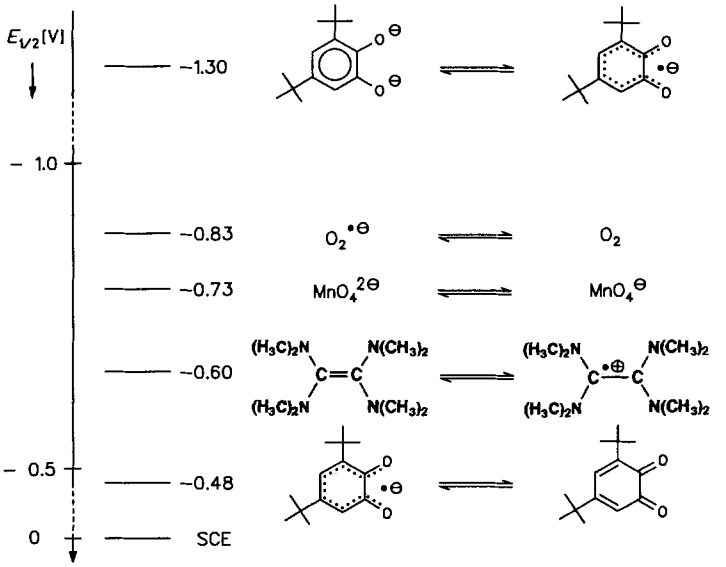
There are many rules of thumb for the "art of oxidation", which facilitate planning and performing of redox reactions and reduce problems in the ensuing effort to isolate multiply oxidized molecules and, especially, to grow single crystals; for instance:

1) For the gas phase ionization of medium-sized molecules with IE_1^V between 6 and 11 eV, considerably higher energies are needed than obtained on electron insertion, for which electron affinity values EA_1 often remain below 1 eV.

2) The oxidation potential of about +1.6 eV[4] determined for the system $AlCl_3/CH_2Cl_2$, which due to its lack of oxygen proves especially advantageous for air- and water-sensitive nonmetal compounds,[1a, 4, 60] corresponds to a first vertical ionization energy $IE_1^V < 8$ eV[4] and can be increased on exchange of the Lewis acid $AlCl_3$ by $SbCl_5$. For the single-electron transfer involved, both structurally characterized radical-cation salts $[M^{\bullet\oplus}][AlCl_4^{\ominus}]$[61] and $ClH_2C\text{–}CH_2Cl$[61] detected by gaschromatography in the reaction mixture suggest that the carbocation presumably generated by $Cl^{\ominus}$ abstraction $AlCl_3 \rightarrow AlCl_4^{\ominus}$ from CH_2Cl_2 could be reduced according to $CH_2Cl^{\oplus} + e^{\ominus} \rightarrow CH_2Cl^{\bullet}$ to a chloromethyl radical, which reacts further, for example, by dimerization.

3) Aprotic conditions ($c_{H\oplus} < 1$ ppm), which can be achieved by additional treatment of the solution with Al_2O_3 heated to glowing in vacuo,[62] are also essential for oxidations $M \rightarrow M^{\bullet\oplus} \rightarrow M^{\oplus\oplus}$, because in the second redox half-system reduction necessarily occurs to a more electron-rich and therefore often easily protonated species.

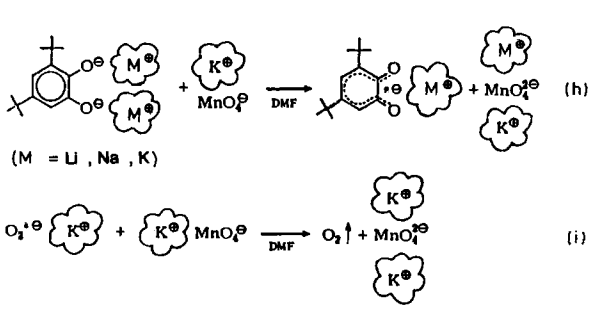
4) In order to chose as selective as possible an oxidizing reagent to avoid side and successive reactions, the measurement of an electrochemical series for the evaluation of optimum redox conditions is strongly recommended. From the series for dimethylformamide(DMF)[63] (Scheme 18) it follows, for instance, that 3,6-di(*tert*-butyl)catecholate salts are



Scheme 18. Part of an electrochemical series in DMF [63].

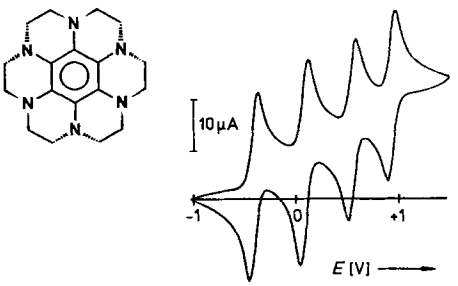
oxidized by a purple $KMnO_4$ solution only to the semiquinone radical anion and not to the *ortho*-quinone [Eq. (h)], or that $KMnO_4$ is reduced by hyperoxide radical anion salts selectively, and because O_2 escapes, quantitatively to the dark green manganate(VI) dianion[63] [Eq. (i)].

5) The two redox reactions [Eq. (h) and (i)], chosen as examples, also illustrate the advantageous use of crown



ethers[64a] or cryptands[64b] with cation-selective diameter as "solubility broker" for insoluble salts.

6) The often favorable reversibility of redox processes can be proven by cyclic voltammetry, although the different oxidation conditions at the electrode surface have to be taken into account. As spectacular example, hexaazaoctadecahydrocoronene is presented. Four consecutive reversible one-electron oxidation steps have been observed[56a] (Scheme 19) and in perfect accord, salts $M^{n\oplus}(X^{\ominus})_n$ with oxidation numbers $n = 1$ to 4 were isolated and structurally characterized.



Scheme 19. Cyclic voltammogram of hexaazaoctadecahydrocoronene [50c].

For multiple oxidations, several additional "rules of thumb" exist. Thus larger molecules are more easily oxidized if the positive charge is effectively delocalized, for example, into suitable donor substituents. The resulting molecular cations can be kinetically stabilized by steric shielding by bulky groups. On the other hand, however, with increasing molecular size often only small structural changes are observed. For a given molecule, quantum chemical calculations are invaluable.[21]

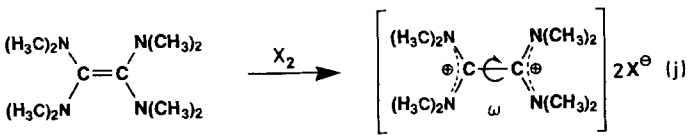
Essential requirements for successful multiple oxidations of organic molecules and the isolation of their polycation salts are therefore: the right intuition—advantageously based on a knowledge of perturbation effects in chemically related known compounds and its verification by suitable experimental data from PE spectroscopy, cyclic voltammetry, or ESR/ENDOR spectroscopy, as well as quantum chemical calculations—a portion of luck in selecting the oxidizing reagent as well as the solvent, and, last but not least, skilled hands, which optimize—as before in the preparation of dibenzenesodium sandwich (Section 2) and other radical contact ion complexes (Section 4)—the redox and crystal growth conditions.

5.2. Salts of Dications of Tetrakis(dimethylamino)ethene, Tetramethoxythianthrene and Tetrakis(dimethylamino)-*para*-benzoquinone

All precursors for the salts of dications discussed in this section are tetrasubstituted by donor groups, because even the double ionization to energetically favorable dications $M^{2\oplus}$ require energies between 12 eV and 15 eV.

5.2.1. *Tetrakis(dimethylamino)ethene*

The rather unusual molecule[65] exhibits a first vertical ionization energy of only 6.13 eV (Fig. 9a), that is, only 1 eV higher than that of the sodium atom at 5.14 eV (Scheme 9). Reaction with oxygen-free water, therefore, oxidizes the electron-rich compound M containing four electron pairs on the N centers—presumably under evolution of hydrogen—to its radical cation $M^{\cdot\oplus}$ characterized by ENDOR spectroscopy[67] (Fig. 9b). Halogens such as Cl_2 or Br_2 accomplish a two-electron oxidation to the dication $M^{2\oplus}$[21,65] [Eq. (j)].



The dichloride, dibromide, or bis(hexafluorophosphate) salts can be isolated, single crystals grown, and their structures determined[21,68] (Fig. 9c), for which quantum chemical calculations[21] predict C–C single bonds and molecular halves twisted relative to each other (Scheme 6 and Section 6).

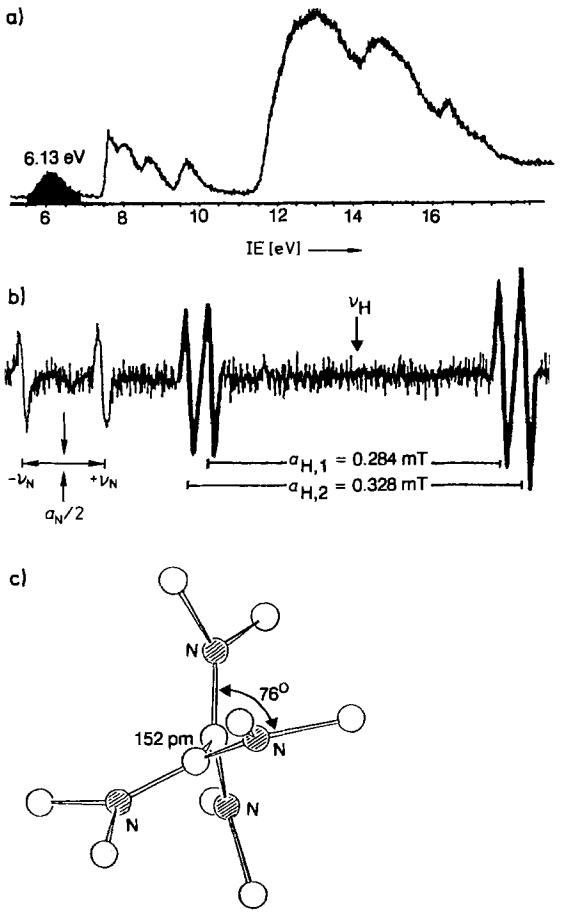


Fig. 9. Tetrakis(dimethylamino)ethene: a) Helium (I) photoelectron spectrum (intensity in cps) in the gas phase; b) ENDOR spectrum of the radical cation in water showing the ^{14}N coupling and two different ^{1}H couplings; c) single crystal structure of the dications [21] of $[((H_3C)_2N)_2{}^{\oplus}\text{–}{}^{\oplus}C(N(CH_3)_2)_2](Cl^{\ominus})_2$.

A more drastic structural change of a molecule on two-electron oxidation than observed for tetrakis(dimethylamino)ethene can hardly be imagined! On comparison with

the neutral compound (Section 7.2), both molecular halves are now twisted by 76°, the C–C double bond is stretched by 14 pm (!) to a C–C single bond, and the $(H_3C)_2N$ pyramids become completely planar. A rationalization is offered by the energetically favorable charge delocalization in two cyanine subunits $>N\cdots C^{\oplus}\cdots N<$ each containing three centers and four π electrons (Section 6.1).

5.2.2. *2,3,6,7-Tetramethoxythianthrene*

Contrary to the corresponding hydrocarbon anthracene with 14π-electrons, 2,3,6,7-tetramethoxythianthrene is not planar but folded as a butterfly (Fig. 10a). The same structure has been determined for the parent compound $C_{12}H_8S_2$[69b] and rationalized by the increase in its number of π electrons by two relative to planar anthracene on sulfur

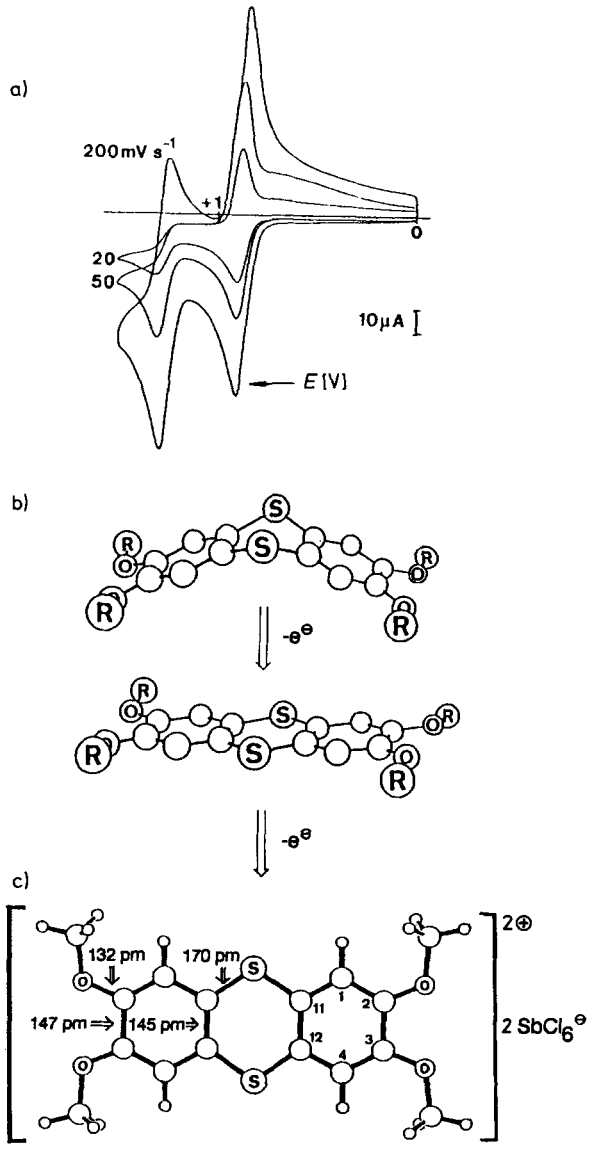

Fig. 10. 2,3,6,7-Tetramethoxythianthrene: a) Cyclic voltammograms in Al_2O_3-dried CH_2Cl_2/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ under argon (recording velocities between 20 and 200 mVs^{-1}); b) structure diagrams for the one-electron oxidation to the radical cation [69a,c] and for the bis(hexachloroantimonate) dication salt [70] (cf. Table 2).

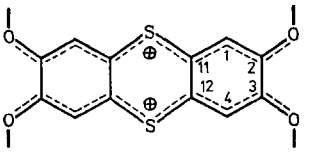
inclusion. One-electron oxidation by $NO^{\oplus}SbCl_6^{\ominus}$ or I_2 generates a blue radical cation, the σ skeleton of which is already planarized[69c] (Fig. 10b), although the "ideal" 14π electron configuration is still exceeded by 1. Cyclic voltammetric measurements under aprotic conditions and with increased recording velocity[70] show, in addition to the first half-wave potential at +0.88 V, a second reversible oxidation step at 1.27 V (Fig. 10b). Reaction with $SbCl_5$ in CH_2Cl_2 (cf. Section 5.1) under argon and aprotic conditions ($c_{H^{\oplus}}$ <1 ppm) yields a green solution, from which black rhombic crystals with a metallic luster grow after several days, which shine dark red when viewed under a cool-light lamp. The structure determination at low temperature[70] produces an unexpected result (Fig. 10b).

In contrast to any expectation of "aromaticity" for the tetramethoxythianthrene dication, which now contains 14π electrons for the three annelated six-membered rings, a π system enlarged by the methoxy oxygens to a total of 18 centers is found, the σ skeleton of which exhibits shortened O–C bonds and elongated C–S bonds 132 and 170 pm long, respectively, as well as lateral and inner C–C bonds of the outer rings stretched to 147 pm and 145 pm (Fig. 10c). A comparison with the essential bond distances d_{CX} of the neutral molecule M and the radical cation $M^{\bullet\oplus}$[69c] (Table 2) suggests that the structure of the dication $M^{2\oplus}$ can be best described by two fourfold connected, positively charged chains H_3CO–CCC–$S^{\oplus}$–CCC–OCH_3. This assumption is

Table 2. Bond lengths of 2,3,6,7-tetramethoxythianthrene and its molecular cations.

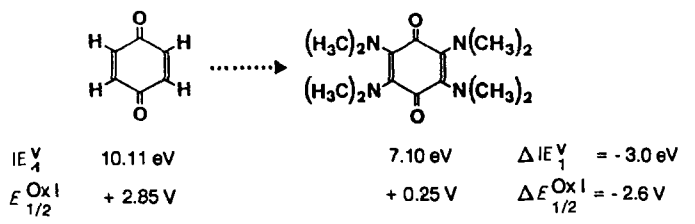


d_{CX} [pm]	M	$M^{\bullet\oplus}$	$M^{2\oplus}$
C2-C3	141.0	143.0	147.2
C11-C12	138.3	139.5	145.3
C1-C2	138.0	136.2	138.7
C1-C11	139.7	140.0	140.1
C11-S	177.6	172.3	169.5
C2-O	136.9	134.9	131.5

supported by geometry-optimized MNDO calculations,[70] which satisfactorily reproduce both the structure and the color of the dication. The enthalpies of formation ΔH_f^{MNDO} [$kJ\,mol^{-1}$] are calculated to be −311 for tetramethoxythianthrene M, +406 for its radical cation $M^{\bullet\oplus}$ and +1501 for its dication $M^{2\oplus}$, form which adiabatic ionization energies $IE_1^a(M \rightarrow M^{\bullet\oplus}) \approx 7.4$ eV and $IE_1^a(M^{\bullet\oplus} \rightarrow M^{\oplus\oplus}) \approx 11.4$ eV are estimated. Their sum, approximately 18.8 eV = 1810 $kJ\,mol^{-1}$, illustrates the energies required for the twofold ionization of molecules in the gas phase (Section 5.1). The energy needed for twofold oxidation in solution, however, can be considerably reduced by solvation. Thus for the dication of tetrakis(dimethylamino)-*p*-benzoquinone presented next, the MNDO enthalpies of formation are calculated to be lower by about 500 $kJ\,mol^{-1}$ for geometry-optimized solvation by eight water molecules.

5.2.3. *Tetrakis(dimethylamino)-p-benzoquinone*

p-Benzoquinone, the textbook example for two consecutive and each reversible single-electron transfer reductions of organic π systems, can be "umgepolt" by four dimethylamino substituents[60d] (Scheme 20). Tetrakis(dimethylamino)-*p*-benzoquinone, therefore, can be both reduced to its semiquinone radical anion as well as oxidized to its semiquinone radical cation[61d] (Fig. 11a).



Scheme 20. First vertical ionization energies and half-wave oxidation potentials of *p*-benzoquinone and its tetrakis(dimethylamino) derivative.

This rather unusual redox behavior of the electron-rich compound containing four N lone pairs is due to delocalization of the positive charge into the dimethylamino substituents. The oxidation by $SbCl_5/CH_2Cl_2$ allows the preparation of a black dication salt $M^{2\oplus}[SbCl_6^{\ominus}]_2$[71] (Fig. 11b), the single crystal structure of which has been determined as has that of the likewise black, sterically overcrowded neutral compound *M* (Section 7.1, Scheme 31). Accordingly, and contrary to the expectation from the irreversible second oxidation potential (Fig. 11a), the molecular skeleton of tetrakis(dimethylamino)-*p*-benzoquinone survives on removal of two electrons (Fig. 11b). Two 6π electron/5-center cyanine chains[71] are formed, which are twisted relative to each other by 35°, thereby reducing the steric strain in the neutral compound (Scheme 31).

In detail, the C–C double bonds are stretched by 9 pm (!) towards C–C single bonds, the different C–C bond lengths adjacent to the O=C groups become equal, the C–N bonds shorten by up to 10 pm (!) and all dimethylamino groups planarize. The charge distribution q_μ^{AM1} (Fig. 11c) calculated for the quantum chemically reproducible structure[71] is in accord with a delocalization of the positive charges along the two N-C-C(O)-C-N$^\oplus$ cyanine chains (Section 6.1) predominantly into the peripheral methyl groups.

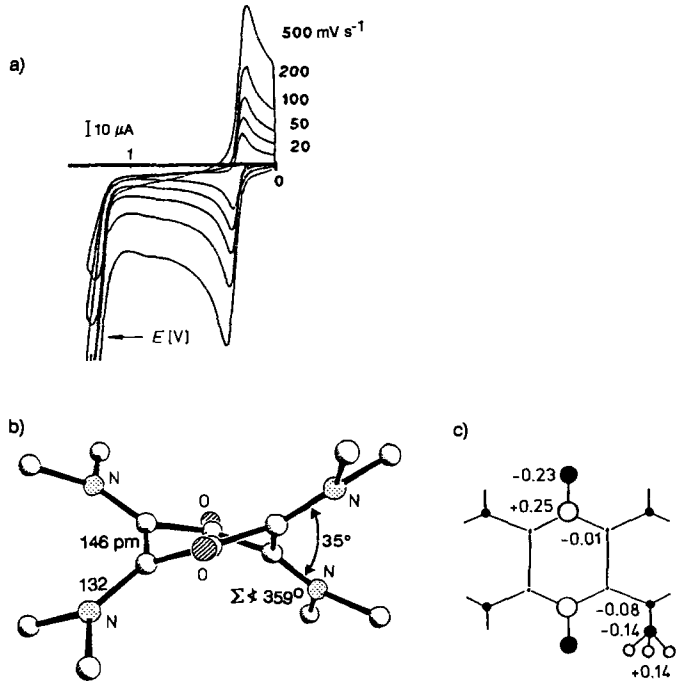


Fig. 11. Tetrakis(dimethylamino)-*p*-benzoquinone: a) Cyclic voltammograms in DMF/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ (v = 20 to 500 mVs^{-1}, ΔE_1 = 70 mV, ΔE_2 irreversible); b) single crystal structure of the dication bis(hexachloroantimonate); c) AM1 charge distribution.

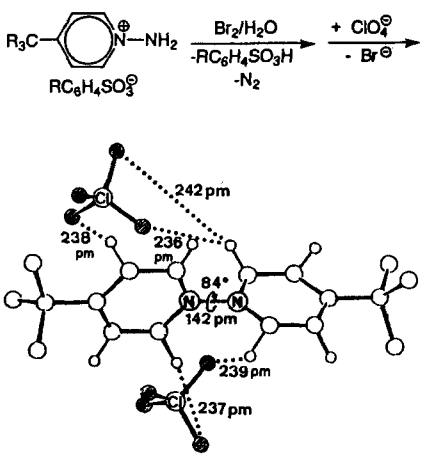
5.3. Perspectives: Molecular Polycations by Oxidative Coupling or by Acid/Base Reactions

Polycation salts of molecules can be obtained not only by decrease in the number of electrons in a molecule, enforced by oxidation, $M - n(e^{\ominus}) \rightarrow M^{n\oplus}$ (Sections 5.1 and 5.2), but also by several other routes. Representative examples[72–75] will illustrate their preparation by oxidative coupling $2M - 2(e^{\ominus}) \rightarrow [M^{\oplus} - {}^{\oplus}M]$ as well as by multiple acid/base reactions such as amination $MX_n + n(B) \rightarrow [MB_n^{\oplus}](X^{\ominus})_n$, protonation $M + 2(H^{\oplus}) \rightarrow [H^{\oplus}M^{\oplus}H]$ or cation chelatation $M + 2(Met^{\oplus}) \rightarrow [Met^{\oplus}M^{\oplus}Met]$, and highlight the structural changes observed.

5.3.1. *4,4'-Di(tert-butyl)-1,2'-dipyridinium Diperchlorate*

Oxidation of suitably substituted *N*-aminopyridinium salts yields—possibly via a tetrazene intermediate[76]—dipyridinium salts (Scheme 21). Single crystals could be grown only after anion exchange $Br^{\ominus} \rightarrow ClO_4^{\ominus}$. Their structure determined in a nitrogen flow at 100 K, in which all hydrogen centers have been located,[72a] causes some headache concerning the dihedral angle (ω = 84°) between the two each planar pyridinium rings connected by an N–N single bond of 143 pm: the isoelectronic correspondence >C=C< → >N$^{\oplus}$–$^{\oplus}$N< would suggest planarity as has



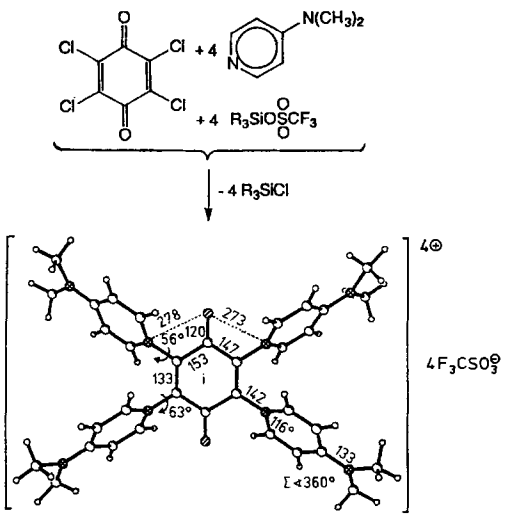
Scheme 21. Preparation and structure of 4,4'-di-*tert*-butyl-1,1'-dipyridinium diperchlorate.

been proven, for instance, for biphenyl planarized in the solid state[77] or for sterically shielded tetraalkylhydrazine dications.[78]

Comprehensive MNDO energy hypersurface calculations[72a] predict that a substantial enthalpy of 75 kJ mol^{-1} is required to enforce coplanarity of the two pyridinium rings in the dication, which may be classified as being anomeric.[79] However, the distances between some ring hydrogens and the perchlorate counter anions are only between 236 pm and 242 pm (Scheme 21) and, therefore, within the range of hydrogen bonds.[80, 81] The short intermolecular distances support the unexpected twisting of the two molecular halves of the 1,1-dipyridinium dication to almost perpendicular to each other, which according to the MNDO calculations should lead to a favorable charge distribution.

5.3.2. *Tetrakis(dimethylaminopyridinio)-p-benzoquinone Tetrakis(triflate)*

Among the derivatives of *p*-benzoquinone, the unusual molecular properties of the fourfold dimethylaminopyridinio-substituted dark red tetracation marks it as being special: the two reversible half-wave reduction potentials are lowered by +1.24 V and by +1.30 V to +0.73 V and to +0.16 V(!). Its rather elegant one-pot preparation from chloranil in almost quantitative yield proceeds by a fast transamination via the first-formed 4-dimethylamino-*N*-trimethylsilylpyridinium triflate with elimination of R_3SiCl[82] (Scheme 22).



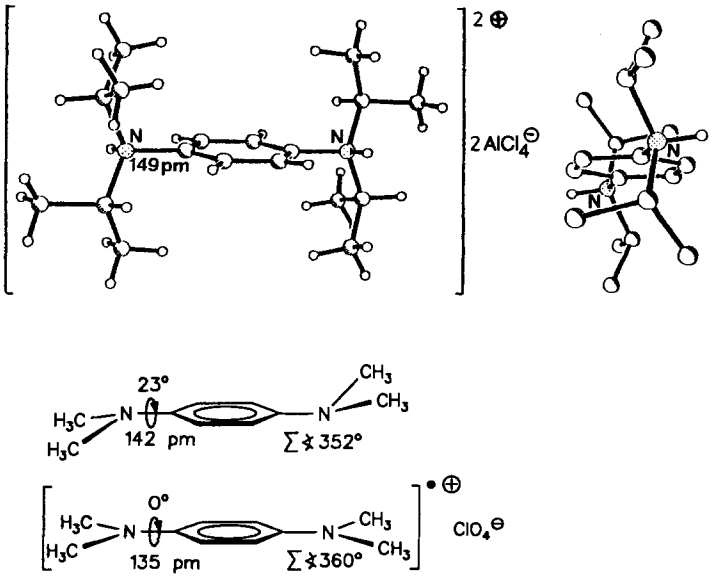
Scheme 22. Preparation and structure of tetrakis(dimethylaminopyridinio)-*p*-benzoquinone tetrakis(triflate); i: center of inversion, R = CH_3 (cf. text for details).

The structure determination[72b] shows layers of the bulky tetracations, each interspersed with two disordered independent triflate anions and two whose contact distances to the centers of the longer C–C(O) bonds are 280 pm. The C–C bonds flanking the quinone groups attract attention because of differing lengths of 147 pm and 153 pm (Section 6.2), as do the completely planarized dimethylamino groups. They are connected by a rather short CN distance of only 132 pm to the pyridine ring, which exhibits an *ipso* angle at the nitrogen center of only 116° (Scheme 12). The intramolecular O···N distance is shorter than the sum of the interference radii (290 pm, Section 7.1). MNDO calculations predict for each pyridinio- and amino-nitrogen center a charge of −0.2 and thus support an extensive delocalization of the four positive charges over the whole cyanine-like distorted molecular skeleton (Scheme 22).

5.3.3. *N,N,N′,N′-Tetraisopropyl-p-phenylenediammonium Bis(tetrachloroaluminate)*

This salt of a "nonredox" dication crystallized on attempts to oxidize the *N*-tetraisopropyl-substituted *p*-phenylenediamine (which exhibits the surprisingly low first ionization energy of only 6.6 eV[73]) with $AlCl_3/CH_2Cl_2$ (Section 5.1). Instead of the possibly rather hydrolysis-sensitive product[73] containing one electron less than the well-investigated "Wurster's Blue" salts,[83] however, the compound containing a doubly protonated dication was isolated. Although its structure (Scheme 23) does not exhibit any unexpected pecularities, it is—like numerous analogous literature examples—well suited to disclose differences between oxidized and protonated molecular cations.

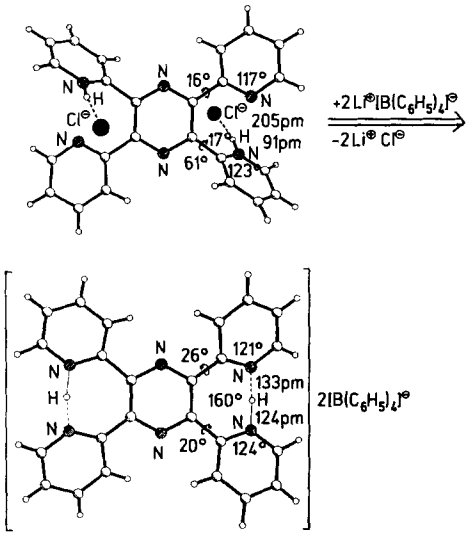
The structural comparison (Scheme 23) documents that the (R)N–C_{phenyl} bonds are elongated on protonation of the neutral molecule, but shortened on its oxidation. In the diammonium salt, the different isopropyl groups are twisted by 56 and 77° out of the plane of the ring; on electron removal $M \rightarrow M^{\bullet\oplus}$, the dihedral angle ω(CC-NC) closes from 23 to 0° and the dimethylamino groups are completely planarized. The *ipso* angles in the arene ring (Scheme 12) reflect the dissimilar charge delocalization: for $R_2HN^{\oplus}$ acceptor groups they amount to 122°, while for the R_2N donor groups twisted by 117° and 116° they are below the normal value of 120° as expected.



Scheme 23. Two views of the structure of *N,N,N′,N′*-tetraisopropyl-*p*-phenylenediammonium bis(tetrachloroaluminate) [74] and selected structural data for *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine [84] as well as its "Wurster's Blue" perchlorate [83c].

5.3.4. Tetra(2'-pyridyl)pyrazine Dichloride and Bis(tetraphenylborate)—Examples for "Chemical Mimesis" Involving Inter- and Intramolecular Hydrogen Bridges

Increasing interest in conformational changes, particularly of biochemical importance, prompted the selection of tetra(2'-pyridyl)pyrazine as a model compound:[62] it contains six N electron pairs in five almost rigid rings that, however, are flexible around the connecting C–C bonds. We succeeded in growing single crystals of its HCl adduct and its diprotonated $^{\ominus}B(C_6H_5)_4$ salt and determined their structures[74] (Scheme 24), which due to the "naked" $Cl^{\ominus}$ and the phenyl-embedded $R_4B^{\ominus}$ counterions exhibit different hydrogen bonds.



Scheme 24. Comparison of the structures of the dichloride and bis(tetraphenylborate) salts of diprotonated tetra(2'-pyridyl)pyrazine [74].

In the neutral molecule tetrakis(2'-pyridyl)pyrazine, neighboring pyridine rings are twisted out of the pyrazine ring plane by 50° in the same direction; the C-N-C ring angles are 117°.[74] On twofold HCl addition, diagonally opposite pyridine rings are protonated and their twist angles increase to 61° due to H bonds of 205 pm[81] to the electron-rich chloride ions. Simultaneously, the *ipso* angles at the pyridinio nitrogens (Scheme 12) increase to 123° as expected. Resalting by addition of lithium tetraphenylborate and recrystallization of the salt now containing phenyl-embedded and therefore no longer protonable counteranions, generates intramolecular hydrogen bonds between each pair of adjacent pyridine rings, the *ipso* angles of which increase to more than 120°[74] (Scheme 24). The H bonds are almost symmetrical, exhibiting N ··· H distances of 124 pm and 133 pm and a 160° angle at the H center. At present we are also attempting the crystallization of an analogous salt in which both protons are substituted by metal ions $Met^{\oplus}$:[75] to form the two anticipated energetically favorable $Met^{\oplus}$-tris(*N*-chelates), all pyridine substituents would have to rotate around their bonds to the pyrazine rings. We have succeeded in growing crystals of many other compounds with unusual hydrogen bonding.[75]

In concluding this outlook, it should be emphasized that molecular polycations, accessible by many different routes, are indeed attractive subjects of research; a plethora of available experimental data, from vertical ionization energies to adiabatic half-wave oxidation potentials in solution (Section 5.1), offers inspiring hints, and the structural changes observed, from the twisted ethene dication through the stretched dication of thianthrene to the twisted dication of *p*-benzoquinone (Section 5.2), are tremendous. From the wealth of known nonmetallic multiple cations, the planar rings $S_4^{2\oplus}$, $N_2S_2^{2\oplus}$ and $S_4N_4^{2\oplus}$, the dumbbell-shaped $S_7^{\oplus}$-S_5-$S_7^{\oplus}$ or the prismane $Te_6^{4\oplus}$ are quoted as representative. Together with the preceding discussion of "nonredox" polycations accessible by protonation, alkylation, amination, or metal cation chelation, for example, they round off the various perspectives required to predict and to prepare molecules perturbed by positive charges and to draw conclusions from their structures.

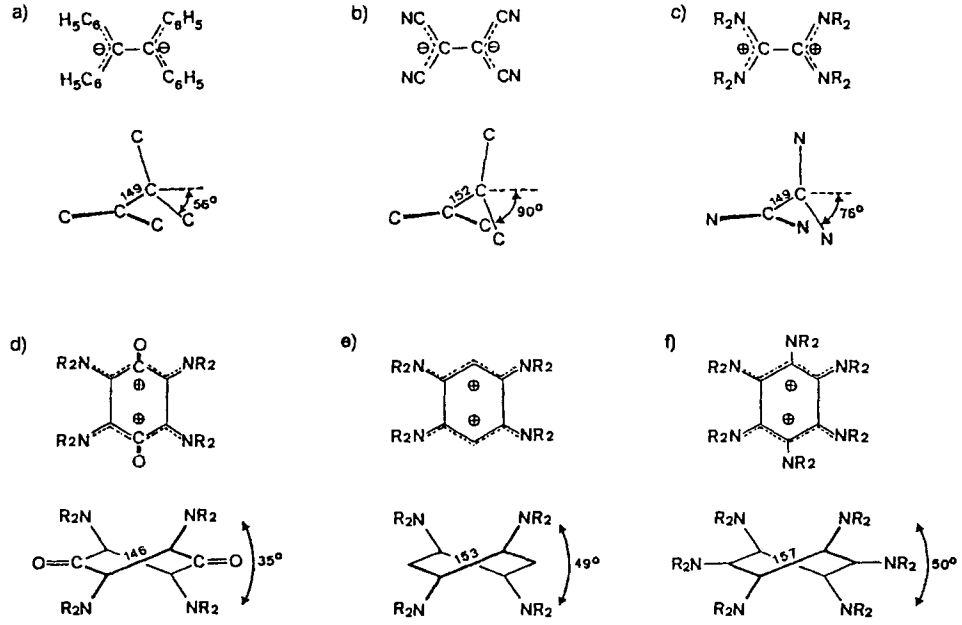
6. Structural Changes Accompanying Redox Reactions: More Favorable Charge Delocalization on Cyanine Distortion

6.1. Ethene and Six-Membered Ring Dianions and Dications as Prototypes

The remarkable structural changes on reduction of unsaturated hydrocarbons (including C–C bond formation, double-bond shift, or the substituent-dependent decrease or increase of *ipso* angles in six-membered rings) have already been emphasized (Section 3). On twofold reduction of ethene derivatives the double bond is stretched to a single bond and the two negatively charged molecular halves twist relative to each other (Sections 2.1 and 4.3). The twofold oxidation of donor-substituted ethenes distort the molecular skeleton in a similar way (Section 5.2).

In close analogy, the C=C bonds within the six-membered ring of the tetrakis(dimethylamino)-*p*-benzoquinone dication are also elongated and the two positively charged subunits R_2N–CC(O)C–$NR_2^{\oplus}$ are likewise distorted to a twist conformation. The literature provides additional examples such as the dications of 1,2,4,5-tetrakis- and hexakis(dimethylamino)benzene[86] (Scheme 25).

The structural changes in ethene and six-membered ring dianions and dications (Scheme 25) can be rationalized by a simple model based on the "coupling principles in organic dyes",[87a] developed more than 25 years ago. Although discussed then in terms of energetically favorable π-charge delocalization, of special importance are the changes in the σ framework.[88] In general, cyanine chains are characterized by the distribution of an even number n of π electrons over an odd number N of π centers.[87] The prototypes selected (Scheme 25) are classified as follows: ethene dianions with two cyanine-like subunits (Scheme 25a: $n = 4$, $N \approx 3$ or 25b: $n = 6$, $N = 5$), ethene dication also with two cyanine-like subunits (Scheme 25c: $n = 4$, $N = 3$), and six-membered ring dications with two cyanine-like subunits (Scheme 25d to f: $n = 6$, $N = 5$, partly branched). The C–C distances between the cyanine-like subunits lie in the range 146 (d) to

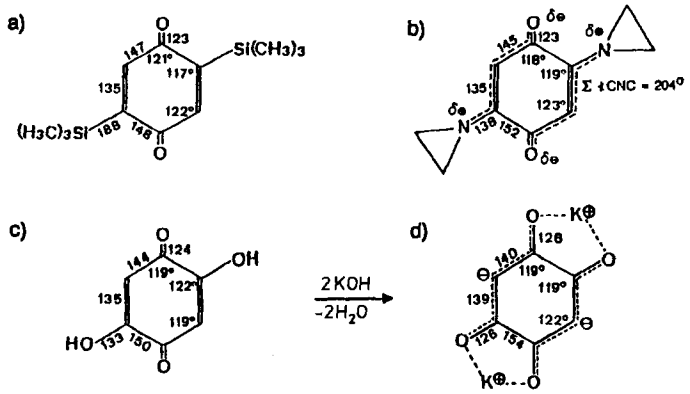


Scheme 25. Prototypes of dianions and dications of ethene and six-membered ring compounds with cyanine-like distortions. a) Cf. Fig. 3 [12]; b) see Table 1 [50c]; c) see Fig. 9c [21]; d) see Fig. 11b [71]; e) [86a]; f) [86b].

157 pm (f) and the corresponding dihedral angles ω in the range 35 (d) to 90° (b).

6.2. The Cyanine Principle

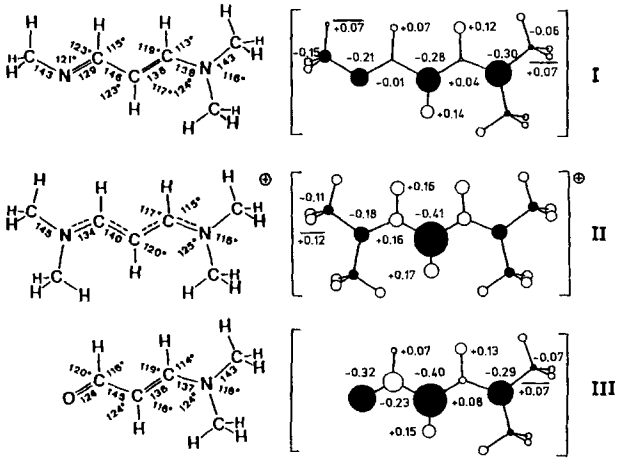
Many other molecules also exhibit cyanine-like distorted structures. Thus in contrast to 2,5-bis(trimethylsilyl)-*p*-benzoquinone[89a] (Scheme 26a), in the 2,5-dialkylamino derivatives with a similarly planar six-membered ring (Scheme 26b), an equilibration of the bond lengths along the NCCCO chains can be recognized.[89b] Drastic structural changes are observed in the planar dianion salt[90a] of 2,5-dihydroxy-*p*-benzoquinone,[90b] which is prepared by an acid/base reaction without any changes in the number of π electrons (Scheme 26c and d).



Scheme 26. Comparison of the structures of selected *p*-benzoquinone derivatives (cf. text).

The cyanine principle[87] so far has been explored predominantly based on parametrized π-LCAO/MO calculations[87a, b, 91] and the long-wavelength excitation energies of cyanine chains simulated by applying the approach of an "electron in a box" (FEM).[92] Because of the considerable changes in the molecular σ skeleton, we have repeated semiempirical[87c] calculations for the essential building blocks of the compounds presented as prototypes (Schemes 25 and 26) using the AM1 procedure[93] and fully optimizing the geometry of each example.[94] For the neutral compounds, strongly alternating bond lengths along their central NCCCN or OCCCN chains are calculated (Scheme 27; **I** and **III**), whereas in the cyanine cation $NCCCN^{\oplus}$ the bonds are already largely equalized (Scheme 27, **II**). In addition, and especially for the merocyanine derivative (**III**) and the tetramethyl-1,5-diazapentadiene cation (**II**), a pronounced charge alternation is predicted.

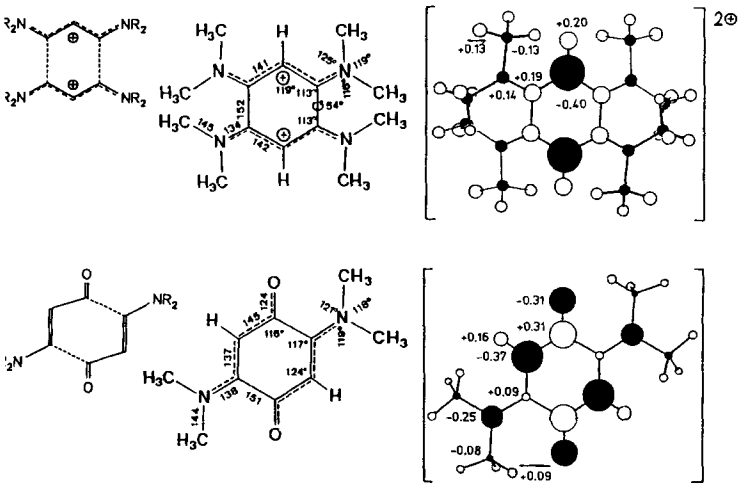
Combination of two cyanine subunits such as $R_2N\text{-}CCC\text{-}NR_2^{\oplus}$ (**II**) to approximate the dication of tetrakis(dimethylamino)benzene (Scheme 25e), or two merocyanines (**III**) to simulate 2,5-bis(dimethylamino)-*p*-benzoquinone



Scheme 27. Geometry-optimized AM1 structural data (left) and charge distributions (right) for cyanine building blocks with different end groups (cf. text).

(Scheme 26b) according to a "molecules in molecule" approximation yields after each complete geometry-optimization the AM1 structural parameters and charge distributions shown in Scheme 28.

Both calculated structures resemble the experimentally determined ones (Schemes 25e and 26b) even in detail (bond lengths ± 2 pm, bond angles $\pm 2°$). Thus for 1,2,4,5-tetrakis(dimethylamino)benzene dication, the elongated ring C–C bonds of 153 pm are calculated to be 152 pm, and even the twist angle between the cyanine subunits of 49° is satisfactorily reproduced (Scheme 28, 54°). Again alternating



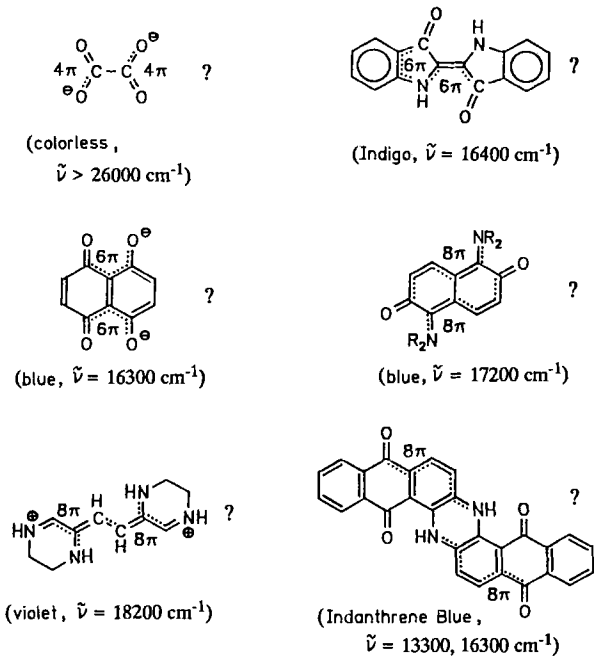
Scheme 28. Geometry-optimized AM1 structural data (left) and charge distributions (right) for 1,2,4,5-tetrakis(dimethylamino)benzene dication and for 2,5-bis(dimethylamino)-*p*-benzoquinone.

charge distributions result along the R_2N–CCC–NR_2 chains, and according to the considerable average contribution of +0.26 calculated for each H_3C group, the positive charges are preferentially located on the periphery of the molecule. Within the six-membered ring positive partial charges are predicted for all C centers of the long C–C ring bonds and accordingly, the electron density between them should be lowered. The cyanine distortion, that is, the bond equalization along the 6-electron/5-center subunits, also becomes apparent in 2,5-bis(dimethylamino)-*p*-benzoquinone, especially on comparison with its merocyanine building blocks (Scheme 27, **III**) and as expected, the calculations predict long C–C bonds between the two cyanine chains (Scheme 28, 151 pm). The appropriate C centers are again positively charged and, therefore, offer a plausible explanation for the—on first sight rather strange—different lengths of the C–C bonds that flank the O=C groups in 2,5-bis-(dimethylamino)-*p*-benzoquinones. Note also that the amino substituents should be close to planar (sum of angles at the nitrogen centers are about 359°), the molecular skeletons are slightly twisted and for each of the four H_3C groups a total charge of +0.19 is calculated (Scheme 28).

Consequently, it is the energetically favorable, alternating ($\sigma + \pi$) charge distribution along the cyanine chains that causes the bonds between the partially positively charged ring-C centers to stretch and thereby facilitates the twisting between the molecular halves. Even when starting from hexagonal six-membered ring skeletons, the quantum chemical ($\sigma + \pi$) geometry optimization does not lead to a local energy minimum with enhanced cyclic delocalization, which often is misleadingly termed "aromatic". On the contrary, a preferred distribution of an even number of π electrons over a distorted σ skeleton with an odd number N of centers results.[88] Hence, the cyanine principle is a general[87] and powerful structural perturbation concept.[21, 70, 71, 86, 91]

6.3. Cyanine Perturbations: Multifarious Possibilities and CSD Search

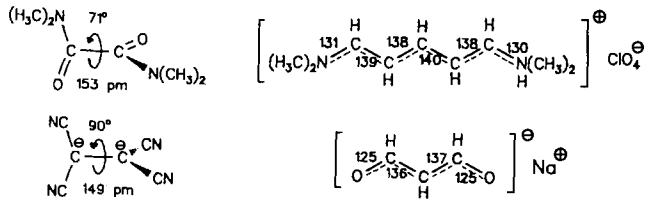
Already 25 years ago, before the ethene and six-membered ring distortions were widely known (Scheme 25 and 26), the "test compounds" for cyanine perturbations[87a] depicted in Scheme 29 were proposed.



Scheme 29. Potential test compounds proposed to substantiate cyanine distortions.

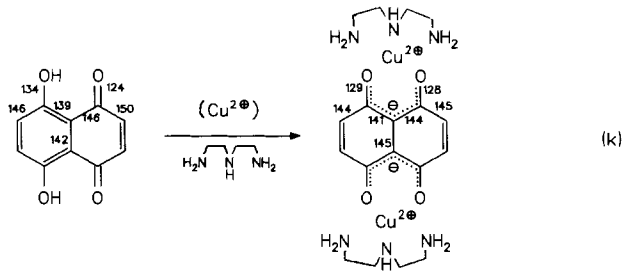
A search in the Cambridge Structure Data (CSD) file reveals that for many of the proposed test compounds either no entries are detected or unexpected structures are found. For instance, the potassium salt of the oxalate dianion[95] is planar—possibly due to advantageous stack packing—but nevertheless shows an unexpectedly long bond length of 157 pm. Indigo is also planar[96a] (as is thioindigo[96b] in which no intramolecular hydrogen bonds form), and the bonds lengths of between 135 pm and 158 pm for its five-membered rings as well as its C–C double bond of 132 pm do not suggest any merocyanine-like equalization. The same applies to the known structure of "Indanthrene Blue".[97] In contrast, cyanine-like skeletal distortions are[87b] reported, for instance, for tetramethyloxamide,[98] (5-dimethylamino-2,4-pentadienylidene)dimethylammonium perchlorate,[99] the tetracyanoethylene dianion[56] (see also Scheme 25), or the sodium salt of 3-hydroxyprop-2-enal[100] (Scheme 30).

Convincing skeletal changes are also observed for 5,8-dihydroxy-1,4-naphthoquinone[101a] on complexation of



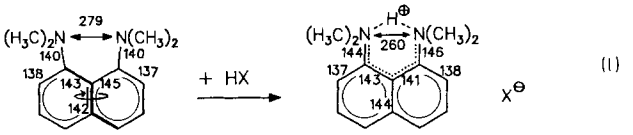
Scheme 30. Compounds displaying cyanine-like skeletal distortions.

$Cu^{2\oplus}$ ions[101b] [$r_{Cu^{2\oplus}} = 72$ pm, see Scheme 30 and Eq. (k)]. The C–OH and C=O bonds, differing by 10 pm in the free quinone, and, the flanking C–C bonds become equal and the central ring C–C bond is elongated. Analogous effects have



(k)

been determined for 1,8-dimethylaminonaphthalene, the prototype "proton sponge",[81] on salt formation [Eq. (l)], for example with $HOTeF_5$[102a, b] or with the *C*-hydroxy-*ortho*-carborane 1,2-HO-C(Ph)$C_2B_{10}H_{10}$.[102c, d] The proto-



(l)

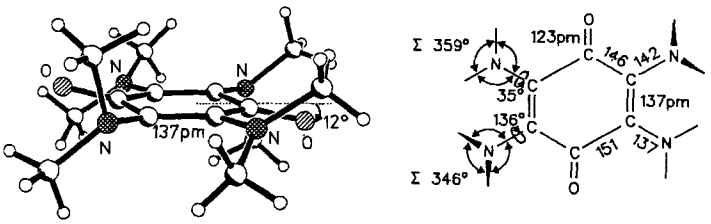
nation simultaneously removes the steric strain caused by the two dimethylamino substituents in the naphthalene *peri* positions, which widens the N···N distance to 279 pm under considerable distortion of the molecular framework. Because the N···$H^{\oplus}$···N hydrogen bond formed is only slightly tilted out of the molecular plane, the effect of the positive charge on the σ skeleton becomes apparent.[88] An analogous effect occurs on cation complexation [Eq. (k)].

Summa summarum, the cyanine structure perturbation principle constitutes, if applied with caution and sense of proportion, a heuristic rule useful in devising experiments. For an improved evaluation, however, a quantum chemical geometry-optimization of the target molecule or molecular ion is recommended[93] (Schemes 6, 26 and 28). If the "cyanine intuition" is confirmed, especially as regards the resulting charge distribution (Section 5.2 and 6.2), then the probability of scoring a large number of hits for surprising structures is high [cf. Schemes 25 or Eq. (k)]. Since various combinations of donor and acceptor substituents for the manifold classes of compounds are conceivable and positively charged molecular ions can be prepared not only by redox reactions (Section 5.1) but also by protonation, alkylation, amination, or cation chelation (Section 5.3), a wide area for future research opens. The results to be expected might also provide answers to the "what came first, the hen or the egg" question:[88] can an energetically favorable π delocalization provoke structural distortions or is an already distorted σ skeleton a prerequisite?

7. Steric Overcrowding by Substituents $-Si(CH_3)_3$, $-N(CH_3)_2$ or $-CH(CH_3)_2$

7.1. Selected Literature Examples and Interference Radii

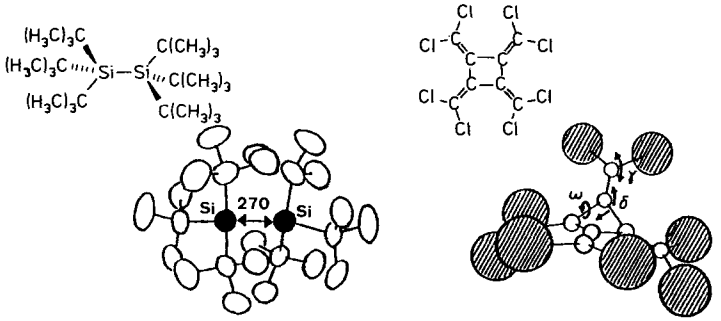
Sterically overcrowded and, therefore, structurally distorted molecules and molecular ions already have been repeatedly discussed or quoted, for example, tetrakis(trimethylsilyl)hydrazine radical cation (Section 1.2), tetraphenylethene (Section 2.1), and 1,3-dinitro-2-*tert*-butylbenzene (Scheme 11c). The "umgepolten" molecule 1,2,4,5-tetrakis(dimethylamino)-*p*-benzoquinone, which exhibits unusual properties (Scheme 20), displays a sterically enforced chair conformation in the solid state[71] (Scheme 31).



Scheme 31. Single crystal structure of tetrakis(dimethylamino)-*p*-benzoquinone.

The voluminous $(H_3C)_2N$ substituents[81] in which the interference radius of each methyl group is about 200 pm press the O=C bonds lying between them out of the central C_4 skeletal plane of the quinone in opposite directions by interplanar angles OCC_2-CC_2 of 12°. The dimethylamino groups are twisted and flattened and connected to the centers of the six-membered ring by varying CN bond distances. The resulting different n_N/π- and σ-CN-interactions deform the quinone skeleton. Thus the lengths of the C–C bonds adjacent to the O=C groups differ by 5 pm, providing another example for merocyanine-like distortions of dialkylamino-substituted quinones (Section 6.2).

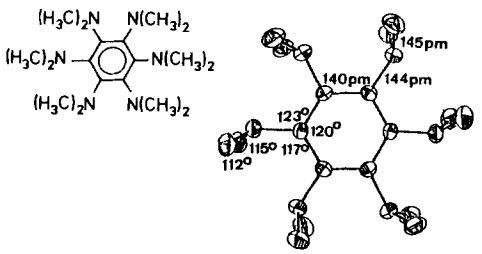
From the thousands of documented molecules whose frameworks are distorted through steric overcrowding by bulky substituents groups, hexakis(*tert*-butyl)disilane[103a] is selected here because of its spectacularly stretched Si–Si bond, and octachlorotetraradialene[104] because of its drastically changed angles (Scheme 32). The disilane derivative contains cogwheel-like, intermeshed *tert*-butyl groups, and its space-filling model shows an ellipsoid with an almost closed surface of hydrogens (omitted in Scheme 32). It exhibits Si–C bonds stretched to 199 pm and an especially interesting Si–Si central bond of 270 pm, longer than that of $(H_3C)_3Si$-$Si(CH_3)_3$ by an exceptional 36 pm.[103] The Pauling bond order, $n = 10^{[d(1) - d(n)]/60}$ ($d(1)$ = length of a normal single bond, $d(n)$ = length of the bond in question), of the



Scheme 32. Single crystal structures of hexakis(*tert*-butyl)disilane and of octachlorotetraradialene.

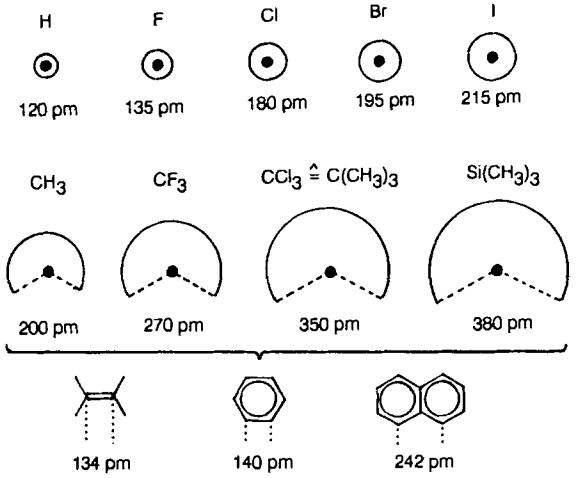
latter amounts to only 0.26, and therefore interactions within the "van der Waals skin" have to contribute considerably to the cohesion of this and other strange organosilicon molecules.[105] In contrast, octachlorotetraradialene (Scheme 32) releases its steric strain almost exclusively by the angle changes. In a completely planar molecule, the four Cl···Cl contact distances between adjacent Cl_2C groups would be only 270 pm,[104] which is considerably smaller than the sum of two van der Waals radii for chlorine (Scheme 34, 360 pm). The four-membered ring folds to give a dihedral angle ω(CC-CC) of 27°, and the Cl_2C groups are tilted alternately up and down as a result of additional bending at the two double-bond centers by $\delta = 194°$ and $\gamma = 188°$, accomplishing an apparently still tolerable Cl···Cl contact distance of 332 pm.[104]

However, whoever bases his predictions for hexakis(dimethylamino)benzene on the drastic changes of bond lengths and angles possible (Scheme 32) or on the undulating six-membered rings of sterically overcrowded benzene derivatives such as $C_6(CF_3)_6$,[106a] $C_6(Si(CH_3)_3)_6$,[106b] and $C_6(NO_2)_3(N(CH_3)_2)_3$[106c] and expects that its six bulky $(H_3C)_2N$ substituents should cause a more severe structural distortion than in tetrakis(dimethylamino)-*p*-benzoquinone (Scheme 31) will be bitterly disappointed. Its C_6N_6 skeleton[86b] (Scheme 33) exhibits approximately C_{6h} symmetry (!) and all of its bond lengths and angles are found to be within normal tolerance limits.



