In recording an STM image, the tip is scanned in an x, y plane over the sample surface while the tunneling current flows between the sample and the tip along the orthogonal z direction. In practice, greater control over a broader dynamic range is afforded when the instrument is operated in the constant current mode: under the control of a feedback loop, a fixed current is maintained between tip and sample by allowing the tip to adjust its distance from the sample automatically as it scans over surface features. This motion of the tip in the z direction is then plotted as surface contours. Typical values for scanning parameters range from millivolts to a few volts for the bias voltage between tip and sample, and picoamperes to nanoamperes for the tunneling current. These are adjustable parameters, used to maximize resolution for each individual sample.

In imaging organic materials, the STM samples only the layer or layers closest to the interface with the conducting substrate. Under feedback loop control, the tunnel tip advances through macroscopic quantities of organic material until it reaches a distance from the substrate that sustains a tunneling current, typically 5–10 Å. At this distance the tunneling and scanning parameters are optimized and the images are recorded. Physical contact between the tip and substrate is avoided to prevent damage to either. Confirmation of the proximity of the tip from the substrate during scanning is provided by studies which show that both substrate and adsorbate images can be recorded (nearly) simultaneously.[9–12] This is done by rapidly switching between the two sets of parameters that optimize the recording of each. It is still being debated whether this process disrupts the assembled film reversibly or irreversibly.[12] Some perturbations in the adsorbate layer have been documented.[13] Typical values for voltage and currents in experiments are 0.3–1 V and 0.05–1 nA to resolve the adsorbates and 0.1–0.3 V and 0.3–10 nA to resolve the substrate.[9, 12, 13]

It can take from several seconds to several minutes to record an image, depending on the scan size, the surface roughness, and the level of resolution. Fast scan rates (kHz) can produce series of images that are then stored on video tape. In reviewing the data, the successive frames are played back as a "movie".[14] This mode of data storage and presentation is advantageous in monitoring dynamic processes, on the timescale of the STM measurements—seconds to hours (see Section 1.3).

Most scanning tunneling microscopes are operated at room temperature; however, instruments have been customized to operate at variable temperatures. Examples are STMs operated at low temperatures of 1–4 K in ultrahigh vacuum (UHV).[15–17] Mildly elevated temperatures (30–85 °C) have been achieved in instruments operated in air by simply incorporating a heated stage under the sample.[9, 18] For recording STM images during higher temperature experiments (up to 725 K), the STM has been incorporated into a controlled environment and coupled with other surface science tools.[19, 20] For example, variable temperature STM imaging (150–450 K) of chemical processes in UHV can be performed in a surface analysis chamber that also permits monitoring chemical reactions that occur at temperatures too high for stable operation of an STM (up to 1200 K). This was achieved in a design where the sample and STM were not in thermal contact, but remained in close proximity within the chamber, affording rapid cooling (a few degrees per second) of the sample to stable imaging temperatures.[19, 21] In the following section, studies are presented in which these instruments are used.

1.3. Dynamics

The STM is able both to monitor the dynamics of processes in real time and to induce atomic and molecular rearrangements. Events of atomic and molecular manipulation can be performed.[16, 17, 22] For example, xenon atoms[16] and carbon monoxide molecules[17] were deposited with an STM tip in preselected patterns on metal surfaces in an instrument held at liquid helium temperature ($\sim$ 4 K). At room temperature, silicon atoms were individually removed from their crystal lattice and redeposited elsewhere.[22]

Phase transitions were monitored in semiconductor surfaces and in organic adsorbates. In the field of semiconductors, thermally activated phase transformations on silicon[20, 23] and germanium[24] were studied, documenting phenomena of diffusion of atoms, reactivity of step edges, and defect stability. A stable, high-termperature STM enabled in situ "watching" of the dynamic behavior of single

silicon atoms at temperatures up to 850 K.[20] In the field of organics, a smectic-to-isotropic phase transition was induced in a liquid crystal by the scanning action of the STM tip at elevated temperatures (see Section 6).[18]

The dynamics of certain phenomena have also been recorded in the form of "before-and-after" STM images. Examples include the process of graphitization of ethene on a platinum surface[19] (see Section 7.3), layer-by-layer etching of metal chalcogenide surfaces,[25] and domain-boundary shifts of hydrocarbons adsorbed on graphite.[26]

The extension of STM into electrochemistry is resulting in new STM configurations with electrochemically active electrodes as the tunneling tip or planar sample[27–29] In most of these studies, the STM was operated in situ in the electrochemical cell, submerged in electrolyte; for example, in this configuration, the potential-induced reconstruction of a Au (111) surface was observed[29] and assessed as comparable to the reconstructed gold surfaces observed by STM in UHV.[30] In another electrochemical approach, the STM tip was configured as an ultramicroelectrode and thus was called the Scanning Electrochemical Microscope.[28] With this instrument, dynamic processes such as redox reactions of bound enzymes and adsorption isotherms are now undergoing scrutiny on the 100 nm scale by electrochemical reactions between the tip and its surroundings.

1.4. Field Effects

Of tantamount importance is the influence of the applied voltage across the tunnel junction on the material being studied. If one normalizes the applied voltage to laboratory dimensions by simply linearly scaling from the tunneling distance of several angstroms, one arrives at electric field strengths on the order of about $10^8\ Vm^{-1}$ (from potential/distance $\approx 10^{-1}\ V/10^{-9}\ m$). This field strength is of a similar magnitude as those measured in experiments on the Stark effect in spectral hole burning, where a single molecule can experience an effective internal field of $10^8\ Vm^{-1}$ arising from the environment of surrounding molecules.[31] Future work will focus on coupling the approaches of STM and photochemical hole burning.

Other questions which will catalyze future work in this field arise in constructing a model for the environment of the molecule under the STM tip. They involve the issues of conductance and polarizability of the surrounding medium[32, 33] and creation of surface charges and charge trapping on the substrate.[34]

There is no doubt that electric field strengths can be large enough to induce further reactions. Evidence is accumulating for field-induced and field-enhanced effects in the tunnel junction.[35–37] Among these reports is the deposition of gold particles from a gold tip by field evaporation of tip atoms enhanced by the proximity of the substrate;[35] selective ionization and desorption of silicon atoms from a silicon crystal by field evaporation, mediated by the STM tip;[23] and CVD (chemical vapor deposition) lithography in the tunnel junction onto silicon wafers from gold- and tungsten-containing volatile organometallic precursors.[37]

1.5. Difficulties and Artifacts

The apparent success of the STM in obtaining atomically and molecularly resolved images of materials has been accompanied by a fair share of "failures". These failures can be divided into those experiments that give no recognizable results, and those results that mislead. The first category speaks to the practical difficulties in preparing organic samples for scanning; the hurdle is to arrive at a conformation of the molecule on the substrate that is both immobilized and oriented to give identifiable and reproducible images (see Sections 3.2 and 4.1). The present state-of-the-art of interpreting STM images requires that the molecule present a readily recognizable shape to differentiate its outline from random features in the STM image. A goal, of course, is to increase the STM image database with reproducible images of known molecules to the point of bestowing confidence on the identification of "unknowns" or amorphous samples.

The STM's capacity for high resolution is not restricted to the materials intentionally under study. It is also sensitive to

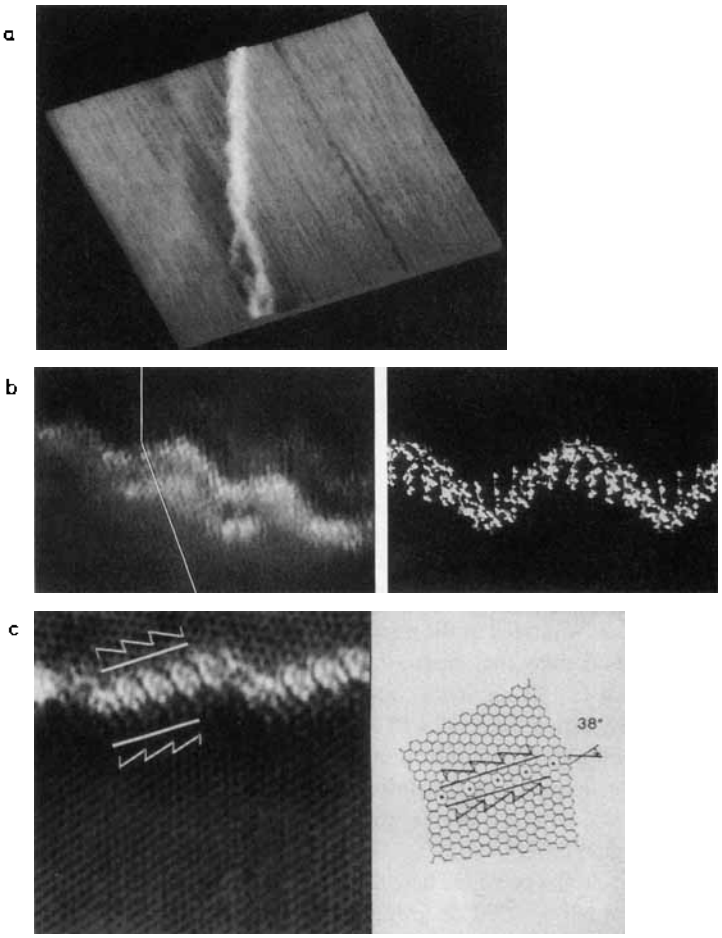

Fig. 3. STM images of features in or on graphite itself that mimic features of macromolecules [39]: a) Scanned area: $190 \times 190\ Å^2$. A grain boundary in graphite, collected with a "faulty" STM tip composed of two minitips that record simultaneously and produce an image which mimics the winding conformation of two DNA strands. b) Scanned area: $110 \times 78\ Å^2$. Left: A grain boundary in graphite. This image resembles a single strand of DNA (scanned with a double tip), which is modeled with a computer molecular graphics program on the right. c) Scanned area: $76 \times 76\ Å^2$. A graphite surface, showing the intersection of two domains with different orientations. The bright polymerlike feature arises from a 38° misorientation between the two domains. Adjacent sketch shows the origin of the defect relative to the graphite lattice vectors.

impurities. The field has been subjected to self-criticism with certain reported results, particularly in the fields of molecular biology[38, 39] and polymer research.[40] This reevaluation resulted from the discovery in several laboratories that substrates *alone* can produce images with features akin to those of molecules.[38–41] These features can be traced to defects or step edges in the substrate lattice, to tip shape, or to spurious impurities (Fig. 3). Additional artifacts can be introduced by the STM tip.[42, 43] A commonly observed one is a convolution of the tip shape into the sample's image. For example, in the case of a "double tip", images of apparent dimer-like features can be traced back to simultaneous imaging of a single surface feature by two points on the STM tip.[44] The healthy effect of these alarms is to compel researchers to be more vigilant in analyzing images and to tighten standards in reporting results.

1.6. Studies of Long-Range Electronic Structure

The STM's sensitivity to electron energy levels is not limited to the atomic scale. It is also capable of detecting electron density distribution over larger regions. A good example is provided by STM images of semiconductors. Unlike metals, in which the electronic state density on the surface correlates closely with the atoms' positions, semiconductors can show preferential localization of states over specific sites in the surface. For example, charge density waves resulting from a Peierls phase transition (a periodic lattice distortion accompanied by a change in band structure) have been recorded on $TaSe_2$ and TaS_2 as a $(\sqrt{13} \times \sqrt{13})$ superlattice of ~ 12.4 Å periodicity superimposed on the atomic lattice periodicity of ~ 3.4 Å.[45]

1.6.1. Graphite

Another example of an electronic superstructure is given by one of the most studied, yet still enigmatic materials, graphite. In Figure 4b of Rb-intercalated graphite (C_8Rb), a (2×2) superlattice of electron distribution is evident, presumably pinned to the underlying dopant ions.[46] Figure 4c demonstrates that the Rb-doped graphite is a dynamic system. Over 15–30 minutes at room temperature, the boundaries have shifted from a (2×2) to a $(\sqrt{3} \times 4)$ pattern, mirroring an equilibration and diffusion of electrons (and possibly ions) with time. All of this information is superimposed on the STM's atom-by-atom map of the carbon lattice of graphite (Figure 4a).

It should be added here that large-scale patterns have been recorded by STM on graphite even in the absence of (intentional) doping agents.[41] Various explanations for these superlattices have been proffered, among which is the rotation of the topmost layer of graphite relative to the stack of layers below.[41]

In scanning the basal plane of graphite, a puzzle of localized electronic structure presents itself: typical STM images of graphite display only every other carbon atom of the hexagonal lattice. In producing these "50 percent" images, the STM is exhibiting its sensitivity to the difference in electronic environments of two carbon sites. It has been proposed that the STM is distinguishing between those carbon atoms (α sites) which are situated directly over a carbon atom in the underlying graphite layer, and those carbon atoms (β sites) which are not (see sketch accompanying Figure 4a). Calculations predict a higher electronic density of states at the Fermi level for β sites than α sites.[47]

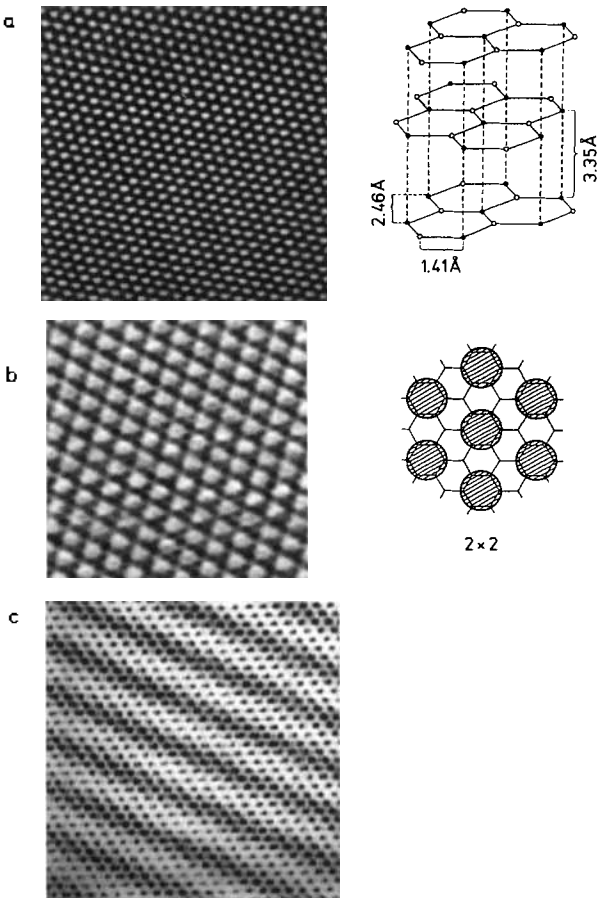

Fig. 4. STM images of the intercalation process in graphite[46]. a) Scanned area 60×60 Å^2. Undoped, pristine graphite, showing the position of every second carbon atom (see text) in a hexagonal pattern with a lattice constant of 2.46 Å. Accompanying sketch shows inter- and intraplanar distances. Dark circles are carbons that lie directly above/below a carbon atom in the adjacent layer; open circles are those carbons that lie above/below the centers of a hexagon in the adjacent layer. b) Scanned area 50×60 Å^2. Rubidium-doped graphite, C_8Rb, immediately after doping. Adjacent sketch shows the placement of the Rb^+ dopant ions relative to the hexagonal graphite lattice. c) Scanned area 50×60 Å^2. The same rubidium-doped graphite, C_8Rb, ~15–30 minutes after doping. The new contrast pattern in the STM image, arising from the intercalated graphite's electronic structure, indicates that a redistribution of electron density has occurred in the interim.

An intriguing recent observation is that from a single sheet of graphite on a platinum crystal (see Section 7.3), *still* only 50% of the graphitic carbon atoms appear in the STM images.[19] This calls into question previous explanations for graphite images that invoked underlying layers of graphite in the electronic interactions that produced the 50% images of the graphite surface.[47]

1.7. The Scanning Tunneling Microscope as a Local Spectroscopic Tool

An extension of scanning tunneling microscopy that still holds much potential is spectroscopy. Several approaches to garnering information about the band structure of samples have already been taken. Some examples are briefly listed here: the density of states of occupied and unoccupied π surface states on a silicon(111) surface was recorded, along with doping-induced shifts in the density of states arising from a shift in the surface Fermi level;[48] also on silicon, entire I–V curves were obtained with spatial resolution in a study of a chemical reaction of the surface with ammonia;[49] STM studies on the compound semiconductors GaAs and $ReSe_2$ illustrated the method of voltage dependent imaging as a way of understanding spatially resolved electronic structure;[50] and the superconducting gap was measured in the type-II superconductor $NbSe_2$ by using a low-temperature STM operating at 1–2 K.[15]

Finally, on a related topic, an STM and a variation, the scanning capacitance microscope, have been used to probe the relaxation of photoexcited carriers on a silicon surface on a picosecond timescale.[51] Using the instrument's tip as a local detector, the investigators have monitored the system's return to equilibrium by measuring surface photovoltage.

2. Scanning Tunneling Microscopy of Inorganic Materials

The image of silicon in Figure 2 is one example of STM studies on inorganic materials. In fact, most STM studies have been performed on surfaces that chemical nomenclature would classify as inorganic[52] (to set them apart from the carbon-containing organic surfaces). They are derived from diverse classes of materials and include single crystal metals, semiconductors, superconductors, and even thin insulating layers. Since the emphasis of this paper is on organic materials, the "inorganic" studies will not be described further, except to provide some examples and references. Examples of metal surface processes that have been investigated by STM include CO-induced structural transformation of platinum,[53] oxidation of copper, [54] electrochemical potential-induced surface reconstruction of gold,[29] and atomic-scale electroplating with copper.[55] Among semiconductors, silicon has been most widely studied,[2, 7, 20, 22, 23, 48, 51, 56] in addition to GaAs,[50, 57] InSb,[58] and $ReSe_2$.[50] Papers on STM studies of oxides and oxide formation deal with SiO_n,[59] ZnO_n,[60] RuO_n,[61] and NiO_n.[62] A review[45] covers the transition metal dichalcogenides $TaSe_2$, TaS_2, $NbSe_2$, VSe_2, $TiSe_2$ and TiS_2. Finally, STM studies on superconductors have detected flux lines and morphological screw dislocations in addition to atomic lattices: $Bi_2Sr_2Ca_1Cu_2O_{8+x}$,[63] $Tl_2Ba_2Ca_1Cu_2O_{8+x}$,[64] $Y_1Ba_2Cu_3O_{7-x}$,[65] and $NbSe_2$.[15]

3. Scanning Tunneling Microscopy of Organic Materials

In STM studies of organic materials, the layer of molecules deposited onto the conducting substrate must be sufficiently thin (≤ 10 Å) to allow electrons to tunnel between the tip and the conducting substrate. Although numerous pathways have been proposed, the actual mechanism for electron transport through these insulating organic materials is still under debate (see Section 3.1). Nonetheless, a rapidly growing list of organic materials is being inspected with the STM, including ordered monolayers,[66, 68] polypeptides,[69] polysaccharides (denatured),[70] conducting polymers,[71] fullerenes,[72] nucleic acid bases,[10, 73] and biological materials[66, 74, 75]. The topic has been covered in several review articles as well.[76]

3.1. Tunneling Mechanism through Organic Materials

Organic materials have been studied by STM predominantly in the form of thin films. Since the bulk organic material itself is (usually) not intrinsically conductive, it is deposited as a thin layer of adsorbate on a conducting substrate, thin enough still to allow electrons to tunnel between the tip and substrate. Thus, the combination of adsorbate and underlying substrate acts as the planar electrode that is raster scanned by the tip. Despite the insulating nature that most organic materials display in bulk, within the tunnel junction they do not impose an impenetrable insulating barrier. The applied voltages in these STM experiments (0.5 to 1.9 eV) are well below the band gaps that characterize most of these organic materials in spectroscopic and electrochemical measurements (5 to 10 eV). Nonetheless, images reflecting the adsorbate's molecular structure are obtained from these samples with the STM.

The mechanism by which images of adsorbates on conducting substrates are obtained is not straightforward. The tunnel junction is made up of three components: two electrodes and the space between them, the latter being occupied by organic molecules in the case of organic adsorbates. Instead of considering these components individually in a theoretical treatment of the tunnel junction, one can consider tunneling into states of a "hybrid" material at this interface. This hybrid is composed of the material in the area of contact between the substrate and the adsorbate, the two being in intimate contact with each other. Furthermore, the hybrid is likely not a single species, but rather a gradient of species as a function of distance from the electrode surface, as in the description of classical boundary conditions. (The difference from the classical situation is that in the case of the tunnel junction's angstrom-scale dimensions, the boundary is the entire reaction site.) This description is not exclusive to the adsorbate–substrate interaction; it also characterizes states on the tip arising from adsorption of organics on the metallic atoms of the tip. The material at these interfaces can be described in analogy to organometallic complexes in which ligands are bonded to metals through bonds such as π bonds, where no formal charge transfer has occurred but both ligand and metal orbitals have been perturbed by each other's presence. In this scenario, tunneling occurs into or out of a hybrid material that has accessible energy levels and an electron distribution that mirrors the adsorbate's molecular structure. A somewhat related mechanism of localized modulation of the substrate's work function by a polarizable

adsorbate has been postulated.[77] Other models or techniques to describe some aspect of electron transport through adsorbates or solvents have been proposed, including atomic and molecular orbital calculations,[9,43,78-80] resonant tunneling,[81,11] deconvolution of tunneling data to recover densities of states,[82] ionic conduction,[83] and favorable molecular configurations that lower the effective barrier height and promote charge exchange.[84]

3.2. Sample Preparation

There is no single set method for preparing organic materials for scanning. The chief requirement is immobilization, that is, the organic adsorbate must remain (or appear to remain) stationary under the scanning probe. Physisorption has been the most common means of attaching molecules to the conductive substrate.[85] Chemisorption has been operative in UHV STM studies on clean metal crystals exposed to submonolayers of organic reactants[19,80,86,87] and on covalently bound thin films, such as thioalkyls on gold.[66]

In most of these STM studies, the organic materials have assembled into ordered planes of molecules, typically thousands of angstroms in dimension, by processes of self-assembly or registration with the substrate. Registration can be viewed in analogy to surface science processes for growth of one material on another.[67] In the example of epitaxial growth, the internal order of an overlayer is dictated by the registry (lateral positions of atoms in a surface) of the underlayer. The growing number of STM results indicate that many organic adsorbates assume an ordered orientation analogous to epitaxial growth when they are absorbed on an ordered substrate. Individual molecules are locked into position by their interaction with the underlying surface and their closely packed lateral neighbors. The images of the planes are then recorded as ordered arrays, consisting of individual molecules as subunits. In some studies of particularly high resolution, molecular subunits of moieties or atoms are observed individually.

Alkylation might enable images of certain organic molecules to be acquired, because alkyl chains energetically favor 2-D crystallization (see Section 7.1). Of course, the steric nature of the parent molecule will have to be taken into account so that the contact area between molecule and surface is not overly compromised.

A major requirement for a good STM substrate, besides conductivity, is flatness. If data are to be recorded on the molecular scale, then the rms (root mean square) roughness of the substrate must be on or below this scale. Layered materials that are easily cleaved afford good surfaces, particularly for sample preparation in air. These include graphite,[88] MoS_2,[89,90], WSe_2,[68e] and mica (metal-coated for conductivity).[91] Other flat, conductive surfaces used for adsorption of organics have included melted gold spheres,[92] PtC-coated glass,[75] metal single crystals and semiconductors.[72c,93] The last two are usually employed under inert (typically vacuum) conditions.

Sample preparation involves primarily introduction of the organic adsorbate to the conductive substrate. Samples have been prepared for scanning by a variety of deposition techniques: sublimation, adsorption from solution, melting, and application of a neat liquid. Regardless of the preparation technique, the STM samples only the layer or layers closest to the interface with the conducting substrate.

Several alternative sample configurations have been found. For example, if the organic layer itself is conductive, it can act as the planar electrode, as in the case of charge-transfer salts[94] and conducting polymers.[71] Additional, puzzling cases have been found in which tunneling has occurred through relatively thick layers (e.g., tens to hundreds of angstroms) of organic material that is traditionally considered electronically insulating, for example, paraffins,[95] Langmuir–Blodgett (LB) films,[68] and lipids.[32] Alternate electron pathways from tip to conductive support have been proposed, such as surface and defect conductivity, to rationalize the tunneling currents detected through these particularly thick organic samples,[96] but to date their mechanism of conductivity and image contrast remains an enigma.

As shown in the above examples, successful imaging can be performed on sample surfaces in a variety of environments, for instance, in vacuum, under solutions, or in air. However, all of these cases share the requirement that the sample consist of or be deposited onto a conducting plane which acts as the second electrode in the tunneling process.

4. Specific Studies: Imaging Liquid Crystals

As mentioned above, the largest number of STM results are emerging from organic adsorbates that are highly ordered on surfaces. Although this might appear to be a restrictive requirement, many molecules in fact take on a degree of intermolecular order when placed on an ordered substrate.[67] For example, acetone and DMSO have provided images with long range order when deposited on graphite.[97] The class of organic molecules that has been most extensively imaged to date is liquid crystals, which are molecules displaying more highly ordered phases than a normal liquid. They are favorable molecules for STM study since they self-organize to form a stable molecular lattice. This lattice is then anchored to the graphite basal plane through surface–adsorbate interactions. STM images depict the highly ordered two-dimensional molecular "crystals" that form on surfaces such as graphite and MoS_2. Following an early success in imaging these materials,[98] many research groups[100] have contributed additional pieces to the puzzle of adsorbate packing on surfaces. The distinct patterns and high degree of order that these molecules display on assembly facilitate identification with the STM. Particularly important for interpreting the images is the differentiation of adsorbate structure from the underlying substrate structure. Their readily identifiable molecular shapes make this discrimination particularly easy for liquid crystals. Furthermore, the diversity of molecular compositions among liquid crystals allows for systematic studies on large numbers of analogues with common core structures. However, as discussed elsewhere in this article (Section 4.4), the role of the underlying substrate in determining adsorbate images can not be underestimated.

4.1. Liquid Crystal Sample Preparation

STM studies of liquid crystals have been performed under ambient conditions on instruments located in standard laboratory environments.

The choice of preparation technique depends, in part, on the phase of the liquid crystal at the experiment's operating temperature (usually room temperature). For example, a material in the smectic or nematic phase at room temperature can be introduced as a neat, macroscopic drop onto the substrate, or a material that is crystalline at room temperature might be melted onto a warmed substrate, followed by slow cooling to the operating temperature.[9, 11] Alternatively, the instrument can be operated at elevated temperatures.[9, 18]

Since present scanning and imaging methods require immobilizing the molecules so that they are not continually displaced by the action of the scanning tip, the characteristic behavior of liquid crystals to form extended ordered phases makes them ideal objects for STM investigations. The ability of the STM to focus on the monolayer(s) closest to the substrate provides new information on the role of the substrate in affecting long- and short-range intermolecular order. The driving force for assembly comes from both intermolecular and adsorbate–substrate interactions; evidence for both is described below.

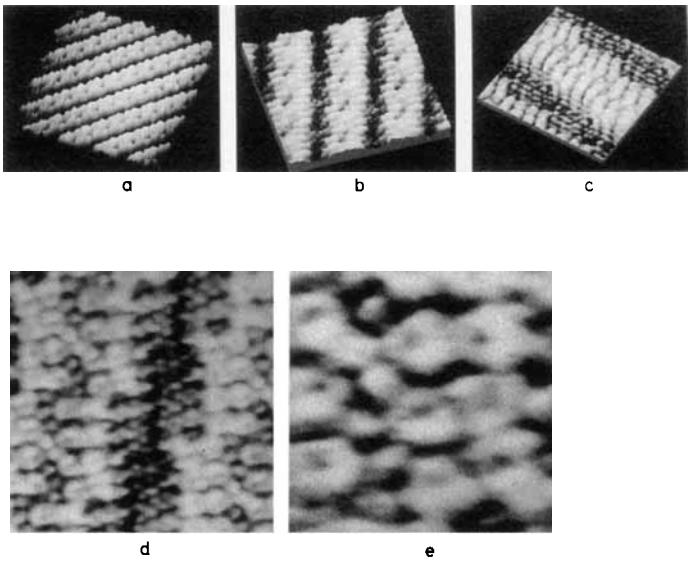

Fig. 5. STM images of 8CB (**1a**) on a graphite substrate [9,98,101]. a) Scanned area 250 × 250 Å^2. Long-range order of smectic planes, side-on. b) Scanned area 114 × 114 Å^2. Smectic layers resolved as rows of molecules. c) Scanned area 57 × 57 Å^2. Cyanobiphenyl headgroup differentiable from alkyl tails. d) Scanned area 57 × 57 Å^2. Individual phenyl groups resolved as rings. e) Scanned area 25 × 25 Å^2. Dipolar alignment seen in interdigitation of CN groups.

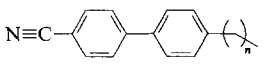
4.2. Alkylcyanobiphenyls[*]

The first use of the STM to study the ordering of liquid crystals on graphite was published in 1988.[98] The initial material studied, 4-*n*-octyl-4′-cyanobiphenyl, (8CB, **1a**) has since proven to be especially popular in STM studies of organic adsorbates.[9, 11, 89, 90, 101, 103].



1a, $n = 7$
1b, $n = 9$
1c, $n = 11$
1d, $n = 5$
1e, $n = 6$

STM images of 8CB on the graphite basal plane have been collected on various scales, from large areas (250 × 250 Å^2) to smaller areas (20 × 20 Å^2) (Figs. 5 and 6).[9] In large scans, (Fig. 5a) the long-range ordering of molecules is evidenced as rows, 38 Å wide and extending for hundreds of angstroms. Occasionally these rows terminate at domain boundaries (Fig. 6a, b) that originate either within the organic layer or in the underlying substrate (discussed further in Section 5).[98, 105–107]

On narrowing the scan range to 112 × 112 Å^2 and then to 57 × 57 Å^2, the increased resolution distinguishes rows of parallel molecules (Fig. 5b, c). The cyanobiphenyl head group appears as a brighter oval, while the alkane tail appears as a fainter chain (areas of higher and lower current, respectively. See Section 1.2). Each row interacts in amphiphilic fashion with neighboring rows: head-to-head and tail-to-tail.

From these images it can be seen that the molecules are lying on the graphite surface, as opposed to extending their long axes out normal to the substrate plane, as in LB films (Fig. 7). The rows are subdivided into discrete packets of molecules, each packet, or unit cell, containing eight molecules. Each consecutive unit cell is laterally offset ~7 Å from its neighboring cell within the row. This periodic offset, every eight molecules, is possibly a mechanism by which strain from incommensurate packing is relieved. Close examination of the angle formed between the biphenyl group and the alkyl group reveals a progressive increase in angle, from 12° to 35° on going from the first to the fourth molecule on one side of the unit cell (better discerned in Figure 9). This bond angle could be reflecting, or accommodating, an increasingly unfavorable lattice match between the adsorbate and substrate structures which is relieved every eighth molecule by an offset of the entire unit cell by 7 Å. This is a description of a "molecular solution" to incommensurate packing: the unit cell assembly of eight molecules accommodates the mismatch until a point where the lattice mismatch becomes predominantly unfavorable; then the row is broken, and a new repeat unit of eight molecules is assembled.

In another perspective of a scan area of 57 × 57 Å^2, the individual rings of the biphenyl unit are visible (Fig. 5d). The biphenyl groups appear as pairs of bright rings and the aliphatic tails as darker zig-zag chains of spots, each spot associated with an alternating methylene group (Fig. 5c, d; see also Fig. 9). The position of the cyano group can also be seen as a bright spot off the phenyl ring, *para* to the biphenyl linkage. In images like these of phenyl groups which resolve as actual ringlike structures, the rings are considered to be lying flat on the substrate. This conclusion is supported by comparing intermolecular distances from various images in order to correlate the larger intermolecular distances measured (e.g., 6.5 Å) with flat-lying rings and the smaller inter-

[*] Names like cyanobiphenyls in this section and Sections 4.5.1 and 4.5.2 are treated as trivial names. The IUPAC nomenclature for cyanobiphenyl is biphenylylcyanide or biphenylcarbonitrile.

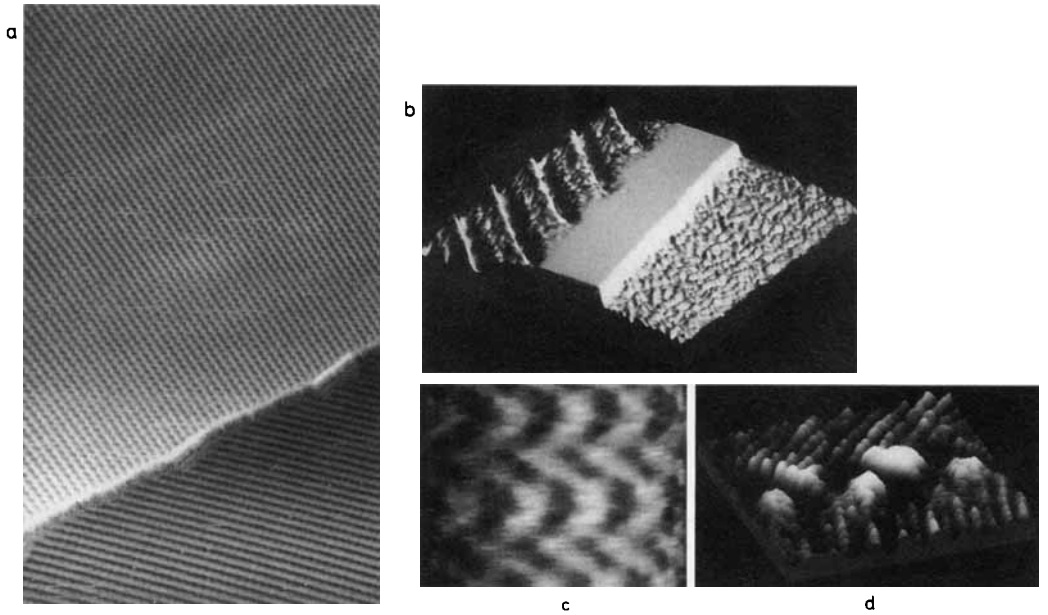


Fig. 6. STM images of boundaries: a) Scanned area 1350×2600 Å^2. 10CB (**1b**) on graphite with a step height of 3.5 Å (one layer of graphite)[106]. b) Scanned area 150×150 Å^2. 8CB (**1a**) on graphite. A smectic plane terminates at a step edge of ~ 10 Å. The contrast in this image is adjusted to optimize resolution of the molecular rows on the upper plane, so the higher central section of the image is out of the range of the STM electronics (see text). The lower plane is shown in Figure 6c, with optimized scanning parameters. c) Scanned area 105×105 Å^2. The lower plane of Figure 6b, brought into better resolution, revealing a moiré pattern for the packing of 8CB on graphite[105]. d) Scanned area 72×72 Å^2. 5CBN (**6**) on graphite. A boundary between two domains oriented 30° to each other[98].

molecular spacings (e.g., 5.5 Å) with tilted rings (the approximate diameter of a phenyl ring is ~ 5.4 Å[108]. This point will be discussed further in the next section with the example of 6CB (**1d**).

One of the most outstanding features of these STM images of 8CB is illustrated in Figure 5e, a scan area focused on the interaction between vicinal headgroups (25×25 Å^2). Figure 5e provides a direct view of interdigitation, where cyano groups are aligned side-by-side yet in opposing directions. This alignment reduces electrostatic repulsions between the dipoles of the cyano groups (Fig. 8) by striving to "cancel" the dipole moment of the nitrile (C≡N) group. Dipolar alignment has been considered a major driving force in the assembly of CN-containing liquid crystals.[109] Now, with the STM, it can actually be visualized, molecule by molecule. In images like that of Figure 5e, the power of the STM as a tool in characterizing intra- and intermolecular order is clearly demonstrated.

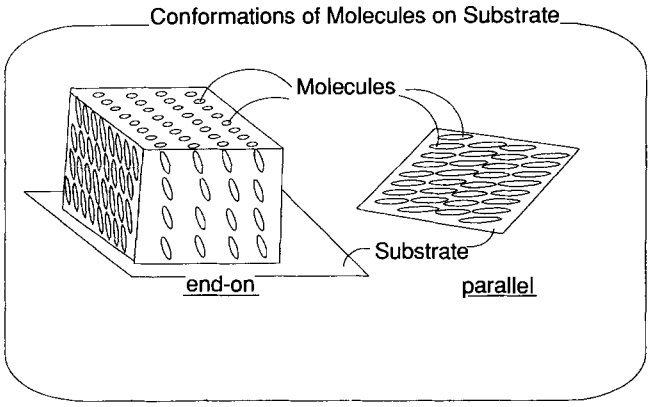

Fig. 7. Schematic representation of molecular orientation on a substrate for the classes of molecules discussed in the text. The end-on conformation is observed in the AFM studies of LB films (see Section 12) and the parallel conformation is recorded in the STM studies of liquid crystals (see Section 4).

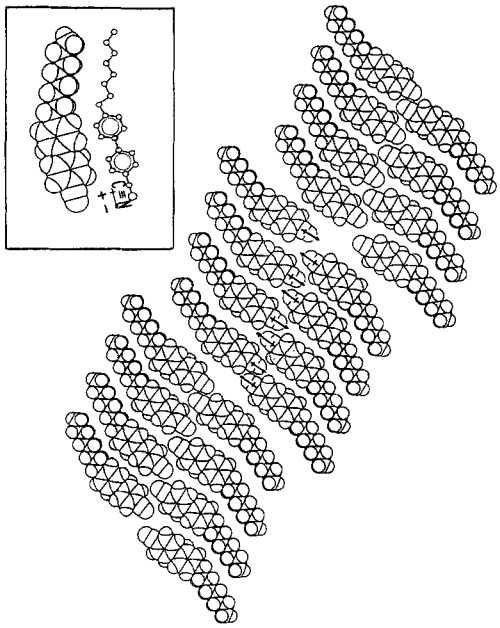

Fig. 8. Cartoon depicting the cyanobiphenyl molecules **1** in the alignment observed in the STM images of Figures 5 and 9. The alignment of nitrile dipoles is highlighted.

4.3. Systematic Studies of Alkylcyanobiphenyl Homologues

The current lack of a definitive theory for STM imaging of organic molecules that was discussed earlier is compensated,

in part, by the ability of organic chemists to make systematic modifications in the molecules and to monitor the changes in the STM images.

Table 1 is a list of organic systems for which images with "submolecular" recognition have been recorded. Prominent among these are liquid crystals, particularly the alkylcyanobiphenyls. Therefore, the following discussion of systematic studies on organic compounds will focus on the alkylcyanobiphenyls by assembling and integrating data from various laboratories worldwide.

Table 1. Representative STM studies on organic materials.

Class	Structure	Reference
liquid crystals	$N\equiv C-C_6H_4-C_6H_4-(CH_2)_xCH_3$, $x = 5 \rightarrow 11$ **1**	[11, 89, 98, 101, 116] [9, 90, 104, 107]
	$N\equiv C-C_6H_4-C_6H_4-OC_4H_9$ **2**	[18, 77]
	$N\equiv C-C_6H_4-(c\text{-}C_6H_{10})-C_5H_{11}$ **6**	[98, 116]
	$N\equiv C-(c\text{-}C_6H_{10})-(c\text{-}C_6H_{10})-C_3H_7$ **3**	[18, 77]
	$C_9H_{19}-C_4N_2H_2-C_6H_4-OR$; $R = C_6H_{13}$, C_9H_{19} **4**, **5**	[18, 77, 116]
	$C_8H_{17}O-C_6H_4-CO_2-C_6H_4-C_6H_4-C(O)C^*H(CH_3)C_6H_{13}$	[99]
n-alkanes	$CH_3(CH_2)_nCH_3$	[12, 118–121]
n-alcohols	$CH_3(CH_2)_nOH$	[12, 120, 121]
carboxylic acids	$CH_3(CH_2)_nCOOH$	[121, 126]
DNA bases	guanine	[10]
	adenine	[73]
	thymine	[73]
arenes	benzene	[86]
	naphthalene	[87]
	phthalocyanine	[80]
	perylene dianhydride	[13]
	p-di(dodecyl)benzene	[121]
	graphite clusters	[18]

4-*n*-Alkyl-4′-cyanobiphenyls **1** (*n*CB, n = number of carbon atoms in the alkyl chain) are well-known and well-used in both academic and industrial studies of liquid crystals. Many of the *n*CB molecules studied to date by STM order similarly on graphite. For example, both decyl and dodecyl derivatives pack in extended rows, approximately two molecules wide (Fig. 9), with the same head-to-head orientation seen for 8CB (Fig. 5).[101] These rows are derived from smectic planes, viewed side-on. Actually, their degree of order is more crystalline than smectic, with very regular correspondence between rows as well as within the rows. Although it is more accurate to refer to the patterns viewed in these pictures as two-dimensional crystals, the tendency has been to borrow nomenclature from the traditional field of liquid crystals in describing molecular orientation in the STM images.

A linear relationship is recorded between increasing alkyl chain length and increasing (smectic) row spacing for cyanobiphenyl derivatives of different alkyl chain lengths (Fig. 9 and 10).[101] For example, the width of the "unit cell" of eight

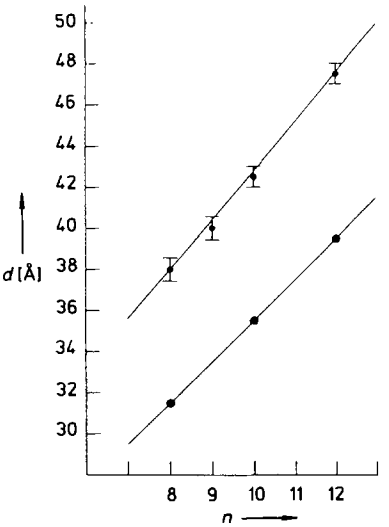

Fig. 10. Dependence of smectic spacing d on number of carbons n in the tail of cyanobiphenyl derivatives **1** from STM measurements (◆, data from [101] and X-ray diffraction (●, data from [109]).

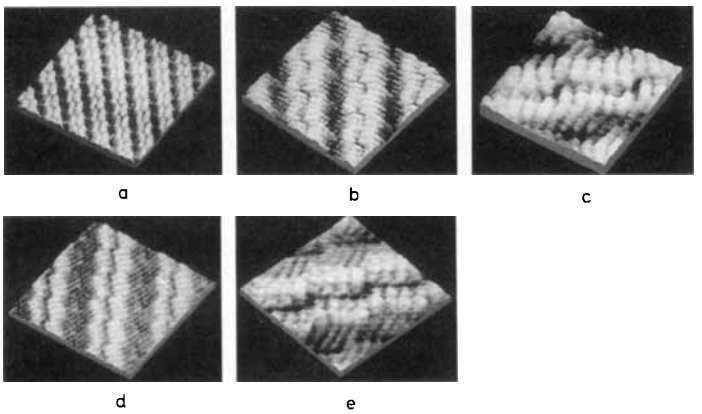

Fig. 9. STM images of 10CB (**1b**) and 12CB (**1c**) on a graphite substrate [9,101]: a) Scanned area 285 × 285 Å². Long-range order of 10CB showing side-on arrangement of smectic planes. b) Scanned area 114 × 114 Å². Smectic layers of 10CB resolved as rows of molecules, with "unit cells" of 10 molecules. c) Scanned area 57 × 57 Å². The changing bond angle between tail and head groups of 10CB is evident on going from the first to the fifth molecule on one side of the unit cell. d) Scanned area 114 × 114 Å². Smectic layers of 12CB resolved as rows of molecules, with "unit cells" of eight molecules. e) Scanned area 57 × 57 Å² 12CB.

molecules in 8CB (**1a**), measured from the terminal methyl group across the interdigitated heads to the terminal methyl group of the molecule opposite, is 38 Å. This width is 43 Å in 10CB (**1b**), the decyl derivative with two more methylene units per molecule, and 47 Å in 12CB (**1c**). The stepwise increases of 4–5 Å on going from octyl to decyl to dodecyl derivatives corresponds to a predictable increase in chain length of 1.25 Å per methylene unit (note: there are two molecular lengths per row width).

Extension of the series in the opposite direction, to shorter chain lengths, results in more changes than just narrowing of the widths of the rows. The hexyl derivative 6CB (**1d**) forms a pattern which resembles that of the higher weight analogues (long rows of parallel molecular axes and head-to-head contact);[104, 110] however, it differs in the orientation of phenyl rings relative to the underlying substrate (Fig. 11). With 6CB, every second biphenyl unit appears to be canted, wedged between its two adjacent biphenyl neighbors, which are lying flat. The hexyl tails in these images are less obvious than their higher molecular weight homologues, perhaps due to thermal motion.

Since 6CB, 8CB, 10CB, and 12CB all share a common head group structure, the cyanobiphenyl unit, one looks to

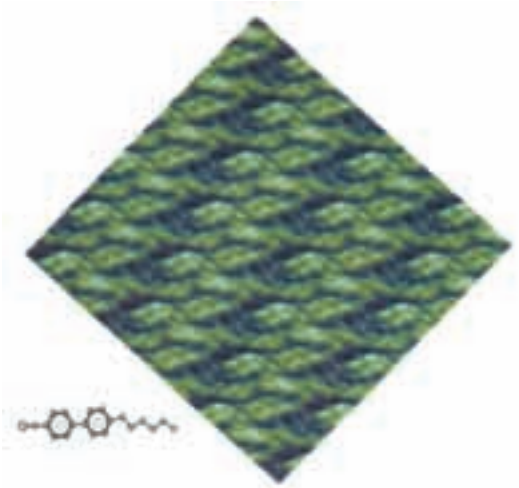

Fig. 11. STM image of 6CB (**1d**) on graphite (scanned area 70×70 Å^2). The ring structure is resolved in every second molecule within a row, which is interpreted as biphenyl groups alternately lying flat or canted relative to the flat, underlying graphite substrate [110].

the influence of the tail in explaining the differences in their images. The principle change on proceeding from the dodecyl (C12) through the decyl (C10) to the octyl (C8), and finally to the hexyl (C6) derivative in the cyanobiphenyl series is the successive shortening of the alkyl component by two methylene units (~ 2.5 Å). Thus, the rather major difference in the position of C6 molecules on the surface indicates that n = hexyl is below a threshold for the alkyl group to influence (to a certain extent) the ordering to the nCB molecules. Apparently, at shorter chain lengths the alkyl component is below the "critical mass" required for strongly directing the intermolecular ordering that is common to 8CB, 10CB, and 12CB on graphite. The lack of well-ordered tails in 6CB perhaps releases the constraint on the phenyl head groups to accommodate alkyl tail intermolecular spacing. (The width of an alkyl chain is ~ 4 Å and that of a flat-lying phenyl ring ~ 5.4 Å.)[108] The interactions of the head groups having little "tail mass" to constrain them could be the dominating driving force in the alternate 6CB packing pattern. In any case, the lower observed order in the hexyl chain is consistent with the fact that 6CB is in the nematic phase at room temperature, the temperature of the STM experiments, whereas the others are in the more highly ordered smectic phases.

An STM study of 7CB, the heptyl derivative **1e**, produces images that reveal an alternative packing for the nCBs on graphite.[111] In fact, this alternative packing pattern has also been observed on rare occasions with 8CB on graphite (Fig. 13) and with some nCBs on other substrates (discussed in full in Section 4.4). The difference in 7CB's behavior could arise from its odd number of carbons in the alkyl moiety, which subjects it to odd/even alternation effects often observed for alkanes.[111] Like 6CB, 7CB is a room-temperature nematic in the bulk.

Finally, meaurements of interlayer spacings in the smectic phase by STM and by X-ray and neutron scattering[109] give different results. On average, this spacing for 8CB, 10CB, and 12CB is 1.2 times greater when measured by STM (see Fig. 10[101, 109]). This discrepancy is not surprising when the molecules' environment is considered: X-rays and neutrons interact with molecules in the bulk, that is, molecules that are surrounded by like molecules.[67] The STM, however, measures molecular spacings in a layer of molecules located at the "edge" of the bulk, at the interface with a substrate. The factor of 1.2 is due to the influence of the interface such as a lattice mismatch with the substrate on the ordering of the proximal organic adsorbate (see Section 4.4). The shorter spacing in the smectic phase detected by X-rays on the bulk crystal could be due to a number of molecular origins, for example, less extended alkyl tails. This example of a notable difference between results obtained from the bulk and from the interface emphasizes that caution must accompany interpretations of STM images. Direct extensions of phenomena and principles from the bulk to the angstrom scale at interfaces could be misleading.

4.4. Substrate Effects

4.4.1. Graphite as a Substrate

Evidence for substrate effects has been provided by the dependence of unit cell size on alkyl chain length in the series 8CB/10CB/12CB. Close inspection of Figure 9, the STM image of the decyl derivative 10CB, reveals a unit cell of ten molecules—two more than in the case of 8CB (Fig. 5). 12CB again conforms to the 8-molecule unit cell of 8CB. This change in unit-cell size on minor modification of the molecular length implies that energies for bonding to the substrate and bonding to nearest neighbor molecules are comparable. Apparently, the favorable energy of intermolecular interaction is offset by an increasing strain between the substrate and adsorbate every eight or ten molecules, depending on the length of the alkyl chains. The difference in adsorption energies between two consecutive members of the series C12-C10-C8-C6 (where the molecular structure of the head group stays fixed and only the length of the alkyl tail changes) can be estimated at 1.6 eV (≈ 160 J and ≈ 38 kcal) per unit cell (for a unit cell of eight molecules) by applying an approximate value for adsorption energy of 0.1 eV (that is, 10 kJ, ≈ 2.4 kcal) per methylene unit.[112, 113]

Among the proposed mechanisms for registration with the substrate are hydrogen atom positioning over graphite rings.[113, 114] Molecular models can be used to illustrate adsorbate registration with the underlying lattice[90], though one must be wary of carrying bulk parameters of bond lengths and angles over to the interface between the metallic surface and hydrocarbon. Relaxation of these parameters to geometries which are distorted from ground state geometries (as known from the bulk or the gas phase) is worth considering, as are interactions with the image dipole in the underlying substrate.

4.4.2. MoS_2 as a Substrate

Dramatic evidence for the influence of the substrate on adsorbate order is provided in the comparison of STM images from two different substrates. The well-studied liquid crystals of type **1** have also been imaged on MoS_2[89, 90], and the resulting molecular patterns have been compared to those on graphite (Fig. 12). Most striking is the deviation in

the case of 8CB. Instead of the long rows of parallel molecules all aligned head-to-head within a row, on MoS_2 a row is made up of a pattern of alternating head-to-head and tail-to-tail parallel dimers. The attractive contacts between rows come from interactions with neighboring rows; this interface also contains alternating head-to-head and tail-to-tail interactions. In Figure 12 details of the molecular structure of 8CB are noticeably less well-resolved than on graphite; although the alkyl and cyanobiphenyl moieties can be distinguished from each other, both lack internal structure.

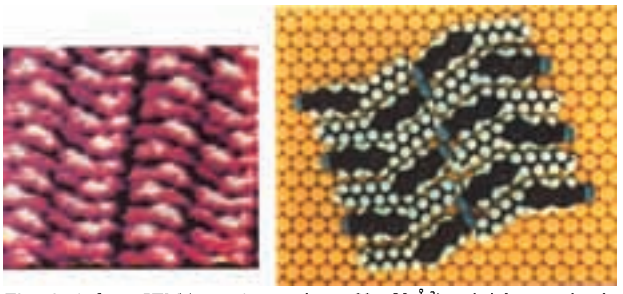

Fig. 12. Left, an STM image (scanned area 80×80 Å^2) and right, a molecular model of 8CB (**1a**) on a MoS_2 substrate [89,90].

10CB and 12CB maintain a similar packing pattern on MoS_2 and graphite.[89,90] For 10CB, where the pattern of molecular packing is the same on these two substrates, the intermolecular spacing within rows of 10CB molecules is greater on MoS_2 than on graphite (5.47 Å vs. 4.25 Å). This is consistent with the larger lattice constant of MoS_2 (3.16 Å compared to graphite's 2.46 Å. See Fig. 4).

It is tempting to conclude from the difference between adsorbate packing patterns on the two substrates that adsorbate–substrate interactions dominate intermolecular ones. In the majority of scans this appears to be so. However, there are a minor number of counter examples which don't allow such a generalization. Figure 12 presents one such exception: 8CB on graphite in the molecular packing pattern more commonly observed on MoS_2.[116] An image of 7CB has also been recorded on graphite with this molecular packing pattern,[111] as noted in the previous section. These exceptions imply that this adsorbate system is in a delicate balance between intermolecular and substrate–adsorbate forces. This balance can be disturbed by obvious influences, such as changing the substrate or the sample's thermal history, as well as by less obvious ones. In some cases the STM image of a "deviant" packing pattern is providing us with a snapshot of a metastable state.

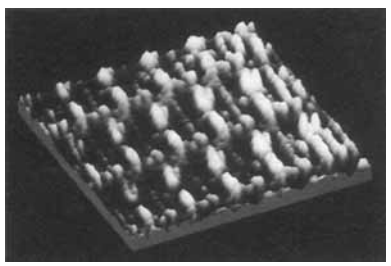

Fig. 13. An STM image [116] of 8CB (**1a**) on graphite (scanned area 105×105 Å^2) with a similar (rare) molecular packing pattern as observed for 8CB on MoS_2 (Fig. 12) [89, 90].

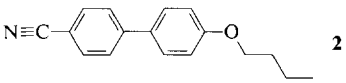
4.5. A Collection of Diverse, Yet Related, Compounds

A few of the other liquid crystals listed in Table 1 are briefly discussed below to point out the effect of modifying chemical functionalities on their STM images.

4.5.1. An Alkoxycyanobiphenyl

In two more examples of liquid crystals containing cyano groups, one (**2**) provides another look at interdigitation of dipoles while the second (**3**) leaves open the provocative question of tunneling mechanisms.[18, 77]



2

In the first, 4-cyano-4′-butoxybiphenyl (4OCB, **2**), the cyanobiphenyl head group is appended to an alkoxy tail four carbons long. The STM images portray parallel molecules arrayed in long rows of head-to-head pairs (Fig. 14a). The cyanobiphenyl head group resolves distinctly as two moieties; its position relative to its opposite neighbor is dictated by the interdigitation of the cyano groups, as discussed earlier for 8CB (see Fig. 5e and 8).

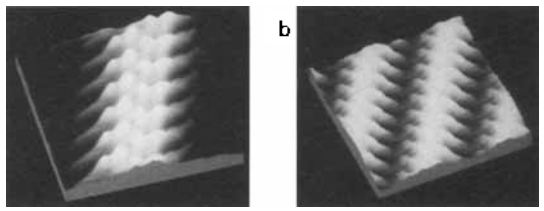


Fig. 14. STM images of two additional CN-containing liquid crystals, 4OCB (**2**) and CCH3 (**3**) on graphite substrates [18,77]. a) 4OCB, scanned area 30×30 Å^2. The biphenyl unit resolves distinctly as two separate features; positioned to reflect the interdigitation of the nitrile groups. b) CCH3, scanned area 52×52 Å^2. The bicyclohexyl and alkyl groups resolve as one continuous feature, again interdigited with the neighboring row. Note that this compound does not contain aromatic structures, so the contrast can not be attributed to transitions in energetically low-lying orbitals of the phenyl unit.

4.5.2. A Cyanobicyclohexyl

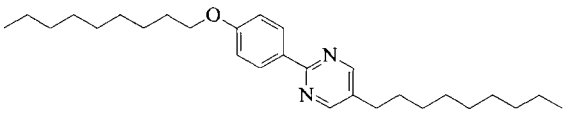
The last CN-containing liquid crystal discussed here is 4-(4-*n*-propylcyclohexyl)cyanocyclohexane (CCH3, **3**), a compound containing no aromatic moiety. Instead, it is composed of a core of two cyclohexyl groups with a cyano group at one

3

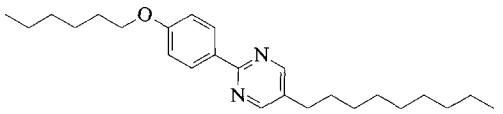
end and a short propyl tail at the other. The image of a single molecule is diffuse, with no distinction between the straight chain hydrocarbon tail and the hydrocarbon core of two cyclohexane units.[18, 77] Perhaps the conformation of the cyclohexyl groups does not allow continuous and close contact between the atoms of the adsorbate and the substrate, a proposed requisite for atomic resolution of adsorbates. The row width (26 Å) resolves as an interdigitated bilayer, directed by the cyano groups. This particular compound was chosen for study by STM in the series of liquid crystals because it contains no aromatic structures. One hypothesis of tunneling through organic adsorbates invokes accessible energy levels in the HOMO and/or LUMO of the phenyl units;[9, 80] this would be consistent with conduction mechanisms proposed for electronically conducting organic molecules.[115] However, Figure 14b demonstrates that no single, particular moiety is "most" responsible for the conductivity, and therefore the contrast that produced these images.

4.5.3. Phenylpyrimidines

"A long aliphatic chain interrupted by an aromatic core" is one description of the members of the 2-(4-alkoxyphenyl)-5-alkylpyrimidines (PYP). Of the two examples from this family of molecules given here, one yields STM images with a repeat unit of a single row of parallel molecules (PYP909); the other shows a repeat unit of two rows, each of a different molecular orientation (PYP906).[18, 77, 116]



4



5

2-(4′-Nonyloxyphenyl)-5-nonylpyrimidine (PYP909, **4**) on graphite produces an image of long rows of parallel molecules, in which the bright oval areas correspond to the phenylpyrimidine cores from which the dimmer, aliphatic side chains extend (Fig. 15a). The molecules are spaced about 6 Å apart. The two substituents on the phenylpyrimidine core come off at two different angles from the core (ca. 15° and 0°); the level of resolution in this image does not allow assignment of the alkyl and alkoxy substituents. Interaction between neighboring rows comes from overlap of the alkyl chains, depicted as small areas of increased current; it is not surprising then that the row width is 25 Å, approximately 7 Å shorter than the molecule's extended length, when this overlap is taken into account.

The second member of the phenylpyrimidine series examined, PYP906 (**5**), is three methylene units shorter than PYP909 in the alkoxy sidechain. The STM image ofPYP906 on graphite also shows long rows of parallel molecular axes, adjacent molecules spaced 6 Å apart, and alkyl substituents forming bond angles of 15° and 0° with the core (Fig. 15b). However, the similarities end here. The long-range repeat pattern of the central ring systems of the molecules reveals that the rows are not all identical; rather, they alternate between two distinctive packing patterns, providing a bilayer repeat unit. The long axes of the aromatic cores of one row form an angle of approximately 180° with the axes of the adjacent row. The reason for the different packing mode is not yet known – it could arise from the odd-even chain length effect cited earlier.

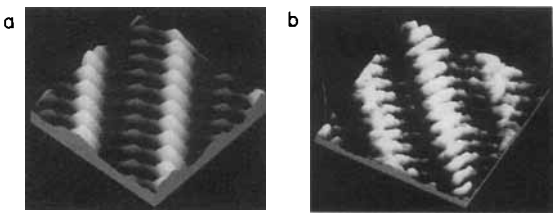


Fig. 15. STM images of PYP 909 (**4**) and PYP 906 (**5**) on graphite substrates [18,77]: a) Scanned area 43 × 52 Å². In PYP 909, the *para*-disubstituted phenylpyrimidine cores resolve as bright ellipses in straight rows. The alkyl and alkoxy substituents resolve as fainter chains that overlap between rows. The overlap appears as a short, brighter stretch in the chain. b) Scanned area 52 × 52 Å². PYP 906 differentiates itself from PYP 909 in the alternating row pattern, constituting a repeat unit of bilayers. The phenylpyrimidine cores of adjacent rows are roughly perpendicular to each other.

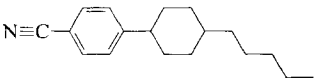
The resolution of STM images of liquid crystals **2**–**5** is on the molecular, or submolecular scale, and not on the atomic scale. However, they still serve well in comparative studies to demonstrate the powerful effect that chemical modification can have on the STM images of similar molecules.

5. Domain Boundaries

Domain boundaries are occasionally observed in the STM images of adsorbates,[11, 26, 98, 107] as seen already in the image of 8CB (**1a**) on graphite which shows the termination of smectic rows (Fig. 6b). In this image, the contrast is adjusted to optimize resolution of the molecular rows; consequently, the higher central section of the image is saturated (that is, out of the dynamic range of the electronics) and appears artificially as a flat, white plane. When the contrast is adjusted for the lower plane of Figure 6b, it resolves into a completely different pattern for 8CB (Fig. 6c), best described as a moiré pattern.[116] This moiré pattern is one of several examples of deviations[107, 116] from the more commonly observed 8CB structure of Figure 5. In the examples of Figures 6a and b, the boundary is probably caused by a step edge in the underlying graphite. Figure 6a illustrates this phenomenon in a particularly good, large-scale image of 10CB recorded over thousands of angstroms and interrupted by a step of 3.5 Å, corresponding to a step of graphite one atom high.[106]

The origin of the boundary in Figure 6d is probably not a defect in the underlying substrate, but an impurity in the overlying adsorbate, even though the boundary separates two domains oriented 30° to each other, an angle consistent with (and perhaps directed by) the sixfold symmetry of the under-

lying graphite.[98] The material in this image, 4-(4-*n*-pentylcyclohexyl)benzonitrile (5CBN, **6**) is nematic in the bulk at room temperature.



6

Individual molecular moieties are not differentiable in this image, other than a regular 2.5 Å spacing between features, a typical distance recorded by STM from alternating methylene groups in alkanes on graphite. The large islandlike features have not been identified. However, it is clear that they are associated with a boundary from which the molecules align.

In these examples of observed discontinuities, the term "domain boundary" has been borrowed from traditional disciplines, for example surface science. The strict definitions might not carry over to the topographical phenomena observed with the STM; nonetheless, the terms are applied, in part to avoid inventing new terms. In fact, the different domains could be different phases, impurities, or degrees of order in either the substrate or adsorbate.

6. A Phase Transition Viewed on the Angstrom Scale

Liquid crystals are ideally suited to the study of phase transitions since they display distinct phase transitions as a function of temperature. To this end, tunneling microscopes have been modified with variable temperature stages.[9, 11, 18] An example[18] is provided in a study of the aforementioned PYP906 (**5**), a room temperature smectic with an isotropic transition at 72 °C in the bulk. On heating the adsorbed PYP906 to 72 °C, no change in order is observed. Surprisingly on continued heating to temperatures 10–15 °C above this temperature the order is still maintained. At 85 °C the order of the mesophase can be intentionally perturbed by lowering the scanning STM tip. In the absence of the perturbing tip, the molecular order persists, even at these elevated temperatures.

These observations reflect a significant physisorption energy of the molecules to the graphite substrate. They could also be reflecting a more highly ordered phase at this temperature on the ordered substrate than in the corresponding bulk phase, requiring more thermal energy for disruption. Such highly ordered surface phases have been postulated to explain unexpected features in the X-ray reflection data of similar liquid crystal molecules.[117]

The roles of variable temperature and variable pressure are currently creating interest and activity in the field of STM and AFM. Most of the published reports are on metal or semiconductor surfaces in UHV (see Section 1.3). More reports on organic systems are sure to appear in the near future.

7. Studies on Alkanes and Arenes

Since the first liquid crystal images were obtained, several other STM studies have been performed on the smaller molecular moieties that constitute part of the liquid crystals' molecular structure: alkanes and arenes. The alkane samples studied to date have been applied to the substrate either neat or by selective adsorption from a solution with sterically bulky solvent, such as iso-octane. Imaging is performed on a substrate surface immersed in this solution. The studies of arenes have been primarily performed in UHV on monolayer or submonolayer coverages deposited on metal single crystals. These contrasting operating conditions have supplied information consistent with each other and with our previous knowledge or intuition about organic molecules such as straight-chain or cyclic configurations and intramolecular carbon–carbon spacing, discussed below.

7.1. Alkanes

One of the most striking examples of STM imaging of organic monolayers has been with long-chain *n*-alkanes.[12, 118–121] The simple chemical structure of these molecules yields clear-cut STM images of hydrocarbon order and registry on a graphite surface (Fig. 16). The STM images of *n*-alkanes also nicely corroborate the images of the hydrocarbon components in the earlier liquid crystal studies (Fig. 5, 9).[9, 101] Images with atomic resolution show the spacing between parallel molecules of dotriacontane (**7**, $C_{32}H_{66}$) to be 4.5 ± 0.5 Å (Fig. 16)[119].

7

Interchain distances measured by X-ray on solid paraffins are in this range; for example, in the triclinic unit cell of *n*-$C_{18}H_{38}$, $a = 4.28$ Å and $b = 4.82$ Å.[125]

In the STM images, within an individual hydrocarbon molecule, interatomic spacings of 2.5 Å are recorded. This value corresponds to the distance between every second carbon in the extended conformation of an *n*-alkane (see diagram in Fig. 16). Which entity gives rise to these 2.5 Å-

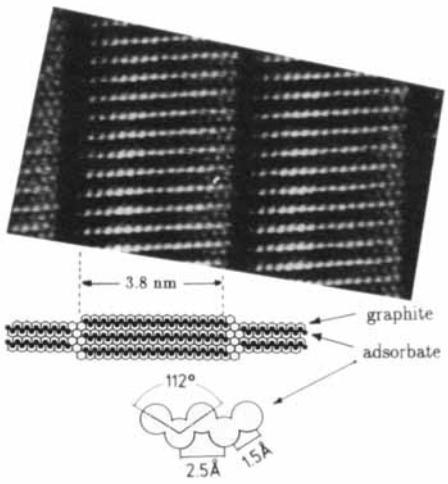


Fig. 16. STM image (scanned area 100 × 60 Å²) and graphic rendition of the paraffin dotriacontane (**7**, $C_{32}H_{66}$) on graphite. The molecules form close-packed rows. The width of the row corresponds to the length of a molecule (38 Å). The bright spots that make up each molecule correspond to every second methylene group, spaced 2.5 Å apart [119].

spaced features is still under debate: their source has been attributed both to tunneling directly into states on the methylene group and to enhanced tunneling into sites in the substrate lattice. (The lattice spacing a_0 of graphite is 2.46 Å; Fig. 4.) In the latter explanation, the hydrocarbon adlayer commensurate with the graphite spacings is assigned the role of enhancing the tunneling current into the substrate.[119] As mentioned in Section 4.4, one should not a priori expect ground state geometry, but rather consider the possibility of distortion of gas-phase or crystalline ground-state geometries on adsorption to the underlying substrate lattice.

In the STM studies on *n*-alkanes, samples are prepared by applying a drop of the alkane either neat or in dilute isooctane and decane solution to the graphite substrate surface. In the latter case, the longer alkanes were preferentially adsorbed out of solution onto the graphite. It has been shown that adsorbed layers of liquids can take on solidlike properties.[127–129] It is likely that the adsorbed hydrocarbon layers imaged with the STM have this solidlike property.

The alkanes of these STM studies are of the higher molecular weight of paraffins. From calorimetric,[114, 122, 123] low energy electron diffraction (LEED),[124] and neutron diffraction studies,[124] they are known to adsorb preferentially from dilute solutions in nonpolar organic solvents to form a close-packed monolayer of molecules oriented with their long axes parallel to the graphite basal plane. The measured heat of adsorption increases uniformly with the chain length and reaches values of 209 kJ mol^{-1} ($\approx$2 eV mol^{-1}, $\approx$50 kcal mol^{-1}) for dotriacontane ($C_{32}H_{66}$, **7**).[114] The calorimetric studies that preceded the STM imaging assigned the overriding driving force for the preferential absorption of long-chain alkanes either to lateral intermolecular interaction or to adsorbate–substrate interaction. In the argument for lateral interaction within the adsorbed layer,[122] the interpretation of the solution isotherms was based on a temperature dependence characteristic of a highly cooperative effect, such as molecular ordering. In the argument for adsorbate–substrate interactions,[114] the driving force for assembly was assigned to the registry of methylene groups in the alkane with underlying hexagons in the graphite. This approach required a compression of the molecular chains by 8–12% relative to their arrangement in the solid paraffin.

Support for the first argument is building from a range of functionalized alkanes whose adsorption behaviors have been studied by both calorimetry and STM. The methods used in the original STM study of alkanes have been applied to imaging functionalized hydrocarbons, such as alcohols,[12, 120, 121] carboxylic acids,[121, 126] and alkylated carbohydrates.[70] Because of the variety of packing modes observed for these assembled adsorbates, the ordering appears to be more a function of the derivatized hydrocarbon's atomic composition than of the unchanging lattice parameter of the underlying graphite.

These STM images of straight-chain hydrocarbons constitute one of the most straight-forward examples of imaging of electric insulators with a current of tunneling electrons.

7.2. Arenes

In the context of modeling catalytically active surfaces, the (111) surface of a crystal of rhodium has been dosed with stoichiometric quantities of benzene and carbon monoxide gases.[130] The surface was then observed in an ultrahigh vacuum instrument.[86] A high-resolution STM image of this system depicts benzene as a three-cornered ring (Fig. 17).

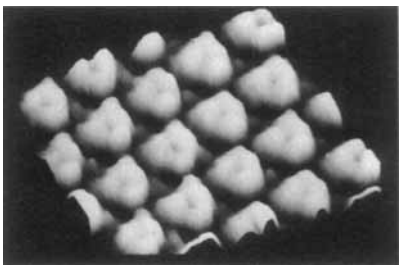

Fig. 17. STM image of benzene and carbon monoxide (molar ratio 1:2) coadsorbed on the (111) surface of a rhodium crystal. The benzene appears as three-cornered rings; the CO, bound end-on through the carbon to the metal surface, is only weakly detected [86].

The triangular shape is ascribed to the registry of the rhodium lattice with three of the benzene's carbons. The barely resolved small bumps in the dark areas at the corners of the benzene rings are assigned to CO; from LEED and high-resolution electron energy loss spectroscopy (HREELS) studies CO is known to bind to the metal end-on through a metal–carbon bond.[130] The current level of understanding of the tunneling mechanism through organic adsorbates cannot yet explain the pronounced difference in tunnel current between the benzene and carbon monoxide molecules. A similar effect has been observed in a combined LEED, X-ray, and STM investigation of perylene dianhydride on graphite.[13] In this study, the tunnel current above the arene rings is distinctly greater than that over the anhydride units; only the perylene moiety is depicted, appearing as a double-ringed structure. The oxygen-containing anhydride eludes detection by STM.

Additional UHV-STM studies of aromatic adsorbates on metals include copper phthalocyanine on copper (100)[80] and naphthalene on platinum (111).[87] In the former, the STM images reveal a submonolayer distribution over the metal surface of isolated phthalocyanine rings with four distinct lobes. In the naphthalene study, three distinct rotational orientations, 120° apart, are observed for the bi-lobed naphthalene molecules on the metal surface.[87] These three orientations correspond to the (3×3) lattice spacing of the platinum substrate.

7.3. The Transformation of Alkenes into Arenes

An outstanding example of the use of the STM to monitor chemical reactions is provided by a study of the reaction pathway from ethene to graphite on a platinum surface.[19] In this study, performed in a variable-temperature UHV apparatus, the individual steps along the thermally activated reaction pathway from adsorption of C_2H_4 on Pt(111) to formation of graphite are documented, including ethylidyne intermediates, 5–10 Å carbon particles, and the penultimate morphology of small islands of graphite (Fig. 18). This particular instrument is capable of high-temperature (to 1070 K) genera-

tion of intermediates and low-temperature (to 180 K) STM documentation of them. The low temperature is necessary to observe the ethene since it converts to ethylidyne at temperatures above 230 K. The low temperature also presumably freezes out low-frequency motions of the ethylidyne surface species that would limit resolution at higher temperatures.

Because of the controlled amounts of ethene used in forming the monolayer on platinum, the final grapite product is one monolayer thick. Several superstructures with periodicities up to 22 Å are evident in the STM images of the final product; they are attributed to the higher order commensurability of the graphite and platinum lattices at different relative rotations (Fig. 18).

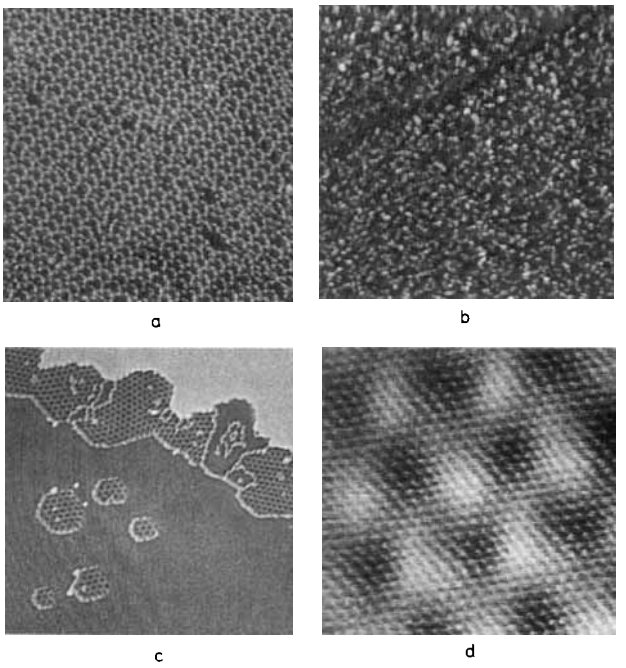

Fig. 18. STM images of stages in the process of graphitization of ethene on a platinum surface[119]. a) Scanned area 200×200 Å^2. A monolayer of ethene adsorbed in a regular pattern on Pt(111), recorded at 150 K. b) Scanned area 1000×1000 Å^2. On heating to 700 K, carbon species have agglomerated into particles, approximately 10–15 Å in diameter, containing no more hydrogen (determined by thermal desorption measurements). A step in the platinum surface runs across the upper left quadrant of the image. Image recorded at room temperature. c) Scanned area 1000×1000 Å^2. Annealing at 900 K creates islands of graphite, 20–30 Å in diameter, on the platinum terraces. Further annealing up to 1230 K results in larger structures of graphite, principally at lower step edges in the platinum, with some large, regularly shaped islands remaining on terraces (this image). Image recorded at room temperature. d) Scanned area 65×65 Å^2. A close-up of a graphite area on the platinum surface. The hexagonal arrangement of dots represent every other carbon in the graphite lattice (see text), spaced with the ~2.5 Å lattice constant of graphite (see Fig. 4). A 22 Å period superstructure is superimposed on the image as a hexagonal array of larger maxima and minima. It arises from the mismatch between the Pt(111) substrate lattice and that of the graphite adlayer.

In the STM images of the single layer of graphite on Pt(111) surfaces, only three of the six carbons in the graphite rings are visible. As mentioned in Section 1.6, this sheds new light onto explanations for the contrast in STM images of bulk graphite; it had been reasoned that only 50% of the carbon in the surface of bulk graphite is imaged due to interactions with the underlying graphite planes.[47] The C_2H_4/Pt(111) STM results now challenge this explanation.

8. Concluding Remarks on the Impact of STM in Chemistry

The physics of tunneling microscopy is contributing to chemistry in diverse ways. The limited width of the probing stream of tunneling electrons (on the order of angstroms) focuses directly on single atoms and the bonds between them. In this way, images are produced of atoms and molecules ranging from phthalocyanines and alkanes to alkylidynes. The method's means of deriving local and direct data from material renders information not only about regular, ordered arrays of atoms and molecules, but also about defects and anomalies in the bonds that hold them together, for instance, missing atoms in a crystal structure and a strained bond angle between a phenyl ring and its alkyl substituent.

For chemistry on the trace level, the STM allows focusing on a single layer of a species or on a submonolayer coverage of adsorbate. These are realms that are often untouchable for they fall below the detection threshold of most techniques.

The STM's role is not limited to passive analysis of chemical species. Instances of STM-induced change, intentional and unintentional, are appearing with increased frequency. The instrument has been used to rearrange matter, atomic unit by atomic unit, to create oligomers from single atoms or molecules, and to induce phase transitions.

Finally, there are many more chemical systems waiting to challenge the technique further into innovative and nonconventional uses. They await the collaboration of imaginative chemists and competent STM instrumentalists.

9. Introduction to the Atomic Force Microscope

Five years after the initial STM experiments, an STM was mounted in a novel configuration above a cantilever.[131] To the underside of the cantilever was mounted a fragment of diamond to act as a stylus. A sample, mounted on a piezo-driven stage, was then placed underneath the stylus and scanned in an x,y plane. Repulsive and attractive interactions between the stylus and the sample surface were registered as deflections in the cantilever and detected quantitatively by the STM positioned above. In this experiment the recording of surface structure directly, with the fine, subnanometer control of piezo devices, was expanded to include nonconducting samples, certainly a larger class of materials than those which conduct. In contrast to the STM, which detects a current of tunneling electrons between a scanning tip and a sample, the atomic force microscope (AFM) does not require electrically conductive surfaces. Instead, the AFM measures interactions between the scanned tip and the surface such as electrostatic, van der Waals, frictional, capillary, and magnetic forces. Like the STM, the measurements are localized, typically over areas nanometers in dimension. For studies of larger scale topographies, the same operating principles are applied with wider range scanners.

The range of samples investigated by AFM to date includes inorganic, organic, and biological materials, as well as technological samples. Since the instrument can be adjusted to sense specific forces, almost no class of materials is unsuitable for this technique, particularly as it is sensitive even to ubiquitous van der Waals forces. The force microscopes have

been adapted for a wide variety of environments as well. For example, since the instrument can operate reliably when the tip–sample interface is submersed in liquid, measurements have been made on operating electrodes,[132] hydrated proteins,[133, 134] and lubricated disks.[135] A number of reviews[2, 136–138, 142] address the rapidly growing presence of AFM in physics and chemistry; some have focused on biology.[74, 139] The emphasis in the following sections is on organic molecules and their assemblies.

To avoid confusion, it should be pointed out that this instrument was originally known as the AFM (*A*tomic *F*orce *M*icroscope). As its use expanded to include detection of forces on various scales and from various different sources, the nomenclature diversified. The term scanning force microscope (SFM) refers to the class of instruments which scan and collect data locally, and includes magnetic force microscopes (MFM), electrostatic force microscopes (EFM), friction force microscopes (FFM), etc. An attempt has been made to simplify the rapidly expanding number of acronyms by creating a generic term for both scanning force and scanning tunneling microscopes: SXM or SPM, for scanning probe microscopes.

9.1. Units

As with the discussion of length units presented earlier in the STM section, it is worthwhile briefly to review units of force and pressure, and their associated energy, before entering into a discussion of techniques that meddle with these parameters.

The force exerted by the measuring AFM probe is in the range of 10^{-9} to 10^{-6} newtons. A newton (N) is the force which imparts to a body of 1 kg an acceleration of 1 $m s^{-2}$. To put this in perspective, an apple on a tree experiences a force due to gravity of about one newton.[140] Typical stylus profilometers exert a force of $\sim 10^{-4}$ N on the samples surface.

An object that is configured as a spring or a cantilever has a characteristic spring constant (or force constant) from which the force exerted by the spring (cantilever) can be calculated. For example, a piece of aluminum foil, cut to a size of 4 mm × 1 mm, has a spring constant of 1 $N m^{-1}$.[142] A Slinky toy displays approximately the same spring constant. A bond between two atoms can be viewed as a spring, with a typical spring constant of 10 $N m^{-1}$ (determined from vibrational frequencies). Typical AFM cantilevers have spring constants of 0.1–100 $N m^{-1}$.

Pressure is defined as a force applied over a certain area: for example, 1 $N m^{-2}$. The units of pressure have the area term already incorporated: 1 $N m^{-2}$ = 1 pascal (Pa) ($\approx 10^{-5}$ atm; $\approx 7.5 \times 10^{-3}$ mmHg). In the AFM experiment, applied pressures are estimated from an approximated contact area between probe and sample: $\sim 10^{-9}$–10^{-8} N applied over 10–100 nm^2 gives pressures of ~10 MPa–1 GPa (10^7–10^9 Pa).

Finally, to put into perspective the magnitude of forces introduced to chemical systems during the AFM measurement, it is worthwhile to include units of energy and their relation to force and pressure. A joule (J) is the amount of energy expended to push with a force of 1 N over one meter (1 J = 1 Nm). (1 cal = 4.18 J and 1 eV corresponds to 100 $kJ mol^{-1}$.) The energy imparted by the AFM probe is estimated to be in the range of ~0.1–50 $kJ mol^{-1}$. This is calculated from a typical force of 10^{-9}–10^{-8} N applied over a vertical distance of 1–5 Å above a surface area of 25–100 nm^2 (which is 100–400 molecules in an end-on orientation with intermolecular spacing of 5 Å, as in Fig. 7 and 22). For comparison, examples of chemical bonding energies include van der Waals (~2 $kJ mol^{-1}$), hydrogen bonding (~20 $kJ mol^{-1}$), and covalent carbon–carbon bonds (~350 $kJ mol^{-1}$).[141]

Evidence that the AFM indeed operates within the energy range of 0.1–50 $kJ mol^{-1}$ is provided in examples of intentional modification of LB films with an AFM: assemblies of molecules held together by van der Waals forces can be disrupted and displaced by careful adjustment of applied forces in this energy range (see Section 12.5).

9.2. The Atomic Force Microscope

The AFM image is a map of information obtained from each point on a surface. A deflection in the cantilever is recorded over each *x,y* coordinate of the sample as it is scanned under the probe, a process which takes from several seconds to several minutes per image, depending on the scan size, the surface roughness, and the resolution. The *x,y*-registered data are then assembled into a 2-D surface map, much as described above for the operation of an STM. However, unlike the STM's map of locally recorded currents, the resulting image from the AFM is a map of forces detected over each point on the sample. This force map is interpreted as a reflection of the surface structure, be it magnetic, electrostatic, or geometric topography.

The contrast in an AFM topography image is based on an arbitrarily chosen gray scale to indicate the relative heights of features on a surface. High features are assigned light shades and low features dark shades. Analogously, in modified AFMs the gray scale is applied to whatever force is being measured; for example, with the friction force microscope, areas of high friction are assigned lighter shades and areas of low friction darker shades.

Forces of 10^{-13} N to 10^{-6} N are measured with the AFM. Typical forces in conventional profilometers are 10^{-4} N over submicron areas. Experimentally, the probing tip is attached to a cantilever-type spring (Fig. 1). During scanning, the tip/cantilever assembly deflects in response to forces sensed in the sample. A displacement sensor then measures those deflections (from the backside of the cantilever) which can be detected down to 10^{-2} Å. The first displacement sensor was based on electron tunneling.[131] Later, sensors based on optical interferometry,[143] optical beam deflection,[144] or capacitance[145] were introduced. Currently the most commonly used force microscope configuration incorporates optical detection methods, which facilitate alignment with the cantilever. Most of the cantilevers and tips in use today are produced by microlithography on silicon or silicon nitride. Cantilevers are designed with dimensions of ~100–200 μm in length, ~10–20 μm in width, and ~0.5 μm in thickness. Tips are typically a few microns high and come to a macroscopic point of ~108°, depending on the manufacturing methods and materials. Different shapes have been made for

special applications, for example, sharp tips are available with angles as steep as $\sim 20°$. The force constant and resonance frequency associated with this configuration are in the range of $\sim 0.1-100$ Newton m^{-1} and $\sim 1-100$ kHz, respectively. To avoid disturbances from ambient vibrations, mechanical designs strive to maximize the resonance frequency of the whole instrument, by keeping the assembled apparatus as compact as possible and incorporating a cantilever with as high a resonance frequency as feasible.

9.3. Coupled Atomic Force and Scanning Tunneling Microsope Measurements

Instruments that are able to measure tunneling current and forces simultaneously are being custom-built.[32, 146] One goal with these instruments is to distinguish between a sample's physical topography and its electronic structure. Another aim is to determine the role of pressure in the tunnel junction in obtaining STM images. Theoretical work is simultaneously evolving on the interrelation between tunneling and force in the several angstrom wide tunnel gap; for example, tip and sample deformation has been proposed in a model of tip–sample forces to explain the (anomolously low) barrier heights recorded in STM measurements.[147] Meanwhile, parallel studies to compare AFM and STM images of the same molecular system are proceeding;[25, 148, 149] for example, similar periodicities have been obtained by the two methods on liquid crystals, although the mechanisms by which the contrasts are generated remain unclear.[149] In a study on metal chalcogenides, AFM measurements have determined that hole formation during STM measurements is caused by abrasion with the scanning probe.[25]

9.4. Variations on the Atomic Force Microscope's Operating Mode

Most scanning force microscopes operate under ambient conditions. More elaborate, customized systems incorporate UHV, controllable atmospheres, variable temperature capabilities, sophisticated software and electronics, and/or interfaces with other analytical instruments. Within the generic description of the operating principles of the scanning force microscope lie many variations. For example, the magnetic force microscope (MFM) incorporates a tip with a magnetic moment so that it can respond to the field of a magnetized sample.[150] In doing so, it can depict magnetic features such as bit patterns. An electrostatic force microscope (EFM) senses isolated charges on surfaces by monitoring the electrostatic interaction between a tip and charged sample.[151] This has proven fruitful, for example, in mapping charge on a polymer surface. In these latter two cases, the detection scheme of the AFM is modified to detect the longer range magnetic and electrostatic forces. Instead of measuring single deflections of a cantilever, a vibrating cantilever is used and the change in the resonance frequency of the cantilever is measured as it interacts with the field imposed by the sample. In this mode, the probe is not in physical contact with the sample, and resolution is possibly more limited, for example, to tens of nanometers.[152] For higher resolution studies, short range forces are detected by operating the AFM in the contact mode. In this mode, repulsive contact forces between tip and sample are monitored. Although the dimensions of the tip are nearly macroscopic (terminating tip radius of ~ 300 Å, height of ~ 3 μm), an attempt is made to limit the point of contact with the sample by applying very small forces to the tip ($\sim 10^{-10}$–10^{-8} N).

9.5. Topography Measurements: Principles

As with scanning tunneling microscopy on organic molecules, theoretical explanations for the rapidly expanding body of AFM experimental results are evolving simultaneously.[153, 154] Models of the interface between the AFM probe and the sample surface include interrelated surface and intermolecular forces.[138, 155] The former are classified under the phenomena of capillary action, adhesion, friction, etc. The latter are derived from attractive van der Waals and repulsive interactions. Ultimately, at the scale that most contact AFM measurements are made, these two regimes merge.

The AFM can be operated in the noncontact, attractive mode or in the contact, repulsive mode. Most of the topographic images of organic systems collected with the AFM have been recorded in the contact mode. Under these conditions, the repulsive part of the Lennard–Jones potential describes the interaction of two bodies as they are brought within several angstroms contact, the model gap for the interface between the AFM probe and the sample surface. The $1/r^{12}$ distance dependence of this repulsion forms the basis for the AFM's ability to detect force gradients over small intermolecular distances. Several calculations have been performed, based on idealized tip and surface interfaces of several atoms,[153] and extending to larger areas over which an exchange of tip and substrate atoms is proposed during plastic deformation.[154] Much work remains to be done in the field.

As with the STM, the possibility that the measuring instrument itself induces the observed results must also be considered, since the estimated, locally applied pressures can be as high as a gigapascal (see Section 9.1). This value is comparable to hydrogen bonding of ~ 20 kJ mol^{-1} and attractive van der Waals forces (dispersion forces, ~ 2 kJ mol^{-1}) that hold molecules together in non-covalent assemblies.[141] Indeed, examples of surface modification with the AFM are increasing, particularly in studies aimed at microlithography (see Section 12.5).

9.6. A Related Technique: Surface Force Apparatus

Finally, it is important to relate the results from the atomic force microscope to those of the surface force apparatus (SFA) since they arise from the same or similar phenomena.[108, 128, 129] The SFA is an arrangement of two cylindrical surfaces placed at right angles to each other to provide a molecularly smooth, small contact area (10^{-4}–10^{-1} mm^2). Samples are placed within this juncture and the force between the two surfaces is measured interferometrically as a function of the thickness of material between them. These

measurements enable the tracking of many properties down to the molecular scale where interesting nonlinearities can occur. For example, when the viscosity of a liquid is studied from the bulk down to the monolayer, a transition to solid-like behavior can be detected for the last layers.[129] Results like these serve to reinforce the caveat about linear scaling of properties from the bulk to the monolayer.

10. Atomic Force Microscopy of Inorganic Materials

As in the case of STM, the preponderance of AFM studies has been performed on materials which would be classified as inorganic, although this is apt to change since AFM is compatible with an aqueous (biological) environment. Crystal lattice parametrs have been measured directly on free-standing, macroscopic crystals of salts and minerals. In the examples of NaCl,[156] LiF,[157] and AgBr,[158] the images are composed of regularly spaced features (4.0, 2.8, and 4.1 Å respectively) corresponding to every second atom in the lattice (Figure 19); that is, the observed periodicity indicates that the instrument is sensitive to only one of the two atomic species. In the AFM images of these ionic crystals, the features have been assigned to the larger of the two ions in the salt (Cl^- in NaCl, F^- in LiF, and Br^- in AgBr) based on a contact hard-sphere model of the crystal surfaces.[157] In contrast, both the anion and cation were observed in an AFM image of KBr performed in a UHV instrument run at liquid helium temperatures.[159]

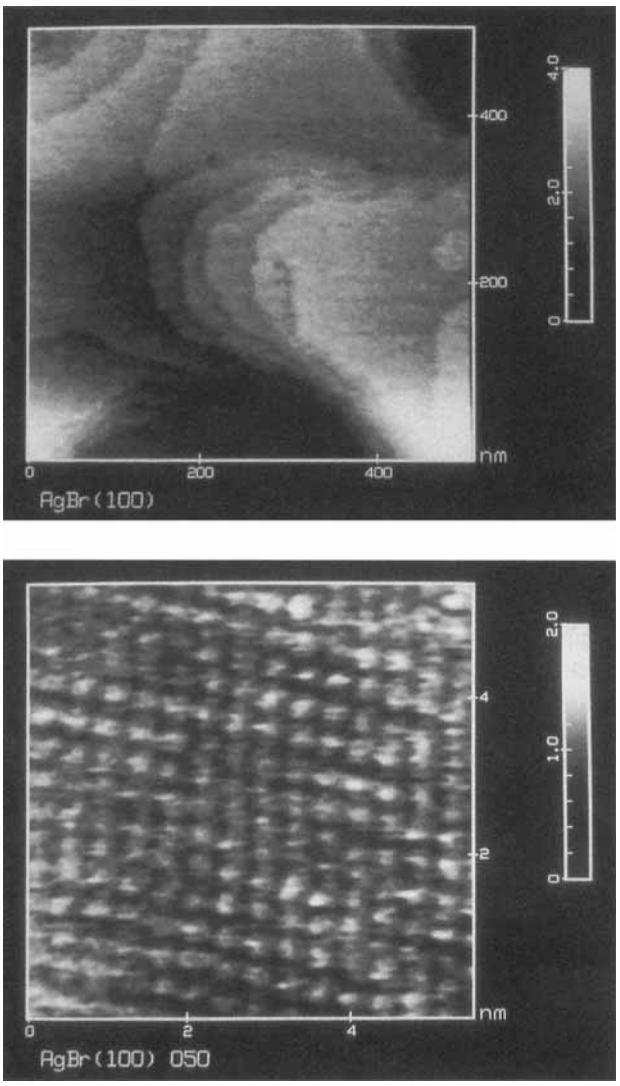

Fig. 19. AFM images of AgBr(100)[158]: a) Scanned area 500×500 nm^2. Crystal surface containing monoatomic steps (2.9 Å) and a screw dislocation (center). b) Scanned area 6×6 nm^2. Crystal lattice with spacing between repeated features of 4.1 Å, corresponding to every second ion in the crystal (presumably the bromine ions, see text).

AFM images of minerals such as the layered compounds mica[160] and molybdenite (MoS_2)[161, 162] contain interatomic spacings corresponding to the elements in the topmost layer of the cleaved samples. The upper layer imaged in MoS_2 was of sulfur atoms, while in mica it was of SiO_4 tetrahedra.

Atomic corrugation has also been observed in the AFM images of graphite,[162, 163] a layered material which has found great popularity as a substrate for STM imaging of organics.[76] AFM studies on the etching process in metal chalcogenides (e.g., $SnSe_2$, $NbSe_2$, TaS_2, SnS_2) correlate etch rates with applied forces and humidity.[25] The same study attributes surface modification to physical tip–sample contact in prior STM studies on the same materials.

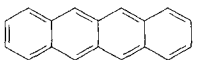
Other AFM studies on inorganic materials include boron nitride,[162] $TaSe_2$,[164] copper on gold,[132] and $ReSe_2$.[51]

11. Atomic Force Microscopy of Organic Materials

The first AFM studies of organic maerials were mainly on macromolecules, for example, fibrin[139] and polydiacetylenes.[165] In some cases, periodicities consistent with the intermolecular distances between smaller molecules (around 5 Å) have been observed, for example in crystals of the amino acid leucine.[166] Only recently have AFM results achieved the resolution needed to distinguish between different molecular orientations[133, 167] or to provide lattice information not already available by other methods.[168]

In the first example, a phospholipid membrane has produced images composed of repeat units with aspect ratios that correspond to the dimensions of individual headgroups (2 Å × 5 Å).[133] This reconstituted lipid is deposited on alkylated mica for scanning and maintained in an aqueous environment during the scanning.

The next examples have been generated in the context of addressing surface reconstructions in organic molecular crystals. Surface photonic processes, excitons, and nonlinear behavior have been implicated in investigations into the physics of organic solids; however, physical sources for these phenomena elude detection, in part due to difficulties in limiting sampling depths to the top layer(s) of molecules in crystals. A comparative study on several molecular crystals has demonstrated the AFM's ability to distinguish a reconstructed arrangement of atoms in a crystal surface from the crystal's internal atomic structure.[167, 168] In the course of a study of fused arenes, the surface of freshly cleaved crystals of tetracene (**8**) was shown to have lattice spacings that cor-



8

Table 2. Crystal lattice parameters of tetracene (**8**) and pyrene (**9**) from X-ray diffraction and AFM measurements [a].

Cmpd	Length of sides [Å]			Angles [°]		
	a	*b*	*c*	α	β	γ
8	7.90	6.03	13.53	100.3	113.2	86.3
	(8.0)	(6.3)				(85.5)
9	13.65	9.26	8.47	90.0	100.28	90
	(6.2)	(6.0)				(58)

respond to their bulk crystal parameters.[167] Table 2 contains the X-ray and AFM data for tetracene. In addition to confirming that the intermolecular spacing on the surface is the same as in the bulk,[169] the AFM image of the surface of tetracene also distinguishes between the two translationally nonequivalent molecules that make up the tetracene unit cell (Fig. 20). This ability arises from the interaction of the

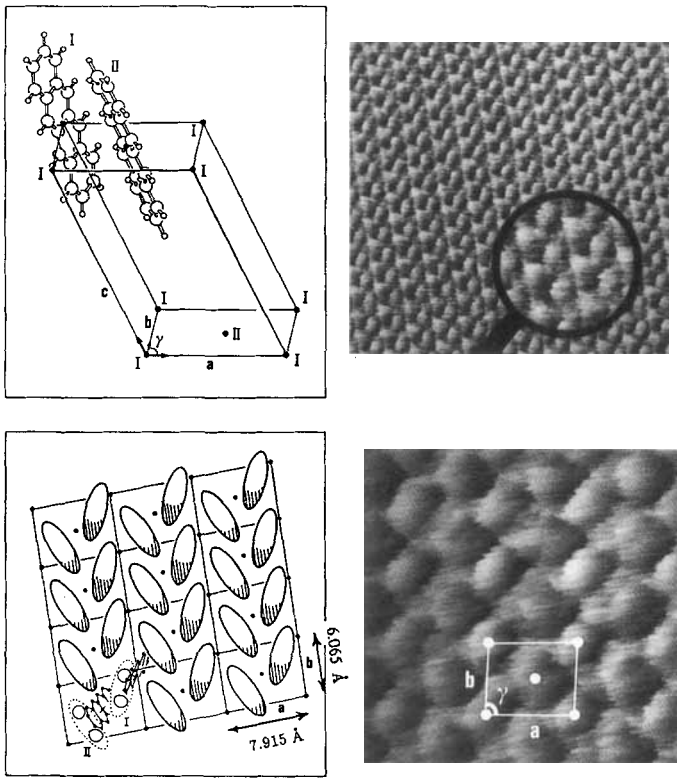

Fig. 20. AFM images and crystal packing of tetracene (**8**)[167]. Top: Scanned area 100×100 Å^2. The scanned crystal surface is the *a,b* cleavage plane. Rows are 8 Å wide, corresponding to the width of the unit cell. The magnified circle is an area of ~ 20 Å in diameter. Bottom: Scanned area 30×30 Å^2. The unit cell parameters measured on the surface of the crystal, marked on the image, correspond to those of the bulk (see Table 2).

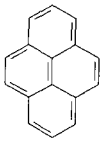
AFM probe with the two different orientations of the molecules in the surface of the unit cell: within the unit cell, they are not parallel to each other (the planes of their σ electron systems are roughly perpendicular) and their short axes intersect with the imaged *a,b* cleavage plane at two different angles. The AFM probe therefore "sees" different surface orientations for the two tetracene molecules: not only are their broad, flat σ systems not parallel to one another, but the molecules are tilted in such a way that their short axes present different angles to the scanned cleavage plane.

However, pyrene (**9**), a different tetracyclic arene, shows no such correspondence between the surface and bulk structure.[168] In the bulk, pyrene molecules exist in pairs with



9

lattice spacing of 8.47 Å and 9.26 Å in the *a,b* plane (Table 2). The two molecules of a dimer are separated by 3.5 Å.[170] AFM images of the surface of a pyrene crystal indicate no evidence of dimers; instead, the surface consists of monomers regularly spaced 6.0 ± 0.3 Å apart (Fig. 21, Table 2). Confirmation that the features are monomers is provided by the density of molecules on the surface: it corresponds fairly well to the surface density of molecules in the dimeric packing pattern. This change in molecular spacing on the surface is perhaps not surprising when the dielectric environment of the surface layer is compared to that of an internal, bulk site. Nonetheless, at present it is difficult to predict when and how a surface will reconstruct.[67] The bulk crystal data, together with the final surface configuration of molecules provided by the AFM, present us with the initial and final points of a physical process. Efforts are currently under way to model the pathway inbetween.

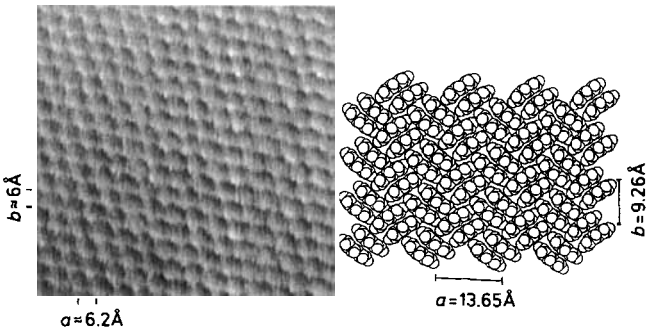


Fig. 21. AFM image (scanned area 100×100 Å^2) and bulk crystal structure of pyrene (**9**) [168,170]. Left: The scanned crystal surface is the *a,b* cleavage plane; however, the unit cell parameters measured on the surface of the crystal (marked on the image) do not correspond to those of the bulk. The surface density of the regularly spaced features in the image support an assignment of monomers to the surface species. Surface area per molecule ≈ 37 Å^2. The bulk crystal packing of dimers oriented perpendicular to one another, and lattice parameters are shown on the right for comparison [168,170]. Surface area per molecule ≈ 32 Å^2.

12. Specific Study: Atomic Force Microscopy on Organic Thin Films

Reports of tailored organic films are appearing with increasing frequency in the technical literature.[171] Often the films serve as models for more complex systems such as idealized membranes for protein adsorption and selective permeation. They are also used increasingly as molecularly

engineered systems for 2-D interfacial processes, for example, nonlinear optics and microlithography.

Films composed of amphiphilic molecules assembled into a high degree of order occur naturally in biological systems in the forms of membranes and micelles. Laboratory-made films are currently synthesized by a variety of techniques, including self-assembly and externally directed, ordered adsorption. Prominent among tailored films are Langmuir–Blodgett (LB) films: they are 3-D assemblies of 2-D ordered layers of amphiphilic molecules that can be made with high precision and reliability (Fig. 23).[171] Briefly, the LB technique involves orientation of amphiphilic molecules at a hydrophobic/hydrophilic interface on a fluid medium, followed by an orderly transfer of the molecules, in the form of a monolayer, from the fluid surface onto a dipped, solid substrate. Repeated dipping yields films of controlled numbers of monolayers. LEED, HREELS, RHEED (reflection high energy electron diffraction) and ATR-FTIR (attenuated total reflectance fourier transform infrared spectroscopy) are among the many analytical techniques that have provided structural information on the lattice structure of the films, such as orientations of molecular axes relative to the substrate plane and interplanar spacings.[171]

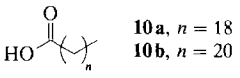
However, gaps exist in our knowledge of molecular systems on scales inaccessible to conventional analytical techniques. For example, some features go undetected because the samples are not crystalline or are too fragile to withstand sample preparation or incident radiation.[172] Furthermore, and perhaps most importantly, features that are randomly distributed throughout a sample elude detection by methods which average over different locations on a sample. With X-rays and related techniques, data is provided primarily from the ordered structures of crystalline domains.

The AFM shares with the STM the ability to access information on a very local and direct scale, over very small dimensions, from microns to angstroms. In doing so, AFM studies have provided thin film information on dimensions not available before, for example, degrees of coverage as manifested by boundaries, holes, and islands; step-heights in samples of mixed monolayers, bilayers, and multilayers; and well-defined interfaces, not only between films and air or substrates, but also between domains within multicomponent films (Section 12.8).

The development of the force microscope has benefited from the organic thin-film samples as well. These have not only provided the AFM a topography to study on both the atomic and macromolecular scale, but have also served as compliant objects for localized manipulation and friction studies. Such studies will also be discussed below.

12.1. Thin Langmuir–Blodgett films: a Bilayer or Two of Cadmium Arachidate

One of the more commonly studied Langmuir–Blodgett films is composed of the cadmium salt of arachidic acid (icosanoic acid, **10a**). For these particular AFM studies, the LB films were prepared as follows:[173] Silicon(111) wafer substrates are pretreated[173] to render their surfaces hydrophobic.[174] The fatty acid salt is deposited onto the silicon



10a, $n = 18$
10b, $n = 20$

substrate during the downstroke into the LB bath with the alkyl "tails" directed toward the hydrophobized surface and the carboxylate head groups away from the surface. On the upstroke of the dipping process, a second monolayer is deposited onto the first to give a bilayer film whose carboxylate headgroups are oriented toward the center of the film, and alkyl tails are oriented toward the two interfaces, with air and with the substrate (Fig. 22). The thickness of this film corresponds to approximately twice the length of the arachidate molecule (~54 Å). Double bilayers of ~108 Å thickness are obtained by performing the above process twice.

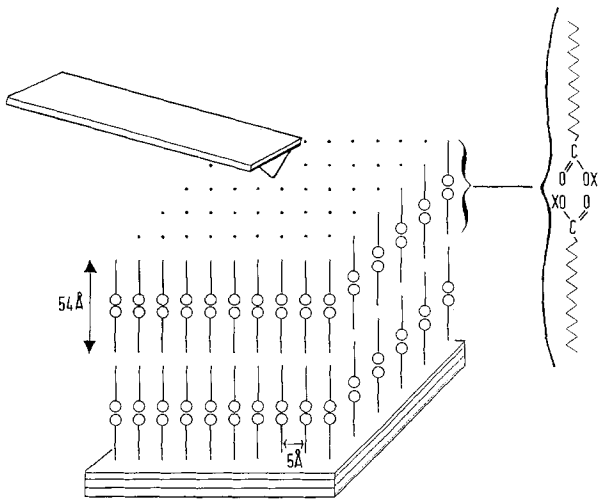


Fig. 22. Schematic representation of a Langmuir–Blodgett film being scanned by an AFM probe. The pictured film is a double bilayer of cadmium arachidate (**10a**) deposited onto a hydrophobized silicon wafer [175,189]. X = Cd, second anion omitted.

AFM images of the LB films of cadmium arachidate produced in this manner contain large expanses of smooth film over 95% of the sample surface (Fig. 23. See also

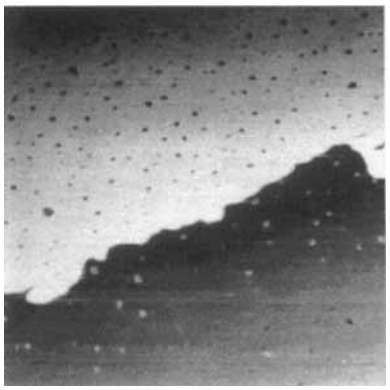

Fig. 23. AFM image (scanned area $3.5 \times 3.5\ \mu m^2$) of the edge of a double bilayer cadmium arachidate film. The flat terraces extend over microns, and cover ~90% of the substrate. A step height is 54 Å which corresponds to a bilayer. The steps are curved and have no preferential orientation. On the flat terraces pores are visible, and on the silicon substrate round islands are visible [175,177,186].

Fig. 26a).[175–177] These planes extend over hundreds of microns. The contours of the organic film on the inorganic substrate can be likened to a coastline. Film edges take on the appearance of geologists' topographical maps, with islands, inlets, peninsulas, and bays reflecting a fluid origin (Fig. 24). The similarity between geography over thousands of kilometers and over thousands of angstroms illustrates the fractal character of nature.

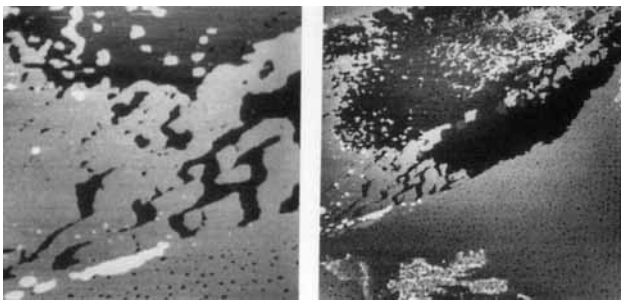

Fig. 24. Additional AFM images of the double bilayer cadmium arachidate films of Figure 23, showing long-range morphology and film boundaries. Islands of material scattered on the film's flat terraces have heights that are also of bilayer dimensions (54 Å). The contours of the film edges resemble coastlines viewed from an airplane [175, 177]. The scanned area in a) is $3.5 \times 3.5\ \mu m^2$ and in b) $10 \times 10\ \mu m^2$.

Step heights of both 54 Å and 108 Å can be observed, corresponding to single and double bilayers. This is particularly visible in larger scale images obtained on films with regions of incomplete bilayer coverage. Single monolayer steps of 27 Å are measured at single bilayer edges and in experiments where a bilayer has been intentionally "peeled apart" with the AFM probe (see Section 12.5).

Interspersed in the large, flat planes of cadmium arachidate are pores of one bilayer depth and 20–100 nm diameter (Fig. 23 and 24). On double bilayer films, pores are a bilayer deep, although occasionally a double bilayer depth is observed. These pores are difficult to detect with other analytical methods because they are randomly distributed; methods which sample over large dimensions in general average signals from regular film features, thereby producing data dominated by signals from the preponderance of ordered molecules. In the particular cadmium arachidate system studied, the total combined area of holes constitutes $\leq 10\%$ of the film's surface. Holes have been found in the surfaces of other Langmuir–Blodgett films, although hole-free films have also been observed (see Sections 12.4 and 12.8). The origin of these localized voids is currently not known. They could reflect bath composition, transferred to the films on deposition. Or they could form subsequent to deposition, for example, as a mechanism to lower surface energy at the interface between the ordered film structure and air or substrate. To resolve these issues, systematic studies on film formation and stability must be pursued. There is also plenty of opportunity here for studying the fundamental properties of 2-D crystals, and for performing molecular dynamics calculations.

12.1.1. Molecular Resolution

On increasing magnification of one of the broad, flat planes of cadmium arachidate, resolution on the scale of individual molecules becomes possible (Fig. 25).[175] Regularly spaced features, ~5 Å apart, are assigned to the methyl termini of the close-packed alkyl tails. The degree of accuracy of these measurements ($\pm 5\%$) does not allow a more rigorous assignment of space group to the observed pseudo-hexagonal packing of molecules. In fact, since the radius of the effective probing stylus tip probably does not lie in the subnanometer range, the ~5 Å molecular spacing is likely a local averaging over many angstroms, that is, over several molecules. However, observation of this 5 Å periodicity does indicate a degree of order in the films on the molecular scale. The packing density (area per molecule) of $24 \pm 2\ Å^2$ is in reasonable agreement with literature values for ordered cadmium arachidate films on metal single crystals (measured by LEED).[178] It is also in qualitative agreement with STM images recorded on LB films on ordered substrates of graphite and WS_2.[68] Apparently, the lack of local order in the surface of the silicon substrate does not prevent ordering of the molecules into regular arrays close to the absorbate–substrate interface; dense and regular packing is recorded on the surface of a single bilayer, at a distance of ~54 Å from the silicon substrate. This observation of long-range order in extremely thin LB films on an amorphous surface demonstrates that the driving force for ordering from intermolecular interactions is great enough to overcome the influence of disorder from the underlying substrate surface.

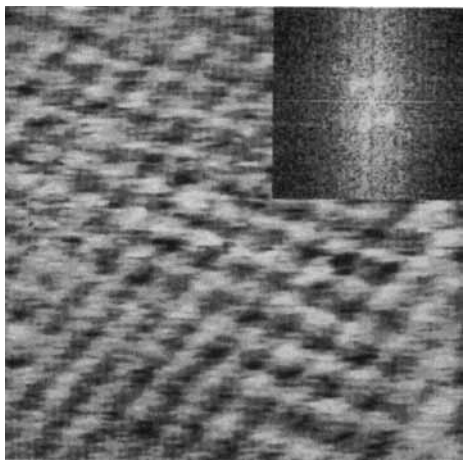

Fig. 25. Higher resolution AFM image, (scanned area $53 \times 51\ Å^2$), of the double bilayer cadmium arachidate film of Figure 23, together with its 2-D fast Fourier transform. The spacing between the protrusions is ~5 Å, which corresponds well to the intermolecular spacing of the alkyl tails (see Fig. 22). Another example of atomic resolution on an LB film is given in Figure 28 [175, 177].

12.2. A Thicker Langmuir–Blodgett film: Cadmium Behenate

LB films prepared from another fatty acid, the cadmium salt of behenic acid (**10b**) have also been examined by

AFM.[179] The cadmium behenate films are thicker than those of cadmium arachidate discussed above: seven bilayers deposited on a hydrophobized silicon substrate.[180] Again, widespread, flat, close-packed films are recorded over a hundred microns (Fig. 26a). In a scan of $100 \times 100\,\mu m$, most evident in the overall flat film are large-scale, irregular "cracks", 10–40 μm long, and all oriented in the same direction. At higher magnification ($5 \times 5\,\mu m$) these cracks turn out to be shallow, only a bilayer deep and 0.5–1 μm wide (Fig. 26b). The bottom surface of a crack shows a similar

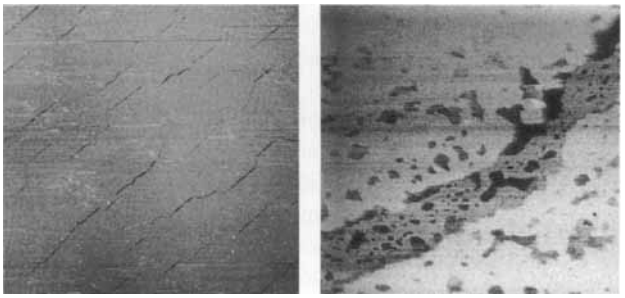

Fig. 26. AFM images of a Langmuir–Blodgett film composed of seven bilayers of cadmium behenate (**10b**) on hydrophobized silicon [180]. a) Scanned area $100 \times 100\,\mu m^2$. A long-range, very flat morphology is observed, interrupted regularly with nearly unidirectional cracks. b) Scanned area $5 \times 5\,\mu m^2$. Increased resolution of the cracks show them to be only one bilayer deep. The scattering of bilayer-deep holes recorded in this film is often observed by AFM in LB films [177, 182].

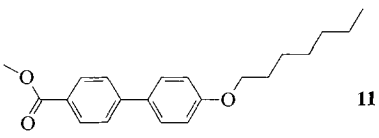
morphology of distributed, irregular holes as the upper surface of the film. The origin of these cracks is not yet known. They could arise during deposition, or later on aging or sample handling.

12.3. A Comparative Film Quality Study on Langmuir–Blodgett films of Liquid Crystals

In a preliminary study comparing the surface structure of two films composed of the same molecules but of different thicknesses, the use of the AFM in tracking qualitative film differences has been demonstrated. The LB technique used in preparing the previous two examples of fatty acid films has been applied to another class of molecules, liquid crystalline alkoxybiphenylesters.[181] Crystalline films of the heptoxy derivative, 4′-*n*-heptoxybiphenyl carboxylic acid methyl ester (**11**), on hydrophobized silicon have been made for AFM studies in two thicknesses: 12 and 20 bilayers (~480 Å and ~800 Å, respectively).[179, 182]



11

Differences in the AFM images from these two samples allow comparison of relative film quality (Fig. 27). For example, a $5 \times 5\,\mu m$ image of the surface of the 12-bilayer film shows the now-familiar, continuous, flat film, interrupted occasionally by holes of one bilayer (40 Å) depth.[182] Images of the 20-bilayer film also exhibit the "hole" morphology. But the thicker film also displays scattered "islands" on the film surface, one bilayer high and 100 nm to 500 nm in diameter. These islands might arise from impurities in the film peparation. Although these two thicknesses of 12 and 20 bilayers represent only two points along a continuum of film-forming steps, a comparison of their images illustrates the utility of the force microscope in tracking film quality during the film-forming process.

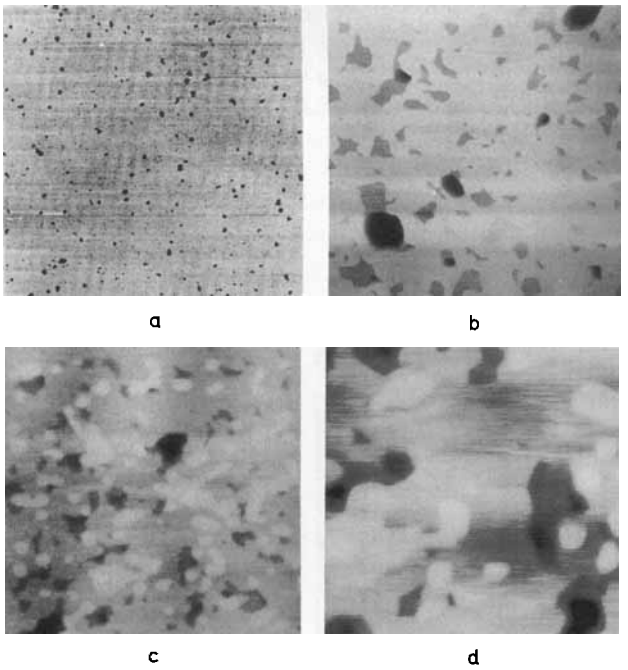


Fig. 27. AFM images of Langmuir–Blodgett films of the liquid crystalline alkoxybiphenylester **11** of different thicknesses and histories [181]. a) Scanned area $50 \times 50\,\mu m^2$. A 12-bilayer film showing overall flat morphology, punctured regularly with holes that are mostly of one bilayer depth (40 Å). b) Scanned area $5 \times 5\,\mu m^2$. Smaller scan area of a). c) Scanned area $5 \times 5\,\mu m^2$. A 20-bilayer film showing, in addition to the flatness and the bilayer-deep holes of the 12-bilayer film, islands of extra material, also one-bilayer high. d) Scanned area $2 \times 2\,\mu m^2$. Smaller scan area of c) [182].

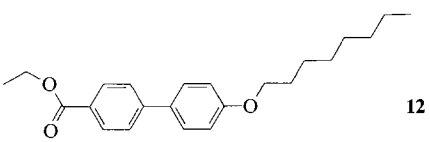
12.4. Transferred, Freely Suspended Films

A similar alkoxybiphenylester molecule to that of the two LB films of the previous section has been handled in another manner to produce a different type of film.[183] A thin film of a two-dimensional fluid of the octoxy derivative, 4′-*n*-octoxybiphenyl carboxylic acid ethyl ester (**12**), is drawn across



12

an aperture at 100 °C to create a freely suspended film,[184] which is then transferred to a hydrophobized substrate,

Fig. 28. AFM images of freely suspended liquid crystalline films, transferred to a hydrophobized silicon substrate [182]. The molecule **12**, an alkoxybiphenylester, is similar to **11** of the LB film of Figure 27, but with minor modification of the substituents [183, 184]. a) Scanned area $5 \times 5\ \mu m^2$. Flat, hole-free, irregularly shaped planes of films are observed. The overall film thickness is ~18–22 nm, corresponding to 8 layers. Layer steps (24 Å) are also measured. b) Scanned area $50 \times 50\ \mu m^2$. In a large-scale image, part of the film resembles a peninsula. The scan also shows the surrounding exposed silicon substrate. Note scattered small islands on the substrate (see text). Darker, square features superimposed on the shore of the peninsula are the result of local manipulation experiments, such as those performed in Figure 30 and described in Section 12.5 [182]. c) Scanned area $12 \times 12\ nm^2$. Molecular resolution, from which lattice constants of 7.3 Å × 5.8 Å with an angle of 71° between them are measured. (Measurement bars superimposed on image.)

cooled, and examined under the AFM in its crystalline phase.[182, 183] Unlike the previously discussed films, these are hole-free. Large, flat planes, microns across and ~18–22 nm (8 layers) thick are observed (Fig. 28). These planes are irregularly shaped and overlayed, resembling ice floes. A measured step height of 24 Å is consistent with layer spacing from X-ray measurements,[182] which corresponds to the length of the molecule. The adjacent surface of the fused quartz (hydrophobized) is widely and randomly dotted with islands. These might arise from the substrate itself, the silanizing agent (octadecyltrichlorosilane), or the film.[186] Molecular resolution on one of the flat film planes yields unit cell dimensions of 7.3 Å × 5.8 Å with an angle of 71° between them. These values are not totally consistent with electron diffraction measurements obtained from this film, which indicates substrate effects or surface rearrangements.[182]

12.5. Local Manipulation

The AFM cantilever is chosen to be "soft" enough to detectibly respond to interactions with the scanned surface, yet "stiff" enough to reversibly maintain its integrity – that is, to be able to return to an equilibrium position between interactions. By modifying the cantilever specifications and/or the scanning conditions, the AFM can be transformed from a relatively passive imaging tool into an active modifying tool. For example, incorporation of stiff cantilevers and tip modulation techniques have led to a system for "plowing through" a polycarbonate film (Fig. 29) in order to write lines, dots, and features on the submicron scale of the cantilever tip.[187, 188] Other examples of localized plastic deformation have been demonstrated on actin filaments and AgBr.[134, 177] Sometimes the features created by the AFM probe are unstable and rearrange to more stable surface configurations. When this occurs on the time scale of the AFM measurement (1 frame of ~250 scans min^{-1} over nanometer dimensions), the AFM can be used to monitor the kinetics of diffusion.[177] Metal-coating an AFM tip has allowed lithography to be performed with linewidths of 70 nm on a photoresist. This was done by applying a bias across the polymer, between an underlying gold film and the metalized tip while scanning.[187c]

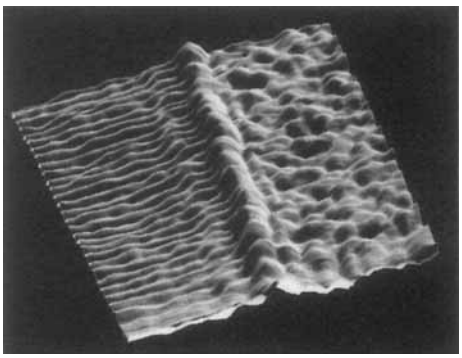


Fig. 29. AFM image (scanned area $1.35 \times 1.35\ \mu m^2$) of a pattern created in a polycarbonate film with an AFM probe. The traces are created by the lateral movement of a lever tip under an applied force (10^{-7} N) higher than that required for imaging. After the pattern is created, its image was recorded under a lower applied force of 5×10^{-9} N. An individual trace is typically 10 nm deep and 70 nm wide [188].

When scanning conditions are changed to increase both the applied force (from 10^{-8} to 10^{-7} N) and scan rate (from 0.5 to 5 $\mu m\, s^{-1}$), holes one or two layers deep can be intentionally introduced into the cadmium arachidate LB films of Section 12.1.[189] Figure 30 shows areas of 0.5–1 μm dimension which have been plowed aside in the top bilayer of the double bilayer of cadmium arachidate discussed above, exposing the bilayer below. Further application of this abrasive technique to the lower bilayer produces holes two bilayers deep and exposes the silicon substrate below. Thus a two-tiered hole with tier heights corresponding to a bilayer thickness has been produced (Fig. 30c).

The film has been observed to respond to this deformation in two ways: either by amassing piled-up debris (typically one bilayer thick) at the hole's edges (Fig. 30b) or by decreasing the density of naturally occurring holes in the vicin-

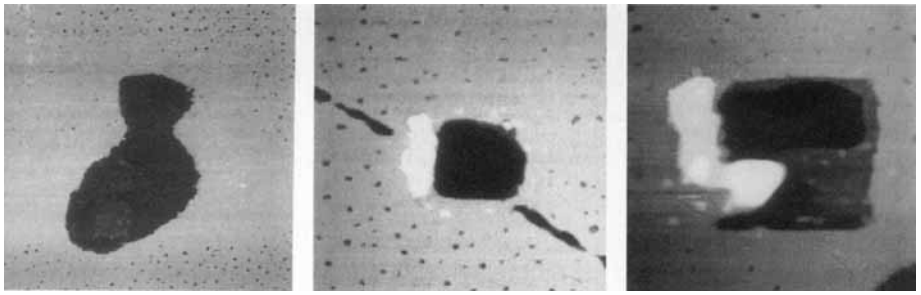

Fig. 30. AFM images of manipulations performed in the double bilayer cadmium arachidate films of Figures 22–25 [175, 177]. a) Scanned area $3.5 \times 3.5\ \mu m^2$. An intentionally scribed hole that has changed its contour over the period of several hours. Note the decrease in pore density surrounding the hole. This decrease could be a result of the pores' role as shock-absorbers during the process of creating the holes with the AFM probe. b) Scanned area $3 \times 3\ \mu m^2$. An intentionally scribed hole superimposed on a naturally occurring linear defect in the film that originates in the substrate. Note that the displaced material from the hole-forming process is amassed at the hole's edge. It is typically one bilayer high. c) Scanned area $1.35 \times 1.35\ \mu m^2$. A hole-within-a-hole. The first hole is created by removing one bilayer over $\sim 0.5 \times 0.5\ \mu m^2$, exposing the underlying bilayer. A second hole, $\sim 0.25 \times 0.25\ \mu m^2$ is then scribed in this underlying layer, exposing the underlying substrate. Displaced film is piled up at the left edge of the hole.

ity of the intentionally scribed hole (Fig. 30a). In this latter mode, the holes appear to behave as "buffers" or "shock absorbers", taking up the extra displaced material within the plane of the film. Some holes made in the cadmium arachidate films have been observed to diffuse and even coalesce over several hours.

Holes one monolayer deep have also been made, when the starting surface is covered by only one bilayer. In this case, the adhesion between substrate and the first monolayer is strong enough to allow removal of the top half of a bilayer without disrupting the bottom half. In all, layers have been "sheared" with an AFM at various levels: between bilayers, within bilayers, and between the substrate and the first bilayer.[177] Relative adhesive strengths can be ordered from these comparative studies, which demonstrate a relative increase in adhesion on going from interplanar, to interlayer, and finally to interfacial interactions. Additional shearing experiments have been performed on multilayer films composed of different classes of molecules, for example, comparing fatty acids,[190] alkoxybiphenyl acid esters,[182] and fluorinated alkanes.[191] These studies show that film composition affects the ease with which intentional modifications in the film are made with the AFM stylus.[189]

12.6. Very Local Friction

The ability of the AFM probe to locally displace adsorbate from the substrate produced a new sample surface – a heterogeneous surface of inorganic silicon and organic bilayer. This surface then became the object of a study using a slightly modified AFM,[190] a friction force microscope (also called the lateral force microscope, LFM) which measures simultanously the lateral and normal deflections of a cantilever-type probe.[192] In this configuration, the microscope's cantilever and detection scheme are constructed to allow measurement of forces acting against the lever that are parallel to the scanned plane,[193] in addition to the more common normal force detection mode in which only lever deflections perpendicular to the sample surface are recorded. Normal deflections provide information on the topography of the surface. Lateral torsions and bending of the cantilever provide information on elastic and inelastic (or, perhaps more accurately, adiabatic and dissipative) interactions with the sample surface. These measurements of lateral forces are of great interest in studies of lubrication and friction, often classified under the term tribology.[194]

The mixed surface of exposed substrate and organic adsorbate has been scanned, to measure both normal and lateral forces (Fig. 31).[177, 190] From the normal forces (Fig. 31a), an image of topography is produced in which two levels of film on an underlying substrate are evident; the contrast scales are assigned such that the upper film is light gray, the lower film is dark gray, and the underlying substrate is black.

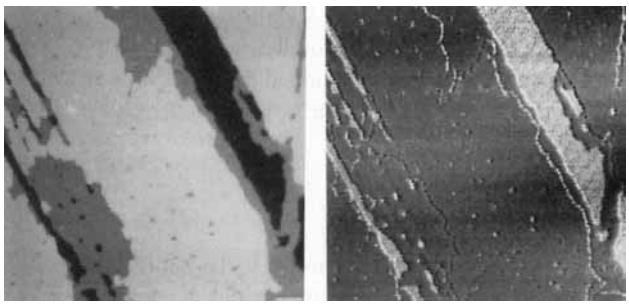

Fig. 31. AFM images recorded on the double bilayer cadmium arachidate films of Figure 23, simultaneously in the normal force mode for topography and lateral force mode for friction [190]. a) Scanned area $3 \times 3\ \mu m^2$. Topography image. Principally three levels are observed: the substrate (darkest), one bilayer (gray) and two bilayers (lightest). Most of the film is a double bilayer. The height difference between these levels corresponds to the thickness of a bilayer, ~ 54 Å. Occasional islands of extraneous bilayer are seen on top of the double bilayer. b) Scanned area $3 \times 3\ \mu m^2$. Friction image. The difference in the lateral force signals from the bilayer and double bilayer surfaces is small. In fact, often only at the interface (step) between these two is any contrast observed (and this contrast is due to torsion, not friction). However, the difference between the lateral force signal from the organic layers and that from the silicon substrate is significant (intensity ratio 1:10). Comparison of the normal and lateral force images demonstrates that the lateral force measurement is sensitive to material properties derived from chemical composition (see text).

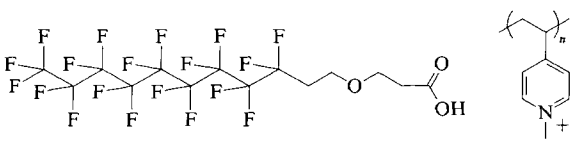
The difference in height between adjacent levels is 54 Å, consistent with the thickness of a bilayer cadmium arachidate LB film. Occasional, small islands of extraneous material are encountered on the top surface of the film. From this image, however, no compositional information is provided; that is, only the absolute height differentiates the lower substrate from the upper organic film. In contrast, the frictional force measurement (Figure 31 b) affords additional information about material properties of the surface from the interaction between the two components in dynamic contact with each other during the measurement: the probe and the particular area on the surface. In this measuring mode, the tip responds remarkably differently to interactions with the organic film and interactions with the silicon, shown as darker and light areas, respectively, in Figure 31 b. The lateral response to the organic film remains rather constant, whether on the single or double bilayer level. In fact, were it not for a lateral, torsional response to the edge of the upper bilayer during scanning (seen as thin contour lines at borders and spots at holes), the LFM image would be devoid of indication that a second bilayer exists. The frictional forces between the probe and silicon are approximately ten times those between the probe and the organic film, reflecting the difference in material properties of the inorganic and organic layers quite consistently. This order of magnitude reduction in friction on coating a surface with an organic layer is consistent with measurements made on boundary lubrication in the traditional materials science field of tribology.[194, 195]

Interpretation of these early images indicating local variations in the friction coefficient on both the micron and molecular scale is still preliminary. It will undoubtedly require previous knowledge of macroscopic phenomena such as "stick–slip" behavior in lubrication, and then modification for the unprecedented local scale of these measurements.

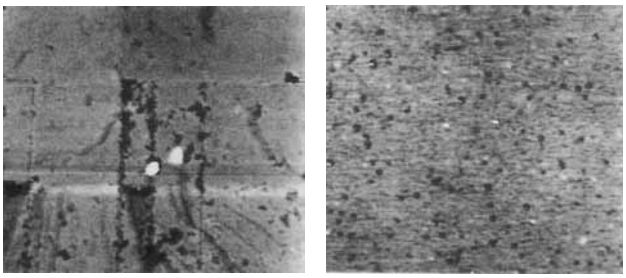
12.7. A Comparative Study: Fluorocarbon vs. Hydrocarbon Surface

Langmuir–Blodgett films assembled from fluorinated carboxylic acids have provided fluorinated surfaces with which to study the response of the AFM probe to a chemically modified surface.[191, 197] The representative films presented here have been synthesized according to established LB techniques from a partially fluorinated carboxylic acid **13**.[198] The subphase is *N*-methylated polyvinylpyridine (14).[199]



13 **14**

LB films of arachidic acid (**10a**) on the same polyvinylpyridine subphase have also been measured as a control experiment. Comparison of the behaviors of the two films—from the perhydroarachidate and the fluorocarbon terminated carboxylate—indicate a higher degree of cohesive in-plane binding within the fluorocarbon film (Fig. 32 b) than in the hydrocarbon film (Fig. 32 a). Distinctively different surfaces are recorded from the two films during the AFM measurements. The fluorinated film is characterized as resistant to deformation, robust, and fairly homogeneous. The hydrocarbon film is randomly defaced with cracks and holes, and is more deformable. Earlier studies on the mechanical properties of fluorinated Langmuir–Blodgett films also reported a better resistance to rupture during sliding than their hydrogen-containing counterparts.[196]



a b

Fig. 32. AFM images comparing Langmuir–Blodgett films composed of a normal, hydrogenated carboxylate **10a** to that of a partially fluorinated carboxylate **13**. Both films are prepared in the same manner with an *N*-methylated polyvinylpyridine **14** as subphase on hydrophobized silicon (100) [198, 199]. (See schematic drawing in Figure 33.) a) Scanned area $5 \times 5\ \mu m^2$. A film of perhydro arachidate (ions of **10a**) shows long-range, flat morphology, irregularly decorated with defects and holes. b) Scanned area $5 \times 5\ \mu m^2$. A film of partially fluorinated anions of carboxylic acid **13** shows long-range, homogeneous morphology.

12.8. Mixed Monolayers: Distinguishing Domain Boundaries

The ability of the AFM to document surface features on thin, somewhat fluid organic films has, by now, been well demonstrated in this article. One challenge lies in differentiating subtle features, such as compositional changes *within* a film. An ideal system to test the LFM for sensitivity to differences between materials is a mixed monolayer of two chemical species. Many issues are raised on constructing such films, including molecular miscibility and segregation into domains. How is the origin of bulk properties related to domain size: do localized properties of individual molecules or domains scale up to the macroscopic whole?

The localized properties of adhesion, elasticity, and friction have now been probed with a force microscope within single domains in LB films composed of mixtures of molecules with hydrocarbon and fluorocarbon moieties.[191, 197] A representative film is presented here, which is synthesized according to establish LB techniques from a 1:1 molar mixture of arachidic acid (**10a**) and partially fluorinated carboxylic acid **13**.[198] The subphase is *N*-methylated polyvinylpyridine **14**.[199] The mixed film is therefore composed of the two molecular species from the previous comparative study of fluorocarbon and hydrocarbon films. The mixed film images show distinct, phase-separated domains that have distinct properties (Fig. 33). From the topography image, boundaries within the film define circular, flat-topped

domains of 500 nm to 1000 nm in diameter that are ~16 Å higher than the surrounding flat film. Because of the difference in molecular lengths between the two component molecules (arachidic acid is ~25 Å long and the partially fluorinated carboxylic acid **14** is ~20 Å long), the higher, circular domains are assigned to the hydrocarbon. Further experiments with more closely controlled monolayers of the two components are under way.[191]

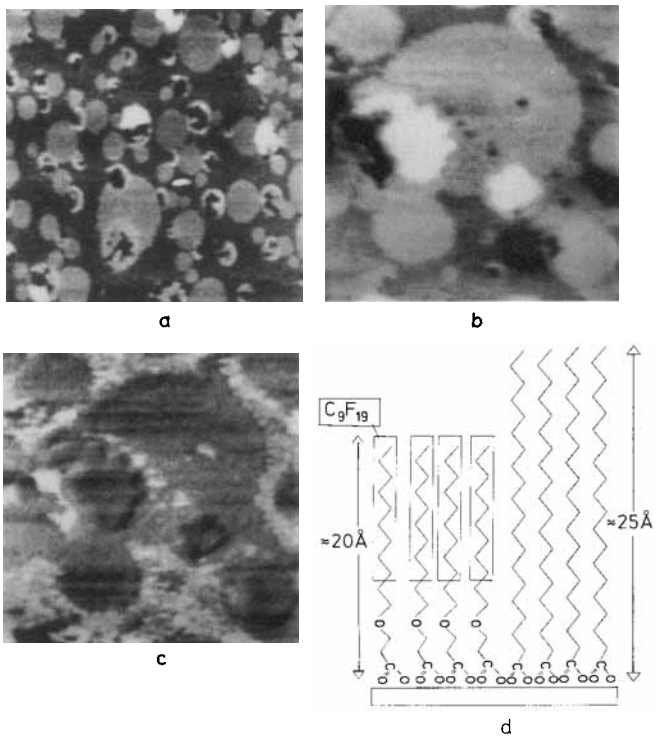


Fig. 33. AFM images recorded on a LB film comprising a mixed layer of the two components of the films of Figure 32: anions of perhydroarachidic acid (**10a**) and the fluorinated carboxylic acid **13**. The normal and lateral force modes are compared, each yielding different information [191, 197]. The accompanying schematic drawing is intended as a qualitative description of the LB film components, and neglects such features as tilt angles and intermolecular spacing. a) Scanned area $5 \times 5\ \mu m^2$. Topography image. Flat, circular domains are ~16 Å higher than surrounding flat film. They are attributed to the longer perhydrocarboxylate. Note that holes occur only in these hydrocarbon domains, consistent with the hydrocarbon film of Figure 31, and extend down to the substrate (darkest features). The surrounding flat film is hole-free, which supports its assignment as fluorocarbon (see Figure 31). Occasional islands are scattered across the films (highest, brightest features), the origin of which can not be identified from this topography image. b) Scanned area $2 \times 2\ \mu m^2$. Topography image on the same film as in a). c) Scanned area $2 \times 2\ \mu m^2$. Friction image recorded simultaneously over the same area as in b). Lateral force signal differentiates between the material compositions of the domains. The fluorinated regions respond with higher friction than the hydrocarbon domains (see text). In this recording mode, it is possible to ascertain the origin of the scattered islands since they give the same friction response as the circular hydrocarbon domains. The highest friction (brightest areas) is recorded over the silicon substrate, exposed at the bottom of the holes. The relative friction (hydrocarbon:fluorocarbon:silicon) in this sample is 1:4:10. d) Schematic representation of the composition of the mixed layer of anions of **10a** and **13** on a polymer with cationic centers.

Holes in the film are confined to the large, circular domains assigned as hydrocarbon domains; this is not surprising since in the control study above, only the hydrocarbon film shows evidence of holes while the fluorinated film remains fairly uniform. The holes in the mixed films are irregularly shaped, and extend down to the substrate (~50 Å deep). Using the AFM tip as an indenter reveals that the hydrocarbon regions are more deformable than the fluorocarbon regions, again consistent with the control films and an apparent higher in-plane binding among the fluorinated chains.

Lateral force measurements (Fig. 33c) indicate a fourfold higher friction over the fluorinated regions than over hydrocarbon regions. This perhaps goes against our social familiarity with teflon cookware (and labware); however, further studies on wettability will have to be carried out to bridge this gap between the macro- and the micro-world. On the scale of the AFM measurement, this higher friction on the fluorocarbon is accompanied by (and perhaps explained by) a higher local elasticity measurement. Higher elasticity could be explained by the greater stiffness of fluorocarbon chains. This result is supported by earlier investigations of sliding friction between monolayers in which fluorinated Langmuir–Blodgett films were found to have higher shear strengths than their hydrogen-containing counterparts.[196] These studies also reported that despite the high shear strengths, the fluorinated films showed good resistance to rupture during sliding – a result consistent with the observation that it is very difficult to puncture the fluorinated surfaces with the AFM probe.

Finally, scattered islands of 'extraneous' material appear in the topography image as higher (brighter) spots sitting atop the hydrocarbon domains (Fig. 33b). The lateral force image assigns these a hydrocarbon identity, based on their low friction signal identical with that observed from the hydrocarbon domains (Fig. 33c). This is an assignment of composition that is not possible in the topography mode, which tracks absolute physical features, nearly independent of the material make-up. Lateral force measurements reflect a more intimate interaction between the probe and the scanned surface, which reflects some material properties.

This final example of the mixed hydrocarbon–fluorocarbon films serves as an apt concluding study for the use of the AFM and its derivatives in the investigation of film surfaces. Surface topography of extensive planes, holes, and distinct domains are documented. These features are then embellished with compositional information from lateral force measurements that assign higher friction to fluorinated regions, and track impurities to hydrocarbon origin.[191, 197]

13. Concluding Remarks on the Atomic Force Microscope in Chemistry

In focusing on the last layer of molecules between two media, the effect of one material on the other can be assessed. This statement is of fundamental importance for friction and lubrication, adhesion and diffusion, or miscibility and phase separation. The AFM is entering into these and other disciplines, although it is reasonable to question just what properties and phenomena are being sampled on the molecular scale.

When scanning, the forces exerted by the probe itself must be questioned. Such a localized perturbation is difficult to corroborate with a second technique since most other techniques operate on a larger scale. Despite this lack of quantifi-

cation, researchers are taking advantage of the intentional physical displacement of material by the AFM probe to create tiny designer structures. This kind of localized manipulation of material has been performed on polymers, membranes, and salts.

The AFM's sensitivity to only the topmost nanometers of a material is at once a strength and a drawback. This superficial regime often eludes other analytical techniques which average over greater depths and lateral distances and require deconvolution of signals from reciprocal space. The AFM provides direct information about surface structure, down to the molecular scale. On an optimistic note, the downside of being confined to the surface layer(s) provides the challenge to the next generation of experiments to apply the fine, local resolution of AFM to the interior interstices of 3-D samples.

14. Concluding Remarks on the Impact of the Scanning Tunneling Microscope and the Atomic Force Microscope on Chemistry: The Emperor's New Clothes

The STM and AFM are able to provide information about molecular environments not directly observed before. The two methods are not redundant. They probe different properties on different scales. The STM probes electronic levels of atoms and molecules over a sampling area defined by the confined stream of tunneling electrons, on the order of 1 Å. From the STM one obtains atomic topography when electronic structure coincides with atomic structure. The AFM senses forces originating in surfaces: van der Waals, magnetic, electrostatic, etc. The effective sampling area of an AFM is determined by the interactive area of the tip, typically hundreds of angstroms. From the AFM one obtains maps of molecular topography when local material properties, such as elasticity, coincide with molecular structure. The AFM can be customized to sense specific forces, thereby producing maps of, for example, charge distribution or friction over a surface. The STM has the potential of performing localized spectroscopy. In recording electronic structure over an atom or two, chemical analysis is added to the topographical information. The fact that the STM sample must be conducting, or in very close proximity to a conductor, places a limitation on what samples can be studied. With the AFM, this restriction is lifted, rendering the AFM more suitable for most organic materials, and biological systems. In particular, biological systems will benefit from the AFM's ability to operate in native environments, such as the physiological conditions under which in vivo processes take place.

Samples have been taken from the formal disciplines of catalysis, optics, surface science, and tribology. What the STM and AFM work from these seemingly diverse areas has shown is that on the molecular scale, the departmentalization becomes artificial, and the molecules are returned to their unclassified, bare selves. In this analogy to the fairy tale, "The Emperor's New Clothes", we have the opportunity to transcend the artificial boundaries between chemistry, physics, and biology and look instead for the commonality of properties on the molecular scale. This is not to over-simplify the beautiful diversity of materials, but rather to foster a wider perspective when thinking about the results that these instruments produce and about future systems for study.

Finally, both the STM and AFM are still in a stage of continuous development and change. Both have caught molecules in the act of dynamic processes, rearrangements and reconstructions of surfaces. The database of credible images is growing and will soon allow the identification of unknowns. This will be supported by the concomitant development of other localized probes coupled into the scan head that will provide elemental and spectroscopic information. The use of such combined and compatible techniques will enable us proudly to reclothe the Emperor.

I take great pleasure in acknowledging colleagues John Foster, Jackie Spong, Ed Barrall, Bob Twieg, Doug Smith, Wolfgang Heckl, Ernst Meyer, Rene Overney, Dario Anselmetti, Gero Decher, Doug Thomson, Masamichi Fujihira, Terry Lang, John Hemminger, and George Comsa for their fine technical abilities in operating the instruments and recording credible images, and/or for their enthusiasm and encouragement in making inroads for these new instruments into chemistry. I would also like to acknowledge the helpful input of my colleagues and my family's perseverance during the writing of this article. The support of IBM Research and The University of Basel (H.-J. Güntherodt) is gratefully acknowledged.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications. Many have become classics of the chemical literature. The 30 year review index was compiled to provide easy access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last pages of the German and English editions.

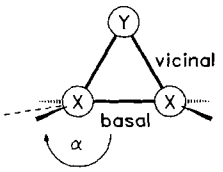
The electronic version of the index is available on 5¼" and 3½" diskettes and costs DM 98.00 or sFr 96.00 (plus shipping costs). This is your last chance to order a copy of the **printed version.** In order to clear out our warehouse we are selling the remaining lot for the reduced price of DM 48.00, £ 19.00, or sFr 41.00 (plus shipping costs). Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28. U.S. customers please contact VCH Publishers, Inc., 303 N.W. 12th Avenue, Deerfield Beach, FL 33442-1788; Telephone 1-(800) 422-8824; Telefax (305) 428-8201.**

Compounds with Three-Membered Rings Containing Boron

By *Hansjörg Grützmacher**

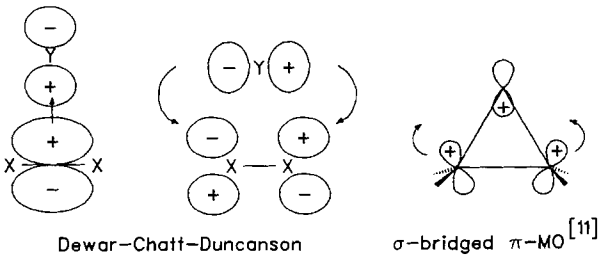
Apart from the well-established cyclopropanes, a series of homologous cyclopropanes of the general formula X_3 ($X = CR_2$, SiR_2, GeR_2, SnR_2) has also been prepared in the last few years. Several derivatives of these compounds, obtained by replacing a ring building block X by a different one (Y, e.g., CR_2, SiR_2, NR, O, S, Se, Te), have also been structurally characterized.[1-6]

Common features of the molecular structures determined can be summarized as follows: if a ring building block X in an X_3 three-membered ring is replaced by a heteroatom or a group Y of greater electronegativity, the basal X–X bond is shortened. Within a series X_2Y this reduction in the bond length increases with increasing electronegativity of the ring building block Y. At the same time the angle α, a measure of the planarization at the basal atoms, increases (Scheme 1).



Scheme 1.

The unusual molecular properties of three-membered rings have stimulated numerous quantum chemical studies. In accordance with the Dewar–Chatt–Duncanson model developed for transition metal–olefin complexes, the bonding in heterocyclopropanes can be described in a simplified way as a π complex of the X=X unit and the ring building block Y (Scheme 2).[7] The observed shortening of the basal X–X

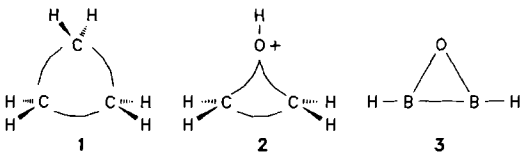


Scheme 2.

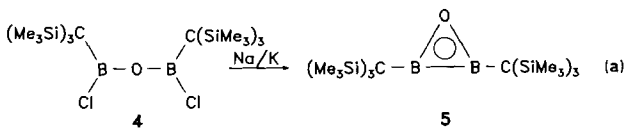
bond with increasing electronegativity of Y is therefore considered to result from reduced backbonding from an occupied p(Y) orbital into the π^* orbital of the X=X unit. Alternatively, the molecular structures of three-membered rings can be explained by a high contribution of the "σ-bridged π orbital" in the bonding molecular orbitals.[11] Cremer and Kraka have translated this "molecular orbital model" into an "electron density model" for three-membered rings.[8] In qualitative agreement with the π complex model a deformation of the σ electron density is found, which is reminiscent of that of a π bond and which is delocalized in the plane of the three-membered ring (surface delocalization). The path of the maximum (valence) electron density (MED), however, does not agree with the nucleus–nucleus axes Y–X and X–X, but takes a bent course.

It is possible to distinguish between cases with outwardly (convex) and inwardly (concave) bent bonds. Cyclopropane **1** is an example for the first case and protonated oxirane **2** an example for the second.[8a] Therefore, a short distance between the nuclei in the X–X unit is not necessarily a result of particularly high π character in this bond, but of a strong bend. In actual fact, the calculated length of the bent C–C and Si–Si bond in the series of heterocyclopropanes agrees well with those of the corresponding single bonds.[1] In both models it is possible to establish simple rules, which allow the prediction of the geometries of heterocyclopropanes as well as substituent effects.[8b, 10]

According to calculations by Allen et al. the parent compound of the oxadiboriranes $(HB)_2O$ (**3**) has a remarkable geometry.[11] The calculated B–B bond length in **3** is only



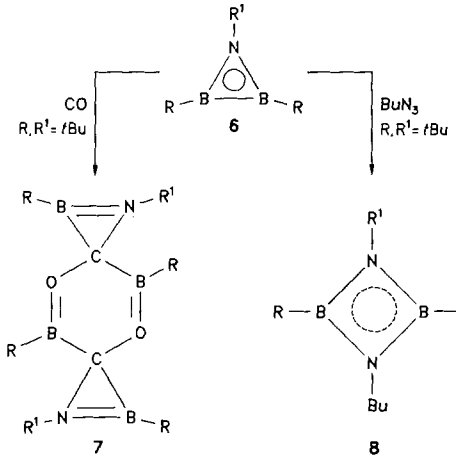
1.594 Å and the H-B-B-H grouping is almost linear ($\alpha = 173.9°$). Paetzold et al. have now been able to synthesize the first alkyl-substituted oxadiborane **5** in a rather a simple way [Eq. (a)].[12] They started from a chlorine-substituted diboryloxide **4**, which was coupled reductively with sodium/potassium alloy to give **5**. Previously, Nöth et al. and also Paetzold et al. sucessfully prepared azadiboranes **6**;[13] however, these either had amino groups (isopropylamino;



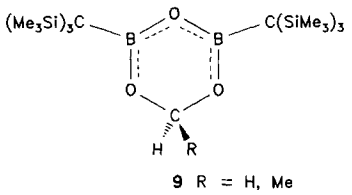
2,2,6,6-tetramethylpiperidino) at the boron atoms which interact strongly with the electronically unsaturated boron atoms, or the crystals were not suitable for an accurate structural investigation. Also in **5** the oxygen atom is disordered with respect to the crystallographic C_2 axis; nevertheless, the ring geometry can be determined accurately enough. In good agreement with the calculations a very short B–B bond

[*] Priv.-Doz. Dr. H. Grützmacher
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-W-6900 Heidelberg (FRG)

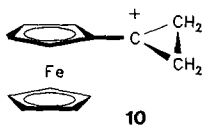
(1.60 Å) and an almost linear C-B-B skeleton (177.7°) are found. The B–O distances are not that well reproduced (obsd B–O 1.55, 1.52 Å; calcd B–O 1.409 Å). The packing of the B-O-B three-membered ring in the sheath of the very bulky, lipophilic $(Me_3Si)_3C$ ("trisyl") substituents, however, transforms it into a chemical "rock": in contrast to the remarkably reactive azadiborirane **6**, R = R^1 = *t*Bu, **5** does not react with O_2, H_2O, CO, azides, BH_3, phosphanes, or alkynes. The reaction of **6**, R = R^1 = *t*Bu, with CO leads to the tricyclic product **7**, whose structure with two B-N-C



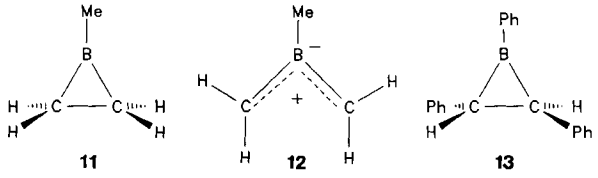
three-membered rings is confirmed by an X-ray structural analysis.[14] With azides the azadiborirane ring can be expanded to give diazadiboretidine **8**. Only reactions of **5** with formic or acetic acid to give **9** (R^2 = H and Me, respectively) were observed.



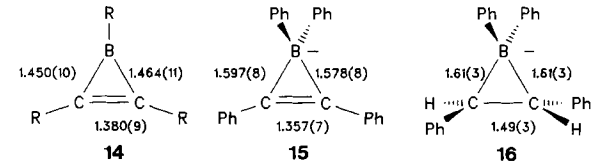
On the basis of the isolobal analogy B $\leftrightarrow$ C^+, boriranes are related to cyclopropyl cations. The latter generally isomerize exothermically ($\Delta G = -38$ kcal mol^{-1}) to give allyl cations. An exception is the most recently prepared cyclo-



propyl cation **10**, which, because it is stabilized by a ferrocenyl group, can be studied by NMR spectroscopy in solution at −60 °C.[15] Methylborirane (**11**) is in contrast 27.5 kcal mol^{-1} more stable than its isomer **12**.[16] Denmark et al. recently reported indications for 1,2,3-triphenylborirane (**13**) with a thermal stability (>150 °C).[17]



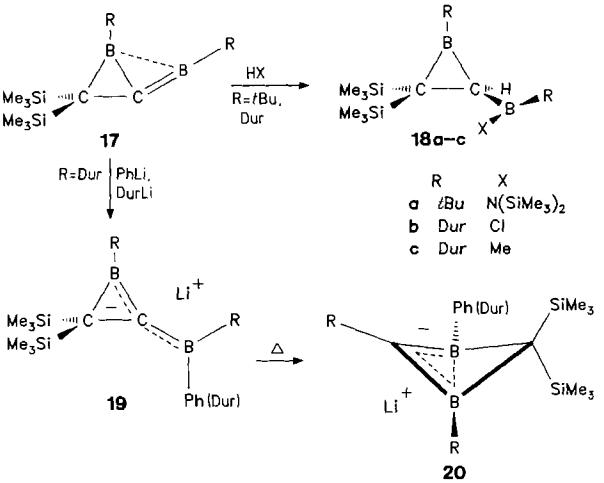
Following the synthesis and complete characterization of the three-membered ring compounds containing boron, **14**, **15**, and **16** (Scheme 3),[18, 19] Berndt et al. have now success-



Scheme 3. The C_2B ring compounds **14**–**16** with the relevant experimentally determined B–C bond lengths [Å] given. R = 2,4,6-trimethylphenyl.

fully prepared the first boriranes **18a–c** from the borandiylboriranes **17a,b** (Scheme 4). The molecular structures of **18a** and **18c** have been confirmed by X-ray crystal structure analysis.[20]

The new three-membered rings **18a–c** supplement the family of the heterocyclopropanes with an example in which a significantly more electropositive ring building block Y = BR replaces a more electronegative X = CR_2. Furthermore, an R_2B group as strong π acceptor is connected to a ring carbon atom. The structure determined experimentally with a highly extended basal C–C bond (1.636 Å) is in agreement with the theoretical results. Thermally (60 °C, 46 h),

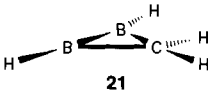


Scheme 4. Dur = 2,3,5,6-tetramethylphenyl.

18a rearranges into a *C*-borylaminomethyleneborane, and at higher temperature (120 °C, 4 h) the borirane **18c** rearranges into a 1,2,3,4-tetrahydro-1,3-diboranaphthaline. The authors explain these results by the cleavage of a ring bond (basal C–C bond, or C–B bond) opposing the R_2B substituents, but in both cases the proposed rearrangements leave enough room for speculation.

Finally, Berndt et al. have reported the first unequivocal proof of a negatively charged homoaromatic system **20**, which they obtained from the thermolysis of **19**, the addition product of aryllithium compounds to the borandiylborirane **17b** (Scheme 4).[21] The fact that this compound actually possesses the cyclic delocalized π bonding system of a homoaromatic compound with 2π electrons is revealed by NMR spectroscopy. In comparison with **19** the signal due to the tricoordinate carbon atom in **20** is shifted to lower field by about $\Delta\delta = 60$ (**20**: $\delta = 162.9$; **19**: $\delta = 106.0/110.6$). The crystal structure was determined by X-ray structural analysis. The C_2B_2 ring is folded about the B–B axis by roughly 33°; the transanular B–B distance (1.792 Å) is in the range of bonding B–B interactions. The energy barrier $\Delta G^{\neq}$ (176 K) for ring inversion was estimated by dynamic NMR spectroscopy at approximately 7.9 kcal mol^{-1}. The experimental results were supported by ab initio calculations [fold angle 34°, B–B distance 1.859 Å; ΔE (ring, folded)$-\Delta E$ (ring, planar) $= -7.4$ kcal mol^{-1}, $\delta(^{13}C) = 169$ (IGLO)]. The somewhat lower calculated bond order of the 1,3 interaction relative to that in the homocyclopropenium ion (0.23 vs 0.40) can be attributed to the lower electronegativity of the boron atom in comparison with the carbon atom.

Molecular chemistry is alive! Together with the authors of the papers discussed we look forward to and eagerly await new boron-containing three-membered rings. The synthesis of a diborirane **21**, in particular, now seems to be almost



21

within reach. For this compound the calculations predict a carbon atom with a planar coordination geometry.[22]

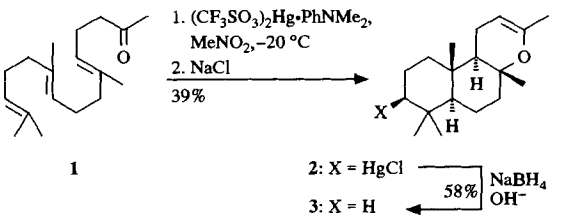
Cascade Cyclizations

By *H. Martin R. Hoffmann**

Cascade cyclizations, also called tandem, zip, or domino reactions, are multiple consecutive cyclizations which have fascinated organic chemists for more than 35 years. Several reasons account for this interest. Rings are not built up tediously step by step, but convergently in one fell swoop. Proper induction and termination of the cyclization cascade provide a major challenge, as does stereocontrol over the generation of several new chiral centers. To this end, a suitable tether must be constructed, the conformation and stereoelectronics of which facilitate coupling and ring closure.

Multiple consecutive cyclizations can be triggered by stoichiometric and catalytic amounts of reagents. Biomimetic cascades of cations which follow the biogenetic isoprene rule,[1] were among the first reactions of this type to be studied. Thus, many functionalized polyenes containing 1,5-diene units have been cyclized to give higher terpenes.[2]

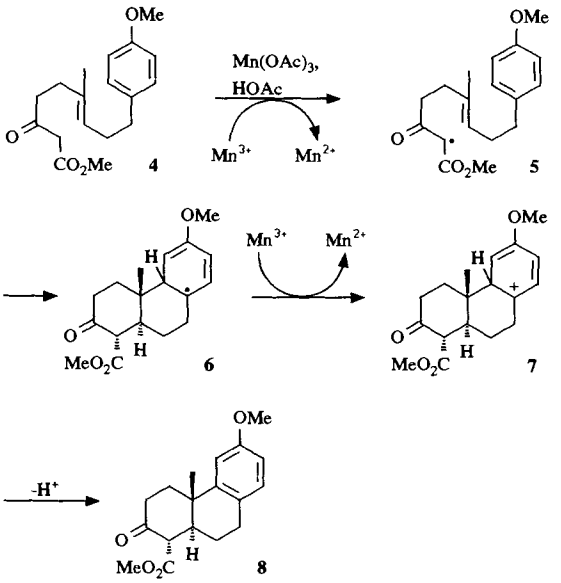
Recently, these reactions have been terminated in a novel way with internal oxygen nucleophiles such as carbonyl, hydroxyl, and β-ketoester groups. For example, *trans,trans*-farnesylacetone (**1**), readily available from farnesol, was submitted to the Nishizawa cyclization protocol[3] with mercuric triflate/*N,N*-dimethylaniline to give sensitive endocyclic enol ether **2**, capable of surviving in the presence of the electrophilic trigger. Demercuration of **2** furnished sclareol oxide **3**,[4] a well known constituent of clary (*Salvea sclarea*) which fulfills Ohloff's syntriaxial rule[5] and is used as a precursor of ambergris odorants.



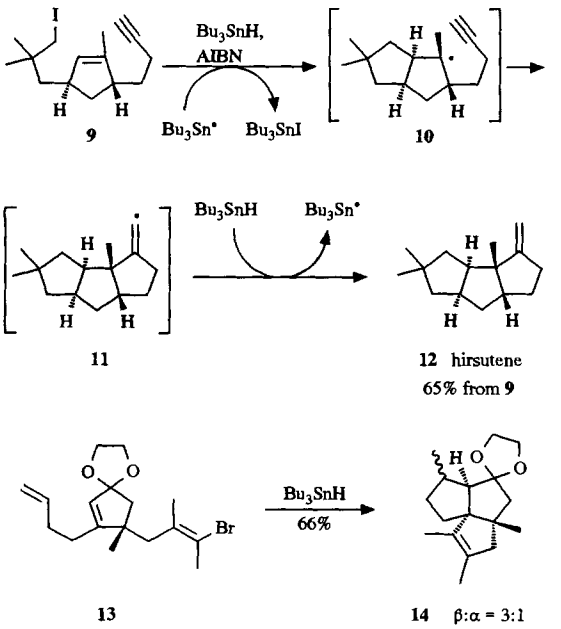
More conventionally, tandem cyclizations of polyenes have been initiated with a variety of other electrophiles including protons, bromine cations, Lewis acids,[2] sulfenium ions (from methyl benzenesulfenate $PhSOCH_3$ and BF_3[6]) and benzeneselenenyl triflate PhSeOTf.[7]

In the 1980s radical reactions emerged as efficient processes for carbon–carbon bond formation in the synthesis of natural products. An oxidative cyclization is the central step in Snider's synthesis of podocarpic acid.[8] The reaction is induced by electrophilic radical **5**, which is generated from the enol precursor by a one-electron oxidation. Termination of the cascade is feasible by the oxidation of **6** to cation **7** and straightforward deprotonation.

Perhaps the best known tandem radical cyclizations terminating in radical rather than ionic fashion were developed by



Curran et al. and relate to the synthesis of both linear (**9** → **12**) (AIBN = azobis(isobutyronitrile) and angular triquinanes (**13** → **14**).[9] The formation of the less stable vinyl radical **11** from the more stable tertiary radical **10**



might seem surprising at first glance. However, the reaction is accompanied by loss of a weak acetylenic π bond and formation of a strong vinylic carbon–carbon bond. Furthermore, termination by hydrogen atom transfer affords a strong vinylic carbon–hydrogen bond (CH_2 = CH–H, ΔH^0 = 108 kcal mol^{-1}) which compares with ΔH^0 = 91 kcal mol^{-1} for the bond between hydrogen and a tertiary carbon atom. Thus, the success of the cyclization may depend on factors other than those in cationic cyclizations in which the stability of the cation generated on termination is often critical. It is also obvious that the stereochemistry of the vinylic bromide **13** (*E* or *Z*) is irrelevant to the success of the cascade, since the resulting vinylic radical is linear.

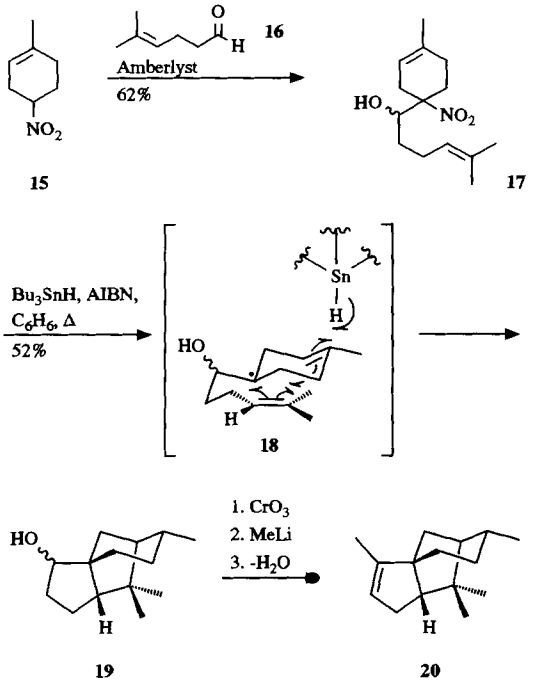
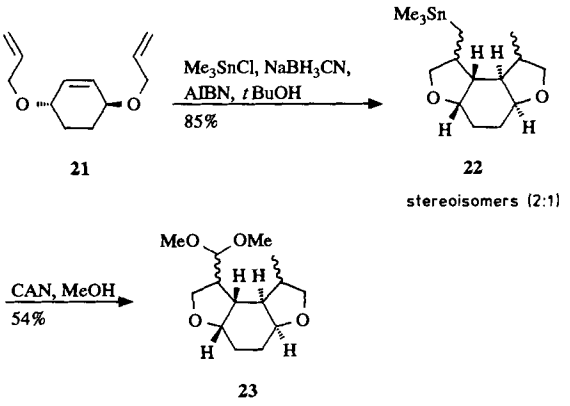
Recently, the cedrane skeleton **19** was constructed in two steps from nitroolefin **15** and the γ,δ-unsaturated aldehyde **16**.[10] As in the synthesis of **14** from **13**, the key step is the tandem cyclization **18** → **19**, consisting of consecutive 5-*exo*-trigonal ring closure reactions. Delivery of the hydrogen atom in the terminating step occurs antiperiplanar to the face of the double bond, resulting in an equatorial methyl group. As in the examples above, the two five-membered rings in **19** must be *cis*-fused, since a *trans*-bicyclo[3.3.0]-octane substructure would be too strained.

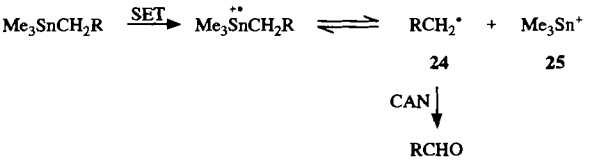
The synthesis of **19** also testifies to the synthetic versatility of the nitro group in reactions of three fundamental mechanistic types, namely, pericyclic, ionic, and free radical. Nitroolefin **15** is the Diels–Alder adduct of isoprene and nitroethylene. The nitro group not only activates the dienophile, but also controls regioselectivity ("*para*"). Nitroalcohol **17** is formed in an ionic nitroaldol reaction (Henry reaction). Finally, since the nitro group is attached to a tertiary carbon in **17**, it serves as a convenient leaving group in the generation of the tertiary radical **18**,[10] thus demonstrating excellent overall efficiency in the use of this one functional group.



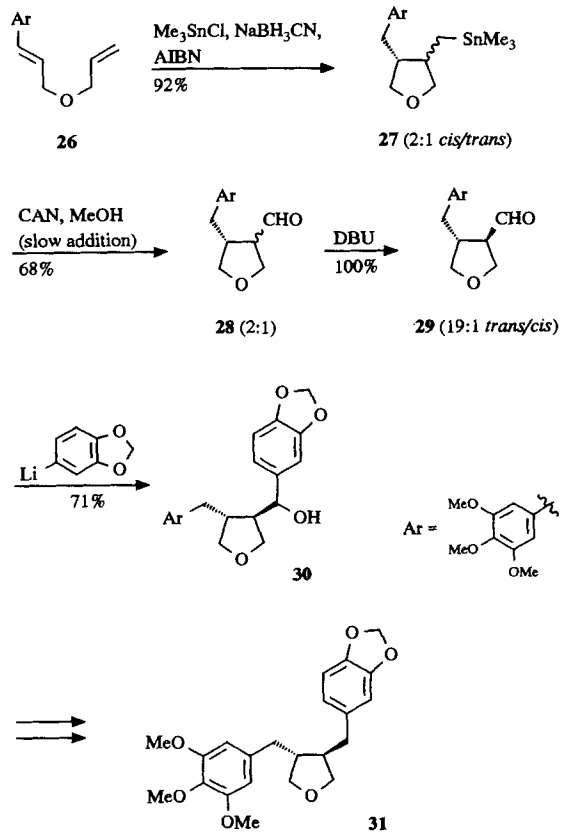
Hanessian and Léger[11] have recently cyclized a series of dienes and trienes with trimethyltin hydride Me_3SnH rather than Bu_3SnH. Me_3SnH is sterically less encumbered and therefore probably more reactive than Bu_3SnH. It has been generated conveniently in situ, from Me_3SnCl and $NaBH_3CN$, which is superior to the more reactive $LiAlH_4$ as a hydride donor. The (trimethylstannyl)methyl group in the cyclization product **22** does not lead the synthesis into a cul-de-sac, since this group can be converted into a masked aldehyde by a novel oxidative destannylation. The oxidation probably involves single-electron transfer (SET) from stannane to $(NH_4)_2Ce(NO_3)_6$ (CAN) to produce a (trimethylstannyl)methyl radical cation which disproportionates reversibly to the most stable radical, namely, the primary



radical **24** (rather than Me$^\bullet$) and trimethylstannylium ion **25**. Even if the double cyclization had been successful with Bu_3SnH instead of Me_3SnH, any differentiation of alkyl groups during the oxidation step would have been lost!

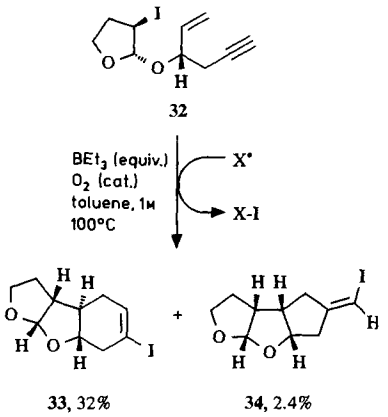


A monocyclization reaction was applied in the synthesis of the lignan antibiotic burseran (**31**).[12] Starting from 1,6-diene **26**, Hanessian and Léger prepared tetrahydrofuran **27**,



substituted in the 3 and 4 positions with typically the *cis* isomer predominating. Since tetrahydrofurans such as **27** and related five-membered heterocycles are usually difficult to obtain with substituents in the 3 and 4 positions, the radical route is very useful. Oxidation of **27** with CAN gave the aldehyde **28**, without attack of the electron-rich aromatic moiety or alteration of the ratio of isomers (2:1) of **27**. Further steps furnished (±)-burseran (**31**), which was also obtained enantiomerically pure when the racemic mixture was resolved at an earlier stage in the synthesis (DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene).

The stereochemical outcome of cyclization cascades such as **9** → **12**, **13** → **14** is dictated by the stereochemistry of the central five-membered ring which serves as a platform for the construction of two new rings. For example, for steric reasons radical **10** has little option but form *cis-anti-cis*-fused hirsutene **12** (cf. also **21** → **22**). In contrast, not only the conformation must be decided but also the choice between a C-C double bond and a C-C triple bond must be made in the reactions of the radicals generated from functionalized 1,5-enyne **32**, which has recently been shown to enter into radical-mediated, sequential 5-*exo*-trigonal, 6-*endo*-digonal cyclizations. The 6-*endo*-digonal closure is unusual in itself and requires heating to 100 °C. The overall reaction **32** → **33** + **34** is a cycloisomerization, that is, the radical chain is driven by iodine atom transfer. Interestingly, the cascade has



also been terminated by hydrogen atom transfer (with catalytic amounts of cobaloxime and $NaBH_4$) under milder conditions, that is at 50 °C. The tricyclic compound **33** arises from an "abnormal" boat transition state with transoid pseudo-axial substituents, whereas formation of compact dioxatriquinane **34** requires a cisoid chair transition state. According to a CAS online search, both the tricyclic 5 · 5 · 6 ring system in **33** and the corresponding 6 · 5 · 6 ring system are new.[13]

Synthetic methods based on reactions of radicals have come of age and are now almost standard procedures for carbon–carbon bond formation.[14, 15] High chemoselectivity, stereoselectivity, and the possibility of working without protecting groups as well as taking advantage of umpolung provide new opportunities for using old compounds. In this fashion, the "reaction windows" of organic reactions are defined more clearly. Apart from many obvious and important practical applications and advantages, the intellectual base of organic chemistry has been broadened and strengthened decisively.

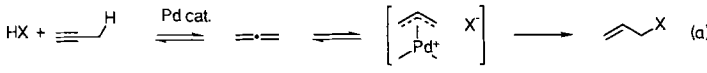
Intermolecular Additions and Cycloisomerizations by a Pd-Catalyzed Sequence of an Intramolecular Redox Reaction and an Addition**

By *Barry M. Trost,* Walter Brieden,* and *Karl H. Baringhaus*

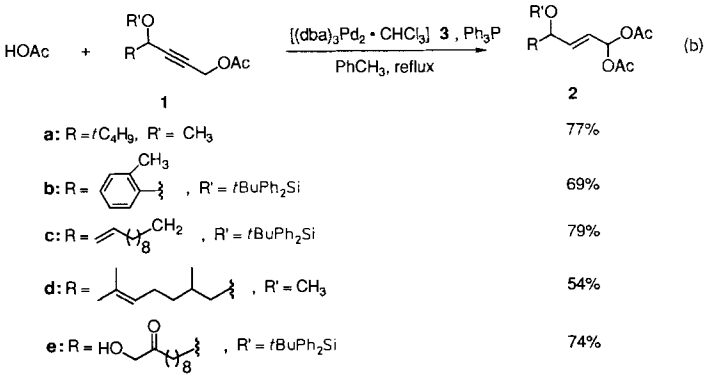
Adjusting oxidation states by intramolecular hydrogen shifts[1, 2] is more efficient and "atom economical" than conventional reduction/oxidation sequences in organic synthesis. Such hydrogen shifts may generate trappable reactive intermediates, ultimately leading to simple additions.[3] This fits in with our program to enhance atom economy[4]—that is, to minimize the number of atoms required in the building blocks of a reaction sequence and to maximize the use of processes that require only catalytic amounts of any additional reactants—and to generate macrocycles by cycloisomerization.[4, 5] Our previous work suggested that a hydridopalladium complex isomerizes acetylenes to allenes.[2a] We postulated that the latter may undergo a second hydropalladation to form a π-allylpalladium complex, which could undergo a subsequent addition [Eq. (1)]. This overall



(a)

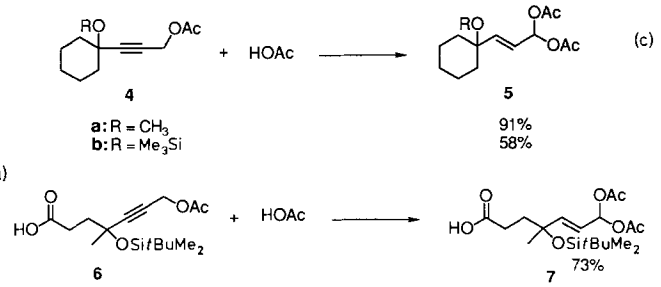
process would constitute an internal redox reaction and an addition. We wish to report the development of such a process whereby propargylic acetates are converted into novel allylic *gem*-diacetates.[7]

In initial experiments the propargylic acetate **1a** was treated with 2.5 mol% tris(dibenzylidenacetone) complex **3** and 35 mol% triphenylphosphine in toluene with 5 equivalents of acetic acid. The resulting geminal diacetate **2a** was isolated in 77% yield exclusively as the (*E*) isomer (proven by NMR spectroscopy) [Eq.(b)]. Only slightly lower yields (72%) were obtained with as little as 1 equivalent of acetic acid. A precipitous drop in yield (to 28%) resulted when a palladium complex with an acceptor ligand like trifurylphosphine was used. When complexes with bidentate ligands like bis(diphenylphosphino)butane (dppb) were employed, the reaction was shut down completely. Replacement of the methoxy group OR′ in **1a** with a siloxy substituent (**1b**) led again exclusively to the geminal diacetate product, in this case **2b**. In all the cases examined all the products were obtained as (*E*) isomers.

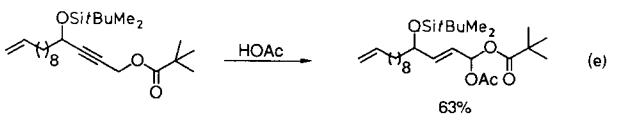


(b)

Reaction (b) exhibits excellent chemoselectivity. Neither double bonds (**1c** and **1d**), nor carbonyl and hydroxyl functions on the R group (**1e**) are affected. Compounds **4** and **6**, both derived from ketones, react as smoothly as compounds **1a–e** to give the corresponding geminal diacetates **5** and **7** [Eqs.(c) and (d)]. Remarkably, even compounds with carboxyl groups react analogously when 13 equivalents of acetic acid are used to suppress the intramolecular reaction with the acid function. Mixed geminal carboxylates such as **8** are also available [Eq.(e)].



(c)
(d)



(e)

Gratifyingly, this new sequence consisting of an intramolecular redox reaction and an addition may be performed intramolecularly in relatively concentrated solutions to gener-

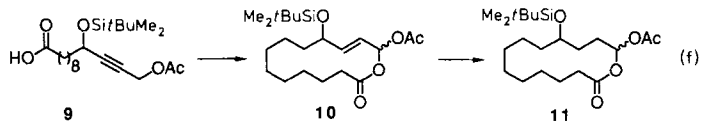
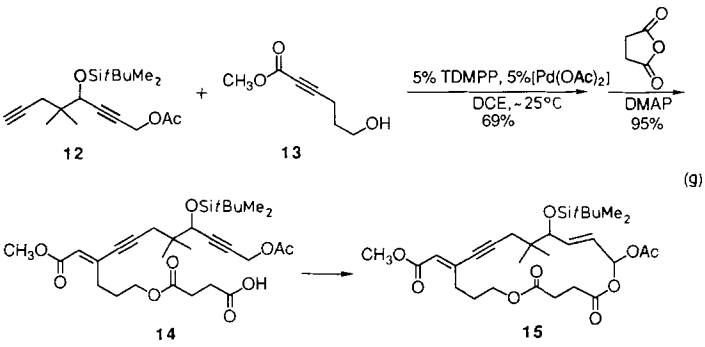
[**] This research was supported by the National Science Foundation, the General Medical Sciences Institute of the National Institutes of Health (NIH) and the Deutsche Forschungsgemeinschaft (stipends for W. B. and K. H. B.) The mass spectra were recorded at the Mass Spectrometry Facility of the University of California at San Francisco, which is sponsored by the Division of Resources of the NIH.

ate macrocycles [Eq.(f)]. For example, a 0.01 M solution of carboxylic acid **9** in benzene was heated at reflux with 3–5 mol% **3** and 30 mol% triphenylphosphine for 16 h to furnish the macrolide **10** in 52% yield as a 1.5:1 mixture of isomers. The 15.5–15.7 Hz coupling constants for the



9 10 11 (f)

olefinic hydrogens suggested that the product was a mixture of diastereomeric acetates, both with (*E*) geometry, rather than (*E*) and (*Z*) olefins. This conclusion was confirmed by the catalytic hydrogenation of the product mixture to a similar mixture of saturated isomeric macrolides **11**. The chemoselectivity of the cyclization is established by the reaction of diyne **14** [Eq. (g)], readily available from our Pd-catalyzed coaddition of the terminal acetylene **12** with ynoate **13**



12 13 14 15 (g)

(TDMPP = tris(2,6-dimethoxyphenyl)phosphine, DCE = 1,2-dichloroethene, DMAP = 4-dimethylaminopyridine).[8] The excellent yield of macrodiolide **15** (87–90%) illustrates the innocuousness of the normally reactive yneoate units in substrate **14** under these reaction conditions. The diastereoselectivity here (4:1) is higher than that observed in the cyclization leading to **10** and suggests that the diastereoselectivity depends upon substituents on the tether.

To our knowledge the Pd-catalyzed sequence of intramolecular redox reaction and addition described here leading to synthetically interesting geminal dicarboxylates is unprecedented. It stands in contrast to the Pd^0 catalyzed substitution reactions of propargyl carboxylates[9] and the Pd^{2+} catalyzed additions of carboxylic acids to triple bonds.[10] The isomerization of an alkyne to an alkene was reported recently, however, as the first step in the isomerization of alk-2-ynedi-1,4-ols to 1,4-dicarbonyl compounds.[2b] Rhodium and ruthenium complexes also have been reported to catalyze direct addition to triple bonds.[11] The new reaction described here also exhibits excellent atom economy and should allow access to highly functionalized macrolides.

Experimental Procedure

Acetic acid (0.150 mL, 2.62 mmol) was added to a solution of **3** (33.8 mg, 0.0327 mmol) and triphenylphosphine (89.1 mg, 0.340 mmol) in toluene (20 mL) at 20–30 °C. After 5 min **4a** (325 mg, 1.54 mmol) was added and the resultant mixture heated at reflux for 20 h. The reaction mixture was concentrated under vacuum and the residue chromatographed directly (silica gel, hexane/ethyl acetate, 10:1) to give **5a** (379.5 mg, 91% yield).

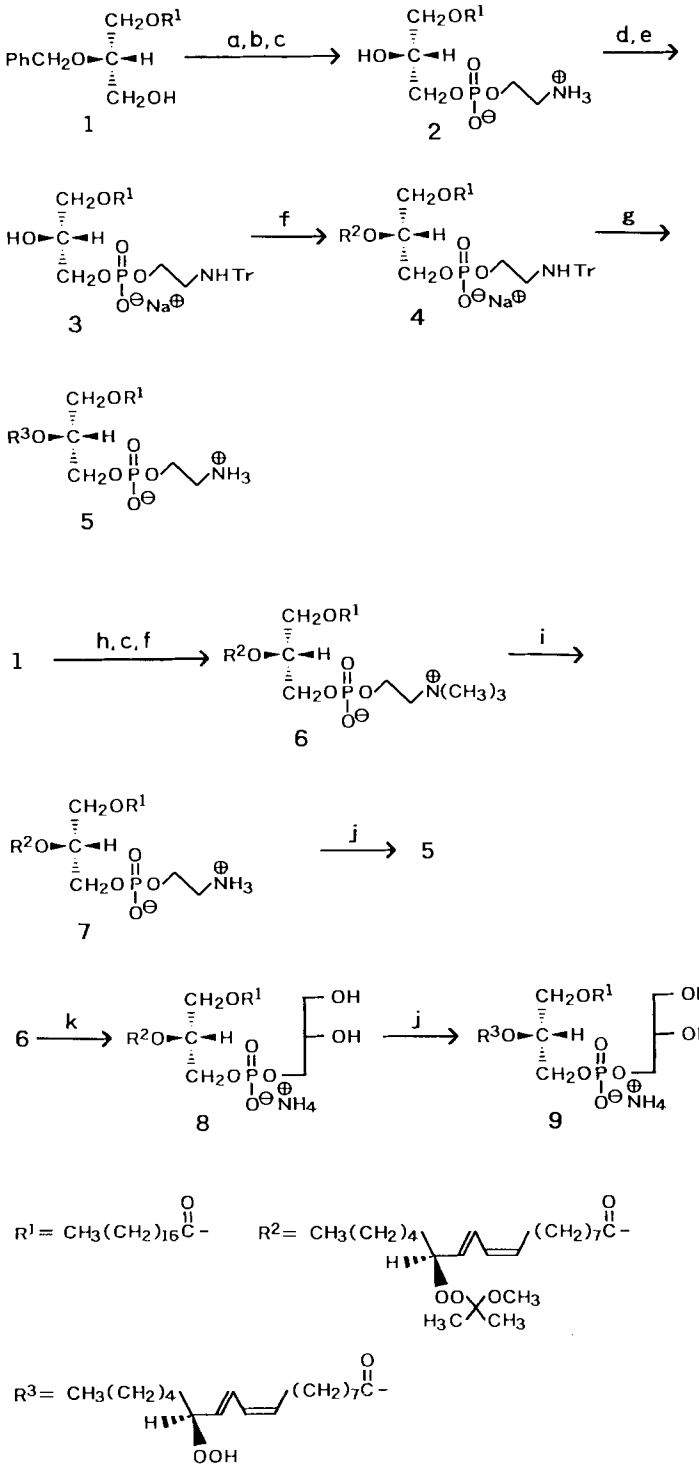
ously reported the synthesis of a phospholipid hydroperoxide, 1-stearoyl-2-[13-(*S*)-hydroperoxy-(9*Z*, 11*E*)-octadecadienoyl]-*sn*-glycero-3-phosphocholine.[2] Here we wish to describe the syntheses of optically active hydroperoxides of phosphatidylethanolamine and phosphatidylglycerol containing a hydroperoxidized linoleic acid moiety.



Scheme 1. Reagents for the syntheses of phospholipid hydroperoxides **5** and **9**. a) $POCl_3$, $H_2NCH_2CH_2OH$; b) H_3O^+; c) $H_2/Pd(OH)_2$; d) TrCl, NEt_3; e) Na_2CO_3; f) DCC, DMAP, R^2OH; g) $AcOH/H_2O/THF$ (4:1:5); h) $POCl_3$, choline tosylate; i) $H_2NCH_2CH_2OH$, phospholipase D; j) $THF/AcOH/H_2O$ (4:2:1); k) glycerol, phospholipase D. Tr = trityl, DCC = Dicyclohexylcarbodiimide, DMAP = 4-dimethylaminopyridine.

The synthetic routes to these compounds are shown in Scheme 1. Optically active 1-stearoyl-*sn*-glycerol **1** (100% optical purity) was prepared by enantioselective, lipase-catalyzed stearoylation of 2-*O*-benzylglycerol with vinyl stearate.[2] The optically active 1-stearoyl-*sn*-glycerol obtained was converted to 1-stearoyl-*sn*-lysophosphatidylethanolamine **2** according to the method of Eible.[3] The nucleophilicity of its amino group was decreased by tritylation, which afforded **3**. A hydroxy group of the phosphatidyl glyceride **3** was then esterified by the DCC method (DCC = dicyclohexylcarbodiimide) with 13-(*S*)-α-methoxyisopropylperoxy-(9*Z*, 11*E*)-octadecadienoic acid (96% optical purity), which was prepared from linoleic acid by the action of soybean lipoxygenase followed by the acetalization of a hydroperoxy group with 2-methoxypropene.[2] This esterification gave rise to **4** (24% yield from **2**). On treatment of **4** with a mixture of THF, AcOH, and H_2O (5:4:1) at 45 °C for 24 h, the acetal and trityl residues were simultaneously removed. The desired hydroperoxide **5** was obtained without any side reactions (83% yield). The hydroperoxide was purified by preparative thin-layer chromatography (TLC) on silica gel with a mixture of methanol, chloroform, and 28% ammonium hydroxide (15:30:2; $R_f = 0.6$) as eluent. The presence of a hydroperoxy group in **5** was confirmed by potassium iodide coloration, and its structure was deduced from the ^1H NMR and FAB mass spectra.[4]

The second route to **5** involved transphosphatidylation catalyzed by phospholipase D. The glycerol **1** was converted to the choline peroxide **6** as described previously.[2] In the presence of excess (58 mol equiv) of ethanolamine in acetate buffer (0.1 M, pH 5.6), **6** was treated with phospholipase D (153 units) from *Streptomyces sp.*[5] at ambient temperature for 3 h. Usual workup and isolation by preparative TLC on silica gel afforded **7**, from which the final product **5** was obtained by hydrolysis of the peracetal with a mixture of $THF/AcOH/H_2O$ (4:2:1). All the analytical and spectroscopic data of **5** prepared by the two synthetic routes were consistent.

Phosphatidylglycerol hydroperoxide **9** was also synthesized by a similar approach. The hydroperoxide **9** was purified by TLC with a mixture of methanol, chloroform, and 28% ammonium hydroxide [(70:130:1); $R_f = 0.48$] as an eluent. Its structural integrity was confirmed by ^1H NMR spectroscopy and FAB mass spectrometry.[4]

In conclusion, two kinds of pure, optically active phospholipid hydroperoxides **5** and **9** were synthesized for the first time through protection of the hydroperoxy group by acetalization and the amino group by tritylation, and subsequent simultaneous deprotection followed by transphosphatidylation catalyzed by phospholipase.

The toxicities towards human endthelial cells of both hydroperoxides are now being investigated. The present chemical and enzymatic approaches can be applied to the other biologically important phospholipid hydroperoxides with well-defined chemical structures.

Azidoiodoiodine(1+) Hexafluoroantimonate: The First Binary Nitrogen–Iodine Cation**

By *Inis C. Tornieporth-Oetting, Peter Buzek, Paul von Ragué Schleyer,* and Thomas M. Klapötke**

So far only two neutral binary iodine–nitrogen compounds have been described, which as a result of the very labile I–N bond[1] and the associated thermodynamic instability are both explosive: NI_3[2] (or $NI_3 \cdot NH_3$[3]) and IN_3[4]. Our attempts at the synthesis of the $[NI_4]^+$ ion analogous to $[NCl_4]^+$[5] have so far been unsuccessful.[2] We report here, the preparation and characterization starting from iodoazide, of the first binary iodine–nitrogen cation.

The reaction of iodoazide freshly prepared from silver azide and iodine in $CFCl_3$ (R-11) with I_2/SbF_5 (intermediate formation of "[I][SbF_6]", see ref. [6]) leads to the formation of a $[I_2N_3]^+$ salt [Eq. (a)].

$$IN_3 + 1/2\ I_2 + 3/2\ SbF_5 \xrightarrow{-90\,°C/-40\,°C} \underset{\mathbf{1}}{[I_2N_3]\,[SbF_6]} + 1/2\ SbF_3 \quad (a)$$

After removing the $CFCl_3$ at −50 °C and dissolving the product mixture in SO_2 (−50 °C) **1** can be separated from SbF_3 which is insoluble in SO_2 (evidence from MS, IR spectroscopy). The compound **1**, which is deep carmine red both in the solid state as well as in solution, is more easily accessible from the reaction of fresh AgN_3 with $[I_3][SbF_6]$ in liquid SO_2 [Eq. (b)], since here the step of pumping to dryness (**caution**: high danger of explosion) is no longer necessary.

$$AgN_3 + [I_3]\,[SbF_6] \xrightarrow{-50\,°C} AgI + \mathbf{1} \quad (b)$$

If **1** is prepared according to Equation (b), only the precipitated AgI (analytically proven) needs to be separated by a low-temperature filtration, and the residual SO_2 solution can be used directly for the characterization by Raman spectroscopy.[7] The Raman spectrum of **1** (Fig. 1) shows, apart from the bands of the solvent SO_2 and those of the $[SbF_6]^-$ ion, only bands which can be assigned unequivocally to the $[I_2N_3]^+$ ion.[7] It is noteworthy that the I–I stretch in **1** (182 cm^{-1}) in comparison to that in iodine I_2 (215 cm^{-1}) is shifted to lower wavenumber, whereas the N–I stretch in **1** (355 cm^{-1}) in contrast to that in IN_3 (338 cm^{-1}) is observed at higher wavenumber (Table 1). The position of the N–I vibrational bands of **1** corresponds to a calculated bond distance of 2.72 Å and thus also agrees with the empirical correlation between the I–I bond length and the wavenumber of the I–I vibration (Table 1). Similarly, the calculated N–I bond length in **1** (2.07 Å) which is shorter than that in IN_3 (2.13 Å) is in good agreement with the spectroscopic data.

Table 1. I–I and N–I bond lengths d and vibrational frequencies ν [17].

	ν(I-I) [cm^{-1}] calcd. [a]	exp.	d(I-I) [Å] exp.	calcd. [c]	ν(N-I) [cm^{-1}] exp.	d(N-I) [Å]
$[I_2]^+$	237	235 [6]	2.56 [6]	2.65		
I_2	208	215 [6]	2.66 [6]	2.73		
$[I_3]^-$	113	114 [9]	2.90 [10]	2.99		
IN_3					338 [4]	2.13 [b]
$[I_2N_3]^+$	188	182		2.72 [b]	355	2.07 [b]

[a] Estimated from: $\nu[cm^{-1}] = -1170.8 + 1356.0d[Å] - 314.9d^2[Å^2]$ [8]. [b] MP2 optimized [c] MP2/Basis.

We have estimated the enthalpy for the reaction carried out according to Equation (c) for the thermodynamically

$$IN_3(g) + 1/2\ I_2(s) + 3/2\ AsF_5(g) \longrightarrow [I_2N_3][AsF_6](s) + 1/2\ AsF_3(l) \quad (c)$$

comparatively stable $[I_2N_3][AsF_6]$[6]—as a result of better accessibility of the data—based on a simple Born–Haber cycle (see ref. [2, 6]) to be $\Delta H°(c) = -20 \pm 4$ kcal mol^{-1}.[17] With $\Delta H_f°(IN_3) = +90.2$[11] and $\Delta H_f°(AsF_5) = -295.6$ kcal mol^{-1}[6] a standard heat of formation for $[I_2N_3][AsF_6]$ of $\Delta H_f°([I_2N_3][AsF_6]) = -275$ kcal mol^{-1} is obtained. The decomposition given in Equation (d) is, however, strongly favored with $\Delta H°(d) = -97$ kcal mol^{-1} [6] (furthermore $[I_2]^+$ dimerizes exothermally to $[I_4]^{2+}$ [6]), and both N_2 (gas discharge) and $[I_2]^+$ ($[I_4]^{2+}$) were observed as decomposition products of **1** in solution above −10 °C ($[I_2]^+$ also occurs as the decomposition product at −50 °C, if the laser power for the Raman spectroscopy exceeds 25 mW). The desired slow decomposition of a sample of **1** prepared according to Equation (b) afforded (after separation of AgI,

$$[I_2N_3][AsF_6](s) \longrightarrow [I_2][AsF_6](s) + 3/2\ N_2(g) \quad (d)$$

yield > 90%) $[I_4][SbF_6]_2$ in approximately 90% yield (residual nitrogen content ca. 0.4–0.5%; cf. **1**, calcd. 7.9%) [Eq.(e)].

$$2\,\mathbf{1} \longrightarrow [I_4][SbF6]_2 + 3\,N_2 \qquad (e)$$

It would have been also conceivable that the reaction of IN_3 with "I^+" [Eq.(a)] could have resulted in a particle isomeric to the cation in **1**. Since the strong asymmetric N_3 vibration (ν_{as} = 2067 cm^{-1})[7] in the Raman spectrum made the linear arrangement of the two iodine atoms at the N_3 unit seem unlikely,[14] we calculated a structure with a bent I_2 unit and another with C_{2v} symmetry for the cation in **1** based on ab initio MO calculations (Fig. 2). The calculations were

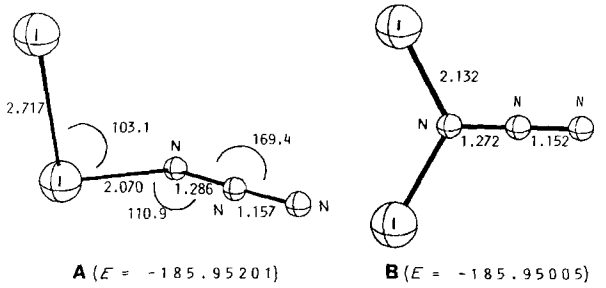

Fig. 2. MP2 optimized structures for the $[I_2N_3]^+$ ion, basis sets see text; (bond angles [°], distances [Å], energies [Hartree])[17]: **A**: nonplanar, chainlike structure of the cation in **1**, **B**: energetically next most favorable C_{2v} structure.

carried out with the Gaussian 90 program using the 6-31 + G* standard basis set for nitrogen.[15a, b] For iodine a quasi-relativistic pseudopotential[16a] and a [5s5p1d]/(3s3p1d)(DZ + P) basis set were used.[16b] The geometries were fully optimized in accord with the electron correlation according to Møller–Plesset 2nd order (MP(FU)). In agreement with the experimental spectroscopic results, the ab initio calculation also shows that the nonplanar chainlike structure of the $[I_2N_3]^+$ ion proposed by us is favored by about 1 kcal mol^{-1} to the (not observed) C_{2v} structure.

In a detailed work we will report the ab initio calculations of IN_3 and other energetically more unfavorable, terminal coordinated and cyclic $[I_2N_3]^+$ ions as well as about an improved preparative method for the preparation of IN_3 in gram quantities.

Experimental Procedure

A solution of $[I_3][SbF_6]$ (0.50 g, 0.81 mmol) in SO_2 (5 mL) at −70 °C was added to a suspension of AgN_3 (0.12 g, 0.80 mmol) [freshly prepared, washed with ethanol and ether, and dried in vacuo] in SO_2 (2 mL). After the mixture was swirled for 3 h at −50 °C it was filtered by decantation the precipated AgI under constant cooling [7,18]. **Caution**: The explosive nature increases greatly from AgN_3 to IN_3 to **1**! Compound **1** often shows also below −20 °C explosive decomposition.

[18] Attempts at recording of a ^{14}N NMR spectrum of a SO_2 solution of $[I_2N_3][SbF_6]$ were unsuccessful (cf. ref.[2]). Furthermore, we were also not in the position to carry out a favorable synthesis for AgN_3, starting from commercial $^{15}NH_4Cl$.

Control of the Reaction of *n*-Butyllithium with Benzo[*b*]tellurophene by the Solvent—Either Metalation or Tellurium–Lithium Exchange To Give an Interesting Lithiostyryllithium**

By *Adalbert Maercker,* Heinrich Bodenstedt,* and *Lambert Brandsma*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 65th birthday

The reductive cleavage of diphenylmethylene cyclobutane with elemental lithium leads to 2,5-dilithio-1,1-diphenyl-1-pentene (**1**), which is rearranged by a 1,7 proton shift into the stable dilithio compound **2a**.[1] According to 2D NMR investigations[2] **2a** has a lithium double bridge, similar to the metalated addition product of *n*-butyllithium with diphenylacetylene (tolane) **2b**.[3]

It was now of interest to prepare the parent compound of both compounds **2** with $R^1 = R^2 = H$, that is, (*Z*)-2-lithiostyryllithium (**8**). The readily accessible benzo[*b*]tellurophene (**4**)[4] was clearly a potential starting material that should be

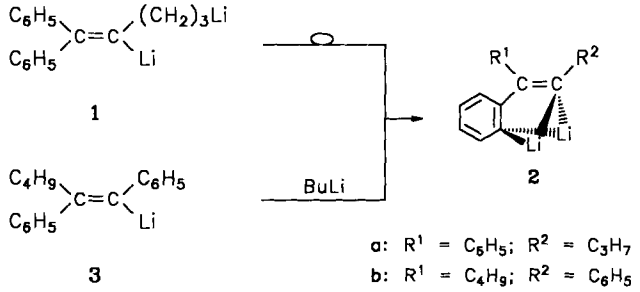
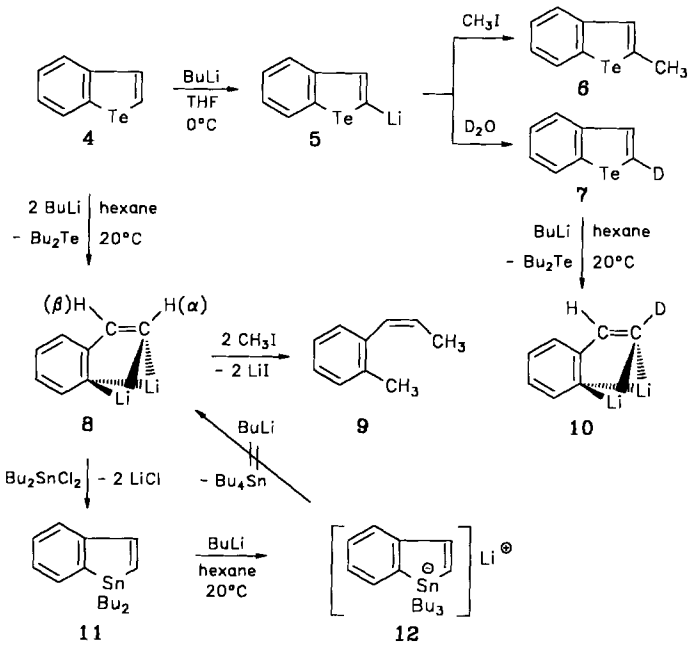
[**] Polylithiumorganic Compounds, Part 18. This work was supported by the Fonds der Chemischen Industrie. Part 17: A. Maercker, K.-D. Klein, *J. Organomet. Chem.* **1991**, *410*, C35–C38.



converted stereospecifically into **8** by tellurium–lithium exchange.

However, if benzo[*b*]tellurophene (**4**) is treated under the usual conditions for tellurium–lithium exchange[5] with *n*-BuLi in THF, then at −78 °C no reaction occurs, whereas at 0 °C—as also previously in diethyl ether at room temperature[6]—exclusively α-metalation was observed leading to 2-lithiobenzo[*b*]tellurophene (**5**). The reaction of **5** with methyl iodide afforded **6**[6] in 88% yield, and from deuterolysis **7** is obtained with a degree of deuteration of > 98% in the α position.



Surprisingly, the reaction of *n*-BuLi with **4** in hexane as solvent occurred very differently. If the components are stirred under an inert atmosphere at room temperature, within 5–10 min a fine, light-brown precipitate is formed, which proved to be the pure dilithium compound **8** (94% yield). The powder, which is beige when dry, is highly pyrophoric and dissolves in diethyl ether to give a red-brown solution. Following hydrolysis the mother liquor, apart from the theoretically expected quantities of dibutyltellurium, contains only traces of styrene.

The reaction of a suspension of **8** in hexane with methyl iodide or—better—dimethylsulfate affords pure **9**,[7] which is identical with the *cis* part of a *cis–trans* mixture prepared as a reference. Interestingly, 1,1-di-*n*-butylbenzo[*b*]stannophene (**11**) (82% yield, Table 1) formed from **8** and di-*n*-butyldichlorostannane could not be converted back into **8** by tin–lithium exchange. On the contrary the reaction in hexane stopped at the deep violet ate-complex **12** (Table 1). Stannates of the type **12** are discussed[8] as intermediates of the tin–lithium exchange and have been detected already for other special cases.[9]

In contrast, the conversion of **11** into **8** is achieved via the diiodo compound **13** (Table 1), which undergoes a double iodine–lithium exchange. The Wittig reaction of bromo-

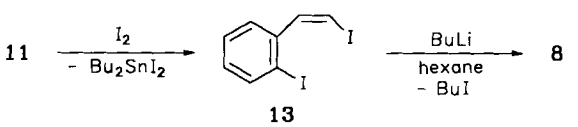
methylenetriphenylphosphorane[10] with *o*-bromobenzaldehyde in contrast affords a *cis–trans* mixture of the corresponding dibromo compound, which in contrast to **13** does not lead to a sterically uniform product after halogen–metal exchange.



For the preparation of **8** there are therefore no suitable alternatives to the tellurium–lithium exchange **4** → **8**. It is noteworthy that this reaction was successful in a hydrocarbon solvent; furthermore, **8** is the first dilithium organic compound with two different anionic centers, which was made accessible by a tellurium–lithium exchange.

The structure and stereochemistry of the lithiostyryllithium (**8**) are also derived from the NMR spectra.[11] Particularly characteristic in the ^{1}H NMR spectrum (80 MHz, [D$_{10}$]diethyl ether) is the doublet of the vinyl proton in the β position to the lithium atom at δ = 8.50 (^3J = 17.0 Hz), which, as expected, yields a singlet[12] in the α-deuterated compound **10**, and the doublet of the aryl proton in the *ortho* position to the lithium atom at δ = 7.96 (^3J = 6.7 Hz). The doublet of the vinyl proton in the α position (δ = 7.17) relative to the lithium atom lies partially beneath the signals of the remaining arene protons (δ = 6.8–7.1), so only the peak at lower field (δ = 7.25) can be seen. Obviously no signal is detected for **10** in this region. The ^{13}C and ^{6}Li NMR spectra (Table 1) are in agreement with a dimeric structure for **8**, as this has already been observed for compounds **2**[2, 3] under certain conditions. The result[11] is however novel and unex-

pected in that this information can already be taken from the spectra recorded at room temperature, whereas cooling to $-70\,^{\circ}C$ was necessary for the resolution of the $^{13}C,^{6}Li$ coupling in **2**.

Experimental Procedure

A solution of 1.6 M *n*BuLi (50 mL, 80 mmol) in hexane (Metallgesellschaft, Frankfurt am Main) was added under argon at room temperature to **4** (6.9 g, 30 mmol)[4]. This formed a pale yellow, clear solution which after 5–10 min clouded and became light brown as a result of precipitated **8**. After the mixture was stirred for 3 h (magnetic stirrer), the precipitate was separated by decantation, washed three times with dry pentane (50 mL), and dried in vacuo. Yield: 3.3 g (94%) **8** as a fine, beige powder which ignites immediately on contact with air.

"[Cp*Co=CoCp*]" is a Hydride**

By *Jörg L. Kersten, Arnold L. Rheingold, Klaus H. Theopold,* Charles P. Casey, Ross A. Widenhoefer,* and *Cornelis E. C. A. Hop*

Recently, bis(η^5-pentamethylcyclopentadienyl)dicobalt ([Cp*Co=CoCp*], **1**) was reported to have been prepared by a metal-atom vapor synthesis employing cobalt and pentamethylcyclopentadiene.[1] This unusual compound features a formal Co–Co double bond without any bridging ligands.[1] Some of the physical properties and the reactivity of **1** were surprising to us in light of the proposed structure. Despite its even valence electron count (28 valence electrons per dimer, Co^{I}, d^{8}), **1** was reported to be paramagnetic. It apparently did not react with ethylene or carbon monoxide. Finally, the X-ray crystal structure featured considerable residual electron density ($2.5\,e\,Å^{-3}$) in a position bridging the two metal atoms. Sensitized to the difficulty of characterizing paramagnetic hydrides by our recent work on $[\{Cp^{*}Cr(\mu_3\text{-}H)\}_4]$,[2] we wondered whether **1** might not contain bridging hydride ligands,[3] and if this compound could be prepared by straightforward solution chemistry. Herein we report the combined results of independent experiments in this regard by two laboratories (in Delaware and Wisconsin), which led us to conclude that **1** is really the mixed-valent cobalt hydride $[Cp^{*}_{2}Co_2(\mu_2\text{-}H)_3]$.[4]

In work carried out at the University of Delaware, reaction of $[\{Cp^{*}Co(\mu\text{-}Cl)\}_2]$[5] with 0.5 equivalents of $LiAlH_4$ at ambient temperature in THF gave a dark red solution. Subsequent removal of THF, extraction with pentane, filtration, and evaporation of the solvent yielded the crude reaction product as a black solid. ^{1}H NMR analysis of this solid in [D_6]benzene revealed two major broad resonances at $\delta = 62.0$ and 29.6 of roughly equal intensity, besides minor diamagnetic contaminants. Vacuum sublimation at 50 °C afforded a purple solid, which could be further purified by recrystallization from pentane. The resulting material (**2**) exhibited one resonance in the ^{1}H NMR spectrum ([D_6]benzene) at $\delta = 29.6$. The sublimation residue was recrystallized from pentane to yield black crystals; the ^{1}H NMR spectrum ([D_6]benzene) of the latter consisted of a single broad resonance at $\delta = 62.0$, very close to the value reported for **1**. As the original report gave NMR shifts in [D_8]toluene ($\delta = 61.3$ at 30 °C),[1] we recorded spectra in the same solvent ($\delta = 63.0$ at 20 °C and 60.3 at 30 °C). Given the apparent temperature dependence of the chemical shift, we considered all of these values to be identical within experimental uncertainty.

Presuming to have prepared **1** by an alternate route, we determined the crystal structure of our black compound ex-

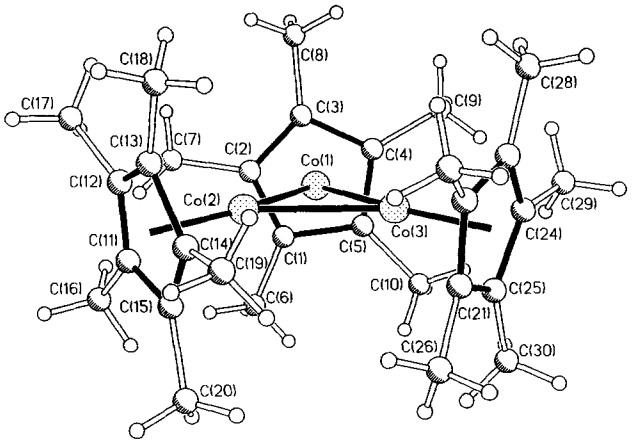

Fig. 1. The molecular structure of $[Cp^{*}_{3}Co_3(\mu_2\text{-}H)_3(\mu_3\text{-}H)]$ (**3**). The hydride ligands were not located and thus are not shown. Selected bond distances [Å] and angles [°]: Co(1)-Co(2) 2.479(4); Co(1)-Co(3) 2.472(4); Co(2)-Co(3) 2.477(4); Co-C 2.109 (average); Co(2)-Co(1)-Co(3) 60.0(1); Co(1)-Co(2)-Co(3) 59.8(1); Co(1)-Co(3)-Co(2) 60.1(1). The Cp* centroids are displaced below the Co_3 plane by an average distance of 0.193 Å.

hibiting the $\delta = 62.0$ resonance. To our consternation it turned out to be a trinuclear cobalt complex (**3**, see Fig. 1).[6] Whereas its cobalt atoms form an almost perfect equilateral triangle, the Cp* centroids are all displaced by approximately 0.2 Å to one side of the plane defined by the metal atoms. This distortion presumably results from the presence of stereochemically active hydride ligands. No hydrides could be located during the structure solution and refinement; however, based on mass spectral measurements (see below) we suggest that **3** has four such ligands. Three of the latter probably bridge the edges of the Co_3 triangle on the side opposite to the Cp* ligands, while the fourth hydride ligand presumably caps the other trigonal face, thus giving **3** the formula $[Cp^*_3Co_3(\mu_2\text{-}H)_3(\mu_3\text{-}H)]$.

We have also determined the crystal structure of the other reaction product, **2**.[7] Much to our surprise its structure (see Fig. 2) was that previously reported for **1**! The unit cell parameters, as well as the bond distances, were close enough to the published values to virtually ensure that this compound is identical to **1**, whatever its true chemical nature. Compari-

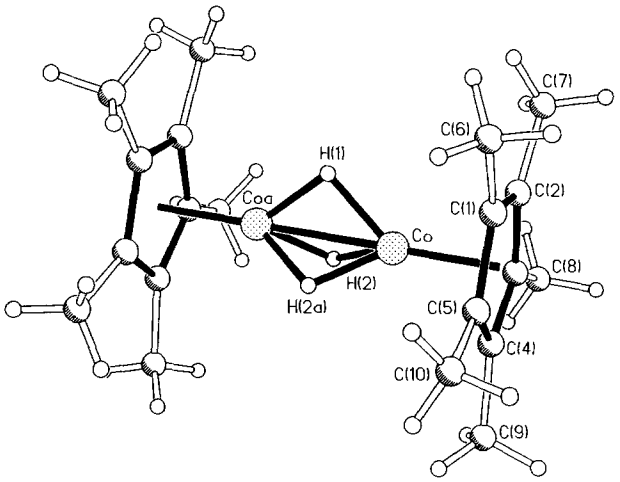

Fig. 2. The molecular structure of $[Cp^*_2Co_2(\mu_2\text{-}H)_3]$ (**2**). Selected bond distances [Å] and angles [°]: Co-Co_a 2.249(1) [**1**: 2.253(1) [1]]; Co-C 2.074 (average); Co-Cp*-centroid 1.681 [**1**: 1.689]; Co-H(1) 1.50(4); Co-H(2) 1.50.(6); Co-H(2a) 1.42(5); Co-H(1)-Co_a 97(3); Co-H(2)-Co_a 101(3).

son of the final R factors (this work: $R = 0.030$, $R_w = 0.040$; previously reported: $R = 0.040$, $R_w = 0.062$) indicated our structure determination to be the more reliable. After anisotropic refinement of all non-hydrogen atoms, the difference map revealed the presence of several peaks of residual electron density (ca. 0.5 eÅ^3), consistent with hydride ligands bridging the Co–Co bond. The best structural model featured three bridging hydride ligands; however, their positions as determined by X-ray diffraction must of course be viewed with some caution. Given the apparent contradiction between our observations and the reported NMR spectrum of **1**, it was important to confirm that the crystal used in our structure determination consisted of material exhibiting an ^{1}H NMR resonance at $\delta = 29.6$. Dissolution of said crystal in a minimal amount of [D_6]benzene yielded a faintly purple solution, and extended accumulation of scans confirmed the presence of a broad resonance at approximately $\delta = 31$ and the complete absence of any signal near $\delta = 60$.

To confirm the presence of hydride ligands in **2** and **3**, their synthesis was repeated using $LiAlD_4$. A sample of **2** prepared with $LiAlH_4$ exhibited a weak IR band at 1231 cm^{-1} (KBr), which was replaced by a very weak band at 806 cm^{-1} in material isolated from a reaction with $LiAlD_4$. These observations also suggest the presence of bridging hydride ligands in **2**.[8] The IR spectra of labeled and unlabeled **3** were indistinguishable. The mass spectrum of **2**, recorded under very mild ionization conditions (sample temperature 50 °C, electron energy 10 eV), showed its base peak at m/z 391, consistent with the formula $[Cp^*_2Co_2H_3]$. Under similar conditions the mass spectrum of **3** contained a strong peak at m/z 586, consistent with the molecular ion of $[Cp^*_3Co_3H_4]$.[9] At room temperature, solid **2** exhibited an effective magnetic moment (μ_{eff}) of 2.2(2) μ_B; this value is only slightly higher than the spin-only moment for one unpaired electron. Whereas pseudo-octahedral Co^{III} should be diamagnetic, the Co^{II} ion in the ligand field of a Cp* ligand and three hydrides (forming a trigonal piano stool) is expected to give rise to one unpaired electron, in accord with the measurement. Reaction of **2** with 4.0 equivalents of gaseous HCl (THF, 60 °C) liberated only 2.00(6) equivalents of H_2 (measured with a Töpler pump). We suggest that initial protonation may induce reductive elimination of H_2, thereby reducing the pool of hydrides available for protonation.

Parallel work carried out at the University of Wisconsin began with the reaction of cobalt(III) complex $[\{Cp^*CoCl_2\}_2]$[10] with excess $LiAlH_4$ in ether for 10 hours, followed by quenching of the reaction mixture with EtOH at −80 °C. The ^{1}H NMR spectrum in [D_6]benzene showed a 1:3 ratio of the resonances at $\delta = 62.1$ (**3**) and 29.6 (**2**) for the two major paramagnetic products. When the reaction was carried out at −45 °C for 30 minutes before quenching with EtOH at −80 °C, a 63% isolated yield of a 4.5:1 mixture of **3** and **2** was obtained. Recrystallization of the mixture from hexane gave the pure black paramagnetic complex **3** with a ^{1}H NMR resonance at $\delta = 62.4$ in [D_8]toluene at 22 °C, very close to the value reported by Schneider for **1**.[1] The high-resolution mass spectrum of **3** had a signal for the molecular ion at m/z 586.1819 (M^+; calcd 586.1825) and 587.1886 (^{13}C isotopomer; 32.8% of M^+; calcd 587.1858, 34.6% of M^+), consistent with the formulation $[Cp^*_3Co_3H_4]$.

The reported failure of **1** to react with CO appeared highly unusual. Casey et al. recently prepared $[Cp^*(CO)_2Re{=}Re(CO)_2Cp^*]$,[11] which has a Re=Re bond[12] supported by semibridging carbonyl groups; this complex reacted instantaneously with CO at −80 °C to produce $[\{Cp^*(CO)_2Re\}_2(\mu\text{-}CO)]$. The reaction of a black solution of **3** with CO (1 atm) produced a yellow-orange solution within 10 minutes at ambient temperature. ^{1}H NMR analysis with C_6Me_6 as an internal standard showed quantitative formation of $[Cp^*Co(CO)_2]$.[13] Gas chromatography of the gases over the solution showed the presence of H_2, and comparison with standard mixtures indicated a Co:H ratio of 1.02 ± 0.04, corresponding to 82% yield of H_2 from $[Cp^*_3Co_3H_4]$. Reaction of **3** with $CH_2{=}CH_2$ and with CCl_4 also released H_2. The effective magnetic moment of **3** determined by the Evans NMR method[14] was 3.9 ± 0.2 μ_B, consistent with the presence of multiple unpaired electrons.

Reaction of **2** (isolated by vacuum sublimation, see above) with CO rapidly produced $[Cp^*Co(CO)_2]$ (80% yield) and H_2 (66% yield; Co:H 2:2.46). The determination by the Evans method indicated an effective magnetic moment of 1.8 ± 0.2 μ_B in solution, consistent with the one unpaired electron predicted by MO calculations.[3]

In consideration of the results detailed above, we conclude that [Cp*Co=CoCp*] (**1**) remains unknown. The complex whose crystal structure was previously interpreted as that of **1** has the formula $[Cp^*_2Co_2(\mu_2\text{-}H)_3]$ (**2**). Furthermore, the

complex whose ^{1}H NMR spectrum was assigned to **1** is probably identical to $[Cp^*_3Co_3(\mu_2\text{-}H)_3(\mu_3\text{-}H)]$ (**3**). While both **2** and **3** can apparently be prepared by reaction of cobalt atoms with Cp*H, they are also accessible by simple solution procedures. We are now exploring the reactivity of these paramagnetic hydrides.

[6] Crystal data for **3**: $C_{30}H_{48}Co_3$, $M_r = 586.5$, monoclinic, $P2_1/n$, $a = 14.941(3)$, $b = 10.728(4)$, $c = 18.078(4)$ Å, $\beta = 90.43(3)°$, $V = 2897.6(10)$ Å^3, $Z = 4$, $\rho_{calc} = 1.338$ g cm^{-3}, $T = 243$ K. Of 4683 reflections collected ($4° < 2\theta < 48°$, Siemens P4, $Mo_{K\alpha}$) 4387 were independent, and 1748 were observed ($5\sigma F_o$). All examined specimens of the trimer diffracted weakly and somewhat asymmetrically. Criteria for the rejection of asymmetric reflections were lowered slightly to increase the available data. During attempted anisotropic refinement of all non-hydrogen atoms, several carbon atoms (3–5, 21, and 22) refined to "non-positive definite" values and were returned to isotropic status. All methyl-group hydrogen atoms were placed in idealized locations. The hydride ligands were not located. The highest and lowest peaks on the final difference map were 1.12 and -0.91 eÅ^{-3}. $R(F) = 9.79\%$ and $R(wF) = 12.70\%$.

[7] Crystal data for **2** (values in square brackets are those reported for **1** [1], note temperature difference!): $C_{20}H_{33}Co_2$, $Fw = 391.3$, monoclinic, $P2/c$, $a = 9.540(2)$ [9.533(1)], $b = 8.572(2)$ [8.514(2)], $c = 12.588(3)$ [12.376(2)] Å, $\beta = 105.62(2)°$ [105.95(1)°], $V = 991.4(4)$ [965.8] Å^3, $Z = 2$, $\rho_{calc} = 1.314$ g cm^{-3}, $T = 235$ K [100 K]. Of 2044 absorption-corrected reflections collected ($4° < 2\theta < 52°$, Siemens P4, $Mo_{K\alpha}$), 1951 were independent and 1410 were considered observed ($6\sigma F_o$). The centrosymmetric space group alternative was initially preferred from the statistical distribution of the normalized structure factors; the successful refinement validated this choice. All nonhydrogen atoms were refined anisotropically. Methyl-group hydrogen atoms were placed in calculated positions based on at least one found location per methyl group. The bridging hydrogen atoms were located from a difference map and isotropically refined. The highest and lowest difference peaks were, respectively, 0.35 and -0.25 eÅ^{-3}. $R(F) = 3.03\%$ (4.70% for all data) and $R(wF) = 3.98\%$ (4.51% for all data) for 108 refined parameters. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

Tetrakis(η^1-phosphabenzene)nickel**

By *Christoph Elschenbroich,* Mathias Nowotny, Andreas Behrendt, Werner Massa,* and *Sigrid Wocadlo*

Complexes of Ni in the oxidation state zero must be stabilized by strong σ donor/π acceptor ligands such as CO, RNC, PF_3 or $P(OR)_3$.[2] The function of weaker coordinating moieties such as alkenes, organophosphanes, and pyridines critically depends on the chelate effect. Thus, for example, homoleptic neutral nickel complexes with pyridine as a ligand are unknown[3a]—as are neutral complexes $[M(py)_m]$ of other metals[3b–i]—in contrast to the chelate bipyridine complex $[Ni(bpy)_2]$.[4] During our research into the coordination chemistry of heteroarenes of Group 15 we have now studied the modes of bonding of phosphabenzene to Ni^0[3j]. Since from the experience so far gained for heteroarenes C_5H_5E (E = N, P, As) with increasing atomic number of E, η^6 coordination predominates over η^1 coordination,[5–7] the formation of the homoleptic complex $[(\eta^6\text{-}C_5H_5P)(\eta^1\text{-}C_5H_5P)Ni]$ with 18 valence electrons could not be a priori excluded. We have now found, however, that the reaction of bis(1,5-cyclooctadiene)nickel (**1**) with phosphabenzene **2** forms tetrakis(η^1-phosphabenzene)nickel (**3**) in the form of orange, air-stable crystals, which are thermally stable up to 180 °C [Eq.(a)]. In solution **3** is air sensitive.

$$\underset{\mathbf{1}}{[(cod)_2Ni]} + 4\,\underset{\mathbf{2}}{C_5H_5P} \xrightarrow[25\,^\circ C]{CH_3\ C_6H_{11}} \underset{\mathbf{3}}{[(\eta^1\text{-}C_5H_5P)_4Ni]} + 2\,cod \qquad (a)$$

Analogous reactions with pyridine or arsabenzene lead to decomposition with deposition of a nickel slurry.[21] Compound **3** is the first homoleptic $\sigma(\eta^1)$ neutral complex of a heteroarene; it complements the $\pi(\eta^6)$ complexes **4**,[5] **5**,[1] and **6**[7] prepared by us previously.

The X-ray structural analysis[8] reveals the tetrahedral framework of **3** with point symmetry $\bar{4}$ (S_4) and almost ideal tetrahedral angles P-Ni-P of 108.6 and 109.9°; the most important bond parameter is the distance Ni–P = 212.7 pm (Fig. 1). To our knowledge shorter Ni–P distances are only found in $[Ni(PF_3)_4]$ (210–211 pm)[10a] and in $[Ni\{PF_2(2\text{-thienyl})\}_4]$ (209.3 pm),[10b] whereas typical values for Ni–P distances in tetrahedral organophosphane nickel complexes lie in the range 214–220 pm.[11] The short Ni–P distance indicates considerable double bond character between these elements, $Ni \xrightarrow{\pi} P$ back bonding being favored by the relatively low energy of the $b_1(\pi^*)$ ligand orbital,[12] the large MO coefficients at the P atom in this orbital,[13] and the low promotional energy of the configuration $Ni^0(d^{10})$.[14] The P–C and C–C distances in the phos-

[**] Metal Complexes of Heteroarenes, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the NATO Scientific Affairs Division.-Part 3: [1].

phabenzene ligands in **3** are the same within the limits of error and in comparison to those of the free ligands,[15] slightly shortened. The six-membered rings are planar (maximum deviation from a best-fit plane 0.4(4) pm), and the Ni–P bond (1.7°) is slightly bent "upward" (Fig. 1). The inclination of the rings towards the P-Ni-P′ plane, which contains the $\bar{4}$ axis, is $\pm 58.5°$; thus the two "upper" and "lower" rings, which can be mutually transformed by the twofold axis lie almost perpendicular to each other (84.9°). The upper rings form an interplanar angle of 62.9° with the lower ones.

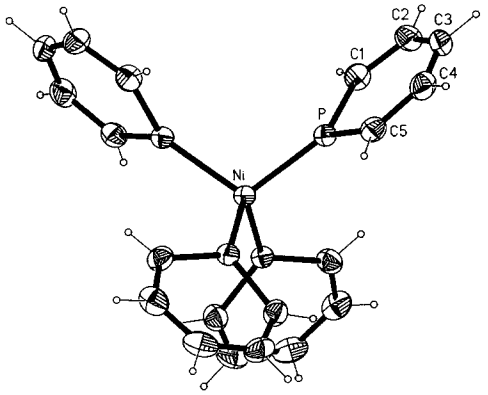

Fig. 1. XP drawing [9] of a molecule of **3**. Vibrational ellipsoids with 50% probability of occupation, selected bond lengths [pm] and angles [°]: Ni-P 212.74(5), P-C1 171.4(2), P-C5 171.8(2), C1-C2 138.0(3), C2-C3 138.7(3), C3-C4 137.2(3), C4-C5 138.6(3); C-H 87(2)–94(2); P-Ni-P′ 108.57(2), P-Ni-P″ 109.93(1), Ni-P-C1 129.45(6), Ni-P-C5 129.17(7), C1-P-C5 101.34(9), P-C1-C2 124.8(2), C1-C2-C3 123.1(2), C2-C3-C4 122.8(2), C3-C4-C5 123.7(2), P-C5-C4 124.2(2).

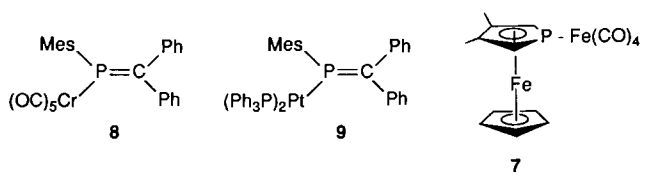
In addition to the bond length criterion a high Ni–P bond order in **3** is also suggested by the ν(Ni–P) stretching frequency. Thus, in the Raman spectrum the totally symmetric stretch a_1 is observed at 168 cm^{-1} which lies in the range of the absorptions of related complexes such as [Ni{P(OMe)$_3$}$_4$] (178 cm^{-1}), [Ni{P(OEt)$_3$}$_4$] (169 cm^{-1}), and [Ni(PF$_3$)$_4$] (195 cm^{-1}). Since experimental findings (drastic reduction of the proton affinity according to $C_5H_5N > C_5H_5P$; P in C_5H_5P is not quaternized by R_3O^+[16]) as well as the results of quantum chemical calculations[17] indicate a decrease in the σ electron density at the heteroatom, the surprisingly high stability of **3** must be traced to the π bonding contribution to the Ni–P bond. To a lesser extent this also seems to apply to the η^1 coordination of phosphaferrocene to the [Fe(CO)$_4$] complex fragment in **7**[18a] as well as of mesityl(diphenylmethylene)phosphane in **8**[18b] and in **9**, R = mesityl.[18c] Since such a Ni(3d$_\pi$)–P(3p$_\pi$) interaction decreases with increasing orbital contraction at the central atom it is not surprising that the cation $3^{+\cdot}$ proves to be unstable in solution: cyclic voltammetry attests to irreversibility for the pair $3^+/3^0$ even at −40 °C [anodic peak potential E_{pa} = 0.41 V in DME/nBu$_4$NClO$_4$ at glassy carbon versus a saturated calomel electrode (SCE)]. The reduction $3^0/3^-$ ($E_{pc(1)} = -2.11$ V) is also irreversible. This cathodic wave is followed by a second step ($E_{pc(2)} = -2.28$ V) assigned to the reduction of the free ligand by comparison with authentic phosphabenzene.



Solutions of **3** appear orange in benzene or methylcyclohexane and dark brown in THF. The same change in color also results for solutions of **3** in hydrocarbons with increasing temperature. Since in both cases the change in color can be reversed by the addition of small quantities of phosphabenzene this observation points to the existence of a dissociation equilibrium $[(\eta^1\text{-}C_5H_5P)_4Ni] \rightleftharpoons [(\eta^1\text{-}C_5H_5P)_3Ni] + C_5H_5P$. This assumption is supported by the presence of an isosbestic point (λ = 471 nm), which lies between the absorption maximum of **3** (λ_{max} = 389 nm) and a weak maximum ($\lambda \approx 530$ nm), which can possibly be assigned to the compound $[(\eta^1\text{-}C_5H_5P)_3Ni]$ or its solvate (Fig. 2). Yet, in the ^{1}H and ^{31}P NMR spectra of **3** in solution signals for the free ligand and the threefold coordinated complex are not observed. If free ligand is added, the spectra show an additional signal to that of the complex **3** and the $J(^1H,^{31}P)$ couplings can be resolved. Evidently, a situation prevails which Tolman[19a] referred to as type I (low complex dissociation, slow ligand exchange). The dissociation of **3** is surprising since for [Ni(PMe$_3$)$_4$], which possesses ligands of almost identical Tolman cone angle[19b] (θ(PMe$_3$) = 118°, θ (C_5H_5P) = 116°), such a partial cleavage is not observed.[20]

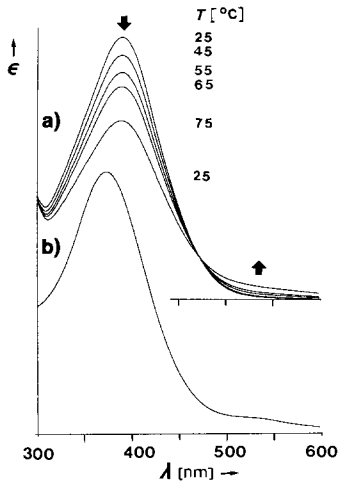


Fig. 2. UV/VIS spectra of $[(\eta^1\text{-}C_5H_5P)_4Ni]$ (**3**) a) in benzene at different temperatures and b) in THF at 25 °C.

Experimental Procedure

3: Phosphabenzene (0.45 g, 4.68 mmol) was added dropwise to [Ni(cod)$_2$] (212 mg, 0.77 mmol), dissolved in methylcyclohexane (50 mL) and stirred, whereupon a fine crystalline orange solid precipitated immediately, which was separated and taken up with the addition of phosphabenzene (0.1 mL) in THF (20 mL). After filtration the filtrate was layered with hexane (20 mL) at 4 °C. Within a day **3** (180 mg, 0.41 mmol, 53%) separated in the form of orange needles, m.p. 199 °C (decomp.), correct C,H, analysis. FD/MS: m/z 442 ($M^{\oplus}$, 100%); UV/VIS (benzene): λ_{max} [nm] (ε) = 389 (21 500); ^{31}P NMR (121.5 MHz, [D]$_8$THF + C_5H_5P, 25 °C): δ = 213.3, $\Delta\delta$ (relative to free C_5H_5P) = 6.3; ^{1}H NMR (300 MHz, [D]$_8$THF, 25 °C, TMS): δ = 8.20 (^2J(P,H) = 24.6 Hz; H-2,6), 7.65 (H-3,5), 7.17 (H-4), $\Delta\delta$(C_5H_5P) = −0.57 (H-2,6), −0.22 (H-3,5), −0.38 (H-4); ^{13}C NMR (125.77 MHz, [D]$_8$THF, 25 °C):

$\delta = 146.9$ ($^1J(C,H) = 157.2$ Hz; C-2,6), 136.4 ($^1J(C,H) = 155.9$ Hz; C-3,5), 124.0 ($^1J(C,H) = 158.5$ Hz; C-4), $\Delta\delta(C_5H_5P) = -8.2$ (C-2,6), -1.7 (C-3,5), -5.8 (C-4).

[8] Crystal structure determination of **3**: An orange single crystal of dimensions ca. $0.27 \times 0.13 \times 0.10$ mm^3 was measured on a four-circle diffractometer (CAD4, Enraf-Nonius, $Mo_{K\alpha}$ radiation, graphite monochromator) at 193 K. It proved to be tetragonal, space group $P42_1c$, $Z = 2$, with the lattice constants refined from 25 reflections with $\theta > 15°$ $a = 1219.7(2)$, $c = 686.6(1)$ pm and a density $\rho_{calcd} = 1.440$ Mg m^{-3}. In total 4623 reflections (complete sphere in the reciprocal space up to $\theta = 23°$) were collected. After a numerical absorption correction ($\mu = 12.6$ cm^{-1}, min./max. transmission 0.85/0.89) there were ($R_{int} = 0.017$) 701 independent reflections, all $F > 4\sigma(F)$. The structure was solved by direct methods and refined with anisotropicic temperature factors for all heavy atoms [9]. The high quality of the data set allowed all the H atoms to be localized and be freely refined with isotropic temperature factors. Furthermore, the correct orientation of the structure to the polar axis could be clearly determined by refinement of Rogers η parameter [9] (to 1.00(3)). By the use of an extinction correction and a weighting according to $1/\sigma^2(F_0)$ reliability factors of $R = 0.013$, $wR = 0.014$ were achieved, whereas for the inverted structure only $R = 0.031$ and $wR = 0.037$ were obtained. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft for wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56415, the names of the authors, and the journal citation.

Catalytic Oxidation of Partially and Fully Fluorinated Olefins with Osmium Tetroxide**

By *Wolfgang A. Herrmann,* Stefan J. Eder,* and *Wolfgang Scherer*

The oxidation of olefins catalyzed by osmium tetroxide is a reliable method for the synthesis of vicinal *cis* diols.[1] The catalytic and stereochemical efficiency of this reaction can be explained by the formation of an intermediate cyclic osmate(VI) ester from the olefin and OsO_4 in the presence of pyridine bases, which undergoes hydrolytic cleavage. Current literature is still based on the assumption that very electron-poor olefins do not react with the metal oxide, and thus are also not oxidizable.[1, 2] We report here the contrary, namely, the formation of cycloadducts of partially and fully fluorinated olefins and their conversion into fluorinated diols and products of subsequent reactions.

Fluoroalkenes **1a–i** including those in which fluorine is directly bound to the carbon atoms of the double bond (**1e–i**), react with osmium tetroxide in hexane in the presence of pyridine and other nitrogen-containing bases at room temperature without irradiation.[3] In all cases, the isolable, thermally stable, cyclic osmate(VI) esters **2a–i** were obtained quantitatively within minutes or hours according to Scheme 1. Tetracyanoethylene **1j** is converted into the analogous cycloadduct **2j**. In comparison to the known complexes of this type, the fluorinated derivatives **2e–i** are extremely sensitive to hydrolysis.

The structure of the new osmate esters was determined by a single-crystal X-ray diffraction study of **2h**.[4] Complex **2h**

has a *trans*-configurated linear osmyl group $(OsO_2)^{2+}$ with octahedral geometry about the osmium center (Fig. 1). A comparison with the structures of non-fluorinated osmate esters shows that the numerous electron-withdrawing groups do not affect the structural parameters of **2h**.[5]

The thermolysis and hydrolysis of the new osmate esters are dependent upon their constitution: hydrolysis of the fluoro- and cyano-substituted osmate esters occurs primarily on the ring systems. Hydrolysis of **2e** and **2f, j**, for example, provides the respective isolable hydroxyacetato and oxalato complexes **4** and **5**. Continued hydrolysis yields the corresponding osmium-free hydroxycarboxylic acid and dicarboxylic acids (Scheme 1). Of the series of osmate esters examined, **2f**, derived from tetrafluoroethylene **1f**, is most thermally labile:[6, 7] when **2f** is heated under vacuum at 150 °C, the previously unknown difluoride **6** is obtained as a stable pyridine complex in 80% yield by elimination of oxalyl fluoride. Esters **2a–e** and **2g–i** are thermally stable to at least 110 °C, **2h** to approximately 190 °C.

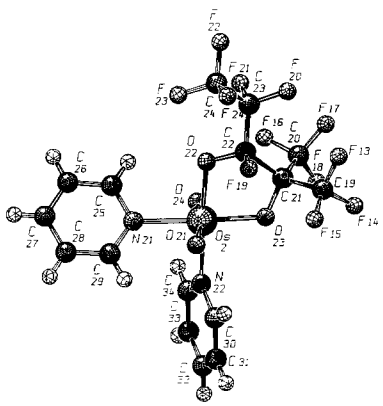

Fig. 1. SCHAKAL representation of one of the two crystallographically independent molecules of the perfluorinated osmate ester **2h**. Selected distances [pm] and angles [°]: Os2-O21 173.2(5), Os2-O24 172.3(5), Os2-O22 199.6(5), Os2-O23 196.9(5), Os2-N21 212.8(7), C21-O23 138.6(9), C22-O22 132.0(9), C21-C22 159(1), C22-F19 143.9(9); O22-Os2-O23 81.9(2), Os2-O23-C21 116.2(5), O22-C22-C21 112.4(7).

Aside from these exceptional cases, the hydrolysis of osmate esters **2a–d** with electron-withdrawing groups such as CF_3 and C_6F_5 is synthetically useful. For synthetic application the catalytic variant of this reaction appears to be especially advantageous. Thus the typical fluoroolefins **1a–d** can be converted under standard conditions into the 1,2-diols **3a–d** by treatment with potassium hexacyanoferrate(III), with hydrogen peroxide as the primary oxidant on free or supported[8] osmium tetroxide, or with the salt $K_2[OsO_2(OH)_4]$. A representative selection of data on these reactions is listed in Table 1. When α-fluoroalcohols are formed (e.g. from **1e–i**), ketones or 1,2-diketones arise after spontaneous elimination of HF (Table 1). Although this loss of fluorine appears to be a drawback, this method holds promise for the preparation of fluorinated mono- and diketones in special cases, since fully fluorinated olefins are often more easily accessible than their partially fluorinated congeners.

Table 1. Catalytic oxidation of selected fluoroolefins with H_2O_2 or $K_3[Fe(CN)_6]$.

Fluoroolefin	Oxidation product	Oxidant H_2O_2 cat.	Oxidant $Fe^{(III)}$ cat.	stoichiometric
1a	**3a**	67%	95%	>99%
1b	**3b**	68%	>99%	>99%
1c	**3c**	85%	98%	>99%
1d	**3d**	48%	>99%	>99%
1g	$HOOC-CO-CF_3$	80%	63%	80%
1h		87%	70%	80%
1i		88%	83%	>90%
		70%	> 99%	>99%
		99%	> 99%	

We demonstrate here that even the most electron-poor olefins undergo OsO_4-catalyzed oxidations. The reduced reactivity of chloroolefins relative to their fluorine counterparts is explained by a size effect; in all other respects the chloroolefins behave analogously.[7] The procedure is also applicable to strained fluoroolefins, for example norbornene derivatives.

Our results cannot be rationalized with the frequently held conception of the mechanism of the osmylation as the electrophilic attack of osmium tetroxide on the olefin. The pyridine base effect discussed by Corey et al. and Hoffmann et al.[9] is more applicable. According to this mechanistic description, the polarized *cis*-OsO_2 group reacts by a [2 + 3] cycloaddition (*trans* influence of the pyridine base). The remarkable reactivity of polar fluoroolefins such as vinylidene fluoride $F_2C{=}CH_2$ (**1f**), $(CF_3)_2C{=}CF_2$, and $F(CF_3)C{=}C(OC_6H_5)_2$ supports this interpretation.

Although α-hydroxyfluorides react further by elimination of HF, the catalytic variant of the reaction sequence described here provides a new, convenient route to oxygenated organofluorine compounds. Osmium tetroxide can now be considered a universal oxidizing agent for olefins. The optimization of the less toxic, immobilized variants[8] is thus of even greater importance.

Experimental Procedure

2f: C_2F_4 was separated from the stabilizing agent α-pinene by cooling to −35 °C, and was then passed through a solution of OsO_4 (2.00 g, 7.9 mmol) in toluene (80 mL) and pyridine (1.3 mL) at 25 °C. After a few minutes **2f** separated as an ochre precipitate. The reaction mixture was concentrated and the residue dried under vacuum to give analytically pure **2f**. Yield 4.0 g (99%). M.p. 143 °C (decomp)[10a]. After compound **2f** was heated for 6 h at 135 °C/10^{-3} Torr, the residue was recrystallized from CH_2Cl_2 (−30 °C) to give analytically pure $[(py)_2OsO_2F_2]$ in 80% yield[10b].

Catalytic oxidation with hexacyanoferrate(III): $K_2[OsO_2(OH)_4]$ (100 mg, 0.27 mmol), pyridine (0.36 mL), $K_6[Fe(CN)_6]$ (14.7 g, 45 mmol), and K_2CO_3 (6.2 g) were dissolved in a mixture of H_2O (100 mL) and *t*-C_4H_9OH (100 mL)[11]. This solution was vigorously stirred while 15–20 mmol of the olefin was added. The reaction mixture was stirred for 24 h, $Na_2SO_3 \cdot 7H_2O$ (11.4 g) was added, and the mixture stirred an additional 1 h. The organic phase was separated, the aqueous phase washed with CH_2Cl_2 (2 × 50 mL), the collected organic layers dried over $MgSO_4$, and concentrated. For yields see Table 1.

Catalytic oxidation with hydrogen peroxide: OsO_4 (80 mg, 0.315 mmol) was dissolved in THF (30 mL) and immobilized on cross-linked poly(4-vinylpyridine) (Reillex 402, 1 g)[8]. An "oxidation solution" made from *tert*-butanol (100 mL) and 30% H_2O_2 (25 mL) and dried over aqueous $MgSO_4$ was used along with the heterogeneous catalyst to oxidize the olefins listed in Table 1 (25–100 mmol). Standard workup, for yields see Table 1.

High Molecular Weight Polypropylene through Specifically Designed Zirconocene Catalysts

By *Walter Spaleck,* Martin Antberg, Jürgen Rohrmann, Andreas Winter, Bernd Bachmann, Paul Kiprof, Joachim Behm,* and *Wolfgang A. Herrmann**

Only a few years after the discovery of the isotactic polymerization of propylene with zirconocene catalysts,[1,2] more than 250 patents and numerous original publications document a fascinating, rapid development. Nevertheless, all variants of these "stereorigid" zirconocene/methylalumoxane catalysts remained merely of academic interest. Practical application failed because of the insufficient molecular mass of the polymeric products. For instance, the catalyst **1** described first gave only polymeric waxes with $M_w < 30000$ g mol^{-1} under technically reasonable conditions (> 40 °C) in the presence of methylalumoxane (MAO) as cocatalyst.[1,3] Modification of the zirconocene complexes brought only gradual improvements.[4–6] The structurally analogous hafnium derivatives[7] could also not solve the technical problems,

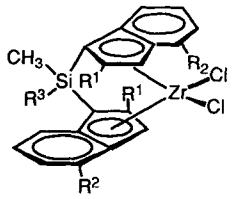
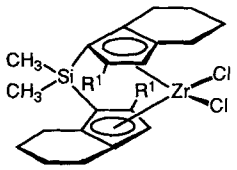
because their activities were less than 5% of those of the reference zirconocene catalysts.[8] Under these peripheral conditions, the required demand for pure hafnium would make catalyst production particularly uneconomical. This report on the synthesis of polypropylene of molecular mass far above $M_w = 100000\ g\,mol^{-1}$ announces the technical breakthrough for polymerization with zirconocene catalysts.

A glance at Table 1 shows that for the polymerization of propylene with the catalysts **2b** and **3b** the molecular weight of the polymers formed at technically acceptable reaction temperatures are drastically higher than those formed with the complexes known to date (**2a** and **3a**), in spite of the only slight variation in the catalyst system. In the simplest case the



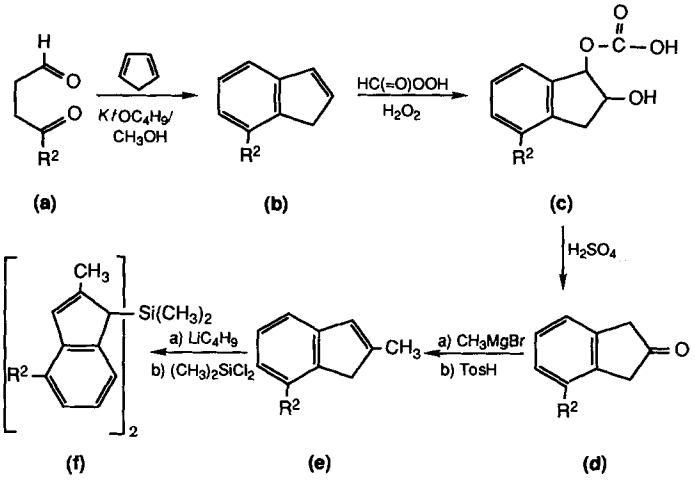
2a-e



3a,b

introduction of a methyl group at the indenyl ligand ($R^1 = CH_3$; **2b**) in the immediate proximity of the silylene bridge suffices. This change alone increases the molecular weight of the polymer fivefold and provides distinctly improved tacticity (> 96%; m.p. 145–148 °C). Although the same effect can be achieved with the hafnium derivative **2a'**, it shows only a fraction of the activity of the zirconium reference catalyst **2a** (Table 1; see also [8]). Larger 2-substituents adjacent to the bridge ($R^1 = C_2H_5$, **2c**), do not result in improved polymer properties. However, another substituent in 4-position, that is, at the annelated benzene ring, effects a further increase in molecular weight ($R^2 = iC_3H_7$, **2d**), and this complex is much more active than the reference catalyst **2a**. Furthermore, the isotacticity also increases (98%, m.p. 152 °C). The catalyst **2d** is therefore a realistic candidate for technical applications. Modification of R^3 on the silyl group can also be advantageous for high molecular weight polymers, as indicated by the exchange of methyl (**2b**) by phenyl (**2e**).

The underlying ligand system of those catalysts **2**, in which $R^1 = CH_3$, was synthesized from the ketoaldehyde (a) according to the new, generalizable sequence outlined in Scheme 1.[9, 10]



Scheme 1. Synthesis of the ligand systems of catalysts **2**. Yields of the individual steps: (b) 52%, (c) + (d) 79%, (e) 50%, (f) 91%. $R^2 = CH(CH_3)_2$.

The R^1 effect seems to be of a general nature, since it is also observed in the tetrahydroindenyl derivatives **3** (Table 1). Replacing H (**3a**) with CH_3 (**3b**) doubles the polypropylene mass and increases the isotacticity. Nevertheless, the achievable molecular weights are much lower than those of the analogous systems of **2** with aromatic six-membered rings. This demonstrates that for technical catalysts for propylene polymerization not only the 2-alkyl substitution but also the benzoannelation of the five-membered ring is crucial.

Although our results appeared to be able to be explained by a distortion of the catalyst framework, this conclusion proved false, because the molecular structures of the reference catalyst **2a** and its methyl derivative **2b** are identical in all parameters (Table 2, Fig. 1 and 2).[11] As may be seen in Figure 2, right, the methyl groups present in **2b** in 2-position are turned away from the spatial segment relevant for catalysis. A direct steric influence of this group on the chain termination reaction and thus on the polymer mass is therefore not expected.[12, 13] In our opinion an electronic effect is dominant. It is reasonable to assume[14] that a decrease in the local Lewis acidity at the (cationic) zirconium atom of the active species[2, 15] lowers its tendency to abstract a β-H atom. The number of chain terminations thereby decreases and the molecular mass thus increases (**2a** → **2b**). Additional alkyl substitution enhances this effect (**2d**), while loss of aromaticity of the six-membered ring weakens it drastically (**3b**). The alkyl substituents in 2- and 4-position provide in

2d the currently optimal catalyst by increasing the basicity of the aromatic ligand without placing a steric obstacle in the path of the growing polymer chain.

In accord with this interpretation, electron-withdrawing substituents lower the molecular mass. A 5-chloro substituent in the catalyst yields molecular weight of $M_w = 9900\ g\,mol^{-1}$ for polypropylene;[16a] similar effects are known for bridged and nonbridged indenyl complexes of the same type.[16b, c]

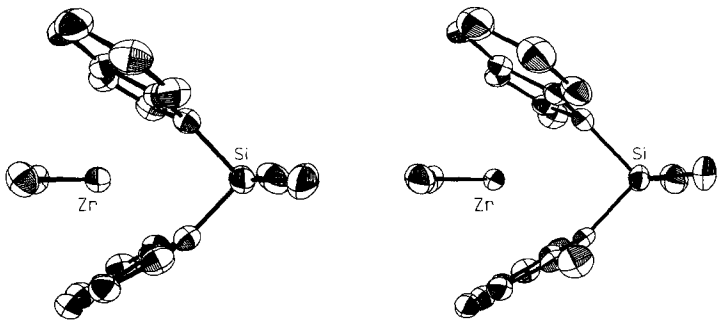

Fig. 2. Comparison of the structure of the catalysts **2a** (left) and **2b** (right); view onto the edge of the Zr plane (ORTEP drawing).

The higher stereospecificity (higher proportion of isotactic pentads, polymer's higher melting point) observed with all these new complexes **2b–d** compared with the parent catalyst **2a** is striking. A subordinate spatial effect of the substituents on the exact position of the reactant at the active site must therefore be assumed.

Our interpretation of these results suggests that another optimization of the catalysts derived from the indenyl complex **2a** would be possible if the effects of the 2- and 4-substituents can be combined in a way to avoid steric hindrance at the active site. Modified CVFF force field calculations have shown that all these derivatives should have the same framework structures as **2a** and **2b** within experimental error.[17]

Experimental Procedure

All manipulations were conducted in an inert argon atmosphere.

Ligand systems: A solution of the relevant indene [9,18a] (30 mmol) in THF (30 mL) was slowly treated with a solution of butyllithium (12 mL, 30 mmol, 2.5 M) in *n*-hexane at 25 °C and heated for 1 h under reflux. The solution was then added dropwise to a solution of dimethyl- or methylphenyldichlorosilane (15 mmol) in THF (10 mL) at 25 °C and stirred for 15 h. The mixture was poured onto ice water and extracted with diethyl ether. The residue remaining after removal of the solvent was chromatographed on silica gel 60. The unchanged starting material for the ligand was eluted with solvent mixtures of *n*-hexane/CH_2Cl_2 (between 20:1 and 10:1); yield 35–60%.

2a–2e: A solution of the appropriate indene (10 mmol) in THF (30 mL) was treated with a solution of butyllithium (8 mL, 22 mmol, 2.5 M) in *n*-hexane at 25 °C and stirred for 15 h. The solvent was removed, and the solid residue washed with *n*-hexane and dried in vacuum (oil pump) for 5 h. The powdered dilithium salt was added to a suspension of $ZrCl_4$ (2.33 g, 10 mmol) in CH_2Cl_2 at −78 °C. The mixture was allowed to warm to 25 °C (15 h) and was then evaporated to dryness under vacuum. The process yielded a 1:1 mixture of the *rac* and *meso* isomer. The residue was dried at 10^{-3} Torr and extracted with toluene. The pure racemate (an orange-yellow crystalline powder) was recovered from the extract by crystallization (− 35 °C); further recrystallization is possible from CH_2Cl_2 or THF; yield of pure compound 10–25% (*rac*).

3a,b: The aromatic analogues **2a,b** were hydrogenated according to [18b]. Yield 50%.

Propylene polymerization: A dry 16-L, thermostatable steel reactor was charged with nitrogen and 10 L of liquid propylene at 30 °C. Then a solution of methylalumoxane in toluene (30 mL, 40 mmol Al; average molar mass 950 $g\,mol^{-1}$) was added. Simultaneously, 0.02 mmol of metallocene was dissolved in an identical solution of methylalumoxane in toluene (20 mL) and left to stand for 15 min to be "activated". The orange-red solution was then added to the reactor. The reactor was heated to 50 °C and kept at this temperature for 1 h. The reaction was stopped by the addition of isopropanol (10 mL), cooled, the pressure released, and the product dried in vacuum. The yield was determined by weighing.

Polymer analysis: Molecular masses were determined by gel permeation chromatography (as solution in 1,2-dichlorobenzene at 135 °C; molar mass distribution M_w/M_n in total < 3), melting points by DSC, triad isotaxies and proportion of isotactic pentades by ^{13}C NMR spectroscopy [18c] (Bruker WP 300, 110 °C, hexachlorobutadiene/$CDCl_2CDCl_2$).

[13] A theoretical consideration of the problem leads to the conclusion that methyl substitution at the 2-position does not influence the transition state of the polymerization reaction [12a]. This statement seems to be substantiated since the quoted loss of stereospecificity is actually observed on 3-methyl substitution. The + I effect of the methyl substituents, which improves the molecular mass of polypropylene, is also seen in the series of $(CH_3)_2$Si-bridged cyclopentadienyl complexes; cf. [5].

Phosphorus(v) Selenides with Phosphorus in a Trigonal-Planar Environment**

By *Alfred Schmidpeter,* Georg Jochem, Konstantin Karaghiosoff,* and *Christian Robl*

In phosphorus(v) chalcogenides the phosphorus atom is generally tetracoordinated: dichalcogeno(organo)-λ^5-phosphanes **1**, Y = S, Se, form dimers **2**,[1,2] and phosphinoyl halides **4** show no tendency to dissociate with the formation of a chalcogeno(diorgano)phosphonium ion **3**.

The tricoordinate phosphorus atom in **1** and **3** should be highly electrophilic. Compounds **1** and **3** are therefore postulated as the reactive species for the O/S exchange with Lawesson reagent[1] or for the $AlCl_3$ catalyzed electrophilic substitution with thiophosphinoyl chlorides.[3]

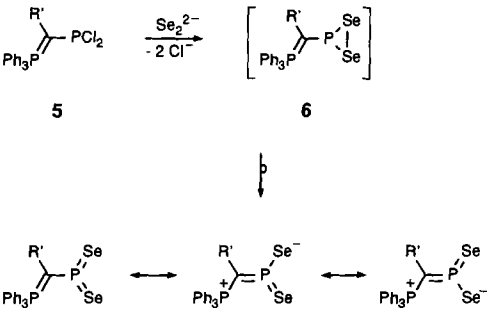
1 **2** **3** **4**

For Y = S the monomers **1** with R = Me, Et could be detected as the products of the gas-phase thermolysis of **2**.[4] In the condensed phase so far only one representative of **1**, namely with the large 2,4,6-tri-*tert*-butylphenyl substituent, has been described and structurally confirmed;[5] the corresponding compound with Y = Se is also known.[6] To our knowledge there is so far not sufficient evidence for **3**.

Both of the above equilibria are shifted to the left with ylide substituents R. Monomeric dithioxo- and diselenoxo-λ^5-phosphanes **1** and ionic selenophosphonium halides **3** can be isolated because of the stabilizing effects of these R groups.

Dichloro[organo(triphenylphosphonio)methanidyl]phosphanes **5**[7] react smoothly with sodium diselenide in THF to give the corresponding ylide-substituted diselenoxo-λ^5-phosphanes **7**, which can be isolated as orange-yellow crystals.

The reaction comprises a reduction of the diselenide and an oxidation of the phosphorus. The ylide-substituted diselenaphosphirane **6** assumed as intermediate, however, cannot be observed. Compound **7** is formed by cleavage of the Se–Se bond and flattening of the coordination environment of the phosphorus. In the case of S instead of Se, and H instead of the ylide substituent, a value of −9 kcal mol^{-1} is calculated for the corresponding ring opening.[8] In view of the comparable electronegativities of S and Se, a similar value is to be expected for the selenium compound; however, because of the ylide substituent the formation of **7** should be considerably more favorable energetically.



5 **6**

7, R' = Me, Et, Ph, *m*-MeC_6H_4

The structure of compounds **7** follows from their NMR spectra. The most important information is the nonequivalence of the two selenium atoms. This shows that the two parts of the molecule (ylide and PSe_2 moiety) are planar and lie in a common plane and cannot easily be twisted against each other, and that thus the 1,4-dipolar resonance formulas are of great importance. In contrast to this, the planes of the aryl group and of the PS_2 moiety in the aforementioned compound **1** with R = 2,4,6-tri-*tert*-butylphenyl and Y = S lie almost perpendicular to each other (dihedral angle = 80°).[5] Thus, the phosphorus atom is sterically protected and remains trigonal planar coordinated. In contrast, tricoordination is electronically stabilized by the ylide substituent in **7**.

The ^{31}P NMR spectra of **7** (at 25 °C) show doublets at $\delta \approx 21$ and 214 for the PPh_3 and PSe_2 group, respectively, with ^2J(P,P) about 40 Hz. Thus, the PSe_2 signal of **7** lies in

the same region as that of tBu$_3$C$_6$H$_2$PSe$_2$ (δ = 273),[6] however, at somewhat higher field. It is accompanied by two pairs of satellites. In keeping with this, the ^{77}Se NMR spectrum shows a doublet each for the isotopomer with ^{77}Se *trans* and *cis* to R′ at $\delta \approx$ 600, ^1J(Se,P) average 816 Hz, and at $\delta \approx$ 495 (R′ = Me, Et) and 575 (R′ = Ph, *m*-tolyl), ^1J(Se,P) average 844 Hz. The isotopomer with two ^{77}Se atoms (R′ = Et) contributes satellites with ^2J(Se,Se) = 133 Hz. The assignment of the ^{77}Se signals is based on the fact that the second shift mentioned is strongly dependent on whether R′ is an alkyl or an aryl group, since the *cis*-positioned aryl group has an anisotropic effect. This assignment, however, is only provisional.

The X-ray structural analysis[9] of a single crystal of **7**, R′ = Ph, reveals that here also discrete molecules occur without detectable interactions (shortest intermolecular Se–Se distance 6.04 Å, shortest intermolecular P1–Se distance 6.04 Å, Fig. 1). The intramolecular Se–Se distance (3.68 Å)

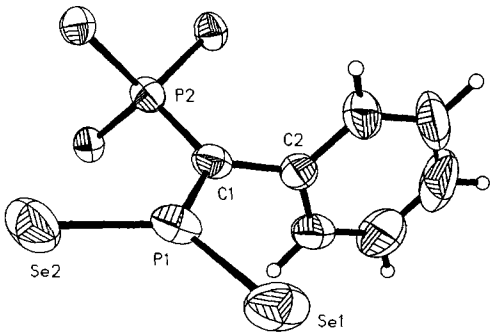

Fig. 1. Crystal structure of **7**, R′ = Ph, (of the P-positioned phenyl groups only the *ipso* carbon atom is given, thermal ellipsoids with 50% probability). Bond lengths [Å] and angles [°] (with standard deviations): P2-C1 1.751(5), P1-C1 1.696(5), P1-Se1 2.081(2), P1-Se2 2.079(2); P2-C1-C2 116.3(3), C2-C1-P1 120.7(4), P1-C1-P2 122.9(4), C1-P1-Se1 117.0(2), Se1-P1-Se2 124.5(1), Se2-P1-C1 118.4(2).

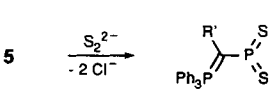
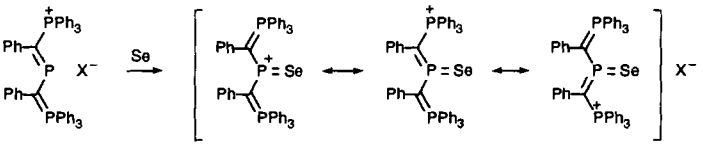
is also too great for a Se–Se bond to be considered. Both the ylide carbon atom and also the phosphorus atom have planar coordination environments; the two planes are only tilted towards each other by about 9.7°. The central P–C distance is almost as short as in the P=C unit of a bismethylene-λ^5-phosphorane[10] and, thus, confirms the participation of the polar resonance formulas. The two P–Se distances are not significantly different.

In the same way, dichlorophosphanes **5** react with sodium sulfide affording the ylide-substituted dithioxo-λ^5-phosphanes **8**. Their structure is revealed by the ^{31}P NMR data, which are very similar to those of **7**: $\delta \approx$ 22 (PPh_3), 243 (PS_2); ^2J(P,P) about 50 Hz.



8

The bisylide-substituted monochlorophosphanes (Ph_3P-R′C)$_n$PCl$_{3-n}$ with n = 2, which follow the compounds **5** (n = 1) in the series of the ylide-substituted chlorophosphanes, are ionic "phosphenium" chlorides (IUPAC nomenclature phosphanylium chlorides) **9**, X = Cl.[7] In comparison to other phosphenium ions[11] the central phosphorus atom of these cations is not only a weaker acceptor but also more nucleophilic. Thus, it reacts with gray selenium in a base-catalyzed reaction with the formation of bisylide-substituted selenoxophosphonium chloride **10**, X = Cl, which is isolated as yellow crystals.



9 **10**

From the NMR data it follows that the product is ionic like the starting compound, despite the oxidation of the phosphorus, and monomeric: $\delta(^{31}P)$ = 24.1 (d, PPh_3), 196.6 (t, PSe), ^2J(P,P) = 68.7 Hz; $\delta(^{77}Se)$ = 276.7 (d), ^1J(Se,P) = 846.8 Hz. The addition of $AlCl_3$ to a solution of **10**, X = Cl, in dichloromethane does not change the NMR shifts of the phosphorus atoms. In order to further support the ionic structure and to supplement these findings, the preparation was repeated starting from **9**, X = Br. The NMR data of the product were the same, thus confirming the presence of a cation not influenced by the anion.

Compounds **10** are not only the first chalcogeno(diorgano)phosphonium halides but also the first isolated salts of chalcogenophosphonium ions in general. Diaminothioxophosphonium salts with PF_6^-,[12] $AlCl_4^-$,[13,14] and $GaCl_4^-$ [14] counterions are proposed in solution. In the solid state, however, the assumed tetrachloroaluminates are found to be either the $AlCl_3$ adduct of the covalent chlorothioxo-λ^5-phosphane, or the cation dimerizes just like the corresponding selenoxo cation,[14] or their cation is stabilized by transferring a methyl group from a N(SiMe$_3$)$_2$ substituent to the phosphorus.[14] In all cases the phosphorus atom thus attains tetracoordination.

Experimental Procedure

7, R′ = Ph: **5** (3.64 g, 8.0 mmol), R′ = Ph, was stirred with Na_2Se_2 (0.88 g, 8.0 mmol)[15] in THF (25 mL) at 20 °C. After 5 h the NaCl formed was filtered off with a frit, the orange filtrate was concentrated under vacuum to 15 mL and mixed with benzene (5 mL). Orange prisms of **7**·0.5 C_6H_6 crystallized over a period of several days; yield 3.20 g (69%), m.p. 143–145 °C.

10, X = Cl: To a solution of **9** (2.43 g, 3.2 mmol), X = Cl, in dichloromethane (4 mL) was added gray selenium (0.50 g, 6.4 mmol) and diethylamine (0.12 g, 1.6 mmol). After the mixture was stirred for 3 h at 20 °C the unreacted selenium was filtered off with a frit, the orange-red filtrate was concentrated to about half of its original volume and mixed with benzene (8 mL). Yellow needlelike crystals of **10**·C_6H_6 (1.57 g, 53%) were obtained, which when dried under vacuum crumbled to a yellow powder, m.p. 144–148 °C (decomp).

The Structure of the [1.1]Ruthenocenophane Dication: Metal–Metal Bond Formation and the Consequences of Proximity

By *Ulrich T. Mueller-Westerhoff,* Arnold L. Rheingold,* and *Gerhard F. Swiegers*

When the [1.1]ruthenocenophane **1** was first synthesized[1] and studied,[2] one of the most surprising results was its unusually low oxidation potential. Whereas, relative to the reversible oxidation of ferrocene near 400 mV, the mononuclear ruthenocene is oxidized at a much higher potential (irreversible two-electron oxidation at 920 mV),[2, 3] the [1.1]ruthenocenophane showed a reversible two-electron oxidation at 380 mV to a stable diamagnetic dication $\mathbf{1}^{2+}$. The ^{1}H NMR

$[Ru_2(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^5\text{-}C_5H_4)_2]$ **1**

data (four Cp-H multiplets and a sharp singlet for the CH_2 bridges) seemed difficult to interpret,[2] because the sharpness of the bridge proton signal appeared to indicate a rapid rotational exchange, as was familiar from the neutral metallocenophanes of iron and ruthenium.[4] However, this did not allow a satisfactory assignment of the four ruthenocene multiplets; the structural details had to be left unresolved.

A plausible structural proposal was advanced by Taube et al.[5] when the oxidation product of osmocene was isolated and structurally characterized: the dication $[Cp_2Os]^{2+}$ reacts with a neutral osmocene to form the dimer $[Cp_4Os_2]^{2+}$, containing an Os–Os bond. A related structure could exist in our ruthenocenophane dication.

The recent improvement in the synthesis of ruthenocene[6] enticed us to apply this method to the synthesis of **1** and enabled its isolation in reasonable yields. The oxidation of **1** to $\mathbf{1}^{2+}$ was accomplished by reaction with benzoquinone and $BF_3 \cdot Et_2O$ in CH_3CN. Single crystals of the **1**-$(BF_4)_2$ were grown by slow diffusion of Et_2O into a CH_3CN solution of this salt.

The results of X-ray diffraction studies[7] on these crystals fully confirm Taube's proposal.[5] A Ru–Ru bond holds the molecule rigidly in an unusually twisted conformation (Fig. 1). Viewed down the Ru–Ru axis, the two ruthenocene

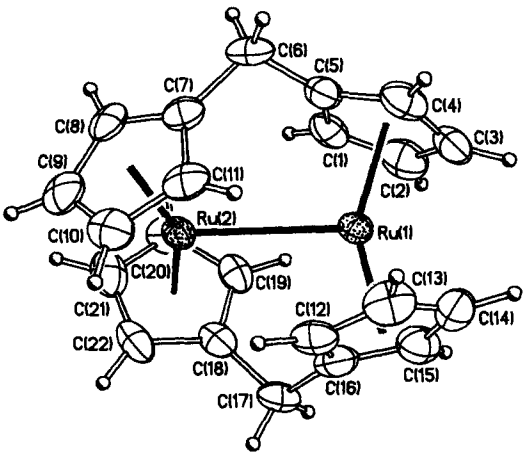

Fig. 1. View of $\mathbf{1}^{2+}$ (ORTEP), drawn with 35% thermal ellipsoids. Hydrogen atoms have arbitrary radii.

units in $\mathbf{1}^{2+}$ form an angle of approximately 75°, as measured by the angle between the two centroid-Ru-centroid planes (Fig. 2). To allow the two ruthenium atoms to approach each other, the Cp rings deviate from coplanarity and form a dihedral angle between the Cp planes of 28° (average

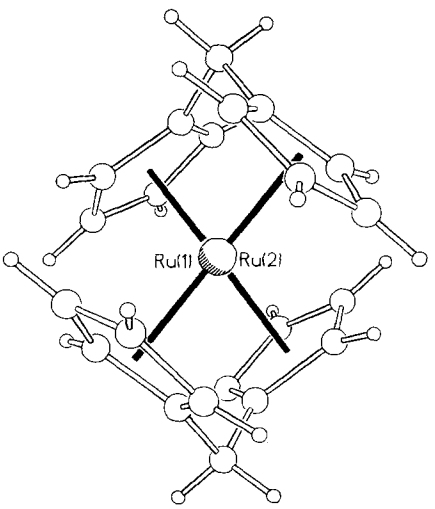

Fig. 2. View of $\mathbf{1}^{2+}$ along the Ru–Ru bond, showing the strong twist and the equivalence of the bridge protons.

centroid-Ru-centroid angle 152°). The resulting Ru–Ru bond of 2.953(1) Å must be considered to be a single bond (the Os–Os distance in $[Cp_4Os_2]^{2+}$ is 3.04 Å, in agreement with the very similar atomic radii of Ru and Os). The Cp ligands are approximately staggered and the two α protons and the two β protons of each ring are nonequivalent. The two protons of each CH_2 bridge appear different in the projection of Figure 1, but a view along the Ru–Ru axis (Fig. 2) clearly shows their equivalence. This structural detail explains the observed ^1H NMR data.

Comparison of the structure of the neutral precursor **1** (Fig. 3) with those of the Fe–Fe and the Fe–Ru [1.1]metallocenophanes[8] shows that all three are twisted to relieve the steric crowding of the inner α hydrogens but that **1** is more twisted (twist angle 33.4°) than the other two. Consequently, the metal atoms in **1** approach more closely than in the other two cases (4.70 vs. 4.82 and 4.80 Å, respectively). This still is far beyond metal–metal bonding distances, and the two ruthenocenes in **1** are fully independent and symmetrical, with exactly coplanar Cp ligands in each subunit.

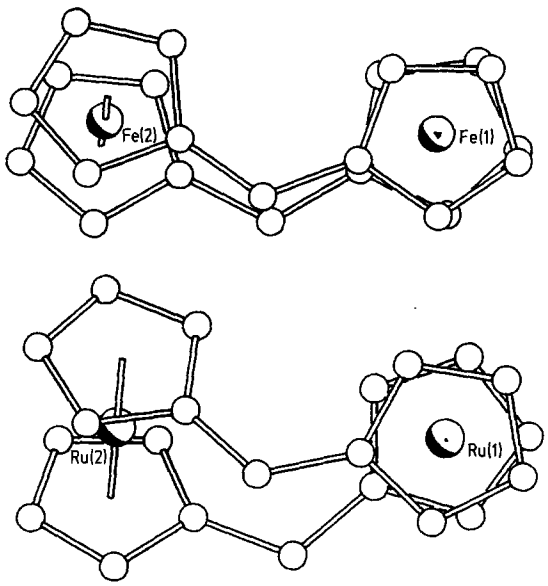

Fig. 3. Schematic top views of [1.1]ferrocenophane and [1.1]ruthenocenophane (**1**), as revealed in single-crystal X-ray diffraction studies. The Fe–Fe distance is 4.82 Å, but the more twisted **1** has a shorter Ru–Ru distance of 4.70 Å. There is no indication of any distortion of the metallocenes (the M–C distances all are equal within standard deviations).

It is of interest to analyze and compare the oxidations of ruthenocene and [1.1]ruthenocenophane. Under the usual conditions, the oxidation of Cp_2Ru is an electrochemically irreversible two-electron process at relatively high (>900 mV) potential.[9] The initially formed dication can be stabilized by adding a second, neutral metallocene (Fig. 4, Path A), which of course, first has to be located in the surrounding solution.[10,11] In [1.1]ruthenocenophane **1**, however, a second metallocene is in the immediate vicinity, and the "dimer" state is reached directly. This corresponds to a pathway (Fig. 4, Path B) in which the expected high-energy intermediate (consisting of one ruthenocene dication linked to a neutral ruthenocene) and the separate reactions $[Cp_2Ru \rightarrow Cp_2Ru^{2+} \rightarrow Cp_4Ru_2^{2+}]$ are avoided.

An obvious interpretation is that the closeness of the two ruthenium atoms leads to a metal–metal interaction in the neutral molecule and that Ru–Ru bond formation lowers the

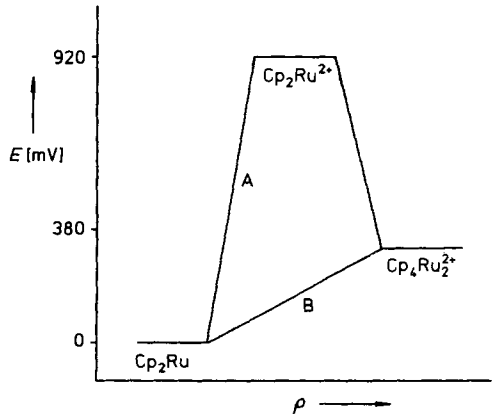

Fig. 4. Energies (in mV relative to $[Cp_2Ru]$) of the oxidation products of ruthenocene. ρ = reaction coordinate

activation energy of the oxidation process. However, the structure of the neutral species **1** shows[8] no obvious sign of metal–metal interaction. In its absence, the removal of two electrons would have to occur from only one $[Cp_2Ru]$ unit. Since this would require an oxidation potential above 900 mV, which experimentally is not the case, another explanation must be sought, to account for the fact that two electrons are lost from an orbital of much higher energy than in ruthenocene itself.

It is a unique structural feature of **1** that the two ruthenocenes can approach closer than in any solution experiment with independent ruthenocenes.[11] We suggest that the low oxidation potential and the electrochemical reversibility in **1** must be a consequence of this spatial proximity. In fact, a nonbonding interaction between the two Ru atoms produces the unusual redox properties. As shown in Figure 5, the crucial interaction is between two filled d AOs which face each other, leading to a splitting of these two levels into a bonding and an antibonding orbital. This interaction does not consti-

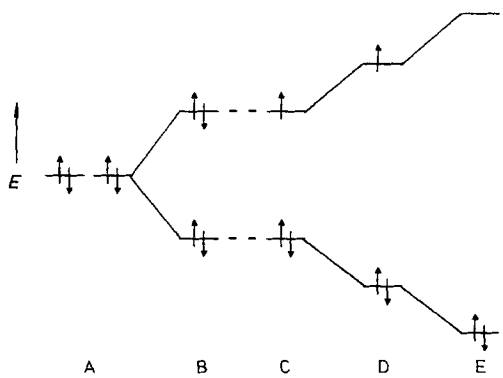

Fig. 5. Qualitative molecular orbital diagram of the relevant 4d AOs and Ru–Ru bond formation in the oxidation of [1.1]ruthenocenophane. A: degenerate, noninteracting 4d orbitals in the absence of Ru–Ru interactions; B: splitting of the 4d levels due to interaction leads to no net bonding (bond order $p = 0$); C: removal of one electron results in $p = 0.5$ and increased splitting; D: the second electron is lost more easily than the first and a Ru–Ru single bond (E, $p = 1.0$) is formed.

tute a metal–metal bond because the net bond order is zero.[13,14] Upon oxidation, an electron is removed from the antibonding orbital, which accounts for the lowering of the oxidation potential. Loss of an electron from this orbital results in an increase in the bond order to 0.5 and therefore

increased splitting. A second electron can then be removed at an even lower potential, which explains why the oxidation process involves two electrons. Loss of the second antibonding electron leads to a bond order of 1.0 for the Ru–Ru single bond. In solution, **1** undergoes a rapid *syn-syn* exchange[4] with a strongly twisted transition state containing nearly orthogonal ruthenocenes. This brings the two Ru atoms very close (Ru–Ru distance estimated from models, 3.6 Å). This further increases the splitting and leads to the very low oxidation potential.

None of the above considerations would be relevant if the reaction product were not stabilized by some form of intramolecular interaction.[15] In another case in [1.1]metallocenophane chemistry[16] we have seen independent evidence that the proximity of a reaction partner and the stabilization of the product (in an unusual way by the formation of a C-H-C bond) are the deciding factors which allow the reaction to occur. The reaction $\mathbf{1} \rightarrow \mathbf{1}^{2+}$ is driven by the proximity of the metals and stabilization of the product through a Ru–Ru bond. The ease with which this bond can form in the oxidation of **1**, especially when compared to the conditions in the oxidation of $[Cp_2Ru]$ itself, is a consequence of the interaction of the two proximate metals. The existence of a metal–metal bonding interaction or of ligand-mediated interactions in **1** is not a prerequisite.

[7] Crystallographic data for **1**-$(BF_4)_2$: $C_{22}H_{20}B_2F_8Ru_2$, dark red, nearly black crystals, $M_r = 636.13$, monoclinic, *Ia*, $a = 15.726(6)$, $b = 20.012(6)$, $c = 14.721(6)$ Å, $\beta = 106.06(3)°$, $V = 4452(3)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.898$ g cm^{-3}, $T = 294$ K, $R(F) = 0.0399$ for reflections with $F_o \geq 3\sigma(F_o)$ ($R(F) = 0.0415$ for all data). The crystallographic asymmetric unit contains two dications and four anions; the cations are chemically identical. The centrosymmetric space group, *I2/a*, was initially preferred because $Z = 8$, and **1**-$(BF_4)_2$ had two potential crystallographic twofold axes. However, structure development beyond the metal atoms was not possible; in the final structure, none of the molecular twofold axes are aligned with the crystallographic *b* axis. The Rogers test was used to determine the correct enantiomorph ($\eta = 0.92(5)$ for the reported enantiomer). Further details of the crystal structure investigation are available on request from the Director of the Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK) on quoting the full journal citation.

[8] Full details of the X-ray diffraction study of **1**-$(BF_4)_2$ will be reported separately, together with the structures of the [1.1]metallocenophanes of iron and ruthenium: A. Rheingold, U. T. Mueller-Westerhoff, G. F. Swiegers, T. J. Haas, *Organometallics*, in press.

[9] A recent communication (M. G. Hill, W. M. Lamanna, K. R. Mann, *Inorg. Chem.* **1991**, *30*, 4690) has shown that all three metallocenes can undergo quasi-reversible one-electron oxidations in noncoordinating media. The oxidation of $[Cp_2Ru]$ under these conditions occurs at an even higher potential (1.03 V) than we observed. For the present case, a mechanism based on two reversible one-electron oxidations is not applicable, because it would, as in the parallel case of [1.1]ferrocenophane, lead to two well-separated waves.

[10] In chemical oxidations, such as by halogens, the dication can also be stabilized by addition of a halide ion to form the monocation $[Cp_2RuX]^+$. Oxidation at a Hg electrode leads to the dication $[Cp_2Ru(\mu\text{-Hg})RuCp_2]^{2+}$ [3i].

[11] This consideration might suggest that the oxidation potentials of $[Cp_2Ru]$ and $[Cp_2Os]$ are concentration-dependent, and should show a lowering of the potential at high concentrations. This has not been tested experimentally. In cyclic voltammetry, the peak potential of an oxidation also may shift to more negative voltage (and that of a reduction to more positive ones) if a subsequent and rapid reaction follows the initial electron transfer (EC mechanism), and such potential shifts are concentration-dependent [12]. Thus, the rate of Ru_2 cation formation will certainly be much higher on oxidation of **1** than of ruthenocene itself. The observed decrease in oxidation potential clearly reflects this trend, although the magnitude of the difference (540 mV) cannot be explained this way.

[12] A. L. Bard, L. R. Faulkner, *Electrochemical Methods*, J. Wiley & Sons, New York, **1980**, Chapter 11.

[13] This is strictly true only in the "complete neglect of overlap" approximation. If nonzero overlap integrals are considered, the antibonding orbital is destabilized more than the bonding one is stabilized, which leads to a net repulsive interaction (e.g. in He_2). Given the 4.7 Å Ru–Ru distance, in **1** the Ru–Ru overlap integrals will be vanishingly small and their complete neglect is the best choice.

[14] Similar interpretations have been invoked to explain the chemistry of binuclear Pt, Rh, and Ir complexes. For a related interpretation, see: D. C. Smith, V. M. Miskowski, W. R. Mason, H. B. Gray, *J. Am. Chem. Soc.* **1990**, *112*, 3759. UM-W wishes to thank H. B. Gray (California Institute of Technology) for helpful discussions on this point.

[15] A low-potential two-electron oxidation involving metal–metal bond formation has, however, also been seen in a case where the metals are assumed to be not close to each other in the neutral species: N. G. Connelly, A. R. Lucy, J. D. Payne, A. M. R. Galas, W. E. Geiger, *J. Chem. Soc. Dalton Trans.* **1983**, 1879. See also: W. E. Geiger, *Prog. Inorg. Chem.* **1985**, *33*, 276. Our results suggest that a nonbonding metal–metal interaction exists in this case as well.

[16] For instance, the deprotonation of [1.1]ferrocenophane by BuLi in THF leads to a carbanion that is stabilized by a C-H-C bond. However, it is not possible to deprotonate diferrocenyl methane under the same conditions, because it does not have any means to stabilize the resulting carbanion: U. T. Mueller-Westerhoff, A. Nazzal, W. Prössdorf, *J. Am. Chem. Soc.* **1981**, *103*, 7678.

Octakis(1,1,2-trimethylpropyl)octasilacubane: Synthesis, Molecular Structure, and Unusual Properties**

By *Hideyuki Matsumoto,* Koichi Higuchi, Soichiro Kyushin, and Midori Goto**

Polycyclic compounds of Group 4 elements Si, Ge, and Sn continue to attract considerable attention.[1–4] In recent years, we have studied the synthesis and properties of polycyclopolysilanes consisting of fused four-membered rings;[5, 6]

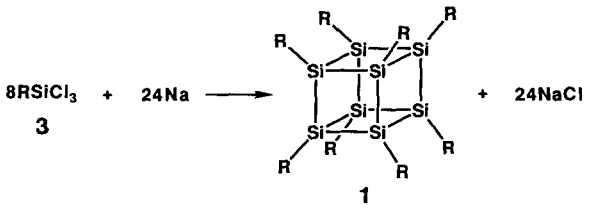
[**] This work was supported by a Grant-in-Aid for Scientific Research of Priority Area of Organic Unusual Valency (03233105 to H. M.) and of Molecular Design (02230101 to H. M.), from the Ministry of Education, Science and Culture, Japan. We also thank Shin-etsu Chemical Co. Ltd., Toshiba Silicone Co. Ltd., and Yuki Gousei Kogyo Co. Ltd. for financial support.

the primary goal of our study is to assess the electronic properties arising from their strained Si–Si σ-bonded frameworks. Earlier we reported on the synthesis of $Si_8(SiMe_2tBu)_8$ (**2**), the first octasilacubane.[6, 7] Ab initio molecular orbital calculations, however, predict that a silyl-substituted octasilacubane, $Si_8(SiH_3)_8$, is 10 kcal mol^{-1} less strained than an alkyl-substituted derivative, Si_8Me_8, at HF/6-31G* level, due to the electronic perturbation of the Si_8 ring by the silyl substitution.[8] This prompted us to synthesize octakis(1,1,2-trimethylpropyl)octasilacubane (**1**), which provides the first opportunity for assessing the electronic properties of the peralkyl Si_8 framework.[9]

The reductive coupling of (1,1,2-trimethylpropyl)trichlorosilane (**3**)[10] with sodium in toluene yielded peralkyloctasilacubane **1** (2.6% yield) (Scheme 1).[11] Compound **1** was characterized by IR and NMR spectroscopy, mass spectrometry, and X-ray crystallography.[12]



Scheme 1. R = CMe_2CHMe_2.

Compound **1** forms red-orange crystalline prisms (m.p. 220.0–221.5 °C, decomp, sealed tube), which are moderately soluble in organic solvents [benzene, toluene, hexane, 3-methylpentane (3-MP), THF, CH_2Cl_2, and $CHCl_3$]. It is surprisingly stable in air: **1** in crystalline form exhibits no change in color upon exposure to atmosphere for two weeks and can be handled without the protection of an inert atmosphere.[13] Therefore, the 1,1,2-trimethylpropyl group is a promising protective moiety for conferring a kinetic stability upon the octasilacubane framework. Also important to note is the thermodynamic stability of the framework. In a thermogravimetric analysis **1** remained stable under argon to 200 °C, after which gradual weight loss occurred. In the mass spectrometer, the dominant mode of fragmentation for **1** is the initial loss of a 1,1,2-trimethylpropyl group followed by successive loss of an olefin, 2,3-dimethyl-2- or 2,3-dimethyl-1-butene; the eight-membered charged ions remain intact under electron impact conditions.

The molecular structure of **1** (Fig. 1) is slightly distorted from an ideal octasilacubane geometry: the molecule possesses only one C_2 axis passing through the midpoint of Si1–Si1′ and Si3–Si3′ bonds; the Si–Si bond lengths range from 2.398(2) to 2.447(2) Å, and the Si-Si-Si bond angles vary from 87.2(1) to 92.6(1)°; the Si–C bond lengths lie between 1.963(5) and 1.978(6) Å, longer than the normal value; the Si-Si-C [116.2(2)–133.4(2)°] and the Si-C-C [104.5(4)–114.5(4)°] bond angles show scatter within a wide range. This distortion from an ideal cube may be due to the strained structure, caused by the need to minimize steric repulsion from eight bulky 1,1,2-trimethylpropyl groups. The packing of molecules in the unit cell is shown in Figure 2. The closest intermolecular C···C contact [C(3)···C(3) 3.72 Å] is less than the contact distance of 4 Å between the van der Waals radii of terminal methyl groups. Therefore, crystal packing forces may also have some influence on the molecular structure of **1**.

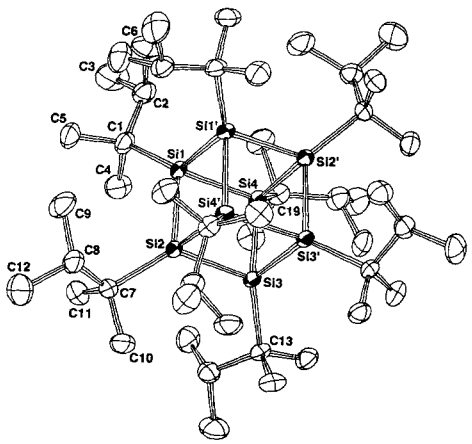


Fig. 1. Molecular structure of R_8Si_8 **1**, (R = CMe_2CHMe_2). Primed atoms are related to nonprimed atoms by the crystallographic C_2 axis at 0, *y*, 1/4 in the unit cell. Selected bond lengths [Å] and bond angles [°]: Si1-Si2 2.425(2), Si1-Si4 2.420(2), Si-Si1′ 2.447(2), Si2-Si3 2.416(2), Si2-Si4′ 2.398(2), Si3-Si4 2.424(2), Si3-Si3′ 2.440(2), Si1-C1 1.963(5), Si2-C7 1.963(5), Si3-C13 1.964(5), Si4-C19 1.978(6); Si2-Si1-Si4 90.5(1), Si2-Si1-Si1′ 87.2(1), Si4-Si1-Si1′ 91.5(1), Si1-Si2-Si3 89.5(1), Si1-Si2-Si4′ 92.6(1), Si3-Si2-Si4′ 89.6(1), Si2-Si3-Si4 90.6(1), Si2-Si3-Si3′ 90.5(1), Si4-Si3-Si3′ 88.4(1), Si1-Si4-Si3 89.4(1), Si1-Si4-Si2′ 88.5(1), Si3-Si4-Si2′ 91.3(1), Si2-Si1-C1 126.2(2), Si4-Si1-C1 116.2(2), Si1′-Si1-C1 133.4(2), Si1-Si2-C7 124.2(2), Si3-Si2-C7 127.9(2), Si4′-Si2-C7 122.6(2), Si2-Si3-C13 121.1(2), Si4-Si3-C13 131.1(2), Si3′-Si3-C13 123.7(2), Si1-Si4-C19 128.5(2), Si3-Si4-C19 125.0(2), Si2′-Si4-C19 122.8(2), Si1-C1-C2 110.0(4), Si1-C1-C4 104.5(4), Si1-C1-C5 114.5(4), Si2-C7-C8 110.6(3).

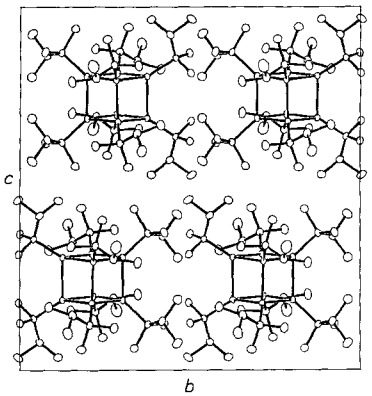

Fig. 2. Arrangement of molecules of **1** in the unit cell (*a* projection).

The highly strained silicon framework in **1** gives rise to unusual electronic properties. The UV/VIS spectrum of **1** exhibits absorption maxima at 252 (ε = 30800), 350 (ε = 850), and around 500 nm (ε = 70) (Fig. 3)[14–16]. By comparison, the corresponding spectrum of the persilyl deriva-

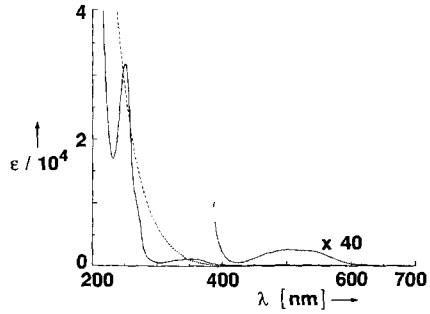

Fig. 3. UV/VIS spectra of octasilacubanes **1** (—) and **2** (– – –).

tive **2** showed only tailing absorption commencing at 470 nm. The absorption maximum of 500 nm, which is responsible for the red-orange color of **1**, is the longest wavelength electronic transition in any cyclopolysilanes with an all-silicon σ framework [e.g., 304–412 nm for $(R^1R^2Si)_3$][1, 17] suggesting a small HOMO–LUMO energy difference. A cyclic voltammogram of **1** (CH_2Cl_2, Bu_4NClO_4, standard calomel electrode (SCE), room temperature) showed an irreversible wave with anodic peak potential at 0.43 V. This value reflects the high strain energy of the Si_8 framework and is less positive than that observed for other cyclic polysilanes (e.g., 0.72 V (CH_2Cl_2, SCE) for $[Si(CH_2tBu)]_3$].[18]

Experimental Procedure

1: All manipulations were carried out under argon atmosphere. To a suspension of sodium sand (3.4 g, 150 mmol) and toluene (170 mL) was added dropwise a solution of **3** (10.4 g, 47.3 mmol) in toluene (40 mL) at 120 °C over 40 min. The resulting mixture was stirred for 5 hours. The reaction mixture was filtered to remove sodium chloride and excess sodium. After removal of toluene, the residue was taken up in hexane (10 mL). Column chromatography on silica gel 60 with hexane as eluent, and crystallization from butan-2-one afforded **1** (0.140 g, 2.6% yield), as a red-orange powder. Recrystallization from pentane gave an analytically pure sample of **1** (0.110 g), as red-orange prisms. ^{1}H NMR (200 MHz, C_6D_6): δ = 2.45 (sept, J = 6.8 Hz, 8H; CH), 1.54 (s, 48H; $C(CH_3)_2$), 1.19 (d, J = 6.8 Hz, 48H; $CH(CH_3)_2$); $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6): δ = 38.07 (CCH), 36.18 (SiC), 26.15 (CCH_3), 20.82 ($CHCH_3$); $^{29}Si\{^1H\}$ NMR (17.9 MHz, $C_6D_5CD_3$): δ = 22.24; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2948, 2864, 1453, 1371, 1360, 1148, 1125, 1084, 742; EI-MS (25 eV): rel. intensities *m/z* (R = CMe_2CHMe_2): 908 (12, M + 4), 907 (65, M + 3), 906 (74, M + 2), 905 (94, M + 1), 904 (100, M^+), 819 (48, Si_8R_7), 735 (24, $Si_8R_6(H)$), 651 (48, $Si_8R_5(H_2)$), 567 (13, $Si_8R_4(H_3)$), 483 (10, $Si_8R_3(H_4)$), 399 (9, $Si_8R_2(H_5)$).

[11] The low yield of **1** is presumably due to the large steric demands imposed upon the cyclization process. In fact, the major products from the reductive coupling reaction showed strong Si-H absorption bands in the IR spectra, but the structures of the products were not further examined. In relevant work, Masamune et al. have reported that reductive oligomerization of $Cl_2tBuSiSitBuCl_2$ with lithium naphthalenide in dimethoxyethane proceeded in a unique and somewhat unexpected manner to provide tricyclo[2.2.0.0^{2,5}]hexasilanes and tetracyclo[3.3.0.0^{2,7}.0^{3,6}]octasilane.[3b,c] Also, Weidenbruch et al.[3d] and Sakurai et al.[3f] have described the synthesis of a tetracyclo[3.3.0.0^{2,7}.0^{3,6}]octagermane derivative by the oligomerization of $X_2tBuGeGetBuX_2$ (X = Br, Cl) or $tBuGeCl_3$.

Kobayashi, *Rikagaku-Kenkyujo Hokoku*, **1978**, *55*, 69). 102 hydrogen atoms (all but 2 atoms) found in the difference Fourier map and fixed, all non-hydrogen atoms anisotropic, overall isotropic temperature factor for hydrogen atoms, R = 0.0396, R_w = 0.0416. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.

[13] Compound **1** is more stable to air-oxidation than the persilyl compound **2**, which decolorizes upon exposure to the atmosphere for several days at room temperature [6].

[14] The longest wavelength absorption was fitted by three Gaussian peaks with relative intensities of 1/5.5/1. These peaks have their maxima at 464, 508, and 561 nm, respectively.

[15] Recently, it has been reported that blue colloidal sodium-metal particles formed during the reaction of dichloromethylphenylsilane with sodium in diethyl ether and that they showed a single broad absorption band centered around 560 nm (R. E. Benfield, R. H. Cragg, R. G. Jones, A. C. Swain, *Nature* **1991**, *353*, 340). However, crystals of **1** were found by atomic absorption spectrometry to contain only 0.039% sodium. Therefore, the possibility that the absorption around 500 nm is due to the colloidal sodium can be virtually excluded.