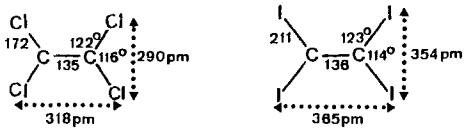
Scheme 33. Single crystal structure of hexakis(dimethylamino)benzene.

A qualitative estimate of the space filled by substituents is also of importance for the "kinetic stabilization" of those thermodynamically stable molecules that can be generated in the gas phase under unimolecular conditions but rapidly polymerize on condensation.[107, 108] Embedding them in "alkyl cotton" consisting of inert substituents renders possible the isolation of derivatives or short-lived parent compounds such as $H_2C = NH$[107a] or $H_2Si = CH_2$[107b]. For an estimate, the "interference", "interaction", or "van der Waals" radii[109] are often taken into consideration (Scheme 34); they are derived from ionic radii or molecular structures,[109a] de Broglie wavelengths, collision cross-sections, or critical data,[109b] as well as from force-field calculations.[103c] They are angle- and direction-dependent[109a, d] and are occasionally unrealistically overestimated.[103e] For a definition, it has been proposed that the van der Waals volume of a molecule cannot be penetrated by that of another at thermal energies corresponding to room temperature.[109b] Some frequently used literature values[109a, f] are contrasted with the C–C distances in the basic hydrocarbons ethene, benzene, and naphthalene in Scheme 34 to provide a scale.



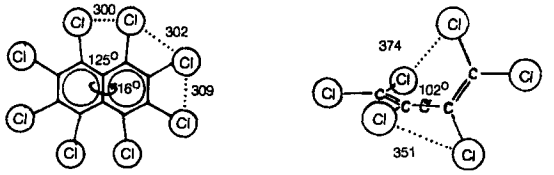
Scheme 34. Comparison of interference radii of frequent substituents with the C–C distances in basis hydrocarbons.

Despite the obvious usefulness of interference radii for qualitative estimates, restrictions are advisable. To begin with single-center substituents, which allow more straightforward remarks, the structures of planar tetrachloro- and tetraiodoethene determined by gas-phase electron diffraction[110] display distances between vicinal and especially between the geminal halogen centers that are far smaller than the sum of the interference radii (Schemes 34 and 35).



Scheme 35. Structures of tetrachloro- and tetraiodoethene in the gas phase.

As concerns Hal_2C groups, therefore, the assumption of a spherical electron-density distribution around the individual halogen centers[109a, d] is unjustified as expected. On the other hand, the intermolecular contacts, for example, in octachlorotetraradialene (Scheme 32) can still be discussed within the concept of interference radii. The Cl···Cl distances of 332 pm, resulting after the angles changes specified, are compressed by about 8% relative to the sum of van der Waals radii of 360 pm (Scheme 34). Two additional structural ob-



Scheme 36. Single crystal structure of octachloronaphthalene and gas-phase structure of hexachlorobutadiene.

servations for perchlorinated unsaturated hydrocarbons round off the impression (Scheme 36): One of the shortest intramolecular Cl···Cl distances of 300 pm has been determined between the *peri* positions of chiral octachloronaphthalene (symmetry D_2)[111] and in *gauche* hexachlorobutadiene (symmetry C_2), the molecular halves containing the two double bonds are twisted by 102° relative to each other[112] to avoid Cl···Cl contact distances of only about 270 pm that would result for a planar *trans* configuration.

For substituent *groups*, the interference radii (Scheme 34) represent only the maximum value for unhindered rotation and, therefore, can be considerably undercut with space-saving and, in particular, staggered conformations (see, for instance, Scheme 33). Thus, in the intermeshed structure of hexakis(*tert*-butyl)disilane (Scheme 32), the shortest intramolecular C···C distance between the molecular halves amounts to 334 pm and, therefore, is 17% shorter than the sum of the van der Waals radii of two methyl groups (400 pm, Scheme 34).

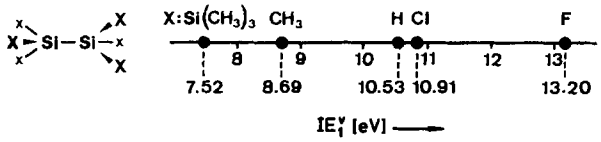
The preceding remarks on advantages, rules of thumb, and recommendations for caution concerning the use of interference radii are necessarily incomplete. Within the scope given, the dynamic aspects[109c, d] (Fig. 2) or the usefulness of structure predictions by force-field[103c] and energy-hypersurface calculations[1, 6] (Sections 1.1 and 5.1), which are nowadays possible also for larger molecules on fast work stations, can only be indicated. For the following own contributions to studies on sterically overcrowded molecules, a combination of partly intuitive interference radii considerations, measurement of characteristic molecular properties, and as careful as possible a quantum chemical exploration of the pathways through the space spanned by the $(3n-6)$ degrees of freedom of n-atom ensembles and containing numerous local minima proved to be advantageous.

7.2. Prototype Molecules from Frankfurt: $((H_3C)_3Si)_3Si$–$Si(Si(CH_3)_3)_3$, $((H_3C)_2N)_2C{=}C(N(CH_3)_2)_2$ and $N(CH(CH_3)_2)_3$

All three selected molecules have been investigated, because their space-filling substituent groups allow an energetically favorable delocalization of the positive charge in their radical cation ground states, accessible by vertical ionization or adiabatic oxidation (Section 5.1).

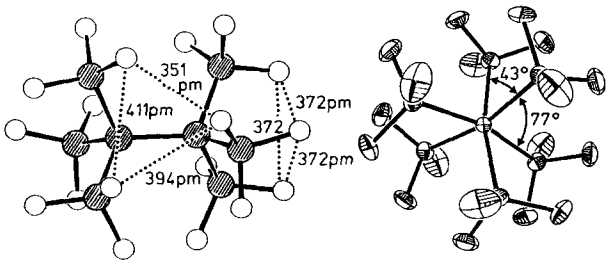
7.2.1. *Hexakis(trimethylsilyl)disilane*

In accordance with the parametrized $\sigma_{SiSi}/\sigma_{SiSi}$ interaction model,[1a, 8h, 113] the title compound exhibits the lowest first vertical ionization energy of all disilane derivatives investigated so far[104] (Scheme 37).



Scheme 37. First vertical ionization energies of disilane derivatives.

Hexakis(trimethylsilyl)disilane crystallizes in the space group $R\bar{3}c$ with 12 molecules of D_3 symmetry per unit cell.[114] The steric overcrowding by 18 peripheral methyl groups (Scheme 38) is especially evident in the stretched central Si–Si bond of 240 pm and the other six of 239 pm, in the dihedral angles ω(SiSi-SiSi) of 43 and 77°, as well as in intramolecular C···C distances as short as 351 pm, which demonstrate the interlocking of the methyl groups since the interference radii us for CH_3 is about 200 pm (Scheme 34). The intermeshing of the molecular halves obviously reduces the substituent compression considerably, because the more sterically strained hexakis(*tert*-butyl)derivative (Scheme 32) exhibits comparable dihedral angles ω(CSi-SiC) of 45 and 75°.[115]



Scheme 38. Single crystal structure of hexakis(trimethylsilyl)disilane. Left: side view; right: view along the Si-Si axis.

A ^{1}H NMR spectrum recorded at 190 K does not show any signal splitting for the 42 equivalent methyl hydrogen centers; the rotational barriers must therefore be smaller than 20 kJ mol^{-1}. Regrettably, no persistent radical cation can be generated despite the low first vertical ionization energy (Scheme 37) and in agreement with the irreversible first oxidation potential in aprotic solution (Section 5.1).

7.2.2. *Tetrakis(dimethylamino)ethene*

The extremely electron-rich molecule M[65] containing four nitrogen electron pairs exhibits a first vertical ionization of only 6.13 eV[66] and therefore is immediately oxidized like sodium metal on dissolving in water, presumably according to $2M + 2H_2O \rightarrow 2(M^{\oplus}OH^{\ominus}) + H_2$ (Section 5.2). The ENDOR spectrum[67] of its radical cation (Fig. 9), which could not be isolated so far, inexplicably shows two different ^{1}H couplings. This observation, together with the structurally proven cyanine-like deformation of its dication (Sections 5.2 and 6.1), prompted the determination of the structure of neutral compound[116] (Fig. 12). Since it melts at

0 °C, a single crystal had to be grown on the goniometer needle in a cold N_2 flow.[116] In the gas-phase electron diffraction experiment, the evaporation temperature of the hardly volatile compound had to be kept below 100 °C[116] because of potential thermal decomposition.[65]

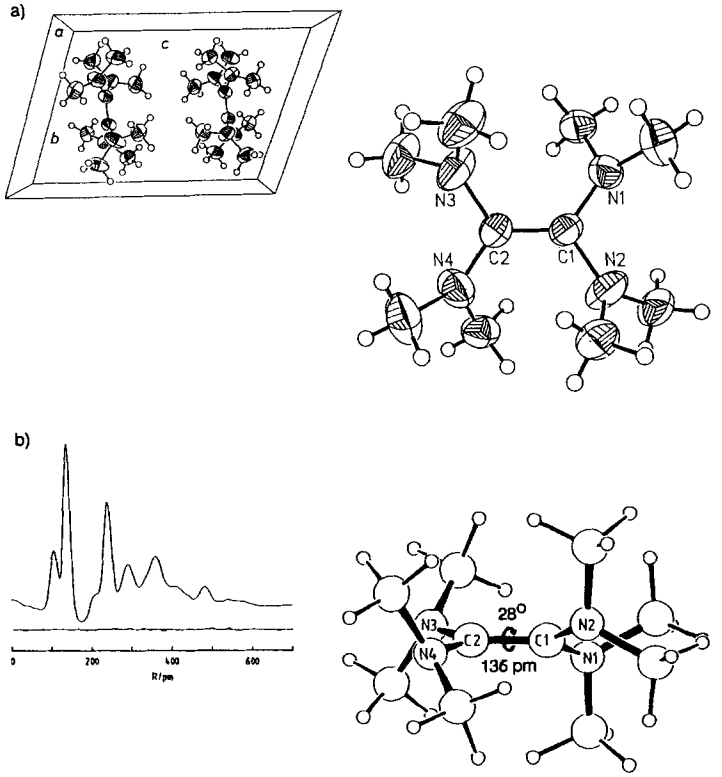


Fig. 12. Structures of tetrakis(dimethylamino)ethene. a) Single crystal determination: unit cell containg 2 molecules (intermolecular H···H distances > 243 pm) and averaged (disordered) molecular structure. Important distances and angles: C-C 135, C-N 140, N-C(H) 141–145 pm; $\omega(N_2C\text{-}CN_2)$ 28°. b) Gas-phase determination: radial distribution function and molecular structure. Important distances and angles: C-C 136, C-N 140, N-C(H) 141 to 145 pm, $\omega(N_2C\text{-}CN_2)$ 28°, N-C-N 118°, ω(CC-NC) 55°; angle sum around N 351°.

The solid-state and the gas–phase structure of tetrakis (dimethylamino)ethene agree well;[116] small deviations can be traced especially to the disordering of the dimethylamino groups in the crystal. The steric overcrowding by the four bulky $(H_3C)_2N$ substituents[71, 81, 86b] becomes visible in their considerable flattening (Fig. 12b: angle sum around N 351°) and, in particular, in the twisting of the two molecular halves relative to each other (Fig. 12: $\omega(N_2C\text{-}CN_2) = 28°$). This is further substantiated on comparison with the dihedral angles of other ethene derivatives:[117] The present world record is held by bis(biphenyl-2,2′-diyl)ethenes with up to 40° twist and, in addition, a C-C bond stretched to 139 pm. Tetrakis(*tert*-butyl)ethene is still unknown and molecules that closely resemble it, tetrakis(trimethylsilyl)- and tetrakis(1-methyl-cyclopropyl)ethene, are twisted by 29.5°[118] and 20°.[117] Tetrakis(isopropyl)ethene, isoelectronic to the title compound, surprisingly contains a planar $C_2C{=}CC_2$ skeleton,[117] which also suggests a considerable spatial demand for the nitrogen lone pairs.

The single crystal data of tetrakis(dimethylamino)ethene as well as the gas-phase data, which exclude packing effects (Fig. 12), enable rationalization of essential molecular properties. The low first vertical ionization energy[66] cannot be explained by considerably reduced n_N/π-interactions relieved by the 40° turn of the N lone pairs out of an averaged π plane ($\cos^2 40° = 0.6$),[1b] but can be traced directly to the considerable flattening of the dimethylamino groups, because triisopropylamine, which also displays an almost planar NC_3 skeleton[119] (see Fig. 13), shows an extremely low value for IE_1^V of only 7.18 eV. The associated lowering of the N inversion barrier simultaneously provides a molecular dynamics argument (Fig. 2) for the single ^1H NMR signal measured at room temperature.[65] In conclusion it should not be concealed that the structure of the neutral molecule does not resolve the mystery of the two different ^1H ENDOR couplings for its radical cation $M^{\bullet\oplus}$ (Fig. 9); increased efforts, therefore, are being dedicated to the growth of a single crystal of a radical cation salt $[M^{\bullet\oplus}]X^{\ominus}$.

7.2.3. *Triisopropylamine*

The triisopropylamine molecule[119] constitutes an excellent example for conclusions about structure drawn from suitable data (Section 1). Initial target of the investigations was the preparation of a trialkylamine with a low first vertical ionization energy, that is, a radical cation ground state in which the positive charge is stabilized by the surrounding alkyl groups and which could potentially also be oxidized adiabatically to attempt the isolation of its radical cation salts $[M^{\bullet\oplus}]X^{\ominus}$ (Section 5.1). Indeed triisopropylamine, accessible according to the literature by a three-step synthesis including $CN \rightarrow CH_3$ Grignard exchange, exhibits a rather low first ionization energy of only 7.18 eV (Fig. 13a), which is 1.3 eV (!) below that of trimethylamine and comparable to that of a phosphorus ylide.[120] To our bewilderment, however, a reversible one-electron oxidation potential recorded by cyclic voltammetry was noticed (Fig. 13b), because this can only be expected when all H–C bonds are perpendicular to the N lone pair and thus prevents the usual H elimination from an intermediate immonium cation $R_2N^{\oplus}{=}CR_2$.[119] Certainty about a flattened radical cation structure was provided by the ESR spectrum showing exclusively a N triplet (Fig. 13c), which meant that potential couplings of the 21 (!) hydrogens were smaller than the signal width. Quantum chemical geometry-optimization supported a planar NC_3 skeleton in the radical cation and suggested the same for the neutral molecule.

According to a careful literature search, triisopropylamine is the first trialkylamine for which a sterically enforced planarization of the NC_3 pyramid and the associated formation of a p-type nitrogen lone pair could be structurally proven.[121] This structure (Fig. 13d) is in accord with all the experimental data obtained so far and also with the results of quantum chemical calculations (Fig. 13a–c),[119] which predict a small dipole moment and a charge distribution polarized according to the effective nuclear charges from the negative nitrogen to the positive isopropyl groups. The rather low inversion enthalpies estimated for varying C-N-C angles by MNDO FORCE and AM1 calculations suggest for triisopropylamine a shallow double-minimum potential.

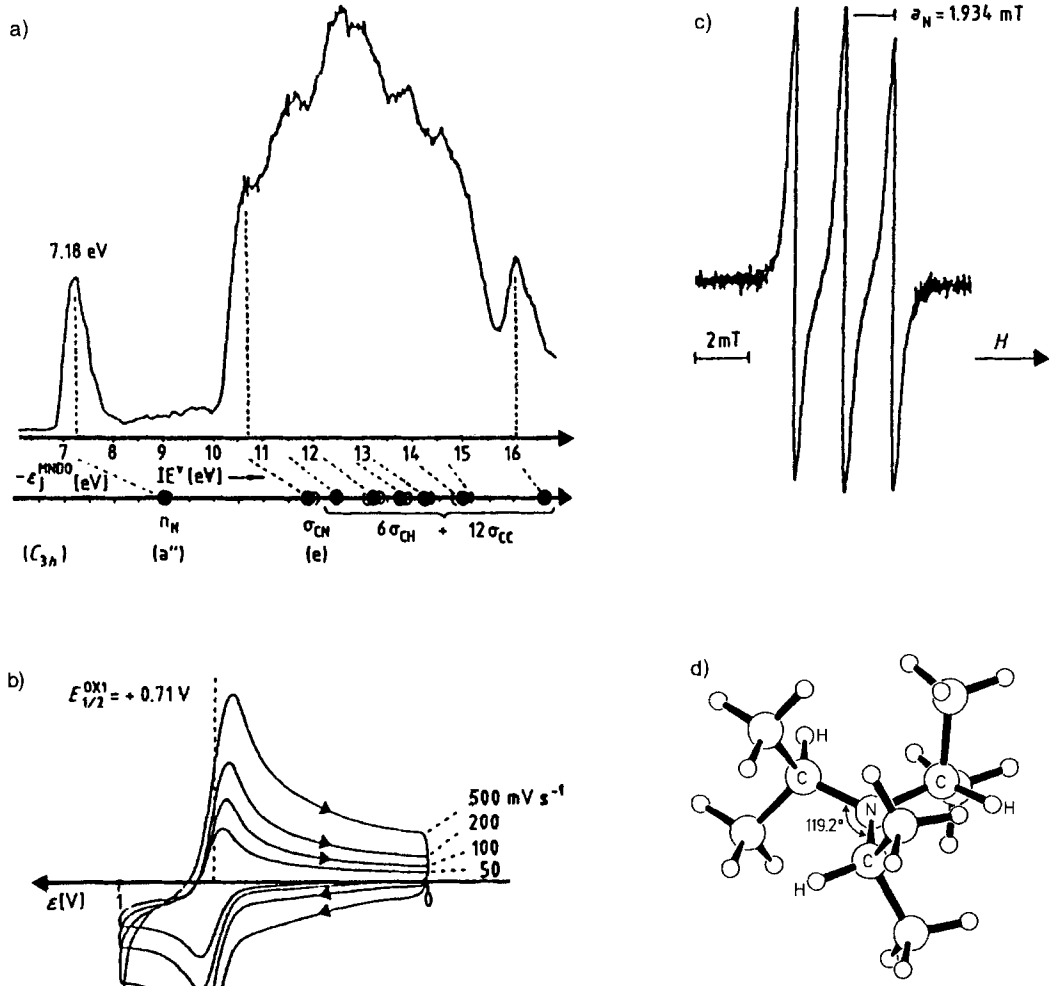

Fig. 13. Selected measurements for triisopropylamine: a) He(I)-PE spectrum up to 16 eV with Koopmans's assignment based on MNDO eigenvalues; b) cyclic voltammograms in THF/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ at 243 K (recording velocities $v = 50$ to 500 mVs^{-1}); c) ESR spectrum of the radical cation generated by SbF_5/CH_2Cl_2 at 200 K; d) structure in the gas phase determined by electron diffraction.

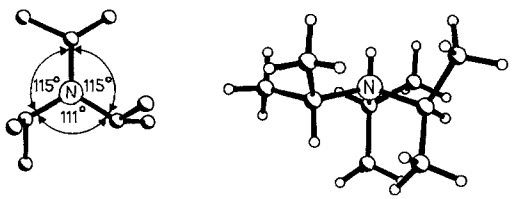
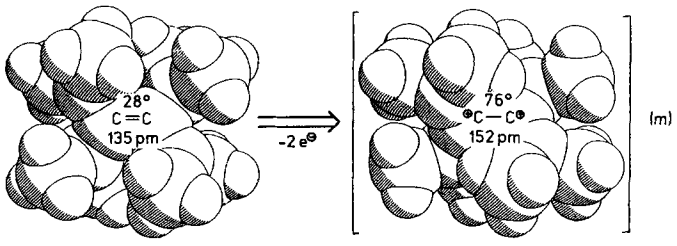
Single crystals of the salt $((H_3C)_2HC)_3NH^{\oplus}Cl^{\ominus}$ have been grown in the interim; and their structure was determined at 90 K[122] (Scheme 39). Although we had hoped for



Scheme 39. Single crystal structure of triisopropylammonium hydrochloride at 90 K.

a protonation of the p-like nitrogen lone pair of the almost planar triisopropylamine molecule, the structural changes observed demonstrate an interesting possibility for the arrangement of three bulky isopropyl groups around a four-coordinate center: one takes up a horizontal position. The angle sum about N of 341° confirms the deviation from an ideal tetrahedron (angle sum = 327°), and angles of 115° on both sides of the horizontal isopropyl group illustrate that steric strain still exists. From interference radii considerations (Scheme 34), it is remarkable that the C-N-C angle between two other $(H_3C)_2HC$ substituents can be compressed to 111°.

In conclusion, the relationship between structural effects due to charge perturbation and steric overcrowding must be emphasized, although they have been dealt with separately for didactic reasons. Tetraphenylethene was chosen as a suitable example for a reduction reaction (Section 2.1). The cyanine-like distortion in its dianion (Fig. 3 and Section 6.1), that is the elongation of the C=C bond by 13 pm and the



twisting of the molecular halves by 56°, renders possible the formation of a contact ion pair at the previously shielded central C–C bond. The same applies to the double oxidation of tetrakis(dimethylamino)ethene [Eq. (m)], in which both charge perturbation and relief of steric compression operate in the same direction.

Once more, this evidence shows that molecular states—despite interesting individual facets (Scheme 5)—have to be considered as an entity (Figs. 1 and 2) and that "actually, everything is more complicated".

8. Summary and Perspectives

This review reports essential results of two years' structural investigation starting from and stimulated by suitable molecular-state data as well as their quantum chemical calculation. It contains more than 30 structures determined for the products of the reduction of unsaturated phenyl-substituted hydrocarbons with alkali metals (Sections 2 and 3), for radical contact ion pairs (Section 4), for molecular polycation salts (Sections 5 and 6), as well as for sterically distorted compounds (Section 7). A selection of literature observations supplement and extend the review. Our current intensified investigations will allow us to acquire experience in the design, preparation, and growth of single crystals of charge-perturbed and sterically overcrowded molecules as well as in their quantum chemical interpretation.

8.1. Useful Rules of Thumb for the Design and Preparation of Distorted Molecules

Experimental data, structural parameters, and quantum chemical results can be summarized in molecular state considerations, which in addition allow the comparison of perturbations of chemically related molecules and molecular ions.[11] This point of view provides the following interdependent, frequently useful, and partly obvious rules of thumb both for the design of distorted molecules and for their preparation:

1) Suitable molecular-state data such as (adiabatic) half-wave redox potentials or (vertical) ionization energies, which can be either measured, calculated, or estimated from correlations between related compounds, usually provide valuable hints for highly selective electron-transfer reactions (cf. for example, Section 5a).

2) UV/VIS spectra, often satisfactorily reproduced by CI calculations (cf. Section 5.2), and especially the isobestic points observed, can be helpful in optimizing difficult crystal growth conditions and, above all, in the selection of the solvent.

3) ESR/ENDOR spectra and their temperature dependence prove valuable in the attempts to crystallize paramagnetic molecular-ion salts; the spin populations obtained simultaneously can usually be correlated with calculated charge distributions.

4) Known structural parameters often offer only unsatisfactory predictions for strong charge perturbation in molecular ions. Similarly the interference radii estimated from them are a poor indicator for severe overcrowding in molecules and often only cover some aspects of the many degrees of freedom (cf. Sections 6.5 and 7.1). On the other hand, correlations with substitution perturbations frequently allow the discovery of stimulating consequences (Sections 2.3 and 3.3).

5) In general, energy hypersurface and partly also force-field calculations under full geometry-optimization allow the reproduction of structures of molecules (Sections 2.6 and 7), of molecular anions and their contact ion aggregates (Sections 2, 3, 4, and 6), as well as of molecular cations (Sections 5 and 6) in a satisfactory way and even their correct prediction. Metal countercations always have to be taken into account (Sections 2 and 3), and counteranions in case of hydrogen bond formation (Section 5.3).

6) Discussions of appropriate data based on quantum chemical results, the reliability of which can be tested in suitable correlations, will always provide a wealth of additional aspects (cf. for example Sections 1.1, 2.1, 5.2, or 6.2).

7) Comparisons between experimental and/or calculated molecular-state data (Section 1.3) based on first and second order perturbation arguments provide reliable conclusions,[92b] but leave room for fantasy on the evaluation of "chemically related compounds". They can increase the hit probability in the design of distorted molecules considerably.

Most important is the success of the preparative effort. A satisfactory solution of the multiparameter problem of striking optimum conditions for the growth of frequently temperature-, air-, proton-, and light-sensitive single crystals definitely needs a grain of luck, as does their suitability for the structure determination.

8.2. What We Still Do Not Know

Despite all the fascination for this research area, which was new to us, and the achieved quantum chemical comprehension of some molecular structures, we cannot disguise our disatisfaction with regard to the question "what crystallizes, how, and why?" This problem is inherent in crystallization, which as prototype of molecular self-organization[123] is presently again[124] receiving much world-wide attention.[103c, 125] Thus, further improved force-field calculations enable the rationalization of interactions in the crystal—as exemplified by diphenyl, which is twisted by 40° in the gas phase but planar in the crystal.[103c] Structures of hydrocarbons within certain space groups can be reproduced by a molecular cluster approach: specified arrangements are generated by symmetry operators and their energies calculated approximately; tetramethyldibenzocyclooctene ($P\bar{1}$) is quoted as a successful example.[125] Dipole moments do not exert any significant influence on the crystallization in certain space groups.[125b] Better suited are presumably stronger interactions such as caused by multiple hydrogen bonds or by the Coulomb attraction between separated stacks of disklike donor and acceptor components in organic conductors.

The specific example of molecular anion salts also shows that more is unknown than is known. Thus the effects of countercations and of their solvation on the resulting crystal structure have been investigated only sporadically (cf. Sections 2.4 or 3.2) and remain largely uncomprehended.

Serendipity led to the discovery that, for instance, the tetracyanoethene radical anion under comparable conditions in dimethoxyethane solution crystallizes with solvent in salts $[TCNE^{\cdot\ominus}Met^{\oplus}(dme)_1]_\infty$ containing six-coordinate $Na^{\oplus}$ or seven-coordinate $K^{\oplus}$ ions, but without solvent with $Cs^{\oplus}$ as $[TCNE^{\cdot\ominus}Cs^{\oplus}]_\infty$ (Section 4.3). The tetraphenylbutadiene dianion is found within the very same crystal either in η^3-coordination with two $[Na^{\oplus}(dme)_2]$ counterions, or "naked" with completely solvent-separated $[Na^{\oplus}(dme)_3]$ ions (Section 2.4). Even more confused is the situation in ether solutions: the reductions of organic hydrocarbons with alkali metals take place through a network of equilibria (Sections 3.1 and 4.1) until the molecular anions or dianions, generated partly by protonation, C–C bond formation, or double-bond shift (Sections 2.2, 3.1, and 3.2), finally crystallize, sometimes in intra- or intermolecular dibenzenesodium sandwich structures (Section 2.4). Despite all tentative interpretations, here again many questions remain unanswered, from "how is the electron transferred from the metal mirror?" through "do the solutions contain metal atoms or metal clusters?" back to the initial "what role is played by solvent cages especially during the crystallization?"[126] Without further specification, a comparably large number of questions on oxidation reactions—although partly of different type—need answers.

Altogether, more questions are raised than answered in this report or, put positively, there is a lot of stimulation for numerous future experiments.

Our report covers two years of fascination by structures of charge-perturbed and sterically overcrowded molecules. Within this period, former "gas-men" and "solution-ladies" turned into "stone age people", to take a primordial morning look using a cold-light lamp at the crystals growing from deep-coloured solutions in Schlenk traps under argon. We like to express our gratefulness to all, who have helped us in our learning process. Above all, thanks go to my friend and former colleague Dieter Fenske (now Technical University Karlsruhe), who together with his co-workers K. Merzweiler and H. Goesmann, supported our first steps in the use of a four-circle diffractometer. My present colleague, Robert Schlögl, and Dr. W. Bensch from his group, have generously provided the measurement time as well as their experience in solution of structures. Support also came from Professor E. Egert and his co-workers Dr. J. W. Bats and Dr. M. Dyrbusch. Joint research projects link us with Dr. W. Bensch (University of Frankfurt), with Dr. H. Borrmann, Dr. W. Hönle, Professor H. G. von Schnering, and Professor A. Simon (Max-Planck Institute for Solid State Research, Stuttgart-Büsnau), with Dr. E. Herdtweck and Professor W. A. Herrmann (Technical University, Munich), as well as with Professor H. Oberhammer and his co-worker S. Liedle (University Tübingen). Generous financial grants have been provided by the Deutsche Forschungsgemeinschaft and Land Hessen, the research project has also been supported by the Fonds der Chemischen Industrie, the Alexander von Humboldt (Z. H.) and the Adolf-Messer-Foundations.

[24] Other known dianions of ethene derivatives $X_2C{=}CX_2$ have, for example, been prepared as follows: a) X_2C = fluorenylidene (M. Walczack, G. D. Stucky, *J. Organomet. Chem.* **1975**, *97*, 313), by deprotonation of bifluorene with LiR; b) X = CN (D. A. Dixon, J. S. Miller, *J. Am. Chem. Soc.* **1987**, *109*, 3656), by reduction of tetracyanoethene with $[(CP^*_2)Co]$; c) X = $Si(CH_3)_3$ (A. Sekiguchi, T. Nakanishi, C. Kabuto, H. Sakurai, *J. Am. Chem. Soc.* **1989**, *111*, 3748), by reduction with lithium metal in THF. None of these ethene dianion salts forms a stringlike structure, presumably because in a) the dianion is sterically shielded, in b) the $Co^{\oplus}$ counterion is embedded in a sandwich and in c) the THF-solvated $Li^{\oplus}$ ions are localized on both sides of the C–C double bond because of their small radius.

[25] For the unusual sandwichlike coordination of sodium, an extensive literature search produced the following parallels: a) Lithium-7b*H*-inde-

no[1,2,3-*jk*]fluorenide (D. Bladauski, H. Dietrich, H. J. Hecht, D. Rewicki, *Angew. Chem.* **1977**, *89*, 490; *Angew. Chem. Int. Ed. Engl.* **1977**, *16*, 474) contains one dodecahapto-coordinated $Li^{\oplus}$ ion between the coaxial phenyl rings which are separated by a distance of 386 pm; b) In lithium 1,1,3,3-biphenyl-2,2'-diylpropenide diethyl ether (D. Bladauski, D. Rewicki, *Chem. Ber.* **1977**, *110*, 3920), the Li-di(η^6-phenyl)-sandwich structure is opened by 56° due to the additional R_2O solvation; c) $(H_5C_6)_3CNA \cdot TMEDA$ also shows a stringlike structure (H. Köster, E. Weiss, *J. Organomet. Chem.* **1979**, *168*, 273), but $Na^{\oplus}$ ion prefers a relatively short bond of 264 pm to the central carbanion carbon center rather than a polyhapto coordination to the phenyl groups; d) In 1,3-diphenylallyllithium diethyl ether (G. Boche, H. Ethrod, M. Marsch, W. Massa, G. Baum, W. Mahdi, *Angew. Chem.* **1986**, *98*, 84; *Angew. Chem. Int. Ed. Engl.* **1986**, *25*, 104), instead of an intramolecular dibenzenelithium sandwich, a polymer chain is formed. See also [19].

[26] Numerous alkali-metal cation half-sandwich compounds are known (cf. [19]). In addition, the contact-ion triples a) terphenyl disodium-hexakis(tetrahydrofuran) should be mentioned (J. H. Noordick, H. M. Doesburg, P. A. J. Prick, *Acta Crystallogr. B* **1981**, *37*, 1659) and b) bis-(dimethoxyethanelithium) salt of the 1,2,4,5-tetrakis(trimethylsilyl)-benzene dianion (A. Sekiguchi, K. Ebata, C. Kabuto, H. Sakurai, *J. Am. Chem. Soc.* **1991**, *113*, 7081), which each contain a sodium or lithium ion on both sides of a benzene ring, and c) the intramolecular phosphonium-bisbenzylide complexes of $Na^{\oplus}$ and $K^{\oplus}$ (H. Schmidbaur, U. Deschler, B. Milewski-Mahrla, B. Zimmer-Gasser, *Chem. Ber.* **1981**, *114*, 608).

[27] Y. Ohsima, S. Yamamoto, N. Nakata, K. Kuchiku, *J. Phys. Chem.* **1987**, *91*, 4696. For tetraphenylallene we have obtained the following structure parameters from a single-crystal structure determination: C=C 132 pm, ∢ C=C=C 173.5°, $\omega(C_2C\text{-}CC_2)$ 87° (H. Bock, R. Ruppert, unpublished).

[28] Selected examples of structure determinations for allyle ions of alkali metals: a) $C_3H_3Li \cdot PMDTA$ (E. Weiss, U. Schürmann, H. Dietrich, W. Mahdi, *J. Organomet. Chem.* **1987**, *332*, 299); b) $C_3H_3Li \cdot TMEDA$ (H. Köster, E. Weiss, *Chem. Ber.* **1982**, *115*, 3422); c) 1,3-diphenylallyllithium diethyl ether [25e].

[29] For this purpose the following parameters have been optimized [14]: $U_{ss} = -4.611$ eV; $U_{pp} = -2.3643$ eV; $\xi_s = 0.73384$ a.u.; $\xi_p = 0.82957$ a.u.; $\beta_s = 1.14529$ eV; $\beta_p = -1.14101$ eV; $\alpha = 1.26193$ Å^{-1}; $g_{ss} = 7.20$ a.u.; $g_{sp} = 5.18$ a.u.; $g_{pp} = 5.43$ a.u.; $g'_{pp} = 4.233$ a.u., $h_{sp} = 0.6428$ a.u.

[30] The reductive C-C bond formation e.g. of silylated ethenes by reaction with alkali metals has been reported for $Ph_3SiHC=CH_2$ (J. J. Eisch, R. J. Beuhler, *J. Org. Chem.* **1963**, *28*, 2876) and for $(Me_3Si)_2C=CH_2$ (M. Kira, T. Hino, Y. Kubota, N. Matsuyama, H. Sakurai, *Tetrahedron Lett.* **1988**, *29*, 6939). Crystal structures cannot be found in the Cambridge Structural Data File: the reaction course is supported by deuterolysis, by reoxidation, as well as by ring closure with R_2SiCl_2 to silacyclopentane derivatives.

[34] Cf. the examples given in H. Bock, *GIT-Fachz. Lab.* **1991**, *35*, 557.

[35] The MNDO/Cl calculations have been performed by using the program SCAMP. All configurations from the six inner, partly occupied molecular orbitals were considered in each case. As reaction coordinate the distance C···C between the linked C centers has been chosen, and the structures have been pointwise completely geometry-optimized. For Na, the optimized parameters [29] have been applied.

[77] The crystal structure of biphenyl (G. P. Charbonneau, Y. Delugeard, *Acta Crystallogr. Sect. B* **1976**, *32*, 1420) showing a dihedral angle $\omega = 0°$ and a C–C distance of 149 pm can be reproduced by force-field calculations (J.-H. Lii, N. L. Allinger, *J. Am. Chem. Soc.* **1989**, *111*, 8576). In the gas phase, however, phenyl rings are twisted relative to each other by $\omega = 44°$ and a C–C distance of 151 pm is observed (A. Almenningen, O. Bastiansen, L. Fernholt, B. N. Cyvin, S. J. Cyvin, S. Sandal, *J. Mol. Struct.* **1985**, *128*, 59).
[78] On oxidation $M \rightarrow M^{\oplus} \rightarrow M^{\oplus\oplus}$ the N–N bond distance of 149 pm in 2,7-diazatetracyclo[6.2.2.2.^{3,6}.0.^{2,7}]tetradecane decreases first to 133 pm and then to 127 pm, and the N centers are increasingly planarized (angle sums 336°, 355°, and 360°). The dication possesses a dihedral angle $\omega(C_2N^{\oplus}\text{-}^{\oplus}NC_2)$ of 0° [7b]. In contrast, the threefold bridged dication $N^{\oplus}(CH_2CH_2CH_2CH_2)_3N^{\oplus}$ shows a N–N single bond of 153 pm (R. W. Alder, A. G. Orpen, J. M. White, *J. Chem. Soc. Commun.* **1985**, 949).

What subscribers and authors have to say about Angewandte Chemie:

Jean-Marie Lehn, Université Louis Pasteur, Strasbourg:

"I consider Angewandte Chemie as one of the top not only chemical but scientific journals... It presents the highly effective combination of well chosen, exciting and thorough review articles, reflecting timely topics that cover a very broad range in science, with short but informative communications reporting specific advances of particular interest for chemistry. It is also carefully produced and nicely presented, which adds to the reading pleasure."

The Folding of Squalene; An Old Problem has New Results

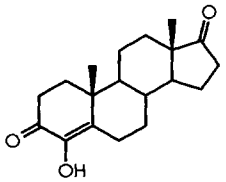
By *Rolf Bohlmann**

The importance of steroids in reproduction[1] and sexual differentiation has been known since the sixties. Other classic applications of steroids in medical therapy include the corticoids as anti-inflammatory agents and steroidglycosides from Digitalis for the treatment of heart deficiencies. Synthetic organic chemistry received a strong push from the solution of the regio- and stereochemical questions raised by this class of compounds. The realization of the enantioselective total synthesis of several steroids on an industrial scale was a major milestone in steroid research,[1, 2] which may have falsely led many researchers to believe that this topic is now closed.

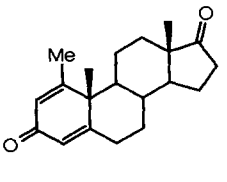
The previously mentioned effects of steroids are observed in nature and optimized in part by the results of biological and chemical research. This is not true for antihormones, which counteract the effects of hormones. Because this process is not observed in nature, no directed searches for antihormones were undertaken. Thus the discovery of the first highly active antiandrogens was purely serendipitous.[3]

Hormonal effects can be switched off by means other than through antihormones. The results of basic research on steroid biogenesis imply other methods.[4] The biogenesis of different hormones from cholesterol requires many reactions, which are catalyzed by a number of enzymes. When the exact sequence and the enzymes involved are known, one can prevent the biogenesis of a hormone by hindering a specific enzyme necessary for its synthesis.

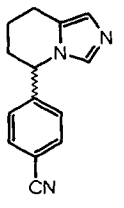
A success in this sense[5] is the development of selective aromatase inhibitors,[6] which interfere with the formation of estrogen and thus reduce its effect. Examples of aromatase inhibitors in the development of the treatment of hormone-dependent tumors are the steroids formestane **1** and atamestane **2**,[7] as well as the non-steroid fadrozole **3**.



1



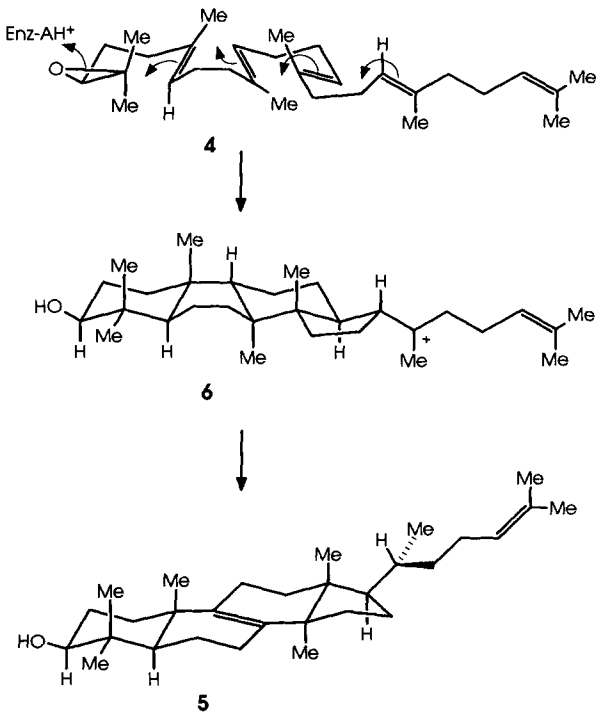
2



3

These examples show how important basic research is for the recognition of new applications. Despite the possible total syntheses of steroids and diverse partial syntheses, many questions remain unanswered. In this context the importance of several more recent reports regarding the biogenesis of steroids is apparent.

The most remarkable step in the biosynthesis of cholesterol is certainly the folding of squalene and the fourfold cyclization of 2,3-oxidosqualene (**4**) to lanosterol (**5**). This remarkable reaction is mediated by sterolcyclase in only one step (Scheme 1). The purification of this especially interesting enzyme was not achieved for a long time, because it is a membrane-bound system with low stability and solubility; however, Corey et al. recently succeeded in purifying the enzyme.[8] The key to success was the clever choice of an affinity matrix, which mimicked the hydrogen bonds and the hydrophobic frame of squalene.



Scheme 1. Fourfold cyclization of oxidosqualene **4** to lanesterol (**5**).

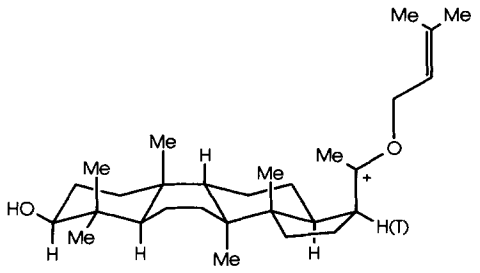
The precleaned microsomes containing sterolcyclase were concentrated by chromatography on DEAE-sepharose and DEAE-cellulose, and the active fraction was subsequently purified on the affinity column. The isolated enzyme can be stored at 0 °C at least 14 days without loss of activity. Thus, the cloning of the sterolcyclase gene and eventually the solution of the structure of the enzyme should be possible.

As long as the three-dimensional structure of an enzyme is not known, its mode of action can be studied only by treating natural or synthetic model compounds with the enzyme preparations. Changes in constitution can be studied especially well with isotopically labeled compounds. Several research groups verified the constitutional correctness of the folding of squalene by experiments with variously labeled starting material. Therefore, it is quite surprising that in this well-known reaction the stereochemistry of the 17 and 18 positions is apparently understood correctly only now.

[*] Dr. R. Bohlmann
Institut für Arzneimittelchemie der Schering AG
Müllerstrasse 170-178, D-W-1000 Berlin 65 (FRG)

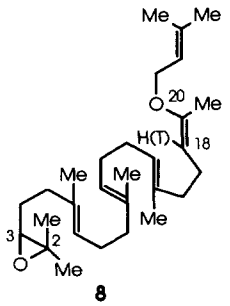
Cationic protosterol **6** derived from squalene has a side chain in the 17β position according to the latest investigations,[9] not an 17α side chain as all previous investigations assumed. This mistake made the stereochemistry of the neighboring C20 difficult to decipher. The erroneous configuration of this center would have required an unusually long 120° twist, instead of a shorter 60°, in the enzyme. In order to explain this inconsistency various hypthotheses were proposed employing "nonclassical" carbocations and so-called X groups on the enzyme.

Further support of the 17β stereochemistry in intermediate **7** of the sterol biogenesis is provided by the result of the incubation of the 20-oxa analogue **8** of 2,3-oxidosqualene.

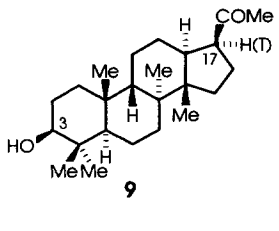


7

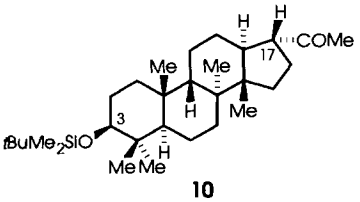
Surprisingly, the thermodynamically instable 17β-acetyl derivative **9** forms stereoselectively. Compound **9** can be converted via the 3-*tert*-butyldimethylsilyl ether to the more stable 17α isomer by heating with 1% sodium hydroxide solution at 50 °C for 2h. The 18-tritio derivative of compound **7** was also prepared and cyclized. As expected, the tritium was detected in the 17α position of the labeled **9**. The tritium was removed completely by the basic isomerization mentioned above.



8



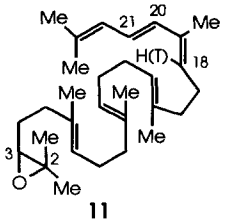
9



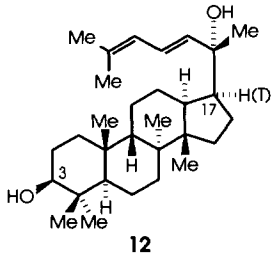
10

These results motivated new studies of the stereochemistry of the biotransformation of 20,21-dehydro-2,3-oxidosqualene (**11**).[11] These investigations showed that only the (18*E*) isomer **11** is converted by the purified enzyme into protostanediol **12**. The structure of this compound was determined from ^{1}H NMR spectra of a derivative.

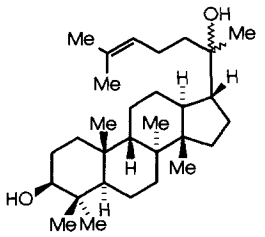
Again the formation of the five-membered ring generates the 17β side chain. The regioselectivity of the hydroxylation displays a preference for C20. With reference to the (18*E*) double bond in 20,21-dehydro-2,3-oxidosqualene **11**, the new C–C and C–O bonds formed are *trans* diaxial.



11

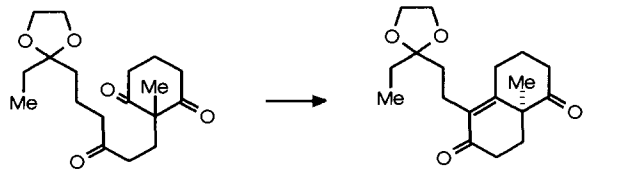


12

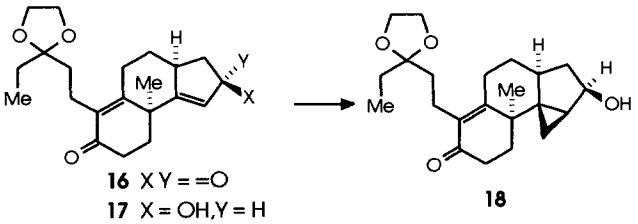


13

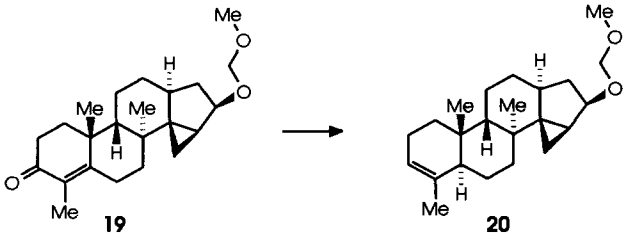
Insight into the complex mechanistic and stereochemical relationships of these reactions was made possible by elegant research in preparative organic chemistry. A new enantioselective total synthesis of protostendiol **13**[11] was developed for purposes of comparison. The enantioselective step is an aldol cyclization[12] of the triketone **14** in the presence of (*S*)-phenylalanine and (+)-camphor sulfonic acid. After a



14 **15**



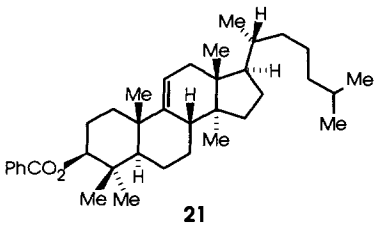
16 X Y = =O
17 X = OH, Y = H **18**



19 **20**

reaction time of 24 days at 23 °C endione was isolated in 77% yield and with 98% *ee*. Subsequent regio- and stereoselective annelation in three steps provided the tricyclic diendione **16**. One reaction in this sequence required one equivalant of mercuric chloride as a catalyst.

The molecule was elaborated further by a regio- and stereoselective reduction of enone **16** to the 16β alcohol **17**, in which the five-membered ring was set up for the introduction of the 14,15β methylene group in **18**. This group served as precursor for the 14β methyl group and also directed the introduction of the 17α side chain. In the last part of the synthesis starting from enone **19**, an allyl–diazene rearrangement[13] was used to establish the not easily accessible A/B-*trans* ring junction in **20**.



21

After a total of over 20 steps with an overall yield of less than 3% the synthesis was concluded by the conversion of **13** into dihydroparkeolbenzoate **21** and comparison with authentic material. This "success" is relative when one recalls that the natural biosynthesis of protostendiol **13** requires a single step. The simple replacement of hydrogen for a methyl group in oxidosqualene **4**, however, diverts the enzymatic pathway leading to the formation of a different product.[14]

The recent results cited here show how complex questions can be approached today by the complementary efforts in biochemistry, microbiology, molecular biology, and synthetic chemistry.

Perlithiated and Hyperlithiated Methane

By *Adalbert Maercker**

In 1983 when Schleyer, Pople, et al.[1] prophesied the considerable stability of hexalithiomethane (CLi_6) on the basis of ab initio calculations, certainly no one expected that experimental proof of this hyperlithiated methane with a hexacoordinated carbon atom would follow only a few years later. But H. Kudo[2] at the Japan Atomic Energy Research Institute achieved just this! Because the calculations are only relevant for discrete molecules in the gas phase, it was logical to search for these molecules with mass spectrometry first. It was a long journey with many setbacks,[3] and even January 1990 the goal was still far off. The method of choice was Knudsen-effusion mass spectrometry, which was previously used to detect Li_4O and Li_5O.[4] Unfortunately, the changes in the original[3] apparatus leading to those successful experiments were not reported.

Crystalline dilithioacetylene (C_2Li_2) was heated to 1000 K in a molybdenum Knudsen cell with a radio-frequency generator. The resulting mixture of gases was introduced directly under high vacuum ($< 10^{-5}$ Pa) into a quadrupole mass spectrometer through a 0.3 mm wide orifice [Eq.(a)]. Besides

$$C_2Li_2(s) \xrightarrow{1000\,K} Li(g) + Li_2(g) + CLi_3(g) + CLi_4(g) + CLi_6(g) \qquad (a)$$

CLi_3 and CLi_4, which had already been identified (although curiously in the reverse order of intensity),[3] traces of CLi_6 were detected for the first time. Three signals in the intensity ratio of 0.1 : 0.5 : 1.0 were observed at m/z 52 ($[^{12}C^6Li_2{}^7Li_4]^+$ and $[^{13}C^6Li_3{}^7Li_3]^+$), m/z 53 ($[^{12}C^6Li^7Li_5]^+$ and $[^{13}C^6Li_2{}^7Li_4]^+$), and m/z 54 ($[^{12}C^7Li_6]^+$ and $[^{13}C^6Li^7Li_5]^+$).

These signals in the expected intensity ratio were not detected in the background spectrum or when the ionization energy was less than 9 eV (the optimal setting was 13.0 eV). The mass spectrum from the original report is shown in Figure 1.

The existence of CLi_6 is thus certain; however, the theoreticians still do not agree on the bonding relationships.[1, 5, 6] Schleyer et al.[1] as well as Reed and Weinhold[5]

[*] Prof. A. Maercker
Institut für Organische Chemie der Universität
Adolf-Reichwein-Strasse, D-W-5900 Siegen (FRG)

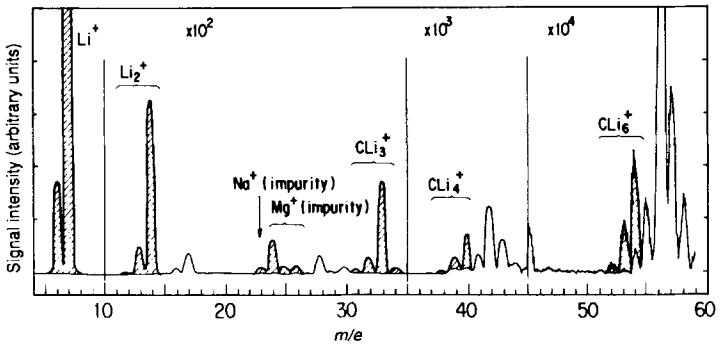

Fig. 1. Mass spectrum of the gas mixture formed from C_2Li_2(s) in a Knudsen cell at 1052 K. Shaded regions: molecular peaks; the thin line is the background spectrum.

doubt that the carbon atom is hypervalent, strictly speaking, and assign two of the total of ten valence electrons to Li–Li bonds which build a metal cage around the central atom. Ritchie[6] disregards these Li–Li bonds on the basis of Bader's electron density analysis, a method which provided rather curious results for other lithium compounds as well. Preparative organic chemists can most likely contribute little to the understanding of these findings. It should be mentioned that pentalithiomethane (CLi_5), also predicted by calculations to be very stable,[1] has not yet been found by Kudo.[2, 3] This neutral molecule should not be confused with the cation CLi_5^+, which Lagow[7] detected by mass spectrometry in 1982 from the flash vaporization of tetralithiomethane (CLi_4).

In contrast to the hyperlithiated methane CLi_6, perlithiated methane CLi_4 is accessible by synthesis; however, its preparation is by no means trivial. CLi_4 was first prepared, again in a Knudsen cell, from the cocondensation under vacuum of lithium vapor and tetrachloromethane on a cold-finger cooled with liquid nitrogen [Eq.(b)].[8] This technique although optimized still provides a maximum of 40% tetralithiomethane together with 58% $C_2Li_2$and traces of other compounds. Unfortunately, it has not yet been possible to separate the resulting mixtures of polylithiated hydrocarbons, and even the separation from the lithium matrix is difficult.[8]

$$CCl_4 + 8\,Li(g) \xrightarrow[-4\,LiCl]{750\,^\circ C} CLi_4 \xleftarrow[-4\,LiCl]{8\,t\text{BuLi/cyclopentane}} C(HgCl)_4 \qquad (b)$$

For the synthesis of larger amounts of tetralithiomethane there is currently no practical alternative to mercury–lithium exchange.[9] Tetralithiomethane is a gray, extremely pyrophoric solid. Because it is insoluble in hydrocarbons, it can be washed free of the excess *tert*-butyllithium and di-*tert*-butylmercury easily. The salt-free product can be obtained if one starts with tetrakis(ethylmercurio)methane; however, lithium chloride does not generally interfere with subsequent reactions.

Perlithiated hydrocarbons such as tetralithiomethane have been termed "lithiocarbons" in analogy to "hydrocarbons". Much more easily accessible than the perlithioalkanes are certain perlithioalkynes, since butyllithium can remove quantitatively not only the hydrogen atoms on sp-hybridized carbon atoms, but also those of the methyl group of propyne, for example [Eq.(c)].[10]

$$HC{\equiv}C{-}CH_3 \xrightarrow[hexane]{n\text{BuLi}} \underset{(75\%)}{C_3Li_4} \qquad (c)$$

C_5Li_4 can be synthesized analogously from 1,3-pentadiyne. Finally, the family of perlithiated hydrocarbons includes trivial compounds like dilithioacetylene (C_2Li_2) and dilithiodiacetylene (C_4Li_2) composed completely of sp-hybridized carbon atoms. Calculations have already been conducted for hexalithiobenzene (C_6Li_6),[11] and experimental evidence is eagerly awaited.

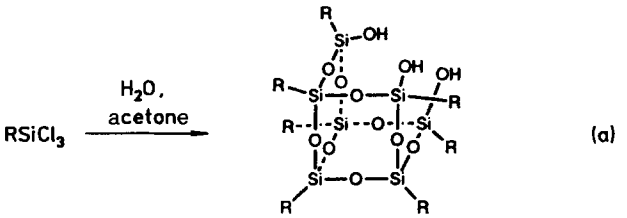
Model Compounds for Metal Oxides on SiO_2 Surfaces

By *Frank T. Edelmann**

Numerous important processes in the petrochemical industry are catalyzed by metal oxides immobilized on SiO_2 supports.[1] Highly selective catalysts of this type play a significant role in the oxidation of hydrocarbons[2] and the oxidative coupling of methane,[3] as well as in the metathesis[4] and polymerization[5] of olefins and alkynes. Despite highly refined methods of analysis, mechanistic studies and structural investigations of immobilized compounds are still extremely difficult. The exact nature of the SiO_2 surfaces themselves is often a subject of controversy.[6] Thus, much current research is concerned with the synthesis and characterization of compounds which may model the specific surface morphologies of SiO_2 supports and their interactions with metal oxides on the molecular level.

One compound that is much better suited for modeling the SiO_2 surface than Me_3SiOH or Ph_3SiOH, trisilanol **1**, was prepared by Feher et al.[7] Compound **1** is formed in the kinetically controlled hydrolysis of cyclohexyltrichlorosilane [Eq.(a)]. Under the specified reaction conditions, complete



hydrolysis of $c\text{-}C_6H_{11}Si(OH)_3$ requires about three years! However, preparatively useful quantities of **1** can be "harvested" after only a few weeks.[7] The comparison of the molecular structure of **1** (**A**) with the (111) octahedral face of the cristobalite modification of SiO_2 (**B**) reveals an astonishing geometrical relationship. Common to both structural units is a concave silicon–oxygen cavity, whose outer rim is formed by six silicon and six oxygen atoms. The arrangement of potential O-donor centers is also quite similar.

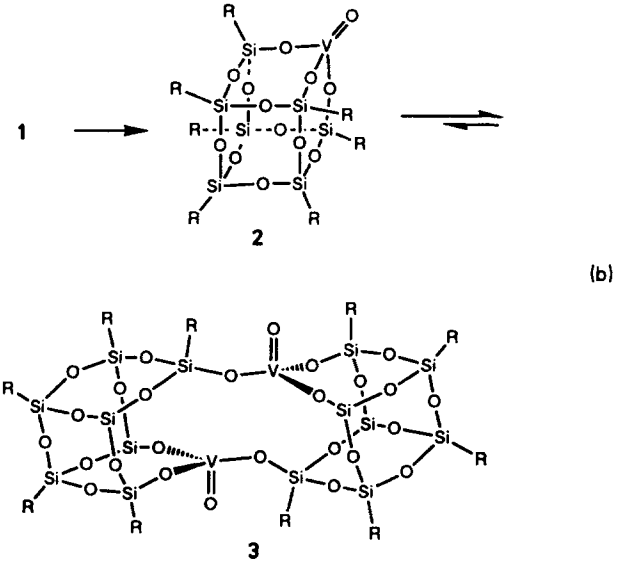
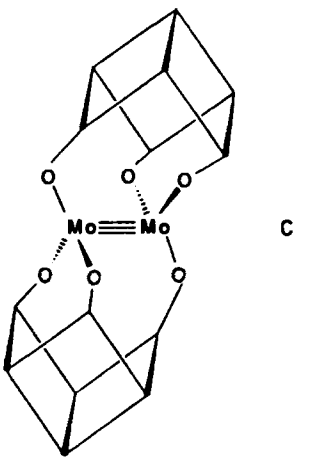
Institut für Anorganische Chemie der Universität
Tammannstrasse 4, D-W-3400 Göttingen (FRG)

*P*olyhedral *oligom*etalla*ses*qui*s*iloxanes (POMSS) are accessible by the reaction of **1** with suitable metal compounds. For example a typical POMSS, **2**, is formed in the reaction of **1** with $[(n\text{PrO})_3\text{VO}]$, $[(Me_3SiCH_2)_3VO]$, or $VOCl_3$.[9] A monomer/dimer equilibrium between **2** and **3** exists in solution [Eq.(b)]. Compound **2** can realistically be considered a



model for a vanadium-containing heterogeneous catalysts, since it is capable of polymerizing ethylene and 1,3-butadiene. In contrast, the comparable vanadiumsiloxide $[(Ph_3SiO)_3VO]$ is inactive under identical reaction conditions!