[16] Compound **1** is photoactive under UV irradiation. In a preliminary experiment, upon irradiation (> 300 nm) at 77 K, a 3-MP glass of **1** in a sealed evacuated UV cell showed a new absorption band at 708 nm, the intensity of which attained the highest value after 0.5 h. This band, however, disappeared after the glass was warmed to the room temperature. Work including a trapping experiment is under way.

Structure of a Product of Double Addition to C_{70}: $[C_{70}\{Ir(CO)Cl(PPhMe_2)_2\}_2] \cdot 3C_6H_6$**

By *Alan L. Balch,* Joong W. Lee*, and *Marilyn M. Olmstead*

Studies of the chemical behavior of the fullerenes have shown that they can undergo multiple addition reactions.[1] However, isolation and structural characterization of isomerically pure products of these addition reactions have

proven difficult. For the multiple addition products of C_{60}, published structural information is limited to $[C_{60}\{Pt(PEt_3)_2\}_6]$,[2] its palladium analogue,[2] and $C_{60}Br_{24}$.[3] Multiple additions to C_{70} have been mentioned,[4] but until now no structural information on these was available.

In previous work we have shown that Vaska's complex, $[Ir(CO)Cl(PPh_3)_2]$, reacts readily and reversibly with C_{60}[5] and C_{70}[6] to yield adducts in which the fullerene binds in an η^2 fashion through a double bond common to two six-membered rings (6-6 ring junction) to the iridium atom. By utilizing $[Ir(CO)Cl(PPhMe_2)_2]$, which is known to be more reactive than $[Ir(CO)Cl(PPh_3)_2]$ in oxidative-addition reactions,[7] we have succeeded in placing two metal complexes on the exterior surface of C_{70}.

Treatment of C_{70} with a six- to twelvefold molar amount of $[Ir(CO)Cl(PPhMe_2)_2]$ in benzene produces black, feather-shaped crystals of **1**[8] [IR (fluorolube): $\tilde{\nu}[cm^{-1}] = 2001$ (C≡O), $^{31}P\{^1H\}$ NMR (121.7 MHz, CD_2Cl_2, 25 °C): $\delta = -38.7$]. The broad single in the ^{31}P NMR spectrum appears as eleven individual lines at −70 °C. This suggests that several isomers are in dynamic equilibrium in solution. However, both the observation of a uniform, characteristic morphology and identical cell constants for crystals from several different preparations suggest that crystalline samples contain exclusively the isomer reported here.

$[C_{70}\{Ir(CO)Cl(PPhMe_2)_2\}_2] \cdot 3C_6H_6$ **1**

The molecular structure, as revealed by an X-ray diffraction study, is shown in Figure 1, left.[9] The molecule possesses a crystallographically imposed twofold axis which bisects the C35–C35′ bond. Each iridium atom is bound to a 6-6 ring junction at opposite poles of the C_{70} molecule. The attachment of the iridium atoms to the a-b bonds of C_{70} is similar to that seen earlier in $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPh_3)_2]$.[6] The positioning of the two substituents can be explained by combination of structural and electronic factors. The a-b bonds of C_{70} are the 6-6 ring junctions that have the highest degree of pyramidalization within the molecule. Since η^2-coordination of olefins causes pyramidalization of the two carbon atoms involved, it is not surprising that the iridium fragment preferentially binds at the a-b sites. Once one iridium complex has added to C_{70}, it is likely that the local steric and electronic effects will direct further reactivity away from that pole of the molecule. At the opposite pole, there is a choice of three distinct a-b bonds (A, B, and C in Fig. 1, right) to which the second iridium atom can add. In **1**, the second addition has occurred at site B. At site C, the two substituents would be furthest apart, while at site A they would be closest together. Careful examination of computer-generated representations of these three possible structures reveals no untoward contacts that would disfavor the formation of any form, even for addition at A where the two iridium complexes would be closest.

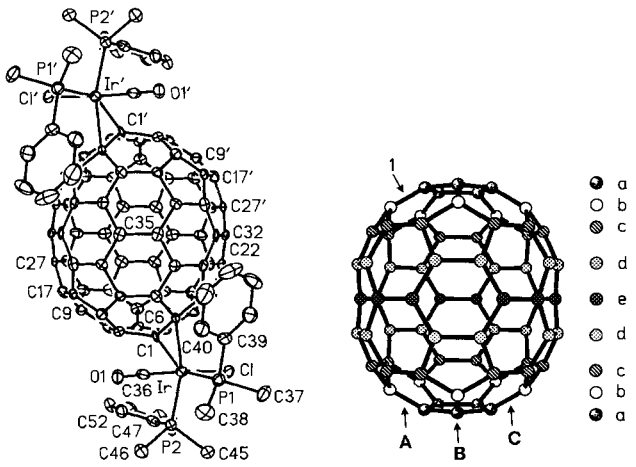

Fig. 1. Left: A perspective view of **1** with 50% thermal contours for all atoms. Selected distances [Å]: Ir-C1, 2.194(7); Ir-C6, 2.156(7); C1-C6, 1.523(11); the e-e bonds C31-C32, 1.456(11); C33-C34, 1.464(12); C35-C35′, 1.448(18). Right: Idealized structure of C_{70}. 1 indicates the bond at which the first addition occurs **A**, **B**, and **C** mark possible sites for the second addition.

The form of the C_{70} molecule in **1** conforms to the structural features noted earlier for $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPh_3)_2]$[6] and for those predicted theoretically for the unsubstituted molecule.[10, 11] Average bond lengths in Å (excluding those modified by iridium coordination) are: a-a, 1.44(1) Å; a-b, 1.39(1); b-c, 1.46(1); c-c, 1.37(1); c-d, 1.44(1); d-d, 1.43(1); d-e, 1.42(1); and e-e, 1.46(1). The report of an unusually short e-e distance that came from an electron diffraction study of a C_{70} film is not confirmed by this structure.[12]

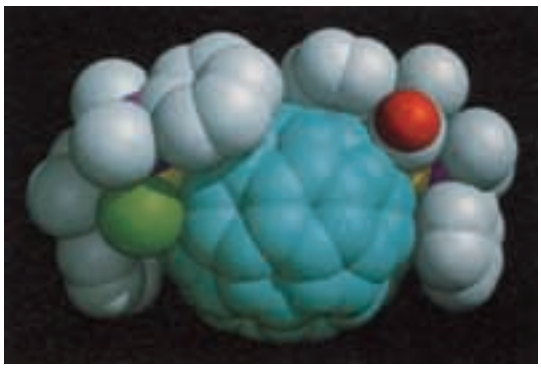

Fig. 2. A view of **1** showing van der Waals surfaces. Notice how the phenyl substituents hug the surface of C_{70}. C_{70} is light blue; other carbons, white; oxygen, red; chlorine, green; iridium, yellow; and phosphorus, purple.

We have previously noted that arene/fullerene π–π contacts are important factors in the solid-state structure of fullerene derivatives.[13] In the case of **1**, the phenyl substituents of the phosphane ligands lie over the surface of the C_{70} portion although these could have assumed positions further from the C_{70} portion by simple rotation of the PMe_2Ph unit about the Ir-P bonds (see Fig. 2). Moreover

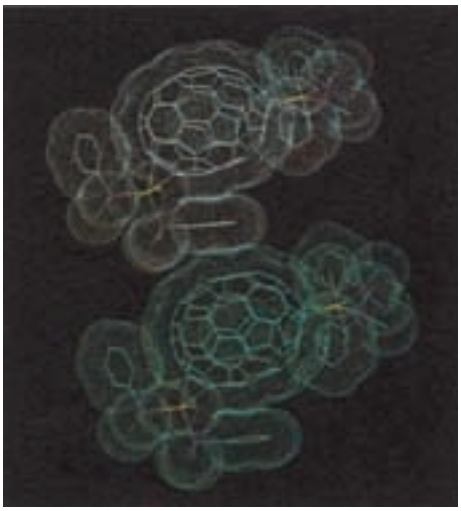

Fig. 3. A view of the contact of two molecules of **1** in the solid state. Van der Waals surfaces are represented by dots, and the two molecules appear in different colors.

adjacent molecule of **1**. This close approach of two molecules of **1** is shown in Figure 3. The three benzene solvent molecules in **1**, however, do not adopt positions that place their flat surfaces in contact with the C_{70} unit. These benzene molecules are merely occupying what would otherwise be voids within the solid.

In summary, a double addition product of C_{70} has been structurally characterized. Because of potential differences in the chemical reactivity of the eight discrete bond types in C_{70}, it may be easier to characterize multiple addition products for C_{70} than for C_{60}.

Experimental Procedure

A yellow solution of 84 mg (0.16 mmol) of $[Ir(CO)Cl(PMe_2Ph)_2]$ in 0.5 mL of benzene was added to a reddish brown solution of 20 mg (0.024 mmol) of C_{70} in 12 mL of benzene. The resulting solution was thoroughly mixed and then allowed to stand undisturbed for four days. The black, crystalline product was collected by filtration and washed with benzene and ethyl ether. Yield: 30 mg, 60% based on C_{70}.

[8] When the ratio of C_{70} and $[Ir(CO)Cl(PPhMe_2)_2]$ in benzene is 1:1, $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPhMe_2)_2]\cdot 2C_6H_6$ crystallizes as black, rectangular needles that are visually distinctly different from **1**. They form in the triclinic space group $P\bar{1}$. A completed X-ray diffraction study to be published separately shows that this product closely resembles $[(\eta^2\text{-}C_{70})Ir(CO)Cl(PPh_3)_2]$ [6] where the iridium is bound to an a-b bond of C_{70}.

[9] Crystal structure analysis of **1** at 130 K: $C_{122}H_{62}Cl_2Ir_2O_2P_4$, monoclinic space group $C2/c$, $a = 17.893(4)$ Å, $b = 20.988(5)$ Å, $c = 22.127(5)$ Å, $\beta = 103.51(2)°$, $Z = 4$, $\rho_{calcd} = 1.758$ mg m^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), Siemens R3m/V; 9262 independent reflections, 6360 observed reflections with $F > 4.0\,\sigma F$, $R = 0.054$, $R_w = 0.051$. As is typical for this class of compounds, the Cl and CO groups are disordered [6]. The figure shows the predominant form (0.64 fractional occupancy). Solution by direct methods (SHELXTL PLUS (VMS)). avium Trisaccharide (Serovar 21) for the Preparation of a Neoglycoprotein for Immunological Studies**

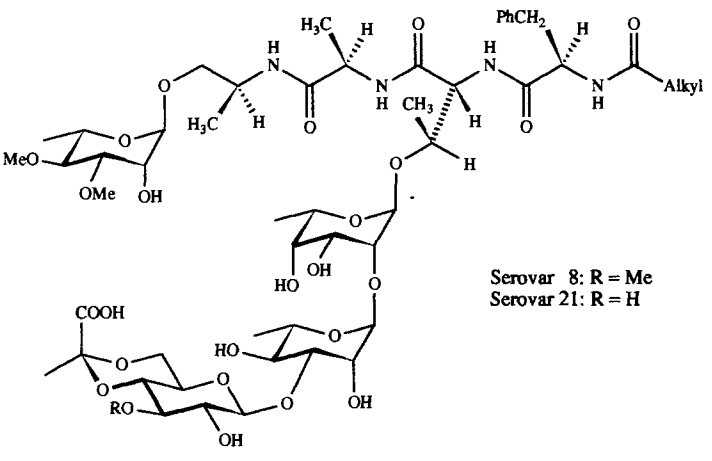
By *Thomas Ziegler**

Dedicated to Cornelis P. J. Glaudemans on the occasion of his 60th birthday

Disseminated infections by microorganisms of the MAI complex (*Mycobacterium avium intracellulare*), which normally do not cause diseases, are often observed in AIDS patients as serious complications.[1-3] The early recognition of the infection and the clear diagnostic discrimination between these "atypical" mycobacteria and tuberculosis (*Mycobacterium tuberculosis, bovis*) is essential for the specific treatment of the infection. However, this is only possible after laborious and time-consuming cultivation of the isolated bacteria.[4] A quicker and more selective detection of atypical mycobacteria (e.g., serologically, by ELISA techniques or skin tests) would therefore be desirable for routine clinical examinations. However, access to MAI-specific antigens that enable the preparation of suitable antisera or the determination of antibody titers is necessary for such tests. A recent attempt to use MAI-specific protein antigens showed that interfering cross-reactions with antigens of *M. tuberculosis* can occur, which thus prevents an unambiguous diagnosis.[5]

Far more promising is the use of species-specific oligosaccharide haptenes, which are found in the characteristic glycopeptidolipids of the cell membrane of MAI.[6-8] These are tri- to pentasaccharides that form an *O*-glycosidic linkage with the threonine unit of a tetrapeptide (Scheme 1). The



Scheme 1. Structure of the MAI glycopeptide lipids (serovars 8 and 21).

protein-bound disaccharide residue α-L-Rha*p*-(1 → 2)-6-deoxy-α-L-Tal*p* is conserved for all MAI serovars, whereas the serologically differentiable species are determined by the saccharide residue at the nonreducing end.[9] The serovars 8 and 21, which both bear an immunodominant 4,6-pyruvylated

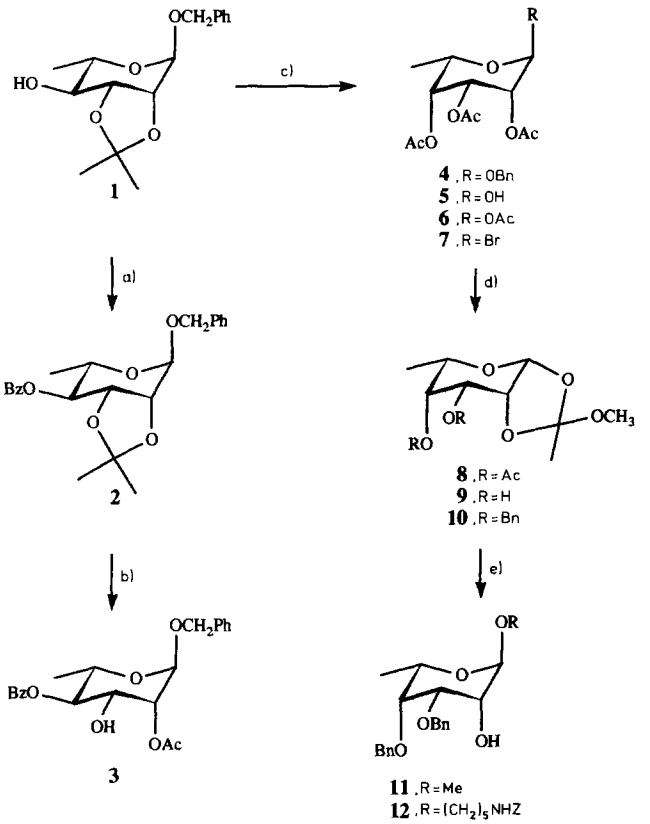
[**] This work was supported by the Deutsche Forschungsgemeinschaft. Abbreviations used: *p* = pyranose, Rha = rhamnose, Tal = talose, Bn = benzyl, Bz = benzoyl, Ac = acetyl, Z = benzyloxycarbonyl, Tos = tosyl, TMSOTf = trimethylsilyltriflate, BSA = bovine serum albumin, PBS = phosphate buffered saline, EE = ethyl acetate, RT = room temperature.

β-D-Glc*p* residue are particularly interesting.[9, 10] We now describe an efficient chemical synthesis of a trisaccharide neoantigen of MAI (serovar 21), which can be employed directly for diagnostic purposes or for the preparation of specific antibodies. For the first time the complete synthesis of a complex oligosaccharide containing a pyruvate acetal was possible.

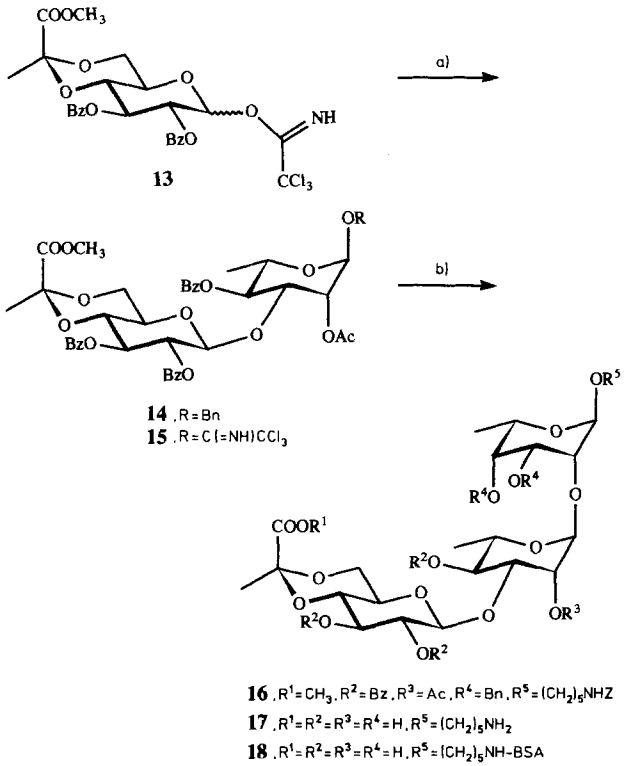
A blockwise construction of the trisaccharide was chosen for the synthesis so that a minimum of manipulation of protecting groups was required. The monosaccharide building blocks **3** and **12** were synthesized from the readily accessible[11–14] L-rhamnopyranoside derivative **1** (Scheme 2).



Scheme 2. Synthesis of the monosaccharide building blocks **3** and **12**. a) BzCl in pyridine. b) 1) AcOH (90%); 2) $MeC(OMe)_3$, TosOH (cat.) in DMF; 3) AcOH (80%). c) 1) Ref. [8]; 2) H_2, Pd (10% on activated charcoal) in EE; 3) Ac_2O in pyridine; 4) HBr in AcOH, → 94% **7**. d) 1) 2,6-lutidine in MeOH; 2) NaOMe (cat.) in MeOH; 3) BnBr, NaH in THF. e) 1) $HO(CH_2)_5NHZ$, $HgBr_2$ (cat.) in MeCN; 2) NaOMe (cat.) in MeOH, →18% **11**, → 55% **12**.

Benzoylation of **1** yielded the crystalline derivative **2** (72%), which was converted into the L-rhamnosyl acceptor **3** (65%). The 6-deoxy-L-talosyl acceptor **12** should bear a 5-aminopentyl aglycon so that the saccharide can be subsequently linked to a protein. For the synthesis of **12**, compound **1** was transformed into the known L-taloside **4**.[12, 13] After hydrogenation of the benzyl group (**4** → **5**) and acetylation, the resulting tetraacetate **6** was treated without further purification with HBr to afford 2,3,4-tri-*O*-acetyl-6-deoxy-α-L-talopyranosyl bromide (**7**, 94%). The latter was subsequently converted into the orthoester **8** with methanol. After cleavage of the acetate groups at O3 and O4 (Zemplén and benzylation of the intermediate **9**, the yield of the L-talopyranose derivative **10** was 79%. All synthetic steps for the conversion **4** →**10** proceeded without the formation of by-products, which made the time-consuming isolation and characterization of the intermediates **5**–**9** unnecessary. This contributed to the efficiency of our chosen synthesis of **10**. Reaction of **10** with 5-benzyloxycarbamidopentanol catalyzed by $HgBr_2$[15] and deblocking of the 2-position afforded the desired acceptor **12** (55%). Also produced as a side product was L-talopyranoside **11** (18%), which was recently prepared differently and used in the synthesis of the MAI tetrasaccharide (serovar 4).[8] The overall yield of the building blocks **3** and **12** was thus 47% (based on **1**) and 40% (based on **4**), respectively.

The construction of the MAI trisaccharide was now begun from the nonreducing end (Scheme 3), which required a suitable pyruvylated glucosyl donor. The trichloroacetimidate **13** proved particularly valuable for this purpose. It can be synthesized easily from glucose.[16] The trimethylsilyltriflate-



Scheme 3. Synthesis of the MAI neoglycoprotein **18** from the precursors **3**, **12**, **13**. a) 1) **3**, 10 mol% TMSOTf in CH_2Cl_2, 1 h, −20 °C, →72% **14**,; 2) H_2, Pd (10% on activated charcoal) in EE, 3 h, RT; 3) Cl_3CN, K_2CO_3 in CH_2Cl_2, 4 h, RT, →77% **15**. b) 1) **12**, 10 mol% TMSOTf in CH_2Cl_2, 1 h, −20 °C, →70% **16**; 2) NaOMe (cat.) in MeOH, 24 h, RT; 3) NaOH in H_2O, 48 h, RT; 4) H_2, Pd (10% on activated charcoal) in H_2O, 12 h, RT, → 76% **17**; 5) **17** (10 μmol), BSA (0.3 μmol), glutardialdehyde solution (28%, 15 mL) in PBS buffer (pH 7.2), 1 h, 0–4 °C, then $NaBH_4$ (0.3 g), 1 h, 0–4 °C; 6) dialysis against PBS, then lyophilization →**18**.

catalyzed coupling of **3** and **13** by the inverse addition procedure[17] furnished the crystalline β-(1 → 3)-linked disaccharide **14**. Hydrogenation of the latter and subsequent reaction with trichloroacetonitrile afforded the diglycosyl donor **15** (77%). The protected trisaccharide was finally prepared in 70% yield by coupling of **12** and **15**. Both glycosylation steps proceeded diastereoselectively; in neither case could the undesired anomer be detected. For the deblocking of **16**, first the acyl residues were cleaved (Zemplén), and then the methyl ester of the pyruvate acetal was saponified, followed by a hydrogenolytic cleavage of the benzyl groups. The deprotected trisaccharide **17** was obtained in 76% yield.

Attachment of saccharide **17** to a carrier protein can be achieved by different methods.[18–20] However, the use of the heterobifunctional coupling reagent 3-maleimidopropionyl-*N*-hydroxysuccinimide ester[21] yielded, after lyophilization, an insoluble conjugate with bovine serum albumin (BSA) that was therefore unsuitable as neoantigen. Advantageous, on the other hand, was the particularly simple and quick attachment of **17** to BSA with glutardialdehyde. The concentrations chosen here for the coupling step (Scheme 3) by this method provided a highly soluble neoglycoprotein **18** that contained 12 mol **17** per mol BSA according to the determination of bound sugar by the phenol–sulfuric acid method.[22] The conjugate **18** should therefore be ideally suited tor further immunological studies.

Novel Strategies for the Synthesis and Crystallization of Electrophilic Dinuclear Cations: Solution and Solid-State Properties of $[Re_2(NCCH_3)_{10}][Mo_6O_{19}]_2$ **

By *Stacey N. Bernstein* and *Kim R. Dunbar**

Dedicated to Professors F. Albert Cotton and Richard A. Walton

Beginning with the earliest reports in 1858, mononuclear transition metal acetonitrile complexes have been a topic of considerable interest to inorganic chemists,[1] but surprisingly little is known about analogous metal–metal bonded species; in fact only two examples have been reported to date, namely, $[M_2(NCCH_3)_{10}]^{4+}$ (M = Mo, Rh),[2] these being derived from acidification or alkylation reactions of $M_2(O_2CCH_3)_4$. Recent years have seen a marked increase of interest in acetonitrile cation complexes, particularly with respect to their use as precursors for metal–containing polymers and molecular materials,[3] catalysts,[4] and biologically relevant coordination compounds.[5] We now report two entirely new strategies for the synthesis of novel solvated dinuclear cations beginning from halide and phosphine complexes.

Reactions of $[(n\text{Bu})_4N]_2[Re_2Cl_8]$ with $HBF_4 \cdot Et_2O$ in CH_3CN/CH_2Cl_2 solvent mixtures produced, in approximately 15% yield, a bright blue solid characterized as **1**.[6]

$[Re_2(NCCH_3)_8][BF_4]_4$ **1**

[**] This work was supported by the National Science Foundation (Grants CHE-89149, CHE-8403823, CHE-8908088, and CHE-88-00770), the Camille and Henry Dreyfus Foundation, and the National Institutes of Health (Grant No. 1-S10-RR04750-01). We thank Dr. J. Amarasekera and Professor T. J. Pinnavaia for help with the TGA analyses and Dr. J. Ledford for the XPS studies. We also thank Dr. A. Quillevéré for helpful discussions and Dr. D. Ward for help with the ORTEP.

Analogous protonation reactions of $[Re_2Cl_4(PnPr_3)_4]$ also led to **1**, and in much higher yields (ca. 80%). Single crystals of the $[BF_4]^-$ salt were obtained by slow diffusion of CH_2Cl_2 into a CH_3CN solution of **1** over a period of 3 days.[7] Preliminary X-ray results of **1** revealed a body-centered cubic lattice that shows a threefold disorder of the dirhenium units. Poor diffraction coupled with considerable refinement difficulties for three independent cubic crystals prompted us to resort to an unusual strategy to reduce the crystal symmetry and improve packing: we replaced the small tetrahedral $[BF_4]^-$ counterions with large octahedral $[Mo_6O_{19}]^{2-}$ polyoxometalate anions. This not only led to a perfectly ordered array of dinuclear cations within the interstices provided by the anions, but opened up the possibility of studying solid-state reactivity of the trapped solvated cations as well.

$[Re_2(NCCH_3)_{10}][Mo_6O_{19}]_2$ **2**

The molybdate salt **2** was prepared by an anion exchange reaction of **1** and $[(nBu)_4N]_2[Mo_6O_{19}]$ in CH_3CN; crystals suitable for X-ray studies were grown by slow diffusion of separate CH_3CN solutions of the two salts that were layered in a sealed tube.[8] Single-crystal X-ray data revealed its identity as $[Re_2(NCCH_3)_{10}][Mo_6O_{19}]_2 \cdot 4CH_3CN \cdot 2H_2O$. The ORTEP plot of the three constituent ions in **2** is depicted in Figure 1, and a selection of important distances and angles are listed in the caption. The molecule crystallizes in the

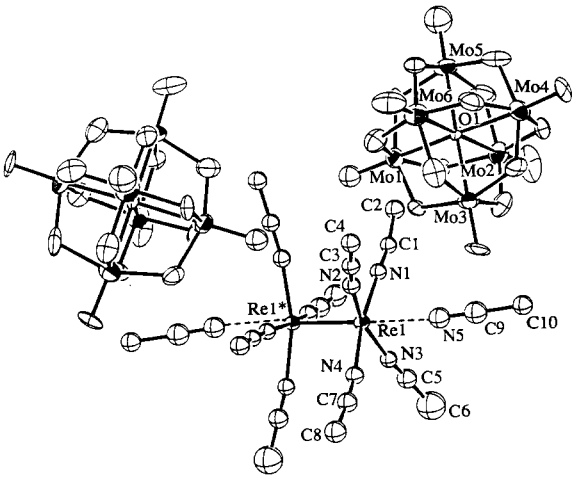

Fig. 1. Selected distances [Å] and angles [°] for **2**: Re1-Re1* 2.259(4); Re1-N1 2.07(3); Re1-N2 2.02(3); Re1-N3 2.06(2); Re1-N4 2.16(3); Re1-N5 2.51(3); N1-C1 1.06(3); N2-C3 1.12(3); N3-C5 1.18(3); N4-C7 1.13(4); N5-C9 1.09(3); C1-C2 1.33(5); C3-C4 1.47(4); C5-C6 1.37(4); C9-C10 1.39(4); Re1-Re1*-N1 97.8(6); Re1-Re1*-N2 92.6(7); Re1-Re*-N5 174.6(6); Re1-N1-C1 170(3); N1-C1-C2 179(4); Re1-N2-C3 176(2); N2-C3-C4 172(3); Re1-N5-C9 168(3); N5-C9-C10 178(4).

monoclinic space group $C2/c$, and the midpoint of the Re-Re bond resides on a twofold symmetry axis. Each Re^{II} center is pseudooctahedral, consisting of four nearly planar CH_3CN ligands and two additional vertices defined by a weakly interacting axial CH_3CN group (Re–N = 2.51 (3) Å) and the other Re atom. The new molecule adopts a staggered conformation in which the two $Re(NCCH_3)_4$ units are rotated by $\chi_{av} = 44.5\ (1)^\circ$, as expected for a triply bonded species. The Re–Re distance of 2.259 (4) Å in **2** falls in the range observed for dirhenium compounds containing metal–metal triple bonds of the electron-rich $\sigma^2\pi^4\delta^2\delta^{*2}$ configuration, although the metal centers are highly charged in **2** and are not coordinated to strong σ or π donors such as phosphine or halide ligands.[9] In the $[Mo_6O_{19}]^{2-}$ anion, the average Mo–O distances correlate well with those previously observed.[10] The three-dimensional packing arrangement within a 10 Å radius from the center of the Re–Re bond revealed that the $[Re_2]^{4+}$ cations occupy pseudooctahedral sites in the lattice defined by the spherical $[Mo_6O_{19}]^{2-}$ anions.

An IR spectrum of crystals of **2** reveal absorptions arising from coordinated CH_3CN and the $[Mo_6O_{19}]^{2-}$ counterion.[11] The IR spectrum of **1** exhibits similar absorptions for coordinated CH_3CN and $[BF_4]^-$.[11] A ^1H NMR spectrum of **1** in CD_3CN exhibits a resonance at $\delta = +3.37$ attributed to the equatorially bound CH_3CN groups and a minor feature at +1.95 due to free CH_3CN.[12] The electronic spectrum of **1** in the visible region consists of a very broad low-energy transition at λ_{max} (ε) = 663 nm (630 $M^{-1}cm^{-1}$) in addition to a strong feature of nearly equal intensity at 593 nm (590 $M^{-1}cm^{-1}$) with two shoulders, located at 458 and 866 nm. Bands in the UV region fall at 244 (2.7×10^4 $M^{-1}cm^{-1}$) and 203 nm (5.1×10^4 $M^{-1}cm^{-1}$). Electrochemical measurements performed in 0.05 M $[(nBu)_4N][BF_4]/CH_3CN$ solutions revealed, surprisingly, an extremely accessible quasi-reversible reduction at $E_{1/2} = +0.24$ V along with two irreversible reductions at $E_p^c = -0.20$ V and -0.76 V vs. Ag/AgCl.[13] These results are in sharp contrast to the redox properties of other complexes containing triple bonds of the type $\sigma^2\pi^4\delta^2\delta^{*2}$, which exhibit one or two accessible oxidations but not reductions. The high charge of the cation coupled with the fact that the supporting ligand set comprises only moderate-strength σ-donors undoubtedly contributes to the electrophilic character of **2**.

A test of the thermal stability of **2** by thermogravimetric analysis under N_2 (Fig. 2) reveals that loss of coordinated CH_3CN is essentially quantitative upon gradual heating to 350 °C.[14] The resulting black amorphous mixed-metal oxide constitutes the first example of a ternary ReMo oxide of any type. Preliminary studies by X-ray photoelectron spectroscopy (XPS) confirmed the absence of carbon or nitrogen components and revealed that Mo^{VI} and two different oxidation states of Re are at the surface of the material. Further characterization by transmission electron spectroscopy, neutron scattering, and EXAFS are in progress. Similar materials have been synthesized from the salts $[M_2(NCCH_3)_{10}][M'_6O_{19}]_2$ (M = Mo, Rh; M' = Mo, W).

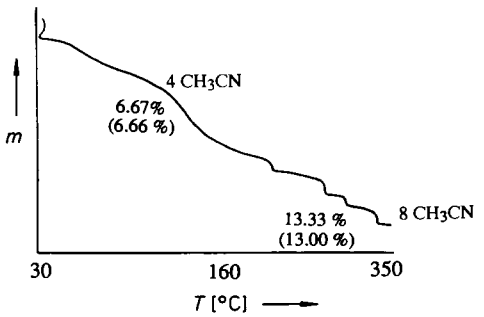

Fig. 2. Thermogravimetric analysis curve for a sample of $[Re_2(NCCH_3)_8][Mo_6O_{19}]_2$ heated under N_2 to 350 °C. The salt undergoes sequential loss of all 8 CH_3CN groups to yield a ternary oxide. m = weight of the sample. The percentages refer to the theoretical (experimental) weight loss.

This paper reports two findings of importance to molecular and solid-state chemistry of transition metals. The fact that a hitherto unknown dinuclear solvated cation may be easily synthesized from $[Re_2Cl_8]^{2-}$ and $Re_2Cl_4(PnPr_3)_4$

complexes is remarkable, considering the demonstrated stability of such species.[9] This method is currently being extended to related complexes of W and Os.[15] Furthermore, the low-temperature desolvation approach to mixed-metal oxides from salts comprising acetonitrile cations and various polyoxometalate anions is a potentially very useful route to new oxides of previously unknown stoichiometries and structures. In principle, one may carefully select the identity of the metals to optimize properties such as catalytic activity and magnetism, especially if 3d metals are included.

Experimental Procedure

1: $[(n\mathrm{Bu})_4\mathrm{N}]_2[\mathrm{Re}_2\mathrm{Cl}_8]$ (1.00 g, 0.865 mmol) was dissolved in 50 mL of CH_3CN and treated with 5 mL of $HBF_4 \cdot Et_2O$ (85% HBF_4 solution). After complete addition of the acid, the pressure in the reaction vessel was reduced to remove gaseous HCl, and 200 mL of CH_2Cl_2 was slowly added. The solution was heated under reflux for five hours, after which time the intensely blue solid was collected, washed with CH_2Cl_2 and Et_2O, and dried in vacuo. Yield 150 mg, 15%.

Alternative procedure: $[\mathrm{Re}_2\mathrm{Cl}_4(P\mathrm{Pr}_3)_4]$ (350 mg, 0.303 mmol) was suspended in a mixture of CH_3CN (10 mL) and CH_2Cl_2 (3 mL) and treated with 1 mL of $HBF_4 \cdot Et_2O$ under reduced pressure. The reaction mixture turned green within 5 min and gradually became blue after heating at reflux for 12 h. The solution was then treated with 20 mL of CH_2Cl_2 to yield a bright blue solid which was collected, washed with CH_2Cl_2 and Et_2O, and dried in vacuo. Yield 253 mg, 80%.

[6] Reactions of $[\mathrm{Re}_2(O_2C_4H_7)_4Cl_2]$ with $AgBF_4$ followed by Et_3OBF_4 also produce low yields of **1**. K. R. Dunbar and A. Quillevéré, unpublished results.

[7] Compound **1** crystallizes in a body-centered cubic space group with lattice parameters 29.22(1) Å and $V = 24947(22)$ Å^3.

[8] Calculated for $[\mathrm{Re}_2(\mathrm{NCCH}_3)_8][\mathrm{Mo}_6O_{19}]_2$: C 8.09, H 1.02, N 4.72. Found: C 8.39, H 1.20, N 4.78. Allowances for small amounts of residual CH_3CN in the lattice improves the analysis. Crystal data for $\mathbf{2} \cdot 4CH_3CN \cdot 2H_2O$ at $-90\,^\circ$C: $C_{24}H_{40}N_{12}O_{40}Mo_{12}Re_2$, $M = 2742.44$, monoclinic space group $C2/c$ with unit cell parameters $a = 18.36(2)$, $b = 22.67(2)$, $c = 17.45(2)$ Å, $\beta = 90.31(9)^\circ$, $V = 7263(22)$ Å^3, $Z = 4$, $\varrho_{calcd} = 2.508$ g cm^{-1}, and $\mu(\mathrm{Mo}_{K\alpha}) = 54.03$ cm^{-1}. The intensity data were collected on a Rigaku AFC6-S diffractometer by an ω-2θ scan technique. 6508 unique data were collected in the range $6 \le 2\theta \le 50^\circ$ and corrected for Lorentz and polarization effects. The intensities of three check reflections decreased by ~60%; a linear correction factor was applied to account for this considerable decay. An empirical absorption correction based on azimuthal scans of several reflections with χ near 90° was also applied. A total of 2805 data with $F_o^2 > 3\sigma(F_o^2)$ were used to refine 298 variables to residuals of R (R_w) = 0.066 (0.083) and quality-of-fit of 2.56. The largest shift/esd in the final cycle was 0.13; the largest peak in the final difference Fourier map was 1.95 e$^-$/Å^3 and is the ghost of a Re atom. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK), on quoting the full journal citation.

$[Ga(C_5H_5)]$: Synthesis, Identification, and Ab Initio Investigations**

By *Dagmar Loos, Hansgeorg Schnöckel,* Jürgen Gauss,** and *Uwe Schneider*

Monovalent compounds of the third main group are interesting synthetic targets in inorganic chemistry.[1] Whereas for the heavier elements gallium, indium, and thallium[2] as well as for boron[3] a series of formally monovalent compounds are well known and have been characterized in detail, the corresponding aluminum compounds have only been obtained recently in solution[4–7] and as solids.[5] Of particular interest in this context is the synthesis and crystal structural analysis of $[Al_4Cp^*_4]$, $Cp^* = C_5Me_5$,[5] which shows an Al_4 tetrahedron with each Cp* bonded η^5 to one of the aluminum atoms. Besides the tetramer, the monomer was recently obtained by warming a solution of $[Al_4Cp^*_4]$ in toluene up to 100 °C and was then identified by NMR spectroscopy.[7] The unambiguous assignment of the NMR signal was possible due to the theoretical calculation of the ^{27}Al NMR shifts. Following the successful preparation of [AlCp*], [GaCp] (**4**) was the only missing member in the series of the cyclopentadienyl compounds of the monovalent third main group elements. [InCp] and [TlCp], $Cp = C_5H_5$, were described more than 35 years ago by E. O. Fischer et al.[8] and H. Meister[9], respectively.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. R. Ahlrichs for his generous support and for many helpful discussions.

We report in this communication the preparation of [GaCp] (**4**), the first molecular, organometallic compound of monovalent gallium. The synthesis is achieved in an analogous way to that of the cyclopentadienylaluminum(I) compounds[5] by the reaction of a metastable solution of GaCl (**1**) in toluene/diethyl ether[10, 11] with $[MgCp_2]$ (**2**) [Eq. (a)]. Compound **3**, which precipitates in a crystalline

$$\underset{\mathbf{1}}{GaCl_{solv.}} + \underset{\mathbf{2}}{[MgCp_2]} \xrightarrow{PhCH_3/Et_2O} \underset{\mathbf{3}}{\tfrac{1}{2}[CpMgCl \cdot Et_2O]_2} + \underset{\mathbf{4}}{[GaCp]} \quad (a)$$

form at $-30\,^{\circ}C$, was characterized by an X-ray structural analysis.[12] Compound **4** is also formed if [LiCp] is used instead of magnesocene [Eq. (b)].

$$\underset{\mathbf{1}}{GaCl_{solv.}} + [LiCp] \xrightarrow{PhCH_3/Et_2O} LiCl + \underset{\mathbf{4}}{[GaCp]} \quad (b)$$

In both cases the formation of metallic gallium occurs as a side reaction. This finding corresponds to the formation of metallic indium in the synthesis of [InCp].[13]

The ^{71}Ga NMR spectra[14] of the solutions obtained from reactions (a) and (b) reveal a single signal at $\delta = -714$ with a full width at half-maximum of 250 Hz.[15] This resonance at very high field suggests by comparison with the shifts reported by H. Schmidbaur for arene complexes of monovalent gallium[2] that [Ga^{I}Cp] has been formed. The assignment is also supported by ab initio calculations, which we will discuss in the second part of this communication, and is also in agreement with NMR spectroscopic investigations of other low-valent main group cyclopentadienyl compounds. Thus, the resonances of the metal atoms of $[SnCp_2]$,[16] $[SiCp^*_2]$,[17] [AlCp*],[5, 7] and [TlCp][18] are observed at very high field compared with those of normal-valent species. As a result of the shielding effect of the Cp group, however, the ^{6}Li NMR signals of [LiCp] and its derivatives are also shifted to higher field.[19]

The isolation of pure **4** by removal of the solvent in vacuo has not been successful. At $-50\,^{\circ}C$ **4** condenses together with the solvent in the receiving flask cooled to $-196\,^{\circ}C$ and can be detected by NMR spectroscopy.[14, 20] The δ values are -714 (^{71}Ga), 106.8 (^{13}C), and 5.71 (^{1}H). Furthermore, **4** can also be detected by mass spectrometry[21] in the gas phase above the receiving flask cooled to $-70\,^{\circ}C$: at 20 eV excitation energy the signals of the highest mass are those due to monomeric **4** at m/z 134 and 136.[22] Their intensity ratio corresponds to that of the natural $^{69}Ga/^{71}Ga$ isotope distribution. By comparison of the intensities of the solvent and of the [GaCp] peak the vapor pressure of [GaCp] (**4**) at $-70\,^{\circ}C$ can be estimated to about 0.1 to 1 mbar. Thus, it is of the same order of magnitude as the partial pressures of the solvents toluene and ether used in the synthesis.

Solid, colorless **4** can be obtained if pentane is added to the condensate at room temperature. However, because of its high volatility **4** could not be isolated in a pure form free of solvent. These attempts were furthermore hampered by the photolability and the extreme air-sensitivity of **4**.

Since according to electron diffraction studies[23, 24] the monovalent metals form η^5 bonds to the cyclopentadienyl ring in the homologous monomeric compounds [TlCp] and [InCp], and since ab initio calculations predict the same bonding for [AlCp],[25] an analogous structure should be expected for [GaCp] (**4**). To confirm this expectation and to support the interpretation of the experimental results, we carried out ab initio calculations[26] for the structure of **4** as well as for its spectroscopic properties.

The structure calculated with the MP2 method[27] which explicitly considers electron correlation effects is shown in Figure 1.[28] Like the corresponding aluminum compound[29] the equilibrium structure of [GaCp] has C_{5v} symmetry. The distance of the metal atom to the center of the ring is 209.6 pm, thus only slightly greater than in [AlCp] (203.7 pm). A Mulliken population analysis[30] shows that strong π(Cp)–π(Ga) interactions are responsible for the stability as in the case of [AlCp]. Figure 2 shows a contour line diagram of the MO $7e_1$, which contains the main contributions of the π(Cp)–π(Ga) bonding.

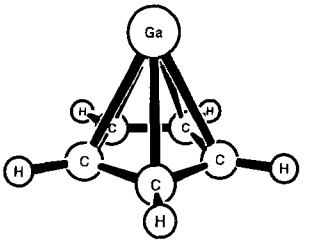

Fig. 1. Calculated structure of **4**. The geometrical parameters obtained with the MP2 method are: $r(GaC) = 242.0$, $r(CC) = 142.0$, $r(CH) = 108.7$ pm, and $\sphericalangle(HCX) = 179.7°$. X denotes the center of the Cp ring; the hydrogen atoms point away from the gallium atom.

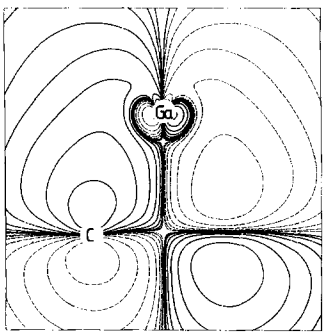

Fig. 2. Contour line diagram of the molecular orbital $7e_1$ (HOMO in e_1 symmetry), which makes the main contribution to the π(Cp)–π(Ga) bonding.

A force field calculation (analytical second derivatives of the SCF energy with respect to the nuclear coordinates) for the geometry obtained with the SCF method reveals that the calculated C_{5v} structure corresponds to a minimum on the potential hypersurface: as the calculated vibrational frequencies collected in Table 1 show, only real frequencies result for the C_{5v} structure of [GaCp] (**4**). For an IR spectroscopic characterization of **4** the frequency of the Ga–Cp stretching mode (a_1) is most significant. The calculated values of 272 cm^{-1} (SCF) and 285 cm^{-1} (MP2)[31] can serve as a reference for the IR spectroscopic identification of **4**, in particular since the calculated intensities (57.5 km mol^{-1} (SCF) and 42.1 km mol^{-1}(MP2)) indicate that the corresponding band should be relatively intense. Further confirmation of the assignment might be obtained by the detection of the $^{69}Ga/^{71}Ga$ isotopic pattern with a calculated splitting of 2 cm^{-1}.

Of particular importance for the confirmation of the experimental results given here is the calculation of the ^{71}Ga NMR shift of **4**.[32] The SCF method yields $\delta = -635$, a value which deviates by about 80 ppm from the experimental shift of $\delta = -714$, whereas the chemical shift calculated with the MP2 approach, $\delta = -696$, is in good agreement with the experiment.

Thus, the ab initio calculations support the conclusion drawn from the experiments that monomeric **4** is formed by

Table 1. Calculated IR spectra of **4** [harmonic vibrational frequencies $\tilde{\nu}$ in cm^{-1}, IR intensities I in km mol^{-1}].

the reaction of GaCl (**1**) with $[MgCp_2]$ (**2**) or [LiCp]. Furthermore, the calculations confirmed the expected C_{5v} structure with η^5 bonding between gallium and the cyclopentadienyl ring.

Experimental Procedure

A solution of **2** (1.7 mmol) in toluene (9.5 mL) was added dropwise to a dark red solution of **1** (3.0 mmol) in toluene/diethyl ether (11 mL) at −78 °C. After the solution was kept at −30 °C for 7 days, colorless, cubic crystals **3** (318 g, 95%) were separated from the yellow solution. By recondensation at ca. 10^{-2} mbar a colorless, air-sensitive solution of **4** (ca. 50%) in toluene and diethyl ether was obtained in the receiving flask at −196 °C.

Lett.* **1989**, *155*, 325; U. Schneider, R. Ahlrichs, H. Horn, A. Schäfer, *Angew. Chem.* **1992**, *104*, 327; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 353.
[30] R. Mulliken, *J. Chem. Phys.* **1955**, *23*, 1833, 2343. For the population of the 4pπ orbitals a value of 0.23 is obtained.
[31] Only the frequencies and intensities of the vibrations with a_1 symmetry were calculated with the MP2 method. The force constant matrix was determined by numerical differentiation of the analytically calculated forces.
[32] The chemical shifts were calculated with the GIAO (gauge-including atomic orbitals) method (R. Ditchfield, *Mol. Phys.* **1974**, *27*, 789), which guarantees gauge invariance by the use of explicitly field-dependent atomic orbitals. For a description of the GIAO method within the framework of the SCF approximation see K. Wolinski, J. F. Hinton, P. Pulay, *J. Am. Chem. Soc.* **1990**, *112*, 8291; M. Häser, R. Ahlrichs, H. P. Baron, P. Weiss, H. Horn, Theor. *Chim. Acta*, in press. For GIAO calculations within the framework of the MP2 approach see J. Gauss, Chem. *Phys. Lett.* **1992**, *191*, 614. In the SCF calculations the following basis sets were used: Ga [14s10p6d/8s6p4d] with $\eta(4d) = 0.2$, Cl [12s9p2d/7s6p2d] with $\delta(d) = 1.1258$ and 0.375, C [10s5p2d/6s3p2d] with $\eta(d) = 1.386$ and 0.462 as well as H [5s1p/3s1p] with $\eta(p) = 0.8$ (see ref.[28]). The basis sets in the MP2 calculations were the same as those for the geometry optimizations. In the MP2 calculations polarization functions were only used for heavy atoms. Conversion of the calculated shielding constants σ into the usual experimentally obtained relative shifts δ is possible with the experimental known value for $[GaCl_4]^-$ of $\delta = +247$.[2] As a comparison of the SCF and MP2 results shows, electron correlation effects are of no great significance for the calculation of the shielding constants of Ga in [GaCp] (**4**) $\Delta\delta = \delta(MP2) - \delta(SCF) = -18$, whereas for $[GaCl_4]^-$ the correlation correction with a value of $\Delta\delta = -78$ is no longer negligible. Calculations with different basis sets indicate that the remaining error can be estimated to approximately 20 to 30 ppm.

$[Ga_4\{C(SiMe_3)_3\}_4]$ with a Tetrahedral Ga_4 Skeleton**

By *Werner Uhl,* Wolfgang Hiller, Marcus Layh,* and *Wolfgang Schwarz*

Recently, we synthesized and determined the crystal structure of an organoelement compound with a gallium–gallium bond (**1**), which is formed in good yields by the reaction of

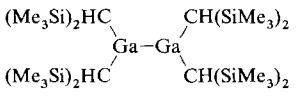
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

readily accessible $Ga_2Br_4 \cdot 2$ dioxane[1] with four equivalents of bis(trimethylsilyl)methyllithium.[2] Because of the high stability and the planar and thus unusual molecular structure of **1**, we are trying to synthesize further derivatives, in



1

order to thoroughly characterize this new class of compounds. However, with sterically less demanding substituents and analogous reaction conditions disproportionation occurs exclusively with the formation of elemental gallium and gallium(III) derivatives.[3]

Tris(trimethylsilyl)methyllithium suitable for the introduction of a sterically more demanding group has so far only been described as an adduct with ethers or amines;[4] the reactions of these derivatives with the gallium(II) bromide dioxane adduct gave tris(trimethylsilyl)methane $HC(SiMe_3)_3$ as the only isolable product, which is probably formed by the reaction of the alkyllithium compound with the complex-bound solvent molecules. In contrast, when a suspension of the gallium compound in *n*-pentane was combined at $-60\,^{\circ}C$ with a solution of the ether-free Li compound recently prepared for the first time by us[5] in the same solvent, the initially colorless reaction mixture changed from yellow to pale red upon warming. After the usual workup procedures we isolated a dark red, crystalline compound, tris(trimethylsilyl)methylgallium(I) (**2**) with the gallium atom in the unusual[6] oxidation state + I which is formed by disproportionation.

The molar ratio of the starting materials of 1:3 given in Equation (a) corresponds to the setup for optimized yields; **2** is also formed as the major product by changing this ratio

$$4\ Ga_2Br_4 \cdot 2\ \text{dioxane} + 12\ LiC(SiMe_3)_3 \longrightarrow$$

$$\underset{\mathbf{2}}{[\{GaC(SiMe_3)_3\}_4]} + 12\ LiBr + 4\ \text{"}GaBr[C(SiMe_3)_3]_2\text{"}$$

in the range from 1:2 to 1:4 and is obtained as a pure substance after repeated recrystallization from *n*-pentane or toluene. As by-products we isolated a little tris(trimethylsilyl)methane as well as small quantities of the colorless 1,3-disiletane $[Me_2Si{-}C(SiMe_3)_2]_2$,[7] which is probably formed by the elimination of MeLi from $LiC(SiMe_3)_3$ or of a GaMe fragment from a corresponding gallium compound via a silaethene intermediate. Because of this side reaction the dialkylgallium bromide formulated in Equation (a) and to be expected from an ideal course of the disproportionation is not isolated; however, after the separation of the crystalline products from the mother liquor a highly viscous residue remains, which shows a large number of signals of unidentifiable compounds in the ^1H NMR spectrum.

Compound **2** is remarkably thermally stable and decomposes only above 255 °C; in the air it can be stored for several months without change. Depending on the method of characterization one of several degrees of oligomerization is determined: in the mass spectrum only the monomer with a relative intensity of 100% is detected, and the isotope pattern agrees very well with the calculated distribution of masses. Heavier fragments, such as those expected for oligomeric units, are not observed. The cryoscopic molar mass determination in benzene in the usual concentration range ($0.023\ mol\,L^{-1}$) indicates approximately a trimer, whereas with increasing dilution the dissociation increases and at $0.0014\ mol\,L^{-1}$ finally only the monomer is present. The UV/VIS spectrum shows absorptions at 252, 294, and 435 nm. On the basis of a comparison with the spectra of the bis(trimethylsilyl)methyl-substituted digallium(4) (**1**) (360 nm[2]) and diindium(4) compounds (380 nm[8]) we attribute the long-wavelength absorption to the presence of metal–metal bonds. It is exceptionally intense and, in contrast to the two other bands, only falls completely in the measurable intensity range at very high dilution, then, however, it surprisingly has the lowest extinction. Optically, this is noticeable from a change in the solution from red to pale yellow. We attribute these observations to the monomerization of **2** increasing with the dilution of the sample.

The crystal structure determination of **2** reveals an almost undistorted tetrahedral Ga_4 skeleton (Fig. 1). The molecules are disordered via a pseudo mirror plane in $x = 0.25$, which approximately coincides with a triangular face of the tetrahedron (Ga 1, Ga 2, Ga 3); nevertheless with occupation factors of 0.77 and 0.23 for the two positions a satisfactory refinement of the structural parameters[9] of the Ga_4 skeleton was possible. The Ga–Ga distances in the cluster are

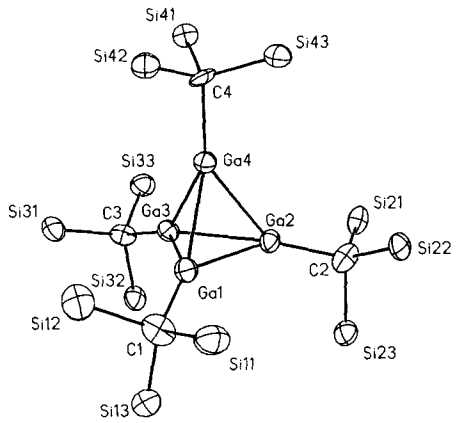


Fig. 1. Crystal structure of **2** (ellipsoids with 40% probability). For the sake of clarity the methyl groups of the $SiMe_3$ moieties were omitted from the drawing. Selected bond lengths [pm] and angles [°]: Ga1-Ga2 269.2(4), Ga1-Ga3 268.5(4), Ga1-Ga4 268.0(4), Ga2-Ga3 270.2(3), Ga2-Ga4 268.9(4), Ga3-Ga4 267.8(4), Ga1-C1 206(2), Ga2-C2 206(2), Ga3-C3 207(2), Ga4-C4 211(2); Ga-Ga-Ga 59.6(1)–60.5(1), Ga-Ga-C 143.4(6)–146.3(7).

267.8(4) to 270.2(4) pm (average: 268.8 pm); thus as expected they are approximately 15 pm longer than in the tetraalkyldigallium(4) derivative **1** with an isolated Ga–Ga bond (254.1(1) pm[2]). Analogous differences in distances (11 pm) are observed between $[Al_4Cp^*_4]$, $Cp^* = C_5Me_5$, also with a tetrahedral cluster structure (Al–Al 276.9(5) pm)[10] and the dialuminum(4) derivative isotypical to **1** with an isolated Al–Al bond (266.0(1) pm).[11] In addition the Ga–C bond lengths (average 208 pm) are significantly longer than standard values[2] and lie in the range obtained recently by our research group for bonds to bridging carbon atoms.[3] Compound **2** supplements the series of recently published tetrahedral molecules from elements of the third main group: tetra(*tert*-butyl)tetraborane(4)[12] and tetrakis(pentamethylcyclopentadienyl)tetraaluminum(4).[10] Meanwhile, we have obtained the indium compound analogous to **2** by the same method from $In_2Br_4 \cdot 2$ TMEDA and $LiC(SiMe_3)_3$.

Experimental Procedure

All operations were carried out in an atmosphere of purified argon with dried solvents.

To a suspension of $Ga_2Br_4 \cdot 2$dioxane [1] (0.79 g, 1.24 mmol) in *n*-pentane (20 mL) was added dropwise a solution of tris(trimethylsilyl)methyllithium [5] (0.89 g, 3.7 mmol) at $-60\,^{\circ}C$ in 30 mL of the same solvent. After the mixture was warmed to room temperature it was stirred for a further hour, filtered, and the red filtrate was concentrated to ca. 10 mL and cooled to $-30\,^{\circ}C$. The precipitating impurities were discarded. The mother liquor was concentrated to a few mL; at $-60\,^{\circ}C$ **2** crystallized in the form of dark red columns, mixed together with the disiletane described in the text,[7] which can be enriched by sublimation in vacuo. Following repeated recrystallizations of the crude product from *n*-pentane, cyclopentane, or toluene, pure **2** was finally obtained in a yield of 0.21 g (56%).

Decomp. (under argon): 255 °C. Molar mass (by cryoscopy in benzene) [g mol^{-1}]: obsd 848 (0.023 mol L^{-1}), 322 (0.0014 mol L^{-1}): calcd 903.9 (trimer) and 301.3 (monomer); MS (425 K, 20 eV): *m/z* 300 (M^+(monomer), 100%), 285 ($M^+ - CH_3$, 90%); ^{1}H NMR (C_6D_6, 200 MHz): $\delta = 0.51$; $^{13}C\{^1H\}$ NMR (C_6D_6, 50.32 MHz): $\delta = 7.7$ ($SiMe_3$), no signal for α-C; IR (Nujol, CsBr plates): $\tilde{\nu}$ [cm^{-1}] = 1270 m (sh), 1260 s, 1255 m (sh) δCH_3; 1030 w (br); 865 vs, 845 vs, 805 w (sh), 775 w, 730 w ρCH_3(Si); 695 vw (sh), 680 m, 660 m (sh), 655 m νSiC_3; 585 s νGaC; 460 w; UV/VIS (*n*-pentan): λ_{max} [nm] (ε) = 252 (5000), 294 (6000), 435 (2000).

[9] Five diffraction data sets of **2** were collected for different crystals and under different conditions. They all gave the tetrahedral Ga_4 structure with approximately the Ga–Ga distances given in Figure 1; they showed, however, significantly different disorders, especially in the region of the $SiMe_3$ groups, which were in part not completely localized. The best structural model up to now is shown in Figure 1 and described in the following: $[Ga_4\{C(SiMe_3)_3\}_4]$·cyclopentane; diffractometer CAD 4; $Cu_{K\alpha}$ radiation; −60 °C; programs VAXSDP and SHELXTL; orthorhombic, $P2_12_12_1$; $a = 1361.6(3)$, $b = 1694.2(4)$, $c = 3061.5(6)$ pm; $V = 7062.3$ Å^3; $Z = 4$; crystal dimensions $0.2 \times 0.2 \times 0.3$ mm; θ–2θ scan; 4021 measured values with $F > 6\sigma(F)$; 553 parameters; $R = 0.087$. The molecule is disordered via a pseudo mirror plane in $x = 0.25$; whereas the C, Si, and Ga atoms were fully refined anisotropically for the more occupied position, for the second position this was only successful for the free apex of the tetrahedron. This was used for the optimization of the occupation factor (0.77 to 0.23). The positions of the atoms in the region of the almost common base face were each calculated anew for the less occupied position via the pseudo mirror plane; most of them could not be sensibly refined and were therefore included rigid in the calculation of the structure factors. By the use of substituents of lower symmetry it should be possible to eliminate the disorder of the almost spherical molecules **2** in the solid state. We are currently trying therefore to synthesize appropriate derivatives for a more exact structural determination. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-56418, the names of the authors, and the journal citation.

$[V(SNC_9H_6)_3]$ and $[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$, Homoleptic Vanadium(III) Complexes with Sulfur–Nitrogen Donor Ligands, and $[V(SNC_5H_4)_3]^-$, the First Thiolatovanadium(II) Complex**

By *Gerald Henkel,** *Bernt Krebs,* and *Wilfried Schmidt*

In the vanadium-based nitrogenases discovered only a few years ago,[1] the metal atom is bound to sulfur and probably also to nitrogen and/or oxygen atoms simultaneously.[2] In our search of useful model complexes for biologically active vanadium centers we have investigated various reactions of di- and trivalent vanadium with bifunctional chelating ligands. We[3] and others[4] have already reported the results from the reaction of VCl_3 with ethane-1,2-dithiolate. Interestingly, the dinuclear species $[V_2(SCH_2CH_2S)_4]^{2-}$ with four thiolato bridges formed in this reaction cannot be cleaved with additional thiolate to mononuclear trischelate complexes. Such a disassembly is probably unfavorable because of coulombic repulsions. Similar arguments can also be used to explain why pure homoleptic thiolato complexes of divalent vanadium have not been observed so far.

The problem of charge can be circumvented effectively when the bifunctional ligands possess a (charged) thiolate function as well as a formally uncharged donor atom.[5] We report here the synthesis and characterization of mononuclear homoleptic thiolatovanadium complexes that are stabilized by bidentate ligands with sulfur and nitrogen donor functions.

The reaction of $VCl_2 \cdot 4MeOH$[6] with sodium pyridine-2-thiolate in acetonitrile gave rise to the complex anion **1**, which could be isolated as the tetraphenylphosphonium salt **2**. In contrast, when $VCl_2 \cdot 4MeOH$ was treated with sodium aniline-2-thiolate under the same conditions, the vanadium atom was oxidized and the complex anion **3** was obtained,

$[V(SNC_5H_4)_3]^-$	**1**	$[Ph_4P][V(SNC_5H_4)_3]$	**2**
$[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$	**3**	$[Ph_3MeP][V(SNH_2C_6H_4)_2(SNHC_6H_4)]$	**4**
$[V(SNC_9H_6)_3]$	**5**	$[V(SNC_9H_6)_3] \cdot MeCN$	**6**

the ligands of which are not protonated to the same extent. Anion **3** was crystallized as the triphenylmethylphosphonium salt **4**. The neutral complex **5** was formed in the reaction of VCl_3 with quinoline-8-thiolate and precipitated as solvate **6** from acetonitrile in the form of red-green needles.

To our knowledge, compound **2** is the first structurally characterized thiolatovanadium(II) complex (Fig. 1). The coordination environment of each of the vanadium atoms is distorted octahedral and composed of three sulfur and three nitrogen atoms of the pyridine-2-thiolato ligands. Opposite to each nitrogen is a sulfur atom from the neighboring ligand which gives rise to a *facial* arrangement of the donor atoms of the same type. The mean metal–ligand distances are 2.545 (V–S) and 2.113 Å (V–N). The three four-membered chelate rings are completely planar within the experimental error.

[**] This research was supported by the Deutsche Forschungsgemeinschaft, the Bundesminister für Forschung und Technologie, and the Fonds der Chemischen Industrie.

The complex salt **2** forms chiral crystals (space group $P1$) from acetonitrile. The unit cell contains two symmetry-independent complex anions **1** which can be superimposed.[7] Minor differences in geometry are attributed to packing effects. The sample under investigation contained complex anions in the Λ configuration.

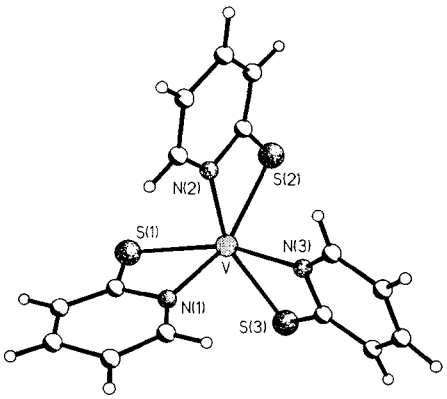

Fig. 1. The complex anion $[V(SNC_5H_4)_3]^-$ (**1**) in crystals of **2**.

In the complex anion **3** (Fig. 2), the three ligands are present in two different protonation states. Whereas two ligands have one thiolate group and a neutral amine function each, in the third ligand both the mercapto group and the amine function are deprotonated. Salt **4** is thus the first known compound in which both an electronically neutral amine function and a charged amide function are bound to the same metal center. The coordination is distorted octahedral with a *facial* arrangement of the donor atoms of particular type. As in **1**, this causes the thiolate groups of the ligands to adopt a *trans* orientation to the amine or amide groups of the neighboring ligands. The coordinated amide group is distinguished by its comparably short bond to vanadium (1.94 Å). This group also exerts a significant *trans* effect; the sulfur atom opposite to the amide group (V–S 2.508 Å) is on the average 0.090 Å further away from the vanadium center than the other two sulfur atoms (V–S 2.418 Å). The mean $V-N_{amine}$ bond is 2.18 Å in length. The complex salt **4** crystallizes in the space group $P2_1$[7] and, as in the case of **2**, with two symmetry-independent complex anions **3**. These are found as mirror images of each other so that in the crystal investigated **4** is racemic (Λ and Δ isomers).

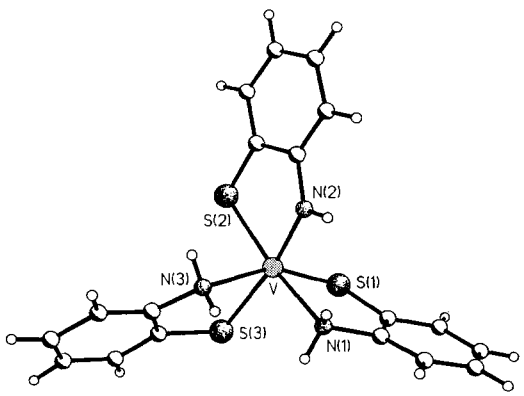

Fig. 2. The complex anion $[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$ (**3**) in crystals of **4**.

Crystals of **6** have inversion centers and are composed of mononuclear neutral trischelate complexes **5**, which differ fundamentally from the related complex anions **1** and **3** with respect to the orientation of the donor atoms.[7] The quinoline-8-thiolato ligands are positioned so that a distorted octahedral coordination of the vanadium atom with *meridional* arrangement of the donor atoms of a particular type results (Fig. 3). Two statistically equivalent orientations of the molecule are found in the crystal; they can be superimposed exactly by a 180° rotation about the axis that passes through the middle of a S···S edge of the octahedron and through the central atom. The mean V–S and V–N bond lengths, 2.364 and 2.18 Å, respectively, fall within the range expected for single bonds.

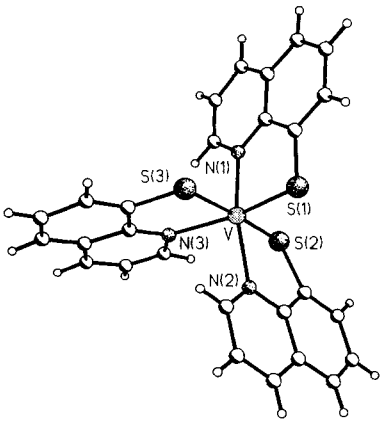

Fig. 3. The neutral trischelate complex $[V(SNC_9H_6)_3]$ (**5**) in crystals of **6**.

We have also determined the oxidation states of the vanadium atoms in the trischelate complexes **1**, **3**, and **5** directly by magnetic measurements. The susceptibilities determined fit the Curie law from 90 to 296 K. The experimental magnetic moment for complex salt **2** is $\mu_{exp} = 3.73\ \mu_B$; this value deviates only slightly from the spin-only value of divalent vanadium (d^3, $\mu_{eff} = 3.87\ \mu_B$. As anticipated, the observed magnetic moments for compounds **4** and **6**, $\mu_{exp} = 2.85$ and $2.78\ \mu_B$, respectively, are somewhat smaller. This convincingly confirms the assignment (V^{3+}, d^2, $\mu_{eff} = 2.83\ \mu_B$) made on the basis of the X-ray structure analyses.

Experimental Procedure

2: A solution of sodium (0.35 g, 15 mmol) in EtOH (25 mL) was treated with pyridine-2-thiol (1.66 g, 15 mmol) and concentrated to dryness. The residue was taken up in MeCN (10 mL), the suspension again concentrated to dryness, and finally treated again with MeCN (70 mL). To this was added $VCl_2 \cdot 4MeOH$ (1.25 g, 5 mmol); the solution turned deep violet immediately upon addition. After the reaction mixture was stirred for ca. 1 h, the small amount of a black precipitate that had formed was filtered off. The filtrate was treated with Ph_4PBr (2.10 g, 5 mmol) and kept at room temperature. After 2 d, compact, deep dark-red crystals had formed which appear black in direct light.

4: Sodium (0.4 g, 17 mmol) and aniline-2-thiol (1.57 g, 15 mmol) were dissolved in EtOH (20 mL). The solution was then concentrated to dryness, the yellow residue treated with MeCN (20 mL), the resulting suspension again concentrated to dryness, and subsequently taken up again in MeCN (70 mL). After addition of $VCl_2 \cdot 4MeOH$ (1.25 g, 5 mmol), the reaction mixture immediately became a clear, red solution. This was stirred for ca. 1 h and then filtered to remove a black precipitate. The filtrate was treated with Ph_3MePBr (1.79 g, 5 mmol) and kept at + 5 °C. Compact, dark red crystals formed in the course of a week.

6: Sodium (0.35 g, 15 mmol) and quinoline-8-thiol (2.97 g, 15 mmol) were dissolved in EtOH (25 mL). After this solution was concentrated to dryness, the resulting yellow residue was taken up in MeCN (50 mL). To this solution was added VCl_3 (0.79 g, 5 mmol), and the color of the reaction mixture changed

from yellow to red and finally to green. After the reaction mixture had been stirred for about 1 h, a black precipitate was filtered off. The filtrate was kept at −20 °C, and after a few days small, red-green needles separated from the solution.

Novel Metal Thiolates: $[Co_2(SC_3H_7)_5]^-$, the First Complex with Face-Sharing MS_4 Tetrahedra**

By *Gerald Henkel*,* and *Stefan Weissgräber*

Transition metal complexes with thiolato ligands are a well-studied class of compounds. Not only are they important model complexes for the study of biological metal–sulfur centers,[1] but they are also suitable starting materials for the synthesis of mixed sulfido–thiolato clusters.[2]

A common feature of thiolato complexes with divalent metal atoms and sterically unemcumbered ligands is the coordination number 4; the central atom often has tetrahedral or, less frequently, square-planar coordination geometry. The latter type of coordination is generally limited to complexes with d^8 metal centers.[3] The mononuclear square-planar anions $[Cr(SCH_2CH_2S)_2]^{2-}$[4] and $[Fe(SC_6H_4S)_2]^{2-}$[5] are exceptions; both have bifunctional 1,2-dithiolato ligands.

Besides the mononuclear complexes with the general formula $[M(SR)_4]^{2-}$, metal thiolates with tetrahedral coordination also include the respective di- and tetranuclear complexes $[M_2(SR)_6]^{2-}$ and $[M_4(SR)_{10}]^{2-}$. In the dinuclear complexes the MS_4 tetrahedra are linked by common edges, in the tetranuclear ones by common vertices. Compounds with other connectivities were previously not known; even the only reported trinuclear thiolates with tetrahedral coordination, $[Hg_3(SCH_2CH_2S)_4]^{2-}$[6] and $[Hg_3(SCH_2C_6H_4CH_2S)_4]^{2-}$,[7] are constructed of either only edge-, or vertex- and edge-sharing MS_4 tetrahedra. We report here on a homoleptic thiolatocobalt(II) complex, the first compound to contain two MS_4 tetrahedra which share a face.

Cobalt(II) nitrate was treated with sodium propane-2-thiolate in methanol/DMF. After subsequent addition of tetramethylammonium chloride, a black product could be isolated, the analytical data of which was completely consistent with a complex salt of composition $[Me_4N]_2[Co_4(SC_3H_7)_{10}]$ and thus with a complex anion which adopts the adamantane-like structure. However, this initial assumption was soon questioned because of the color which is unusual for complexes of this type.

According to the results of an X-ray structure analysis,[8] the novel dinuclear compound **1** (Fig. 1 left) was formed instead under the reaction conditions described above. This complex anion differs fundamentally from other metal thiolates in the binding arrangement of its ligands.

symmetry). The separation of the cobalt atoms in the dinuclear complex is remarkably short (2.491(1) Å) and results from the unusual arrangement of the five thiolate S atoms which occupy the vertices of a trigonal bipyramid and simultaneously also surround the two metal atoms in a tetrahedral fashion (Fig. 1 right). The cobalt atoms thus occupy the centers of two sulfur tetrahedra, which have a common face (S3-S4-S5). The three bridging ligands are positioned so that the isopropyl groups have a paddlewheel-like arrangement, that is, they are symmetric with respect to a local threefold axis. Two different orientations of the complex anion are found in the crystal which are superimposable by a simple rotation. One of the orientations appears to be energetically favored with an occupancy of approximately 64%.

The two CoS_4 tetrahedra are distorted in a very characteristic manner. The ideal geometry would not only lead to very small bond angles of about 39° at the bridging sulfur atoms, but also to an unrealistically short metal–metal distance of about 1.52 Å. The observed structure results from an ideal tetrahedral arrangement when the bipyramid is stretched along the apices until the bonding angles at the bridging atoms approach the mean value of 65.4°. At the same time the Co–Co distance increases to 2.491 Å while the mean distance between the three sulfur atoms of the bridging ligands decreases to 3.362 Å. Consequently, the mean (μ-S)-Co-(μ-S) angle is also quite small (93.58°).

The Co–S bonds of the terminal thiolato ligands are not completely parallel to the Co–Co axis. The slight tilt (8.1°) gives rise to three different S-Co-(μ-S) angles (mean values 115.3, 123.2, and 129.1°). The mean lengths of the Co–(μ-S) and Co–S bonds, 2.307 and 2.210 Å, respectively (average 2.283 Å), are somewhat shorter than those in other thiolatocobalt(II) complexes; this is especially evident in the comparison with the dinuclear complex anion $[Co_2(SC_2H_5)_6]^{2-}$, in which each Co atom is bound to two terminal and two bridging thiolato ligands. The corresponding values here are 2.355 and 2.270 Å for the *syn*, and 2.363 and 2.273 Å for the *anti* conformation.[2]

The example of *syn*- and *anti*-$[Co_2(SC_2H_5)_6]^{2-}$[2] clearly illustrates that in complexes with tetrahedral CoS_4 units and monofunctional ligands, the change from edge- to face-sharing has a drastic influence on the Co–Co distance. For the *anti* isomer, this change results in an increase of 0.554 to 3.045(2) Å (+ 22.2%) relative to **1**, and for the *syn* isomer of 0.529 to 3.020(3) Å (+ 21.2%).

The situation is somewhat different for complexes that are strained as a result of specific ligand influences, for example $[Co_2(SCH_2C_6H_4CH_2S)_3]^{2-}$ with edge-sharing CoS_4 tetrahedra.[9] Here the bifunctional ligands are bound so that the central $Co_2(\mu\text{-}S)_2$ four-membered ring is significantly folded. Although the Co–Co distance is thereby reduced to 2.786(1) Å, this value is still 0.3 Å longer than in the title compound **1**.

These results show that the chemistry of complexes with thiolato ligands is much more diverse than originally assumed. We suggest that the surprising formation of units with tetrahedral coordination which have common faces is controlled by specific electronic properties of the ligands. We already have the first experimental evidence of the existence of novel iron thiolates with bitetrahedral Fe_2S_5 centers.

Experimental Procedure

All reactions were conducted in a glovebox under nitrogen.

A solution of $Co(NO_3)_2 \cdot 6H_2O$ (1.46 g, 5 mmol) in methanol (20 mL) was added dropwise to a stirred solution of sodium isopropanethiolate (1.23 g, 12.5 mmol) in methanol/DMF (20 mL, 1:1) whereby the reaction mixture turned black. After the addition of the cobalt solution was complete, the reaction mixture was treated with Me_4NCl (0.55 g, 5 mmol) and filtered. Diethyl ether (25 mL) was added to the filtrate, and the mixture was stored at −26 °C. In the course of a few days black rectangular prisms formed. Yield: 1.51 g (2.66 mmol, 53.2%). Correct C,H,N analysis. UV/VIS (MeCN): λ_{max} [nm] (ε) = 294 (4500), 332 (4900), 351 (5300), 388 (5600), 538 (500), 598 (500), 778 (300).

On the Mechanism of Coherent Dihydrogen Tunneling in Transition Metal Trihydrides**

By *Hans-Heinrich Limbach,* Gerd Scherer, Marcus Maurer,* and *Bruno Chaudret*

The solution ^{1}H NMR spectra of transition metal trihydrides (T) exhibit very large temperature-dependent scalar coupling constants J between the metal-bonded hydrogen atoms H_a and H_b (Fig. 1).[1–7] Zilm et al.[5] and Weitekamp et al.[6] have clearly identified this phenomenon as a mutual quantum exchange process between the two identical forms T and T*, characterized by a coherent hydrogen tunneling frequency that is directly related to the observed exchange coupling J. At high temperatures the hydrogen atoms are subject to a classical, that is, stochastic exchange process which can be characterized by a rate constant k.[3] The quantum process was treated in terms of a one-dimensional tunneling model. Since the reaction coordinate had not yet been

discussed in detail,[6, 7] we explored different possible reaction pathways for the hydrogen motion and checked their compatibility with the experimental results.

In the one-dimensional approximation one can imagine two different reaction pathways (Fig. 1). In I the reaction

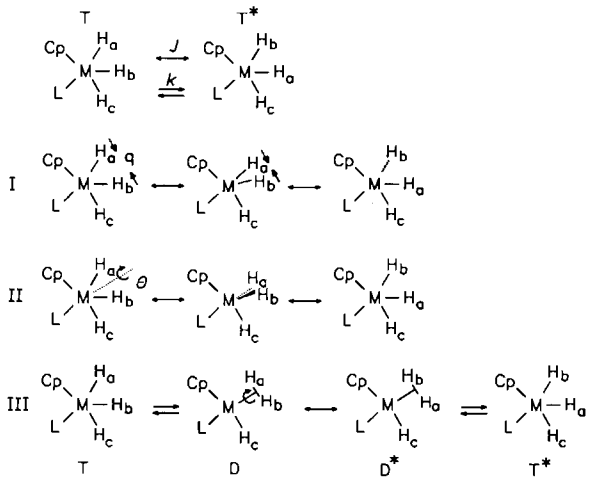

Fig. 1. Mutual hydrogen exchange in a metal trihydride complex (M = Ru, Ir, Nb; L = ligand) between the degenerate forms T and T*. J is the coherent tunnel frequency, k the classical exchange rate constant. H_b and H_c are also subject to a similar exchange process. I: The reaction coordinate corresponds to the motion of the two hydrogen atoms along their internuclear distance vector $\boldsymbol{q}$. II: The reaction coordinate corresponds to a rotation of angle θ of the internuclear distance vector around an axis in the MH_aH_b plane. III: The reaction takes place in two steps: firstly, a metastable dihydrogen complex D is formed by an activated rate process; subsequently, rotational tunneling takes place in D.

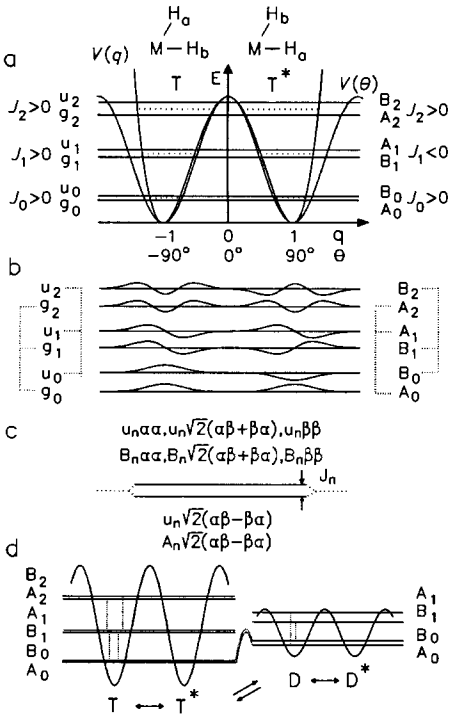

Fig. 2. a) One-dimensional potential curves $V(q)$ and $V(\theta)$ and corresponding energy eigenvalues (schematically) for the coherent hydrogen exchange according to pathways I and II. J_n is the splitting of the nth pair of states, also called exchange coupling constant. b) Eigenfunctions (schematically) of the states in Figure 2a. c) Energy level diagram and combined antisymmetric spatial and nuclear spin functions for the nth pair of states (schematically); α and β are the usual single nuclear spin functions. d) One-dimensional potential curves for pathway III.

coordinate corresponds to the internuclear H_a–H_b distance vector $\boldsymbol{q}$, and in II to the angle θ of a rotation around an axis located in the MH_aH_b plane perpendicular to $\boldsymbol{q}$. In pathway III first an intermediate dihydrogen complex D is formed by an activated rate process in which the rotation to D* takes place. The formation of D can be characterized by an equilibrium constant $K = \exp(-\Delta S/R)\exp(-\Delta H/RT)$, where ΔH is the reaction energy and ΔS the reaction entropy. Theoretical evidence for a metastable D state has been obtained recently by ab initio calculations.[8]

The eigenvalues and eigenfunctions for the double minimum potential $V(\boldsymbol{q})$ of pathway I[9] and for the periodic potential $V(\theta)$ of pathway II[10] can be calculated and are shown schematically in Figure 2. The wave functions are given in good approximation as the sum or the difference of the isoenergetic harmonic oscillator functions of the left and the right potential well. In pathway I the states are either symmetric (g) or antisymmetric (u) with respect to inversion at the center of the H_a–H_b distance vector, while in pathway II they are symmetric (A) or antisymmetric (B) with respect to the C_2 symmetry operation. It follows from Figure 2 that the energy splittings $J_n = E_{u_n} - E_{g_n}$ are always positive but that the sign of $J_n = E_{B_n} - E_{A_n}$ alternates. According to the Pauli exclusion principle the total wave function must be antisymmetric for a pair of protons. Therefore, it is necessary to combine the spatial antisymmetric with the symmetric nuclear spin states and vice versa as shown in Figure 2c[5, 6]. The diagram of Figure 2c cannot be distinguished from the energy level diagram of an ordinary scalar, coupled two-spin system in the absence of an external magnetic field,[5, 6] where the energy splitting corresponds to the magnetic scalar coupling constant J^{mag}. Therefore, the energy splitting J_n has been called exchange coupling constant.[5, 6]

Thus, the MH_aH_b group in the vibrational state n will contribute the spectral features of an ordinary AX, AB, or A_2 spin system to the ^1H NMR spectra, characterized by the effective scalar coupling constant $J_n + J^{mag}$ and the chemical shift difference $\Delta\nu_n$ between the exchanging protons.

In real proton-transfer systems the reaction barriers can change when vibrational modes that couple to the reaction coordinate are excited,[11, 12] or when the reactive system interconverts between different molecular conformations or environments.[13] In the trihydride exchange problem one can expect that the rotational barrier is greatly reduced in the dihydrogen state D as indicated schematically for pathway III in Figure 2c.

The question now arises as to how the observed exchange couplings are related to the individual exchange couplings in the different states. Generally, in polyatomic molecules, fast stochastic vibrational relaxation takes place within picoseconds,[14] which destroys coherent tunneling together with solvent relaxation on a timescale typical for NMR spectroscopy.[15] However, in the case of trihydride complexes, vibrational relaxation takes place only within the manifold of states of the same spatial symmetry[6] as indicated in Figure 2 by broken lines. Relaxation between states of different symmetry would require a conversion of nuclear spins states, which is a slow process. In addition, stochastic exchange between the trihydride form T and the dihydrogen form D in pathway III will also be faster than nuclear spin conversion. The averaging between vibrational and conformational states indicated in Figure 2b and c can be described in terms of usual dynamic NMR theory.[16] If this process is very fast, the usual signal pattern of an averaged AX, AB, or A_2 spin system will be obtained that is characterized by an averaged exchange coupling constant J. Since the different states are populated

according to the Boltzmann distribution, the average tunnel splitting J becomes a function of temperature T.

To elucidate the behavior of $J(T)$ for the different pathways we have performed numerical calculations. Some representative results are shown in Figure 3.[17] A variation of

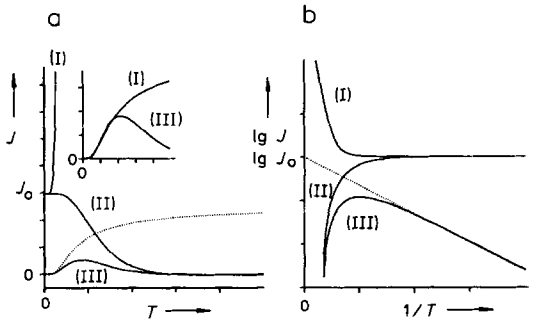

Fig. 3. Average exchange coupling constants J vs. temperature T (Fig. 3a) and lg J vs. $1/T$ (Fig. 3b) calculated [17] for pathways I to III with particular parameter sets. The broken line represents the equilibrium constant of formation of the metastable dihydrogen intermediate D from the trihydride form T. J_0 for pathways I and II were set equal to $J_{0D}\exp(-\Delta S/R)$ of pathway III.

the parameters used, namely, energy barriers, hydrogen atom distances, ΔH and ΔS values, did not seem to change the general shapes of the curves significantly. For pathway I we observe a behavior described previously:[5, 6] J is equal to J_0 at low temperatures and increases exponentially when T increases. By contrast, for the rotation pathway II J decreases as temperature is increased and eventually becomes zero. This behavior has not yet been discussed before in the trihydride case; it is, however, well known in the case of methyl group tunneling.[19] Finally, for pathway III where tunneling in the trihydride form has been neglected, first an increase of J with T is expected as the lowest lying tunneling states of D are populated and then a decrease as the higher tunneling states in D are occupied. At low temperature an Arrhenius-type equation holds for all pathways [Eq. (1)]. E_1 is the average energy of the first excited pair of vibrational states. If the

$$|J - J_0| \approx |A|\exp(-E_a/RT) \qquad (1)$$

$|A| \approx J_1$, $E_a \approx E_1$ (pathways I and II)

$|A| \approx J_{0D}\exp(-\Delta S/R)$, $E_a \approx \Delta H$, $J_0 = 0$ (pathway III)

low-temperature approximation is not valid E_1 and J_1 will be overestimated when experimental data are interpreted in terms of Equation (1). By contrast, in the case of pathway III, ΔH and $J_{0D}\exp(-\Delta S/R)$ will be underestimated. It follows from Equation (1) that pathways I and III can practically only be distinguished if either a temperature independent value of $J = J_0 \neq 0$ can be observed at low temperature or a decrease of J with increasing T at the high temperature. In order to illustrate this difficulty we have scaled the two functions in the inset of Figure 3a to each other by multiplication with an arbitrary factor.

We have plotted in Figure 4 the experimental values of lg J vs. $1/T$ for the examples that have been reported. We obtain fairly straight lines within the error limits. Since all J values increase with increasing temperature, pathway II can be rejected, but the experiments cannot distinguish unambiguously between pathway I and III, since no evidence is found either for the temperature-independent low-temperature value $J = J_0$ expected for I, or for the decrease in J at high temperature predicted for III. At high temperature J is obscured by the onset of classical stochastic exchange. The

values of $|A|$ and E_a depend somewhat on the estimated values of the magnetic scalar coupling constant J^{mag}. We note in Figure 4 a large variation of the slopes of the curves, that is, of the E_a values, a circumstance which can easily be explained in terms of pathway III with a structural dependence of reaction enthalpies ΔH between the trihydride and the dihydrogen form. It is a little bit more difficult to explain this variation in terms of the model of pathway I, although not impossible.[5d] The latter will involve a very high barrier since the nuclei occupy the same position at $q = 0$. Therefore, in fact a combined one-dimensional inversion/rotation pathway was discussed previously[5, 6] in which the two nuclei only approach a certain minimal distance, that is, they slide along each other. This pathway would, however, need a two-dimensional description from which it could be discerned whether the tunnel splittings will alternate in sign or not as vibrational excitation occurs, that is, whether J should really increase or decrease with temperature.

In conclusion, we have proposed a novel mechanism (pathway III in Fig. 1) as an alternative origin of exchange couplings in transition metal trihydride complexes. This pathway represents the simplest model that is in agreement with the experimental observations. We hope to obtain more information on this problem by measuring the exchange couplings over a wider temperature range as well as the rate constants k of the classical exchange processes including the multiple kinetic HH/HD/DD isotope effects.[20]

[17] The average value for J was calculated according to the following equation [18]:

$$J = \nu_{12} - \nu_{34},\ \nu_{ij} = \sum_n (E_n^i - E_n^j)\{\exp[-E_n^i/RT] - \exp[-E_n^j/RT]\}/\sum_n \{\exp[-E_n^i/RT] - \exp[-E_n^j/RT]\}$$

where E_n^i, $i = 1,4$ refers to the well known energy levels of the AX, AB, or A_2 two-spin system in the nth environment, here the nth pair of split states as indicated in Figure 2. As long as J is much smaller than the Zeeman energy one can show that this equation reduces to the simpler form [6]

$$J = \sum_n J_n \exp[-E_n/RT]/\sum_n \exp[-E_n/RT]$$

where E_n is the average energy of the nth pair of states. The energies were calculated according to references [9, 10] assuming three pairs of split states below the barrier.

Diastereoselective Addition of Allylsilanes to Aldehydes: Synthesis of Enantiomerically Pure Homoallylic Alcohols**

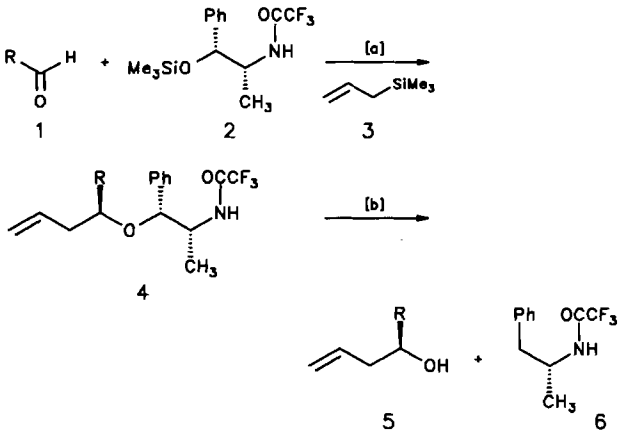
By *Lutz F. Tietze,* Angelika Dölle,* and *Kai Schiemann*

Dedicated to Professor Theophil Eicher on the occasion of his 60th birthday

Homoallylic alcohols are interesting synthetic building blocks which can be prepared quite simply by the Lewis acid induced addition of allylsilanes to aldehydes.[1] Numerous procedures have been developed to allow access to these compounds in enantiomerically pure form.[2] Usually the aldehydes are converted with chiral diols into cyclic acetals, typically dioxolanes, dioxanes, dioxolanones, or dioxanones.[3, 4] Acyclic acetals have also been employed; however, poor selectivity was achieved. One negative aspect of these methods is that the acetals are frequently formed as mixtures of diastereomers which must then be purified. Chiral homoallylic alcohols may also be prepared by the reaction of aldehydes with chiral, nonracemic, allyl–metal compounds often with very good selectivities.[6]

We describe here a method for the direct and simple preparation of homoallylic ethers with excellent *de* values (> 99%) from aliphatic aldehydes and trimethylsilyl ether derivatives of chiral 1,2-aminoalcohols.

The best results were obtained with the trimethylsilyl ether of (1*R*,2*R*)-*N*-trifluoroacetylnorpseudoephedrine (**2**) (Scheme 1).[7] Two equivalents of the aldehydes **1a–g** were stirred at



Scheme 1. Synthesis of the homoallylic alcohols **5** (R groups see Table 1). [a] CH_2Cl_2, −78 °C, 0.1 equiv TMS-OTf. After 1 h, addition of allyltrimethylsilane **3** and another 0.1 equiv TMS-OTf. [b] THF, liquid NH_3, −78 °C, 2.5 equiv sodium. After 15 min, addition of methanol.

−78 °C with one equivalent of **2** in dichloromethane in the presence of 0.1 equivalents of the trimethylsilyl trifluoromethanesulfonate (TMS-OTf) for one hour. The reaction mixture was then treated with two equivalents of allyltrimethylsilane **3** and 0.1 equivalents of TMS-OTf at −78 °C, and allowed to stir for 48 hours at this temperature. After aqueous workup and chromatography (silica gel, *tert*-butyl methyl ether/petroleum ether) the homoallylic ethers **4a–g** were obtained in total yields of 49–81% (Table 1). Side products in these reactions are the desilylated **2** (< 5%), the oxazolidine derivatives **7** (10–25%), and the acetals **8** (< 5%). If aromatic aldehydes **1h–k** are employed, the stereoselectivity is reduced (Table 1).

Application of other aminoalcohols as chiral inductors resulted in considerably lower yields and stereoselectivities. Reactions of aliphatic aldehydes with the trimethylsilyl ethers of (1*S*,2*R*)-*N*-trifluoroacetylnorephedrine and (1*S*,2*R*)-*N*-trifluoroacetylephedrine provided products with respective *de* values of 52–78, and 56–62% and respective yields of 25–

j	C_6H_4-*m*-Br	89	82 [f]	−101.2	114.7	0
k	C_6H_4-*p*-OMe	80	96 [f]	−125.4	103.5	75

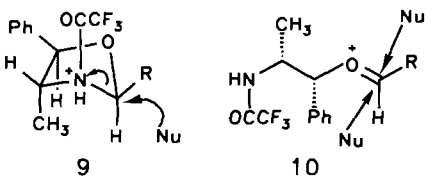
[a] Amount of recovered **2** in parentheses. [b] Determination by GC (Chromopack WOCT CP Sil 19CB, 0.22 mm × 50 m, H_2). [c] Optical rotation of **4** ($c = 1$ in chloroform). [d] Melting point of **4**, recrystallized from *tert*-butyl methyl ether/petroleum ether. [e] The major product has (*R*) configuration. [f] The major product has (*S*) configuration. [g] The alcohol in the crude reaction mixture was derivatized and then detected.

63 and 32–34%. Even worse results were obtained with aromatic aldehydes.

The homoallylic ethers **4a–g** could be converted by reductive cleavage with sodium in liquid ammonia[8] into the homoallylic alcohols **5a–g** in good yields without racemization (Table 1; THF, 2.5 equiv sodium, −78 °C, 15 min). As an additional product the enantiomerically pure amphetamine **6** was obtained which can easily be removed by distillation or chromatography (silica gel, *tert*-butyl methyl ether/petroleum ether). The homoallylic ether **4k** prepared from *p*-methoxybenzaldehyde may also be cleaved selectively to **5k** and **6**; the reductive cleavage of the homoallylic ethers **4h–j** obtained from aromatic aldehydes **1i,j** and cinnamaldehyde did not proceed as desired.

For the determination of the absolute configuration of **5**, an 87:13 mixture of the enantiomers of *ent*-**5b** and **5b** was esterified with (*R*)-(+)-α-methoxy-α-trifluoromethyl-phenylacetyl chloride, and examined by spectroscopy. The absolute configuration of the homoallylic alcohols could be deduced following Mosher's rules[9] from the positions of the signals for 2-H_2 and 4-H_2 of the ester of **5b** ($\delta = 1.61, 2.41$), and for 2-H_2 and 4-H_2 of the ester of *ent*-**5b** ($\delta = 1.69, 2.35$). The assignment was confirmed by comparison of the optical rotation of (*R*)-dodec-1-en-4-ol (**5d**) ($[\alpha]_D^{20} = +10.5$, $c = 0.65$ in CCl_4) with the literature value ($[\alpha]_D^{20} = +10.2$, $c = 3.5$ in CCl_4).[4]

The high stereoselectivity of the reaction is probably due to the selective formation of the oxazolidinium ion **9**, which is subsequently opened in an S_N2-type reaction. This hypothesis is also supported by the appearance of side product **7**; interestingly, treatment of **7** with **3** in the presence of Brönsted or Lewis acids does not lead to **4**. The low selectivity achieved



when aromatic aldehydes are employed may be explained by the existence of the acyclic oxonium ion **10**. The possible mesomerism when R is a phenyl group should make this intermediate lower in energy than when R is a alkyl group.

[7] The hydrochloride of (1*R*,2*R*)-norpseudoephedrine was dissolved in methanol and treated with 1.1 equiv triethylamine. After the addition of 1.2 equiv methyl trifluoroacetate (0 °C), the reaction mixture was stirred for 15 h at room temperature. The solvent was removed completely under vacuum and the residue dissolved in dichloromethane. This solution was cooled to 0 °C, treated with 2.5 equiv triethylamine and 1.2 equiv chlorotrimethylsilane, and stirred for 15 h at room temperature. After aqueous workup the trifluoroacetylated silyl ether was purified by distillation [B.p. 78 °C (0.01 mbar); $[\alpha]_D^{20} = +16.0$ ($c = 1$ in methanol)].

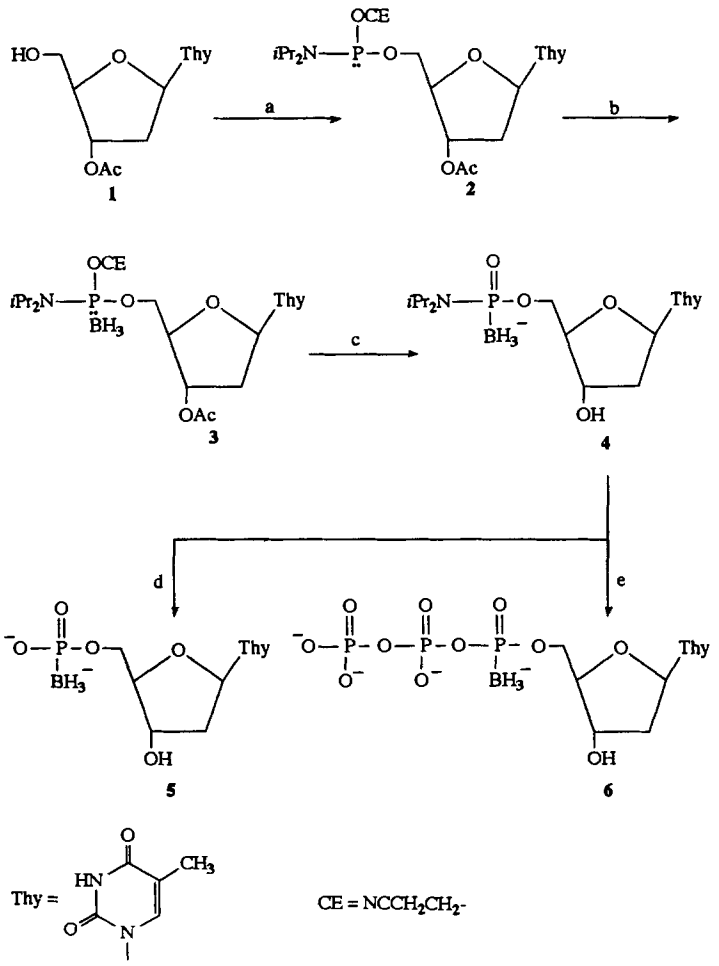
[**] Boron-Containing Nucleic Acids, Part 3. This research was supported by the U.S. National Institute of Health (1 R43 AI 30887-01) and the American Cancer Society (NP 741). The HPLC study by F. Huang is gratefully acknowledged. – Part 2: [2].

tively,[1] in which a negatively charged BH_3 group replaces one nonbridging O^- of a phosphate group. Boranophosphates of types **5** and **6** have charge distributions and a prochiral (**5**) or chiral (**6**) phosphorus atom analogous to those of the nucleoside 5′-thiophosphates or nucleoside 5′-*O*-(1-thiotriphosphates), respectively. Because of these similarities it has been anticipated that the boranophosphates may be useful like the thiophosphates in biochemical and molecular biological investigations. The latter have found widespread applications in the study of the stereochemistry of enzyme-catalyzed nucleotidyl- and phosphoryltransfer reactions[3] and have been successfully employed in sequencing,[4] oligonucleotide-directed mutagenesis[5] and the labeling of hybridization probes.[6] An additional pharmacological application for boranophosphates may be as carriers of ^{10}B in boron neutron capture therapy for the treatment of cancer.[7]

The crucial step in the synthesis of compounds **5** and **6** (Scheme 1) is the attachment of the BH_3 group to the phosphorus atom. This was performed at the stage of the nucleoside 5′-phosphite by using the exchange reaction[8] with an amine–borane. 3′-*O*-Acetylthymidine **1** was phosphitylated with (CEO)P(N*i*Pr$_2$)Cl[9] to give **2**. Phosphite **2** was treated in situ with excess *i*Pr$_2$EtN · BH_3. The postulated product of this reaction, phosphite · borane **3**, was not isolated but converted directly to **4** with NH_4OH. Acid hydrolysis of **4**[10] gave **5**,[11]



Scheme 1. Synthesis of boranophosphates **5** and **6**: a) (CEO)P(N*i*Pr$_2$)Cl, *i*Pr$_2$NEt, 4-dimethylaminopyridine, CH_3CN, 20 °C, 1 h; b) *i*Pr$_2$NEt · BH_3, 20 °C, 12 h; c) MeOH/conc. NH_4OH (1.5:1), 20 °C, 5 h; d) 0.1 M aqueous trifluoroacetic acid, 20 °C, 0.5 h; e) $(Bu_3NH)_2H_2P_2O_7$, *N*,*N*-dimethylformamide, 55 °C, 4 h.

Table 1. Selected physical data of **5** and **6** [a,b].

5: ^1H NMR: $\delta = 0.149$ (dq, $^1J(B,H) = 84.0$ Hz, $^2J(P,H) = 21.6$ Hz, 3H; BH_3), 1.787 (s, 3H; CH_3), 2.147–2.291 (m, 2H; 2′-H), 3.715–3.811 (m, 2H; 5′-H), 3.978 (unresolved, 1H; 4′-H), 4.424 (unresolved, 1H; 3′-H), 6.182 (t, $^3J(H,H) = 6.9$ Hz, 1H; 1′-H), 7.690 (s, 1H; 6-H); $^{31}P\{^1H\}$ NMR: $\delta = 79.3$ (q, $^1J(P,B) = 168$ Hz); ^{11}B NMR: $\delta = -37.9$(m); UV(H_2O): λ_{max}[nm] (ε)$_{max}$ λ_{min}-[nm] = 268 (9100) 236 (pH 2.0 and 7.0), 268 (7500) 244 [pH 11.0]; MS (electrospray ionization, 3000 V): *m/z* 321 (**5** + 3H)$^+$; DC: $R_{dTMP} = 1.25$; RP-HPLC (C_{18}, A: 0.02 M KH_2PO_4, B:CH_3CN, 0 → 25% B/5 min, 3.0 mL min^{-1}, t_R = 4.98 min).

6: ^1H NMR: $\delta = -0.249$–0.804 (2 br.m, 3H; BH_3), 1.780, 1.788 (2s, 3H; CH_3), 2.194–2.216 (m, 2H; 2′-H), 3.961–4.168 (2*m*, 3H; 4′-H, 5′-H), 4.449–4.497, 4.536–4.584 (2m, 1H; 3′-H), 6.190 (t, $^3J(H,H) = 6.7$ Hz, 1H; 1′-H), 7.571, 7.557 (2s, 1H; H-6); $^{31}P\{^1H\}$ NMR: $\delta = -21.4$ (t, $^2J(P,P) = 21.4$ Hz, 1P; P^2), −5.50 (unresolved, 1P; P^5), 82–84 (br.m, 1P; P^1); ^{11}B NMR: $\delta = -38.6$ (m, $^1J(B,P) = 137$ Hz, $^1J(B,H) = 92$ Hz); MS: *m/z* 498 (**6** + 4H + NH_4)$^+$; DC: $R_{dTTP} = 1.40$; RP-HPLC (C_{18}, A: 0.2 M triethylammonium acetate, pH = 7.5, B:methanol, 0 → 10% B/20 min, then 10% B/10 min, 4.0 mL min^{-1}, t_R = 20.91 (60%) and 24.57 (40%) min.

[a] All NMR measurements were conducted in D_2O + 0.1 M NaOD at 20 °C and 300 (^1H), 121.4 ($^{31}P\{^1H\}$, 85% H_3PO_4), or 28.7 (^{11}B, BF_3 · Et_2O) MHz. [b] Thin-layer chromatography (TLC) was performed on silica gel 60 F_{254} plates with a solvent mixture of 1-propanol/NH_4OH/H_2O (11:7:2). R_{dTMP} and R_{dTTP}: R_f values relative to dTMP and dTTP, respectively.

whereas the reaction of **4** with excess $(Bu_3NH)_2H_2P_2O_7$[12] yielded **6**.[13] Compounds **5** (52%) and **6** (30%, 3:2 mixture of phosphorus diastereoisomers according to HPLC) were isolated after ion-exchange chromatography on a QA-cellulose[HCO_3^-] column as HPLC-pure ammonium salts (Table 1).

Preliminary studies on **5** show that thymidine (dT) is the sole UV-absorbing hydrolysis product between pH 1–13. The fact that **5** does not hydrolyze to give thymidine 5′-phosphate (dTMP) reflects the stability of the P–BH_3 bond to water. Like monoalkyl phosphates that have a maximum rate of hydrolysis around pH 4,[14] **5** is least stable in the slightly acidic pH range. This suggests that the mechanism of the hydrolysis of **5** is analogous to that of the monoalkyl phosphates and proceeds via $H_3BPO_2^-$, the borane derivative of monomeric metaphosphate in the transition state.[15] At the same time, **5** is significantly more labile than monoalkyl phosphates.[16]

Acid phosphatase [EC 3.1.3.2] from sweet potato or 5′-nucleotidase [EC 3.1.3.5] from *Crotalus adamanteus* venom completely hydrolyzes **5** to dT. On the other hand, **5** is a very poor substrate or, like thymidine 5′-thiophosphate,[17] may even be an inhibitor of alkaline phosphatase [EC 3.1.3.1] from *Escherichia coli*. In accordance with the above findings, hydrolysis of triphosphate **6** by acid phosphatase or 5′-nucleotidase also gives dT, while that by alkaline phosphatase yields **5**.

Compound **6**—possibly only one of two diastereoisomers analogous to the thiotriphosphates[18]—can substitute for thymidine 5′-triphosphate (dTTP) in the extension of a deoxyribo 17-mer primer by Sequenase (modified T7 DNA polymerase) using a 25-mer template containing one 2′-deoxyadenosine residue. Extension was performed at 37 °C for 15 min with 0.1 μM primer/template and 6.5 units of the enzyme in the presence of 100 μM 2′-deoxyadenosine 5′-triphosphate, 2′-deoxycytidine 5′-triphosphate, 2′-deoxyguanosine 5′-triphosphate, and either 100 μM **6** or 100 μM dTTP. The extension products were separated by denaturing polyacrylamide gel electrophoresis. Autoradiography showed that in both cases the primer was extended to completion without any detectable pause.

These preliminary results indicate that boranophosphates may open a new chapter in nucleotide chemistry.

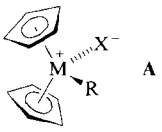
Cationic Metallocene Polymerization Catalysts. Synthesis and Properities of the First Base-Free Zirconocene Hydride**

By *Xinmim Yang, Charlotte L. Stern,* and *Tobin J. Marks**

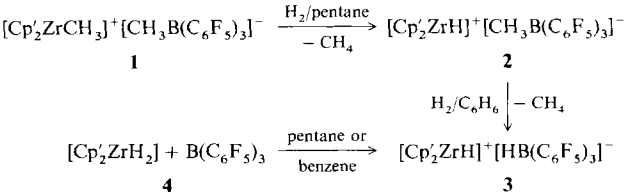
Growing evidence from spectroscopic studies of reactions and investigations of model compounds[1] indicates that the active components of potent[2] and highly stereoselective[3] homogenous and heterogenous olefin polymerization catalysts based on Group 4 metallocenes and Lewis acids (e.g., Al_2O_3,[4] alumoxane,[2, 5] and organoboranes[6]) are electrophilic, base-free, cation-like alkyl complexes of type **A** (M = Ti, Zr, Hf; R = alkyl).[7, 8] Since hydrogenolysis and β-hydride eliminination are essential for the molecular



A

weight control and chain-transfer processes in metallocene-centered olefin polymerization, elucidating the presently unknown chemical and structural properties of the corresponding cationic metallocene hydrides (bis(cyclopentadienyl)-hydridometal(IV) cations) would be of great interest. We report here on the synthesis, reactivity, and structural characterization of the first base-free cationic zirconocene hydride.[9] This compound displays high electrophilicity and polymerization activity and also offers further insight into the structure and dynamics of ion-pairing in such species.

The metallocene cation **1** (Cp′ = η^5-(CH$_3$)$_5$C$_5$)[6] undergoes rapid, stepwise hydrogenolysis to yield mono- and dihydrido complexes **2** and **3**, respectively (Scheme 1). Alternatively, **3** can be prepared by hydride abstraction from **4**.[10]



Scheme 1. Hydrogenolysis (**1** → **2** → **3**) and hydride abstraction (**4** → **3**) as routes to the cationic hydrido complexes **2** and **3**.

Complexes **2** and **3** were characterized by standard spectroscopic and analytical techniques (see Experimental Procedure). In the ^{1}H NMR spectra, the downfield shifts of the Zr–H resonances (δ = 7.70 (**2**), 8.18 (**3**) vs. δ = 7.46 (**4**)) are particularly instructive. The signal of the B-bound H atom in **2** exhibits the expected broadening due to the ^{11}B quadrupole,[11] and any Zr–H/B–H exchange processes at 0 °C are slow on the NMR timescale. Very high electrophilicity is evidenced by the facile Zr–H/C–D exchange reactions exhibited by **2** and **3** in deuterated aromatic solvents ($t_{1/2}$ for the disappearance of the Zr–H signal is ca. 12 h and 6 min, respectively, in C$_6$D$_6$). In the IR spectra (Nujol mulls), the $\tilde{\nu}_{Zr-H}$ modes of the cationic hydrides are shifted to higher frequencies: **2**, $\tilde{\nu}_{Zr-H}$ = 1642 ($\tilde{\nu}_{Zr-D}$ = 1174) and **3**, $\tilde{\nu}_{Zr-H}$ = 1663, 1604 cm^{-1}.[12] The analogous values for **4** and [Cp′$_2$Zr(H)(O*t*Bu)][10] are 1555 and 1582 cm^{-1}, respectively.

The crystal structure of **3** (Fig. 1)[13] consists of a [Cp′$_2$ZrH]$^+$ ion with a "bent-sandwich" structure (unexceptional metrical parameters)[6, 10a, 14] weakly coordinated to a [HB(C$_6$F$_5$)$_3$]$^-$ ion. The most interesting aspect of the ion-pairing is the non-involvement of the B–H functionality (a priori, structure **B** might be anticipated based upon several known examples of **C**[6, 14]). The reason appears to be a combination of steric and electronic factors, with the latter involving weak, but nonnegligible Zr···F–C interactions.[15] Thus, the Zr–F separations here (Zr–F1 = 2.416(3)

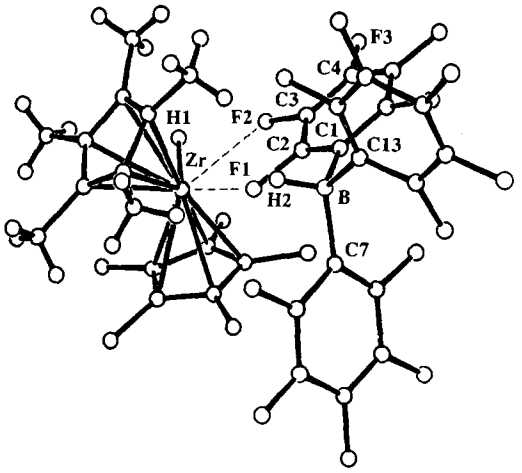

Fig. 1. Molecular structure of **3**. Important distances [Å] and angles [°]: Zr-H1 2.00(5), Zr-H2 4.87(5), Zr-F1 2.416(3), Zr-F2 2.534(3), B-H2 1.06(6); H2-B-C1 104(3), H2-B-C7 109(3), H2-B-C13 105(3), C1-B-C7 112.9(4), C1-B-C13 111.9(4), H1-Zr-F1 128(1), H1-Zr-F2 65(1). Only one of the two possible orientations of the disordered Cp′ ring is shown.

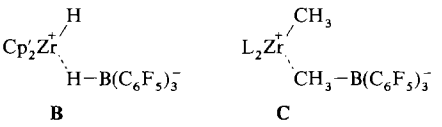

B **C**

L = Cp′, 1,2-$(CH_3)_2C_5H_3$

and Zr–F2 = 2.534(3) Å) can be compared to those in Cp_2ZrF_2 (1.98(1) Å)[16] and in the cation in **5** (2.108(2) and 2.118(2) Å).[14] A small but significant elongation in the C2–F1 separation (1.396(5) Å) versus C–F_{av} (1.354(4) Å) is also evident. The boron valence angles are approximately tetra-

$[Cp'_2Zr(CH_3)(\mu\text{-}F)Zr(CH_3)Cp'_2]^+[CH_3B(C_6F_5)_3]^-$ **5**

hedral. Interestingly, the ^{19}F NMR spectrum of **3** at −75 °C is consistent with the symmetry found in the solid state (Fig. 1); however, as the temperature is increased to −20 °C rapid exchange of the fluorine sites within the rings and between the rings is observed.

Compounds **2** and **3** are active homogenous catalysts for olefin polymerization. Ethylene polymerization proceeds rapidly at 25 °C/1 atm to yield linear (by NMR)[17] polyethylene ($M_w = 4.34 \times 10^5$; $M_n = 1.54 \times 10^5$ by gel permeation chromatography (GPC)). The turnover rate N_t is approximately 32 s^{-1} (3.2×10^6 g polyethylene (mol Zr)$^{-1}$ h^{-1} atm^{-1}). Propylene polymerization proceeds at 0 °C in toluene to yield atactic (by ^{13}C NMR)[17] polypropylene ($M_w = 3900$; $M_n = 2500$ by GPC) with $N_t \approx 2.1$ s^{-1} (3.2×10^5 g polypropylene (mol Zr)$^{-1}$ h^{-1}); analysis of the end groups of the polypropylene by ^1H and ^{13}C NMR spectroscopy indicates 90% vinyl/isopropyl and 10% vinylidene/*n*-propyl structures. Both the kinetic data and product microstructures are therefore comparable to those associated with $[Cp'_2Zr(CH_3)_2]$/methylalumoxane catalysts.[2, 6, 18]

These results afford the first picture of the properties of base-free zirconocene hydrides. Noteworthy are the electrophilicity, polymerization activity, and the presence of ion-pairing effects not based on bridging hydrogen atoms.

Experimental Procedure

All operations involving air- and moisture-sensitive complexes were carried out under rigorously anhydrous and anaerobic conditions.

2: $Cp'_2Zr(CH_3)_2$ (82 mg, 0.21 mmol) and $B(C_6F_5)_3$ (123 mg, 0.24 mmol) were transferred into a 25 mL reaction flask. Pentane (15 mL) was condensed in at −78 °C. The flask was then backfilled with 1 atm of H_2. The suspension was stirred at −78 °C for 2 h, then at 25 °C for 15 h. It was filtered, and the product, a light yellow solid, was collected, washed with pentane, and dried under vacuum. Yield, 80%. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.70 (s, 1H; ZrH), 1.48 (s, 30H; Cp′), 0.10 (br. s, 3H; BCH_3); ^{19}F NMR (282 MHz, C_6D_6, 25 °C); δ = −132.94 (d, ^3J = 22.6 Hz, 6F; *o*-F), −159.80 (t, ^3J = 20.6 Hz, 3F; *p*-F), −176.02 (m, 6F; *m*-F); IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1642 (Zr-H), 1174 (Zr-D). Correct C,H analysis.

3: Procedure A: A procedure similar to that for **2** was employed except the reaction was carried out in benzene (in which **2** is soluble). Procedure B: $[Cp'_2ZrH_2]$ (150 mg, 0.41 mmol) and $B(C_6F_5)_3$ (230 mg, 0.45 mmol) were allowed to react in 15 mL of toluene in a 25 mL flask at −78 °C for 0.5 h, then at 25 °C for 1 h. The resulting solution was filtered. Pentane (25 mL) was condensed onto the toluene filtrate resulting in the formation of yellow powdery product which was then isolated by filtration, washed with pentane, and dried under vacuum. Yield, 75%. ^1H NMR (300 MHz, [D_8]toluene, 0 °C): δ = 8.18 (s, ZrH), 3.98 (br, d, BH), 1.50 (s, Cp′); ^{19}F NMR (282 MHz C_6D_6, 25 °C): δ = −137.08 (br. s, 6F; *o*-F), −160.75 (t, $^3J \approx 20.6$ Hz, 3F; *p*-F), −168.36 (br. s, 6F; *m*-F); IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1663, 1604 (Zr-H), 2364 (B-H). Correct C, H analysis.

Ethylene and propylene polymerizations were carried out using procedures described previously[6,19]. In a typical ethylene polymerization experiment, a solution of **3** (7.5 mg in 5 mL of toluene) was quickly injected with a gas-tight syringe equipped with a spraying needle into a 250 mL flask containing 50 mL of toluene which was rapidly stirring (and pre-saturated) under 1 atm of rigorously purified ethylene. The reaction was quenched with CH_3OH after a short time period (78 s) at which point copious amounts of polymer precipitated. Polymer was collected using standard procedures yield 0.61 g. In a typical propylene polymerization experiment, a flame-dried quartz pressure tube was charged with 7.5 mg of **3** together with 4 mL of toluene and 10–15 mL of rigorously purified liquid propylene. After 2 h of vigorous stirring at 0 °C, unreacted monomer was vented. Polymeric product was collected using standard procedures; yield 5.5 g. Polymerization experiments conducted on a larger scale (1 L reactor) and for longer durations gave similar polymerization activities[20].

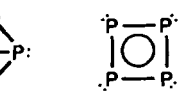
The Formation of *cyclo*-P_4 Ligands with Maximum Electron Donor Ability**

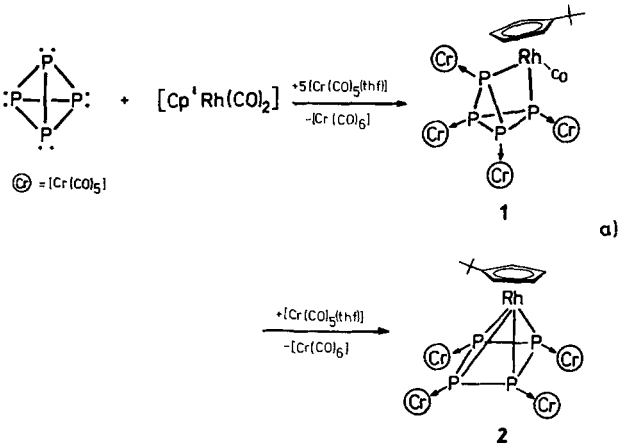
By *Manfred Scheer,** *Christa Troitzsch*, and *Peter G. Jones*

The transformation of the P_4 tetrahedron **A** to the *cyclo*-P_4 **B** is observed for the reaction of white phosphorus with carbonyl chromium and carbonyl tungsten complexes.[1] The *cyclo*-P_4 ligand in the $[(CO)_4M\{\eta^4\text{-}P_4[M(CO)_5]_4\}]$ (M = Cr or W) formed has twelve valence electrons (VE) available for the overall complex. The question of the mechanism of the transformation of **A** into **B** is answered by the results of the three-component reaction (a) of P_4 and $[RhCp'(CO)_2]$ ($Cp' = \eta^5\text{-}C_5H_4t\text{Bu}$) in the presence of $[Cr(CO)_5(thf)]$[2] at 60–70 °C.



A B

The tetraphosphane complexes **1** and **2** are formed by the reaction (a); with a large excess of $[Cr(CO)_5(thf)]$ **2** is formed exclusively. Compound **2** can also be obtained by the thermolysis of **1**.



Compound **1** forms black platelets and **2** red needles which are readily soluble in CH_2Cl_2, moderately soluble in benzene, and slightly soluble in *n*-pentane. Both compounds can be handled in the air for a short period of time. Their solutions also only decompose in the air after quite a long time (ca. 30 min).

Compounds **1** and **2** were characterized by NMR and IR spectroscopy as well as by mass spectrometry.[6]

The crystal structural analysis of **1**[7] (Fig. 1) reveals two independent molecules with very similar structural parameters. Compound **1** contains a tetraphosphabicyclobutane ligand, an open-edged P_4 tetrahedron, which is bound along its open P–P edge to a [RhCp′(CO)] complex fragment. All the P atoms are also coordinated via their lone pairs to $[Cr(CO)_5]$ complex fragments. The P···P distance of the

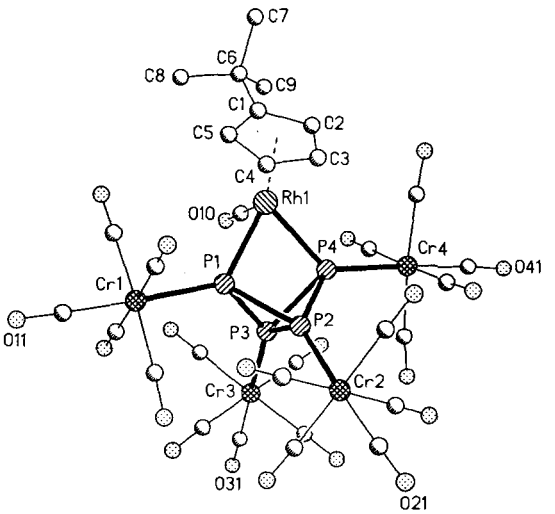


Fig. 1. Crystal structure of **1** (only one of the two independent molecules is shown).

open edge 2.815(4) Å (2.808(4) Å) is greater than in the Co complex **3** (2.606(1) Å),[8] whose P_4M skeleton is isostructural with that of **1**. Also the P–P bond lengths (P1P2, P1P3, P2P4, P3P4) are on average (2.222(4) Å) slightly longer than those in **3** (2.210(2) Å) (d_{PP} = 2.21 Å for the single bond). They correspond more closely to those in the tetraphosphabicyclobutanes **4**[9] and **5**,[10] which contain sterically demanding organic substituents. In contrast to **3**–**5**, the P–P bond between the bridgehead atoms P2 and P3 in **1** (2.201(3) Å for both independent molecules) is lengthened (**3**: 2.158(2), **4**: 2.129, **5**: 2.166(2) Å). Obviously the lengthening of the P–P bonds of the tetraphosphabicyclobutane skeleton is caused by the coordination of the lone pairs of all P atoms to sterically demanding $[Cr(CO)_5]$ complex fragments.

$[CoCp^*(CO)(\eta^2\text{-}P_4)]$ **3**

$Cp^* = \eta^5\text{-}C_5Me_5$

$P_2(PR_2)$ **4**, R = $N(SiMe_3)_2$
5, R = 2,4,6-$tBu_3C_6H_2$

The bonds P1–Cr1 and P4–Cr4 (2.335(2)–2.350(3) Å, average 2.344 Å) are slightly longer than P2–Cr2 and P3–Cr3 (2.308(2)–2.329(2) Å, average 2.321 Å). The P–Cr bonds in **1** are longer than those in complexes such as **6** (2.301(4) Å)[11] and **7** (2.307(5) Å)[11] with P_1 and P_2 ligands, respectively.

$[Fe_3(CO)_6\{\mu_3\text{-}PCr(CO)_5\}\{\mu_3\text{-}PFe(CO)_4\}]$ **6**

$[Fe_2(CO)_6(\mu\text{-}CO)\{\mu,\eta^2\text{-}\{PCr(CO)_5\}_2\}]$ **7**

$[Co(triphos)\{\eta^3\text{-}P_3[Cr(CO)_5]_2\}]$ **8**

triphos = $MeC(CH_2PPh_2)_3$

In the sterically bulky complex **8** with a P_3 ligand[12] the P–Cr bonds (2.426(4) Å) are somewhat longer than in **1**. The fold angle of the tetraphosphabicyclobutane skeleton in **1** (94° (93°)) is only slightly less than in **3** (95°), **4** (95.2°), and **5** (95.5°).

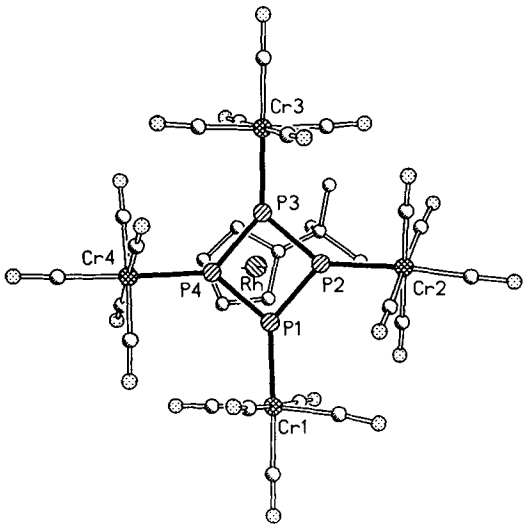

Fig. 2. Crystal structure of **2** (view of the *cyclo*-P_4 moiety).

The crystal structure of **2**[7] reveals a planar *cyclo*-P_4 ligand, which is capped centrosymmetrically by a Cp'Rh cap, and the lone pairs of all P atoms coordinate to the $[Cr(CO)_5]$ complex fragments (Fig. 2). The P–P bond lengths are very similar (2.143(2)–2.160(2) Å, average 2.149 Å) and shorter than single bond lengths. Only the distance between the atoms P3 and P4 (2.160(2) Å) is slightly lengthened in contrast to the others (2.146(3) Å). The reason could be that one C–C edge of the Cp' ligand is arranged above this P–P bond, whereas only corners of the Cp' ligand lie above the other P–P edges (Fig. 2). A kite-shaped distortion of a *cyclo*-P_4 ligand is observed in **9**,[13] where the CO groups of the capping $[NbCp^*(CO)_2]$ complex fragment are parallel to the elongated bonds of the P_4 ligand.

$[NbCp^*(CO)_2(\eta^4\text{-}P_4)]$ **9**

The four P atoms in **2** form a plane at a distance of 1.88 Å from the capping Rh atom (Fig. 3). The Cp' plane and the *cyclo*-P_4 ligand are inclined to each other by about 7°, which is traced back to the repulsion of the *t*Bu group of the Cp' ligand with the $[Cr(CO)_5]$ group at the P2 atom. Thus, the Cr2 atom is deflected away from the plane of the remaining three Cr atoms by about 0.38 Å, which is found about 0.22 Å below the P_4 plane. The P2–Cr2 distance (2.327(2) Å) is insignificantly greater than the average P–Cr bond length of 2.321(2) Å.

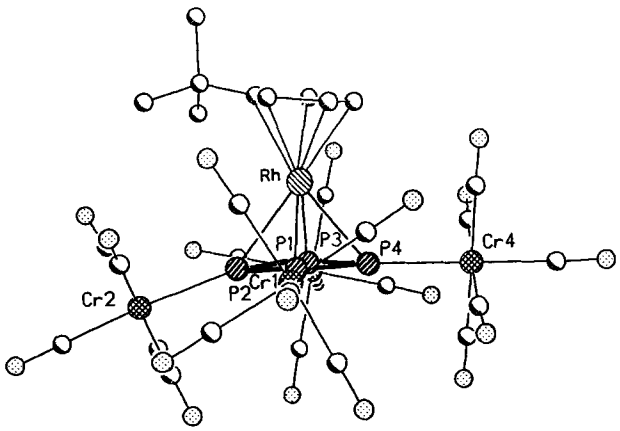

Fig. 3 Crystal structure of **2** (side view).

The structure of the products **1** and **2** provides an explanation of the method of formation of **B** starting from the tetrahedron **A**. Firstly, a P–P edge of the P_4 tetrahedron is opened by the Rh complex. Only in this step are the lone pairs of all phosphorus atoms of the now formed tetraphosphabicyclobutane chemically active for coordination [14] and coordinate to pentacarbonylchromium(0) complex fragments with the formation of **1**. The attack of a second [RhCp'(CO)] complex at the P–P edge is prevented by the $[Cr(CO)_5]$ groups. Therefore the CO abstraction at the coordinating Rh complex triggers the opening of a further P–P bond in the molecule **1** and complex **2** is formed with a planar *cyclo*-P_4 moiety. The P_4 ligand in **1** provides ten and in **2** twelve VE to the overall complex.

Experimental Procedure

To a solution of P_4 (140 mg, 1.13 mmol) and $[Cr(CO)_5(thf)]$ (6.78 mmol) in THF (25 mL), prepared by the UV irradiation of a THF solution of $[Cr(CO)_6]$ (1.6 g), was added $[RhCp'(CO)_2]$ (316 mg, 1.13 mmol). The solution was stirred at room temperature for 10 min and subsequently for 10 min at a bath temperature of 60–70 °C and evaporated to dryness under vacuum. The solid was suspended in *n*-pentane (40 mL) and filtered off over a frit. It was extracted hot with the filtrate. The volume of the pentane extract was reduced to a fifth in vacuo, and a mixture (0.45 g) of **1**, **2**, and $[Cr(CO)_6]$ crystallized at 5 °C. The latter was sublimed under high vacuum at 60 °C. The fractional crystallization of the residue from CH_2Cl_2 at 0 °C afforded **1** (110 mg, 8.5%) and **2** (150 mg, 12%). The residue from the filtration of the pentane extraction was taken up in CH_2Cl_2, whereby a further 0.3 g of solid was obtained, from which an additional 200 mg (16%) of **2** could be obtained at 0 °C.

[2] The reaction (a) without $[Cr(CO)_5(thf)]$ takes a different reaction pathway. According to our investigations no reaction occurs between $[RhCp'(CO)_2]$ and P_4 up to 110 °C. The reaction of P_4 with $[RhCp^x(CO)_2]$ ($Cp^x = \eta^5\text{-}C_5Me_4Et$) at 110° in toluene leads to the tetraphosphabutadiene derivative $[RhCp^x(P_4)\{RhCp^x(CO)\}]$[3] and at even higher temperatures to $[(RhCp^x)_2(\mu,\eta^2\text{-}P_2)_2]$, which has two separate P_2 moieties [4]. The reaction to give $[RhCp^x(CO)(\eta^2\text{-}P_4)]$ is only observed if the dimeric compound $[\{RhCp^x(CO)\}_2]$ is used as the starting material [5].

Synthesis and Biological Activity of D-3-Deoxy-3-Fluorophosphatidylinositol—A New Direction in the Design of non-DNA Targeted Anticancer Agents**

By *Alan P. Kozikowski,* Werner Tückmantel,* and *Garth Powis*

Ligand-activated growth factor and mitogen receptors activate phosphatidylinositol (PtdIns) phospholipase C, which hydrolyzes phosphatidylinositol 4,5-biphosphate to form inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3] and diacylglycerol.[1] Ins(1,4,5)P_3 releases Ca^{2+} from nonmitochondrial stores to increase the cytoplasmic free Ca^{2+} concentration, whereas diacylglycerol is an activator of protein kinase C (PKC).[2] The increase in cytoplasmic free Ca^{2+} concentration and the increased activity of PKC leads to a sequence of events that culminate in DNA synthesis and cell proliferation.[3] Recently, another pathway through which PtdIns can function as a signal molecule has been identified and linked to the action of some growth factors and oncogenes. Phosphatidylinositol-3′-kinase (PtdIns-3′-kinase) is found associated with a number of protein tyrosine kinases, including the ligand-activated receptors for insulin, platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and colony stimulating factor (CSF), as well as oncogene protein tyrosine kinases.[4] The PtdIns-3′-kinase phosphorylates the D-3 position of the *myo*-inositol ring of PtdIns to yield a class of PtdIns-3′-phosphates that cannot be hydrolyzed by PtdIns phospholipase C,[5] and therefore appear to exert their signaling action independently of the inositol phosphate pathway. The relative contributions of the inositol phosphate and PtdIns-3′-kinase signaling pathways in mediating the effects of growth factors and oncogenes on cell proliferation remain to be determined.[6]

We have recently reported on the synthesis and biological activity of a variety of 3-substituted 3-deoxy-*myo*-inositol derivatives.[7] Some of these compounds exhibit antiproliferative effects toward both normal and transformed cell lines, while a subset of these compounds has been found to selectively block the growth of oncogene transformed cells. Based upon results obtained from the study of a tritiated derivative of D-3-azido-3-deoxy-*myo*-inositol,[8] we believe that these analogues may owe their action to the blockade of mitogenic signals issuing from the action of PtdIns-3′-kinase. However, because the antiproliferative action of all of the analogues synthesized to date decreases significantly in the presence of normal serum concentrations of *myo*-inositol (40 μM), it is unlikely that these compounds will be active in vivo.[7] Therefore, we have considered the possibility of preparing a phosphatidylinositol derivative substituted at the 3-position of the *myo*-inositol ring in order to examine its inhibitory effects on cell growth. Since the ability of an inositol isostere to block the action of PtdIns-3′-phosphate depends upon its incorporation into a membrane-associated phosphatidylinositol—a transformation that would require competition of the isostere with endogeneous inositol for uptake as well as reaction with PtdIns synthetase—the direct administration

of a PtdIns isostere would circumvent these earlier steps in order to arrive at the presumed active structure (see Fig. 1).

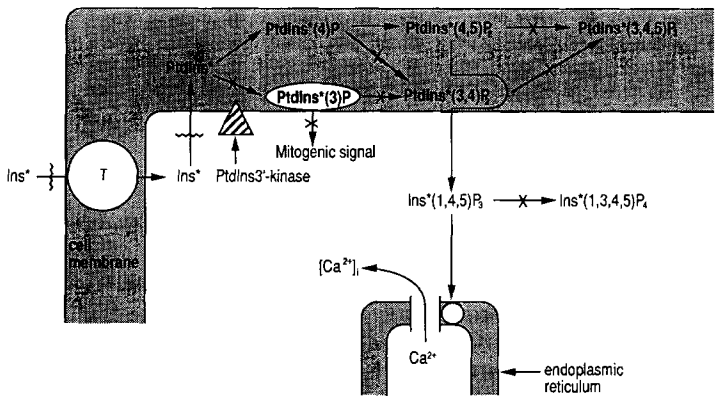

Fig. 1. Possible pathways for D-3-substituted *myo*-inositol analogues in the cell. Ins* is the analogue that is taken up by the *myo*-inositol transport process. It is then incorporated into inositol phospholipids and may give rise to D-3-substituted inositol phosphates or D-3'-substituted phosphatidylinositols. The formation of some of the phosphatidylinositol phosphates and inositol 1,3,4,5-tetrakisphosphate is blocked (indicated by crossed out arrows) because of the substitution at the D-3-position. T = transport protein. The wavy line indicates where Ins* and Ins compete.

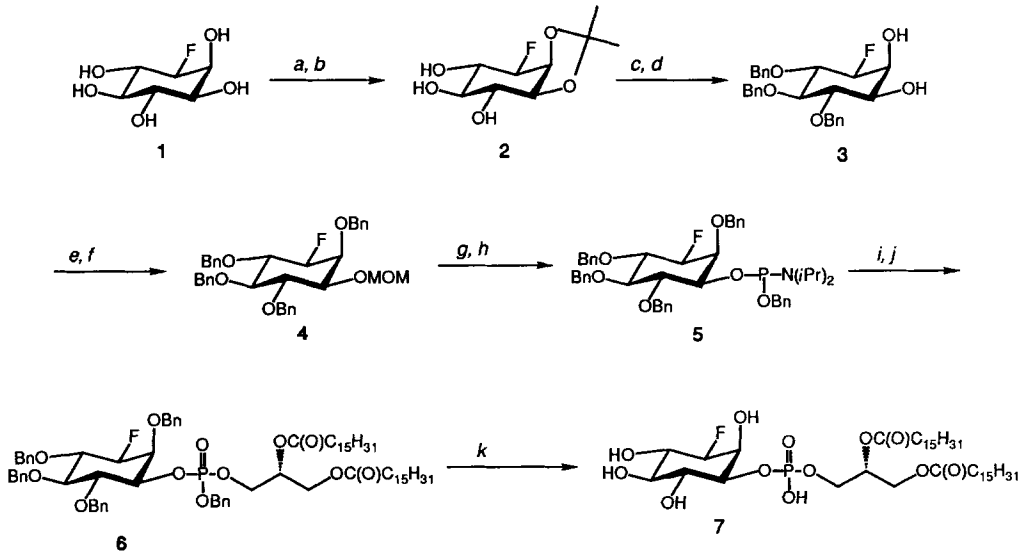
To test this hypothesis, a D-3-deoxy-3-fluorophosphatidylinositol (**7**, 3-FPI) was synthesized starting from D-3-deoxy-3-fluoro-*myo*-inositol (**1**). As illustrated in Scheme 1, **1** (prepared by methods described previously[9]) was transformed into the fully protected intermediate **4** by a sequence of conventional steps. The MOM protecting group was removed, and the 1-position phosphitylated with benzyloxybis(diisopropylamido)phosphorus to afford **5**. Next, **5** was coupled with 1,2-dipalmitoyl-*sn*-glycerol (Sigma), and the phosphite oxidized to phosphate (**6**). Finally, all benzyl groups were removed by hydrogenolysis over $Pd(OH)_2/C$ in *t*BuOH. *t*BuOH was chosen as the solvent to minimize the possibility of transesterification of the palmitoyl groups of the diacylglycerol moiety. Of all of the steps executed to procure **7**, the hydrogenolysis reaction proved to be the most capricious, and the conditions detailed in step k were established only after considerable experimentation. Satisfactory ^1H, ^{13}C, ^{19}F, and ^{31}P NMR spectra were obtained for this PtdIns analogue,[10] which notably appears to represent the first analogue of this genre to have been synthesized.[11]

Table 1. Inhibition of cell growth by 3-FPI (**7**) and D-3-deoxy-3-fluoro-*myo*-inositol (**1**). IC_{50} values in μM with standard deviations [a].

Compound	Mouse Cell Type NIH 3T3	v-*sis* NIH 3T3
7	110 ± 20	107 ± 15
7 + *myo*-inositol	99 ± 13	81 ± 11
1	7,000 ± 130	1,100 ± 600
1 + *myo*-inositol	NT [b]	NT [b]

[a] The NIH 3T3 and v-*sis* NIH 3T3 cells were plated at 5×10^3 cells in 1.6 cm diameter culture wells for 24 h in Dulbecco's Modified Eagle Medium (DMEM) with 10% heat-inactivated calf serum, and then grown in *myo*-inositol free DMEM or DMEM with 10% dialyzed heat-inactivated calf serum for 3 days in the presence of the analogues. The number of attached cells was measured with an automated cell counter. All incubations were conducted in quadruplicate. Values listed are the concentration of analogue which produces 50% inhibition of cell growth (IC_{50}). [b] NT = nontoxic, that is, $IC_{50} > 33$ mM.

The cell growth inhibitory properties of 3-FPI toward wild-type mouse NIH 3T3 and v-*sis* NIH 3T3 cells were studied (Table 1).[7] The IC_{50} was found to be approximately



Scheme 1. Synthesis of D-3-deoxy-3-fluorophosphatidylinositol **7**; MOM = methoxymethyl, Bn = benzyl. Reagents and conditions: a) 2-methoxypropene (4 equiv), camphorsulfonic acid (cat.), dimethylformamide (DMF), 80 °C, 4 h (84%); b) AcCl (cat.), $MeOH/CH_2Cl_2$ (1/2), room temperature (RT), 20 min (80%); c) NaH (10 equiv), $PhCH_2Br$ (10 equiv), DMF, 9.5 h, 0 °C → RT (96%); d) 37% HCl (cat.), MeOH, RT, 20 h (100%); e) Bu_2SnO (1 equiv), MeOH, reflux, 70 min; $MeOCH_2Cl$ (1.1 equiv), DMF, 0 °C, 1 h (66%); f) NaH (2 equiv), $PhCH_2Br$ (3 equiv), DMF, RT, 5 h (98%); g) $MeOH/H_2O$/37% HCl (100/10/1), reflux, 8 h (93%); h) $BnOP(NiPr_2)_2$ (1.2 equiv), diisopropylammonium tetrazolide (0.5 equiv), CH_2Cl_2, RT (97%); i) 1,2-dipalmitoyl-*sn*-glycerol (1.08 equiv), tetrazole (2 equiv), CH_2Cl_2/CH_3CN (1/1), RT, 5 h, 35–40 °C, 64 h (79%); j) *t*BuOOH (1.5 equiv), 0 °C, 1.5 h, RT, 3 h (92%); k) 5 atm H_2, 20% $Pd(OH)_2/C$, *t*BuOH, RT, 1 d (71–83%).

100 μM in both cell types. For comparison, Table 1 also shows the effects of D-3-deoxy-3-fluoro-*myo*-inositol which was 10 to 70 times less active as an inhibitor of cell growth.[7] Of considerable significance, however, is the finding that while the growth inhibitory effects of the inositol isostere (**1**) were completely inhibited by the presence of *myo*-inositol at physiological levels (40 μM) in the medium, the presence or absence of *myo*-inositol had no effect on the activity of 3-FPI (**7**). 3-FPI also inhibited colony formation by HT-29 human colon tumor cells in soft agarose (IC_{50} 37 ± 3 μM).

The measured IC_{50} values are within a range that should make studies with 3-FPI in blocking tumor cell growth in vivo possible. While the synthesis of other substituted PtdIns analogues that may show cell selectivity as well as an improved potency is under way, it is clear that disruption of the PtdIns-based signaling events may provide an exciting new direction in the discovery of non-DNA targeted anti-cancer agents.

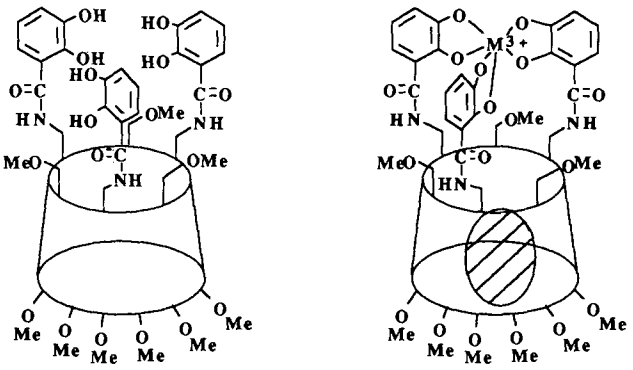
Synthesis and Complexation Properties of a Cyclodextrin-Derived Siderophore Analogue

By *Anthony W. Coleman,* Chang-Chun Ling,* and *Marcel Miocque*

The natural siderophores, exemplified by enterobactin,[1,2] parabactin,[3–5] and agrobactin,[3–5] are a class of molecules excreted by microorganisms to sequester and solubilize iron under iron-deficient conditions. Structurally, they are composed of three bidentate ligands allowing the octahedral geometry necessary for Fe^{III}. In many cases the required three bidentate ligands, often spermidine units, are incorporated into the same skeleton.

Recently, considerable efforts have been dedicated to the synthesis of analogues of the natural siderophores. Raymond et al.[6–8] and Vögtle et al.[9–11] have synthesized macrocycles containing three catechol units in a favorably geometric arrangement using 1,3,5-trisubstituted benzene derivatives, and these systems have a proven efficiency in ferric ion coordination. Most recently Raymond et al.[12] have used tris(ω-aminoalkyl)amines as building blocks in the synthesis of 2,3-dihydroxyterephthalamide derivatives. We are interested in preparing siderophore analogues with a cyclodextrin framework. Cyclodextrins are cyclic oligosaccharides possessing an axial symmetry arising from the presence of six, seven, or eight α-1,4-glucopyranose units (giving α, β, and γ cyclodextrins, respectively). Their structure, a truncated cone with two hydrophilic faces surrounding a less polar cavity, allows the inclusion of a wide variety of guest molecules.[13] The advantage of these cyclodextrin siderophores should be their potential to coordinate biologically and pharmaceutically interesting ions while retaining a "free" cavity in which a second series of molecules can be included and transported. To this end we have synthesized the ligand $6^A,6^C,6^E$-triamino-*N*,*N*′,*N*″-tris(2,3-dihydroxybenzoyl)-pentadeca-*O*-methyl-α-cyclodextrin (**1**, H_6L), which possesses a threefold axial symmetry (Scheme 1).



1

Scheme 1. Schematic representation of the structures of ligand **1** (left) and its complexes (right). The hatched oval symbolizes an included active molecule.

Our experience with the multiple tritylation of α-cyclodextrin[14] led us to synthesize **1** (Scheme 2) via the previously described $6^A,6^C,6^E$-triamino-pentadeca-*O*-methyl-α-cyclodextrin trihydrochloride (**6**),[15] prepared now by an im-

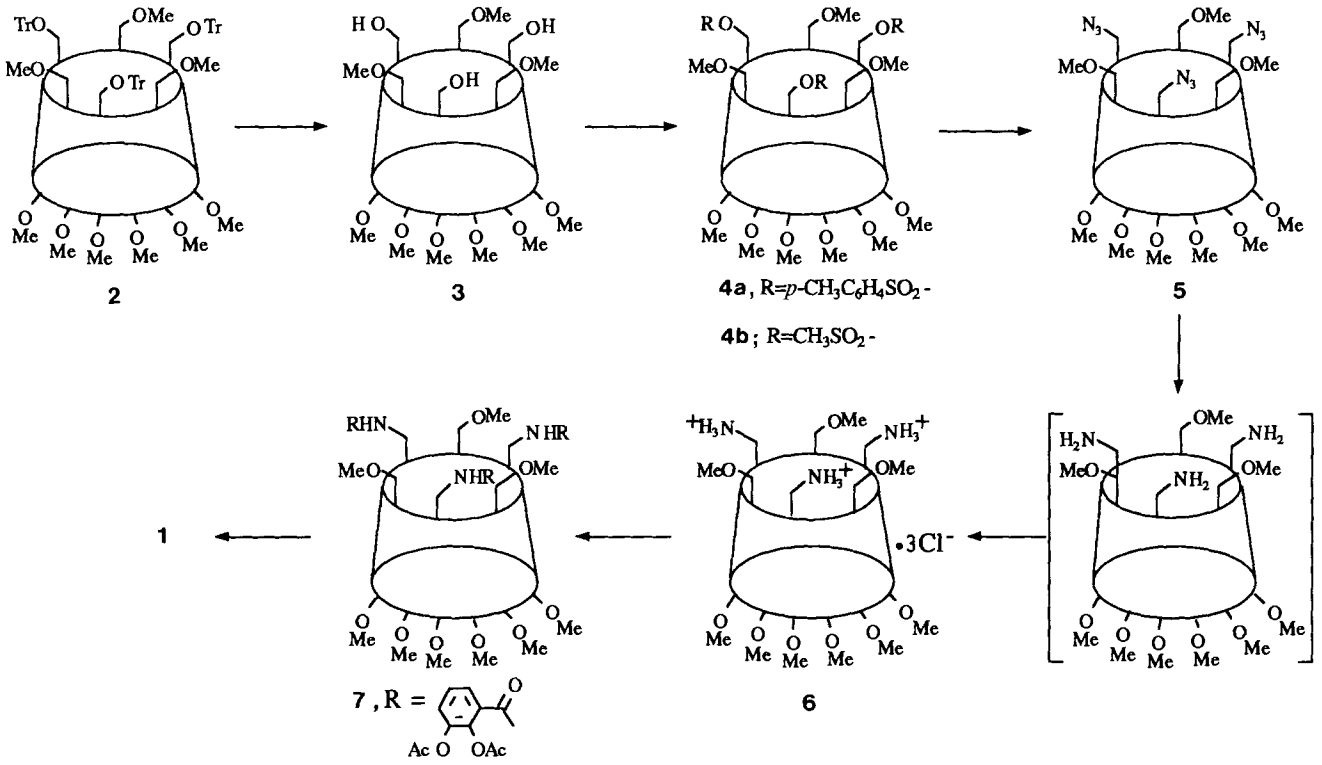

Scheme 2. Synthesis of ligand **1**. Tr = trityl.

proved method. Derivative **2** was smoothly detritylated with HBF_4 (34%)/CH_3CN[16] in good yield (87%), whereas the method of Boger et al.[15] (concentrated HCl/$CHCl_3$) led generally to incomplete detritylation at 0 °C and partial hydrolysis of cyclodextrin at room temperature. The trihydroxyl derivative **3** was converted into both the trimesylate **4a** and tritosylate **4b** in 63% and 96% yields, respectively. These compounds were converted to triazide, which was reduced with triphenylphosphine–ammonia to give the triamine as the hydrochloride salt. Treatment of **6** with 2,3-diacetoxybenzoyl chloride[17] in anhydrous tetrahydrofuran with triethylamine as base gave the protected ligand **7** in 82% yield. The acetate groups were removed with $NaOCH_3/CH_3OH$ to provide the desired ligand **1** in 97% yield.

The ^1H NMR spectra of the two catechol-containing derivatives **7** and **1** clearly show retention of the threefold molecular symmetry and the rotational liberty of the catechol groups. Spectra of **1** in [D_6]DMSO display two doublets (δ = 5.04 and 4.84) and a triplet (5.95) corresponding to the two types of anomeric protons and one type of amide protons, respectively. The two signals due to the protons of the phenol groups are observed at δ = 13.6 (*ortho*) and 8.95 (*meta*). The ^{13}C NMR spectrum of **1** in $CDCl_3$ confirms the expected symmetry: a single CONH signal is observed at δ = 170.3, two C-1 signals at δ = 100.4 and 99.4, and one CH_2NH signal at δ = 40.7.

Complexation of $FeCl_3$ by **1** in water [**1**/$FeCl_3$ = 1/1, 2.59×10^{-4} M; μ = 0.10 M (NaCl)] was studied spectrophotometrically in the pH range 3–11. At pH values greater than **4** the dark red color of the complex is observed, and an absorption maximum is recorded at 545 nm. Between pH 6.88 and 8.20, a sharp isosbestic point at 563 nm is found; between pH 8.25 and 9.40 a second (at 535 nm) is observed. A potentiometric titration experiment of the aqueous solution of **1**/$FeCl_3$ (1/1) proves that the two isosbestic points are due to two protonation equilibria ($FeLH^{2-} + H^+ \rightleftharpoons FeLH_2^-$; $FeL^{3-} + H^+ \rightleftharpoons FeLH^{2-}$). Using the Schwarzenbach plot,[18] we were able to calculate the first protonation constant $\lg K_{FeLH^{2-}} = 8.4$, and the second protonation constant $\lg K_{FeLH_2^-} = 7.4$, as both plots follow linearity.

The extremely strong binding of Fe^{3+} by the ligand **1** precludes a direct measurement of the formation constant $K_{FeL^{3-}}$ which is defined in Equation (a). Thus a competition

$$K_{FeL^{3-}} = \frac{[FeL^{3-}]}{[Fe^{3+}][L^{6-}]} \quad \text{(a)}$$

experiment[19] was carried out at pH 7.85 with solutions containing a tenfold excess of EDTA at 25 °C. Equilibrium was attained after 24 h according to the spectrophotometric results. The ligand protonation constants of **1** are still unknown, but if one reasonably assumes that the logarithms of the first three protonation constants of ligand **1** correspond to those of dihydroxybenzamide (7.6, 8.4, 9.2) and the remaining three protonation constants are 12.1,[19] then the stability constant K^* dependent on proton concentration [Eq. (b)] can be determined as $10^{2.82}$. The formation con-

$$K^* = \frac{[FeL^{3-}][H^+]^3}{[Fe^{3+}][H_3L^{3-}]} \quad \text{(b)}$$

stant $K_{FeL^{3-}}$ can then be calculated as 10^{39}, a value comparable with those of other cyclic ligands (10^{40} for CYCAM,[7] 10^{38} for CYCAMS[20]), but still several orders of magnitude lower than that of enterobactin (10^{52}).[19]

In order to test the capacity of **1** to both complex metal ions and transport organic molecules, we have studied its interaction with diamagnetic Al^{3+} in D_2O at pD 11 [**1**/Al-$(NO_3)_3$ = 1/1]. The complexation is reflected by the dramatic shifts of the aromatic protons (Fig. 1a,b) and also the methyl protons of the B, D, and F glucopyranose units (3.35 to 2.85 ppm). The retention of the threefold symmetry before and after complexation is evident from the simplicity of the spectra and the observation of only two doublets for the anomeric protons.

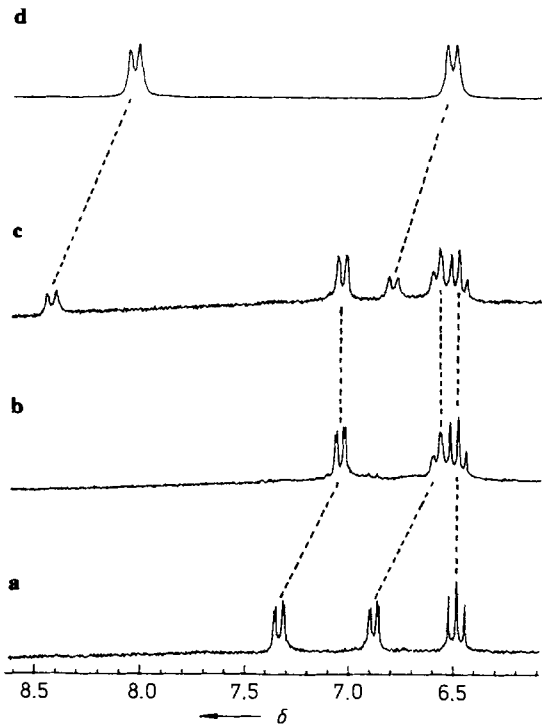

Fig. 1. ^{1}H NMR spectrum of the aromatic protons of a) ligand **1**, b) ligand **1** + $Al(NO_3)_3$ (1:1), c) ligand **1** + $Al(NO_3)_3$ (1:1) in the presence of 1 equiv sodium *p*-nitrophenolate, d) sodium *p*-nitrophenolate in D_2O at pD 11.

Inclusion experiments with AlL^{3-} were carried out with *p*-nitrophenolate. The inclusion is clearly demonstrated by the induced chemical shifts for the *ortho* protons which are displaced from 8.0 to 8.4 ppm and *meta* protons, from 6.5 to 6.7 ppm (Fig. 1d,c). The shifts of the aromatic protons of AlL^{3-} are not affected by the inclusion (Fig. 1b,c), whilst some changes are observed for cyclodextrin protons in the region $\delta = 3.8-4.0$. These observations are in agreement with the simultaneous complexation of a metal ion and inclusion of an organic molecule within the cyclodextrin cavity.

We have synthesized an α-cyclodextrin-derived siderophore and demonstrated its ability to complex Fe^{III} and Al^{III}. With Al^{III} simultaneous formation of an inclusion complex was also evident.

Experimental Procedure

3: To a stirred solution of **2** (2.42 g) in acetonitrile (40 mL), was added tetrafluoroboric acid (34%, 2.0 mL). This mixture was stirred at room temperature for 30 min, then Et_3N (1.4 mL) was added. The solvent was evaporated and the residue was subjected to column chromatography to give **3** [15] (1.30 g, 87%).

4a: A solution of **3** (200 mg), *p*-toluenesulfonyl chloride, and *N,N*-dimethylaminopyridine (50 mg) in anhydrous pyridine (3 mL) was stirred for 48 h. H_2O (0.5 mL) was added and the solution was diluted with ethyl acetate (15 mL). This solution was washed with H_2O (15 mL), HCl (2 M, 15 mL), NaOH (2 M, 15 mL), and H_2O (20 mL), dried over Na_2SO_4, and concentrated. Column chromatography (EtOH/$CHCl_3$ = 4/96 v/v) gave **4a** (174 mg, 63%). ^{1}H NMR ($CDCl_3$, signal assignments from the spectra of COSY DQF at 500 MHz): δ = 7.71 (6H, d, tosyl), 7.29 (6H, d, tosyl), 4.89 (3H, d, H-1_{ACE}), 4.85 (3H, d, H-1_{BDF}), 4.58 (3H, m, H-6_{ACE}), 4.34 (3H, dd, H-$6'_{ACE}$), 4.02 (3H, m, H-5_{BDF}), 3.91 (3H, H-6_{BDF}), 3.83 (3H, H-5_{BDF}), 3.70 (3H, H-4_{BDF}), 3.55 (3H, H-3_{BDF}), 3.42 (3H, H-$6'_{ACE}$), 3.38 (3H, H-4), 3.14 (3H, dd, H-2_{BDF}), 3.04 (3H, dd, H-2_{ACE}).

4b, **5** and **6** are prepared according to the published procedure [15].

7: Compound **6** (100 mg) and 2,3-diacetoxybenzoyl chloride (119 mg) were dissolved in anhydrous THF (5 mL) at 0 °C, then Et_3N (0.33 mL) was added. After 1 h the temperature was allowed to rise to room temperature, and the reaction was continued for 15 h. H_2O was added and the solvent was evaporated. The residue was redissolved in ethyl acetate (60 mL), and this solution was washed with H_2O (15 mL), saturated $NaHCO_3$ solution (2 × 15 mL), and H_2O (15 mL), dried over Na_2SO_4, and concentrated to dryness. Column chromatography (MeOH/CH_2Cl_2 = 5/95 v/v) gave **7** as a white solid (117 mg, 82%). IR (KBr), $\tilde{\nu}_{max}$[cm^{-1}] = 3463, 1779, 1665; ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.62 (3H, t, CONH), 5.14 (3H, d, H-1), 5.02 (3H, d, H-1), 3.15 (9H, s, MeO-6_{BDF}), 2.18 (9H, s, Ac), 2.22 (9H, s, Ac). ^{13}C NMR (J. Mod., 50 MHz, $CDCl_3$): δ = 167.8, 167.9 (COO), 165.1 (CONH), 142.7 (C-2'), 139.9 (C-3'), 129.9 (C-1', 126.6, 125.9 (C-4',5',6'), 99.2 (C-1), 83.6, 81.9, 81.8, 81.5, 81.1, 81.0 (C-2,3,4), 71.3, 70.1 (C-5_{ACE}, C-5_{BDF}), 70.6 (C-6_{BDF}), 61.5 (MeO-2_{ACE}, MeO-2_{BDF}), 59.1 (MeO-6_{BDF}), 58.0, 57.9 (MeO-3_{ACE}, MeO-3_{BDF}), 41.0 (C-6_{ACE}), 20.4 (CH_3). Correct C,H,N analyses.

1: Compound **7** (100 mg) was dissolved in absolute methanol (degassed, 5 mL), and $NaOCH_3$ (20 mg) was added. The solution was stirred under argon for 1 h, and the solvent was evaporated. The residue was redissolved in degassed water (5 mL) and the pH of the solution adjusted to 7. This solution was extracted with ethyl acetate (20 mL), then the organic phase was separated and washed with H_2O (2 × 10 mL), dried over Na_2SO_4, and concentrated to dryness. The residue was recrystallized from ethyl acetate/hexane to give analytically pure **1** (84 mg, 97%). IR (KBr): $\tilde{\nu}_{max}$[cm^{-1}] = 3302, 1640. ^{1}H NMR (200 MHz, [D_6]DMSO): δ = 13.60 (3H, s, OH-2'), 8.95 (3H, s, OH-3'), 5.95 (3H, t, CONH), 5.04 (3H, d, H-1), 4.84 (3H, d, H-1). ^{13}C NMR (J. Mod., 50 MHz, $CDCl_3$): δ = 170.3 (CONH), 149.1 (C-2'), 145.8 (C-3'), 118.6, 116.0 (C-4',5',6'), 113.8 (C-1'), 100.4, 99.4 (C-1), 84.5, 82.2, 82.1, 81.9, 81.1 (C-2,3,4), 71.7, 70.4 (C-5), 70.8 (C-6_{BDF}), 61.9, 61.6 (MeO-2), 59.5 (MeO-6), 58.2, 57.8 (MeO-3), 40.7 (CH_2NH-6_{ACE}). Correct C,H,N analyses.

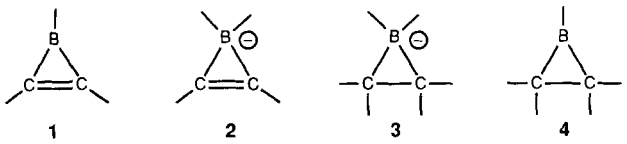
Boriranes: Structures and Thermal Ring Openings**

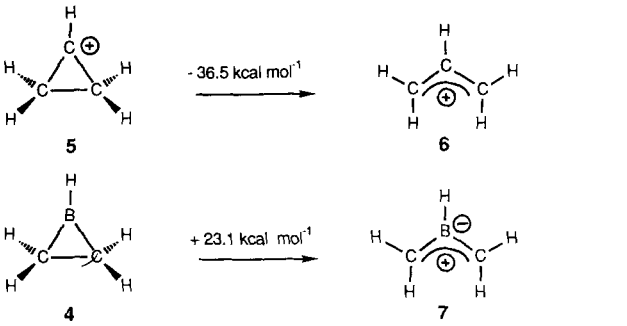
By *Peter Willerhausen, Günter Schmidt-Lukasch, Claudia Kybart, Jürgen Allwohn, Werner Massa, Michael L. McKee, Paul von Ragué Schleyer,* and *Armin Berndt**

Although borirenes **1**,[1] boratirenes **2**,[2] and boratiranes **3**[2] have been completely characterized in spectroscopic and structural investigations, simple[3] boriranes **4** have only been studied theoretically.



1 **2** **3** **4**

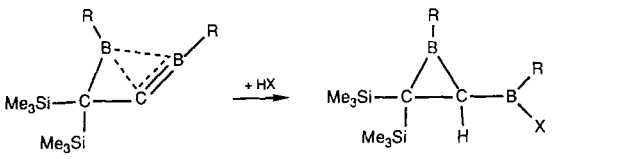
Boriranes are isoelectronic with the cyclopropyl cations (**5**), whose disrotatory ring opening to allyl cations (**6**) has been extensively investigated.[6, 7] The analogous ring opening **4** → **7**, endothermic according to calculations,[6] has not been observed experimentally.[8] We describe here the first crystal structures of boriranes and the thermal cleavages of their C–C and C–B bonds.



5 **6** **4** **7**

Scheme 1. The relative energies are calculated at the MP2 (FULL)/6.31G*// MP2(FULL)/6-31G* level.

Boriranes **4a** and **4b** were obtained from the additions of $HN(SiMe_3)_2$ and of HCl to the B–C double bonds of boranediylboriranes **8a**[9] and **8b**, respectively.[5] Compound **4b** reacted with methyllithium to give **4c**.



8a : R = *t*Bu
8b : R = duryl

4a : R = *t*Bu, X = $N(SiMe_3)_2$
4b : R = duryl, X = Cl
4c : R = duryl, X = CH_3

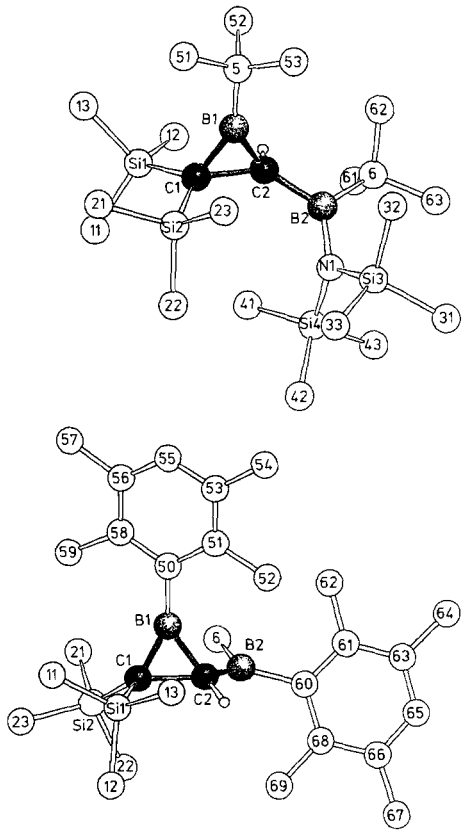

Fig. 1. Top: Crystal structure of **4a** (Schakal). Projection approximately 30° from the B1-C1-C2 plane. Bottom: Crystal structure of **4c** (Schakal). Projection roughly on the B1-C1-C2 plane.

The crystal structures of **4a** and **4c** are shown in Figure 1.[10] Table 1 compares important distances and angles of **4a** and **4c** to those calculated for *B*-methylborirane **4d**[6c] (MP2/6-31G*) and **4e** (6-31G*).

Table 1. Important distances [pm] and angles [°] in **4a**, **4c**, and **4d**.

	4a	**4c**	**4d**	**4e** (6-31G*)
C1-C2	163.6(5)	162.0(5)	155.1	156.4
C1-B1	150.0(5)	149.5(5)	153.4	151.9
C2-B1	153.9(5)	158.0(5)	153.4	155.6
C2-B2	156.8(5)	152.9(5)	–	155.1
C5-B1 [a]	155.6(5)	154.8(5)	154.9	156.2
B2-C2-B1	139.2(3)	115.0(3)	–	117.7
B2-C2-C1	139.4(3)	129.3(3)	–	123.3
C6-B2-C2-B1 [b]	−98.8(5)	−44.8(5)	–	−49.6
X-B2-C2-C1 [c]	−5.2(6)	−163.4(3)	–	−162.2
C6-B2-C2-C1 [b]	168.5(4)	20.3(6)	–	18.9
X-B2-C2-B1 [c]	87.5(5)	131.6(3)	–	129.3

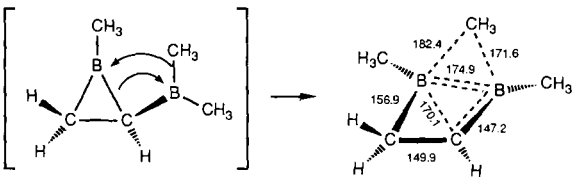
[a] **4c**: C50 instead of C5, **4d**, **4e**: C3 instead of C5. [b] **4e**: C5 instead of C6. [c] **4a**: X = N1, **4c**: X = C60, **4e**: X = C4.

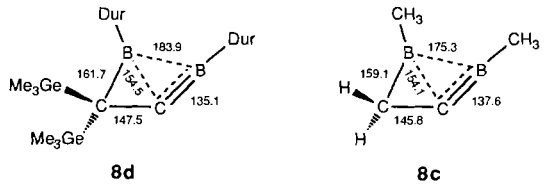
Relative to the B2-C2-B1 and B2-C2-C1 angles in **4c** (115.0 and 129.3°, respectively), the larger angles in **4a** (139.2 and 139.4°, respectively) as well as the long C2–B2 bond (156.8(5) versus 152.9 pm in **4c**) can be attributed to strong steric interactions. These data argue against significant electronic interaction of the boryl substituent with the borirane ring in **4a**. The bond between the carbon atom with the two trimethylsilyl substituents and the B1 atom is 3.4 pm shorter than the related bond in **4d**. This difference results from hyperconjugation of the C–Si bond with the empty p orbital

of the boron atom in the three-membered ring. The markedly longer C1–C2 bond (Δ = 8.5 pm, **4a** versus **4d**) is rationalized by the steric interactions between the large, *cis* substituents on C1 and C2.

The C2–B1 bond (158.0 pm) in **4c** is considerably longer than that in **4d** (153.4 pm); the C1–B1 bond in **4c** is even shorter than that in **4a**. This relationship is reminiscent of those found in cyclopropylcarbinyl cations[11] and in cyclopropylboranes:[6c] the distal bonds in the three-membered ring are shortened, while the vicinal bonds are lengthened. In contrast, the vicinal bonds are *not* equivalent in borylboriranes **4**. The bond with the electropositive boron substituent has stronger σ–π interactions with the exocyclic electron-poor center than the bond with the electronegative C atom. In **4c** the C2–B1 bond describes a torsion angle of 40° with the axis of the p oribital of the exocyclic boron atom; the torsional angle involving the C2–C1 bond, on the other hand, is 72°.

The electronic influence of the diorganylboryl substituents on the structure of the borirane ring in the absence of the steric and additional electronic effects of the trimethylsilyl and aryl groups was investigated by ab initio calculations on dimethylboryl-*B*-methylborirane (**4e**). When electron correlation is included (MP2/6-31G*), a bridged structure **4e*** results. Note the similar features of the bridged methyleneborane **8** which has a C2–B2 single bond and an additional methyl bridge.

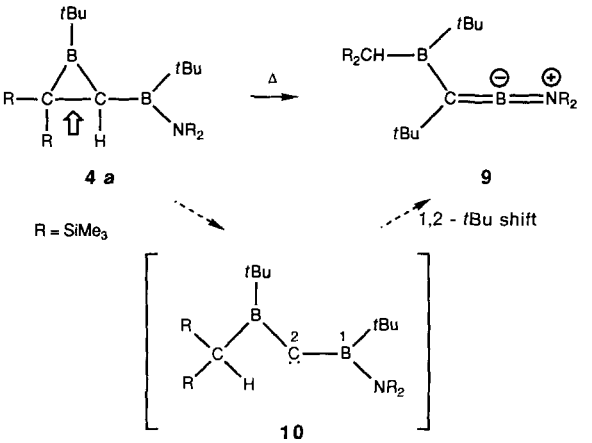




Thus the geometry of **4e** (MP2-6-31G*) cannot serve as a model for **4c**. The electron deficiency of the boron atom of the three-membered ring in **4c** is apparently reduced relative to that in **4e** by C–Si hyperconjugation and π–π delocalization through the duryl ring (see NMR data). The larger substituents may also help prevent the formation of a bridge.

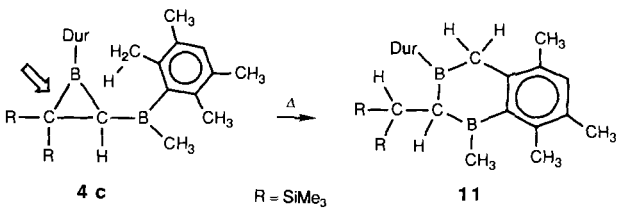
The ^{13}C NMR signals of the C atoms in the borirane ring are relatively sharp for such boron-bound species. This may be attributed to the high p character of the bonds in the three-membered ring. The correspondingly increased s character of the exocyclic C–H bonds is evident in the large ^{13}C–H coupling constants for the C–H groups adjacent to two boron atoms: 115 (**4a**), 142 (**4b**), and 140 Hz (**4c**) (cf. 96 Hz for **11**). The relatively small coupling constant for **4a** and the large B1-C2-B2 and C1-C2-B2 angles (139.2 and 139.4°, respectively) reflect the increased s character of the C2–B2 bond, and thus the reduced s character in the C2–H bond. The shielding of the boron atom in the ring in **4a** (δ = 77) compared to that in **4d** (calculated with IGLO: δ = 93.4[6c]) can be considered further evidence of the C–Si hyperconjugation. The B ring atoms of boriranes with aryl substituents are shifted another $\Delta\delta$ = 5–8 ppm relative to those with *tert*-butyl substituents. The effects of π–π interactions between the boron atom in the three-membered ring and the aryl ring are also evident in the deshielding of the *ortho* C atoms (144.3), the shielding of the *ipso* C atom (131.1), and the small angle (26.1°) between the planes of the borirane and the aryl rings.

When compound **4a** was heated in chloroform for 46 hours at reflux, *C*-borylaminomethyleneborane **9** was the only reaction product detected by ^{13}C NMR spectroscopy. The structural data for **9**[12] are in good agreement with those of known aminomethyleneboranes.[13]



The C–C bond of the borirane ring is cleaved during the conversion of **4a** into **9**. We assume that diborylcarbene[14] **10** may be formed initially by the migration of the proton from the C atom between the two boron atoms to the C atom with the two trimethylsilyl groups. 1,2-Migration of the *tert*-butyl group from the boron atom bearing the amino substituent to the neighboring carbene C atom would then lead to **9**.

When heated in toluene at reflux for four hours, **4c** rearranges into tetrahydrodiboranaphthalene **11** (roughly 80%) and an unknown product. As for similar boriranes,[16] the preferred reaction is cleavage of the Si_2C–*B* bond of the borirane ring by the addition of a C–H bond of an *ortho* methyl group at the duryl group at the exocyclic boron atom.



The structure assigned to **11** is supported by the ^{13}C NMR spectrum: broad signals for the C atoms of the CH_2 group bound to boron at δ = 32.9 (triplet, $J(^{13}C\text{-}H)$ = 116 Hz) and for the CH group at δ = 66.7 (doublet, $J(^{13}C\text{-}H)$ = 96 Hz), as well as the sharp signal at δ = 15.3 (doublet, $J(^{13}C\text{-}H)$ = 105 Hz) for the methine C atom of the $(Me_3Si)_2CH$ group *not* bound to boron (Table 2).

Cleavage of the borirane C–B bond adjacent to the exocyclic boron atom occurs during the reaction of **8a,b** with ethyl vinyl ether. The 2,5-dihydroboroles **13a,b**[17] are formed even at room temperature. The vinylboriranes **12a,b** are probable intermediates; these react under considerably

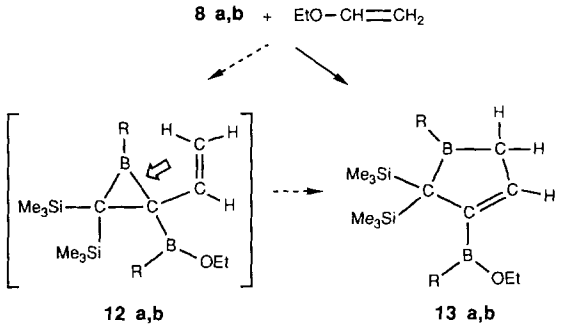


Table 2. Selected data for compounds **4a**, **4c**, **9**, **11**, and **13**.

4a: Colorless crystals, m.p. 180 °C (decomp.), yield: 65%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.20 (s, 18H, $SiMe_3$), 0.08, 0.29 (each s, each 9H, $SiMe_3$), 1.05, 1.18 (each s, each 9H, *t*bu), 1.54 (s, 1H, BCH); ^{13}C NMR (100 MHz, $CDCl_3$, −40 °C): δ = 2.2, 3.5, 4.7, 4.9 (each q, each 3C, $SiMe_3$), 16.3 (s, 1C, CSi_2), 23.6, 29.7 (each br. s, each 1C, CMe_3), 27.5, 30.7, (each q, each 3C, $C(CH_3)_3$), 33.4 (br. d, 1C, BCH, $^1J(^{13}C,H)$ = 115 Hz); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 69, 77.

4c: Colorless crystals, m.p. 128 °C (decomp.), yield: 55%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.20, 0.44 (each s, each 9H, $SiMe_3$), 1.04 (s, 3H, B-CH_3), 2.14, 2.35, 2.39, 2.65 (each s, 24H, *o*- and *m*-CH_3), 7.02, 7.33 (each s, each 1H, *p*-H), the signal for B_2CH could not be localized; ^{13}C NMR (125 MHz, $CDCl_3$, −40 °C): δ = 1.4, 5.2 (each q, each 3C, $SiMe_3$), 15.1 (br. q, 1C, B-CH_3), 19.4, 20.2, 20.3, 20.5, 20.9, 21.3 (each q, 8C, *o*- and *m*-CH_3), 22.3 (s, 1C, CSi_2), 38.6 (br. d. 1C, B_2CH, $^1J(^{13}C,H)$ = 140 Hz), 130.6 (d, 1C, *p*-C), 131.1 (br. s, 1C, *i*-C), 132.7, 133.2, 133.7, 133.8 (each s, each 1C, *o*- or m-C), 134.2 (s, 2C, *m*-C), 137.5 (d, 1C, *p*-C), 144.3 (s, 2C, *o*-C), 151.3 (br. s, 1C, *i*-C); ^{11}B NMR (96 MHz, toluene, 90 °C): δ = 72, 78.

9: Colorless crystals, m.p. 184 °C (decomp.), yield: 68%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.10, 0.32 (each s, each 18 H, $SiMe_3$), 1.00, 1.20 (each s, each 9 H, *t*bu), 1.47 (, 1H, Si_2CH); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 2.6, 4.4 (each q, each 6C, $SiMe_3$), 20.5 (br. d, 1C, BCH, $^1J(^{13}C,H)$ = 91 Hz), 25.8 (br. s, 1C, $BCMe_3$), 32.2 (s, 1C, $CCMe_3$), 33.5, 35.9 (each q, each 3C, $C(CH_3)_3$), 86.8 (br.s, 1C, CB_2); ^{11}b NMR (96 MHz, $CDCl_3$, 25 °C): δ = 70, 58; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1614, 1662 (4:1, ^{11}B = C, ^{10}B = C).

11: Colorless crystals, m.p. 162 °C (decomp.), yield: 45%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.00, 0.12 (each s, each 9 H, $SiMe_3$), 0.97 (s, 1H, Si_2CH), 1.38 (s, 3H, B-CH_3), 1.94, 2.10, 2.25, 2.28, 2.32, 2.37, 2.47 (each s, each 3H, *o*- and *m*-CH_3), 2.78, 3.08 (each 1H, AB, ^2J(H,H) = 22.3 Hz), 4.04 (s, 1H, B_2CH), 7.01, 7.15 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, $CDCl_3$, −30 °C): δ = 0.0, 2.8 (each q, each 3C, $SiMe_3$), 14.8 (d, 1C, Si_2CH, $^1J(^{13}C$-H) = 105 Hz), 16.4 (br. q, 1C, B-CH_3), 19.3, 19.5, 19.8, 20.2, 0.26, 20.29, 21.3 (each q, each 1C, *o*- and *m*-CH_3), 32.8 (br. t, 1C, CH_2, $^1J(^{13}C,H)$ = 116 Hz), 66.3 (br. d, 1C, B2CH, $^1J(^{13}C,H)$ = 96 Hz), 130.7 (d and s, 2C, *p*-C and *o*- or *m*-C), 133.2 (d, 1C, *p*-C), 131.9, 133.3, 133,9. 134.3, 134.4, 135.5, 138.3 (each s, each 1C, *o*- and *m*-C), 144.7, 146.3 (each br. s, each 1C, *i*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 83.

13b: Colorless crystals, m.p. 167 °C (decomp.), yield: 67%. – ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 3.7 (q, 6C, $SiMe_3$), 17.0 (q, 1C, CH_2-CH_3), 19.4, 19.57, 19.61, 22.1 (each q, each 4C, *o*- and *m*-CH_3), 40.3 (t, 1C, B-CH_2, $^1J(^{13}C,H)$ = 119 Hz), 52.6 (s, 1C, Si_2C), 63.1 (t, 1C, OCH_2), 130.1, 130.8 (each d, each 2C, *p*-C), 131.0, 132.8, 133.4, 134.4 (each s, each 2C, *o*- and *m*-C), 141.4, 147.3, 153.3 (each br. s, each 1C, *i*-C and BC = CH), 158.5 8d, 1C, BC = *CH*, $^1J(^{13}C,H)$ = 161 Hz); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 47, 92.

milder conditions than those required by vinylcyclopropanes[18] to give the corresponding five-membered compounds. We conclude that all types of bonds in the three-membered rings of suitably substituted boriranes can open thermally.

Stereoselective Synthesis of Phosphate-Modified Building Blocks of DNA**

By *Wendelin Samstag* and *Joachim W. Engels**

Dedicated to Professor Fritz Eckstein on the occasion of his 60th birthday

As a result of little electrostatic repulsion, nonionic DNA analogues form very stable complexes with complementary

[*] Prof. Dr. J. Engels, Dipl.-Chem. W. Samstag

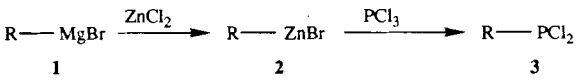
Niederurseler Hang, D-W-6000 Frankfurt am Main 50 (FRG)

oligonucleotides[1] and are resistant towards cellular nucleases.[2] They have long half-lives in living systems and diffuse more easily through cell membranes.[3] Nonionic DNA analogues are thus excellent candidates for the study of DNA–DNA and DNA–protein interactions, as well as for application as antisense oligonucleotides. Among the nonionic oligonucleotides analogous to phosphate oligomers are the phosphotriesters, phosphoramidates, and alkylphosphonates. The alkylphosphonates are characterized by particularly high stability towards nucleases and therefore the oligonucleoside methylphosphonates belong to the most extensively studied compounds for the antisense approach.[4] Difluoromethyl- and phenylphosphonates have also been synthesized and are currently under investigation.[5, 6] The influence of the methyl group of the methylphosphonate on helix formation has not yet been elucidated in detail. We therefore reasoned that it would be interesting to incorporate sterically bulkier organic groups as modification at the phosphorus atom to study their effect on stereoselection and thus to influence the configuration and the molecular geometry by design. We report here a simple experimental access to predominantly *Sp*-configurated alkyl- and benzylphosphonates, based on the reaction of organozinc halides with PCl_3.

The reaction of the Grignard reagent **1** with $ZnCl_2$ gives the organozinc halides **2**, which react further with PCl_3 to yield the desired alkyl- or benzyldichlorophosphanes **3** (Scheme 1).

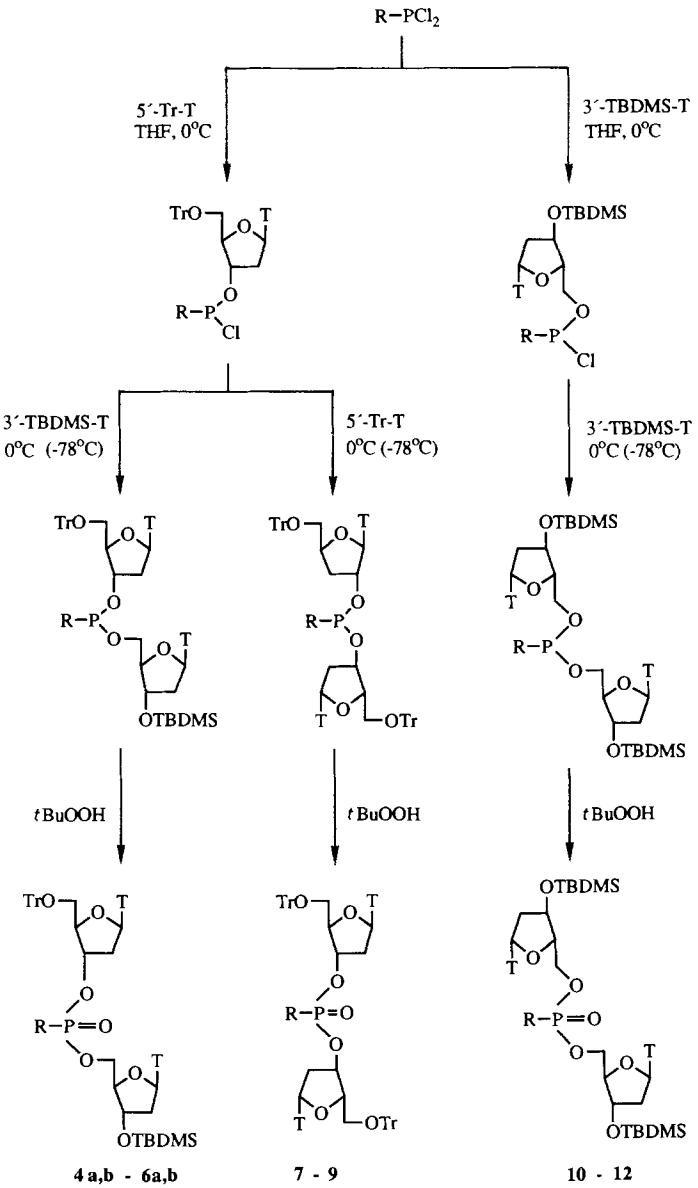


Scheme 1. Synthesis of the phosphonylation reagents. R = *i*Pr, benzyl, (*S*)-(+)-2-methylbutyl.

In a one-pot reaction, the phosphonylation reagent **3** is treated successively with two protected nucleosides. The resulting phosphonous acid diester is oxidized without prior isolation to its alkyl- or benzylphosphonate (**4**–**12**) by addition of *tert*-butylhydroperoxide (Scheme 2).

The symmetric reference compounds, 3′-3′- and 5′-5′-linked phosphonates **7**–**9** and **10**–**12**, respectively, are accessible by treating two equivalents of each of 5′-*O*-tritylthymidine and 3′-*O*-(*tert*-butyldimethylsilyl)thymidine with the phosphonylation reagent. Reaction of 5′-*O*-tritylthymidine and 3′-*O*-(*tert*-butyldimethylsilyl)thymidine with $RPCl_2$ yields **4**–**6**, which contain the 3′,5′-linkage. The 3′,3′-phosphonates **7**–**9** are always formed as side products, but the formation of **10**–**12** (on reaction of 3′-*O*-(*tert*-butyldimethylsilyl)thymidine with unchanged $RPCl_2$) can easily be suppressed by a small excess (0.06 equiv) of 5′-*O*-tritylthymidine.

The introduction of this modification generates a chiral center at the phosphorus atom. The compounds **4**–**6** form two diastereomers (**a**, **b**) that can be separated by preparative reverse-phase HPLC. As also observed for the methylphosphonates, the *Rp*-configurated isomer has the shorter retention time. According to the latest findings an unambiguous assignment by ^{31}P NMR spectroscopy is not possible.[10] The configuration of the diastereomers **4** was determined with the ROESY NMR technique.[7] To do so, the ROEs between the benzylic methylene protons and the sugar protons in the immediate vicinity must be measured. Interestingly, according to our current assignment a selection in favor of the *Sp* isomer is observed, whereas in the synthesis of the



Scheme 2. Synthesis of the 3′,5′- (**4**–**6**), 3′,3′- (**7**–**9**), and 5′,5′-linked (**10**–**12**) alkyl- and benzyl phosphonates. **4**, **7**, **10**: R = *i*Pr; **5**, **8**, **11**: R = benzyl; **6**, **9**, **12**: R = (*S*)-(+)-methylbutyl. The compounds **4**–**6** occur as diastereomers. These *Rp*/*Sp* isomers are labeled **a** or **b**.

methylphosphonates the *Rp* isomer is always formed preferentially (Table 1).

The configuration at the phosphorus atom has a drastic influence on the stability of duplexes of modified oligonucleotides and complementary sequences. Oligonucleoside–methylphosphonates with predominantly *Rp*-configurated diastereomers afford more stable hybrids with complementary DNA than the naturally occurring analogues, while duplexes with predominantly *Sp*-configurated isomers are less

Table 1. Dependence of the diastereoselectivities on the substituents at the phosphorus atom at different temperatures.

P substituent	*T* [°C]	*Rp*/*Sp*	P substituent	*T* [°C]	*Rp*/*Sp*
methyl	+4	2.0:1.0	isopropyl	+4	1.0:2.8
methyl	−78	5.0:1.0	isopropyl	−78	1.0:3.9
benzyl	+4	1.0:1.6	(*S*)-(+)-2-methylbutyl	+4	1.0:2.2
benzyl	−78	1.0:2.7	(*S*)-(+)-2-methylbutyl	−78	1.0:2.8

stable.[9] The reason for this behavior is not clear. We hope to throw more light on the subject by building the new nucleosidephosphonates into oligonucleotides and studying their behavior toward duplex formation. As UV and CD measurements on many diastereomerically pure methylphosphonate dimers show, the bases of the *Rp* dimer occur in the stacked form, whereas the extended form prevails for the *Sp* isomer.[10] In the *Sp* configuration of the phosphodiester linkage, the substituent at the P atom is in a pseudoaxial position and thus in the vicinity of the nucleoside bases. Since this is the clearly preferred isomer in the synthesis presented here, the possibility exists that the structure of the molecule can be intentionally changed by a suitable choice of substituents. Now, further influence of either a steric, electronic, or covalent nature opens a new field for molecular modeling at DNA molecules.

The preferential formation of one isomer is in accord with our concept of the reaction mechanism. The diastereomeric selection takes place at the reaction of the monoester with the second nucleoside; we assume that it is a $S_N2(P)$ mechanism. The two approaches from which the attack can be initiated are blocked to different extents by the trityl protecting group on one side and the substituent at the phosphorus on the other. One approach is thereby energetically favored.[11] If the substituent at the phosphorus atom is small, the attack is predominantly from this side and affords the *Rp* configurated product. However, if the substituent at the P atom is bulky, the attack from the side of the trityl group is more favorable, and the *Sp* isomer forms preferentially. In this case the yield decreases, since the space around the phosphorus atom in the monoester is already severely congested. Even the use of a chiral substituent, here (*S*)-(+)-2-methylbutyl, does not lead to a further increase in the diastereomeric ratio. Phosphorusamidites are also easily accessible as building blocks for solid-state synthesis via the monoester step; however, no statement about stereoselectivities and yields is yet possible.

Experimental Procedure

3: A solution of $ZnCl_2$ (0.1 mol) in ether was added dropwise under argon at 0 °C to the Grignard compound **1** (0.1 mol) dissolved in ether (300 mL). A gray precipitate formed. The suspension was stirred for 15 min before it was transferred to an addition funnel and added dropwise to a boiling solution of PCl_3 (0.3 mol) and ether (50 mL). The mixture was stirred for a further 1 h under reflux, cooled to room temperature, and filtered by suction, and the residue washed with ether. The filtrate was evaporated to dryness, and the recovered solid fractionated in a stream of argon. ^{31}P NMR (121.5 MHz, $CDCl_3$, 295 K, 85% H_3PO_4 external): benzyldichlorophosphane: $\delta = 179.3$; dichloroisopropylphosphane: $\delta = 199.8$; dichloro-(*S*)-(+)-2-methylbutylphosphane: $\delta = 198.1$.

4–**6**: 5′-Tritylthymidine (0.76 mmol) and 3′-(*tert*-butyldimethylsilyl)thymidine (0.725 mmol) were coevaporated with THF into separate tapered flasks. THF (2 mL), collidine (1.5 mmol), and phosphonylation reagent **3** (0.745 mmol) were placed in a flask that had previously been degassed by heating, flushed with argon, and sealed with a septum. The solution was cooled to 4 °C before the nucleoside, protected at the 5′-position and dissolved in 3 mL of THF, was added within 5 min with stirring from a Hamilton syringe. A white precipitate formed. After 10 min the 3′-protected nucleoside dissolved in THF was added at 4 °C or −78 °C within 5 min, and the mixture was stirred for a further 30 min. Either at 4 °C or after thawing to −20 °C, the product was oxidized with *tert*-butylhydroperoxide within 10 min. The suspension was evaporated to dryness, and the residue taken up in $CHCl_3$ (150 mL). The mixture was washed with 5% $NaHCO_3$ solution, 5% Na_2SO_4 solution, and H_2O, then dried over Na_2SO_4, and filtered. The solvent removed in a rotary evaporator, and the residue was dissolved in a little $CHCl_3$. The product was precipitated with *n*-hexane, filtered by suction, washed, and dried on a vacuum line (oil pump). Yield based on unchanged TrT: **4a,b**: 47% (4 °C), 38% (−78 °C); **5,b**: 56% (4 °C), 28% (−78 °C); **6a,b**: 31% (4 °C), 11% (−78 °C). Preparative HPLC separation of the diastereomers: **4a,b**: Lichrospher RP-C18 Semiprep. 5 μm; 3 mL min^{-1} triethylammonium acetate (TEAA) 0.1 M/CH_3CN 28/72 isochratic. **5a,b**: Bondapack C18 prep. 10 μm; 15 mL min^{-1} TEAA 0.1 M/CH_3CN 51/49 isochratic. **6a,b**: Bondapack C18 prep. 10 μm; 15 mL min^{-1} TEAA 0.1 M CH_3CN 47/53 isochratic. ^{31}P NMR (121.5 MHz, $CDCl_3$, 295 K, 85% H_3PO_4 external): **4**: $\delta = 29.1$ (*Rp*), 28.1 (*Sp*); **5**: $\delta = 37.9$ (*Rp*), 37.1 (*Sp*); **6**: $\delta = 34.9$ (*Rp*), 34.0 (*Sp*).

Fullerene Sugars: Preparation of Enantiomerically Pure, Spiro-Linked *C*-Glycosides of C_{60}**

By *Andrea Vasella,* Peter Uhlmann, Christian A. A. Waldraff, François Diederich,** and *Carlo Thilgen*

Whereas the initial fullerene research primarily focused on the physical properties of the pure carbon spheres, synthetic chemists lately have become interested in their functionalization, especially that of C_{60}. Examples for reactions with fullerenes are the hydrogenation,[1] halogenation,[2] epoxidation,[3] the formation of exohedral transition metal complexes,[4] cycloadditions and carbene additions,[5] as well as alkylations and arylations.[6] In agreement with the expectations for molecules with multiple reactive sites, many of these derivatizations yielded nonseparable mixtures of constitutional isomers and polyfunctionalized compounds. In some cases, selective conversions were achieved,[2–5] leading to well defined and pure compounds.

In this paper we describe the preparation and complete characterization of the fullerene sugars **4** and **5**, which were obtained in good yields from the reaction of C_{60} with nucleophilic glycosylidene carbenes. These spiro-linked C-glycoside-like compounds are of interest because they are the first chiral *and* enantiomerically pure derivatives of fuller-

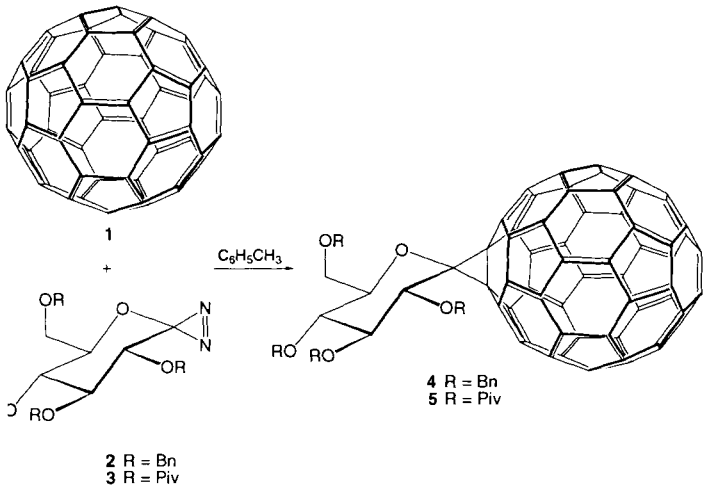
[**] Glycosylidene Carbenes, Part 9. We thank D. Nanz, T. Plüss, and O. Zerbe for recording the NMR spectra and V. Purghart, Spectronex AG, for recording the mass spectra. Part 8: A. Linden, A. Vasella, C. Witzig, *Helv. Chim. Acta*, in press.

enes. In addition, deprotection of the sugar residues should generate ambiphilic buckyballs and therefore provide an entry into investigations of the biochemical and pharmacological potential of this fascinating class of compounds.

As precursors of nucleophilic or ambiphilic carbenes, alkyl- and acyl-protected 1-azi derivatives of monosaccharides react with acceptor- and donor-substituted alkenes to yield spiro-linked glycosylidene cyclopropanes.[7-9] In a similar way, the *O*-benzyl protected diazirine **2**[10] reacted with C_{60} (**1**) to afford the monoglycosylated adduct **4** in 55% yield (74% based on reacted **1**) (Scheme 1). Evidence for double or even multiple carbene additions as the main side-reactions was obtained by ^{1}H NMR spectroscopy. The significant difference in the R_f values of **1** and **4** (ΔR_f (toluene): 0.38, SiO_2) facilitated the chromatographic purification of **4** and the almost complete recovery of unreacted **1**. In analogy, the *O*-pivaloylated diazirine **3**[9] afforded the addition product **5** (ΔR_f (toluene): 0.67) in 54% yield (76% based on reacted **1**).



Scheme 1. Synthesis of the fullerene sugars **4** and **5**. Bn = benzyl, Piv = pivaloyl.

The formation of **4** and **5** through monoaddition is confirmed by elemental analyses and NMR data. The ^{1}H NMR spectrum of **4** shows chemical shifts and coupling patterns typical of *O*-benzyl protected derivatives of glucose in the $^4C_1$ conformation. Compared to known *O*-benzyl protected glycosylidene cyclopropane derivatives,[7] the ^{1}H NMR resonances of the new compound (**4**) are shifted downfield; the signal for the proton on C2 is shifted the most ($\Delta\delta = 1$). The signals of the glycosylidene moiety of **5** are also shifted significantly downfield in comparison to the related known cyclopropanes;[9] the signal for the proton on C2 is particularly affected ($\delta = 6.77$). The coupling constant $^{2,3}J$ (3.9 Hz) in **5** indicates a remarkable deformation of the chair conformation, probably as a result of steric interactions between the C_{60} moiety and the pivaloyloxy group at C2.

In the ^{13}C NMR spectra of **4** and **5** (Fig. 1), the resonances of the carbon atoms C2 to C6 appear in the typical chemical shift region $\delta = 68-86$ and $\delta = 62-75$, respectively. Evidence for a cyclopropane structure is obtained by comparison of the NMR data with that of known glycosylidene cyclopropane derivatives.[7,9] In particular, the peaks at $\delta = 74.04$ and 72.81, respectively, (probably C1) as well as the two peaks of identical, but lower intensity at 78.24 and

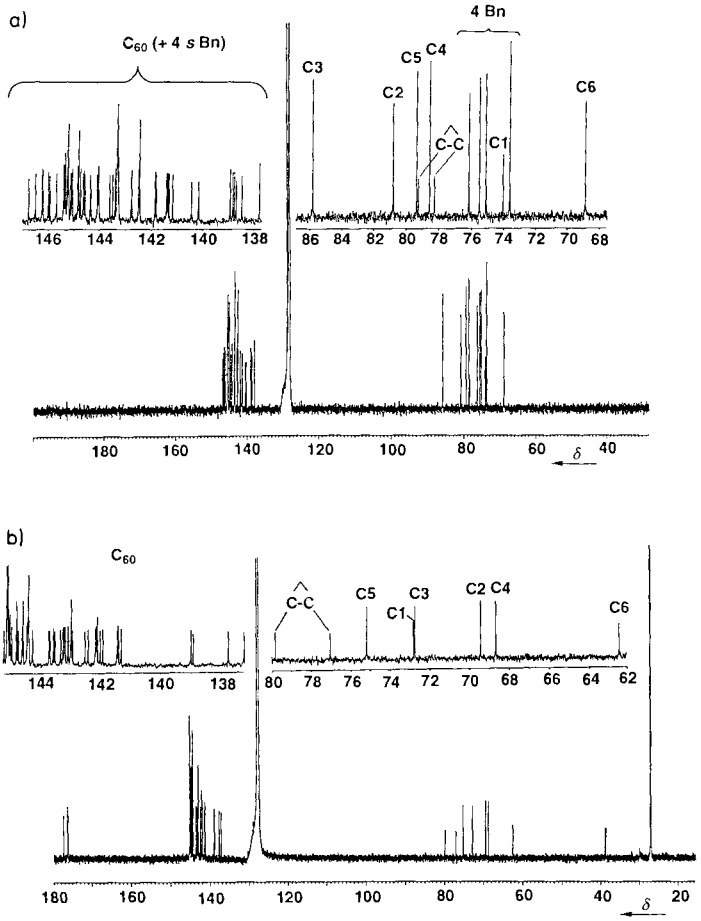


Fig. 1. ^{13}C NMR spectra (150.7 MHz, C_6D_6) of **4** (a) and **5** (b).

79.29 (**4**) and 77.05 and 79.84 (**5**) are characteristic of a three-membered ring structure. In the region $\delta = 137-147$, 48 and 44 singlets (partially overlapping) for **4** and **5**, respectively, are observed, arising from the C_{60} moieties.

Besides the characteristic bands of the glycosylidene residue, the IR spectra of **4** and **5** exhibit four (1426, 1186,

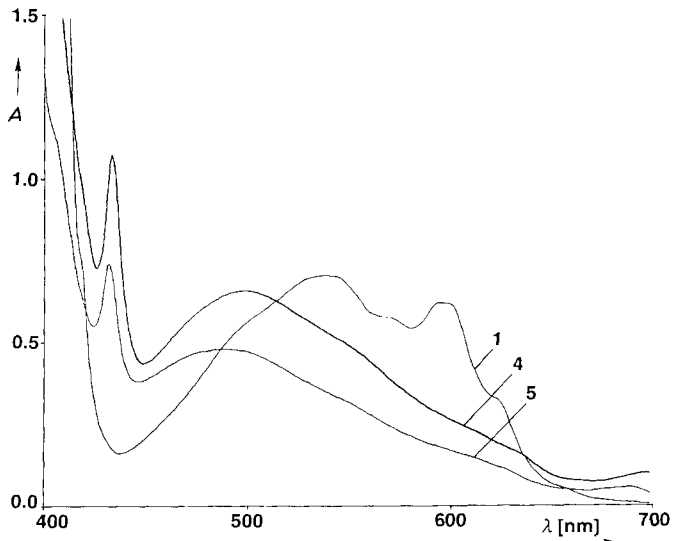

Fig. 2. UV/VIS spectra (toluene) of **1**, **4**, and **5**.

574, 526 cm^{-1}) and three (1428, 574, 527 cm^{-1}) bands, respectively, of the fullerene moiety. The UV/VIS spectra of **4** and **5** (Fig. 2) are nearly identical, and absorption maxima are located at 499 ($\varepsilon = 2660$) and 489 nm ($\varepsilon = 1802$), respectively, and at 433 ($\varepsilon = 1629$) and 432 nm ($\varepsilon = 1163$). Both spectra show the same loss of the C_{60} absorption fine structure between 500 and 650 nm, and the absorption maxima resemble those of the buckminsterfullerene oxide, $C_{60}O$.[3b]

Interestingly, the CD spectra of **4** and **5** (Fig. 3) exhibit several maxima and differ significantly from each other. It is not clear yet whether the differences originate directly from the protecting groups or indirectly from a conformational change of the fullerene framework. The interpretation of the

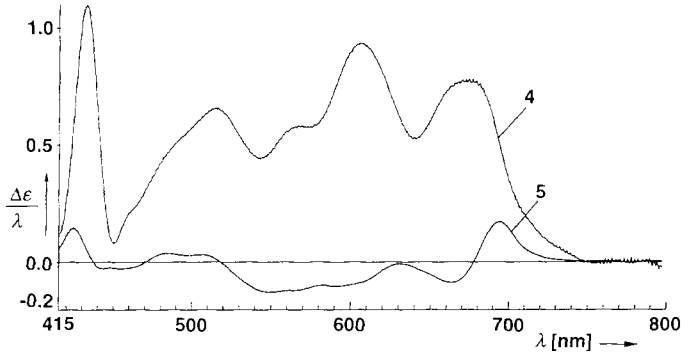

Fig. 3. CD spectra [$\Delta\varepsilon/\lambda$] of **4** (toluene, $c = 0.402$ mM) and **5** (toluene, $c = 1.19$ mM).

CD spectra, the proof for the regioselectivity of the addition, the nature of the cyclopropane unit, and the deprotection of the sugar moieties are currently subjects of further investigations.

Experimental Procedure:

4: A solution of 35 mg (0.049 mmol) of **1** in 35 mL of toluene was treated with 26.7 mg (0.049 mmol) of **2** under argon at 23 °C. The solution was stirred for 3 h, and a color change from violet to wine red was observed. The solvent was removed under vacuum, and the brownish residue was purified by flash chromatography (SiO_2, toluene) to yield 33 mg (55%) of **4** in addition to 9 mg (26%) of unreacted **1**. The product can be precipitated as a brown powder from a toluene solution by addition of methanol. R_f (SiO_2, toluene): 0.43; UV/VIS (toluene): λ_{max} [nm] (ε) = 433 (2660), 499 (1629); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3060w, 3027w, 2920w, 2855w, 1604w, 1536w, 1495m, 1452m, 1426m (C_{60}), 1402w, 1359m, 1319w, 1249w, 1208m, 1186w (C_{60}), 1155m, 1089s, 1073s, 1028m, 1002m, 907w, 840w, 799w, 732s, 695s, 645w, 594w, 574w (C_{60}), 562w, 550w, 526s (C_{60}), 479w, 462w; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta \approx 7.35-7.06$ (m; 20 arom. Configuratively Stable Dipeptide Aldehydes from D-Glucosamine Hydrochloride**

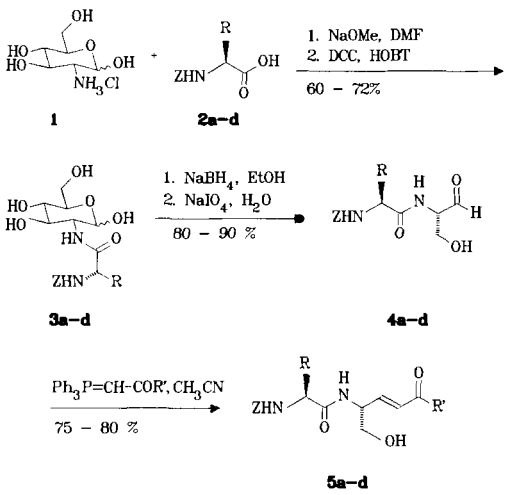
By *Thomas Kolter, Annegret Klein,* and *Athanassios Giannis**

Chiral N-protected α-amino aldehydes play an increasingly important role in preparative organic chemistry;[1] however, they are not completely attractive synthetic building blocks because of their chemical and configurative instability.[1] To solve this problem, suitable protecting groups for the amino function have been developed to prevent the racemization of the amino aldehydes during their synthesis, storage, and in subsequent reactions. Rapoport et al.[2] adopted the phenylfluorenyl group, while Reetz et al.[3] studied the *N,N*-dibenzyl function, which in addition leads to notable diastereoselectivity in the addition of organometallic reagents to the protected aminoaldehydes.[3]

With D-glucosamine hydrochloride (**1**)[4] as a chirality-transfer agent, we found an efficient route to *N*-Boc-L-serinal (Boc = *tert*-butoxycarbonyl), a chemically and configuratively stable α-amino aldehyde which can be treated with stabilized phosphorus ylides to provide the corresponding allyl amino alcohols without racemization.[5] This induced us to replace the Boc protecting group with *N*-benzyloxycarbonyl-protected chiral amino acids[6] and thus considerably broaden the synthetic potential of the N-protected serinaldehydes.

Amino aldehydes **4**, with an *N*-benzyloxycarbonylamino acid residue, are available in two steps from D-glucosamine hydrochloride in gram amounts (Scheme 1). These are crystalline substances that can be stored at room temperature and are chemically and configuratively stable. We attribute the unusual stability of these compounds to their oligomeric structure;[7] because of the formation of an intramolecular hemiaminal and an intermolecular hemiacetal, the α H atom has considerably reduced acidity. Thus, in the complex ^{1}H NMR spectra of compounds **4** only a weak (<0.1 H) signal is seen in the range of aldehyde protons. The configuration of the chiral center, the α C atom, was retained under the conditions of the Wittig reaction with stabilized phosphorus ylides. The amino aldehydes **4** were treated with a twofold excess of the phosphorus ylide in refluxing acetonitrile. The resulting Wittig products **5** with *E*-configured double bonds were isolated in 75–80% yield and provided simple ^{1}H NMR spectra.



Scheme 1. Synthesis of the configuratively stable dipeptide aldehydes **4a–d** and peptide Michael acceptors **5** from D-glucosamine hydrochloride **1** and protected amino acids **2a–d**. Z = CO_2CH_2Ph, DCC = dicyclohexylcarbodiimide, HOBT = *N*-hydroxybenzotriazole, DMF = *N,N*-dimethylformamide. **a**: R = *i*Pr, **b**: R = CH_2*i*Pr, **c**: R = CH_2Ph, **d**: R = Me, **5a**: R = *i*Pr, R' = O*t*Bu, **b**: R = CH_2*i*Pr, R' = O*t*Bu, **c**: R = CH_2Ph, R' = O*t*Bu, **d**: R = *i*Pr, R' = Me.

Because these α-amino aldehydes with the *N*-benzyloxycarbonyl-protected amino acid residue can also be considered as dipeptide aldehydes with defined stereochemistry, the method described here provides a new route to peptide aldehydes. The first isolation of naturally occurring peptide aldehydes was conducted by Umezawa, and they are of great pharmacological interest as protease inhibitors.[8]

Compounds related to the peptide Michael acceptor **5** have been described as novel irreversible inhibitors of thiol-proteases.[9]

Experimental Procedure

All new compound were characterized by ^{1}H NMR spectroscopy, (high-resolution) mass spectrometry, and elemental analysis. Representative procedures are given.

3a: A solution of **1** (4.32 g, 20 mmol) in DMF (80–100 mL) cooled to 0 °C was treated with sodium methoxide (1.08 g, 20 mmol). The mixture was stirred for 10 min at 0 °C, then **2a** (5.02 g, 20 mmol), hydroxybenzotriazole (5.40 g, 40 mmol), and finally dicyclohexylcarbodiimide (4.54 g, 22 mmoL) were added. After the reaction mixture had been stirred for 1 h, the cooling bath was removed and the mixture stirred another 24 h at room temperature. The precipitate was then removed by filtration, the filtrate treated with diethyl ether (800 mL), and the resulting mixture stored in a refrigerator. The crystalline product that formed was filtered off, and a further crop could be obtained when the filtrate was diluted with diethyl ether. The crude product was recrystallized from ethanol. Yield: 5.90 g (71.5%) **3a**.

M.p. 215 °C (decomp). R_f (dichloromethane: methanol = 4:1) = 0.74. Anomeric ratio $\alpha:\beta = 1:4$. ^{1}H NMR (200 MHz, [D$_6$]DMSO): δ = 0.82 (d, J = 6.5 Hz, 3H), 0.87 (d, J = 6.5 Hz, 3H), 1.93 (m, 1H), 3.00–3.70 (m, 7H), 3.85–4.02 (m, 1H), 4.38–5.10 (m, 6H), 6.48 (d, J = 4.7 Hz, 0.2H), 6.55 (d, J = 6.0 Hz, 0.8H), 7.08 (d, J = 9 Hz, 0.2H), 7.17 (d, J = 9 Hz, 0.8H), 7.24–7.40 (m, 5H), 7.65 (d, J = 7.8 Hz, 0.8H), 7.83 (d, J = 7.8 Hz, 0.2H). Correct C,H,N analysis for **3a**. 0.5 H_2O.

4a: Glucosamine derivative **3a** (4.12 g, 10 mmol) was dissolved in ethanol (250 mL) and treated with sodium borohydride (0.57 g, 15 mmol). After the reaction was complete (monitored by TLC), the reaction mixture was filtered through celite and the volatiles were removed by distillation. The residue was taken up in water (250 mL), neutralized with 2N sulfuric acid, and the resulting solution of the polyol with treated with a solution of sodium periodate (6.42 g in 100 mL water, 30 mmol). When starting material could no longer be detected by TLC (dichloromethane: methanol = 4:1), the reaction mixture was extracted with dichloromethane (4 × 100 mL). The collected organic layers were dried over magnesium sulfate and the solvent removed under reduced pressure. The aldehyde was obtained as a white solid. Yield: 2.7 g (8.37 mmol, 83.7%) **4a**.

M.p. 150 °C. $[\alpha]_D$ +16.8(c = 1.1, DMSO). R_F (CH_2Cl_2/MeOH = 10:1) = 0.44, 0.53. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.82–1.08 (m, 6H), 1.95–2.20 (m, 1H), 3.35–4.40 (m, 4H), 4.55–5.95 (m, 4H), 6.90–8.00 (m, 6.9H), 9.55–9.65 (m, 0.1H). Correct C,H,N analysis for **4a** · H_2O. MS (70 eV): $C_{16}H_{22}N_2O_5$ (M^+) calcd.: m/z 322.1529, found: m/z 322.1528: IR: $\tilde{\nu}$ [cm^{-1}] = 3400 (s, shoulder), 3300(s), 3.080(w), 3060(w), 3020(w), 2950(s), 2920(m), 2860(w), 1700(s), 1650(s), 1520(s), 1250(s), 1090(s), 1030(s), 750(m), 700(s).

5a: Aldehyde **4a** (1 equiv) was dissolved in acetonitrile (3 mmol in 50 mL), and after the addition of *tert*-butoxycarbonylmethylenetriphenylphosphorane (2 equiv) the mixture was heated at reflux for 4 h. The reaction mixture was then neutralized with the calculated amount of acetic acid, the solvent removed by distillation, and the remaining oily residue chromatographed on silica gel eluting with hexane:acetone (2:1). Compound **5a** was obtained as a white solid. Preparation: 1.0 g (3.1 mmol) **4a**, yield: 1.0 g (2.38 mmol, 76.8%) **5a**.

M.p. 120–122 °C. $[\alpha]_D$ −16.4 (c = 0.5, $CHCl_3$), R_F (hexane:acetone = 2:1) = 0.32.

^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.93 (d, 6.8 Hz, 3H; CH_3), 0.97 (d, 6.8 Hz, 3H; CH_3), 1.45 (s, 9H; $(CH_3)_3$), 2.09 (m, 1H; 3'-CH), 2.99 (t, 6.0 Hz, 1H; OH), 3.63 (m, 1H; 5-H_A), 3.71 (m, 1H; 5-H_B), 4.01 (dd, 8.4 Hz, 6.6 Hz, 1H; 2'-H),

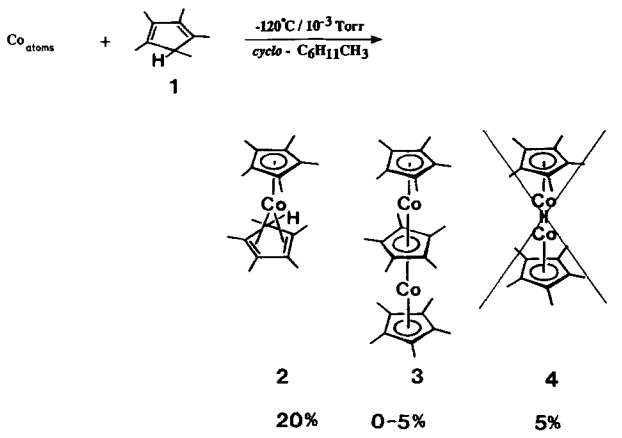
CORRIGENDUM

On the Reaction of Pentamethylcyclopentadiene with Cobalt Atoms: A Reexamination**

By *Jörg J. Schneider**

Over a year ago we reported in this journal the reaction of pentamethylcyclopentadiene Cp*H (**1**) with cobalt atoms.[1] We described the formation of the mononuclear η^4-η^5-sandwich complex **2**, as well as the two Co_2 compounds **3** and "[Cp*Co=CoCp*]" (**4**).[1] Theoretical studies by Abrahamson et al.[2] and preparative work by Theopold et al.[3] prompted us to investigate the title reaction anew. Our former interpretation of the identity of **4** is corrected here.

We succeeded in separating **2** from the multinuclear reaction products **3** and **4** by chromatography and could isolate them as crystals from the eluate by repeated crystallization.[1] A reexamination by mass spectrometry (15 eV, high resolution) of single crystals of **4** yielded a base peak at *m/z* 391.12427 (calculated for $[Cp^*_2Co_2H_3]$ **5**: 391.12461). The ^{1}H NMR study of solutions of these single crystals shows a signal at $\delta_{para} = 29$ (CH_3 on Cp*). More recent MS and ^{1}H NMR investigations of crystals from the mother liquor of **3** and **4** gave a base signal of *m/z* 586 (10 eV, calculated for $[Cp^*_3Co_3H_4]$ **6**: 586.52) and a ^{1}H NMR signal at $\delta_{para} = 61$ (CH_3 on Cp*). This signal had been incorrectly assigned to **6** previously.[1] Because of the almost identical composition, the elemental analyses in general could not distinguish between **4** (now **5**) and **6**. Our initial MS studies of the crude



materials (standard conditions, 70 eV) also gave no evidence of the presence of different compounds with *m/z* 391 and 586.[1]

In conclusion, $[Cp^*_2Co_2]$ (**4**) remains unknown. The compound we described as $[Cp^*_2Co_2]$ is, in fact, $[Cp^*_2Co_2H_3]$ (**5**). $[Cp^*_3Co_3H_4]$ (**6**) is the major component in the eluate of the chromatography after separation of **2** (yield of **6**: 10%), but we formerly did not recognize this.[4]

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Modern Synthetic Methods 1992. Vol. 6. Edited by *R. Scheffold*. Verlag Helvetica Chimica Acta, Basel/VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. 489 pp., hardcover DM 108.00.—ISBN 3-906390-00-4/3-527-28489-3/1-56081-255-9

The 6th International Symposium on Modern Synthetic Methods was held on the 4th and 5th of May 1992 in Interlaken. The proceedings volume of this latest in a well-established series of symposia contains reviews on the following topics: "Regio- and Stereoselective Formation of Enolates and the Consequences of Enolate Configuration and Subsequent Reactions", by C. H. Heathcock; "Acetylenes in Synthesis", by E. Winterfeldt; "Superbases as Powerful Tools in Organic Synthesis", by M. Schlosser; "Enantiopure Building Blocks from Sugars and their Utilization in Natural Product Synthesis", by F. W. Lichtenthaler; "Carbohydrate Synthesis via Thiazoles", by A. Dondoni; and "Protective Group Strategies in the Synthesis of Functionalized Carbohydrates", by C. A. A. van Boeckel.

All the contributions reflect the latest state of knowledge, with detailed literature references extending up to 1991. The convenient arrangement of subject matter and the clear schemes make for easy reading. It is pleasing to note that, as a general rule, a reaction arrow represents only a single transformation. All the articles except the one on alkynes contain many examples of laboratory recipes, which enable one to work through the syntheses. Unlike previous volumes there is, for the first time, a subject index, which is a valuable aid when using the book.

C. H. Heathcock gives a lucid overview of the chemistry of enolates, from its beginnings up to the present state of knowledge. Reactions leading to regio- and stereoselective formation of enolates are discussed in detail. The author then describes the influence of the configuration of enolates on the stereochemistry of subsequent reactions, especially aldol additions.

E. Winterfeldt reports on the latest developments in the use of alkynes in synthesis. These include thermal and organometallic reactions of alkynes, such as $[2\pi + 2\pi]$-cycloadditions, 1,3-dipolar additions, Diels–Alder, en, and pericyclic reactions, free radical and carbene reactions, and reactions of organometallic compounds. Some applications of ionic reactions of alkynes are also described.

M. Schlosser deals with the preparation and synthetic applications of superbases. Methods for forming metal–carbon bonds and for activating metal compounds by forming superbases are described, as well as the use of superbases in achieving metalation at aliphatic, olefinic, and heterocyclic positions. The review is completed by examples of arene metalations influenced by neighboring groups, and of regio- and stereocontrolled reactions of allylic carbanions prepared from superbases.

The use of cheap carbohydrates as precursors for the preparation of enantiomerically pure synthetic building blocks, and their applications in natural products syntheses, are discussed by F. W. Lichtenthaler. The emphasis is on syntheses using simple, easily obtainable reagents and protecting groups, and on avoiding the need for laborious work-up procedures.

A. Dondoni devotes his contribution to the synthesis of carbohydrates by the addition of aldehydes to thiazole derivatives. By means of this versatile synthetic strategy one can, in a stepwise procedure, stereoselectively build up the carbon skeleton of a sugar around one, two, or three carbon atoms by combining a suitable 2-substituted thiazole derivative with an aldehyde.

C. A. A. van Boekel describes syntheses of biologically active oligosaccharides, in particular of heparin fragments. The regio- and stereoselective synthesis of these highly functionalized molecules is achieved by the clever use of appropriate protecting group techniques and glycosidation methods.

Each of these articles provides an excellent overview of the topic covered, and offers a rapid way into it for the newcomer. The book can therefore be recommended unreservedly for all synthetic chemists and also for advanced students, and it should be in every chemical library. The sturdy binding (an improvement on the previous paperback volumes) and the careful preparation of the volume, including the index, complete the favorable overall impression.

Fritz Theil

Design and Optimization in Organic Synthesis. (Series: Data Handling in Science and Technology, Vol. 8.) By *R. Carlson*. Elsevier, Amsterdam, 1991. XVI, 536 pp., hardcover HFl 330.00.—ISBN 0-444-89201-X

During the last few years many books on the design of experiments have been virtually thrown onto the market. It is all the more pleasing, therefore, that Rolf Carlson has allowed time for his contribution to the subject to mature, and has produced a book that is excellent from both the pedagogic and scientific standpoints. It is by no means merely "... yet another introductory text on statistics written by a non-statistician", as Carlson, who is himself an organic chemist at the University of Umea, the stronghold of chemometrics in Sweden, fears in his preface that it might be judged.

This book of around 500 pages includes a brief but comprehensive index, a detailed bibliography, references to suitable software, about 30 pages of tables, a few graphics, and a number of detailed examples. There are 19 chapters, six of which might be described as the essential core of the book: "Models as tools" (Ch. 3), "Two-level factorial designs" and "Two-level fractional factorial designs" (Chs. 5 and 6), "Response surface methods" (Ch. 12), "Principal properties" (Ch. 15), and "Quantitative relations between observed responses and experimental variations" (Ch. 17).

 © *VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992* *0570-0833/92/1010-1393 $ 3.50+.25/0*

In "Models as tools" the concept of a model is developed, and the types of models generally used for the design of experiments are described. The reader first encounters statistics towards the end of this chapter, in connection with the validation of models. The two chapters on factorial designs (together with Chs. 4, 7, and 8) contain a detailed treatment of factorial screening, and in particular they explain the connection between calculated primary effects and interaction effects and the response surface models that are treated in more detail in Chapter 12. This chapter also introduces quadratic models and uses this concept to describe the yields of various reactions. Chapter 15 is concerned with principal component analysis, and its application to selecting a few test systems from a very large number of possibilities (different catalysts, solvents, etc.). Chapter 17 then considers how one investigates the effects of the reaction conditions on the most important product characteristics (descriptors), and explains the PLS (partial least squares or projections to latent structures) method.

The rest of the chapters serve to put the statistical methods described into the context of organic chemistry. Thus, there are three chapters on strategies (Chs. 1, 13, and 16); these are concerned with general strategies for organic synthesis, strategies for optimizing reaction conditions, and strategies for selecting test systems. Unfortunately, however, there are also three short chapters on optimization methods, which interrupt the flow of the book to some extent, and do not have any direct applications (p. 242: "... applications in organic chemistry are, however, remarkably few"). Possibly these methods have been included in the book so that in later chapters they can serve as a sort of heuristic basis for the selection of suitable test systems, in connection with applications of principal component analysis.

To summarize, this book makes worthwhile reading for the organic chemist who would like to plan his or her work a little more systematically, or who simply wishes to find out what statistical methods applied to the design, interpretation, and optimization of experiments are all about.

Principles of Nuclear Magnetic Resonance Microscopy. By *P. T. Callaghan.* Clarendon Press, Oxford, 1991. XVII, 492 pp., hardcover £ 60.00.—ISBN 0-19-853944-4

This monograph is the first handbook devoted to NMR imaging at microscopic resolution. It covers recent technical developments as well as a broad range of applications to biological, mineral, and synthetic materials in a rapidly growing area of research. Examples range from small laboratory animals to eggs, from pathological tissue specimens to plants, and from sandstones to polymers.

NMR microscopy is defined as the acquisition of proton NMR images with volume elements smaller than $(0.1\ \mathrm{mm})^3$. While two-dimensional images often exhibit an in-plane linear resolution that is about one order of magnitude better than the chosen slice thickness, three-dimensional imaging aims at isotropic spatial resolution. Although the achievable resolution is much coarser than for optical and electron microscopy, significant advantages of the NMR approach are due to (i) the examination of the full three-dimensional structure of a sample without restriction to its surface, (ii) the non-destructive investigation of biological materials or even living systems, and (iii) the potential for dynamic studies of functional properties.

Although not specifically indicated, the book is structured into three main parts, complemented by a small section on hardware considerations. The first part of the monograph comprising Chapters 1–3 (170 pages) deals with imaging principles, basic NMR, and magnetic field gradients in NMR imaging, respectively, and thus covers the whole range of essentials for microscopic imaging by NMR. More difficult theoretical parts may be skipped by the neophyte, but will turn out to be useful for a rigorous treatment at later stages. In addition, principles such as the Fourier transformation and the convolution theorem are discussed with many illustrative examples and figures. The introduction to NMR is confined to some basic quantum mechanics emphasizing the classical treatment (Bloch equations) of magnetizations subject to simple radiofrequency (r.f.) pulse sequences (excluding two-dimensional NMR spectroscopy). The use of magnetic field gradients for NMR imaging is discussed in great detail. Starting from spin density projections of a sample obtained by acquiring its NMR signal in the presence of a magnetic field gradient, the chapter describes slice-selective excitation, NMR image reconstruction, and actual r.f. pulse and gradient sequences popular in medical NMR imaging.

The second part formed by Chapters 4 and 5 (150 pages) focusses on the principles and applications of NMR microscopy. Limitations of the spatial and temporal resolution are addressed that are due to the achievable signal-to-noise ratio (SNR), short NMR relaxation times, molecular self-diffusion and other motions (macroscopic movements, flow, intracellular streaming, fluid penetration of solid materials, swelling of polymers, etc.), and the presence of magnetic field inhomogeneities caused by susceptibility differences in the sample. An almost complete summary of applications is given that creates a realistic picture of the state of the art (1990), by presenting numerous examples from both the "liquid" phase and the solid state. Where appropriate, the applications are accompanied by further detailed descriptions of more complex NMR techniques. For example, microscopy studies of nuclei other than protons may require heteronuclear polarization transfer to improve the SNR, while NMR imaging of solid specimens may be performed in conjunction with spectral line-narrowing by multi-pulse techniques and/or magic angle spinning synchronized to rotating magnetic field gradients.

The third part, Chapters 6–8 (120 pages), expands in considerable detail on the relevance of translational motions for NMR microscopy. Following largely theoretical discussions of various types of mobility and their effects on the NMR signal, more practical aspects are concerned with NMR imaging methods to visualize or even quantitatively determine properties such as anisotropic and/or restricted diffusion, or spatial distributions of flow velocities. The final chapter (20 pages) discusses the design of optimized gradient coils for generating strong, uniform, and time-varying magnetic field gradients as required in high-resolution NMR imaging.

A strength of this book is a detailed and comprehensive coverage of NMR imaging, including fundamental NMR techniques and mathematical treatments. This provides the necessary background information, particularly for those readers who are primarily concerned with microscopy as a problem-solving tool, but have little or no experience in NMR. However, my feeling is that many parts will be best appreciated by physicists, but not so easily followed by specialists from other areas of this multidisciplinary field. Microscopy studies are extensively discussed in a major part of the book and include many up-to-date examples. The tabu-

lated summaries provide an excellent overview and facilitate access to the original literature. While some of the examples may soon become outdated due to continuous and rapid progress, the adequate outline of the principles and problems will make this book a useful investment for those interested in the future potential of NMR microscopy.

The Chemistry of Amidines and Imidates. Vol. 2. (Series: The Chemistry of Functional Groups; series editor: *S. Patai*). Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester, 1991. XIV, 918 pp., hardcover £ 225.00.—ISBN 0-471-92457-1

This bulky second volume on amidines and imide esters, in Patai's well-known and comprehensive series, fulfills two functions. Firstly, nine of the sixteen chapters expand on topics treated in Volume 1 (1975) by including work published up to 1989, mostly with new authors. Secondly, the remaining seven chapters deal with new aspects of the title compounds that were not covered in Volume 1. Many of the chapters also report on the guanidines, which are closely related chemically, and also in some cases on (hetero)cyclic amidines and imidates. Eight of the chapters are concerned with physicochemical and spectroscopic properties, while the other eight deal with syntheses and mechanisms.

The first three chapters are concerned with the structures and dynamics of the title compounds. Chapter 1 (G. Häfelinger and F. K. H. Kuske) contains a clear and comprehensive presentation of general aspects and of theoretical results, mainly from ab initio calculations, which are then compared with the available experimental data. Chapter 2 seems somewhat anomalous. In it the authors (T. M. Krygowski and K. Woźniak) present results, in a condensed form, obtained by applying statistical methods to analyze more than 600 crystal structures. Only 22 literature references are given, mainly to the authors' own publications, and thus one is not given proper access to the original literature. Although Chapter 3, by C. L. Perrin, overlaps in places with Chapter 1, it is interesting since the emphasis is mainly on dynamic and stereoelectronic aspects.

Chapter 4 (I. Buśko-Oszczapowicz and J. Oszczapowicz) deals with chromatography and spectroscopy, and Chapter 5 (S. Fornarini) with mass spectrometry. Other chapters are devoted to thermochemistry (Ch. 6, K. Pihlaja), the acid-base and complexation chemistry of the title compounds (Ch. 12, J. Oszczapowicz), and to electronic effects (Ch. 13, J. Shorter).

The synthesis of amides, imidates, and guanidines, and their reactions are treated in Chapters 7 and 8 (G. V. Boyd), 9 (D. G. Nelson), 10 (Y. Yamamoto and S. Kojima), and 11 (I. Min-kin and I. E. Mikhailov). Here the great importance of these classes of compounds for the synthesis of a wide variety of heterocyclic ring systems of pharmaceutical significance becomes clearly evident. The book concludes with some more specialized chapters on radiation chemistry (Ch. 14, Z. B. Alfassi), catalytic properties (Ch. 15, P. Ahlberg and L. Swahn), and electrochemistry (Ch. 16, J. S. Jaworski and M. K. Kalinowski).

Comparing the coverage with my own collection of literature references shows that in general the authors have been thorough in their searches and careful in their selection. The fact that a number of East European authors have contributed shows that science too is deriving benefits from political changes, as also is the thorough coverage of publications from the East. This volume in the Patai series therefore succeeds well in the aim of providing a key to the original literature, although some of the chapters (e.g. Chs. 1, 3, 6, 12, 13) have more of a monograph character, and thus invite more careful study. This excellent work is indispensable for scientific libraries.

My 132 Semesters of Chemistry Studies. By *V. Prelog*. American Chemical Society, Washington, DC, 1991. XXIV, 120 pp., hardcover $ 24.95.—ISBN 0-8412-1772-6

In an article on the Czech chemist Emil Votoček (G. B. Kauffman and F. Jursík, *Chem. Br.* **1989**, *25*, 495), I mistakenly referred to Vlado Prelog as deceased. Our library provided me with the supposed date of his death, and in view of the lengthy duration of his career and the near-classic status of his contributions to chemistry (he is truly a legend in his own time), I neglected to verify the date. I am now delighted to report that this prolific and still active octagenarian has written his scientific memoirs as the shortest volume published to date (Prelog is succinct and modest about his achievements) in Jeffrey I. Seeman's projected series of 22 autobiographies of prominent organic chemists, *Profiles, Pathways, and Dreams*.[*] With characteristic, self-deprecating humor, he chose the title of his book to reflect his post-1976 "retirement" position of "postdoctoral student" at Zürich's Eidgenössische Technische Hochschule (ETH). The Latin subtitle, "Studium chymiae nec nisi cum morte finitur" (The study of chemistry is concluded only with death) underscores his lifelong commitment to chemistry. As a perfectionist, he was unwilling to draft his manuscript in English despite his superb fluency in this language. His German text was felicitously translated by his friend David Ginsburg, who died before completing the translation, which was finished by Otto Theodor Benfey.

Born on July 23, 1906 in Sarajevo, Yugoslavia, Prelog served as a "flower boy" on the occasion of the ill-fated visit (June 28, 1914) of Austrian Archduke Franz Ferdinand, whose assassination provided the spark that ignited World War I. Following his parents' separation in 1915, he lived with his aunt in Zagreb, Croatia, where he spent his first three years of high school (*Realgymnasium*) and at the age of 12 began his first experiments in his home chemistry laboratory. A 1918 portrait of this juvenile chemist (without goggles!) is one of the book's 34 formal and informal illustrations. His first article (*Chem.-Ztg.* **1921**, *45*, 736) was written when he was 15. After completing high school in Zagreb in 1924, he entered the Chemical Engineering School of Prague's Institute of Technology, from which he received his Ing.-Chem. (1928) and doctorate (1929). He remained in Prague carrying out research until 1935, when he became a poorly paid lecturer (docent) (1935–40), and subsequently Associate Professor (1940–41) at the University of Zagreb. With the help of Nobel laureates Richard Kuhn and Leopold Ružička, in 1941 he emigrated from German-occupied Zagreb to Zürich, where he has remained ever since at the ETH (*Privat-Dozent* 1942; Associate Professor 1947; Professor 1950–76).

[*] See also: H. Hopf, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1190.

These personal details notwithstanding, Prelog concentrates primarily on the chemical contributions of himself and his collaborators (some 400 papers with about 100 *Doktoranden*)—work on alkaloids and other natural products, heterocyclic compounds, dyes, medicinal products, adamantane, organ extracts, steroids, medium-sized rings, microbial metabolites, antibiotics, transannular reactions, asymmetric syntheses, stereoselectivity of microbial and enzymatic reactions, and the seminal Cahn–Ingold–Prelog (CIP) nomenclature system for stereoisomers. Nevertheless, in a book replete with numerous structural formulas, equations, and reaction schemes as well as almost 200 references, this charming and witty Nobel (1975) laureate does not neglect his travels, lectures, meetings, and interactions with dozens of internationally known scientists (the volume reads like a *Who's Who* of organic chemists). Despite his well-deserved reputation as a raconteur, it was only on Seeman's urging that Prelog related in an epilogue just seven of his innumerable anecdotes "because stories are mostly apocryphal, or at least, they tend to deviate from the truth, and I wished to avoid that." I highly recommend this inexpensive, fascinating, and informative book to practicing chemists and anyone interested in the history of chemistry and the conduct of research.

Dictionary of Plants Containing Secondary Metabolites. By *J. S. Glasby*. Taylor and Francis, London, 1991. 488 pp., hardcover £ 95.00.—ISBN 0-85066-423-3

Research into the immense potential of biologically active compounds found in the plant kingdom, where the number of species is estimated as between 250000 and 500000, is currently undergoing a remarkable renaissance. The practical aim underlying these efforts is to find new structural themes for developing biologically active compounds. During the course of evolution plants have developed many secondary metabolites with regulatory or protective functions, which are now becoming increasingly recognized, and these offer good opportunities for such developments. At the very beginning of the interdisciplinary chain of research that may lead to a biologically active structure, one needs to find out what, if any, phytochemical studies have already been carried out on the chosen plant species; getting this information demands a thorough search of the widely scattered literature.

This book by J. S. Glasby is intended as an aid to carrying out that task. In this comprehensive work nearly 8500 species of higher plants, as well as lichens and mosses, are listed alphabetically according to genus and species, together with the substances that they contain, arranged under compound classes. The accompanying literature citations extend up to the end of 1987. Linked to this main part of the dictionary is an index of compounds, containing an impressive total of nearly 18300 secondary metabolites. Altogether this is the fruit of a painstaking compilation; the amount of information is so great that this must surely be approaching the limit of what a single author can achieve, as one soon finds on starting to examine the book in more detail. Nevertheless, the book's weakness undoubtedly lies in its lack of completeness, a fact that is also referred to by the author himself in his short preface. Whereas some classes of compounds are very fully represented, one searches in vain for the steroid alkaloids havanin, aculeamin, or epikibatalin, the tropane alkaloids schizanthin A and B, and the lichen constituents rangiformic acid and ovoic acid with their botanical origins, to name just a few examples. Only three of the nine triterpenes found in two Araliaceae are listed, and of the 23 brassinosteroids discovered in plants up to 1987, one again finds only three. Also one cannot fail to notice that a good many printing errors have crept in, both in the plant names and the compound names.

Despite these reservations, this sturdily bound work of reference should prove useful, at least as a first source of information on the subject of secondary metabolites in plants. If the plant species or compound that one is looking for cannot be found in this book, there is no alternative but to carry out one's own literature search with the help of a data bank.

Solid State Chemistry—Compounds. Edited by *A. K. Cheetham* and *P. Day*. Oxford University Press, Oxford, 1992. XII, 304 pp., hardcover £ 40.00.—ISBN 0-19-855166-5

As a sequel to the book "Solid State Chemistry—Techniques" from the same editors in 1988, this second volume contains contributions by various authors dealing with classes of compounds that are important in modern solid state chemistry. The largest emphasis is on compounds with especially interesting electronic properties, such as superconductors (J. Etourneau, Bordeaux), low-dimensional solids (P. Day, London), and metal cluster compounds (A. Simon, Stuttgart). The second focus of interest is on materials that are important in relation to heterogeneous catalysis. This includes chapters on zeolites (J. M. Newsam, San Diego), layer structures (A. J. Jacobson, Houston), and an introduction to heterogeneous catalysis (A. W. Sleight, Oregon), although this chapter is very brief compared with the rest of the contributions. The book is completed by a short article on ferroic materials (C. N. R. Rao and K. J. Rao, Bangalore).

The introductory chapter (P. A. Cox, Oxford) is concerned with the electronic structures of solids. Unfortunately, this topic is only treated very superficially, the information given being hardly more than one finds in a general textbook. At this point an easily understandable introduction to the band theory (*k*-space, band structures, density of states, etc.) would certainly have been more appropriate, as a knowledge of that would be extremely useful in the chapters that follow (on compounds with one-dimensional physical behavior, and metal-rich compounds). The literature references for this first chapter, which in any case seem very incomplete, should at least have directed the reader to relevant review articles such as those by R. Hoffmann or J. K. Burdett.

The material in the subsequent chapters is arranged according to the chemical composition and structural characteristics of the various classes of compounds. The chapters on superconductors, metal clusters, layer-forming compounds, and zeolites succeed particularly well in elucidating the relationships between chemical composition, the structure of the solid, and the resulting physical and chemical properties. Furthermore, indications are often given of opportunities for interesting studies in the future. Thus, the book can certainly be recommended for the user groups en-

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/1010-1396 $ 3.50+.25/0

visaged by the editors, namely students about to take their final examinations and scientists engaged in solid state research.

An important foundation for any kind of experimental investigation on chemical compounds is the preparative chemistry involved. Unfortunately this important topic is given only a small amount of space in this book. A notable exception to this is the comprehensive and clearly written chapter on zeolites, which gives in about 50 pages a well-balanced overview of the compositions, structures, methods of preparation, properties, characterization, and applications of this important group of materials. In contrast most of the other chapters give no information on methods for synthesizing the compounds discussed. On the other hand, theoretical aspects occupy a considerable proportion of the book. For example, nearly a half of the chapter on superconductors is devoted to theoretical considerations that are normally covered in textbooks (BCS theory, thermodynamic aspects, etc.). However, the second part of this chapter contains details of known superconducting materials, arranged under compound classes. This clearly shows the great variety of chemical compositions and structures with superconducting properties. This is followed by a concise discussion of the structural and atomic characteristics that seem to be important in relation to superconductivity.

The very informative and concise chapter on metal clusters also succeeds well in explaining the structural and chemical conditions that lead to the occurrence of metal-rich compounds. Here too the book does not merely list compounds, but explains interrelationships and analogies. Considered as a whole this book offers the reader an interesting insight into the latest developments and knowledge in modern solid state chemistry. Although the selection of topics cannot be regarded as covering the whole of solid state chemistry, the particular aspects treated are of broad interest and considerable importance. The interested reader will therefore look forward eagerly to the follow-up volume mentioned by the editors in the preface, which will contain further articles on topics such as solid electrolytes, and materials with properties relevant to magnetic and optoelectronic applications.

Biotechnology. A Multi-Volume Comprehensive Treatise. Vol. 4. Measuring, Modelling and Control. 2nd edition. Edited by *K. Schügerl*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991. XIII, 658 pp., hardcover DM 490.00.—ISBN 3-527-28314-5/1-56081-154-4

This volume in the "Biotechnology" series is the first one to appear in the second edition of the series. The book is intended to be equally useful to university academics, scientists in research institutes, and practical users of biotechnology. It offers a valuable resource for the reader who wishes to become familiar with particular aspects of measurement and control in the field of biotechnology.

The volume is divided into four main areas: measuring instruments, measurement techniques, modeling, and control/automation, which are treated in 19 chapters altogether. Its attractive features include the clear division of the subject matter, with a list of contents and symbols for each chapter which makes the book especially easy to use, the uniformity of the typography, and the quality of the figures. Despite the fact that the introduction at the beginning is rather short, the book offers the reader far more than just a narrow view of each specialized area. For example, Chapter 13 on models for aerobic waste-water treatment processes begins with a brief discussion of the purpose and usefulness of models, which goes far beyond merely generating and manipulating large amounts of numerical data. Chapter 14, on anaerobic water treatment, is complementary to the previous chapter, and contains a good introduction to the thermodynamics and kinetics of the relevant processes. Altogether one is given a good coherent overview of the field. Exceptions such as the very brief and rather isolated Chapter 8, on sampling techniques, merely serve to emphasize the consistency of the rest.

The book's coverage is not limited to describing the current state of the art in the various topics: some of the chapters treat topics which, although not at present familiar to everyone, are certain to become more important in the future, such as assessing the conditions in bioreactors (Chapter 7). On the other hand, whether the use of expert systems (Chapter 19) will become established in practice remains to be seen.

Despite the fact that some chapters are of an advanced theoretical nature, examples of practical applications are also often mentioned; thus, an entire chapter (Chapter 12) is devoted to a case study on the optimization of yeast production. Chapter 2 links the theory and practice of gas analysis in fermentation processes in a highly instructive way. I agree with the comment, made by the volume editor in the preface, that the discussion of the control of downstream processing remains too brief in the present edition, due to the lack of information on this topic.

Although individuals may be somewhat deterred by the price of DM 490.00 for this single volume, no specialist library should be without the book, and everyone interested in the field is strongly recommended to make use of it.

Reaction Mechanisms of Inorganic and Organometallic Systems. By *R. B. Jordan*. Oxford University Press, Oxford, 1991. 292 pp., hardcover £ 30.00.—ISBN 0-19-506945-5

This book is the result of a one-semester course given to senior undergraduate and graduate students by the author over the past 20 years. It is a well-balanced presentation, which not only goes into the basic principles involved, but also gives a detailed account of mechanistic studies, dealing with inorganic, organometallic, and bioinorganic systems.

The first two chapters are devoted to the tools of the trade, rate law and mechanism, in which an appropriate account of the experimental and theoretical background for the study of reaction mechanisms is given. Chapter 3 is devoted to ligand substitution reactions in which typical tests for particular mechanisms are treated in much detail. The account includes a well-balanced presentation of the present understanding of such processes. Stereochemical changes in inorganic and organometallic compounds are treated in Chapter 4. Ligand substitution, insertion, and oxidative addition reactions of organometallic systems are treated in Chapter 5, along with a discussion on catalytic hydrogenation of alkanes and homogeneous catalysis by organometallic compounds. Chapter 6 is devoted to a treatment of oxidation–reduction reactions, in which inner-sphere and outer-sphere electron

transfer reactions, as well as intervalence and electron transfer in metallo-proteins, receive adequate attention. The topic of inorganic photochemistry is presented in Chapter 7. Most of the selected examples originate from classical coordination compounds (Co^{III}, Rh^{III}, Cr^{III}), but some information is also included on organometallic systems. Details on the intimate reaction mechanisms of excited state species are not given. In the final chapter the author discusses mechanistic studies on bioinorganic systems, and treats reactions of vitamin B_{12}, carbonic anhydrase, and enzymatic reactions of dioxygen. Following this chapter a series of problems taken from the literature are given, which enables the student to check his understanding of the material presented.

Throughout the book ample references to the most recent work (up to 1990) are included. The book is easy to read, it is technically well finished, and should be very popular among students interested in this area. It is highly suitable for the level it is aimed at, and it is obvious from the clear treatment that the author is an active researcher in this area.

Rudi van Eldik

Oligonucleotides and Analogues. A Practical Approach. (The Practical Approach Series.) Edited by *F. Eckstein*. Oxford University Press, Oxford, 1991. XIV, 313 pp., paperback £ 22.50.—ISBN 0-19-963279-0

Since the publication of the last book on this topic [*Oligonucleotide Synthesis. A Practical Approach*. (Ed.: M. Gait), **1984**], there have been further rapid developments in the synthesis of oligonucleotides and their analogues, and until now these have not been summarized in monograph form. Oligonucleotides are now attracting increased interest in the scientific world, owing to their potential as therapeutically active compounds (antisense oligonucleotides, ribozymes, aptamers) and their applications in DNA diagnostics, and methods for synthesizing them have therefore assumed a special importance. In this book the editor has very successfully remedied the gap that existed in the literature, and one can confidently predict that it will become a frequently cited standard work.

The book's twelve chapters provide the reader with a good knowledge of the theory and practice of methods for synthesizing the compounds named in the title, in the form of detailed laboratory recipes. Unmodified oligodesoxynucleotides can nowadays be synthesized without difficulty using commercially available DNA synthesizers, as described in the first chapter, but if even minor variations in the molecule are required one needs to adopt completely different strategies. These are dealt with in the subsequent chapters. The compounds whose syntheses are described include oligoribonucleotides, 2′-*O*-methylribooligonucleotides, and oligonucleotides with modified bases. As examples of analogues with modified phosphate backbones, the chapters deal with methylphosphonates, phosphorothioates, and phosphorodithioates. Another part of the book is concerned with the synthesis of oligonucleotide-conjugate molecules, e.g., conjugates with chemical nucleases and with non-radioactive labeling groups. Such groups may be introduced via the 5′ or 3′ terminal positions, via bases, or via the phosphate backbone. As well as recipes for synthesis and purification, methods are also given in some cases for applications, e.g., in the isolation of proteins by affinity-selection, in DNA sequencing, in DNA hybridization, and in antisense cell culture experiments.

It is, of course, inevitable that with such a many-faceted subject it has not been possible to cover every aspect. Nor, indeed, has the editor sought to achieve completeness in that sense. Nevertheless, this reviewer would have liked to see further chapters included, e.g., on phosphoramidates and on the scale-up of oligonucleotide syntheses. Also methods for purification and analysis, the importance of which is often underestimated, deserved to be given a separate chapter. They are included, but are scattered throughout the book under the individual compound classes.

The individual contributions are written by recognized experts, who in many cases have themselves had an important role in the development of the areas covered. Nevertheless, where it seemed appropriate they have avoided describing their own work in detail, giving instead an account of the current state of the art, with a beneficial effect on the book's quality. Furthermore, there is no overlapping between the chapters, thanks to the editor's good organization.

In keeping with the good reputation of the "Practical Approach" series in this respect, there is a degree of consistency in the presentation that is unusual in a multi-author book. The list of contents and the key-word index are entirely satisfactory, and attention has even been given to such little matters as providing a list of suppliers of chemicals. The book will soon find its way onto the shelves of all students and scientists with an active interest in the applications of oligonucleotides.

The Photochemistry of Stilbenoid Compounds and Their Role in Materials Technology

By Herbert Meier*

Stilbenes and compounds containing stilbene units in their structures form the material basis for numerous research projects in photophysics and photochemistry. Moreover, because these compounds are easy to synthesize and are thermally and chemically stable, they are taking on an increasingly prominent role in the area of materials science investigations into optical, electrical, and optoelectronic properties. In accordance with the interdisciplinary nature of such studies, this article aims to provide a bridge extending from molecular theory and photophysical measurements, through preparative applications, to material effects and their potential technical applications.

1. Introduction

Stilbenes (**1**) are certainly one of the most thoroughly studied classes of compounds from the standpoint of mechanistic and preparative photochemistry. Considerable attention is devoted to stilbenes in modern textbooks on photochemistry,[1] and they have been covered in numerous reviews.[2] Theoretical calculations and the application of modern physical methods such as time-resolved laser spectroscopy in the picosecond and femtosecond range, jet studies, and photoacoustic measurements are yielding an increasingly detailed knowledge of the fundamental photophysics and photochemistry of these systems. However, they are now revealing that even such apparently simple processes as the *cis–trans* (or *Z–E*) isomerization of stilbenes are actually complex and still inadequately understood in detail. Recently materials science investigations have increasingly provided a stimulus for further fundamental research. The connection between stilbenoid compounds and light is a theme that has implications for optical brighteners, laser dyes, optical data storage, photoconductors, photoresists, photochemically crosslinked polymers, nonlinear optics, and many more areas of application. Thus the photochemistry of stilbenoid compounds has taken on an interdisciplinary character, and the number of publications appearing each year has grown at a remarkable rate.

By stilbenoid compounds we mean systems that are made up of stilbene units, ranging from (*E*)- and (*Z*)-stilbene (1,2-diphenylethene, **1**) through oligostyrylarenes (e.g., **2** and **3**) up to poly(phenylenevinylene)s (PPVs, **4**).

In all these four types of compounds, benzene rings are linked by 1,2-ethenediyl groups. This feature is associated with a strong absorption in the UV/VIS spectrum corre-

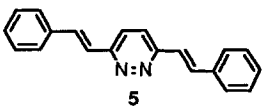
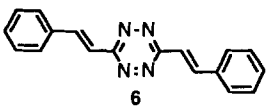
sponding to the excitation of π electrons of the conjugated ethenediyl group into π* orbitals. Substituted chromophores still fall within the definition of stilbenoid compounds if they do not impose their own characteristic photochemistry on the compounds. Heteroatoms such as nitrogen may also be introduced into the ring skeleton, provided that their lone pairs of electrons do not result in a completely different photophysical and photochemical character. Thus, the almost colorless compound 3,6-distyrylpyridazine (**5**) is essentially similar to the hydrocarbon **2** in its photochemical behavior, whereas the deep red compound 3,6-distyryl-1,2,4,5-tetrazine (**6**) shows typical tetrazine properties.[3]



5



6

The introduction of heteroatoms or substituents, or even the presence of certain types of basic stilbenoid units, can result in additional weaker adsorption bands close to the strong $\pi \rightarrow \pi^*$ transition, which often completely or partially obscures them. When they occur in the spectrum at shorter wavelength than the main band, their effect can be neglected. Even in cases where an S_2 state becomes populated, a fast radiationless transition to such an S_1 state ($S_2 \rightsquigarrow S_1$) usually occurs. On the other hand, if the weak band is situated on the longer wavelength side of the main band, it can have a much greater effect. Either direct excitation of the S_1 state or internal conversion $S_2 \rightsquigarrow S_1$ then gives an electronically excited singlet state with different photophysical, and possibly also photochemical, properties. Nevertheless, if the energy difference is small and mixing of the S_1 and S_2 states occurs, this can actually favor the photochemical behavior of the stilbenes (see Section 4.1).

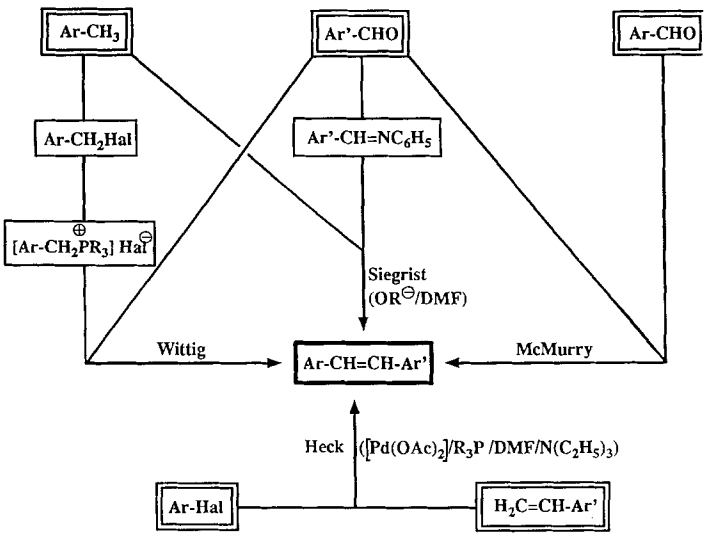
The photochemistry of stilbenoid compounds in their pure state or in inert media can be divided into four types of reactions: a) *Z*–*E* isomerizations, b) cyclizations, c) cyclodimerizations, and d) oligomerizations. If additional components are present, other reactions may be added to this list. This is not the case for a simple energy transfer, is sometimes the case when a charge transfer occurs, and always the case for photoadditions or photocycloadditions with other reaction partners. The last reaction type will not be considered in this article.[4] A brief discussion of synthetic routes to stilbenoid systems will be followed by an account of the fundamental molecular theory and the photophysics, and of the individual types of photoreactions. Lastly the article will discuss the applications of the photophysical and photochemical properties of stilbenoid compounds in materials technology.

2. The Synthesis of Stilbenoid Compounds

The methods for the synthesis of stilbenoid compounds can be classified into two groups. On one hand are those in which the stilbene units arise directly during the construction of the carbon skeleton by formation of single or double carbon–carbon bonds. On the other hand are methods in which the carbon skeleton is first constructed and the olefinic double bonds are subsequently introduced.

Altogether there are many synthetic routes, and consequently only the advantages and disadvantages of the most important methods will be considered here. Structural and configurational purity of the products are of extreme importance for applications in materials technology.

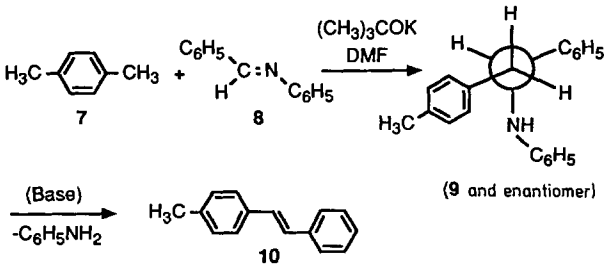
Scheme 1 summarizes three methods for forming C=C bonds: the Wittig–Horner reaction,[5] the Siegrist method,[6] and the McMurry reaction.[7] Starting from methylarenes



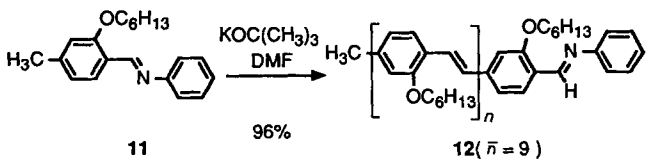
Scheme 1. The most important synthetic routes to stilbenoid compounds. Hal = halogen, DMF = dimethylformamide.

Herbert Meier, born in 1939 in Prague, studied Chemistry and Mathematics at the University of Tübingen and the Freie Universität Berlin, obtaining his doctorate under Eugen Müller in Tübingen in 1968 on the Mills-Nixon effect. After habilitating there in Organic Chemistry and Photochemistry in 1972, he continued as dozent and in 1975 as extraordinary professor. In 1982 he accepted a professorship as successor to L. Horner at the Johannes Gutenberg University in Mainz. His research interests include the synthesis and application of strained carbo- and heterocycles with emphasis on photolytic and pyrolytic methods and the study of photosensitive materials. He is co-author of a widely known textbook on spectroscopic methods in organic chemistry.

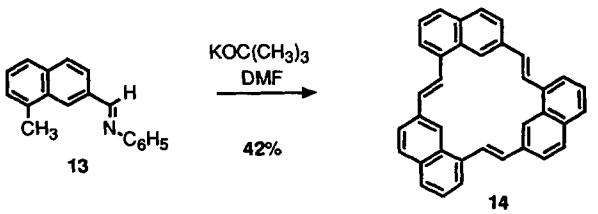
and/or aromatic aldehydes one obtains 1,2-diarylethenes in good yields. The total yields of the Siegrist method is often inferior to those of the other two methods—its main advantage is its remarkably high stereoselectivity. For example, our syntheses of **10** (Ar = *p*-$CH_3C_6H_4$ and Ar′ = C_6H_5) showed that the selectivity is more than 1000:1 in favor of the *E* configuration.[8] The decisive factor here is the anti-elimination (E2 or E1cB) from the least energetic conformation **9**.



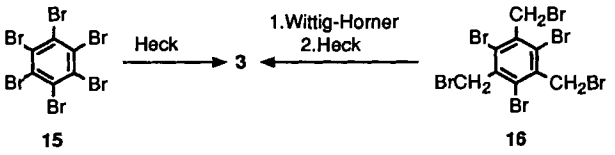
Of the two other methods of forming a C=C bond, neither the stereoselective variants[9] nor a subsequent catalytic *Z*/*E* isomerization yields a higher fraction of the *E* conformer than the thermodynamic equilibrium value.[10] All three methods can be used to build compounds with a chain structure of the poly(phenylenevinylene) type **4**. The Siegrist method is especially suitable for this purpose, not only because of its stereoselectivity but also because it gives nearly quantitative yields when the acidic character of the CH_3 group is increased by the presence of the methyl group and the imine function in the same molecule as in **11**.[11]



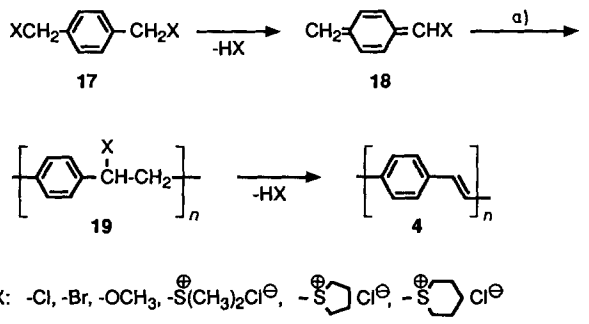
Besides linear polycondensations it is also possible to achieve cyclocondensations. This affords an easy preparative route to the arene-condensed [18]annulenes (e.g. **14**), which are nonplanar and thus, in principle, stilbenoid systems.[12]



With none of the above three methods of forming C=C bonds can four or more styryl groups be linked into one central arene ring. However, this objective can be achieved by using the Heck reaction[13] to form four or more C–C bonds in the last stage of the reaction (see Scheme 1). Thus, for example, hexastyrylbenzene (**3**) can be prepared either from hexabromobenzene (**15**) and styrene[14] or from **16** by a triple Wittig–Horner reaction and a triple Heck reaction.[15]



The Heck reaction is also useful for synthesizing linear polymers with stilbene units.[16] A particular problem with all multiple condensation reactions that afford relatively rigid molecules is the products' poor solubility, because precipitation causes a premature termination of the reaction. This can be avoided by introducing groups such a alkyl, alkoxy, or alkoxycarbonyl, which increase the solubility. Another possibility is to form the carbon skeleton in a first stage and then to introduce the double bonds. This method is often used to synthesize poly(phenylenevinylene)s (PPV, **4**) via so-called precursor polymers.[17, 18]



Scheme 2. Synthesis of **4** via precursor polymers. a) Polymerization.

The use of sulfonium moieties as leaving groups has been found to have particular advantages.[19, 20] With increasing size of the groups X and increasing rigidity of the prepolymers such as **19**, the structural consistency of the PPV chains increases, but the degree of ordering between the chains is reduced.[20]

3. Stilbenoid Compounds in the Ground State

3.1. Molecular Parameters of (*E*)- and (*Z*)-Stilbene

X-ray structural analysis of crystalline (*E*)-stilbene shows that the molecule is nearly planar.[21] Electron diffraction measurements in the gas phase indicate a structure with C_2 symmetry and a twist angle θ of about 32° for the phenyl groups.[22] Molecular mechanics calculations[23, 24] yield appreciably smaller θ values, but show that the anharmonic potential curve for rotation of the benzene rings out of the plane of the double bond is very flat. If one ensures that there is no surplus vibrational energy, as in ultra-cold jet conditions, one can assume a quasi-planar structure for (*E*)-**1** with

C_{2h} symmetry.[21] Electron diffraction studies indicate that (*Z*)-**1** has a propeller-type structure with C_2 symmetry and a twist angle $\theta = 43°$,[25] in good agreement with theoretical calculations, notably by the MM2'[24] and AM1[23] methods. There is some uncertainty regarding the torsion at the olefinic double bond, which in contrast to the situation for the *E* isomer cannot automatically be assumed to be negligible. Relative to other structural parameters, a noticeable feature is the opening of the bond angles α at the olefinic carbon atoms, which are somewhat larger in the *Z* isomer (129°) than in the *E* isomer (126° or 127°).[21,22,25] From the geometric data a greater degree of electron delocalization can be predicted for (*E*)-**1** than for (*Z*)-**1**. However, in both cases the benzene rings are linked together through an olefinic bridge with no additional resonance stabilization;[26-28] thus the average resonance energy per π electron is even smaller than in benzene.[26,29]

3.2. Thermal *Z*/*E* Isomerization

In the ground state S_0 there is a high activation barrier separating (*E*)- and (*Z*)-**1** (Fig. 1). Differential thermal analysis shows that the $Z \rightarrow E$ isomerization in the pure phase does not become efficient until the temperature reaches about 300 °C. The thermogram has a maximum at 385 °C, and the activation energy is calculated[30] to be $192 \pm 9\ kJ\,mol^{-1}$. Measurements in the gas phase[31-33] give similar results. For isomerization reactions in solution the activation energies are probably slightly lower. In solution, however, it is difficult to exclude the possibility of catalysis by trace impurities, since there is a great variety of catalysts that can influence the *Z*/*E* isomerization of stilbenoid compounds; these range from metals such as palladium to nonmetals such as iodine. The latter is often used in preparative work to establish the *Z*/*E* equilibrium. The iodine molecules can be induced to dissociate either thermally or photochemically. Figure 1 shows the energy profile for the *Z*/*E* equilibration of stilbene, drawn with values found by Saltiel et al.[34] from measurements in *tert*-butylbenzene; the value for the Arrhenius activation energy E_a is in agreement with a measurement by Kistiakowsky et al.[35]

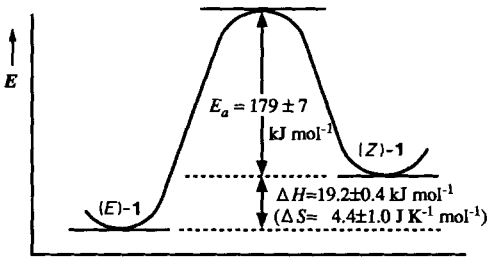


Fig. 1. Energy profile for the thermal equilibration of (*Z*)- and (*E*)-stilbene (**1**) in *tert*-butylbenzene. Rk = reaction coordinate.

The published values for $\Delta G°$ range from 10.7 to $23.8\ kJ\,mol^{-1}$; the data determined from the equilibrium constants (15.5[36] and $17.6\ kJ\,mol^{-1}$[34]) are more reliable than those obtained from corrected heats of combustion[37] or heats of hydrogenation.[38] According to this the proportion of the *Z* isomer under thermal equilibrium conditions is small; for example, at 30 °C in benzene it is less than 0.1%, and it increases to slightly more than 1% in *tert*-butylbenzene at 188 °C.[34] For the great majority of stilbenoid compounds, the proportion of the *Z* isomer in the thermal equilibrium remains small ($\leq 5\%$). However, for PPV compounds **4**, even a small fraction of the double bonds in the *Z* configuration can result in serious defects in the material.

4. Stilbenoid Compounds in Electronically Excited Singlet States

4.1. Electronic Excitation and Physical Deactivation Processes

Both (*E*)- and (*Z*)-stilbene (**1**) have strong UV adsorption bands. As can be seen from Figure 2, the band at longer wavelength is weaker in the *Z* than in the *E* isomer, and shifted slightly to shorter wavelengths. At low temperatures

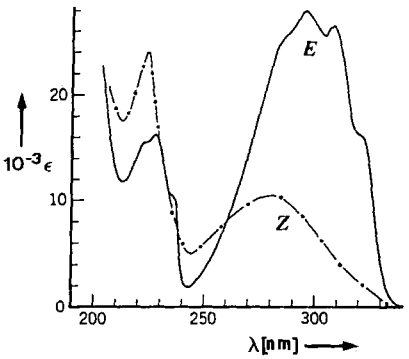

Fig. 2. UV spectra of (*E*)- and (*Z*)-stilbene (**1**) in hexane at room temperature.

the spectrum of (*E*)-**1** shows a well-defined vibrational structure, whereas the band of the more severely twisted (*Z*)-**1** continues to show no fine structure.

Figure 3 depicts the HOMO–LUMO electronic transition $\pi_7 \rightarrow \pi_8^*$. The highest occupied orbital π_7 is localized to a large extent in the region of the olefinic double bond. Consequently, the electronic excitation process reduces the bond order of the C=C bond, with a corresponding effect on the relevant stretching vibration. This effect is greatest in the gas phase, where the $S_0 \rightarrow S_1$ transition in (*E*)-**1** reduces the C=C vibrational frequency from 1654 cm^{-1} to about 1550 cm^{-1}; the olefinic double bond lengthens (136 to 144 pm), whereas the adjacent bonds to the phenyl groups contract from 148 to 142 pm.[39,40]

The dipole moment of asymmetrically substituted (*E*)-stilbenes is greater for the S_1 state than for the ground state. This effect can be described by the empirical relationship $\mu(S_1) = 3.11\ \mu(S_0) - 1.46$.[44] A more extreme effect can occur for donor–acceptor disubstituted stilbenes. For example, (*E*)-4-dimethylamino-4'-cyanostilbene (**20**) forms a TICT (*t*wisted *i*ntramolecular *c*harge *t*ransfer) state, which gives rise to an additional fluorescence band. In the S_1 state of this

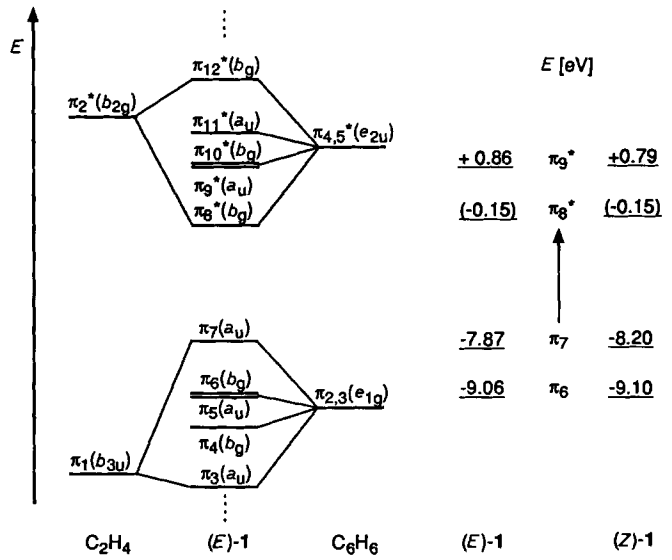

Fig. 3. Correlation diagram for the highest occupied π-orbitals and lowest unoccupied π^*-orbitals of (*E*)-stilbene, derived from ethene and benzene, showing the HOMO–LUMO electronic transitions: (*E*)-**1**: $A_{1g} \rightarrow B_{1u}$ (idealized point group C_{2h}) and (*Z*)-**1**: $A \rightarrow B$ (point group C_2). The orbital energies *E* correspond to ionization energies *I* measured by photoelectron spectroscopy [41, 42] and to electron affinities *EA* measured by electron transmission spectroscopy (ETS) [43]; the LUMO energies given in parentheses have been calculated by the Pariser-Parr-Pople (PPP) method [43], since the stable anions cannot be measured by ETS because $EA > 0$.

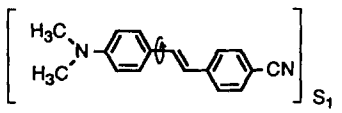
molecule, the twisting of the 4-dimethylaminophenyl moiety competes with rotation about the double bond (isomerization).[45]



20

Physical deactivation of the S_1 state can occur by fluorescence ($S_1 \rightarrow S_0$), by internal conversion (IC, $S_1 \rightsquigarrow {}^1S_0$), and by intersystem crossing (ISC, $S_1 \rightsquigarrow T_1$). For (*E*)-**1** the fluorescence quantum yield ϕ_F has been measured as 0.07–0.08 at room temperature,[46] and 0.90 at 77 K;[47] at still lower temperatures it may approach the limiting value of 1.0. For a long time it was assumed that (*Z*)-**1** does not fluoresce in solution at room temperature, but only does so in glasses at low temperatures or in the vibrationally relaxed state in jet experiments. Recently, however, the emission spectrum has been successfully measured in hexane at room temperature.[48] The spin inversion or ISC process, leading to the least energetic triplet state T_1, plays only a very minor role for (*E*)-stilbene. The fluorescence intensity of pure (*E*)-**1** in solution at room temperature shows a monoexponential decay,[46, 49, 50] from which average fluorescence lifetimes τ of between 80 and 140 ps have been measured for this exited state. At 77 K the value of τ increases to 1.2–1.4 ns.[49] For (*Z*)-stilbene the mean lifetime of the S_1 state is considerably shorter (0.7–1.4 ps).[51] Evidently for both (*E*)- and (*Z*)-**1**, "chemical" deactivation of the S_1 state into product channels (see Sections 4.2 and 4.3) is of great importance. The relative contributions of physical and chemical deactivation processes depend not only on the temperature and the medium, but also on the excess thermal energy relative to the origin of the $S_0 \rightarrow S_1$ transition, as is shown by results from supersonic jet experiments.[52] A crucial factor in this context is the existence of activation thresholds along the reaction coordinates (see Section 4.2). Higher excited singlet states S_n with energies close to that of S_1 exist. On the basis of results from two-photon spectroscopy and also from theoretical calculations, it has been postulated[53] that (*E*)-**1** has at least six additional excited singlet states below 50000 cm^{-1}. When these states become populated they decay only partly to S_1 by internal conversion, since they can also lead directly to the product channels.[54]

An investigation of arenes with two or more styryl groups reveals that these can be divided into two categories. Figure 4 shows spectra for two typical examples. (*E,E*)-1,4-Distyrylbenzene (**2**) belongs to category I.[55, 56] These compounds are spectroscopically rather similar to the parent compound (*E*)-stilbene (**1**). For **2** a strong absorption band (λ_{max} = 353 nm) overlaps with the fluorescence band in the region of the $0 \rightarrow 0$ transition. The excitation (Exc) and absorption (A) spectra are identical. The fluorescence quantum yield ϕ_F at room temperature is 62%.[55, 57] (*E,E*)-1,2-Distyrylbenzene (**21**) represents category II.[55] Its absorption is less intense than that of **2** and shows a hypsochromic shift. The excitation spectrum differs from the absorption spectrum, ϕ_F is considerably smaller (11%), and a large Stokes shift is observed between the absorption and fluorescence bands. The latter effect provides a very simple criterion for distinguishing between the two categories. The *meta*-substituted compound **22** behaves similarly to the *ortho*-substituted compound **21**.[56]

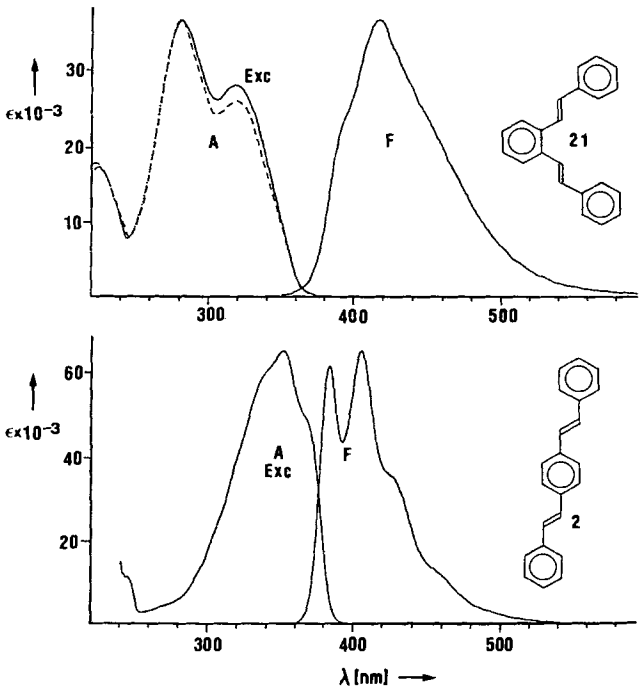


Fig. 4. Absorption, excitation, and fluorescence spectra (A, Exc, F) for (*E,E*)-1,2- and (*E,E*)-1,4-distyrylbenzene (**21** and **2**, respectively) in ethanol at room temperature.

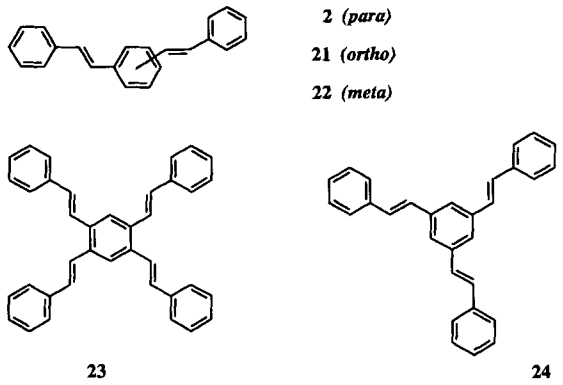

Stilbenoid systems often exist as several rotamers, which can differ in their photophysical and photochemical properties.[2k, 55] Thus, the fluorescence decay curves are not always monoexponential. For example, seven rotamers are theoretically possible for (*E,E,E,E*)-1,2,4,5-tetrastyrylbenzene (**23**); the statistical distribution is 4:4:2:2:2:1:1. So far as the actual populations are concerned, at least three conformers are excluded from the outset on steric grounds because their energies are too high; the remainder show identical fluorescence behavior in toluene at room temperature, with a mean fluorescence lifetime of $\tau = 7.8$ ns.[56] A contrasting example is (*E,E,E*)-1,3,5-tristyrylbenzene, **24**, for which both theory and experiment indicate the existence of two rotamers. Under the same conditions as above the τ values are 9.4 and 13.6 ns, while at 50 K in hexane they are 16.4 and 43.0 ns (Fig. 5). When one compares the τ values for the two categories of stilbenoid compounds, a further important difference becomes apparent; this is especially obvious from the intrinsic lifetimes $\tau_o = \tau\phi_F^{-1}$. Whereas τ_0 is of the order of 1 ns for (*E*)-**1** and other compounds of category I, the intrinsic lifetimes in category II are up to 300 times greater. Corresponding differences are found in the behavior of the two categories of compounds in bimolecular photoreactions (see Section 4.4). In category I the absorption band at longer wavelength ($S_0 \rightarrow S_1$) corresponds to an allowed electronic transition A → B, whereas in category II the intensity of the $S_0 \rightarrow S_1$ transition is weak (A → A). In the example of **24** in Figure 5, the latter transition can be seen on the long-wavelength side of the strong band.[56]

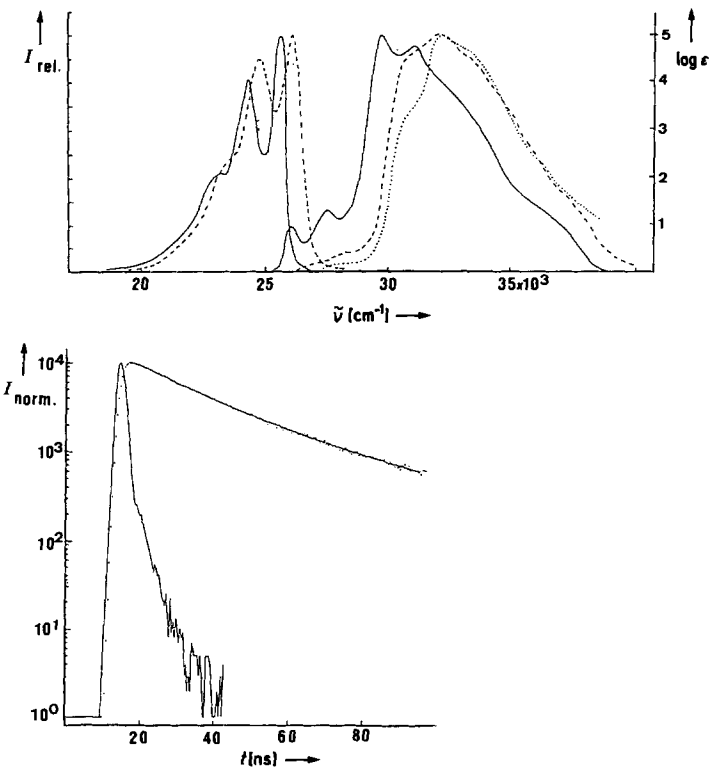

Fig. 5. Top: Absorption, excitation, and fluorescence spectra [56] for **24** in hexane [···· absorption (293 K), ---- excitation and fluorescence (293 K), —— excitation and fluorescence (50 K)]; bottom: fluorescence decay curve for **24** in hexane at 50 K ($\tau_1 = 16.4$ ns, $\tau_2 = 43.0$ ns, with pre-exponential factors $A_1 = 0.121$, $A_2 = 0.045$) [56].

The difference in the nature of the $S_0 \rightarrow S_1$ excitation process already becomes apparent from a simple MMX calculation for 1,3- and 1,4-distyrylbenzene (**22** and **2**, respectively), as shown in Figure 6. The $b_g \rightarrow a_u$ electronic excitation process in **2** corresponds to the transition $S_0(A_g) \rightarrow S_1(B_u)$, whereas the $a_2 \rightarrow a_2$ excitation in **22** corresponds to the transition $S_0(A_1) \rightarrow S_1(A_1)$. The configurational interaction does not alter the fact that in each case the HOMO–LUMO transition leads to the band of lowest energy. Unlike the $A_g \rightarrow B_u$ transition, the $A_1 \rightarrow A_1$ transition is polarized only in the direction of the C_2 symmetry axis, that is, perpendicular to the longitudinal extension of the molecule **22**. Measurements of the polarization P again provide a distinction between categories I and II. The high values of P for the bands of substances in category I are in contrast to the low values for those in category II, since the absorbing and emitting states are not identical, and a difference in direction between the transition moments leads to depolarization. If the bands are partly separated (as in Fig. 5, top), P changes at the crossover point.[58]

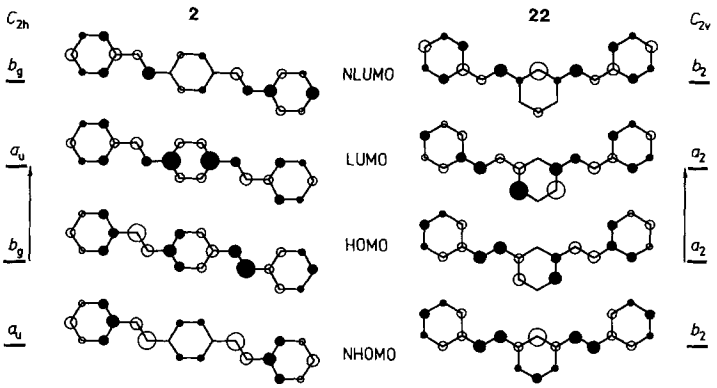

Fig. 6. Frontier orbitals for **2** and **22**, and HOMO–LUMO electronic transitions (selected conformers).

Figure 7 shows for a number of styrylbenzenes a comparison of the energies of the 0 → 0 transitions of the weak absorption A, the strong absorption B, and the fluorescence F, measured at 77 K in hexane or ethanol. For compounds in category I the energies are typically in the sequence F, B, A, whereas for category II the sequence is F, A, B. This observation also sheds a new light on the simplest of the criteria for distinguishing between categories I and II, namely the large Stokes shift between the strong absorption band and the fluorescence band. The fluorescence transition $S_1 \rightarrow S_0$

should always be related to the absorption transition $S_0 \rightarrow S_1$, even when this absorption can only be recognized as a weak shoulder on the strong absorption band, or is actually completely hidden by the latter. Adopting this procedure ensures that overlapping of the bands occurs in the region of the $0 \rightarrow 0$ transition (see also Fig. 5). In general it can be stated that stilbenoid systems in which (linear) conjugation is blocked, either on a priori grounds or due to steric hindrance, will belong to category II.

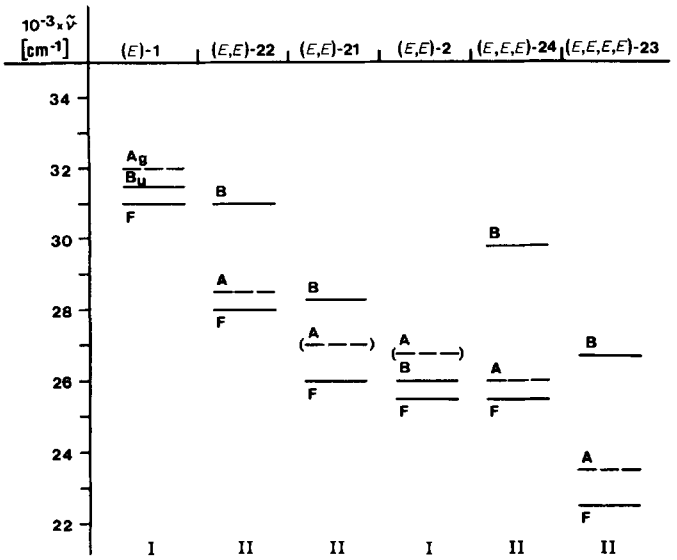

Fig. 7. Schematic diagram showing the energies of the $0 \rightarrow 0$ transitions for the allowed absorption (B), the forbidden or weak absorption (A), and the fluorescence (F) for selected styrylbenzenes in categories I and II.

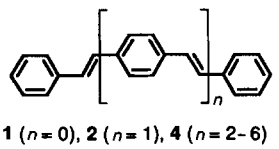
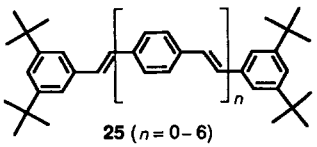
After the discussion of sterically hindered or blocked conjugation, we now examine the situation in greatly extended conjugated systems. In this context we consider the series of compounds **1**, **2**, and **4**, with the all-(*E*) configuration. The poor solubility of compounds **4** with $n \geq 2$ present difficulties; it is therefore better to make comparisons with compounds **25** containing *tert*-butyl substituents, which have been studied by K. Müllen et al.[59] Whereas for **4** the limit of convergence appears to be reached at $n = 4$, for **25** a more reliable limit in the region $n = 7$ to 10 can be assumed.[59] For



1 ($n = 0$), **2** ($n = 1$), **4** ($n = 2$–6)



25 ($n = 0$–6)

	λ_{max} [nm] (solvent)[60]	λ_{max} [nm]/chloroform[58]
$n = 0$	295 (hexane)	≈ 309
$n = 1$	350 (hexane)	360
$n = 2$	385 (chloroform)	387
$n = 3$	385 (dioxan, 80°C)	403
$n = 4$	388 (dioxan, 80°C)	412
$n = 5$	388 (dioxan, 80°C)	418
$n = 6$	388 (1-methylnaphthalene, 90°C)	415

Scheme 3. Dependence of the absorption on the chain length for compounds **1**, **2**, **4**, and **25**.

the corresponding monoanions an effectively conjugated chain segment is not reached until nine or ten stilbene units are present.[59] The effective conjugation length is essentially limited by the torsion of the benzene rings; this effect is expected to be even more pronounced in solution than in the solid. The oligo- and poly(phenylenevinylene)s with all-(*E*) configuration show strong fluorescence bands which, like the adsorption bands, are shifted to longer wavelengths as *n* is increased. Our measurements, which are not yet completed, indicate that on increasing *n*, ϕ_F passes through a maximum (see Section 6.3).

4.2. *Z*/*E* Isomerization

The *cis–trans* or *Z–E* isomerization of stilbenes has been known for more than 80 years;[61] in recent years it has received much attention as a model reaction for the study of ultra-fast reaction kinetics.[2j] The first detailed mechanism was proposed in 1967/68 by Saltiel.[62] The more recent models based on that of Saltiel have mainly continued to assume one-dimensional reaction coordinates. Reducing the reaction coordinate to a single molecular parameter, the torsion angle θ about the olefinic double bond, is a crude simplification; nevertheless, the sections $E(\theta)$ through the potential energy surfaces then correctly describe the basic features of this photoisomerization. Figure 8 shows the Orlandi–Siebrand model,[63] in which the direct *E–Z* isomerization reaction follows a nonadiabatic mechanism, characterized by the avoided crossing of the lowest electronically excited singlet state $S_1(B_u^*$ or $B^*)$ with a doubly excited state $S_2(A_g^*$ or $A^*)$. Experimental evidence has also been obtained[64] for

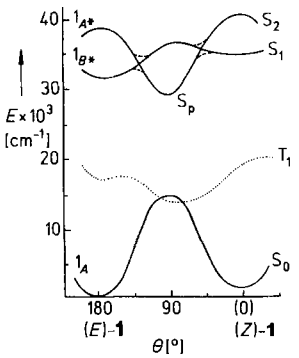


Fig. 8. Schematic reaction profile for the *E*/*Z* isomerization of stilbene (**1**). The reaction coordinate θ is the torsion angle about the olefinic double bond.

an S_n state, corresponding to a two-photon transition. According to an ab initio calculation,[63] the energy of B_u^* increases in the range from $\theta = 180° - 90°$, whereas that of A_g^* decreases. The vibrationally induced internal conversion leads over an activation barrier to the energy minimum S_p, which was previously called a phantom singlet state.[62] A similar reaction sequence leads from the (*Z*) configuration ($\theta \cong 0°$) to S_p. However, whereas the barrier between S_1 and S_p can have a value up to 15 kJ mol^{-1} for (*E*)-**1**, that on the *Z* side is less than 4 kJ mol^{-1}.[51, 65, 66] Thus, temperature has an appreciable influence on the competition between fluorescence and $E \rightarrow Z$ isomerization.[2e] On the *Z* side the competition from fluorescence is much less important than the alternative reaction path of photocyclization (see Sec-

tion 4.3). The lifetime of S_p is less than 150 fs.[51] The system in the representative area for the twisted state rapidly jumps through a funnel to an area near the saddle point on the ground state surface S_0, and from there with similar probability moves along the surface to the ground state configurations (*Z*)- and (*E*)-**1**. Results from laser studies with femtosecond resolution are consistent with an isomerization model with a spatially fixed C_2 symmetry axis.[51, 67]

Many details of the Orlandi–Siebrand model are still unclear. For example, it is uncertain whether the energy profile for the S_1 (*B*) state has a maximum at $\theta = 90°$, or whether there is a monotonic increase up to $\theta \simeq 0°$.[63] A monotonic increase could explain why a small fraction (0.16–0.20%) of the (*Z*)-stilbene molecules in the S_1 state does not follow the isomerization path described, but undergoes an adiabatic process forming (*E*)-**1** in the S_1 state, which is detected by the fluorescence from (*E*)-**1**.[48] An important modification to the Orlandi–Siebrand model was introduced by Hohlneicher and Dick,[53] who showed that (*E*)-**1** has a whole series of electronically excited singlet states with higher energy than S_1 and *A*- and *B*-type symmetry. Twisting of the molecule by the angle θ increases the energy of these states, except for an A^* state with the $\pi\pi^*$ configuration of the ethenediyl group, whose energy is reduced. Thus, depending on the symmetry there is either crossing of surfaces, or interactions in which crossing is strongly or weakly avoided. A minimum at S_p on the potential energy curve, flanked by an activation threshold corresponds to a weakly avoided crossing of the falling A^* state S_5 with a rising A^* state S_3.[53] To investigate the involvement of a higher excited singlet state, Sumitani and Yoshihara[54] devised an interesting experiment. They used a laser pulse at 266 nm wavelength to excite (*E*)-**1** to the S_1 (B_u) state, and 90 ps later a second pulse at 532 nm to raise the energy into an S_n (A_g) state. The second pulse has the effect of weakening the fluorescence $S_1 \rightarrow S_0$, with a corresponding increase in the isomerization tendency. This applies even at 90 K, a temperature at which single excitation no longer leads to isomerization. Thus, the activation barrier can be circumvented by directly populating the $S_n(A_g{}^*)$ state.

An alternative model for *Z*/*E* isomerization is the proposal by Troe.[68] MNDO-CI calculations provide no evidence for the nonadiabatic involvement of higher excited singlet states. The apparent cause of the experimentally observed barrier is the change in the configurational interaction in S_1, which is greater in the *E* configuration ($\theta = 180°$) than for $\theta = 90°$. The photostationary equilibrium for direct *Z*/*E* isomerization can be calculated for monochromatic irradiation from the quantum yields and the extinction coefficients, according to Equation (a). Since the ratio of the quantum

$$\frac{[Z]}{[E]} = \frac{\phi_{E\rightarrow Z}\,\varepsilon_E}{\phi_{Z\rightarrow E}\,\varepsilon_Z} \qquad \text{(a)}$$

yields is usually close to 1, it is possible by a suitable choice of the wavelengths to obtain a high degree of enrichment in one configuration. For example, with $\lambda = 313$ nm 91.5% conversion of (*E*)-**1** into the *Z* configuration can be attained.[69] This method is of particular interest from a preparative standpoint in cases where one of the two configurational isomers is difficult or impossible to obtain in other ways.[70]

The rate of the isomerization of the *E* isomer to the *Z* isomer depends to a large extent on the medium. The reverse ($Z \rightarrow E$) isomerization for (*Z*)-**1** in the first electronically excited singlet state is complete in 1–2 ps, even in highly viscous media.[71, 72] As the lifetime of the S_p state is also very short, the (*E*)-stilbene molecules formed are "hot", that is, not in thermal equilibrium with their environment.[65] Medium effects such as solvation, temperature, pressure, and especially viscosity, have been studied in detail.[51, 73–82] A typical result is the observed lowering of the activation barrier in alcohols (polar, protic media) relative to that of hydrocarbons.[75, 78, 82] The application of the Kramer's theory[83] to account for the viscosity effects observed in this isomerization is somewhat controversial, but it gives useful results in most cases.[2i] An important point to bear in mind here is that the macroscopic viscosity is not a good measure of the microscopic friction. To account for this discrepancy, Saltiel et al.[74] have defined a specific microviscosity based on diffusion coefficients. Substituents can drastically alter the dynamics of the isomerization. In Figure 9 the initial phases of the isomerizations (*E*)-**1** → (*Z*)-**1** and (*E*)-**26** → (*Z*)-**26** when irradiated in cyclohexane and in hexadecane are compared. The more viscous medium has a considerably greater retarding effect on the isomerization of the long-chain substituted system **26**.[94]

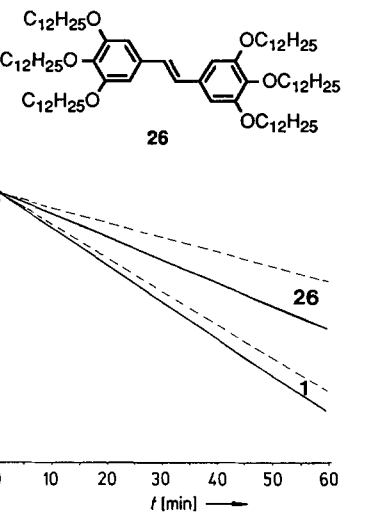

Fig. 9. Initial disappearance of the *E* configuration of **1** and **26** during irradiation at $\lambda = 313$ nm [84]; – – – in hexadecane, — in cyclohexane. This nearly linear early phase is followed by an asymptotic approach to the photostationary equilibrium, which is not shown.