Only a few of the wealth of results are highlighted here. Parts of zeolite structures[10] as well as the silylation of silica[11] can also be modeled by **1**. The reaction of $[Mo_2(O\text{t}Bu)_6]$ with two equivalents of **1** in the absence of Lewis base results in the cleavage of all the O*t*Bu ligands and formation of the dinuclear complex **4**; the central Mo–Si

framework of **4** is shown in **C**. Here an intact Mo≡Mo unit is fixed to both SiO ligands.[12]

$[Mo_2\{(c\text{-}C_6H_{11})_7Si_7O_{12}\}_2]$ **4**

Feher's trisilanol **1** is formally a heptameric condensation product of $c\text{-}C_6H_{11}Si(OH)_3$. The direct synthesis of a model compound for metal oxides on SiO_2 surfaces from a stable silantriol was first described by Roesky et al.[13] Controlled hydrolysis of tBuSiCl$_3$ in the presence of aniline furnishes tBuSi(OH)$_3$, which does not undergo condensation, in 94% yield. Undulating layers are found in the crystal in which the silantriol units are interconnected by hydrogen bonds. tBuSi(OH)$_3$ reacts with Re_2O_7 in a molar ratio of 1:1 with condensation and substitution giving rise to the tetranuclear rhenium siloxide shown in Figure 1.

$$4\ t\text{BuSi(OH)}_3 + 4\ Re_2O_7 \longrightarrow [\{t\text{BuSiO(ReO}_4)\}_4] + 2\ Re_2O_7 \cdot H_2O + 4\ H_2O \quad (c)$$

Compound **5** is the first well-defined, structurally characterized transition-metal complex synthesized from a silantriol. Its synthesis demonstrates a new approach to preparing soluble, metal-containing silicates.

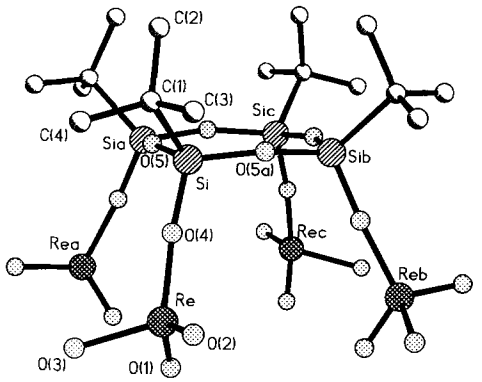


Fig. 1. Structure of **5** in the crystal.

Even the smallest of these model compounds can be considered a true highlight. Until recently metal complexes with SiO ligands were completely unknown.[14] Complexes of type $[M(SiO)L_n]$ could not be detected in matrix studies, much less be isolated.[15] A significant step in the direction towards Si analogues of metal carbonyls was achieved by Schnöckel et al. with their IR spectroscopic proof of [PdSiO] (**6**).[16] This complex is formed when SiO and palladium atoms are deposited simultaneously on a helium-cooled copper surface. According to the spectroscopic data, **6** has a linear, Si-bridged structure. The absorption band of the SiO stretching vibration is at 1246.3 cm^{-1}. The experimental and theoretical results show that the bonding relationships in **6** are comparable to those in [PdCO], that is, that in SiO ligands the σ-donor bond is also reinforced by π-acceptor contributions.

The Epidemic Spread of Fullerene Research**

By *Tibor Braun**

A recent review in this journal[1] has motivated me to share the results of our studies which examine fullerene research from a different angle.

In general the spread of new achievements in science follows a rule according to which the number of researchers attracted by the new achievement is graphically represented by an S-shaped curve.[2] At the start, diffusion of the basic idea is rather slow. After a while, a steep increase follows, and finally the "saturation" point is reached when the rate of diffusion slows down. The growth process has been described by Goffman[3,4] who modeled the transmission of ideas as an epidemic process. In general, the "epidemic" process in a medical sense is based on the conversion of a susceptible state to an infective one whereby the transition is caused by exposure to some infectious material. The process is relevant not only to infectious disease but can be generalized for many situations. All that is needed is the appropriate interpretation of the components of the process, that is, susceptible, infective, and removed populations, infectious material, intermediary host, latency period, disease, etc. People are susceptible to certain ideas and resistant to others. Once individuals are "infected" with an idea the chances are good that they may infect others after some period of time. Such a process can result in an intellectual "epidemic" (Table 1).[3] We considered the recent discovery[5,6] and outbreak of research on fullerenes a topical example of an intellectual epidemic.

Table 1. The epidemic model according to Goffman et al. [3].

Components of the epidemic process	Epidemic disease	Intellectual epidemic
Agent	Infectious material (bacteria, virus)	Idea
Infective population	Ill people	Authors of papers
Susceptible population	People who may be infected given effective contact with the infectious material	Readers of papers who may be infected given effective contact with the idea
Removal	Immunity or death	Loss of interest or death

A database on the fullerene papers published between 1980 and 1991 has been compiled using the CD-ROM version of the Science Citation Index. The compiled database is restrictive, since it includes only papers published in refereed journals. A statistical evaluation of the database was then conducted. As evident from Figure 1, the increase in the number of publication on fullerenes has been really spectacular. In Tables 2–5 the distribution of fullerene papers according to countries, institutions, authors, and journals is given.

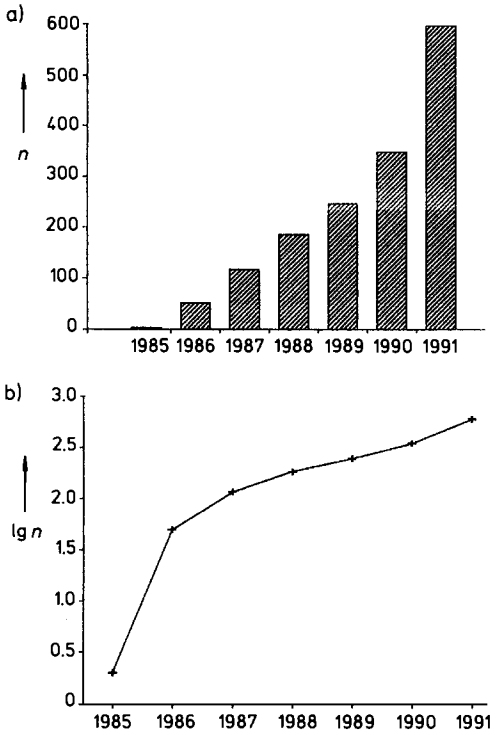

Fig. 1. Increase in the number of publications on fullerene research since 1985. a) Linear scale, b) logarithmic scale.

As expected, the USA is way ahead of the pack in the fullerene publication race with the UK, Germany, Japan, France, and Sweden in the next positions. As is often the case in basic research, most of the fullerene research has been done at universities, but as Table 3 indicates industrial re-

Table 2. Competition in fullerene research according to country.

[**] The author would like to emphasize that the data in this letter is based on and extracted from a database which is not a comprehensive bibliography of the fullerene literature. The database does include most of the research articles on this topic published in refereed journals. Editorial note: Confirmation of the data presented in the tables with two research groups active in the fullerene area revealed that the collated numbers are conservative. In any case, the trend indicated is certainly correct.

search laboratories are quite well represented. The "high flyers" among the authors are, of course, the discoverers of the fullerenes; however, the competition is not far behind (Table 4).

The first two papers on the most important advances in fullerene research were published in *Nature*. At the moment, however, the most important channels of publication are four chemistry journals (Table 5). The interdisciplinarity of the topic is nicely illustrated by the listings for the journals *Zeitschrift für Physik, Astronomy and Astrophysics, Computers and Mathematics,* and *Journal of Materials Research.*

In the epidemic model of scientific communication in the field of fullerene research, we have considered all researchers having the background necessary for becoming involved in this topic as susceptibles. In our database individuals are categorized as infectives the year their first paper is published. The total population of fullerene authors represents the infective population.

The Goffman model treats the epidemic process with a system of differential equations which describe the rates of change of the number of susceptible, infective, and removed individuals. Both stochastic and deterministic versions of the model have been discussed. Here we present a simplified

graphical version of the model by showing the change in the number of fullerenes authors (infectives) versus time. Figure 2 shows the corresponding curve (dI/dt vs. t). An epidemic growth is evident beginning in 1990.

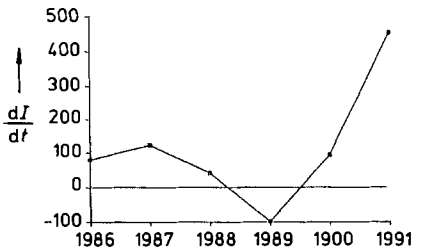

Fig. 2. Yearly increase in the the number of authors I in fullerene research.

A more complicated question to answer is who may be considered the true instigator of this epidemic. Although there was a synergetic aspect to the research beginning with the original discovery in 1985[5] and the many studies which followed, the real outbreak of the epidemic can be related to the publication of the paper on solid C_{60} by Krätschmer, Huffman, et al.[6]

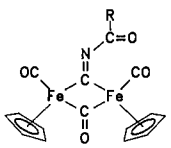
Tetraferrioazaallenium—Product of a Novel Reaction of Coordinated CN^-**

By *Wolf Peter Fehlhammer* Andreas Schröder, Joachim Fuchs,* and *Ernst-Ulrich Würthwein*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

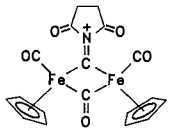
The mobility of the cyano ligand in the dinuclear complex anion $[Fe_2(CN)Cp_2(CO)_3]^-$ opens up new possiblities for its chemistry.[1] For the first time reactions can also occur at the bridging position in which the *N*-nucleophilicity of the primary terminal CN^- is drastically increased. Herein we report the aprotic cleavage of the CN triple bond with dicarboxylic acid chlorides under very mild conditions and the fixation of the resulting μ-carbidoiron fragment to a second cyanodiiron complex anion.

The alkylation and protonation of the terminal CN ligand of $[Fe_2(CN)Cp_2(CO)_3]^-$ led directly to *bridging* aminocarbyne ligands (CNR_2 and CNH_2, respectively); a monoalkylation to give the isocyanide was achieved only with bulky alkyl groups, a monoprotonation to give CNH was unsuccessful.[2a] On the other hand, even with excess acylation agent only μ-(*mono*acyl)isocyanide complexes of the type **1** were obtained,[2b] and the reaction with succinyl dichloride, in which the formation of the *di*acylaminocarbyne cation **2** should be entropically favored, yielded mainly the tetranuclear complex **3**, that is, the acylation of two cyano complex anions was favored. Oxalyl chloride, for which an intramolecular diacylation is not possible, reacted analogously to give **4**.

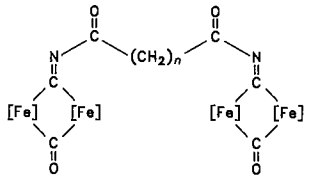


1

[Fe]=Fe(Cp)CO



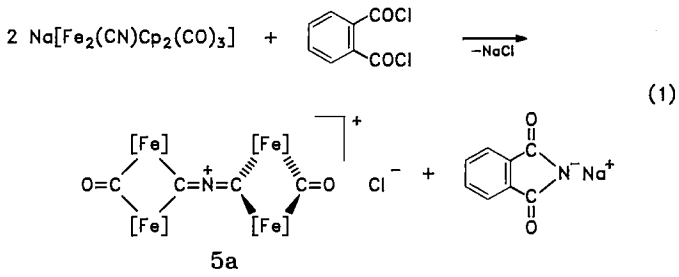
2



3 $n=2$
4 $n=0$

During the synthesis of **3** (*Experimental Procedure*) a small quantity of red crystals precipitated from the reaction solution, to which we initially attributed no significance. However, the saltlike product showed an IR spectrum with unusually few bands, reminiscent of the parent carbonyl compound $[\{FeCp(CO)_2\}_2]$, and a strikingly low nitrogen content; according to the ^1H NMR spectrum, apart from cyclopentadienyl no further organic ligands are present. Later this product proved to be identical with **5a**, the major product from the reaction of $Na[Fe_2(CN)Cp_2(CO)_3]$ with phthaloyl dichloride, which follows a completely unexpected course.

From the stable red substance **5a**, which crystallizes readily in 59% yield, the salts **5b** (anion = BF_4), **5c** (PF_6), **5d** (ClO_4), **5e** (BPh_4) can be prepared by anion exchange. The analyses of the salts gave nitrogen contents which were in agreement with only ca. 1/2 N atom per $Fe_2Cp_2(CO)_3$ unit. Together with the molecular mass of the cation determined by positive ion FAB mass spectrometry, this suggested the formulation of a CNC-bridged tetranuclear complex. We have now analyzed the often observed white growths from the red crystals and identified them as sodium phthalimide, which is plausible both chemically and from the balanced equation [see Eq. (1)].



5a

(1)

In order to assign the IR bands ^{13}C-labeled $[Fe_2(^{13}CN)Cp_2(CO)_3]^-$ was treated with phthaloyl chloride, and by the subsequent Cl/BPh_4 exchange converted into $[^{13}C]$ **5e**,

$[Cp_2(OC)_3Fe_2(^{13}CN^{13}C)Fe_2Cp_2(CO)_3]BPh_4$ $[^{13}C]$ **5e**

whose IR band at 1741 cm^{-1} shows the largest bathochromic shift ($-22\ cm^{-1}$) and thus indicates a high ν_{as}(CNC) contribution. Two singlets each for the Cp ligands in the ^1H and ^{13}C NMR spectra and two ^{13}C resonance signals of the terminal CO ligands seem at first glance to be more indicative of a bent azaallyl unit with *exo* and *endo* Fe centers than of a linear azaallenium structure with equivalent iron atoms. However, from the X-ray structure analysis of **5e**[3] the latter is seen to be the case. Figure 1 (top) shows the crystal structure of the cation of **5e**; in Figure 1 (bottom) a space-filling model of **5e** is shown. The cation is constructed from two *cis* configurated $Fe_2Cp_2(\mu\text{-}CO)(CO)_2$ units bonded through an almost linear ($\sphericalangle$ C7–N–C8 = 172.3(9)°) CNC bridge. Further clear evidence for a formulation as a tetraferrioazaallenium ion comes from the identical C7–N (1.24(1) Å) and C8–N (1.24(1) Å) distances, which are typical for CN double bonds, as well as from the angle of 87.1(1)° between the Fe1Fe2C7N and Fe3Fe4C8N planes. The

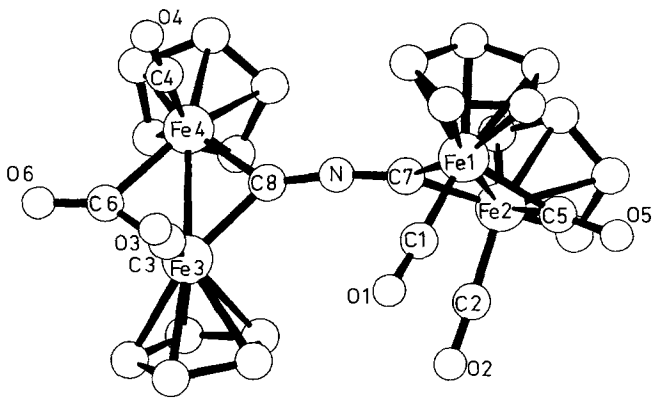
angle is halved by the C_2 axis through the N atom—the only (although not crystallographic) symmetry element of the axially chiral cation, which thus possesses *two* sets of equivalent Cp and terminal CO ligands. This structure is obviously retained in solution and is also in agreement with the previously discussed results from NMR spectroscopy.



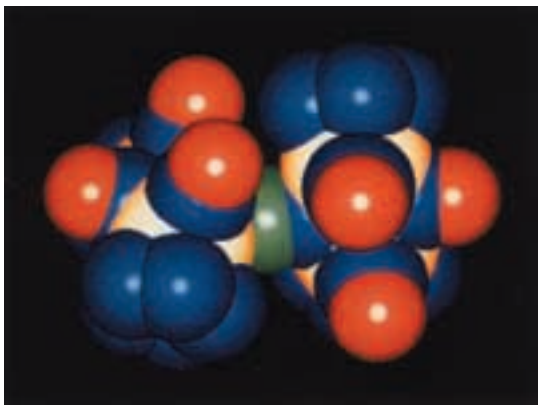


Fig. 1. Top: crystal structure of **5e** (SCHAKAL). Selected distances [Å] and angles [°]: Fe1-Fe2 2.529(4), Fe3-Fe4 2.529(4), Fe1-C7 1.900(8), Fe2-C7 1.851(9), Fe3-C8 1.916(9), Fe4-C8 1.912(10), C7-N 1.24(1), C8-N 1.24(1); C7-N-C8 172.3(9). Torsion angles [°]: Fe1Fe2C5/Fe1Fe2C7 161.9, Fe3Fe4C6/Fe3Fe4C8 166.9, Fe1Fe2C7N/Fe3Fe4C8N 87.1.
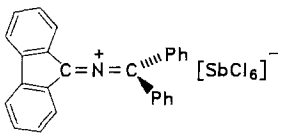
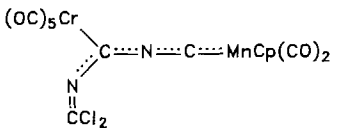
Bottom: space-filling model of **5e**. Color code: Fe (yellow), C (blue), O (red), and N (green).

Linear azaallenium ions are found both in purely organic salts such as **6**,[4a] and also in mono- and dinuclear organometallic complexes such as $[Cr(CO)_5C{=}N{=}CtBu_2]X$ ($\sphericalangle$ CNC = 171.7(4)°[5]), and **7** ($\sphericalangle$ CNC = 172.9(4)°),[6] respectively. Also calculations on the corresponding tetralithi-



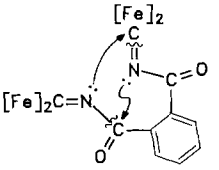
6



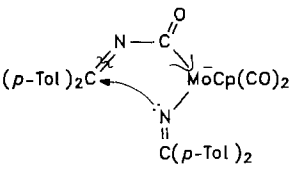
7

ated model compounds demonstrated that the cumulene form $Li_2C{=}N{=}Li_2^+$ with D_{2d} symmetry was lowest in energy. It shows almost the same C=N bond lengths (1.236 Å) as **5e**.[7] The same is true for the C=N bond lengths calculated by ab initio 6-31G* geometry optimization[8] in the parent compound 2-azaallenium $H_2C{=}N{=}CH_2^+$ (D_{2d}, 1.237 Å[9]), which are significantly shorter than those in the arene-substituted derivative **6** (1.27–1.28(1) Å[4a]). The continual preference for the cumulene over the tautomeric bent 2-azaallylium form as well as the agreement of the measured and calculated C=N bond lengths in the given examples show that substituents of metal complex fragments have no special structure-determining influence on the C=N=C framework. In contrast to this, lone pair donor substituents (-OR, $-NR_2$) result in marked C=N bond lengthening and bending at the N atom.[4b]

For the mechanism of formation of **5**, the only notable comment that can be made at this time is that the CN bond even in *mono*acylisocyanide bridges is greatly extended[10] ($[Fe_2Cp_2(\mu\text{-}CNCOC_6F_5)(CO)_3]$: C–N = 1.261(6) Å,[2b] $[Fe_2Cp_2\{\mu\text{-}CNC(O)SEt\}(CO)_3]$: C–N = 1.24(1) Å[11]), and consequently the most likely event upon *di*acylation is a CN bond cleavage. However, since there is no evidence at all for the existence of *N-di*acylated cyano bridges, we favor a reaction pathway via the bis(μ-acylisocyanide diiron) complex **8**.[12]



8



9

A similar mechanism was formulated for the distantly related azaallenium formation from a ketimide and $[Mo(Cl)Cp(CO)_3]$, in which the latter plays the role of phthaloyl dichloride. CN bond cleavage and new linkage probably take place in this mechanism in a 2:1 (ketimide/Lewis acid) adduct **9** with the variation that the heterocumulene remains π bonded in the complex assembly and the formally triply negatively charged N atom is again found in the cyanate byproduct.[13] Finally a 2:1 (*N*-acylaldimine/Et^+) intermediate analogous to **8** was proposed for the alkylation of *N*-benzylidene carboxamides, which leads to higher and lower oxidized 2-azaallenium salts by a formal disproportionation.[14]

Furthermore, interesting parallels can be drawn between [Eq. (1)] and the transformations of CO in clusters as well as on surfaces. These reactions, studied particularly in connection with the Fischer–Tropsch synthesis, are also characterized by a primary (e.g. acyl-supported (!)[15, 16]) C≡O bond cleavage, which however generally leads to *isolable* μ-carbido complexes.[17] However, reaction sequences of the form schematically summarized in Equation (2) occur whose formal similarity with the reaction sequence discussed here [Eq. (3)] is very surprising.[18]

$$[M_x]CO \rightarrow [M_x]\,C \xrightarrow{CO} [M_x]CCO \qquad (2)$$

$$[Fe_2]CN\{\rightarrow [Fe_2]C\} \xrightarrow{NC[Fe_2]} [Fe_2]CNC[Fe_2] \qquad (3)$$

Experimental Procedure

3 (**5a**): To $Na[Fe_2(CN)Cp_2(CO)_3]$ (1.00 g, 1.80 mmol)[1] in THF (40 mL) at −60 °C was added succinyl dichloride (140 mg, 0.90 mmol). The green solution changed immediately to red. Within 3 h a small amount of a bright red precipitate was formed, which was collected on a cooled frit (−30 °C) and dried under vacuum. This substance was identical with **5a** (see below). The filtrate was concentrated to dryness, and the residue was first precipitated from THF/ether, then recrystallized from a concentrated THF solution at −78°. This resulted in

a dark red powder (260 mg, 37%; m.p. 176–180 °C), which from analysis contained 2 mol THF. IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 1989 vs, 1966 s, (ν($CO_{term.}$)), 1802 vs, br (ν($CO_{bridging}$)), 1727 s (ν(C=O)), 1685 s, br (ν(CN)); MS (80 eV, inlet temperature 150 °C): *m/z* 788 (5%) [M^+], 760(4), 732(2), 704(3) [$M^+ - n$CO, n = 1–3], 436(8), 408(4), 380(11) [$Fe_2Cp_2(CO)_nCNR^+$, n = 3–1], 268(12) [$Fe_2Cp_2CN^+$], 242(33) [$Fe_2Cp_2^+$], 186(100) [$FeCp_2^+$].

5a: A vigorously stirred solution of Na[$Fe_2(CN)Cp_2(CO)_3$] (1.00 g, 1.80 mmol) in THF (40 mL) was treated with phthaloyl dichloride (185 mg, 0.90 mmol) in THF (10 mL) at −60 °C. Within a few minutes the solution changed from green to dark red and was then allowed to warm to room temperature. The mixture was stirred for 4 h, the solvent then removed under vacuum, and the residue taken up in acetone and filtered. By the addition of a little ether an off-white product settled out initially. It was identified as sodium phthalimide by comparison with an authentic sample. Further addition of ether led to the precipitation of dark red **5a** (770 mg, 59% yield; m.p. 210 °(decomp.)), which was recrystallized from acetone/*n*-hexane. IR(THF): $\tilde{\nu}$ [cm^{-1}] = 2001 vs, 1964 s (ν($CO_{term.}$)), 1826 s (ν($CO_{bridging}$)), 1777 vs, br (ν(C=N=C)); ^{1}H NMR (270 MHz, CD_3OD, 25 °C): δ = 5.52, 5.25 (both s; Cp); positive-ion FAB-MS (DMSO/glycine/xenon/5 × 10^{-5} Torr): *m/z* 690 (19%) [M^+], 662(6), 634(29), 606(9), 578(11), 550(17), 522(8) [$M^+ - n$CO, n = 1–6], 513(7), 485(10), 457(14), 429(20), 401(8) [$Fe_3Cp_3(CNC)(CO)_n^+$, n = 4–0], 324(43) [$Fe_2Cp_2(CN)(CO)_2^+$], 268(21) [$Fe_2Cp_2CN^+$], 186(100) [$FeCp_2^+$], 147(22) [$FeCpCN^+$].

The complexes **5b**–**5e** were prepared from **5a** by anion exchange with the corresponding alkali metal salts in methanol. **5e**: brick-red rhombic crystals, m.p. 240 °C (decomp.). $\tilde{\nu}$ [cm^{-1}] = 2011 vs, 1983 s (ν($CO_{term.}$)), 1834 s (ν($CO_{bridging}$)), 1774 vs, br (ν(C=N=C)), 1600 m, 1549 m (ν(Ph)); ^{1}H NMR ([D$_6$]DMSO): δ = 7.32–6.78 (m, 20 H. Ph), 5.61, 5.29 (both s, 20 H; Cp); ^{13}C NMR ([D$_6$]DMSO): δ = 261.3 (C=N=C), 259.6 ($CO_{bridging}$), 210.8, 209.9 ($CO_{term.}$), 135.5, 125.2, 121.4 (Ph), 90.3, 89.7 (Cp).

All new compounds gave correct elemental analyses (C,H,Fe,N).

Photodimerization of Cinnamic Acid in the Solid State: New Insights on Application of Atomic Force Microscopy**

By *Gerd Kaupp**

Still in its infancy, atomic force microscopy (the abbreviation AFM is also used for the atomic force microscope)[1] is an extremely sensitive surface imaging technique suitable for studying organic solid-state reactions. The microscope scans surfaces with atomic tips to give images of van der Waals forces or contours of constant van der Waals forces with magnification up to atomic resolution. An important field of research is the photochemistry of organic crystals.[2] The application of AFM promises new insights into this field where, especially for topochemically allowed photoreactions, information is urgently required, because these conversions mostly do *not* proceed topotactically. Furthermore, multiproduct topochemistry[3] and many exceptions to topochemistry are known.[4, 5] Finally, the formation of new crystalline or amorphous phases are traditionally *not* treated by topochemistry even if a "reaction cavity principle" is additionally invoked; instead solid solutions are suspected, without proof, up to high conversions (e.g., 50%).[4]

Since AFM studies on gas/solid reactions have revealed six fundamental mechanisms for phase transformation (formation of flat coverings, volcanoes, craters, floes, valleys/ridges, and propagating zones),[2b, 6] the formation of new crystalline phases[7] during the classic reactions of topochemistry was an obvious choice for investigation. These are the photolyses of α-*trans*-cinnamic acid (α-**1**) to form α-truxillic acid (**2**) and of β-*trans*-cinnamic acid (β-**1**) to form β-truxinic acid (**3**).[7]

We now report our AFM observations, which confirm the existence of surface reactions involving substantial material

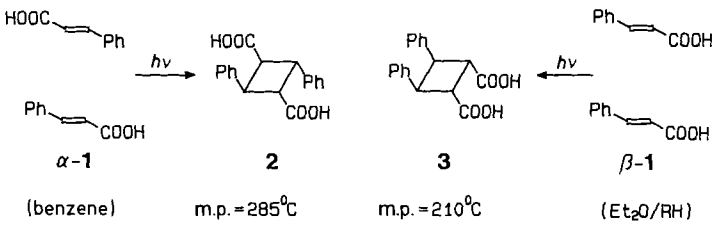
transport during the phase transformation, although at exactly this point minimal atomic and molecular movement has been postulated.[2a, 7]

If the smooth, shiny (010) faces of single crystals of α-**1** are irradiated ($\lambda > 300$ nm), not only α-truxillic acid (**2**) forms,[7] but also an as yet unknown minor product (2–3% at 0–70 °C);[8] however, no benzaldehyde or (*Z*)-cinnamic acid is observed. Modification β-**1** affords β-truxinic acid (**3**) as overwhelming major product. Under the best possible control of the phase purity of β-**1**, **3** and **2** are obtained in 96:4 ratio by exposure to sunlight while maintaining the temperature at 20 °C (β-**1** → α-**1** conversion takes place above 45 °C).[7] Our surface photolyses at 0–20 °C confirmed that besides **3** and a little of **2**, no other dimer is formed from β-**1**. Traces of (*Z*)-cinnamic acid are formed only when the reaction is far advanced (0.75% at 50% conversion), and again no benzaldehyde can be detected. The photolyses are thus highly selective, and contamination by side products is almost entirely suppressed.



When the largest surfaces of the crystals are mounted as near horizontal as possible in the AFM (<10° deviation), the progress of the reaction involving phase transformation can be followed for very low conversion by direct scanning of the van der Waals surface.[8] The (010) surface of the single crystals of α-**1** is very smooth (Fig. 1a). Low steps and hills (< 40 nm) can be recognized. The hills grow on exposure to air in three days, up to three times their original height, and are probably composed of hydrated **1** (see below). On irradiation (1 min) of the fresh surface, in contrast to previous suppositions,[7, 9] an oriented surface reaction occurs (Fig. 1b,c), which forms a thin covering on the surface. This is divided into zones by parallel furrows, which intersect the *c* axis at an angle of about 45°. The trenches which probably compensate for a density increase after the photoreaction (density of the crystals according to X-ray analysis: α-**1** 1.242;[7] **2** 1.35 g cm^{-3}[9]) are 1600–3200 nm apart. Thus, a horizontal material transport takes place during the formation of the new crystalline[7] phase. According to the depth of the trenches (Fig. 1b, c), the new phase is approximately 100 nm thick, corresponding to about 300 molecular layers, which is the initial penetration depth of the 313 nm light that predominantly causes the excitation under the given reaction conditions.[8]

Perpendicular to the major furrows and emanating from them, ice-floelike upheavals begin to form (vertical transport components) (Fig. 1b,c), which on further photolysis (10 min, separate experiment) develop into layered plates about 100 nm thick (Fig. 1d). However, this makes the crystal cloudy, permeated with cracks parallel to the original trenches, and it can only be scanned with the AFM at a few places at this stage.[2b] The clearly directed transport processes cannot be explained by the topochemical reaction cavity principle and would not be expected on that basis.

Figures 1b–d are not artifacts caused by hydration of the product. Figure 1e shows that hydration occurs to a small extent after exposing the sample of Figures 1b,c to air for 3 h.[10] In this process, volcanolike[2b, 6] hills up to 100 nm high (gas/solid reaction[11]) are formed. Also at this point, the solid material—according to the powder records in reference [7] it is crystalline—can be scraped off with a needle under the stereomicroscope parallel to the main crystal face.

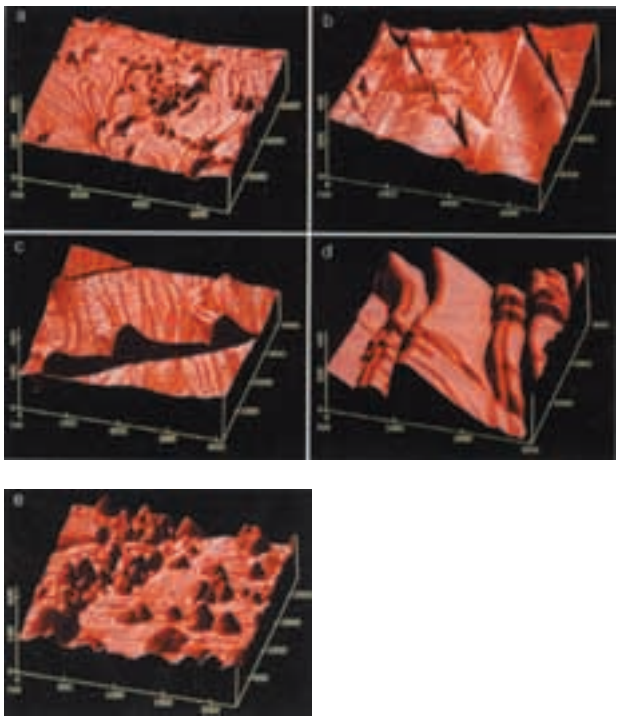


Fig. 1. AFM images of the main crystal face (010) of α-**1**: a) fresh, b) 0° after 1 min irradiation, c) 180° after 1 min irradiation, d) 90° after 10 min irradiation, e) surface 1b,c after 3 h exposure to air at 18 °C.

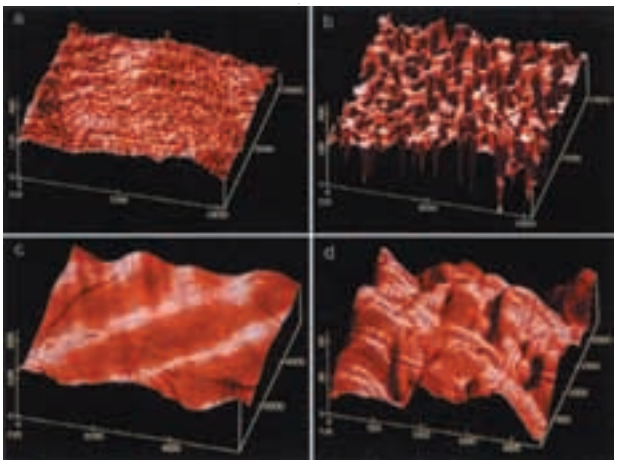

Fig. 2. AFM images of the main crystal face (100) of β-**1**: a) fresh, b) after 1 min irradiation, c) after 7 min irradiation, d) surface 2c after 10 h exposure to air at 18 °C.

In the case of β-**1**, both the main surface (100) and the almost half as wide side edge (010) can be studied with AFM. Figures 2a and 3a show that there are considerable differences. The main face is smoother (Fig. 2a), while the narrow edges reveal a floelike structure (Fig. 3a). Both in air and under high vacuum the irradiation (1 min) of the main face leads to crater formation (Fig. 2b), that of the side edge to

volcano formation (Fig. 3b). This is accompanied by substantial material transport. The typical crater depths are 200 nm for a diameter of 500 nm, and the volcanoes are about 400 nm high. Interestingly, complementary phase transformations thus take place on crystal surfaces perpendicular to each other. On further irradiation (7 min) complete leveling of both surfaces occurs. At this point, therefore, material is very effectively transported vertically in the direction of the original crystal faces (Fig. 2c, 3c). These unexpectedly complicated surface transformations could not be predicted from the topochemical reaction cavity principle.[4] They are good starting points for the elucidation of the molecular mechanism of material transport on photolysis,[12] as are the characteristic differences in the crystal faces before irradiation (Fig. 2a, 3a).

Surprisingly, even after photolysis the characteristics of the irradiated main and side faces are different. This suggests that different phases of β-truxinic acid (**3**) are formed. After 10 h hydration[10] in air, extended hills and valleys (Fig. 2d) or round craters (Fig. 3d) are observed as typical gas/solid reactions.[6, 11] No detailed interpretation of this remarkable difference is yet possible.

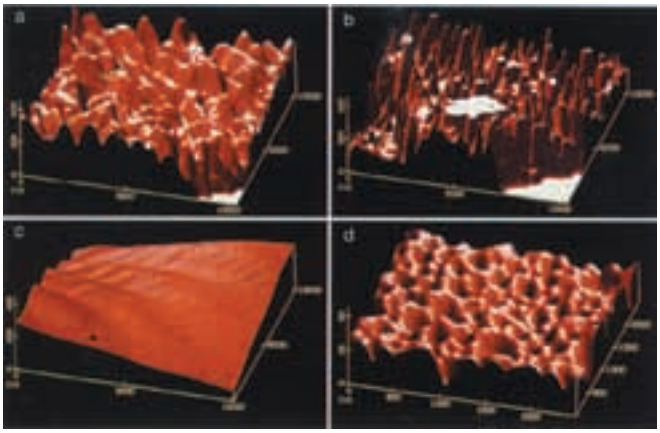

Fig. 3. AFM images of the side face (010) of β-**1**: a) fresh, b) after 1 min irradiation, c) after 7 min irradiation, d) surface 3c after 10 h exposure to air at 18 °C.

The AFM results show that photoreactions on solids take place on the surface when irradiation is selective. Compression by the crystal environment is not apparent even for low conversion. It appears that the chemical formation of new phases for photoreactions and gas/solid reactions are related processes.[6] Since the light does not penetrate very deeply into the crystal and has considerable intensity gradients, the progress of the photodimerization reaction as surface reaction that proceeds increasingly toward the interior of the crystal when the photoproducts do not absorb is probable in any case, whether topochemically "allowed" or "forbidden".[13] The AFM images are immediately discernible and open up completely new, unexpected details that cannot be obtained with other techniques (including electron microscopy). Clearly atomic force microscopy is a technique with which processes hardly understood till now can be studied, in particular new phase formation in crystal reactions under the common (and even preparative) practices of selective irradiation, because here the important details for the mechanism are not averaged out as, for instance, in X-ray structural analyses but are directly visible and interpretable.

From the crystal packing determined by X-ray methods, the orientation that has a geometric advantage for the reaction can be deduced, in particular for long, extended molecules. X-ray structural analysis is the method of choice for the study of the very rare single crystal to single crystal photodimerizations[14] and provides densities as well as molecular orientations that are extremely significant for the interpretation of phase transformation mechanisms. Nevertheless, with the unsuspected and remarkable transport phenomena made visible by AFM, the many exceptions[3–5] to the topochemical postulate become easier to understand. From here a new beginning is possible.

Kaupp, **1983**, unpublished; our analysis shows the necessary twofold symmetry that is not present in results published later, but essentially agrees with these in all other details (in contrast to the product distribution and the interpretation of their results): C. R. Theocharis, W. Jones, J. M. Thomas, M. Motevalli, M. B. Hursthouse, *J. Chem. Soc. Perkin Trans. 2* **1984**, 71–76; H. Frey, G. Behmann, G. Kaupp, *Chem. Ber.* **1987**, *120*, 387–393; G. Kaupp, H. Frey, G. Behmann, *ibid.* **1988**, *121*, 2135–2145; S. Mohr, *Tetrahedron Lett.* **1979**, 3139–3140; *ibid.* **1980**, 593–594.

[4] This inability is particularly noticeable for the photodimerization of anthracene and 9-anthracenecarbonitrile: see the discussion in M. D. Cohen, *Angew. Chem.* **1975**, *87*, 439–447; *Angew. Chem. Int. Ed. Engl.* **1975**, *14*, 386–394; M. D. Cohen, *Mol. Cryst. Liq. Cryst.* **1979**, *50*, 1–10. In the "reaction cavity principle" formulated there it is postulated that the product molecules must fit into the cavity as well as possible for solid solutions to form in the starting crystal, and that the product crystallizes out when the solubility limit is exceeded. For cinnamic acid, it is suspected that up to 50% conversion might occur prior to recrystallization.

Photodimerization of Anthracenes in the Solid State: New Results from Atomic Force Microscopy**

By *Gerd Kaupp**

The technique of atomic force microscopy (AFM) enables the phase transformations in topochemical photoreactions to be studied in detail for the first time.[1] The elucidation of the dimerization reaction of anthracenes seems to be most important, because here the most serious violations of the topochemical rules are observed. Already the [4 + 4] photodimerization of anthracene is topochemically forbidden.[2] Anthracene derivatives that crystallize in the α type, for example 9-Cl-, 9-Br-, 9-CH_3-, 9-CO_2CH_3-, and 9-$CONH_2$-anthracene,[3] give the topochemically allowed head/tail dimers. On the other hand, only two of the anthracene derivatives crystallizing in the β type, 1,5-dichloro- and 1-(2,4-dichlorophenyloxycarbonyl)anthracene form the anticipated head/head dimers. The β type crystals of 9-Cl-, 9-CHO-, and 9-CN-anthracene yield exclusively the "wrong" head/tail photodimers, and many other β type crystals such as 9-Br-, 9-CO_2CH_3-, 9-CO_2H-, and 1,10-dichloroanthracene are photostable despite favorable intermolecular distances.[3] The attempts at explanation up to now [4, 5] have not implicated the formation of the new phases and mention the possibility of surface reactions only sporadically. We report here on phase transformations on the crystal surface of typical anthracene derivatives that are observed by atomic force microscopy upon selective irradiation into the long-wavelength absorption band. Such irradiation techniques have been used in all previous investigations.[5] We found no fundamental differences between topochemically allowed and forbidden reactions, but in all cases observed formation of new phases that build features that look like floes.

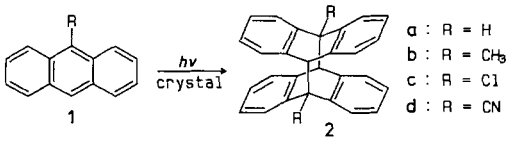
Anthracene (**1a**) crystallizes from ethanol in monoclinic prismatic scales. The main crystal face (001) reveals small corrugations and 2–4 nm high steps under the AFM (Fig. 1a). After two minutes irradiation in air or under high vacuum, the dimer **2a** forms, in spite of being topochemically forbidden.[2] Figure 1 shows clearly that the phase change



of the crystalline product involves substantial vertical transport of material (perpendicular to the a/b plane). Hilly ridges up to 16 nm high form along the steps, while at the foot of each step a furrow appears. Since the reaction **1a** → **2a** is not accompanied by a decrease in the density (the density of monoclinic anthracene calculated from X-ray structural analysis is 1.24,[6] that of orthorhombic dianthracene, 1.28[7]), horizontally layered material is piled up on the original steps. On longer light exposure (5 and 12 min) the hills grow to a maximum height of about 50 nm, merging together increasingly to form floes (Fig. 1c, d). The surface material becomes

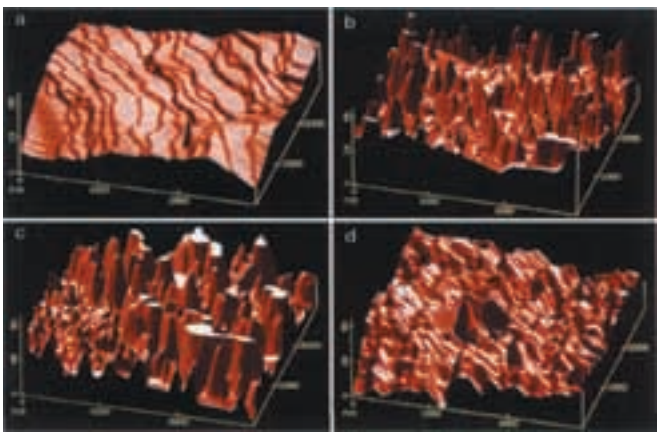


Fig. 1. AFM images of the main crystal face (001) of **1a**: a) fresh; b) after irradiation for 2 min; c) after irradiation for 5 min; d) after irradiation for 12 min.

easily detachable under the stereomicroscope. The penetration of the photochemically active light (predominantly λ = 365 nm) can be estimated to about 200 nm if an ε value of about 7000, that is, comparable with solution spectra, is assumed for the solid-state absorption.[8] The molecular regrouping takes place within this range, and only then does the light penetrate into deeper layers.[9] Figure 1 contains much more direct information than electron microscopy images with 9000-fold magnification, in which the origin of slightly changing contrasts is unclear.[10]

To exclude thermal effects during photolysis and to demonstrate the reliability of the AFM measurements the nonreactive anthracene-9-carboxylic acid **1**, R = CO_2H (crystallized from CH_3OH, platelets, main crystal face (100); Fig. 2a, b), and 9,10-dibromoanthracene (from benzene, triclinic, main crystal face (010); Fig. 2c, d) were irradiated. Identical images were obtained before and after exposure to

light in air for 20 and 30 minutes, respectively, even at high sensitivity, and the same sites of the crystals could be found again.

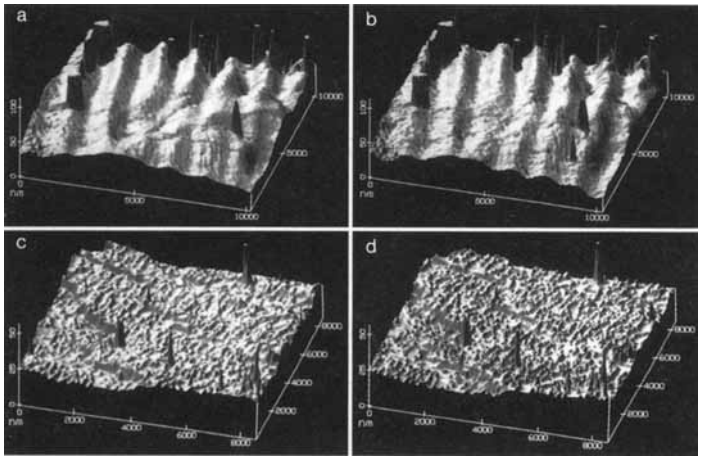

Fig. 2. AFM images of the main crystal faces of 9-anthracenecarboxylic acid (100) a) before and b) after irradiation for 20 min and of 9,10-dibromoanthracene (010) c) before and d) after irradiation for 10 min.

The derivatives 9-methylanthracene (**1b**, monoclinic prisms from toluene) and 9-chloroanthracene (**1c**) crystallize in the α type, pairing head to tail, and yield—as predicted from topochemical considerations—the head/tail photodimers **2b**[11] and **2c**, respectively. Here too, substantial transport processes are shown to take place in the vertical direction from the beginning of the exposure. Although the (100) face of **1b** is quite rough, Figures 3a and b depict very clearly already after 1 min irradiation hill- and floelike growths of considerable height (up to 150 nm). Longer exposure times (5 min, Fig. 3c) do not increase the height but the breadth of the ridges. The greater magnification at the same stage (Fig. 3d) shows the presence of well-formed floes clearly separated, which form an easily detachable white crust.

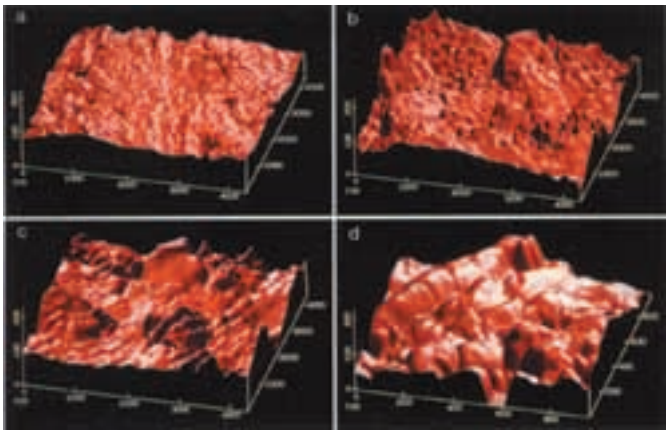

Fig. 3. AFM images of the main crystal face (100) of **1b**: a) fresh; b) after irradiation for 1 min; c), d) after irradiation for 5 min.

Cracks can now be seen under the stereomicroscope. The assumption of minimal atomic and molecular movement during the formation of solid solutions in the crystal's interior[2] can clearly *not* be supported by these observations.

In 9-chloroanthracene (**1c**, platelets from dichloroethane) the floe formation is particularly pronounced when the morphologically dominant face (interplanar spacing $d =$ 7.015(4) Å; a clearcut assignment to one of the two reported modifications of **1c**[3] was not possible) is irradiated for 1 min (Fig. 4). The floes are slightly tilted and at different heights up to 80 nm take on a preferred direction. After 5 min irradiation this direction is approximately maintained, but the floes have become much more substantial and have partly merged. Thus, a horizontal transport immediately follows the vertical, and in this second phase of the reaction the photodimerization in and on the floes is probably completed.

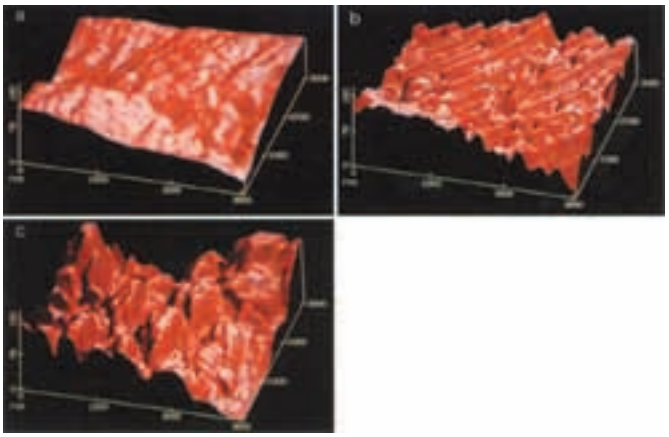

Fig. 4. AFM images of the main crystal face (100) of **1c**: a) fresh; b) after irradiation for 1 min; c) after irradiation for 5 min.

Till now the behavior of 9-anthracenecarbonitrile (**1d**), which crystallizes in the β type, seemed the most difficult to understand, since despite favorable topochemical prerequisites, instead of the head/head dimer the "wrong" head/tail dimer **2d** is formed.[3, 11] In Figure 5 it is apparent that already after 1 min irradiation, ridges of quite different heights (30 or 200 nm) develop with a preferred direction approximately along the original corrugations. These grow and finally form more and more pronounced floelike structures (Fig. 5),

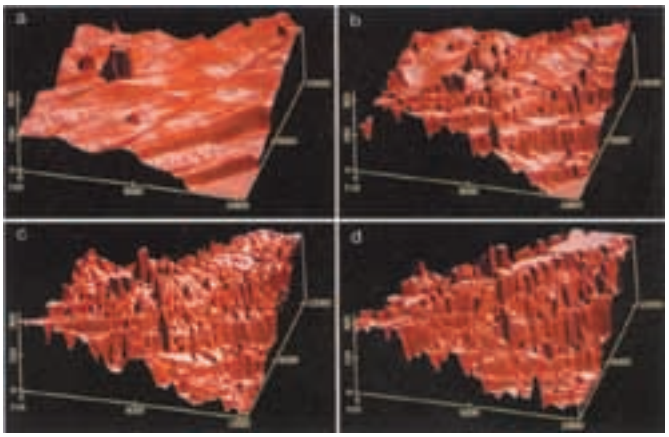

Fig. 5. AFM images of the (010) face of **1d**: a) fresh; b) after irradiation for 1 min; c) after irradiation for 6 min; d) after irradiation for 20 min.

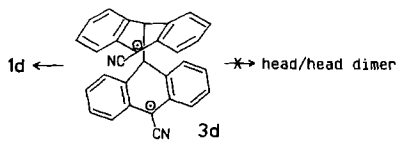
analogous to the behavior **1a**, **b**, and **c**. The densities determined by X-ray crystallography are 1.30 for orthorhombic **1d**[12] and 1.309 for triclinic **2d**.[13] Thus here, irrespective of the crystal system, there is no special mechanism, as might have been presumed, because in this reaction every second anthracenecarbonitrile molecule must formally rotate through 180°.

The AFM results reemphasize[1] that photoreactions of solids take place at the surface, when the long-wavelength band is selectively irradiated. Again, compressions by the crystalline environment do not play a decisive role even at low conversion. This makes quite plain that new phase formations must not be overlooked in the elucidation of solid-state photolyses. Also one must consider that despite a complete reorientation of the molecules (Fig. 1, 3, 4, 5) the packing of the original molecules in the crystal definitely provides an advantage in regioselectivity, which is indeed taken advantage of when no opposing factors override and when additional electrostatic effects (in the corresponding head/tail diradical, in contrast to **3d**) favor the ring closure.

Although the density is not decreased in these photodimerizations, local pressure nevertheless apparently builds up in the stacklike crystals of **1**,[3] which finally leads to reorientation and transport vertical to the largest faces of the original crystals. The resulting dimers **2** are thicker and shorter than the flat disks of **1**, which leads not to volcano[1] formation but to floe formation when the original surfaces are broken preferably at weak points. Figures 1, 3, 4, and 5 show this feature for the first time in rich detail for real (not averaged) surfaces.

On the basis of these AFM images showing comprehensive transport phenomena, it is not surprising that the anthracene reaction centers situated far apart[2] can come together for reaction.[14]

The explanation for the complete absence of the head/head dimer of 9-anthracenecarbonitrile in favor of **2d**[3] must be founded in the known diradical mechanism[15] and its polar effects:[16] the diradical **3d**, while favored electronically and also by the crystal packing, has the disadvantage of electrostatic repulsion on bond formation between the two radical centers. It would therefore rather cleave to form two molecules of **1d**. A permanent chemical change only occurs when two molecules of **1d** meet in opposite orientations of the crystal packing. Apparently the versatile transport phenomena provide ample opportunity. Alternatively, the same result could be achieved if a labile head/head dimer (see [11]) forms as intermediate from **3d** in low yields and initiates the phase transformation (as occurs with the isolable dimers **2**) to finally decompose thermally via **3d** (see also [5]).



These results of AFM investigations lay the foundations of new, more comprehensive theories on the reactivity of organic crystals. The static picture of crystal reactivity as deduced from X-ray crystallography must be complemented by the dynamics of phase transformation. Such dynamics could be deduced from X-ray crystallography only in the case of single crystal to single crystal or at least topotactic conversions. Further knowledge of nontopotactic reactions will be gleaned from irradiation with polarized light of different intensities and through the as yet technically unattainable AFM study of very narrow crystal edges.

Experimental Procedure

For details of the AFM measurements, see [1]. The crystals were grown from saturated solutions by slow evaporation of the solvent at room temperature, separated by suction, and washed. Selection was aided by a stereomicroscope. The crystal was mounted directly on the AFM with its main face horizontal and irradiated at a distance of 5 cm with a Hanau 150 W Hg high-pressure lamp through Solidex at 18 °C or under high vacuum at a distance of 15 cm at 0 °C for eight to ten times longer. All measurements were repeated several times with fresh crystals. After the measurements at the original site, other sites of the same surface were examined to ensure that the photoreaction took place everywhere and was not perhaps limited to special regions. Analysis of the products was undertaken by HPLC on material scraped from the irradiated crystal. For preparative control experiments, ^{1}H NMR spectroscopy was employed. Only a negligible amount of anthraquinone formation occurred on exposure to air (< 5% of the conversion in all cases).

To determine the Miller indices of the crystal face, several single crystals were introduced into an X-ray diffractometer (Philips PW 1800) in the same orientation as for the AFM measurements. The *d* values were determined and the surface parameters calculated from the known lattice parameters.

[5] G. Wegner proposed that single crystal to single crystal transformations be attempted by irradiation into the outermost absorption edge. It remains to be seen whether in this way the space group of the starting crystal is also fixed in the dimer (which always crystallizes in a different space group), or whether the "correct" head/head dimer of **1d** forms.

Cyclometallaborazines: Borazines with Metal Atoms as Ring Building Blocks: $PhB(MeN)_3(TiCl_2)_2$**

By *Hans-Joachim Koch, Herbert W. Roesky,* Rakesh Bohra, Mathias Noltemeyer,* and *Hans-Georg Schmidt*

Dedicated to Professor Anton Meller on the occasion of his 60th birthday

Borazine was first reported by A. Stock and E. Pohland in 1926.[1] The number of borazines substituted at the ring framework is legion. However, to our knowledge no derivatives are so far known, which contain transition-metal atoms as building blocks in the borazine framework. Only quadrinomial boron-containing metallacycles have already been reported.[2-4]

Methyl-bis[(methyl(trimethylsilyl)aminophenyl)boryl]-amine (**1**), prepared by Nöth et al.,[5] served as the starting material for the synthesis of the target compound and should react with titanium halides via ring closure to give **2**. However, the reaction of **1** with titanium tetrachloride in the molar ratio 1:1 in $CHCl_3$ did not afford **2**, but led instead to a red-brown powder **3** and the substituted borazine **4**[6] in almost quantitative yields (49% each) [Eq. (a)].

We obtained deep red crystals of **3** from THF (also soluble in MeCN) which were suitable for X-ray crystallography. The results of the structure analysis are shown in Figure 1.[7]

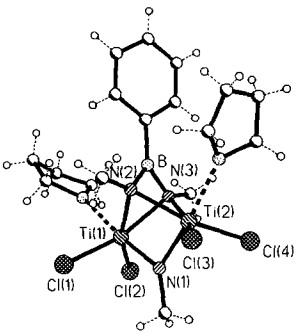

Fig. 1. Crystal structure of **3** with two coordinated THF molecules. Selected distances [pm] and angles [°]: Ti(1)-Ti(2) 273.6(1), Ti(1)-N(1) 188.9(3), Ti(1)-N(2) 212.8(3), B-N(2) 145.3(6), B-N(3) 144.7(5), Ti(2)-N(1) 186.3(3), Ti(2)-N(2) 213.5(3); Ti(1)-N(1)-Ti(2) 93.6(1), Ti(1)-N(2)-Ti(2) 79.9(1), Ti(1)-N(3)-Ti(2) 79.7(1).

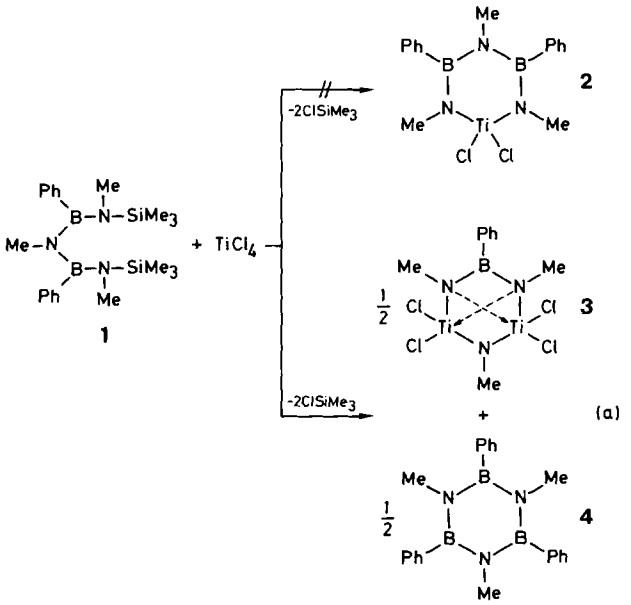
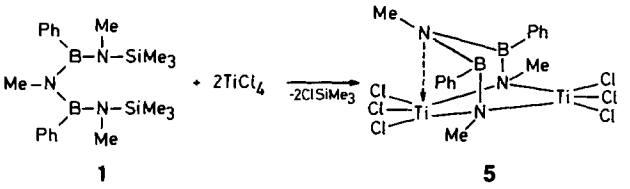
These confirm that **1** reacts with titanium tetrachloride via the insertion of two titanium dichloride units to give **3**. An increase in the yield of **3** cannot be achieved by the reaction of **1** and titanium tetrachloride in the ratio 1:2. Also, a by-product, which could explain the reaction pathway could not be isolated. Only a change in solvent from $CHCl_3$ to hexane led to the unstable intermediate **5**.