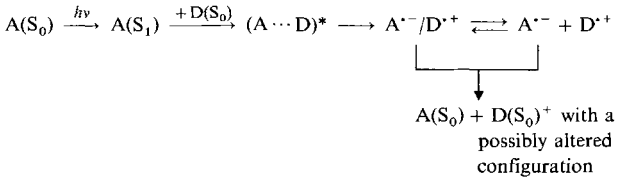
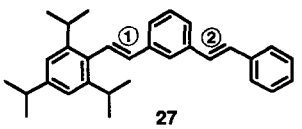
Even more pronounced effects on the photochemical and photophysical properties of stilbenes than those caused by solvent cages occur as a result of adsorption at surfaces,[85, 86] or inclusion in the cavities of zeolites[87] or cyclodextrins.[88] The restricted molecular mobility not only slows down the isomerization, but can also alter the product ratio. Adsorption of substrates accompanied by partial ionization[85] already leads to an intended charge transfer. In fact, the photoisomerization of stilbenes can also proceed by an electron-transfer mechanism.[89–92] For example, if the acceptor (A) 9,10-dicyanoanthracene ($E_s = 2.90$ eV) is irradiated in acetonitrile in the presence of (*E*)- or (*Z*)-**1** as a

donor (D), then the excited single state, $A(S_1)$, and $D(S_0)$ generate, via the exciplex, a radial ion pair consisting of a 9,10-dicyanoanthracene radical anion and a stilbene radical cation.[89] The oxidation potentials are 1.95 eV for (*E*)-stilbene and 2.06 eV for (*Z*)-stilbene. The (*E*)-**1** radical cations have a higher probability of leaving the ion pair solvent cage than the (*Z*)-**1** radical cations. However, although the $E \rightarrow Z$ isomerization has a low efficiency ($\phi \approx 0.002$), only the photoisomerization in the $Z \rightarrow E$ direction is concentration-dependent. The quantum yield ϕ increases linearly with the concentration of (*Z*)-**1** and exceeds the value 1 at about 0.2 M.[89] The reaction chain probably involves dimeric structures (Scheme 4), though the details still need to be clarified.



Scheme 4. Photoisomerization of stilbenes (donor D) in the presence of an acceptor (A) by an electron-transfer mechanism.

Most stilbenoid compounds behave like the parent compound **1** with regard to direct *Z*/*E* isomerization. In oligostyrylarenes all the double bonds can take part in a stepwise process, and in asymmetric cases it is even possible for the isomerization to take place preferentially on the less sterically favored side. For example, in **27** the quantum yield for the isomerization of double bond ① is significantly greater, despite the fact that in the photostationary state the *Z* configuration of double bond ② predominates (Scheme 5).[93]



27

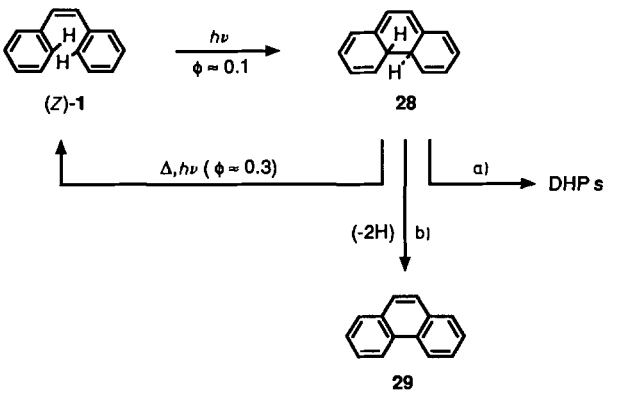
	①	②	
$\Phi_{E \rightarrow Z}$	0.34	0.026	
photostationary equilibrium:	*E*	*E*	8 %
	Z	*E*	20 %
	E	*Z*	31 %
	Z	*Z*	41 %

Scheme 5. Quantum yield for the $E \rightarrow Z$ isomerization of **27** and the position of the photostationary equilibrium with respect to the double bonds ① and ②.

A special case is that of stilbenoid compounds with extended conjugation. Even for 1,4-distyrylbenzene (**2**) the quantum yield for the photoisomerization (*Z*,*E*)-**2** → (*E*,*E*)-**2** is one to two orders of magnitude greater than for the reverse reaction.[94, 95] AM1 calculations indicate that for an adiabatic reaction sequence the forward and reverse reactions would have to overcome activation thresholds on the S_1 potential energy surface of 25 and 51 kJ mol^{-1}, respectively.[96] Experimental results for the tetra-*tert*-butyl derivative **25** ($n = 1$) support the assumption of a one-way photoisomerization (*Z*,*Z*) → (*Z*,*E*) → (*E*,*E*). It is not yet clear whether the reverse reaction (*E*,*E*)-**2** → (*Z*,*E*)-**2**, which occurs somewhat more readily with derivatives of **2** containing methyl or isopropyl substituents,[95] is a singlet or a triplet process. (The quantum yields are around 1 %, a range in which there is a significant probability of intersystem crossing.) One-way photoisomerization was first observed by Tokumaru et al.[97] for anthryl olefins in the triplet state; H.-D. Becker et al.[98] subsequently found that such adiabatic processes can occur on singlet and triplet potential energy surfaces. Each absorbed photon can produce a rotation about more than one double bond. For still greater conjugation lengths, as in the PPV systems (**4**), isomerization processes have not been observed in all-(*E*) compounds of high configurational purity prepared by the Siegrist method (Section 2).

4.3. Cyclization

The photocyclization of stilbene (**1**) was first observed by Smakula[99] in the 1930s, although the products were identified much later;[100] nowadays the oxidative cyclization of stilbenoid compounds is the method of choice for the synthesis of a wide variety of polycondensed arenes.[2f, g, i] If (*Z*)-**1** is irradiated at $\lambda = 313$ nm, it affords, in addition to the (*E*) isomer ($\phi = 0.35$), *trans*-4a,4b-dihydrophenanthrene (**28**) in a competing reaction with a quantum yield of about 10 % (Scheme 6).[101] In accordance with the orbital symmetry



29

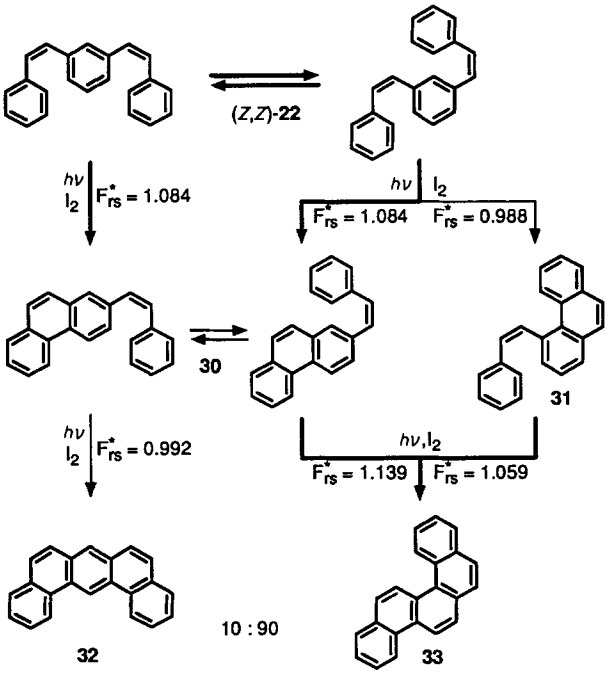
Scheme 6. Cyclization of (*Z*)-**1**. a) isomerization, b) oxidation; DHP = dihydrophenanthrene.

rules, the reaction is a photochemically allowed, conrotatory, electrocyclic ring closure involving six π electrons. (The signs of the orbital coefficients of the LUMO of (*Z*)-**1** at the carbon centers involved correspond to those of the coefficients for 1,3,5-hexatriene.) Dihydrophenanthrene **28** ($\lambda_{max} = 450$ nm) dissolved in isopropanol at room temperature has a mean lifetime of about 9 s.[102] It reverts thermally and photochemically to (*Z*)-**1**. Although the thermal interconversion (*Z*)-**1** ⇄ **28** is forbidden, being a conrotatory process, this only applies strictly for the direction (*Z*)-**1** → **28**, which would have to overcome a high activation barrier of about 220 kJ mol^{-1}.[103] The energy of **28** lies considerably higher on the S_0 energy surface for molecules with the consti-

tutional formula $C_{14}H_{12}$ than that of (*Z*)-**1**; consequently the activation energy E_a for the back reaction is only about 73 kJ mol^{-1}. For substituted compounds, steric effects result in a rather wide spread of E_a values from 30 to 125 kJ mol^{-1}.[2f] Steric effects can also greatly reduce the quantum yield in the photochemical back reaction. According to the theory of the photostationary equilibrium, the enrichment in **28** is markedly dependent on the irradiation wavelength. The optimal conditions are given by $\lambda = 290$ nm (the absorption maximum of **1**), low temperature, and exclusion of ambient light. Dihydrophenanthrene **28** can be removed from the equilibrium mixture by oxidizing with iodine, atmospheric oxygen, or other oxidizing agents. The recently discovered iodine/propene oxide system is especially effective.[104] Oxidation occurs irreversibly to give phenanthrene, (**29**). If there is a suitable leaving group (halogen, alkoxy, CN, CH_3, etc.) at the 4a position, the reaction can also proceed under nonoxidative conditions.[2c] An alternative to complete aromatization is, in principle, a partial aromatization by isomerization of 4a,4b-dihydrophenanthrene to 1,2-, 1,4-, 3,4-, or 9,10-dihydrophenanthrene.[105] The first double 1,3-H shift proceeding with a high yield was the formation of *trans*-9,10-dihydrophenanthrene-9,10-dinitrile on irradiation of 2,3-diphenylmaleic dinitrile.[106] Pericyclic H shifts, and even suprafacial thermal [1,5]shifts, can rarely compete with dihydrophenanthrene ring-opening, and consequently these isomerizations are usually carried out as base- or acid-catalyzed reactions.[105]

In principle this method of synthesis can be used to prepare a very wide variety of condensed arenes and heteroarenes. Instead of the olefinic double bond, C=N, N=NH, C=NH, NH-CO, or N=CO groups, or even O, N and S bridging groups can be used.[2g] The reaction mechanisms then proceeds through tripled states; however, in the standard example of the stilbenoid systems (*Z*)-**1** → **28**(→ **29**), only pure singlet states are involved. Following the electronic excitation $S_0 \rightarrow S_1$, the adiabatic process takes place over an activation barrier of 5–6 kJ mol^{-1}, in competition with the process $S_1 \rightarrow S_p$.[101, 107] The branching ratio between these two routes is about 30:70. Subsequently a return to the ground state of either (*Z*)-**1** or **28** occurs, again in the ratio 70:30, resulting in a final quantum yield of about 10% for the formation of dihydrophenanthrene.[107, 108] Since (*Z*)-**1** is continuously formed during the irradiation from the equilibrium (*E*)-**1** ⇄ (*Z*)-**1**, despite the only moderate quantum yields, product yields for the arenes vary from good to very good. With cyclohexane/iodine/atmospheric oxygen as medium, phenanthrene itself is obtained with a yield of 73%.[109] In cases where several different cyclization reactions are possible, considerable effort has already been devoted to seeking criteria for predicting the preferred reaction path. If the free valencies in the S_1 state for the C centers that are to be linked are represented by F_r^* and F_s^* then $F_{rs}^* = R_r^* + F_s^*$ should be preferably greater than 1. If several combinations can be formulated, the pair with the greatest value of F_{rs}^* is expected to be realized.[110–113] This simple rule works well in practice, apart from a few exceptions. As an example we consider here 1,3-distyrylbenzene (**22**).[111, 113, 114]

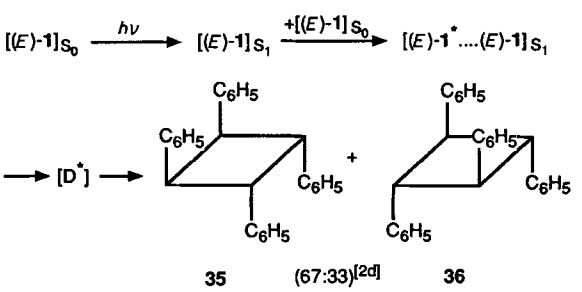
As expected, the main product (70%) from **22** is benzo[*c*]chrysene (**33**) but an 8% yield of dibenz(*a*,*j*)anthracene (**32**) is also obtained.[114, 115] Substituents can greatly influence the course of the photocyclization.[115] In the cyclization of 1,2-distyrylbenzene (**21**) to picene, and of 1,4-distyrylbenzene (**2**) to dibenzo[*c*,*g*]phenanthrene and benzo[*g*,*h*,*i*]perylene, a direct reaction path is ruled out on the basis of the F_{rs}^* values; Laarhoven et al.[113] assume an indirect route via dimeric intermediates (see Section 4.4). In consi-



dering alternative reaction paths one must take into account that the selectivity can be achieved at the thermal oxidation stage as well, since the cyclizations are always reversible.[116] Finally, this method has been used to prepare a wide variety of helicenes,[117] and even asymmetry syntheses are possible by using polarized light,[118] chiral substituents,[119] chiral solvents,[120] or cholesteric liquid crystalline phases.[121]

4.4. Cyclodimerization

The photocyclodimerization of (*E*)-stilbene (**1**) was discovered as early as the beginning of the twentieth century by Ciamician and Silver,[122] who rank among the pioneers of photochemistry. The structure of the main product **35** was determined 45 years later by Fulton and Dunitz.[123] The side product **36** was identified in the 1960s by Shechter



et al.[124] The first excited singlet state S_1 undergoes a stereospecific $[\pi^2s + \pi^2s]$ cycloaddition by diffusion-controlled formation of nonfluorescent singlet excimers **34**. These excimers, which correspond to flat energy minima,[125] transfer to the minima D* of doubly excited singlet state for a pericyclic geometry of the intermediate ("pericyclic minimum") and are rapidly deactivated to the ground state of the products.[126]

The geometry at the pericyclic minimum causes the energy of the D* state to dip below that of the degenerate S_1 state of these excimers within a narrowly defined local region. The avoided crossing of the energy surfaces probably results in a small energy barrier in the reaction profile. Excimers and pericyclic minima determine the stereochemistry and, in the asymmetrical case, also the regiochemistry. Predicting the regiochemistry is difficult, since according to perturbation theory the head-to-head adducts should give the most stable excimers and the head-to-tail adducts the most stable pericyclic minima.[126] The stereoselectivity of the cycloaddition is also linked to the formation of excimers. (*Z*)-**1** has an S_1 state that is much too short-lived, but also it does not, as a molecule in the ground state, take part in the formation of an exciplex $[(E)\text{-}\mathbf{1}^* \cdots (Z)\text{-}\mathbf{1}]S_1$.[127] Thus (*E*)-**1** dimerizes in concentrated solutions under irradiation to form **35** and **36**, (*Z*)-**1** does not dimerize, even in the pure liquid state, and a mixture of (*Z*)-**1** and (*E*)-**1** does not give a mixed cycloadduct. Irradiation at shorter wavelengths leads to stereoselective cycloreversion of the four-membered rings:[128, 129] irradiating with $\lambda = 254$ nm at 300 K causes scission of **35** and **36** to form (*E*)-**1** with quantum yields of 84% and 62%, respectively. Typically, the C–C bond that bears groups in a *cis* configuration is preferentially cleaved (the "*cis effect*").[128] The limiting quantum yield for the dimerization in concentrated solution is 77%.[2h] In principle, the forward and reverse reactions can involve different mechanisms. Whereas a 1,4-diradical is not an intermediate in the dimerization of stilbene,[130] it may take part in the back reaction;[128, 129] the observed stereoselectivity does not rule out the possibility of a short-lived 1,2,3,4-tetraphenylbutane-1,4-diyl species in the singlet state. A diradical of this kind has also been postulated to account for the formation of 1,2,3-triphenyl-1,2,3,3a-tetrahydroazulene with a 10% yield during the irradiation of 1,2,3,4-tetraphenylcyclobutane.[131]

According to a strikingly simple theory developed by Caldwell,[132] one can predict the cyclodimerization behavior from Equation (b), which gives the resonance integral γ in the transition state of the C–C bonds to be linked. The

$$\gamma = (2E_T - E_S)/c^2 \qquad \text{(b)}$$

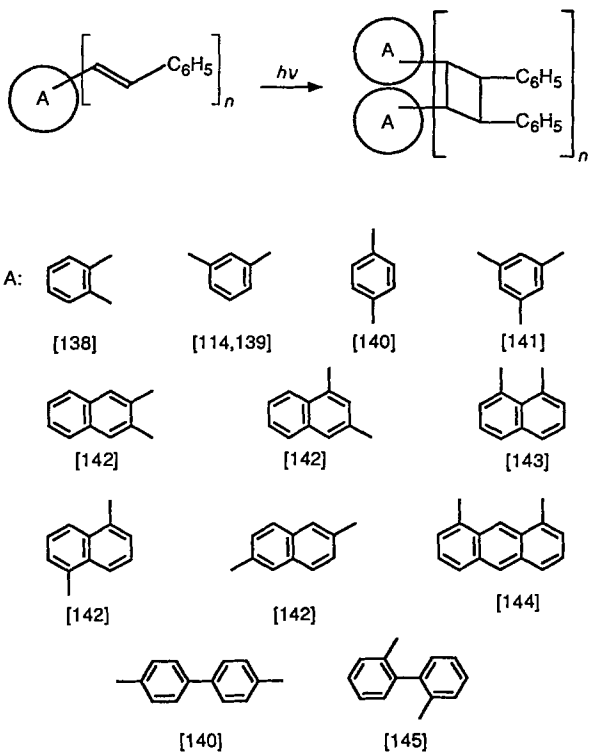
smaller the value of γ, the more efficient the cyclodimerization process. When the triplet energy E_T is 205 kJ mol^{-1}, the singlet energy E_S is 357 kJ mol^{-1}, and c^2 the sum of the products of the HOMO and LUMO orbital coefficients at the reactive centers is 1.55, an extremely favorable value of γ (34 kJ mol^{-1}) is obtained for (*E*)-**1**. For styrene this value is 51 and for a simple alkene about 67 kJ mol^{-1}.[132]

Here one should not forget that efficient monomolecular processes exist for the deactivation of the S_1 state in (*E*)-**1** (see Sections 4.1 and 4.2). Thus the quantum yield for the photocyclodimerization increases with the concentration c of (*E*)-**1**, at the expense of fluorescence and $E \rightarrow Z$ isomerization. For preparative work it is desirable to have $c \geq 0.1$ mol L^{-1}. At small concentrations the dimerization comes to a standstill, as the molecules in the first excited singlet state can no longer meet a dimerization partner by diffusion within their lifetime. Aqueous or alcoholic solutions are exceptions that form stilbene aggregates down to 10^{-6} M and therefore give favorable conditions for dimerization.[133, 134] For example, the distribution of products on irradiating 5.5×10^{-4} M solutions of (*E*)-**1** in benzene and water for 24 hours is summarized in Table 1.[133]

Table 1. The dependence of the product ratio for the irradiation of (*E*)-**1** (24 h, 5.5×10^{-4} M) on solvent.

Solvent	(*E*)-**1**	(*Z*)-**1**	Cyclization	Dimerization
benzene	12	84	4	0
water	33	11	33	22
water /LiCl	27	7	25	42

Addition of lithium chloride affects the water structure in a way that favors dimerization of (*E*)-**1**. On the other hand, β-cyclodextrin or the micelle-forming salt, sodium dodecylsulfate, form hydrophobic cavities which favor a deaggregation of stilbene in water, thereby reducing the dimerization tendency.[133] (*E*)-**1** cannot be dimerized in the crystalline form, since the average distance between two adjacent double bonds is greater than 420 pm.[135] For some substituted stilbenes, however, topochemically controlled cyclodimerizations in the crystalline state are known. For ex-



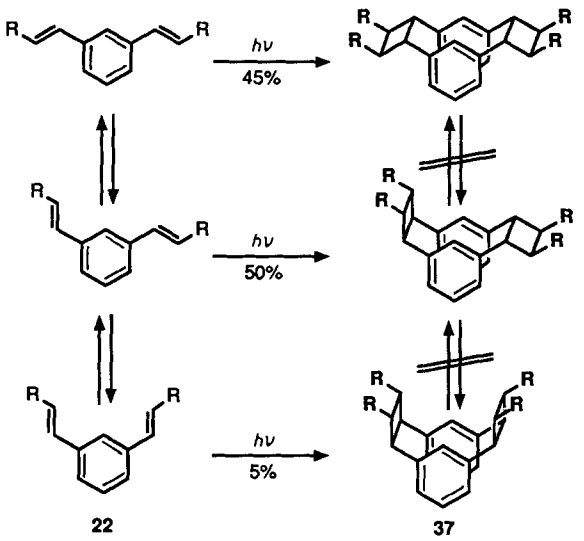
Scheme 7. Formation of cyclophanes through photocyclodimerization. The lines on the arenes mark the positions of the styryl substituents, and the numbers in square brackets the relevant reference.

ample, whereas the photolysis of (*E*)-2,4-dichlorostilbene in solution gives both a head-to-head and a head-to-tail cycloadduct of type **35**, in the solid state one finds an excimer emission band and selective formation of only the head-to-head product.[136]

An extension of the principle of photocyclodimerization to oligostyrylarenes yields special cyclophane systems in which the central arene rings (decks) are linked through four-membered rings (Scheme 7).[137] In concentrated solutions competition from intramolecular cycloaddition reactions is usually negligible. An exception is 2,2'-distyryldiphenyl,[145] in which cyclophane formation is largely suppressed. Moreover, adsorption on silica gel completely alters the photochemistry of for example, 1,2-distyrylbenzene (**21**) in favor of monomolecular processes.[146]

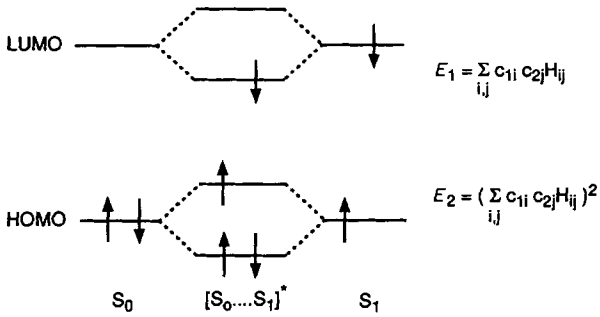
Regiospecific head-to-head cycloadditions are an essential precondition for all dimerizations to cyclophanes of the type shown in Scheme 7. In addition, there is a high degree of stereoselectivity in some cases.[142]

Here again the formation of excimers is a key factor. This is illustrated by the example of the double photocyclodimerization of 1,3-distyrylbenzene (**22**; Scheme 8, R = C_6H_5).[114, 139] This compound can exist as three rotamers; the form shown in Scheme 8, bottom left is the least abundant, owing to its slightly higher steric energy. The three



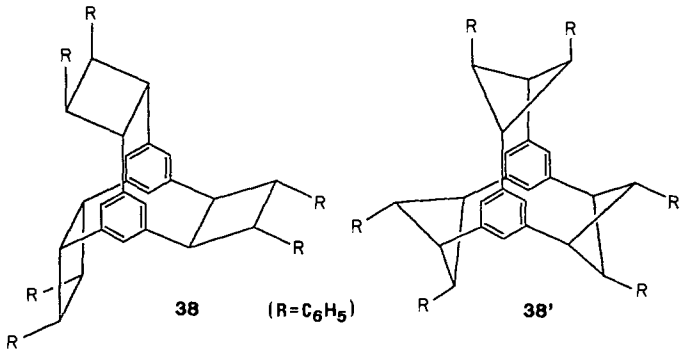
Scheme 8. Formation of three cyclophanes from three rotamers of compound **22**.

rotamers lead to different *syn*-[2.2](1,3)cyclophanes. According to the "NEER" principle (*n*on*e*quilibrium of *e*xcited *r*otamers), the original distribution between the rotamers is preserved in the S_1 state.[147] After the first four-membered ring has been formed, the distribution in the S_0 state might change, but since the steric conditions are similar to those in **22**, the rotamer populations remain essentially unaltered. The thermodynamically unfavorable *syn* stereochemistry becomes fixed by the formation of excimers. The stabilization energies *E* for these complexes, which exist only in the S_1 state, can be estimated from first-order, and/or second-order perturbation theory.[142] The HOMO–HOMO and LUMO–LUMO interactions play a crucial role. The expressions for E_1 and E_2 involve a summation over all the pairs *i,j* of overlapping π centers for molecules 1 and 2 (Scheme 9).



Scheme 9. Frontier orbital interactions for the formation of excimers.

By far the largest stabilization is achieved by the maximal overlap that occurs when the molecules are in a parallel arrangement. *Anti*-[2.2] (1.3)cyclophanes are therefore ruled out. This also serves to explain the head-to-head selectivity. From (*E,E,E*)-1,3,5-tristyrylbenzene (**24**) one obtains exclusively [2.2.2](1,3,5)cyclophane **38**, despite the fact that a triple head-to-tail dimerization would yield the much less strained [3.3.3](1,3,5)cyclophane **38'**.[141] However, for the latter interaction E_1 and E_2 both are zero.



Thus, neither the photocyclization (Section 4.3) nor the photocyclodimerization reactions are controlled by the energy content of the products. Compounds **22** and **24** are category II stilbenoid chromophores; because of the relatively long lifetime of the S_1 state, dimerization can still occur even in dilute solutions ($c \approx 0.5 \times 10^{-3}$ M).

The principle of repeated photocyclodimerizations (oligomerizations) of stilbenoid compounds offers interesting possibilities for building up polymers[148, 149] (see Section 6.2).

5. Stilbenoid Systems in the Triplet State

5.1. Excitation and Physical Deactivation

For stilbene itself and for most stilbenoid compounds the quantum yield for intersystem crossing $S_1 \rightsquigarrow T_1$ is extremely small ($\phi_{ISC} \approx 0.002$).[2e] To populate the T_1 state the energy

transfer requires a triplet sensitizer. However, substituents such as nitro groups, halogens, or aroyl groups can increase ϕ_{ISC}.[150, 151] For example, 4-nitrostilbene in benzene yields 86% of the triplet state for the *E* configuration and 59% for the *Z* configuration.[151, 152] If chlorine or bromine are substituents, ϕ_{ISC} has values between 0.1 and 0.5, and singlet and triplet processes are observed simultaneously.[2c, 2j]

The physical deactivation of the T_1 state in stilbenoid compounds by phosphorescence is so limited that it is difficult to detect; for example, for (*E*)-**1** in ethanol at 77 K, ϕ_P is not greater than 10^{-5}.[153] The heavy atom effect[154] or the restriction of molecular mobility increases the phosphorescence.[153, 155] Nevertheless, even for (*E*)-4-nitrostilbene in ethanol at 77 K, a large majority of the molecules undergoes the transition into the T_1 state, but only about 0.03% subsequently emit phosphorescence radiation (λ_{max} = 614 and 673 nm); the fluorescence quantum yield, $\phi_F = 3 \times 10^{-3}$, is still ten times greater than that for phosphorescence.[153] By far the most efficient process is radiationless deactivation[151, 156] (see Section 5.2). The lifetime of the triplet state under these conditions is around 10 ms; deuterium substitution increases the lifetime,[156] whereas bromine and other heavy atoms reduce it.[153]

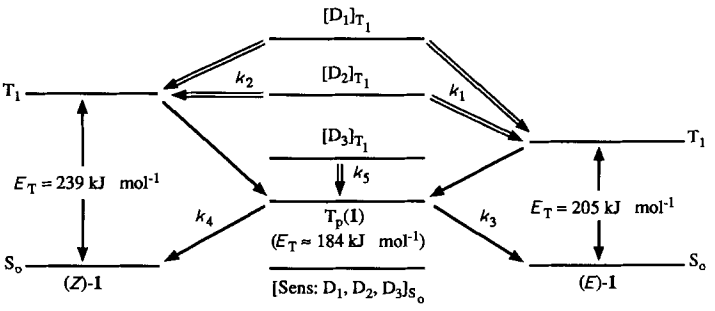
5.2. Sensitized *Z*/*E* Isomerization

The pioneering studies on triplet-sensitized *Z*/*E* isomerization in stilbenes were carried out in the 1960s by Hammond et al.[157] The sensitizers (donors) D_1 with triplet energies E_T of at least 255 kJ mol^{-1} transfer their energy to (*E*)-**1** and (*Z*)-**1** in a diffusion-controlled process. The model in Scheme 10 proceeds from an initial donor–acceptor collision complex, which generates T_1 states without change of spin (corresponding to vertical transitions, which retain the ground state geometry). From the triplet state $[(E)\text{-}\mathbf{1}]_T$, a relaxation process takes place on the T_1 potential energy surface, leading to a state T_P, which represents a molecule twisted through 90° (formerly called a "phantom triplet").[157] The ground state energy surface S_0 should intersect or touch the T_1 hypersurface in the immediate vicinity of T_P, so that a transition to $[(Z)\text{-}\mathbf{1}]S_0$ or $[(E)\text{-}\mathbf{1}]S_0$ can occur (see Fig. 8).[34, 158] The exact form of the potential surface is not known with certainty. The $[(E)\text{-}\mathbf{1}]_T$ and T_P states are relatively close together in energy, and consequently the order of these can alter, and different equilibria can become established depending on the solvent.[158] When the *E* configuration approaches the geometry of T_P, one can assume a small activation threshold; this is less likely to occur on the *Z* side of the reaction profile. Unlike $[(Z)\text{-}\mathbf{1}]_T$, T_P can transfer its triplet energy to an acceptor.[24, 159] The mean lifetime of T_P at room temperature is about 60 ns.[159, 160]

The photostationary equilibrium of the triplet-sensitized reaction can be described by Equation (c). For a high sen-

$$\frac{[(Z)\text{-}\mathbf{1}]}{[(E)\text{-}\mathbf{1}]} = \frac{k_1}{k_2} \cdot \frac{k_4}{k_3} \qquad (c)$$

sitizer energy, one has $k_1 \approx k_2$, and the value of $k_4/k_3 = \phi_{E\to Z}/\phi_{Z\to E}$ is also approximately 1, resulting in equilibria with 50–60% of the *Z* isomer. For the benzophenone-sensi-



Scheme 10. Model for the energy transfer from donors D_1, D_2, and D_3 to stilbene 1 in the sensitized *Z*/*E* isomerization. Sens = sensitizer.

tized reaction (E_T = 289 kJ mol^{-1}) the quantum yields are $\phi_{Z\to E} = 0.41$ and $\phi_{E\to Z} = 0.55$, resulting in a ratio $[(Z)\text{-}\mathbf{1}]/[(E)\text{-}\mathbf{1}] = 58:42$. The sum of the quantum yields is 0.96, which is very close to 1, suggesting that a common intermediate (T_P) is involved. If the triplet energy of the donor is reduced to 239 kJ mol^{-1}, the same as the triplet energy of (*Z*)-**1** the transfer to the **Z** configuration is considerably slowed down by a small activation barrier. However, in this case (sensitizer D_2) an efficient energy transfer to $[(E)\text{-}\mathbf{1}]_T$ still takes place. In the formula for the photostationary equilibrium state the important term is the ratio k_1/k_2, and the *Z* fraction is increased. If one has a sensitizer D_3 with a triplet energy E_T (equal to that of (*E*)-**1**) of 205 kJ mol^{-1} or less, the energy transfer to $[(E)\text{-}\mathbf{1}]_T$ should also cease. In fact, however, an energy transfer is still observed even in this situation, although it is less efficient.[157, 158] As Figure 10 shows, the *E* fraction in the photostationary equilibrium then increases again. A likely explanation is that there is a nonvertical ener-

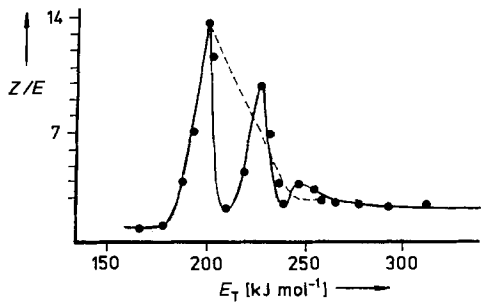


Fig. 10. Photostationary *Z*/*E* equilibrium for the isomerization of stilbene (**1**) with triplet sensitizers of different energies *E*, [157]. The dashed line shows the theoretical curve expected for a diffusion-controlled energy transfer involving spectroscopic states.

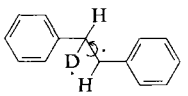
gy transfer process with the formation of T_P ($E \simeq$ 184 kJ mol^{-1});[160] such a process has smaller activation enthalpy on the (*Z*) side (and a slightly more negative activation entropy).[158] The question then arises whether, in principle, an energy transfer with formation of T_P can also occur for D_1 and D_2.[158] Other models involving vibrationally excited molecules[161] or triplet exciplexes[1a] have also been proposed as alternatives to the nonvertical energy transfer. Balzani, Orlandi, et al. have discussed this problem from both the classical and quantum-mechanical standpoints.[162] Derivations from the theoretical curve shown in Figure 10 indicate that, leaving aside differences in the methods used to

determine the data, steric effects too can have an important influence on the energy transfer process. An interesting example of this is again provided by **27**. In contrast to the direct photolysis situation, in the benzophenone-sensitized reaction the quantum yields for the isomerization (*E,E*)-**27** → (*Z,E*)-**27** are small on the sterically hindered side ($\phi = 0.026$) and large on the other side ($\phi = 0.49$). The quasi-stationary equilibrium state has the ratios[93] (*E,E*):(*Z,E*):(*E,Z*):(*Z,Z*) = 39:8:44:9. In 1,4-distyrylbenzene (**2**), the extended conjugation leads to a very low efficiency for the $E \rightarrow Z$ isomerization in the S_1 state (see Section 4.2), whereas the benzophenone-sensitized reaction has a quantum yield of 53%.[95] Triplet-sensitized *E–Z* isomerization is of particular synthetic interest in cases where direct photolysis fails. For preparative purposes one can also use polymer-bound sensitizers[163] or sensitizers which favor the *E* isomer.[164] To end this section it should be mentioned that sensitized *Z/E* isomerization can also be achieved by means of an electron transfer process [Equation (d)]. Here, of

$$[D]_{S_1} \xrightarrow{+A} [D^{\bullet+}A^{\bullet-}]_{S_1} \xrightarrow{ISC} [D^{\bullet+}A^{\bullet-}]_{T_1} \xrightarrow[-D]{} [A]_{T_1} \longrightarrow \cdots \qquad \text{(d)}$$

course, *Z/E* isomerization can, in principle, also occur at the stages where one has radical pairs or charge-transfer stabilized exciplexes. This leads into the topic of photocatalysis. Thirty years ago such mechanisms were discussed by Schenck et al.[165] If a donor D (or an acceptor) forms a σ bond to the stilbene system, rotation about the formerly olefinic bond is possible (Scheme 11). In the singlet case this process is similar to catalysis by iodine.



Scheme 11. A *Z/E* isomerization at the radical ion pair stage can lead to rotation about the former double bond.

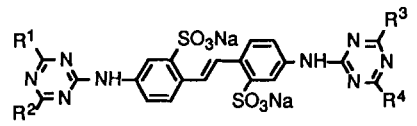
6. Applications in Materials Science

Stilbenoid systems and light is a many-faceted topic in materials science, and has grown rapidly in importance in the last few years. Some of the most important applications, which are either already technological realities or show potential are optical brighteners, laser dyes, scintillators, light-emitting diodes, optical switching, optical data storage, photopolymerization, photochemical crosslinking, photoinitiators, photoresists, photoconductors, and nonlinear optics.

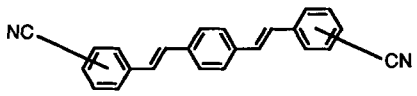
In this review the emphasis will be on recent developments, and an attempt will be made to illustrate the link between the photophysics and photochemistry of stilbenoid compounds and the technology.

6.1. Utilization of Light Emission

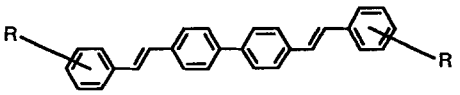
The high quantum yield of fluorescence of many stilbenoid compounds led to their early introduction as optical brighteners. The first successful products of this kind appeared on the market during the 1940s under the trade name Blankophor®; these products (**39**) were derivatives of 4,4′-diaminostilbene-2,2′-disulfonic acid.[166] Incorporating heterocyclic rings such as 1,3,5-triazines, 1,2,3-triazoles, or benzoxazoles improves their fluorescence properties; nevertheless, the resulting products are different from fluorescent dyes in which the chromophores themselves are entirely heterocyclic. Optical brighteners based on **39** continue to play a major role in industrial processes, but there are also other technologically interesting products such as **40** and **41**, based on the stilbenoid structures (*E,E*)-1,4-distyrylbenzene and (*E,E*)-4,4′-distyrylbiphenyl.[167] The common physical characteristics of compounds **39**–**41** are a strong UUV/VIS absorption with a maximum between 350 and 375 nm and an intense fluorescence band (ϕ_F of nearly 1) in the range from 415 to 445 nm. Thus the absorbed UV radiation is converted to light in the violet to blue-green region, compensating for the yellow cast of many textiles, papers, plastics, etc. To overcome the blue deficiency of these materials it is also important that both the absorption band and the fluorescence band fall off steeply on the longer wavelength side.



39(R^i = NHR′, NR_2', OR′ ...)



40

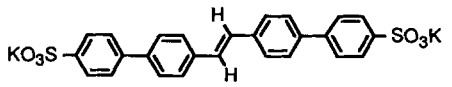


41(R = SO_3Na, OCH_3, Cl)

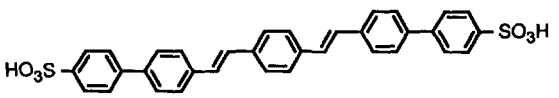
The closer ϕ_F is to 1, the less likely is it that the S_1 or T_1 states will lead to unwanted photoreactions. Of these, the one that must be considered most seriously is the isomerization of the *E* isomer to the nonfluorescent *Z* isomer. In the compounds **39**–**41**, however, the quantum yield for the $E \rightarrow Z$ isomerization is small, especially in the absorbed state (see Section 4.2). In this case the nature of the interaction with the support, which can extend from simple contact to covalent bonding, is very important.[168, 169] Another unwanted reaction could occur when singlet oxygen, which is extremely reactive, is generated; depending on the nature of the substituents, stilbene-based optical brighteners can sometimes function as sensitizers or quenchers for singlet oxygen.[168]

The good fluorescence properties of stilbenoid compounds also make them interesting as scintillators[170, 171] and laser dyes.[172] Continuous dye lasers were developed in 1970 by Peterson, Tuccio, and Snavely.[173] Because of their tunability, dye lasers are now found in a very wide variety of

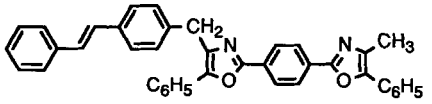
applications. They can also be used to generate extremely short pulses—less than 30 fs.[174] The electronic excitation of the dissolved fluorescent dye, known as optical pumping, is achieved by means of a flash tube or gas laser; very often an excimer laser (based on xenon chloride or krypton fluoride) is employed. A typical fluorescent dye of the stilbenoid type is **42**, generally known as stilbene-1.



42



43



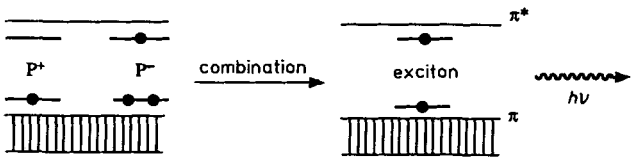
44

When an argon ion laser is used as the excitation source, the tunable wavelength range extends from 395 to 435 nm in the violet.[175] The typical dye laser is a four-level laser. The excitation of the fluorescent dye from the ground state to a vibrational level of the S_1 state ($S_0 \rightarrow S_1^v$) is followed by relaxation into the lowest vibrational level of S_1, from which spontaneous and stimulated emission of the fluorescence radiation occurs ($S_1 \rightarrow S_0^v$). The relaxation to the lowest vibrational level of S_0 occurs very rapidly; thus, only a low population in the S_1 state is necessary for the population inversion on which the laser action depends. An important criterion for suitability as a laser dye is a high fluorescence quantum yield; it is therefore appropriate to carry out tests on the stilbenoid compounds developed as optical brighteners, to assess their suitability as laser dyes.[176-178] Such experiments are usually confined to the violet to blue spectral emission region. A serious disadvantage is the tendency of the dyes to fade,[175] caused by the conversion of stilbenes from the *E* configuration to the nonfluorescent *Z* configuration, which then undergoes secondary photoreactions.[179, 180] the partial quantum yields in the range $313 \leq \lambda \leq 365$ for **42** in oxygen containing ethylene glycol are given in Equation (e).

$$(E)\text{-}\mathbf{42} \underset{\phi = 0.5}{\overset{\phi = 0.016}{\underset{h\nu}{\rightleftharpoons}}} (Z)\text{-}\mathbf{42} \xrightarrow[\phi = 0.0001]{h\nu} \text{secondary products} \quad \text{(e)}$$

Using a laser dye based on 1,4-distyrylbenzene as the chromophore suppresses the $(E) \rightarrow (Z)$ isomerization. For **43** the value of $\phi_{E \rightarrow Z}$ is only 1×10^{-5}, and the proportion of the *Z* isomer in the photostationary equilibrium is reduced to 4%.[179] Stilbenes are also employed for a quite different purpose in laser dye technology, as triplet quenchers, since significant competition from the intersystem crossing process $S_1 \rightsquigarrow T_1$ would reduce the fluorescence yield. A better alternative to mixing a triplet quencher with the dye is to attach it to the dye by covalent, nonconjugative bonding. The first successful application of this principle was realized in the bisoxazole laser dye **44**.[181]

Another way of achieving light emission with stilbenoid compounds of high molecular mass is electroluminescence. Poly(arylenevinylene)s with opposite charge carriers can form excitons, which dissipate their energy by light emission, as shown in Scheme 12.[182-184] The interaction of positive



Scheme 12. The formation of excitons, which lose energy by emission of light. P^+,P^- are polarons.

and negative polarons P causes a splitting of the energy levels in the band gap, with the result that the doubly occupied level falls back into the π band, whereas the empty level is raised to π*. A material for use in a light-emitting diode should have ionization potential and electron affinity values that ensure balanced flows of positive and negative charge carriers from the attached electrodes. Also both types of charge carriers must be able to travel far enough in the material to allow the formation of excitons. The fluorescence process responsible for the electroluminescence competes with multiphonon emission (internal conversion), the formation of triplet states (intersystem crossing), exciton–exciton annihilation, and lastly exciton–polaron and exciton–bipolaron interactions. Bipolarons are very efficient "catalysts" for the radiationless decay of excitons.[183] The yield of emitted photons per transferred electron is usually small. However, in a remarkable experiment[183] the photon yield for a PPV copolymer was increased from 0.01% to 0.3% by incorporating about 10% of 2,5-dimethoxy-*p*-phenylenevinylene units into the chain. The homopolymer of the dimethoxy compound has a band gap of about 2.1 eV, which is 0.3–0.4 eV smaller than that of PPV, but its photoluminescence is much lower. Its incorporation into the copolymer in the optimal proportion of 10% produces local energy sinks in the chain, which act as "exciton traps", resulting in an enhanced radiation emission.[183] Using calcium instead of aluminum as the electrode material can even increase the efficiency to more than 1%.[184]

6.2. Utilization of Photochemical Transformations

Whereas reactions stimulated by light are a nuisance in the materials applications discussed in Section 6.1, photochemical processes in stilbenoid compounds provide the basis for the materials and effects described in this section. A new field of study concerns the effects of light on liquid crystalline (LC) systems containing stilbene chromophores, which are calamitic or discotic mesogens.[185-187] One can easily envisage that highly ordered smectic or nematic phases may be modified by $E \rightarrow Z$ isomerization, cyclodimerization, or polymerization to such an extent that the mesophases under-

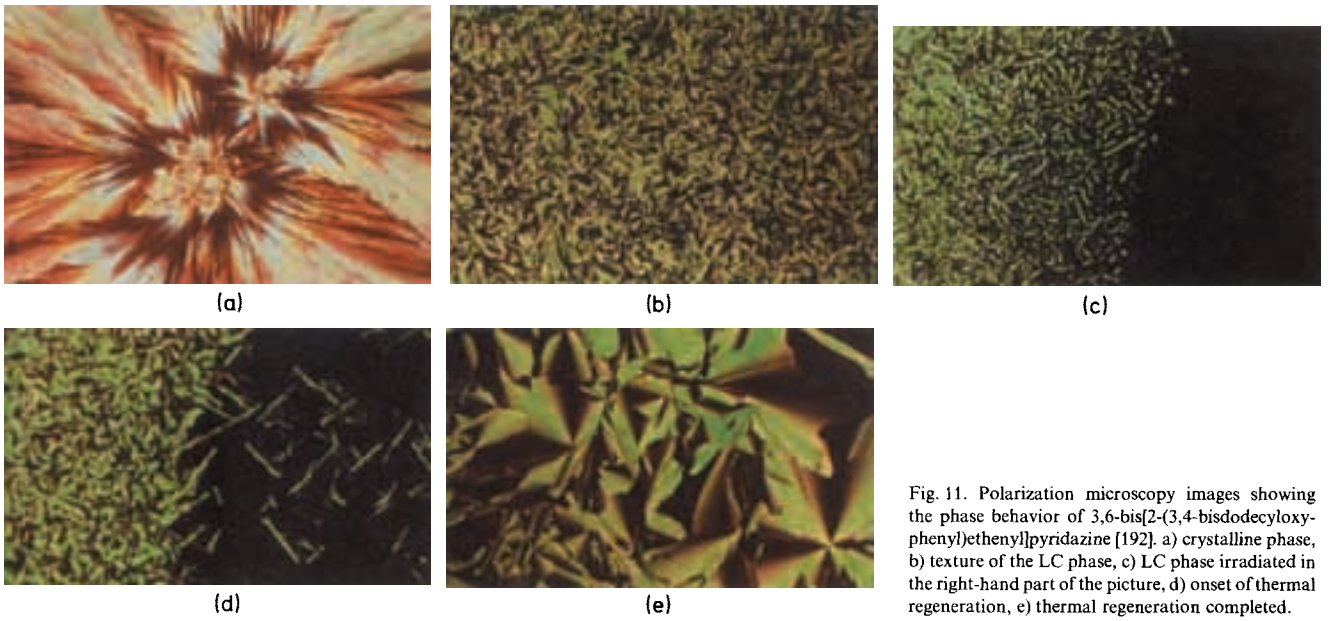


Fig. 11. Polarization microscopy images showing the phase behavior of 3,6-bis[2-(3,4-bisdodecyloxyphenyl)ethenyl]pyridazine [192]. a) crystalline phase, b) texture of the LC phase, c) LC phase irradiated in the right-hand part of the picture, d) onset of thermal regeneration, e) thermal regeneration completed.

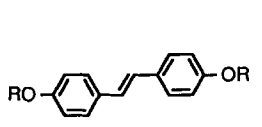
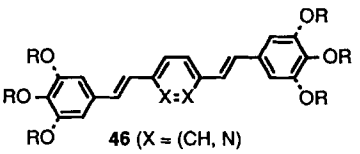
go a transition to the isotropic melt phase well below the original clearing point. Here a distinction must be made between reversible and irreversible processes. Based on the change in the optical properties which accompanies the phase transformations, these effects find application on the one hand in optical switches, and on the other hand in permanent optical data storage. As the following examples show, liquid crystalline phases are observed in a wide variety of stilbenoid compounds.

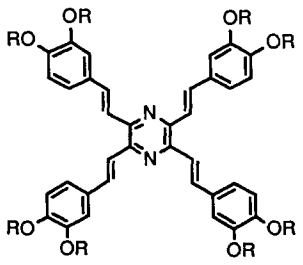
(*E*)-stilbenes such as **45** with *p*-alkoxy substituents were among the earliest LC systems described in the literature;[188] to these have since been added many other stilbene derivatives containing alkyl, alkylamino, and ester groups,



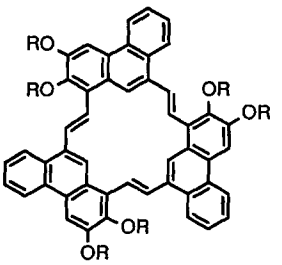
45



46 (X = (CH, N)



47

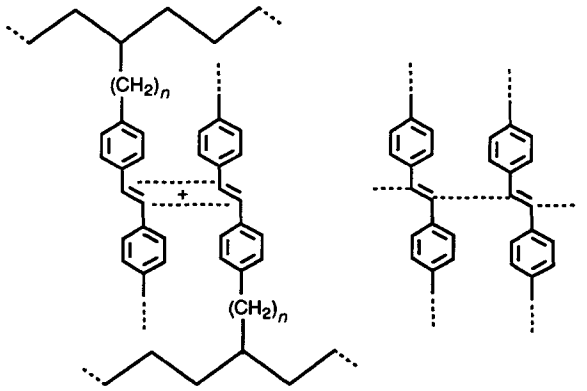


48

and also push–pull compounds containing nitro groups.[189] If one increases the length of the rod-shaped mesogen, as in the compounds **46**, then in addition to *p*-substitution one can have long-chain alkoxy substituents at one or even both of the *meta* positions.[185, 191] The calamitic systems are then transformed into phasmidic systems.[190] The compounds **47** and **48** are new types of discotic mesogens.[12, 191] Figure 11 illustrates a reversible breakdown of a liquid crystalline phase under UV illumination.[192]

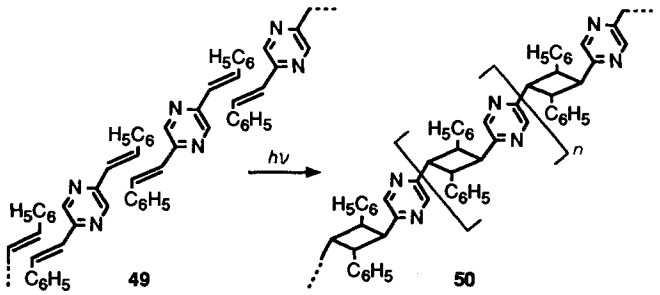
Only a very small degree of conversion is sufficient to break down the LC phases; the photocyclodimerizations and photopolymerizations are irreversible processes, the $E \rightarrow Z$ transformation is reversible. In highly viscous LC phases, isomerizations of the stilbenoid compounds can only take place with difficulty compared with experiments in solution; on the other hand, the high degree of ordering in these phases favors dimerizations. However, these are limited to the formation of only one four-membered ring. We have not so far found any examples of cyclophanes in LC phases of stilbenoid compounds (see Section 4.4). Since the S_1 state is expected always to result in a higher proportion of irreversible reactions, research activity is tending to concentrate more on triplet sensitization. The aim is to develop a multicomponent system consisting of a stilbenoid mesogen/chromophore, a triplet sensitizer absorbing at long wavelengths, and a catalyst for the thermal back reaction ($Z \rightarrow E$ isomerization). The cyclization of stilbene units (Section 4.3) should also be of interest in this area of materials science, if liquid crystals based on helicene structures can be prepared. Finally, stilbene units can be incorporated into the backbone or side chains of polymers,[193] which creates materials with light-sensitive LC phases.

This topic leads into the general principle of photo-crosslinking of polymers through stilbene units (Scheme 13).[194] The basis of a negative photoresist is a soluble polymer that becomes insoluble as a result of crosslinking. Although it has often been postulated that photopolymerization of stilbenoid systems in solution involves the formation of four-membered rings, our experience indicates that the dominant mechanism is usually a free radical chain reaction, leading to polymers with little structural uniformity. Hasegawa et al.[148] recognized a considerable time ago that a repeated photocyclodimerization in the solid state could be an interesting principle for building polymers.[149] Here again the topochemically controlled reaction is associated with a fa-



Scheme 13. Photo-crosslinking of polymers through stilbene units.

vorable arrangement of the C=C bonds in the crystal lattice (see Section 4.4); however, lattice defects can play an important role in the progress of the reaction. For example, whereas (*E,E*)-1,4-distyrylbenzene (**2**) is photostable in the crystalline phase, the aza analogues (*E,E*)-1,4-bis[2-(2-pyridyl)-ethyl]benzene[195] and (*E,E*)-2,5-distyrylpyrazine (**49**) form photopolymers such as **50**.[148]



6.3. Other Electrical, Optical, and Optoelectronic Applications

This last section will review some applications of stilbenoid compounds in materials technology in situations where neither photochemical transformations nor light emission are desired. It was originally thought that polymers of high structural purity with fully conjugated chains would be electrical conductors.[196] Using poly(1,4-phenylenevinylene) (**4**) as example Hörhold and Opfermann[197] were able to show that, in fact, these polymers were semiconductors of high resistivity, with a relatively large band gap of about 2.4 eV. Oxidative or reductive doping was found to increase the conductivity σ from less than 10^{-15} S cm^{-1} by many orders of magnitude—in extreme cases even up to 3×10^3 S cm^{-1}.[17] In the context of this article the photoconductivity of undoped poly(arylenevinylenes) is of particular importance. With direct illumination or triplet-sensitization, remarkably high values of the photocurrent I have been measured. The dependence $I(\lambda)$ of intensity on wavelength observed on irradiating unsensitized PPV films is very similar to the absorption curve. The maxima of the two curves are close together in the visible region, at wavelengths between 400 and 600 nm depending on substitution. Figure 12 shows typical capacitor discharge curves measured in the dark and with illumination, together with results on the sensitivity as a function of wavelength.

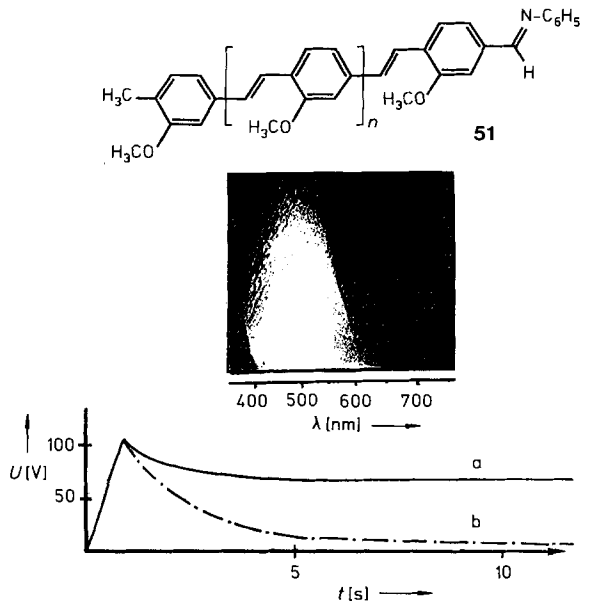


Fig. 12. Measurement of the photoconductivity of the PPV system **51** in a dispersed film, showing the decay of the voltage $U(t)$ and the sensitivity as a function of wavelength. a) In the dark; b) on irradiation.

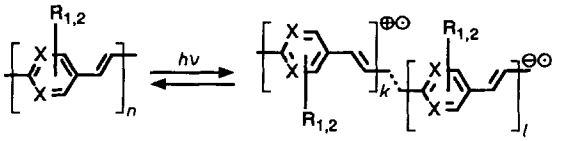
The photoconductivity in PPV can be explained by assuming a light-induced disproportionation into radical ion pairs.[17] The short-lived charge carriers that are generated in this way according to the effectively conjugated chain segments (ECS) theory[17] are undoubtedly augmented at the electrodes by radical ions produced by transfer of charge onto electronically excited particles. The details of the mechanism of conduction are not fully understood; the fast transfer of the charge can be explained by an almost activationless transport in the chain and electron-hopping processes between chains. Mechanistic studies[198a] and synthetic efforts in which the polymer structure **52** is subjected to wide variation[198] should contribute to a better understanding of these effects. Alkoxy groups R in **52** not only reduce the band gap,



52 (X = CH,N; R = OCH_3,...,$OC_{16}H_{33}$)

but also influence the arrangement of the chains in such a way that when the convergence limit for n (see Section 4.1) is exceeded, the photoconductivity passes through a maximum as the length of the side chains is increased. The efficiency of the light-induced ion formation is reduced by the fluorescence of **52**, but is even more drastically affected by photochemical processes. When monochromatic light (λ = 436 nm) in the region of the longer wavelength absorption maximum

($\lambda_{max} \approx 450$ nm) is used for irradiation, ion formation competes with fluorescence ($\phi_F \approx 0.2$), but even when the irradiation is continued for several months no photochemical change in the material is detected. The mean lifetime of the excited state is too short for cyclodimerization to occur (see Section 4.4), and $E \rightarrow Z$ isomerization does not take place, since for $n \leq 3$ the isomerizations proceed in only one direction, $Z \rightarrow E$ (see Section 4.2). If instead the irradiating light is in the short-wave UV region ($\lambda = 254$ nm), **52** is converted relatively quickly into nonconjugated oligomers with $\lambda_{max} \approx 270$ nm; at the same time the photoconductivity disappears.[198] The application of such materials in electrophotographic recording depends essentially on the photostability, and also on the resistance to atmospheric oxygen and bonding agents.

Another highly topical investigation of stilbenoid compounds in materials technology is in connection with nonlinear optical properties. Due to the electric field component of light waves, molecules become polarized. In the case of linear optical behavior the induced dipoles emit radiation of the same frequency. The polarization P is then proportional to the field strength E, which corresponds to the model of a harmonic oscillator. In the anharmonic oscillator model, which is a closer approximation to reality at very high light intensities, P still increases monotonically with E, but no longer linearly [Eq. (f)]. Here, in addition to the linear polar-

$$P = \alpha E + \beta EE + \gamma EEE + \ldots \qquad \text{(f)}$$

izability α, we have the tensors β and γ representing the second- and third-order polarizabilities, the so-called hyperpolarizabilities. In this case, whereas the function describing the E vector of the incoming light waves is sinusoidal, the polarization is nonsinusoidal. The Fourier analysis of the periodic function of the polarization yields a series of sinusoidal components $P(n\omega)$ with $n = 0,1,2,3\ldots$. In addition to the static component $P(0)$, which describes the optical rectification effect, and the fundamental wave $P(\omega)$, we obtain $P(2\omega)$ (second harmonic generation, SHG) and $P(3\omega)$ (third

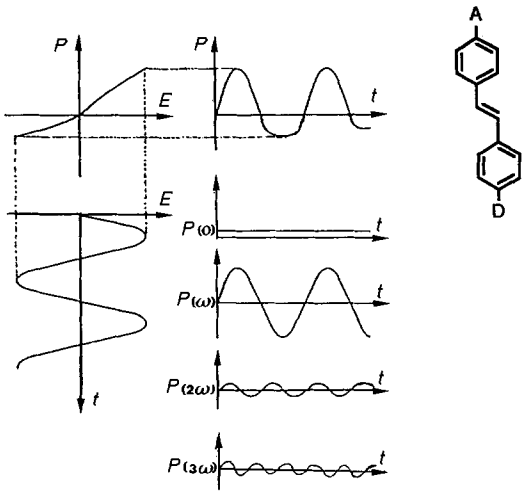


Fig. 13. Polarization $P(t)$ of a stilbene system by the oscillating electric field component $E(t)$ of a light wave, and its resolution into the Fourier components $P(0)$, $P(\omega)$, $P(2\omega)$, and $P(3\omega)$.

harmonic generation, THG).[199] Translating this to the macroscopic level gives Eq. (g). Thus, in addition to the

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE \qquad \text{(g)}$$

linear susceptibility $\chi^{(1)}$, the materials considered here have the nonlinear susceptibilities $\chi^{(2)}$ and $\chi^{(3)}$.[200] These relationships are illustrated in Figure 13 for a stilbene derivative that is assumed to be oriented so that the light wave produces the greatest polarization in the direction of the substituents; the substituents themselves constitute a donor-acceptor pair, as in the canonical structures **53**. The charge transfer band for

53

such a molecule is polarized in the direction of the longest axis. Although in the ground state the dipolar canonical structure is only of minor significance, in the electronically excited singlet state the dipole moment is considerably greater (see Section 4.1). If the stilbene had identical substituents in the 4 and 4′ positions, the molecule would have C_{2h} symmetry with a center of inversion as a symmetry element. For centrosymmetric molecules, $P(E)$ and $P(-E)$ must be equal, which means that in the power series for P the terms with even-numbered exponents are zero. From the condition $\beta E^2 = 0$ it follows that $\beta = 0$. In the monocrystalline form the arrangement of the molecules can still be centrosymmetric even though the individual molecule is not itself centrosymmetric; this means that we can have $\chi^{(2)} = 0$ with $\beta \neq 0$. Push-pull compounds have a tendency to form crystalline arrangements of this kind, and therefore a common procedure is to embed such a chromophore in a polymer matrix and polarize by applying an electric field. For materials technology applications a system with a high quadratic hyperpolarizability is needed, and one therefore aims for noncentrosymmetric structures in which charge transfer transitions can take place at low energies. (*E*)-stilbene derivatives are especially suitable in this respect.[201] As λ_{max} for the electronic transition at longer wavelength increases, β also increases. Plotting log β against log λ_{max} gives a line whose gradient is greater than that for analogous benzene derivatives.[202] Although (*E*)-4-methoxy-3-methyl-4′-nitrostilbene only has a moderately high β-value of $18-26 \times 10^{-30}$ esu (at $\lambda = 1064$ nm), the SHG value for this compound in powder form is very high; it is 1250 times greater than the value for urea [$\chi^{(2)} = (3.4 \pm 1) \times 10^{-9}$ esu], which is often used as a standard.[202, 203] The relevant range of $\chi^{(2)}$ values for organic compounds extends from 10^{-9} to about 10^{-5} esu. Stilbazolium systems are at the upper end of this scale. Instead of using the host–guest relationship of polymers with chromophores having nonlinear optical (NLO) properties, as described earlier, the NLO-active compounds may be directly incorporated into systems that can be photochemically polymerized and crosslinked. In this way one can achieve a high concentration of the NLO-active component.[204] Another interesting development is the production of NLO-active compounds that form thermotropic liquid crystals.[205]

In contrast to compounds with second-order optical nonlinearity, third-order NLO-active systems demand fewer structural preconditions, because the symmetry criterion no longer applies. Unsubstituted (*E*)-stilbene has γ values (THG coefficients) of 27 and 18×10^{-36} esu at $\lambda = 1064$ and 1907 nm respectively.[206] The most promising of the stilbenoid systems are the poly(phenylenevinylene)s in which the largest component of the γ tensor lies in the direction of the extended conjugation. Stretched polymers of this type with chains aligned parallel to each other should give particularly large $\chi^{(3)}$ values. This has been confirmed in studies of the anisotropic behavior.[207] For a uniaxially stretched PPV film the $\chi^{(3)}$ value measured in the stretching direction was 1.2×10^{-9} esu (at $\lambda = 602$ nm).[208] For the 2,5-dimethoxy derivative, which has a smaller band gap, a four-wave mixing experiment in the subpicosecond region yielded, at the same wavelength, $\chi^{(3)} = 4 \times 10^{-9}$ esu.[209] For unorientated PPV films a $\chi^{(3)}$ value of $(1.5 \pm 0.6) \times 10^{-10}$ esu was observed at $\lambda = 1064$ nm.[210] The high light intensities generated by the lasers that are used make high demands on the photostability of the NLO materials. Where possible the direct resonance condition is avoided, and resonance with two-photon transitions should also be excluded.

7. Outlook

Stilbenoid compounds will undoubtedly continue to be a central topic in photochemistry in the future. From the theoretical physicochemical standpoint, flash spectroscopy extending into the femtosecond region is expected to yield further knowledge about the nature of the reactive species along the reaction coordinates followed on light absorption or energy transfer. This will provide new impetus and ideas for synthesis and matrials technology, making it possible to refine ways of either eliminating unwanted radiation effects or increasing the efficiency of the desired photoreactions, depending on the type of application. The road from new substances with interesting properties to fully developed technological materials is often long and arduous. Stilbenes, which are already being used very successfully in a number of industrial sectors, are now making progress on a still wider front.

Cubanes: Starting Materials for the Chemistry of the 1990s and the New Century

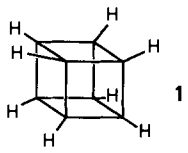
By Philip E. Eaton*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

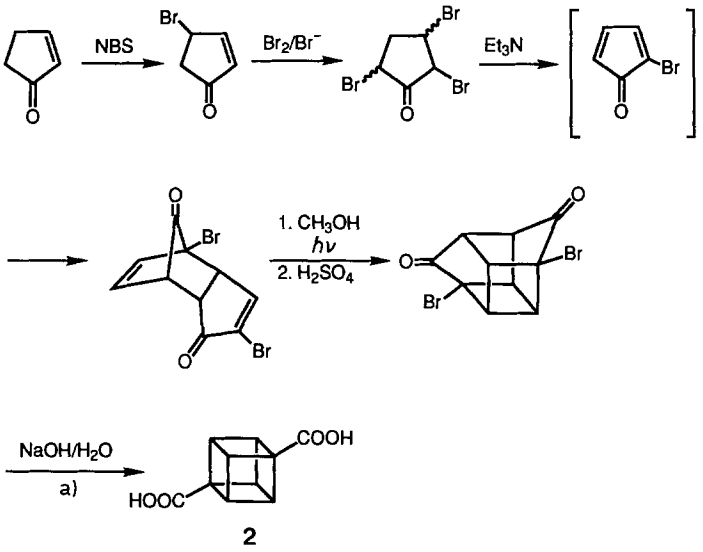
The study of non-natural products has led to a broad understanding of bonding and reactivity in organic chemistry. Many times, compounds thought impossible have been realized in the course of such studies. Cubane, a landmark in the world of "impossible" compounds, has been found to have a rich chemistry, full of the unexpected. The recent renaissance of cubane chemistry, triggered by potential applications of the system to the production of high-energy fuels and the like, has led to many discoveries including the first methods for systematic substitution on strained, saturated systems and a new process for the metalation of arenes, *ortho* magnesiation. Reactive intermediates with exceptional bonding parameters have been uncovered and characterized including 1(9)-homocubene, the most twisted olefin; cubene, the most pyramidalized olefin; cubyl cation, once the "least likely" cation; cubylmethyl radical, a saturated radical that rearranges on the picosecond timescale; and many other extraordinary species. There is certainly good reason to believe that future work in the cubane arena will be at least as productive (probably more so), and that it will help develop a deeper understanding of chemistry.

1. Introduction

Cubane **1** is immensely strained; the geometry at each carbon atom is far from tetrahedral. Originally there was doubt that the skeleton could even hold together.[1] Only later was it appreciated that no kinetically viable paths exist for the thermal rearrangement of cubane. On one hand, orbital symmetry considerations show that the energy of concerted two-bond ring-opening reactions is very high.[2a, b] On the other, there is little to be gained by breaking just one bond, as the concomitant change in geometry is small, and the resulting biradical is still very strained.[2c]



1



2

Scheme 1. The first entry into the cubane system. a) Reflux. NBS = *N*-bromosuccinimide.

2. Entry into the Cubane System

In 1964, at The University of Chicago, Tom Cole and I achieved the first synthesis of the cubane system (Scheme 1).[3] The Favorskii rearrangements (semibenzilic mechanism) by which the bishomocubane system is contracted were the critically important steps. This is true to this day for most cubane syntheses; all but two depend on this reaction.[4]

Even in retrospect, the whole sequence is really rather good, although the early part of the procedure requires the preparation of 4-bromocyclopentenone, a tricky matter. A few years after the original synthesis was published, N. B. Chapman et al. in England,[4c, 5] following up on my work with Hudson on bromocyclopentadienone ketals,[6] found that the ethylene ketal of 2-bromocyclopentadienone could be made easily and undergoes spontaneous dimerization. From this discovery the cubane synthesis ultimately evolved into a simple five-step process providing cubane-1,4-dicarboxylic acid **2** in about 25% overall yield (Scheme 2).

2.1. Availability of Cubanes

The synthesis of **2** has been scaled up and is conducted in small pilot plants by Fluorochem in California and EniChem Synthesis in Milan. Cubane-1,4-dicarboxylic acid is being

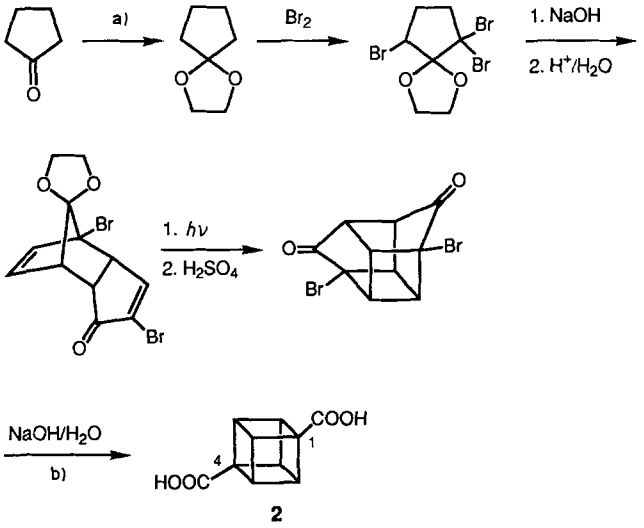
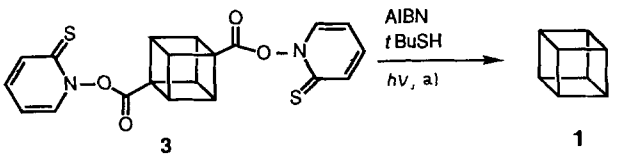


Scheme 2. The best synthetic route known for the cubane system. a) Glycol, H^+; b) reflux.

made in multi-kilogram batches! Nonetheless, as is often the case with experimental compounds, cubane **1** and its derivatives are still expensive to purchase. Fortunately, any good student, having gone through the procedure once to become familiar with its details, can easily make 10 grams of **2** in a month or so. It is a very satisfying procedure and an excellent way to introduce students to the delights of distillation and the thrill of crystallization. It is unfortunate that in today's academic synthesis laboratories these joys are often missed.

2.2. The Hydrocarbon

The original method for the decarboxylation of cubanedicarboxylic acid **2** to provide the pure hydrocarbon itself proceeded via the *tert*-butyl perester.[3] The present method is much superior. Following from the lovely work of Derek Barton et al.,[7] we now use the radical-induced decomposition of diester **3**, which is prepared simply from **2**. Cubane, the hydrocarbon, is thus obtained easily on a 10-gram scale



Scheme 3. The decomposition of **3** provides **1** in good yields. a) Reaction in THF at reflux; irradiation (tungsten filament).

in very nearly quantitative yield. It is beautifully crystalline; alas, the crystals are rhombohedral, not cubic.

3. Physical Properties

Because of its exceptional structure, strain, and symmetry, cubane is a benchmark in organic chemistry. Cubane has been studied extensively, and much concerning its properties has been published.[8] A few physical parameters are given in Table 1.

Table 1. Selected data for cubane.

C–C distance	1.5727 ± 0.0019 Å [a]	Boiling point	≈133 °C
C–H distance	1.118 ± 0.008 Å	Melting point	130–131 °C
Color	transparent [b]	Solubility	≈18 wt% (hexane)
Toxicity	nontoxic	Heat of formation [d]	+144 kcal mol^{-1}
Stability	inert to light, water, air		(+159 kcal mol^{-1})
Decomposition	>220 °C [c]	Strain energy [d]	166 kcal mol^{-1}
Density	1.29 g cm^{-3}		(181 kcal mol^{-1})
Vapor pressure	1.1 mm (25 °C)		

[a] Old value 1.551 Å. [b] To below 200 nm. [c] Very slow. [d] Values not in parentheses from Margrave et al. [12]; values in parentheses from Domalski et al. [13].

The bond lengths given in Table 1 are from a recent electron diffraction study by L. and K. Hedberg et al.[9] and agree reasonably well with the earlier data of Almenningen et al.[10] The C–C bond length is a bit longer than that obtained in the original (and crucial) X-ray structure determination by Fleischer in 1964.[11a] It is interesting that this distance is not much different than the C–C bond length in a simple cyclobutane.[11b] The values for the heat of formation and strain energy given in parentheses below the results of Margrave et al.[12] were derived by Domalski et al. at the U.S. National Institute of Standards from the heat of combustion of 1,4-di(methoxycarbonyl)cubane.[13] We hope soon to have new data directly from combustion of cubane.

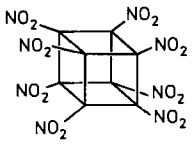
Molecular mechanics calculations, and semiempirical and ab initio quantum mechanical treatments of cubane abound. Robiette et al. have provided an excellent overview.[9] The agreement between methods is fair, but to my mind certainly less than completely reassuring. Whatever one's opinions about the calculated properties of cubane, the bottom line experimentally is that cubane is remarkably stable. Cubane melts just above 130 °C; measurable decomposition occurs only above 200 °C. Martin et al. have shown that the energy of activation for the thermolysis of cubane at 230–260 °C

Philip E. Eaton was born in New York in 1936. He received his undergraduate degree from Princeton University in 1957, then did his Ph. D. work with Peter Yates at Harvard University, graduating in 1961. From 1960 to 1962 he was an assistent professor of chemistry at the University of California at Berkeley. He then accepted a position at The University of Chicago, where he is a full professor. Eaton has received the Rohm and Haas Award for Research, an Alfred P. Sloan Foundation Fellowship, and a Senior Scientist Award from the Alexander von Humboldt Foundation. His research interests include the synthesis of important non-natural products and their applications in materials science.

is 43.1 ±1.0 kcal mol^{-1}, an extraordinarily high value.[2b] Cubane is entirely stable to light, air, water, and most common reagents.

4. The Cubane Renaissance

Although many physical properties of cubane have been measured, until a few years ago cubane was considered just a laboratory curiosity of interest only to academics. That changed in the early 1980s when Gilbert of the U.S. Army Armament and Development Command (now ARDEC) pointed out that cubane's very high heat of formation[12] and its exceptionally high density (1.29 g cm^{-3})[11a]—higher than almost all other hydrocarbons[14]—could make certain cubane derivatives important explosives. His colleagues Sandus and Alster at ARDEC provided theoretical support and estimated that octanitrocubane **4** might be 20–25% more effective than HMX (octogen), the present-day standard.[15] It is sufficient to comment here that detonation of



4

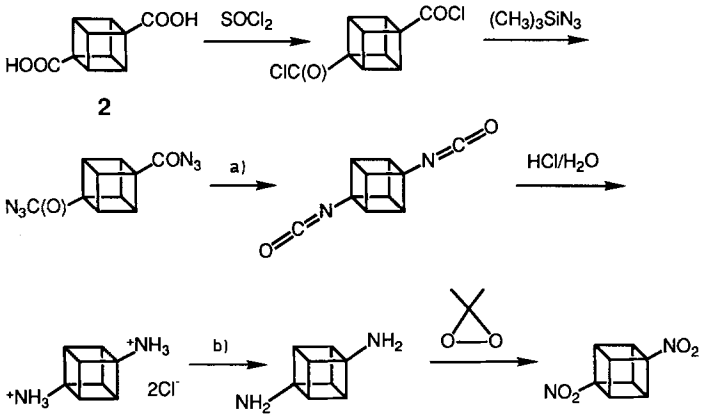
octanitrocubane would lead to an awesome amount of very hot gas [Eq. (a)].

$$C_8(NO_2)_8 \longrightarrow 8\,CO_2 + 4\,N_2 \qquad (a)$$

Miller at the U.S. Office of Naval Research realized quickly that some substituted cubanes could be very useful propellants for the space and "Star Wars" programs. The synthesis of **4** and related compounds are formidable tasks. The challenge made us aware that we did not know how to prepare substituted cubanes beyond a very few simple examples.[4] At the time we returned to cubane chemistry in 1983 there was little methodology for taking the most readily available cubane compound, the 1,4-dicarboxylic acid **2**, and doing anything besides manipulating the carboxyl groups.

5. Functional Group Transformations

As it turned out, the carboxylic acid groups of **2**, like most other functional groups on cubane, are exceedingly well-behaved. Most typical functional group transformations can be applied successfully. This can be appreciated in the preparations of 1,4-dinitrocubane worked out at Chicago by Shankar et al. and Wicks et al. (Scheme 4).[16] Here, modern versions of classical methodology are used. These conversions are as easy to do on the cubane system as on any standard carboxylic acid. Note, just as one example of the "convenient" behavior of most cubane derivatives, that the intermediate cubyl-1,4-diisocyanate in Scheme 4 is a stable, crystalline material (m.p. 112–114 °C) and an obvious precursor for polyurethanes. Such materials may find application as high-energy binders for propellants. Cubylamines (and more particularly cubylmethyl amines) are of interest as antiviral agents given the relation of their size and shape to the important drugs Symmetrel® and Rimantadine® (DuPont). 1,4-Dinitrocubane, the final product in Scheme 4, is perfectly easy to handle. It is less shock-sensitive than TNT



Scheme 4. Functional group transformations on the cubane framework. a) Warming; b) neutralization.

and remarkably stable thermally (decomp. 260 °C). [This is not true of some other cubanes; cubyl azides, diazoketones, and diazomethanes are shock sensitive and dangerous. **Caution** is advised in handling any cubane, since all are high-energy compounds. Safety shields should always be used, and particular care should be taken in the workup of crude mixtures that might contain acidic or heavy-metal contaminants.]

6. Substitution on the Cubane Framework

Functional group transformations are useful for preparing many mono- and disubstituted cubanes, as the corresponding carboxylic acids are readily available.[3] But this does not suffice for the preparation of more highly substituted cubanes. As Reddy et al. have shown, substitution of the cubane framework by way of the cubyl radical is fairly easy. However, as is usually the case with radical reactions, mixtures of products are obtained. Light-induced iodination of cubane with *tert*-butyl hypoiodite gives mono-, di-, triiodocubanes, etc.[17] The challenge is to achieve systematic and controlled substitution onto the cubane frame. This requires a real understanding of the structure of cubane.

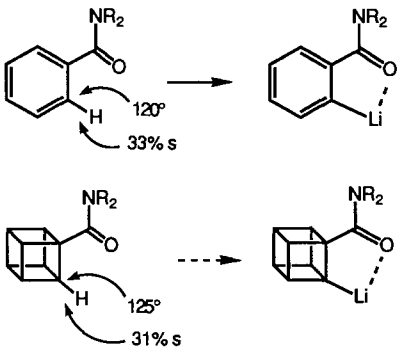
6.1. The Nature of the C–H Bond in Cubane

The geometry of the cubane system dictates substantial rehybridization of the component tetravalent carbon atoms away from sp^3 hybridization. The carbon–carbon bonds become p-rich, and the exocyclic carbon orbital used for the C–H bond becomes s-rich. There is about 31% s character in this orbital as calculated from the observed ^{13}C–^1H coupling constant of 155 Hz.[3, 18] Thus, the hydrogen atoms of

cubane are expected to be more acidic than those of strain-free, saturated hydrocarbons. This has been demonstrated decisively.[19] The kinetic acidity of cubane is about 63000 times that of cyclohexane. Nonetheless, this is far too low to be useful for direct synthetic applications.

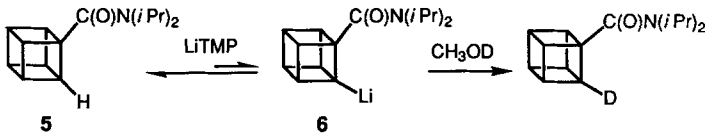
6.2. Amide Activation for *ortho* Metalation

Our idea was to use neighboring group activation to assist metalation of cubane. It was already well known from the work of Meyers, Beak, Snieckus, and others that an amide substituent on an arene aids lithiation in the *ortho* position by activation of the arene hydrogen atom.[20] There are certain similarities between cubanes and arenes: both have C–H bonds with enhanced s character, and in both the adjacent (*ortho*) substituents are forced to be coplanar (Scheme 5). Thus, we speculated that it might be possible to lithiate cubanamides.



Scheme 5. A comparison of important features of benzamide, cubanamide, and their *ortho*-lithiated derivatives. The similarity between arenes and cubanes is reflected in the similar CCH angle and amount of s character in the C–H bond.

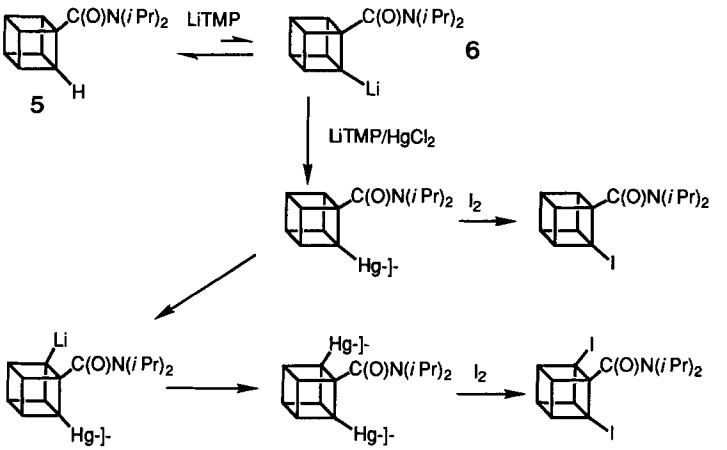
The seminal work was done in my laboratory by Graziano Castaldi.[21] He showed that a small equilibrium concentration of the *ortho*-lithiated derivative **6** is indeed formed when the diisopropylamide **5** of cubanecarboxylic acid is treated with a large excess of a strong, non-nucleophilic base like lithium tetramethylpiperidide (LiTMP). (Alkyllithium reagents are not suitable because they attack the amide group.) When the reaction mixture was quenched with CH_3OD the recovered cubanamide contained approximately 3% deuterium in the 2 position (*ortho*); dideuterated material could not be detected.



This result was very satisfying to us as physical organic chemists since it was logically derived and demonstrated that activated saturated systems can be metalated.[22, 23] Nonetheless, this observation alone was not particularly useful in synthesis. A small concentration of a carbanion in the presence of a huge excess of base is not an easy thing to work with.

6.3. Transmetalation

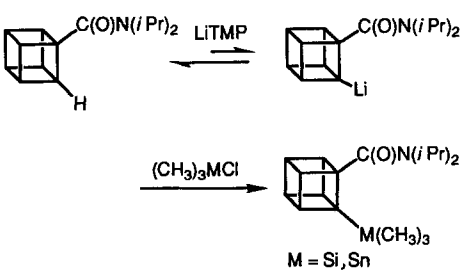
In a key step forward, Castaldi showed transmetalation to be the golden link in the synthesis of substituted cubanes.[21] When lithiation of a cubanamide is performed in the presence of mercury salts, the lithium compound first formed is quickly mercuriated, and the very polar C–Li bond is replaced by the more nearly covalent (and relatively inert) C–Hg bond. In this way, the starting material **5** can be completely converted into a metalated cubane (Scheme 6). The



Scheme 6. Metalation/transmetalation: a method for the complete metalation of the activated cubane framework.

amide group is important in stabilizing the intermediate lithiated cubane, but not the mercuriated compound. Once lithium is replaced by mercury, the amide group is again able to assist removal of another *ortho*-hydrogen atom, and the process can continue.

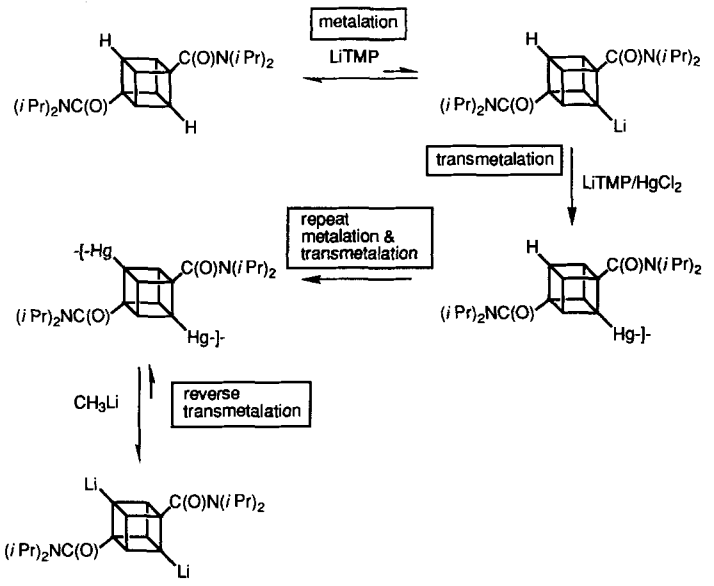
Metalation/transmetalation is the basis of a complete synthetic methodology for the preparation of a great variety of substituted cubanes. Mercuriated cubanes are useful for the formation of halocubanes, as the C–Hg bond is readily cleaved by halogens such as iodine. Other metalated cubanes are more reactive and thus more useful. Higuchi et al. showed that zinc, silicon, and tin derivatives of cubane could be made in a similar way (Scheme 7) and are of great synthetic utility.[24]



Scheme 7. Preparation of silyl- and stannylcubanes by metalation/transmetalation.

6.4. Reverse Transmetalation

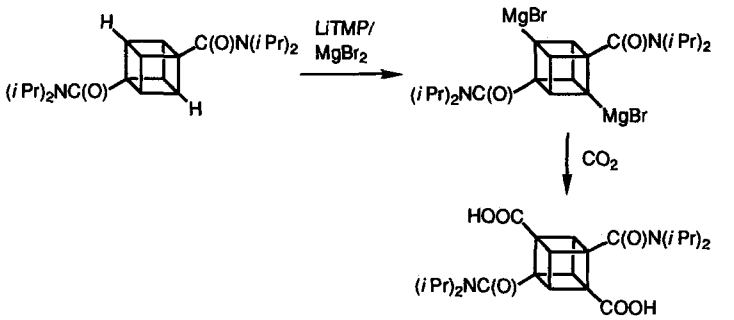
Cunkle, a postdoc in my group, worked out a reverse transmetalation methodology for converting mercuriated cubane compounds into more reactive metallocubanes.[25a] This extraordinary (if roundabout) process allows the quantitative preparation of dilithiated cubanes (Scheme 8), materials not available by direct lithiation of cubanamides. The method has also found use in the synthesis of dimetalated arenes.[25b]



Scheme 8. Metalation/transmetalation/reverse transmetalation: a roundabout route to not easily accessible compounds.

6.5. Cubyl Grignard Reagents

Bashir-Hashemi at Geo-Centers introduced transmetalation with magnesium salts and thereby provided easy access to cubyl mono- and bis-Grignard reagents.[26] This works exceedingly well. The conversion proceeds by stepwise lithiation/bromomagnesiation. The second metalation of the

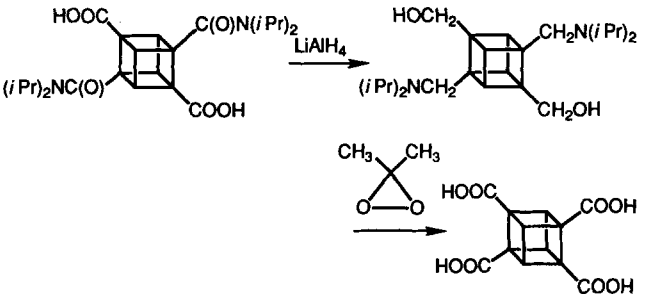


Scheme 9. *ortho*-Magnesiation by metalation/transmetalation: a useful method.

cubane framework occurs at a position remote from the first—quite understandable considering the polarities of the intermediates. Further metalation does not take place. In most cases, the overall conversion of these reactions is extraordinarily good; in the example shown in Scheme 9 yields of 90–95% are easy to achieve in both small- and large-scale runs.[27]

6.6. The Amide Activating Group

The diisopropyl amide activating group used in these various reactions was chosen because it is quite inert to the amide bases employed for *ortho* metalation. As always, there is a price to be paid for the luxury of judicious choice: such amides cannot be hydrolyzed to the corresponding carboxylic acid, the functional group most amenable to further transformations. For a time this problem was the "Achilles heel" of the reaction sequence. We did find finally that borane reduction of the amide followed by oxidation of the amine so produced with dimethyldioxirane (Scheme 10)[27a] or (on larger scale) with potassium permanganate provided a successful solution.[27b]

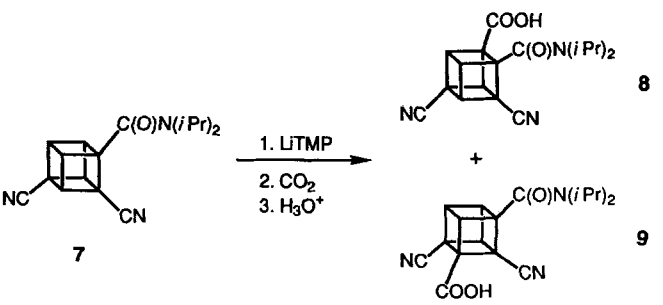


Scheme 10. A novel way to "hydrolyze" a recalcitrant amide group.

Bottaro, Schmitt, et al. introduced later the use of the *tert*-butyl ethyl amide as an activating group for *ortho* metalation that could be completely hydrolyzed in strong acid.[28] Subsequently, we found that just the *tert*-butyl group alone can be removed in mild acid, and then the resulting amide (in our case a methyl amide) can be taken to the free carboxylic acid with either acid- or, better, base-catalyzed hydrolysis.

6.7. *ortho* Magnesiation

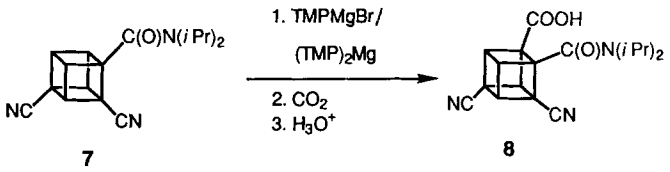
In the course of extending our work to the synthesis of cubanes with different substitution patterns, we found that treatment of the 2,4-dicyanocubanamide **7** with LiTMP gives two isomeric tetrasubstituted cubane carboxylic acids (**8** and **9**) after carboxylation.[29] The electron-withdrawing



effects of the cyano groups along with the amide stabilizes both intermediate lithiated cubanes so well that only a small excess of LiTMP is needed to achieve fairly complete deprotonation even at −78 °C. In the initial lithiation step, the activation of a cubane C–H bond by two flanking cyano groups rivals the *ortho* activation by the one amide group. This results in competitive lithiations and a mixture of products. In attempts to achieve greater selectivity in this reaction, we examined the effect of added $MgBr_2$. When the ratio of LiTMP to $MgBr_2$ was 1.5:1, the product ratio was improved to 9:1 favoring carboxylation *ortho* to the amide function. This suggests an important, previously unknown reaction: direct magnesiation by TMPMgBr (a Hauser base)[30] and/or by $(TMP)_2Mg$. Lee and Xiong in my laboratory have expanded this idea into a powerful new process dubbed *ortho* magnesiation, and we have found that magnesium amide bases are exceedingly useful in synthesis.[31, 32]

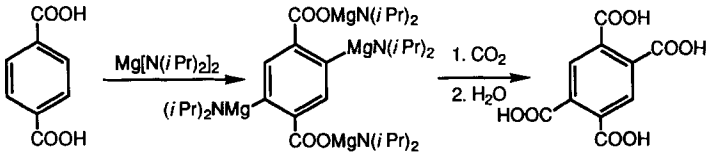
These bases can be made very simply. The reaction of 2,2,6,6-tetramethylpiperidine (TMPH) in refluxing THF with one equivalent of ethylmagnesium bromide or with 0.5 equivalents of dibutylmagnesium gives, respectively, clear solutions of TMPMgBr and $(TMP)_2Mg$. The reactions are complete within a few hours. Solutions of the corresponding diisopropylamine derivatives can be obtained similarly.[31] These magnesium amide bases are stable in refluxing THF for hours. In this way they differ markedly from the corresponding lithium amides, which rapidly decompose at this temperature; indeed, LiTMP is unstable above 0 °C in THF. Since the magnesium amide bases can be used in refluxing THF, reactions with materials of otherwise low solubility or low reactivity are possible.

When dicyanocubanamide **7** is treated with TMPMgBr or $(TMP)_2Mg$ the only product after carboxylation (90% yield!) is **8** in which the carboxyl group is next to the amide activating group.[29] This reaction proceeds well even at −78 °C. The inductive effect of the cyano group clearly enhances the reaction, but the cyano group itself is not an *ortho* director for magnesiation.



7 8

The uses of *ortho* magnesiation extend far beyond the cubane system; for example, the method can be applied productively to aromatic systems. "By-products" such as this have arisen often from our work on the cubane system and as in this case have brought new, important insights. Since the original work by Gilman on *ortho* lithiation of substituted arenes, it has always been assumed that the metalation depends crucially, if not exactly explicably, on the properties of lithium. Now we know that direct *ortho* magnesiation can be accomplished as well. Such processes complement *ortho* lithiation and sometimes also offer distinct advantages, as shown in the new synthesis of pyromellitic acid (**10**). This,

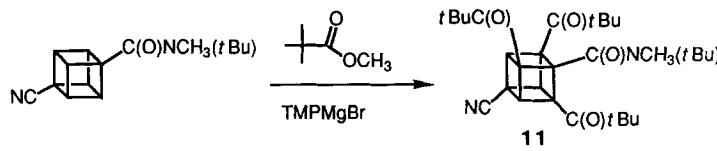


10

and further extensions of the *ortho* magnesiation process are discussed in more detail elsewhere.[31, 33–35]

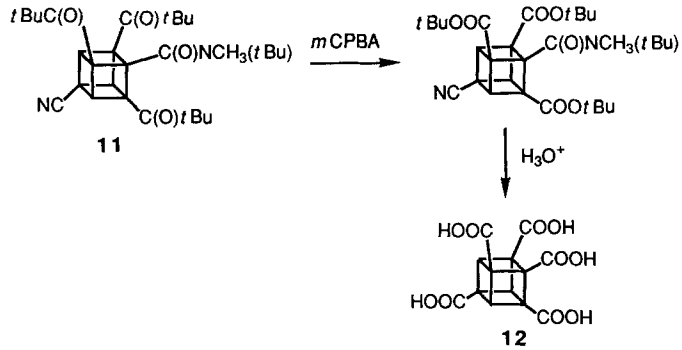
7. Synthesis of Cubanes with Different Substitution Patterns

Although activation by a single amide group suffices for the metalation of cubanes, the presence of additional electron-withdrawing groups enhances reactivity enormously. 4-Cyanocubanamide is much more reactive than the unsubstituted amide. Magnesiation occurs quickly and exclusively *ortho* to the amide. As Puranik, a postdoc in my group, has shown for certain cases, namely when the electrophile can coexist with the base, it is possible to substitute all three positions *ortho* to the amide in a wonderfully simple, one-pot reaction proceeding by sequential metalations. Thus, for example, 4-cyanocubanamide can be converted directly into the tri(*tert*-butylcarbonyl) derivative **11**.[36]

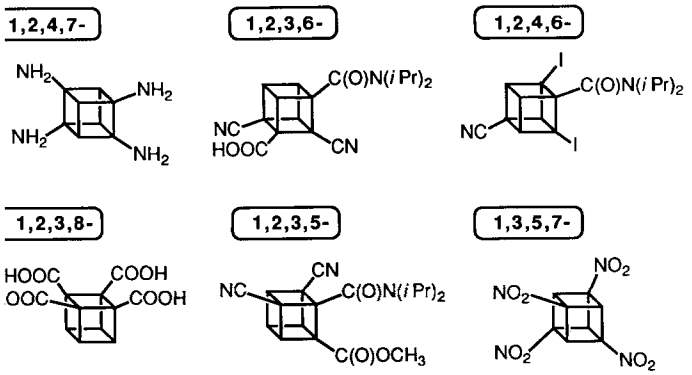


11

As the Baeyer–Villiger oxidation of *tert*-butyl cubyl ketones is completely specific—only the *tert*-butyl group migrates—triketone **11** can be converted easily to the polycarboxylated cubane **12**.[36]



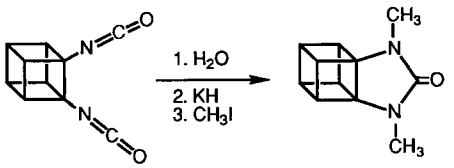
We have used processes like these to produce many different cubanes. It is fair to say that almost any combination or permutation of functional groups and positions on the cubane nucleus can be achieved now by fairly simple chemistry.[37] In Scheme 11, for example, are six tetrasubstituted



Scheme 11. Tetrasubstituted cubanes with different substitution patterns.

cubanes we have made, each with a different substitution pattern.

We have even synthesized cubanes like **13** with fused heterocyclic rings.[38] Quite different from expectation these "heteropropellano cubanes" are remarkably stable. The nitrogen atoms can be alkylated or nitrated without interference from ring-opening reactions. Interestingly, the C–C bond shared by the urea ring and the cubane system is substantially shorter than the equivalent bond in cubanes or cyclic ureas. The origin of this effect is not known.[38]



13

8. Cubane as a Building Block for Pharmaceuticals

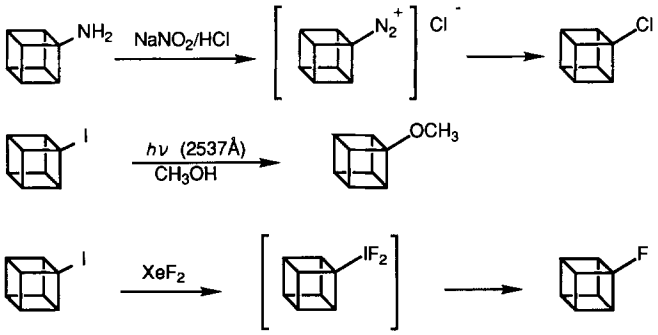
Because the cubane frame is rigid, substituents have precise spatial relationships to one another. The distance across the cube (the body diagonal) is almost the same as that between the *para* positions of the benzene ring. On cubane, one can add substituents in "the benzene plane", as well as above and below it, so to speak. This offers fascinating possibilities for the synthesis of new pharmaceuticals. A number of cubane derivatives have already been obtained which show interesting activity in anti-AIDS and anti-tumor screens. Admittedly, the activity/toxicity balance is not yet satisfactory. We do know, however, that the cubane system is not inherently toxic; most cubanes are biologically innocuous. The search for pharmaceutically significant cubanes has just begun. At this point, cubane should be viewed as a biologically stable, lipophilic platform on which the chemist can install a wide choice of substitutents in a variety of well-defined spacial relationships. Developments in drug design programs should allow the judicious choice of substituents.

9. Cubanes as Precursors to Reactive Intermediates

Having solved the problems associated with the synthesis of substituted cubanes, we can now start with the cubane system, itself an extraordinary structure, and move outward in our continuing exploration of the limits of bonding in organic compounds.

9.1. Cubyl Cation

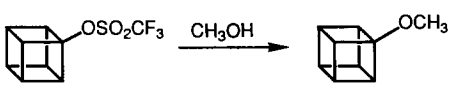
One of the biggest surprises we have had in our work was the discovery that cubyl cation is much more accessible than expected.[39] Everything about cubyl cation seems unfavorable: 1) The geometry about the positively charged carbon atom is very far from flat; 2) the exocyclic orbitals in cubane are s-rich; 3) hyperconjugative stabilization would require high-energy, cubene-type structures. Ab initio calulations (6-31G*, without electron correlation) place cubyl cation about 20 kcal mol^{-1} higher in energy than *tert*-butyl cation and about 5 kcal mol^{-1} higher in energy than 1-norbornyl cation.[40] Nevertheless, we came across numerous reactions (Scheme 12) that might involve the intermediacy of the cubyl cation.[41]



Scheme 12. Substitution reactions of cubane derivatives that probably proceed via the cubyl cation.

9.1.1. Solvolysis of Cubyl Triflate

Since some of the substitution reactions in Scheme 12 do not have clearly defined mechanisms, and there are possibilities for front-side attack, "hot intermediates", etc., we turned to an examination of simple solvolysis reactions.[39a] As it turned out, the solvolysis of cubyl triflate **14** in pure dry methanol is remarkably facile. Its half-life at 70 °C is only



14 **15**

15 minutes. The reaction is very clean. No rearrangement is observed, and the only product is cubyl methyl ether **15**. Labeling studies have established that the methoxy group is

attached to the same carbon as the original triflate group. There is no hydrogen scrambling nor skeletal rearrangement.

9.1.2. A Comparison of Experimental and Calculated Solvolysis Rates

Cubyl triflate is very much more reactive than 1-norbornyl triflate which is not solvolyzed noticeably by methanol at 70 °C even after 250 hours. In hexafluoroisopropanol at 60 °C norbornyl triflate is only 90% solvolyzed in 85 hours, whereas cubyl triflate is converted completely in this solvent to cubyl hexafluoroisopropyl ether within 5 minutes at room temperature.

The logarithm of the S_N1 solvolysis rate is, in a first approximation, inversely related to the difference in the strain energy of the non-ionized starting material and the intermediate cation. Schleyer et al.[42] have shown that this energy difference can be estimated successfully by careful application of molecular mechanics calculations. In Table 2 published rate data for solvolysis have been adjusted (in so far as possible)[43] to a common set of conditions, and are compared to the values predicted by molecular mechanics. The

Table 2. Comparison of the experimentally determined and the calculated relative rates of solvolysis of some tertiary tosylates in acetic acid at 70 °C.

Tosylate	Exp.	Calc.	Tosylate	Exp.	Calc.
tert-butyl	1	1	1-norbornyl	10^{-13}	10^{-14}
1-adamantyl	10^{-3}	10^{-4}	cubyl	10^{-10}	$<10^{-25}$
1-bicyclo[2.2.2]octyl	10^{-7}	10^{-8}			

agreement is within one or two orders of magnitude—astonishing considering the substantial corrections. Cubyl tosylate is the exception; here the theoretical and experimental rates of hydrolysis differ by more than 15 orders of magnitude!

9.1.3. The Bonding in Cubyl Cation

Why is cubyl cation so much more easily formed than expected?[44] Put another way, what differentiates the cubane derivative from the other compounds in Table 2? As discussed earlier in Section 6, the geometric constraints inherent in the cubane skeleton force significant rehybridization in the bonding orbitals of carbon away from sp^3. The C–C bonds in cubane are p-rich in comparison to those in the other systems listed in Table 2. The electronic structure of the bonding system in cubane is quite different from that of the others; molecular mechanics does not take this into account.[45] The matter has been treated quantitatively by Borden and Hrovat with ab initio 6-31G* calculations including electron correlation.[40] This has led to the conclusion that the positive charge is delocalized by interaction with the strained C–C bonds in cubane; namely, there is positive bond order between the p orbital at the positively charged carbon atom and the p orbital aligned with it at each of the β carbon atoms (C3). Population analysis reveals that the γ-CH (C4) and α-CH (C2) groups bear considerable positive charge (0.16), more than the β-CH groups.

9.1.4. Substituent Effects on the Rate of Solvolysis of Cubyl Triflate

Considering the calculated charge distribution in cubyl cation, it is not surprising that electron-withdrawing substituents at position 4 (body diagonal, *para*) suppress solvolysis effectively (Table 3). We were unable to detect any signif-

Table 3. Comparison of the half-lives $t_{1/2}$ for the hydrolysis of a number of 4-substituted cubyl triflates.

4-X-1-Triflate	T [°C]	$t_{1/2}$	4-X-1-Triflate	T [°C]	$t_{1/2}$
X = H	20	< 5 min [a]	H	25	67 h [c]
CH_3O	60	> 133 h [a]	CH_3	25	200 h [c]
Cl	60	> 20 d [a]	$(CH_3)_3Si$	25	37 min [c]
CF_3SO_3	100	[b]	$(CH_3)_3Sn$	25	[d]

[a] In $(CF_3)_2CHOH$. [b] Reaction time in $(CF_3)_2CHOH$ was too long to measure. [c] In CH_3OH. [d] Reaction time in CH_3OH was too short to measure.

icant solvolysis of the bistriflate of cubane-1,4-diol after it was heated in methanol at 85 °C for 5 days, in aqueous 80% ethanol at 100 °C for 5 days, or in hexafluoroisopropanol at 100 °C for 6 days.[46] On the other hand, as Borden et al. insightfully pointed out,[40] π-donor substituents cannot stabilize cubyl cation effectively, since the C-to-substituent bond at C4 is along the axis of the cylindrically symmetric LUMO of the cation.[47] Thus, substituents such as methyl and methoxy normally associated with the hyperconjugative and resonance stabilization of cations fail to do so in cubyl cation. Indeed, as can be seen in Table 3, only their destabilizing inductive effects are mirrored in the observed rates. The symmetry restriction limiting the stabilizing effects of π-donor substituents of course does not apply to σ donors. Jian Ping Zhou in my laboratory has found that silyl and tin substituents at C4 markedly enhance the rate of solvolysis of cubyl triflates.[48] Indeed, solvolysis of 4-trimethylstannylcubyl triflate in methanol is so fast (about 3000 times faster than cubyl triflate) that its rate could only be obtained by extrapolation from the reaction of the corresponding mesylate.

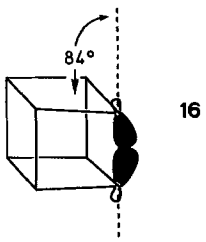
9.2. Dehydrocubanes

Cubane is a saturated hydrocarbon of extraordinary geometry and strain. Although it was once dismissed as impossible, it has been shown to be stable. Similarly, cubyl cation has been found to be far more readily accessible than once imagined. With these lessons in mind, it is prudent not to dismiss other uncommon notions out of hand.

9.2.1. 1,2-Dehydrocubane (Cubene)

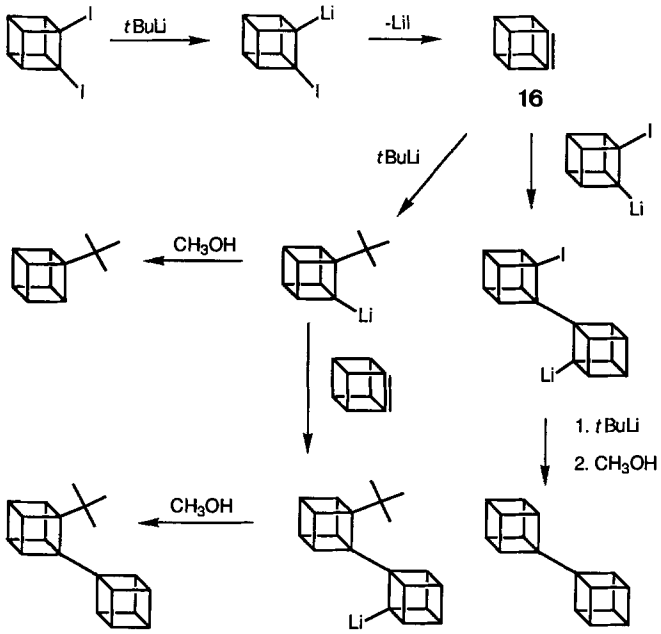
1,2-Dehydrocubane, cubene **16**, is the most extreme example of a pyramidalized olefin.[49, 50] Obviously, the ge-

ometry about the vinyl carbon atom can be nowhere near planar. Hrovat and Borden have calculated a pyramidalization angle of 84° for **16**.[50b]



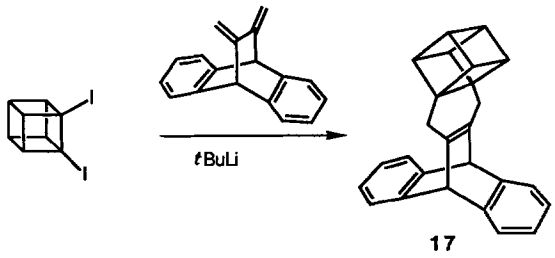
16

Using the newly developed methods for the synthesis of substituted cubanes discussed earlier, Maggini, a postdoc in my group, prepared 1,2-diiodocubane.[51] He found that the chemistry of this vicinal dihalide could be rationalized most efficiently by invoking the intermediacy of cubene (Scheme 13).[51] Critical to the reasoning behind this hypothesis is the fact that reaction of monoiodocubane with *tert*-butyllithium gives essentially only cubyllithium; no significant amount of *tert*-butylcubane is formed. The formation of *tert*-butylcubane and cubylcubanes in the reactions of 1,2-diiodocubane presumably reflects the susceptibility of cubene to nucleophilic attack. Certainly, nucleophilic addition to highly strained olefins is well precedented in the lovely work of Szeimies et al. on bridged bicyclobutenes.[49]



Scheme 13. The reaction of 1,2-diiodocubane with *t*BuLi.

Cubene is an immensely strained, relatively "open", and sterically unhindered olefin. As such, it can be expected to be very reactive in Diels–Alder additions. Indeed, when the deiodination of 1,2-diiodocubane was conducted at room temperature with *tert*-butyllithium in benzene in the presence of 11,12-dimethylene-9,10-dihydro-9,10-ethanoanthracene, the 1:1 Diels–Alder adduct **17** was formed in 64% isolated yield. Cubane-on-a-pedestal!

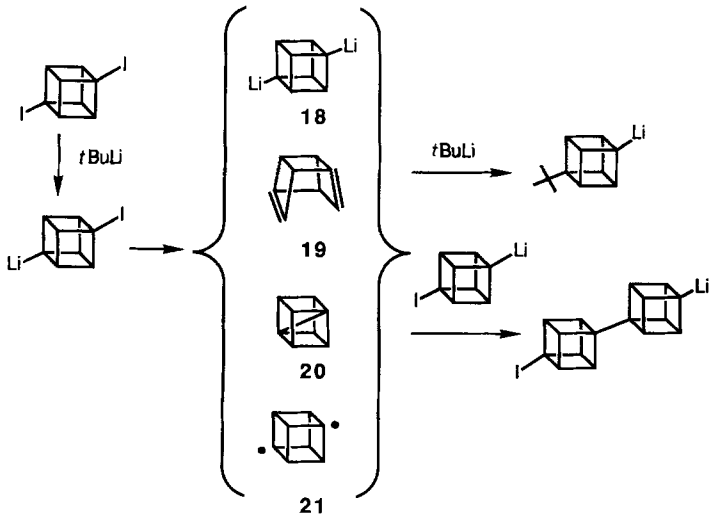


17

9.2.2. 1,4-Dehydrocubane (1,4-Cubanediyl)

The extraordinary chemistry of 1,2-diiodocubane induced us to examine the 1,4-diiodo compound,[52] a material readily available from cubane-1,4-dicarboxylic acid.[53] In my laboratory, Tsanaktsidis showed that the reactions of 1,4-diiodocubane with alkyllithium reagents (Scheme 14) give rise to products related to those obtained from the reactions of 1,2-diiodocubane, that is, materials resulting from the nucleophilic additions of lithium compounds to some very reactive intermediate.[54]

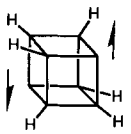
Our labeling experiments provide good evidence that the products arise from a symmetrical intermediate. There are a number of possible structures, for example **18**–**21**, but some of these can be eliminated from serious consideration. 1,4-Dilithiocubane (**18**) can be prepared if the exchange reaction between 1,4-diiodocubane and *tert*-butyllithium is conducted at −100 °C; **18** behaves as would be expected, quite differently from the intermediate generated in the reaction performed at −70 °C. It is not likely that Grob fragmentation of the diiodide gives **19**, surely a reactive olefin, since the addition of suitable trapping dienes like furan and 9,10-diphenylisobenzofuran does not change the observed course of the reaction. Borden et al.[55] and Michl et al.[56] have calculated independently that structure **20** with a body-diagonal bond is unlikely given its exceedingly high strain and



Scheme 14. Possible intermediates **18**–**21** in the reaction of 1,4-diiodocubane with *t*BuLi.

orbital phase mismatch.[57] Ab initio calculations by both groups indicate that the actual intermediate is probably 1,4-cubanediyl (**21**).

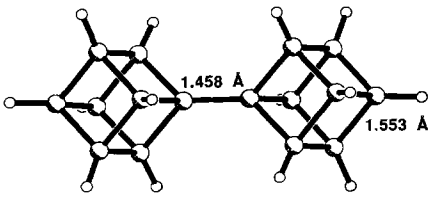
The singlet state **22** of 1,4-cubanediyl is calculated to be > 10 kcal mol^{-1} more stable than the triplet state, a result of substantial through-bond interaction. Indeed, 1,4-cubanediyl does not behave like a diradical. It does not react with cyclohexene; neither hydrogen abstraction from, nor addition to the olefin is observed. Michl et al. have obtained spectroscopic evidence for cubanediyl by matrix isolation (argon, 12 K) of the products from the gas-phase metal-induced dehalogenation of 1,4-dihalocubanes.[56]



22

10. Cubylcubanes and Oligocubanes

Cubene (1,2-dehydrocubane) and 1,4-cubanediyl (1,4-dehydrocubane) are enormously strained compounds which cannot be isolated under standard conditions. They both undergo nucleophilic additions very readily, and this has provided us access to the cubylcubane series (see Schemes 13 and 14). Gilardi[58] has shown by X-ray structure analysis that the central cubylcubane bond is exceedingly short (1.458 Å, Scheme 15) as might be expected, since the exocyclic orbitals of cubane are s-rich and close to the nucleus.[59] The central bond in cubylcubane has about the same length as the C–C single bond made from sp^2 orbitals in 1,3-butadiene. Note that the central bond in adamantyladamantane, constructed from sp^3 orbitals, is 1.578 Å long.[60]

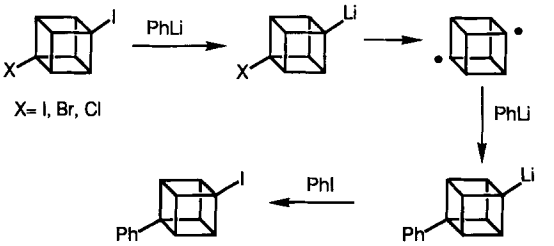


Scheme 15. The molecular structure of cubylcubane. The C–C bond lengths were determined by X-ray structure analysis [58].

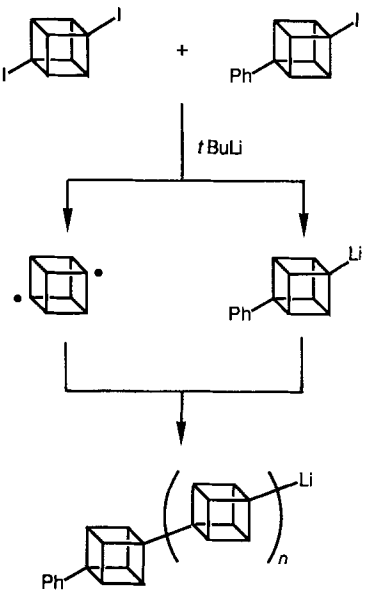
10.1. Arylated Cubylcubanes

Tsanaktsidis[54] found that 4-haloiodocubane reacts with phenyllithium to give, ultimately, 1-iodo-4-phenylcubane. He demonstrated that the reactions proceed by way of the 1,4-diyl (Scheme 16).[49]

K. Pramod extended and modified the sequence in a way that permits the preparation of a host of [*n*]cubylcubanes (Scheme 17).[61, 62]

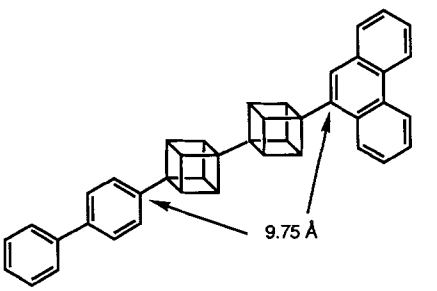


Scheme 16. The reactions of 4-halo-1-iodocubanes with phenyllithium.



Scheme 17. The key steps in the synthesis of arylated [*n*]cubylcubanes.

The [*n*]cubylcubanes have rigid, rod-shaped skeletons and allow the preparation of sets of compounds with interacting groups separated in space by precise distances. Each cubane unit adds 4.15 Å to the length of the molecule. Pramod developed smooth methods to place different arene substituents at opposite ends of cubylcubanes. Thus, for example, he could trap the product from Scheme 17, the lithiocubane with $n = 2$, with phenanthrene-9,10-epoxide and then dehydrate the resulting intermediate to give **23**.[62]

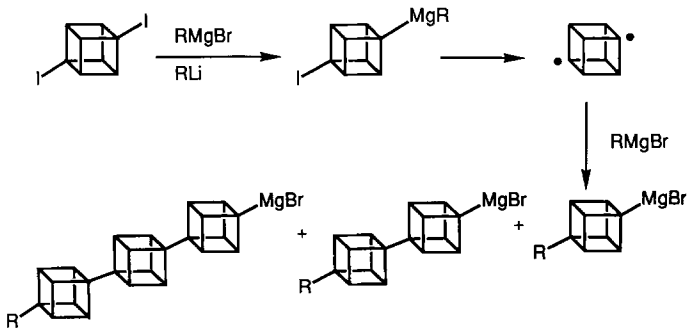


23

The group of Gerhard Closs (deceased May 24, 1992), my late colleague at The University of Chicago, is now measuring the rates of electron transfer between such substituents as a function of the distance separating them.

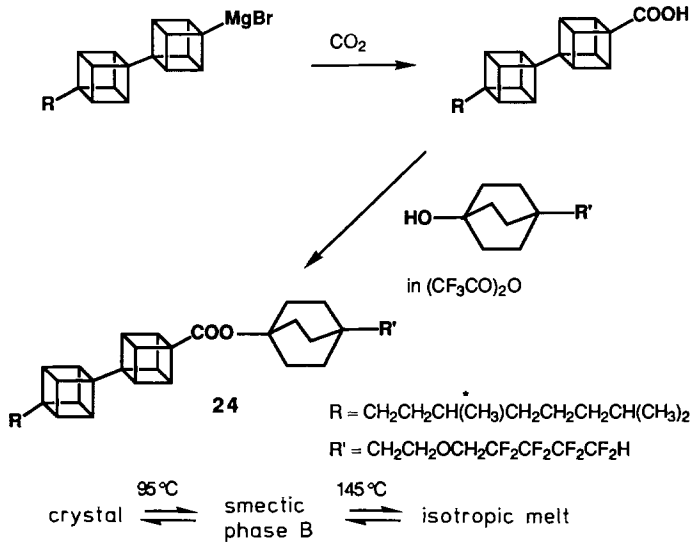
10.2. Alkylated Cubylcubanes

The preparation of alkyl-substituted cubylcubanes in good yield by the addition of alkyllithium reagents to cubanediyls is more difficult than the synthesis of the aryl analogues. Nucleophilic addition reactions most probably proceed by way of single-electron transfers, and a good match of the orbital energies is required for this to be effective. Aryl- and cubyllithium add easily to 1,4-cubanediyl, but alkyllithium reagents do not. Yusheng Xiong in my laboratory found a way around this limitation by making intelligent use of Grignard intermediates as shown in Scheme 18.[63]



Scheme 18. The key steps in the synthesis of alkylated [*n*]cubylcubanes. In the first step, RLi is added slowly. R = methyl, butyl, or a long-chain substituent.

The Grignard products can be taken on in a variety of ways. One of particular interest to us at this time is the possibility of making liquid crystals with exceptional properties (e.g. UV transparency) from oligocubanes.[64] To this end Xiong has prepared materials like **24** as shown in Scheme 19.

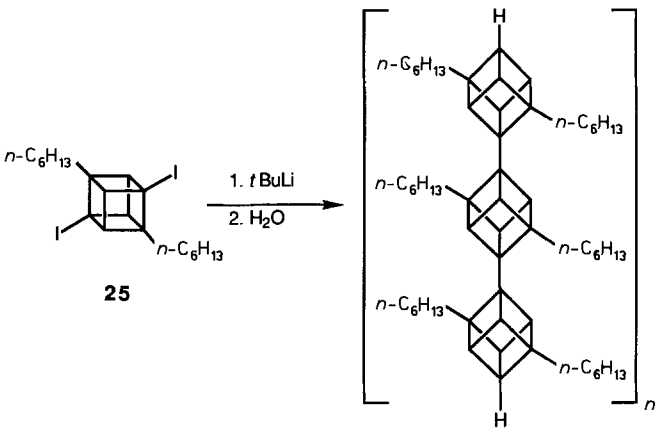


Scheme 19. Synthesis of trial liquid-crystalline compounds derived from cubylcubane.

It is worth noting here that esterification of the cubylcubanecarboxylic acid in Scheme 19 with the highly hindered bicyclo[2.2.2]octan-1-ol cannot be achieved in standard ways. The successful esterification conducted in trifluoroacetic anhydride depends on the formation of cubylacyl cation, an intermediate whose existence was demonstrated by Xiong using NMR spectroscopy.

10.3. Higher Cubylcubanes

As the number of linked cubane units increases, that is, as n increases, the solubility of [*n*]cubylcubanes plunges; at $n = 3$ most are essentially insoluble in ordinary solvents. This problem can be relieved by having moderately long alkyl substituents on the "monomer". Virtuani has converted 2,7-di-*n*-hexyl-1,4-diiodocubane (**25**) into the corresponding diyl, whose polymerization, presumably initiated by addition of 4-iodo-1-lithio- or 2,7-di-*n*-hexyl-1,4-dilithiocubane, gives an oligomeric cubylcubane with a molecular weight of approximately 10000. This corresponds to a polycubyl rod about 150 Å long containing on average 40 cubane units![65]

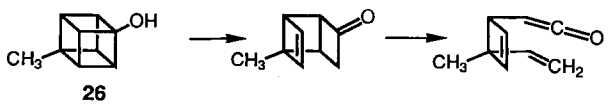


11. Ring-Opening Reactions of Cubanes

Cubane and many substituted cubanes are very stable compounds, indeed remarkably so considering the extreme strain energy of the skeleton (> 166 kcal mol^{-1}). There is no symmetry-allowed, concerted pathway for ring opening. When reagents or substituents open other paths, the molecule rearranges.

11.1. Electron-Rich Cubanes

Although cubanols can be isolated with care, they are fragile. 4-Methylcubanol **26**, like the others, opens by way of homoketonization to a tricyclooctenone, which in turn rearranges further to a vinylcyclobutenylketene.[66] Cubyl-



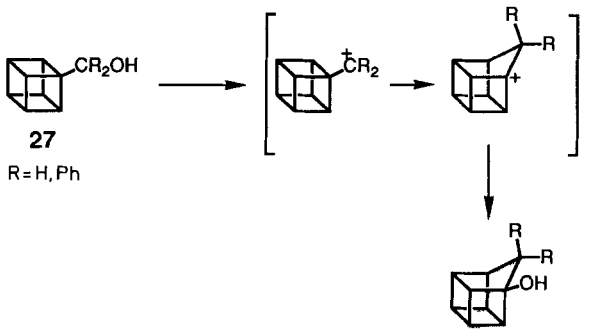
amines show similar ring-opening proclivities, but their ammonium salts are quite stable. Clearly, the ring-opening process is initiated by the shift of electrons into the ring. The tendency toward ring opening is greater when there is an electron acceptor at C2. No cubylamine or cubanol with a carbonyl substituent *ortho* to the electron donor has ever been obtained. Similarly, 2-nitrocubylamine has never been isolated. A simple push–pull mechanism can easily rationalize the rapid bond cleavages which account for the instability of such compounds.

11.2. Cubane–Homocubane Rearrangements

The framework of homocubane is at least 20 kcal mol^{-1} less strained than that of cubane. When a path is opened, cubanes rearrange to homocubanes.

11.2.1. Cubylcarbenium Ions

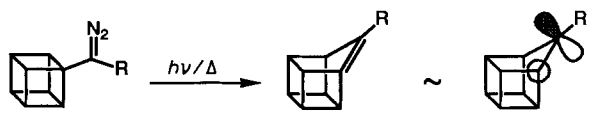
Great care is necessary in the isolation of cubylmethyl alcohols such as **27** with a nucleofuge on the methyl carbon atom. These compounds are exceedingly fragile and rearrange into the homocubyl system with exceptional ease.[67]



This probably occurs by way of a tight ion pair, as the usual product is primarily that of internal return. The Wagner–Meerwein 1,2 shift occurs even when the positively charged carbon atom is stabilized by two phenyl groups.

11.2.2. 1(9)-Homocubenes

K.-L. Hoffmann in my group showed that cubyl phenyl diazomethane **28** on thermolysis or photolysis is converted

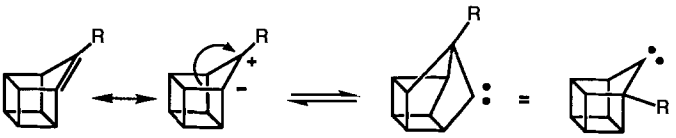


28a: R=Ph
28b: R=H

29

to 9-phenyl-1(9)-homocubene **29a**.[68] Later, Jones showed that the same reaction occurs when R = H.[69]

The 1(9)-homocubene system contains the most twisted C–C double bond known. If rehybridization and pyramidalization did not occur the angle between the p orbitals of the unsaturated carbons would be 90°. This is the anti-Bredt olefin nonpareil! Its chemistry is extraordinary. 1(9)-Homocubenes rearrange to 9-homocubylidenes. These conversions are amongst the rare examples of the rearrangement of an olefin to a carbene.[70] For the cases at hand, using ^{13}C-labeling, Appell et al. have shown that the rearrangement occurs reversibly,[71] and White et al. have proven that it proceeds by the shift of a C–C bond in the homocubane framework.[72] The rearrangement can best be rationalized by invoking a zwitterionic contributor to the olefin structure (Scheme 20). Platz, Jones, et al. have determined the equilibrium constant for the olefin–carbene rearrangement.[73]

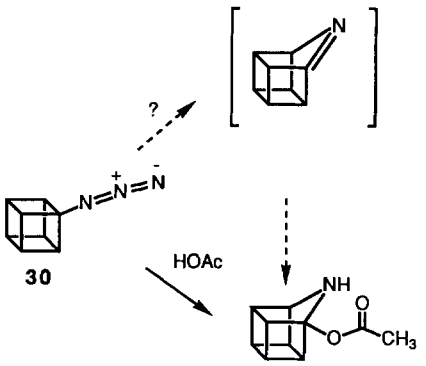


Scheme 20. Rearrangement of 1(9)-homocubenes to the corresponding homocubylidenes.

The investigation of such 1(9)-homocubene species is a very active area.[73] Most recently we have obtained optical spectra of *para*-substituted 9-phenylhomocubenes frozen out in 77 K glasses.[74] We shall discuss these in detail elsewhere.

11.2.3. 9-Azahomocubene

The solvolysis of cubyl azide **30** may also proceed by way of a homocubene, in this case 9-azahomocubene.[75] As yet



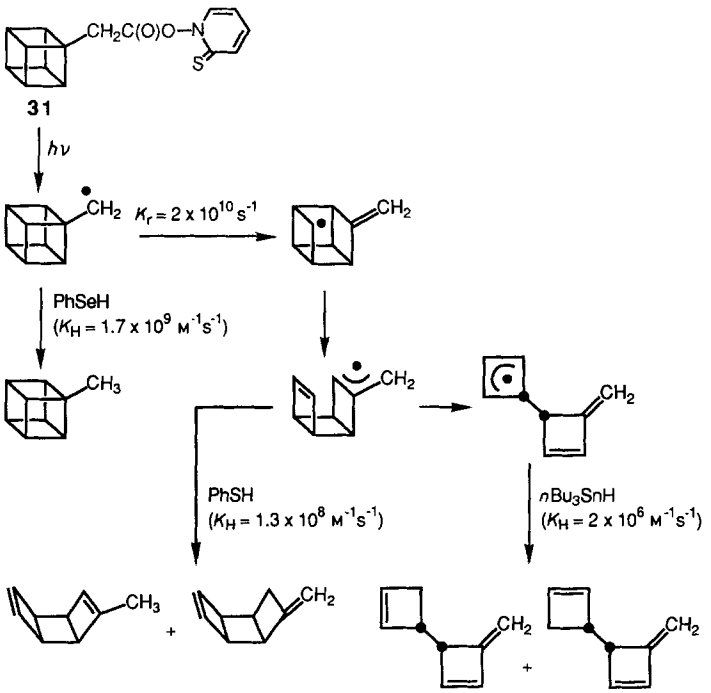
30

there is no proof for the intermediacy of such an anti-Bredt imine;[76] the observed acetolysis product could also be accounted for by a mechanism in which solvolysis, C–C bond migration, and nitrogen loss are linked together.

12. Cubylmethyl Radicals

The cubylmethyl radical has been generated from cubylmethyl bromide and from the *N*-hydroxy-2-pyridinethione

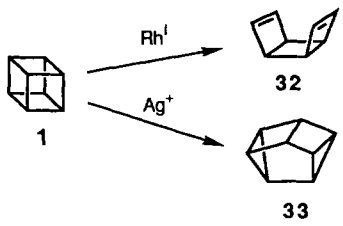
ester **31** of cubylacetic acid under various conditions favoring hydrogen-atom transfer to the radical. The behavior of the radical has been studied in detail by Yip Yu Chi in my laboratory[77a] and with Newcomb[77b] at Wayne State University. Methylcubane is formed only in the presence of high concentrations of the hydrogen donor PhSeH. Otherwise the cubylmethyl radical rearranges. There is no evidence of a 1,2 shift to give the homocubyl system, even though this would be extremely favorable energetically. Instead, one, two, or three bonds of the cubane framework cleave, leading to olefinic products. These can be accounted for by a mechanism in which σ bonds break sequentially and regioselectively; processes in which there is good overlap between the radical orbital and that of the breaking bond are favored (Scheme 21).[78] The distribution of products depends qualitatively on the survival time of the radical intermediates, in other words, on the concentration and effectiveness of the hydrogen-atom-transfer agent. From product distributions, the rate constant for ring opening of the cubylmethyl radical is calculated to be at least $2.7 \times 10^{10}\ s^{-1}$; this value is substantially greater than that of any radical derived to date from a saturated hydrocarbon system. The lifetime of cubylmethyl radical at 25 °C is about 35 ps.[77b]



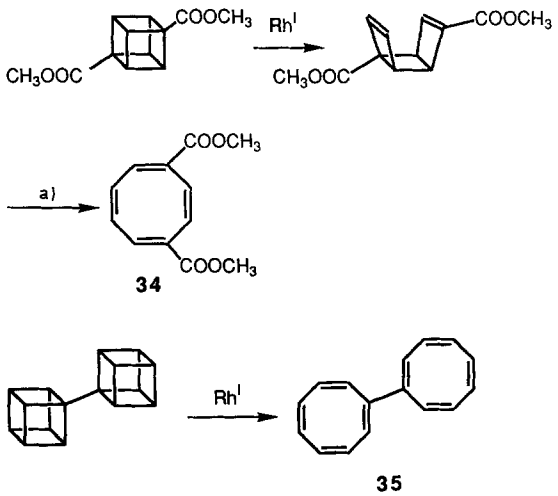
Scheme 21. Generation of the cubylmethyl radical and its reactions with various trapping reagents. The rate constants K for these reactions and the ring-opening reactions are given.

13. Metal-Induced Reactions of Cubanes

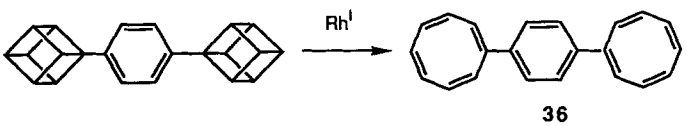
More than 20 years ago Halpern, Cassar, and I showed that various metal catalysts lead to the facile rearrangement or ring opening of cubane at room temperature. Thus, for example, oxidative addition to Rh^I triggers opening of the cubane frame to the *syn*-tricyclooctadiene system **32**.[79] Treatment with Ag^+ or H^+ induces rearrangement to cuneane (**33**).[80]



The details of such reactions were used at the time to help unscramble the very nature of metal-induced olefin rearrangements and olefin metathesis. Now, these early studies are starting to pay off in a different way. The Rh^I-catalyzed ring-opening to *syn*-tricyclooctadiene is particularly useful, because this intermediate is in turn readily converted at 50–60 °C into cyclooctatetraene. In my group, Chou and Pramod have shown that this also works well with substituted cubanes, allowing much easier access to substituted cyclooctatetraenes (e.g. **34**) and oligomeric cyclooctatetraenes (e.g. **35**) than previously possible (Scheme 22).[81] Indeed, the chemistry of cubane opens the way to new and exciting cyclooctatetraene derivatives, for example **36**.



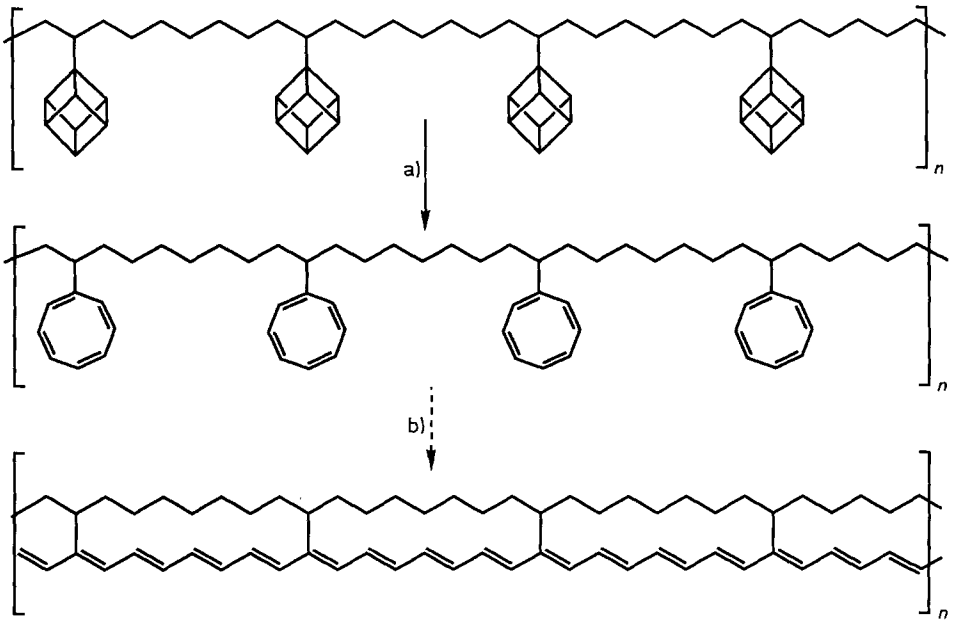
Scheme 22. Metal-induced ring-opening of cubane to give cyclooctatetraene. a) Warming.



14. The Future

Much (but certainly nowhere near all) of the fundamental chemistry of the cubane system is now understood. Many new cubane derivatives and important, new high-energy sys-

tems can be made from cubane. But what about the more pragmatic aspects? Do cubanes have a role to play in practical chemistry? Will they prove to be important outside the university?



Scheme 23. Hypothetical route to polymer-bound polyacetylene. a) [{Rh(norbornadiene)Cl}$_2$]; b) metathesis catalyst.

I think the answer is a clear "yes". Not only are cubanes ideally suited for drug design, high-energy cubanes are also under consideration as explosives and propellants. Racing-car and missile manufacturers are looking to cubanes as the fuels of the future. In other lines of applications, optically transparent cubanes and cubylcubanes have been proposed as building blocks for rigid liquid-crystal compounds. UV-active cubanes, for example cubyl ketones, are readily transformed photochemically into colored cyclooctatetraenes; this conversion could be used for permanent information storage. We are currently focusing our efforts on polymers with cubane in the backbone or as a pendant group along a polymer chain.[82] The cubane subunits in these polymers can be rearranged easily to cyclooctatetraenes. We expect to convert these polycyclooctatetraenes to polyacetylenes by way of ring-opening metathesis polymerization.[83] In this way (Scheme 23), we hope to make polyacetylenes whose properties (e.g. stability, extrudability) are enhanced by the chain being intrinsically part of another polymer (e.g. a polyester or polyethylene). Of course, Scheme 23 is paper chemistry at its most optimistic. Such propositions have innumerable problems, not the least being conformational and configurational irregularities, cross-linking, and back-biting. But it is time that chemists address the possibility of controlled intramolecular polymerization of "polymeric monomers". The early history of cubane lends credence to the old adage that "the impossible just takes a little longer".

Although cubane and cubane derivatives are available on pilot-plant scale, they are still too expensive for industrial applications. Conceptually, cubane can be regarded as a stable oligomer of acetylene, a cheap starting material available in immense quantities. If it were possible to convert acetylene to cubane catalytically, cubane and its derivatives might be made cheaply. Under these circumstances cubanes could become the fuels of choice, not only for military applications but for ordinary transportation as well. One can speculate with some pleasure on the enormous impact this conversion would have on the way we live.

The energy balance of the conversion is good; the tetramerization is energetically favourable even when entropy is considered. One goal we have is to discover how to achieve this conversion and thus complete the transformation of cubane from a laboratory curiosity to an industrial material. I invite your participation.

The U. S. Office of Naval Research, the U. S. Army Research, Development and Engineering Center, the National Institutes of Health, and the National Science Foundation have all helped support my work. Richard Miller at the U. S. Office of Naval Research and Jack Alster at ARDEC have been particularly encouraging. It is a truly a pleasure to acknowledge the work of my students and postdocs. They made our achievements possible, and they made the work itself exciting and fun.

[34] The intermediates in many of these reactions are $R'MgNR_2$ compounds. We have dubbed them "amido Grignard reagents" and are now studying this class of Grignard reagents and their applications in synthesis. A note is made in passing: when these amido Grignard reagents are made from chiral amines, chirality transfer can be (and has been) achieved in C-C bond-forming reactions.

Oxoniobates Containing Metal Clusters

By Jürgen Köhler,* Gunnar Svensson,* and Arndt Simon*

Dedicated to Professor Rudolf Hoppe on the occasion of his 70th birthday

Metal clusters, discrete or condensed, are characteristic of the structures of many compounds which contain transition metals in low oxidation states. The highly reduced oxoniobates support the concept of condensed clusters. They contain Nb_6O_{12} clusters which are either isolated or linked at the apices of the Nb_6 octahedra to form oligomeric chains or networks. The analysis of the bonding relationships allows the identification of different types of Nb atoms and thus the quantitative prediction of valence electron concentrations for finite or infinite structures composed of these condensed M_6X_{12} clusters.

1. Introduction

Metal–metal bonding and metal clusters have changed our understanding of the chemistry of metals in low oxidation states. It is not that long ago that elements in a large section of the periodic table were assigned only integer oxidation states. Only structural insight shows that the oxidation state II for molybdenum in $MoCl_2$—just to take one example—is more or less accidental, as the $[Mo_6Cl_8]^{n+}$ cluster in this compound could well take other values than $n = 4$. The rich chemistry of reduced niobium halides avoids integer oxidation states in spite of strictly stoichiometric compositions. The most metal-rich chlorides and iodides of niobium are $NbCl_{1\,4/6} = NbCl_{2.\bar{3}}$[1] and $NbI_{1\,1/6} = NbI_{1.8\bar{3}}$,[2] and not the dihalides. The allowance for such unusual compositions is due to the fact that any excess of valence electrons on the metal atoms can be used for covalent M–M bonding with the formation of $[Nb_6Cl_{12}]^{2+}$ and $[Nb_6I_8]^{3+}$ clusters in the compounds mentioned above. Such clusters had to be recognized for the understanding of the remarkably strict stoichiometry of NbO,[3] a compound with "divalent" niobium which formally has a defect rocksalt structure but is actually a "condensate" of Nb_6O_{12} clusters linked through all the apices of the Nb_6 octahedra.[4]

Numerous compounds turned out to contain such condensed clusters.[5] In particular, condensation along edges or faces of M_6 octahedra is quite common and leads to a wealth of oligomeric and infinite cluster structures as in, for example, the oxomolybdates[6–8] and molybdenum chalcogenides.[9, 10] Compared to this mode of condensation the linkage through apices of the M_6 octahedra, as found in NbO, was rare and the number of examples negligible. However, after the discrete Nb_6O_{12} cluster had been found in an oxoniobate,[11] one hoped for a rich chemistry for compounds with condensed clusters, intermediates between a compound containing isolated clusters and the final member, NbO, with clusters joined through all the apices. This approach created sufficient interest for the investigation of reduced oxoniobates with a wide variety in the countercations and the Nb/O ratio. The suspicion that reduced oxoniobates might exhibit superconductivity at room temperature[12] led to an increased interest in reduced oxoniobates and resulted in an number of investigations. So far, the hope of finding new high-temperature superconductors has not been fulfilled. Nevertheless, superconductivity below 12 K has been found in various reduced oxoniobates.[13–16]

The field of reduced oxoniobates has grown to such an extent, that at this stage a review seems desirable, in which the known compounds are listed, the structural and bonding principles are outlined, and some physical properties are summarized.

2. Preparation and Characterization

At first glance the syntheses of reduced oxoniobates seem to be rather straightforward. They can be carried out as solid-state reactions from appropriate mixtures of binary or ternary starting compounds with Nb and NbO as reducing agents. In spite of this rather basic approach, special care is necessary for a number of reasons. Most of the starting materials and products are solids up to very high temperatures leading to low reaction rates even at temperatures above 1300 K. At these temperatures volatile components like alkali metal oxides may react with the container material. In order to prevent evaporation of the reaction components inert gas atmosphere is thus always preferred over vacuum. Reduced oxoniobates, in particular those in which the Nb atoms have an average oxidation state well below IV, have very low oxygen partial pressures[18] and call for special container materials. Most often sealed Au, Pt, or Nb ampules or corundum crucibles are used; in the latter two cases, the ampule or the reaction mixture is protected by an Ar-filled quartz ampule.[19–21] Ampules made solely of quartz can be used at temperatures up to 1500 K; however, the walls of the reaction vessel are attacked to some extent.[11, 20, 22, 23] Alkaline or alkaline earth compounds react partially with formation of silicates. When traces of moisture are present, chemical transport reactions lead to noticeable changes in the compositions of the products, for example the formation of Nb_5Si_3 via $SiO_{(g)}$.[24] Closed Pt tubes allow temperatures up to 1800 K. Nb ampules seem best for the syntheses as they do not introduce any components not already in the starting materials. They can be used above

2300 K in an inert gas atmosphere. However, Nb ampules can be used only for the preparation of the most reduced compounds which are stable in equilibrium with elemental Nb.

Of course, what has been said about container materials holds true for the system components. Only oxides of very electropositive metals can be used to provide the countercations in the reduced oxoniobates, because all others will be reduced to their elemental state during the synthesis.

Besides Nb and NbO, carbon has also been used to reduce mixtures of $BaCO_3$ and Nb_2O_5 under vacuum at temperatures between 1500 and 1900 K.[25, 26] It is even possible to reduce $BaNb_2O_6$ in a hydrogen flow at 1600 K with the formation of $Ba_2Nb_5O_9$.[27]

Mineralizers or fluxes such as alkaline or alkaline earth fluorides, chlorides, or borates have been used successfully to reduce the necessary reaction temperatures, in particular, to obtain single-crystal specimens.[20, 22, 28–32] However, fluxes can lead to unintended changes of the compositions of the reaction products. Phosphates cannot be used as flux materials since they are reduced with the formation of NbP.[33] In several cases a compound did not form when a flux was employed, as was seen for $NaNb_3O_6$. When using fluorides as mineralizers one always has to bear in mind that fluorine can be incorporated into the crystal lattice and is indistinguishable from oxygen in X-ray investigations.

In many cases the crystal structures of reduced oxoniobates proved to be extremely complicated, and single crystals were essential for solving their structures and determining their compositions. Others, fortunately, were simple enough to be solved by X-ray powder methods. Particularly for the more reduced oxoniobates the early investigations were limited to microcrystalline products; here high-resolution electron microscopy gave valuable insight into structures and structural relationships.

3. On the Way Toward Clusters

Besides many examples of fully oxidized oxoniobates a large number of reduced phases with Nb atoms in oxidation states between IV and V are known. With a few exceptions

Jürgen Köhler was born April 11, 1953, in Bobenheim am Rhein (FRG). He studied chemistry at the Justus-Liebig-Universität in Giessen and completed his doctorate in 1984 under the direction of R. Hoppe in the area of alkali metal oxogallates and oxothallates. Since 1984 he has been in the research group of A. Simon at the Max-Planck-Institut für Festkörperforschung in Stuttgart. His research interests focus on the preparation and characterization of metal-rich oxides and reduced fluorides of the rare-earth metals, as well as the oxidation of metals at low temperatures. He is also interested in the development of new methods for recognizing relationships between crystal structures.

Gunnar Svensson was born in 1960 in Sweden. He received his Ph.D. in 1989 at the Institute for Inorganic Chemistry at the University of Stockholm under the direction of L. Kihlborg. He received an Alexander von Humboldt stipend in 1991 and joined the research group of A. Simon for a year, during which he prepared and characterized reduced oxoniobates. He has been on the staff of the Institute for Inorganic Chemistry at the University of Stockholm since 1992. His research interests lie in the preparation of transition metal oxides and oxonitrides and their characterization with high-resolution electron microscopy as well as with powder and single-crystal X-ray diffraction.