Together with **5**, compound **4**, traces of **3**, and a red-brown TiN-containing polymer were also formed. Compound **5** is yellow, crystalline, and is obtained in a yield of 17.5%. The crystal structure analysis showed two molecules of **5** in the asymmetric unit.[8]

On the basis of the structures of **3** and **5** (Fig. 2) as well as the experimental results the following reaction sequence seems plausible: in the first step, **1** reacts with two equivalents of titanium tetrachloride to give **5**. Compound **5** then decomposes very rapidly via an S_{Ni} reaction to give **3** and one equivalent of $PhBCl_2$. The $PhBCl_2$ then reacts with a further equivalent of **5** to give **4**, whereby two equivalents of titanium tetrachloride are liberated which themselves then react again with **1**.

The structure of **3** can be described as a geometric body whose surface consists of four, bent, irregular squares, or as a tetrahedron whose apexes are N(2), N(3), Ti(1), and Ti(2), which on the N(2)–N(3) edge is bridged by a boron atom and on the Ti(1)–Ti(2) edge is bridged by a nitrogen atom. The

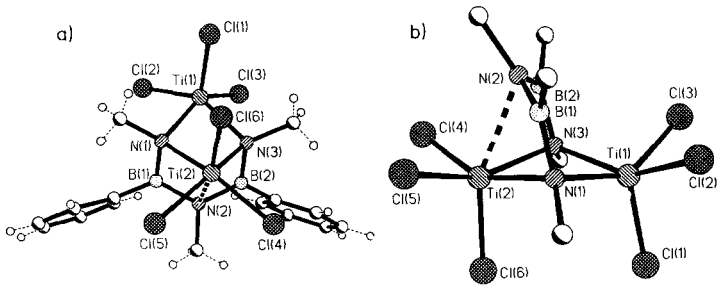

Fig. 2. Crystal structure of **5**. a) top view, b) side view. Selected distances [pm] and angles [°]: Ti(1)-Ti(2) 326.4(1), Ti(1)-N(1) 209.6(4), Ti(1)-N(3) 210.8(3), B(1)-N(1) 145.0(6), B(2)-N(2) 147.2(7), B(2)-N(3) 146.3(6), Ti(2)-N(1) 210.7(3), Ti(2)-N(3) 212.2(4); Ti(1)-N(1)-Ti(2) 101.9(2), N(1)-Ti(1)-N(3) 75.6(1).

reason for this nonplanar configuration are the strong intramolecular Ti–N interactions [Ti(1)–N(3) 213.0(3) and Ti(2)–N(2) 213.5(3) pm], which, if the THF ligands are considered, lead to a distorted octahedral environment of the titanium atoms. The lengths of the Ti–N bonds to the threefold coordinated nitrogen atom [Ti(1)–N(1) 188.9(3) and Ti(2)–N(1) 186.3(3) pm] are similar to that in $[(\eta^5\text{-}C_5H_5)TiCl_2N(SiMe_3)_2]$ [187.9(3) pm].[9] Shorter Ti–N bonds are found in the compounds $[Ph_2P(S)N{=}TiCl_2\cdot 3\,C_5H_5N]$ [172.0(2) pm][10] and $[(\eta^5\text{-}C_5Me_5)Ti(Cl){=}NtBu\cdot C_5H_5N]$ [169.8(4) pm].[11] The Ti–N bonds to the fourfold coordinated nitrogen atoms are significantly longer [Ti(1)–N(2) 212.8(3) and Ti(2)–N(3) 214.1(3) pm].

Compound **5** can best be described as a bicyclo[3.1.1]heptane derivative. The titanium atoms are coordinated differently, whereas Ti(1) is surrounded in a distorted tetragonal pyramidal manner, Ti(2) is surrounded in a distorted octahedral manner [intramolecular Ti(2)–N(2) interactions (244.4 pm)]. The other Ti–N bond lengths (average 210.2 pm) correspond to those in $[Ph_2P\{\mu\text{-}N(SiMe_3)\}_2TiCl_2\{NPPh_2N(SiMe_3)_2\}]$[12] (average 210.3 pm). Similar Ti–Cl distances to those in **5** (average 222.1 pm) are present in $[(\eta^5\text{-}C_5H_5)TiCl_2N(SiMe_3)_2]$[13] (average 227.1 pm).

The boron–nitrogen framework of **1** is influenced very little by the titanium atoms in **5**, as a comparison of the structures of **5** and **1**[14] shows; the B–N distances are only an average of 2.9 pm longer in **5**. In contrast, the Ti–Ti distances for **3** and **5** are significantly different [273.6(1) and 326.4(2) pm, respectively]. This may be explained by the variation of the bridge lengths in **3** (N–B–N) and in **5** (N–B–N–B–N). Compound **5** can only be stored for a long period of time as a crystalline solid under inert conditions. In solution, **5**, in contrast to **3**, is very unstable and decomposes within 2–3 minutes to give **3** and **4**.

Experimental Procedure

3: To a solution of **1** (2.05 g, 5.0 mmol) in $CHCl_3$ (40 mL), $TiCl_4$(0.95 g, 5.0 mmol) in $CHCl_3$ (20 mL) was added dropwise at room temperature. The suspension was refluxed for 4h, then allowed to cool to room temperature and a red-brown precipitate was filtered off. Finally the powder was extracted several times in $CHCl_3$ and thus compounds **3** (0.99 g, 2.4 mmol, 49%) and **4** (0.84 g, 2.4 mmol, 49%) were obtained. **3**: m.p. = 135 °C (decomp); IR(nujol/KBr): $\tilde{\nu}$[cm^{-1}] = 2955vs, 2925vs, 1461s, 1377s, 721m. Correct C, H, N, Cl analyses. ^{11}B NMR (80.21 MHz, CD_3CN, $OEt_2\cdot BF_3$ ext.): δ = 24.1 (s). – ^{1}H NMR (250.13 MHz, CD_3CN, TMS ext.): δ = 7.5 (m, Ph, 5H), 4.5 (s, Me, 3H), 3.6 (s, Me, 6H). – EI-MS: *m/z* 413 (M^+, 14%).

5: To a suspension of **1** (2.05 g, 5.0 mmol) in hexane (40 mL), $TiCl_4$ (1.90 g, 10.0 mmol) in hexane (20 mL) was added dropwise at room temperature. The reaction mixture was refluxed for 3h and subsequently filtered whilst still hot. Yellow crystals of **5** together with a red -brown solid, precipitated out from the filtrate at −25 °C. The crystals were sorted out. Yield 0.50 g (0.88 mmol, 17%). m.p. = 105 °C (decomp). IR(nujol/KBr): $\tilde{\nu}$[cm^{-1}] = 1660m, 1498m, 1456vs, 1378vs, 1262s, 1181s, 1111s, 988s, 702s, 518vs. Correct C, H, N, Cl analyses. ^{11}B-NMR (80.21 MHz, C_6D_6, $OEt_2\cdot BF_3$): δ = 2.2(s). – ^{1}H-NMR (250.13 MHz, C_6D_6, TMS ext.): δ = 7.3 (m, Ph, 10H), 3.8 (s, Me, 6H), 2.7 (s, Me, 3H).

$[t\text{BuSiO(ReO}_4)]_4$, a Model Compound for Metal Oxides on Silicate Surfaces—Synthesis from the Stable Triol $t\text{BuSi(OH)}_3$ and Re_2O_7**

By *Norbert Winkhofer, Herbert W. Roesky,* Mathias Noltemeyer,* and *Ward T. Robinson*

Dedicated to Professor Heinz Harnisch on the occasion of his 65th birthday

Transition metal oxides on silicon dioxide supports find wide application as catalysts in the petrochemical industry.[1, 2] But to a large extent, the processes taking place on the catalyst surface are not understood. Their study is hindered by the complicated structure of these silicate surfaces, making the synthesis of model substances essential. Feher et al.[3, 4] succeeded in preparing the heptameric condensation

product of cyclohexylsilanetriol, providing a series of transition-metal derivatives of cubic siloxanes and their derivatives; starting from formal condensation products of phenylsilanetriol, Shklover et al. and Struchkov et al.[5, 6] characterized a cobalt- and a nickelsiloxane cluster.

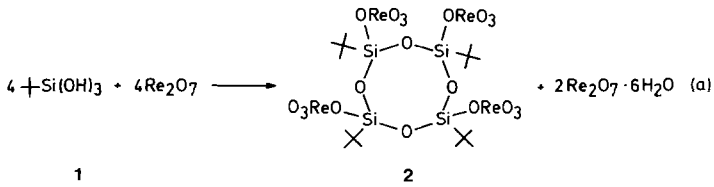
For some time we have been interested in the suitability of di(*tert*-butyl)silanolate as an anchor for metal oxide fragments. Starting from di(*tert*-butyl)silanediol, we can indeed attach metal complex fragments in high and moderately high oxidation states.[7]

As far as we know, syntheses from free silanetriols have not yet been described, a deficiency which needs to be remedied because this route is expected to be similar to the practical preparation of siloxane catalysts, and the surfaces of the resulting products should thus have similar morphologies to the catalyst surfaces. However, suitable silanetriols were not available. Silanetriols are postulated as intermediates in the industrial preparation of silicon;[8] but on account of their extreme tendency to undergo condensation reactions, most silanetriols cannot be isolated in substance. The few exceptions have large organic residues.[9–12] Their synthesis is in part laborious and sometimes the condensation reactions can be suppressed only for a short while. Preparation by hydrolysis reactions requires very special reaction conditions, as detailed below.

In 1955 already Wiberg et al. described the hydrolysis of tBuSiCl$_3$.[13] They obtained the tetrameric compound (tBuSiO$_{1.5}$)$_4$. Recently the same reaction was conducted under different conditions by P. D. Lickiss et al. affording the dimeric [tBu(OH)$_2$Si]$_2$O.[14] We report here the preparation of the primary hydrolysis product tBuSi(OH)$_3$ (**1**). This compound is exceptionally stable to condensation and precipitates in high yield from a simple reaction with commercially available starting materials.

For its preparation we basically followed the method of Takiguchi.[9] tBuSiCl$_3$ was dissolved in dry diethyl ether and added dropwise to an emulsion of stoichiometric quantities of water and aniline cooled in ice. Removal of the hydrochloride and concentration of the filtrate caused **1** to precipitate as colorless crystals in 94% yield. The exact reaction conditions are crucial. The hydrolysis product **1** is soluble in water, dimethyl sulfoxide (DMSO), and tetrahydrofuran, but almost insoluble in hexane or chloroform. In the ^{1}H NMR spectrum ([D$_6$]DMSO) we observed two signals [$\delta = 0.85$ (tBu), 5.50(OH)] and in the ^{29}Si NMR spectrum (D$_2$O) a singlet ($\delta = -38.8$). The X-ray crystal structure analysis[15] revealed that molecules of **1** are linked by hydrogen bonds to form corrugated layers (Fig. 1). Interactions between the layers are prevented by the hydrophobic *tert*-butyl groups. Cyclohexylsilanetriol also occurs in a similar structure,[12] but (Me$_3$Si)$_3$CSi(OH)$_3$[11] and (Me$_3$Si)$_3$SiSi(OH)$_3$[11] form cagelike structures.[12] As yet these are the only silanetriols whose structures are characterized. The Si–O bond lengths [161.3(4), 163.4(3), 163.1(4) pm] and the Si-O-Si angles [105.8(2), 110.5(2), 106.6(2)°] are comparable with those of known compounds.[11, 12] The hydrogen atoms were all located experimentally, and the interatomic O–O distances (O1···O3 270.5, O1···O2 270.4 pm) are consistent with strong hydrogen bonding.

The reaction of **1** with Re_2O_7 in a 2:1 molar ratio affords [tBuSiO(ReO$_4$)]$_n$ (n = 3, 4) after cleavage of water and exchange of H for ReO$_3$ [Eq. (a)]. The initial precipitate is a



fine gray, very air-sensitive powder. Recrystallization from boiling acetonitrile gave transparent crystals of **2** ($n = 4$) suitable for X-ray structure analysis. All ReO$_3$- and tBu-containing units are *cis* to one another (Fig. 2).[16]

Taking the ^{1}H NMR and ^{29}Si data into account we assume that **2** rearranges rapidly in solution, forming the thermodynamically more stable modification on crystallization. To our knowledge it is the first defined, structurally proven transition-metal compound synthesized from a silanetriol. It thus opens a new way to soluble metal-containing silicates. We are now investigating indications from mass spectrome-

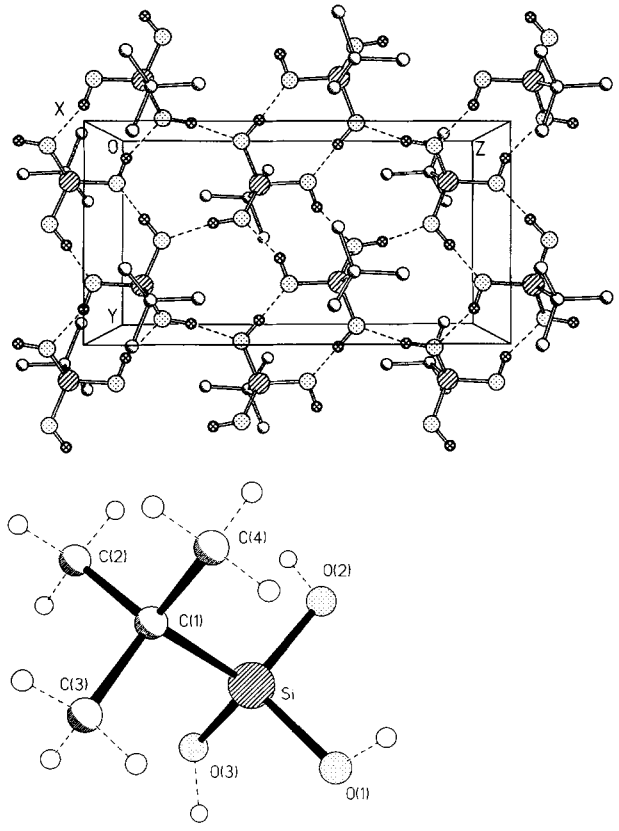


Fig. 1. Top: Packing of **1** in the crystal. The Si, O, and C atoms are represented as in the lower part of the figure. H atoms are shown as crosshatched spheres. Bottom: Structure of **1** in the solid state; bond lengths and angles given in text.

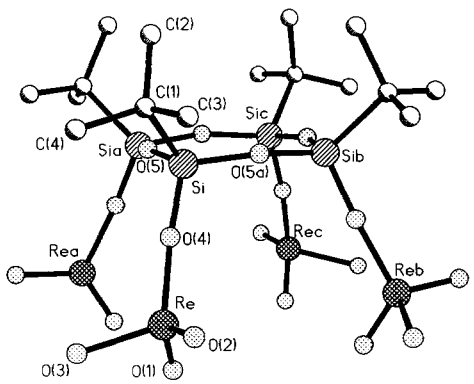

Fig. 2. Structure of **2** in the solid state [16].

try that the analogous six-membered ring is formed as an intermediate or side product.

Experimental Procedure

1: tBuSiCl$_3$ (25 g, 0.13 mol) were dissolved in dry diethyl ether (about 100 mL). This solution was added dropwise over a period of one hour to a vigorously stirred emulsion of water (7.1 mL, 0.39 mol) and aniline (35.7 mL, 36.5 g 0.39 mol) in dry diethyl ether (about 1.5 L) cooled in ice. After the addition the mixture was stirred for a further 12 h while warming to room temperature. Thereafter the precipitated hydrochloride was filtered off, and the clear filtrate concentrated by distillation (34 °C, 760 Torr). Soon small needlelike crystals formed. The crystals were filtered off when the volume reached approximately 200 mL. From the crystalline product (12.4 g, 0.09 mol), crystals suitable for X-ray analysis could be selected. The mother liquor was concentrated under reduced pressure till a few mL remained. A further 4.3 g of amorphous material was obtained. The total was thus 16.7 g (0.12 mol, 94%). Decomposition at 206 °C; correct C, H analyses. MS (EI): m/z 136 $[M]^+$. IR (Nujol/KBr): $\tilde{\nu}$ [cm^{-1}] = 3100w, 1038w, 1010w, 914s, 886s, 844w, 808w, 721w. ^{1}H NMR (80 MHz, [D$_6$]DMSO, TMS ext.): δ = 0.85 (s, 9H; tBu), 5.50 (br s, 3H; OH); ^{29}Si NMR (49 MHz, D$_2$O, TMS ext.): δ = −36.8.

2: Re_2O_7 (2.42 g, 5.0 mmol) and **1** (1.36 g, 10.0 mmol) were placed in a flask, suspended in toluene (40 mL), and heated for 4 h at reflux. This procedure afforded a whitish gray suspension and a few drops of a black oily substance (0.77 g), which were separated by filtration. Removal of the solvent from the filtrate under vacuum left a yellowish oil, which when mixed with 5 mL of pentane spontaneously yielded a white solid. This was filtered off and dried for three days at 10^{-2} Torr at room temperature (yield: 1.73 g, 1.2 mmol, 49%). Extraction with boiling acetonitrile and subsequent crystallization at room temperature furnished square single crystals. Decomposition at 138 °C; correct C, H analyses; MS (EI): m/z 1347 (35%) $[M-t\text{Bu}]^+$, 57 (100%) $[t\text{Bu}]^+$; IR (Nujol/KBr): $\tilde{\nu}$ [cm^{-1}] = 1261s, 1095s, 1018s, 955w, 800s, 722w; ^{1}H NMR (400 MHz, CD_3CN, TMS ext.): δ = 0.95–1.05 (m, 10H; tBu), 1.05–1.15 (m, 9H; tBu); ^{29}Si NMR (79 MHz, CD_3CN, TMS ext.): δ = −52.89 – −59.22 (m).

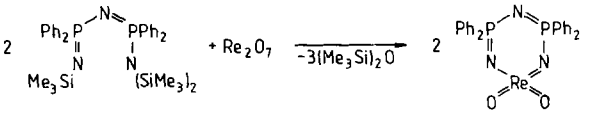
Cyclophosphazene Metal Oxides, a New Class of Compounds, and Model Compounds for the Polymerization of Phosphazenes**

By *Reinhard Hasselbring, Herbert W. Roesky,** and *Mathias Noltemeyer*

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

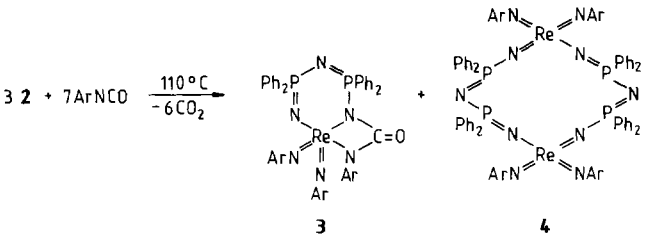
Cyclometallaphosphazenes[1] are of significance since they are precursors for interesting polymers[2] and the low-valent metal atoms can participate in cycloadditions.[3] For kinetic reasons the polymers should be free from halogen atoms. This could be achieved if phosphazene oxide and metal oxide building blocks were combined.

The reaction of the acyclic, completely silylated phosphazene **1**[4] with Re_2O_7, by elimination of siloxane, led to the first cyclophosphazene metal oxide **2**. Since **2** only dissolves upon heating in polar solvents such as dimethylsulfoxide (DMSO), pyridine, acetonitrile, or water with decomposition, only the absence of silyl protons can be determined by NMR spectroscopy. However, elemental analysis, mass spectrometry, and IR spectroscopy confirm the composition of **2**. The compound is air- and water-stable at room temperature.



1 **2**

If **2** is allowed to react with an excess of ArNCO (Ar = 2,6-diisopropylphenyl) a mixture of products is obtained, which contains the cyclophosphazene metal imides **3** and **4**. At first, **3** crystallized as deep red needles from toluene/n-hexane at −25 °C, then after ca. three weeks **4** appeared in the form of orange prisms. The crystals of **4** were



3 **4**

suitable for a single crystal X-ray structure analysis, whereas suitable single crystals of **3** could only be obtained from acetonitrile at room temperature. The molecular structure of **3** is shown in Figure 1.

The [2+2] cycloaddition of the isocyanate at the ReN double bond of **2** (or **5**) leads to a distorted square-pyramidal arrangement of the ligands at the rhenium center in **3**. An otherwise possible planarity of the six-membered ring is

[*] Prof. Dr. H. W. Roesky, R. Hasselbring, Dr. M. Noltemeyer, Institut für Anorganische Chemie der Universität Tammannstrasse 4, D-W-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

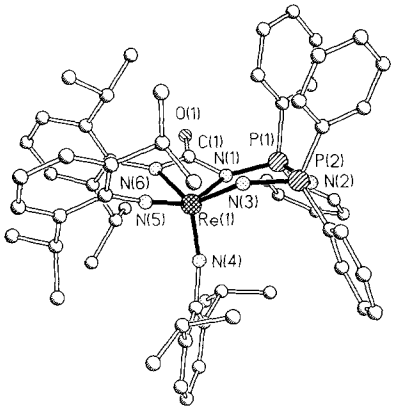


Fig. 1. Molecular structure of **3** [5]. Selected distances [pm] and angles [°]: Re(1)-N(1) 219.9(3), Re(1)-N(3) 186.2(3), Re(1)-N(4) 174.2(3), Re(1)-N(5) 176.2(3), Re(1)-N(6) 204.8(3), P(1)-N(1) 163.8(3), P(1)-N(2) 159.5(4), P(2)-N(2) 160.1(4), P(2)-N(3) 161.7(3), N(1)-C(1) 137.6(5), N(6)-C(1) 138.0(5), O(1)-C(1) 121.3(5); N(1)-Re(1)-N(3) 86.1(1), N(1)-Re(1)-N(4) 94.9(1), N(3)-Re(1)-N(4) 110.6(1), N(1)-Re(1)-N(5) 150.2(1), N(3)-Re(1)-N(5) 100.8(1), N(4)-Re(1)-N(5) 109.3(1), N(1)-Re(1)-N(6) 61.0(1), N(3)-Re(1)-N(6) 127.4(1), N(4)-Re(1)-N(6) 112.0(2), N(5)-Re(1)-N(6) 93.0(1), N(1)-P(1)-N(2) 109.7(2), N(2)-P(2)-N(3) 117.9(2), Re(1)-N(1)-P(1) 131.8(2), P(1)-N(2)-P(2) 120.8(2), Re(1)-N(3)-P(2) 132.7(2).

therefore removed (average deviation from the plane: 20 pm). The bond length between Re(1) and N(1) (219.9 pm) lies in the range of a coordinated bond;[6] all other bonds within the ring system are shorter than single and longer than double bonds. N(1) and N(6) can also be considered as donor atoms of an unsymmetrical Re^{VII} ureato complex.[7]

In the dimetallatetraimidophosphazene **4** (Fig. 2),[8] which is only isolated in very small quantities, the Re centers show an almost tetrahedral coordination, and the twelve-membered ring is puckered.[9] We assume that **4** is formed by a [2+2] dimerization of **5** (via **6**).

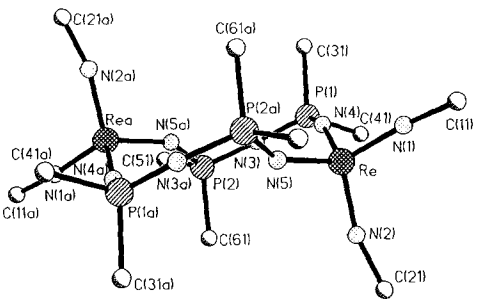

Fig. 2. Molecular structure of **4** (for the aryl groups only the C atoms directly bonded are shown). Selected distances [pm] and angles [°]: Re-N(1) 174.5(4), Re-N(2) 174.3(5), Re-N(4) 183.2(6), Re-N(5) 184.0(6), P(1)-N(3) 157.7(4), P(1)-N(4) 159.0(7), P(2)-N(3) 158.4(6), N(5)-P(2a) 159.8(7), N(1)-Re-N(2) 110.9(2), N(1)-Re-N(4) 107.8(3); N(2)-Re-N(4) 112.3(3), N(1)-Re-N(5) 110.0(3), N(2)-Re-N(5) 106.7(3), N(4)-Re-N(5) 109.1(3), N(3)-P(1)-N(4) 120.5(3), P(1)-N(3)-P(2) 139.1(5), Re-N(4)-P(1) 159.6(4), Re-N(5)-P(2a) 147.9(3), N(3)-P(2)-N(5a) 117.0(3).

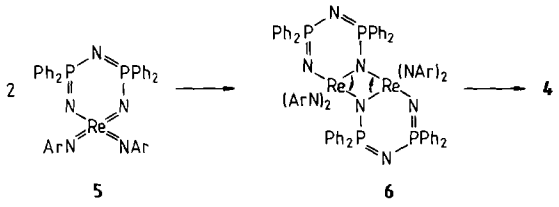
Regarding the structure and mechanism the comparison with the well-studied λ^5-azaphospholes is interesting. In that case, an equilibrium is formed between the monomer and dimer (which so far we have not been able to establish for cyclometallaphosphazenes), and [2+2] cycloadditions of ketones and aldehydes are possible. However, ring systems such as **4** are unknown.[10]

It is improbable that **2** is already present as a twelve-membered ring since the mass spectrum gives no indications



of it. On the other hand, compound **4** is mass spectrometrically clearly different from **3**. However, it appears plausible that **2** is dimeric (analogous to **6**) in the solid state, since the only known cyclotriazaphosphorin metal oxide $[N{=}PPh_2{-}N{=}C(4\text{-}CF_3C_6H_4){-}N{=}ReO_2]_2$, which has been established by a single crystal structure investigation, is also dimeric.[11]

In the presence of Lewis acids, the polymerization of $P_3N_3Cl_6$ leads to the corresponding polymer. Therefore, the formation of a phosphonium ion is assumed, which, as the rhenium atom in **5**, initiates the cycloaddition.[12] It is apparent that if the [2+2] selfaddition is continued to yet larger molecules, it could represent a novel polymerization mechanism by cyclophosphazenes.

Experimental Procedure

2: **1** (4.0 g, 6.3 mmol) in THF (30 mL) was added dropwise to a solution of Re_2O_7 (1.5 g, 3.1 mmol) in THF (30 mL). After 5–6 h, only a fine powdery white product precipitated out of the dark solution. The mixture was stirred for a further 2 d at room temperature, then the solid was filtered off and washed with THF. Yield 2.5 g (63%); m.p. 234 °C; ^{1}H NMR (80.13 MHz, [D$_6$]DMSO, TMS ext.): δ = 7.0 – 8.0 (m); IR (KBr): ν [cm^{-1}] = 1438 m, 1270 s, 1214 s, 1135 s, 1129 vs, 1110 s, 935 s (Re = O), 920 s (Re = O), 721 m, 705 m, 692 m, 575 m, 532 s, 500 m; MS (70 eV): *m/z* 631 (M^+, 100%, ^{187}Re).

3 and **4**: **2** (0.4 g, 0.63 mmol) and ArNCO (1 mL, excess) were refluxed in toluene (5 mL) with evolution of CO_2 for 16 h. After the removal of all volatiles under vacuum at 80 °C, the remaining solid was recrystallized from toluene/*n*-hexane at −25 °C. Yield of **3** 0.35 g, (48%); m.p. 240 °C; ^{1}H NMR (250.133 MHz, $CDCl_3$, TMS ext.): δ = 0.6 (d, 12 H), 0.8 (d, 6 H), 0.9 (d, 12 H), 1.1 (d, 6 H), 3.5 (m, 6 H), 6.8–8.0 (m, 29 H); ^{31}P NMR (101.246 MHz, $CDCl_3$, 85% H_3PO_4 ext.): δ = 17.2 (d), 18.2 (d); IR (nujol): ν [cm^{-1}] = 1671 vs, 1256 s, 1198 s, 1120 s, 1056 s; MS (70 eV): *m/z* 1152 (M^+, 5%, ^{187}Re), 949 (M^+ − ArNCO, 100%). Yield of **4**: ca. 5 mg; m.p. 270 °C; MS (70 eV) : *m/z* 1898 (M^+, 100%, ^{187}Re).

O–H Bond Activation in the Gas Phase: The Reactions of Water and Methanol with $[FeCH_3]^+$ **

By *Ofer Blum, Detlef Stöckigt, Detlef Schröder,* and *Helmut Schwarz**

Dedicated to Professor Heinz Harnish on the occasion of his 65th birthday

Although water and methanol are among the cheapest available resources, very little has been done to utilize their economically attractive, robust O–H bond by transition-metal-mediated catalysis.[1] The O–H bonds in water and methanol has been cleaved by transition metals in solution,[1] in solid noble gas matrices,[2, 3] on surfaces,[4] or on iron clusters,[5] resulting in potentially useful metal hydroxides or metal alkoxides. In the gas phase, iron and manganese carbonyl anions[6] and $[HCr(CO)_3]^-$ activate water readily.[7] C–H cleavage predominates in the reaction of methanol with $[Mn(OC)_3]^-$[8] and $[V(OC)_5]^-$.[9, 10] Oxophilic early transition-metal cations (V^+)[11] and neutral metal atoms (Sc, Y, and La)[12] form metal oxides upon reactions with water and methanol. Mo^+ dehydrogenates methanol, but because no labeling experiments were performed, the mechanism 1,1- or 1,2-elimination could not be deduced.[13] 1-Propanol and higher *n*-alcohols react with late transition-metal cations by C–H rather than O–H functionalization.[14] Fe^{II} alkoxides of the general structure $[FeO(CH_2)_nCH_2OH]^+$ ($n = 1-7$) were, however, recently observed to expel molecular hydrogen unimolecularly, and labeling experiments demonstrate that in the course of H_2 evolution the CH_2OH group of the Fe^{II} alkoxide is oxidized to an aldehyde group.[15a] The Fe^+ mediated CH_4 loss from *o*-methoxyphenol was explained in terms of an *ortho* effect resulting in the cleavage of the phenolic O–H bond.[15b] Water or methanol[16] activation by cationic, late transition-metal fragments is as yet unknown. Here we report the O–H bond activation of water and methanol by cationic $[FeCH_3]^+$ and suggest a mechanism that is in keeping with the experimental findings, especially the unusually large kinetic deuterium isotope effects for these reactions.

$$[FeCH_3]^+ + H_2O \xrightarrow{0.94} FeOH^+ + CH_4 \quad (a)$$
$$[FeCH_3]^+ + H_2O \xrightarrow{0.06} [(H_3C)Fe(OH_2)]^+ \quad (b)$$

$[FeCH_3]^+$ generated under FTICR conditions (FTICR = Fourier Transform Ion Cyclotron Resonance)[17] reacts slowly with water to afford mainly $[FeOH]^+$ and CH_4 [Eq. (a)]. At longer reaction times, the secondary adduct products $[FeOH(OH_2)_n]^+$ ($n = 1, 2$) are observed [Eq. (b)]. Control experiments for various trapping and cooling periods and different relative pressures of water and argon brought no substantial change in the branching ratio or the reaction rates, indicating that the activation of water is not caused by excited $[FeCH_3]^+$. A rate constant of $6(\pm 1) \times 10^{-12}$ cm^3 molecule^{-1}s^{-1} is obtained for the slightly exothermic reaction (a)[24] (-6 kcal mol^{-1}[25]). However, since its efficiency ($k_{prod.}/k_{coll.}$) is only 0.3% of the calculated collision limit ($k_{ADO}(H_2O) = 1.9 \times 10^{-9}$ cm^3 molecule^{-1}s^{-1}[26]) a significant activation energy is involved. A substantial kinetic isotope effect $k_H/k_D \geq 20$ is calculated from the rates of reactions (a) and (c).[27]

$$[FeCH_3]^+ + D_2O \xrightarrow{0.04} FeOD^+ + CH_3D \quad (c)$$
$$[FeCH_3]^+ + D_2O \xrightarrow{0.96} [(H_3C)Fe(OD_2)]^+ \quad (d)$$

Only the O–H bond is activated in methanol [Eq. (e)], as evidenced by the products in [Eq. (f)]. Loss of CH_2O [Eq. (g)], observed at longer reaction times, is indicative of the generation of $[FeOCH_3]^+$.[28] A rate constant of $4(\pm 0.8) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and an efficiency of 25% ($k_{ADO}(CH_3OH) = 1.7 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1})[26] were observed for reaction (e). Reaction (f) showed a deuterium isotope effect ($k_H/k_D = 15 \pm 3$).

$$[FeCH_3]^+ + CH_3OH \longrightarrow [FeOCH_3]^+ + CH_4 \quad (e)$$
$$[FeCH_3]^+ + CH_3OD \longrightarrow [FeOCH_3]^+ + CH_3D \quad (f)$$
$$[FeOCH_3]^+ + CH_3OX \longrightarrow [HFe(XOCH_3)]^+ + CH_2O \quad (g)$$
$$(X = H, D)$$

The reactions of both water and methanol with $[FeCH_3]^+$ are thought to follow the mechanism depicted in Scheme 1. The initial ligation of the dipolar water or methanol mole-

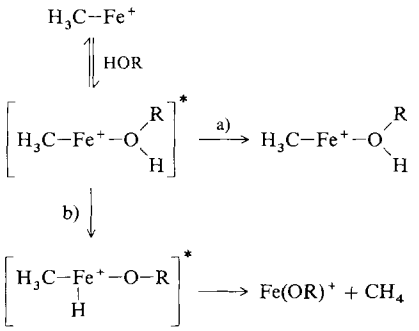
cules to the $[FeCH_3]^+$ cation is favored by the attractive forces between them. Observation of the adduct $[H_3CFe(OX_2)]^+$ (X = H, D) supports this claim. The low reaction efficiency and the observation of a large kinetic isotope effect reveal the existence of a kinetic barrier for the breaking of the O–X bond (X = H, D). The unusual magnitude of the deuterium kinetic isotope effect renders a multicentered transition structure[29] unlikely for the O–H activation, for which a lower k_H/k_D value is anticipated. The O–H cleavage is therefore assumed to take place while the oxygen is ligated to the metal center (Scheme 1: $[H_3CFe(ROH)]^+ \rightarrow [CH_3Fe(H)OR]^+$). A direct hydrogen transfer from the oxy-



Scheme 1. The proposed mechanism of the O–H bond activation by $[FeCH_3]^+$ (R = H, CH_3). a) Relaxation by collision with argon atoms (R = H); b) slow reaction.

gen atom to the carbon of the methyl group cannot be ruled out, but is unlikely.[30] Such a mechanism is expected to be influenced by the distance between the hydrogen-donating and -accepting atoms, which is not expected to change significantly if R is a hydrogen atom or a methyl group.

An activation of the O–H bond two orders of magnitude faster in methanol than in water can be explained by the 15 kcal mol^{-1} weaker O–H bond strength[25] in methanol. This mechanism, which corresponds to an O–H oxidative addition mechanism, is supported by the striking difference (three orders of magnitude) between the reaction rates of $[FeCH_3]^+$ and $[Fe(^{18}OH)]^+$ with water, the latter occurring at 50% of the collision-rate. There must be a fundamental mechanistic difference between the two processes. The exchange reaction $[Fe(^{18}OH)]^+ + H_2{}^{16}O \rightleftarrows [Fe(^{16}OH)]^+ + H_2{}^{18}O$ is more likely to proceed by hydrogen transfer mechanism to a lone electron pair on the oxygen atom (Eigen mechanism) rather than by oxidative insertion.

[16] The C–O cleavage in methanol by Fe^+ or $[Fe(CD_3OH)]^+$ is endothermic (ca. 11 kcal mol^{-1}) and is probably caused by excited iron cations: J. Allison, D. P. Ridge, *J. Am. Chem. Soc.* **1979**, *101*, 4998.
[17] The apparatus (a Spectrospin-CMS-47X Fourier Transform ion cyclotron resonance instrument equipped with an external ion source [18]) and its operation have been previously described [19]. Briefly, Fe^+ is formed through laser desorption/ionization [20] by focusing the beam of a Nd:YAG laser (Spectron Systems, fundamental frequency 1064 nm) onto a stainless steel target. The ions are extracted from the source and transferred into the analyzer cell by a system of electrostatic potentials. The external ion source, transfer system, and ICR cell are differentially pumped by three turbomolecular pumps. After deceleration, the ions are trapped in the field of the superconducting magnet (Oxford Instruments, maximum field strength of 7.05 T). The $^{56}Fe^+$ isotope is isolated by using FERETS [21], and allowed to react with pulsed-in CH_3I to generate $[FeCH_3]^+$ [22]. H_2O or CH_3OH was present at a stationary pressure of $1-2\times10^{-8}$ mbar. Argon was present as a buffer gas with a constant pressure of $0.2-1.5\times10^{-7}$ mbar for collisional quenching of any excited states formed in laser desorption/ionization and for removal of translational energy remaining from the transfer to the ICR cell. Prior to the reaction of $[FeCH_3]^+$ with D_2O the FTICR instrument was flushed with D_2O (5×10^{-7} mbar; 6 h). Nevertheless, H_2O molecules remained adsorbed to the cell wall. An 8% hydrogen content was deduced from the ratio between the adducts $[H_3CFe(OHD)]^+$ and $[H_3CFe(OD_2)]^+$. In the case of CH_3OD the residual CH_3OH content was derived from i) internal ion source ionization of CH_3OD (15 eV), and ii) the isotope distribution of the adduct $[HFe(XOCH_3)]^+$ after long reaction times. The parameters for the absolute pressure determinations are taken from [23]. All functions of the instrument were controlled by a Bruker Aspect 3000 minicomputer.

[24] The formation of the adduct $[H_3CFe(OH_2)_2]^+$ is probably due to collisional stabilization and depends on the argon pressure. Its observed formation rate at an argon pressure of 1×10^{-7} mbar is ca. 1×10^{-21} cm^6 molecule^{-2} s^{-1}. However, radiative association cannot be excluded.
[25] Thermochemical data: S. G. Lias, J. E. Bartmess, J. F. Liebman, J. L. Holmes, R. D. Levin, W. G. Mallard, *J. Phys. Chem. Ref. Data* **1988**, *17*, Suppl. 1.
[26] The ADO (averaged dipole orientation) ion-molecule collision rate constant is calculated according to T. Su, M. T. Bowers, *Int. J. Mass Spectrom. Ion Phys.* **1973**, *23*, 347.
[27] Because reaction of $[FeCH_3]^+$ with D_2O was slow, the pressures of D_2O and Ar were increased to 1.5 and 3.0×10^{-7} mbar, respectively. This experiment is affected by a residual hydrogen content in D_2O [17], and almost all $[Fe(OH)]^+$ stems from this source. For this reason the value given for the kinetic isotope effect represents a lower limit. Accordingly, the correction of the branching ratios given in reactions (c) and (d) for the different pressure was neglected.

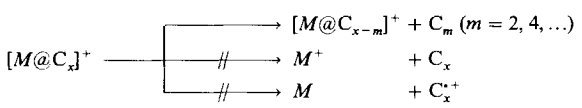
Sequential Insertion of ^3He and ^4He in $C_{60}^{\bullet+}$**

By *Thomas Weiske* and *Helmut Schwarz**

Dedicated to Professor Edward W. Schlag on the occasion of his 60th birthday

For the preparation of endohedral fullerene complexes, in which an atom or molecule M is trapped inside the cavity,[1] and for which the symbol $M@C_x$ was proposed,[2] so far two methods have been adopted: 1) During the laser vaporization of doped graphite, any atoms M accidently attached to the inside of the growing carbon sheet are included. Typical examples are $M@C_{60}$ (M = La, Ni, Na, K, Rb, Cs), $La@C_x$ (x = 70, 74, 82) and the doubly doped $Y_2@C_{82}$.[2, 3] 2) In a bimolecular high-energy collision, atoms M penetrate the shell of the fullerenes. As a result of the mechanism of the collision process, only small inert atoms have a chance of being fired into the cage, from which there is no easy escape due to high barriers. In mass spectrometric experiments, so far, He, Ne, and Ar have been inserted into $C_{60}^{\bullet+}$ and $C_{70}^{\bullet+}$.[4] Recently the production of a neutral $He@C_{60}$ cluster was also achieved by the gas-phase reduction of the corresponding radical cation.[5] A shrinkage of the cage ("shrink-wrap" mechanism[6]) with the retention of the inserted atom, which occurs upon intense excitation with the loss of C_2 or multiple units of C_2, is common to all endohedral complexes. On further excitation, if the cage becomes too small to surround the "imprisoned" atom, the fullerene is blown apart (Scheme 1).



Scheme 1.

Herein we report the sequential insertion of one ^3He *and* one ^4He atom in $C_{60}^{\bullet+}$.[7] The experiment was carried out using a BEBE tandem mass spectrometer (B magnetic and E electric sectors).[8] Technical details of the experiment can be taken from the work describing the neutralization of $[He@C_{60}]^{\bullet+}$,[5] since the considerations there are also valid for the double penetration of the $C_{60}^{\bullet+}$ cage discussed here.

A mixture of C_{60} and C_{70} (> 90% C_{60}) is vaporized in the ion source by heating to 550 °C and ionized with electrons (70 eV). For the production of $[He@C_{60}]^{\bullet+}$, the field strength of the magnet B1 is chosen such that the $C_{60}^{\bullet+}$ ions (m/z 720) are transmitted; the electrical sector E1 has a field strength which allows ions with a kinetic energy of E_K = 5000 eV to pass. Since, for the inelastic collision of $C_{60}^{\bullet+}$ with ^3He in the collision chamber located between B1 and E1 (transmission, T = 40%) the kinetic energy of $C_{60}^{\bullet+}$ is reduced by the center-of-mass-energy, E_{cm}, of the collision complex (E_{cm} = 21 eV for $C_{60}^{\bullet+}$ ions being accelerated to 5000 eV), the accelerating potential is increased by this same value. Under these conditions only $[^3He@C_{60}]^{\bullet+}$ (m/z 723) and inelastically scattered $^{12}C_{60}^{\bullet+}$ ions pass the sector E1. The insertion of a further helium atom occurs by inelastic collisions with stationary ^4He gas in the collision chamber (40% T) located between E1 and B2. Obviously, in this case the inelastically scattered $C_{60}^{\bullet+}$ ions also react with ^4He. The product ions of the bimolecular reactions are recorded by a "linked scan" of B2/E2 = constant[9] (Fig. 1).

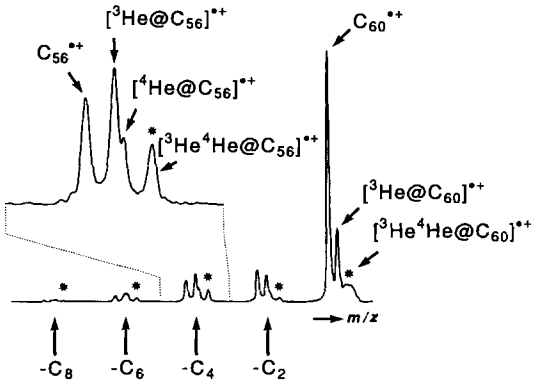


Fig. 1. Sequential insertion of ^3He and ^4He in $C_{60}^{\bullet+}$ by bimolecular high energy collisions:

$C_{60}^{\bullet+} \xrightarrow{^3He} [^3H@C_{60}]^{\bullet+} \xrightarrow{^4He} [^3He^4He@C_{60}]^{\bullet+}$

The signals marked with a star correspond to the formation of insertion products containing one ^3He *and* one ^4He atom.

The "triplet" structure of the $C_x^{\bullet+}$ ions (x = 60–52) with the mass differences Δm = 3, 7 (Fig. 1) proves the consecutive insertion of the two helium atoms ^3He and ^4He.[10] Furthermore, the insert in Figure 1 proves that with improved resolution also the product of the reaction of inelastically scattered $C_{60}^{\bullet+}$ with ^4He becomes visible.

The experiment described here provides a method for the construction of endohedral fullerene adducts of the general structure $AB@C_x$. Crucial to the method is the ability of finding the appropriate "energy windows" necessary for obtaining optimal effective cross sections of the high energy collisions of $C_{60}^{\bullet+}$ ions with the stationary target atoms.

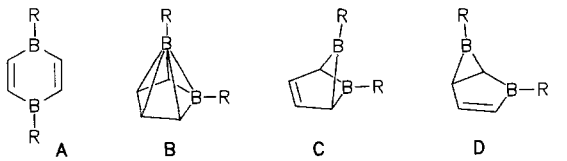
[10] We have also carried out the reverse sequence, i.e. initial insertion of ^{4}He and then ^{3}He ($C_x^{\cdot+}$ triplets with Δm = 4, 7). As a result of the energetics of the inelastic collisions [see 4f,i,j] we were not surprised to observe that the relative transmittances for the production of $[^3He^4He@C_x]^{\cdot+}$ are different from those for $[^4He^3@C_x]^{\cdot+}$ (x = 60–52). Analogous considerations are also valid for the production of $[^4He_2@C_x]^{\cdot+}$ ($C_x^{\cdot+}$ triplet with Δm = 4, 8).

Formation of a 2,5-Diborabicyclo[2.1.1]hexane Derivative and Its Conversion to a Tetracarbahexaborane**

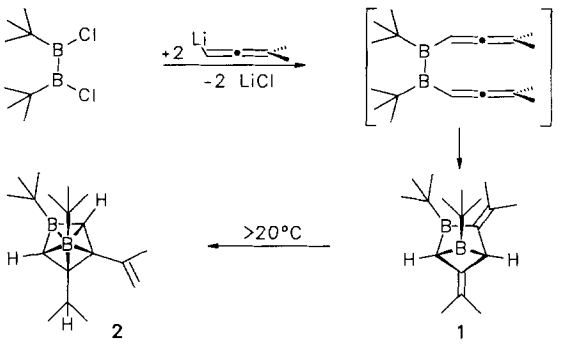
By *Markus Enders, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Preparative and theoretical investigations into the stability of the C_4B_2 compounds **A**,[1] **B**,[2] and **C**[3] have shown that the conversion of the organoborane into the carborane structure is controlled by the substituents R bound to boron. With one amino and one methyl substituent the carborane is still stable; two amino substituents (R = N iPr$_2$) lead to the bicycle **D**. The temperature-dependent ^{1}H NMR spectra indicate that **C** and **D** are in equilibrium.[3]



Herein we report a new reaction path to the tetracarbahexaborane **B** from the unsaturated organoborane **1**, a framework isomer of **D** (Scheme 1). In **1**, as in **D**, two sp^2 hybridized B and C atoms as well as two sp^3 hybridized C atoms are present in the C_4B_2 framework; a *nido*-carborane formation is not hindered by the substituent at boron but by the two π systems. After rearrangement of **1** into a 1,3-diboretane bridged by the two isopropylidene groups in the 2,4-position and by H migration, the carborane **2** with an isopropyl and an isopropenyl substituent is formed, whose constitution was determined by the measurement of nuclear Overhauser effects (NOE) in the proton NMR.



Scheme 1. ^{11}B NMR data for **1**: δ = 33, 66; for **2**: δ = −42, 24.

Whereas amino-substituted diallenylborane and diallenyldiborane(4) derivatives are stable,[4] the bicycle **1** is unexpectedly formed from the reaction of 1,2-di-*tert*-butyl-1,2-dichlorodiborane(4)[5] with 3,3-dimethylallenyllithium in 48% yield. The crystal structure analysis of **1** (Fig. 1)[6] shows a 1-boretane bridged in the 2,4-position. The strong

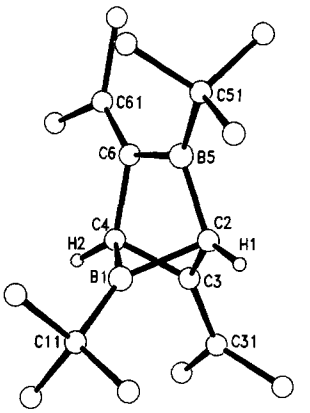


Fig. 1. Molecular structure of **1**. Selected distances [Å] and angles [°]: B1-C3 1.744(9), B1-C2 1.658(8), B1-C4 1.595(9), C2-C3 1.491(7), C3-C4 1.501(7), C3-C31 1.370(6), C2-B5 1.521(7), C4-C6 1.483(7), B5-C6 1.584(8), C6-C61 1.344(6); C2-B1-C4 86.1(5), C2-C3-C4 95.9(5) B1-C2-C3 67.0(4), B1-C4-C3 68.5(4).

folding of the four-membered ring (angle between the planes C4-B1-C2 and C2-C3-C4 is 105°) leads to a short distance between B1 and C3 of 1.74 Å. This indicates a 1,3-transannular interaction between the free p orbital at B1 and the exocyclic double bond at C3, which also explains the remarkable high-field shift in the ^{11}B NMR spectrum (δ = 33). A comparable interaction is found in the Diels–Alder dimer of 2,3,4,5-tetramethyl-1-phenylborole.[7] Also in agreement with this is the fact that the exocyclic substituents (C11 at B1, C31 at C3) do not lie in a plane with the other substituents at B1 and C3 (as is expected by sp^2 hybridized atoms), but are bent toward the center of the ring (8 and 16°, respectively), which favors a transannular interaction.

In the ^{1}H NMR spectrum of **1** the hydrogen atoms of the boretane give rise to two doublets (δ = 3.62, 3.90,

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, and the BASF AG.

^4J(H,H) = 5.6 Hz), and for two of the four inequivalent methyl groups of the isopropylidene substituents a quartet (^4J(H,H) = 0.6 Hz) is observed. In the ^{13}C NMR spectrum at room temperature six primary and three quarternary C atoms are observed, and the B–CH atoms show two broad signals at δ = 73.1 and 56.6. Additionally, the quaternary C3 atom at δ = 141 and a broad signal for the C atoms of the *tert*-butyl groups bound to boron are observed on cooling to 250 K.

By framework rearrangement and migration of a hydrogen atom from one isopropylidene group to the other and simultaneously raising the coordination numbers of the boron atoms from three to four and six, respectively, the racemate of **2** is formed. The ^{11}B NMR spectrum shows two signals at δ = 24.1 and −41.9 for the basal and apical boron atom, respectively. The existence of an isopropenyl unit (δ = 5.20 (m,1H), 5.05 (m,1H), 1.85 (m,3H)) and a diastereotopic isopropyl group (δ = 3.01 (sept,1H), 1.02 (d,3H), 0.99 (d,3H)) in the ^{1}H NMR spectrum proves that the H migration has occurred. The two H atoms on the carborane framework produce two doublets at δ = 4.38 and 4.33.

If the methyl protons of the isopropyl group are irradiated, one H atom (δ = 4.38) of the basal CH groups and one H atom of the isopropenyl group (δ = 5.20) show an NOE (8% and 3%). When the CH_3 group of the isopropenyl substituent is irradiated, it is exactly the other way around (NOE at δ = 4.33 (9%) and 5.05 (6%)). This shows that the C_3H_5 and C_3H_7 groups are adjacent and have one H substituent each as a neighbor.

The reaction introduced here is novel since the organoborane **1** can be isolated before the formation of the *nido*-tetracarbahexaborane **2** occurs. Compared with the endocyclic ones in the 1,4-diboracyclohexadiene, the exocyclic double bonds of **1** hinder a rapid rearrangement to the carborane. Only after framework rearrangement and migration of a H atom, one electron of each localized π bond can be made available for cluster formation; thus **1** is kinetically stabilized. The surprising formation of **1** and the rearrangement to **2** are subject to further investigations.

Experimental Procedure

1: To a solution of 1-bromo-3,3-dimethylallene (4.41 g, 30 mmol) in diethyl ether (20 mL), *n*-butyllithium (2.5 M solution, 12 mL) was added at −78 °C. After 30 min 1,2-di-*tert*-butyl-1,2-dichlorodiborane(4) (3.10 g, 15 mmol) in pentane (30 mL) was added dropwise. This was warmed to room temperature, filtered, and after the removal of the solvent distilled as a green-yellow liquid. Yield 1.93 g (47.6%), b.p. 70 °C/10^{-3} Torr, m.p. 65 °C(pentane). ^{1}H NMR (C_6D_6): δ = 0.98 (s, 9H), 1.28 (s, 9H), 1.55 (q, 3H, ^4J(H,H) = 0.6 Hz), 1.66 (q, 3H, ^4J(H,H) = 0.6 Hz), 1.85 (s, 3H), 1.98 (s, 3H), 3.62 (d, 1H, ^4J(H,H) = 5.6 Hz), 3.90 (d, 1H, ^4J(H,H) = 5.6 Hz). – ^{11}B NMR (C_6D_6): δ = 33, 66 (1:1). – ^{13}C NMR ([D_8]toluene, 250 K): δ = 18.5 (B-C_q), 22.6 (CH_3C), 22.7 (CH_3C), 23.9 (CH_3C), 26.5 (CH_3C), 29.2 ((CH_3)$_3$C), 29.3 ((CH_3)$_3$C), 56.5 (B-CH), 73.4 (B-CH), 115.7 (C_q), 126.3(C_q), 141 (B-C_q), 148.2 (C_q). – EI-MS: *m/z* 270 ($M^{\oplus}$, 3.0), 57 ($C_4H_9^+$, 85.6), 56 ($C_4H_8^+$, 100), 41 ($C_3H_5^+$, 88.2).

2: A solution of **1** (30 mg, 0.11 mmol) in [D_8]toluene was heated in an NMR tube to 100 °C. After 90 minutes only the signals of the carborane **2** are present in the ^{1}H NMR spectrum. The reaction half-time is approximately 15 minutes. ^{1}H NMR(C_6D_6): δ = 0.85 (s, 9H), 0.99 (d, 3H, ^3J(H,H) = 6.7 Hz), 1.02 (d, 3H, ^3J(H,H) = 6.7 Hz), 1.36 (s, 9H), 1.85 (m, 3H), 3.01 (sept, 1H, ^3J(H,H) = 6.7 Hz), 4.33 (d, 1H, ^4J(H,H) = 3.5 Hz), 4.38 (d, 1H, ^4J(H,H) = 3.5 Hz), 5.05 (m,1H), 5.20 (m,1H). – ^{11}B NMR(C_6D_6): δ = 24.1, -41.9 (1:1). – ^{13}C NMR ([D_8]toluene, 230 K): δ = 12 (B-C_q), 17.5 (B-C_q), 21.5 (CH_3), 24.2 (CH_3), 24.4 (CH_3), 26.4 ($CH(CH_3)_2$), 31.7 ((CH_3)$_3$C), 32.1 ((CH_3)$_3$C), 79.5 (B-CH), 80.5 (B-CH), 110.1 (C_q), 117.3 (=CH_2), 119.7 (C_q), 136.8 (CCH_3). – EI-MS: *m/z* 270 ($M^{\oplus}$, 100), 255 ($M^{\oplus}$ − CH_3, 22.1), 227 ($M^{\oplus}$ − C_3H_7, 26.9), 213 ($M^{\oplus}$ − C_4H_9, 66.2).

Equilibria between Nonclassical and Classical Boron Compounds, Competition between Aromaticity in Two and Three Dimensions**

By *Holger Michel, Dirk Steiner, Sigrid Wočadlo, Jürgen Allwohn, Nicolaos Stamatis, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Anton Meller on the occasion of his 60th birthday

Nonclassical boron compounds **2** are considerably lower in energy [1] than their classical isomers **1** and **3**.[2, 3] This can be explained by the three-dimensional aromaticity of **2**.[1, 4] Conversion of the benzo derivatives **4** into **5**, during which the two-dimensional aromaticity of the fused benzene ring would be lost, could not be observed for compounds of type **4**.[5, 6] Therefore, is the three-dimensional aromaticity in

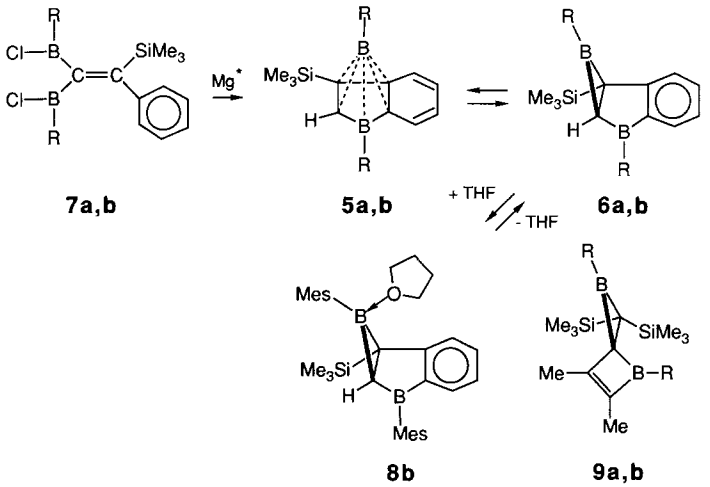
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. B. Bogdanović, Max-Planck-Institut für Kohlenforschung, Mülheim, for information concerning the production of highly reactive magnesium (cf. [11]).

tetracarbahexaboranes(6) unable to compete with the two-dimensional aromaticity in benzene rings? Herein we report on rapidly established equilibria between the nonclassical and classical boron compounds **5a, b** and **6a, b**, respectively, which are the result of a competition between these two kinds of aromaticity.

Compounds **5a** and **5b** are formed by the reaction of **7a**[8] and **7b**[9], respectively, with Bogdanović magnesium.[11, 12]



Scheme 1. **a**, R = *t*Bu; **b**, R = 2,4,6-trimethylphenyl (Mes); Mg* = highly reactive Mg (prepared as described by Bogdanović).

The structure of **5a** was deduced from the chemical shifts in the ^{11}B NMR spectrum, which with $\delta = -50.7$ and $+24.1$ correspond approximately to the typical values of tetracarbahexaboranes(6)[3] at $\delta \approx -45$ and $+18$ for apical and basal boron atoms, respectively. The structure of **5b** was confirmed by a crystal structure analysis (Fig. 1).[13]

The distances in **5b** agree satisfactorily with those calculated for the parent compound $C_4B_2H_6$ (**2**),[1] and with those determined from microwave spectroscopy;[15] only the distances between the apical boron and carbon atoms of the fused ring are significantly longer (ca. 15 pm). Corresponding longer distances were also observed for the π complexes of other benzoboroheterocycles.[5] B1 lies 127(3) pm above the almost-planar, BC_4 five-membered ring (deviations from a best plane max. 5(3) pm), towards which the plane of the six-membered ring (max. deviation 3(3) pm) is slightly inclined with an interplanar angle of 4.7(4)°. The C4–C5 and C3–C8 bonds of 145.6(9) and 148.8(9) pm, respectively, are considerably longer than in benzene. The moderate quality of the crystal structure data could be responsible for the fact that the 1,3-diene character of the C5–C6–C7–C8 arrangement of atoms is not more clearly recognizable. As predicted for three-dimensional arenes, which have a five-membered ring with a capping boron,[4] the C2–Si bond is inclined towards the cap from the plane of the five-membered ring (ca. 5.6(3)°).