Arndt Simon was born in January 1940 in Dresden. He started his chemistry studies in 1960 at the University of Münster and received his Ph.D. in 1966 for his research with H. Schäfer. After his habilitation in 1972 he became a professor of inorganic chemistry in Münster. He was made a member of the Max-Planck-Gesellschaft and director at the Max-Planck-Institut für Festkörperforschung in Stuttgart in 1974. In 1975 the University of Stuttgart made him an honorary professor. He turned down offers from the University of Münster (successor of H. Schäfer, 1979) and Cornell University (successor of M. J. Sienko, 1985). His research interests range from the studies of metal-rich compounds such as alkali metal suboxides, cluster compounds of heavy d metals, and metal-rich binary and ternary halides of the lanthanoids to the development of new apparatus (Guinier–Simon camera), and the structure and phase transformations in molecular crystals. Further interests include the structure relationships of intermetallic compounds and the investigation of superconductors with the goal of understanding the chemical basis for the phenomenon.

these compounds crystallize in several basic structure types, namely perovskite,[34, 35] tetragonal tungsten bronze (TTB),[36, 37] and $Ba_3Nb_8O_{21}$ types.[38, 39] As in the block-type structures,[40–43] these compounds are built mainly from NbO_6 octahedra. They do not have direct M–M bonds even when they are metallic. These compounds contrast the more reduced nonmetallic oxides $ANbO_2$ (A = Li, Na),[44, 45] which adopt a filled MoS_2 structure in which the A atoms occupy octahedral voids between trigonal-prismatic NbO_2 layers. It is not unusual that atoms with d^2 configuration prefer trigonal-prismatic coordination. The short Nb–Nb distances ($LiNbO_2$ 290, $NaNbO_2$ 295 pm) give evidence for M–M bonding, and Extended Hückel (EH) calculations provide further support.[46]

Although $LiVO_2$ undergoes a phase transition with formation of trigonal V_3 clusters having short V–V distances,[47] this could not be found for the corresponding niobates. Deintercalation of $LiNbO_2$, by the way, leads to Li_xNbO_2 ($x \approx 0.45$) which becomes superconducting at temperatures below 11 K.[13] This property seems closely related to a tendency towards structural instability caused by charge density waves, that is, a tendency to distortion accompanied by cluster formation. Such transitions from a delocalized to a localized electronic system are well known, for example for NbO_2.[48–50] In the high-temperature (HT) form of NbO_2 the chains of *trans*-edge-sharing NbO_6 octahedra are undistorted, the electrons are delocalized, and the compound is metallic. In the low-temperature (LT) form every second joined edge is lengthened, and the Nb atoms form pairs with short Nb–Nb distances (274 pm) corresponding to Nb–Nb single bonds (Fig. 1).[*]

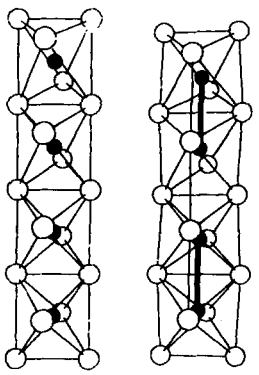

Fig. 1. Chains of *trans*-edge-sharing NbO_6 octahedra in HT-NbO_2 (left) and LT-NbO_2 (right).

A discrete Nb_2O_8 cluster (Fig. 2) was first discovered in the isotypic compounds $NaNb_3O_{6-x}F_x$ ($0 \leq x \leq 0.5$),[20, 51] $Ca_{0.75}Nb_3O_6$,[52] and $Ca_{0.95}Nb_3O_6$.[53] Similar units are also found as molecular species, for example $[Re_2Cl_8]^{n-}$,[54] as well as in the crystal structures of reduced rare earth rhenium oxides such as $La_4Re_6O_{19}$.[55] In the above-mentioned compounds with Nb_2O_8 clusters each Nb–Nb dumbbell is surrounded by four additional Nb atoms with octahedral coordination (indicated by dashed lines in Fig. 2). In $NaNb_3O_6$ the Nb–Nb distances within the dumbbells of Nb(1) atoms are 262 pm and between atoms Nb(1) and Nb(2) 308 pm.

[*] In this and subsequent figures the Nb and O atoms are represented by small black and large white circles, respectively. Large cations (Fig. 4 and following) are denoted by hatched circles.

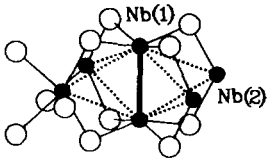

Fig. 2. Nb_2O_8 cluster in $NaNb_3O_6$ and related compounds together with surrounding Nb atoms and a coordination octahedron for one of these. Heavy lines indicate Nb–Nb multiple bonding, dotted lines weak Nb–Nb bonding.

The corresponding distances in the isotypic Ca compounds are a little shorter. The long Nb–Nb distances can still be interpreted in terms of weak M–M bonding. An extensive discussion of the bonding on the basis of EH calculations[56] for $NaNb_3O_6$ supports the hypothesis that the Nb–Nb bond within the dumbbell is a double bond and that some additional Nb–Nb bonding to the four surrounding Nb atoms is present.

4. Principles of Structures Based on the Nb_6O_{12} Cluster

The compounds to be discussed in this section contain the most complicated as well as very simple structures. The common principle in these structures is the common close-packing of structural units which have comparable sizes. These units are O atoms, Nb_6 octahedra, and large A atoms which serve as countercations. The description of the compounds will start with those containing discrete Nb_6O_{12} clusters and end with those with condensed cluster phases.

4.1. Discrete Nb_6 Octahedra

Since the early discovery of a compound containing discrete Nb_6O_{12} clusters[11] a whole series of reduced oxoniobates with such clusters has been found (Table 1). A $Nb_6O^i_{12}O^a_6$ cluster is shown in Figure 3. The twelve O atoms above the edges of a Nb_6 octahedron belong to the inner sphere and form a cuboctahedron. They are designated O^i if they belong to one cluster, or O^{i-i} if they connect adjacent clusters.[4] As many as six O atoms above the apices of the octahedron constitute the outer ligand sphere and may belong to one cluster only (O^a), or link clusters with identical (O^{a-a}), as well as different functionality (O^{a-i}, O^{i-a}).

In each compound given in Table 1 the Nb–Nb distances in the Nb_6O_{12} cluster fall within the narrow range of 279–289 pm. The distances between the Nb and O^a atoms are usually between 215 and 235 pm, while Nb–O^i distances range from 202 to 213 pm, which is about $1/2 \times \sqrt{2} \times d_{Nb-Nb}$ (285 pm). Therefore, each Nb atom lies no further than 5 pm from the plane formed by four surrounding O^i atoms (inside the cuboctahedron). This situation is different with Nb_6X_{12} clusters with X = Cl or Br in which the distances d_{Nb-Nb} are much smaller than $\sqrt{2} \times d_{Nb-X}$ resulting in a contraction of the M_6 octahedron relative to the X_{12} cuboctahedron. For topological reasons the Nb_6O_{12} clusters are therefore much more suited for a condensation through the apical atoms then the corresponding halide clusters; in addition, ligand deficiency is easier to attain with (divalent) oxygen than with (monovalent) halogen atoms.

As mentioned above, O atoms, Nb_6 octahedra, and, if present, large atoms of the electropositive metal A (A = Na,

K, Rb, Sr, Ba, La, Eu) form a conventional close-packing. Smaller M atoms fill tetrahedral (M = Al, Si, Mg, Mn), octahedral (M = Nb, V, Mg, Mn), and trigonal-bipyramidal voids (M = V, Nb) within the O sublattices. These additional atoms stabilize the structures and formally act as electron donors for the Nb_6O_{12} clusters.

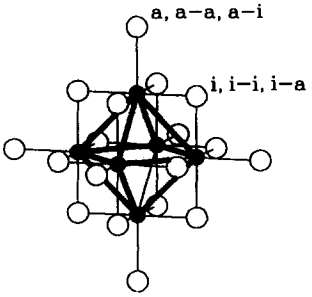

Fig. 3. $Nb_6O^i_{12}O^a_6$ cluster with notations according to ref. [4].

In the following discussion the structural principle of a common close-packing is outlined in more detail. The structures known at present can be described and compared on the basis of only a few features. As usually done with close-packed arrangements of spheres, the packings are decomposed into 3^6 layers[57] which are of four types in the structures discussed here. The first is made up solely of O atoms, the second consists of A and O atoms, the third contains O atoms and Nb_6 octahedra, and the fourth is composed of O and A atoms together with Nb_6 octahedra. The latter two allow an infinite number of different arrangements (and compositions). Only the layer types with Nb_6 octahedra shown in Figure 4 a–e have been found so far. The layers shown in Figure 4a and b have Nb_6:O ratios of 1:3 and 1:6, respectively. They represent the limiting cases with all O atoms bonded as O^{i-i} (layer a) and O^i atoms (layer b). A particularly simple case in between with both O^i and O^{i-i} atoms is one which contains linear chains with O^{i-i} bridges

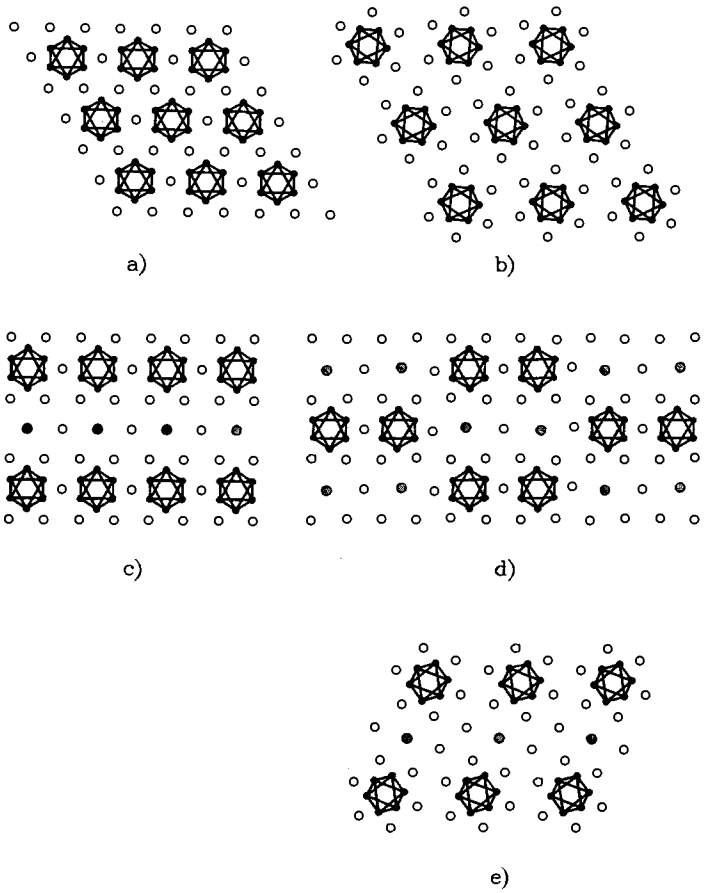

Fig. 4. Common close-packed layers of large cations, O atoms, and Nb_6 octahedra as found in reduced oxoniobates with discrete Nb_6O_{12} clusters.

as in $Nb_6O^i_4O^{i-i}_{2/2}$. Such chains separated by AO chains occur in the layers c and have the composition ANb_6O_6. Variations are possible when the chains are terminated by "chemical shear".[86] Layer d is an example of a layer with only one O^{i-i} bridge. It has the composition $Nb_6O_{11} + A_2O =$

$A_2Nb_6O_{12}$. Last but not least, layer e is related to type b in so far as all O atoms around the Nb_6 octahedron are of O^i type. Such nonconnected cluster sections are combined with a zigzag AO_2 chain to yield a layer with the composition ANb_6O_8.

There are certain (trivial) rules to be obeyed when stacking such individual layers. Three O atoms are added above and below the Nb_6 unit in order to complete the Nb_6O_6 fragment and form a Nb_6O_{12} cluster. A stacking of only type a layers leads to the structure of NbO. In metal-rich oxoniobates with discrete Nb_6O_{12} clusters discussed in subsequent sections, layers of types a–e are always surrounded by pure O or AO_x layers.

For a simplified description of the existing compounds it is helpful to limit the discussion to characteristic slabs formed from several layers. Figure 5 summarizes the different kinds which have been found. Type I slabs contain the Nb_6O_{12} clusters and are of primary interest. The index a–e is included in the notation to indicate the kind of central

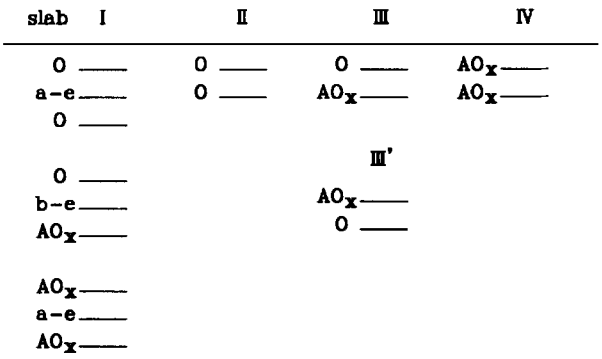

Fig. 5. Schematic representation of characteristic slabs formed from close-packed layers in compounds with discrete Nb_6O_{12} clusters (see text).

layer according to Figure 4. No differences are made, however, with respect to whether the envelope consists of pure O or AO_x layers. These differences enter the notation (II–IV) for the types or contacts between the cluster slabs.

Layers a: The structures of $M_3Nb_6O_{11}$ (M = Mn, Mg),[19, 21] and $Na(V_{3-x}Nb_x)Nb_6O_{14}$[62] (idealized $NaV_2Nb_7O_{14}$) contain type I_a slabs (Figs. 6 and 7). The particularly simple atomic arrangement in $Mg_3Nb_6O_{11}$ is well suited to illustrate the system of notation. The sequence I_a,

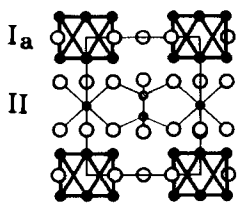

Fig. 6. Projection of the structure of $Mg_3Nb_6O_{11}$ on (100) in the range $-0.5 \leq x \leq +0.5$. Small gray circles represent Mg atoms. MgO_4 tetrahedra and MgO_6 octahedra are highlighted.

II... indicates that layer a is surrounded by layers of O atoms and that the resulting type I_a slabs are simply stacked. Mg atoms occupy one-fourth of the tetrahedral and one-fourth of the octahedral holes between the layers of O atoms in such a way that the MO_6 octahedra and MO_4 tetrahedra are

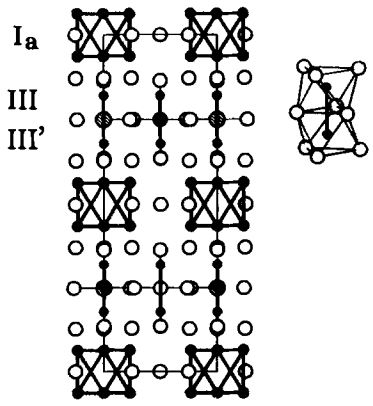

Fig. 7. Projection of the structure of $NaV_2Nb_7O_{14}$ on (100) in the range $-0.5 \leq x \leq +0.5$ and the separate drawing of a V_2O_9 cluster.

linked only by shared corners. The structure of $Na(V_{3-x}Nb_x)Nb_6O_{14}$ can be described by the sequence I_a, III, III' .... The combination of III and III', in this case, results in a hexagonal stacking of the O, AO_x, and O layers leading to trigonal-bipyramidal voids occupied by Nb atoms. Moreover, pairs of face-sharing O_6 octahedra are present, both of which are filled by V atoms forming V_2O_9 clusters. Such M_2X_9 clusters are known, for example, from the halides $Cs_3M_2Cl_9$ (M = Cr, Mo, W).[60, 61] The M atoms are shifted towards one another in the case of M = Mo and W to form short M–M bonds of 261 and 251 pm, respectively. The lack of M–M bonding when M = Cr is indicated by shifts in opposite directions (d_{Cr-Cr} = 313 pm). The V_2O_9 cluster has the same topology as the Cr complex; however, the V–V distance is short enough (256 pm) that M–M bonding must be assumed. The distances between the V atoms and O atoms of the common face are 207 pm and longer than the other V–O distances of 199 pm.

Layers b: Six structure types containing type I_b slabs have been found so far. They all crystallize in trigonal space groups with *a* axes of nearly equal length (777–784 pm). The number of layers per unit cell in a structure can be calculated by dividing the length of the *c* axis by the average repeat distance of neighboring layers ($\approx$235 pm).

The simple sequence I_b, III'... is found in the structure of $BaSiNb_{10}O_{19}$;[63] the isotypic compound $KSiNb_{10}O_{19}$[33] is also known (Fig. 8). Single Nb and Si atoms occupy octahe-

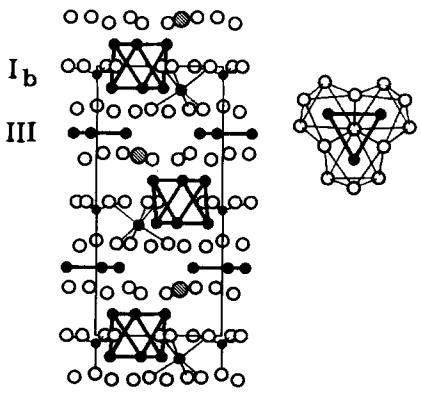

Fig. 8. Projection of the structure of $BaSiNb_{10}O_{19}$ on (210) together with a drawing of a Nb_3O_{13} cluster (d_{Nb-Nb} = 282 pm).

dral and tetrahedral sites, respectively, within slab I_b. Additional Nb atoms fill three adjacent octahedral voids in III'. The common edges of the coordination octahedra are rather long (314 pm), and the Nb atoms form a Nb_3 triangle with short Nb–Nb distances (282 pm). Thus, $MSiNb_{10}O_{19}$ contains a second metal cluster, Nb_3O_{13}, as well as Nb_6O_{12}. The M_3O_{13} cluster is well known from the oxomolybdates, $M_2Mo_3O_{13}$ (M = Li, Zn, Sc, Ni...),[64, 65] which have a variable number of valence electrons (6–8) in M–M bonding states.[66, 67] A comparable variability of the electron count is found with halide clusters Nb_3X_8 (X = Cl, Br).[68, 69] As will be shown later, the Nb_3O_{13} cluster can act as an electron buffer in reduced oxoniobates.

A sufficient amount of Si is necessary for the formation of $KSiNb_{10}O_{19}$, otherwise a compound with nearly the same composition, $K(Si_xNb_{1-x})Nb_{10}O_{19}$,[33] but a completely different structure is formed which is isotypic to $Na(Si_xNb_{1-x})Nb_{10}O_{19}$ ($x \approx 0.75$)[22, 70] (Fig. 9). In this structure type I_b slabs are directly joined, and these twin slabs alternate with intermediate slabs III and III' to form the sequence I_b, I_b, III, III' .... As in $BaSiNb_{10}O_{19}$, octahedral and tetrahedral holes within I_b are occupied by Nb and Si atoms, respectively. Yet, there is a crucial difference. Since the coordination tetrahedron about Si has a common face with one of the coordination octahedra about Nb, they can be occupied only alternately (Fig. 9). The $Si^{IV}:Nb^{V}$ ratio is approximately 0.75, and the variation of this ratio is another type of electron buffer. The occupation of octahedral voids within III and III' by Nb atoms follows the same pattern as in $BaSiNb_{10}O_{19}$; however, another mode of cluster formation arises from these neighboring slabs. Nb atoms pair up across the slabs (d_{Nb-Nb} = 274 pm), that is, the NbO_6 octahedra are joined along common edges as in LT-NbO_2 (Fig. 1). This bonding situation is typical for Nb^{IV} with a d^1 configuration.

The compound $A_3Al_2Nb_{34}O_{64}$(A = Na, K) provides one more example of a structure type[22, 23] that contains all the features discussed so far, and in spite of its complexity, illustrates the underlying simple building block system. The structure is described by the sequence I_b, III', I_b, III, I_b, III, III'... (Fig. 10). Single Nb atoms fill octahedral voids within slabs I_b, and Al atoms occupy tetrahedral voids. M–M-

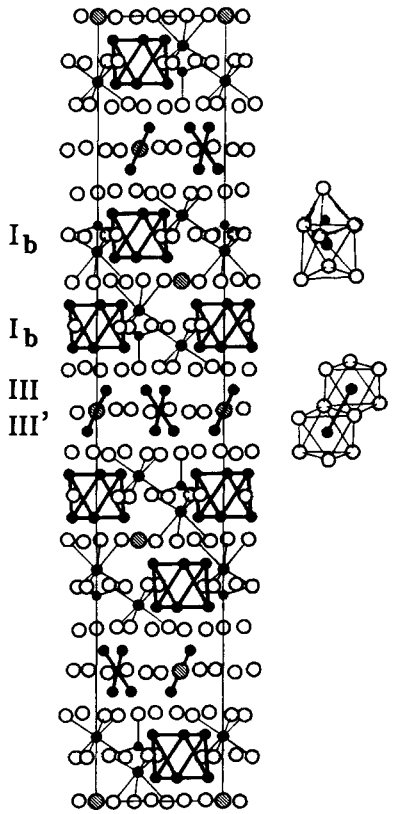

Fig. 9. Projection of the structure of $Na(Si_xNb_{1-x})Nb_{10}O_{19}$ on (210) with separate drawings of the Nb_2O_{10} cluster and the adjacent octahedral and tetrahedral voids which are occupied alternately with Nb and Si, respectively.

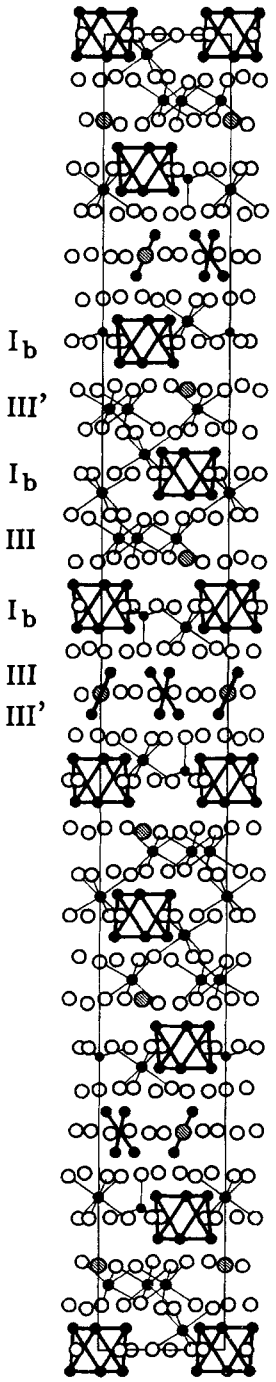

Fig. 10. Projection of the structure of $Na_3Al_2Nb_{34}O_{64}$ on (210).

bonded Nb_2 units are formed across neighboring slabs III, III' as in $Na(Si_xb_{1-x})Nb_{10}O_{19}$. The octahedral voids in the single slabs of types III and III' are occupied as in $BaSiNb_{10}O_{19}$, but in contrast, the Nb–Nb distances within the Nb_3O_{13} unit are considerably longer (317 pm).

In the structures of $Ba_3Si_2Nb_{20.8}O_{44}$,[11] $M_4(SiNb)_2Nb_{35}O_{70}$ (M = K, Rb),[33, 71] and $Ba_2Nb_{15}O_{32}$[32] one more feature is added (Figs. 11–13). Neighboring AO_6 layers lead to the formation of type IV slabs. Only one-seventh

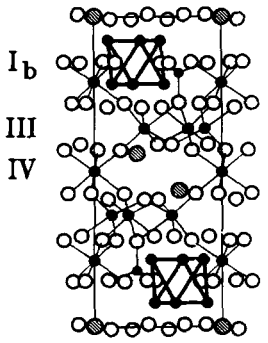

Fig. 11. Projection of the structure of $Ba_3Si_2Nb_{20.8}O_{44}$ on (210).

of the octahedral voids between the layers can be occupied, resulting in more highly oxidized compounds with an O:Nb ratio ≥ 2.0 in contrast to the compounds discussed previously in which the O:Nb ratio is < 2.0. The existence of only a few links between the layers of type IV slabs always leads to platelike crystals and easy cleavage parallel to IV. Besides these mechanical consequences of the weak bonding between the layers, there are chemical consequences. The distances between AO_6 layers and thus the size of the octahedral void can vary and allow an occupation by Nb atoms in different oxidation states (IV, V, or of intermediate valency). Thus, we meet yet another kind of electron buffer in the reduced oxoniobates.

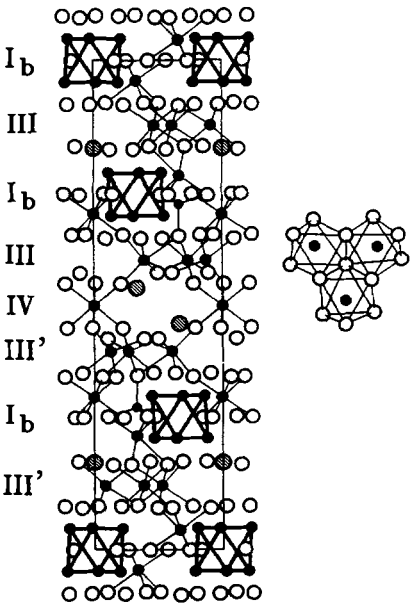

Fig. 12. Projection of the structure of $Rb_4(SiNb)_2Nb_{35}O_{70}$ on (210) together with a drawing of a Nb_3O_{13} unit ($d_{Nb \cdot Nb} = 335$ pm).

More about the electronic buffer mentioned previously, the Nb_3O_{13} unit, can be learned from $Rb_4(SiNb)_2Nb_{35}O_{70}$.[71] As seen in Figure 12 there are two different kinds of such units. Those which are sandwiched by two I_b slabs exhibit Nb–Nb distances of 306 pm indicating weak Nb–Nb bonding; in contrast those between slabs I and IV have Nb–Nb distances of 335 pm. In all compounds known so far, shortened Nb–Nb distances within Nb_3O_{13} units are only observed if these units are embedded between type I_b slabs, cf. $BaSiNb_{10}O_{19}$, $Ba_3Si_2Nb_{20.8}O_{44}$, and $Ba_2Nb_{15}O_{32}$.

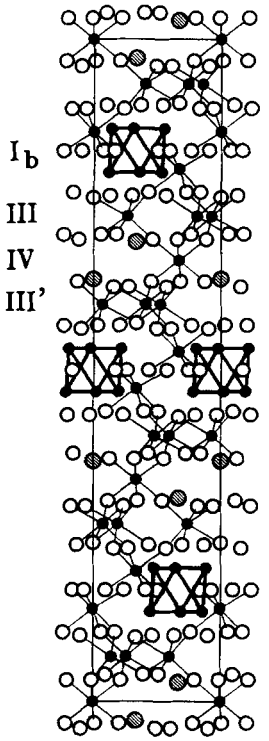

Fig. 13. Projection of the structure of $Ba_2Nb_{15}O_{32}$ on (210).

$Rb_4(SiNb)_2Nb_{35}O_{70}$ allows for a most intricate adjustment of electronic balance. Besides the buffer systems previously discussed, the $Si^{IV}:Nb^{V}$ ratio in adjacent tetrahedral and octahedral voids (cf. $Na(Si_xNb_{1-x})Nb_{10}O_{19}$) and the partial occupation of the cuboctahedral voids with Rb atoms come into play. As will be discussed later, this introduces considerable ambiguity into the determination of a "magic" concentration of valence electrons for the Nb_6O_{12} cluster.

Layers c: The structure of the compounds ANb_8O_{14} (A = K, Sr, Eu)[72, 28, 73] is shown in Figure 14. Type I_c slabs are stacked simply with a repeat length of 930 pm for two I_c

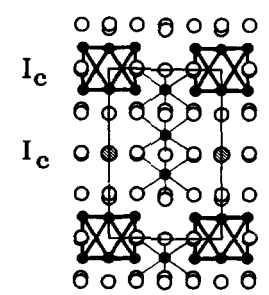

Fig. 14. Projection of the structure of $SrNb_8O_{14}$ on (010) in the range $-0.25 \leq x \leq +0.25$. The NbO_6 octahedra are highlighted; I_c slabs appear different because of a relative shift by 0.5 in the viewing direction.

slabs. Adjacent voids are filled by Nb atoms such that two NbO_6 octahedra have a common corner. Together with the surrounding A atoms, the part of the structure between the clusters represents a fraction of the perovskite structure. Many more examples of such intergrowth will be described in connection with condensed clusters.

Layers d: Larger countercations in ANb_8O_{14} (A = Ba, La) lead to structures significantly different from that of $SrNb_8O_{14}$. Although an isotypic phase of $BaNb_8O_{14}$[30] was observed, the broad lines of the X-ray diagram indicate severe disorder. Careful annealing leads to a new structure which still contains some disorder (C-centered lattice type[30]) or is entirely ordered (primitive lattice[32]). The ordered structure of $BaNb_8O_{14}$ with a simple stacking of I_d slabs is shown in Figure 15. The infinite chains of O^{i-i} linked Nb_6O_{12} clusters as they occur in $SrNb_8O_{14}$ are interrupted after two clusters. This chemical shear also disrupts the linear arrangement of Ba atoms. As a result the surrounding O_{12} cuboctahedron is larger than between I_c slabs. $LaNb_8O_{14}$[72] has been found with only an even more pronounced disorder.

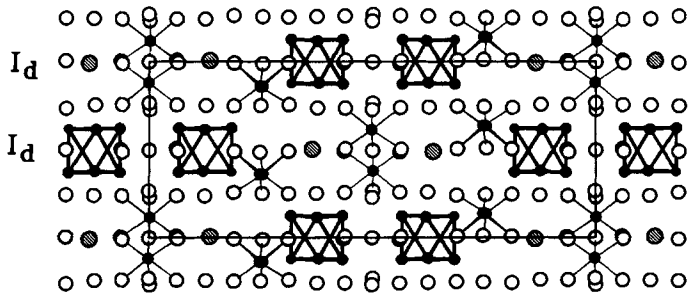

Fig. 15. Projection of the ordered structure of $BaNb_8O_{14}$ on (100) in the range $-0.25 \leq x \leq +0.25$. I_d slabs appear different because of a relative shift by 0.5 in the viewing direction.

Layers e: Finally, I_e slabs connected to one another are found in the structure of $NaNb_{10}O_{18}$[29] (Fig. 16). Compared to the structure of $SrNb_8O_{14}$, the Nb_6 octahedra here are even more separated as no O^{i-i} bridges occur. Four additional Nb atoms occupy octahedral sites, which are linked along shared edges to form a chain fragment. The central Nb–Nb distance is 294 pm, two outer Nb–Nb distances are 313 pm. The outer Nb atoms of such chain fragments exhibit short distances to Nb atoms of the cluster (309 pm), in contrast to the corresponding distances in $SrNb_8O_{14}$, which are considerably longer (330 pm).

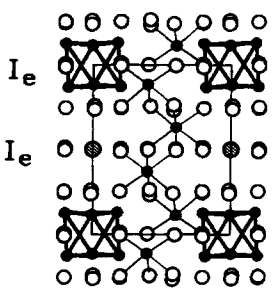

Fig. 16. Projection of the structure of $NaNb_{10}O_{18}$ on (001) in the range $-0.25 \leq x \leq +0.25$. I_e slabs appear different because of a relative shift by 0.5 in the viewing direction.

The structures discussed so far are built from discrete Nb_6O_{12} clusters linked by O atom bridges. In the following section structures will be shown in which such units share Nb atoms, resulting in condensed clusters.

4.2. Condensed Nb_6 Octahedra

Nb_6O_{12} clusters can be condensed in one, two, or three dimensions. Although a number of such compounds has been found during the last four years, at present $K_4Al_2Nb_{11}O_{21}$ is the only representative with oligomeric clusters.[74, 75] This compound contains two Nb_6 units condensed at a common vertex to form the cluster $[Nb_{11}O^i_{20}]O^a_{10}$ (Fig. 17). The Nb–Nb distance from the central Nb atom to the eight neighboring Nb atoms (289 pm) is significantly longer than the others in the cluster (280 or 284 pm).

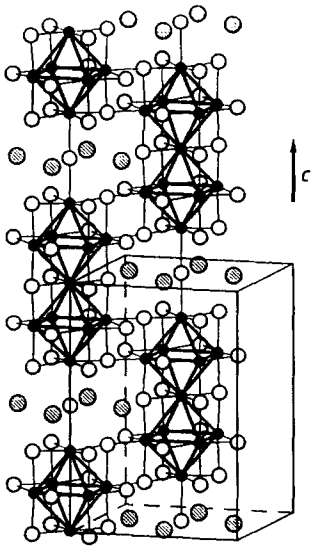

Fig. 17. Unit cell and a characteristic section of the structure of $K_4Al_2Nb_{11}O_{21}$.

Each cluster is connected to eight neighboring clusters by O^{i-a} bridges forming a three-dimensional network. This linkage yields rather short Nb–Nb distances of 308 pm between clusters, which will be discussed later in more detail. In the z direction the clusters are rather weakly connected by two linear O^{a-a} bridges.[76] Within the three-dimensional cluster framework the voids are occupied by K and Al atoms.

As in compounds containing discrete Nb_6O_{12} clusters, the atomic arrangement in $K_4Al_2Nb_{11}O_{21}$ can be rationalized in terms of a common close-packing of K and O atoms together with Nb_6 units. The close-packed arrangement itself can be decomposed into columns which present an alternation of the $Nb_{11}O_{30}$ cluster and a fragment of the perovskite-type structure.

One can imagine an alternative kind of intergrowth between perovskite-type fragments and infinitely condensed Nb_6O_{12} clusters as fractions of the NbO structure by extending the structural principles discussed for compounds with discrete Nb_6O_{12} clusters. As mentioned earlier, simple stacking of only Nb_6O_3 layers leads to the NbO structure

(Fig. 4a). Three such layers are outlined in Figure 18. If a limited number of NbO layers is sandwiched by pure O atoms, slabs cut parallel {111} from the NbO structure with the general formula $Nb_{3n+6}O_{3n+11}$ (n = number of layers) result. The limiting cases are the NbO structure itself ($n = \infty$) and the Nb–O framework of $Mg_3Nb_6O_{11}$ ($n = 0$). Any structures with $1 \leq n < \infty$ are possible but unknown at present. A similar stacking of only layers c leads to a general formula $A_nNb_{4n+2}O_{6n}$. The limiting cases here are ANb_4O_6 ($n = \infty$), a compound which exists with A = Ba[31] (see Fig. 18b), and the Nb–O framework of $SrNb_8O_{14}$ ($n = 1$). Again none of the possible intermediate structures with $1 < n < \infty$ has been observed so far. In contrast to the limited number of structures based on the NbO-type layers cut parallel {111}, intergrowth phases based on layers cut parallel {100} have been frequently observed in the K–, Sr–, Ba–, and Eu–Nb–O systems, and have turned out to be veritable treasure troves of condensed cluster compounds.

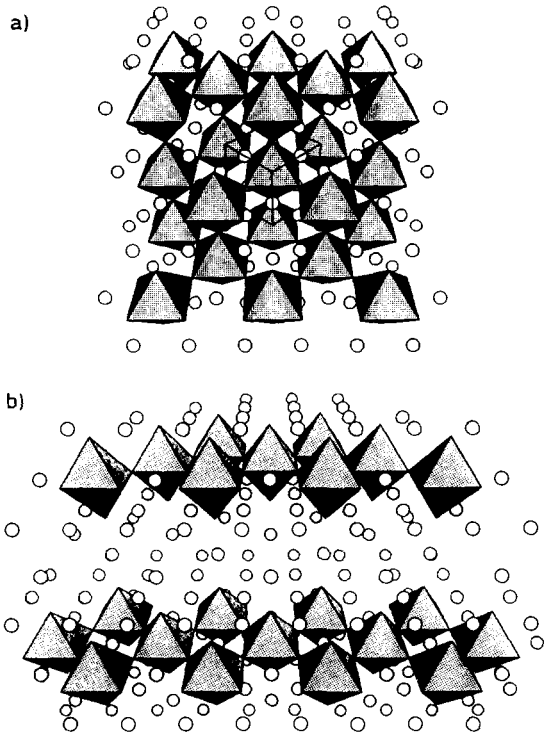

Fig. 18. The structures of a) NbO projected along [111] showing the 3D-condensed Nb_6 octahedra and b) $BaNb_4O_6$ projected along [112] revealing layers of 2D-condensed Nb_6 octahedra.

The arrangements of atoms in NbO[3, 77] and $BaNbO_3$[34, 78, 79] fit together well (Fig. 19). It is therefore possible to mutually dilute them. Either the three-dimensional condensate of Nb_6O_{12} clusters in NbO can be fragmented by a systematic insertion of perovskite-type sections or the perovskite-type section can be intersected by fragments of the NbO structure. Thus, a remarkably complex chemistry results. Intergrowth of the perovskite and NbO structure along [100] results in at least one short axis (410–419 pm). This short repeat unit corresponds approximately to the heights of the Nb_6 as well as the NbO_6 octahedra and therefore makes the compounds excellent candidates for investigation by High-Resolution Electron Microscopy (HREM).

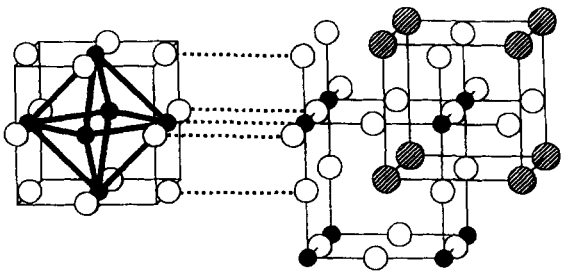

Fig. 19. Topological similarity of the structure of NbO (left, a = 421 pm) and $BaNbO_3$ (right, a = 408.5 pm for $Ba_{0.95}NbO_3$).

4.2.1. α-Phasoid

The high melting points of niobium oxides and BaO are the cause of considerable disorder in the oxoniobates prepared without flux at "moderate" temperatures (1300–1500 K). The phase diagram for BaO–NbO–NbO_2 is shown in Figure 20. HREM images of the samples with compositions close to the line NbO/$BaNbO_3$ are shown in Figure 21.

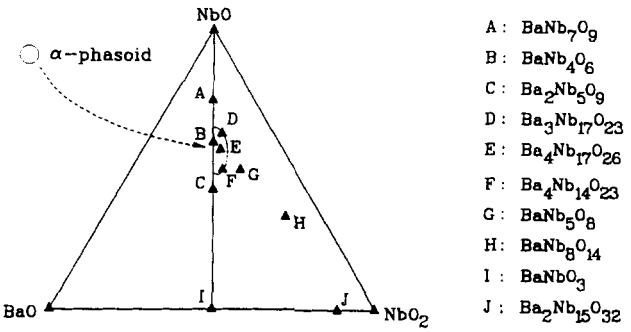

Fig. 20. The BaO–NbO–NbO_2 system. The region with the approximate composition of the α-phasoid is circled.

Crystals can be found in an area near NbO in which perfect regions of the NbO-type structure are intersected by single perovskite-type layers (Fig. 21a). The metal atoms in the Nb_6 octahedra forming the NbO slabs appear as large black spots, or rather crosses, and the perovskite slabs are clearly recognized as light stripes. In crystals with an excess of the perovskite component the situation may be inverted (Fig. 21b). Large domains of the perovskite are intersected by single layers of the NbO-type structure. The square net of metal atoms in the perovskite domains is clearly seen.

A change in the composition toward NbO leads to the compound $Ba_2Nb_5O_9$ which has regular layered intergrowth (Fig. 21c); this structure will be discussed later in detail. Moving still further toward NbO, a remarkable compound with a Ba:Nb ratio of approximately 1:4 exists as a homogeneous "phase" in the shaded region to the right of the $BaNbO_3$/NbO line.[80]

In crystals of this compound the two-dimensionally extended blocks of both structure types are shown before decomposition into one-dimensional fragments (Fig. 22a). The dark crosses again correspond to columns of Nb_6 octahedra and the smaller spots in between to the Ba and Nb atoms in the perovskite-type regions. Despite the amount of disorder in the crystals, one can assume that the columns along the

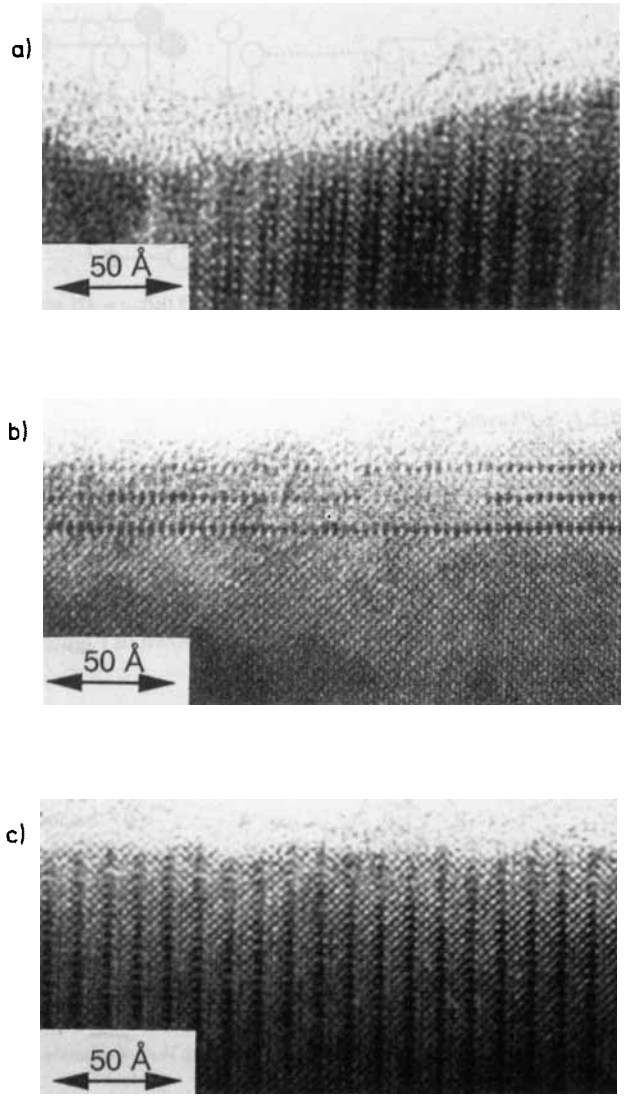

Fig. 21. a) HREM image of a crystallite exhibiting 1D intergrowth of perovskite (light) in NbO (dark). b) HREM image of a crystallite exhibiting 1D intergrowth of NbO in $BaNbO_3$. c) HREM image of $Ba_2Nb_5O_9$ viewed along [001]. Dark lamella of NbO are interleaved with a square lattice of dark spots corresponding to Ba and Nb atoms.

viewing direction are not interrupted and that the number of defects is very limited along these columns.[81-83]

The exact meaning of the term "phase" may be questioned here. The less rigidly defined term "phasoid" introduced by Magnéli[84, 85] can be used very appropriately as a common description of these intergrowth structures. Of course, such a phasoid, called α-phasoid in the Ba–Nb–O system,[82] is thermodynamically instable, but it forms because the difference in its energy of formation compared to possible discrete phases is rather small. Apparently, shortly after the reaction has started, this disordered intergrowth forms rather quickly, and once the phasoid has formed the reaction stops at moderate temperatures.[87]

The one-dimensional structural features of the α-phasoid which contrast the layered intergrowth near NbO or $BaNbO_3$ deserve some comment. If one considers the different types of intergrowth that are probably due to a slight but significant difference in the metrics of NbO and $BaNbO_3$, single slabs of the minority component can adjust to the crystal structure of the majority component. If the ratio $BaNbO_3:Nb_3O_3$ is close to one, large and in particular two-dimensionally extended blocks are avoided, because small fragments of both structures can mutually adjust more easily.

The HREM images of the α-phasoid are rather easy to interpret in spite of the complexity of its intergrowth. A magnification of the region marked in the image and two possible interpretations are shown in Figure 22. The smaller spots in the perovskite blocks correspond to strings of Nb and O atoms (41 and 8 electrons, respectively) and Ba atoms (56 electrons) which are aligned parallel to the viewing direc-

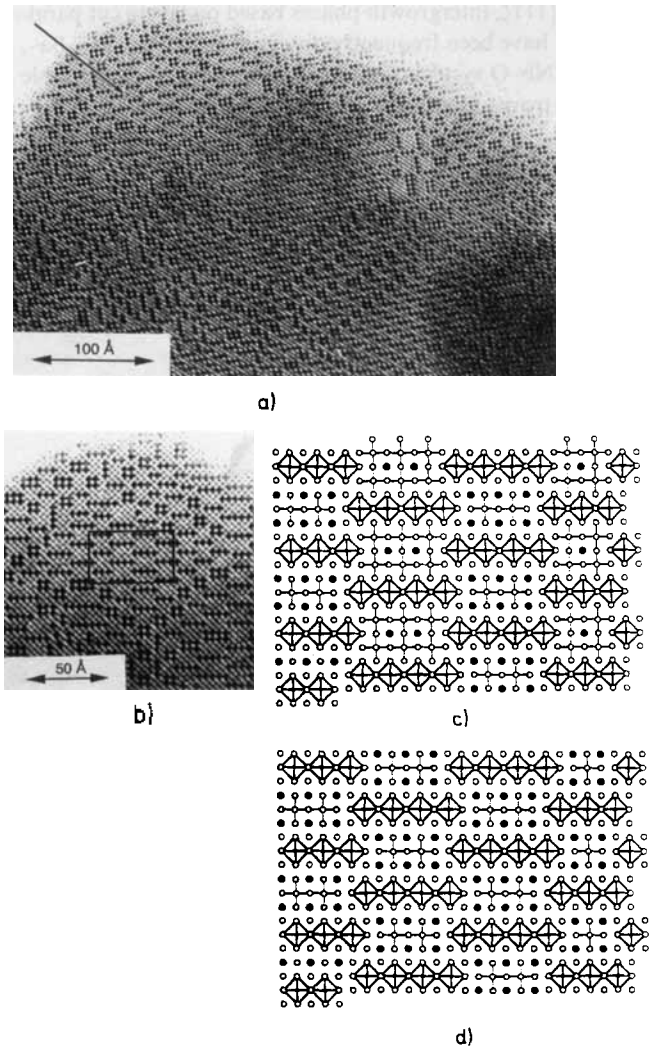

Fig. 22. a) HREM image of the α-phasoid in the Ba–Nb–O system. NbO blocks are seen as large spots or crosses, and the Ba and Nb atoms in the perovskite blocks as smaller spots in between. b) Enlargement of the area marked in a). Two different interpretations of the enclosed area are indicated in c) and d). In c) the perovskite matrix between the NbO blocks is assumed to be coherent; in d) perovskite blocks between the NbO blocks are independently oriented. The models yield a Nb:Ba ratio of 5.2 for c) and 3.4 for d).

tion approximately 290 pm apart. The average number of electrons in the two types of strings are rather similar. As a result, structure models differing only in the distribution of the metal atoms among the projected positions can give rise to more or less identical simulated HREM images. This

makes it difficult to distinguish between models as shown in Figure 22c and d without further information from X-ray structure analyses of ordered phases.

In Figure 22a one can see many regions of the image with rather ordered distributions of uniformly sized blocks, which are interpreted in terms of "microphases".[82] Although these regions are quite small, their identification has helped to systematize and to give a better understanding of the structural and compositional variations within the α-phasoid. These microphases can then be considered members of many different homologous series.

To simplify the discussion the following notation will be used as a description of the cluster substructures. The NbO-type substructures are described in terms of the matrix $[p \times q \times r]$, where p, q, and r refer to the number of condensed Nb_6 octahedra in the three directions of space. A discrete Nb_6O_{12} cluster and NbO are represented by $[1 \times 1 \times 1]$ and $[\infty \times \infty \times \infty]$, respectively. A similar description, $\{s \times t \times u\}$, is used for the perovskite units, where s, t, and u correspond to the number of perovskite-type units as well as the number of A atoms. In general, each NbO-type block is linked to four neighboring blocks by O^{i-a} bridges, resulting in rather short Nb–Nb intercluster distances (ca. 300 pm). The O^{i-a} linkage also separates the perovskite blocks from one another thus enabling them to orient out of phase with respect to each other.

An infinite number of homologous series can be derived from combinations of $[p \times q \times r]$ and $\{s \times t \times u\}$. However, for practical reasons only four basic series are considered[82] (Fig. 23). According to the notation given above they are described as $[p \times q \times \infty]$ with $1 \leq q \leq \infty$ and p = constant. Increasing values of q correspond to an increase of the sizes of the NbO- and simultaneously the perovskite-type blocks. The end members of all series are of the type $[p \times \infty \times \infty]$ and

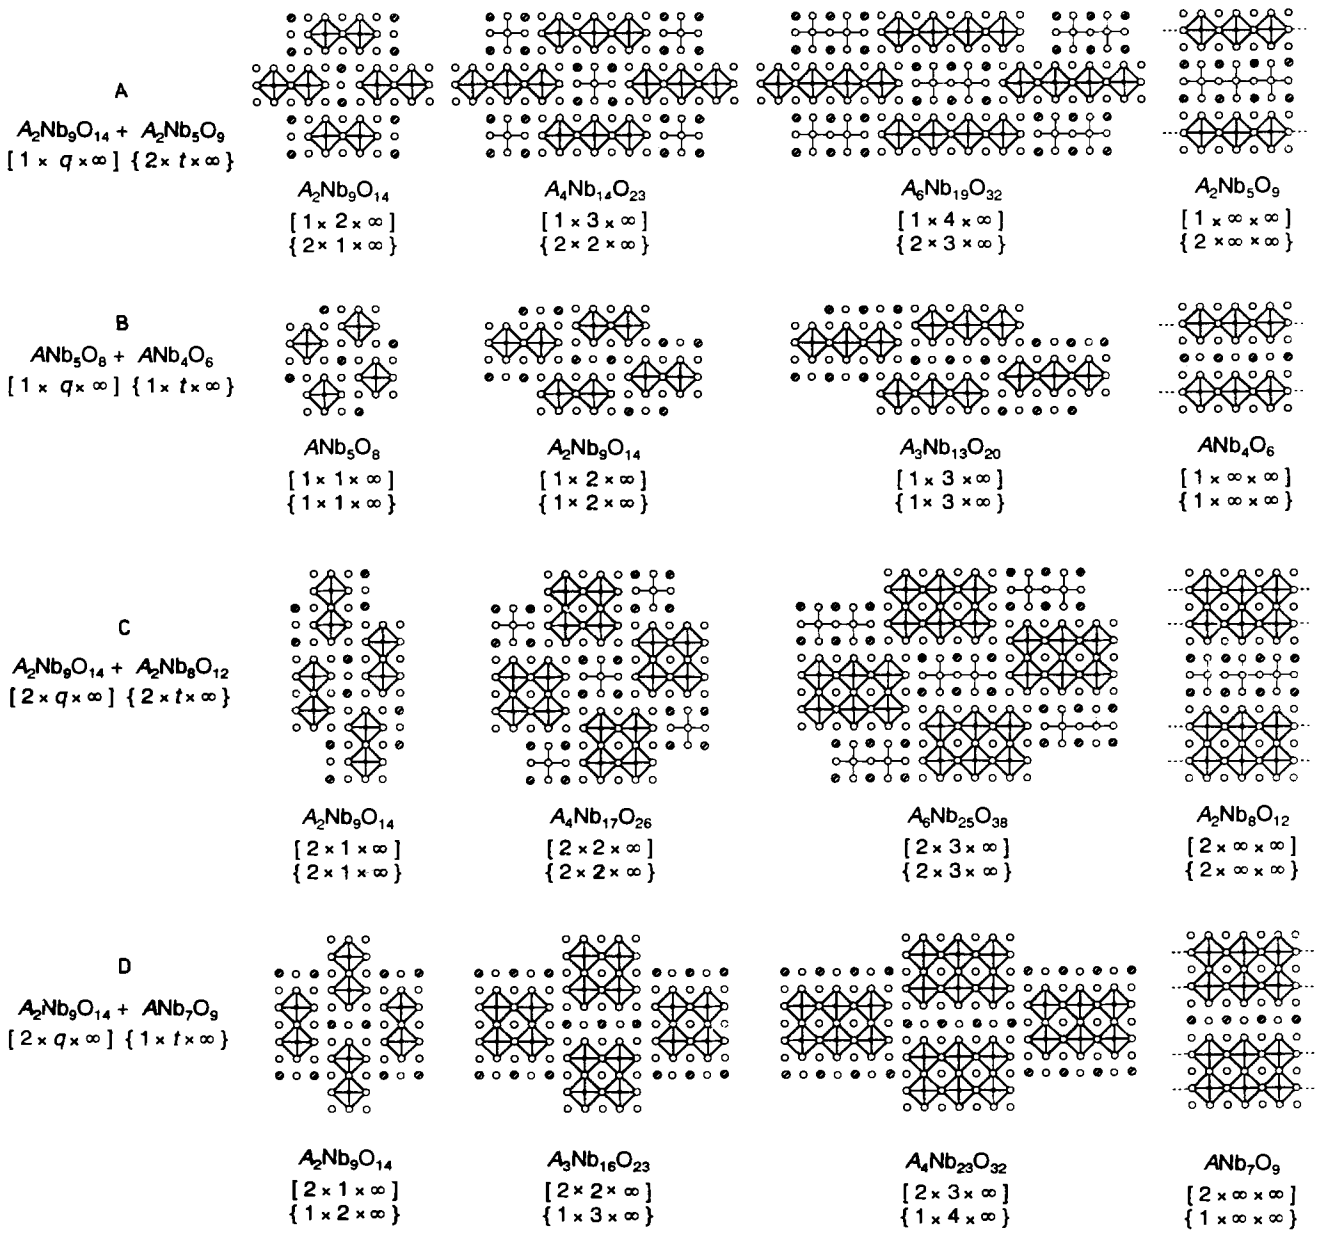

Fig. 23. Four homologous series A–D describing intergrowth compounds between perovskite and NbO structures. Each homologous series corresponds to $\{s \times t \times \infty\}$ with s = const, $t = 1, 2, \ldots \infty$ and $[p \times q \times \infty]$ with p = const, $q = 1, 2, \ldots \infty$. The end members with $t = q = \infty$ form a homologous series of their own, $A_sNb_{s+3p}O_{3s+3p}$.

Table 2. Unit cell parameters [pm] and properties of compounds containing condensed Nb_6O_{12} clusters.

thus represent structures containing two-dimensionally condensed Nb_6O_{12} clusters. These structures belong to a series of $A_sNb_{s+3p}O_{3s+3p}$ where s is the number of perovskite-type slabs $\{s \times \infty \times \infty\}$ and p the number of NbO-type slabs $[p \times \infty \times \infty]$.

4.2.2. Ordered Structures

There are many examples in the literature in which ranges of homogeneity could be split into discrete ordered line phases by careful choice of the preparative conditions.[88–92] Several of the phases predicted in the homologous series of reduced oxoniobates (Fig. 23) have been synthesized (Table 2). We concentrate here on the discussion of the Ba compounds which present the largest diversity.

Three compounds have been found with one-dimensionally condensed clusters. $Ba_{1-x}Nb_5O_8$ ($x = 0.2$)[25] contains single chains of the type $[1 \times 1 \times \infty]$ which alternate with single columns of perovskite units $\{1 \times 1 \times \infty\}$ containing barium atoms cuboctahedrally coordinated by O atoms (Fig. 23). This phase is the starting member of the series B depicted in Figure 23. The structure is based on Rietfeld refinement on neutron powder data leading to a significant Ba atom deficiency.

Trimers $[1 \times 3 \times \infty]$ of cluster chains are found in $Ba_4Nb_{14}O_{23}$,[94] again one of the phases in Figure 23. The compound occurred together with the α-phasoid. Its structure was characterized from HREM images, and the unit cell parameters were obtained from X-ray powder patterns. Within each perovskite block of the size $\{2 \times 2 \times \infty\}$ one Nb atom occupies an octahedral void. Quadruple chains $[2 \times 2 \times \infty]$ together with perovskite blocks $\{2 \times 2 \times \infty\}$ are found in $Ba_4Nb_{17}O_{26}$.[95, 96] The calculated X-ray powder pattern fits the observed powder pattern; however, the given atomic positions are not very accurate.[97]

More accurate structural data are available for the phases with two-dimensionally condensed Nb_6O_{12} clusters. These are $BaNb_4O_6$,[26, 31] $Ba_2Nb_5O_9$,[26, 31] and $BaNb_7O_9$ (Fig. 24).[98] All belong to the series $A_sNb_{s+3p}O_{3s+3p}$. The first member is $BaNb_4O_6$ with $s = 1$ and $p = 1$. Its structure therefore exhibits a regular alternation of single NbO-type slabs $[1 \times \infty \times \infty]$ and single perovskite-type slabs $\{1 \times \infty \times \infty\}$. The apical Nb atoms in the NbO layers are also constituents of the perovskite layers in between. A step toward an extended perovskite-type $BaNbO_3$ is realized in $Ba_2Nb_5O_9$. Single slabs of NbO alternate with double slabs of perovskite according to $[1 \times \infty \times \infty]$ and $\{2 \times \infty \times \infty\}$, respectively. Figure 24b shows that the perovskite slabs contain additional Nb atoms in octahedral environments. Thus the Ba atoms have the complete first and second coordination spheres of the extended perovskite structure. The corresponding step toward an extended NbO structure, on the other hand, is realized in $BaNb_7O_9$. Here, double slabs of NbO-type are stacked with single perovskite-type slabs according to $[2 \times \infty \times \infty]$ and $\{1 \times \infty \times \infty\}$, respectively (Fig. 24c).

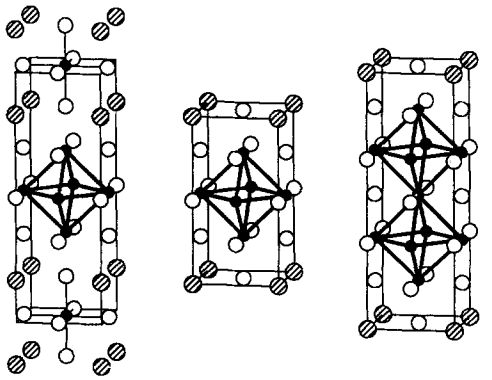

Fig. 24. Crystal structures of a) $Ba_2Nb_5O_9$, b) $BaNb_4O_6$, and c) $BaNb_7O_9$ on (100).

Several compounds with the previously described structures could be synthesized with A = K, Sr, Eu because of the compatibility in atomic structure and unit cell metrics.[99] These are "KNb_4O_6"[100, 101] and $A_2Nb_5O_9$ (A = K,[101] Sr,[101–103] Eu[73, 95]). The last two compounds were also prepared with mixed cations A: $SrBaNb_5O_9$[101] and $Eu_{1-x}Ba_xNb_5O_9$ ($0 \leq x \leq 2$).[95]

Single-crystal structure analyses have been performed on $BaNb_4O_6$,[31] $Ba_2Nb_5O_9$,[31] $BaNb_7O_9$,[98] and $Sr_2Nb_5O_9$.[102] The structural parameters for "KNb_4O_6"[100] have been determined by profile refinement of X-ray powder patterns. Only unit cell parameters and very approximate atomic coordinates have been reported for $K_2Nb_5O_9$[101] and $Eu_2Nb_5O_9$.[73]

The severe structural disorder indicated in some of the refinements is not surprising considering the easy formation of the α-phasoid discussed previously. The compositions of compounds may therefore deviate significantly from the compositions of the idealized structures. The methods of HREM and X-ray diffraction complement each other and together allow for a detailed understanding of such deviations. To give an example, both powder diffraction and energy dispersive microanalysis of individual crystallite fragments of "KNb_4O_6" unequivocally indicate Nb deficiency with a Nb:K ratio of about 3.4. A possible explanation for this result was found in the HREM images.[100] In Figure 25a a number of structural defects can be seen. The NbO-type slab, in particular, is terminated and continues as a perovskite-type slab. The suggested model for this defect is

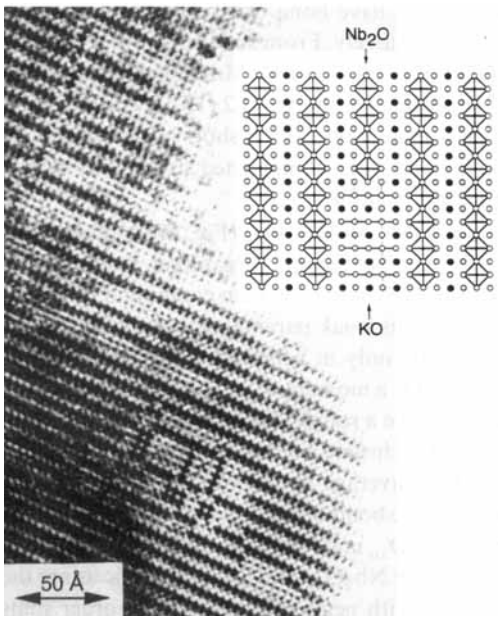

Fig. 25. a) HREM image of "KNb_4O_6" with both ordered and disordered areas. Inset: Graphic interpretation of the transition between a NbO- and a perovskite-type slab.

shown in Figure 25b. As a result of this defect the composition of the phase is $K_{1+x/2}Nb_{4-x}O_6$ with the experimentally determined value $x \approx 0.24$.[100] Another kind of (expected) disorder is shown for crystals of $BaNb_7O_9$ in Figure 26, where some of the NbO double slabs are replaced by single slabs.

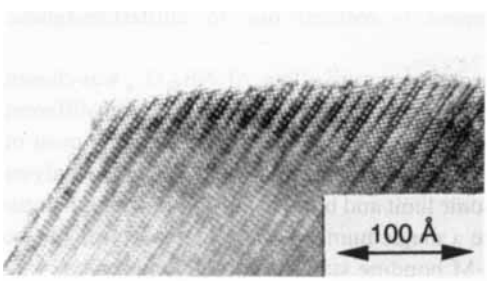

Fig. 26. HREM image showing defects in $BaNb_7O_9$ wherein the $[2 \times \infty \times \infty]$ NbO slabs have been replaced by $[1 \times \infty \times \infty]$ slabs.

Whereas HREM clearly explains the disorder phenomena observed in X-ray structure analyses of reduced oxoniobates, the latter provide sufficiently accurate structural parameters for an analysis, for example, of the mutual adjustment of the different structure types in the intergrowth phases. A comparison of the known Ba oxoniobate structures with two-dimensionally condensed clusters reveals a gradual increase of the lengths of the comparable axes with the relative amount of NbO-type slabs, or to put it in other terms, with the degree of condensation of the Nb_6O_{12} clusters (Fig. 27). The relief of strain by mutual adjustment is apparent from distortions of the coordination polyhedra. In $BaNb_4O_6$, $Ba_2Nb_5O_9$,[31] and $BaNb_7O_9$[98] the BaO_{12}

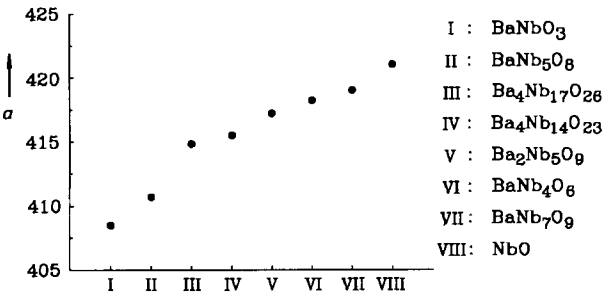

Fig. 27. Plot of the shortest unit cell axes of the reduced compounds in the Ba–Nb–O system versus the relative amount of NbO in the structures.

cuboctahedra are stretched in the *ab* plane (2%) and contracted (2%) along the *c* axis compared to bulk $Ba_{0.95}NbO_3$. The same kind of distortion, but larger due to the greater strain relief needed, is found in $Sr_2Nb_5O_9$ (3.0 and 3.7%)[102] and in KNb_4O_6 (3.1 and 3.5%).[100] The average A–O bond lengths that result are close to the values found for the corresponding bulk perovskites (Table 3). The adjustment of the NbO_6 octahedra to the NbO slab in the *ab* plane results in Nb–O bond lengths of 207.0 pm in $Sr_2Nb_5O_9$ and 208.6 pm in $Ba_2Nb_5O_9$.

Although the interatomic distances within the perovskite-type parts of the structures can be understood in terms of mutual adjustments, such reasoning does not explain

Table 3. A–O and Nb–Nb bond lengths [pm] in the structures containing Nb_6O_{12} clusters together with A–O bond lengths [pm] in oxoniobates with perovskite structure.

Compound	Average d_{A-O}	Range d_{A-O}	Average d_{Nb-Nb}	Range d_{Nb-Nb}

changes of the Nb–Nb distances within the NbO-type parts. One must also take into account the electron balance in the structures. In the perovskite phases $ANbO_3$ (A = Sr, Ba) the Nb atoms have the oxidation state IV. Because of similar distances within the NbO_6 octahedra in $A_2Nb_5O_9$, the oxidation state IV could also be assigned for the Nb atoms, implying that ten valence electrons per unit cell are available for M–M bonding in the NbO-type section as in $BaNb_4O_6$. However, all Nb–Nb bonds in $Ba_2Nb_5O_9$ are significantly shorter than in $BaNb_4O_6$ (Table 3). This difference is evidence of an electron transfer δ from the single Nb atoms to the cluster atoms resulting in $10 + \delta$ valence electrons involved in M–M bonding. The shorter Nb–O and Nb–Nb bonds in the respective NbO_6 and the Nb_6 units of $Sr_2Nb_5O_9$ then should be associated with an even larger charge transfer. This discussion leads to the more general topic of chemical bonding in reduced oxoniobates with discrete and condensed Nb_6O_{12} clusters which will be discussed in the next section.

5. Structures, Properties, and Bonding

Most of the reduced oxoniobates are mixed-valent compounds, that is, they contain niobium in different oxidation states. In descriptions of the phases with discrete clusters it has been mentioned that certain structural components, for example Nb_3O_{13} units, may act as electron buffers. In the discussion of the intergrowth phases, structural details indicate a charge transfer between perovskite- and NbO-type subunits. A more detailed analysis is necessary in order to reach a quantitative understanding of the electron balances in these phases. The final aim of such analysis is to find "magic" numbers for the electron concentrations in specific discrete clusters and condensed cluster structures. Arguments based on bond length/bond strength, and band structure calculations will be used in conjunction with observed properties of the compounds to reach this goal.

5.1. Bond Order Sums

A simple approach for relating bond lengths and bond orders was first introduced by Pauling.[104] This idea was further developed by many others and successfully applied to determine oxidation states[105] and electron concentrations in M–M bonded systems such as reduced oxomolybdates.[106] To derive the bond order or bond strength s corresponding to an experimental distance r, Equation (a) intro-

$$s = \exp[(r_o - r)/B] \qquad \text{(a)}$$

duced by Brown[107] is widely used, where B is normally set to 37 pm, and r_o is an empirically determined parameter for a single bond between two elements. The reference distance r_o for Nb–O bonds has been determined to be 191.1 pm from 228 different oxoniobates with an estimated standard deviation of 3.1 pm. Bond order summations have been performed for most of the reduced oxoniobates. The results of such calculations will be presented for selected examples of increasing complexity and discussed with respect to possible conclusions as well as to limitations of the procedure.

The compounds $Mg_3Nb_6O_{11}$ and $Mn_3Nb_6O_{11}$ are greenish black semiconductors. $Mg_3Nb_6O_{11}$ is nonmagnetic, that is, the diamagnetism is nearly compensated by a temperature-independent paramagnetism as often found for cluster compounds containing only paired electrons. $Mn_3Nb_6O_{11}$ has a magnetic moment $\mu_{eff} = 5.83\ \mu_B$ close to that expected for Mn^{2+} ions. The ionic limit $(Mg^{2+})_3(Nb^{16/6+})_6(O^{2-})_{11}$ leads to 14 electrons in M–M bonding states for the Nb_6O_{12} cluster.

Bond order summations for $Mg_3Nb_6O_{11}$ ($Mn_3Nb_6O_{11}$) clearly indicate a hierarchy in bond strengths. The average bond order sums for the O^i and O^a atoms are 2.11 and 1.84, respectively, indicating that the inner sphere of O atoms is strongly bonded to the Nb_6 core to form a rigid $Nb_6O^i_{12}$ cluster. The rigidity of the cluster framework hardly allows for full adjustments of the sizes of individual voids filled by the M^{2+} ions. The Mg(Mn) atoms in both the octahedral and tetrahedral voids have bond order sums of 2.07 (2.20) and 1.80 (1.98), respectively. From such bond order summations the number of electrons in M–M bonding states of the Nb_6O_{12} cluster is calculated to be 13.2 (13.4). The deviation from 14, which is mainly due to the short Nb–O^i distances, must be born in mind when complicated structures are analyzed as in the next example.

The structure of $Na_3Al_2Nb_{34}O_{64}$ (Fig. 10) contains four chemically different Nb atoms organized according to $(Nb_6)_3(Nb_3)_2(Nb_2)_3(Nb)_4$. The golden compound is a semiconductor and exhibits weak paramagnetism which follows the Curie–Weiss law only in a limited temperature range. Between 20 and 200 K a moment $\mu_{eff} \approx 2.2\ \mu_B$ is found. Bond order summations give a rough idea of the electron distribution. In the Nb_6O_{12} cluster, similar to $Mg_3Nb_6O_{11}$, the O^i and O^a atoms have average bond order sums of 2.12 and 1.90, respectively. The bond order sums for the Al (3.05) and Nb atoms in the Nb_2O_{10} units (4.00) are in perfect agreement with expectation. The Nb_2O_{10} unit is diamagnetic as are the four NbO_6 entities with pentavalent Nb (bond order sums 4.72 and 4.75). The Curie–Weiss behavior of the compound must therefore originate from either the Nb_6O_{12} clusters, the Nb_3O_{13} entities, or both. There might be some indication for an occupied M–M bonding state in the Nb_3O_{13} unit. The bond order sum is slightly reduced (4.5 instead of 5.0), and in spite of a more expanded matrix of O atoms in $Na_3Al_2Nb_{34}O_{64}$ the Nb–Nb distances are shorter (317 pm) than in $Ba_2Si_4Nb_{20.8}O_{44}$ (330 pm). Weak M–M bonding in the Nb_3O_{13} units in $Na_3Al_2Nb_{34}O_{64}$ seems to be present and is further corroborated by the sum of Nb–O bond orders for the Nb_6O_{12} cluster which indicates one electron less in M–M bonding states than in $Mg_3Nb_6O_{11}$. It is possible that the observed magnetic moment is reduced due to antiferromagnetic coupling.

The complicated structure of $Na_3Al_2Nb_{34}O_{64}$ was chosen to illustrate the intricate electronic balance between different parts of the structure. Such balance is also found in most of the other phases with discrete Nb_6O_{12} clusters. Analyses based on the ionic limit and bond length/bond strength arguments indicate a magic number of about 14 electrons to be present in M–M bonding states in Nb_6O_{12} clusters.

With only one exception, $NaNb_{10}O_{18}$, all compounds containing discrete clusters are insulators or semiconductors

and hence exhibit electronic delocalization only in certain components like the Nb_6O_{12} cluster. Remarkably, the expected paramagnetism for clusters analyzed as odd-electron species from the ionic limit (13 or 15 electrons) is not observed. If one does not believe in strong antiferromagnetism in all phases, an explanation for the nonoccurence of paramagnetism has to be sought in deviations from the stoichiometry derived by X-ray structure analysis and possibly also in a breakdown of general bond length/bond strength relations in rigid framework structures like the reduced oxoniobates. The following example might serve to spotlight both aspects. The golden $Na(Si_xNb_{1-x})Nb_{10}O_{19}$ ($x \approx 0.75$) contains two crystallographically different kinds of Na atoms (Fig. 12). In particular, those atoms between type I_b slabs are characterized by very low Na–O bond order sums of 0.53. These ions are housed in cages of O atoms that are far too voluminous for Na^+. With ions that are able to change their oxidation state, such a deviation from the expected bond order sum could be entirely misleading. With Na, however, any incomplete electron transfer to the Nb–O framework can be ruled out by ^{23}Na NMR spectroscopic results. These Na atoms are characterized by unusually large temperature factors indicative of a rattling motion. Any Na atom deficiency would therefore be well hidden. In fact, there is evidence that the golden color of the crystals is an extrinsic property; $Na(Si_xNb_{1-x})Nb_{10}O_{19}$ has also been prepared as red transparent crystals.[108]

A partial occupation of cuboctahedral voids by cations, well known from the perovskite-type compounds A_xNbO_3 (A = Sr, Ba), could also occur with the more reduced oxoniobates. This makes the exact determination of the ionic limit and the number of electrons in M–M bonding states of Nb_6O_{12} more difficult. Problems also arise when bond length/bond strength relationships are used for the analyses of structures. These limitations become particularly obvious for the structures with infinitely condensed Nb_6O_{12} clusters.

In the structures containing slabs of NbO alternating with perovskite-type slabs all O atoms which belong to the latter have bond order sums similar to those found in structures with discrete Nb_6O_{12} clusters, whereas the corresponding values for the O^{i-i} atoms coordinated by four Nb atoms inside the NbO-type slabs are usually high (2.34 in $BaNb_7O_9$ to 2.6 in $Sr_2Nb_5O_9$). The increased value is not too surprising since the corresponding O atom in NbO itself has the same kind of coordination and a bond order sum of 2.41. The very high value of 2.6 found for $Sr_2Nb_5O_9$ results from the pronounced structural misfit between the perovskite $Sr_{0.95}NbO_3$ ($a = 402$ pm) and NbO ($a = 421$ pm) which calls for an extreme compromise when the intergrowth structure is formed. Obviously, strong polarization and covalency effects can increase the bond order sum for an O atom to a value which is also found in the CO molecule (2.6). Under such extreme conditions any assignment of oxidation states for the Nb atoms with octahedral coordination must be ambiguous. However, Nb–O bond order sums of 4.6 and 4.3 in the respective structures of $Sr_2Nb_5O_9$ and $Ba_2Nb_5O_9$ indicate some electron transfer from these atoms to the NbO-type slabs, possibly suggesting that these atoms are in an intermediate oxidation state and contribute to the metallic conductivity observed.[127]

5.2. Band Structure Calculations

Band structure calculations by the EH method[110] have been used successfully for the interpretation of bonding in metal-rich oxides such as reduced oxomolybdates,[111, 112] NbO,[113] $LiNbO_2$,[46] and $NaNb_3O_6$.[56] For simple enough structures like NbO self-consistent band structure calculations can be performed[114] which quantitatively support the EH results.[115] To obtain more detailed insight into the complex bonding situation and especially the distribution of valence electrons in reduced oxoniobates, EH calculations were conducted for a number of compounds containing discrete and condensed clusters.[116, 117]

The nature of orbitals in discrete M_6Cl_{12} clusters has been previously examined in detail.[118, 119] Figure 28a shows the corresponding M–M bonding levels a_{1g}, t_{1u}, t_{2g}, and a_{2u} for the $Nb_6O^i_{12}O^a_6$ cluster. Nb–O antibonding character is present in all states. In the case of the a_{2u} level this antibonding contribution dominates and leads to an overall antibonding character. In this respect the oxo cluster differs from the chloro cluster for which the a_{2u} level is overall nonbonding and, hence, easily occupied, for example in species such as $Nb_6Cl_{12}^{2+}$.[120] Interestingly, the closed-shell configuration, which in a valence bond description corresponds to eight three-center two-electron bonds at the faces of the M_6 octahedron,[114, 119] is disadvantageous in the case of the oxo cluster because of a stronger metal–ligand interaction. The occupancy of all M–M bonding states by 16 electrons has not been observed experimentally for the Nb_6O_{12} cluster. In fact, the 14-electron species seems much preferred in agreement with the calculation.

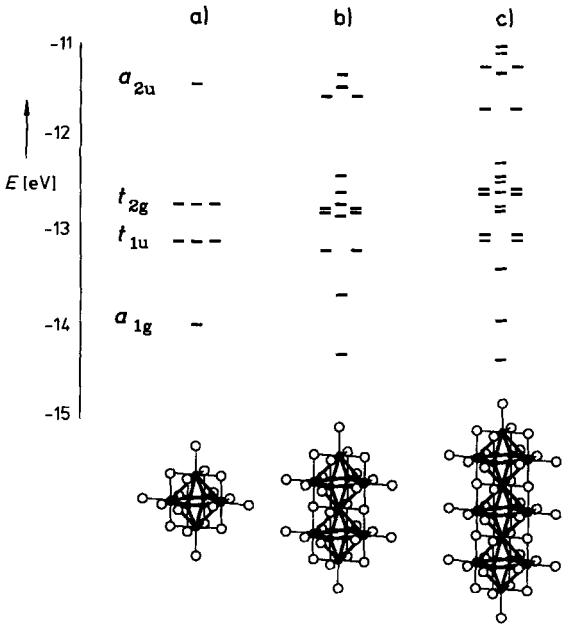

Fig. 28. Energy level diagrams for the metal-centered orbitals of the a) $Nb_6O^i_{12}O^a_6$, b) $Nb_{11}O^i_{20}O^a_{10}$, and c) the (hypothetical) $Nb_{16}O^i_{28}O^a_{14}$ clusters. The diagrams were obtained from full band structure calculations at the Γ point ($k = 0$). In the calculations atomic parameters were used from a) $Mg_3Nb_6O_{11}$, b) $K_4Al_2Nb_{11}O_{21}$, and c) an extended model derived from $K_4Al_2Nb_{11}O_{21}$ with corresponding interatomic distances.

The distortions of the Nb_6O_{12} clusters in all reduced oxoniobates are minor, and therefore the energy level diagram of the discrete cluster can be recognized in the corresponding Density Of States (DOS) for oxoniobates containing such discrete clusters. The band structure of $SrNb_8O_{14}$ depicted in Figure 29 serves as an example. Rather narrow bands appear in the projection of the DOS for the Nb atoms of the cluster below the Fermi level at approximately -14, -13, and -12.5 and -12.2 eV which correspond to the seven low-ly-

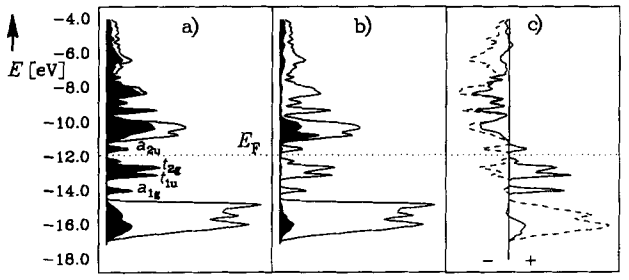

Fig. 29. a) Total DOS for $SrNb_8O_{14}$ with the projection of the Nb cluster atoms (black). The energy levels corresponding to the discrete Nb_6O_{12} cluster are labeled. b) Projection of the DOS for the Nb atoms in octahedral environments, and c) COOP curves for the Nb–Nb (solid) and Nb–O (dashed) interactions in the Nb_6O_{12} cluster.

ing states of the discrete cluster. The band near -11.5 eV corresponds to the a_{2u} orbital. As previously pointed out, the character of this band is overall antibonding because of the dominance of the Nb–O interactions within the cluster which is clearly reflected in the corresponding Crystal Orbital Overlap Population (COOP[111]) curves (Fig. 29b). The optimal stability of the compound is reached with 14 valence electrons in Nb–Nb bonding bands which are entirely filled, in agreement with the DOS and the semiconducting properties of the compound. The Nb_6O_{12} cluster in $SrNb_8O_{14}$ contains indeed all 14 electrons without any significant transfer of negative change to the Nb atoms in octahedral environments, which becomes apparent by inspection of the Atomic Orbital Projection (AOP) for these atoms. The bands near the Fermi level contain essentially no contribution from these Nb atoms.

The situation changes when more than 14 electrons are available for M–M bonding in the Nb_6O_{12} cluster. Other bands originating from interactions between clusters, clusters and adjacent Nb atoms, or between noncluster Nb atoms may then be filled. In $NaNb_{10}O_{18}$, for example, the band corresponding to the a_{2u} level is partly occupied as well as the d band, which originates from the Nb atoms in octahedral environments (Fig. 30). The metallic conductivity of this compound is thus easily explained. The corresponding COOP curves indicate that there are strong bonding interactions between the d orbitals of the octahedrally coordinated Nb atoms in a chain, but not with the Nb atoms of the Nb_6O_{12} cluster (Fig. 30c).

Band structure calculations for metallic $BaSiNb_{10}O_{19}$ (Fig. 31) indicate that Nb–Nb bonding bands of both the Nb_6O_{12} and Nb_3O_{13} clusters are occupied. The d states of the remaining Nb atoms in octahedral environments lie high

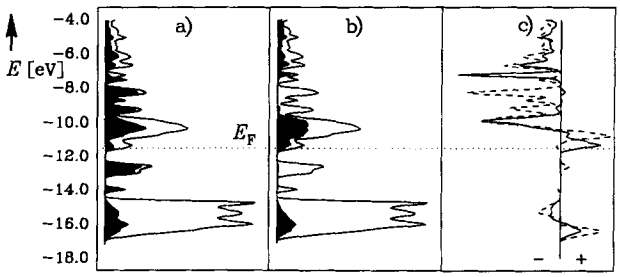

Fig. 30. Total DOS for $NaNb_{10}O_{18}$ with projections for a) the Nb cluster atoms (black) and b) Nb atoms in octahedral environments (black). c) COOP curves for the Nb–Nb interactions between octahedrally coordinated atoms only (solid) and Nb cluster atoms (dashed).

above the Fermi level indicating an oxidation state of v for these atoms.

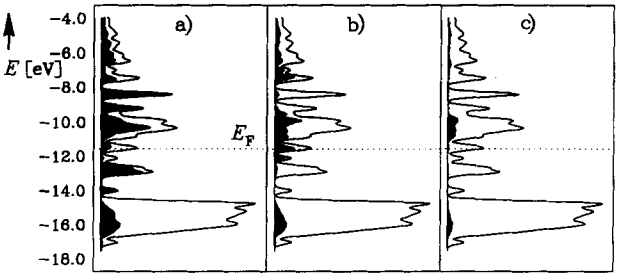

Fig. 31. Total DOS for $BaSiNb_{10}O_{19}$ with projections for a) the Nb cluster atoms (black), b) the Nb atoms of the Nb_3O_{13} unit (black), and c) the remaining Nb atoms in octahedral environments (black).

In order to discuss bonding in the Nb_3O_{13} units with different Nb–Nb distances as they occur in $BaSiNb_{10}O_{19}$, $Rb_4(Si,Nb)_2Nb_{35}O_{70}$, and $Na_3Al_2Nb_{34}O_{64}$, the respective COOP curves are compared (Fig. 32). The familiar energy level scheme (a_2'', e', a_1') for such molecular units[118] is only reflected in the COOP curve for the Nb_3 units in $BaSiNb_{10}O_{19}$, the Nb–Nb distances of which are rather

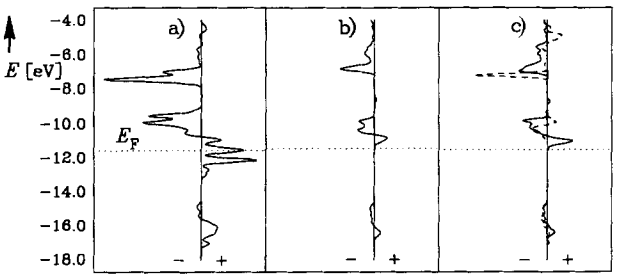

Fig. 32. COOP curves for the Nb–Nb interactions in the different Nb_3O_{13} units of a) $BaSiNb_{10}O_{19}$ (d_{Nb-Nb} = 282 pm), b) $Na_3Al_2Nb_{34}O_{64}$ (d_{Nb-Nb} = 315 pm), and c) $Rb_4Si_2Nb_{35}O_{70}$ (d_{Nb-Nb} = 306 pm (solid) and d_{Nb-Nb} = 335 pm (dashed)).

short (282 pm). Here, the Nb–Nb bonding states are filled to approximately 60% corresponding to four valence electrons in M–M bonding states of the Nb_3 unit instead of six to eight usually found in oxomolybdates such as $M_2Mo_3O_8$.[131] The corresponding COOP curve for $Na_3Al_2Nb_{34}O_{64}$ (d_{Nb-Nb} = 317 pm) shows only a weak unstructured Nb–Nb

bonding band slightly above the Fermi level (Fig. 32b). The situation is similar for $Rb_4(SiNb)_2Nb_{35}O_{70}$ where one kind of Nb_3 unit is located between I_b slabs and exhibits Nb–Nb distances of 306 pm. In the COOP curve for the other type of Nb_3 unit in this structure (d_{Nb-Nb} = 335 pm) the Nb–Nb antibonding state, curiously enough, lies below the Nb–Nb bonding state (Fig. 32c). In this case the Nb–O–Nb interaction is stronger than the direct Nb–Nb interaction; this is comparable to the situation found in CdI_2-type structures which do not exhibit direct M–M bonding.[121]

Before extending the discussion to structures with condensed clusters a word of caution seems appropriate here. All EH calculations were performed with the same parameters for different types of Nb atoms.[117] Since Nb atoms in octahedral environments have a much higher charge than the Nb cluster atoms, the energies of their d states are raised in the calculation with respect to the energy levels of the cluster atoms. If such a relative shift is on the scale of a few tenths of an electronvolt, then the partial occupation of the bands which correspond to the a_{2u} state in $BaSiNb_{10}O_{19}$, $Rb_4(SiNb)_2Nb_{35}O_{70}$, and $Na_3Al_2Nb_{34}O_{64}$ could be an artifact, and the d states close to the Fermi level of Nb atoms in octahedral environments are more or less filled.[132] This also holds true for the electron distribution between Nb atoms of the cluster and the Nb atoms in $NaNb_{10}O_{18}$ with octahedral environments.

The first step of the condensation of Nb_6O_{12} clusters is realized in the $Nb_{11}O_{21}$ cluster in $K_4Al_2Nb_{11}O_{21}$. The M–M bonding levels for the discrete cluster $Nb_{11}O^i_{20}O^a_{10}$ are drawn in Figure 28b. This energy level diagram can also be recognized in the DOS obtained from a full band structure calculation for $K_4Al_2Nb_{11}O_{21}$ (Fig. 33a) indicating the rather localized and therefore dispersionless cluster states. For this cluster an e' orbital results from the combination of t_{2g} orbitals of two monomers which has almost the same energy as the levels derived from a_{2u} orbitals.[74] The COOP curves (Fig. 33b) indicate that this group of orbitals has Nb–Nb bonding and strong Nb–O antibonding character like the a_{2u} orbitals in the monomeric cluster. Therefore, 12 low-lying levels result which can be filled by 24 electrons for the optimal electronic stabilization of this cluster.

The structure of $K_4Al_2Nb_{11}O_{21}$ is well suited for the analysis of the Nb–Nb interaction between clusters with Nb–Nb distances as short as 305 pm across the common O^i–O^a edges. The COOP curves (Fig. 33c), which have been calculated for all Nb–Nb distances between clusters, indicate that the intercluster bonding is negligible compared to the intracluster bonding. The same holds for the short interchain Nb–Nb distance (305 pm) in $BaNb_5O_8$, and it is reasonable to conclude that M–M bonding is also absent between the one-dimensional fragments of the NbO structure in the α-phasoid. The bonding is different than in TiO whose structure is derived from Ti_6O_{12} clusters which are condensed into chains by corner-sharing of the Ti_6 octahedra[5, 133] like in $BaNb_5O_8$. However, there is significant Ti–Ti bonding here between Ti atoms belonging to neighboring chains. In the chain compound Ti_5Te_4 based on corner-condensed Ti_6Se_8clusters,[134] interchain Ti–Ti bonding becomes even dominant and replaces some of the intrachain bonding.

The analysis of a hypothetical linear trimeric cluster is an appropriate transition to the discussion of the infinite chain compound. The energy level diagram for this cluster, $Nb_{16}O^i_{28}O^a_{14}$, with Nb–Nb and Nb–O distances taken from the dimeric cluster is presented in Figure 28c. The Nb–Nb bonding states appear as groups around the energies of the levels for the $Nb_6O^i_{12}O^a_6$ cluster. Seventeen states with Nb–Nb bonding character lie below the energy of the d orbitals for the free Nb atom (−12.1 eV) and eight states above due to strong Nb–O antibonding interactions. Such a trimeric cluster should therefore have its optimal stability with 34 valence electrons in M–M bonding states.

In the discussion of $BaNb_5O_8$ the first step was made toward structures containing infinitely condensed Nb_6O_{12} clusters. All compounds belonging to this class are metallic. The band structure of the infinite chain compound $BaNb_5O_8$ (Fig. 34) is reminescent of the "fingerprint" of levels characterizing the discrete clusters. The energy gap around −12 eV

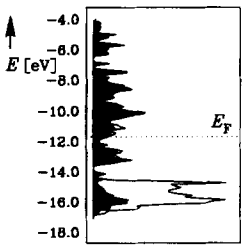

Fig. 34. Total DOS for $BaNb_5O_8$ with the projection of the Nb cluster atoms (black).

which exists for the mono-, di-, and trimeric clusters (Fig. 28) is closed in agreement with metallic property of $BaNb_5O_8$. The band filling corresponds to an optimization with respect to Nb–Nb bonding and Nb–O antibonding interactions (Fig. 34b). An optimized band filling comparable to that of $BaNb_5O_8$ with infinite chains is found for $BaNb_4O_6$ which contains layers of condensed Nb_6O_{12} clusters (Fig. 35). Fewer electrons would not take full advantage of M–M bonding;

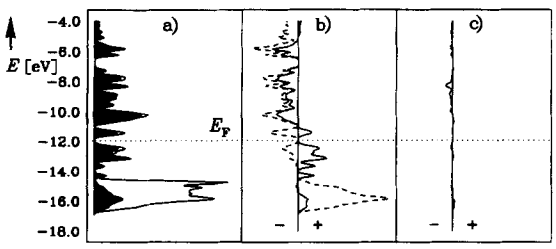

Fig. 33. a) Total DOS for $K_4Al_2Nb_{11}O_{21}$ with the projection of the Nb cluster atoms (black). b) COOP curves for the Nb–Nb intracluster and Nb–O (dashed) interactions, and c) for the Nb–Nb intercluster interactions.

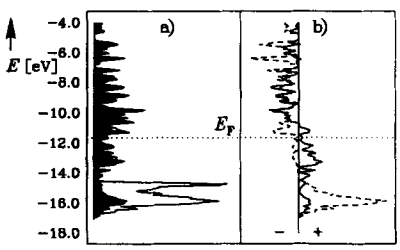

Fig. 35. a) Total DOS for $BaNb_4O_6$ with the projection of the Nb cluster atoms (black). b) COOP curves for the Nb–Nb and Nb–O (dashed) interactions.

more electrons would occupy strong Nb–O antibonding levels. One of the basic questions in the discussion of the related structure of $Ba_2Nb_5O_9$ is the electron distribution between the cluster sheet and the Nb atoms in octahedral environments. Band structure calculations suggest that all d bands arising from the latter atoms lie above the Fermi level and are therefore empty (Fig. 36). As a consequence, the M–M bonding bands of the Nb_4O_6 cluster sheet seem to contain one more electron in $Ba_2Nb_5O_9$ (11) than in $BaNb_4O_6$ (10).

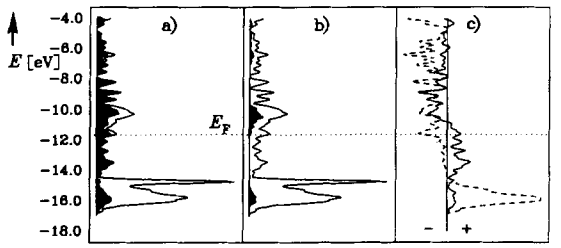

Fig. 36. Total DOS for $Ba_2Nb_5O_9$ with a) the projection of the Nb cluster atoms (black) and b) the Nb atoms with octahedral environments (black). c) COOP curve for the Nb–Nb and Nb–O (dashed) interactions of the Nb cluster atoms.

The observed average Nb–O distances for the Nb atoms in octahedral environments, however, indicate tetra- rather than pentavalency for these atoms. As discussed earlier, the calculated energies for the d bands related to highly charged ions are obviously too high and should be used with caution. However, a partial electron transfer from the cluster layers to these ions obviously occurs and results in an oxidation state $v - \delta$ for the octahedrally coordinated Nb atoms as in bronzes.

Finally, the most metal-rich ordered compound discovered so far, $BaNb_7O_9$, is of particular interest. Close similarities between the DOS for $BaNb_7O_9$ and NbO become obvious upon comparison of Figures 37 and 38. Two layers of the NbO-type structure are sufficient to model the essentials of

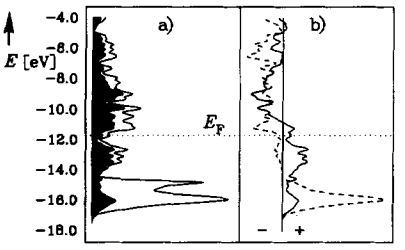

Fig. 37. a) Total DOS for $BaNb_7O_9$ with the projection of the Nb atoms (black). b) COOP curves for the Nb–Nb and Nb–O (dashed) interactions.

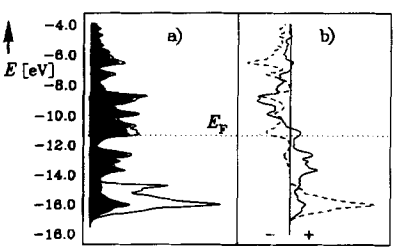

Fig. 38. a) Total DOS for NbO with the Nb projection (black). b) COOP curve for the Nb–Nb and Nb–O (dashed) interactions.

the electronic structure of bulk NbO. The COOP curves for both structures indicate optimal electron concentrations. The bands are filled up to a level at which the Nb–Nb bonding character is just overcompensated by the Nb–O antibonding character. For $BaNb_7O_9$ and NbO this situation is met with nineteen and three electrons, respectively, in M–M bonding bands. The possibility of any further occupation of M–M bonding bands, for example in $BaNb_7O_9$ by a partial substitution of Ba by La, seems highly improbable as bands with strongly antibonding character must then be occupied. On the other hand, a slightly reduced electron concentration could be tolerated, particularly in NbO since the band states down to 0.5 eV below the Fermi level are rather nonbonding due to the compensation of the Nb–Nb bonding and Nb–O antibonding contributions. The partial substitution of Nb by Ti in the structure of NbO found experimentally is in agreement with this result.[135]

To summarize, band structure calculations indicate optimal valence electron concentrations for both discrete and condensed Nb_6O_{12} clusters, governed by an exact balance between Nb–Nb bonding and Nb–O antibonding contributions. These optimal (magic) electron numbers are in close agreement with those derived from the ionic limit.

5.3. Magic Electron Numbers

The structures of oxoniobates based on Nb_6O_{12} clusters cover the whole spectrum from discrete clusters ("zero-dimensional", 0D) to 1D, 2D, and 3D corner-condensed cluster frameworks. The situation therefore seems to be more complicated than with edge-sharing Mo_6 octahedra as observed in oxomolybdates[122–126] or face-sharing as in molybdenum chalcogenides,[9] where in both cases only 1D condensation occurs. On the other hand, both edge and face condensation lead to a loss of the nonmetal atoms above the edges and faces involved in condensation. As a consequence the bonding orbitals of the discrete cluster reorient considerably in systems with edge- and face-condensed clusters. In contrast, condensation at the corners of the M_6 octahedron keeps the M_6X_{12} entity complete and uses only the outer lobes of the M–M bonding orbitals of the discrete cluster.[114] This makes the derivation of optimized electron concentrations (after some thinking) straightforward in the case of corner condensation.

Rules for optimized electron numbers in oligomeric clusters formed from edge-condensed Mo_6O_{12} as well as face-condensed Mo_6Se_8 clusters have been worked out before.[137] They covered the compounds known and were used successfully as guidelines in the search for new compounds.[136] These rules were derived from cutting the infinite chains into Mo_4O_6 and Mo_3Se_3 fragments (face and corner condensation) and combining the electron concentrations for the fragments with those for the single Mo_6O_{12} and Mo_6Se_8 clusters.

The procedure in the case of corner-condensed Nb_6O_{12} clusters is somewhat different. Key systems are the Nb_6O_{12} cluster with 14 electrons in M–M bonding states and hence $14/6 = 2.\bar{3}$ electrons for each of the equivalent Nb atoms, the compound NbO with 3D-condensed clusters and 3.0 electrons per equivalent Nb atom, and finally the dimeric cluster

$Nb_{11}O_{20}$ with 24 electrons in M–M bonding states and three kinds of nonequivalent Nb atoms. The central Nb atom in the $Nb_{11}O_{20}$ cluster has the same environment as the Nb atom in NbO and therefore donates three electrons to three-center bonds in altogether eight faces. The two peripheral Nb atoms are bonded as in the Nb_6O_{12} cluster and therefore contribute $2.\bar{3}$ electrons to M–M bonding in four faces. The remaining eight equivalent basal Nb atoms then need to contribute $16.\bar{6}$ electrons ($\approx 2.0\,e^-$ per Nb atom) to M–M bonding in order to reach the optimal electron count of 24. The same counting scheme leads to $2\times 2.\bar{3} + 2\times 3.0 + 3\times 4\times 2.0 = 34.\bar{6}$ as an optimal number of electrons in M–M bonding states for the trimeric cluster, in close agreement with 17 bonding states in the energy level diagram presented in Figure 28c.

With the electron numbers depicted for the different types of Nb atoms in Figure 39a simple prediction of electron concentrations for all kinds of terminated (oligomers) or infinite (polymers) condensates of M_6O_{12} clusters linked

[15] Transitions to superconductivity below 8 and 6 K have been found in phases with the composition $Ba_{2-x}La_xNb_3O_9$ ($0.2 \le x \le 0.5$) [16]. The transition at 8 K probably originates from NbO_x ($0.0 < x < \le 0.125$) [17].

[76] The O^{a-a} atoms can be replaced by F atoms to give $K_4Al_2Nb_{11}O_{21-x}F_x$ ($0 \leq x \leq 1.0$). It is not possible to determine this replacement by means of structural analysis; however, it clearly shows up in the magnetic behavior and particularly in the lengths of the *c* axes, see Table 2.

[87] A similar phasoid exists in the Sr–Nb–O system.
[88] Vernier phases [89] or other "solid solutions" with fluorite structure such as the CeO_2–Y_2O_3 system and the block structures found among the slightly reduced niobium oxides serve as examples [90–92]. On the other hand, ordered compounds may contain extended structural defects which are the only structural features of a new compound when the appropriate preparative conditions are chosen. For example, before $YBa_2Cu_4O_9$ was actually synthesized it was identified as a defect in $YBa_2Cu_3O_{7-\delta}$ [93].

[108] In some experiments with added NaF as a flux a few red transparent crystals were formed [33]. They exhibit nearly identical structural parameters as the golden crystals except for a slightly different $x \approx 0.8$ and, more importantly, a ring-shaped distribution of the scattering density for Na around the center of the too-large cuboctahedral cavity. Of course, the Na–O bond order sum is slightly increased by such (statistical) off-center positions of Na^+. The result is reminiscent of Na_4Si_4 which was described as having dark metallic luster before it was prepared in pure form as red transparent crystals [109].

Proteins from the D-Chiral World

By *Günther Jung**

Chirality and symmetry in general have always intrigued mankind. This fascination can be traced over the course of thousands of years by reference to many buildings and works of art created by humans with their mirror-image hands. Ever since the work of Louis Pasteur, Emil Fischer, and van't Hoff, stereochemistry has constantly provided chemical research with new impetus. Recently Kent et al.[1] have achieved a much discussed aim by synthesizing the first enzymatically active D-protein. Kent's experience with the optimized total chemical synthesis of many highly pure analogues of the HIV-1 protease,[2, 3] which also yielded single crystals suitable for X-ray analysis, encouraged him to attempt the total chemical synthesis of the 99 amino acid long D-enantiomeric protein chain.

The Merrifield synthesis based on the *t*Boc (*tert*-butyloxycarbonyl) strategy which still dominates in the USA was carried out using a modified Applied Biosystems 430 A synthesizer for fast synthesis cycles. Two syntheses were carried out according to the identical procedure, one using commercially available N^{α}-*t*Boc-L-amino acid derivatives, the other using commercially available N^{α}-*t*Boc-D-amino acid derivatives with the appropriate side-chain protecting groups. As in previous syntheses of crystalline L-HIV-1 protease, α-amino-*n*-butyric acid (Aba) was used as an isosteric replacement for cysteine residues at positions 67 and 95; this modification does not affect folding or enzyme activity. According to the manufacturers of the D-amino acid derivatives, these contained only 0.01–0.08% of L-enantiomers. The coupling was carried out with preactivation by benzotriazolyltetramethyluronium hexafluorophosphate (HBTU) and simultaneous in situ neutralization; this has been shown by Henklein et al.[4] to result in negligible levels of racemization. As a check during the course of the synthesis, samples of peptides cleaved from the resin with hydrogen fluoride were sequenced by matrix-assisted laser desorption time-of-flight mass spectrometry. Up until the present time the properties of the two enantiomeric proteins have been compared using amino acid analysis, ion spray mass spectrometry (L-enzyme: 10748 ± 4 Da, D-enzyme: 10751 ± 3 Da, calculated monoisotopic mass: 10748 Da) and high-pressure liquid chromatography (HPLC). The circular dichroism (CD) spectra revealed, as was to be expected, equal and opposite Cotton effects.

The synthetic D- and L-proteins have identical sequences of amino acids. Therefore, if it is true that the amino acid sequence alone determines the final folded 3-D structure, they should fold in exactly the same way to give identical three-dimensional (tertiary structure) structures. A comparison of the enzyme activities powerfully demonstrates the mirror-image folding (Fig. 1) from the denatured state to the homodimer with correct quaternary structure. Thus the L-enzyme cleaved only the fluorogenic L-hexapeptide substrate, whereas the D-enzyme cleaved only the corresponding D-substrate, 2-aminobenzoyl-all-D-Thr-Ile-Nle-Phe(p-NO_2)-Gln-Arg-NH_2 (Nle = norleucine). Reciprocal chiral specificity was also demonstrated with acetylated D- and L-pseudohexapeptidamide chiral inhibitors with the structure Ac-Thr-Ile-Nle-Ψ[CH_2-NH]-Nle-Gln-Arg-NH_2 (Ac = acetyl). The achiral protease inhibitor Evans Blue was a potent inhibitor of both enantiomers of the enzyme.

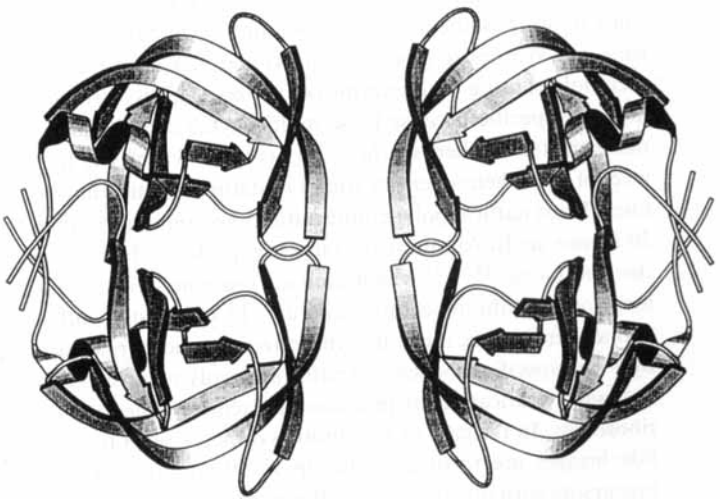

Fig. 1. Three-dimensional structure of the L- (left) and D-HIV proteases (right) (from ref. [1]).

Up to this point everything as was to be expected, most people might say. But do D-proteins offer us any advantages apart from the chiral properties and substrate specificities experimentally demonstrated for the first time? One of the most important advantages is the resistance to proteases as exhibited by many polypeptide antibiotics containing D-amino acids.

It is well established that polypeptides built of L-amino acids form right-handed α-helices and that polypeptides with D-amino acids form left-handed α-helices. Merrifield et al.[5, 6] demonstrated that three helical polypeptides, cecropin A, magainin-2-amide, and melittin, which form potential-dependent ion channels in lipid bilayers, are also antibacterial as D-enantiomers. Another recent paper[10] describes enantiomeric gramicidin A channels. Gramicidin A is a polypeptide antibiotic built up from alternating D- and L-amino acids. In this case, however, the biological activity does not depend on a chiral receptor molecule, that is to say that left- and right-handed channels built from peptide aggregates should allow the passage of ions to the same extent.

There should, however, be a small but noticeable difference in experiments with lipid bilayers, because helices with opposite handedness should interact differently with chiral lipid membranes. Apparently the difference is so small that

it is not measurable even with very sensitive electrical measuring devices (see also ref. [7]). We were able to demonstrate some time ago that homopolypeptides built up from the achiral α-aminobutyric acid (Aib), for example Z-$(Aib)_{10}$-O*t*Bu, interconverted from a left-handed to right-handed 3_{10}-helix and vice versa 1200 times per second. These enantiomeric helices also form ion-conducting channels in lipid bilayers, in spite of the interconversion between the two forms (isotoperization) at room temperature. The three synthetic D-enantiomeric peptide antibiotics with full antibiotic activity are especially interesting because of their resistance to proteases, which means that they may retain their activity when taken orally. Tam[11] also recently synthesized D-peptide antibiotics containing cysteine bridges with antibacterial activity, defensins with a β-pleated sheet structure.

In the majority of the hundreds of known peptide antibiotics, nature has already built in D-amino acids. Microorganisms can synthesize mixed L- and D-peptides as secondary metabolites using multienzyme complexes. This is, however, not very specific because these multienzyme complexes can make mistakes when synthesizing, as is shown by the high level of microheterogeneity found in natural peptide antibiotics. Most natural polypeptide antibiotics contain less than 20 amino acids. Amongst the largest peptide antibiotics are the lantibiotics,[12, 13] which contain D-amino acids in the form of a lanthionine ring structure. In contrast to other peptide antibiotics, these are synthesized by microorganisms by a very specific biochemical pathway involving post-translational modification of precursor proteins synthesized on ribosomes. In the case of lantibiotic synthesis, several disulfide bridges are formed in the up to 60 amino acid long precursors with inversion of configuration at the C_α atom of the original serine and threonine residues.[14]

This recent work shows that peptide chemists are able to synthesize active all-D-peptide compounds and even a pure D-enzyme. In addition, newly elucidated biosynthetic pathways using microorganisms allow, for example, *meso*-lanthionine and α,β-didehydroamino acids to be built into protein structures. Equal chirality of each building block is a prerequisite for a three-dimensional biopolymer with a high percentage of ordered structural elements like the α-helix and β-pleated sheet. A functional enzyme built from D-amino acids and L-amino acids, is conceivable, however, if enough D-amino acids in sequence could form a left-handed α-helix which could then, for example, form a "D-domain" α-helix-turn-β-pleated sheet with a β-pleated sheet of D-amino acids. Other domains could consist of L-amino acids and contain enzymatic cleavage sites. Such a chimera could be constructed by combining segments produced by peptide chemistry and by biotechnology. Recently, there have been promising attempts at the total chemical synthesis of artificial enzymes with the help of templates.[15, 16] In the future, D-domains should be considered in the de novo design of such molecules. The human imagination is held in check only by the size of peptides that can be chemically synthesized, currently around 150 amino acids. This figure may increase to around 250 amino acids by the year 2000 (for details of new developments in solid-phase synthesis see refs. [17, 18]).

The resistance of synthetic D-enzymes to proteases has led to speculation about possible therapeutic applications.[1, 11] D-Enzymes could react with achiral substrates with a long-lived in-vivo activity, because they are resistant to attack by the L-proteases found in mammals. An additional advantage would be that D-proteins are presumably very slightly immunogenic or nonimmunogenic. A boostable and long-lasting immune response requires the processing and presentation of the peptide antigen to the MHC (major histocompatibility complex) molecules to enable recognition by helper T cells (by MHC class II) or by cytotoxic lymphocytes (CTL, by MHC class I). This requires that a peptide fragment with an MHC-specific recognition sequence[19] be cut from the D-proteins, and this is not possible. Nevertheless, the synthesis and purification of a totally nonimmunogenic D-protein is not possible with the present state of technology and methodology. This is not because of the presence of failure sequences in them which are certainly present due to incomplete coupling reactions. Rather, the reason is to be found in the extremely sensitive and highly specific recognition reaction between peptide antigen, MHC molecule, T cell receptor, and associated proteins such as β-microglobin. In fact, this multimeric complex could be used for in-vitro assays for CTL epitopes in the attomole range. None of the current amino acid activation reactions operate without some degree of racemization. So even if very sensitive racemization tests fail to indicate the presence of L-amino acids in D-proteins, recognition is possible due to antibodies already present, and a T cell mediated immunological response is to be expected after repeated application. This means that any traces of material that can be cleaved by L-proteases must be removed, in order to produce D-protein drugs which do not evoke an immune response.

Other nontherapeutic applications, above and beyond purely academic interest, make D-proteins interesting as well. The unfortunately extremely expensive D-enzymes could enable the production of hard-to-produce chiral products. Especially attractive is the enzymatic synthesis or modification of L-carbohydrates. Would it be possible to create an L-sugar world with D-proteins and even an L-RNA/DNA world with L-ribose/L-deoxyribose linked bases?

Let us return to the practical and realizable possibilities which synthetic D-proteins offer. Zawadake and Berg[20] synthesized a D-protein for completely different reasons. They synthesized the iron–sulfur protein D-rubredoxin, which is part of the electron transport chain in microorganisms. The synthetic D-rubredoxin was mixed with synthetic L-rubredoxin to give a racemate, exactly that mixture which one usually tries to painstakingly separate with sophisticated methods. However, the authors obtained through this procedure single crystals of the highest quality with a centrosymmetric space group. This space group led to a simplification of the phase problem and a quicker solution of the structure by X-ray crystallography. In addition, the resolution of the X-ray structural analysis should be greatly improved, and it seems easier to obtain good crystals from the racemate compared to the pure enantiomers. If only the last application proves to be practicable, then at least as far as the protein crystallographers are concerned, the enormous effort put into the synthesis is well worthwhile, as Petsko[11] has already pointed out.

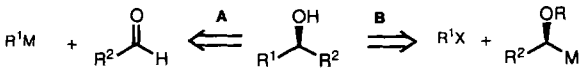
Asymmetric Deprotonation as an Efficient Enantioselective Preparation of Functionalized Secondary Alcohols

By *Paul Knochel**

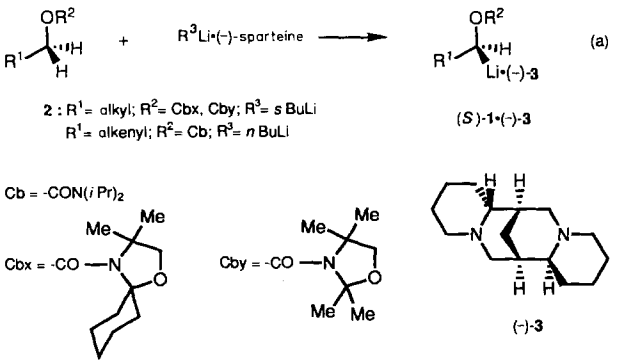
The enantioselective preparation of chiral secondary alcohols has been achieved through a number of methods with great success. One pathway that is widely used is the asymmetric addition of organometallic compounds R^1M to aldehydes[1] (retrosynthetic pathway **A** of Scheme 1). A disconnection involving inversion of polarity[2] is also possible [retrosynthetic pathway **B** of Scheme 1]. In this case, the sec-



Scheme 1.

ondary alcohol is formed by a substitution reaction of an α-oxygen-substituted carbenoid **1**.[3] Although this alternative route has been frequently used for synthetic applications, the multistep procedures[4] required for the enantioselective preparation of the carbenoids have limited the utility of this approach. Furthermore, to be synthetically attractive, the chiral carbenoid has to be configurationally stable under the reaction conditions, and its reaction with electrophiles has to proceed with a well-defined stereochemistry (retention or inversion).

Enantioselective deprotonation reactions have been known for several years and have led to several elegant synthetic applications.[5] Hoppe et al. found that this method allows an expedient access to a wide range of chiral α-oxygen carbenoids **1** [M = Li, Eq. (a), Scheme 1][6–12] starting from readily available achiral carbamates **2** and the complex of an alkyllithium compound and (−)-sparteine **3**.[13]



The deprotonations are complete within a few hours at −78 °C and afford the lithium carbenoid · sparteine complexes (*S*)-**1** · (−)-**3** with excellent enantioselectivities.[6–12] Whereas sparteine complexes of lithiated secondary allyl and primary alkyl carbamates are configurationally stable below −30 °C, those of primary allyl carbamates such as **4** · (−)-**3** are not configurationally stable even at −70 °C. It is, however, possible to use these reagents in synthesis, since the preferential crystallization of the *S* diastereoisomer in pentane/cyclohexane drives the equilibrium completely to one side. After a low-temperature transmetalation of (*S*)-**4** · (−)-**3** with an excess of tetraisopropoxytitanium, the allylic titanium reagent (*R*)-**5** is obtained with inversion of configuration. The addition of various aldehydes to (*R*)-**5**

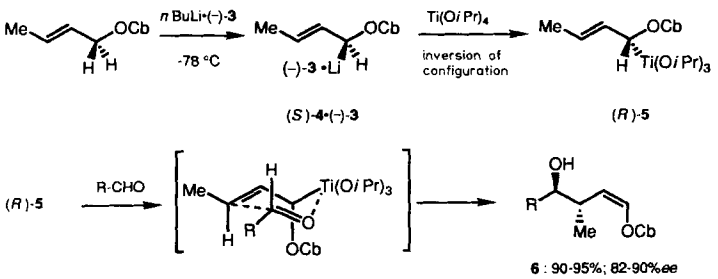
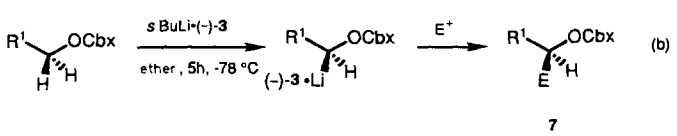
furnishes homoaldol adducts of type **6** with high *anti* diastereoselectivity and very good enantioselectivity (82–90% *ee*) (Scheme 2). They can be further converted into lactones as shown in the synthesis of the insect pheromone (+)-eldanolide (92% *ee*).[6d]



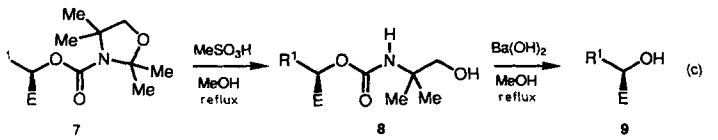
Scheme 2. Enantioselective synthesis of homoallyl alcohols by asymmetric deprotonation.

A crystal structure analysis of a complex between a lithiated primary carbamate and (−)-sparteine **3** unambiguously established the *S* configuration.[14]

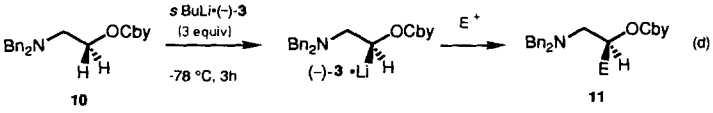
Of considerable interest for synthetic applications are the deprotonations of alkyl carbamates RCH_2OCbx or RCH_2OCby with *sec*-butyllithium · (−)-sparteine, followed by the alkylation with an electrophile.[7] Most electrophiles such as CO_2, Me_3SnCl, Me_3SiCl, MeI, Me_2CHCHO react with retention of configuration to afford protected alcohols of the type **7** [Eq. (b)]. This provides a very general enantioselective synthesis of secondary alcohols. The enantioselectivities of the deprotonations are better than 95% *ee* in most cases. These high enantiodifferentiations are kinetic in nature, and MNDO calculations show that the stabilities of the two diastereomeric ion-pairs (+)-**1** · (−)-**3** and (−)-**1** · (−)-**3** are comparable.[15] Efforts have also been made to determine the structure of the chiral base RLi · (−)-**3**, but only the structure of the complex $(iPrLi)_2$ · (−)-**3** in ether has been determined, by NMR techniques.[16]

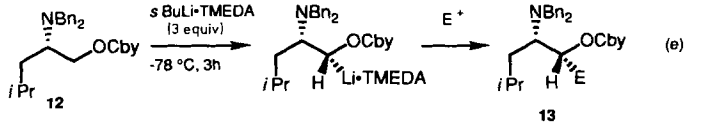


The Cbx-protecting group of **7** can be removed under mild conditions. An acid treatment ($MeSO_3H$, MeOH, reflux, 16 h) affording the intermediate carbamate **8** followed by a basic treatment ($Ba(OH)_2 \cdot 8H_2O$, MeOH, reflux, 4 h) leads to the chiral alcohol **9** [Eq. (c)][7] in excellent yield.

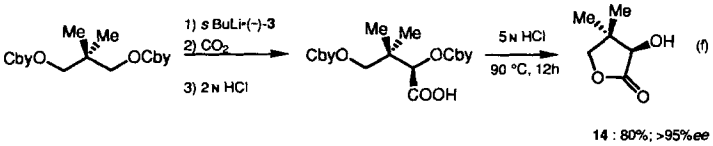


Remarkably, this method can be applied to carbamates bearing a functional group in close proximity to the OCbx or OCby group. High enantiomeric excesses are obtained, although chelating groups such as $N(CH_2Ph)_2$[8, 11] or an OR[9, 10] group are present. Thus the β-dibenzylaminocarbamate **10** can be deprotonated with high enantioselectivity with *s*BuLi · (−)-**3** (3 equiv; −78 °C, 3 h) and treated with various electrophiles to give almost enantiomerically pure 1,2-aminoalcohols **11** [Eq. (d)].[8] Interestingly, the presence of a substituent at the α position to the nitrogen functionality strongly influences the rate and controls the enantioselectivity of the deprotonation. This can be clearly seen in the case of the carbamate **12**, derived from (*S*)-*N*,*N*-dibenzylleucinol. After the reaction with an electrophile, substrate-controlled deprotonation yields the aminoalcohol derivative **13**

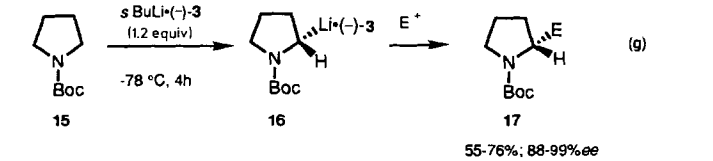




[Eq. (e)].[8] Finally, the utility of the method has been demonstrated by Hoppe et al. with a short enantioselective synthesis of (*R*)-pentolactone **14** [Eq. (f)].[9]



An asymmetric deprotonation of (*tert*-butoxycarbonyl)-pyrrolidines **15** has been recently developed by Beak et al. allowing a highly enantioselective synthesis of a variety of 2-substituted pyrrolidines [Eq. (g)].[17]



The enantioselective deprotonation at the α position to oxygen- or nitrogen-substituted carbamates with RLi · sparteine complexes allows the most practical and efficient synthesis of the corresponding chiral organolithium compounds. The high enantioselectivity of the deprotonation, the high stereoselectivity observed in the course of the reaction of these species with electrophiles, as well as the compatibility with some donating functional groups in the lithium organometallic compound make this methodology a very powerful tool for the construction of nonracemic chiral molecules.

The Structure of Pentamethyltantalum**

By *Thomas A. Albright** and *Huang Tang*

For a d^0 or d^{10} ML_5 transition metal complex there is a spherical field around the transition metal. As a result, the Valence Shell Electron Pair Repulsion (VSEPR) model[1] clearly predicts that a trigonal-bipyramidal (TBP) structure will be preferred over other alternatives, including the square-pyramidal (SP). Force field calculations[2] have also demonstrated that the TBP structure is favored over the SP on purely steric grounds. A number of theoretical studies have been carried out on the structural preferences of d electron counts between zero and ten.[3] In this work, we would like to communicate our theoretical work on two d^0 complexes, $[TaH_5]$ and $[Ta(CH_3)_5]$, in which the influence of strong π-donors and steric bulk of the ligands does not play a role in determining the structure. Our contention is that there is a persistent electronic factor that, contrary to the VSEPR model, favors the SP structure.

An idealized orbital correlation diagram for the TBP and SP structures is given in Figure 1. The electron count is appropriate for a d^0 complex, and for simplicity hydrido ligands are assumed. The construction of these valence orbitals is quite straightforward and has been presented elsewhere[3f] for the structure with D_{3h} symmetry. The orbital lowest in energy, $1a_1'$, does not change much in form or energy on going from TBP to SP geometry. The xy[4] component of the e' set is destabilized (coordinate system on the upper left of Figure 1); overlap between metal d orbitals and hydrogen s orbitals decreases as the H_{eq}-M-H_{eq} angle increases. The $x^2 - y^2$ component of e' stays basically at constant energy. There is some orbital mixing with $2a_1'$ so that it becomes a y^2 orbital at the metal. Likewise, the $2a_1'$ level evolves into an $x^2 - z^2$ function at the metal. The relative energy of $2a_1'$ at the SP geometry depends critically on the H_{ap}-M-H_{ba}[4] angles. With typical angles of approximately 115° (see below),

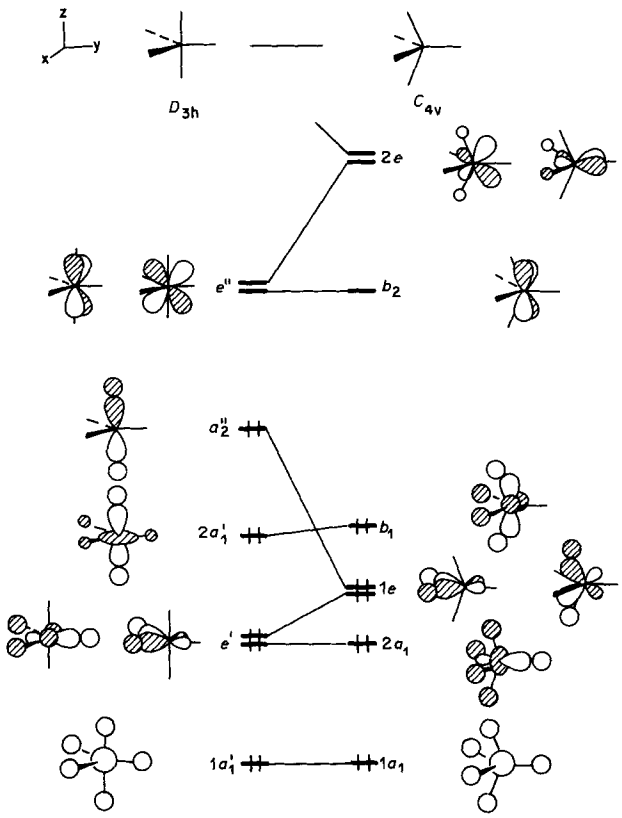

Fig. 1. An orbital correlation diagram connecting the structures of $[TaH_5]$ with D_{3h} (TBP) and C_{4v} (SP) symmetry.

there is a small net loss of overlap between metal d orbitals and the appropriate orbitals of the ligands so that there is a small increase in energy on going from the TBP to SP for this molecular orbital. The a_2'' and e'' levels are absolutely critical to this analysis. At the TBP geometry, the a_2'' orbital has exclusively metal z character and overlaps with the hydrogen s atomic orbitals, whereas the e'' set has rigorously metal xz and yz character with no hydrogen contribution. Upon distortion, the a_2'' level and the yz component of the e'' level strongly intermix so that the former is stabilized considerably, becoming one component of the $1e$ set on the SP side, and metal yz is correspondingly destabilized. Now, a_2'' is filled while the e'' set is empty; consequently, the total stabilization afforded to a_2'' influences greatly which geometry will be the more stable one. In the absence of strong π-donor groups on the ligand, the e''/a_2'' energy gap primarily determines the magnitude of this second-order perturbation.[4] As the electronegativity of the ligands decreases (and the ligand σ-donor strength increases), the energy gap will decrease and a_2'' will be stabilized to a greater extent. Hence, an SP structure for a d^0 complex can be a viable possibility. This argument is simply based on a second-order Jahn–Teller effect; a small energy gap implies a potential distortion of $e'' \times a_2'' = e'$ symmetry which converts a trigonal bipyramid into a square pyramid. A related view draws on the fact that valence p atomic orbitals of the metal lie at a much higher energy than the d set. In a localized sense, the hybridization at the metal will have increased d and less p character at the SP geometry. This will afford greater stabilization when the M–L bond is reasonably covalent.

We appreciate a generous allocation of supercomputer time from the National Science Foundation at the Pittsburgh Supercomputing Center. We are very grateful to Professor A.Haaland (University of Oslo) for communicating unpublished results (see also the following communication).

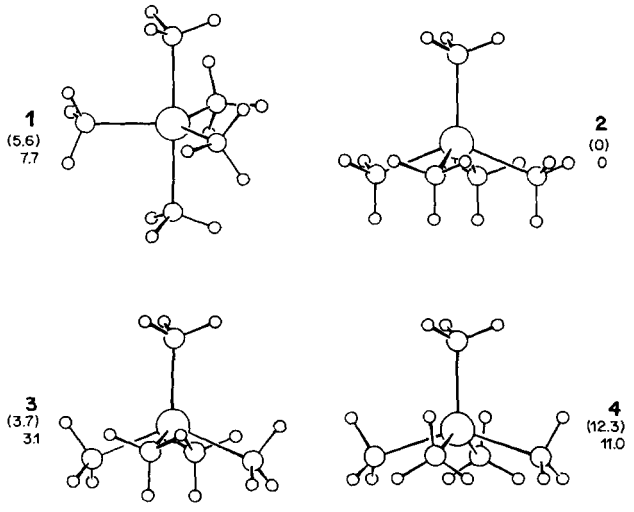
To test these ideas, we have carried out ab initio calculations[5] on $[TaH_5]$ and $[Ta(CH_3)_5]$. $[TaH_5]$ is unknown, although the d^8 complexes $[CoH_5]^{4-}$ and $[IrD_5]^{4-}$ in $Mg_2[CoH_5]$ and $Sr_2[IrD_5]$ are known.[8] At the Hartree–Fock (HF) level, the optimized D_{3h} (TBP) structure was found to have Ta–H_{ax} and Ta–H_{eq} bond lengths of 186 and 174 pm, respectively. Inclusion of electron correlation was carried out at the MP2 level. The Ta–H_{ax} and Ta–H_{eq} distances were found to be 188 and 176 pm, respectively. Likewise, we found little difference between the HF and MP2 optimized structures for the C_{4v} (SP) isomer. The Ta–H_{ap}, Ta–H_{ba} bond lengths and H_{ap}-Ta-H_{ba} bond angles were 180 pm (182), 175 pm (177), and 117.2° (117.6°), respectively, where the numbers in parentheses refer to the MP2 optimized values. Most importantly, at the HF level the C_{4v} structure was found to be 16.4 kcal mol^{-1} more stable than the D_{3h} one. This value increases to 19.9 kcal mol^{-1} at the MP2 level! The vibrational frequencies (MP2 level) for the C_{4v} isomer were computed to be all real, thus categorizing this structure as a minimum on the potential energy surface. However, the D_{3h} structure was found to possess imaginary frequencies of e' and a_2'' symmetry. Therefore, it is a higher order saddle point. Clearly, the contribution of the d orbitals to Ta–H bonding is very large here. One interesting manifestation of this thesis is that the Ta–H_{ba} bonds are shorter than the Ta–H_{ap} bonds. Rossi and Hoffmann[3a] have indicated that the basal M–L bonds should be shorter than the apical ones for a d^0 electron count at the metal only when the L_{ap}-M-L_{ba} angle is less than approximately 98°. However, if the involvement of metal in the b_1 orbital (see Fig. 1) is very large, then this pattern should be retained for even larger angles. The pattern of longer Ta–H_{ax} distances compared to the Ta–H_{eq} ones that we find for the D_{3h} structure is consistent with Rossi and Hoffmann's analysis.[3a]

The orientation of the methyl groups is a complicating feature for $[Ta(CH_3)_5]$. For the TBP isomer, the C_{3h} structure shown by **1** in Scheme 1 would certainly appear to be the most viable on steric grounds. In a preliminary HF calculation on a structure in which the axial methyl groups were rotated by 60° about the Ta–C bond the energy was 2.0 kcal mol^{-1} higher. Optimization of **1** (within C_{3h} symmetry) at the HF level yielded Ta–C_{ax} and Ta–C_{eq} distances of 224 and 216 pm, respectively. The C–H distances and Ta-C-H angles are unexceptional; average values are 110 pm and 111.2°, respectively. Three rotamers, structures **2**–**4** in Scheme 1, were considered for the SP isomer. In each case, only C_s symmetry was imposed on the optimization (HF level). MP2 calculations were then performed on each resulting stationary point. The relative energies (in kcal mol^{-1}) are listed alongside each structure in Scheme 1; the values at the HF level are given in parentheses. The square-pyramidal structure **2** was found to be the most stable. At the MP2 level, the trigonal-bipyramidal structure **1** lies 7.7 kcal mol^{-1} higher in energy. This result is consistent with the electron diffraction structure reported by Haaland and co-workers.[9] The structural details of optimized **2** are compared to the experimental data[9] in Table 1. The agreement between theory and experiment is outstanding! The theoretical values in Table 1 were averaged from those obtained in the full optimization with C_s symmetry. However, the individual bond lengths do not differ by more than 0.5 pm and the bond angles by more than 0.8° (0.1° for the C-Ta-C angles) from those reported.

Table 1. Interatomic distances [pm] and valence angles [°] for $[Ta(CH_3)_5]$ from the HF optimized structure **2** and the corresponding experimental values [9].

Parameter	Theory [a]	Experiment [b]
Ta–C_{ap}	215.4	211(2)
Ta–C_{ba}	218.7	218.0(5)
C–H	109.9	110.6(6)
Ta-C-H	111.2	110.3(16)
C_{ap}-Ta-C_{ba}	111.6	111.7(13)
C_{ba}-Ta-C_{ba}	82.2	82.2(9)

[a] The theoretical values are averaged ones from the optimization in C_s symmetry. [b] Estimated standard deviations are given in parentheses, in units of the last digit.



Scheme 1.

Notice that structure **4** has a very high relative energy (Scheme 1). We feel that the reason for this is primarily steric in origin. In **4** there are four more eclipsing H-C-Ta-C interactions than in **2**. Furthermore, the closest nonbonded H···H distances between adjacent basal methyl groups in **2** are 240 pm, whereas in **4** they are reduced to 217 pm. The latter value lies well within the van der Waals contact, given a van der Waals radius for hydrogen of approximately 130 pm. In the SP rotamer **3**, there are two more eclipsing H-C-Ta-C interactions compared to **1**; however, the orientation of the methyl groups is such that the nonbonded H···H contacts lie far outside of the van der Waals contact. Thus, the energy of **3** lies only 3.1 kcal mol^{-1} higher than **2**. There is evidence from both the ab initio and extended-Hückel wavefunctions for hyperconjugation between the filled methyl group orbitals and the empty d orbitals at the metal. However, no compelling evidence was found that the orientation of the methyl groups is dependent on the magnitude of these hyperconjugative interactions. Furthermore, there is no structural evidence from our optimizations which indicates that the magnitude of hyperconjugation is strong enough to distort the methyl groups toward agostic bonding as seen in other electron-deficient transition metal complexes.[10] We can make no assurances that **2** represents the global minimum. There may be one or more rotamers whose energy lies close to that of **2**. Because of resource limitations

we have also not computed the vibrational frequencies associated with **1–4**. The photoelectron spectrum of $[Ta(CH_3)_5]$ was assigned on the basis of a TBP structure.[11] We hesitate to make an assignment here on the basis of our molecular orbital calculations because the eigenvalues for the valence region around the metal are very sensitive to the orientation of the methyl groups. The finding here that $[TaH_5]$ and $[Ta(CH_3)_5]$ have SP rather than TBP structures nicely confirms the validity of the model outlined above based on second-order Jahn–Teller effects. It is well known[12] that 3d orbitals for vanadium are much more contracted and, hence, overlap more weakly with the orbitals of ligand σ-donor functions than the 4d orbitals of niobium or 5d orbitals of tantalum. Thus, we expect that the structure of the unknown $[Nb(CH_3)_5]$ should be very similar to that found for $[Ta(CH_3)_5]$; however, we expect that the TBP–SP energy difference for hypothetical $[V(CH_3)_5]$ will be considerably smaller than that found here for $[Ta(CH_3)_5]$. The application of the model also fits into the broader context of structural preferences for other d^0 ML_n complexes.[13] We have deliberately avoided examining what will occur when the auxiliary ligands possess strong π-donor functions. The preference of one distinct geometry (TBP or SP) is greatly affected by the number of π-donor functions, as well as whether they are single or double-faced π-donors.

The Structures of Pentamethyltantalum and -Antimony: One Square Pyramid and One Trigonal Bipyramid**

By *Colin Pulham, Arne Haaland,* Andreas Hammel, Kristin Rypdal, Hans Peter Verne,* and *Hans Vidar Volden*

The synthesis of pentamethylantimony $[Sb(CH_3)_5]$ was reported by Wittig and Torsell in 1953.[1] Infrared and Raman spectra of the neat liquid provide strong evidence for an SbC_5 frame of D_{3h} symmetry.[2] ^1H NMR spectra in CS_2 solution consist of one narrow line down to −100 °C, which shows that equatorial and axial methyl groups undergo rapid exchange on the NMR timescale,[3] presumably through Berry pseudorotation.[4] The synthesis of pentamethyltantalum $[Ta(CH_3)_5]$ was reported by Schrock and Meakin in 1974.[5] ^1H NMR spectra in $[D_8]$toluene at −10 °C show that all protons are magnetically equivalent.[5] The photoelectron spectra are consistent with D_{3h} molecular symmetry.[6]

In this communication we report the molecular structures of $[Ta(CH_3)_5]$ and $[Sb(CH_3)_5]$ determined by gas-phase electron diffraction (GED). This study is not only the first investigation of these molecules by diffraction techniques, but the first structure determinations of any pentaalkyl complex.

$[Sb(CH_3)_5]$ was synthesized from $[(CH_3)_3SbCl_2]$ and $LiCH_3$ in diethyl ether;[1, 7] $[Ta(CH_3)_5]$ was synthesized from $[(CH_3)_3TaCl_2]$ and $LiCH_3$ in the same solvent.[5] Both compounds were purified by distillation at reduced pressure.

The GED data were recorded at room temperature with a Balzers Eldigraph KDG-2 with an all-glass inlet system.[8] Since $[Ta(CH_3)_5]$ may detonate spontaneously at room temperature, it was treated according to procedures described in our study of hexamethyltungsten.[9] The data were processed by standard procedures.[10] Atomic scattering factors were taken from ref. [11]. Further information on the intensity data is given in Table 1. The molecular structures were refined by least-squares calculations on the modified molecular intensity curves with diagonal weight matrices.[10]

Molecular models of $[M(CH_3)_5]$ with trigonal-bipyramidal and square-pyramidal coordination of the metal atom are shown in Figure 1. A model with trigonal-bipyramidal coordination, that is, an MC_5 frame with D_{3h} symmetry, may be described by four independent structural parame-

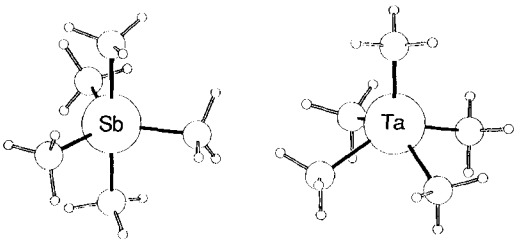

Fig. 1. Molecular models (PLUTON-91 [12]) of $[Sb(CH_3)_5]$ with trigonal-bipyramidal coordination, molecular symmetry (equatorial H atoms excluded) D_{3h}, and of $[Ta(CH_3)_5]$ with square-pyramidal coordination, molecular symmetry (apical H atoms excluded) C_{4v}.

ters: the axial and equatorial bond lengths M–C_{ax} and M–C_{eq}, a mean C–H bond length, and a mean M-C-H valence angle. Least squares refinements of a D_{3h}-symmetric model for $[Sb(CH_3)_5]$ proceeded without difficulty. Ten vibrational amplitudes could be refined in addition to the four structural parameters.[13] The final overall R factor was 0.057. The best estimates for the most important parameters are listed in Table 2,[14] and calculated and experimental radial distribution curves are compared in Figure 2.

[a] Pairs of amplitudes refined with constant difference.

A molecular model of $[M(CH_3)_5]$ with square-pyramidal coordination, in which the MC_5 frame has C_{4v} symmetry, may be described by five independent structure parameters: the apical and basal bond lengths M–C_{ap} and M–C_{ba}, a mean C–H bond length, a mean M-C-H valence angle, and the angle C_{ap}-M-C_{ba}. Least squares refinements of a C_{4v} model for $[Sb(CH_3)_5]$ yielded R factors above 0.12 and failed to converge. When refinements were carried out on a model with C_{2v} symmetry, calculations with starting parameters corresponding to nearly C_{4v} symmetry converged to models with close to D_{3h} symmetry. We conclude that C_{4v}-symmetric models are incompatible with the GED data. Our investigation thus confirms the conclusion reached in the earlier investigation by vibrational spectroscopy.[2]

Although refinements of a D_{3h}-symmetric molecular model of $[Ta(CH_3)_5]$ yielded overall R factors above 0.17, only a limited number of parameters could be refined without divergence. Comparison of experimental and calculated radial distribution curves revealed considerable disagreement in the region around $r = 305$ pm, the value calculated for the nonbonded C_{ax}···C_{eq} distance. Refinements of a C_{4v}-symmetric model proceeded without difficulties to yield a final overall R factor of 0.070. Six vibrational amplitudes were refined along with the five structural parameters.[15] The best estimates for the most important parameters are listed in Table 2, and calculated and experimental radial distribution curves are compared in Figure 2. We conclude that the structure of $[Ta(CH_3)_5]$ is square pyramidal.[16]

We recorded the ^{13}C NMR spectra of $[Sb(CH_3)_5]$ down to $-90\,^{\circ}C$ in CD_2Cl_2 and of $[Ta(CH_3)_5]$ down to $-120\,^{\circ}C$ in a 1:1 mixture of $CFCl_3$ and $[D_8]$toluene. Both spectra consist of one line which remains sharp down to the lowest temperatures. If axial and equatorial methyl groups in $[Sb(CH_3)_5]$ are exchanged by Berry pseudorotation, the transition state presumably has C_{4v} or nearly C_{4v} symmetry.[4] Similarly apical and basal methyl groups in $[Ta(CH_3)_5]$ may exchange over a transition state of D_{3h} or nearly D_{3h} symmetry.

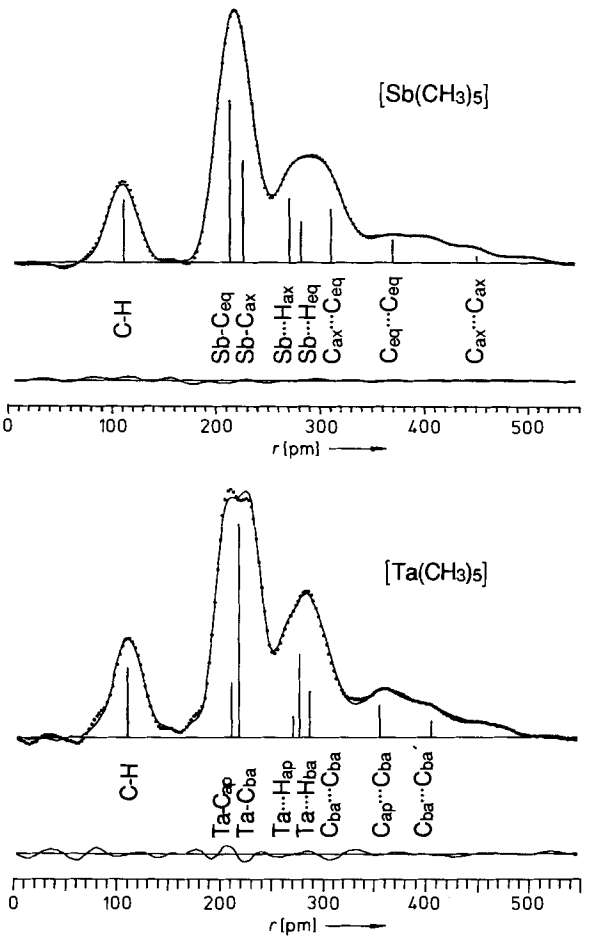

Fig. 2. Calculated (solid line) and experimental (·) radial distribution curves of $[Sb(CH_3)_5]$ (top) and $[Ta(CH_3)_5]$ (bottom). Artificial damping constants $k = 30\ pm^2$.

Thus, even though the two pentamethyl complexes have different equilibrium structures, the ^{13}C NMR spectra indicate that the energy difference between the two coordination geometries is small for both molecules. We have carried out ab initio MO calculations on $[Sb(CH_3)_5]$ with a split valence shell basis set and find that the energy of an optimized C_{4v} model is only 12.1 kJ mol^{-1} higher than that of an optimized D_{3h} model.[17]

The axial bond length in $[Sb(CH_3)_5]$ is about 12 pm longer than the equatorial, and the apical bond in $[Ta(CH_3)_5]$ is probably a few pm shorter than the basal. The average M–C bond lengths in the two compounds are, however, very similar: Sb–C (mean) = 219 pm; Ta–C (mean) = 217 pm.

The small C_{ba}-Ta-C_{ba} angle (82.2(9)°) is remarkable. The square base in $[Ta(CH_3)_5]$ is, however, similar to the rectangular faces in the trigonal-prismatic complex $[W(CH_3)_6]$: in the latter compound the angles defined by the metal atom and neighboring C atoms in the rectangular faces are 76.1(6)° and 86.0(2)°.[9] These angles are difficult to rationalize on the basis of electron-pair or interligand repulsion, and so we suggest that they are caused by an electronic factor.

Because of the small energy differences between the two coordination geometries, any attempt to rationalize the different equilibrium structures of $[Sb(CH_3)_5]$ and $[Ta(CH_3)_5]$ may be likened to performing surgery with a blunt axe. Nevertheless we suggest that the different structures adopted may reflect the different properties of the d orbitals available for bonding. The 5d orbitals of Sb are outside the valence shell, higher in energy, and more diffuse than the valence shell 5s or 5p orbitals. The 5d orbitals of Ta are part of the valence shell and may be more effective in bond formation than the valence shell 6p orbitals.

The three equatorial Sb–C bonds in $[Sb(CH_3)_5]$ may be described as two-center two-electron bonds formed from sp^2 hybrid orbitals on Sb. Bonding between Sb and the two axial C atoms may be described in terms of two-center two-electron bonds formed from two $p_z d_{z^2}$ hybrids on Sb, or in terms of a three-center four-electron system involving the $5p_z$ orbital only.[18] The first description implies that the population of the $5d_{z^2}$ orbital is about one electron, the second that the $5d_{z^2}$ orbital remains unoccupied. Mulliken population analysis of the SCF MO wave functions of $[Sb(CH_3)_5]$ in the D_{3h} configuration yields a total population of the d orbitals of 20.62 and a total population of the d_{z^2} orbitals of 4.32 electrons, corresponding to a $5d_{z^2}$ population of 0.32 compared to a total population of the 5d orbitals of 0.62 electrons. For what they are worth, the Mulliken populations suggest that though a description in terms of three-center four-electron bonding may be more appropriate, the role of the $5d_{z^2}$ orbital is not negligible.[19]

In his classical paper published in 1932, Hultgren set out to form hybrid orbitals from one s, three p, and five d functions, which at the outset were assumed to be equally effective for formation of two-center two-electron bonds.[20] Hultgren required the hybrid orbitals formed to have identical shapes and to have cylindrical symmetry. He found that there were four ways of forming six identical orbitals. Two of the sets contained hybrid orbitals with very small angles between them, but two sets seemed to be well suited for formation of bonds to six (identical) ligands. One set was formed by the well-known octahedral sp^3d^2 hybrids, the other was formed by sp^2d^3 hybrids pointing towards the corners of a trigonal prism with square faces.

Five hybrid orbitals with identical shape may obviously be obtained by removing one hybrid orbital from the set of octahedral or trigonal prismatic hybrids, but there is an additional possibility: five hybrids orbitals pointing towards the corners of a square pyramid. The angle between the hybrid orbital pointing towards the apex and one pointing toward a corner of the base is 120°, and the angle between hybrid orbitals pointing towards neighboring corners of the base is 75.5°. The composition of these orbitals is $sp^{1.2}d^{3.2}$.

In conclusion, we suggest that the 5d orbitals of Ta or W are more effective for bond formation than the 6p orbitals, and that in the absence of significant repulsion between ligands, greater participation of the d orbitals in bond formation favors square-pyramidal over trigonal-bipyramidal, and trigonal-prismatic over octahedral configurations.