The signals in the ^{11}B NMR spectrum of a solution of **5b** ($\delta = +9$ and $+47$ at room temperature), lie well outside the range of the typical chemical shifts of tetracarahexaboranes(6). The NMR signal positions of the boron atoms and those of the carbon atoms C1 to C4 for **5b** are strongly dependent on the temperature (Table 1).

Table 1. Chemical shifts of the framework atoms of **5a** ⇌ **5b**, **5b** ⇌ **6b**, and **8b** at different temperatures.

[a] In [D_8]THF. [b] In *o*-[D_{10}]xylene. [c] In CD_2Cl_2. [d] Numbering of the atoms as in crystal structures (see Figs. 1 and 2). [e] In pentane at −60 °C. [f] At −40 °C. [g] Without assignment.

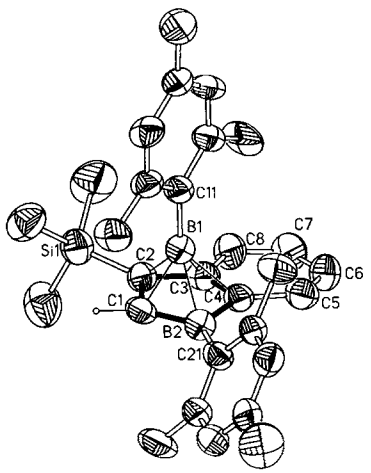

Fig. 1. XP diagram [14] of a molecule of **5b**. The ellipsoids of thermal vibration are drawn at the 50% probability level. Important distances [pm] and angles [°]: B1-C1 167.3(9), B1-C2 171.9(9), B1-C3 184.3(10), B1-C4 186.5(10), B1-B2 187.0(11), B2-C1 149.3(10), C1-C2 150.2(8), C2-C3 144.0(9), C3-C4 141.7(9), C4-B2 156.9(10), C4-C5 145.6(9), C5-C6 140.0(10), C6-C7 139.6(11), C7-C8 136.2(10), C8-C3 148.8(9); B2-C1-B1 72.1(5), B2-C1-C2 114.4(5), C1-C2-C3 102.5(5), C2-C3-C4 113.4(6), C3-C4-B2 109.2(6), C4-B2-C1 99.8(5), C3-C2-Si 133.8(5), C1-C2-Si 123.6(4).

The formation of adducts with Lewis bases is also unusual for tetracarbahexaboranes(6). From **5b** and THF the adduct **8b** is formed, whose crystal structure is shown in Figure 2.[13] The five-membered ring unit is planar with the fused benzene ring (max. deviation from the best plane 5(1) pm), the B1–C1–C2 three-membered ring is bent towards this plane by 114.4(2)°. The C4–C5 and C3–C8 bonds of 141.1(4) and 139.6(4) pm, respectively, are of comparable length to those in benzene. The unusual shortening of the C5–C6 and C6–C7 distances (137.3(5) and 135.8(6) pm, respectively) is probably at least in part due to the anisotropic vibration of the participating atoms mainly within the ring plane (displacements ratio $U3/U1 = 2.4$ to 2.8). The C–B distances in the B1–C1–C2 three-membered ring[16] are significantly shorter than the C–B1 distances in **5b**, the C1–C2 and C2–C3 distances are significantly longer—as is to be expected for a change from multiple-center to two-center bonds.[17]

The ^{13}C NMR spectrum of **8b** in $CDCl_3$ at room temperature is similar to that of **5b** and an equivalent of THF, on cooling it resembles more and more that of **5b** in THF. Apparently **5b** forms a loose adduct with THF. Compound **5a** does not add a THF molecule even in THF at −80 °C.

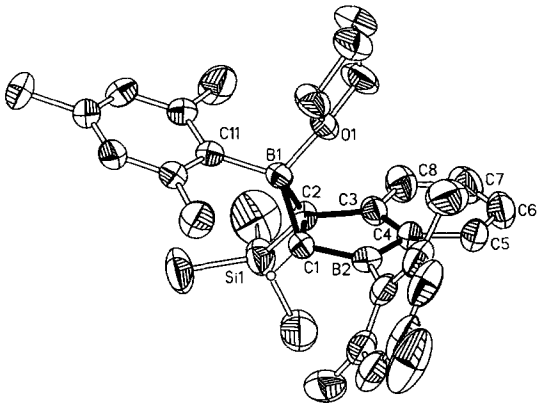

Fig. 2. XP diagram [14] of a molecule of **8b**. The ellipsoids of thermal vibration are drawn at the 50% probability level. Important distances [pm] and angles [°]: B1-C1 162.6(4), B1-C2 158.7(4), B1-O1 158.6(4), B2-C1 152.8(5), C1-C2 157.6(4), C2-C3 151.4(4), C3-C4 140.0(4), C4-B2 156.8(5), C4-C5 141.1(4), C5-C6 137.3(5), C6-C7 135.8(6), C7-C8 140.5(5), C8-C3 139.6(4); B2-C1-B1 121.4(3), B2-C1-C2 109.2(2), C1-C2-C3 102.8(2), C2-C3-C4 114.1(3), C3-C4-B2 109.0(3), C1-B2-C4 104.7(3), C1-B1-C2 58.7(2), C3-C2-Si 116.9(2), C1-C2-Si 113.7(2), C11-B1-O1 109.2.

Nondissociating adducts of type **8** were obtained from **5a,b** and 4-*tert*-butylpyridine. The facile adduct formation is in contrast to the low reactivity of tetracarbahexaboranes(6); thus hexaethyltetracarbahexaborane(6) does not react with trimethylamine oxide even on refluxing in toluene.[19]

All these results can be explained if rapid equilibria between the nonclassical compounds **5a,b** and the classical **6a,b** are assumed. The unusual position of the signals in the NMR spectra result from the weighted-average values $\delta = p\delta_B + (1-p)\delta_A$ of the chemical shifts (δ_A and δ_B) of the components (populations p and $1-p$) participating in the equilibrium ($K = p/1-p$). Their temperature dependence indicates the change of the equilibria with temperature corresponding to $\Delta G = \Delta H - T\Delta S = -RT\ln K$.

Since the ^{11}B NMR signals for **5a** $\rightleftharpoons$ **6a** lie in the range expected for tetracarbahexaboranes(6), it follows that the equilibrium lies mainly on the side of **5a** even at +125 °C. The ^{11}B NMR signals for **5b** $\rightleftharpoons$ **6b**, which are totally different from the expected values for these carboranes, show that already at room temperature comparable quantites of **5b** and **6b** are present. If the following are assumed for the estimation of δ_A and δ_B a) the chemical shifts of **5a** at low temperature are also valid for **5b**, b) the NMR data of the framework atoms of the five-membered rings **6a,b** can be estimated from that of the five-membered ring of **8b**, and c) the $\delta(^{11}B)$ values of the three-membered rings **6a,b** can be estimated from the $\delta(^{11}B)$ of the three-membered rings of **9a** (83[20]) and **9b** (72[21]), then these together with the stated equations and the data[22] in Table 1 result in the thermodynamic approximate values given in Table 2.

Table 2. Thermodynamic parameters of the equilibria **5a** $\rightleftharpoons$ **6a** and **5b** $\rightleftharpoons$ **6b**.

	ΔH [kJ mol^{-1}]	ΔS [J mol^{-1} K^{-1}]	ΔG [kJ mol^{-1}]
5a $\rightleftharpoons$ **6a**:	5.4 ± 0.8	−12.6 ± 8.4	8.8 ± 2.9
5b $\rightleftharpoons$ **6b**:	8.8 ± 0.8	31.9 ± 5.4	−0.8 ± 1.7

The enthalpy differences between **5a,b** and **6a,b** are considerably smaller than the energy difference of 157.0 kJ mol^{-1} calculated for the parent compounds $C_4B_2H_6$ of **2** and **3**.[1] This can be explained by the cancellation of the two-dimensional aromaticity in the benzene ring of **5**. Thus, the equilibria between the nonclassical compounds **5a,b** and classical **6a,b** result from the competition between the two- and three-dimensional aromaticity.

[11] The highly reactive magnesium was produced using the method of B. Bogdanović (personal communication) by the thermolysis of magnesium anthracenide, MgA [12]. For this, MgA (12 g, 28.6 mmol) was refluxed in toluene (150 mL) until the orange color had disappeared. For the separation of the anthracene formed, the solvent pipetted off as soon as the magnesium has settled, should be as hot as possible. The Mg was washed twice (100 mL each time) with first toluene, then toluene/ether (1:1), then ether, it was finally taken up as a suspension in ether (100 mL). To this suspension, a solution of **7b** (12.0 g, 23.8 mmol) was added and the resulting mixture was stirred at room temperature for ca. 15 h. Then the ether was removed under vacuum, the residue taken up in pentane and filtered over a G4 frit to remove the $MgCl_2$ and finally washed with further pentane (2 × 30 mL). The pentane solution was concentrated to ca. 50 mL and crystallized at −18 °C.
5b: Yellow crystals, yield 7.6 g (74%), m.p. 82 °C; from **7a**, the analogue **5a** (m.p. 62–63 °C) was obtained, which can only be separated from a further reaction product, with large losses, by crystallization.

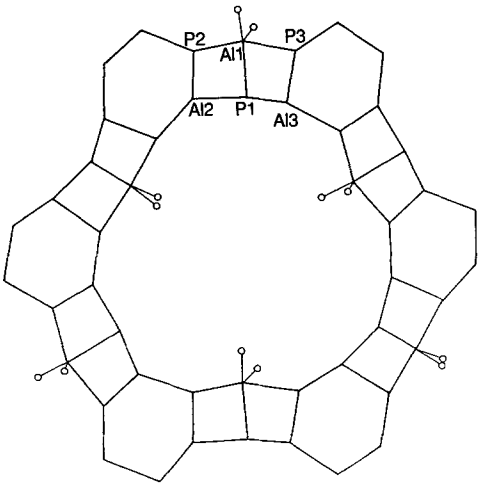
Solid-State NMR Spectroscopic and X-Ray Diffraction Studies of the Low-Temperature Structural Transformation of Hydrated Porous Aluminophosphate VPI-5**

By *João Rocha, Waclaw Kolodziejski, Ian Gameson,* and *Jacek Klinowski**

The aluminophosphate molecular sieve VPI-5 contains 18-membered rings of aluminum and phosphorus atoms, linked via oxygen atoms (Scheme 1).[1, 2] The large channel diameter of ca. 1.2 nm gives the material potential for the separation of large molecules and for catalytic cracking of heavy fractions of petroleum. Several attempts have been made to determine the structure of VPI-5 in detail.[3–6] The most recent refinement of the X-ray diffraction data in the space group $P6_3$ by McCusker et al.[6] is fully consistent with ^{27}Al and ^{31}P NMR spectra.[7–9] A double-rotation NMR study of hydrated VPI-5 has resolved two resonances from tetracoordinated Al and one due to hexacoordinated Al in a 1:1:1 intensity ratio.[10] The signals from tetracoordinated Al are not resolved in the ordinary ^{27}Al MAS (magic-angle spinning) NMR spectrum, and it is of interest to establish whether their quadrupole interaction parameters are sufficiently different for the material to be profitably studied by quadrupole nutation NMR spectroscopy.[11] We have carried out variable-temperature X-ray powder diffraction analyses in tandem with ^{1}H, ^{27}Al, ^{31}P, and ^{27}Al quadrupole nutation MAS NMR studies in the range 180–294 K, using fast spinning rates. These are the first variable-temperature quadrupole nutation studies using MAS. We report that in the range 190–220 K, hydrated VPI-5 undergoes a reversible structural transformation.

The only discernible changes in the X-ray diffraction patterns on cooling the sample from 273 K to 173 K occur in the region shown in Figure 1. All patterns are consistent with earlier work.[6] The (211)-(002), (311)-(102) and (320)-(112) pairs of reflections, unresolved at 273 K, separate on cooling, while the (202) and (410) reflections begin to merge. The explanation is quite straightforward. Measurement of the positions of the (200) and (220) reflections shows that on cooling, the *a* lattice parameter remains essentially unchanged at 1.897 nm. This is not the case with the *c* parameter which



Scheme 1. One layer of the framework structure of hydrated VPI-5 ($P6_3$ symmetry) taken from the stereoscopic view along the [001] direction according to McCusker et al. [6] Aluminum and phosphorus atoms, linked via oxygen atoms (not shown for clarity) are located at the apices of the polygons. P2 and P3, and Al2 and Al3 sites are inequivalent. P sites and Al2 and Al3, are all tetracoordinated. The Al1 site is hexacoordinated as a result of bonding to four bridging oxygens and two "framework" water molecules. Other intracrystalline water is not shown.

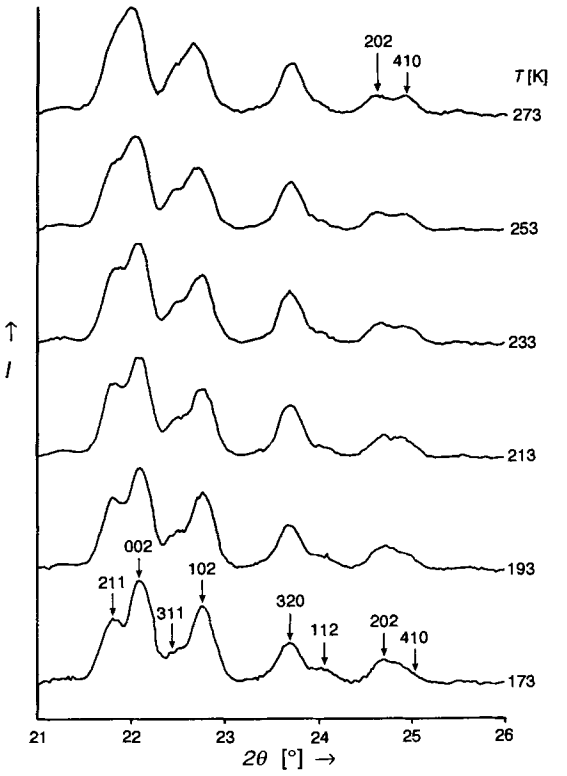


Fig. 1. Variable-temperature X-ray powder diffraction patterns of hydrated VPI-5 between 273 K and 173 K (*I* stands for intensity).

steadily decreases from 0.810 nm at 273 K to 0.805 nm at 173 K. Thus, the position of all the (*hk0*) reflections remains unchanged, while the higher the value of *l* in the (*hkl*) reflections, the more rapid the shift in peak position to higher 2θ (corresponding to smaller interplanar distance). Thus, the (002) reflection moves away from the (211) reflection, as does (112) from (320). Similarly, the separation between the (311) and (102) reflections increases on cooling. In summary, X-ray crystallographic studies showed that the changes in peak positions are continuous, and do not indicate that any phase transition occurs. All the changes are accounted for only by the contraction of the crystallites along the *c* direction.

The ^{27}Al MAS NMR spectra of VPI-5 (Fig. 2a) show two signals in a 2:1 intensity ratio centered at $\delta = 40$ (tetracoordinated Al) and $\delta = -18$ (hexacoordinated Al), respectively. The latter displays a characteristic second-order quadrupole powder pattern which changes significantly with temperature, and can be simulated to yield the quadrupole constant, C_Q, the asymmetry parameter, η, and the isotropic chemical shift, δ_{iso} (Fig. 2b and Fig. 3).

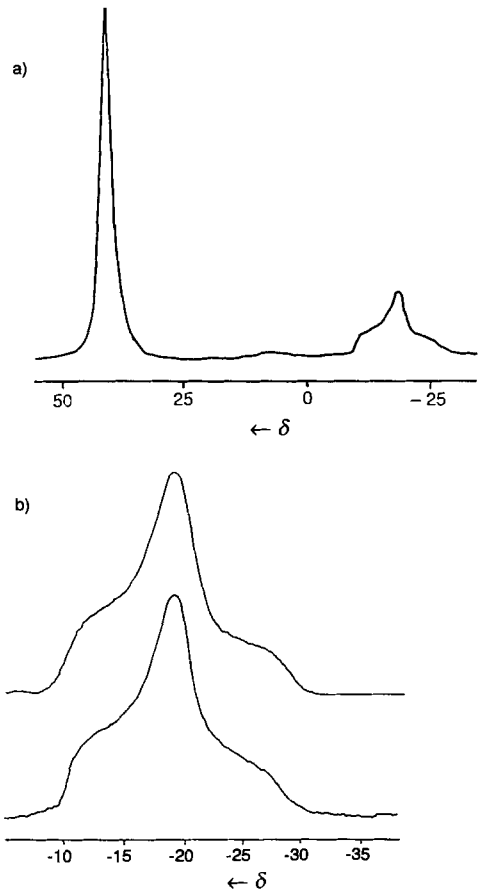

Fig. 2. (a) Room temperature (294 K) ^{27}Al MAS NMR spectrum of hydrated VPI-5 recorded with a spin frequency of 12 kHz. (b) Experimental (lower trace) and simulated (upper trace) second-order quadrupole patterns given by the hexacoordinated Al signal ($C_Q = 3.50$, $\eta = 0.91$, $\delta = -9.9$).

On cooling, the full-width-at-half-maximum Δ of the 40 ppm signal also changes considerably and at 235 K and 180 K ^{1}H decoupling produces a substantial line narrowing. Figure 3 indicates that some structural transformation occurs at 190–220 K. The room temperature quadrupole nutation

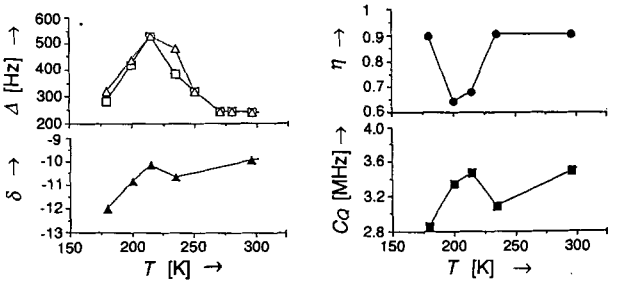

Fig. 3. Variation of full-width-at-half-maximum Δ of the ^{27}Al MAS NMR signal from tetracoordinated Al and isotropic chemical shift δ_{iso} and quadrupole parameters η and C_Q obtained by simulation of the hexacoordinated Al signal (see Fig. 2b), as a function of temperature. In the Δ plot the solid and dashed lines link points obtained from spectra recorded with and without ^{1}H decoupling, respectively. Note that all curves go through a maximum at 190–220 K.

spectrum (Fig. 4, top) has one signal at $\omega_{rf}/2\pi$ and two signals between $\omega_{rf}/2\pi$ and ca. $3\omega_{rf}/2\pi$. This shows that the two signals from tetracoordinated Al, which overlap in the ordinary MAS NMR spectrum, have slightly different quadrupole interaction parameters. The relatively weak spectral feature at $\delta = 38$ and $3\omega_{rf}/2\pi$ is due to a small amount of impurities. At 215 K, the two resonances from tetracoordinated Al are still present, but are less well resolved since the two-dimensional spectrum broadens along F_2 (Fig. 4, middle). However, at 191 K the nutation spectrum is significantly different. In particular, only one signal from tetracoordinated Al is observed (Fig. 4, bottom). On the other hand, at all temperatures studied, the ^{31}P MAS NMR spectra (not shown) display three resonances in a 1:1:1 intensity ratio.[9] It is difficult to imagine how the structure could possibly have *two* crystallographically nonequivalent aluminum sites, but *three* phosphorus sites. We conclude that two of the three aluminum sites are not resolved in the quadrupole nutation 191 K spectrum, because their quadrupole interaction parameters and isotropic chemical shifts are similar.

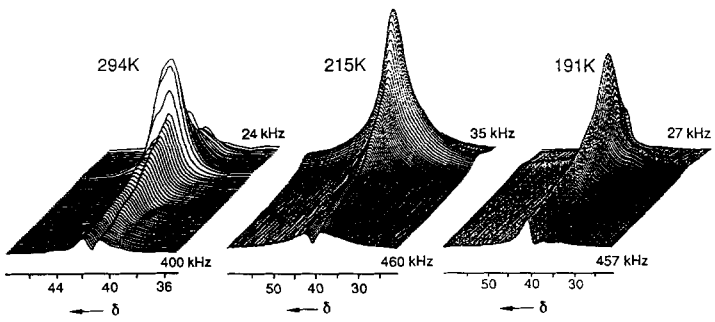

Fig. 4. ^{27}Al quadrupole nutation MAS NMR spectra of hydrated VPI-5 at several temperatures in the region of the signals of tetracoordinated Al.

The room temperature ^{1}H MAS NMR spectrum of hydrated VPI-5 (not shown) displays a broad signal at $\delta = 5$, due to water molecules in the large 18-membered channels. Below room temperature this signal broadens and a rather abrupt change occurs between 200 K and 180 K when a tenfold increase in Δ is observed. This suggests that the motion of the water molecules is effectively frozen. The transformation is fully reversible.

A comparison of the X-ray diffraction and NMR results nicely illustrates the fundamental difference between the two techniques: the spatial range of their sensitivity. NMR spectroscopy is essentially a submolecular technique, and in the case of VPI-5 the ^{31}P and ^{27}Al nuclei are sensitive only to their immediate environment involving at most tens, rather than thousands, of surrounding atoms. Unlike X-ray diffraction, NMR is not sensitive to long-range order. It is clear that the temperature-induced structural changes in VPI-5, as in silicalite,[15-17] involve only very minor modifications in atomic positions, which NMR is far better suited to monitor. Local changes in atomic environments, which can be separately monitored by NMR, may correspond to the same long-range symmetry.

Experimental Procedure

VPI-5 was prepared according to Davis et al. [12] using di-*n*-propylamine (DPA) as a template, hydrated for 12 h (25 wt % water) over a saturated solution of NH_4Cl. Elemental analysis indicates that the DPA content in the samples corresponds to about one molecule per three unit cells.

Powder X-ray diffraction patterns were collected with a Philips PW-1380 horizontal goniometer using $Cu_{K\alpha}$ radiation with a curved graphite monochromator in the diffracted beam. The low-temperature attachment [13,14] contained 30 mg of the sample in symmetrical transmission geometry, packed between two beryllium windows 1 mm apart. The temperature of the sample holder was controlled by a closed-cycle helium refrigerator. Data were collected between $3° \leq 2\theta \leq 60°$ in 0.025° steps with counting for 5 s per point. The temperature was lowered from 273 to 173 K in 5 K steps, at a rate of 1 K min^{-1} and allowing 15 mins for thermal equilibration before each measurement.

^{27}Al MAS NMR spectra were recorded on a Bruker MSL-400 spectrometer at 104.26 MHz (9.4 T) with very short, 0.6 μs (less than 10°), radiofrequency pulses and 0.4–0.5 s recycle delays. The 4 mm double-bearing zirconia rotors were spun in nitrogen gas at 8–12 kHz in the 180–294 K range. Quadrupole nutation spectra were recorded with a radiofrequency field of 115 ± 5 kHz and with MAS at 8–12 kHz. 40 to 64 data points were collected in the t_1 dimension in increments of 0.5 and 1 μs, the damping of the t_1 FID being ca. 30 μs. A sine-bell digitizer filter and zero filling were used in the t_1 dimension and the FIDs were doubly Fourier transformed in the magnitude mode. The chemical shifts are relative to external $[Al(H_2O)_6]^{3+}$. ^1H MAS NMR spectra were recorded at 400.13 MHz with a spinning rate of 7 kHz. In all NMR experiments the temperature was varied in steps of 5–20 K and 15 minutes were allowed for equilibration.

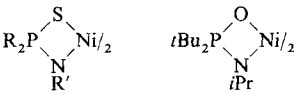
Bis(*P*,*P*-di-*tert*-butylphosphinic-*N*-isopropylamidato-*N*,*O*)nickel(II), a Paramagnetic Planar Complex

By *Thomas Frömmel, Wilfried Peters, Hartmut Wunderlich,* and *Wilhelm Kuchen**

Nickel complexes of the general type **1** are mainly monomeric in noncoordinating solvents and the Ni centers are tetracoordinated. Depending on R and R′ they are either dia- or paramagnetic ($\mu_{eff} \approx 3.1-3.3$ B.M. at room temperature).[1] The electronic spectrum of the diamagnetic compounds of this series shows no absorption bands at wave numbers < 10000 cm^{-1}, whereas in the spectra of the paramagnetic complexes, an absorption band at ca. 6500 cm^{-1} as well as a broad band of relatively high intensity with a maximum at ca. 16500 cm^{-1} are observed. The spectra of the paramagnetic complexes could be explained with ligand field theory under the simplifying assumption of T_d symmetry (instead of C_2 symmetry). On the basis of these magnetic and spectroscopic criteria we assigned a planar or tetrahedral coordination geometry to the different complexes **1**. That these criteria were valid for **1** could be proven by X-ray crystallographic investigations, which showed a planar *trans*-NiN_2S_2 chromophore for **1a** and a distorted-tetrahedral structure for **1c**.[1c]



1 **2**

a, R = *t*Bu, R′ = Et; **b**, R = Me, R′ = *cyclo*-C_6H_{11}; **c**, R = *t*Bu, R′ = *cyclo*-C_6H_{11}

However, several compounds **1** show anomalous magnetic moments ($\mu_{eff} < 2.8$ B.M., spin-only value for two unpaired electrons), which vary strongly with temperature for the dissolved complexes. Thus, for example, **1a** is diamagnetic in the solid state and shows no absorption bands < 10000 cm^{-1} in the remission spectrum. In solution, however, this complex is paramagnetic ($\mu_{eff} = 1.52$ (353 K) to 0.98 B.M. (273 K)) and shows a weak absorption at ca. 6500 cm^{-1}. On the other hand, **1b** shows anomalous magnetic behavior both in the solid state ($\mu_{eff} = 1.18$ B.M. (280 K), Curie–Weiss behavior between 290 and 90 K), and also in solution ($\mu_{eff} = 2.56$ (343 K) to 0.65 B.M. (233 K)). In both cases the characteristic absorptions for tetrahedral complexes of the type **1** are observed, here amongst others one at 6600 cm^{-1}. We explained these results by the formation of a conglomerate of the two isomers in solid **1b** and in the solutions of **1a** and **1b** by an isomeric equilibrium (a), which is shifted to the right with increasing temperature.[1d]

$$\underset{\text{(diamagnetic)}}{\text{planar}} \rightleftarrows \underset{\text{(paramagnetic)}}{\text{tetrahedral}} \qquad \text{(a)}$$

We synthesized the phosphinic amidato complex **2** according to Equation (b). Complex **2** forms olive-green crystals

$$2[t\text{Bu}_2\text{P(O)N}i\text{Pr}]\text{Li} \xrightarrow[-2\,\text{LiCl},\ -2\,\text{PPh}_3]{[\text{NiCl}_2(\text{PPh}_3)_2]} \mathbf{2} \qquad \text{(b)}$$

Institut für Anorganische Chemie und Strukturchemie der Universität Universitätsstrasse 1, D-W-4000 Düsseldorf (FRG)

which are highly soluble in aprotic organic solvents and which decompose gradually on the addition of moist air. The complex is monomeric in benzene.

Complex **2** shows the following characteristics: Magnetic properties: $\mu_{eff} = 3.40$ B.M. (297 K), Curie–Weiss behavior from 293 to 90 K (solid state!); $\mu_{eff} = 3.49$ B.M. (293 K), Curie–Weiss behavior from 293 to 190 K (solution in CD_2Cl_2!). Electronic spectra ($\tilde{\nu}$[cm^{-1}]; ε[L $mol^{-1}cm^{-1}$] in parentheses): 6800 (77), 12220 (36), 16780 (152), 18330 (162) (in toluene); 7300 (in transmission, single-crystal recording);[2] 7300, 17300 (in remission, powder spectrum, $BaSO_4$ as standard). The ^{31}P NMR spectrum of **2** shows a resonance at $\delta = -835$ (CD_2Cl_2, 293 K), which in contrast to that of the analogous thio complex [1c, 9] ($\delta = +127$, 293 K, toluene) is strongly shifted to high field.[1d] Thus, in contrast to **1b**, **2** shows Curie–Weiss behavior as well as a magnetic moment both in the solid state *and* in solution as is usually observed for tetrahedral Ni^{II} complexes. Furthermore, a distinct absorption band is found in the electronic spectra of both phases at a wave number $< 10000\ cm^{-1}$, which is shifted by $500\ cm^{-1}$ to higher values in the spectra of the solid. However, also the appearance of the solid and solution spectra of **2** are different in other ways (in contrast to the corresponding spectra of **1c** which are almost identical).[1d]

On the basis of the criteria mentioned, **2** should be tetrahedral both in the solid state and in solution. Therefore, we were even more surprised when the crystal structure analysis[3] showed that the Ni^{II} center is tetracoordinated but that this complex contains the exactly planar *trans*-NiN_2O_2 chromophore (Fig. 1).[4] Thus, to our knowledge **2** is the first paramagnetic planar Ni^{II} complex whose coordination geometry has been confirmed by X-ray crystallography.

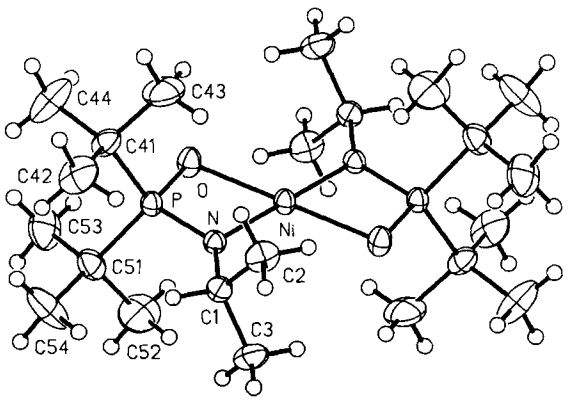

Fig. 1. Molecular structure of **2** (ellipsoids drawn with 25% probability). The complex has $\bar{1}$-C_i symmetry. A higher coordination number for the Ni atoms than four can be excluded since the following shortest distances to atoms of neighboring molecules are calculated: Ni–H 509, Ni–C 586 pm. Selected distances [pm] and angles [°] with standard deviations in parentheses: Ni-N 190.3(2), Ni-O 210.3(2), P-O 151.7(2), P-N 160.4(2), P-C41 184.9(3), P-C51 185.5(3), N-C1 148.0(3); N-Ni-O 74.2(1), Ni-N-P 94.5(1), N-P-O 101.7(1), P-O-Ni 89.6(1), Ni-N-C1 131.4(2), P-N-C1 134.0(2) [5].

According to simple ligand field theory both a low-spin and a high-spin form can be considered for planar Ni^{II} complexes. However, experience so far has shown that the spin-pairing energy is always smaller than term splitting for planar complexes due to the field strength of the ligand and a possible lowering of the symmetry of the ligand field. In contrast to **1**, this is no longer the case for **2** probably as a result of the exchange of S for O. Accordingly, in the electronic spectrum of **2** absorption bands are found at energies which are comparable to those of the tetrahedral complexes **1**. Therefore, in the case of **2**, an assignment of the coordination geometry only on the basis of magnetic and spectroscopic criteria is not possible .

Whether the planar structure of **2** is also retained in solution is as yet unknown. The magnetic behavior of the complex in both phases is almost identical, however, as mentioned, the electronic spectra of **2** in the solid state and in solution are different.

Experimental Procedure

Magnetic measurements were carried out according to Faraday (solid) and Evans (solution).[6] ^{31}P NMR spectroscopy: Bruker AM 200 (81.026 MHz, CD_2Cl_2, 293 K, 85% H_3PO_4).

2: tBu$_2$P(O)NHiPr (92 mmol) (colorless needles from toluene, m.p. 194 °C, $\delta(^{31}P) = 57$ (toluene), prepared from tBu$_2$PNHiPr [7] and 30% H_2O_2 in toluene as according to the literature [8]) in THF (20 mL) was treated with n-butyllithium (92 mmol, 1.6 M solution in hexane) and stirred at room temperature for 2 h. This reaction mixture was slowly added to $[NiCl_2(PPh_3)_2]$ (46 mmol). After the resulting clear solution was stirred for a further 2 h, the solvent was removed under vacuum at room temperature. The residue was taken up in a little toluene and the suspension was centrifuged and the clear solution obtained was kept in the refrigerator for some time. As a result, **2** was obtained as olive-green, hydrolysis-sensitive crystals, which do not change notably up to ca. 270 °C. Yield ca. 45%.

$C_{22}H_{50}N_2NiO_2P_2$ ($M_r = 495.3$), correct elemental analysis, molecular masses (cryoscopic in benzene): 503 (0.207 molal), 507 (0.092 molal); ^1H NMR (200 MHz, CD_2Cl_2, 293 K, TMS): $\delta_{PCCH} = 0.5$, $\delta_{PNCH} = 199$, $\delta_{NCCH} = 14.7$. Because of the strong broadening of the signals no fine structure was observed.

[3] $C_{22}H_{50}N_2NiO_2P_2$ ($M_r = 495.3$): Space group $P2_1/n$ (fully reduced cell, original choice 2), $a = 901.1(1)$, $b = 1507.0(2)$, $c = 1062.2(1)$ pm, $\beta = 97.42(1)°$, $V = 1.4303(3)$ nm^3, $Z = 2$, $\rho_{calcd.} = 1.15$ mg mm^{-3}, $\mu = 0.81$ mm^{-1}. Crystal size $0.4 \times 0.45 \times 0.45$ mm^3, Syntex/Siemens four-circle diffractometer $P2_1/P3$, 4568 reflections ($4 < 2\theta < 60°$, $Mo_{K\alpha}$, $\lambda = 71.073$ pm, graphite monochromator, ω:2θ scan, of 4185 symmetrically independent reflections 2675 observed ($F > 3\sigma_F$). Solution and refinement: SHELXTL-PLUS, $w^{-1} = \sigma^2F + 0.0009F^2$, 133 parameters, $R = 0.049$, $Rw = 0.060$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-55891, the names of the authors, and the journal citation.

[4] **2** forms crystals with edge lengths of between 0.4 and 2 mm, of which the smaller were selected for the crystal structure determination and the larger for the magnetic and spectroscopic measurements. To ensure there were no inhomogenetities of the material the crystallographic data and the single crystal transmission spectrum were redetermined for cleaved pieces of a large crystal. Here, the pairing of the *trans*-planar chromophore with the absorption band at 7300 cm^{-1} was confirmed.

[5] The Ni–N–P–O four-membered ring is planar within ±0.5 pm , the bond angles at N (94.5(1)°), P (101.7(1)°) and Ni (74.2(1)°) are significantly smaller than in **1c** (100.5(1), 102.1(1), and 80.7(1)°, respectively), here only the angle at O (89.6(1)°) is significantly greater than the corresponding angle at S in **1c** (76.6(1)°). The Ni–N distance (190.3(2) pm) in **2** is unexpectedly short in comparison to that in **1c** (194.7(1) pm).

[9] In the meantime, an X-ray structure determination has shown that the complex bis(*P*,*P*-di-*tert*-butylthiophosphinic-*N*-isopropylamidato-*N*,*S*)-nickel(II), the thio analogue of **2**, has a distorted tetrahedral structure.

"Artificial Metabolisms" for the Asymmetric One-Pot Synthesis of Branched-Chain Saccharides**

By *Wolf-Dieter Fessner** and *Christiane Walter*

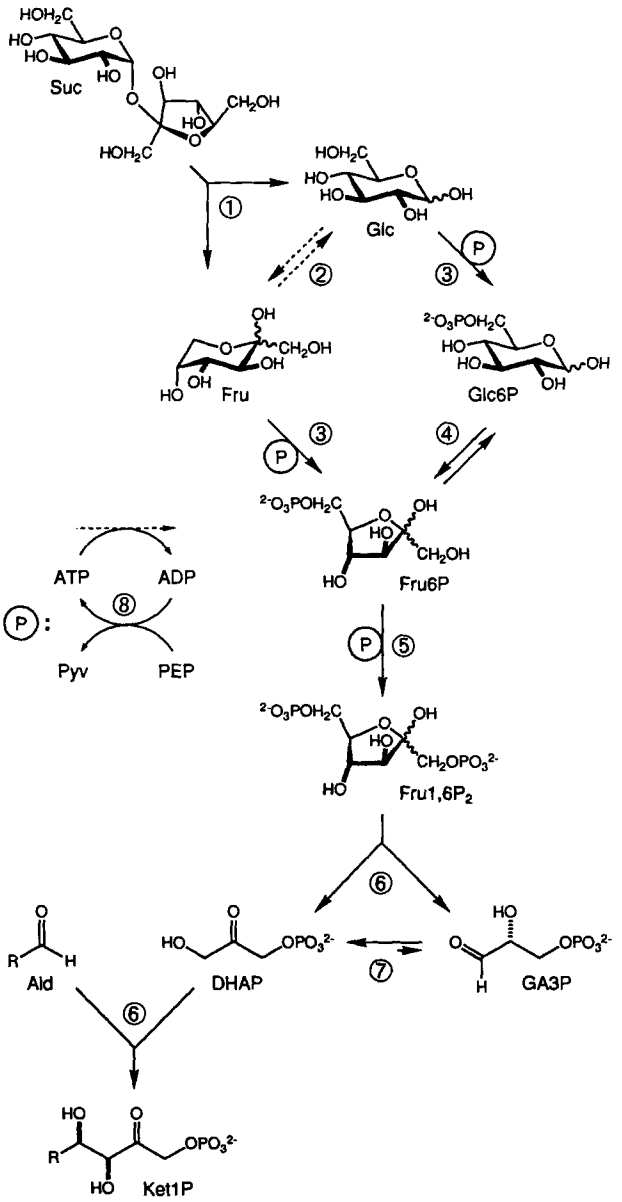
Dedicated to Professor George A. Olah on the occasion of his 65th birthday

The employment of biocatalysts—either as whole cells or as isolated enzymes—in asymmetric synthesis is enjoying increasing attention because of the usually high levels of optical induction, the high selectivities, and the mild reaction conditions.[1] The advantages of their usage are particularly well documented for the conversion of polyfunctionalized compounds such as carbohydrates.[2]

In the context of our program directed at the employment of C–C bond forming aldolases in asymmetric de novo syntheses[3] we have been searching for new means to make the essential substrate dihydroxyacetone phosphate (DHAP) efficiently available.[4] Here we detail the development of multienzyme systems that allow one to exploit regenerating raw materials as an economical source of DHAP for aldol additions using the fructose 1,6-bisphosphate aldolase (FruA). The investigations of these enzyme cascade reactions had been initiated, firstly because of the potential preparative benefit, and secondly to gain insight by qualitative and (semi)-quantitative studies in vitro into the complex kinetic effects operative in such a multiply regulated multienzyme system.[5]

Since the overwhelming number of common enzymes display sufficient activity around pH 7.0, they can be readily combined to ensembles that catalyze specific serial or parallel conversions of shared substrates. By this means, structurally profound conversions become realizable as simple one-pot procedures. Starting with the central function of the FruA in glycolysis to cleave and—in combination with triose phosphate isomerase—symmetrize fructose 1,6-bisphosphate ($Fru1,6P_2$) into C_3 fragments (a reaction that preparatively delivers DHAP in situ[6]), we have assembled additional steps in such a manner (Scheme 1) that glucose, fructose, or sucrose become alternatively accessible as possible precursors. All enzymes involved (cf. caption to Scheme 1) are commercially available, inexpensive, and well characterized.[7, 8] Because this reaction scheme comprises an unusual accumulation of coupled reactions as a new combination of natural, catabolic processes with a nonphysiological, anabolic synthetic component by application of pure isolated enzymes in vitro its designation as *artificial metabolism* seems justified.

We have tested experimentally three different variants for the production of $Fru1,6P_2$: 1) fructose is gradually phosphorylated twice; 2) glucose is first phosphorylated, then isomerized into the ketose form before the second phosphorylation (no adequate enzyme preparation was available to us for the more cost-efficient direct isomerization of glucose into fructose, path②[9]); 3) sucrose is hydrolyzed by invertase to provide both monosaccharides that independently, but convergently, react via the first two pathways, and thereby advantageously exploit the acceptance of the hexokinase



Scheme 1. Multienzymatic one-pot synthesis of ketose 1-phosphates. Cofactor regenerating cycles at phosphorylation steps were detached for clarity (encircled "P"). Abbreviations: Suc = D-sucrose; Glc = D-glucose; Fru = D-fructose; Glc6P, Fru6P = D-glucose(fructose) 6-phosphate; $Fru1,6P_2$ = D-fructose 1,6-bisphosphate; GA3P = D-glyceraldehyde 3-phosphate; DHAP = dihydroxyacetone phosphate; Ald = aldehyde; Ket1P = ketose 1-phosphate; ADP, ATP = adenosine di(tri)phosphate; Pyv = pyruvate; PEP = phosphoenol pyruvate. Enzymes involved are: ① = invertase (EC 3.2.1.26); ② = xylose isomerase (EC 5.3.1.5); ③ = hexokinase (EC 2.7.1.1); ④ = glucose 6-phosphate isomerase (EC 5.3.1.9); ⑤ = fructose 6-phosphate kinase (EC 2.7.1.11); ⑥ = fructose 1,6-bisphosphate aldolase (EC 4.1.2.13); ⑦ = triose phosphate isomerase (EC 5.3.1.1); ⑧ = pyruvate kinase (EC 2.7.1.40).

for both of the free sugars. As a consequence, from glucose and fructose or from sucrose, a total of two or four DHAP equivalents are acquired, respectively. Two other variations, such as the use of sucrose ($Suc + P_i \rightarrow Fru + Glc1P$) or α-glucane phosphorylase ($Glc_n + P_i \rightarrow Glc_{n-1} + Glc1P$)—attractive because of the reduction in required equivalents of phosphate donor—had to be discarded as impractical because of high enzyme costs or rheological complications.

A kinetic analysis of the longest sequence, which starts from sucrose and involves six enzyme-catalyzed reaction steps (Fig. 1), revealed the following effects: 1) fructose and

[**] Enzymes in Organic Synthesis, Part 3. This research was supported by the Deutsche Forschungsgemeinschaft (Grant Fe 244/2–1), the Wissenschaftliche Gesellschaft Freiburg, and the Fonds der Chemischen Industrie. The generous gift of recombinant bacterial strains by Prof. Dr. D. G. Fraenkel, Harvard Medical School, Boston, is gratefully acknowledged. We thank Dipl.-Chem. O. Eyrisch and Dipl.-Chem. G. Sinerius for samples of purified PFK-2 from *E. coli* and 7, respectively.—Part 2: [3b].

glucose are phosphorylated by hexokinase at almost identical rates; 2) the increase of Fru6P is retarded because of its equilibration to the thermodynamically more stable Glc6P; 3) v_{max} of the fructose 6-phosphate kinase (phosphofructokinase, PFK) remains the limiting factor even at a twofold higher dosage of the enzyme; 4) only on reaching a relatively high concentration of Fru6P (≥ 10 mM[10]) does a period of approximately linear production of Fru1,6P_2 (ca. 20–35 h) commence. The two latter facts are in accord with inhibition

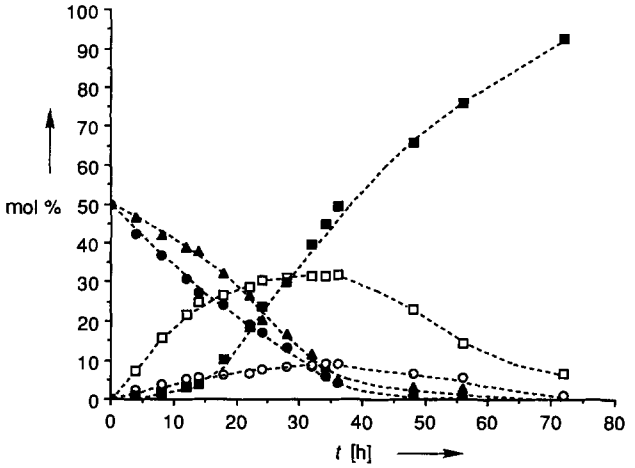

Fig. 1. Progress of the multienzymatic synthesis of fructose 1,6-bisphosphate from sucrose according to Scheme 1 (100 mM Suc, 500 mM PEP, 10 mM $MgCl_2$, 1 U of HK, 3 U of PK, 2 U of PFK, 0.25 U of PGI; 0.5 mL; pH 6.8; 25 °C), determined by assays according to [7b]. For analytical reasons, all consecutive reactions were started *after* the hydrolysis of sucrose by invertase (100 U) was completed. ● = D-Glucose; ▲ = D-fructose; □ = D-glucose 6-phosphate; ○ = D-fructose 6-phosphate; ■ = D-fructose 1,6-bisphosphate.

studies that had identified the PFK as the central regulatory element of glycolysis suffering from inhibition by numerous effectors (e.g. by ATP, PEP, pyruvate). Consequences of the multiple inhibition become distinctly apparent at higher concentrations of all reactants. These complications can indeed be effectively reduced (Fig. 2) by using the allosterically less regulated isoenzyme from *E. coli*, the PFK-2.[11] While the activity of the mammalian enzyme, for example, is almost completely suppressed ($< 5\%$) in the presence of ≥ 150 mM of PEP, the microbial enzyme maintains at least 30% of its activity even at considerably higher PEP concentrations (> 300 mM), which indicates the prevalence of non-competitive inhibition.

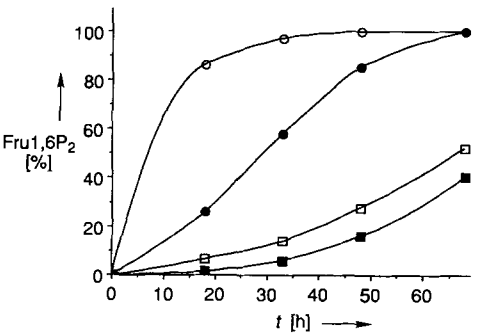

Fig. 2. Comparison of multienzymatic syntheses of fructose 1,6-bisphosphate from sucrose as the result of the type of fructose 6-phosphate kinase (PFK) and variation of the PEP concentration. a) PFK from rabbit muscle (● 25 mM, ■ 100 mM PEP); b) PFK-2 from *E. coli* (○ 25 mM, □ 100 mM PEP). Assays according to [7b].

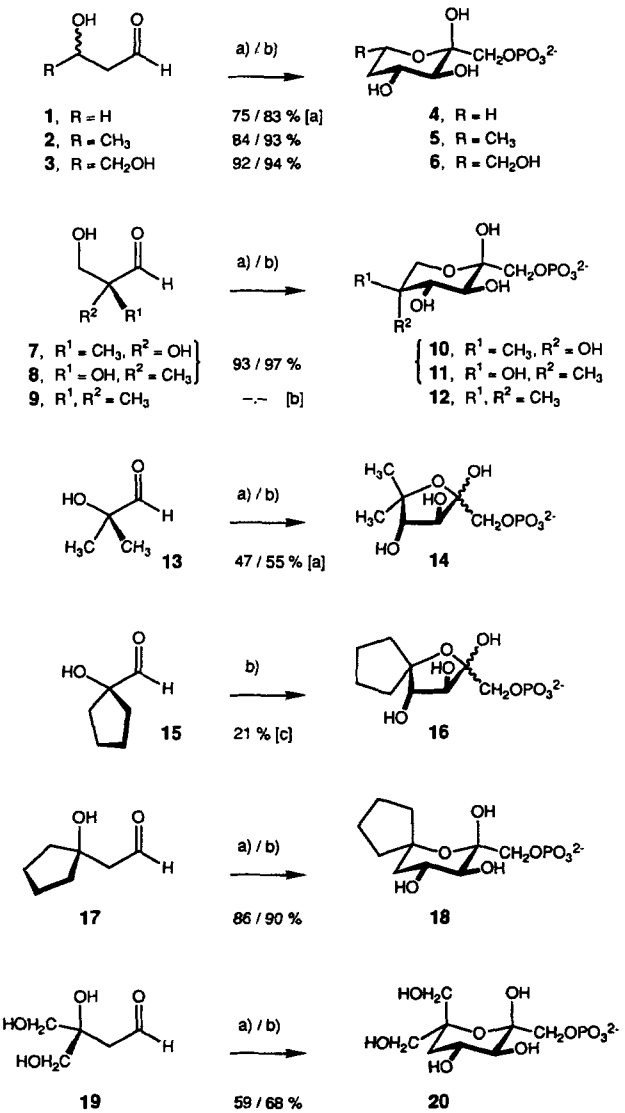
Subsequently, it proved rather unproblematic to combine to this the cleavage and synthesis steps employing the FruA from rabbit muscle, and thereby to arrive at a total of seven cooperatively acting enzymes. While formation of Fru1,6P_2 by consumption of the enol ester PEP is irreversible, the FruA-catalyzed syntheses are reversible. For reasons of charge entropy, however, the overall equilibrium is shifted towards the singly phosphorylated products, a tendency which may be further promoted by a slight excess of aldehyde. Due to the inherently smaller conversion rates of the aldolase for non-natural substrate analogues the aldol addition becomes the limiting step relative to all preceding reactions. This fact requires for its compensation a higher dosage of the FruA at a level inversely proportional to the substrate quality. We have tested the capacity of the method in preparation reactions (0.1–5 mmol Suc ≙ 0.4–20 mmol DHAP) with a series of aldehydes, which had been selected specifically also for reasons of increasing steric hindrance, in order to allow the further mapping of the substrate acceptance of the FruA from rabbit muscle (Scheme 2).[6]



Scheme 2. Enzymatic aldol additions. a) Multienzymatic one-pot synthesis according to Scheme 1 starting from sucrose, glucose, or fructose. b) Synthesis starting from pure fructose 1,6-bisphosphate using FruA-TPI catalysis. [a] Aldehyde was added after quantitative conversion of PEP. [b] No formation of aldol adduct detectable. [c] Reaction was prematurely terminated (conversion corrected yield $\geq 50\%$).

Table 1. NMR data of the aldol adducts [a].

[a] NMR spectra were measured in D_2O at pH 7.0 after ion exchange into the Na^+ form. ^{1}H NMR data (400.1 MHz) are given relative to sodium 3-(trimethylsilyl)-[$^2H_4$]-propionate (TSPNa) (δ = 0.00) as the standard, ^{13}C NMR data (100.6 MHz) relative to CH_3CN (δ = 1.30); coupling constants in Hz.

These studies revealed that geminal dialkyl substitution at C-2 is indeed still tolerated. However, with derivatives of glycol aldehyde (third substituent OH; **7/8** > **13** > **15**) the borderline is reached: similar to the situation for pivaldehyde, higher homologues (e.g., **9**) are no longer accepted. Inhibition of the enzymes by high concentrations of aldehydes proved problematic for individual cases only (e.g. the gradual release of acrolein from **1**[12] required its protracted addition). Relative to alternative syntheses starting from pure Fru1,6P$_2$ (cf. Scheme 2, method b) comparable yields are achieved with the multienzyme reactions. Limitations are encountered with very poor substrate analogues ($v_{rel} \leq 1\%$[6]) such as **15**, since isolation of the products from other phosphorylated components becomes quite difficult. Altogether this method makes available (Table 1) a selection of alkylated (**10**/**11**, **14**), spiro-annulated (**16**, **18**), and branched chain saccharides (**20**) or deoxy sugars (**4**,[12] **5**,[6] **6**) that can be produced only with difficulty by using classical synthetic methodology. A systematic investigation of these unusual sugar derivatives will be possible upon application of aldolases with a different stereochemical preference.[3]

In summary, we have demonstrated that multienzyme systems constructed around aldol additions are practical and efficient techniques to achieve complex transformations of saccharides and related compounds, and that these techniques, in which aldolases play a key role as valuable catalysts for the broadly applicable, highly diastereoselective C–C bond formation, can advantageously be applied to the exploitation of regenerable resources.

Experimental

An aqueous solution of sucrose (1.71 g, 5 mmol) containing PEP-K (5.10 g, 25 mmol) $MgCl_2$ (100 mg, 0.5 mmol), and a catalytic quantity of ATP (60 mg, 100 μmol) was adjusted to pH 6.8. After addition of an aqueous solution of **3** (50 mmol; total volume 200 mL) the mixture was incubated with invertase (yeast; 1000 U), pyruvate kinase (rabbit muscle; 300 U), hexokinase (yeast; 100 U), glucose 6-phosphate isomerase (yeast; 25 U [7a]), fructose 6-phosphate kinase (rabbit muscle; 200 U), fructose 1,6-bisphosphate aldolase (rabbit muscle; 500 U), and triose phosphate isomerase (yeast; 500 U) at room temperature. Conversion was monitored by thin-layer chromatography (saturated ammonia/EtOH 1:1) and by enzymatic assays for PEP/pyruvate and Fru1,6P$_2$ [7a]. The sugar phosphate **6** produced was isolated by application of ion exchange techniques [3a].

The First Reaction of S_5N_6; Structure of a Complex Containing an $S_2N_3^-$ Ligand**

By *Paul F. Kelly, Alexandra M. Z. Slawin, David J. Williams,* and *J. Derek Woollins**

Despite its long history[1] the chemistry of sulfur–nitrogen compounds continues to provide a rich store of unexpected, and at times inexplicable, reactions. This is particularly the

[*] Dr. J. D. Woollins, Dr. P. F. Kelly, A. M. Z. Slawin, Dr. D. J. Williams
Department of Chemistry
Imperial College of Science, Technology and Medicine
South Kensington, London SW7 2AY (UK)

[**] This work was supported by the British Science and Research Council and the Wolfson Foundation.

case for reactions involving metal species. For example, S_4N_4 reacts with the palladium compound **1** to give **2**, **3**,[2] and **4**.[3]

$(PPh_4)_2[Pd_2Cl_6]$ **1** $(PPh_4)_2[Pd_2Cl_6(S_2N_2)]$ **2**

$(PPh_4)_2[Pd_2Cl_4(S_3N_2)]$ **3** $(PPh_4)[PdCl_2(S_2N_2H)]$ **4**

The formation of such diverse products challenges our ability to construct rational mechanisms for sulfur–nitrogen reactions. Typically, the starting material for such a reaction is one of a handful of sulfur–nitrogen reagents such as S_4N_4, $S_4N_5^-$, $S_3N_3^-$, or $S_3N_3Cl_3$. One species which has not, however, found use in the preparation of sulfur–nitrogen metallacycles is S_5N_6;[4, 5] indeed to the best of our knowledge no reactions of any nature have been reported for S_5N_6. This is undoubtedly due in part to the problems in handling it, since the compound is both extremely explosive and very air-sensitive. Here, we report the first successful reaction of S_5N_6.

Stirring a mixture of **1** and S_5N_6 in CH_2Cl_2 for 12 h yielded three products which were crystallized from the resulting solution by slow diffusion of Et_2O. IR spectroscopy reveals two of the products to be **2** and **3**. The third product, **5**, was characterized by X-ray crystallography.[6] The anion in **5** is

$(PPh_4)[PdCl_2(S_2N_3)]$ **5**

essentially planar, with a maximum deviation of 0.10 Å for Cl(1) (Fig. 1). The PdS_2N_3 ring is planar to within 0.035 Å

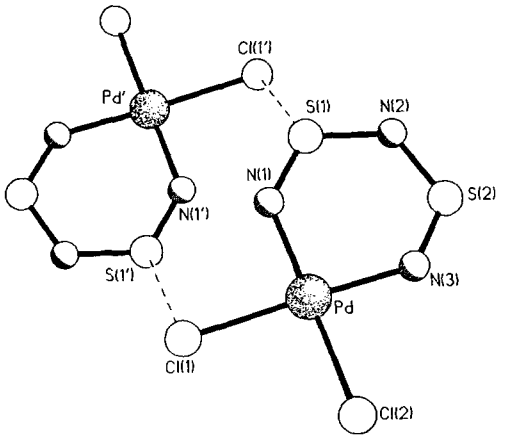

Fig. 1. Structure of a pair of the symmetry-related anions in **5**. Selected bond lengths [Å] and angles [°]: Pd-Cl(1) 2.336(2), Pd-Cl(2) 2.321(2), Pd-N(1) 1.950(6), Pd-N(3) 1.953(6), N(1)-S(1) 1.484(6), N(3)-S(2) 1.489(6), S(1)-N(2) 1.601(7), S(2)-N(2) 1.607(7); Cl(1)-Pd-Cl(2) 92.1(1), N(1)-Pd-N(3) 93.7(2), Pd-N(1)-S(1) 132.2(4), Pd-N(3)-S(2) 132.1(4), N(1)-S(1)-N(2) 120.2(4), N(3)-S(2)-N(2) 120.0(3), S(1)-N(2)-S(3) 121.6(4). Non-bonding contacts: Cl(1)···S(1') 3.56, N(1)···N(1') 3.30, S(1)···N(1') 3.41.

(N(3)) and slightly twisted (ca. 5°) with respect to the $PdCl_2$ plane. The anion has non-crystallographic C_{2v} symmetry; the equivalent ring bond lengths and angles are equal to within statistical significance. Whereas in previously reported MS_2N_3 rings[7–11] (containing the trianionic $S_2N_3^{3-}$ ligand) there is very little variation in the S–N bond lengths within the ring, here there is a marked difference in the lengths of the bonds between the S atoms and bridgehead N atom (average 1.604 Å) and between the S atom and the coordinated N atom (average 1.486 Å). Furthermore, we believe these latter distances to be amongst the shortest S–N bonds yet observed in S–N rings. The only noticeable slight asymmetry in the anion is in the Pd–Cl bond lengths (2.336(2) versus 2.321(2) Å for Cl(1) and Cl(2) repectively). This difference we attribute to a weak intermolecular interaction between Cl(1) and S(1'), 3.56 Å across a crystallographic center of symmetry (Fig. 1).[12] The Pd–N distances are normal. There are no short cation–anion contacts. MS_2N_3 metallacycles have been previously reported, but in all cases the S_2N_3 ligand has been assigned a -3 charge, whereas here it is monoanionic. One example of a protonated $S_2N_3^{3-}$ ligand has been described, the complex anion in **6**.[13] However, from the X-ray analysis there is no evidence

$(AsPh_4)[W(O)Cl_3S_2N_3H)]$ **6**

of protonation of any of the nitrogen atoms of **5**; this is further reinforced by IR studies. Careful measurement of the spectrum of **5** including difference spectra with **1** and **2** does not reveal the presence of any ν(NH) vibrations. ν(NH) vibrations in metal-sulfur-nitrogen systems are usually readily apparent. In the anion of **6**, a medium intensity band at 3275 cm^{-1} is observed.