Cyvin), Elsevier, Amsterdam, **1972**, Chapter 12, p. 183. Correction coefficients for thermal motion $D = r_a - r_a$ and root mean square vibrational amplitudes were calculated from a molecular force field by combining the valence force field of the SbC_5 frame (B. A. Nevett, A. Perry, *J. Mol. Spectr.* **1977**, *66*, 331) with the methyl group force field (A. Müller, W. Nolte, S. J. Cyvin, B. N. Cyvin, A. J. P. Alix, *Spectrochim. Acta* **1978**, *34A*, 383). Nonrefined vibrational amplitudes were fixed at the calculated values.
[14] Since the refinements were carried out with a diagonal weight matrix, the estimated standard devitions listed in Table 2 have been multiplied by a factor of 3.0 to include the uncertainty introduced by data correlation and nonrefined vibrational amplitudes, and then expanded to include an estimated scale uncertainty of 0.1%.
[15] We recorded the IR spectra of $[Ta(CH_3)_5]$ in N_2 and Ar matrices at 20K and the IR and Raman spectra of the solid at 77K, and made tentative assignments for the nine normal modes of the TaC_5 frame of C_{4v} symmetry. A diagonal force field has been obtained and used to calculate Ta–C and C–C vibrational amplitudes. The least squares refinements were made under the constraints of a geometrically consistent r_a structure. The vibrational amplitudes of the Ta–C bonds were fixed at the calculated values. $[Ta(CH_3)_5]$ is thermally unstable. The volatile decomposition products are 98% methane and contain no Ta-containing species [5]. The mole fraction of methane with known molecular structure, L. S. Bartell, K. Kuchitsu, R. J. de Neui, *J. Chem. Phys.* **1971**, *35*, 1211, was included as an additional parameter in the least squares calculations. The resulting value was $x = 0.10(30)$. The scattering power of CH_4 is, of course, much smaller than that of $[Ta(CH_3)_5]$.
[16] Crystalline $[Nb(N(CH_3)_2)_5]$ (C. Heath, M. B. Hursthouse, *Chem. Commun.* **1971**, 145) and gaseous $[Ta(N(CH_3)_2)_5]$ (K. Hagen, C. J. Holwill, D. A. Rice, V. D. Runacles, private communication) adopt distorted square-pyramidal structures. We believe, however, that $[Ta(CH_3)_5]$ is the first five-coordinate d^0 metal complex found to a adopt a square-pyramidal configuration in the gas phase with a pure σ bond to the apical substituent.
[17] SCF MO calculations were performed with the MOLECULE SWEDEN program package: MOLECULE is a vectorized Gaussian integral program written by J. Almlöf, and SWEDEN is a vectorized SCF-program written by P. Siegbahn, B. Roos, P. Taylor, A. Heiberg, J. Almlöf, S. R. Langhoff, and D. P. Chong. For Sb we used a basis set of (15,11,8) primitive Gaussian functions (A. Strömberg, O. Gropen; U. Wahlgren, *J. Comp. Chem.* **1983**, *4*, 181), supplemented by two diffuse d functions with

exponents 0.20 and 0.05 and contracted to ⟨6,5,4⟩. For C we used a (7,4) basis set (F. B. van Duijnevelt, *IBM Technical Research Report No. RJ-945*, **1971**), and for H a (3) basis set (S. Huzinaga, *J. Chem. Phys.* **1965**, *42*, 1293) contracted to ⟨3,2⟩ and ⟨2⟩ respectively. The methyl groups were fixed at the experimental geometry. The optimal Sb–C_{eq} and Sb–C_{ax} bond lengths for the D_{3h} model were 219 and 224 pm, respectively.

Perfluorotriethylamine: An Amine with Unusual Structure and Reactivity

By *Markus Gaensslen, Udo Gross, Heinz Oberhammer,** and *Stephan Rüdiger**

Simple amines NX_3, for example with X = H, F, or Cl, and trialkylamines NR_3 with R = methyl or ethyl have a pyramidal structure with tetrahedral or smaller bond angles at nitrogen. A marked widening of the C-N-C bond angle has recently been observed for triisopropylamine, in which the repulsion between the sterically demanding isopropyl groups forces a flattening of the NC_3 unit with a C-N-C angle of 119.2(3)°.[1] Similarly, fluorination of trimethylamine to $N(CF_3)_3$ also leads to a widening of the pyramidal structure (∢C-N-C) from 110.9(6)° to 117.9(4)°.[2] This pronounced influence of fluorination on the bond angles is remarkable because the C-C-C angle in alkanes is hardly affected by fluorination (e.g., ∢C-C-C is 112.0(10)° in $CH_3CH_2CH_3$ and 113.9(6)° in $CF_3CH_2CF_3$[3]). The structure of perfluorotriethylamine (PTEA) is of particular interest, therefore, to study the influence of fluorination on the nitrogen–carbon skeleton. During the last decade mainly medical research showed an interest in perfluorinated organic compounds. These compounds are less attractive for synthetic chemists because of their extremely low reactivity. The lack of physiological activity of these compounds and their high capacity for dissolving gases render them very promising as components in blood substitutes. The synthesis and isolation of PTEA was achieved by standard methods, as described, for example, in ref. [4]: triethylamine was fluorinated electrochemically in liquid hydrofluoric acid, the crude product was treated with a strong nucleophile, and the PTEA isolated by repeated distillation. The purity of the PTEA, determined by gas chromatography, was 99.2%.

PTEA, like many other perfluorinated compounds, is not crystalline, but solidifies as a glass. Solid-state structure investigations are not, therefore, possible. As a consequence, the structure was determined by electron diffraction (ED) in the gas phase.[5] Many model structures with various symmetries were tested: 1) All three ethyl groups are rotated around the N–C bonds with the same torsion angle τ(N–C) (C_3 symmetry). 2) One methyl group is aligned synperiplanar ($\tau_1 = 0°$) or antiperiplanar ($\tau_1 = 180°$) to the lone pair on nitrogen while the two other methyl groups are rotated with the same angle either in the opposite direction ($\tau_2 = -\tau_3$, C_s symmetry), or 3) in the same direction ($\tau_2 = \tau_3$, C_1 symmetry). The various models were judged under two aspects: the agreement between calculated and experimental radial distribution functions (Fig. 1) and no F···F contacts (except geminal contacts) should be less than 220 pm. If reasonable

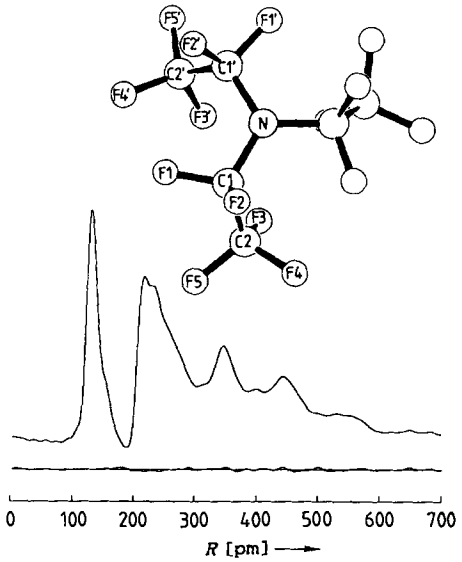

Figure 1. Radial distribution function for PTEA with difference curve and molecular model with atomic numbering.

bond lengths and C-C-C and F-C-F bond angles are assumed, these conditions are only fulfilled by those models with C_3 symmetry, a value for τ(N–C) of approximately 150°, and an almost planar configuration at the nitrogen atom. In addition, a twisting of the trifluoromethyl group about by C–C bond by τ(C–C) from the staggered position must be assumed to obtain complete agreement with the experimental radial distribution.

The preliminary model was then refined with the method of least squares.[6] The agreement between the final model and the experimental data is indicated by the difference curve in Figure 1. The optimized structure parameters are presented in Table 1. The NC_3 unit is almost planar (∢C-N-C = 119.3(4)°). A negligible bending of the N–C bond out of the plane (α = 4.8(27)°) in the direction of the CF_3 groups can be seen. In addition to a widening of the C-N-C angle the steric strain also leads to an increase in the N-C-C angle to

Table 1. Structural parameters for perfluorotriethylamine.

Parameter	Value [a]	Parameter	Value [a]
C–F	133.0(2)	N-C-C	118.2(26)
N–C	148.2(7)	F-C1-F	105.0(16)
C–C	159.2(8)	F-C2-F	108.8(5)
α [b]	4.9(25)	τ(N–C) [c]	147.0(5)
C-N-C	119.3(4)	τ(C–C) [d]	25.6(11)

[a] Distances in pm and angles in degrees. Uncertainties correspond to 3σ values. [b] Angle between an N–C bond and the plane through nitrogen perpendicular to the C_3 axis. [c] Torsion angle about an N–C bond. For τ(N–C) = 0° the C–C bond is synperiplanar to the lone electron pair on nitrogen. [d] Torsion angle about a C–C bond. For τ(C–C) = 0° the CF_3 groups are staggered to the CF_2 groups.

118.2(26)° and a marked increase (about 5 pm) in the N–C and the C–C bond lengths. The N–C bonds are stretched from 142.6(6) in $N(CF_3)_3$ to 148.2(7) in PTEA and the C–C bonds from 154.5(8) in CF_3–CF_3[7] to 159.2(8) in PTEA. In spite of this distortion of the molecular geometry, F···F contacts are present between non-geminal atoms that are considerably shorter than the corresponding van der Waals distance of 270 pm: F1···F'4 = 234, F1···F5 = 256, F3···F'3 = 259, F2···F4 = 260 pm.

The most prominent chemical difference between tertiary amines and their perfluorinated analogues is the strongly reduced basicity of the latter, apparently as a result of the strong electron withdrawing effect of the perfluorinated groups attached to nitrogen, the lone pair of which is partially delocalized over the neighboring CF_2 or perfluoroalkyl groups. The increased electron density on the α carbon atoms leads to a certain reactivity of the CF_2 groups. Thus, under extreme conditions (e.g. oleum at 170 °C or SbF_5 at 100–170 °C) electrophilic attack on an α-C atom is possible, which can lead to perfluorolactams[8] or perfluoroazomethines.[9]

The structure of PTEA also directly reflects its chemical behavior. A partial delocalization of the electron lone pair on nitrogen allows the transition from a pyramidal to an almost planar structure of the NC_3 unit. The arrangement of the CF_3 groups all on the same side of the molecule shows that the residual electron density on nitrogen still has a profound effect on the structure. A model of PTEA with van der Waals radii (Fig. 2) shows that the central nitrogen atom

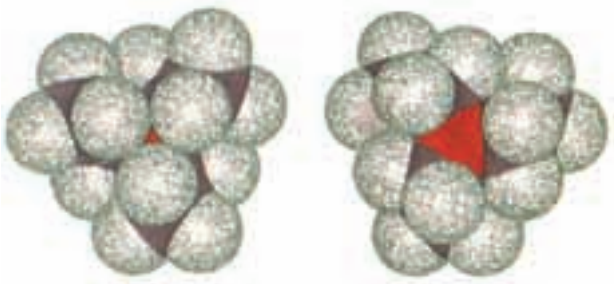

Figure 2. Structure model with van der Waals radii. Color key: N = red, C = black, F = green. View towards the CF_3 groups (left) and towards the CF_2 groups (right).

(in red) is almost completely covered by the fluorine atoms of the CF_3 groups (left) and that more space is available for the lone electron pair in the direction of the CF_2 groups (right).

[5] The ED intensities were recorded with a gas diffractograph KD-G2 for two camera distances (25 and 50 cm) and an accelerating voltage of about 60 kV. The temperature of the sample was −28 °C, that of the nozzle 10 °C, and the pressure of the apparatus was approximately 10^{-5} mbar. For each camera distance two photographic plates (Kodak Electron Image, 13 × 8 cm) were evaluated according to standard methods (H. Oberhammer, W. Gombler, H. Willner, *J. Mol. Struct.* **1981**, *70*, 273). The molecular scattering intensity in the *s*-ranges 20–180 and 80–350 nm^{-1} ($s = (4\pi/\lambda)\sin\theta/2$, λ = electron wavelength, θ = scattering angle) were used for the structure determination. The radial distribution function was calculated by Fourier transformation.
[6] In the least-squares structure refinement, the scattering intensities were modified with a diagonal weighting matrix and known scattering amplitudes and phases (J. Haase, *Z. Naturforsch. A*, **1970**, *25*, 936). For the CF_2 and the CF_3 groups C_{2v} or C_{3v} symmetry was assumed. Vibrational amplitudes were collected in groups according to the type and length of the interatomic distances. Two correlations between geometric parameters are larger than |0.7|: α/N-C-C = 0.97, ∢F-C1-F/∢F-C2-F = 0.85. The *R* factors are 0.086 and 0.037 for the intensities of the 25 cm or 50 cm camera distances.

Product Predictions for Nucleophilic Additions to C_{70}

By *Heinrich R. Karfunkel** and *Andreas Hirsch*

If fullerenes are provided with functional groups, three-dimensional arrangements that are not possible for planar arenes or heteroarenes are generated. To utilize these new opportunities, it is essential that the course of the addition of these groups can be controlled. Besides the addition of radicals,[1] dienes, and 1,3-dipoles,[2, 3] the nucleophilic addition with alkyllithium or Grignard reagents presents further possibilities for derivatizing fullerenes.[3, 4]

Recently we developed a new method of directed nucleophilic addition to a single 6-6 "double bond" (the bond common to the annelated six-membered rings) in C_{60}.[5] Semiempirical quantum mechanical calculations (MOPAC/AM1[6, 7] agreed with the experimental findings: the addition to the 6-6 bond of C_{60} is energetically favored over all other potential additions, irrespective of nucleophile used. This synthetic method can be applied to C_{70} and other fullerenes. However, already for C_{70} the situation is considerably more complex than for C_{60}. The number of conceivable reaction products is too large for chemical intuition alone to predict the result; we employed MO calculations for this purpose.

The nucleophilic addition to C_{70} proceeds in two steps (Scheme 1). Three questions arise: a) Which are the most

1. $C_{70} + Nu^- \longrightarrow C_{70}Nu^-$ (nucleophilic attack)

2. $C_{70}Nu^- + H^+ \longrightarrow C_{70}NuH$ (proton addition)

Scheme 1.

probable isomers of $C_{70}NuH$? b) Is the result in a) dependent on the nature of the nucleophile? c) How reliable are predictions based on calculations?

[*] Priv.-Doz. Dr. H. R. Karfunkel

If a reasonable error tolerance is chosen and it is assumed that no rearrangement takes place on proton addition, the answer is that only two (in the case of $C_{70}t$BuH three) isomers are possible as addition products. These isomers are largely independent of the nature of the nucleophile. Rearrangement on proton addition increases the number of possible isomers slightly.

A nomenclature system for the isomers of $C_{70}XY$ (X,Y are two added groups) does not yet exist. For this reason we introduce a new system here. C_{70} in D_{5h} symmetry has five sets of equivalent atoms arranged radially about the symmetry axis. In Figure 1 these sets are labeled e (for equatorial), 1, 2, 3, and N (for North Pole). For the second hemisphere the corresponding sets of equivalent atoms are given a minus sign.

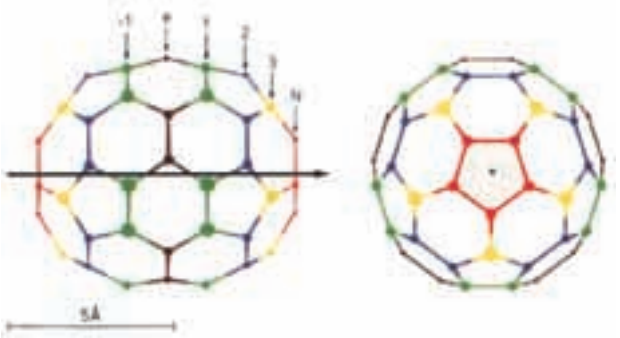

Fig. 1. C_{70} in D_{5h} symmetry, viewed looking at the equator (left) and at the pole (right). The fivefold rotation axis is indicated by the long arrow (left) and the dot (right). The sets of equivalent atoms are indicated in color (pole in red, etc.) and their labeling by arrows (e,1,2,3,N for one hemisphere and -1 etc. for the other).

The first nucleophilic attack can take place at any of these sets and yields five possible isomers of $C_{70}Nu^-$. The next proton addition can proceed at each of the 69 free positions of the anion. Hundreds of products are thus possible in principle. An isomer of C_{70}NuH is characterized by the position of the nucleophilic attack, followed by a slash (/) and the shortest path to the position of the added proton: for example (see also Fig. 2), 2/2 means a nucleophilic attack at set 2 and proton addition at the adjacent atom of the same set; 2/2,3,N corresponds to a 1,4 addition in which the nucleophilic attack is at set 2 and the proton is added to the final atom of the path from 2 via 2 (only one possibility) and 3 (only one possibility), to N (only one possibility); finally 1/e,-1,-1 corresponds to a 1,4 addition across the equator. In some cases the suffixes *t* and *c* (for *trans* and *cis*) are also needed to specify a particular path unambiguously.

Initial geometries were generated with the program MACROMODEL.[8] These were then optimized with MOPAC 6.0[6] through the use of AM1 parametrization (options: EF, PRECISE, and XYZ). All AM1 calculations were performed on a RS-6000 workstation. AM1 calculations were carried out on each of the five isomers of $C_{70}Nu^-$ for each of the three nucleophiles H^-, Me^-, and tBu$^-$. The resulting energies for the geometry-optimized structures (AM1 standard heats of formation or HOF) are presented in Table 1.

Three conclusions about the first step of the nucleophilic addition to C_{70} may be drawn from these results: 1) A nucleophilic attack at the equator does not take place (although the greatest positive charge is localized there). 2) The most probable sites for nucleophilic attack are the positions (or sets) 1 and 2, followed by the pole N. 3) There is excellent agreement for the three nucleophiles. This good correlation of the $C_{70}Nu^-$ energies and our experience with C_{60}[5] (which is experimentally substantiated) allows an efficient global search for the most stable isomers of C_{70}NuH.

Table 1. AM1 standard enthalpies of formation (AM1-HOF) [kcal mol^{-1}] for the five isomers of $C_{70}H^-$, $C_{70}Me^-$, and $C_{70}t$Bu$^-$. The numbers in parentheses ranks the relative energy of the isomers in increasing order.

C_{70} site	Mulliken charge	H^-	Me^-	tBu$^-$
N	+0.0045	961.33(3)	959.03(3)	950.44(3)
3	−0.0098	965.23(4)	962.94(4)	954.33(4)
2	+0.0051	958.07(2)	955.94(1)	947.46(1)
1	−0.0146	957.61(1)	955.94(1)	948.25(2)
e	+0.0243	979.07(5)	977.31(5)	969.64(5)

The time required for the computation makes the calculation of all the isomers of $C_{70}H_2$, C_{70}MeH, and $C_{70}t$BuH impossible. Nevertheless, the results in Table 1 permit a reliable search with little effort. All the $C_{70}H_2$ isomers (a total of 130) that can be generated from the four most stable isomers of $C_{70}H^-$ of Table 1 were found, and their energies calculated (to be sure that none were missed, the products from the unlikely 3/ isomer were also considered). Then only from the most stable isomers of $C_{70}H_2$ (see Table 2) were a small number of C_{70}MeH and $C_{70}t$BuH isomers generated by substitution of a H atom by a methyl or *tert*-butyl group, and their energies calculated. This search methodology can also be applied to higher fullerenes.

Table 2. The relative stability (AM1-HOF in kcal mol^{-1}) of the seven most stable $C_{70}H_2$ isomers. The relative AM1-HOF of the anionic intermediate $C_{70}H^-$ is given in the last column for completeness.

No. (rank)	Isomer	Mulliken charge [a]	Relative AM1 HOF (isomer)	Relative AM1 HOF (intermediate)
1	2/2	−0.25	0.00	0.46
2	N/3	−0.28	1.05	3.72

	(N/3,2,2)	(−0.14)		(7.62)
5	1/1	−0.19	6.80	0.00
6	3/2,2,3	−0.13	6.85	7.62
7	1/1,2,2	−0.12	9.81	0.00
	(2/2,1,1)	(−0.16)		(0.46)

[a] Position of the added proton.

The results for the final products as well as for the anionic intermediates are collated in Tables 2–4. Relative energies are quoted as only the differences in energy are relevant for comparison.

Two aspects of the reliability of the calculations must be taken into account: the reliability of the AM1 calculations and the reliability of the search process for the most stable isomers of C_{70}MeH and $C_{70}t$BuH.

Statistical studies[9] have shown that the error (RMS error) of the AM1 standard enthalpies of formation is approximately 10 kcal mol^{-1}. However, if comparisons of energy

[a] Position of the added proton.

are made within a generic family of substances (e.g., the comparison of structurally similar isomers), the error in these $\Delta\Delta H$ values are almost an order of magnitude smaller.[10] If one considers that the calculations assume idealized relationships, that is, the molecules are in the gas phase and no entropy effects are considered, an error limit of 2.5 kcal mol^{-1} seems reasonable. The conclusions drawn below are based on the assumption that isomers differing in AM1 energy by more than 2.5 kcal mol^{-1} from the most stable isomer may be neglected.

Table 4. The relative stability (AM1 energies in kcal mol^{-1}) of the eight most stable $C_{70}t$BuH isomers.

[a] Position of the added proton.

Since the correlation between the energies of the analogous isomers for the three nucleophiles is good, it is hardly conceivable that other isomers of C_{70}MeH or $C_{70}t$BuH exist, whose calculated AM1 energy differ from that of the 2/2 isomer by less than 2.5 kcal mol^{-1}. Conclusions from the AM1 calculations: irrespective of whether reaction 1 of nucleophilic addition (nucleophilic attack) or reaction 2 (proton addition) is rate-determining, the most probable product for all nucleophiles is the 2/2 isomer. It should be noted that the sets 1 and 2 have twice as many sites as sets 3 and N, which also affects the probabilities. The six most stable isomers (Fig. 2) are at any rate identical, and although there are slight changes in order of stability for different nucleophiles, the correlation between the energies is excellent. In other words, the nucleophilic addition is largely independent of the nature of the nucleophile. As for C_{60}, a 1,2 addition to C_{70} also takes place exclusively at a 6-6 "double bond". A surprising result of the calculations is that in contrast to C_{60}, for C_{70} 1,4 addition products are also anticipated, and predominantly the 1/e,−1,−1 transequatorial isomer. Consideration of the tolerances mentioned above lead to the following predictions: 1) Unless there are

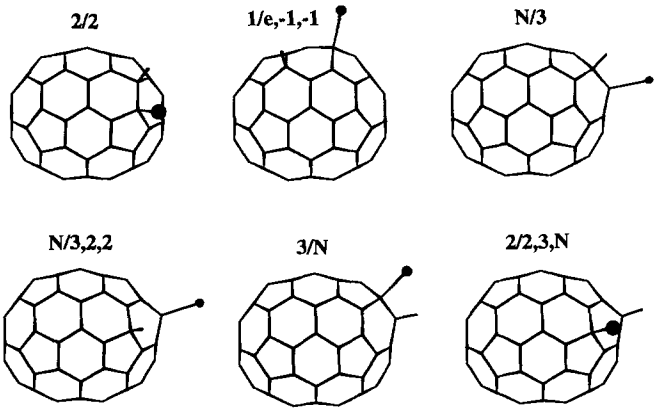

Fig. 2. The six energetically most favorable isomers of C_{70}NuH (viewed from the side). The nucleophile (H, Me, or *t*Bu) is indicated (in perspective) by a solid ball and the added proton by a dash. The labeling of the isomers is derived by giving the position of the nucleophile (character before the slash) followed by the path to the position of the added proton (see text).

rearrangements on proton addition, the 2/2 and 1/e,−1,−1 isomers are possible for $C_{70}H_2$ and C_{70}MeH and the 2/2, 1/e,−1,−1, and 2/2,3,N isomers for $C_{70}t$Bu. 2) If rearrangements take place on proton addition, the 2/2, N/3, and 1/e,−1,−1 isomers are likely for $C_{70}H_2$, the isomers 2/2, N/3, 3/N, and 1/e,−1,−1 for C_{70}MeH, and the 2/2,1/e,−1,−1, N/3, N/3,2,2, 3/N, and 2/2,3,N for $C_{70}t$Bu (Fig. 2). Finally the paper of Balch et al. should be mentioned, which deals with the additions of $[(Ph_3P)_2Pt]$ and $[Ir(CO)Cl(PPh_3)_2]$ to C_{70}.

An unambiguous identification of the isomers by methods other than X-ray diffraction will probably be extremely difficult. For structure elucidation with 2D NMR methods (2D-NOE studies), the interproton distances are of crucial importance. Geometry-optimized AM1 structures reveal that for C_{70}MeH (in which H_{Nu} is the closest proton to the added H^+), the H–H_{Nu} distance is identical for the possible 1,2-addition products (the 2/2, N/3, and 3/N isomers) and amounts to 2.4 Å. The H–H_{Nu} distance for the 1/e,−1,−1 isomer is 2.93 Å. For $C_{70}t$Bu the H–H_{Nu} distances for the 1,2-addition products are identical and are 2.01 Å, while for the 1,4-addition products the H–H_{Nu} distance of the transequatorial 1/e,−1,−1 isomers is 0.5–0.6 Å smaller than in the N/3,2,2 or 2/2,3,N isomers.

Paramagnetic Chiral Smectic C Materials: A New Class of Ferroelectric Liquid Crystals**

By *Mercedes Marcos,* José Luis Serrano, Teresa Sierra,* and *María José Giménez*

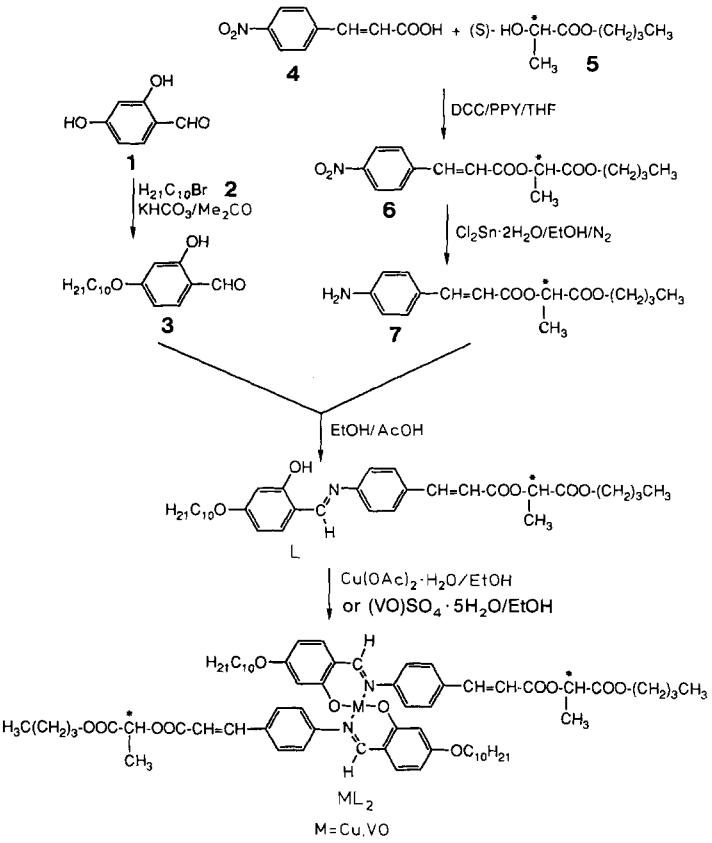
Chiral liquid-crystalline phases, in particular smectic C* phases, have attracted great interest over recent years because of their ferroelectric and nonlinear optical (NLO) properties.[1] Furthermore, interest in the synthesis of liquid-crystalline compounds incorporating transition metal ions is currently increasing, since potential applications originate from the presence of a metal ion in ordered fluid phases.[2] The high electron density of the metallic center may lead to an increase in polarizability and high birefringence, and under the right conditions complexes may exhibit a NLO response.[3]

Up until now, the typical ferroelectric liquid crystals have been chiral rodlike organic molecules. However, recently we described a ferroelectric liquid-crystalline material consisting of a dimer of an *ortho*-palladated azine complex, in which chirality is introduced through chiral carboxylate bridges.[4] Our group has also published several papers on copper(II) and vanadium(IV) Schiff base complexes that exhibit a smectic C phase among other mesphases.[5] This led us to envisage a new class of ferroelectric liquid crystals that incorporate a metallic center in their mesogenic core and have the general structure ML_2 (Scheme 1). These complexes are of special interest, because they are the first paramagnetic, ferroelectric metallomesogens.

The synthesis of ligand L and complexes ML_2 is shown in Scheme 1. Schiff base L, synthesized by condensation of 4-(decyloxy)-2-hydroxybenzaldehyde **3** with chiral amine **7** (see Experimental Procedure), reacts with copper acetate or vanadyl sulfate in a 2:1 molar ratio affording a brown copper complex or a green oxovanadium complex, whose elemental analyses and IR spectra are in full agreement with the proposed structures.

The phase sequence and transition temperature of L and the copper(II) and vanadium(IV) complexes studied by differential scanning calorimetry (rate of heating 10 °C min^{-1}) and optical microscopy are listed in Table 1. The ligand and both the complexes exhibit a chiral smectic C mesophase and a smectic A phase. A photomicrograph of the S_{C^*} phase of the copper(II) complex is shown in Figure 1.

Their physical properties, spontaneous polarization Ps, switching time τ, and rotational viscosity γ, were determined simultaneously by the triangular wave method[6, 7] in 10 μm cells with indium tin oxide (ITO) electrodes coated with polyimide in an electrical field of 30 V peak to peak and 50 Hz for the ligand. For the complexes, the electric field was 40 V peak to peak and it was necessary to decrease the frequency to 40 Hz for CuL_2 and 5 Hz for VOL_2 in order to obtain the Ps saturation values. The dependence of Ps on temperature is shown in Figure 2. A maximum spontaneous polarization Ps_{max} of 44 nC cm^{-2} was measured for the ligand and of 23 and 20 nC · cm^{-2} for the copper and oxovanadium complexes respectively (Table 1). The rotational viscosity of the oxovanadium complex is much larger than that of the copper complex, which is even lower than that for the



Scheme 1. Synthesis of L and ML_2. DCC = dicyclohexylcarbodiimide, PPY = 4-pyrrolidinopyridine.

Table 1. Phase transitions, spontaneous polarization Ps_{max}, rotational viscosity γ_{max}, and switching time τ_{max} for the ligand and their complexes.

Compd	Phase [a] and Phase transition Temperatures [°C]	Ps_{max} [nC cm^{-2}]	γ_{max} [Pa s]	τ_{max} [μs V μm^{-1}]

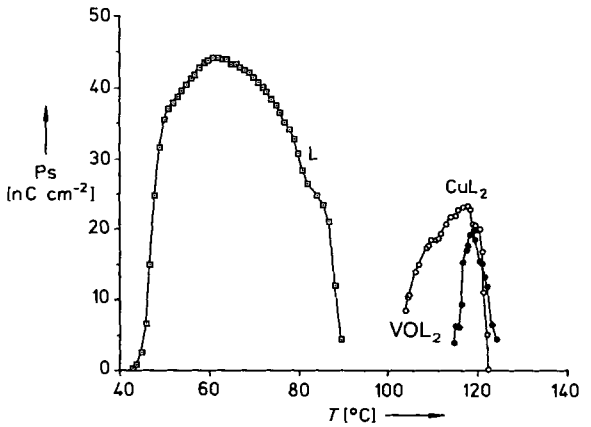

Fig. 2. Temperature dependence of the spontaneous polarization of ligand L and complexes CuL_2 and VOL_2.

ligand. Consequently, as both complexes exhibit similar Ps_{max} values, the switching time is longer in VOL_2 than in CuL_2 (Table 1). These complexes exhibit switching times in the millisecond range, comparable to the switching time exhibited by polymeric ferroelectric liquid crystals,[8] but slightly longer than that of most of ferroelectric organic liquid crystals (FOLCs), which are normally in the range of microseconds.[9] However, it is noteworthy that in this case the switching time for the organic ligand L is also in the range of milliseconds.

The Ps of FLCs is determined by the magnitude of the molecular dipole moment, the relative intramolecular motions of the dipole moment of the chiral part, and the rotation of the molecule around its long axis. As can be seen in Figure 2, the Ps_{max} of the ligand decreases from 44 nC cm^{-2} to 23 or 20 nC cm^{-2} on complexation, probably because the dipole moments of a chain cancel each other out when their orientations differ.

In conclusion, these ferroelectric metallomesogens are interesting not for the usual applications in which classical FOLCs are employed, but rather for applications in which a combination of the ferroelectric properties of the chiral smectic C phase with the magnetic orientability of paramagnetic complexes in a magnetic field is important, as these complexes can be aligned parallel or perpendicular to the magnetic field, depending on the anisotropy of the magnetic susceptibility of the complex.[10]

Experimental Procedure

All compounds were characterized by C,H,N analyses and IR and ^{1}H NMR spectroscopy.

6: (−)-Butyl-L-lactate (**5**) available in 97% enantiomeric purity from Fluka, served as chiral starting material. It was coupled to *p*-nitrocinnamic acid **4** (each 71.8 mmol) with DCC (79 mmol) as esterification agent and PPY (7.18 mmol) as catalyst in dry THF (20 mL) according to the method described by Hassner and Alexanian [11]. The product **6** was purified by flash chromatography (dichloromethane).

7: The nitro group of **6** (25 mmol) was reduced with $SnCl_2 \cdot 2H_2O$ (125 mmol) in ethanol (100 mL) under an inert atmosphere (N_2) according to the Bellamy method [12]. The amine obtained was used without further purification in the condensation step.

L: Schiff base L was synthesized along standard procedures [13] by mixing an ethanolic solution of **3** (5.7 mmol) with chiral amine **7** (5.7 mmol) and a few drops of acetic acid as catalyst, and purified by two recrystallizations from ethanol and hexane. Selected spectroscopic data for L: ^{1}H NMR ($CDCl_3$) δ = 13.52 (s, 1H), 8.52 (s, 1H), 7.73 (d, J = 16.1 Hz, 1H), 7.55 (d, J = 8.4 Hz, 2H), 7.2–7.3 (m, 3H), 6.41–6.54 (m, 3H), 5.20 (J = 6.9 Hz, 1H), 4.16 (t, 2H), 3.98 (t, 2H), 1.84–1.20 (m, 20H), 1.53 (d, 3H), 0.92 (t, 3H), 0.86 (t, 3H); IR (nujol) $\tilde{\nu}$ [cm^{-1}]: 1752, 1719 (CO=O), 1630 (CH=CH), 1630 (C=N) overlapping signals.

ML_2: An ethanolic solution containing copper acetate or vanadyl sulfate (1 mmol) was added to a hot ethanolic solution of L (2 mmol). The color of the reaction solution changed from yellow to green. The solution was refluxed for 1 h and then cooled. The precipitate was collected by filtration and recrystallized from chloroform/ethanol (1/3). The brown copper complex and green oxovanadium compound were characterized by IR spectroscopy and elemental analysis. The ^{1}H NMR spectra of the complexes exhibit large shifts relative to the free ligand, and all signals are broadened as a result of the paramagnetic metallic ion. CuL_2: IR (nujol) $\tilde{\nu}$ [cm^{-1}]: 1755, 1719 (CO=O), 1633 (CH=CH), 1609 (C=N); VOL_2: IR (nujol) $\tilde{\nu}$ [cm^{-1}]: 1761, 1717 (CO=O), 1634 (CH=CH), 1608 (C=N), 976 (V=O).

their crystal structures determined, mainly because they do not form crystals of a quality good enough for single-crystal X-ray analysis. Particularly interesting members of the MeALPO family, in which a divalent metal (Me) substitutes for Al^{3+} in the framework, are MeALPO-36 (Me = Mg, Mn, Co, Ni, Zn) and MeALPO-34 (Me = Mg, Mn, Be, Co). In some MeALPO structures silicon may also replace a fraction of both the phosphorus and aluminum; such products are designated MeALPSOs or MeAPSOs. Most of these are active, uniform heterogeneous catalysts[3, 4] for the conversion of hydrocarbons and methanol. The active sites (readily detachable protons loosely bound to a framework oxygen atom close to the divalent metal) are distributed in a uniform manner throughout the bulk of the microporous solid and are accessible to small reactant molecules.[5, 6] MeALPO-34 has a framework structure exactly analogous to that of the zeolitic mineral chabazite ($Ca_6[Al_{12}Si_{24}O_{72}] \cdot 40H_2O$), but that of MeALPO-36 has hitherto not been known. We describe herein how the three-dimensional structure of this catalyst was solved on the basis of evidence garnered from high-resolution electron microscopy,[7, 8] electron diffraction, and other methods including energy minimization.[9]

Monophasic samples of MgALPO-36, MgALPSO-36, and ZnALPO-36 were synthesized according to published procedures.[10] The similarity of their X-ray powder diffraction patterns indicates that they have the same framework structure. Thin sections of the needlelike crystals (both parallel and perpendicular to the needle axis) of specimens of the ZnALPO-36 (taken as representative) were examined under the electron microscope. The diffraction patterns and high-resolution images suggested an orthorhombic cell, approximately $13.1 \times 21.6 \times 5.0$ Å, with two one-dimensional, wide-pored channels (known from previous adsorption measurements[10] to be bounded by twelve tetrahedrally surrounded atoms) parallel to the c axis and situated at 0,0 and $a/2$, $b/2$ in the unit cell.

The determination of the short 5 Å c axis was particularly helpful, because it restricts the possible structures to those built up of zigzag chains of tetrahedra parallel to the short axis. Examples of such structures include the zeolites bikitaite,[11] cancrinite,[12] Theta-1,[13] and ZSM-23[14] as well as the aluminum phosphate ALPO-31.[15] A consideration of possible frameworks of appropriate dimensions and with the observed size and spatial distribution of unidimensional, large-pore channels suggests a trial structure with idealized symmetry *Cmcm*, illustrated in Figure 1a. (Initial coordinates were refined by using distance least-squares (DLS)[16] constraints on the bond lengths and angles applicable for high silica zeolites.)

We next took advantage of computational methods designed to achieve energy minimization of the solid with respect to its structural parameters, using the procedures that have proved to be a powerful tool for modeling the structure of high silica zeolites.[17] We have applied the METAPOCS[9, 18] method for the minimization of the lattice energy at constant pressure, which allows cell dimensions and symmetry elements to relax in addition to the atomic coordinates. We first replaced each tetrahedrally surrounded atom by a silicon atom; which approximates to keeping Al and P disordered in terms of the long-range structural order. The resulting structure remained orthorhombic (*Cmcm*), and the atoms shifted little from their values refined by DLS. However, we know that in ALPOs, and also probably in MeALPOs and MeALPSOs where the degree of substitution of Al for Me, and Si for P and Al is small, the Al (and Me) and P atoms will be strictly ordered on alternate tetrahedra. Therefore, by putting Al and P (ordered) into the high-symmetry *Cmcm* structure (thereby breaking the mirror and glide symmetry), and by using Al and P potentials derived by van Beest et al.[19] the lattice energy was again minimized. Because of the presence of mirror planes perpendicular to a in the high-symmetry form, only one distinct Al/P ordering scheme is possible. The resulting triclinic cell ($a = 13.46$, $b = 22.17$, $c = 5.29$ Å; $\alpha = 90.16$, $\beta = 92.01$, $\gamma = 89.95°$) retained $C\bar{1}$ symmetry and was close to pseudomonoclinic. The atomic coordinates are given in Table 1.

The X-ray powder diffraction profiles simulated from the atomic coordinates and cell parameters derived from the energy-minimized "SiO_2" and "AlPO" structural models are given in Figure 2a. They can be compared with experimental X-ray diffraction patterns of the representative aluminophosphate MgALPSO-36 recorded in dry helium with a special in situ cell[20] at temperatures of 150 and 375 °C (Fig. 2b). The close agreement of the diffraction pattern of the high-symmetry "SiO_2" structure with that of the pattern obtained experimentally at high temperature is clear. However, at the lower temperature, the (131) peak is split ($\Delta 2\theta = 0.375°$), and the entire profile approximates much more closely to that predicted from the "ALPO" energy-minimized structure, although the predicted lattice parameters are larger (by about 2.5 %) than those actually observed.

The diffraction pattern collected at the lower temperature was then matched by applying the Rietveld profile method.[21, 22] The atomic coordinates obtained from the

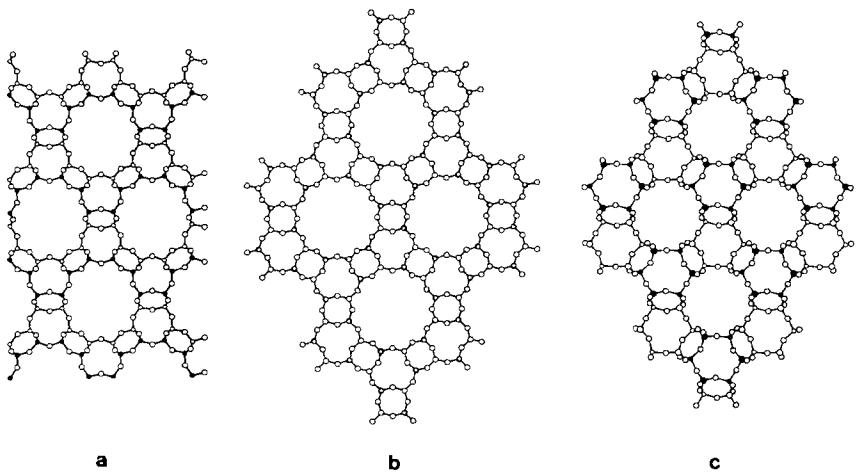

Fig. 1. a) and b) Projections down [001] of the high-symmetry (Al and P disordered) models for MeALPO-36 (*Cmcm*) as a generalized structure and calcined ALPO-5 [24], respectively; c) projection of the structure of aluminosilicate cancrinite. For a) and c) the open circles representing tetrahedrally coordinated atoms are separated in the direction of the z axis by a distance of $c/2$ from those tetrahedrally coordinated atoms represented by closed circles. In c) the smaller tetrahedrally surrounded atoms represent Al, the larger Si.

O(12)	0.5077	0.7629	0.2457

"ALPO" energy minimization were used, and the lattice and thermal parameters refined. No attempt was made to refine the 54 independent atomic coordinates because of the limited amount of reflection intensity data available from the powder diffraction data. The final fit is illustrated in Figure 3. The average bond lengths for Al–O 1.71(1) and P–O 1.48(1) Å are identical (within experimental error) with the values obtained from a single-crystal study of ALPO-5.[23]

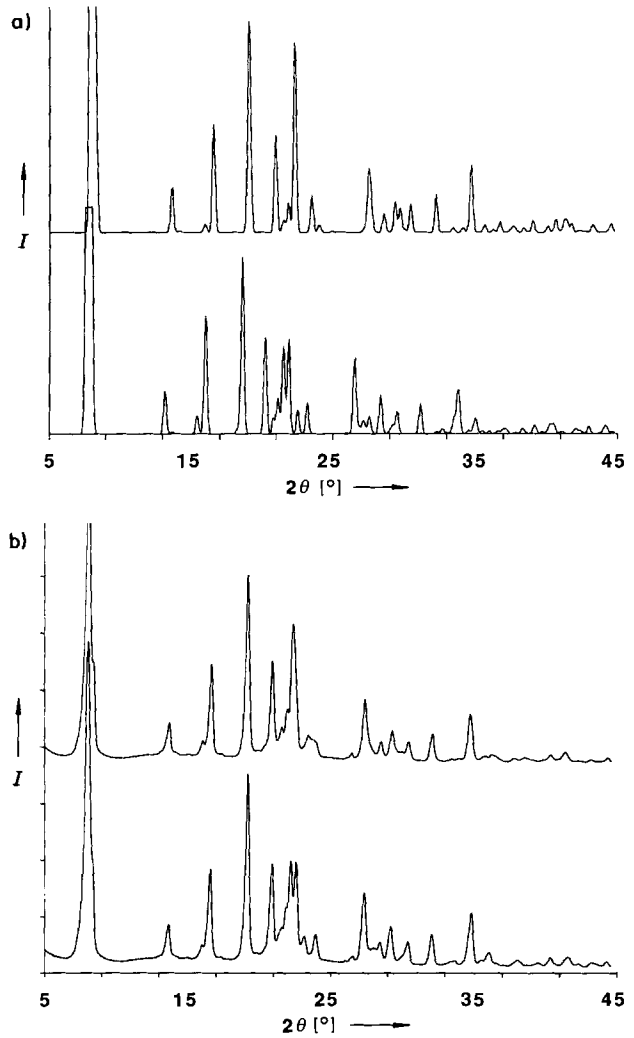

Fig. 2. a) Simulated X-ray diffraction patterns for SiO_2 (top) and ALPO (bottom) energy-minimized structures. b) Experimental X-ray diffraction patterns for MgALPSO-36 recorded at 375 (top) and 150 °C (bottom). I = intensity in arbitary units.

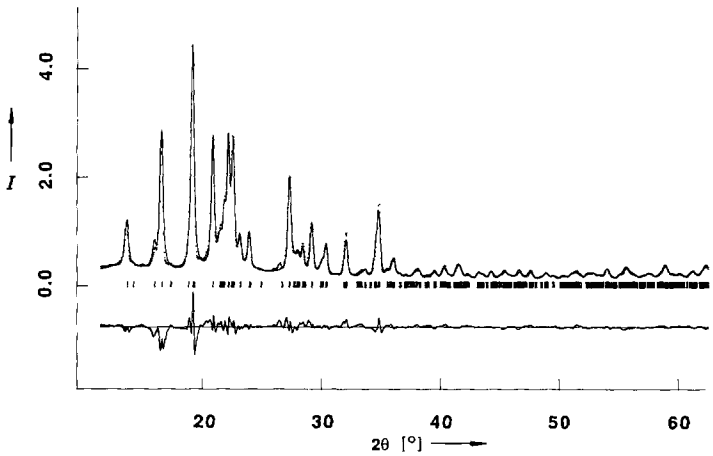

Fig. 3. Experimental (dots) and fitted (solid line) diffraction profiles (top) with difference plot (bottom) and peak markers (middle) for the X-ray diffraction data collected at 150 °C and for the atomic coordinates from the ALPO energy minimization (I = counts $\times 10^{-4}$). The refined cell parameters for MgALPSO-36 are $a = 13.161(2)$, $b = 21.649(3)$, $c = 5.189(1)$ Å, $\alpha = 89.96(2)$, $\beta = 92.17(2)$, and $\gamma = 90.02(3)°$. The isotropic temperature factors (U_i) of the tetrahedrally surrounded atoms (constrained to be a single value) and of the oxygen atoms (a single, independent value) refined to 0.015 and 0.030 $Å^2$, respectively. The final weighted profile R-factor (R_{wp}) was 0.098.

For comparison, DLS refinement was performed in the same unit cell and space group, with Al/P ordering, and with experimental bond lengths from the single-crystal study of ALPO-5.[23] The DLS-derived atomic coordinates were within 0.06(2) Å for the tetrahedrally surrounded atoms and 0.10(7) Å for the oxygens of the energy-minimized structure and fitted the observed X-ray diffraction data well ($R_{wp} = 0.112$ as against 0.098 for the energy-minimized structure).

The framework of MeALPO-36 is built of four- and six-membered rings and contains wide-pore channels bounded by twelve-membered rings half at $z = 0$ and half at $z = 1/2$ (Fig. 4). In projection, MeALPO-36 (Fig. 1a) is similar to ALPO-5 (Fig. 1b[24]) and possesses nearly identical adsorption properties. (However, in ALPO-5, the largest apertures are effectively circular, and the smallest are squares, whereas in MeALPO-36 both the largest and smallest apertures are oval.) MeALPO-36 is also very similar to the zeolite cancrinite in projection (Fig. 1c), and an aluminophosphate with the cancrinite structure could easily intergrow on the (010) plane of MeALPO-36. We are currently investigating whether such intergrowths can explain faults determined by high-resolution electron microscopy (HREM) on the (010) plane of ZnALPO-36.

Two significant general conclusions may be drawn from this work. First, the use of energy minimization procedures in elucidating structural detail is likely to be widely applicable to other solids (irrespective of whether or not they are uniform catalysts), particularly those that are available only as powders. Details of distortions away from idealized symmetry—expected in ALPOs as a consequence of strict Al/P ordering—may be predicted with a physical model rather than relying on diffraction data. Whereas for MeALPO-36 it is possible to approach the energy-minimized structure by

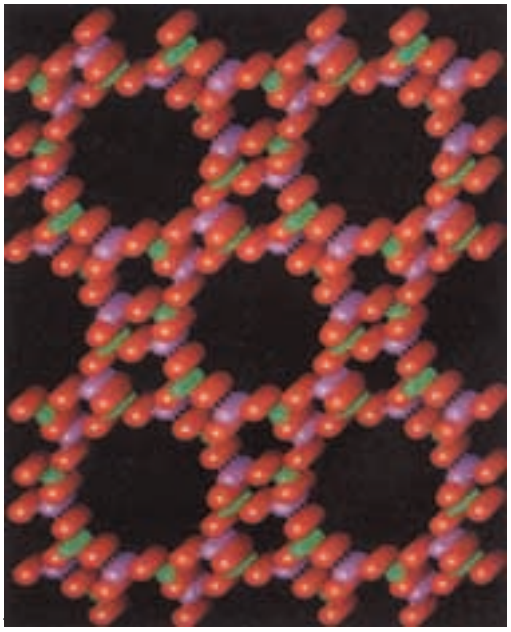

Fig. 4. The energy minimized "ALPO" structure for MeALPO-36, Me = Mg, Zn, etc. Note that Al and P alternate in the tetrahedra. Red = oxygen, green = phosphorus, violet = aluminum (+Me in synthesized samples).

DLS-modeling, this requires prior knowledge of the unit cell and space group, which cannot generally be determined unambiguously. Second, a knowledge of the three-dimensional structure of uniform heterogeneous catalysts (such as that of MeALPO-36) provides far greater insight into the properties of the catalyst than is the case for nonuniform, multicomponent ones (such as a typical Fischer–Tropsch, supported catalyst).

After completing this study we became aware of an as yet unpublished report of the structure of MeALPO-36, Me = Mg.[25] This report gives details of the average disordered structure in space group $C2/c$ with $a = 13.1$, $b = 21.6$, $c = 5.2$, $\beta = 92.0°$.

Experimental Procedure

Samples of MgALPO-36, MgALPSO-36, and ZnALPO-36 (seeded with MgALPO-36) were prepared from gels with tripropylamine as a base [10] by heating the gels under autogenous pressure in a Teflon-lined autoclave at 110 °C for 24 h and 150 °C for 22 h. The bulk Mg:Al:P, Mg:Al:P:Si, and Zn:Mg:Al:P contents were 0.14:0.86:1.00, 0.04:0.91:0.90:0.15, and 0.04:0.03:0.91:1.01, respectively, as determined by inductively coupled plasma (ICP) atomic emission spectrometry. The organic template was removed by calcination in oxygen at 550 °C for 12 h. Electron microscopy was performed on a Philips CM30 microscope operating at 300 keV. DLS calculations, X-ray powder profile simulations, and plotting were performed with Biosym Technologies Catalysis software on a Silicon Graphics Personal Iris workstation. Energy refinements were performed with the METAPOCS code on a CONVEX C210 computer. X-ray diffraction patterns were collected with flat-plate geometry on dehydrated samples in an environmental GTP cell under flowing helium with a Siemens D500 diffractometer with a STOE rotating anode Cu X-ray source operating at 6 kW with a Ni filter. The profile refinement was performed over the range $2\theta = 11$–$63°$ with the GSAS program of Larson and Von Dreele [26].

Decamethylcucurbit[5]uril**

By *Anthony Flinn, Gordon C. Hough, J. Fraser Stoddart,** and *David J. Williams*

Rigid toroidal receptor molecules, which resemble collars,[1] belts,[1] and doughnuts,[2] have appealing molecular architectures. On the one hand, they may be regarded as progenators of molecular cages:[3] on the other hand, they can serve as components in the construction of molecular abacuses.[4] The synthesis of cucurbituril[5] during the last decade demonstrated the use of self-assembly[6] in synthesis to construct a rigid, hollow structure of D_{6h} symmetry consisting of six glycoluril units mutually linked by pairs of methylene groups to form a macropolycyclic array. Molecular modeling suggests that both the immediately lower and higher order homologues of this cyclic hexamer have almost strain-free structures. Here, we describe the synthesis of a cyclic pentamer **2** by self-assembly of dimethylglycoluril (**1**) (Scheme 1) and the full structural characterization of **2** (Fig. 1).

1 2

Scheme 1.

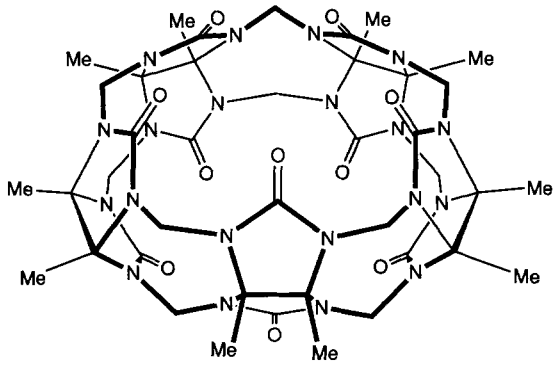

Fig. 1. The structure of decamethylcucurbit[5]uril (**2**).

The X-ray structural analysis[8, 9] of the crystalline material obtained from dilute HNO_3 shows (Fig. 2) that, in the solid state,[9] the decamethylcucurbit[5]uril[10] molecule (**2**) deviates only slightly from D_{5h} symmetry. The crystallographic symmetry is C_2. Despite the steric crowding associated with the adjacent Me substituents around the periphery of the molecule, all the atoms that comprise its equatorial plane are coplanar to within 0.06 Å. The formation of the cyclic pentamer involves a small amount of molecular strain, which is reflected in an enlargement of the NCN angles at the bridging methylene groups from 109° to between 114 and 116°. There is, however, no out-of-plane distortion at any of the nitrogen atoms. The inclusion of a "molecule of nitric acid"[11] within the molecular cavity of **2** results (Fig. 3) in a distortion of the pentagonal arrays of carbonyl oxygen atoms that form the portals of the receptor. The angles between adjacent atoms of these arrays are in the range 103–114°, and the associated O···O distances are between 3.14 and 3.22 Å. The exterior surface of the molecular receptor is discus-shaped with a diameter of about 15 Å and a thickness of about 9 Å. The diameter of the interior along the σ_h plane is approximately 6 Å. The diameters of the oxygen-bounded portals are about 2.5 Å. The inclusion of HNO_3, or the NO_3^- ion, within the molecular cavity demonstrates that these portals can expand to permit the passage of this guest through the orifice. The nature of the binding of HNO_3, or the NO_3^- ion, within the receptor cannot be defined precisely. There are, however, short contacts of 2.82 and 2.85 Å between two of the three $(H)NO_3$ oxygen atoms and the oxygen and carbon atoms of two different carbonyl groups. The former could represent a hydrogen bonding interaction and the latter an electrostatic one.

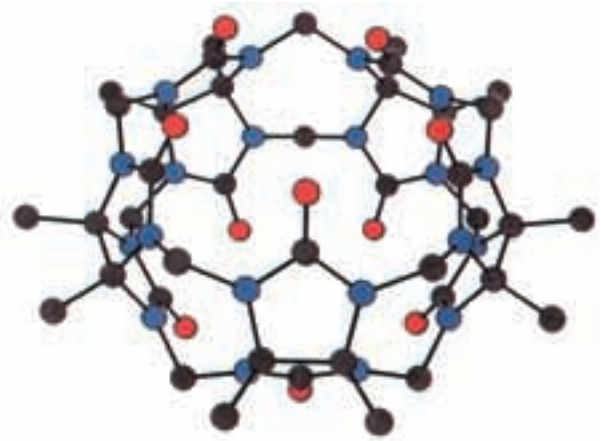

Fig. 2. The ball-and-stick representation of the structure of **2**. Gray C, blue N, pink O.

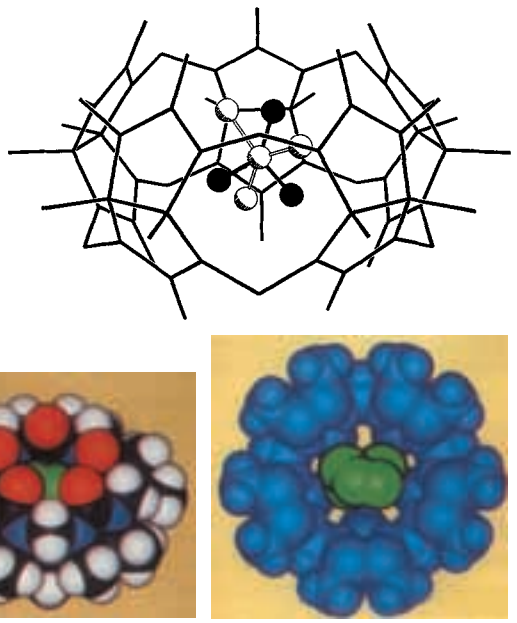

Fig. 3. Top: The positioning of the disordered nitric acid "molecule" within the molecular cage of **2**. The O atoms of the differently oriented nitric acids are depicted, one shaded, and the other unshaded. Bottom left: The space-filling representation of this inclusion complex. Black C, blue N, red O, green nitric acid "molecule". Bottom right: A space-filling representation of **2** · nitric acid viewed along the principal axis of **2** showing the interior of the molecular cavity produced by removing the upper rim of atoms and groups in **2**. Host molecule, blue: guest molecule, green.

The self-assembly,[6] isolation, and unambiguous characterization of decamethylcucurbit[5]uril[10] (**2**) raises the prospect of synthesizing a family of cucurbituril receptors in addition to the previously characterized cyclic hexamer formed between glycoluril and formaldehyde.

Experimental Procedure

2: Dimethylglycoluril (**1**) (4 g, 23 mmol), 37% aqueous HCHO solution (8 mL), concentrated HCl (16 mL), and H_2O (5 mL) were heated under reflux for 2 h. H_2O (70 mL) was added, and the dark red solution was heated under reflux for a further 1 h, before being allowed to cool gradually. The precipitate was collected by filtration, washed (H_2O), and dried in vacuo to give **2** as a white solid. Yield: 750 mg, 16%; m.p. > 280 °C; positive-ion FAB-MS: *m/z* = 971, 989, and 1009 for $[M + H]^+$, $[M + H_3O]^+$, and $[M + K]^+$, respective-

ly; ^{1}H NMR (300 MH]$_z$, CF_3CO_2D): $\delta = 1.99$ (s, 30H), 4.61 (d, $^2J = 16$ Hz, 10H), 6.04 (d, $^2J = 16$ Hz, 10H); ^{13}C NMR (75 MHz, CF_3CO_2D): $\delta = 16.9$, 44.1, 78.3, 156.3. Single crystals suitable for X-ray crystallography were obtained from a solution of **2** in dilute HNO_3 by slow evaporation over a period of 12 months.

[7] V. L. Himes, C. R. Hubbard, A. Mighell, A. J. Fatiadi, *Acta Crystallogr. Sect. B* **1978**, 34, 3102. A compound has been obtained (N.-Y. Shih, PhD Thesis, University of Chicago at Illinois, **1981**; *Diss. Abstr. Int. B* **1982**, *42*, 4071) from the condensation of dimethylglycoluril with formaldehyde under acidic conditions. This compound was assumed to be a cyclic pentamer or tetramer on the basis of an elemental analysis and the failure to form inclusion complexes with alkylamines in aqueous formic acid solutions.

[8] Siemens P4/PC diffractometer, ω-scans, $Mo_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and the major occupancy atoms refined anisotropically, the minor occupancy atoms isotropically. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

[9] Crystal data for $2 \cdot 3HNO_3 \cdot 6H_2O$: monoclinic, $a = 24.693(5)$, $b = 17.744(4)$, $c = 13.293(3)$ Å, $\beta = 116.39(3)°$, $V = 5217$ Å^3, space group $C2/c$, $Z = 4$ (the molecule has crystallographic C_2 symmetry) $\varrho_{calcd} = 1.614$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.4$ cm^{-1}, 2603 independent observed reflections with $|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 45°$, refined to $R = 0.067$, $R_w = 0.070$. The HNO_3 units occupy one full and two partial occupancy sites in the asymmetric unit, and the water molecules eight partial occupancy sites.

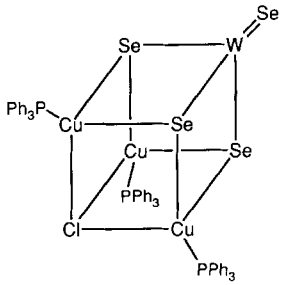
[10] We propose a simple nomenclature system for cucurbituril derivatives which is reminiscent of that proposed for the calixarenes (C. D. Gutsche, *Calixarenes*, Royal Society of Chemistry, Cambridge, **1989**, p. 26). The number of glycoluril or substituted glycoluril units is indicated by the number inside the square brackets. Substituents at the ring junction between the five-membered rings in the glycoluril units are indicated by a prefix.

[11] It should be noted that, in dilute aqueous solution, nitric acid is approximately 93% dissociated at 0.1 M concentration (F. A. Cotton and G. Wilkinson, *Advanced Inorganic Chemistry*, 5th ed, Wiley, New York, **1988**, p. 113).

The $[(\mu_3\text{-}WSe_4)_3(\mu_3\text{-}Se)_2(Cu_3)_2]^{4-}$ Anion, an Inorganic Cluster with a Pinwheel Shape**

By *Christopher C. Christuk, Mohammad A. Ansari,* and *James A. Ibers**

The rich chemistry of soluble sulfidometalates has been developed over the past two decades. There are now numerous examples of both homometallic[1] and mixed-metallic[2] compounds. Although the chemistry of selenido- and telluridometallates is very new,[3] most species that have been prepared have no sulfido analogues. Examples include $[Ni_4Se_4(Se_3)_5(Se_4)]^{4-}$,[4] $[Ni_4Te_4(Te_3)_4(Te_2)_2]^{4-}$,[5] $[In_2(Se_4)_4(Se)_5]^{4-}$,[6] $[NbTe_{10}]^{3-}$,[7] and $[W(AsSe_5)_2]^{2-}$.[8] In the search for new selenidometalates we investigated the chemistry of cubane-like clusters based on the MSe_4^{2-} core (M = Mo, W). Using the cubane **1**[9] we have synthesized the striking anion **2**.



1

$[(\mu_3\text{-}WSe_4)_3(\mu_3\text{-}Se)_2(Cu_3)_2]^{4-}$ **2**

The precursor **1** is prepared from the stoichiometric reaction of $(NPr_4)_2[WSe_4]$, $[Cu(PPh_3)]^+$, and NH_4Cl in dimethylformamide (DMF). It has the same basic structure as other known cubanes,[2, 10] although their reaction chemistry has not been probed. A slurry of Li_2Se (15 mg, 0.16 mmol) in DMF (10 mL) was added with stirring to **1** (239 mg, 0.16 mmol) and NEt_4Cl (26 mg, 0.16 mmol) in 15 mL DMF under anaerobic conditions in oven-dried glassware. Red microcrystals filled the solution. Heating for 45 min produced a clear red solution that was filtered and stored at −15 °C. Deep red, block-shaped crystals of $(NEt_4)_4$-**2** · 2DMF were obtained after two weeks (34 mg, 32% yield).[11] The supernatant was pale, suggesting that most metal-containing species were no longer in solution. Precipitation of LiCl, heat, and insolubility of the NEt_4^+ salt of the anion provide the driving forces for the reaction. We speculate that the cubane is opened upon reaction with Se_2^{2-} and these remnants are linked by Se atoms. There is no spectroscopic evidence for the formation of $SePPh_3$.

The structure[12] of **2** (Fig. 1) can be described as two Cu_3 triangles (Cu1,Cu3,Cu5 and Cu2,Cu4,Cu6) bridged by tridentate WSe_4^{2-} ligands and capped by Se atoms (Se14 and Se13, respectively). Charge balance suggests that this anion contains the formal oxidation states Cu^I and W^{VI}. The Cu–Cu distances within the equilateral Cu_3 triangles (Cu-Cu-Cu angles between 58.1(1)° and 62.5(1)°), each capped by a Se atom, average 2.880(3) Å, while distances between these eclipsed Cu_3 triangles range from 3.519(3) to 3.580(3) Å. These distances between the triangles are too large for Cu–Cu interactions, and hence the structure cannot be described in terms of a Cu_6 trigonal prism. Numerous Cu_3 triangles[13] and chalcogen-capped M_3 triangles[2, 14] have been observed, but none in which these two features are present in the same molecule. While MQ_4^{2-} units (M = Mo, W, Q = S or more rarely Se) frequently act as monodentate[2] and bidentate[2, 15] ligands, there are far fewer examples in which they act as tridentate[2, 9, 10] or tetradentate[16] ligands. In anion **2** the WSe_4^{2-} ligands are tridentate.

The coordination at the W centers remains nearly tetrahedral: the angles range from 106.8(1)° to 110.9(1)°, slightly smaller than the related angles in the starting material **1**

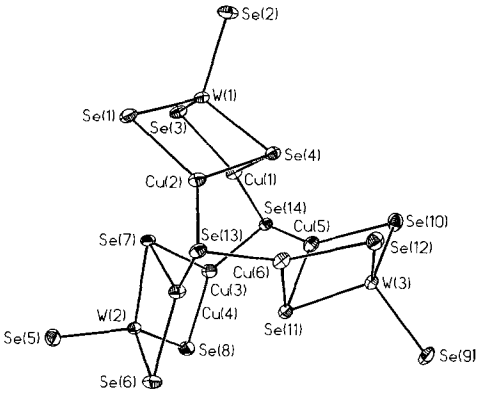

Fig. 1. Sketch of the structure of **2**. The thermal ellipsoids are shown at the 50% level. Selected bond lengths [Å] and angles [°]: W(1)-Se(1) 2.339(2), W(1)-Se(2) 2.289(2), W(1)-Se(3) 2.338(2), W(1)-Se(4) 2.400(2), W(1)-Cu(1) 2.741(2), W(1)-Cu(2) 2.734(3), Cu(1)-Se(3) 2.369(3), Cu(1)-Se(4) 2.386(3), Cu(1)-Se(14) 2.339(3), Cu(1)-Cu(3) 2.842(3), Se(1)-W(1)-Se(2) 110.2(1), Se(1)-W(1)-Se(3) 109.2(1), Se(1)-W(1)-Se(4) 109.3(1), W(1)-Se(3)-Cu(1) 71.2(1), W(1)-Se(4)-Cu(1) 69.9(1), Se(3)-Cu(1)-Se(4) 108.5(1), Se(3)-Cu(1)-Se(14) 125.0(1), Se(4)-Cu(1)-Se(14) 124.1(1), Cu(1)-Se(14)-Cu(3) 75.0(1), Cu(1)-Se(14)-Cu(5) 76.2(1), Cu(3)-Se(14)-Cu(5) 74.1(1).

(108.13(8)°–111.4(1)°). Variations in Se_{bridge}-W-$Se_{terminal}$ compared with Se_{bridge}-W-Se_{bridge} angles closely mirror those observed in related compounds.[2, 17] Angles about the capping Se atoms are acute (between 74.1(1)° and 79.3(1)°) similar to analogous angles for other capping chalcogens.[16, 18] The steric limitations imposed by the WSe_4^{2-} ligand result in the placement of the capping Se atoms away from the center of the cluster. A slight opening of the Se-Cu-Se angles (108.2(1)°–109.8(1)°) from those in the starting cubane **1** (104.2(1)°–108.6(1)°) probably also arises from steric effects.

Four types of Se atoms are present in **2**: capping Se atoms bonded to three Cu atoms and three-, two-, and one-coordinate Se atoms in the WSe_4 moieties. Consequently, three different ranges of Cu–Se bond lengths are observed: 2.327(3)–2.347(3) Å (capping Se), 2.355(3)–2.369(3) Å (two-coordinate Se), and 2.385(3)–2.388(3) Å (three-coordinate Se) as opposed to the average Cu–Se distance of 2.408(3) Å in the parent cubane.[9]

The W–Se bond lengths similarly fall into three categories. Terminal Se atoms are found at an average distance of 2.290(2) Å from the W atoms, an elongation from the 2.201(4) Å distance observed in **1**. The W–Se_{bridge} distances, which average 2.376(3) Å in the cubane, lengthen to 2.397(3) Å for three-coordinate Se atoms or shorten to 2.344(2) Å for two-coordinate Se atoms. An average W–Cu distance of 2.738(3) Å in the WSe_4Cu_2 moiety may imply a slightly stronger W^{VI}–Cu^{I} interaction than in the cubane where the average distance is 2.753(3) Å and where the orbitals of three Cu atoms, rather than two, compete for overlap with those of the W atom.

Synthesis of Esterase-resistant 9-*O*-Acetylated Polysialoside as Inhibitor of Influenza C Virus Hemagglutinin

By *René Roy**, *Fredrik O. Andersson*, *Günter Harms*, *Sørge Kelm*, and *Roland Schauer*

Human infections by influenza viruses are mediated by the adherence of the viral membrane protein hemagglutinin to the host-cell glycoproteins and glycolipids.[1] Recent X-ray data,[2] proton NMR spectroscopic studies,[3] and inhibition experiments with synthetic sialosides[4] have clearly defined the minimum and effective structural ligand requirements of the viral hemagglutinin. These receptor determinants have

[*] Prof. Dr. R. Roy, Dr. F. O. Andersson

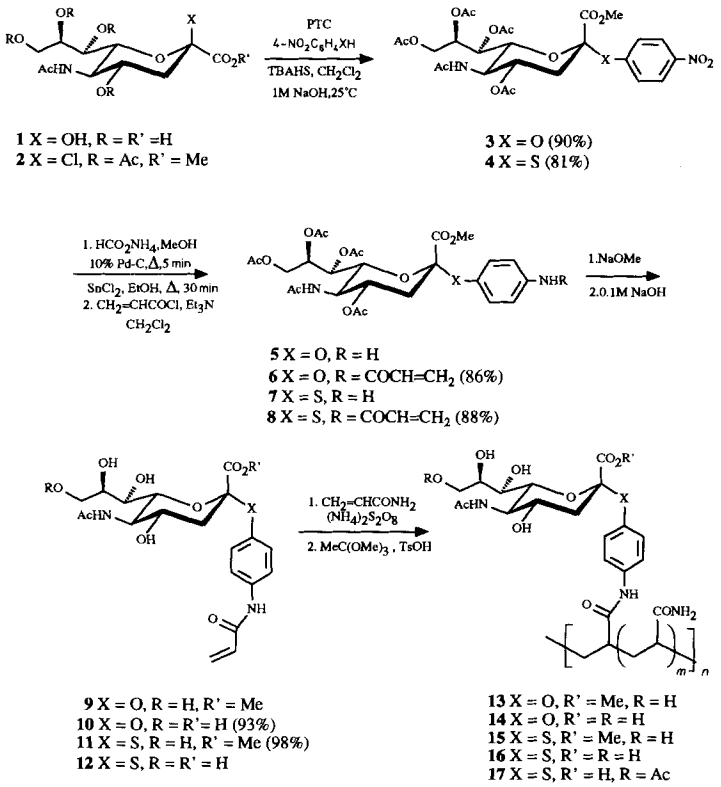
Kiel (FRG)

been identified as the sialic acid *N*-acetylneuraminic acid (Neu5Ac, **1**) for influenza A and B viruses[1–5] and its corresponding 9-*O*-acetylated derivatives (Neu5,9Ac$_2$) for influenza C virus isolates.[6] The influenza C viruses also possess a receptor-destroying enzyme, which was characterized as a sialate 9-*O*-acetyl esterase.[6] The binding site for Neu5,9Ac$_2$ (hemagglutinin) and the acetyl esterase activity are located together with a fusion activity on a single viral glycoprotein.[7]

Moreover, influenza A and B viruses contain a sialidase besides hemagglutin. Thus, a general strategy for the prevention of viral adherence to the host cell may reside in the design of sialidase-resistant sialic acid conjugates. To be of general use, these synthetic inhibitors must be "universal" and stable target receptors. At the same time, they should have several binding sites ("be multivalent") in order to account for the low binding affinities of α-sialosides to the hemagglutinin, since a dissociation constant K_d of only 2.8×10^{-3} M has been determined.[3] Previous work on the synthesis of sialic acid containing neoglycoproteins[8] and glycopolymers[8, 9] allowed the design of suitable influenza A virus inhibitors.[10] This approach was recently confirmed by other groups.[11] Furthermore, divalent sialosides have also been used to study the influence of spatial structure on their binding to the hemagglutinin.[12]

Recent findings have also established that hemagglutinin inhibition is not the sole factor that can prevent infections.[10] It could be postulated that the sialidase activity, common to all influenza A and B viruses, also participates in a complementary fashion to the infection and the spreading



Scheme 1. Ts = $CH_3C_6H_4SO_2$.

of the virus particles. To answer these questions we have synthesized glycopolymers containing multivalent sialic acid, which should act as both hemagglutinin and sialidase inhibitors.

The general strategy for the stereospecific synthesis of the aryl α-sialoside precursors is based on phase transfer catalysis (PTC). The synthesis of the new glycopolymers is depicted in Scheme 1 and involves acrylamide copolymerization of suitable *N*-acryloylated carbohydrate derivatives.[13] Thus, transformation of Neu5Ac (**1**) into the known acetochloroneuraminic acid[14] glycosyl donor **2** was effected in two steps following previously modified procedures (1: MeOH, H^+; 2: AcCl, AcOH).[8] Stereospecific introduction of the *para*-nitrophenyl- and *para*-nitrophenylthio-α-sialosides (**3** and **4**, respectively)[15] was effected using PTC conditions in dichloromethane and tetrabutylammonium hydrogen sulfate (TBAHS) as catalyst (90% and 81% yield, respectively; for physical properties, see Table 1). No β-glycoside was detected in the crude reaction mixtures. However, some dehydrochlorination and hydrolysis by-products were formed

in small quantities. Catalytic transfer hydrogenation with ammonium formate and 10% Pd–C provided the unstable *para*-aminophenyl derivative of the glycoside **5**, which was *N*-acryloylated directly (CH_2=CH–COCl, Et_3N, CH_2Cl_2) to provide **6** in 86% yield from **3**. The above reducing conditions were unsuccessful when applied to the *S*-glycoside **4**. However, **4** could be successfully reduced with tin(II) chloride in refluxing ethanol. *N*-acryloylation of crude **7**, as described above, provided the *para*-*N*-acryloylaminophenylthio-α-sialoside (**8**) in 88% overall yield from **4**. Zemplén de-*O*-acetylation (NaOMe, MeOH) of the *O*- and *S*-glycosides **6** and **8** afforded the *N*-acryloylaminophenyl glycosides **9** and **11** as methyl ester in almost quantitative yields. Hydrolysis of the methyl ester with an aqueous solution of 0.1 M NaOH gave the free acid **10** in 93% yield. When these conditions were applied to the *S*-glycoside **11**, the methyl ester was partly hydrolyzed to give **12** only in low yield. This hydrolysis was accompanied by extensive Michael addition of the hydroxide ions to the *N*-acryloylamino function (detected by ^{1}H and ^{13}C NMR analyses). After several attempts at hydrolysis with different conditions, the methyl ester of the thiosialoside (**11**) was used in the polymerization reaction.

The monomeric precursors **10** and **11** were copolymerized with acrylamide in various molar ratios in a deoxygenated mixture of dimethyl sulfoxide and water (1:2) with ammonium persulfate as initiator in a boiling water bath, or with *N,N,N',N'*-tetramethylethylenediamine (TMEDA) at room temperature. After 10 min further quantities of the initiator were added when required (monitored by TLC). The reac-

tions were stopped after 15–20 min (heat) or 12 h (TMEDA, room temperature). The reaction mixtures were exhaustively dialyzed against distilled water and freeze-dried to provide the water-soluble polymers **13** and **15** in yields ranging from 60 to 77%. The ratio of acryloylamine units to sialosides within the glycopolymer was controlled by the ratio in the reaction mixture. This feature is typical for *N*-acryloyl carbohydrate monomers[13] and differs from those of the slow reacting alkenyl glycosides.[8] Polymers with sialic acid to acrylamide ratios of 1:5 and 1:10 were thus prepared. Methyl ester hydrolysis of the polymer **15** containing *S*-glycoside (0.1 M NaOH) afforded a quantitative yield of the free polymer **16**. The sialic acid content of the polymers were determined with ^{1}H NMR spectroscopy. Their reactivity with wheat germ agglutinin was demonstrated by using standard serological methods. The molecular weights of the polymers were estimated at between 75–150 kDa by gel permeation chromatography on a TSK G-4000 SWXL column.[13]

The *S*-sialosyl glycopolymer **16** features characteristics that possibly allow interaction with both hemagglutinin and sialidase of influenza A or B viruses. However, in hemagglutination inhibition assays with human erythrocytes,[4] polymer **16** did not inhibit the hemagglutinin of X31 and X31HS influenza A virus (H3N2) at concentrations up to 0.8×10^{-3} M in sialic acid residues. In previous studies with a different polyacrylamide glycopolymer containing Neu5Ac,[10] hemagglutination inhibition was reported at much lower concentrations. However, the density of Neu5Ac in these polymers was higher (1:7 instead of 1:10). The hemagglutination inhibition of such polymers varies over orders of magnitude depending on the density of the sialic acid residues.[11] In addition, the spacer used may influence the inhibitory potency as has been shown for X31 with the aglycon of monomeric sialic acid analogues.[16]

In contrast to influenza A and B viruses, influenza C virus requires 9-*O*-acetyl sialosides as receptors.[6] To study the interaction of influenza C virus with this kind of polymer as well, selective 9-*O*-acetylation was attempted. This modification was directed at the synthesis of an inhibitor of influenza C virus. A selective orthoester/hydrolysis sequence was performed under known conditions[17] (1: $MeC(OMe)_3$, TsOH; 2: H_3O^+) to provide 9-*O*-acetyl *S*-α-sialoside polymer **17** in quantitative yield (recovery). The ^{1}H NMR spectrum of the polymer showed that about 70% of the sialic acid residues contained *O*-acetyl groups, and these were located exclusively at the C9 position (Table 1, *Experimental Procedure*). Attempts to push the reaction further provided polymers with more than one acetyl group per sialic acid residue. Binding of influenza C virus (Johannesburg/1/66) to glycopolymer **17** was demonstrated in a microtitre plate assay[18] (Fig. 1). Furthermore, in a hemagglutination inhibition assay[4] with murine erythrocytes, glycopolymer **17** inhibited influenza C virus at concentrations as low as 3.3×10^{-6} M. The specificity towards 9-*O*-acetylated sialic acid residues was shown by the lack of binding of influenza C virus to the glycopolymer **16** and its methyl ester **15**.

Interestingly, the 9-*O*-acetylated glycopolymer **17** was a poor substrate for the virus esterase (Fig. 2). This suggests that the structural requirements for the biological activity of

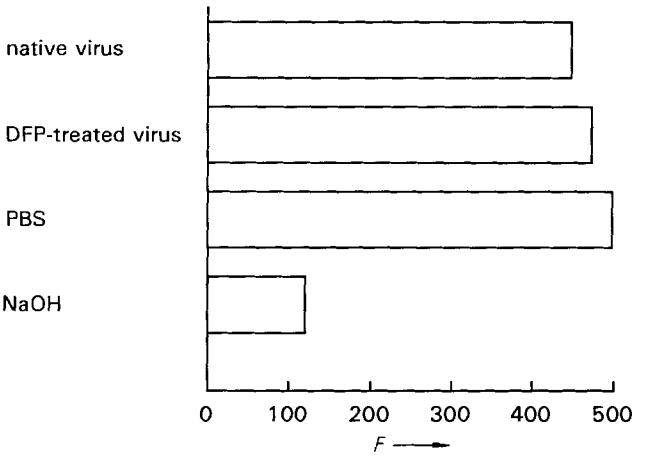

Fig. 2. Resistance of glycopolymer **17** to influenza C esterase. F = relative fluorescence as a measure of the esterase activity. 250 μg of glycopolymer **17** was incubated at 37 °C in 35 μL PBS with native influenza C virus (1.9 mU esterase) or DFP-treated (DFP = diisopropylfluorophosphate) virus in 35 μL for 1 h. Reactions were stopped by adding 315 μL ice-cold PBS, and virus was removed by centrifugation at $10^5 \times g$ for 90 min. As control, 250 μg of glycopolymer **17** was saponified with 0.1 M NaOH or PBS at 0 °C for 1 h. The reaction was stopped by adding an equal volume of 0.1 M HCl or NaCl, respectively, and diluted to 350 μL with PBS. To determine the amount of 9-*O*-acetyl groups remaining on glycopolymer **17** after these treatments, 100 μL were coated onto microtitre plate wells in triplicate and assayed as described for Figure 1.

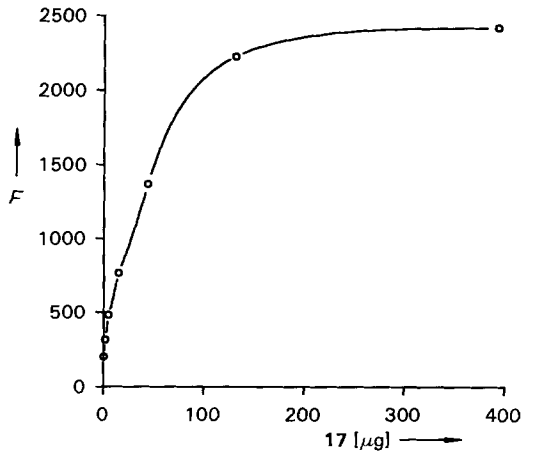

Fig. 1. Binding of influenza C virus to glycopolymer **17**. *F* = relative fluorescence as a measure of the esterase activity. The amount of substance **17** indicated was coated to microtitre plate wells in 100 μL phosphate buffer solution (PBS), pH = 7.2, approximately 12 h. Influenza C virus was allowed to bind to these wells. The amount of bound virus was then determined by assaying the esterase activity with the fluorogenic substrate 4-methylumbelliferyl acetate as described [18].

the hemagglutinin and the esterase are different. Similar observations were made with natural compounds. For example, whereas influenza C virus binds well to 9-*O*-acetylated gangliosides,[18] the *O*-acetyl groups of these compounds are hydrolyzed only very slowly by the esterase.[19] These findings show that compound **17** may serve as a basis for the development of esterase-resistant drugs designed to combat influenza C infections.

Experimental Procedure

Polymerization: A solution of **11** (10.3 mg, 22 μmol) and acrylamide (7.7 mg, 109 μmol, 5 equiv) in a deaerated water–dimethyl sulfoxide mixture (2:1, 300 μL) was treated with ammonium persulfate (15 μL of a 100 mg mL^{-1} solution) and stirred at 100 °C for 15 min. After a further 15 min and 25 min, more ammonium persulfate solution was added (15 μL). This process ensured that all the monomer **11** had reacted. After 30 min, the reaction mixture was cooled and dialyzed against distilled water. Lyophilization afforded **15** as a white fluffy powder (10.8 mg, 60%). ^{1}H NMR showed a ratio of sialic acid residues to acrylamide of 1:5. Transformation of **15** into **16** was conducted in 0.1 M NaOH at room temperature (approximately 12 h). Dialysis and freeze-drying as above

provided pure **16** devoid of the CO_2Me signal at $\delta = 3.70$. Transformation of **16** into **17** as described in ref. [17] afforded **17** which showed the characteristic *O*-acetyl signal in the ^1H NMR spectra (D_2O, $\delta = 2.0$, signal intensity corresponds to 0.7 acetyl units). Moreover, the signals of H9a and H9b in **17** appeared downfield at $\delta = 4.00$ and 4.20, respectively, in accord with the structure. Molecular weight determination of **15**–**17** were effected on a Waters 991/625 LC HPLC system equipped with a diode array detector and a TSK G-4000 SWXL column (7.5 × 300 mm) as described in ref. [13c].

N-Perbenzylation of Oligopeptides with P4-Phosphazene Base; A New Protecting-Group Technique for Modification and Solubilization of Peptides in Apolar Organic Solvents**

By *Thomas Pietzonka* and *Dieter Seebach**

Peptides are normally constructed from the appropriate amino acids. The modification of a peptide, not at the side chains but directly at the carbon atoms of the peptide skeleton itself, seemed impossible a short time ago. We have already been able to form lithium enolates of sarcosine units in oligopeptides containing up to eleven amino acids, and to treat them with electrophiles, to achieve C,C-bond formation if the amino acid following the sarcosine was *N*-methylated[1] (see **1**). Problems arise because of the low solubility in aprotic media of many peptides required for enolate formation,[2] the necessity to remove all NH and OH hydrogen atoms from the peptide (polylithiation!), and the impossibility of demethylation of *N*-methyl groups, the presence of which is objectionable in most cases.

We have recently discovered that the P4-phosphazene base **2** developed by Schwesinger and Schlemper[3] is able to mediate alkylation of BOC- or Z-protected linear and cyclic peptides. At low temperature in THF, in the presence of benzyl or allyl bromide, alkylation occurs at all NH groups of the peptide backbone and, if available, at the terminal COOH group too [see the conversions of BOC-valyl-glycyl-leucine (**3a**) to the products **3b** and **3c** in Scheme 1, and further examples (**4**–**12**) in Table 1]. For these reactions the peptide need not initially be in solution: even the extremely sparingly soluble tetrapeptide derivative **8a** (≤ 0.8 mg mL^{-1} THF at $-75\,^{\circ}C$)[2a] reacts under these conditions, and dissolves completely. In general, the perbenzylated peptides are readily soluble in apolar solvents, as is reflected by their R_F values on thin-layer silica plates (see Table 1). For example, perbenzylated BOC-Val-Gly-Leu **3b** is very soluble in pentane (!).

The new benzyl and allyl derivatives may be viewed as protected peptides. Debenzylation of the amine nitrogens is not possible by hydrogenolysis, but occurs easily through the procedure developed by Weygand and Steglich[5] (liquid am-

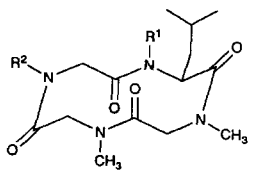
monia/sodium). Thus, the BOC peptides **3a** and **5a** were regenerated from the corresponding benzyl derivatives **3b** and **5b**. The BOC peptides can be cleaved into their components on treatment with concentrated HCl at 110 °C. The amino acids obtained were derivatized to the (*N*-pentafluoropropionyl)isopropyl esters and analyzed by gas chromatography on a Chirasil-Val GC column.[6] It was observed that no epimerization occurred at either of the stereogenic centers on the way to the tetrabenzylated peptide and back. Analysis by NMR spectroscopy of the chromatographically uniform, linear, perbenzylated peptide products is complicated by the presence of many rotamers, even at 180 °C. Nevertheless, an examination of the products by FAB mass spectrometry not only showed the correct molecular weight, but also the expected *N*-benzyl amino acid fragment peaks. In addition, the increase in specific optical rotation $[\alpha]_D$ after the introduction of benzyl groups is noteworthy (up to fivefold, see Table 1). In contrast to those of the open-chain peptides (**3a**–**9a**), the NMR spectra of the cyclic tetrapeptides (**10a**–**12a**)[1c] are very well resolved, containing sharp signals. The positions of the benzyl groups can be clearly determined, mainly by NOE measurements. Thus, we discovered that for *cyclo*-(Leu-Sar-Sar-Gly) (**12a**) the first *N*-benzylation occurs at the glycine unit (→**12b**), and the second at the leucine-*N* atom (→**12c**).[7]

Preliminary investigations have shown that benzyl-protected peptides (after hydrogenolytical removal of the *C*-terminal benzyl group) can be methylated by treatment with 2 equivalents of lithium diisopropylamide (LDA)/CH_3I in THF, via the corresponding lithium enolate of the glycine unit. However, the P4-base is also able to deprotonate the sarcosine CH_2 group of benzyl-protected peptides. Thus, the dibenzylated product **12c** was *C*-alkylated with a further equivalent benzyl bromide (→**12d**). Using optimal reaction conditions, we were able to isolate the tribenzylated compound **11c** as the main product in 80% yield, starting from *cyclo*-tetrapeptide **11a**.[8] As in the case of **12c**, hydrogen H_{Si} of the sarcosine adjacent to the valine was replaced by a benzyl group (precursor **11b** contains a total of seven α-carbonyl hydrogen atoms!).



12b (R^1 = H, R^2 = CH_2Ph)

Experimental Procedure

To a solution of 138 mg (0.45 mmol) of *cyclo*-(Leucyl-sarcosyl-sarcosyl-glycine) **12a** in THF (5 mL) was added 0.25 mL (1.6 mmol) of benzylbromide. The mixture was cooled to −100 °C and 0.70 g (1.1 mmol) of P4-base in THF (2 mL) introduced carefully, dropwise, in order to control the resulting exothermic reaction. After the reaction mixture had been stirred for 3 h at −78 °C, it was allowed to warm to room temperature. The solvent was then evaporated, and the crude product purified by flash chromatography (SiO_2/5% MeOH in diethyl ether). Yield: 100 mg (46%) **12b** colorless powder. M.p. 206.5–207.5 °C; $[\alpha]_D$ +18.1 (*c* = 0.98 in MeOH); ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.91 (d, $^3J(H,H)$ = 7 Hz, 3H; CH_3), 1.00 (d, $^3J(H,H)$ = 7 Hz, 3H; CH_3), 1.40–1.75 (m, 2H; CH_2-Leu), 1.78–1.90 (m, 1H; CH-Leu), 3.00 (s, 3H; CH_3-N), 3.11 (s, 3H; CH_3-N), 3.15 (d, $^3J(H,H)$ = 18 Hz, 1H; H-Gly), 3.30 (d, $^3J(H,H)$ = 14 Hz, 1H; H-Sar_2), 3.65 (d, $^3J(H,H)$ = 14 Hz, 1H; H-Ph(Gly)), 3.72 (d, $^3J(H,H)$ = 18 Hz, 1H; H-Sar_1), 4.06 (d, $^3J(H,H)$ = 18 Hz, 1H; H'-Gly), 4.32 (dxd, $^3J(H,H)$ = 25 Hz, 2H; CH_2-Ph(Leu)), 4.57 (d, $^3J(H,H)$ = 18 Hz, 1H; H'-Sar_1), 5.27 (d, $^3J(H,H)$ = 14 Hz, 1H; H'-Sar_2), 5.52 (t, $^3J(H,H)$ = 6 Hz, 1H; CH-Leu), 7.2–7.6 (m, 10H; aromatic H).

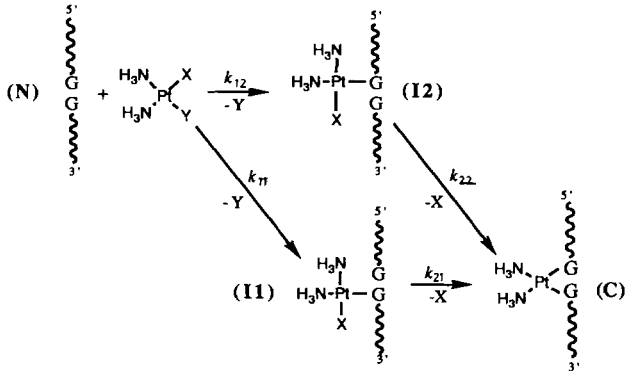
[7] The crystal structure of compound **12c** has been solved. It confirms the conformation of the 12-membered ring represented in the structural formula. Detailed data will be published in the future.
[8] Minor quantities of *C*-benzylated products also form with linear peptides, but they can be separated by flash chromatography because of their higher R_F values. Starting from tetrapeptide **8a** a heptabenzyl derivative was obtained as the main product. The structure has not been determined as yet, but from the GC analysis mentioned in the text above, the alanine unit in product **8b** has not epimerized.

Crosslinking of Adjacent Guanine Residues in an Oligonucleotide by *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$: Kinetic Analysis of the Two-Step Reaction**

By *Florence Gonnet, Jiři Kozelka,** and *Jean-Claude Chottard*

The antitumor drug *cis*-diamminedichloroplatinum(II) ("cisplatin") binds to DNA to form preferentially the d(GpG) intrastrand crosslink.[1] This macrochelate is formed in a two-step process (Scheme 1), and the reactive platinum species is one of the hydrolyzed cisplatin forms, that is, *cis*-$[PtCl(NH_3)_2(H_2O)]^+$ (X = Cl^-; Y = H_2O) or *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (X = Y = H_2O). Between 60 and 65% of the DNA-bound platinum appears as the GG crosslink, as shown both by in vitro and by in vivo experiments.[2-7] This percentage significantly exceeds the probability of finding a guanine residue adjacent to another, and since the reactions in Scheme 1 are irreversible under the experimental conditions, the guanine residues in GG sequences must be more reactive than in other positions. The origin of this differential guanine reactivity is unknown. One possible factor is the enhancement of the negative potential at the guanine N7 atom caused by a neighboring guanine, which is predicted by ab initio calculations.[8] However, as we have recently shown using molecular modeling,[1] nonbonding interactions in the transition state,[9] that is, those between the platinum ligands and the DNA residues adjacent to the guanine being platinated, could also play a role. Such a mechanism would be ligand-dependent, which opens the interesting possibility of influencing the binding selectivity of the platinum complex by an appropriate choice of ligands.



Scheme 1. Binding of a *cis*-$[Pt(X)(Y)(NH_3)_2]$ complex (X, Y = leaving groups) to a GpG sequence of an oligonucleotide.

One question that arises is whether the 5'-guanine of a d(GpG) sequence enhances the reactivity of the 3'-guanine, or vice versa. No answer to this question could be given so far, since it was not possible to measure the rate constants for the platination of the two guanines (k_{11} and k_{12} in Scheme 1) separately.

In this paper, we describe a technique that enables the measurement not only of the two primary platination rate constants k_{11} and k_{12} but also of the two chelation constants k_{21} and k_{22} and apply it to the reaction between the single-stranded oligonucleotide d(TpGpG) and the diaqua form of cisplatin, *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$. The method consists of treating known amounts of oligonucleotide with approximately stoichiometric platinum complex in aqueous solution and, at intervals, taking aliquots which are quenched by addition of a saturated KCl solution and cooled to liquid nitrogen temperature. The conserved aliquots are subsequently analyzed by HPLC. Figure 1 displays a typical chromatogram showing peaks for all four species **N**, **I1**, **I2**, and **C** defined in Scheme 1 for d(TGG). The high resolution of our system allows a precise integration of peaks, and thus an accurate determination of the concentrations. A computer program written in our laboratory calculates for each time t_i the four concentrations $[\mathbf{N}]_i$, $[\mathbf{I1}]_i$, $[\mathbf{I2}]_i$, and $[\mathbf{C}]_i$, based on assumed rate constants k_{11}, k_{12}, k_{21}, and k_{22}, and optimizes the fit by iteration on the constants as described in the appendix.

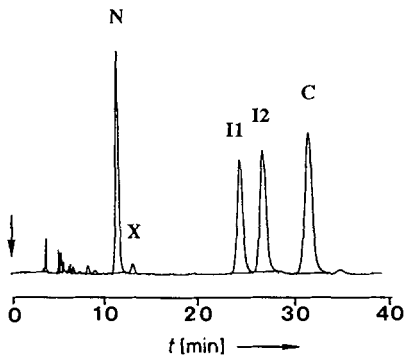


Fig. 1. A typical HPL chromatogram for a stoichiometric reaction of d(TGG) (10^{-3} M) with *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ in 0.1 M $NaClO_4$, after quenching by addition of an excess of KCl. T = 293 K; pH = 4.4; t = 12 min (X = impurity; for the other identifiers, see Scheme 1).

Since, in general, only the concentration of the platinum complex can be determined precisely (that of the oligonucleotide is measured by means of UV absorbance), the excess (or shortfall) of oligonucleotide with respect to the platinum complex is used as a fifth variable. The correct functioning of the program has been tested in two control experiments in which a defined large excess of oligonucleotide was employed. The excess determined by the program deviated by up to 10% from the value determined by UV spectroscopy, which corresponds to the error of the concentration measurement. The four rate constants determined in these two control experiments were similar to those found in the other runs.

Figure 2 shows a typical fit of the four concentration curves, after optimization of the five variables, for the reaction of d(TGG) with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$. The following rate constants were obtained for this system at 293 K (mean values of five experiments):

$k_{11} = 0.90 \pm 0.07\ M^{-1}s^{-1}$ $\quad k_{12} = 0.89 \pm 0.08\ M^{-1}s^{-1}$
$k_{21} = (1.76 \pm 0.09)\ 10^{-3}s^{-1}$ $\quad k_{22} = (1.27 \pm 0.09)\ 10^{-3}s^{-1}$

Apparently, in this trinucleotide the two guanine residues are equally reactive. The chelation of the 3'-intermediate **I1** is slightly faster than that of the 5'-intermediate **I2**.

Our ultimate goal in this research is to compare the rate constants for reactions of oligonucleotides of different lengths and sequences (including duplexes) with different

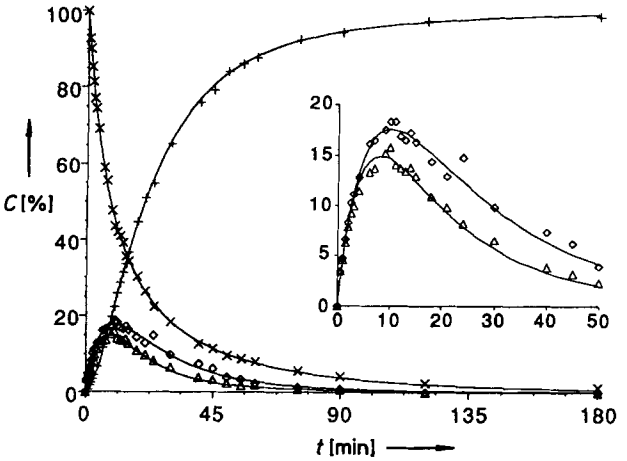

Fig. 2. Calculated curves and observed values for the four relative concentrations [N] (x), [I1] (Δ), [I2] (○), and [C] (+).

platinum complexes. An understanding of the high affinity of cisplatin towards GG sequences, and specifically, of the role that the ligands play in this affinity, will possibly provide a means to modify this affinity by appropriate changes in the ligands. In this way, it should be possible to test whether there is a relationship between sequence-specific DNA binding and antitumor activity of platinum complexes.

The kinetic analysis of a reaction between TGG and *cis*-$[PtCl(NH_3)_2(H_2O)]^+$ is currently being investigated in our laboratory. The experimental procedure is exactly the same as with the diaqua complex *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$, since the quenched products are the same. However, the evaluation of the rate constants is more complicated because of the equilibrium (a).

$$cis\text{-}[PtCl(NH_3)_2(H_2O)]^+ + H_2O \rightleftharpoons cis\text{-}[Pt(NH_3)_2(H_2O)_2]^{2+} + Cl^- \quad (a)$$

The determination of the rate constants for the reaction system with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ is prerequisite for the more complex system involving *cis*-$[PtCl(NH_3)_2(H_2O)]^+$. As far as other platinum complexes are concerned, their reactions with oligonucleotides can be analyzed by our method, provided that the starting, intermediate, and final products can be quenched in a simple way and separated by HPLC.

Experimental Procedure

The reactions were typically initiated by mixing a solution of about 2 μmol of d(TGG) (measured by UV spectrophotometry, $\varepsilon_{254} = 22170\ M^{-1}cm^{-1}$) [10] in 0.1 M $NaClO_4$ with a solution containing 2 μmol of *cis*-$[Pt(NO_3)_2(NH_3)_2]$ (prepared according to Ref. [11]) in 2 mL H_2O. The pH of the mixture was adjusted to pH = 4.4 by addition of $HClO_4$. After an initial increase to pH = 4.5 resulting from liberation of coordinated water, the pH decreased slowly to a value of 4.3, presumably due to dissolution of CO_2 from the atmosphere. The reaction temperature was kept at 293 ± 0.2 K. In initial intervals of 30 s (beginning) to 15 min (end), aliquots of 30 μL were withdrawn and quenched with 30 μL of a saturated KCl solution in an Eppendorf tube, and after 1.75 min incubation at 293 K (conversion of monoaqua to monochloro adducts) [12], dipped into liquid nitrogen and stored at 77 K until they were analyzed by HPLC. The cooling to 77 K is important, since at 193 K (dry ice temperature), the monocoordinated species **I1** and **I2** (Scheme 1) still slowly convert to the chelate **C**, despite KCl excess. As the subsequent HPLC analyses are quite time-consuming, and thus some of the samples have to be conserved for several days, this slow conversion significantly modifies the relative concentrations.

The HPLC analyses were performed on a Spectra Physics SP 8800 Chromatograph with a Nucleosil C18 column (250 × 4.6 mm ID, 5 μm, 100 Å; Macherey Nagel). Standard operating conditions were: mobile phase, ammonium acetate buffer (Merck, 0.01 M, pH = 4.70) and acetonitrile (Merck, 95:5 v/v); flow rate 0.8 mL min^{-1}; $T = 298$ K. At the detection wavelength of 255 nm, the absorbance of the reaction mixture decreased by 4% during the reaction; this decrease correlated roughly with the formation of the chelate **C**. The concentration of **C** based on peak integration was therefore corrected by a factor of 1.04.

Identification of the monoadducts was achieved by using enzymatic digestion of the corresponding fractions by the exonuclease Venum phosphodiesterase (VPD, Sigma). VPD digests the 5'-monoadduct (**I2**) to *cis*-$[PtCl(NH_3)_2d(TpG\text{-}N7)]$ and dpG, whereas the 3'-monoadduct (**I1**) remains undigested [13].

Appendix

The integration of the differential equations describing the kinetics of the reaction system shown in Scheme 1 yields the following expressions for the four concentrations [N], [I1], [I2], and [C], at the time t (W = excess of *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ over the oligonucleotide **N**):

$$[N] = \frac{W}{e^{(k_1 t + A)W} - 1}$$

$$A = \frac{\ln(W/[N]_0 + 1)}{W};\ k_1 = k_{11} + k_{12};\ W = [Pt] - [N]$$

$$[I1] = k_{11} e^{-k_{21}t} \int [N]([N] + W) e^{k_{21}t} dt$$

$$[I2] = k_{12} e^{-k_{22}t} \int [N]([N] + W) e^{k_{22}t} dt$$

$$[C] = [N]_0 - [N] - [I1] - [I2]$$

The integrals in the expressions for [I1] and [I2] were calculated numerically with time steps of 1 s. The optimization procedure was based on perpendicular distances of the experimental points from the calculated curves (**p** in Fig. 3), rather than on vertical distances corresponding to the difference between calculated and experimental concentrations (**v** in Fig. 3). This approach, which takes into account the experimental errors for both time and concentration, is, of course, meaningful only if both variables are scaled in units corresponding to the uncertainty in their measurement.

In the minimized function (1), $\mathbf{p}_i^{\mathbf{X}}$ are the perpendicular deviations of the experimental points i from the calculated curve, determined as from Equation (2).

$$F = [\sum_i (\mathbf{p}_i^{\mathbf{N}})^2]^2 + [\sum_i (\mathbf{p}_i^{\mathbf{I1}})^2]^2 + [\sum_i (\mathbf{p}_i^{\mathbf{I2}})^2]^2 + [\sum_i (\mathbf{p}_i^{\mathbf{C}})^2]^2 \quad (1)$$

$$\mathbf{p}_i^{\mathbf{X}} = \{[\mathbf{X}]_i^{obs} - [\mathbf{X}]_i^{calc}\} \cos\alpha = \{[\mathbf{X}]_i^{obs} - [\mathbf{X}]_i^{calc}\}(1 + \tan^2\alpha)^{-1/2} \quad (2)$$

with $\tan\alpha = \{d[\mathbf{X}]^{calc}/dt\}_i \{s(t)/s([\mathbf{X}])\}$

$[\mathbf{X}]_i^{obs}$ and $[\mathbf{X}]_i^{calc}$ are the observed and calculated concentrations of the product **X** at the time t_i, and $s(t)$ and $s([\mathbf{X}])$ are the errors in the determination of time and concentration, estimated to be 4 s and 2% of the initial oligonucleotide concentration, respectively. The individual sums in Equation (1) were taken as the second power to prevent the program from fitting one curve considerably worse than the others. Our optimization procedure used a grid search algorithm [14].

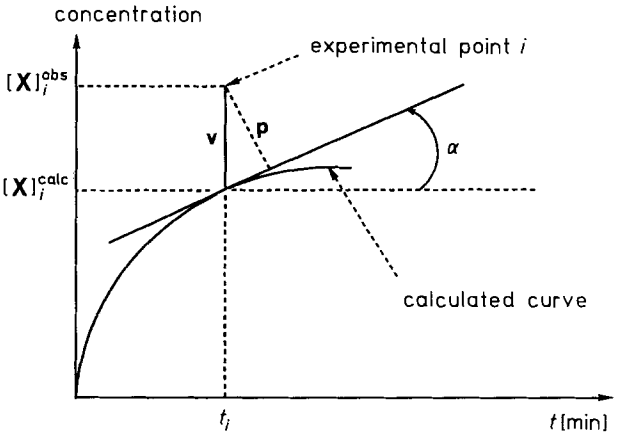

Fig. 3. Two distances relating an experimental point with the calculated curve: **v**, the vertical distance; **p**, the normal to the curve through the experimental point. In the linear approximation, $\mathbf{p} = \mathbf{v} \cos\alpha$. The variables are scaled in units of their inherent experimental errors. Whereas **v** reflects only the uncertainty in the concentration measurement, **p** takes into account the imprecision of both variables.

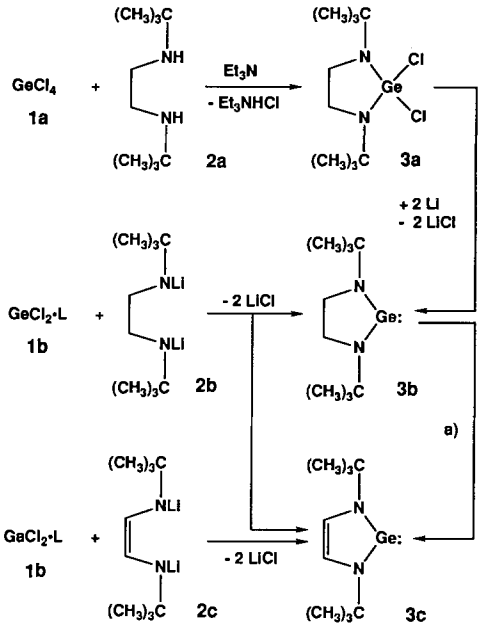
Stable Cyclic Germanediyls ("Cyclogermylenes"): Synthesis, Structure, Metal Complexes, and Thermolyses**

By *Wolfgang A. Herrmann,* Michael Denk, Joachim Behm, Wolfgang Scherer, Franz-Robert Klingan, Hans Bock, Bahman Solouki,* and *Matthias Wagner*

Substituted ethylenediamine **2a** and its derivatives form volatile, spirocyclic titanium amides, which precipitate from the gas phase (produced thermally or plasma-induced) as titanium carbonitrides.[1] We discovered that this type of ligand is generally suited for the stabilization of main group and subgroup elements with unusual valencies and report here on new applications in the chemistry of germanium.

The cyclic germanium(IV) diamide **3a**[2] was formed in almost quantitative yields from $GeCl_4$ (**1a**) and diamine **2a** in the presence of triethylamine. Reductive dehalogenation of **3a** then provided the new germanediyl ("germylene") **3b** (Scheme 1).[3] In another approach to **3b** the dilithium salt **2b** was allowed to react with germanium dichloride·1,4-dioxane (**1b**). Surprisingly, the CC-unsaturated germanediyl **3c** obtained by a formal dehydrogenation was isolated as a side product (Scheme 1). Compound **3c** can be prepared



Scheme 1. a) $+[(CH_3)_3Si]_2NLi$; $-[(CH_3)_3Si]_2NH$, $-LiH$; THF, 2 h, 60 °C. L = 1,4-dioxane.

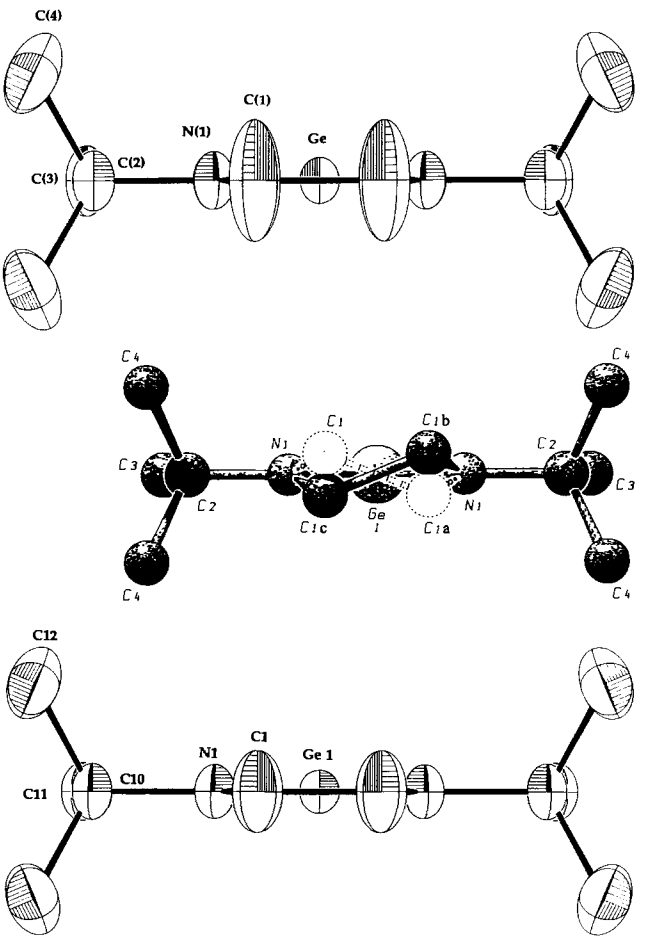


Fig. 1. Top: Crystal structure of **3b** at −70 °C (ORTEP, without hydrogen atoms, thermal ellipsoids at the 50% probability level). Middle: Model of the disorder in **3b** (SCHAKAL, see text). [**] Cyclic Metal Amides, Part 2. This research was supported by the Bundesministerium für Forschung und Technologie. Part 1: ref. [1b].

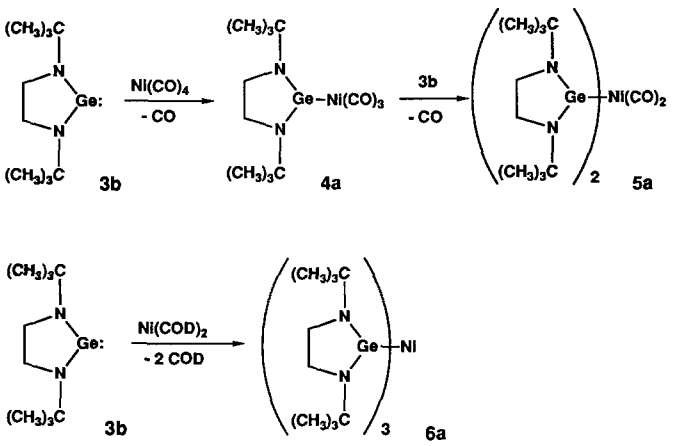
cleanly from treatment of the dilithium salt **2c** with **1b** (85%).[4]

Both germanediyls are infinitely stable at 25 °C under inert gas. The extraordinarily volatile compounds (both sublime at 45 °C and 1 Torr; **3b**: m.p. 45 °C, **3c**: m.p. 51 °C) are highly prone to hydrolysis. Compared to **3b**, compound **3c** is less reactive, thermally more stable, and can even be handled briefly in air in the crystalline state. Germanediyls **3b** and **3c** are monomeric not only in solution (osmometry) and in the gas phase (CI-MS, electron diffraction[5a]), but also in the solid state (Fig. 1), and thus belong to a rare class of compounds.[6] Merely replacing the *t*-butyl groups on the N atom with methyl groups leads to dimerization or trimerization.[6] The tin derivative analogous to **3b** is dimeric.[5b]

According to the X-ray structure analysis of **3b**,[7a] the atoms of the C_2N_2Ge five-membered ring appear to lie in a mirror plane, which could imply a planar framework. However, the large vibration ellipsoids of C1 and C1′ (view parallel to the mirror plane, Fig. 1 top) cannot be rationalized completely in terms of thermal vibrations. In addition, the C1–C1′ bond is too short (142.8(7) pm) for a CC single bond. These features can be explained by a model in which the disorder is caused by two superimposed twist conformations (Fig. 1 middle).[7a] The refinement of this model provides the same *R* values,[7] but leads to a CC bond length (157.1(7) pm) reasonable for a single bond. Calculations also predict that **3b** should have a twist conformation in the ground state.[10a] In contrast, **3c** is planar (Fig. 1 bottom);[7b] the bond lengths and bond angles at germanium differ only marginally from those of **3b** and give no evidence of electronic differences between the two molecules.

$[Ni(CO)_4]$ reacts with **3b** to furnish the monogermanediyl complex **4a**, and with excess **3b** to give the bis(germanediyl) complex **5a** (Scheme 2). The structure of **5a**[8] was determined by X-ray diffraction (Fig. 2). The zero-valent metal atom has an almost ideal tetrahedral coordination geometry, the respective carbonyl and germanediyl ligands are nonequivalent, and the GeN_2C_2 five-membered rings are nonplanar, as in the free ligand **3b**. Their CC bonds thus appear to be shortened, but this effect is caused once again by a twist disorder of the ethylene bridge. The angles at N, Ge, and N′ are almost identical to those in **3b**. Germanium has trigonal-planar coordination (sum of the angles is ca. 360°). Each N_2GeNi plane is coplanar with a carbonyl group. The resulting nonequivalence of the two *tert*-butyl groups of each germanediyl ligand is also evident in solution [$^1H/^{13}C$ NMR; coalescence temperature + 65 °C (^{13}C NMR)]. The Ni–Ge distances (ca. 230 pm) are not shorter than the single bonds in the few known germylnickel complexes.[9] As the ^{15}N NMR and IR data (νCO) show, the nickel atom (d orbitals) cannot compete effectively with N–Ge backbonding: $[Ni(CO)_4]$ 2057 (T_2), $[Ni(CO)_2\{P(C_6H_5)_3\}_2]$ 2000 (A_1)/1941 (B_1), **5a** 2003 (A_1)/1945 (B_1) cm^{-1}; the corresponding force constants for CO stretching have the following respective values $\kappa = 17.9$, 14.1, and 14.2 $N\,cm^{-1}$. Thus, germanediyl **3b** is a ligand with relatively good σ-donor and poor π-acceptor qualities, and in this respect is similar to triphenylphosphine.



Scheme 2.

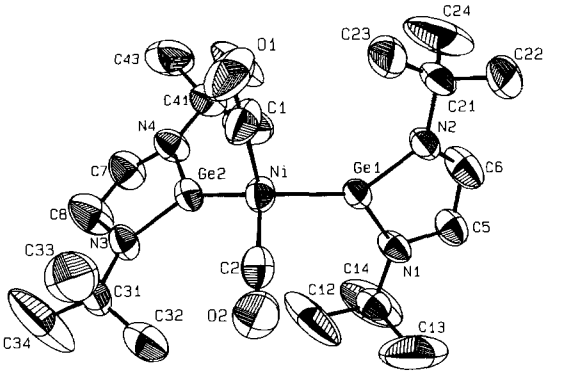


Fig. 2. Crystal structure of **5a** (ORTEP, without hydrogen atoms, thermal ellipsoids at the 50% probability level). Selected distances [pm] and angles [°]: Ge1-Ni 229.69(4), Ge2-Ni 229.13(3), C1-Ni 177.2(3), C2-Ni 176.9(2), C1-O1 113.1(2), C2-O2 113.3(2), Ge-N1 182.6(2), Ge1-N2 181.9(1), Ge2-N3 183.0(1), Ge2-N4 181.3(2); Ge1,Ni,Ge2 106.67(1), C1,Ni,C2 111.6(1), Ge1,Ni,C1 113.71(8), Ge1,Ni,C2 106.3(1), Ni,C1,O1 176.4(3), Ni,C2,O2 176.3(2), N1,Ge1,N2 88.62(7), N3,Ge2,N4 89.22(7), Ge1,N1,C5 112.2(1), Ge1,N1,C11 129.3(1), C5,N1,C11 118.3(2), Ge1,N2,C6 111.8(1), Ge1,N2,C21 129.8(1), C6,N2,C21 118.1(2).

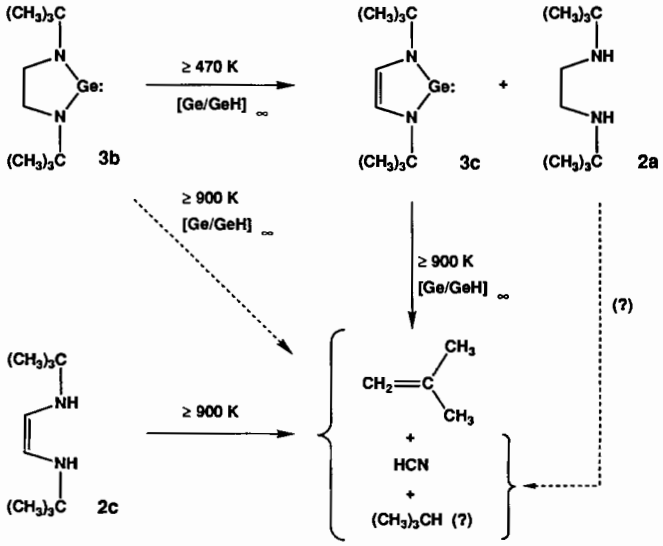
Ab initio calculations of the model compound $(NH_2)_2Ge$: (planar ground state, symmetry point group C_{2v}) showed unexpectedly strong Ge–N backbonding. The barrier to rotation about the first Ge–N bond with pyramidalization is 12.8 kcal mol^{-1}, about the second 21.8 kcal mol^{-1}. The second NH_2 group apparently provides some of the charge density which the Ge atom loses when the first NH_2 group is orthogonal.[10]

The reaction of **3b** with $[Ni(1,5\text{-cod})_2]$ (cod = cyclooctadiene), furnished the extremely air- and moisture-sensitive tris(germanediyl) complex **6a** (Scheme 2), which crystallized as brick-red crystals from *n*-hexane. The NMR spectra (^1H, ^{13}C, ^{15}N) indicate that the compound has D_{3h} symmetry.

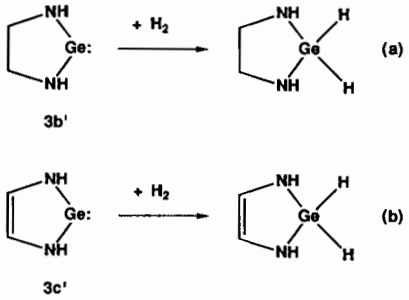
Investigations of the chemical vapor deposition (CVD) to $[Ge]_\infty$ or $[Ge/GeH]_\infty$ were conducted in a flow tube under controlled conditions;[11a, b] the gas was analyzed by photoelectron (PE) spectroscopy. Surprisingly, the thermolysis of **3b,c** gave rise to isobutene and HCN; H_2 could not be detected. Besides the ionization pattern of isobutene,[11c] the region of contourless bands between 11–16 eV presumably also contains the one of isobutane. The thermolyses analyzed by PE spectroscopy suggest the following reaction sequence for the extrusion of $[Ge]_\infty$ or $[Ge/GeH]_\infty$ (Scheme 3). At 470 K **3b** decomposes to **3c** and **2a**. At 900 K **3b** and **3c** give identical PE spectra in which isobutene and HCN can be identified by their characteristic ionization peaks besides residual **3c**. These results indicate that the CVD decomposition of **3b,c** may be optimized for the preparation of (hydrogen-containing) germanium layers.

The different thermal stabilities of the saturated and unsaturated cyclogermanediyls were approximated by ab initio



Scheme 3.

calculations[10a] of the hydrogenation enthalpies of the model compounds **3b'** and **3c'** [isodesmic Eqs. (a) and (b)]. The unsaturated cyclogermanediyl **3c'** is 41 kJ mol^{-1} lower in energy than the saturated compound **3b'** (RHF/LANL1DZ//RHF/LANL1DZ); when electron correlation is included (MP2/LANL1DZ//RHF/LANL1DZ), **3c'** is 54 kJ mol^{-1} more stable than **3b'**.[10a] The optimized geometry is in excellent agreement with the structural data (Fig. 1). In the triplet state, in which seven electrons occupy the π molecular orbitals of **3c'**, there is *no* significant difference between the hydrogenation enthalpies of the model compounds and those of the hypothetical germane derivatives [Eqs. (a) and (b)].



The theoretical and experimental results (planarity, ^{1}H/^{15}N NMR data,[2, 3, 5a] reduced reactivity) can best be explained by assuming a cyclic delocalization of the π electrons in **3c** in the ground state. In light of the results reported here, as well as the work of Arduengo et al.[12] on the structurally analogous carbenes (C instead of Ge), the corresponding silanediyls should also be stable.

Experimental Procedure

3b: A solution of **3a** (1.29 g, 4.12 mmol) in THF (5 mL) was treated with Li granules (57 mg) (the reaction mixture turned brown). After 5–6 h the solvent was removed under vacuum and replaced with *n*-pentane (10 mL). Filtration (G3 Schlenk frit) and evaporation of the solvent gave a thick, light yellow oil, which upon sublimation (1 Torr, 40 °C) provided analytically pure **3b** in the form of colorless needles (750 mg, 75%). Occasionally a small amount of a yellow, volatile impurity was observed which could be removed by sublimation.

3c: A solution of *N*,*N'*-bis(*tert*-butyl)-1,4-diazabutadiene (59.4 mmol, 1 molequiv) in THF (200 mL) was treated with Li granules (830 mg, 0.12 g-atom, 2 molequiv) and stirred overnight (reaction mixture turned red). A solution of **1b** (13.8 g) in THF (50 mL) was added dropwise at 25 °C over 10 min (reaction mixture turned brown and warmed to 30–40 °C). The solvent was removed under vacuum after 1 h, the residue stirred with *n*-pentane (100 mL), and the mixture filtered (G3 or G4 Schlenk frit). The solvent was evaporated, and sublimation provided **3c** as dull colorless needles (11.5 g, 80%). Correct complete analysis.

4a: [Ni(CO)$_4$] (5 mL, excess) was added dropwise to a stirred solution of **3b** (900 mg, 3.705 mmol) in THF (5 mL) at 25 °C. After a short induction period, a vigorous evolution of gas began and lasted ca. 3 min (reaction mixture turned pale yellow). After 1 h at 25 °C, the solvent was removed under vacuum, the orange-yellow, clear, glasslike residue taken up in *n*-pentane (10 mL), and the solution stored at −25 °C (1 d) and −78 °C (1 d). **4a** was obtained as colorless crystals with a slightly gray tinge (1.17 g, 82%). ^{1}H NMR (270 MHz, C_6D_6, 25 °C): δ = 1.23 (s, CH_3); 3.08 (s, CH_2); ^{13}C NMR (100.54 MHz, C_6D_6, 25 °C): δ = 32.2 (q, ^1J(C,H) = 125 Hz; CH_3), 48.7 (t, ^1J(C,H) = 136 Hz; CH_2), 55.5 (s; $C(CH_3)_3$), 195.9 (s; CO); ^{17}O NMR (36.64 MHz, [D_8]toluene, 25 °C, D_2O standard): δ = −197.1 (s; CO); ^{15}N NMR (40.51 MHz, C_6D_6, 25 °C, CH_3NO_2 standard): δ = −226.1 (s).

5a: To a solution of **3b** (900 mg, 3.705 mmol) in *n*-hexane (5 mL) was added [Ni(CO)$_4$] (161 μL, 0.212 g, 1.235 mmol). After a short induction period, a vigorous evolution of gas began and lasted ca. 3 min. The solvent was removed by distillation under vacuum and the residue heated at 90 °C (oil bath temperature) in a sublimation apparatus under high vacuum for 1 d. The clear, glassy remaining material was taken up in *n*-pentane (10 mL) and crystals formed at −25 °C. Yellow, transparent prisms were obtained (830 mg, 75%). IR (Nujol, CsI): ν(CO) = 2003 (s), 1945 (s) cm^{-1}; ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 1.41, 1.48 (s; CH_3), 3.09 (s; CH_2); ^{13}C NMR (100.54 MHz, [D_8]toluene, 25 °C): δ = 31.9, 32.2 (q, ^1J(C,H) = 125 Hz; CH_3), 48.6, 48.7 (t, ^1J(C,H) = 136 Hz; CH_2), 55.4 (s, $C(CH_3)_3$), 195.7 (s; CO); ^{17}O NMR (36.64 MHz, C_6D_6, 25 °C, D_2O standard): δ = 207.7 (s); ^{15}N NMR (40.51 MHz, C_6D_6, 25 °C, CH_3NO_2 standard): δ = −222.2 (s). Correct complete analysis.

6a: A solution of **3b** (840 mg, 3.46 mmol) in THF (5 mL) at −78 °C was treated with [Ni(1,5-cod)$_2$] (317 mg, 1.15 mmol) (reaction mixture turned red immediately). The reaction mixture was allowed to warm to 25 °C, and the volatiles were removed by distillation. The remaining material was heated at 60 °C (oil bath temperature) for 2 h under argon and then 8 h under vacuum. The red-brown crystalline residue was dissolved in *n*-hexane (10 mL) and cooled to −30 °C for ca. 15 d to provide deep red needles (810 mg, 89%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 1.45 (s; CH_3), 3.24 (s; CH_2); ^{13}C NMR (100.54 MHz, [D_8]toluene, 25 °C): δ = 32.4 (q, ^1J(C,H) = 125 Hz; CH_3), 48.6 (t, ^1J(C,H) = 135 Hz; CH_2), 54.5 (s; $C(CH_3)_3$); ^{15}N NMR (40.51 MHz, [D_8]toluene, 25 °C, CH_3NO_2 standard): δ = −234.7 (s); CI-MS (isobutene, positive ions): *m*/*z* 242 (LGe^+, 100%); CI-MS (isobutene, negative ions): *m*/*z* 749 (**6a**$^{\cdot -}$ − 3CH_3, 42%), 394(30), 315(23), 279(10), 208(9), 149(100). Correct complete analysis.

[7] a) X-ray structure analysis of **3b** ($C_{10}H_{22}GeN_2$): Irregular fragment of a crystal obtained by sublimation. Systematic extinctions $h00$ ($h = 2n+1$) and $0k0$ ($k = 2n+1$), space group $P\bar{4}2_1m$ (no. 113), $a = 998.09(4)$, $c = 643.12(5)$ pm, $V = 640 \cdot 10^6$ pm^3, $Z = 2$, $\rho_{calc} = 1.259$ g cm^{-3}, Enraf-Nonius CAD4, $\lambda = 71.07$ pm ($Mo_{K\alpha}$, graphite monochromator), $T = -70$ (±3) °C, range of measurement $1.0° < \theta < 25.0°$, ω-scan, scan width $(1.2 + 0.25\tan\theta)°$ (±25%) before and after each reflection to determine the background, $t_{max} = 60$ s, empirical absorption correction based on Ψ-scan data, $\mu = 23.2$ cm^{-1}, no decomposition, direct structure determination, difference Fourier technique, 620 independent reflections, of which 620 had $I > 0.01\sigma(I)$, 67 parameters refined by full-matrix least-squares, reflection/parameter relationship 9.25, all six heavy atoms except C1 with anisotropic thermal motion parameters, all hydrogen atoms found and independently refined, anomalous dispersions accounted for, shift/error < 0.001, residual electron density 0.20 Δe_o Å^{-3} (105 pm off the Ge atom) and $-0.31\ \Delta e_o$ Å^{-3}, $R = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o| = 0.017$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.019$. The refinement of the other enantiomer gave a larger R value (0.0263). Three additional sets of data were collected from another crystal between −35 and −110 °C for further support the model of disorder. All four measurements confirm the model of disorder and thus the nonplanarity of the C_2N_2Ge ring, since the large vibration ellipsoids were shown to be temperature invariant and best rationalized by disorder. The structure refinement provided almost identical behavior for the main axes of the thermal parameters. b) X-ray structure analysis of **3c** ($C_{10}H_{20}GeN_2$): $a = 1378.40(4)$, $b = 1403.12(3)$, $c = 641.45(1)$ pm, $V = 1240 \cdot 10^6$ pm^3, measurement at −50 °C, $\rho_{calc} = 1.289$ g cm^{-3}, $\mu = 30.2$ cm^{-1}, $Z = 4$, orthorhombic crystal system, space group $Pmmn$, Enraf-Nonius CAD4, $\lambda = 154.184$ pm, $Cu_{K\alpha}$, graphite monochromator), $\omega/2\theta$-scan, 4635 measured reflections, $(-h, \pm k, \pm l)$ of which 1143 were independent, structure determination with Patterson methods and difference Fourier syntheses, empirical absorption correction, transmission coefficients 0.8592–0.999, 118 refined parameters, $R = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o| = 0.035$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.029$, residual electron density + 0.68, −0.76 Δe_o Å^{-3}. c) Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-56578, the names of the authors, and the journal citation.

[8] X-ray structure analysis of **5a** ($C_{22}H_{44}Ge_2N_4NiO_2$): $a = 965.1(1)$, $b = 1671.8(2)$, $c = 1811.5(2)$ pm, $\beta = 101.51°$, $V = 2864 \cdot 10^6$ pm^3, measurement at 25 °C, $\rho_{calc} = 1.39$ g cm^{-3}, $\mu = 33.8$ cm^{-1}, $F_{000} = 1248$, $Z = 4$, monoclinic crystal system, space group $P2_1/c$, Enraf-Nonius CAD4, $\lambda = 154.184$ pm ($Cu_{K\alpha}$, graphite monochromator), $\omega/2\theta$-scan, 5288 measured reflections $(\pm h, -k, +l)$, 4651 of which were independent, 4645 used for refinement, structure solution with Patterson methods and difference Fourier syntheses, empirical absorption correction, transmission coefficients 0.939–0.999, 280 refined parameters, $R = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o| = 0.052$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.049$, residual electron density + 0.98, −0.74 Δe Å^{-3}. Quest for Higher Ladderanes: Oligomerization of a Cyclobutadiene Derivative**

By *Goverdhan Mehta,* M. Balaji Viswanath, G. Narahari Sastry, Eluvathingal D. Jemmis,* D. Sivakumar K. Reddy,* and *Ajit C. Kunwar**

The name [*n*]-ladderane has been given to novel molecular arrays composed entirely of linearly concatenated cyclobutanes for example, **1**.[1] Thus, cyclobutane, bicyclo[2.2.0]-hexane, and tricyclo[4.2.0.0^{2,5}]octane are [1]-, [2]-, and [3]-ladderane, respectively. These multifused, cyclobutanoid systems hold great promise as spacers in view of the latitude they offer in terms of rigidity, distal variation, steric disposition, and an accommodating σ framework. However, only [2]-ladderanes have been exploited as spacers thus far.[2] Ladderanes with $n \geq 11$, which possess functional groups at the terminal rings [e.g., **2** ($x \geq 9$)], have been considered as precursors of configurational isomers of higher [*n*]-prismanes for example, israelane **3** and helvetane **4**.[3, 4] However, to our knowledge, the ladderane route to the fascinating hydrocarbons **3** and **4** has never progressed beyond the realm of fanciful ideas.[4, 5] The major impediment in the exploitation of the potentially rich chemistry of ladderanes has been their inaccessibility. It has not yet been possible to assemble a linear array of more than four cyclobutane rings, and only a handful of [4]-ladderanes are known.[6] Herein, we report a new approach for the rapid assembly of higher ladderanes, and describe the characteristics of [5]- and [7]-ladderane derivatives.

The simplest and shortest approach to the higher ladderanes **1**/**2** ($x \geq 3$) would be by the controlled oligomerization of a cyclobutadiene. However, cyclobutadiene and its derivatives are known to dimerize only.[7] If we can understand why the oligomerization of cyclobutadiene does not proceed beyond the dimer stage, it should be possible to design cyclobutadiene derivatives that may exhibit enhanced

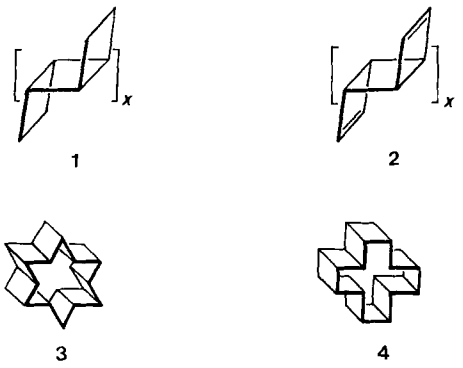
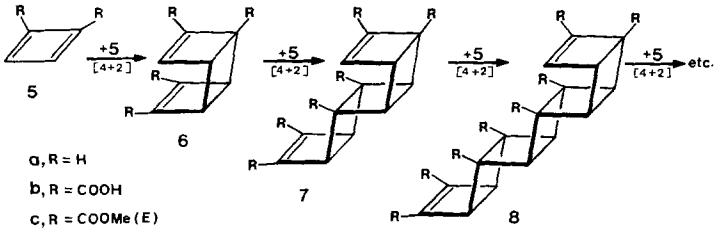
propensity towards further [4 + 2] cycloaddition and thus promote a cycloaddition cascade process leading to higher ladderanes **2**. To this end, we examined the frontier orbitals



involved in the oligomerization and performed molecular orbital calculations at the AM1 level.[8] The HOMO–LUMO and LUMO–HOMO gaps calculated for oligomerization of **5a**, **b** are given in Scheme 1. The HOMO–LUMO gap of 8.46 eV for the dimerization of **5a** is within the range of successful [4 + 2] reactions.[9] The reaction of the dimer **6a** with **5a** has a considerably larger HOMO–LUMO or LUMO–HOMO gap (9.64 and 9.70 eV, respectively). Reactions with a HOMO–LUMO gap larger than 9.0 eV tend not to be very facile.[9] Formation of the tetramer **8a** from **5a** and **7a** has an equally unfavorable HOMO–LUMO (LUMO–HOMO) gap of 9.68 (9.64) eV. Electron withdrawing groups in the 1,2 position as in **5b** should reduce the HOMO and LUMO of the system. While this may not affect the dimerization substantially, it could facilitate further oligomerization because the HOMO and LUMO in this case have to be from different molecules.

Accordingly, the dicarboxylic acids **5b**–**8b** were optimized at the AM1 level. Scheme 1 shows that for the dimerization of **5b**, the HOMO–LUMO gap is somewhat lower



Reaction	HOMO–LUMO (LUMO–HOMO) [eV]	
	R = H	R = CO_2H
5 + **5** → **6**	8.46	8.12
5 + **6** → **7**	9.64 (9.70)	8.37 (9.29)
5 + **7** → **8**	9.68 (9.64)	8.35 (9.29)

Scheme 1.

than that for **5a**. The HOMO–LUMO gaps calculated for the trimerization and the tetramerization (8.37 and 8.35 eV, respectively) are even more encouraging. These are more than 1 eV lower than those calculated for the parent system, and therefore **5b** can be considered a good candidate for oligomerization.

Based on these predictions, the tricarbonyl iron complex of dimethyl 1,2-cyclobutadienedicarboxylate (**9**) (1.2 mmol)[10] was treated with cerium(IV) ammonium nitrate (CAN, 5 equiv) in dry acetone (10 mL, 0–5 °C), which liberated the methyl ester **5c** (Scheme 2). Usual workup and chromatography led to the isolation of three crystalline products, dimer **6c**, trimer **7c**, and tetramer **8c** in an approximate 3:2:1 ratio and 55% yield along with minor quantities of uncharacterized products. The structures of **6c**–**8c** were revealed by their high-field ^1H and ^{13}C NMR parameters, which indicated the presence of four, six, and eight methylester moieties, respectively (Table 1). All the protons were duly assigned on

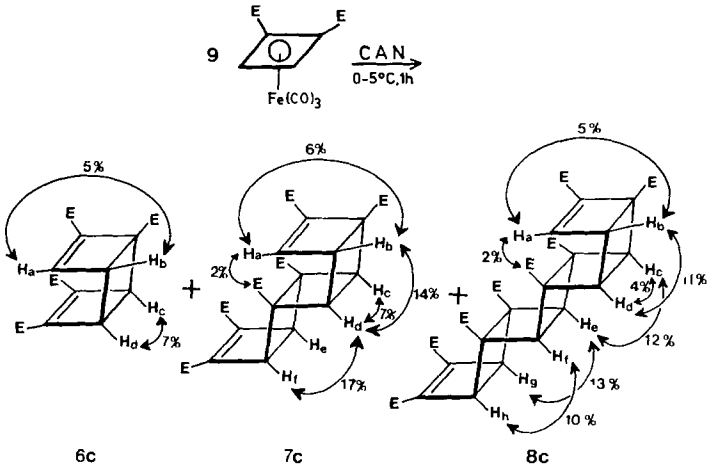
the basis of expected chemical shifts and decoupling data. The stereochemistry of the oligomers **6c**–**8c** was determined by detailed and complimentary NOE experiments (Scheme 2). These assignments were further confirmed by the analysis of NOESY spectra.

The regio- and stereochemistry of the ladderanes **6c**–**8c** are in agreement with the results of the calculations carried out for **5b**–**8b**. For example, the regio- and stereochemistry of **6c** follows from the coefficients and the energies of the HOMO and LUMO of **5c** and potential secondary orbital interactions during the dimerization. Similarly, the regiochemistry of **7c** is dictated by the LUMO of **6c**, which is



Scheme 2. E = COOMe.

localized on the more substituted double bond. The stereochemistry of **7c**, in the absence of any secondary orbital interaction, is determined by steric interactions. The formation of **8c** follows the same pattern.

Structures **7c** and **8c** have five and seven linearly fused cyclobutane rings, respectively, as well as many ester groups positioned on one face. This "polarofacial" disposition should confer special properties on these compounds and make them interesting as spacers and new materials. We are actively pursuing these aims, particularly the synthesis of even higher ladderanes.

Ether-Soluble Ti^0 and Bis(η^6-arene)titanium(0) Complexes from the Reduction of $TiCl_4$ with Triethylhydroborate**

By *Helmut Bönnemann** and *Barbara Korall*

The reduction of transition metal salts with alkali metal triethylhydroborates in THF yields finely divided, noncrystalline metal powders.[1] We have found that the analogous reaction of titanium or zirconium halides leads surprisingly to ether-soluble metal species.

Within 2 hours $TiCl_4 \cdot 2\,THF$ and $TiCl_3 \cdot 3\,THF$ reacted in THF with $K[BEt_3H]$ with evolution of H_2 to give brown-black solutions from which roughly 90% of the precipitated KCl could be removed by filtration. Solvent and BEt_3 (identified by ^{11}B NMR spectroscopy) were removed under vacuum (10 Pa) leaving a black residue which was extracted with THF. This THF solution was treated with pentane to give a brown-black precipitate, which according to elemental analysis was composed of 23.7% C, 4.4% H, 7.9% O, 0.3% B, 8.5% Cl, 8.8% K, and 46.7% Ti; after thorough drying under vacuum this solid was pyrophoric. The K and Cl components were identified as KCl by X-ray diffraction measurements. The material contained almost no boron. It dissolved in THF and ether but was insoluble in pentane and in arene solvents. Complete dissolution in THF provided a 0.5 M solution which could be concentrated without formation of a precipitate to approximately 2.5 M by distilling off THF.

During the reduction only about one mol of H_2 was released per mol of titanium. The hydrogen which is not accounted for, approximately one mol, should be found bound to titanium. To test this hypothesis we conducted the reduction with $K[BEt_3D]$. During the reaction, 48% of the amount of D_2 theoretically anticipated was released. In the protonolysis of the reaction mixture with 2 N HCl a mixture of HD and H_2 formed [Eq.(a)]. Following Equation (a) the D/Ti ratio in "TiD_m" was determined to be $m = 2$ from the amount of HD produced from material with a known titanium content.

$$\text{"}TiD_m\text{"} + nH^+ \longrightarrow m\,HD\uparrow + (n-m)/2\,H_2\uparrow + Ti^{3+} \qquad \text{(a)}$$

After workup and drying, the product had a D/Ti ratio of only $m = 0.3$. Thus, compound **1** is found in solution, but it loses hydrogen under vacuum. Our results are best summarized in Scheme 1.

$$TiCl_4 \cdot 2\,THF + 4\,K[BEt_3H] \xrightarrow[2\,h,\,40\,^\circ C]{THF} \underset{\mathbf{1}}{(TiH_m \cdot x\,THF)_{soluble}} + 4\,BEt_3 + 4\,KCl\downarrow + (2-m/2)\,H_2\uparrow$$

$$\text{vacuum} \;\Big|\; \begin{array}{l} -\,BEt_3 \\ -\,THF \\ -\,H_2 \end{array} \Big\downarrow$$

$$\underset{\mathbf{2}}{Ti \cdot 0.5\,THF}$$

Scheme 1. The course of the reduction of $TiCl_4$ with $K[BEt_3H]$ in THF.

[*] Prof. Dr. H. Bönnemann, Dr. B. Korall
Max-Planck-Institut für Kohlenforschung
Postfach 101353, D-W-4330 Mülheim an der Ruhr (FRG)

[**] We thank Dr. K. Seevogel for recording the IR spectra on a Nicolet FT-IR spectrometer 7199 and interpreting them, Dr. G. Block (Krupp Industrietechnik GmbH, Essen) for X-ray diffractograms, Prof. Dr. R. Courths (Universität-Gesamthochschule Duisburg) for XPS spectra with ESCALAB Mark II, and Prof. Dr. P. Kleinschmit (Degussa AG, ZN Wolfgang) for the gift of the metal sponges.

The protonolysis of **2** with 2N HCl provided 1.5–2 mol of H_2 per mol of titanium. Theoretically, 1.5 mol H_2 are expected for Ti^0. This shows that in **2** Ti^0 has various amounts of residual hydrogen.

According to the IR spectrum of **2** intact THF is coordinated to the metal center. Neither the IR nor ^1H NMR spectra give evidence of Ti-bound hydrogen. Likewise, there is no spectroscopic proof of a cleavage of THF by Ti^0. In the X-ray diffractogram of **2** besides the reflections of the KCl impurity only a diffuse, small peak at $2\theta = 30°$ is seen, the position of which matches that of the peak of amorphous titanium. The accompanying lattice distance, approximately 0.3 nm, corresponds to that in metal. In the XPS spectrum of **2** (Fig. 1d) the Ti 2p peak is found 2.3 eV higher in energy than in the spectrum of TiO_2 (Fig. 1a). Although metallic titanium as finely divided as **2** was not available for control experiments, it can be deduced from the XPS spectra (Fig. 1) that titanium in **2** is almost as reduced as titanium metal. The

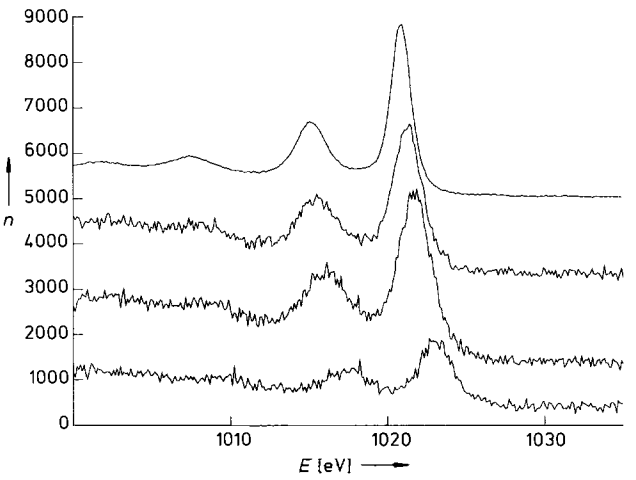

Fig. 1. XPS spectra (double peak $Ti\,2p_{1/2}$ and $Ti\,2p_{3/2}$) of a) TiO_2,b) TiO_2 from **2**, c) a sample of **2** with an oxidized surface, d) Ti·0.5THF **2**. n = Number of recorded pulses.

lack of the typical broad peak between 990 and 1010 eV for **2** indicates the absence of TiO_2 (no oxidation of the sample during the measurement). As a comparison for the measured values, the curves from TiO_2 produced from **2** (Fig. 1b) and from an oxidized sample (Fig. 1c) are also displayed.