The reaction of S_5N_6 with **1** demonstrates the usefulness of this S–N compound in the formation of new structural types. The formation of **5** suggests that the $S_2N_3^-$ ligand also has a potentially important role in the chemistry of S–N metallacycles.

Experimental Procedure

5: A mixture of solid S_5N_6 [5] (0.13 g, 0.53 mmol) (**Caution**: explosive!) and **1** (0.286 g, 0.26 mmol) was treated with CH_2Cl_2 (50 mL) and the resulting solution stirred 12 h, during which time it slowly darkened and then lightened in color. The volume was reduced under vacuum to a few mL and the solution filtered then layered with Et_2O. Slow diffusion for 24 h yielded a mass of crystalline product which was washed with Et_2O and dried under vacuum. Three different types of crystals were present in the resulting mixture: brown plates together with orange needles and very dark black-red plates. The crystals were separated manually. The brown plates and orange needles were identified by IR spectroscopy as **2** (115 mg, 37%) and **3** (45 mg, 15%), respectively. Correct C,H,N-analysis. IR (without PPh_4 bands) $\tilde{\nu}$ [cm^{-1}] = 1126(m), 858(vs), 409(m), 308(m).

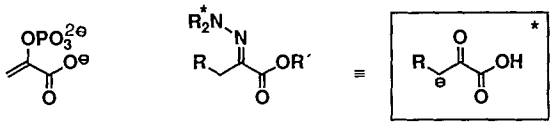
Enantioselective Synthesis of 3-Substituted 2-Ketoesters**

By *Dieter Enders,* Hubert Dyker,* and *Gerhard Raabe*

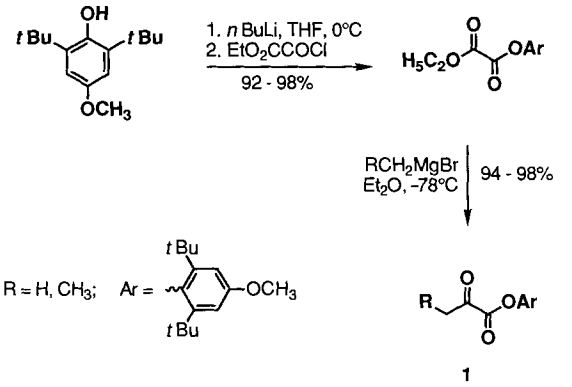
Dedicated to Professor Günther Maier on the occasion of his 60th birthday

As phosphoenolpyruvate (PEP) **A**, pyruvic acid plays a central role in the biosynthesis of sialic acids and ulosonic acids,[1] whereby phosphoenolpyruvate undergoes C–C linkage to aldehydes by means of aldol reactions catalyzed by aldolases. Important natural products such as *N*-acetylneuraminic acid, 3-deoxy-D-*manno*-octulosonic acid (KDO), and 3-deoxy-D-*arabino*-2-heptulosonic acid 7-phosphate (DAHP), the precursor of shikimic acid, are formed in this way. Chemical equivalents of phosphoenolpyruvate—metalated derivatives of pyruvic acid, for example chiral hydrazones **B** (R = H), or more generally derivatives of 2-ketocarboxylic acids[2]—can be considered d^2 synthons **C**.[3] In recent years several such systems have been examined,[4] but to our knowledge no efficient general reagent for the transfer of the synthon **C** to electrophiles in diastereo- and enantioselective reactions is available.



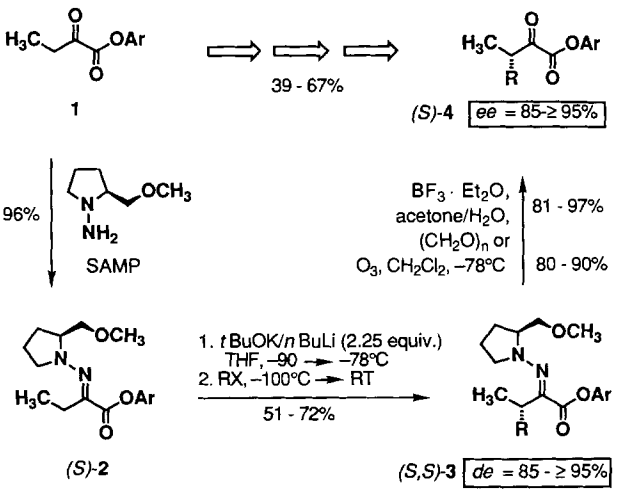
A (PEP) **B** **C**

We now report on the synthesis of a chiral, homologous PEP equivalent **B** (R = CH_3) by the application of our SAMP-/RAMP- hydrazone method[5, 6] and the use of **B** in the synthesis of highly enantio-enriched 3-substituted 2-ketoesters. Our initial attempts at metalating hydrazones of methyl and *tert*-butyl pyruvate and trapping them with electrophiles were unsuccessful and led primarily to self-acylated products. Only after we sterically blocked the ester reactivity as the 2,6-di-*tert*-butyl-4-methoxyphenyl ester[7] was the direct manipulation of the corresponding azaenolates possible. The two-step synthesis of 2-ketoester **1** succeeded in a simple fashion and in excellent yields by the esterification of ethyl oxalyl chloride with the lithium salt of 2,6-di-*tert*-butyl-4-methoxyphenol followed by the chemoselective nucleophilic addition of methyl or ethyl Grignard reagents to the unsymmetrical ethyl aryl oxalate (Scheme 1).



Scheme 1. Synthesis of 2-ketoester **1**.

The reaction of 2-ketoester **1** with (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP)[6, 8] provided the (*E*)-configured hydrazone (*S*)-**2** as a pale yellow solid in almost quantitative yield. The subsequent metalation with 2.2 equivalents of Lochmann–Schlosser base in tetrahydrofuran at −90 to −78 °C yielded highly reactive azaenolates, which were alkylated by a number of alkyl halides at −100 °C in good yields (51–72%) and with high diastereomeric excesses (*de* = 85 to >95%) to furnish hydrazones (*S,S*)-**3**. If less base was used, the alkylation did not go to completion. By the oxidative cleavage with ozone the alkylated hydrazones were converted in good yields and without racemization to the final products (*S*)-**4**, which were purified by flash chromatography (Scheme 2). This last step is not suitable for compounds like (*S,S*)-**3d** which are easily oxidized by ozone. In such cases the SAMP hydrazone can be converted to ketoesters (*S*)-**4** with boron trifluoride–ether in acetone/water with the addition of paraformaldehyde. This method was previously employed in a similar way for the cleavage of dimethylhydrazones.[9] In comparison to the oxidative cleavage this method gave somewhat better yields; however, reac-



Scheme 2. Enantioselective synthesis of the 3-substituted 2-ketoester **4**.

[*] Prof. Dr. D. Enders, Dipl.-Chem. H. Dyker, Dr. G. Raabe
Institut für Organische Chemie der Technischen Hochschule
Professor-Pirlet-Strasse 1, D-W-5100 Aachen (FRG)

[**] This research was supported by the Fonds der Chemischen Industrie and the companies Degussa, BASF, Bayer, and Hoechst (donation of chemicals). H.D. thanks the Fonds der Chemischen Industrie for a Kekulé fellowship.

tion times of one to two days were required (monitored by thin-layer chromatography).

The enantiomeric excess of the 3-substituted ketoester (*S*)-**4a** was determined by a ^{1}H NMR shift experiment with Eu(hfc)$_3$, and proved that the cleavage with ozone and boron trifluoride–ether proceeded without racemization. In the other cases the enantiomeric excesses are based on the diastereomeric excesses of hydrazones **3** as determined by ^{13}C NMR spectroscopy. The enantiomers (*R*)-**4** are accessible simply by changing the chiral auxilliary (RAMP instead of SAMP), as was demonstrated for (*R*)-**4e** and (*R*)-**4h**.

Table 1. The highly enantio-enriched 3-substituted 2-ketoesters **4** prepared by the enantioselective alkylation of 2-ketoesters **1** via the SAMP hydrazones (*S*)-**2**.

[a] Yield of the pure ketoester **4** after cleavage of hydrazone **3** with ozone or $BF_3 \cdot Et_2O$ (in parentheses). [b] Determined by ^{1}H NMR shift experiments with Eu(hfc)$_3$ and/or by ^{13}C NMR spectroscopy of the hydrazone intermediate, whose absolute configuration is given in parentheses. [c] m.p. 56–57 °C. [d] m.p. 78–79 °C. [e] RAMP was used as the chiral auxiliary.

The absolute configuration of hydrazones **3**, and thus also of ketoesters **4**, was determined by X-ray structure analysis of (*S*,*S*)-**3e** (Fig. 1).[10] The (*S*) configuration found at the newly formed stereogenic center is in agreement with that predicted by the postulated mechanism for electrophilic substitutions via SAMP/RAMP hydrazones.[14]

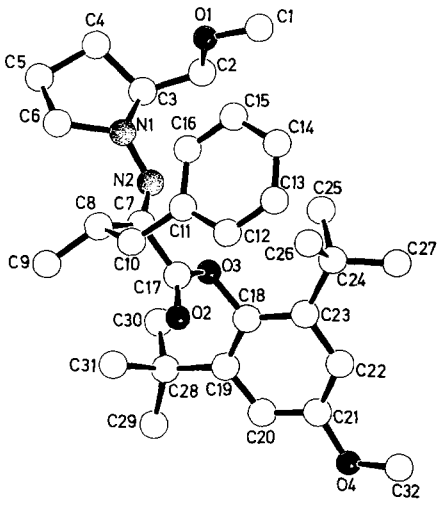

Fig. 1. Structure of (*S*,*S*)-**3e** in the crystal (Schakal plot[15]).

This method permits for the first time the highly enantioselective transfer of a homologous pyruvate unit to electrophiles.[16] Preliminary enzyme-mimetic applications of this new procedure to asymmetric aldol reactions are promising and should allow a simple and stereoselective approach to important natural products and drugs.[17]

Experimental Procedure

A solution of 6.6 mmol Lochmann–Schlosser base was prepared by the addition of a solution of *n*BuLi in *n*-hexane (4.4 mL, 1.5 M) to a solution of potassium *tert*-butoxide (0.74 g) in THF (20 mL) at –78 °C under argon. This solution was cooled to –90 °C, and hydrazone (*S*)-**2** (1.3 g, 3 mmol) dissolved in THF (4 mL) was added. The reaction mixture was stirred for 2 h and allowed to warm to –78 °C. The reaction mixture was then cooled to –100 °C, and a solution of 6.6 mmol of the alkyl halide in 3 mL of THF was added dropwise. The reaction temperature was held at –100 °C for 2 h before the solution was allowed to warm to 0–10 °C over 12 h. The solution was neutralized by the addition of glacial acetic acid (0.4 g, 6.6 mmol) in water (2 mL) and then extracted with ether (200 mL). After the phases were separated, the ethereal phase was washed with a buffer solution (10 mL, pH 7) and saturated NaCl solution (10 mL) and dried over $MgSO_4$. The solvent was removed in vacuum, and the crude hydrazone was purifed by flash chromatography (silica gel, petroleum ether/ethyl acetate 9:1).

For the cleavage, 1 mmol of the hydrazone was dissolved in CH_2Cl_2 (50 mL) and cooled to –78 °C under argon. Ozone was passed through the solution at that temperature until the reaction was complete (reaction progress monitored by TLC). After the excess ozone was dispelled with argon, the reaction mixture was allowed to warm to room temperature. The solvent was removed in vacuum, and the product was purified by flash chromatography (silica gel, petroleum ether/ethyl acetate/isopropanol 95:5:1). Alternatively, the hydrazone was dissolved in 10 mL acetone and 1 mL water, and $BF_3 \cdot Et_2O$ (0.38 mL, 3 mmol) was added dropwise. Paraformaldehyde (0.15 g, 5 mmol) was then added, and the reaction mixture was stirred 15 h at room temperature. To ensure complete reaction another portion of $BF_3 \cdot Et_2O$ (0.38 mL, 3 mmol) was added, and the reaction mixture was stirred another 12–24 h (reaction progress again monitored by TLC). Solvent was removed in vacuum, and the residue was taken up in ether, washed with saturated NH_4Cl solution (5 mL) and saturated NaCl solution (5 mL), and dried over $MgSO_4$. After evaporation of the solvent the crude product was purifed by flash chromatography as described above.

Biochemical Degradation of Cyanamide and Dicyandiamide**

By *Lydia M. Estermaier,* A. Heidemarie Sieber, Friedrich Lottspeich, Dagmar H. M. Matern,* and *Guido R. Hartmann*

Dedicated to Professor Heinz Harnisch on the occasion of his 65th birthday

Nitrate is the predominant form of nitrogen in the soil available to most plants grown under normal field conditions and is taken up as such as a source of nitrogen. It is produced from ammonium ions by oxidation catalyzed by soil microorganisms (nitrification).[1] Due to the cation exchange properties of soil, NH_4^+ is more easily accumulated than NO_3^- which is rapidly lost by leaching.[2] Most artificial fertilizers contain nitrogen in the form of nitrate or ammonium ions. However, the first synthetic compound used as nitrogen fertilizer was cyanamide, which is synthesized from calcium carbide and atmospheric nitrogen in an exothermic reaction. Despite its relatively high cost, cyanamide is still used in agriculture and horticulture as a nitrogen fertilizer, particularly in the form of its calcium salt, because of its other useful properties. In addition to its ability to provide nitrogen it acts also as a herbicide (defoliating weeds),[3] pesticide, fungicide, and bactericide.[4] In this last function it is also utilized for the deodorization of liquid manure. Cyanamide is also active in halting the dormancy of grape vines[5] and other fruits. This discovery opened a new field of application as plant growth regulator.

Dicyandiamide, the product of dimerization of cyanamide, is applied in agriculture as an inhibitor of nitrification. It prevents the oxidation of NH_4^+ by *Nitrosomonas europea*[6] and thereby stabilizes the supply of nitrogen available in the soil.

The mechanism of the biological degradation of these compounds poses an interesting ecological problem. When applied to fields, cyanamide usually disappears within a couple of days, depending on the soil and its moisture content. It was clear from the beginning that some catalytic mechanism must be involved in the degradation. For a long time it was thought that inorganic catalysts present in the soil are involved in this process, until the experiments of Ernst[7] clearly showed the preponderance of biological mechanisms, although the biochemistry of this particular degradation was not elucidated.

An inducible enzyme, cyanamide hydratase (EC 4.2.1.69), highly specific for the hydration of cyanamide (but not dicyandiamide) to urea, was first detected in the soil fungus *Myrothecium verrucaria*[8] and purified to homogeneity.[9] However, it is unlikely that this enzyme is generally responsible for the biological degradation of cyanamide in the soil, since it is expressed by the fungus only in the complete absence of any other nitrogen source, and expression immediately stops if another nitrogen source becomes available.

Hofmann et al.[10] described another enzymatic activity in extracts of commercial soybean flour which catalyzes the disappearance of cyanamide. We have purified this cyanamide-degrading enzyme from soybean flour (type I, not roasted, Sigma, Munich) in six steps to apparent homogeneity. Its molecular mass is about 600000, and it consists of six identical subunits. The first 23 amino acids at the *N*-terminus of the subunit were sequenced using the methodology described by Eckerskorn et al.[11] The sequence was the same as that at the *N*-terminus of urease from jack bean.[12] These findings suggested that the isolated enzyme may be identical to urease from soybean.

We therefore tested the commercially available, highly purified urease from jack bean (*Canavalia ensiformis*) (type VII, Sigma, Munich) for its ability to degrade cyanamide. Such a comparison disclosed that jack bean urease indeed exhibited the same specific enzymatic activity (310 ± 20 nmol min^{-1} mg^{-1}), and the same K_m value (0.15 ± 0.05 M) with cyanamide as substrate as the enzyme from soybean. Similarly the optimum of pH (7.0) and temperature (70 °C) was the same. In the reaction two moles of ammonia were formed for each mole of cyanamide consumed. Obviously urease catalyzed a cyanamide hydrolase reaction [Eq.(a)].

$$H_2N\text{-}CN + 2H_2O \longrightarrow 2NH_3 + CO_2 \qquad (a)$$

Additional evidence that urease is responsible for the cyanamide hydrolase activity was provided by the effect of specific inhibitors of urease;[13, 14] all of them inhibited the cyanamide hydrolase activity (Table 1).

To determine the substrate specificity we have tested not only cyanamide but also cyanamide derivatives such as *N*-formylcyanamide, acetylcyanamide, and benzoylcyanamide for hydrolysis by urease. But even with a 100-fold greater enzyme concentration than that used in the experiments with unsubstituted cyanamide and with prolonged incubation times up to 24 h, no hydrolysis was detectable.

Since cyanamide is hydrolyzed by urease we investigated also cyanic acid as a substrate. In contrast to cyanamide, cyanic acid is rather unstable at pH 7.0 and decomposes rapidly without addition of a catalyst. Nevertheless, the degradation of this compound is also distinctly enhanced by

[**] These investigations have been supported by SKW Trostberg AG and the Fonds der Chemischen Industrie. We are very grateful to Prof. M. H. Zenk and Dr. T. Kutchan, Munich, for generous help with plant cell cultures and for discussions and to Dr. R. J. Youngman, Trostberg, for information. We wish to thank Prof. K. Kobashi, Toyama, for *N*-isopentenoylphosphoric trisamide and Prof. A. Böck and G. Müller, Munich, for the supply of bacterial strains.

Table 1. Effect of inhibitors of jack bean urease on cyanamide hydrolase activity. The conditions of incubation were similar to those of the cyanamide hydratase assay [9], but with 10 mM Tris/HCl buffer 7.4 at 50 °C (Tris: tris(hydroxymethyl)aminomethane). Cyanamide or urea were determined as described [9,23]. *N*-isopentenoylphosphoric trisamide [14] was obtained from Professor K. Kobashi, Toyama. *N*-phenylphosphoric trisamide was synthesized according to Kobayashi [24].

Inhibitor	Concentration [μM]	Cyanamide hydrolase activity [a] [%]	Urease activity [b] [%]
sodium fluoride	20000	48	34
acetohydroxamic acid	20	45	48
hydroquinone	40	45	48
N-isopentanoylphosphoric trisamide	5	60	4
N-phenylphosphoric trisamide	50	34	34

[a] 530 urease units $\times mL^{-1}$ were applied for the cyanamide hydrolase reaction; [b] 3 urease units $\times mL^{-1}$ were applied for the urease reaction.

urease. One mole of ammonia is formed per mole of depleted CNO^-, which suggests reaction (b).

$$HO\text{-}CN + 2HOH \longrightarrow H_2CO_3 + NH_3 \qquad (b)$$

Obviously urease exhibits cyanase (EC 3.5.5.3) activity.[15] As in the case of cyanamide (Table 1), low concentrations (5–30 μM) of phenylbisamidophosphate and phenylphosphoric trisamide inhibited the enzymatic hydrolysis of cyanate although only by 30 to 55%.

A relatively large number of compounds structurally related to urea or cyanamide are hydrolyzed by urease from jack bean, although the rate of hydrolysis is 100 to 1000 times less lower than with urease (Table 2). Obviously, at a low level of

Table 2. Compounds related to urea or cyanamide as substrate of jack bean urease. In our experiments the incubation conditions at 38 °C of Dixon et al. [16] were applied. Cyanamide and dicyandiamide were determined according to [9, 25].

Substrate	k_{cat} [s^{-1}]	K_m [M]	Ref.
urea ($H_2N\text{-}CO\text{-}NH_2$)	3500	0.003	[a]
semicarbazide ($H_2N\text{-}CO\text{-}NH\text{-}NH_2$)	30	0.06	[16]
hydroxyurea ($H_2N\text{-}CO\text{-}NH\text{-}OH$)	12	0.002	[16]
methylurea ($H_2N\text{-}CO\text{-}NH\text{-}CH_3$)	0.075	0.22	[16]

[a] This work.

activity the substrate specificity of urease is rather broad but not unlimited, since derivatives such as guanylurea and cyanourea were not degraded at all, even when we used a urease concentration 100 times higher. Related in structure to cyanourea is dicyandiamide. Thus we have tested also dicyandiamide as a possible substrate of urease.

Unexpectedly, this compound hydrolyzed. The K_m value was almost the same and the k_{cat} value was only nine times less than that for cyanamide (Table 2). Furthermore, the reaction showed a similar dependence on pH and temperature as the enzymatic hydrolysis of cyanamide suggesting that both hydrolytic reactions are catalyzed by the same enzyme.

Analysis of the reaction products revealed that the enzymatic hydrolysis of dicyandiamide led to approximately equal amounts of cyanourea and ammonia. This suggests the following hydrolytic reaction [Eq.(c)].

$$H_2N\text{-}C(NH)\text{-}NH\text{-}CN + HOH \longrightarrow H_2N\text{-}CO\text{-}NH\text{-}CN + NH_3 \qquad (c)$$

This hydrolysis is rather substrate-specific, since guanidine, for example, is not hydrolyzed by urease. Recently, a *Rhodococcus* species was discovered[17] which also degrades dicyandiamide to cyanourea. However, the stoichiometry of this reaction was not determined. The catalysis of the conversion of dicyandiamide to cyanourea belongs to a type of enzymatic reaction that is different from the other reactions catalyzed by urease (urea aminohydrolase) such as the hydrolysis of cyanate or cyanamide. With dicyandiamide as substrate, the hydrolysis of an imino group is catalyzed. Arginine deiminase (EC 3.5.3.6) is another enzyme that catalyzes such a reaction. In contrast to dicyandiamide, hydroxyurea is hydrolyzed by urease to NH_3, CO_2, and H_2NOH.[18]

These findings demonstrate the broad range of reactions that can be catalyzed by the enzyme urease. With respect to the mechanism of catalysis, the question arises of whether all these reactions are catalyzed at the same active center or if urease belongs to the class of "double-headed" enzymes with separate active centers for the various catalytic activities. In this context it may be of interest to note that neither hydroxyurea, hydroquinone, acetohydroxamic acid, nor *N*-isopentenoyl phosphoric trisamide inhibit the hydrolysis of dicyandiamide at a concentration (50 μM) which inhibits the cyanamide hydrolase or urea amido hydrolase activity of urease.

Urease is a widely distributed enzyme found also in plants,[19] and a particularly rich source is the seeds of *Leguminosae*. Therefore it was not surprising that extracts of all such seeds (soybean, mung bean, bush bean, lentil, pea) and of leaves from lentil, pea, and lupine exhibited cyanamide hydrolase activity.

Most of cyanamide and dicyandiamide used in agriculture is applied to the soil. Therefore it is likely that microorganisms in the soil are mainly responsible for the biological conversion and degradation of these compounds. Urease is widely distributed among microorganisms.[19] The question arises whether urease from bacteria in the soil also degrades cyanamide. The answer is not obvious, because bacterial ureases differ from each other and from the plant enzymes in parameters such as size, number of subunits, and nickel content.[20] (Nickel is an essential cofactor for urease activity.) *Bacillus pasteurii* is a gram-positive eubacterium with a particularly high urease activity which occurs in the soil. Its urease consists of four identical subunits (M_r 65000) with a total mass of about 230000,[21] whereas the urease from jack bean consists of six identical subunits (M_r 96600) with a holoenzyme molecular mass of 590000.[13] We compared the substrate-degrading activity of a commercially available preparation of urease from *Bacillus pasteurii* (type X, partially purified powder, 100–200 units per mg, Sigma, Munich) with that of the enzyme from jack bean using urea, cyanamide, and dicyandiamide (Table 3). The plant enzyme was more active than the bacterial urease. This may have been due to the higher purity or due to the fact that both enzymes were not tested under saturating substrate concentrations for technical reasons. Dicyandiamide was metabolized to equal amounts of cyanourea and ammonia by the bacterial urease in an identical manner to the plant enzyme.

Table 3. Hydrolysis of cyanamide and dicyandiamide by urease from jack bean or from *Bacillus pasteurii*. The assay was carried out with 20 mM substrate in 10 mM Tris/HCl pH 8.0 at 50 °C. The disappearance of urea, cyanamide, and dicyandiamide was measured by colorimetric assays as in [23, 9, 25].

Substrate	nmol substrate metabolized at pH 8.0 and 50 °C per min and mg protein by urease from	
	jack beam	*B. pasteurii*
urea	366000 [a]	55000 [d]
cyanamide	176 [b]	9 [e]
dicyandiamide	8 [c]	0.2 [f]

[a] 1.2, [b] 104, [c] 520, [d] 1.2, [e] 436, [f] 8720 units of urease used in the assay.

Inhibitors of urease activity reduced the cyanamide hydrolase activity of the bacterial enzyme (Table 4). This supports the conclusion that the bacterial urease is also responsible for the catalysis of cyanamide degradation. In agreement with the observations made with plant urease, the degradation of dicyandiamide by the bacterial enzyme is not susceptible to inhibition by 15 mM NaF, 100 μM hydroquinone, 50 μM isopentenoylphosphoric trisamide, or 50 μM *N*-phenylphosphoric trisamide.

Table 4. Inhibition of cyanamide hydrolase activity of urease from *Bacillus pasteurii* by urease inhibitors. The enzyme was preincubated with the inhibitor in 10 mM Tris/HCl pH 7.4 for 15 min at 50 °C before addition of substrate.

Inhibitor	Inhibitor concentration [μM]	Cyanamide hydrolysis [a] [%]	Inhibitor concentration [μM]	Urea hydrolysis [b] [%]
sodium fluoride	20000	37	40000	42
acetohydroxamic acid	20	27	20	44
hydroquinone	100	40	40	31
N-phenylphosphoric trisamide	50	46	50	63
N-isopentenoyl-phosphoric trisamide	20	76	0.5	19

[a] 1092 urease units per mL (2 h incubation). [b] 4.4 urease units per mL (15 min incubation).

Cyanamide hydrolase activity was also detected at pH 7.4 and 50 °C in urease containing crude extracts of other soil bacteria such as *Proteus vulgaris, Proteus mirabilis, Klebsiella oxytoca*, and *Mycobacterium phlei* in the range of 0.5–4 nmol cyanamide degradation per min and mg protein.

The fertilizers urea and cyanamide must both be degraded in the soil before they can fulfill their physiological role as suppliers of nitrogen for plants. Urea is degraded efficiently by urease, which is ubiquitous in microorganisms in the soil. Thus in the application of urea as a fertilizer, the abundance of urease may lead to a transitory massive formation of toxic ammonia (ammonium ions) with adverse effects on seed germination, seedling growth, and early plant growth. To eliminate these effects the addition of small amounts of urease inhibitors has been suggested.[22]

For the fertilizer cyanamide the situation is different. Enzymes that degrade cyanamide specifically seem to be much less abundant in the soil. So far only one, cyanamide hydratase, has been discovered[8] and characterized.[9] Its high substrate-specificity for cyanamide poses the interesting question of how this enzyme provides the microorganism with a selective advantage for survival and reproduction, since cyanamide is not found in nature.

An alternative cyanamide-hydrolyzing enzyme is the ubiquitous urease, as we demonstrated above. It catalyzes this reaction much more slowly than the hydrolysis of urea, with the consequence that a massive and instantaneous production of ammonia in the soil is prevented. Thereby the rate of the subsequent nitrification and leakage of nitrate formed from the soil is also diminished.

Because cyanamide and dicyandiamide are not found in nature, the question of how such chemicals are metabolized when they are purposely or inadvertantly released into the environment is raised. One might expect that a biological degradation would not occur, because there has been insufficient time for natural selection and development of suitable degrading microorganisms. However, many such chemicals, including cyanamide, disappear relatively rapidly in nature. In this context one should not overlook the fact that in contrast to the usual conditions in the laboratory the exposure time for degradative processes in natural ecosystems is much longer. It follows that enzymatic processes with much lower reaction rates, like that of the hydrolysis of cyanamide or dicyandiamide by urease from plants and bacteria, may contribute to the removal of toxic synthetic chemicals in the natural environment. For the investigation of enzymes that could be relevant for the metabolism of such chemicals it is therefore important that measurements of substrate specificity should not be limited too narrowly to compounds closely related in structure to the natural substrate and those metabolized with high rates. As was shown here, the substrate specificity of enzymes at low catalytic activity is apparently much broader than previously assumed. It suggests the necessity for further work in this area to develop enzyme assays with much higher sensitivity.

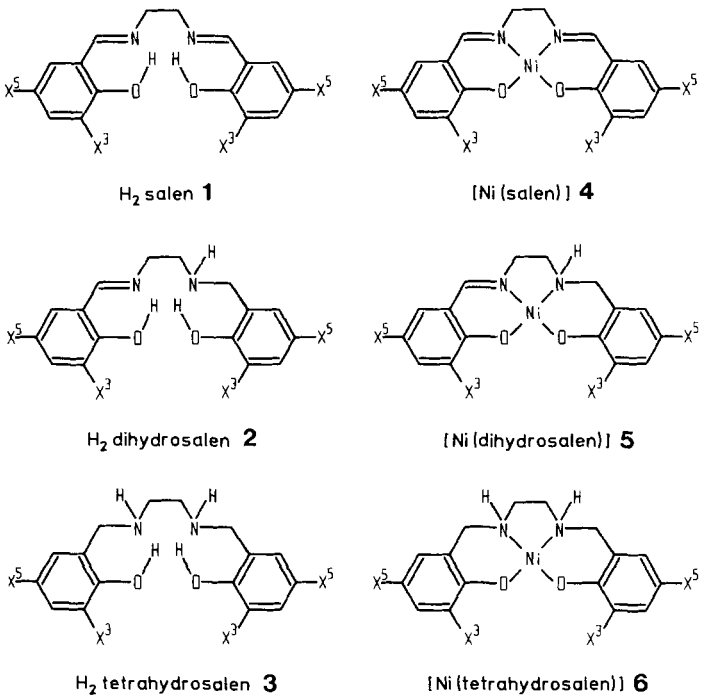
Oxygen Activation on Nickel(II)tetrahydrosalen Complexes with the Formation of Nickel(II)dihydrosalen Complexes**

By *Arnd Böttcher, Horst Elias,* Lutz Müller,* and *Helmut Paulus*

The activation of oxygen in the coordination sphere of transition-metal center is equally important for chemistry and biology and has been known for a long time for Fe-, Co- and Cu-containing active sites of natural systems and the analogous model complexes.[1] In recent years, Ni^{II} complexes with macrocyclic N_5 ligands have been reported,[2] which are also capable of both O_2 addition and activation. Herein, we report for the first time, Ni^{II} complexes with the open-chain N_2O_2 ligand system of tetrahydrosalen **3** (*N,N'*-bis(2-hydroxybenzyl)-1,2-diaminoethane), which are also O_2 active when they constain a specific substitution pattern on the benzene ring of the ligand. Furthermore, the first X-ray structure analysis of such a complex was achieved and it could be shown that in solution O_2 addition takes place at low temperature. At room temperature only one of the C–N bonds of the coordinated tetrahydrosalen ligand is oxidatively dehydrogenated to give dihydrosalen.



Scheme 1. Compounds **1**–**6**: **a**, $X^3 = X^5 = H$; **b**, $X^3 = t$Bu, $X^5 = H$; **c**, $X^3 = t$Bu, $X^5 = Me$; **d**, $X^3 = t$Bu, $X^5 = Cl$.

In comparison to the extensive literature[3] on Ni^{II} salen complexes and also their application as catalysts,[4] only little is known about the corresponding tetrahydrosalen complexes. [Ni(tetrahydrosalen)] **6a**[5] is pale blue, and the Ni atom is probably coordinated in an octahedral fashion[6] as a result of intermolecular Ni–O interactions ($\mu_{exp} = 2.94$ μ_B). However, an X-ray crystallographically determined structure of **6a** is not known. The introduction of bulky substituents (X^3 = *tert*-butyl) prevents intermolecular association for **6b**–**d**. The ligands **3b**–**d** obtained by hydrogenation of **1b**–**d** form cherry-red 1:1 neutral complexes with Ni^{2+} ions, which absorb at $\lambda_{max} = 512-514$ nm in solution ($\varepsilon_{max} = 970-1100\ M^{-1}cm^{-1}$), and are practically diamagnetic ($\mu_{exp} = 0.35$ μ_B for **6c** at 23 °C).

The X-ray structure analysis of **6b**·acetone[7] confirms that the Ni atom is coordinated in a square-planar fashion (Fig. 1). The NiO_2N_2 plane shows a slight tetrahedral distortion (angle between the two chelate six-membered rings is 13.5°), and the two benzene rings are bent slightly upwards and downward, respectively. The Ni–O distances (186.6 and 185.0 pm) and Ni–N distances (193.0 and 189.0 pm) differ only slightly. This is also true for the C–N distances N1–C7 (147.6 pm) and N2–C10 (139.2 pm), however, the shorter C–N distance is still much longer than the C=N bonds in **4a** (129.3 and 130.1 pm[8]). The Ni–Ni distance between the isolated complex units is 538 pm, and the acetone molecule is not coordinated.

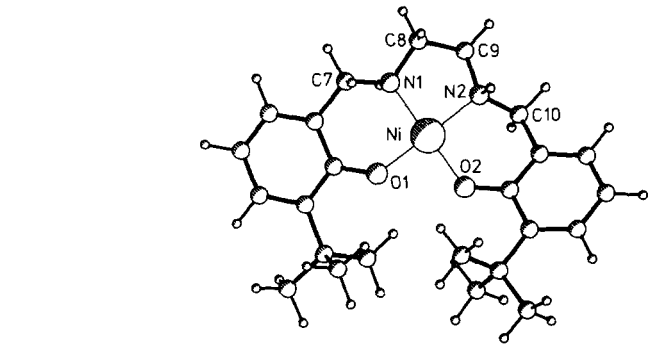


Fig. 1. Crystal structure of **6b**·acetone. Selected bond lengths [pm] and angles [°]: Ni-O1 186.6(3), Ni-O2 185.0(3), Ni-N1 193.0(4), Ni-N2 189.0(4), N1-C7 147.6(5), N1-C8 148.1(5), N2-C9 146.6(6), N2-C10 139.2(6); O1-Ni-O2 86.7(1), O1-Ni-N1 93.4(1), N1-Ni-N2 86.4(2), O2-Ni-N2 93.9(2).

The cherry-red solutions of **6b**–**d** in acetone slowly become yellow-orange in air. Figure 2 shows for **6c** that there is an isosbestic point. The observed changes do not occur when the solutions are saturated with N_2. The correspond-

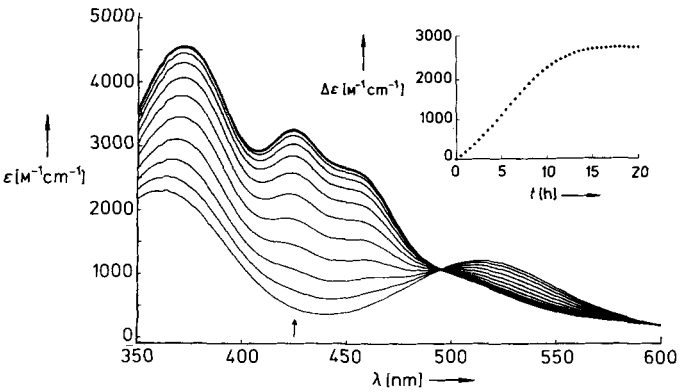

Fig. 2. Spectral changes for the reaction of **6c** with dioxygen in acetone ([**6c**] = 1.24×10^{-4} M, $d = 1$ cm, $T = 20$ °C, $\Delta t = 90$ min) and change of the absorbance at 425 nm with time.

ing complexes [CuL] and [FeLCl] (H_2L = **3b–d**), like the free ligands **3b–d**, are not O_2 active.

Unexpectedly, upon reaction with air under the given conditions, **6b–d** are not dehydrogenated to **4b–d**, but only as far as **5b–d**. This can, for example, be confirmed for **6c** by the characterization of the product **5c** (IR: $\tilde{\nu}$(N–H) = 3180 cm^{-1} together with $\tilde{\nu}$(C=N) = 1620 cm^{-1}; MS (FD): *m/z* 466 for $\mathbf{5c}^{\oplus}$ (100%); ^1H NMR: $(CH_2)_2$ bridge protons at different field; C, H, N analysis), and also of the free ligand **2c** by IR and ^1H NMR spectroscopy as well as mass spectrometry (liberation of **2c** by cyanide treatment of **5c**). Furthermore, the VIS spectrum of **5c** (Fig. 3) shows characteristic absorption features of both **4c** and **6c**; however, it differs significantly from the spectrum of a 1:1 mixture of **4c** and **6c**. The λ_{max} and ε_{max} values are almost the same as those of the complex **5a** synthesized by a different method.[9]

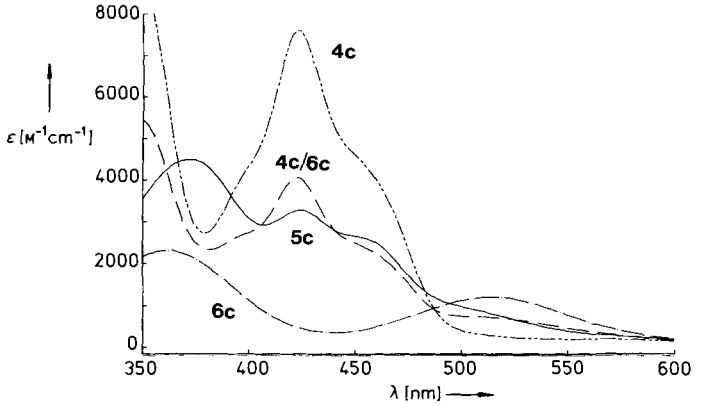

Fig. 3. VIS spectra of **4c**, **5c** (end spectrum from Fig. 2), **6c** and a 1:1 mixture of **4c** and **6c** in acetone ($c = 1.24 \times 10^{-4}$ M, d = 1 cm, T = 20 °C).

The effect of the substituents X[5] on the rate of the reaction of the Ni complexes with O_2 decreases in the order $CH_3 > Cl > H$. If the protons of the ethylene bridge in **6c** are replaced by methyl groups, the reaction becomes considerably slower. For the influence of the solvent on the rate v, the following is approximately [10, 11] valid: v(acetone):v(MeOH):v(toluene, CH_2Cl_2):v(DMF) = 100:15:3:1. The reaction rate in pyridine is virtually zero. Complexes **4b–d** and **5b–d** do not add pyridine (py); in contrast, the complexes **6b–d**, are considerably more Lewis-acidic (see [Eq. (a)]). For example, $K_1 = 0.37$ and $K_2 = 15.8\ M^{-1}$ are

$$\mathbf{6c} + 2\,py \underset{}{\overset{K_1}{\rightleftharpoons}} \mathbf{6c}\cdot py + py \overset{K_2}{\rightleftharpoons} \mathbf{6c}\cdot(py)_2 \qquad (a)$$

obtained for the **6c**/py/acetone system. The adduct **6c**·$(py)_2$ can also be isolated as a solid.

Further results are: 1) If a N_2 saturated solution of **6c** in acetone is allowed to react with acetone saturated with O_2 at −70 °C in a "stopped-flow" spectrophotometer,[12] a sudden ($t_{1/2}$ < 2.5 ms) change of the VIS spectrum is observed, which indicates an O_2 addition. 2) The reaction **6c** → **5c** is first order with regard to the concentration of O_2 and **6c**.[13] 3) During the reaction of **6c** → **5c**, PPh_3 is converted completely into $O{=}PPh_3$ ($[PPh_3]_0 = [\mathbf{6c}]_0$).

Thus, solutions of **6b–d** are O_2 active in that by oxidative dehydrogenation of a C–N bond the dihydrosalen complexes **5b–d** are formed. The rate of the reaction is dependent upon the substituents and the solvent; the Lewis acidity of the Ni center is of great significance for this process.

The described reaction pathway of nickel(II) tetrahydrosalen complexes is of interest for the preparative chemistry (asymmetrical synthesis), for the bioinorganic chemistry of nickel and for catalysis. Further investigations into the stoichiometry and the mechanism of the reaction,[14, 15] and also the role of the solvent[16] are in progress.

Experimental Procedure

1c: 2-Hydroxy-3-tert-butyl-5-methylbenzaldehyde (0.12 mol) in ethanol (200 mL) was slowly reacted with ethylenediamine (0.06 mol). After warming, yellow **1c** crystallized (95%); m.p. 147 °C. ^1H NMR (60 MHz, $CDCl_3$): δ = 1.3 (s, 18H; *t*Bu), 2.1 (s, 6H; CH_3), 3.75 (s, 4H; CH_2), 6.65 (m, 4H; aryl-H), 7.9 (s, 2H; CH); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1620 (C=N).

3c: To **1c** (0.03 mol) in glacial acetic acid (50 mL), solid $Na[BH_3(CN)]$ (0.09 mmol) was added with stirring over 2 h at 20 °C. Then the colorless solution was set to pH 7 with NaOH. Extraction with CH_2Cl_2 and crystallization from ethanol/petrolether afforded needlelike crystals of **3c** (55%); m.p. 137 °C. ^1H NMR (300 MHz, $CDCl_3$): δ = 1.4 (s, 18H; *t*Bu), 2.3 (s, 6H; CH_3), 2.9 (s, 4H; CH_2), 4.0 (s, 4H; CH_2), 6.9 (m, 4H; aryl-H); IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 3290 (N-H); MS (70 eV): *m/z* 412 ($M^{\oplus}$, 63%).

6c: **3c** (2 mmol) in methanol (50 mL) was allowed to react with $[Ni(AcO)_2]\cdot 4H_2O$ and NaOH (4 mmol) (each in a little methanol) with stirring and under an N_2 atmosphere. After the reaction solution was warmed and concentrated, red crystals of **6c** precipitated (70%); m.p. 285 °C (decomp.). ^1H NMR (300 MHz, [D_6]acetone): δ = 1.35 (s, 18H, *t*Bu), 2.1 (s, 6H; CH_3), 2.5 (m, 4H; CH_2), 2.95 (dd, ^2J(H,H) = 12 Hz, ^3J(H,H) < 2 Hz, 2H; CH_2), 3.4 (br.s, 2H; NH), 4.15 (ps t, ^2J(H,H) = ^3J(H,H) = 12 Hz, 2H; CH_2), 6.4–6.7 (m, 4H; aryl-H); IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 3180 (N-H), 3140 (N-H); UV/VIS (acetone): λ_{max}[nm](ε) = 362 (2240), 514 (1100); MS(FD): *m/z* 468 ($M^{\oplus}$, 100%). All C, H, N analyses correct. The complexes **6b** and **6d** can be prepared analogously starting from the corresponding aldehydes.

Oxygen oxidation of **6c**: O_2 was passed through a solution of **6c** (0.1 mmol) in acetone (50 mL) for 48 h at 20 °C. By concentration, red-brown, microcrystalline **5c** was obtained (84%); m.p. 345 °C (decomp.). ^1H NMR (300 MHz, [D_6]acetone): δ = 1.35 (s, 18H; *t*Bu), 2.15 (s, 6H; CH_3), 2.5 (m, 1H; CH_2), 2.7 (m, 1H; CH_2), 3.0 (dd, ^2J(H,H) = 12 Hz, ^3J(H,H) = 2.5 Hz, 1H; CH_2), 3.4 (m, 1H; CH_2), 3.7 (br.s, 1H; NH), 4.3 (ps t, ^2J (H,H) = ^3J(H,H) = 12 Hz, 1H; CH_2), 5.35 (t, ^3J(H,H) = 4.5 Hz, 1H; CH_2), 6.4–6.7 (m, 2H; aryl-H), 6.8–7.0 (m, 2H; aryl-H), 7.6 (s, 1H; CH); IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 3180(N-H), 1620 (C=N); VIS (acetone): λ_{max}[nm](ε) = 424 (3240); MS(FD): *m/z* 466 ($\mathbf{5c}^{\oplus}$, 100 %); correct C,H,N-analysis.

Oxidation of PPh_3: O_2 was passed through a solution of **6c** (0.05 mmol) and PPh_3 (0.05 mmol) in acetone (50 mL) for 48 h at 20 °C, after which the acetone was removed. MS(FD): m/z 466 ($\mathbf{5c}^{\oplus}$, 27%), 278 ($PPh_3O^{\oplus}$, 100); no signal at 262 (PPh_3). MS(FD) of the starting mixture: m/z 468 ($\mathbf{6c}^{\oplus}$,100%), 262 ($PPh_3^{\oplus}$, 12).

[13] The variation of the O_2 concentration was achieved as follows; the acetone saturated with O_2 was so diluted with N_2 saturated acetone, that 80, 60, 40, and 20% O_2 saturation occurred. The reaction was carried out at 20 °C using the "initial rate method".

[14] It is conceivable that the O_2 adduct $\mathbf{6c}\cdot O_2$ has partially the character of a Ni^{III} superoxide.[15]

[16] A referee has rightly pointed out that the high rate of the reaction in acetone could be a result of the intermediate formation of a dioxirane.

Ring Expansion of a 1,2-Diphosphaspiropentane: Formation of a Diphosphamethylenecyclobutane and a 1,4-Diphosphanorbornadiene

By *Catherine Garot, Guita Etemad-Moghadam, Jean-Paul Declercq, Antoine Dubourg,* and *Max Koenig**

Studies of highly strained small-ring compounds have led to an improved understanding of chemical bonding, intramolecular interactions, and reaction mechanisms.[1, 2] Substantial progress has been made on the synthesis and reactivity of oxa-[3] and aza-[4] spiropentanes, the heterocyclic analogues of the well-known and highly strained spiropentane system.[5] All these spiropentanes rearrange to methylenecyclobutane.[6] We now report the first rearrangement of a diphosphaspiropentane not only to the expected diphosphamethylenecyclobutane but also to the unexpected 1,4-diphosphanorbornadiene.

When the diphosphaspiropentane **1**[7] ($\delta^{31}P = -116$) was heated at 100 °C for 5 h in degassed toluene solution, a ring expansion reaction was observed leading to **2** (70%) and **3** (30%) (Scheme 1). The reaction was promoted by addition of azobisisobutyronitrile (AIBN).

Whereas **3** is stable towards air and moisture, **2** is partially oxidized upon contact with air and gives the phosphane oxide **4**. The preferential oxidation of $\lambda^3\sigma^3$ phosphorus atom is probably the consequence of steric effects and the well-known higher stability of phosphane oxide ($\lambda^5\sigma^4$) over phosphaalkene oxides ($\lambda^5\sigma^3$).[8] The compounds **2**, **3**, and **4** are fully

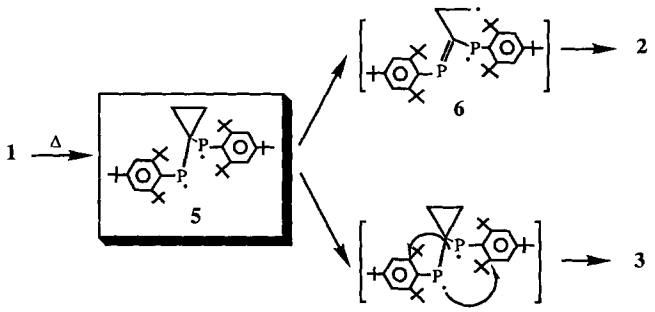
Angles between normals to planes: Plane 1–Plane 2 71.71, Plane 1–Plane 3 90.86, Plane 4–Plane 5 69.94, Plane 3–Plane 6 90.97, Plane 4–Plane 6 56.71, Plane 5–Plane 6 126.45, Plane 1–Plane 4 3.00, Plane 2–Plane 5 1.64.

characterized by ^{31}P, ^{13}C and ^{1}H NMR spectroscopy, IR spectroscopy, and mass spectrometry, as well as by elemental analysis. The structure of the novel heteropolycycle **3**[9] has been confirmed by an X-ray diffraction analysis[10] (Fig. 1).

Compound **2** arises as a result of the expected P–P and C–C bond ruptures (via **5** and **6**, see Scheme 2), whereas 1,4-diphosphanorbornadiene **3** forms quite surprisingly from the common biradical intermediate **5** on cleavage of an *ortho-tert*-butyl group from each of the aryl residues. The anionic[11] and photochemical[12] ring-opening of functionalized diphosphiranes occur via diphosphaallyl anions or diphosphiranyl radical intermediates, respectively. On the other hand, we did not detect any intermediate in their thermal ring-opening which allows us to specify the most likely mechanism (radicalar, biradicalar, or concerted).[13, 14]



Scheme 2. Proposed mechanism for the formation of **2** from **3** and **1**.

The reaction of **1** to afford **3** via **5** must be promoted by the free rotation of aryl groups ($\Delta G^{\neq} = 10$ kcal mol^{-1} at 20 °C for **1**) and the higher strain of the PCP angle in **1**. A similar aromatic substitution involving phosphorus radicals[15] and silylated[16] radicals has been already described for the thermolysis of germaphosphenes and disilacyclopropanes. An analogous rearrangement involving aryl groups has been observed by Niecke et al., who explained the reaction by abstraction of isobutene.[17]

Whereas the ^{31}P NMR spectrum of **3** displays a singlet ($\delta = 29$), the X-ray structure reveals that the bond lengths and angles around each P atom are slightly different (Fig. 1). The angular sum around each phosphorus atom (277°) is higher than the corresponding value (269°) obtained by Mathey in 1-phosphanorbornadiene.[18]

Experimental Procedure

A colorless solution of **1** (0.115 g, 0.194 mmol) in 2.0 mL of degassed toluene was heated in the presence of AIBN (0.320 g, 1.94 mmol, 10 equiv) at 100 °C for 5 h. The solution became yellow. After removal of the solvent, the residue was taken up in hexane. Filtration followed by thin-layer chromatography of the mixture (Merck precoated preparative TLC plates: silica gel 60 F_{254}) with hexane/toluene (90/10) as eluent, and recrystallization from toluene at room temperature afforded 50 mg (44%) of yellow needles of **2**, 23 mg (30%) of pale yellow crystals of **3** (m.p. 232 °C), and 31 mg (26%) of **4**.

One-Dimensional $M^{III}Cu^{II}$ Compounds with an Unprecedented, Tubelike Structural Motif (M = Rare-Earth Metal)

By *Olivier Guillou, Robert L. Oushoorn, Olivier Kahn*, Kamal Boubekeur*, and *Patrick Batail**

The reaction of the dianionic copper(II) complex $[Cu(pba)]^{2-}$ (pba = 1,3-propylenbis (oxamato) ≙ *N,N'*-trimethylendioxamidic acid tetranion) with a divalent metal ion M^{II} in a solvent S affords a bimetallic compound with a chainlike structure and the formula $M[Cu(pba)] \cdot nS$.[1–5] Compounds of this kind exhibit the characteristic behavior of one-dimensional ferrimagnets, that is, the plot of the product of the molar magnetic susceptibility χ_m and the temperature T versus temperature has a minumum. When the

temperature is lowered further $\chi_m T$ increases, which is typical for ferromagnets. Moreover, some of these compounds display a spontaneous magnetization and behave as molecular magnets below a critical temperature T_c.[5] To the best of our knowledge, the highest T_c value reported so far for this kind of material is 30 K.[4]

If the divalent ion M^{II} is replaced by a trivalent ion M^{III}, compounds of higher dimensionality with the formula $M_2[Cu(pba)]_3 \cdot nS$ may be expected. These may favor the onset of a magnetic ordering, in particular if M^{III} carries a high local spin. For this reason we are interested in the synthesis of compounds of the type $M_2[\{Cu(pba)\}_3] \cdot nS$ in which M is a rare-earth-metal ion. Our first attempt yielded compounds of type **1**(M) in which some of the pba ligands

$[M_2(ox)][\{Cu(pba)\}_3Cu(H_2O)_5] \cdot 20\,H_2O$ **1**(M)

had been hydrolyzed to oxalato (ox) ligands bridging the M^{III} ions.[6] With a more exotic method of preparation, we also succeeded in synthesizing the compounds of type **2**(M).

$M_2[\{Cu(pba)\}_3] \cdot 23\,H_2O$ **2**(M)

All compounds with M = La, Ce, Pr, Nd, Sm, Eu, and Gd are isomorphous; however, smaller, trivalent rare-earth-metal ions (from Tb to Yb and Y) lead to a completely different structure. We report here on the remarkable and quite unexpected structure of **2**(Sm) and on the magnetic properties of some of the **2**(M) compounds in which the metal M comprises the series from La to Gd.

We previously demonstrated that the construction of **1** (Gd) was based on the two-dimensional association across oxalato groups of the single $Gd_2[\{Cu(pba)\}_3]$ units leading to the puckered ladderlike structure **I** represented in Figure 1. We then anticipated that **I** could be shifted (e.g. a 90° twist to **I'**) and eventually associated within different structural motifs depending on the method of synthesis and/or the nature of the rare-earth metal. The molecular architecture of **2**(M) is based solely on the condensation of two such "ladders" to **II** (Fig. 1) furnishing a remarkable infinite tubelike structural motif unprecedented in this chemistry.[7] In the pairing of the ladders the ladder "rungs" are redistributed; this demonstrates the conformational flexibility of the $[Cu(pba)]^{2-}$ unit. These units undergo a collective criss-cross shift creating an infinite structural motif with an essentially square cross section and quasi-fourfold symmetry. Thus, we have found the delicate inner framework of elegant simplicity (Fig. 2, view down the *c* axis of the pseudo-tetragonal unit cell; this corresponds to a 90° twist of projection **II** in Fig. 1 out of the plane of the paper). It is readily seen in Figure 2 that the inner $[Cu(pba)]^{2-}$ units, the ladder rungs, intertwine by alternately switching from one edge of a ladder frame to the nearest one orthogonal, thus fusing **I** and **I'** (Fig. 1). Of particular interest is the helixlike pattern of the intertwined ladder rungs, also apparent in Figures 1 and 2. For lack of space we restrict the discussion to several of the **2**(M) complexes and their magnetic properties:[8]

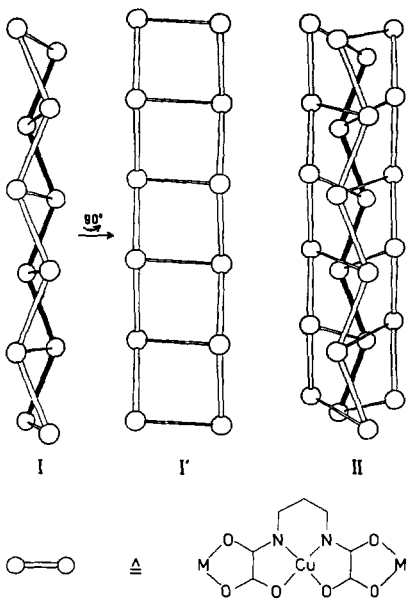

Fig. 1. **I** and **I'** are two representations of the ladderlike structural motif found in **1**(M) from two different views. The condensation of two such orthogonal ladders and the redistribution of the ladder rungs (see text) leads to the tubelike structural motif **II**, which is found in **2**(M).

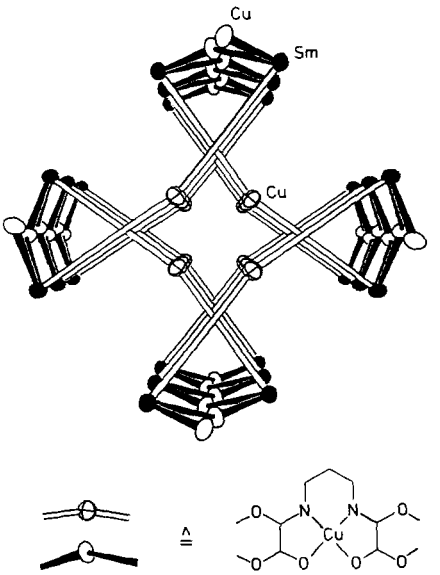

Fig. 2. Schematic representation of the structure of **2**(M) as exemplified by **2**(Sm); view along the *c* axis of the unit cell. The Cu atoms are also shown. The rare-earth-metal atom is surrounded by nine O atoms, of which six are from Cu(bpa) units and three are from water molecules. The Cu atom has square-pyramidal coordination; two O atoms and two N atoms of the pba ligand make up the base, and an O atom of a water molecule forms the apex of the coordination polyhedron. The Sm–Cu separations range from 5.675 to 5.742 Å, and the length of the Sm–Sm rung of the ladder is 11.357 Å.

1) For the **2**(La) compound, which possesses a diamagnetic rare-earth-metal ion, $\chi_M T$ (χ_M is the molar magnetic susceptibility per M_2Cu_3 unit) decreases slightly when the temperature is lowered below 20 K. This indicates that an antiferromagnetic interaction between the Cu^{II} spin carriers take place which is obviously propagated through the La^{III} ion.

2) For **2**(Ce), **2**(Pr), and **2**(Sm), $\chi_M T$ also decreases as T decreases, which may be due to both crystal-field effects around the rare-earth-metal ion and weak antiferromagnetic interactions.

3) **2**(Nd) exhibits a nonmagnetic ground state with $\chi_M T$ approaching zero as T approaches absolute zero. This result is quite unexpected since the local ground state of Nd^{III} is

$^4I_{9/2}$. A perfect compensation of the local magnetic moments within the one-dimensional tubelike network should not happen.

4) The magnetic behavior of **2**(Gd) is totally different from that of the other compounds. Both the temperature dependence of the magnetic susceptibility χ_M at a field strength of 0.1 T and the field dependence of the magnetization M at 2 K have been measured. The results of the former investigation are presented in Figure 3. To temperatures of roughly 30 K,

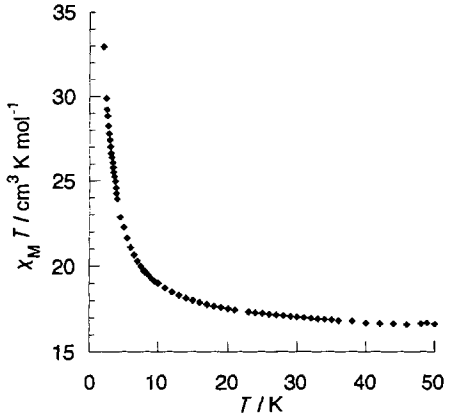

Fig. 3. Plot of $\chi_m T$ versus T for **2**(Gd). Magnetic field strength 0.1 T.

$\chi_M T$ is constant and equal to 16.8 cm^3 K mol^{-1}, as is expected for two Gd^{III} and three Cu^{II} ions that do not interact. When the temperature is lowered, $\chi_M T$ increases more and more rapidly and reaches 33 cm^3 K mol^{-1} at 1.8 K. These data could be fitted with the Curie–Weiss law $\chi_M = C(T-\theta)$ and a Weiss constant $\theta = 1.2$ K, and clearly indicate that the local spins of Gd ($S = 7/2$) tend to align parallel. However, these values do not indicate whether the local spins of Cu ($S = 1/2$) align along the same direction (ferromagnetic behavior) or along the opposite direction (ferrimagnetic behavior). The answer to this question is provided by magnetization measurements. In the low-field regime (from 0 to ca. 0.3 T), M is directly proportional to H, and the slope of the plot is in perfect agreement with the value obtained from the magnetic susceptibility measurements previously discussed. There is no indication of spin decoupling, that is, a change of sign of d^2M/dH^2. When the field is increased further, the magnetization approaches the saturation value $M_S = 17\ N\beta$ (or 95000 cm^3 G mol^{-1}) corresponding to the value anticipated for all local spins aligned along the direction of the external field. The susceptibility and magnetization data are complementary, and unambiguously show that even in the absence of an external magnetic field the local spins tend to align parallel. The Gd^{III} and Cu^{II} ions interact ferromagnetically through the oxamato bridge despite the Gd^{III}–Cu^{II} separation of 5.7 Å. Gd^{III}–Cu^{II} ferromagnetic interactions in discrete molecular species have already been reported.[9, 10]

The versatility of the crystal structures and physical properties of those rare-earth-metal–copper compounds open quite interesting perspectives for novel materials.

Experimental Procedure

2(M): An aqueous solution of $Na_2[Cu(pba)] \cdot 6H_2O$[2,11] (0.05 M) was added dropwise to an aqueous solution of the rare-earth-metal chloride (0.1 M) with vigorous stirring. The solution was stirred for a while, then the light blue precipitate was removed by filtration. The dark blue solution was kept in a temperature-controlled bath at 70 °C. Large cubelike, dark-blue crystals formed within ca. 48 h. The isomorphism of the compounds containing La, Ce, Pr, Ne, Sm, Eu, and Gd was assumed from Debye–Scherrer photographs.

A Cyclometalated Aryloxy(chloro)neopentylidene-tungsten Complex: A Highly Active and Stereoselective Catalyst for the Metathesis of *cis*- and *trans*-2-Pentene, Norbornene, 1-Methylnorbornene, and Ethyl Oleate**

By *Jean-Luc Couturier, Christophe Paillet, Michel Leconte, Jean-Marie Basset,** and *Karin Weiss*

The design of versatile, highly active, and well-characterized catalysts remains one of the main objectives of the research in olefin metathesis.[1] In the past few years, it has been shown that some neopentylidene–tungsten(VI) complexes with alkoxide,[2, 3] imido,[3] or aryloxide ligands[4] are efficient homogeneous metathesis catalysts. Aryloxides prove to be particularly useful ligands since their steric and electronic properties can be varied substantially by changing the nature, the number, and the position of the substituents on the phenoxide ligand. With these ligands, it has been possible to control both the activity and the stereoselectivity

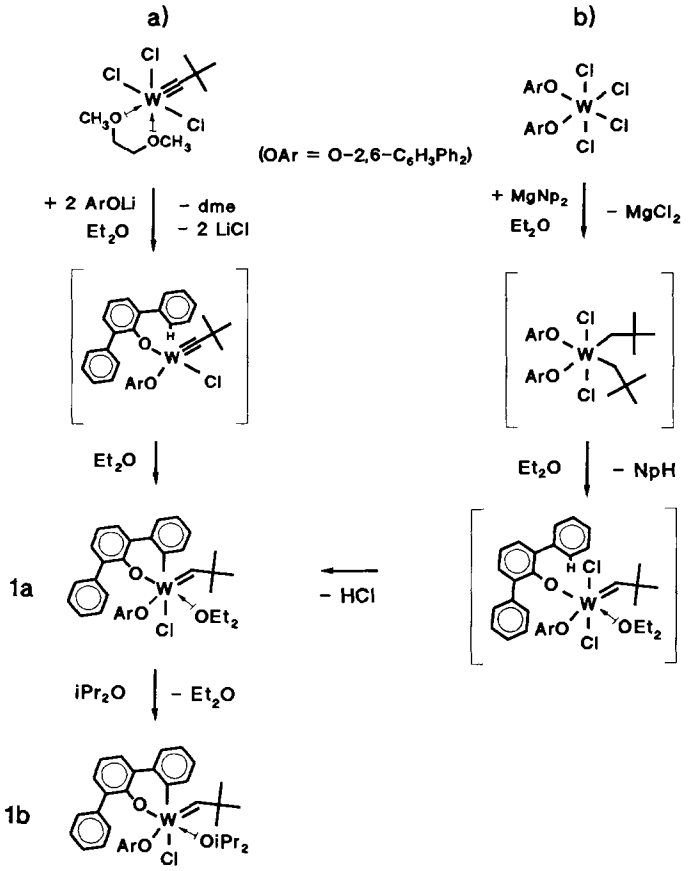
[**] This work was supported by the Société Nationale Elf-Aquitaine and by the Commission of the European Communities. We thank Prof. R. R. Schrock (Massachusetts Institute of Technology) for giving us a preprint of [6b].

of the metathesis reaction.[4, 5] We report here the synthesis and the catalytic properties of a new 2,6-diphenylphenoxy (neopentylidene)tungsten derivative, which has the cyclometalated structure **1a**/**1b** (Scheme 1).



Scheme 1. Two routes for the synthesis of the cyclometalated complexes **1a** and **1b**. Because X-ray structure data are not available, the structures are still hypothetical and are derived from that proposed by R. R. Schrock et al. for the starting complex $[WCl_3(CCMe_3)(dme)]$ [6] and from the known complex $[WCl_4(O\text{-}2,6\text{-}C_6H_3Ph_2)_2]$ [7].

The tungsten complexes **1a**/**1b** can be obtained by two independent routes. Reaction of $[WCl_3(CCMe_3)(dme)]$[6] (dme = dimethoxyethane) with two equivalents of LiOAr (OAr = O-2,6-$C_6H_3Ph_2$) in diethyl ether leads to the orange-brown solid **1a**, which likely arises from path a). The reaction of $[WCl_4(O\text{-}2,6\text{-}C_6H_3Ph_2)_2]$[7] in diethyl ether with one equivalent of $MgNp_2 \cdot$ dioxane (Np = neopentyl) leads, after purification by exchange of diethyl ether with diisopropyl ether, to the orange-brown solid **1b**.[8] The probable sequence of reactions leading to **1b** is path b). **1a** and **1b** were characterized by elemental analyses and ^1H and ^{13}C NMR spectroscopy.[9]

The key step of the two syntheses is the different intramolecular activation of the C–H bond of the arene substituent on the d^0 metal which leads to a stable cyclometalated structure.[10–12] In path a) C–H activation leads to the addition of a hydrogen atom to the carbyne ligand forming a carbene and simultaneous cyclometalation. In path b) the C–H activation leads to the elimination of HCl. The role of the weakly coordinated ether is probably crucial in path a) in which a pentacoordinated W^{VI} center with a possible agostic C–H bond is the precursor of the carbene complex formed via a four-center transition state; this type of sequence is often discussed for the electrophilic activation of C–H bonds.[13]

Complexes **1a** and **1b** are excellent catalysts for olefin metathesis. For example, with **1a** the metathesis equilibrium of 500 equivalents of *cis*-2-pentene or *trans*-2-pentene is reached in 1 min at 25 °C (the equilibrium mixture consists of 2-butene, 2-pentene, and 3-hexene in the approximate ratio of 1:2:1).[1a] **1a** is also highly stereoselective: Extrapolation to 0% conversion shows that the *trans*/*cis* ratios of 2-butene (C_4) and 3-hexene (C_6) in the metathesis of *cis*-2-pentene are 0.01 and 0.00, respectively[14] (at equilibrium, *trans*/*cis* $C_4 \approx 3$ and *trans*/*cis* $C_6 \approx 6$). In the metathesis of *trans*-2-pentene, the *cis*/*trans* ratios of both C_4 and C_6 are equal to 0.004 at 0% conversion. These high stereoselectivities with retention of configuration of the starting olefin are maintained even at high conversions (Figs. 1 and 2). When the

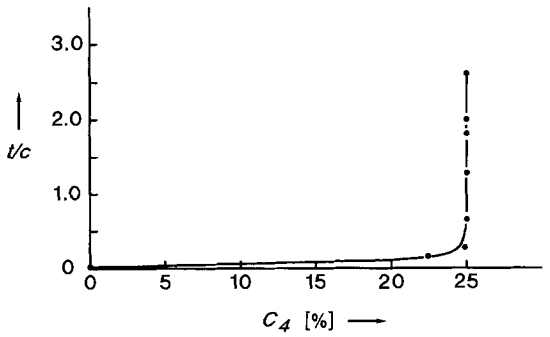


Fig. 1. Metathesis of *cis*-2-pentene catalyzed by **1a**: Plot of the ratio of *trans*- to *cis*-2-butene (*t*/*c*) versus the yield of 2-butene (C_4). *cis*-2-Pentene/**1a** molar ratio = 500/1, $T = 25\,°C$, solvent C_6H_5Cl.

equilibrium of productive metathesis is nearly reached (roughly 25% yield in 2-butene), there is a dramatic change of the configuration of the products due to secondary metathetical isomerization reactions that progressively lead to the ultimate equilibrium *trans*/*cis* ratios.

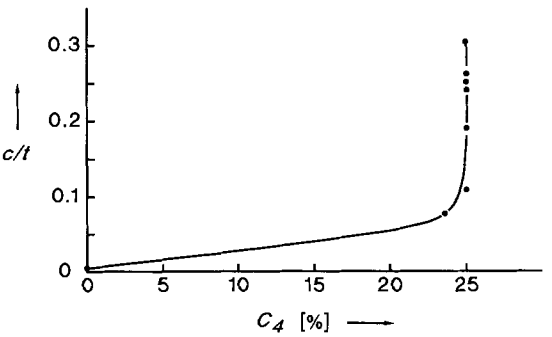

Fig. 2. Metathesis of *trans*-2-pentene catalyzed by **1a**: Plot of the ratio of *cis*- to *trans*-2-butene (*c*/*t*) versus the yield of 2-butene (C_4). *trans*-2-Pentene/**1a** molar ratio = 500/1, $T = 25\,°C$, solvent C_6H_5Cl.

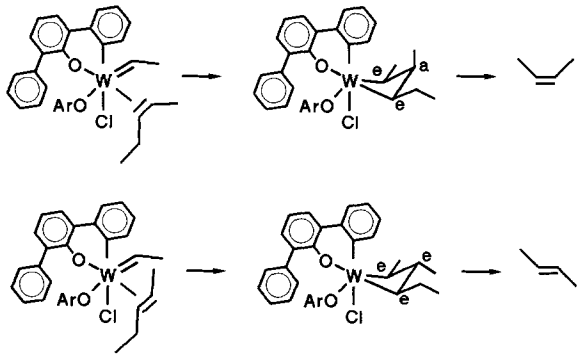
To our knowledge such high stereoselectivities observed almost up to thermodynamic metathesis equilibrium have never been reported in metathesis of 2-pentene with any highly active tungsten-based catalyst. The extremely high retention of configuration of the starting olefin is easily explained on the basis of the favored configuration of the tungstacyclobutane intermediate with two equatorial (e) alkyl groups in the 1 and 3 positions (Scheme 2).[15] One can

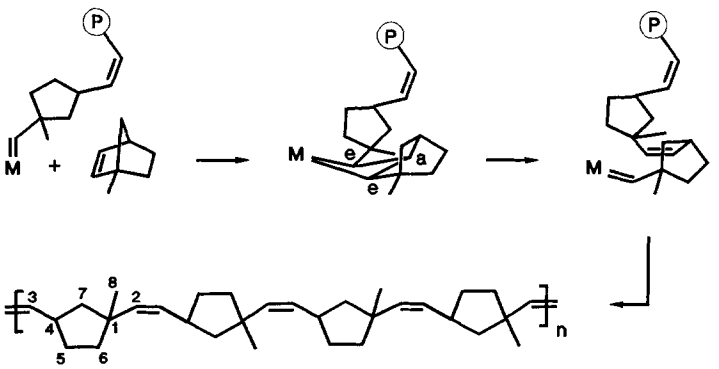


Scheme 2. The two favored tungstacyclobutane intermediates with 1,3-diequatorial alkyl substituents that lead to *cis*-2-butene (in the metathesis of *cis*-2-pentene) and to *trans*-2-butene (in the metathesis of *trans*-2-pentene).

assume that these favored conformations are particularly stabilized by the bulky ligands on tungsten and/or by the rigidity generated by the cyclometalation.

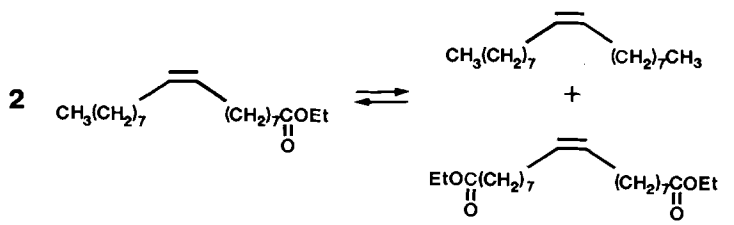
With **1a**, 500 equivalents of norbornene are polymerized at 25 °C in less than one minute.[16] ^{1}H and ^{13}C NMR spectra ($CDCl_3$, 25 °C) indicate that 70% of the C=C bonds have *cis* configuration. This value is in agreement with earlier results found in norbornene metathesis with other stereoselective aryloxy(chloro)carbene-tungsten catalysts.[17]

Polymerization of 1-methylnorbornene with **1a** or **1b** provides a completely head-tail, predominantly syndiotactic poly-1-methylnorbornene with 100% *cis* C=C bonds.[18] Such extremely high stereoselectivity can also be explained on the basis of the favored configuration of the tungstacyclobutane intermediate with the two bulkiest alkyl substituents in 1,3-diequatorial positions (Scheme 3).[20]



Scheme 3. In the ring-opening metathesis polymerization of 1-methylnorbornene with **1a** or **1b** the favored reaction path leads to the formation of a head-tail, *cis* polymer.

Very promising preliminary results were obtained in the metathesis of ethyl oleate (ethyl-9-octadecenoate), an olefin bearing a functional group (Scheme 4). **1a** can convert selectively roughly 50% of 500 equivalents of ethyl oleate[21] into 9-octadecene and diethyl 9-octadecenedioate in 60 min at 25 °C (Fig. 3; the equilibrium mixture consists of ethyl oleate, 9-octadecene, and the diester in the approximate ratio of 2:1:1). To our knowledge, this is the highest activity reported so far for homogeneous catalysts in the metathesis of this type of substrate.[3, 22]



Scheme 4. The equilibrium metathesis reaction of ethyl oleate leads to 9-octadecene and diethyl 9-octadecenedioate.

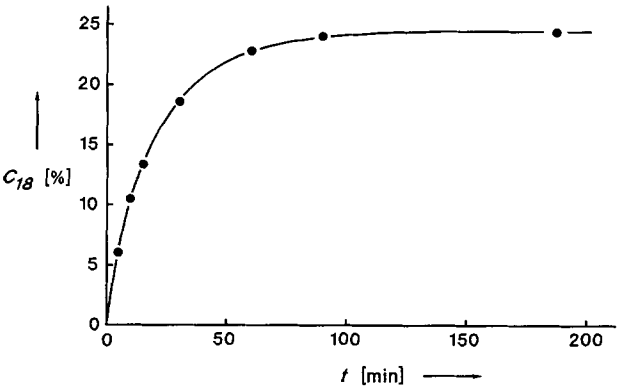


Fig. 3. Metathesis of ethyl oleate catalyzed by **1a**: Plot of the yield of 9-octadecene (C_{18}) versus the reaction time. Ethyl oleate/**1a** molar ratio = 500/1, T = 25 °C, solvent C_6H_5Cl.

[8] In our first study [4] we found that reaction of one equivalent of $MgNp_2$ with $[WCl_4(O\text{-}2,6\text{-}C_6H_3Ph_2)_2]$ in Et_2O led to a compound **A1** whose ^{1}H NMR spectrum ($CDCl_3$) showed a signal at $\delta = 8.7$ for a hydrogen atom bound to a carbene; **A1** proved essentially inactive in the metathesis of *cis*-2-pentene. We have now some indications that suggest that **A1** is a dimeric neopentylidene species (not yet totally identified) resulting from the dimerization of **1a** or **1b**. This dimerization seems to be rather fast in solution (especially in $CHCl_3$ and CH_2Cl_2) but can also be observed in the solid state where the reaction is slower.

[9] Characteristic ^{1}H (100 MHz) and ^{13}C (25 MHz) NMR data for **1a** (C_6D_6, 25 °C): δ(W = CHCMe$_3$) = 10.11 ($J_{W,H}$ = 14 Hz), δ(W = CHCMe_3) = 0.57; δ(W = CH) = 296.66 ($J_{C,H}$ = 130.5, $J_{C,W}$ = 166 Hz), δ(W-C_{ipso}) = 183.15 ($J_{C,W}$ = 115 Hz), δ(W = CHCMe$_3$) = 45.24, δ(W = CHCMe_3) = 31.82. The corresponding data for **1b** are practically identical.

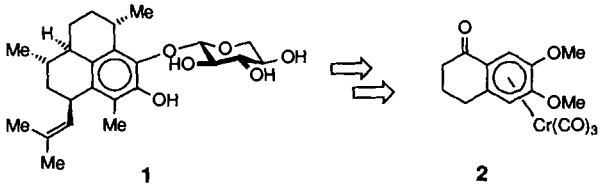
Diastereoselective Complexation of Temporarily Chirally Modified Ligands: Enantioselective Preparation and Configurational Assignment of Synthetically Valuable η^6-Tricarbonylchromium-1-tetralone Derivatives**

By *Hans-Günther Schmalz,* Birgitta Millies, Jan W. Bats,* and *Gerd Dürner*

Dedicated to Professor Gerhard Quinkert on the occasion of his 65th birthday

Chiral transition-metal complexes of achiral π-ligands offer as synthetic building blocks new strategies for the total synthesis of biologically active compounds. If under the influence of the chiral metal-complex substructure, new, permanent chirality centers are generated (diastereoselectively), the competitiveness of such syntheses depends to a large extent on the accessibility of the starting materials in optically active form. In the course of a project in which we want to take advantage of the specific reactivity of η^6-arenetricarbonylchromium complexes[1] for the total synthesis of the antiinflammatory pseudopterosines[2] such as **1**, we required complex **2** (Scheme 1).

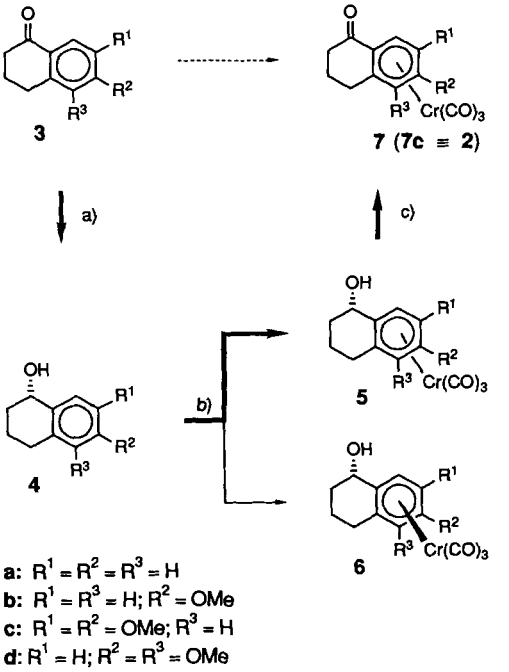
The reported techniques[3] for the preparation of nonracemic η^6-tricarbonylchromium complexes of achiral arene ligands are all based on the resolution of racemic mixtures (involving high losses) and did not satisfy our criteria. Here



Scheme 1.

we describe an efficient enantioselective method for the preparation of **2** and other η^6-tricarbonylchromium-1-tetralone derivatives in defined and selectable absolute configuration.

The heart of our process (Scheme 2) is the diastereoselective complexation[4] of the tetralol derivatives **4**, which are obtained by enantioselective catalytic reduction of the tetralones **3** according to the method of Corey, Bakshi, and Shibata (CBS reduction).[5] A study initially carried out with



Scheme 2. Preparation of nonracemic η^6-tricarbonylchromium-1-tetralone derivatives by a) enantioselective reduction, b) diastereoselective complexation, and c) reoxidation (for reaction conditions and yields see text and Table 2).

Table 1. Diastereoselective complexation of the alcohols *rac*-**4**.

[**] This work was supported by the Fonds der Chemischen Industrie and the Bundesministerium für Forschung und Technologie (project 0318801B, "gezielte Synthese biologisch aktiver Moleküle"). We thank Prof. Dr. G. Quinkert, Frankfurt, for support.

racemic compounds (Table 1)[6] revealed that the complexation that employ Kündig's reagent, tricarbonyl(naphthalene)chromium (method **A**),[7] always afforded (as anticipated)[4] the *syn*-tetralol complexes *rac*-**5** with excellent yields and diastereoselectivities. The substantially better accessible reagent $[Cr(CO)_6]$ gave completely unsatisfactory results under standard conditions (method **B**),[4b, 8] in particular in the synthetically relevant case of *rac*-**4c**.[9] However, by changing the solvent mixture (from nBu_2O/THF = 10:1 to nBu_2O/heptane = 1:1; method **C**) good yields and selectivities were obtained with $[Cr(CO)_6]$ as well.

The transformations carried out in the optically active series are summarized in Table 2.[6] Borane reduction of ketones **3** in the presence of catalyst **9**,[5] which is readily accessible from D-proline via the intermediate **8**, always lead to high chemical (97–99%) and optical yields (Table 2) of the alcohols **4**, from which the pure *syn*-complexes **5** were prepared by complexation and chromatographic separation of the diastereomers. Finally, oxidation with Ac_2O/dimethyl sulfoxide (DMSO)[10] afforded the optically active ketone complexes **7** (and **2**).

Table 2. Preparation of the nonracemic complexes **7** (and **2**) from the ketones **3** according to Scheme 2.

Ketone	Complexation Method [a]	Product	Yield [b] [%]	$[\alpha]_D^{20}$ (in $CHCl_3$)	*ee* [c] [%]

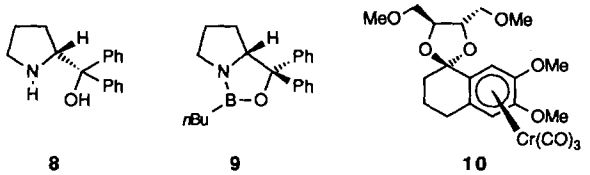
3c	**C**	**2**	66	−818	85
3d	**A**	**7d**	85	−400	94

[a] **A**: $[Cr(CO)_3$(naphthalene)] (1.2 equiv), THF (1.5 equiv), Et_2O, 70 °C (sealed ampule); **C**: $[Cr(CO)_6]$ (1.1 equiv), cat. THF, nBu_2O/heptane (1:1), reflux. [b] Total yield calculated on amount of ketone **3** used. [c] The enantiomeric purity of the reduction products **4**, determined by ^1H NMR spectroscopy of the acetates in the presence of d-Eu(hfc)$_3$ (**4a**, **4c**, and **4d**) or d-Pr(hfc)$_3$ (**4b**), or by gas chromatography on a chiral phase (**4a** and **4b**), agreed well (±2%) with the enantiomeric purities of the ketone complexes determined by ^1H NMR spectroscopy in the presence of d-Eu(hfc)$_3$ (**2**) or d-Pr(hfc)$_3$ (**7b** and **7d**) and/or by comparison of the chiroptical data with reference values (**7a** and **2**).



8 **9** **10**

An X-ray crystal structure analysis[11] of the chiral ketal **10**[12] (Fig. 1) revealed its relative and absolute configuration. Hydrolysis of the ketal function of **10** furnished enantiomerically pure *ent*-**2** (m.p. (decomp.) 176 °C; $[\alpha]_D^{20}$ + 974, c = 0.097 in $CHCl_3$).

The absolute configuration of **2** and thus also those of the precursors **4c** and **5c** were thereby established. Circular dichroism (CD) spectra of the tetralone complexes (Fig. 2) indicated the configurational uniformity of compounds **2**, **7a**, **7b**, and **7d**, which confirmed the earlier assignment for **7a** derived by indirect means.[4a] Furthermore, the absolute configuration of the CBS reduction products obtained by using **9** as catalyst corresponds to expectation.[5] Thus, neither the enantioselection of the CBS reduction nor the characteristics of the CD spectra of the ketone complexes are (significantly) affected by the synthetically valuable methoxy substituents.

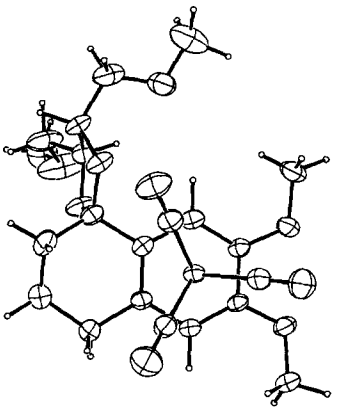


Fig. 1. Structure of **10** in the solid state [11].

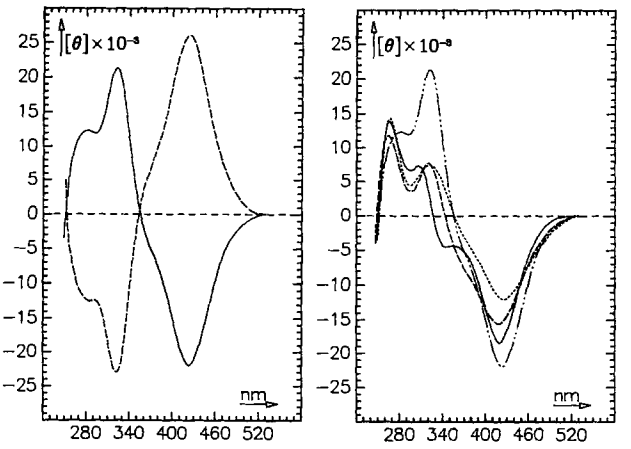

Fig. 2. CD spectra (in MeOH) of ketone complexes; left: **2** (85% *ee*; ——), and *ent*-**2** (>99% *ee*; – – –); right: **2** (85% *ee*; –·–·–), **7a** (92% *ee*; ——); **7b** (85% *ee*; – – –), and **7d** (94% *ee*; ····).

The complexes **7** and their enantiomers, which are also accessible through application of the catalyst *ent*-**9** prepared from L-proline, are expected to serve as valuable building blocks in synthesis. One might anticipate that further enantiomeric enrichment can be achieved through the crystallization of suitable intermediates.

Experimental Procedure

All reactions were performed in the absence of light under argon in degassed, dry solvents.

4c: A solution of $BH_3 \cdot Me_2S$ in THF (0.48 M, 13.2 mL) was added dropwise over 8 h at about 20 °C to 25 mL of a THF solution containing both 2.15 mmol of **9** (prepared from 546 mg of **8** and 241 mg of $nBuB(OH)_2$ by heating for 16 h in 25 mL of toluene in the presence of 4 Å molecular sieves and subsequent removal of the toluene in vacuum) and 2.21 g (10.7 mmol) of **3c**. After the addition of 5 mL of 95% MeOH, all volatile components were removed in vacuum and the residue was flash-chromatographed with hexane/EtOAc (1:1). Yield: 2.18 g (98%, m.p. 72–74 °C).

5c: **4c** (1.0 g, 4.8 mmol), $[Cr(CO)_6]$ (1.28 g, 1.2 equiv), nBu_2O and *n*-heptane (30 mL each), and THF (1 mL) was heated at 150 °C (weak reflux) in an oil bath for 30 h. Removal of the solvent in vacuum and flash chromatography of the residue with CH_2Cl_2/EtOAc (15:1) yielded 1.42 g (86%) of **5c** (m.p. 143–145 °C, decomp.) and about 0.1 g of a mixture of **6c** and unchanged **4c**.

2: A mixture of **5c** (1.31 g, 3.8 mmol) in DMSO (30 mL) and Ac_2O (20 mL) was stirred for 3.5 h at room temperature. The mixture was partitioned between 200 mL of cold 20% NaOH and 300 mL of Et_2O under ice cooling, and the aqueous phase was extracted several times with Et_2O. The combined organic solutions were washed with brine and dried over Na_2SO_4. Flash chromatography with hexane/CH_2Cl_2/EtOAc (10:10:1 to 5:5:1) afforded **2** (1.01 g, 78%) as an orange solid. M.p. 176–178 °C, decomp.; $[\alpha]_D^{20}$ −818, c = 0.111 in $CHCl_3$; IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 1959(s), 1896(s), 1869(s), 1682(s), 1437(m), 1287(s); ^1H NMR (270 MHz, $CDCl_3$): δ = 6.00 (s, 1H), 5.11 (s, 1H), 3.85 (s, 3H), 3.80 (s, 3H), 2.91 (m, 1H), 2.69 (m, 2H), 2.36 (m, 1H), 2.11 (m, 2H); ^{13}C NMR (62.9 MHz, $CDCl_3$, additional DEPT): δ = 21.9(CH_2), 28.0(CH_2), 37.3(CH_2), 56.7(CH_3), 57.3(CH_3), 74.3(CH), 75.5(CH), 87.8, 109.9, 130.5, 135.5, 196.0, 231.3.

[9] A time-resolved study of the reactions by means of HPLC showed that (in contrast to the complexation of 1-indanol [c]) the *syn*/*anti* ratio (**5**:**6**) decreases continuously during the conversions. This loss of selectivity, which is attributable to a change of the $Cr(CO)_3$ group to the opposite π face, is more pronounced (faster), the more methoxy substituents are present on the arene ring. In our laboratory the complete diastereoselection described by Davies et al. in [4b] for the complexation of *rac*-**4a** under similar conditions (19 h reaction time, 36% yield) could not be observed.

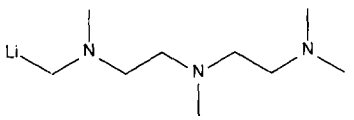
N-Lithiomethyl-*N*,*N*′*N*″,*N*″-tetramethyldiethylenetriamine: The First Alkyllithium Compound which is Monomeric in Hydrocarbons

By *Gerhard W. Klumpp*,* *Hendrikus Luitjes*, *Marius Schakel*, *Franciscus J. J. de Kanter*, *Robert F. Schmitz* and *Nicolaas J. R. van Eikema Hommes*

In hydrocarbon solution alkyllithium compounds usually exist as tetramers or hexamers.[1, 2] Addition of suitable Lewis bases B (ethers, tertiary amines) converts the hexamers into Lewis-base complexes with a tetrameric alkyllithium unit $[R_4Li_4] \cdot n\,B$ ($n = 1–4$)[1]. Further dissociation into dimer complexes $[R_2Li_2] \cdot 4\,B$ is observed only at very low temperatures in THF, and even trace amounts of hydrocarbons suffice to prevent it.[3] By contrast, the presence of polydentate Lewis bases such as *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), which corresponds to two bases B,[3] or *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDTA), which corresponds to three bases B,[4] is advantageous. If the organic groups contained in the aggregates are bulky (R = *tert*-butyl, neopentyl), the aforementioned favorable conditions even allow the formation of complexed monomers $[RLi] \cdot 3\,B$, and dimers $[R_2Li_2] \cdot 4\,B$ are formed in ether.[4].

Due to the chelate effect, intramolecular Lewis-base groups lead to particularly stable complexes. Hence, we have synthesized secondary alkyllithium compounds containing two Lewis-base units. In hydrocarbon solution at room temperature, they exist exclusively as dimers.[5] We have now observed that *N*-lithiomethyl-*N*,*N*′,*N*″,*N*″-tetramethyldiethylenetriamine (**1**), recently prepared by us[6] and containing three Lewis-base groups, is monomeric in hydrocarbon solutions at about 5 °C. As far as we know, this is unprecedented for an alkyllithium compound. Cryoscopy of solutions of crystals of **1**[7] in benzene yielded a value of 1.06 for the degree of aggregation. At 195 K, ^6Li NMR spectra of



1

solutions of crystalline **1** (^6Li-labeled) in pentane exhibit signals at $\delta = 1.75$ (species A) and 1.35 (species B)[**] in an intensity ratio of 1.27:1 which coalesce, regardless of the concentration of **1**, at 227.7 K (36.80 MHz) and 232.2 K (58.88 MHz), respectively.[8] 1:1:1-Triplets at δ = 51.0 and 52.9 [$^1J(^{13}C,^6Li) = 13.9$ Hz] could be recognized in the 100.61 MHz ^{13}C NMR spectrum at 225 K, proving that A and B are monomers whose α carbon atoms bind to a single lithium atom.[9] At low temperatures, other signals in the C,H-decoupled ^{13}C NMR spectra[10] and in the ^1H NMR spectra[11] of pentane solutions of **1**, also indicate the presence of two species in the above ratio. At higher temperatures the signal patterns attributable to (stereo)isomers and diastereotopicity coalesced, and finally the spectra corre-

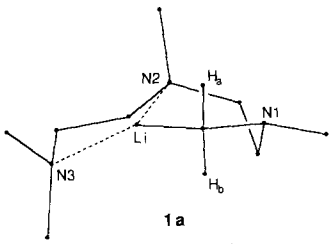
[**] In the following text the experimentally observed species A and B are distinguished from the calculated structures **1a** and **1b**.

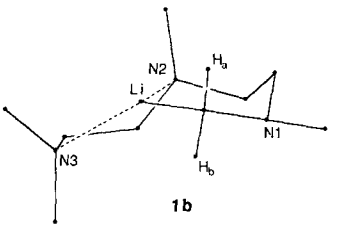
sponding to the averaged structure **1** were obtained. At 275 K ^{13}C-^{6}Li coupling had vanished. A/B interconversion as well as exchange processes, known for ordinary[2a] and for intramolecularly coordinated[5] alkyllithium compounds, are possible causes of the temperature-dependence. The existence of **1** as a monomer is presumably due to steric hindrance of aggregation and to intramolecular Li–N coordination.

MNDO calculations[12] yielded structures **1a**(A) and **1b**(B) as the most stable states of **1**. Remarkably, in **1a, b** N2 and N3 coordinate to lithium as expected ($d_{N2[N3]-Li}$ = 2.22 [2.22] Å), while N1 interacts only weakly, at most (d_{N1-Li} = 2.67 Å). Despite the tricoordinate nature of lithium implied by this result, the enthalpies of formation obtained for **1a, b** are lower than those calculated for potential dimers of **1** containing coordinatively saturated tetracoordinated lithium.[12] Unfavorable steric effects in the dimers seem to be



1a

E_{rel} = 0 kJ mol^{-1}



1b

E_{rel} = 4 kJ mol^{-1}

responsible for their higher enthalpies of formation. The enthalpy of activation calculated for the transformation **1a**(A) → **1b**(B), essentially corresponding to an inversion of N1, amounts to 40 kJ mol^{-1}.[12] This is in satisfactory agreement with the experimental value, $\Delta H^{\ddagger}_{A\rightarrow B} = \Delta H^{\ddagger}_{B\rightarrow A} = 43 \pm 3$ kJ mol^{-1} ($\Delta S^{\ddagger}_{A\rightarrow B} = -28 \pm 13$ J mol^{-1}K^{-1}, $\Delta S^{\ddagger}_{B\rightarrow A} = -26 \pm 13$ J mol^{-1}K^{-1}), derived from the coalescence temperatures T_c of the ^{6}Li resonance signals and of two pairs of ^{13}C signals of A/B (100.61 MHz; NCH_2, $\delta = 56.60 + 56.32$, $T_c = 235.5$ K; $(NCH_2)'$, $\delta = 63.24 + 61.36$, $T_c = 255.2$ K).[14]

Two coalescence phenomena were observed for the signals of the CH_2Li protons: Due to fast A/B interconversion the original four resonance signals of the diastereotopic protons H_a and H_b in A(**1a**) and B(**1b**), respectively, fuse at about 258 K to form two very broad signals[15] (H_a and H_b, respectively, in the averaged structure), which for their part coalesce into a broad singlet[16] at approximately 275 K [$\Delta G^{\ddagger}$ (275 K) ca. 53 kJ mol^{-1}]. This indicates fast exchange and, as a consequence, equivalence of the two diastereotopic protons of the averaged structure. Equivalence of H_a and H_b in A(**1a**) and B(**1b**) is not induced by **1a**/**1b** interconversion, and, according to theoretical studies, inversion of C^-, another possible cause, should only occur in aggregates with comparable ease.[17] Do **1a, b**(A, B), monomeric derivatives of α-aminomethyllithium containing two additional Lewis-base centers, invert easier and in a different way than monomeric methyllithium? The loss of ^{13}C-^{6}Li coupling at higher temperatures suggests Li–C bond breaking in the monomer (allowing for inversion of C^-) or intermolecular Li–C exchange involving dimers of higher energy. Inversion of N2 (MNDO enthalpy of activation 51 kJ mol^{-1})[12] could also lead to H_a/H_b exchange. Clarification of the actual mode requires additional studies.

Stable intramolecular organolithium complexes like **1a, b** and other members of this class of compounds prepared by us[5] are models for labile intermolecular Lewis-base complexes [RLi] · 3 B, [R_2Li_2] · 4 B, and [R_4Li_4] · 4 B, and to some degree their properties (structure, dynamics, reactivity) should be exemplary for those of these solvent- and temperature-dependent components of organolithium reagents, which are of such importance in synthesis.[5, 19]

[11] ^{1}H NMR (250 MHz, [D_{12}]pentane, 195 K [300 K], TMS): δ = 2.40 + 2.10 [2.28] (s + s, ca. 3H + ca. 3H; $N(3)Me_2$, A + B), 2.33 (s, ca. 1.5H; N(2)Me, A), 2.35 (s, ca. 1.5H; N(2)Me, B) [2.37], 2.31 [2.35] (s, 3H; N(1)Me, A + B), ca. 2 (overlapping signals; NCH_2), 1.63 + 1.19 (d + d, ^{2}J(H, H) = 10.4 Hz, 1H; CH_2Li, B + A, coalescence at ca. 258 K), 0.67 + 0.30 (d + d, ^{2}J(H, H) = 10.4 Hz, 1H; CH_2Li, A + B, coalescence at ca. 258 K) [1.03].
[12] In order to correct for known deficiencies of MNDO calculations (overestimation of C–Li bond strength and nonbonding repulsions) 60 kJ mol^{-1} was added to the calculated energy of $(\mathbf{1})_2$,[13] and 21 kJ mol^{-1} was added to all calculated activation enthalpies (N. J. R. van Eikema Hommes, P. von Ragué Schleyer, unpublished results).
[13] E. Kaufmann, K. Raghavachari, A. E. Reed, P. von Ragué Schleyer, *Organometallics* **1988**, *7*, 1597–1607.
[14] Method: H. Shanan-Atidi, K. H. Bar-Eli, *J. Phys. Chem.* **1970**, *74*, 961–963. Although upon increase of temperature all other A/B signal pairs recognizable at low temperature also coalesced, partial overlap with other temperature-dependent signals restricted exact determination of coalescence temperatures to the four cases given. Rate constants evaluated from the estimated coalescence temperatures [241 K (100.61 MHz) and 255 K (62.89 MHz)] of the N(1)$^{13}CH_3$ and N(2)$^{13}CH_3$ A/B signal pairs correspond to those of the A/B exchange as calculated for the respective temperatures from the activation parameters. The linewidths of the pairs of ^{13}C signals $[N(3)Me]_A$ + $[N(3)Me]_B$ and $[N(3)Me']_A$ + $[N(3)Me']_B$ are considerably larger than those of the other signals, and coalescence took place between the measurements at 215 and 225 K (62.89 MHz) without prior

loss of identity of the A and B component in the (better resolved) low-field pair. This suggests that the sequence, Li-N(3) decoordination, inversion of N(3), and Li-N(3) recoordination, causes fast Me/Me' exchange, while A/B exchange is still slow on the ^{13}C NMR time scale.

[15] $\Delta\nu_{1/2}$ ca. 70 Hz. The low-field resonances were obscured by the signals of the residual protons of the solvent [D_{12}]pentane.

[16] $\Delta G^{\neq} = 19.13\, T_c\{9.97 + \log(T_c/\Delta\nu^{-1})\}$, $\Delta\nu$ ca. 230 Hz.

[17] The value of $\Delta G^{\neq}$ (281 K) for stereomutation of C^- in aggregated alkyllithium compounds is ca. 60 kJ mol^{-1} [18]. Calculations for methyllithium indicated the barrier for inversion of C^- in the monomer to be ca. 55 kJ mol^{-1} higher than in the aggregates[13]. On this basis the value of $\Delta G^{\neq}$ (275 K) for inversion of C^- in **1a, b** is expected to be ca. 110 kJ mol^{-1}.

Addition of Benzyl Radicals to Alkenes: The Role of Radical Deformation in the Transition State**

By *Károly Héberger, Manfred Walbiner*, and *Hanns Fischer**

Rate constants for the addition of alkyl radicals to alkenes are influenced strongly by polar and steric effects from substituents of radicals and alkenes. Since the reactions are exothermic ($\Delta H = -50$ to -150 kJ mol^{-1}), the overall reaction enthalpies and radical stabilizations play a minor role, and the transition states are early. This also allows the rationalization of polar effects in terms of orbital interactions of the unperturbed reactants.[1] Calculated transition-state structures vary little with changes in either radical or substrate. As indicated by Figure 1, the forming bond is rather long (215–240 pm), yet the angle of attack is tightly prescribed (107–110°). The alkene center attacked is markedly though not strongly deformed; the other center is hardly affected. Most calculations yield pyramidalized radical centers.[2]

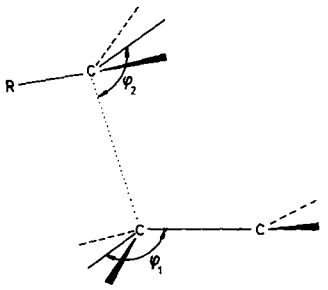

Fig. 1. Transition-state structure for the addition of an alkyl radical to an alkene. Calculated angles for $CH_3 + C_2H_4$: $\varphi_1 = 160°$, $\varphi_2 = 100°$, versus $\varphi_1 = 180°$, $\varphi_2 = 90°$ in the initial state and $\varphi_1 = 125°$, $\varphi_2 = 110°$ in the product state [2d].

In continuation of our previous work on the kinetics of radical additions,[3] we have now determined rate constants for the reaction of benzyl radicals and some *para*-substituted derivatives with a series of monosubstituted and 1,1-disubstituted alkenes. Benzyl is resonance-stabilized by about 50 kJ mol^{-1},[4] and little is known about addition rates of such radicals. The addition of benzyl is estimated to be exothermic, but less so than that of other alkyl radicals.[5] A comparison with rate constants for the addition of other radicals, for instance *tert*-butyl,[3a, b] should reveal the influence of the reaction enthalpy. Furthermore, the SOMO (SOMO = *S*ingly *O*ccupied *M*olecular *O*rbital) energy of benzyl (IP = 7.2 eV) is close to that of *tert*-butyl (IP = 6.7 eV).[6] The latter has clearly nucleophilic behavior,[3a, b] hence benzyl should also be a nucleophilic radical. On *para*-substitution of benzyl, its SOMO energy varies from about -7.9 to -6.3 eV,[6] whereas the stabilization energy is nearly unaffected.[4b] Previously, for *tert*-butyl, a strong dependence of the rate constants on the LUMO energies of the alkenes ($-2.48 \le EA \le -0.21$ eV) had been observed.[3a, b] It might be expected that a similar variation of the benzyl SOMO energy by substitution would cause a similarly strong polar effect.[1]

Figure 2 shows rate constants for the addition of benzyl and, for comparison, *tert*-butyl[7] as a function of the alkene LUMO energy. The linear correlation[3] with the alkene electron affinities for benzyl is significant (lg k_{296} [M^{-1}s^{-1}] = 3.36 + 1.14 EA, 24 measurements, correlation coefficient $r = 0.87$) but weaker than that for *tert*-butyl (lg k_{296} [M^{-1}s^{-1}] = 5.95 + 1.61 EA, 21 measurements, $r = 0.89$). As expected, benzyl is less nucleophilic. The large scatter of the data is not due to experimental error.

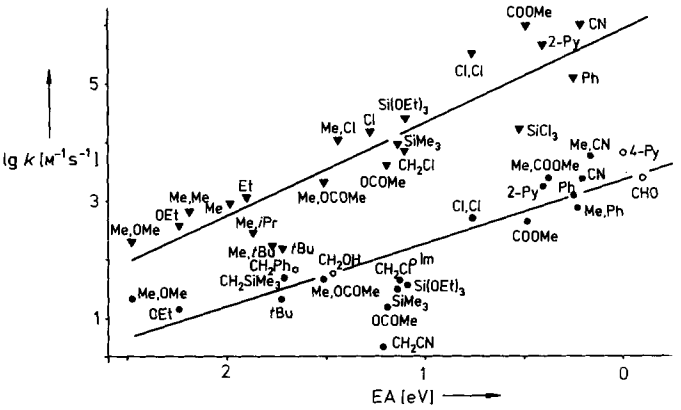

Fig. 2. Rate constants for the addition of benzyl (●○) and *tert*-butyl (▼) to alkenes $H_2C = CY^1Y^2$ (○: EA estimated) in toluene at (23 ± 1) °C. The labels next to the symbols for the benzyl and *tert*-butyl radicals indicate the substituents Y^1 and Y^2 of the alkene. If only one substituent is specified, then $Y^1 = H$ (see also Table 1). Im = imidazolyl, 2-Py = 2-pyridyl, 4-Py = 4-pyridyl.

In general, benzyl radicals react much more slowly than *tert*-butyl with all alkenes, and it is tempting to attribute this to the smaller exothermicity of the addition. However, this is contradicted by the findings that the increased exothermicity in the formation of benzyl-type radicals from styrenes does not increase the rates correspondingly. Moreover, the measured difference in activation energies for the additions of benzyl and *tert*-butyl is on the average 20 kJ mol^{-1}; this is too large to be accommodated by the enthalpy difference of only 38 kJ mol^{-1}. Table 1 presents rate constants for addition of the different *para*-substituted benzyl radicals to selected alkenes. To a first approximation all the radicals show the same weakly nucleophilic behavior. There are differences in detail, but there is no obvious correlation with the radical SOMO energies[6] nor with σ-scales for benzyl substituents.[8] Thus, polar orbital interactions appear to be asym-

metric: Variations in the energy of the alkene LUMO influence the addition of the radical more than corresponding changes in the radical SOMO energy.

The results are compatible with the calculated properties of the transition states (Fig. 1). Detailed analyses of activation energies for methyl additions to alkenes[2a, d] have revealed large repulsive contributions of the deformation energies required for pyramidalization. For the addition of the methyl radical the main contribution comes from the alkene deformation, though the radical is more pyramidalized. This is understandable since the methyl radical has a flat and broad potential energy surface for out-of-plane deformation;[2a, d] the same probably holds for the *tert*-butyl radical which rapidly inverts in a double minimum potential.[9] The molecular frame of benzyl radicals is considerably stiffer, as supported by the very small temperature-dependence of the hyperfine couplings of the α protons.[10] If, like methyl radicals, benzyl radicals also have to be pyramidalized at the attacking carbon to reach the region of dominating attractive interactions, then a larger radical deformation energy is required. This increases the activation energy and decreases the reactivity. Also, both mesomeric and inductive effects decrease upon deformation of the radical, which may explain the low *para*-substituent effects (Table 1). A comparison of the reactivities of various alkyl radicals further supports this view: Most alkyl radicals are nucleophilic like *tert*-butyl and even methyl, despite its much lower SOMO energy of −9.8 eV.[1, 3] Only strong acceptor substituents change the radical character to ambi- or electrophilic.[1, 2, 3, 11]

We suggest that benzyl and other stabilized radicals react comparatively slowly with alkenes because they resist pyramidalization more strongly than other species and not because of the lower exothermicity of the addition. Our results give no hint to the details of the transition-state structure, and calculations would be very helpful in this respect.

Experimental Procedure

The rate constants were measured by kinetic ESR spectroscopy [3] employing photochemical generation of benzyl by α-cleavage of symmetric ketones [12] or by reaction of *tert*-butoxy radicals from the photolysis of di-*tert*-butyl peroxide with *p*-cyanotoluene. The addition obeyed pseudo-first-order kinetics as shown by variation of alkene concentrations. For fast reacting alkenes, product radicals could be detected whose structures confirmed addition to the unsubstituted alkene center. Rate data are averages from 5–10 individual experiments and have standard deviations of at most 30%. Very small rate constants were difficult to measure and may be somewhat high, since side-reactions may have interfered to some extent.

Proof of the Catalytic Activity of a Naked Metal Cluster in the Gas Phase**

By *Patrick Schnabel, Konrad G. Weil,* and *Manfred P. Irion**

Naked metal clusters in the gas phase are usually characterized by a high degree of coordinative unsaturation. They are not only suitable as model substances for heterogeneous catalysis but should themselves be highly selective and effective catalysts. Thus, the search for such new catalysts is often given as a reason for the investigation of their chemical behavior. However, in spite of numerous efforts[1, 2] to our knowledge no synthesis catalyzed by a gas phase metal cluster has so far been reported.[3]

Recently we observed that from a distribution of iron cluster ions Fe_n^+ ($n = 2–13$), which were stored in the ICR cell of a Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer[4] and were exposed to the reactive gas NH_3 at ca. 10^{-7} mbar, only Fe_4^+ reacted through

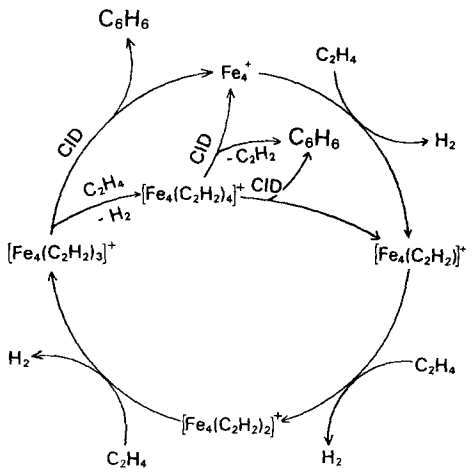
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Röhm-Stiftung. It is part of P. Schnabel's dissertation (Darmstadt, D17).

dehydrogenation of ammonia to give the intermediates $[Fe_4(NH)]^+$ and $[Fe_4(NH)_2]^+$.[8] Ammonia synthesis is presumed to proceed via intermediates formed from (NH) and the iron atoms on the solid catalyst surface,[9] which are similar to the ions we observed. Nevertheless this reaction could not be considered as an example of gas phase catalysis by a naked metal cluster.

Now for the first time clear indications of such catalytic activity have been obtained. If Fe_4^+ ions are isolated by a radio frequency (RF) ejection pulse[11] from Fe_n^+ ions stored in an ICR cell and are exposed to the hydrocarbons ethene or cyclopropane (at ca. 10^{-7} mbar), dehydrogenation reactions occur which for ethene lead to a complex consisting of Fe_4^+ and up to four acetylene ligands. Collision-induced dissociation (CID) with xenon as collision gas leads to the formation of carbides for adducts with less than three acetylene ligands. However, for those adducts whose ligands have attained C_6H_6 stoichiometry, CID leads to the simultaneous loss of all C and H atoms already at a center-of-mass collision energy[12] of ca. 3.2 eV.[10a] This observation together with the kinetic behavior of the adducts[10b] suggest that neutral benzene is liberated in the CID process. (This statement cannot be proven directly from the experiment; however, for reasons of stability we would rather exclude other C_6H_6 isomers.) The naked Fe_4^+ ion is left and in principle can initiate a new cycle.

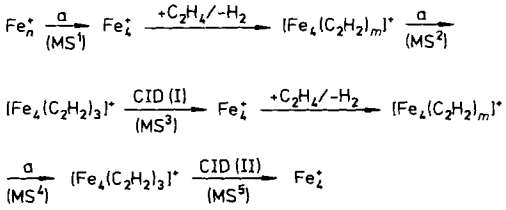
In 1981 Kappes and Staley were the first to prove such catalytic cycles in the gas phase in an analogous procedure with the simple metal ion Fe^+. Here, N_2O oxidized the hydrocarbons C_2H_6, C_2H_4, C_2H_2, C_3H_4, C_3H_6, C_3H_8, and even CO.[13] Recently the oxidation of ethane was studied in greater detail by Schwarz et al. using FT-ICR as well.[14] Analogous to our results the reaction of $[Fe(CO)_n]^+$ with C_2H_2 gave the adduct ions $[Fe(C_2H_2)_m]^+$ ($m = 1-4$). Neutralization reionization mass spectrometry (NRMS) of $[Fe(C_2H_2)_3]^+$ indicated a partial cyclotrimerization of the ligands to give C_6H_6. Here, too, the addition of the third C_2H_2 ligand occurred more easily than the addition of the previous ones; in all probability CID also effected the release of neutral benzene.[15] Our results lead us to the conclusion that the metal cluster ion Fe_4^+ catalyzes the formation of benzene from ethene (Scheme 1). Clear proof of this conjecture had been missing till now.

Through an optimization of the experimental conditions for the ion transfer to the ICR cell[4] we achieved such an increase in the intensities of the ions stored and detected



Scheme 1. Catalytic cycle of the metal cluster ion Fe_4^+ for the synthesis of benzene from ethene.

there that several successive reaction steps could be carried out with them. To prove beyond doubt that the same Fe_4^+ ions induce the synthesis of benzene twice, it was neccessary to carry out the MS^5 experiment shown in Scheme 2.[16]



Scheme 2. Complex MS^5 experiment to prove the recovery of the catalyst Fe_4^+ for the reaction with ethene. a = isolation; $m = 1-3$.

Figure 1 shows the FT mass spectrum of the sputtered and stored/cooled Fe_n^+ cluster ions in the size range $n = 3-8$, and Figure 2a shows the signal of the Fe_4^+ ions isolated from them. By the reaction of the Fe_4^+ ions with ethene the spec-

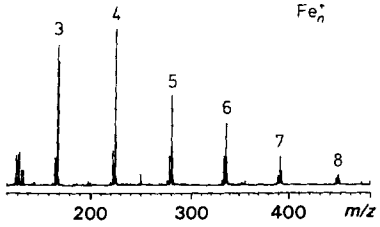


Fig. 1. FT mass spectrum of the Fe_n^+ cluster ions stored/cooled in the ICR cell in the size range $n = 3-8$.

trum of the adduct ions $[Fe_4(C_2H_2)_m]^+$ ($m = 1-3$; Fig. 2b) is obtained. In the next step (Fig. 2c), the ion $[Fe_4(C_2H_2)_3]^+$ is selected and then excited by a RF pulse at its resonance frequency to a translational energy of ca. 36.3 eV. The prima-

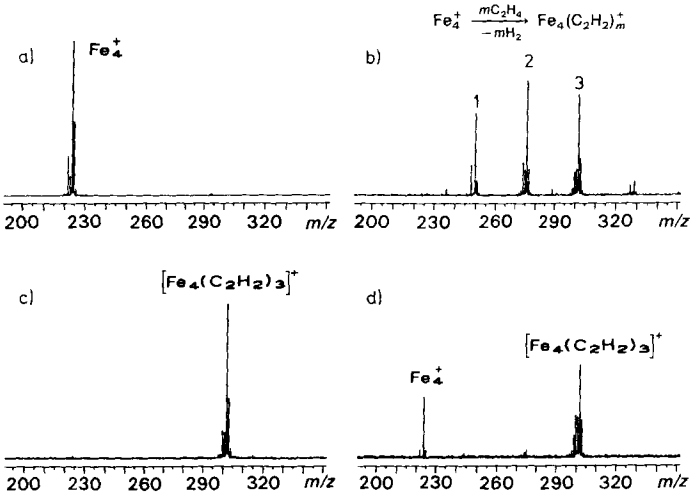

Fig. 2. a) Signal of the isolated Fe_4^+ cluster ions (1st generation). b) FT mass spectrum of the adduct ions $[Fe_4(C_2H_2)_m]^+$ ($m = 1-3$) from the reaction $Fe_4^+ + mC_2H_4 \rightarrow [Fe_4(C_2H_2)_m]^+ + mH_2$ (1st generation; the signal intensities were increased by factor of 2.0). c) Signal of the isolated adduct cluster ions $[Fe_4(C_2H_2)_3]^+$. (1st generation; the signal intensities were increased by factor of 1.5). d) FT mass spectrum of the mother and fragment ions following CID of $[Fe_4(C_2H_2)_3]^+$, 1st generation with xenon as collision gas ($p \approx 10^{-7}$ mbar; $E_{cm} \approx 11$ eV).

ry ion source constantly releases xenon as a background gas into the vacuum up to a pressure of ca. 10^{-7} mbar, which leads to a great number of collisions of the ions excited to a larger cyclotron orbit and thus to their dissociation ($E_{cm} \approx 11$ eV [12]). Finally, the signals of the residual mother ion and the new fragment ion Fe_4^+ are shown in Figure 2d. The whole reaction cycle is repeated once again in an analogous way in Figure 3. (Although the observed intensity inevitably decreases with every step, in this experiment even at the end it is still three to four times more intense than the background noise.)

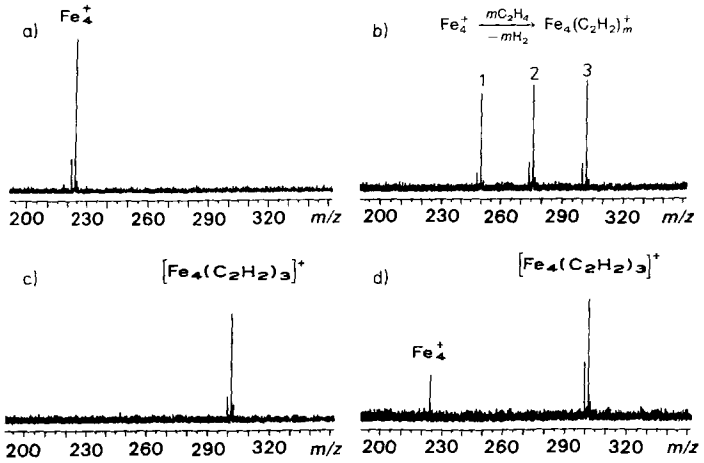

Fig. 3. a) Signal of the isolated Fe_4^+ cluster ions (2nd generation; the signal intensities were increased by a factor of 2.5). b) FT mass spectrum of the adduct ions $[Fe_4(C_2H_2)_m]^+$ ($m = 1-3$) following the reaction of Fe_4^+ with C_2H_4 as in Figure 2b (2nd generation; the signal intensities were increased by a factor of 2.0). c) Signal of the isolated adduct cluster ions $[Fe_4(C_2H_2)_3]^+$ (2nd generation). d) FT mass spectrum of the mother- and fragment ions following CID of $[Fe_4(C_2H_2)_3]^+$, 2nd generation with xenon as collision gas ($p \approx 10^{-7}$ mbar; $E_{cm} \approx 11$ eV).

Thus, the originally produced Fe_4^+ ions have run through the same reaction cycle twice. This demonstrates that a naked metal cluster in the gas phase can indeed act as a catalytic center and repeatedly build up a larger molecule from smaller units.

[4] The FT-ICR mass spectrometer used was home-built with a cubic ICR cell of side length 80 mm, placed in the homogeneous field of an Oxford Instruments 7.05 T superconducting magnet and a Spectrospin data system. Via an Aspect 3000 computer it provided the cell with pulses, registered and Fourier transformed the transient signal.[5] The metal cluster ions are produced by the bombardment of the corresponding metal foil in an external chamber with 20 keV Xe^+ ions from a duoplasmatron ion source [6]. They are injected into the differentially pumped ICR cell by a system of ion optics. A grid in front of the cell decelerates the external ions electrostatically and controls their entrance into the cell. By using a home-made piezoelectric valve at a distance of 8 cm, neon is pulsed in up to ca. 10^{-4} mbar, which by means of collisions helps in trapping the incoming ions and cools them to approximately room temperature.[7] To initiate chemical reactions with the thus thermalized ions, gases can be admitted via continually adjustable leak valves or via a second pulsed valve. Whereas in earlier experiments mainly the first possibility was used [8,10] the ethene in this case was added through the second pulsed valve.

[11] An ion type of a certain mass/charge ratio is isolated in the ICR cell from ions of other masses, by intentionally exciting the ions of unwanted types by a radio frequency (RF) "ejection pulse" thus eliminating them from the cell. A particular variant of this technique is "FERETS" (R. A. Forbes, F. A. Laukien, J. Wronka, *Int. J. Mass Spectrom. Ion Processes* **1988**, *83*, 23).
[12] The center-of-mass energy, E_{cm}, defines the maximum energy, which is transmitted by the collision of a molecule M with an ion I. It is obtained from the masses m_i from the following formula: $E_{cm} = E_{Lab} \cdot m_M/(m_I + m_M)$.

[16] A complex experiment with several mass spectrometric steps (MS^n) requires in a conventional instrument n sectors separated in space. However, in an instrument with ion storage (FT-ICR, quadrupole ion trap) the whole experiment is conducted in the time domain and nothing more than a software extension to include all the pulses is needed. The number n of possible steps is dependent upon the number of mother ions stored originally and the overall efficiency of the MS^n process (fraction of the number of end product ions and the number of original ions) [17]. In FT-ICR the finite ICR cell plate distance limits the cyclotron radius of the ions and thus the maximum number of steps. Supposedly, the practical limit lies at $n = 5$ or $n = 6$ at most [18]. However, already in 1984 MS^5 was demonstrated on organic ions (FT-ICR at 1.4 T magnetic field strength) [19]. With the application of high magnetic fields the experimentalist will run out of ideas rather than of steps to be actually achieved for the MS^n experiment; for example a magnetic field strength of 7 T should allow even MS^{20} [20].

Evidence for [PdSiO] from IR Spectroscopy**

By *Thomas Mehner, Ralf Köppe,* and *Hansgeorg Schnöckel**

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

For a long time simple, coordinatively unsaturated transition-metal carbonyls have been known to exist under matrix conditions. Lately theoretical methods have also been used to study these small molecules such as [PdCO].[1–3] Attempts to generate transition-metal complexes with SiO as ligand in solid argon led to the preparation of [AgSiO].[4] Several theoretical[5,6] and experimental investigations[7] are concerned with the clarification of the bonding relationships in this species. Apparently it is an ion pair Ag^+SiO^-,[9]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

as is shown by the formation of SiO^- with Na^+ or K^+.[10] Here we report the first transition-metal complex containing SiO as ligand in solid argon. With respect to bonding it is similar to carbonyl complexes.

When SiO and palladium atoms were condensed together with argon on a helium-cooled copper surface, we observed in the IR spectrum (Fig. 1) besides the absorption of molecular SiO at 1226.0 cm^{-1} a new band at 1246.3 cm^{-1}, which we assigned to the complex [PdSiO] (**1**).[8] Moreover, the complex [PdCO] (**2**) is generated ($\tilde{\nu} = 2050.0\ cm^{-1}$), since CO (2138 cm^{-1}) is always present in these experiments as impurity.

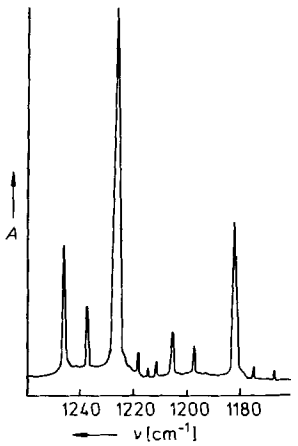

Fig. 1. Section of the IR matrix spectrum after the condensation of Pd atoms with $Si^{16}O/Si^{18}O$.

Annealing the matrix doubles the intensity of the band due to **1** and leads to an additional absorption band at 1237.1 cm^{-1}. Simultaneously [$Pd(CO)_2$] (2044 cm^{-1}) is formed from **2** and CO. Since under these conditions no palladium carbonyl complex with more than one Pd atom is generated, the absorption at 1237 cm^{-1} may be attributed to the complex [(OC)Pd(SiO)] formed from CO and **1**. The formation of [$Pd(SiO)_2$] can be ruled out because the dimerization of SiO is energetically more favorable than the coordination of a second SiO to **1**.[11, 12]

At high CO concentrations (Ar/CO mixtures of 20:1), [(OC)Pd(SiO)] (1237 cm^{-1}) is observed alongside the complexes [$Pd(CO)_n$] ($n = 2-4$) even without annealing. Since no CO absorption is detected,[13] the assignment for the absorption at 1237 cm^{-1} is based initially on theoretical consideration of the bonding in possible products that can form under these conditions but also on the specific experimental conditions under which this absorption is observed.[15]

Qualitative confirmation of the assignment of the SiO band of **1**[16] is provided by the position of the SiO band of the isotopomer [$PdSi^{18}O$] at 1205.8 cm^{-1}. Absorption by the isotopomers with ^{29}Si and ^{30}Si are not observed. They apparently lie beneath the band at 1237.3 cm^{-1} ([(CO)Pd(SiO)]) and 1226.0 cm^{-1} (uncoordinated SiO). The band at 1237.1 cm^{-1} is shifted to 1197.1 cm^{-1} by ^{18}O substitution, which similarly indicates a Si=O vibrational band.

Conclusive confirmation for the assignment of the band at 1246.3 cm^{-1} to [PdSiO] (**1**) is found in normal-coordinate analysis on assumption of a simple valence force field (f(PdSi/SiO) = 0). The measured $^{16}O/^{18}O$ shift of the SiO stretching frequency is satisfactorily reproduced only for a linear silicon-bridged Pd-Si-O molecule[17] on assumption of a Pd–Si frequency of 375 cm^{-1}. The SiO force constant in **1** is calculated to be 8.92 mdyn $Å^{-1}$ (SiO in argon: 9.02) and that of Pd–Si, 2.69 mdyn $Å^{-1}$.

The linear, silicon-bridged structure for **1** (deduced from the spectroscopic data) and the force constants (based on experiment) were confirmed convincingly by ab initio calculations. The relativistic model potential of Sakai et al.,[18] as implemented in the program package CADPAC 4.0[19] that we applied here, was used as basis set for palladium. The quality of this basis[20] was tested by calculations of the excitation energy $4d^{10}(^1S) \rightarrow 4d^9 5s^1(^3D)$ at MP-2 level (exp.: 91.7, calcd: 80.0 kJ mol^{-1}) and by optimization of the geometry of PdH ($^2\Sigma^+$) (exp.: r(PdH) = 153.5, calcd: r(PdH) = 151 pm). The basis sets for Si, C, and O were of TZ2P quality.[21] We performed all calculations at MP2 level taking into account basis-set superposition error.

The results for the structure and for the atomic charges from Mulliken population analyses are summarized in Table 1. The geometry and the force constants correspond to those deduced from the spectra. The Pd–Si bond in **1** is surprisingly strong, since the enthalpy of reaction for Pd + SiO → [PdSiO] is −182 kJ mol^{-1} (basis-set superposition error is taken into account). It is thus of the same order as that for the formation of [PdCO] (−162 kJ mol^{-1}). Furthermore, the frequencies resulting from the calculations (Table 2) confirm the experimental blue shift of the SiO band observed when SiO is coordinated in [PdSiO] ($\Delta\nu_{exp.} = -20.3$, $\Delta\nu_{calcd} = -25.5\ cm^{-1}$).[22]

Table 1. Calculated (MP2) geometries, force constants, and atomic charges (Mulliken) for the linear molecules [PdCO] (**2**) and [PdSiO] (**1**), and the isolated molecules CO and SiO.

	r(Pd-X) [Å]	r(X-O) [Å]	f(PdX) [mdyn $Å^{-1}$] [a]	f(XO) [mdyn $Å^{-1}$] [a]	q(Pd)	q(X)	q(O)
[PdCO]	1.86	1.158	2.85	15.42	0.09	0.19	−0.28
[PdSiO]	2.15	1.528	2.45	8.86	0.0	0.75	−0.75
CO [b]	–	1.134	–	18.38	–	0.09	−0.09
SiO [c]	–	1.529	–	8.69	–	0.51	−0.51

[a] f(PdC/CO) = 0.66 mdyn $Å^{-1}$, f(PdSi/SiO) = 0.007 mdyn $Å^{-1}$. [b] $E_{tot}^{MP2} = -113.143575$ Hartree. [c] $E_{tot}^{MP2} = -364.293021$ Hartree.

Table 2. Measured and calculated (MP2) frequencies for CO, SiO, [PdCO], and [PdSiO] (frequencies in cm^{-1}, intensities in parentheses in km mol^{-1}).

	ν(Pd-X) exp.	ν(Pd-X) calcd	ν(XO) exp.	ν(XO) calcd	δ(PdXO) exp.	δ(PdXO) calcd
SiO			1226.0	1203.4 (9.9)		
[PdSiO]	–	359.0 (6.4)	1246.3	1228.9 (65.6)	–	164.3 (8.9)
CO			2138.0	2133.0 (30.2)		
[PdCO]	–	462.0 (27.2)	2050.0	1969.2 (632.2)	–	343.7 (30.4)

The similar bonding situation in **1** and **2** suggested by these results is underscored by population analyses. The charges on palladium show similar distributions for these Pd complexes (**2**: Pd $4p^{5.97}5s^{0.45}4d^{9.39}p^{0.10}{}_{Pol}$; **1**: $4^{5.97}5s^{0.39}4d^{9.52}p^{0.12}{}_{Pol}$). The theoretical and experimental results presented here show that the bonding relationships in [PdSiO] can be compared with those in [PdCO]; that is, the σ donor bond is strengthened by π acceptor components. The proportion of σ and π bonding, however, differs in **2** and **1**, resulting in a red shift in the frequency of the uncoordinated ligand on coordination in **2**, but a blue shift in **1**.

[12] From an ab initio calculation for linear [(OC)Pd(SiO)] (E_{tot}^{MP2} = −573.873915 Hartree; r(CO) = 1.135, r(PdC) = 2.02, r(PdSi) = 2.25, r(SiO) = 1.525 Å) erhält man folgende Reaktionsenergien.
[PdCO] + SiO → [(OC)Pd(SiO)] $\Delta E = -107.4$ kJ mol^{-1}
[PdSiO] + CO → [(OC)Pd(SiO)] $\Delta E = -87.4$ kJ mol^{-1}
Pd + CO + SiO → [(OC)Pd(SiO)] $\Delta E = -296.4$ kJ mol^{-1}

[13] The corresponding bands in the carbonyl region are possibly hidden by the CO bands of the various carbonylpalladium complexes.

[14] E. P. Kündig, M. Moskovits, G. A. Ozin, *Can. J. Chem.* **1972**, *50*, 3587.

[15] The lowering of the frequency on changing from [PdSiO] to [Pd(SiO)(CO)] is reasonable, because the Pd–Si bond is weakened as a result of a smaller backbonding component. The Si–O bond and its stretching frequency should thus be more similar to the their counterparts in uncoordinated SiO (1226 cm^{-1}). This is also supported by ab initio calculations [12]: both the Pd–C distance in **2** and the Pd–Si distance in **1** are shorter than in [Pd(SiO)(CO)]. The bonding relationships in **2** and [Pd(CO)$_2$] yield additional evidence for the correctness of these arguments: The CO force constant f(CO) is a bonding parameter free from coupling influences. Its value in **2** of 16.97 mdyn Å^{-1} is smaller than that in [Pd(CO)$_2$] (17.16 mdyn Å^{-1} [14]). Thus the CO bond of free CO (f(CO) = 18.36 mdyn Å^{-1} in an argon matrix) more closely resembles that of [Pd(CO)$_2$] than that of **2**. Consequently both the CO bond in **2** and the SiO bond in **1** become more like the bond in uncoordinated CO or SiO on addition of a CO ligand at Pd.

[16] $\tilde{\nu}$(Si^{16}O) = 1226.0; $\tilde{\nu}$(Si^{18}O) = 1182.2 cm^{-1} in an argon matrix.

[17] In an oxygen-bridged complex, the silicon isotope shifts (Pd–O–^{29}Si and Pd–O–^{30}Si) would be much smaller and would therefore be able to be observed as they would not overlap with strong absorptions of other compounds such as [(SiO)Pd(CO)] or SiO. Calculation of the frequencies for [Pd^{29}SiO] and [Pd^{30}SiO] confirm that these bands are hidden by overlap.

[19] R. D. Amos, J. E. Rice, CADPAC: The Cambridge Analytic Derivatives Package, issue 4.0, Cambridge, **1987**.

[20] The 5s and 4d as well as the 4p electrons are treated explicitly in triple-zeta contraction to include any possible contribution of these electrons to the bond formation. As suggested by Sakai and Huzinaga et al. [18], we added two p-like polarization functions (Pd (MP) (5p8s5d2p)/[3p3s3d2p].

[21] S. Huzinaga, *Approximate Atomic Functions. Technical Report 1971*; University of Alberta, Canada, **1971**.

[22] The structural data and bond energies we calculated for [PdCO] agree well with earlier MP2 calculations [2] (where r(Pd–C) = 1.882, r(C–O) = 1.185 Å, ∢(PdCO) = 180°, Pd–C bond energy = −156 kJ mol^{-1}). In a new detailed theoretical work [3], many computational methods and better basis sets than in our calculations were used to investigate the bonding relationships in **2**. Among the computational methods incorporating electron correlation (MP2, MP3, CISD, CISC), the MP2 calculation yielded the largest bond energy (−109 kJ mol^{-1}); that is, also in our MP2 calculations the strength of the Pd–Si bond is a little overestimated: the Pd–Si distance is too small and the bond energy (Pd + SiO → [PdSiO]) too large. This is in accord with the difference in the frequency shift calculated by us (ν_{CO}(CO)-ν_{CO}(PdCO)) of 164 or 122 cm^{-1} [3] and the experimental value of 88 cm^{-1}.

The Structure of C_{60}: Orientational Disorder in the Low-Temperature Modification of C_{60} **

By *Hans-Beat Bürgi, Eric Blanc, Dieter Schwarzenbach,* Shengzhong Liu, Ying-jie Lu, Manfred M. Kappes,* and *James A. Ibers*

The availability of gram quantities of fullerenes[1] and the discovery of superconductivity in C_{60} doped with an alkali metal[2] have led to a broad spectrum of investigations dealing with diverse chemical and physical properties of solid C_{60}. Models of the structure of C_{60} are the starting point for much of this work. In particular for investigations of the solid-state properties, reliable information on the crystal and molecular structure of C_{60} is indispensable.

On the assumption of icosahedral symmetry, the molecules of C_{60} are approximately spherical. They crystallize in a cubic close-packed arrangement.[3] Above 249 K, the molecules are orientationally disordered in the crystal (the probable space group is $Fm\bar{3}m$). X-ray data of C_{60} measured at 110 K on a merohedrally twinned crystal were interpreted in terms of an ordered model in the space group $Pa\bar{3}$ with molecular site symmetry $\bar{3}$.[3] However, the lengths of bonds which are chemically equivalent and related by the icosahedral symmetry $m\bar{3}\bar{5}$ of the molecule differ considerably in this model; the distances also show deviations of up to 0.1 Å from those determined in an electron-diffraction study on gaseous C_{60}.[4] It was noted[3] that the agreement between the observed and calculated structure amplitudes is not nearly as good as would be expected from the internal agreement among symmetry-equivalent reflections, and it was suggested that there may be deficiencies in the model concerning thermal motion or twinning. Analysis[5] of the atomic displacement tensors $\boldsymbol{U}$ from ref.[3] and subsequent inspection of the residual displacements with the graphics program PEANUT[6] showed them to be incompatible with the expected motion of rigid molecules and also suggested the presence of disorder in the structure. In an independent study of C_{60} based on neutron-diffraction measurements on a powder at 5 K[7] and a Rietveld refinement with bond angles restrained to idealized values, the same packing as in ref.[3] was found with bond lengths in good agreement with those obtained from electron-diffraction studies of gaseous C_{60} and with no indication of disorder. The agreement of observed and calculated diffraction profiles was satisfactory. Displacement parameters were not reported in ref.[7]

We have now carried out additional analyses of the single-crystal X-ray diffraction data of ref.[3] collected at 110 K ($Cu_{K\alpha}$) and also of data collected in a similar manner from a second twinned crystal at 153 K ($Cu_{K\alpha}$) and from a third twinned crystal at 200 K and 100 K ($Mo_{K\alpha}$). These analyses show that at these temperatures the molecules are statistically distributed in two orientations: one with a large population (major orientation) as has been found in the earlier

Note added in proof (April 28, 1992): After this paper was submitted, the results of a high-resolution neutron-diffraction experiment on C_{60} powder were published [13].

analyses,[3, 7] and one with small population (minor orientation) related to the major one by an approximate 180° rotation of the molecule about its crystallographic threefold axis. From the population parameter, free-energy differences between the two orientations are estimated. An approximate value of the energy barrier to reorientation is obtained from the molecular libration amplitudes.

Initial coordinates of the ten crystallographically independent atoms defining the molecule in the major orientation were taken from ref.[3] Those of the molecule in the minor orientation were generated from the coordinates of ref.[3] by a rotation of 180° about the $\bar{3}$([111]) axis. The resulting model was then easily refined by the least-squares method with the use of various distance and displacement parameter restraints. For fixing the shape of a molecule 45 distances between nearest and next-nearest neighbors (up to 2.5 Å) were restrained. The orientation of a shape-restrained molecule is defined by a single positional parameter describing the rotation about the $\bar{3}$ axis. Effective rigid-body motion of a molecule was achieved with 82 rigid-link restraints on the displacement parameters.[8] This motion is described by four parameters, namely two mean-square libration amplitudes and two mean-square translation amplitudes parallel and perpendicular to the $\bar{3}$ axis. All restraints had weights of 10^8. The numbers of reflections used in the refinements with intensities larger than three standard deviations were 1296, 783, 740, and 855 at 100 K, 110 K, 153 K, and 200 K, respectively. The corresponding lattice constants are 14.050(6), 14.052(5), 14.061(5), and 14.067(6) Å. The following models were refined:

A: Minimal model: The shape of the molecule was restrained to icosahedral symmetry, and the thermal displacements to rigid-body motion. The ratio of the two nonequivalent bond lengths $d_{6,6}/d_{5,6}$ was fixed at the value 1.401/1.458 obtained by electron diffraction of C_{60} molecules in the gas phase.[4] If the restraints were given very large weights, this model would be characterized effectively by 14 independent variable parameters: the scale factor, the twinning parameter as described by ref.[3], the population factor of the major orientation, the diameter of the molecule, and one positional and four displacement parameters for each of the two orientations.

B: Intermediate model: Thermal displacements were restrained to rigid-body motion, but positional parameters of all ten atoms in both orientations were refined without restraints (except at 200 K where two distances were fixed). This model is described by 71 effective variable parameters.

C: Maximal model: The molecule with the major orientation was refined without any restraints; displacements of the minor molecule were restrained to rigid-body motion. This model is described by 127 effective variable parameters.

The resulting R values, population parameters, bond lengths, and rigid-body mean-square displacements are reported in Table 1; results of the type C refinements at 153 K and the type B refinements at 200 K are found in ref.[9] Results obtained with the data measured at 100 K are similar to those at 110 K but with larger standard deviations. Therefore, only the population parameter $P(100\text{ K}) = 0.780(5)$ is, reported here (type A refinement, $R(F^2) = 0.096$, $S = 1.105$). The twinning parameter was in all cases equal to 0.5, that is, within the estimated standard deviation, indicating equal volume fractions of the twin domains. A completely unrestrained refinement of the data at 110 K with 183 variables converged to a goodness of fit only insignificantly lower than that obtained with the maximal model; some displacement tensors of the minor orientation were negative. We believe that the data do not contain sufficient information to enable all these parameters to be determined reliably.

The refinement of the diffraction data of the twinned crystals leads to two main conclusions: 1) A model with idealized but disordered molecules of C_{60} explains the experimental data much better than a model with ordered C_{60} molecules ($R(F^2) = 0.08$ vs. 0.14 in ref.[3]). 2) Not much additional information on the geometry and the thermal motion of C_{60} may be gained from models with fewer restraints; improvement of the reliability factors is marginal even though the number of variable parameters increases dramatically (Table 1).

Table 1. Results of the refinements of types A–C. P is the population parameter of the major orientation M; that of the minor orientation m is given by $1-P$. $d_{6,6}$ is the average length of a C=C bond in Å shared by two C_6 rings; $d_{5,6}$ is the average length of a C–C bond shared by C_6 and C_5 rings; values for the minor orientation agree well with those for the major orientation. L_1 and L_2 are the mean-square libration amplitudes in $(°)^2$ parallel and perpendicular to the $\bar{3}$ axis. Estimated standard deviations referring to the last figure are given in parentheses; for the averaged distances, they are derived from the deviance of the sample. S is the goodness of fit with an expectation value of 1 for a perfect model.

The general packing pattern of C_{60} is as described in ref.[3, 7]. Each molecule has twelve neighbors in a cuboctahedral environment, i.e. six in the equatorial plane in Figure 1 perpendicular to the crystallographic $\bar{3}$ axis, and three above and three below this plane. However, in the disordered struc-

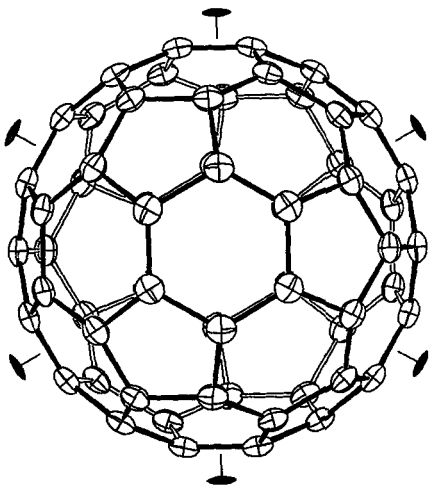

Fig. 1. View down the $\bar{3}$ axis of the molecule, type B refinement at 110 K, major orientation, ellipsoids with 50% probability of occupation. The upper half of the molecule is identified with "filled", the lower half with "empty" bonds. The empty bonds can also be interpreted to represent the upper half of a C_{60} molecule in the minor orientation. On the assumption of icosahedral molecular symmetry, there are non-crystallographic twofold axes perpendicular to the $\bar{3}$ axis and passing through the centers of short C=C bonds (C6–C9 of Fig. 2).

ture there are now in principle four different types of intermolecular contacts (Fig. 2a–d) instead of just one as in the ordered structure (Fig. 2a). Because of its icosahedral symmetry, a C_{60} molecule always presents six C=C bonds to its six neighbors in the equatorial plane, irrespective of its orientation. If the neighbor is in the major orientation, the C=C

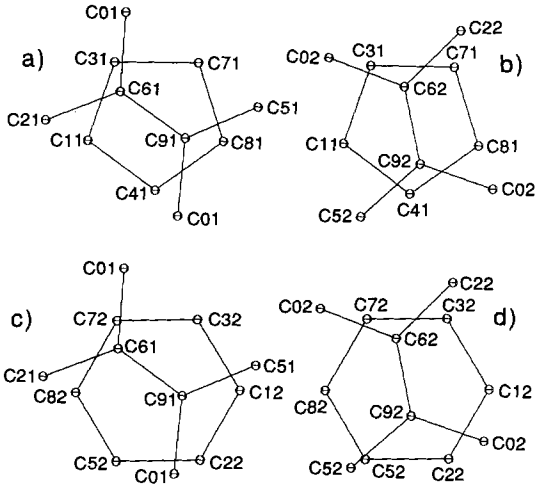

Fig. 2. Intermolecular contacts of C_{60} in the solid state. The molecular orientations are: a) C=C(major)–C_5(major), b) C=C(minor)–C_5(major), c) C=C(major)–C_6(minor), d) C=C(minor)–C_6(minor). The second number of the atom identifier is 1 for the major and 2 for the minor orientation.

bond is presented to a C_5 ring, if it is in the minor orientation to a C_6 ring. In the same way, each of the six neighbors out of the equatorial plane presents one C=C bond to the central molecule irrespective of their orientations. These C=C bonds are seen by C_5 or C_6 rings of the central molecule depending on whether it is in the major or minor orientation. The number and lengths of the shortest intermolecular distances are very similar for all four contacts (Table 2, Fig. 2), especially for contacts a and b. In summary, the surroundings of a molecule and presumably its packing energy are not very dependent on the orientation of its neighbors. All molecules have nearly the same effective potential energy with two not very different minima.

Table 2. Shortest intermolecular contacts. Type B refinement at 110 K (see Fig. 2).

C61-C31	3.140(9)	C62-C31	3.178(12)

C91-C81	3.275(3)	C92-C41	3.282(8)
C91-C41	3.387(3)	C92-C81	3.385(8)
C61-C72	3.128(29)	C62-C72	3.159(30)
C61-C82	3.360(13)	C62-C32	3.278(25)
C91-C32	3.464(25)	C92-C52	3.575(11)
C91-C12	3.507(8)	C92-C22	3.592(10)

On the assumption that the disordered structure is in thermodynamic equilibrium, the free-energy difference of the two molecular orientations can be derived from the population factors, $\Delta G = RT \ln (P^{-1}-1)$. Refinement with the minimal model (type A) gives 1.05(3), 1.07(2), 1.05(2), and 1.10(5) kJ mol^{-1} at 100 K, 110 K, 153 K, and 200 K, respectively. The corresponding enthalpy and entropy differences, $\Delta H = 1.06(5)$ kJ mol^{-1} and $\Delta S = 0.0(4)$ J mol^{-1}K^{-1}, reproduce the four experimental populations within one estimated standard deviation. Extrapolation to 5 K yields a population of the minor orientation of about 10^{-12}, in agreement with the interpretation of the neutron-diffraction data[7] in terms of an ordered structure.[10] Energies calculated from refinements of type C differ by only about 10%. The small energy difference between alternative molecular orientations gives quantitative meaning to the small differences in packing distances described above. Analogous determinations of thermodynamic quantities have been described for conformational interconversions and intramolecular proton transfer.[11]

There are two probable mechanisms for the rotation of the molecule from the major to the minor orientation. One of them is a rotation by $\pm 60°$ (or, less likely, by 180°) about the crystallographic $\bar{3}$ axis; the observed angles derived from the type A refinement at 110 K are $182° \pm 120°$. The other mechanism is a rotation by 41.8° (assuming ideal $m\bar{3}\bar{5}$ symmetry) about one of the three molecular twofold axes perpendicular to the $\bar{3}$ axis shown in Figure 1. This rotation replaces the C_6 ring perpendicular to the $\bar{3}$ axis by one of its three neighboring C_6 rings. The energy barrier to rotation can be estimated from the average mean-square libration amplitudes assuming a sinusoidal approximation to the reorientation potential.[12] For the 60° rotation of C_{60} about the $\bar{3}$ axis, the barrier obtained from L_1 of Table 1, assuming the sixfold term to be dominant, is about 34 kJ mol^{-1} (results from L_1 of major site, type A refinements are 34.3, 33.9, and 36.4 kJ mol^{-1} for 110, 153, and 200 K, respectively). The activation barrier for the 41.8° rotation is likely to be of about the same height, since the mean-square libration amplitude L_2 perpendicular to the $\bar{3}$ axis differs by only about 10% from L_1.

Finally, the C=C and C–C distances between mean carbon positions in the crystal are about 0.01 Å shorter than the mean distances of 1.401(10) and 1.458(6) Å obtained by electron diffraction measurements of gaseous C_{60}.[4] The differences of 0.002 Å between the results of type A refinements can be accounted for by a librational bond-length correction. Results of the type B and type C refinements without shape restraints are consistent with those of the type A refinement. It has been suggested[7] that the distances in C_5 rings involved in short intermolecular contacts are longer than those in C_5 rings not involved in such contacts. Our type B refinements show that for the major orientation the difference is only 0.001 and 0.003 Å at 110 K and 153 K, respectively. This difference is negligible.

[9] Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe Gesellschaft für wissenschaftliche Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) by quoting the identification number CSD-56171, the authors, and the literature reference.
[10] It is highly unlikely that the populations obtained at four different temperatures with three different crystals agree with the equation for ΔG by accident. The systematic temperature-dependence of P is strong evidence for thermodynamic equilibrium. The time necessary to start measurement after the desired temperature of the crystal has been established is tens of minutes and is certainly sufficient for equilibration.

From the population parameters of David et al. we calculate $\Delta H = 1.35(1)$ kJ mol^{-1} and $\Delta S = 1.6(4)$ J mol^{-1} K^{-1}; these values agree essentially with our results. David et al. do not provide intra- and intermolecular distances or libration amplitudes.

Selenonium Hexafluoroantimonate, $H_3Se^+SbF_6^-$**

By *Rolf Minkwitz,* Andreas Kornath,* and *Wolfgang Sawodny*

Dedicated to Professor Alois Haas on the occasion of his 60th birthday

Despite the central significance of the oxonium ion in classic acid–base theory, established and stable H_3O^+ salts were first prepared by K. O. Christe [1] in 1975 by the protonation of water in the super-acidic systems HF/SbF_5 and HF/AsF_5. The considerably less basic hydrogen sulfide is protonated in the same systems, however, the sulfonium salts formed are noticeably more thermolabile than the oxonium salts. $H_3S^+SbF_6^-$ [2] is stable for a short time at room temperature whereas $H_3S^+AsF_6^-$ [3] decomposes at 263 K. The homologous hydrogen selenide is a medium-strong acid [4] even in water, and its basicity is so low that the formation of selenonium ions only occurs under extreme conditions.

The selenonium salt **1** is formed almost quantitatively in HF/SbF_5 at 195 K [Eq. (a)]. However, from the less acidic HF/AsF_5 no salt can be isolated. A telluronium salt cannot be isolated even from HF/SbF_5. H_2Te decomposes spontaneously into the elements at 190 K.

$$H_2Se + HF + SbF_5 \longrightarrow \underset{\mathbf{1}}{H_3Se^+SbF_6^-} \qquad (a)$$

Compound **1** is a colorless solid which is stable (exclusion of air) for ca. one week at 195 K. However, at 213 K, **1** decomposes within minutes with the reformation of its starting materials, and then H_2Se undergoes further decomposition into the elements. Subsequently, the ions H_2Se^+, HSe^+, Se^+, and HF^+ are recorded in the mass spectrum (EI, 70 keV) of **1**.

From an ab initio calculation [5] C_{3v} symmetry can be assumed for the discrete H_3Se^+ ion (d(SeH) = 146.5 pm, $\sphericalangle$(HSeH) = 95.65°), for which four IR- and Raman-active vibrations ($\Gamma_{vib} = 2A_1 + 2E$) are expected. Their experimentally determined positions and intensities (Fig. 1) can be compared with the vibrational frequencies of the isoelectronic AsH_3 [6] given in Table 1. Therefore, an unequivocal assignment is possible.

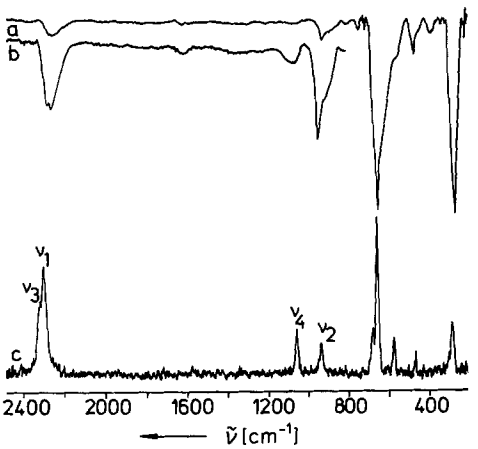

Fig. 1. a) IR spectrum of solid $H_3Se^+SbF_6^-$ (without trituration) between CsBr plates in a low-temperature cell at 163 K. b) Region of the cationic vibrations intensified. c) Raman spectrum of solid $H_3Se^+SbF_6^-$ at 78 K with the cationic vibrations marked.

A calculated force field [7] gives a valence force constant f_r of 3.107 N cm^{-1} and a deformation force constant f_α of 0.334 N cm^{-1}. Thus, the valence force constant is slightly below the value obtained from the anharmonic approximation of H_2Se (f_r = 3.12 N cm^{-1}); [8] for the transition to the cationic H_3Se^+, an increase in the valence force constant is expected. The observed decrease is probably a result of hydrogen bonds in the solid and is in agreement with a lowering of the symmetry in the anion, for which more vibrations than expected were measured (Table 1). The same effect is observed for H_3O^+ salts. [1]

Experimental Procedure

H_2Se and D_2Se were prepared and purified from Al_2Se_3 and H_2O, and D_2O, respectively, according to the literature [9]. SbF_5 was fractionally distilled and HF and DF were dried with fluorine.
In a 30 mL KEL-F reactor dried with fluorine (!), SbF_5 (1 mmol) was dissolved in HF or DF (2 g). The solution was frozen at 77 K and layered with HF or DF

(0.5 g). H_2Se or D_2Se (1 mmol), respectively, were condensed into the reaction mixture and it was slowly warmed to 195 K. The selenonium salt 1 precipitated as a colorless solid on thawing. Excess HF or DF was removed under a dynamic vacuum at 195 K.

Preparative-Scale Separation of C_{60} and C_{70} on Polystyrene Gel**

By *Andreas Gügel, Michael Becker, Dirk Hammel, Lutz Mindach, Joachim Räder, Thomas Simon, Manfred Wagner,* and *Klaus Müllen**

An efficient method for the separation of fullerenes is currently of great importance, because of the world-wide research activities centered around this class of compounds[1]. A mixture of C_{60}/C_{70} was hitherto separated on a milligram scale only, which is due to the very low solubility of the material in common chromatographic solvents[2]. A simple, reproducible, inexpensive, and automatic separation procedure is presently not available. Size exclusion chromatography, which has a number of advantages over the conventional liquid chromatographic methods, displays all of the prerequisites required to solve these problems.[3]

The carbon-cluster mixture employed consisted of about 80% C_{60}, 18% C_{70}, and 2% higher molecular weight fullerenes. The separation was carried out on two different columns (PL-Gel 20 × 600 mm, 10 μm, 500 Å, and Shodex 20 × 600 mm, 5 μm, 50 Å). The elugrams with chloroform and toluene were nearly identical on both columns (Fig. 1): C_{60} elutes before C_{70}, and both have a retention time greater than the total permeation limit.

Thus, adsorption or "matrix" effects involving a form of partition or adsorption phenomena are superimposed on size exclusion, resulting in excessive retention and peak-tailing. Another compound exhibiting this unusual behavior is elemental sulfur, which is also retained beyond the total permeation limit. Because the C_{60}/C_{70} mixture is more soluble in toluene, which improves efficiency, this solvent was used as eluent in all further preparative separations (the solubility is about 6 mg mL^{-1} in toluene).

[**] Note added in proof (April 27, 1992): A communication appeared in the March 13th issue of *J. Org. Chem.* in which similar results were reported: M. S. Meier, J. P. Selegue, *J. Org. Chem.* **1992**, *57*, 1924–1926.

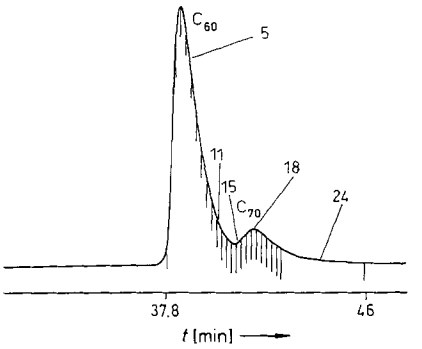

Fig. 1. Separation of C_{60} and C_{70} with cut coints for fractions 5, 11, 15, and 18; column: 20 × 600 mm; stationary phase: PL-gel, 10 μm, 500 Å; mobile phase: 7 mL min^{-1} toluene; detector: UV at 329 nm.

The best fraction cut points for separation were found by investigating certain subfractions (Fig. 1) with field desorption (FD) mass spectrometry[4]. The mass spectra shown (Fig. 2) provide further evidence for the high purity of the products separated. The ^{13}C NMR spectrum of combined fractions 1–11 does not contain a peak arising from C_{70}[4].

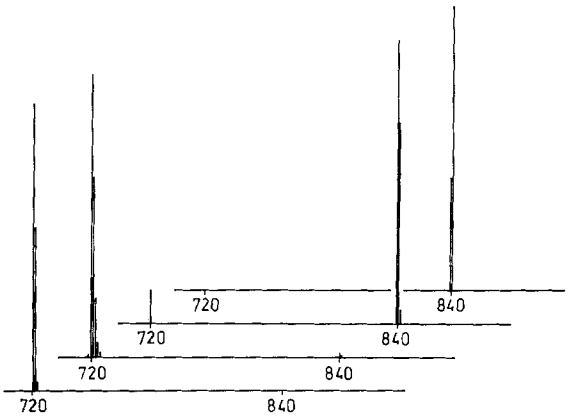

Fig. 2. FD mass spectra of subfractions 5, 11, 15, and 18 (from bottom to top).

With a flowrate of 7 mL toluene per min and repetitive, periodic injections of 6 mL portions of a C_{60}/C_{70} solution, the separation of about 5 g of a C_{60}/C_{70} mixture within 24 h becomes possible. In addition, the eluent can be recovered completely[5].

Moreover, unlike other chromatographic methods like chromatography at higher temperatures,[2a] an extension of the described procedure to larger scale separations is possible simply by increasing the inner diameter of the column.

Experimental Procedure

Apparatus[5]: Elution pump: Master pump M 305 with a 25 SC pump head; injection pump: M 303 with a 25 SC pump head, detector: UV detector M 115 with 0.3 μL flow-through type cell (light path: 0.1 mm); fraction collector 201 C; column: 20 × 600 mm filled with PL-gel (10 μm 500 Å).

Procedure: At 10 min intervals 6 mL of the fullerene solution is injected into the elution stream through a T-connection joining elution and injection pump, and the column. Thus more than one substance zone is present on the column simultaneously and material can be collected continuously. The recovery rate is greater than 90%.

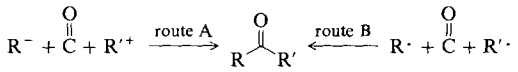
It was shown that the peak separation and therefore the amount of material separable per time unit can be distinctly improved by operating two columns in sequence: A. Gügel, K. Müller, unpublished.

Palladium(0)-Catalyzed Three-Component Coupling Reaction of Allyl Benzoates, Carbon Monoxide, and Zincioesters**

By *Yoshinao Tamaru,* Kengo Yasui, Hidenobu Takanabe, Shuji Tanaka,* and *Keigo Fugami*

"Masked acyl-anion equivalents"[1] have been extensively studied in a last few decades, and many useful methods for the synthesis of ketones have been developed. In planning ketone synthesis, however, the most obvious and straightforward strategy is the connection of two substituents to the carbon atom in carbon monoxide, that is, carbon dioxide is converted directly into a carbonyl group. In principle, two routes are conceivable (Scheme 1). Very recently both the ionic route A[2] and the radical variant B[3] have been realized.



Scheme 1.

Here we report a novel one-pot method of preparing unsymmetrically substituted ketones of types **5** and **6** with a three-component coupling reaction of carbon monoxide, an allyl benzoate, and an organozinc compound as outlined in Scheme 2. The latter two components correspond to R^+ and R^- in route A in Scheme 1. This reaction can be performed very easily: An allyl benzoate **1** is mixed with an organozinc compound (ethyl γ-iodozinciobutyrate (**2**), ethyl β-iodozinciopropionate (**3**), or diethylzinc (**4**)) and a catalytic amount of $[Pd(PPh_3)_4]$. The resulting mixture is stirred under 1 atm of carbon monoxide (a balloon) at an appropriate temperature. The results are summarized in Table 1.

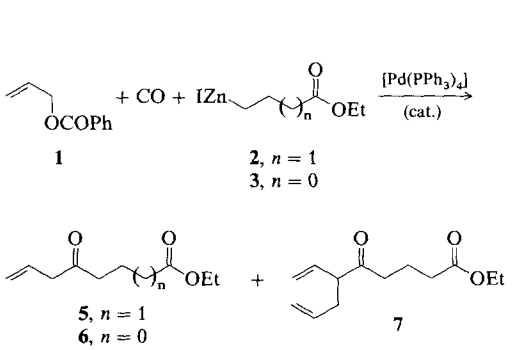

Scheme 2. The allyl groups in **1**, **5**, **6**, and **7** represent a number of derivatives, see Tables 1 and 2.

The course of the reaction is highly dependent on the solvent system. The use of an aprotic dipolar solvent, such as hexamethylphosphoric triamide (HMPA) or *N,N*-dimethylacetamide (DMA), in a small excess to **2** or **3** is essential for the selective formation of **5** or **6**, respectively. The reactions are rather complicated otherwise. For instance, if the reaction of run 7 in Table 1 is conducted in the absence of HMPA (at room temperature for 40 h and then at 35 °C for 40 h; 100% conversion), a complex mixture of products including **6a** (27%), γ-(2-butenyl)-γ-(β-ethoxycarbonylethyl)-γ-butyrolactone (28%, based on benzoate), and many other unidentified products results.[4] The lactone apparently arises from one equivalent of **1a**, one equivalent of carbon monoxide, and two equivalents of **3**. In sharp contrast to **2** and **3**, diethylzinc (**4**) gave the best results for reactions conducted in the absence of HMPA and at lower temperatures (run 9 in Table 1).[5]

6	**1f**	3.0	THF/DMA	4.0	20	**5e** (74)	**7b** (0)

[a] All reactions were conducted with 0.05 equiv. of $[Pd(PPh_3)_4]$ under 1 atm of CO (100% conversion). [b] X = OCOPh. [c] See experimental procedure. [d] Yields refer to the isolated, homogeneous product based on the corresponding starting allyl benzoate **1**. [e] Reaction in tol./HMPA yielded a complex mixture of products.

Under the conditions optimized for the other allyl benzoates (Table 1), the reaction of **2** with allyl benzoate **1g** provided a considerable amount of the doubly allylated product **7a** in addition to **5d** (run 1 in Table 2). The ratio of **5d** to **7a** did not change when the solvent system and the molar ratios of reactants were changed (run 2 in Table 2). In the reaction of **2** with cinnamyl benzoate (**1f**) **7b** was formed, though in lower yield (run 4 in Table 2). Addition of Me_3SiCl promoted the selective formation of **5**, seemingly at the expense of **7** (runs 3, 5, and 6 in Table 2). We have no mechanistic explanation as of yet.[6]

This Pd^0-catalyzed, selective three-component coupling reaction of allyl benzoates, carbon monoxide, and **2** or **3** is especially remarkable, since other types of products are formed in similar reactions: 1) 1,5-hexadienes and diethyl suberate for the Pd^0-catalyzed reaction of allyl benzoates and **2**[7] and 2) diethyl 4-oxopimelates for the Pd^0-catalyzed reaction of 1-ethoxy-1-siloxycyclopropanes (a presumable precursor of ethyl β-palladiopropionates) and carbon monoxide.[8] It should be also noted that allyl benzoates with isomeric allyl groups provided the same ketone with the lowest possible number of substituents at the position α to the carbonyl group (runs 1 and 3, and 5 and 6 in Table 1). This suggests a mechanism involving a π-allylpalladium species as a common intermediate for carbonylation reaction.[9]

Experimental Procedure

5d (run 3 in Table 2): To a solution of $[Pd(PPh_3)_4]$ (0.10 mmol) in 10 mL of dry THF under 1 atm of CO (a balloon) were successively added 2 mmol of **1g**, 8 mmol of Me_3SiCl (stored over Na), and the supernatant (15 mL) of a solution of **2** [0.4 M, prepared from ethyl γ-iodobutyrate (0.4 M), HMPA (0.6 M), and Zn-Cu couple (1.2 equivalents relative to ethyl γ-iodobutyrate) in THF] [10]. The mixture was stirred at room temperature for 30 h, then diluted with ethyl acetete, and washed with aqueous NH_4Cl solution. The organic phase was dried ($MgSO_4$) and concentrated. The residue was chromatographed with hexane-benzene (30 × 1.5 cm, silica gel 60), affording 0.287 g (78%) of **5d**: Bp (0.5 mm Hg) = 105 °C; IR (neat): $\tilde{\nu}$ [cm^{-1}] = 1728, 1643, 1033, 920. ^1H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.25 (t, J = 7.1 Hz, 3H), 1.89 (quint, J = 7.3 Hz, 2H), 2.32 (t, J = 7.3 Hz, 2H), 2.53 (t, J = 7.3 Hz, 2H), 3.17 (d, J = 7.0 Hz, 2H), 4.12 (q, J = 7.1 Hz, 2H), 5.14–5.18 (m, 2H), 5.91 (ddt, J = 17.2, 10.3, 7.0 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$, TMS): δ = 14.1, 18.7, 33.2, 41.0, 47.7, 60.2, 118.7, 130.4, 173.0, 207.6; MS *m/z* Calcd for $C_{10}H_{16}O_3$: 184.1100. Found: 184.1116.

7a (run 1 in Table 2): **7a** (28%) could be easily separated from **5d** (40%) by chromatography over silica gel. Bp (0.5 mm Hg) = 115 °C; IR (neat): $\tilde{\nu}$[cm^{-1}] = 3080, 1732, 1715, 1032, 920. ^1H NMR (400 MHz, $CDCl_3$, TMS): δ = 1.25 (t, J = 7.1 Hz, 3H), 1.87 (quint J = 7.3 Hz, 2H), 2.25 (m, 1H, coalescing to dd, J = 13.8, 7.0 by irradiation at δ = 5.70), 2.30 (t, J = 7.3 Hz, 2H), 2.48 (d.t, J = 17.6, 7.3 Hz, 1H), 2.49 (m, 1H), 2.60 (dt, J = 17.6, 7.3 Hz, 1H), 3.18 (dt, J = 8.8, 7.0 Hz, 1H), 4.12 (q, J = 7.1 Hz, 2H), 4.98–5.07 (m, 2H), 5.15–5.20 (m, 2H), 5.64–5.75 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$, TMS): δ = 14.2, 18.7, 33.3, 35.1, 40.4, 57.2, 60.3, 116.7, 118.2, 135.3 135.8, 173.1, 209.5. MS *m/z* Calcd for $C_{13}H_{20}O_3$: 224.1413. Found: 224.1413.

[4] A detailed study is under progress. Results will be reported in due course.
[5] For example, under conditions similar to those of run 9 in Table 1 in the presence of HMPA *trans*-6-phenyl-5-hexen-3-one was isolated only in 9% isolated yield (45% conversion).
[6] At first, we assumed that **7** was formed by a further allylation of **5** via its zinc dienolate. Thus we added Me_3SiCl to quench the allylation by forming the dienyl silyl ether of **5**. However, this assumption proved to be wrong. When treated with an excess of D_2O, neither the reaction mixture of run 3 in Table 2 nor the mixture of **5** and **2** (3 equiv, at room temperature, 30 min), gave **5** deuteriated at the methylene group flanked by the ketocarbonyl and olefin groups.

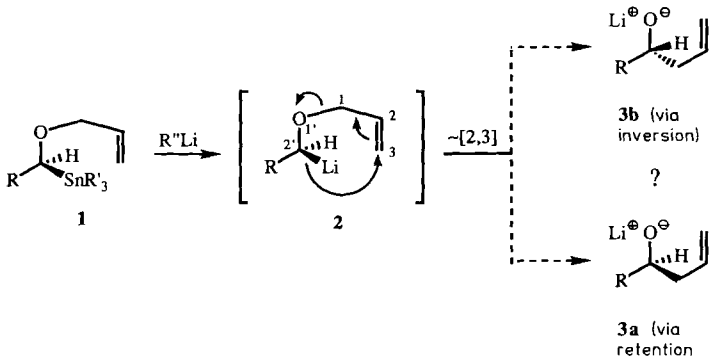
[2,3] Wittig Rearrangements of Nonconjugated Secondary α-Lithioethers: Proof of Stereospecificity and Inversion of the Configuration of the Carbanion C Atom**

By *Rolf Hoffmann* and *Reinhard Brückner**

[2,3] Wittig rearrangements[1] are one-step symmetry-allowed isomerizations of α-metallated allyl ethers **2** to homoallylalkoxides **3**. *Primary* lithioethers of type **2** (R = H), which can be generated by the treatment of *primary* α-stannyl allyl ethers **1** (R = H) with *n*BuLi, rearrange in THF at −78 °C.[2] Analogous tin/lithium exchange reactions with *secondary* α-stannyl methoxymethyl and benzyloxymethyl ethers are stereoselective and lead to lithioethers with retention of configuration.[3] These intermediates are pyramidal and configuratively stable at −78 °C long enough to react with Me_2SO_4, acetone, Me_3SiCl, Bu_3SnI,[3] and other electrophiles[5] with retention of this configuration. Thus we anticipated that a *secondary* α-lithioether **2** (R = chiral alkyl group) would undergo a [2,3] rearrangement faster than it would stereoisomerize. We set out to prepare such lithioethers **2** with defined relative configuration at the carbanion C atom, allow them to rearrange to **3**, and then determine whether this [2,3] Wittig rearrangement proceeds with retention (→ **3a**) or inversion (→ **3b**) of configuration. We report here the results of our investigation.



1 **2**

Nonconjugated secondary α-(trialkylstannyl)acetals[3] and (trialkylsilyl)ethers[6] are readily available from α-(trialkylstannyl)alcohols. In contrast, nonconjugated secondary α-(trialkylstannyl)ethers have not yet been prepared from this same type of precursor in a single operation.[7] This difficulty may explain why α-stannyl allyl ethers of type **1** (R = alkyl), which we require as a precursor of **2**, have not yet been described.

We have succeeded in synthesizing stannyl allyl ether **6** which belongs to this product type (Scheme 1). The synthesis makes use of the facile replacement of the Cl atom in α-chloroallyl ether **5** by $LiSnBu_3$. This approach was reported for *acyclic* α-(trialkylstannyl)ethers in a single case,[7c] whereas applications to the more stable *cyclic* analogues have been reported a number of times.[5b, 7c, 8] The stannylether **6** was obtained from **5** in >72% yield as a 1:1 mixture of diastereomers. Flash chromatography on silica gel provided *syn*-**6** (isomeric purity 92:8 based on the ^1H NMR integration of the C*H*-O-CH_2-CH=CH_2 resonances) and *anti*-**6** (isomeric purity 90:10).[10]

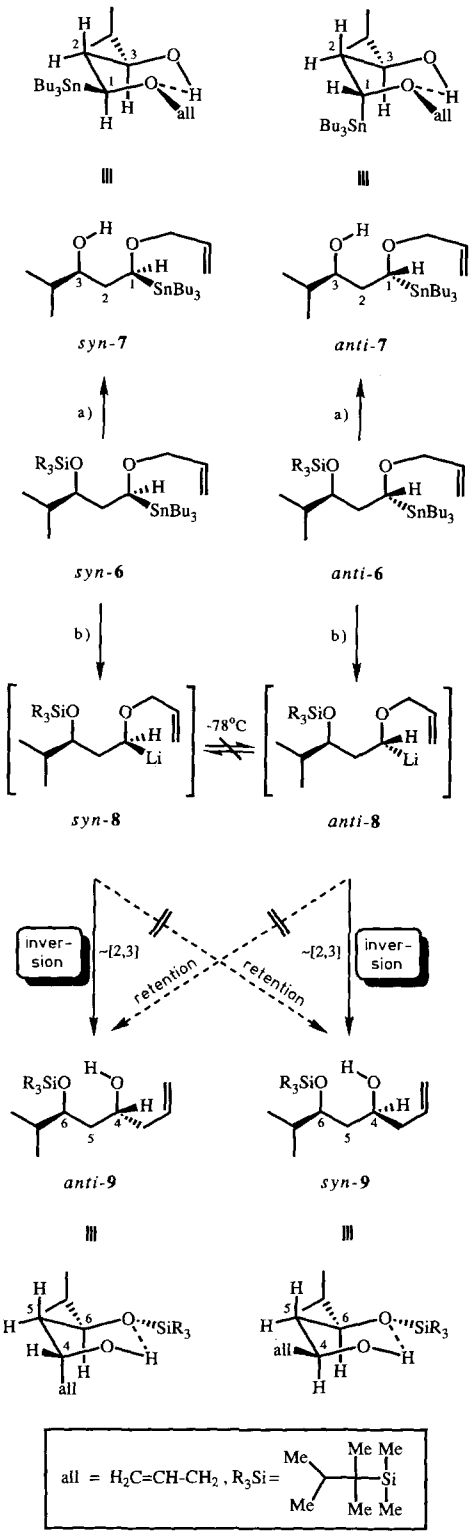
[**] This research was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 347 "Selektive Reaktionen metallaktivierter Moleküle") and the Fonds der Chemischen Industrie. We thank Prof. C. Griesinger and Dipl.-Chem. M. Sattler (Universität Frankfurt) for the 600 MHz ^1H NMR spectra.

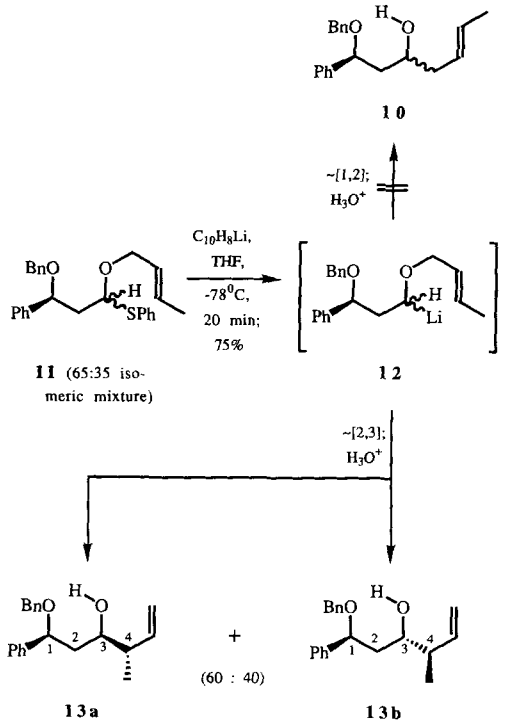


Scheme 2. a) $Bu_4N^+F^-$ (>10 equiv), THF, 60 °C, 6 h (71% *syn*-**7** and 67% *anti*-**7**, respectively). b) *n*BuLi (1.05 equiv), THF, −78 °C, 15 min (67% *anti*-**9** and 89% *syn*-**9**, respectively).

The stannylethers *syn*- and *anti*-**6** were treated with *n*BuLi at −78 °C in THF in separate experiments. Presumably they are converted by tin/lithium exchange to the corresponding lithioethers *syn*- and *anti*-**8** with retention of configuration. The reaction temperature of −78 °C and the total reaction times of 15 min precluded a subsequent epimerization *syn*-**8**⇄*anti*-**8** according to the premises described in the introduction of this report. These conditions were sufficient for complete reaction, and after the Wittig rearrangement the silylated alcohols **9** were collected in yields of 67 to 80%.

Both rearrangements were highly stereoselective: *syn*-**6** provided *anti*-**9** (isomeric purity 95:5 according to the ^1H NMR integration of the 4-H/6-H resonances), and *anti*-**6** furnished *syn*-**9** (isomeric purity 93:7).[13] Because the starting stannylethers *syn*- and *anti*-**6** themselves contained 8 and 10% diastereomers respectively, diastereomeric purity did not apparently suffer in this reaction. The stereochemical complementarity of the two Wittig rearrangements means that they proceed with stereospecificity.

Because lithio allyl ethers could also arise from the [1,2] variation of the Wittig rearrangement,[2, 11b, 14, 15] we had to establish with certainty which mechanism led to the rearrangement product **9**. To this aim we prepared lithioether **12** from **11** according to a procedure described recently,[16] in which the C–S bond of a O,S acetal is cleaved reductively. The isomerization of **12** furnished exclusively **13a** and **13b**,[18] products of a [2,3] rearrangement; product **10** which would be expected from a [1,2] rearrangement was not observed.



According to this result it is most probable that *syn*-**8** → *anti*-**9** and *anti*-**8** → *syn*-**9** are also [2,3] Wittig rearrangements. Thus we could show that the [2,3] Wittig rearrangement of nonconjugated secondary α-lithio allyl ethers proceeds with inversion of the configuration of the carbanion carbon. The same conclusion was also reached by T. Nakai et al.[19] Our findings are in agreement with the transition state calculated by Wu, Houk, and Marshall[4b] for the [2,3] Wittig rearrangement of Li-CH_2-O-CH_2-CH=CH_2 and correspond to the stereochemical relationships seen in the [1,2] Wittig rearrangement of a nonconjugated tertiary lithio allyl ether.[15, 20]