Two titanium–hydrogen compounds are known. α-TiH_x ($x < 0.46$) can be described as elemental titanium with incorporated hydrogen, whereas β-TiH_y (ca. $1 < y < 2$)[2] has a CaF_2-type structure. The radial distribution function of an initial EXAFS analysis fitted with the experimentally determined titanium phase function (of titanium metal) shows three shells of titanium for **2** with the Ti–Ti distances listed in Table 1. A hexagonal structure type similar to that of α-titanium can be deduced from these values. The lattice is somewhat expanded,[4] possibly by the included hydrogen.

The characterization of **2** up to this point supports its description as colloidal titanium stabilized by complexed THF and containing included residual hydrogen. The determination of the particle size by transmission electron microscopy has not been conducted.

The analogous reduction of $ZrCl_4$ with $K[BEt_3H]$ in THF also provided a product soluble in THF; its composition was determined to be 34.1% C, 8.0% H, 11.4% O, 3.7% B,

Table 1. Comparison of the Ti–Ti distances in **2**, α-Ti and β-$TiH_{1.971}$.

Shell	**2**	α-Ti (a = 2.952, c = 4.689 Å [3])	β-$TiH_{1.971}$ (a = 4.440 Å [3])
1	2.96 Å	2.90 Å, 2.95 Å } 2.925 Å 2.95 Å	3.14 Å
2	4.21 Å	4.14 Å	4.44 Å
3	5.68 Å	5.85 Å	5.44 Å

5.2% Cl, 17.9% K, and 19.4% Zr. The purification and closer characterization are not yet complete.

When the reduction of $TiCl_4$ with $K[BEt_3H]$ was conducted in arene solvents (benzene, toluene, *p*-xylene, and mesitylene) instead of THF, the corresponding bis(η^6-arene)titanium complexes were obtained under standard conditions in up to 20% yield.[5] Previously these compounds could be prepared only by the metal-atom vapor technique.[6] The two-step synthesis of the bis(η^6-arene)titanium complexes by reaction of **2** with the appropriate arene did not succeed.

Complex **2** and the bis(η^6-arene)titanium complexes may find application as dopants for noble metal hydrogenation catalysts; this should increase the catalytic activity and the lifetime considerably.[5, 7] Complex **2** and the analogous zirconium compound catalyze the hydrogenation of titanium and zirconium sponges as well as of a hydride battery alloy.

Experimental Procedure

Synthesis of **2**: To a stirred solution of $TiCl_4 \cdot 2THF$ (6.68 g, 20 mmol) in THF (250 mL) at 40 °C was added 70 mL of a 1.15 M solution of $K[BEt_3H]$ (80 mmol) in THF over 2 h. Approximately 20 mmol of H_2 were released during the reaction. After the addition was complete, the reaction mixture was stirred another 30 min at 40 °C. The precipitated KCl was removed by filtration with a D4 frit. BEt_3 (^{11}B NMR (THF, 300 K): $\delta = 76.73$) and THF were removed from the brown filtrate under vacuum (10 Pa), and the residue extracted with THF (100 mL). Insoluble material was removed by filtration, and the filtrate was concentrated under vacuum to a volume of roughly 20 mL. The brown-black precipitate formed by addition of pentane to this solution was filtered and dried under vacuum for 16 h. Yield: 1.68 g (82%) **2**, 5.24 g (88%) KCl. – IR: $\tilde{\nu}[cm^{-1}]$ = 867 s, 915 vw, 1035 s, 1340 br, 1455 w; ^1H NMR ([D_8]THF, 300 K, TMS): $\delta = 1.77$ (m, 2H), 3.61 (m, 2H); MS: m/z 72 ($C_4H_8O^+$); X-ray diffraction: KCl, titanium portion is amorphous (small diffuse peak at $2\theta \approx 30°$); DSC: exothermic reaction at 73 and 147 °C; protonolysis of **2** with 2N HCl provides a H/Ti ratio of 1.7:1.

Reduction of $ZrCl_4$: Procedure analogous to that described for **2**; yield of Zr-containing product: 31.93 g (81%),

Synthesis of the bis(η^6-arene)titanium complexes:

a)Bis(η^6-benzene)titanium: To a solution of $TiCl_4$ (2.2 mL, 20 mL) in benzene (50 mL) in an ultrasonic bath at room temperature was added 160 mL of a 0.5 M solution of $K[BEt_3H]$ (80 mmol) in benzene over 1 h. After the addition was complete the reaction mixture was left in the ultrasonic bath another 1 h. A black precipitate was filtered away from the clear, red solution with a D4 frit and then washed with benzene (3 × 50 mL). The filtrate and the washes were combined and concentrated to dryness. The residue was taken up in pentane, and insoluble material was removed from the red solution by filtering through a D4 frit. The pentane was removed under vacuum, and the residue was recrystallized from pentane. Bis(η^6-benzene)titanium was obtained as deep red, shiny plates. Yield: 0.449 g (11%). ^1H NMR ([D_6]benzene, 300 K, TMS): $\delta = 4.92$ (s, 6H, CH) (according to ref.[8]: δ (in [D_6]benzene) = 5.04); IR (KBr): $\tilde{\nu}[cm^{-1}]$ = 673 vs, 694 vs, 943 s, 973 s, 1406 w, 1478 w (according to ref.[8]: $\tilde{\nu}[cm^{-1}]$ = 946 s, 979 s).

b) Bis(η^6-toluene)titanium: Procedure analogous to that described in a); toluene was used as the solvent. Yield: 1.014 g (22%), satisfactory C,H,Ti analysis. ^1H NMR ([D_6]benzene, 300 K, TMS): $\delta = 2.13$ (s, 3H, CH_3), 5.01 (m, 5H, CH) (according to ref.[8]: δ (in [D_{12}]$SiMe_4$) = 2.15, 4.89); MS m/z 232 [$(H_{16}C_{14})^{48}Ti^+$, 52%], 140 [$(H_8C_7{}^{48}Ti^+$, 100], 138 [$(H_6C_7{}^{48}Ti^+$, 35], 116 [$(H_{16}C_{14})^{48}Ti^{2+}$, 6], 70 [$(H_8C_7)^{48}Ti^{2+}$, 4], 48 [$^{48}Ti^+$, 13).

c) Bis(η^6-*p*-xylene)titanium: Procedure analogous to that described in a); *p*-xylene was used as the solvent, reaction mixture treated for 4 h in the ultrasonic bath. Yield: 0.462 g, (9%). ^1H NMR ([D_6]benzene, 300 K, TMS): $\delta = 1.96$ (s, 6H, CH_3), 4.84 (s, 4H, CH); MS: m/z 260 [$(H_{20}C_{16})^{48}Ti^+$, 100%], 154

$[(H_{10}C_8)^{48}Ti^+$, 85], 152 $[(H_8C_8)^{48}Ti^+$, 41], 130 $[(H_{20}C_{16})^{48}Ti^{2+}$, 14], 77 $[(H_{10}C_8)^{48}Ti^{2+}$, 9], 48 $[^{48}Ti^{2+}$, 5].

d) Bis(η^6-mesitylene)titanium: Procedure analogous to that described in a); mesitylene was used as the solvent, reaction mixture treated for 16 h in the ultrasonic bath. Yield: < 5%. ^{1}H NMR ([D$_6$]benzene, 300 K, TMS): δ = 1.99 (s, 9H, CH_3), 4.74 (s, 3H, CH); (according to ref.[8]; δ (in [D_{12}]$SiMe_4$) = 1.96, 4.69); MS: *m/z* 288 $[(H_{24}C_{18})^{48}Ti^+$, 100%], 168 $[(H_{12}C_9)^{48}Ti^+$, 42], 166 $[(H_{10}C_9)^{48}Ti^+$, 38], 144$[(H_{24}C_{18})^{48}Ti^{2+}$, 21], 48$[^{48}Ti^+$, 4].

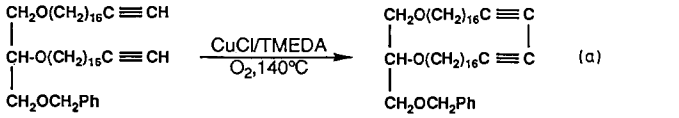
High-Yield Synthesis of Lipid Systems with Giant Rings**

By *Fredric M. Menger,* Stephen Brocchini,* and *Xiangyang Chen*

Phospholipids, a major constituent of biological membranes, possess two alkyl chains each made up of 14–18 carbon atoms (see e.g. **I**). Since the chains are connected only at the ester ends, they have a certain amount of freedom within the membrane bilayer to bend, reorient, and interdigitate.[1] We wondered how membrane behavior (e.g. thermotropic properties,[2] permeability,[3] etc.) would be affected when the two distal ends are joined as in **II**, thereby restricting independent motion. Answering this simple but intriguing question required the synthesis of "giant rings" up to 72 atoms in size.[4] Any synthesis chosen to construct the macrocyclic lipids[5] had to proceed in high yields if we were to secure sufficient amounts for subsequent physical/chemical studies.[2, 3] And the route had to be flexible enough to give, in addition to the looped diesters, the diether analogues (interesting molecules because of their similarity to lipids of archaebacterial thermophiles).[6] Our answer to the synthetic challenge is described in the ensuing text.



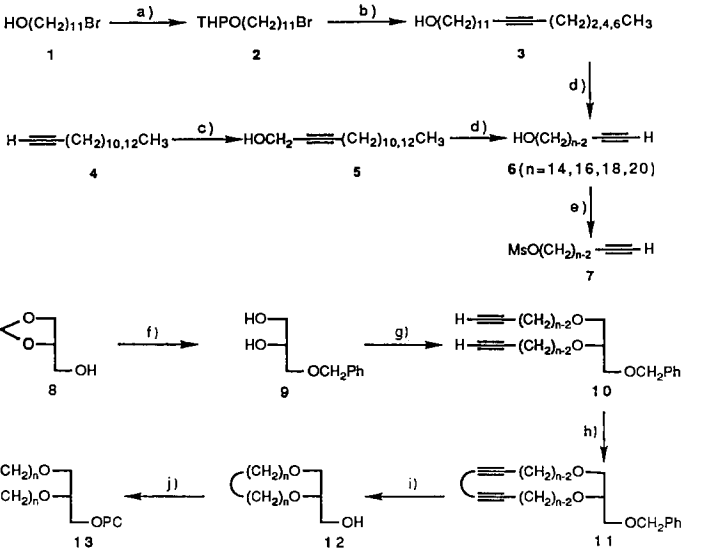
(a)

Our method is based on Glaser oxidation of dialkynyl compounds [Eq. (a)]. When the reaction was carried out by slow addition of the dialkynyl compound (syringe pump, 4–5 h), and at higher than usual temperatures (140 °C), yields were consistently and reproducibly high (Table 1). The procedure seems preferable to those used in the only two previously reported syntheses of cyclic lipids.[5]

Table 1. Yields for high-temperature Glaser cyclization of seven giant-ring lipids [a].

Lipid type	Ring size	Yield [%]
Diester	32	52
Diester	36	64
Diester	40	60, 68
Diether	32	78, 79
Diether	36	83
Diether	40	77, 78, 85
Diether	44	71

[a] Reactions were conducted with 0.9 to 2.8 g diyne as described in the text. Yields refer to the amounts of material after purification by column chromatography.



Scheme 1. a) Dihydropyran (DHP), *p*-TsOH, 90%; b) 1. 1-alkyne, *n*BuLi, hexamethylphosphoric triamide (HMPA); 2. MeOH, *p*-TsOH, pH = 3–4, 75%; c) 1. *n*BuLi, HMPA; 2. $(CH_2O)_n$, 84%; d) 1. Li, $H_2N(CH_2)_3NH_2$; *t*BuOK, (from **3**), 44% (from **5**), 70%; e) MesCl, Et_3N, 90%; f) 1. $PhCH_2Cl$, dimethylsulfoxide (DMSO), powdered KOH; 2. 10% HOAc, 90 °C, 66%; g) powdered KOH, DMSO, **7**, 76%; h) O_2, CuCl, TMEDA, 140 °C, 71–85%; i) H_2, 10% Pd/C, 60–74%; j) 1. 2-chloro-2-oxo-1,3,2-dioxaphospholane, Et_3N, benzene, 2 h; 2. Me_3N, MeCN, 60–65 °C, 48 h, 35–66%.

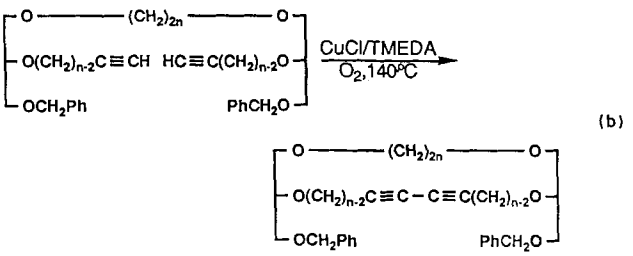
A total synthesis of the cyclic ether lipids, incorporating our high-temperature Glaser cyclization as its key step, is given in Scheme 1. The corresponding cyclic diester phospholipids were prepared by first esterifying (*R*)-3-benzyloxy-1,2-propanediol with two equivalents of an ω-alkynyl fatty acid and then proceeding as outlined for **10** → **13** in Scheme 1.

Reaction (b) exemplifies the surprising ease with which giant rings are constructed under the modified Glaser condi-



tions described here. Thus, chromatographically pure macrocycles of 64 atoms ($n = 14$) and 72 atoms ($n = 16$) were formed in 66 and 54% yield, respectively. Reaction (b) provides an entry into new "double" phospholipids.

It is unclear why giant-ring formation is so efficient, especially since the chains are devoid of substituents that often aid ring closures leading to macrocycles. Perhaps van der Waals attractions promote side-by-side alignment of the chains, although this would favor both intramolecular closures and the competing intermolecular reactions.

Differential scanning calorimetry studies[7] show that the cyclic ester lipids have higher transition temperatures than their acyclic counterparts. For example, transition temperatures of 41.7, 55.6, and 66.5 °C have been recorded for the acyclic series with 16, 18, and 20 carbon atoms per chain, respectively. Linking the chain ends raises these values to 50.4, 70.1, and 82.6 °C, respectively. Clearly, cyclization produces a substantial barrier to chain-melting.

Experimental Procedure

In a typical cyclization reaction 0.37 g of copper(I) chloride and 0.60 mL of tetramethylethylenediamine were added to 200 mL of reagent-grade xylenes in a 500 mL, three-necked flask fitted with a reflux condenser. Oxygen was bubbled through the mixture with a glass pipet while heating at 140 °C with an oil bath. A solution of 1.02 g of the diyne in 40 mL of xylenes was added over 4 h with a syringe pump. The reaction mixture was cooled and concentrated to dryness. The residue was dissolved in 300 mL of ethyl acetate and washed with 100 mL of water and 5% HCl. The organic layer was dried over Na_2SO_4 and the solvent removed to give the crude product. The material was purified by chromatography (60 Å silica gel, 200–425 mesh) eluting with ethyl acetate/hexane (1:6) to obtain 0.78 g (77%) of product (pure by NMR spectroscopy). Hydrogenation of the giant ring and cleavage of the benzyl group gave an alcohol with the correct elemental analysis and ^1H NMR, ^{13}C NMR, and FAB mass spectra.

Arborols Based on Luminescent and Redox-Active Transition Metal Complexes**

By *Scolastica Serroni, Gianfranco Denti,* Sebastiano Campagna,* Alberto Juris, Mauro Ciano,* and *Vincenzo Balzani**

The development of strategies for synthesizing supramolecular species ("nanostructures") with specific functions is one of the most important challenges now facing chemistry.[1] "Cascade molecules"[2–4] (also called arborols or dendrimers) are of great interest in this regard. We have designed a strategy to obtain arborols, based on transition metal complexes, which exhibit interesting photophysical and electrochemical properties. In this paper we illustrate our synthetic strategy and report the properties of a luminescent and redox-active arborol which contains 22 metal centers.

[**] This work was supported by the Ministero della Università e della Ricerca Scientifica e Tecnologica and by the Consiglio Nazionale delle Ricerche (Progetto Finalizzato Chimica Fine II and Research Grant 91.03355-CT03). We wish to thank V. Cacciari for technical assistance.

The arborols described here are polynuclear metal complexes with Ru^{II} as the metal ion, 2,3-bis(2-pyridyl)pyrazine (2,3-dpp) as the bridging ligand, and 2,2'-bipyridine (bpy) as the terminal ligand (Fig. 1). Extension to other metal ions (e.g., Os^{II}), bridging ligands (e.g., 2,5-dpp), and terminal ligands (e.g., 2,2'-biquinoline) is straightforward.[5]

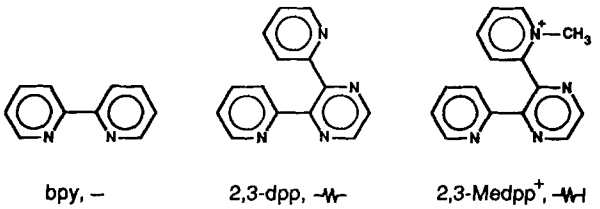

Fig. 1. Formulas, abbreviations, and graphic symbols for the ligands.

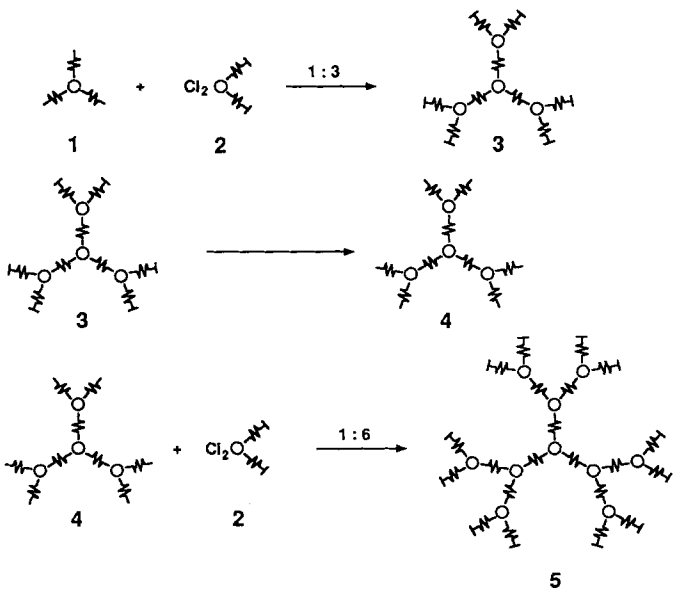
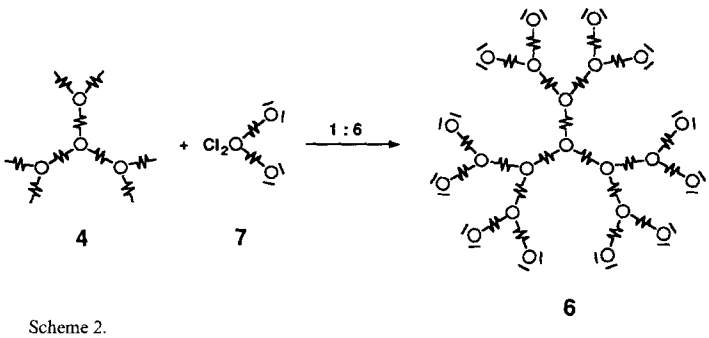
The synthetic method, illustrated in Scheme 1 (for the symbols see Fig. 1), is based on a protection/deprotection procedure in which a complex is used as a ligand and another is used as a metal ("complexes-as-ligands/complexes-as-metals" synthetic strategy).[5, 6] The first step is the construction of a core, $[Ru(2,3\text{-}dpp)_3]^{2+}$ (**1**), which contains three open sites for chelation (complex as ligand). At each of these sites, a bifurcate branch can be grafted (Scheme 1, top) by using the novel $[Ru(2,3\text{-}Medpp)_2Cl_2]^{2+}$ (**2**) building block (for 2,3-$Medpp^+$ see Fig. 1). The dication **2** contains two easily replaceable Cl^- ligands (and therefore the complex can play the role of a metal) and two bridging ligands in which the chelating sites not used for metal coordination have been protected by methylation. The reaction of **1** with **2** leads to the novel tetranuclear metal complex **3** (first generation of our arborols). Deprotection of the six peripheral chelating sites of **3** (Scheme 1, middle) yields compound **4**, to which six units of the building block **2** can again be grafted, to yield a second-generation compound (**5**, Scheme 1, bottom). In principle, the above procedure can be iterated to obtain larger species by a divergent synthetic approach. If the bridging ligands of the building block **2** are replaced by simple chelating ligands like bpy, the species obtained are "sterile" since they can no longer be used as "cores" for larger structures.



Scheme 1. The circles represent ruthenium atoms. The other symbols are explained in Figure 1.

To explore the feasibility of the synthetic strategy illustrated in Scheme 1, we prepared the docosanuclear[7] metal complex **6** (Scheme 2) which, to our knowledge, is the largest Werner-type transition metal complex obtained so far.

The dication **1** was prepared as previously described.[5a, 8] The treatment of 2,3-$Medpp^+$[9] with $RuCl_3 \cdot 3H_2O$ in water/ethanol 1:2 (v/v) containing a sevenfold excess of LiCl afforded **2** (yield 90% after purification by size exclusion chromatography (SEC)). Reaction of **2** with **1** (3:1 molar ratio; water/ethanol 1:2; pretreatment with $AgNO_3$) gave **3** in 70% yield after purification. Demethylation of the chelating sites of **3** (dry CH_3CN, large excess of diazabicyclo[2.2.2]octane (DABCO), reflux) gave rise to **4** (yield 60% after purification). The novel compounds **2**–**4** were characterized by elemental analysis (as PF_6^- salts), by NMR, IR, UV/VIS, and luminescence spectra, and by their conductivities and electrochemical behavior.[10] Reaction of **4** with the trinuclear building block $[Ru\{(\mu\text{-}2,3\text{-}dpp)Ru(bpy)_2\}_2Cl_2]^{4+}$ (**7**)[9] gave **6** in 73% yield after purification (Scheme 2).[13, 14]



Scheme 2.

If the PF_6^- counterions are neglected, **6** is made of 1090 atoms, has a relative molecular mass of 10890, and an estimated size of about 5 nm. Its absorption spectrum extends across the UV/VIS spectral region (ε = 681500 $M^{-1}cm^{-1}$ at 284 nm and ε = 202400 $M^{-1}cm^{-1}$ at 542 nm). It exhibits a luminescence band with a maximum at 784 nm in acetonitrile solution at room temperature and at 730 nm in methanol/ethanol 4:1 (v/v) at 77 K (rigid matrix), as expected for peripheral $[Ru(bpy)_2(\mu\text{-}2,3\text{-}dpp)]^{2+}$ units.[5, 11e, f] Upon electrochemical oxidation, a peak corresponding to twelve electrons is observed at 1.52 V vs. saturated calomel electrode (SCE) (ΔE_p = 220 mV), as expected for oxidation of twelve equivalent and weakly interacting peripheral units.[5b, 17]

In conclusion, we have designed a general synthetic strategy to obtain luminescent and redox-active arborols from building blocks made of transition metal complexes. By choosing building blocks of different composition (e.g., $[Cl_2Os(2,3\text{-}Medpp)_2]^{2+}$ or $[Cl_2Ru(2,5\text{-}Medpp)_2]^{2+}$ in the place of **2**), it will be possible to obtain arborols made of concentric shells each chemically different,[5b] that is, to create species with a high information content which could be used for the design of photochemical molecular devices[18] (e.g., for light harvesting in solar energy conversion systems[19]).

[10] NMR: ^{1}H NMR spectrum of **2** and **3** in [D$_3$]acetonitrile solution showed several signals between $\delta = 4.20$ and 4.47 that can be attributed to *N*-methyl groups of different stereoisomers. These signals completely disappear on demethylation and are, in fact, absent in **4**. Conductivity values (Ω^{-1}cm^{-1}mol^{-1}; 1.0×10^{-3} M solutions in acetonitrile, 20 °C): **2**, 364.0; **3**, 874.7; **4**, 472.3. IR [5, 9, 11]: the most characteristic bands are those of bridged (system of four bands between 1470 and 1390 cm^{-1}), unbridged (990 cm^{-1}), and *N*-methylated (1626 cm^{-1}) 2,3-dpp ligands. UV/VIS spectra (acetonitrile solutions) [5, 11]: ligand-centered 2,3-dpp bands: λ_{max} [nm] (ε, [M^{-1}cm^{-1}]): **2**, 304 (25100); **3**, 296 (137000); **4**, 264 (108000); metal-to-ligand charge transfer bands: λ_{max} [nm] (ε, [M^{-1}cm^{-1}]): **2**, 575 (8490); **3**, 456 (42600); **4**, 461 (38200). Luminescence at 298 K (in acetonitrile solution) [5]: λ_{max} [nm]: **3**, 714; **4**, 722; at 77 K (methanol/ethanol 4:1 (v/v) rigid matrix) [5]: λ_{max} [nm]: **3**, 700; **4**, 698. Compound **2** is not emissive. Electrochemical oxidation (potentials [V] vs. SCE; number of electrons involved; ΔE_p [mV] [12]: **2**: +0.63, 1, 70, **3**: +1.70, 3, 110; electrochemical analysis of **4** was prevented by adsorption of the compound at the electrodes.

[12] Acetonitrile was used as solvent and tetrabutylammonium tetrafluoroborate as supporting electrolyte. Cyclic voltammograms were usually obtained at a scan rate of 20 mV s^{-1}. Differential-pulse voltammetry was performed with a scan rate of 20 mV s^{-1}, a pulse height of 50 mV, and a duration of 50 ms. Ferrocene (5×10^{-4} M) was employed as a reference. The multielectron nature of some peaks was elucidated as in ref. [5b].

[13] [Ru{(μ-2,3-dpp)Ru(bpy)$_2$}$_2$Cl$_2$](PF$_6$)$_4$ (**7**) (0.084 g, 0.042 mmol) in water/ethanol 1:1 (v/v) (5 mL) was treated with silver nitrate (0.014 g, 0.084 mmol). After the mixture had been stirred at room temperature for 2 h, a solution of [Ru{(μ-2,3-dpp)Ru(2,3-dpp)$_2$}$_3$](PF$_6$)$_8$ (**4**) (0.025 g, 0.007 mmol) in ethylene glycol (3 mL) was added. The reaction mixture was refluxed for seven days, then cooled to room temperature. AgCl was separated by repeated centrifugations, the mother liquor concentrated by evaporation in vacuum, and an excess of solid NH_4PF_6, methanol (2 mL), and diethyl ether (10 mL) were added. The crude product was filtered off and then purified by SEC on Sephadex G-75 (acetonitrile eluant). The eluate was concentrated in a rotary evaporator to 2 mL, and the product **6** was recovered as a cyclamen (very dark reddish purple) powder by addition of diethyl ether (about 15 mL). Yield: 0.086 g (73%) after purification. Anal.: Calcd. including 25 H_2O: C 36.2, H 2.6, N 10.0. Found: C 35.9, H 2.3, N 10.4. Conductivity [Ω^{-1}cm^{-1}mol^{-1}] (1.0×10^{-3} M solution in acetonitrile, 20 °C): 2297.4. IR: system of four bands between 1470 and 1390 cm^{-1}, typical of bridged 2,3-dpp. No typical band for unbridged 2,3-dpp at 990 cm^{-1} is present.

[14] In principle, the complexes **1**–**7** can exist as different isomers, depending on the arrangement of the ligands around the metal ions. A careful analysis of the 2D-COSY 400 MHz ^{1}H NMR spectrum of the [Ru(2,3-dpp)$_3$]$^{2+}$ precursor that permitted a complete assignment of the signals [15], has shown that the purified material was obtained as a mixture of the *mer* and *fac* isomers in which the *mer* isomer was predominant (92%). The oligometallic complexes can also be a mixture of several diastereoisomeric species, since each metal center is also a stereogenic center. For these reasons structural investigations on these systems are difficult [11e]. Differences arising from the presence of isomeric species are not expected to be large in the electrochemical and spectroscopic results described in this paper [16].

A New Approach to Bis(arene)titanium(0) and -titanium(−1) Complexes; Structure of Bis(arene)titanates(1−)

By *David W. Blackburn, Doyle Britton,* and *John E. Ellis**

Dedicated to Professor Wolfgang Beck on the occasion of his 60th birthday

Until very recently[1] bis(arene)titanium complexes were prepared only by metal atom–ligand cocondensations that employed either titanium[2–7] or potassium[8,9] atoms as key reagents. These procedures required the use of specialized equipment[10] unavailable to most chemists. We now report the syntheses of compounds of this class that do not utilize metal atoms or metal-atom reactors and also describe the first structural characterizations of bis(arene)titanate monoanions, of which only two examples were previously known.[11] Our method involves the reduction of $TiCl_4 \cdot 2\,THF$ by arene anions and requires only conventional laboratory apparatus and procedures.

Although there is a rich tradition in employing arene anions, especially the naphthalene radical anion, in inorganic and organometallic syntheses,[12] surprisingly few reports on their designed use as reagents for the syntheses of bis(arene)metal complexes exist.[13,14] Indeed, to our knowledge, [Cr(biphenyl)$_2$]$^+$[15] and [Cr(tetralin)$_2$][16] are the only examples of such compounds to be isolated from the interaction of arene anions and transition metal reagents in syntheses not involving the use of metal atoms.[17]

Equations (a) and (b) summarize the syntheses of new Ti compounds, (see Experimental Procedure for further details).

W. B. thanks the NSF for a predoctoral fellowship. Part 29: J. E. Ellis, K.-M. Chi, A. J. DiMaio, S. R. Frerichs, J. R. Stenzel, A. L. Rheingold, B. S. Haggerty, *Angew. Chem.* **1991**, *103*, 196; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 194.

$$TiCl_4 \cdot 2THF + 5K(arene) \xrightarrow[THF]{-78\,^\circ C} \underset{\mathbf{K[1]},\ \mathbf{K[2]}}{K[Ti(arene)_2]} + 3arene + 4KCl \quad (a)$$

$$K[Ti(arene)_2] + 1/2\,I_2 \xrightarrow[THF]{-78\,^\circ C} \underset{\mathbf{3,\ 4}}{[Ti(arene)_2]} + KI \quad (b)$$

1, **3**: arene = biphenyl **2**, **4**: arene = 4,4′-di-*tert*-butylbiphenyl

The deep purple, paramagnetic anions **1** and **2** were isolated as satisfactorily pure $[K([15]crown\text{-}5)_2]^+$ or [K([2.2.2]-cryptand)]$^+$ salts ([2.2.2]cryptand = 4,7,13,16,21,24,-hexaoxa-1,10-dazobicyclo[8.8.8]hexacosane) in 70–80% yields, while the deep green, diamagnetic metallocenes **3** and **4** were best obtained by an in situ oxidation of freshly prepared **1** and **2**, respectively, with I_2 in [Eq. (b)]. Potassium ion complexants were unnecessary in the latter syntheses, which provided 20–30% yields of satisfactorily pure **3** and **4**. These complexes are both thermally robust species as pure solids (decomp ca. 170 °C) and have NMR and mass spectra which are consistent with the assigned formulations (cf. Experimental Procedure). The purified complexes **3** and **4** do not appear to be contaminated by products of the type $[Ti_2(arene)_2]$ or $[Ti_2(arene)_3]$, analogous to known chromium complexes where arene is biphenyl.[18]

Anion **1** has been shown to undergo facile carbonylation at low temperature to provide, after workup, a 56% isolated yield [Eq. (c)] of the known [K([2.2.2]cryptand)]$_2$

$$2[K([2.2.2]cryptand)][\mathbf{1}] + CO(1\ atm) \xrightarrow[-70\,^\circ C,\ 12\,h]{THF} [K([2.2.2]cryptand)]_2[Ti(CO)_6] + \ldots \quad (c)$$

$[Ti(CO)_6]$.[19] This is the first reaction to be reported for a bis(arene)titanate(1−) and suggests that similar complexes are involved in the original, "phosphane-free" alkali metal naphthalenide route to $[Ti(CO)_6]^{2-}$.[19] It is anticipated that these and related labile bis(arene)titanium species will have a rich chemistry.

Single-crystal X-ray studies on **1** and **2** as [K([2.2.2]-cryptand)]$^+$ salts were carried out to confirm their existence in the solid state and thereby provide the first structural characterization of bis(arene)metalates(1−) of the Group 4 elements.[20] Figure 1 depicts the unit cell of [K([2.2.2]cryptand)][**1**] showing two independent bis(biphenyl)-titanate(1−) ions, **1A** and **1B**, which are essentially *anti* and *syn* rotamers, respectively. Both **1A** and **1B** are situated at a center of symmetry in the unit cell. In **1A** the Ti atom lies on the inversion center as the ion is completely ordered. The center in **1B** is between two half-occupied Ti positions.[21] The disorder of the Ti atoms is paralleled by a real but not obvious disorder in the phenyl rings since each phenyl ring depicted is the superposition of equal numbers of bound and free rings. Since the positions of the carbon atoms in the latter are averaged, large uncertainties are present in the interatomic distances for **1B**: average Ti–C distance is 2.2(2) and the average C–C distance in the ring 1.40(2) Å. However, the corresponding values for **1A** are more precise and informative: the average distances are Ti–C 2.27(2), C–C in the bound ring 1.42(1), C–C in the free ring 1.39(1), Ti–ring plane 1.78(2) Å. The dihedral angle between the bound and free ring is 31°. The bound rings in **1A** are eclipsed, parallel

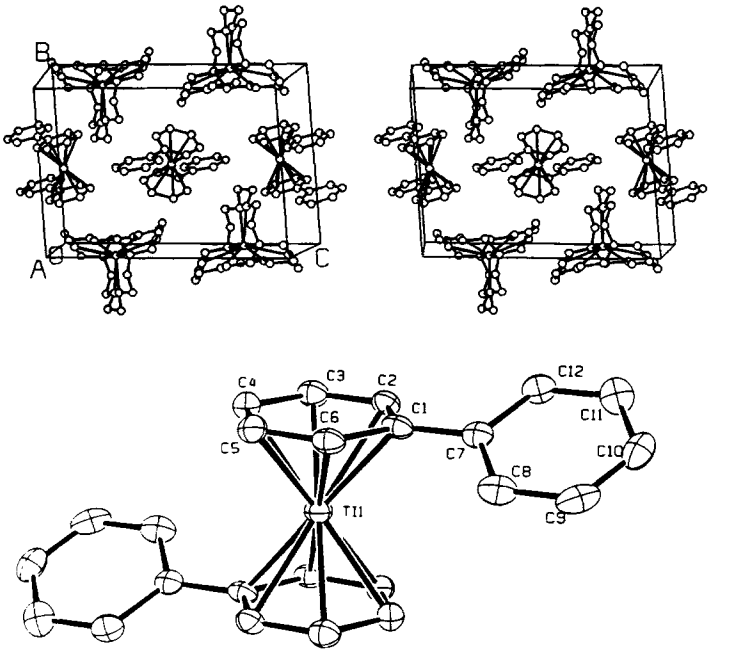

Fig. 1. Top: Stereoview of the unit cell of [K([2.2.2]cryptand)][**1**] showing independent anions **1A** and **1B** and cations. Note that the *syn* rotamer, **1B**, lies on a center of symmetry, and the titanium has half occupancy at each site. For clarity one of the two titanium positions in **1B** has been omitted. Each ring in **1B** is an average of one bound and free phenyl group, and therefore the carbon positions are averaged. Bottom: View of **1A**. Important bond lengths [Å]: Ti-C1 2.290(4), Ti-C2 2.284(4), Ti-C3 2.277(5), Ti-C4 2.271(5), Ti-C5 2.265(4), Ti-C6 2.256(5), C1-C2 1.416(6), C1-C6 1.442(6), C2-C3 1.418(6), C3-C4 1.414(6), C4-C5 1.412(7), C5-C6, 1.421(7), C1-C7 1.472(6), C7-C8 1.394(7), C7-C12 1.402(6), C8-C9 1.386(7), C9-C10 1.386(7), C10-C11 1.371(7), C11-C12 1.387(7).

to each other, and planar. Corresponding data for **2** (Fig. 2) are quite similar to those for **1A**, that is, the average distances are Ti–C 2.29(4), C–C in the bound ring 1.42(2), C–C in the free ring 1.38(2), Ti–ring plane 1.79(1) Å; the bound rings are planar. However, unlike **1**, the bound rings are tilted (dihedral angle 7.6°), and their distance from each other is greatest (3.7 Å) near the *tert*-butyl groups. Also, as shown in a view of **2** approximately down the centroid–centroid vector of the bound rings (Fig. 2 bottom), the latter are substantially staggered, apparently to minimize interactions of the 4-*tert*-butylphenyl and 4′-*tert*-butylphenyl substituents on neighboring rings. In both salts the cations are well separated from the anions in the crystalline lattices, and the geometry of the [K([2.2.2]cryptand)]$^+$ units is essentially identical and in good agreement with the structure of the corresponding iodide salt.[22] Bis(benzene)titanium(0) and bis(toluene)titanium(0) are the only other bis(arene)titanium species for which structural data have been reported.[23] They both contain shorter Ti–ring plane (average 1.74 Å) and Ti–C distances (average 2.24 Å) than those in **1** and **2**. Bis(mesitylene)vanadate(1−) is apparently the only other anionic bis(arene)metal complex to have been structurally characterized.[24]

We are currently investigating whether arene anions are generally useful for the syntheses of bis(arene) complexes of other metals.

Experimental Procedure

All operations except the carbonylation step were conducted under an atmosphere of argon.

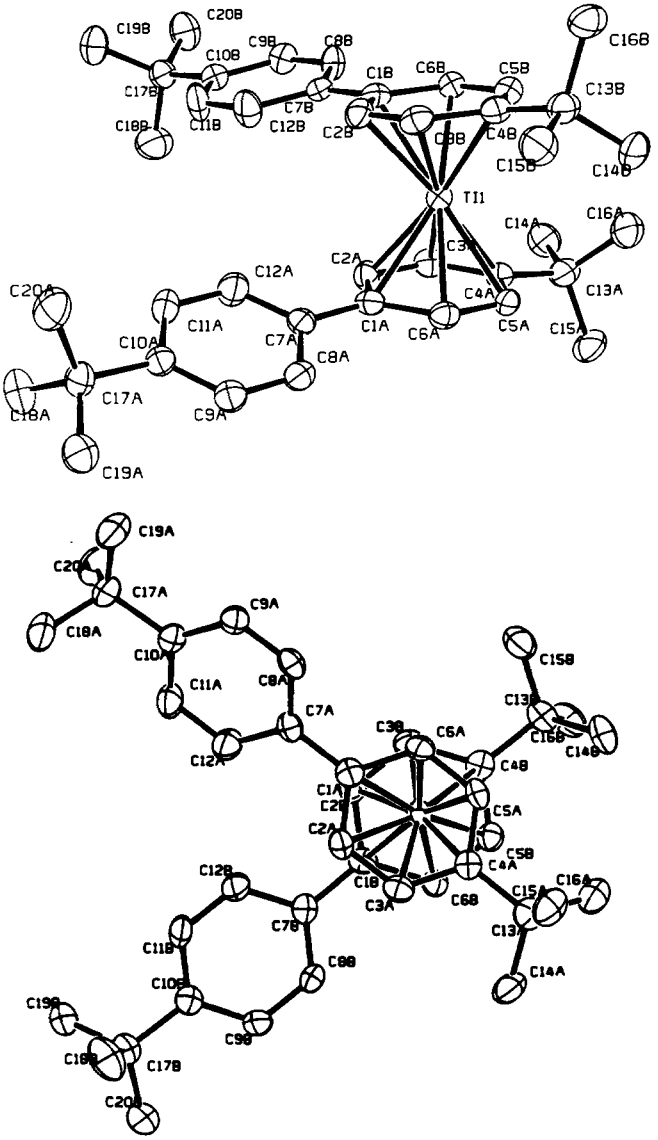

Fig. 2. Top: Molecular structure of **2**. Important bond lengths [Å]: Ti-C1A 2.299(6), Ti-C2A 2.254(5), Ti-C3A 2.267(6), Ti-C4A 2.318(5), Ti-C6A 2.283(6), Ti-C1B 2.286(6), Ti-C2B 2.250(6), Ti-C3B 2.284(6), Ti-C4B 2.334(6), Ti-C5B 2.298(6), Ti-C6B 2.273(6), C1A-C2A 1.426(8), C1A-C6A 1.434(8), C2A-C3A 1.416(8), C3A-C4A 1.419(8), C4A-C5A 1.423(8), C4A-C13A 1.539(8), C1A-C7A, 1.471(8), C7A-C8A 1.388(8), C7A-C12A 1.393(8), C8A-C9A 1.397(8), C9A-C10A 1.394(8), C10A-C11A 1.372(9), C11A-C12A 1.384(8), C10A-C17A 1.537(8). Bottom: View of **2** approximately down the centroid–centroid vector of the bound rings.

[K([15]crown-5)$_2$][**1**]: A cold (−78 °C) solution of $TiCl_4 \cdot 2THF$ (1.67 g, 5.00 mmol) in THF (175 mL) was added to a deep blue solution (−78 °C) of $K[C_{12}H_{10}]$ (25.2 mmol) in THF (200 mL). The reaction mixture changed to the deep purple color, characteristic of **1**, while the solution slowly warmed from −78 °C to room temperature over 15 h. It was then filtered into a solution of [15]crown-5 (2.2 g, 10 mmol) in THF (25 mL). After the mixture had been stirred for 2 h, the solvent was removed in vacuo. The resulting crude product was purified by crystallization from THF/heptane and washed thoroughly to remove unchanged biphenyl. In this manner 3.13 g (75% yield based on Ti) of purple-black microcrystalline solid was obtained (correct analysis for C, H, K, Ti). The corresponding $[K([2.2.2]cryptand)]^+$ salt was prepared and isolated by the same procedure in 81% yield. A saturated THF solution of the latter product was layered with excess diethyl ether/heptane (2:1 by volume). Long swordlike iridescent green crystals were slowly deposited from this solution over ten days at room temperature. One of these was selected for the X-ray study.

Reaction of [K([2.2.2]cryptand)][**1**] with CO: A cold solution (−70 °C) of [K([2.2.2]cryptand)] [**1**] (1.00 g, 1.30 mmol) in THF (250 mL) was stirred under CO at atmospheric pressure for 12 h while slowly warming to room temperature. A soluble carbonyl complex of unknown composition and an insoluble component were present. The latter was isolated and recrystallized from pyridine/THF; yield: 0.38 g (56%) of the previously described $[K([2.2.2]cryptand)]_2[Ti(CO)_6]$ [19].

[K([2.2.2]cryptand)][**2**] · THF: By analogous methods the reaction of $TiCl_4 \cdot 2THF$ (0.541 g, 1.62 mmol) with $K[4,4'\text{-}tBu_2C_{12}H_8]$ (9.80 mmol) in THF (300 mL) provided a deep purple solution which was filtered, the filtrate stirred with [2.2.2]cryptand (1.22 g, 3.24 mmol) for 3 h at room temperature, and the solvent removed in vacuo. The resulting crude black solid was crystallized from THF/pentane to provide 1.72 g (93% yield based on Ti) of purple-black microcrystalline product, which provided satisfactory elemental analyses (C,H). A cold saturated THF solution of this material was layered with excess heptane. After seven days at −30 °C square platelike crystals had formed, which were used in the X-ray study.

3: A solution of K[**1**] was prepared as described above from the reduction of $TiCl_4 \cdot 2THF$ (3.34 g, 10.0 mmol) by $K[C_{12}H_{10}]$ (51.4 mmol), and a solution of I_2 (1.27 g, 5.00 mmol) in THF (100 mL) was then added dropwise at −40 °C. Removal of solvent from the resultant green solution gave a crude product. This was crystallized from THF/pentane to provide 0.82 g (23% based on $TiCl_4 \cdot 2THF$) of deep green microcrystalline **3**, which gave satisfactory elemental analyses (C, H, Ti; m.p. 170 °C (decomp)). ^1H NMR (300 MHz, C_6D_6, 20 °C): $\delta = 4.9$ (m, 6H; bound ring CH); 5.38 (m, 4H; bound ring CH); 6.9–7.2 (br m, 10H; free ring). $^{13}C\{^1H\}$NMR (75 MHz, C_6D_6, 20 °C) $\delta = 83.0$, 83.6, 84.1 (bound ring C); 124.8, 125.5, 129.0 (free ring C), quaternary carbons not observed; high-resolution mass spectrum: calcd for $^{12}C_{24}\ ^1H_{20}\ ^{48}Ti$: 356.1044; found, 356.1060.

4: A solution of K[**2**] was prepared as described above from the reduction of $TiCl_4 \cdot 2THF$ (1.67 g, 5.00 mmol) by $K[4,4'\text{-}tBu_2C_{12}H_8]$ (25.2 mmol) in THF (400 mL) at −70 °C, and a solution of I_2 (0.63 g, 2.50 mmol) in THF (50 mL) added dropwise at room temperature. After 39 mL of the latter had been added, the purple color of K[**2**] was replaced by the dark green color of **4**, and the addition of I_2 was stopped. Removal of solvent from the reaction mixture gave a crude product, from which free 4,4'-di-*tert*-butylbiphenyl was removed by sublimation (75 °C, 10^{-5} Torr). Recrystallization of the residue from pentane provided 0.81 g (28% based on $TiCl_4 \cdot 2THF$) of greenish-black **4**; satisfactory elemental analyses (C, H, Ti; m.p. 175 °C (decomp)). ^1H NMR (300 MHz, C_6D_6, 20 °C) $\delta = 1.18$ (s, 18H; *t*Bu of free ring), 1.26 (s, 18H, *t*Bu of bound ring), 5.08, 5.44 (AA'BB', $J = 8$ Hz, 8H; protons on bound ring), 7.29, 7.52 (AA'BB', $J = 9$ Hz, 8H; protons on free ring) $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 20 °C) $\delta = 31.5$ ($C(CH_3)_3$ on free ring), 32.3 ($C(CH_3)_3$ on bound ring), 34.4 ($C(CH_3)_3$ on free ring), 34.9 ($C(CH_3)_3$ on bound ring), 83.5, 85.3 (*C*H groups of bound ring), 95.6 ($CC(CH_3)_3$ of bound ring), 117.0 (CC_5H_4tBu of bound ring), 124.2, 125.6 (*C*H groups of free ring), 139.1 ($CC(CH_3)_3$ of free ring), 148.1 (CC_5H_4tBu of free ring). Assignments of the ^1H and ^{13}C NMR signals of the uncoordinated ring in the complex were made on the basis that they closely matched those of the free arene ligand (same solvent, temperature, concentration). The remaining signals were then assigned to those of the coordinated ring. High-resolution mass spectrum: calcd for $^{12}C_{40}\ ^1H_{52}\ ^{48}Ti$: 580.3548; found, 580.3514.

[20] Crystal data for [K([2.2.2]cryptand)][**1**]: $C_{84}H_{112}N_4O_{12}K_2Ti_2$: triclinic, $P\bar{1}$ (no. 2), $a = 11.250(7)$, $b = 11.338(6)$, $c = 15.90(1)$ Å, $\alpha = 94.50(5)$, $\beta = 105.34(6)$, $\gamma = 95.02(5)°$, $V = 1937(5)$ Å^3, $Z = 1$, $\varrho_{calcd} = 1.323$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 3.72$ cm^{-1}, Crystal dimensions: $0.60 \times 0.50 \times 0.15$ mm^3. The intensities of 7581 reflections were measured at -105 °C ($0 < \theta < 26°$) on an Enraf-Nonius CAD 4 diffractometer using $Mo_{K\alpha}$ radiation. The structure was solved by direct methods and all non-hydrogen atoms were refined anisotropically (full-matrix least squares). For 4806 unique observed reflections [$(I) \geq 2.0\,\sigma(I)$], $R = 0.061$ and $R_w = 0.082$. Crystal data for [K([2.2.2]cryptand)][**2**] · THF: $C_{62}H_{96}N_2O_7KTi$: monoclinic $P2_1/n$ (no. 14), $a = 11.829(9)$, $b = 21.40(1)$, $c = 23.77(1)$ Å, $\beta = 91.95(5)°$, $V = 6013(1)$ Å^3, $Z = 4$, $\varrho_{calcd.} = 1.180$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 2.58$ cm^{-1}, crystal dimensions: $0.55 \times 0.55 \times 0.35$ mm^3. 9574 reflections were measured at -101 °C ($0 < \theta < 24°$) on an Enraf-Nonius CAD4 diffractometer using $Mo_{K\alpha}$ radiation. The structure was solved by direct methods and all non hydrogen atoms were refined anisotropically (full matrix least squares). For 5142 unique observed relections [$(I) \geq 2.20\,\sigma(I)$], $R = 0.057$ and $R_w = 0.067$. Further details of the crystal structure investigations are available on request from the Director of Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW (UK) on quoting the full journal citation.

[21] When first solved, the structure appeared to contain both $[Ti(biphenyl)_2]^-$ and the "dimeric" $[Ti_2(biphenyl)_2]^-$. However, the R value was poor (0.099) and the temperature factor for the titanium in the dimeric anion was about twice the size of the atoms to which it was connected. This, and the chemical evidence, suggested that the "dimer" was really another form of $[Ti(biphenyl)_2]^-$ in a disordered centric location. Refinement with Ti2 having half occupancy converged with $R = 0.061$ and with a reasonable temperature factor.

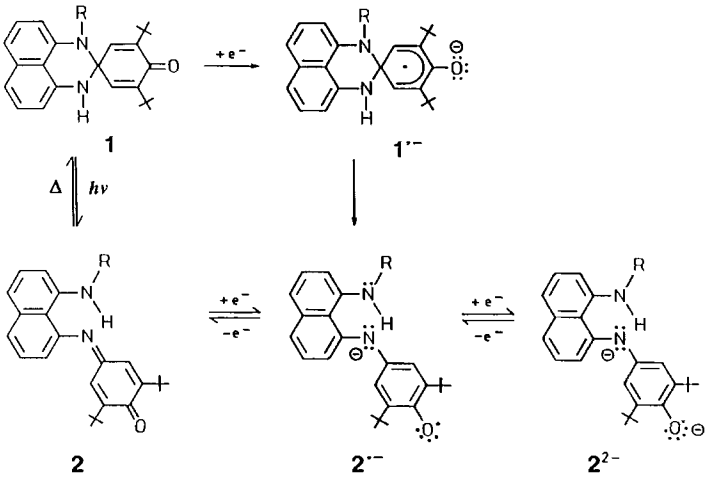
Molecular Switching by Electron Transfer—the Spiroperimidine/Quinonimine System**

By *Josef Salbeck, Vitaly N. Komissarov, Vladimir I. Minkin,* and *Jörg Daub**

Building blocks for molecular memory devices, sensors, and switches contain components with two or more metastable states. Dyes containing functional groups occupy a prominent position amongst them.[1, 2] According to previous studies, spiroperimidine (**1**) shows photochromic behavior; the forward reaction forming quinonimine (**2**) was photochemical ($\lambda_{max} = 615$ nm, in hexane) and the reverse reaction **2** → **1** thermal (Scheme 1).[3] We now report a reversible rearrangement **1**/**2** with electrochemical activation.



Scheme 1. R = CH_3.

The cyclic voltammogram of **1** (Fig. 1a) shows an irreversible reduction signal [$E_p^r = -2150$ mV vs. ferrocene (Fc)], two back-oxidation signals shifted to distinctly more positive potentials (E_p^{o1} and E_p^{o2}), and a pronounced crossing effect (arrow) of reduction and oxidation traces (trace crossing). Such a curve form is evidence for the stability and reactivity of the radical anions and can be attributed to a homogeneous disproportionation of the radical anion $\mathbf{1}^{\bullet-}$.[4]

We deduce from the thin-layer voltammogram (Fig. 1b) that two electrons are transferred on reduction, whereas the two oxidation steps are one-electron transfers. Furthermore, a multisweep experiment shows that from the second cycle a corresponding reduction signal is present for both oxidation steps, while the original reduction signal of the starting compound no longer appears: **1** is thus reduced to a dianion in a multistep process consisting of electrochemical and chemical substeps (ECE step sequence). Through the valence isomerization occurring at the radical anion stage, $\mathbf{1}^{\bullet-} \rightarrow \mathbf{2}^{\bullet-}$, the acceptor capability of the compound is raised so much that the redox potential for dianion formation of the quinoid form becomes more positive than E_p^r. For this reason only a single, but more intense wave is observed for the first reduction in the cyclic voltammetric experiment. After reversing the potential scan, two distinctly separated voltammetric signals appear, which correspond to the oxidation of $\mathbf{2}^{2-}$ via $\mathbf{2}^{\bullet-}$ to **2**. Since in the thin-layer voltammogram the compound **2** formed in the first cycle cannot diffuse away from the electrode into the solution and the thermal rearrangement of **2** to **1** is slow at room temperature, the subsequent cycles show only the reduction of **2** via $\mathbf{2}^{\bullet-}$ to $\mathbf{2}^{2-}$ and the corresponding back oxidation. The original signal for **1** is no longer observed. The overall process is summarized in Scheme 1.[5] The cycle **1** → $\mathbf{2}^{2-}$ → $\mathbf{2}^{\bullet-}$ → **2** induced by reduction/oxidation is also confirmed by UV/VIS/near IR spectroelectrochemistry. With this experimental technique the

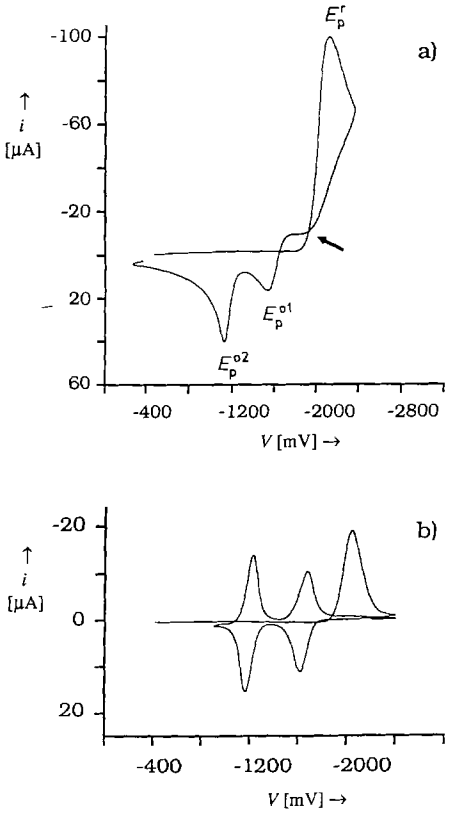

Fig. 1. Cyclic voltammetry (CV): a) semi-infinite conditions, reduction of **1** and back oxidation (in acetonitrile/nBu$_4$NPF$_6$ 0.1 M, $c = 2.5$ mM, $v = 250$ mVs^{-1}), b) thin-layer CV (double cycle), layer thickness $d = 15$ μm, $v = 25$ mVs^{-1}.

thermal back reaction of the electrochemically formed quinoid form to the spiro form (**2** → **1**) could also be detected, which proves the complete reversibility of the overall cycle. The absence of side reactions during the transformations is characterized by isosbestic points. Electrochemical and spectroscopic data of the individual species and intermediates are listed in Table 1.

Table 1. Reduction potentials $E_{1/2}$ and the position of the absorption bands λ [medium: acetonitrile/nBu$_4$NPF$_6$ (0.1 M)].

2$^{\bullet-}$	−1705	347, 525, 800
2^{2-}		209, 260 (s), 336, 415

[a] $E_{1/2}$ (vs. Fc). [b] Peak potential, irreversible.

The spectroelectrochemistry yields even more evidence for the mechanism (Scheme 2) of the electrochemically induced valence isomerization: derivative voltabsorptometry, in which the first derivative of the absorption signal is recorded at a particular wavelength during a potential sweep,[6] reveals that the reduction of **1** to **2**$^{2-}$ passes through the quinonimine radical anion **2**$^{\bullet-}$.

In Figure 2 the signal at 525 nm, the position of the most intense absorption of **2**$^{\bullet-}$, and the thin-layer voltammogram registered at the same time are depicted. In derivative

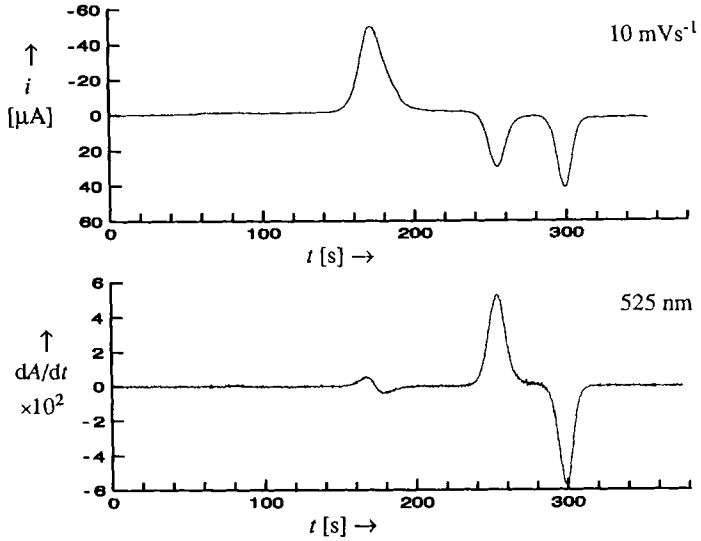

Fig. 2. Derivative voltabsorptometry during the reduction of **1** and the back oxidation of **2**$^{2-}$ to **2**. Top: Thin-layer CV in current/time (i/t) mode (in acetonitrile/nBu$_4$NPF$_6$ 0.1 M, $c = 2.5$ mM, $v = 10$ mVs^{-1}). Bottom: Simultaneously registered derivative voltabsorptogram at 525 nm.

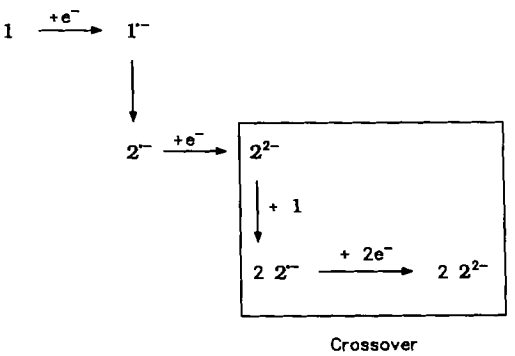
voltammetry a positive peak corresponds to the formation, and a negative peak to the disappearance of the species absorbing at the particular wavelength. Thus a positive peak in the derivative voltabsorptogram occurs at 525 nm simultaneously with the reoxidation signal of **2**$^{2-}$ to **2**$^{\bullet-}$ in the cyclic voltammogram, whereas the further oxidation of **2**$^{\bullet-}$ to **2** is accompanied by a negative peak at this wavelength. During the reduction of the spiroperimidine compound **1** to quinonimine dianion **2**$^{2-}$ the interesting effect of a sinusoidal wave can be seen in the derivative voltabsorptogram; that is, in the course of this reduction a species that absorbs at 525 nm is formed as intermediate. The interpretation that this intermediate is the quinonimine radical anion **2**$^{\bullet-}$ is supported by the observation that at 800 nm, the position of the second absorption band of **2**$^{\bullet-}$, the same effect occurs.

The radical anion **1**$^{\bullet-}$ formed from **1** rapidly converts into **2**$^{\bullet-}$, which is immediately reduced further to **2**$^{2-}$ at the existing electrode potential. Moreover, **2**$^{2-}$ reacts further with **1** in a homogeneous redox reaction to form two molecules of **2**$^{\bullet-}$ that are in turn reduced at the electrode to **2**$^{2-}$ (Scheme 2). The redox cycle in the frame explains both the absorption of **2**$^{\bullet-}$ that appears as an intermediate and the



Scheme 2. Schematic representation of the intermediate steps in the formation of the quinonimine dianion **2**$^{2-}$.

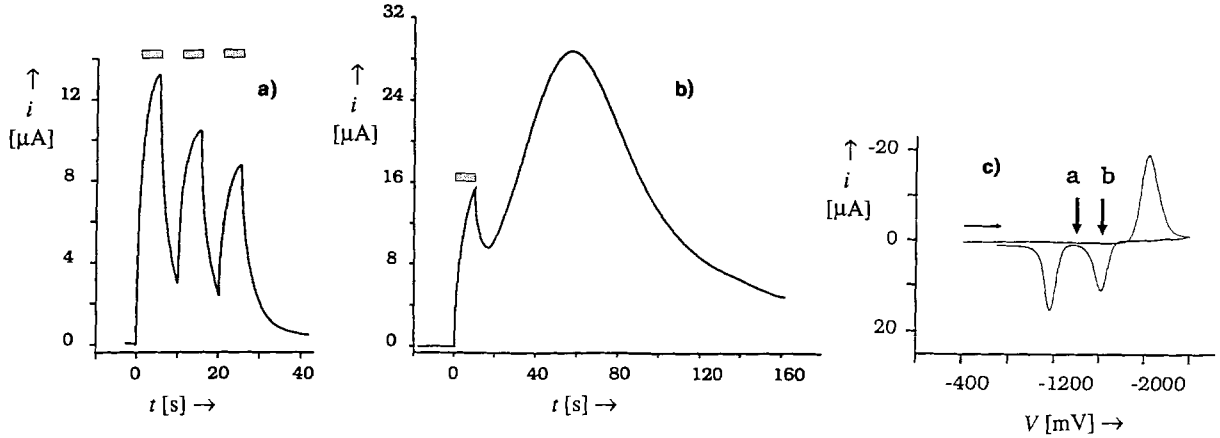


Fig. 3. Photomodulation amperometry: variation in the current signals on illumination with visible light (filter (Schott BG 14) indicated by a gray rectangle; medium acetonitrile/nBu$_4$NPF$_6$ 0.1 M, c = 2.5 mM). a) Working potential −1400 mV vs. Fc; b) working potential −1600 mV vs. Fc; c) record of the working potentials a and b.

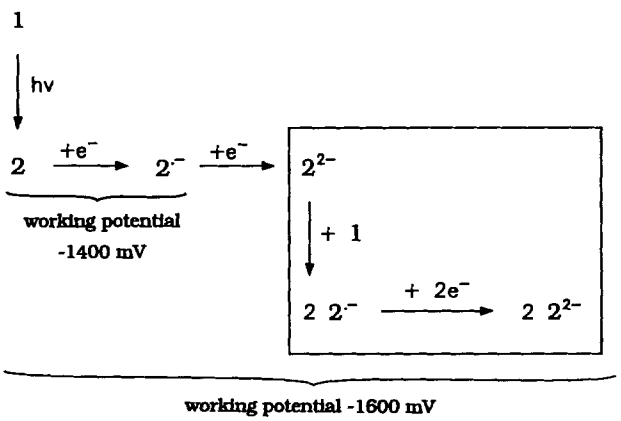
trace crossing effect that is seen in the cyclic voltammogram under bulk conditions.

The amperometry "modulated by photochemistry" depicted in Figure 3 presents additional evidence for the proposed mechanism. By this method **2** is generated by irradiation from **1** (photochromism) in a spectroelectrochemical thin-layer cell under potentiostatic conditions. On applying a potential at which **2** is reduced to $\mathbf{2}^{\bullet-}$ (see Scheme 3 and Fig. 3c), a cathodic current is observed as signal, which decays again after extinguishing the light (Fig. 3a). The slow decrease in amplitude for the subsequent light pulses is explained by the decrease in concentration of **1** in the thin-layer cell.



Scheme 3. Schematic representation of the course of the reaction in the photomodulation amperometry experiment.

If the working potential of the photomodulation amperometry is set at a value at which **2** is reduced to the dianion, the curve depicted in Figure 3b is obtained. A light pulse of 10 s, as in the previous experiment, causes a steep increase in the current, which, however, does not drop to zero on closing the shutter, but after an initial decrease, rises to a new maximum before again decreasing slowly. The photomodulation thus provides further support for the mechanism of Scheme 2, in which the cathodically generated dianion $\mathbf{2}^{2-}$ accelerates the reduction of **1**.

Whereas in the experiment in Figure 3a, only the first direct electrochemical reduction of the photochemically generated **2** to $\mathbf{2}^{\bullet-}$ is responsible for the current, in the second the reduction of the photochemically generated **2** proceeds to the dianion $\mathbf{2}^{2-}$ as well (Scheme 3). This is also observed in the greater height of the signal. In the dark the homogeneous cycle continues further: the $\mathbf{2}^{2-}$ formed reduces neutral **1** with the formation of two molecules of $\mathbf{2}^{\bullet-}$. The $\mathbf{2}^{\bullet-}$ formed in this step is reduced further to $\mathbf{2}^{2-}$ at the electrode until the entire content of **1** in the thin-layer cell has been transformed. This also confirms that the electrochemically induced valence isomerization of **1** takes place *at the radical anion stage*.

These studies show a) the properties of a multiswitchable spiroperimidine/quinonimine system, b) the application of combination methods of spectroscopy and electrochemistry for the mechanistic elucidation of this electron-transfer reaction, c) the detection of an electron-transfer catalysis by photomodulation amperometry, and d) the close relationship between the photoreaction driven by "inner electron excitation" and a reaction induced by intermolecular electron transfer.

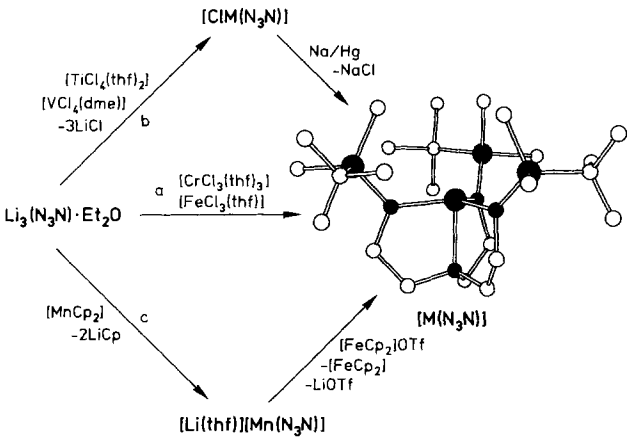
Trigonal-Monopyramidal M^{III} Complexes of the Type $[M(N_3N)]$ ($M = Ti, V, Cr, Mn, Fe$; $N_3N = [(t\mathrm{BuMe_2Si)\ddot{N}CH_2CH_2]_3N}$)**

By *Christopher C. Cummins, Jenny Lee, Richard R. Schrock,* and William D. Davis*

We wish to report the syntheses of a series of unusual monopyramidal complexes, $[M(N_3N)]$ (M = Ti, V, Cr, Mn, and Fe; $N_3N = [(t\mathrm{BuMe_2Si)\ddot{N}CH_2CH_2]_3N}$), in which the trigonal-monopyramidal (TMP) coordination geometry is enforced by the triamido ligand[1-4] and the empty axial coordination position is encircled by sterically demanding trialkylsilyl substituents. In this work the TMP geometry[5-7] is represented for the first time among early transition metal complexes. The object of this work is to synthesize inorganic or organometallic complexes with metals in relatively high oxidation states that contain unusual substrates, including complexes that contain dinitrogen or partially reduced dinitrogen ligands (N_2H_x).[8,9] A potentially important feature of the TMP geometry is the availability of three d orbitals (d_{xz}, d_{yz}, and d_{z^2}) for substrate binding, a circumstance that is analogous to that found in complexes that contain the $W(\eta^5\text{-}C_5Me_5)Me_3$ core.[10].

The M^{III} target molecules were prepared by one of three methods (Scheme 1), each of which employs white, crystalline, pentane-soluble $Li_3[N_3N]\cdot Et_2O$.[1] The Cr (green) and Fe (brown) derivatives were prepared by the "direct" route a. In the "reduction" route b yellow Ti^{IV} and blue-black V^{IV} monochloro complexes[1] were prepared first and then reduced by sodium amalgam in pentane[11] to the blue (Ti) and aquamarine (V) $[M(N_3N)]$ complexes. The "oxidation" route c was employed to provide dark green $[Mn(N_3N)]$; a pink, pentane-soluble compound formulated as $[Li(thf)][Mn(N_3N)]$ (by analogy with the known $[Li(thf)][Mn\{N(SiMe_3)_2\}_3]$[12]) was generated first from manganocene[13] and then oxidized in cold ether with $[FeCp_2]OTf$.[14] All M^{III} complexes can be prepared in gram quantities, and can be purified readily by recrystallization from pentane.[15]



Scheme 1. Methods for the synthesis of $[M(N_3N)]$ complexes for a) M = Cr, Fe; b) M = Ti, V; c) M = Mn.

The TMP geometry was verified by an X-ray diffraction study of $[V(N_3N)]$[24] (see Fig. 1 and Scheme 1). The symmetry of the complex is close to C_3, with V and the apical amine donor lying on the pseudo-threefold axis. The vanadium atom is displaced slightly from the equatorial N_3 plane (by 0.16 Å) in the direction of the vacant coordination site, which leads to an average $N_{eq}\text{-}V\text{-}N_{ax}$ angle of 85.3°. The planes of the planar amido groups and the threefold axis are nearly coincident (average $Si\text{-}N_{eq}\text{-}V\text{-}N_{ax}$ dihedral angle 12°), and therefore the $t\mathrm{BuMe_2Si}$ groups point almost straight up and encircle the vacant coordination site. Comparison of this structure with that obtained recently for

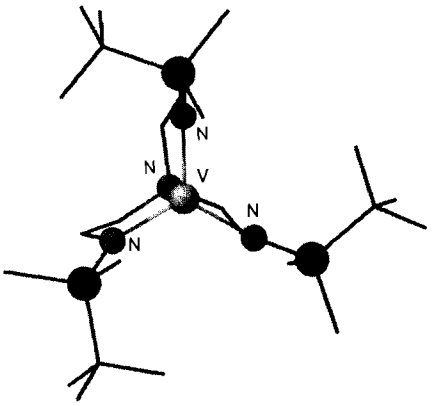


Fig. 1. Crystal structure of $[V(N_3N)]\cdot 0.5$ toluene.

$[ClV\{(Me_3SiNCH_2CH_2)_3N\}]$[1] reveals lengthened $V\text{–}N_{amide}$ bonds (average 1.930 vs. 1.883 Å), consistent with an increase in ionic radius on going from V^{IV} to V^{III} (0.67 and 0.78 Å respectively), while the bond between V and the axial nitrogen atom is shortened (2.083 vs. 2.238 Å), as should be expected in the absence of any ligand in the *trans* position. A preliminary X-ray study (as yet incompletely refined) of the analogous Cr^{III} complex reveals a similar coordination geometry.

The $[M(N_3N)]$ complexes are all high spin, as indicated by comparison of the observed magnetic moments (Evans method[16,17]) with the theoretical spin-only values (Table 1). Extended Hückel calculations (in which the threefold axis serves as the z axis) suggest that the d_{z^2} orbital (a, σ^*) is close in energy to the $d_{x^2-y^2}$, d_{xy} set (e, σ^*), while the d_{xz}, d_{yz} set (e, nonbonding) is relatively low lying. Despite

their paramagnetic nature, all the complexes give rise to assignable proton NMR spectra (see Table 1 and *Experimental Procedure*) in which the isotropic shift and signal width increase substantially as a function of the number of unpaired spins. Solution IR spectra of the five $[M(N_3N)]$ complexes are very similar, and all were found to be monomeric in pentane (Signer method[18]). These data suggest that all five species are structurally analogous, monomeric species in the solid state and in solution.

That trigonal-monopyramidal complexes may lead to unusual binding of substrates is presaged by the observation of reversible binding of carbon monoxide to $[Ti(N_3N)]$ ($\tilde{\nu}_{CO} = 2003\ cm^{-1}$), a reaction that is accompanied by a color change from blue to green and a shifting and broadening of the ^1H NMR signals attributed to the triamide ligand. We could find no other example of a reversible binding of carbon monoxide to a d^1 metal center.[19] We are continuing to explore the reaction chemistry of complexes with first row transition metals that contain the N_3N ligand, but are also interested in designing related $(RNCH_2CH_2)_3N$ ligands that may be stable to protic environments and in synthesizing complexes with heavier metals, especially Ta, Mo, or W.

Experimental Procedure

$[Ti(N_3N)]$: To a flask containing 40 mL pentane at −40 °C was added $[TiCl_4(thf)_2]$ [20] (1.990 g, 5.959 mmol) with stirring, followed by $Li_3(N_3N) \cdot Et_2O$ (3.020 g, 5.198 mmol). The reaction mixture was allowed to warm to 25 °C and stirred 12 h, at which point the precipitated LiCl was filtered. The ^1H NMR spectrum of an aliquot of the crude orange filtrate revealed the presence of only $[ClTi(N_3N)]$, indicating essentially quantitative reaction. The orange filtrate was concentrated to dryness, and the solid yellow-orange residue was dissolved in a minimum amount of pentane; the product crystallized at −40 °C as yellow needles (1.220 g in two crops, 2.143 mmol, 41%). ^1H NMR (C_6D_6): $\delta = 3.447$ (t, CH_2), 2.288 (t, CH_2), 1.112 (s, *t*Bu), 0.360 (s, $SiMe_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): 63.88 (CH_2), 51.93 (CH_2), 27.71 ($SiC(CH_3)_3$), 22.08 ($SiCMe_3$), −2.21 ($Si(CH_3)_2$). Satisfactory C,H,N-analysis. To a stirred solution of $[ClTi(N_3N)]$ (760 mg, 1.335 mmol) in 15 mL pentane was added Na/Hg (0.5%, 17.369 g, 3.776 mmol Na), and the reaction mixture was allowed to stir 72 h. After the gray Na/Hg/NaCl mixture was allowed to settle, the blue solution was decanted and filtered, and concentrated to dryness. The crystalline residue was dissolved in a minimum amount of pentane and chilled to −40 °C, whereupon blue crystals were obtained (374 mg, 701 μmol, 52%). ^1H NMR (C_6D_6): $\delta = 5.25$ ($\Delta\nu_{1/2} \approx 40$ Hz, 18H, $SiMe_2$), 1.15 ($\Delta\nu_{1/2} = 11$ Hz, *t*Bu), −0.93 ($\Delta\nu_{1/2} = 49$ Hz, CH_2), −18.77 ($\Delta\nu_{1/2} = 54$ Hz, CH_2). Mol wt (pentane): calcd. 533.88, found 504. Satisfactory C,H,N analysis.

$[V(N_3N)]$: To a flask containing 250 mL pentane at −40 °C was added $[VCl_4(dme)]$ [21] (2.791 g, 9.867 mmol) with stirring, followed by $Li_3(N_3N) \cdot Et_2O$ (5.000 g, 8.607 mmol). The reaction mixture was allowed to warm to 25 °C and stirred for 14 h, at which point the precipitated LiCl was filtered off, and the solvent was removed from the blue-black filtrate in vacuo. The gummy residue was dissolved in a minimum amount of pentane, and the solution was cooled to −40 °C to give green-black crystals (1.609 g). A ^1H NMR spectrum of the crystalline product showed it to be a mixture of 28% $[ClV(N_3N)]$ (^1H NMR (C_6D_6): $\delta = 1.77$ ($\Delta\nu_{1/2} = 45$ Hz, $SiMe_2$), 0.85 ($\Delta\nu_{1/2} = 23$ Hz, *t*Bu), −16.21 ($\Delta\nu_{1/2} = 186$ Hz, CH_2), −40.84 ($\Delta\nu_{1/2} = 308$ Hz, CH_2)) and 72% $[V(N_3N)]$. The mixture was dissolved in pentane (40 mL) and treated with Na/Hg (13.55 g, 0.5%, 2.945 mmol Na). The reaction mixture was stirred for 12 h, at which point the NaCl/Na/Hg mixture was allowed to settle. The aquamarine pentane solution was decanted and filtered, and the filtrate was concentrated in vacuo to give a crystalline residue that was dissolved in a minimum amount of toluene. The toluene solution was cooled to −40 °C to give 1.148 g (2.138 mmol, 73%) of crystalline $[V(N_3N)]$. ^1H NMR (C_6D_6): $\delta = 6.63$ ($\Delta\nu_{1/2} = 750$ Hz, $SiMe_2$), 1.93 ($\Delta\nu_{1/2} = 190$ Hz, *t*Bu), −19.83 ($\Delta\nu_{1/2} = 1440$ Hz, CH_2), −84.18 ($\Delta\nu_{1/2} \approx 2600$ Hz, CH_2). Mol wt (pentane): calcd. 536.94, found 456. Satisfactory, C,H,N analysis.

$[Cr(N_3N)]$: To a stirred slurry of $[CrCl_3(thf)_3]$ [22] (2.957 g, 7.892 mmol) in 80 mL pentane at −40 °C was added $Li_3(N_3N) \cdot Et_2O$ (4.000 g, 6.885 mmol). The reaction mixture was allowed to warm to 25 °C and stirred for 48 h, at which point the precipitated LiCl was removed by filtration. The filtrate was concentrated to dryness, and the residue was dissolved in a minimum of pentane. The pentane solution was chilled to −40 °C to give 1.639 g of green crystals (3.047 mmol, 44%). ^1H NMR (C_6D_6): $\delta = 43.36$ ($\Delta\nu_{1/2} = 1430$ Hz, $SiMe_2$), 0.02 ($\Delta\nu_{1/2} = 370$ Hz, *t*Bu). Mol wt (pentane): calcd. 538.00, found 531.

$[Mn(N_3N)]$: To a stirred solution of $[MnCp_2]$ [13] (1.593 g, 8.606 mmol) in 30 mL THF was added solid $Li_3(N_3N) \cdot Et_2O$ (5.000 g, 8.607 mmol) in portions over a period of 1 min. After 3 h the solvents were removed in vacuo, and the residue was extracted with 125 mL of pentane. The pentane solution was filtered through a bed of Celite to remove LiCp (89% isolated yield of LiCp, ^1H NMR (C_5D_5N): $\delta = 6.430$ (s, Cp)), and the filtrate was concentrated to dryness. The residue was recrystallized from a minimum of ether/pentane to afford 3.235 g of light pink crystals of $[Li(thf)][Mn(N_3N)]$ (5.218 mmol, 61%) in two crops. To a stirred solution of $[Li(thf)][Mn(N_3N)]$ (750 mg, 1.210 mmol) in ether at −40 °C was added solid $[FeCp_2]OTf$ [14] (405 mg, 1.210 mmol); the color rapidly changed to dark green. The reaction mixture was allowed to warm to 25 °C and stirred for 2 h, at which point the solvents were removed in vacuo. The residue was extracted with 30 mL pentane, LiOTf was removed by filtration, and the filtrate was concentrated in vacuo. Ferrocene was removed by sublimation at room temperature over a period of 5 h (0.05 Torr) onto a probe cooled to −78 °C. The remaining green-black solid was taken up in a minimum amount of pentane, and the solution was chilled to −40 °C to give 336 mg of green-black crystals (621 μmol, 51%). ^1H NMR (C_6D_6): $\delta = 38.40$ ($\Delta\nu_{1/2} = 960$ Hz, $SiMe_2$), 0.02 ($\Delta\nu_{1/2} = 316$ Hz, *t*Bu). Mol wt (pentane): calcd. 540.94, found 552. Satisfactory C,H,N analysis.

$[Fe(N_3N)]$: To a stirred solution of $Li_3(N_3N) \cdot Et_2O$ (3.04 g, 5.233 mmol) in 70 mL THF at −40 °C was added $[FeCl_3(thf)]$ [23] (1.226 g, 5.233 mmol) all at once. The reaction mixture was allowed to warm to 25 °C and stirred for 3 h, at which point the solvents were removed in vacuo, and the residue was extracted with 100 mL pentane. The extract was filtered and the filtrate was concentrated to dryness in vacuo. The residue was dissolved in a minimum of pentane, and the solution was chilled to −40 °C to give 1.347 g of brown microcrystals (2.486 mmol, 48%) in two crops. ^1H NMR (C_6D_6): $\delta = 36.50$ ($\Delta\nu_{1/2} = 1360$ Hz, $SiMe_2$), 13.90 ($\Delta\nu_{1/2} = 646$ Hz, *t*Bu). Mol wt (pentane): calcd. 541.85, found 556.

[24] Data were collected at −72 °C on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated $Mo_{K\alpha}$ radiation. A total of 8416 reflections were collected to a 2θ value of 54.9°, of which 8057 were unique

($R_{int} = 0.032$); equivalent reflections were merged. The structure was solved by a combination of Patterson and difference Fourier techniques. The final cycle of full-matrix least-squares refinement was based on 5784 observed reflections ($I > 3.00\sigma(I)$) and 326 variable parameters and converged (largest parameter shift was less than 0.009 times its esd) with $R = 0.060$ and $R_w = 0.063$. A final difference Fourier map showed no chemically significant features. Crystal data are $a = 13.084(2)$, $b = 13.089(2)$, $c = 13.194(2)$ Å, $\alpha = 60.08(1)$, $\beta = 64.78(1)$, $\gamma = 72.88(1)°$, $V = 1762(1)$ Å^3, space group $P\bar{1}$, $Z = 2$. Catecholates as σ- and π-Donating Ligands: The Synthesis and Structure of $(Et_4N)_2[W(CO)_4(O_2C_6H_4)]$ and the "Sixteen Electron" Analogue Resulting from CO Dissociation**

By *Donald J. Darensbourg,* Kevin K. Klausmeyer, Brian L. Mueller,* and *Joseph H. Reibenspies*

Carbon dioxide insertion into the metal–oxygen bond of metal hydroxides, alkoxides, and aryloxides is a fundamental step in several chemical and biochemical catalytic processes. Notable among these processes are the coupling of CO_2 and epoxides to provide cyclic carbonates[1] or polymeric materials,[2] and the hydration of CO_2 to afford carbonic acid.[3] Attendant with reactions involving low-valent anionic Group 6 metal alkoxy- or aryloxycarbonyl complexes is the lability of the carbonyl ligands which can subsequently lead to β-hydrogen elimination or metal aggregation reactions.[4] In this communication, we report the synthesis and structural characterization of carbonyl catecholatotungsten complexes and the effect of the π-donating property of these dihydroxo ligands on the reactivity patterns of the metal complexes.

A solution of $[W(CO)_5thf]$ (prepared photochemically from 1.9 mmol of $[W(CO)_6]$ in tetrahydrofuran) was transferred to a Schlenk flask containing 3.8 mmol of $(Et_4N)(OC_6H_4OH)$ and stirred. An orange powder precipitated within one hour and orange crystals of **1** were isolated by filtration (1.3 g or 90% yield) and recrystallization from CH_3CN/ether. The infrared spectrum of **1** in CH_3CN exhibited ν_{CO} vibrations at 1975(w), 1829(vs), 1807(m, sh) and 1773(m) cm^{-1}. Two sharp doublets of equal intensity were observed for the CO ligands in the ^{13}C NMR spectrum at $\delta = 217.6$ ($J_{W,C} = 165$ Hz) and 207.5 ($J_{W,C} = 131$ Hz).

$(Et_4N)_2[W(CO)_4(O_2C_6H_4)] \cdot HOC_6H_4OH$ **1**

Definitive assignment of the structure of **1** was obtained by X-ray crystallography; the result is shown in Figure 1.[5] The solid-state structure of **1** is characterized by continuous hydrogen bonding between the bridging catechol moiety and two adjacent dianions. The structure shows typical hydrogen-bond lengths (O···O 2.535(10) Å[6]) and tungsten to oxygen-bond lengths of 2.175(11) Å. One notable feature in the structure is the deviation from linearity of the axial carbonyl groups (C-W-C angle of 167.3(8)°).

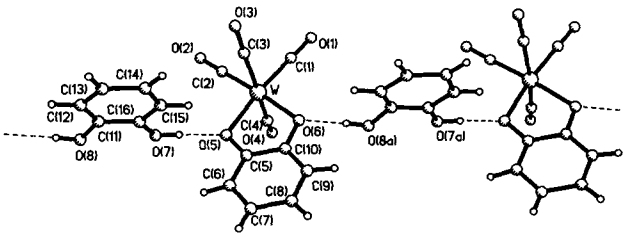

Fig. 1. Ball-and-stick representation of the non-hydrogen atoms of the anion of **1**.

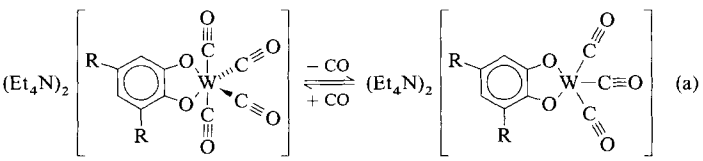
The complex **2** containing only coordinated catechol was obtained by reacting 1.6 mmol of **1** with three equivalents of

$(Et_4N)_2[W(CO)_4(O_2C_6H_4)]$ **2**

NaOMe in acetonitrile. $Na_2O_2C_6H_4$ and excess NaOMe were removed by filtration through Celite, and dark orange crystals (yield 0.91 g, 82%) were obtained upon addition of THF/Et_2O to the filtrate. As anticipated, the ν_{CO} vibrations of **2** in CH_3CN (1965(w), 1817(vs), 1800(m,sh) and 1763(m) cm^{-1}) are shifted to lower frequencies than those of **1**, indicative of some hydrogen bonding of **1** in solution as well. Similarly the two ^{13}C NMR resonances in CH_3CN shift downfield to $\delta = 219.6$ ($J_{W,C} = 159$ Hz) and 208.8 ($J_{W,C} = 133$ Hz). More importantly, in contrast to species **1**, the carbonyl ligands in the non-hydrogen-bonded form of the complex are fluxional. Coalescence of the two carbonyl carbon signals into one symmetrical peak at $\delta = 214.2$ occurred at temperatures greater than 23 °C.[7] The activation parameters for the CO exchange were determined to be $\Delta H^{\ddagger} = 12.0 \pm 0.7$ kcal mol^{-1} and $\Delta S^{\ddagger} = -4.5 \pm 2.5$ cal K^{-1} mol^{-1}.[8] The facile nature of this process is attributed to the π-donor property of the catecholato ligand. This conclusion is supported by the fact that upon addition of excess catechol, which forms hydrogen bonds to the ligated catechol and hence diminishes its π-donor character, the fluxional process is slowed down.[9] Furthermore, in the instance where the catecholate ligand contains electron-releasing *tert*-butyl substituents in the 3,5-positions (→ **4**), the coalescence temperature is much lower than ambient temperature.



(a)

2, R = H
4, R = *t*Bu

3, R = H
5, R = *t*Bu

In a slower process, **2** readily expels CO to provide the tricarbonyl derivative **3** [Eq. (a)].[10] Formation of **3** was indicated by the two bands for the ν_{CO} vibrations in CH_3CN

(1863(s) and 1726(vs) cm^{-1}), and a single broad ^{13}C NMR signal at $\delta = 234.2$ at $-35\,^{\circ}C$. Upon exposing an acetonitrile solution of **3** to a carbon monoxide atmosphere, **2** is regenerated rapidly and quantitatively. Hence, an equilibrium between the 18-electron complex **2** and its formally "16-electron" unsaturated species **3** exists in solution. Because the reaction is carried out in a strongly coordinating solvent, CH_3CN, it is possible that CH_3CN is in the coordination sphere of **3**.

Synthesis of the 3,5-di-*tert*-butyl derivative of **2** was accomplished in a completely analogous manner. The ν_{CO} region of the solution infrared spectrum indicated the presence of both the tetra- and tricarbonyl species (**4** and **5**) even in the absence of a CO atmosphere, that is, a four band pattern (1962(w), 1815(s), 1796(m,sh), and 1755(m) cm^{-1}) and a two band pattern (1859(s) and 1721(vs) cm^{-1}), respectively. Consistent with the presence of the electron-donating *t*-butyl groups, this equilibrium lies farther to the right than that formulated in Equation (a). The ^{13}C NMR spectrum of the tetracarbonyl derivative, stabilized by a CO atmosphere, exhibited three resonances at $\delta = 220.2, 219.8$, ($J_{W,C} = 161$ Hz) and 209.0 ($J_{W,C} = 136$ Hz) of intensity ratio 1:1:2 at $-40\,^{\circ}C$. That is, the two equatorial CO ligands are not equivalent because of the unsymmetrically substituted catecholate ligand. The coalescence of the three carbon signals occurred at temperatures above $5\,^{\circ}C$.

Proof of the structure of the tricarbonyl derivative **5** was obtained by X-ray crystallography (Fig. 2).[11] The structure is quite similar to that previously reported for its manganese analogue,[12] in which the coordination geometry is intermediate between trigonal bipyramidal and square pyramidal, and there is no CH_3CN in the metal's coordination sphere. The tungsten atom lies out of the plane defined by the two carbonyl carbon atoms, C1 and C2, and one of the catecholate's oxygen atoms O5 by 0.048 Å (towards the axial O4 atom). The O4-W-C3 angle is 166.7°. The W–O5 bond, which is *ortho* to the electron-releasing *t*-butyl substituent, is significantly shorter than the W–O4 bond (2.059 vs. 2.154 Å). Indeed, both W–O bond lengths are shorter than those in the tetracarbonyl species **1**. Concomitantly, the W–C1 bond, which is closest to *trans* to O5 ($\sphericalangle$O5-W-C1 = 143.3°), is the shortest W–C bond. The bond lengths within the catecholato ligands in complexes **1** and **5** are extremely similar.

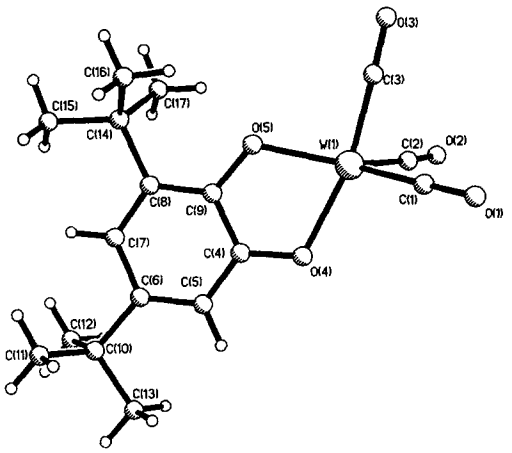

Fig. 2. Ball-and-stick representation of the non-hydrogen atoms of the anion of **5**.

These results emphasize the emerging opinion that strongly π-donating hydroxo ligands stabilize unsaturated organometallic derivatives.[13] The reactivity of the coordinatively unsaturated derivatives **3** and **5** with dihydrogen or carbon dioxide are currently under investigation. Preliminary observations indicate that these catecholato complexes readily react with one equivalent of CO_2 at low temperature to afford cyclic carbonato metal complexes.

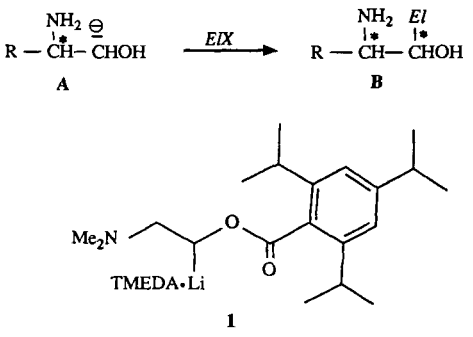
Stereoselective Generation of 1-Acyloxy-2-amino Carbanions by Deprotonation; Synthesis of Enantiomerically and Diastereomerically Pure β-Amino Alcohols**

By *Jörg Schwerdtfeger* and *Dieter Hoppe**

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 65th birthday

Synthetic equivalents of 2-amino-1-hydroxy carbanions **A** that allow the preparation of more highly substituted 2-amino alcohols **B** by stereoselective electrophilic substitutions are hitherto unknown.[1] In the one related example, Beak et al.[2] generated the racemic, dipole-stabilized 2,4,6-triisopropylbenzoate **1** and isolated its deuterium analogue. We report here a simple and highly stereoselective approach to this problem.



Lithiocarbanions of type **2** unsubstituted in the alkyl portion can be prepared by the enantioselective deprotonation of the related *O*-alkylcarbamates with *sec*-butyllithium/(−)-sparteine[3] with high stereoselectivity. The trick is protecting the hydroxyl group while simultaneously activating the neighboring methylene protons by means of the sterically demanding, and yet acid-labile, 1,3-oxazolidine-3-carbonyl group and stabilizing the ion pair by chelation. The enantiomers are differentiated in the deprotonation because of the complex ligand (−)-sparteine (**3**); the *Si* proton is abstracted with selectivities > 95% *ee* to give configurationally stable lithium (1*S*)-(acyloxy)alkanides of type **2**. These compounds can be substituted with most electrophiles with retention of stereochemistry.[3, 6] The alkyl group R may have alkoxy substituents[7] in the γ and δ positions without deleterious effects on the yield and stereoselectivity.

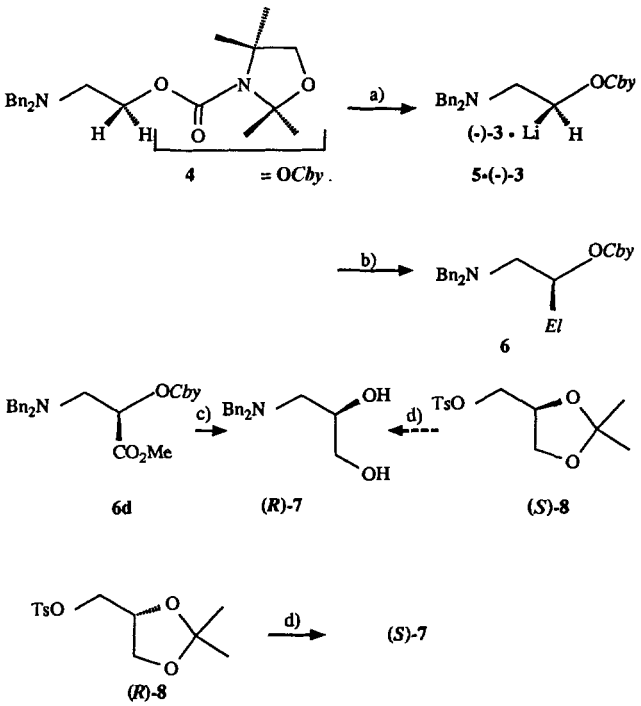
[**] This research was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Pharmaforschungszentrum of Bayer AG, Wuppertal.

We had anticipated that the *N*,*N*-dialkylamino group in the substrate would compete with (−)-sparteine in complexation and that the stereoselectivity would suffer.[8] To our surprise carbamate **4**,[9, 10] obtained from 2-(*N*,*N*-dibenzylamino)ethanol, was deprotonated smoothly with 3 equiv *sec*-butyllithium/(−)-sparteine in diethyl ether at −78 °C. The intermediate ion pair **5**·(−)-**3** was trapped with electrophiles to provide the expected substitution products **6**[10] in good yields and with enantiomeric enrichments of > 95%[11] (Scheme 1, Table 1). The (*R*) configuration of **6d** was confirmed by conversion into diol (*R*)-**7**;[12] its enantiomer (*S*)-**7** was synthesized from the commercially available glycerin derivative (*R*)-**8** for comparison.[12] The racemates *rac*-**6** were obtained in similar yields when *N*,*N*,*N*′,*N*′-tetramethylenediamine (TMEDA) was used instead of (−)-**3**.



Scheme 1. a) 3 equiv *s*BuLi/(−)-**3**, Et_2O, −78 °C, 3 h; b) EIX; c) $LiAlH_4$; d) 1. Bn_2NH, $C_6H_5CH_3$, 65%; 2. $MeSO_3H$, MeOH, 65%. Bn = benzyl.

Carbamate **9**[9, 10], derived from (*S*)-*N*,*N*-dibenzylleucinol,[13] could not be deprotonated at −78° with *sec*-butyllithium/(−)-sparteine. When TMEDA was used as a complexing agent, however, the lithium complex **10** was formed and subsequently methylated to give the diastereomerically pure substitution product **11a**[10] (Scheme 2, Table 1). The liberation of the hydroxyl group led to amino alcohol (2*R*,3*S*)-**12a**,[14] which is also the major product from the substrate-controlled Grignard addition of methylmagnesium iodide to (*S*)-*N*,*N*-dibenzylleucinal **13**.[13] Thus the *Re* proton in **9** was replaced exclusively. The internal and external chiral inductions oppose because of the pronounced *Si* preference of the *sec*-butyllithium/(−)-sparteine complex. This is reflected in the markedly reduced reactivity of the "mismatched pair".[15]

Similar results were obtained with the (*S*)-prolinol derivative **14**.[9, 10] Here too, deprotonation in the presence of TMEDA provided lithium compound **15**, and the *Re* proton

was replaced exclusively (Scheme 3, Table 1). The configuration of the acetone adduct **16g** was confirmed by an X-ray structure analysis.[16] We also observed a deprotonation when (−)-sparteine was employed, but the subsequent methylation led to the uniform *u* diastereomer **16a** in lower yield. This implies that the diastereoselectivity is controlled by the stereogenic center in the substrate. In the addition of prostereogenic aldehydes to the carbanionic intermediates **10** and **15**, only minimal stereodifferentiation was observed at the carbonyl group (see Table 1, **11f** and **16f**).

The conversion of the methylation product **16a** via **17a**[3, 10, 17] into the free amino alcohol **18a**[3, 10, 17, 18] demonstrates that the amino[19] and hydroxyl[3] groups can be removed by standard procedures.

We have found a novel, broadly applicable method for the highly stereoselective synthesis of β-amino alkanols and 2-amino-1-hydroxycarboxylic acids. Moreover, we have proven that *N*-benzylamino groups are capable of effecting differentiation not only between diastereotopic faces[13] but also between diastereotopic groups like protons.

Experimental Procedure

A solution of 1.0 mmol of the carbamate and 3.0 mmol of the diamine in 8 mL of anhydrous diethyl ether at −78 °C was treated with 3.0 mmol[20] of *sec*-butyllithium (ca. 1.4 M in cyclohexane/hexane). The reaction mixture was stirred at −78 °C for 3 h, 3.0 mmol of the electrophile was added, and the reaction mixture was then allowed to warm to room temperature. After workup with diethyl ether and water (2 mL), the crude product was purified by flash chromatography on silica gel or alumina (activity 2–3) eluting with diethyl ether/pentane. An excess of carbon dioxide was used as the electrophile in the preparation of the methyl esters **7a** and **16d**. The reaction mixture was acidified to pH 5 with 2 N HCl and the crude carboxylic acids treated with diazomethane.

^{99m}Tc Labeled Biotin Conjugate in a Tumor "Pretargeting" Approach with Monoclonal Antibodies**

By *Peter Koch* and *Helmut Robert Mäcke**

An important link between chemistry, biology, and medicine is the synthesis and use of bifunctional chelators specific for radioactive metal ions and designed for covalent coupling to biomolecules.[1] Among the biomolecules used clinically as radiopharmaceuticals are monoclonal antibodies (MAbs).[2] In particular, tumor-associated MAbs are potential diagnostic and therapeutic agents when labeled with γ-ray emitting (i.e. image producing) or particulate radiation emitting (i.e. cytotoxic) radioisotopes. Although somewhat successful in diagnosic applications, MAbs have drawbacks such as slow blood clearance and unspecific binding to normal tissues. This results in an unfavorable tumor/nontumor ratio and, more importantly, in a high and unnecessary radiation exposure for the patient.

One promising way to circumvent the problem of long-circulating, radioactive antibodies is the so-called pretargeting strategy. We report on the successful development of the chemical and physicochemical science of such a strategy with the avidin/biotin system.[3] The approach is schematically depicted in Figure 1. It has been used in a variety of biochemical studies, for example a strategy for selective protein cleavage,[4] and in many analytical in vitro applications.[5]

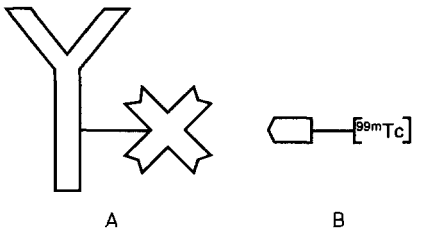

Fig. 1. Schematic representation of the antibody/avidin/biotin pretargeting approach. Avidin is a glycoprotein (M = 68000) with four binding sites for biotin ($K_D = 10^{-15}$ M^{-1}) which is a naturally occurring vitamin. A = Conjugate of MAb (left) and avidin (right), B = conjugate of PnAO–biotin and ^{99m}Tc.

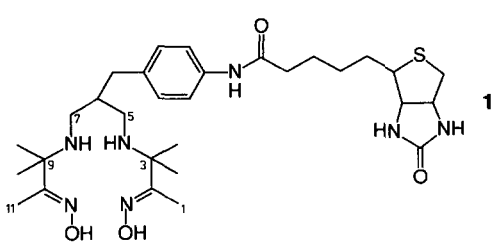
In the pretargeting strategy, avidin is covalently attached to a tumor-specific antibody at a site that does not interfere with the biological activity of the antibody. The nonradioactive conjugate is injected and allowed to localize in the tumor for several days. Finally, a radiolabeled biotin derivative is injected. Because of its fast blood clearance it binds quickly and irreversibly to avidin at the tumor site and can be localized by imaging with an external gamma camera. The radionuclide of choice is ^{99m}Tc, a transition metal which has a short half-life and optimal nuclear physical characteristics for use in vivo. As the metal-coordinating properties of biotin are very weak,[6] the molecule must be modified by conjugation to a bifunctional ligand. Such a conjugate must then fulfill the following requisites: 1) fast formation of the ^{99m}Tc chelate under mild conditions at a $^{99m}TcO_4^-$ concentration of roughly 10^{-7} M; 2) high kinetic stability of the ^{99m}Tc-labeled conjugate under physiological conditions, that is, no transfer of the radionuclide to competing ligands in serum and tissue; 3) retained biological activity of modified biotin, in other words, its binding to avidin must be complete.

We synthesized a PnAO–biotin derivative **1**[7] (Fig. 2, Table 1) by treatment of (+)-biotin *N*-hydroxysuccinimide ester with copper(II) 6-*p*-aminobenzyl-3,3,9,9-tetramethyl-4,8-diazaundecane-2,10-dionedioxate in anhydrous dimethyl sulfoxide, followed by removal of the protecting Cu^{2+} ion with NaCN, and purification of the conjugate by medium-pressure chromatography (MPLC) on silica gel



1

Fig. 2. Biotinylated 6-*p*-aminobenzyl-3,3,9,9-tetramethyl-4,8-diazaundecane-2,10-dionedioxime = PnAO–biotin = **1**.

FAB-MS (8 keV): m/z 604 (M^+)

[a] The NMR signals could be assigned with HCCORR and COLOC experiments.

with acetonitrile/25% NH_3 10/1.[8] The synthesis of the ^{99m}Tc complex depends on two important, fairly restrictive requisites. The preparation must start with an approximately 10^{-7} M solution of TcO_4^- in physiological saline, that is, the starting material, generator-eluted TcO_4^-, is present in low concentrations and must be reduced to an oxidation state suitable for coordinative binding. This is usually done with Sn^{2+} as a two-electron reducing agent in the presence of tartrate or citrate. These weak ligands are used to avoid formation of Tc/Sn colloids and serve to transfer technetium(v) to the biomolecule-conjugated ligand. We developed a labeling protocol on this basis which gives 99% labeling yield within 15 min at room temperature and physiological pH (see *Experimental Procedure*).

Quality control of ^{99m}Tc–PnAO–biotin was performed with high-pressure liquid chromatography (HPLC). The labeled conjugate (> 99%) eluted after 2 min 18 s, TcO_4^- after 1 min 30 s, and the ^{99m}Tc–tartrate complex after 1 min 5 s.

The biological activity of ^{99m}Tc–PnAO–biotin was tested in two related experiments. In the first, the labeled conjugate was mixed with avidin at 37 °C in phosphate buffer (pH 7.4) and incubated for 10 min with shaking. The mixture was then subjected to gel filtration (Sephadex G50). Approximately 99% of ^{99m}Tc was bound to the high-molecular-weight protein avidin, which indicated that the modified biotin retained its biological activity. In the second experiment, which more closely resembled the situation in a solid tumor, the binding capacity was checked with avidin immobilized on beaded agarose. ^{99m}Tc–PnAO–biotin was slowly passed through the column (1 mL per min) and the column washed with phosphate buffer (pH 7.3). 98 ± 2% (average of five experiments) of the radioactivity was strongly bound to the immobilized avidin, again showing that the modified biotin retained its high affinity for avidin.

The kinetic stability of ^{99m}Tc–PnAO–biotin in terms of loss of the metal ion, disproportionation, or transfer of ^{99m}Tc to serum proteins was determined by its incubation with phosphate-buffered saline solution (pH 7.3, 37 °C) over 24 h. Aliquots were taken (after 1, 2, 3, 4, 5, 6, 12, 18, and 24 h) and analyzed by HPLC and TLC (silica gel, isopropanol/25% NH_3 9/1). No significant loss of bound ^{99m}Tc was found within the first 6 h, and after 24 h only 2.5% TcO_4^- was detected. In a second experiment freshly prepared human serum was incubated with ^{99m}Tc–PnAO–biotin and analyzed by gel filtration (Biogel P2). The conjugate proved to be stable under these conditions as well.

Physicochemical data show that the Tc–PnAO complex is neutral and lipophilic: it can be readily extracted into diethyl ether and does not move on paper electrophoresis. PnAO derivatives have been tested as chelators for technetium, and an X-ray crystal structure revealed five-coordinate ^{99m}Tc in one such complex with a Tc=O unit at the apex of a square pyramid and the tetradentate ligand in a pseudo-macrocyclic arrangement with an intramolecular hydrogen bond between the oxime oxygen atoms. On coordination of TcO^{3+} the two amine nitrogens lose their protons resulting in the neutral complex.[9]

After its sterility and pyrogenicity (pyrogen = fever-producing substance) had been tested, ^{99m}Tc–PnAO–biotin was successfully applied in a three-step approach in the diagnosis of patients with different types of tumors, and a clinical trial on 15 patients with brain tumors was completed. The stability found in the in vitro experiments was confirmed in vivo. Moreover, the high affinity of ^{99m}Tc–PnAO–biotin for tumor-associated avidin was shown by imaging with an external gamma camera. A typical example of a positive scan of a brain tumor is shown in Figure 3.[10] This is the first use of a ^{99m}Tc complex in a pretargeting approach in patients. Similar complexes for use in therapy are being developed.

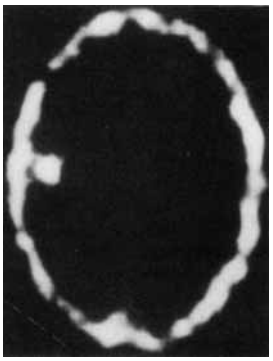

Fig. 3. Single-photon emission computed tomography (SPECT) scan of a patient with a brain tumor 30 min after injection of ^{99m}Tc–PnAO–biotin. Tumor-specific avidinated MAb was injected 3 days before. The tumor can be seen on the left side.

Experimental Procedure

The nine-step synthesis of **1** will be published elsewhere.

Labeling of **1** with ^{99m}Tc: 1.7 mL of a N_2-purged solution containing 900 μg (1.49 μmol) **1**, 4.5 μg (0.02 μmol) $SnCl_2 \cdot 2H_2O$ and 8.05 mg (28.5 μmol) potassium sodium tartrate tetrahydrate was adjusted to pH 7.5 with NaOH. To this solution was added 740–1100 MBq $^{99m}TcO_4^-$, freshly eluted from a generator. The mixture was left at room temperature for 15 min and after sterility filtration was ready for quality control and injection. For highly specific activity labeling, the excess of unlabeled PnAO–biotin was easily removed with a C_{18} Sepak cartridge. The more hydrophilic PnAO–biotin was washed from the cartridge with water, whereas ^{99m}Tc–PnAO–biotin was removed with methanol, and the solvent was evaporated at 40 °C with a stream of N_2. The residue was dissolved in phosphate buffer for injection.

[10] In a few patients the pretargeting approach was compared with the usual direct application of a ^{99m}Tc labeled antibody. The pretargeting approach showed the tumor very clearly with very little unspecific uptake and a good tumor/nontumor ratio, whereas the direct labeling showed high unspecific uptake. The comparative study will be published elsewhere, but supplementary material is available on request.

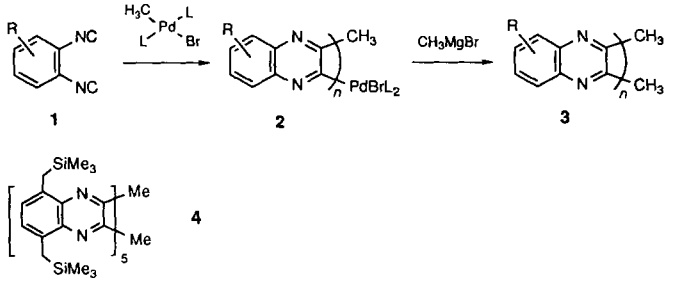
Enantioselective Polymerization of 1,2-Diisocyanoarenes—Synthesis of Optically Active, Helical Poly(quinoxaline-2,3-diyl)s

By *Yoshihiko Ito*,* *Eiji Ihara*, and *Masahiro Murakami*

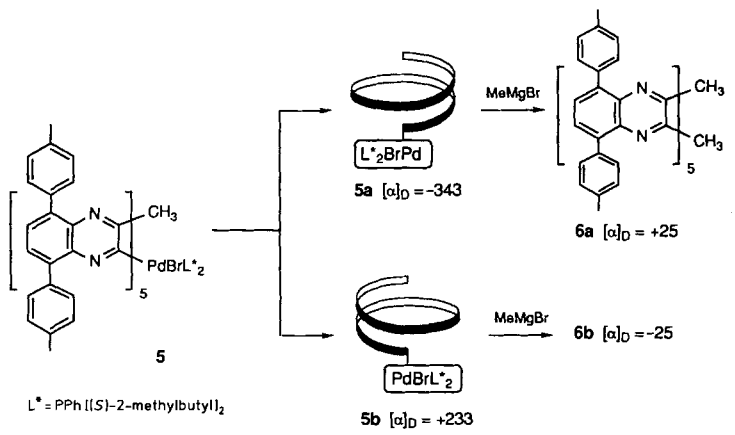
The synthesis of an optically active polymer from an achiral monomer using a chiral catalyst is a significant challenge.[1] We now report an enantioselective polymerization of 1,2-diisocyanoarenes induced by new chiral palladium catalysts having helical conformations.

We reported recently that a new living polymerization of 1,2-diisocyanoarenes **1** was catalyzed by *trans*-bromo(methyl)bis(phosphine)palladium(II) to give poly(quinoxaline-2,3-diyl)s **3** with narrow molecular weight distributions.[2] Noteworthy was that several of the propagating palladium(II) complexes **2**, which were still reactive in the polymerization, were isolated and fully characterized.

The X-ray crystallographic study of pentamer **4**, revealed a helical structure (Fig. 1).[3] This finding prompted us to undertake a synthesis of optically active poly(quinoxaline-2,3-diyl) **3**, whose chirality emanates from the helical



structure. Oligomerization of 1,2-diisocyano-3,6-di-*p*-tolylbenzene (4 equiv) catalyzed by *trans*-bromobis[bis{(*S*)-2-methylbutyl}phenylphosphine]methylpalladium(II) (1 equiv) gave a mixture of oligo(5,8-di-*p*-tolylquinoxaline-2,3-diyl)palladium(II) complexes in quantitative yield. Gel permeation chromatography (GPC) on polystyrene allowed the isolation of pentamer **5**. Of note was that subsequent highly resolved, preparative high-pressure liquid chromatography (HPLC) permitted the separation of two isomers **5a** and **5b** (3:4), which were conformationally stable in solution. Circular dichroism (CD) spectra of **5a** and **5b** showing large Cotton effects are nearly mirror images of each other and indicative of enantiomers with opposite helicities (Fig. 2). After removal of the chiral bis(phosphine)palladium(II) moiety by the reaction with methylmagnesium bromide, **5** gave quinque(quinoxaline-2,3-diyl)s **6**, which have identical spectroscopic properties[4] and optical rotations in opposite directions; **6a** $[\alpha]_D = +25$ ($c = 0.1$, $CHCl_3$), **6b**:$[\alpha]_D = -25$ ($c = 0.1$, $CHCl_3$). The CD spectra of **6a** and **6b** exhibit weak Cotton effects. Based on these results, the two isomers **5a** and **5b** were assigned to the diastereomers which arise from



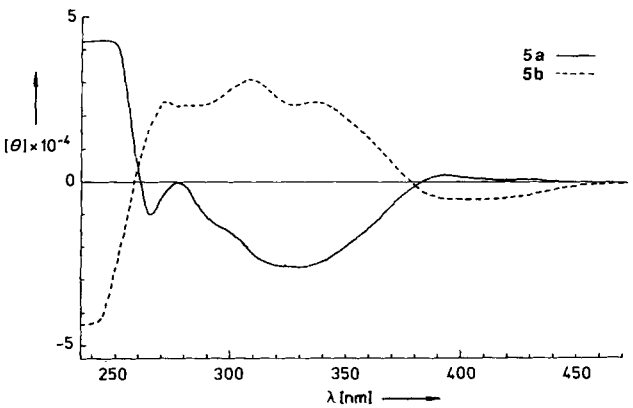


Fig. 2. CD spectra of **5a** and **5b** in CH_2Cl_2.

the combination of the helical secondary structure and the chirality of the phosphine ligand.

We thought that the rigid and stable conformations of **5a** and **5b** might induce further polymerization of 1,2-diisocyanoarenes with stereocontrol, resulting in the extension of the helical chain. Indeed, enantioselective polymerization of 1,2-diisocyano-3,6-dimethyl-4,5-bis(propoxymethyl)benzene (**7**)[5] was accomplished with the diastereomerically pure palladium(II) complex **5a** as a chiral initiator. After removal of the chiral palladium(II) moiety, optically active poly(quinoxaline-2,3-diyl) **8a** ($[\alpha]_D = +165$ ($c = 0.54$, $CHCl_3$), $M_n = 11\,200$ (vapor-pressure osmometry in $CHCl_3$)) was obtained which showed a larger optical rotation and much more distinct Cotton effects than **6a** (Fig. 3).[6] Similarly, the other diastereomer **5b** gave poly(quinoxaline-2,3-diyl) **8b**,

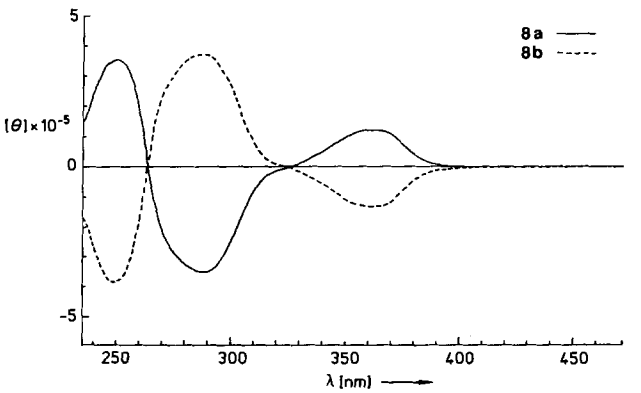

Fig. 3. CD spectra of **8a** and **8b** in CH_2Cl_2.

whose optical rotation is almost identical, but with the opposite sign ($[\alpha]_D = -171$ ($c = 0.56$, $CHCl_3$), $M_n = 10\,000$ (vapor-pressure osmometry in $CHCl_3$)). The CD spectrum of **8b** is the complete mirror image of that of **8a** (Fig. 3). These observations indicate that poly(quinoxaline-2,3-diyl)s **8a** and **8b** have helical structures which are the mirror images of each other.

Experimental Procedure

1,2-Diisocyanoarenes: 1,2-Diisocyano-3,6-di-*p*-tolylbenzene and **7** were prepared from the corresponding 1,2-diformamidoarenes by the procedure previously reported [7].

5: MeMgBr (2 mmol, 2M solution in ether) was added to a solution of *trans*-bis[bis{(*S*)-2-methylbutyl}phenylphosphine]dibromopalladium(II) (66 mg, 86 μmol) in benzene (5 mL) cooled in an ice-water bath and then stirred for 20 min. The mixture was quenched with water and extracted with benzene. The collected organic phases were dried, and the solvent was removed under vacuum to give *trans*-bis[bis{(*S*)-2-methylbutyl}phenylphosphine]bromo(methyl)-palladium(II) (57 mg, 81 μmol) in almost pure form. To this were added 1,2-diisocyano-3,6-di-*p*-tolylbenzene (99 mg, 0.32 mmol) and THF (5 mL). The mixture was stirred at room temperature for 12 h and then concentrated to afford a mixture of oligo(5,8-di-*p*-tolylquinoxaline-2,3-diyl)palladium(II) complexes quantitatively. Pentamer **5** (48 mg) was isolated by preparative GPC (polystyrene, $CHCl_3$). Two isomers **5a** and **5b** were separated by preparative HPLC on silica gel (hexane: EtOAc:EtOH = 200:20:1). **5a**: UV (CH_2Cl_2): λ_{max} [nm] (ε) = 263 (139000); $[\alpha]_D = -343$ ($c = 0.7$, $CHCl_3$). **5b**: UV (CH_2Cl_2): λ_{max} [nm] (ε) = 263 (175000); $[\alpha]_D = +233$ ($c = 0.8$, $CHCl_3$).

8a: A solution of **7** (31 mg, 0.10 mmol) and **5a** (4.9 mg, 2.2 μmol) in THF (6 mL) was stirred at room temperature for 36 h before MeMgBr (0.6 mmol, 2 M solution in ether) was added. After the reaction mixture had been stirred for 1 h, water was added, and the mixture was extracted with $CHCl_3$. The collected organic phases were dried, and the solvent was removed under vacuum. Preparative GPC (polystyrene, $CHCl_3$) afforded **8a**. Yield: 27 mg (78%). UV (CH_2Cl_2): λ_{max} [nm] (ε) = 287 (905000), 349 (345000).

8b: Following the procedure for **8a**, **7** (30.5 mg, 0.10 mmol) and **5b** (4.9 mg, 2.2 μmol) provided **8b**. Yield: 28 mg (83%). UV (CH_2Cl_2): λ_{max} [nm] (ε) = 288 (912000), 349 (339000).

Details of the CD spectral analysis will be published in due course.

Triphosphatrisilacyclohexanes as Tridentate Coronands in Cr and Mo Complexes: Activation of Si–H in an Early Stage versus Phosphane Coordination

By *Matthias Driess,* Michael Reisgys,* and *Hans Pritzkow*

Dedicated to Professor Hermann Schildknecht on the occasion of his 70th birthday

Only isolated examples of cyclic multidentate phosphane ligands such as phospha crown ethers are known, and these

[*] Dr. M. Driess, Dipl.-Chem. M. Reisgys, Dr. H. Pritzkow

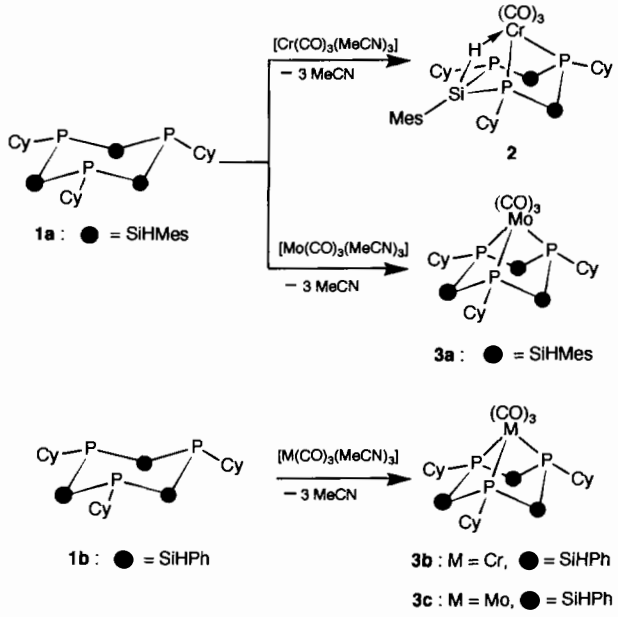
[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank the referees for valuable tips.

are difficult to prepare.[1] Nevertheless, an increasing demand exists for such phosphane ligands containing a large potential for varying the substituents, so that the design of metal complexes (e.g. as catalytic active substances) may be achieved more efficiently than is possible with acyclic systems. The difficult access to cyclic multidentate organophosphanes contrasts with the simple synthesis of cyclophosphasilanes,[2] whose suitability as chelate ligands in organometallic chemistry has hardly been studied.[3] The only cyclophosphasilane with a P_3Si_3 ring framework that has been described is $(PhP–SiPh_2)_3$, which can coordinate through three phosphorus atoms to $[Mo(CO)_3]$, but not to $[Cr(CO)_3]$.[4] Till now, neither the free ligand nor the complex with $[Mo(CO)_3]$ has been structurally characterized.

We report here on the first hexaorgano-substituted, crystalline triphosphatrisilacyclohexanes **1a,b** (Scheme 1) containing one Si–H bond per Si atom and their unusual coordination to $[M(CO)_3]$ fragments (M = Cr, Mo). Ligand **1a** and the $[Cr(CO)_3]$ fragment surprisingly form the Si,H,Cr



Scheme 1. Synthesis of complexes **2** and **3**. Cy = cyclohexyl, Mes = 2,4,6-trimethylphenyl (mesityl). The Si-bound H atoms are located in axial positions in all compounds.

three-center two-electron complex **2**, and only with $[Mo(CO)_3]$ is the anticipated coordination by three phosphorus atoms observed (**3a**). In contrast, **1b** functions exclusively as a tridentate phosphane ligand towards $[M(CO)_3]$ (M = Cr, Mo; **3b,c**). The P_3Si_3 heterocycles **1a,b** (Table 1) are formed by cyclocondensation of $RSiHCl_2$ (R = Mes, Ph) with LiPH(Cy). The P_3Si_3 ring inverts rapidly in solution on the NMR timescale. Similar ring flexibility and low inversion barriers at phosphorus atoms occur in $(PhP–SiPh_2)_3$ and $(HP–SiMe_2)_3$.[4] The substituents at Si and P are expected to occupy equatorial positions because of their bulk; a single-crystal X-ray analysis confirms this for **1a** (Fig. 1). The P_3Si_3 ring is in a chair conformation and is considerably distorted on account of the different endocyclic bond angles at phosphorus and silicon.

If ligand **1a** is stirred with $[Cr(CO)_3(MeCN)_3]$ in benzene at 25 °C, **2** forms instead of the chromium complex

M.p. 215–220 °C (decomp)

two-electron bond is shown beyond doubt by the ^{29}Si and ^{1}H NMR spectra: **2** yields three ^{29}Si NMR signals split into multiplets by ^{31}P and ^{1}H coupling. Experiments with selective ^{1}H decoupling confirm the assignment of the multiplet at $\delta = -45.2$ to the ^{29}Si nucleus participating in the Si,H,Cr bond. The $J_{Si,H}$ coupling constant of 135.7 Hz is the largest value reported for a complex with agostic Si–H bonding.[6] In contrast, the ^{29}Si nuclei in **2** whose Si–H bonds are not affected show typical $^{1}J_{Si,H}$ coupling constants of 210.9 and 228.6 Hz. In related three-center complexes with manganese and chromium as coordination centers, $[(\eta^5\text{-}C_5R_5)(CO)LMn(H)SiR_3]$ and $[(\eta^6\text{-}C_6Me_6)(CO)_2Cr(H)(SiHPh_2)]$, the values of the coupling constants lie between 65 and 80 Hz, which is considered a sure sign of a Si–H bond.[6] The value drops to 10–20 Hz if no Si–H bonding interaction is present. Probably the relatively weak Si–H activation in **2** is mainly attributable to the special geometric features of the molecule. Apparently in this case the coordination through the Si–H bond instead of through the third phosphorus atom lessens the unfavorable steric interactions of the substituents in the Cr complex. At any rate the exchange of the chromium atom for the larger molybdenum atom is enough to result in **3a** in which all three phosphorus atoms of **1a** are coordinated to the metal center.

In the ^{1}H NMR spectrum the agostic proton of **2** is easily distinguished from the nonagostic protons: the H atom coordinated to Cr gives rise to a doublet at characteristically high field ($\delta = -7.69$, $J_{P,H} = 33.6$ Hz), whereas the signals for the other two H atoms occur at $\delta = 5.64$ ($J_{P,H} = 26.1$ Hz) and $\delta = 6.50$ (overlapping signal group).

The constitution of **2** derived from the NMR spectra was confirmed by an X-ray crystal structure analysis (Fig. 2).[7] The H atoms bound to Si could be localized with the difference Fourier map, and the Si–H, Cr–H, and Cr–Si distances are all in accord with the finding that the Si,H,Cr three-center bond represents an unusually early stage of Si–H activation. The Si–H distance in the Si,H,Cr bridge is 1.52(4) Å, while the nonagostic Si–H bonds are on average 1.36(4) Å long. The Cr–Si distance (agostic Si) of 2.616(1) Å is distinctly longer than that in Cr complexes with terminally bound silyl ligands. The Cr–H distance (agostic H) is 1.75(5) Å long. In contrast, the related complex also containing a Si,H,Cr three-center bond, $[(\eta^6\text{-}C_6Me_6)(CO)_2Cr(H)(SiHPh_2)]$,[6] has clearly shorter Cr–H (1.61(4) Å) and Cr–Si distances (2.456(1) Å) and at the same time a longer Si–H bridgehead bond (1.61(4) Å) and normal terminal Si–H bond lengths (1.39(3) Å). Moreover, the Cr atom in **2** is coordinated to the atoms P1 and P2 that are in 3- and 1-position relative to the agostic Si atom.

The ligand **1a** reacts with $[Mo(CO)_3(CH_3CN)_3]$ to form **3a**, which is convincingly shown by the NMR spectra (Table 1). The crystal structure analysis[8] (Fig. 3) shows that the P_3Si_3 ligand is forced into a pronounced crownlike chair conformation by its tridentate coordination to the Mo atom.

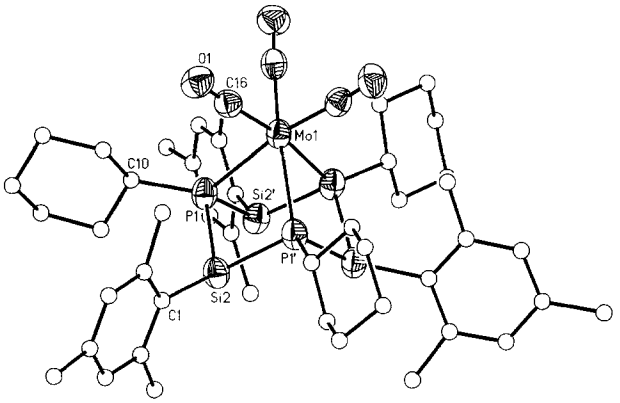

Fig. 3. Molecular structure of **3a** in the crystal. Selected distances [Å] and angles [°]: Mo1–P1 2.616(2), Mo1–C16 1.936(6), P1–Si2 2.290(2), P1–Si2' 2.284(2); P1-Mo1-P1' 74.8(1), P1-Si2-P1' 88.0(1), Si2-P1-Si2' 97.2(1).

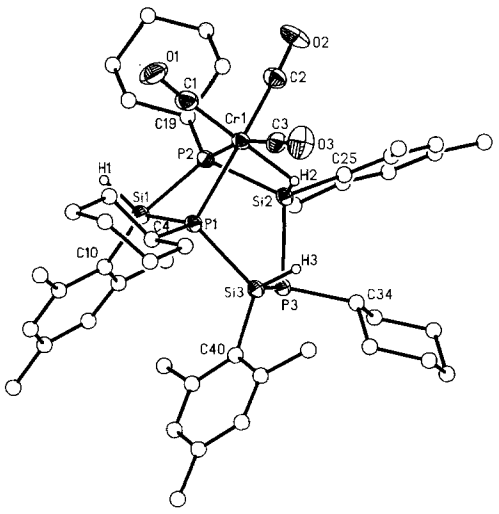

Fig. 2. Molecular structure of **2** in the crystal. Selected distances [Å]: Cr1–P1 2.407(1), Cr1–P2 2.372(1), Cr1–P3 4.24, Cr1–Si2 2.616(1), Cr1–H2 1.75(5), P1–Si1 2.279(2), P1–Si3 2.271(2), P2–Si2 2.208(2), P2–Si1 2.229(2), P3–Si2 2.272(2), P3–Si3 2.250(1), Si1–H1 1.34(5), Si2–H2 1.52(4), Si3–H3 1.38(4).

In contrast to **1a**, **1b** (phenyl instead of mesityl groups at Si) surprisingly reacts not only with $[Mo(CO)_3]$ but also with $[Cr(CO)_3]$ to afford analogous compounds **3b** and **3c**. This finding was confirmed by NMR spectroscopy (Table 1) and the crystal structure analyses of **3b,c**.[9] The crystallographic investigations of the complexes **3** reveal no significant structural variations. That the bulky mesityl group determines the different behavior of **1a** toward $[Cr(CO)_3]$ is clear from molecular models. If the phenyl groups are exchanged for mesityl groups in the crystallographically determined structure of the Cr complex **3b**, the structure obtained is less favorable than that of **2** because of the *ortho* methyl groups on the phenyl groups. We assume that **2** does not form by rearranging from this less stable isomer, but by the stepwise ligation of $[Cr(CO)_3(MeCN)_3]$ to **1a**. The *syn* position of the Si-bound H atoms and chromium in **2** arises without difficulty from the inversion of the configuration of the phosphorus atoms P1 and P2. Further investigations into whether the competition between Si–H activation and phosphane coordination in cyclophosphasilanes is also influenced by *electronic* effects such as the nature of the metal and its oxidation state are under way.

Experimental Procedure

1a: $C_6H_{11}PH_2$ (4.5 g, 39 mmol) was dissolved in THF (50 mL) and lithiated with *n*BuLi in hexane (2.5 M, Aldrich, 39 mmol) at about −70 °C. The resulting lithium phosphide solution was added within 30 min to a solution of MesSiH-

Cl_2 (4.27 g, 19.5 mmol) in THF (100 mL) at −60 °C. After removal of the volatile components under vacuum (10^{-2} Torr), the residue was taken up in benzene (30 mL) and filtered to remove LiCl. The filtrate was evaporated to dryness in vacuum, and the residue taken up in hexane. At −5 °C **1a** crystallizes as a colorless solid (2.32 g, 2.9 mmol, 45%).

1b: From $C_6H_{11}PH_2$ (5.4 g, 46.5 mmol) in Et_2O (80 mL), a solution of LiHPC$_6H_{11}$ was prepared analogously to the procedure for **1a**. To this lithium phosphide solution at −70 °C, a solution of $PhSiHCl_2$ (8.23 g, 46.5 mmol) in Et_2O (30 mL) was added slowly. The mixture was allowed to warm to 25 °C, then stirred for 2 h, and again cooled to −90°C. A solution of *t*BuLi (27.3 mL, 46.5 mmol; 1.7 M in pentane, Aldrich) was added. The suspension was warmed to 25 °C within 8 h and evaporated to dryness under vacuum (10^{-2} Torr). The residue was extracted with hot toluene. Cooling to −30 °C yielded **1b** as a colorless solid (4.13 g, 6.26 mmol, 40%).

2: **1a** (750 mg, 0.95 mmol) and $[Cr(CO)_3(MeCN)_3]$ (250 mg, 0.96 mmol) were stirred with benzene (40 mL) at 25 °C in a Schlenk tube for about 16 h. The solvent was removed under vacuum, and the residue taken up in CH_2Cl_2 (10 mL) and filtered. The filtrate was added dropwise with stirring to pentane (50 mL), upon which **2** precipitated as an ochre solid. Yield: 340 mg, 0.37 mmol, 38.9%.

3a: **1a** (440 mg, 0.56 mmol) and $[Mo(CO)_3(MeCN)_3]$ (180 mg, 0.59 mmol) were suspended in hexane (80 mL) and heated in a closed Schlenk tube (Teflon tap) for 6 h at 60 °C. The solvent and volatile components were removed under vacuum, and the bright red residue dissolved in CH_2Cl_2 (40 mL). After filtration, crystallization at −10 °C yielded orange-red crystals (510 mg, 0.53 mmol, 94.6%).

3b: **1b** (1.68 g, 2.56 mmol) and $[Cr(CO)_3(MeCN)_3]$ (660 mg, 2.55 mmol) were treated with pentane (50 mL) in a Schlenk tube and heated for 20 h at 40 °C. A yellow precipitate formed, which was filtered off, dissolved in CH_2Cl_2 (10 mL), and again filtered. **3b** precipitated on addition of pentane as a yellow solid (yield: 910 mg, 1.14 mmol, 44.5%).

3c: In an analogous synthesis to that of **3b**, **1b** (480 mg, 0.73 mmol) was allowed to react with $[Mo(CO)_3(MeCN)_3]$ (220 mg, 0.72 mmol) in hexane (10 mL) at 60 °C. Red crystals were obtained by crystallization from CH_2Cl_2 (480 mg, 0.57 mmol, 78%).

Multifield Saturation Magnetization Measurements of Oxidized and Reduced Ribonucleotide Reductase from *Escherichia coli*

By *Mohammed Atta, Corinne Scheer, Pascal H. Fries, Marc Fontecave,* and *Jean-Marc Latour**

Ribonucleotide reductases are found in all living organisms where they catalyze the conversion of ribonucleotides to deoxyribonucleotides, an essential step in DNA biosynthesis. The enzyme from *Escherichia coli* has been shown to consist of two homodimeric subunits R1 and R2.[1] The X-ray crystal structure determination[2] of the oxidized form of protein R2 has shown that its active site contains a binuclear iron center similar to the one found in hemerythrin. However, its resolution was insufficient to identify clearly the nature of the group bridging the two iron atoms; the presence of an oxo bridge was demonstrated from spectroscopic measurements.[1, 3] In accord with this, a magnetic susceptibility study[4] has shown that the two high-spin iron(III) ions are strongly antiferromagnetically coupled; however, due to experimental limitations a precise determination of the exchange interaction was not achieved ($-J = 106 \pm 22$ cm^{-1}; $H = -2J\,S_1 \cdot S_2$). A tyrosyl residue, essential for the enzyme function, is present about 5 Å from the closest iron atom.

Much less is known, however, on the binuclear iron center of the reduced enzyme. Reduction of the iron center is an essential step during the formation of the tyrosyl radical and the resulting activation of the enzyme.[5] Mössbauer experiments[6] have concluded that the two iron sites are essentially equivalent and that the spin coupling between the two iron(II) ions, if present, is smaller than the zero-field splittings. On the other hand Ehrenberg et al. have determined the coupling from NMR studies ($-J = 5 \pm 5$ cm^{-1}) and concluded that the interaction in the iron center is weak, if it exists at all.[7] Accordingly, a weak exchange interaction is anticipated for reduced ribonucleotide reductase. In hemerythrin, protonation of the oxo bridge occurs simultaneously with reduction of the diiron(III) center,[8] and an analogous process might be operative in ribonucleotide reductase. The magnetic interaction between two iron ions depends critically on the nature of their bridging ligands. It is well known that carboxylate bridges are poor mediators of exchange interactions in these systems. Magnetic susceptibility measurements performed both on proteins and on synthetic analogues clearly identify the range of values of the magnetic exchange interaction associated with every bridging ligand.[9] Starting from a high value ($-J = 80$–140 cm^{-1}) for oxo derivatives, this interaction decreases with protonation to $-J = 10$–50 cm^{-1} for a hydroxo bridge.[10] A weak but definitely positive value of J is supposedly associated with further protonation in several natural systems.[8, 11] It follows that magnetization studies constitute a valuable tool for investigating the transformations involved in the reduction of the diiron center.

In this paper, we report multifield saturation magnetization studies of both the oxidized and the reduced forms of ribonucleotide reductase. The high exchange interaction cal-

culated here provides additional support for the presence of an oxo bridge in the oxidized enzyme; moreover, magneto-structural correlations suggest that the diiron center is structurally similar to the one found in methemerythrin derivatives. In the case of reduced ribonucleotide reductase, this study points to an extremely weak exchange interaction, if it exists at all; this strongly suggests that the oxo bridge has been protonated and then eliminated during reduction. A structural hypothesis is proposed accordingly.

Multifield saturation magnetization data were collected on two different protein samples,[12] R2 and reduced R2, with a SHE 900 SQUID susceptometer according to the procedure outlined by Day et al.[13] The sample was contained in a quartz bucket etched overnight with a 10% HF solution. Measurements were performed in the 5–200 K temperature range at six field strengths (0.5, 1, 2, 3, 4, and 5 T). The data was treated according to the method of Day et al.[13]

Figure 1 illustrates the magnetic properties of oxidized ribonucleotide reductase as the temperature dependence of the product of the magnetic susceptibility and the

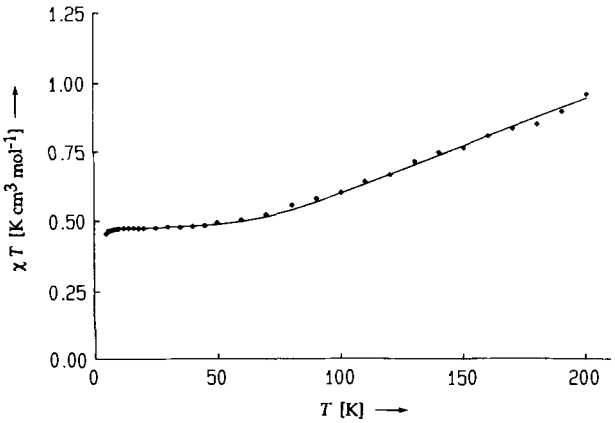

Fig. 1. Oxidized R2: Temperature dependence of the product of the magnetic susceptibility and the temperature. The experimental data (•) are the mean values of the data collected at the six field strengths. The solid line corresponds to the theoretical values (see text).

temperature. This curve clearly shows a plateau at $\chi T \approx 0.45\ \mathrm{K\,cm^3\,mol^{-1}}$ at temperatures lower than 50 K and an increase of χT at higher temperatures. Such behavior is fully consistent with an isolated spin $S = 1/2$ contributing to the plateau ($\chi T \approx 0.4\ \mathrm{K\,cm^3 mol^{-1}}$) and an antiferromagnetically coupled pair of high-spin Fe^{III} ions, whose contribution is negligible at low temperature. Simulation of the experimental data with an equation derived from the corresponding Heisenberg Hamiltonian, taking into account the presence of a small amount (p) of adventitious high-spin Fe^{III}, leads to the best fit parameters $g = 2.00$, $J = -84(5)\ \mathrm{cm^{-1}}$, and $p = 0.022(2)$. This value of J is at the upper end of the range estimated by Ehrenberg et al.[4] ($-128 < J < -83\ \mathrm{cm^{-1}}$). Undoubtedly, such a strong antiferromagnetic coupling is indicative[9] that the iron atoms are bridged by an oxide ion, in agreement with the conclusions drawn from spectroscopic measurements.[3]

Analyzing the structural and magnetic properties of three dozen (μ-oxo)diiron(III) complexes, Gorun and Lippard[14] have recently proposed a correlation between the exchange interaction (J) and the Fe–O distance (P), the shortest exchange pathway between the two iron(III) ions. Introducing the above J value into this relation leads to a value of 1.82 Å for the Fe–O distance P and 130° for the Fe-O-Fe angle on using the Fe–Fe distance of 3.3 Å obtained from the X-ray analysis. The same value of the Fe-O-Fe angle was deduced from resonance Raman data.[15] These values are quite reasonable for a (μ-oxo)(μ-carboxylato)diiron(III) entity[9] and in very good agreement with the ones measured on methemerythrin derivatives.[16]

Figure 2 presents the magnetization data of reduced ribonucleotide reductase over the 5–200 K temperature range at six field strengths. In Figure 2a the susceptibilities for the six fields are plotted versus the inverse temperature; Figure 2b displays the variation of the product χT with the temperature for the two extreme fields (0.5 and 5 T).

The spin Hamiltonian for the two exchange-coupled iron spins $S = 2$ is given in Equation (a), where the anisotropic Zeeman interaction $\mathscr{H}_{iz}$ is represented by Equation (b). J is

$$\mathscr{H} = -2J\vec{S}_1 \cdot \vec{S}_2 + \sum_{i=1,2} [D(S_{iz}^2 - 2) + E(S_{ix}^2 - S_{iy}^2) + \mathscr{H}_{iz}] \quad \text{(a)}$$

$$\mathscr{H}_{iz} = \mu_B(g_x H_x S_{ix} + g_y H_y S_{iy} + g_z H_z S_{iz}) \quad \text{(b)}$$

the isotropic coupling constant. D and E are the axial and rhombic parameters of the zero-field splitting (ZFS) tensors which are assumed to be equal for both ions. The usual hypothesis is made that for each ion the ZFS tensor and the Zeeman g factor can be simultaneously diagonalized.[17a] The calculations have been performed while fixing or floating the various parameters to assess their relative importance. It follows from this procedure that inclusion of the rhombicity in the calculation (either as $E \neq 0$ or as $g_x \neq g_y$)

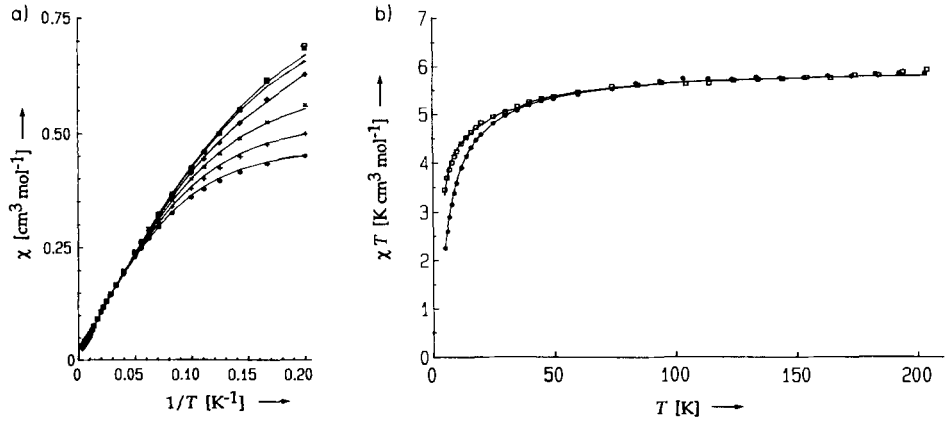

Fig. 2. Reduced R2: a) Dependence of the magnetic susceptibility on the inverse temperature at the six experimental fields: 0.5 (□), 1 (△), 2 (○), 3 (×), 4 (+), and 5 T (*). The solid lines are the calculated values (see text). b) Temperature dependence of the product of the magnetic susceptibility and the temperature at the two extreme field strengths: 0.5 (□) and 5 T (*). The solid lines are the calculated values (see text).

leads to a slight but hardly significant improvement of the statistical index. In any case, the E value never exceeded 1 cm^{-1} and g_x never differed from g_y by more than 0.1. On the other hand, a small J value was found and fixing J to 0 induced a significantly poorer fit. Accordingly, the final calculations were done with five parameters: J, D, $g_x = g_y$, g_z.

The solid lines in Figure 2 were calculated with the following set of parameters:[18] $g_x = 1.63(5)$, $g_y = 1.63(5)$, $g_z = 2.56(5)$, $J = 0.3(2)\ cm^{-1}$, and $D = 9.8(5)\ cm^{-1}$. The value estimated for the axial zero-field splitting is comparable to the one observed for deoxyhemerythrin derivatives,[8, 11] but the most remarkable feature is the extreme weakness of the exchange interaction J. In the case of reduced hemerythrin $-J$ is $12-38\ cm^{-1}$, in agreement with the presence of a hydroxo bridge.[8] A further protonation to an aqua bridge is presumed to occur with the binding of some exogeneous anions and results in the decrease of the exchange interaction. When the counterion is azide, the coupling even changes sign ($J = 1.7\ cm^{-1}$)[11] and the interaction becomes ferromagnetic, which leads to an EPR-active $S = 4$ ground state of the deoxyHrN_3 protein. In its reduced form methane monooxygenase (MMO), another diiron protein, presents the same kind of EPR signal characterized by a high g value ($g \approx 16$).[19] It is worth mentioning that reduced ribonucleotide reductase from *E. coli* is EPR silent[20] for conditions under which deoxyHrN_3 and reduced MMO exhibit the high g value spectrum. This observation might suggest that a water molecule is not the ligand bridging the iron atoms in reduced ribonucleotide reductase, but which bridging ligands could then be present in reduced ribonucleotide reductase? During reduction of the oxidized enzyme, a weakly binding aqua bridge could conceivably be formed upon protonation of the oxo bridge and subsequently be replaced by the carboxylate group from glutamate 238. This residue is terminal and monodentate in oxidized R2 and would become bridging and bidentate in the reduced protein. From the structural analysis of a wealth of carboxylato metal complexes, Lippard et al.[21] have shown that such a change in the coordination mode of a carboxylate residue from terminal to bridging is a viable possibility. Moreover, the carboxylate group from aspartate 84 would probably become monodentate resulting in the hypothetical situation illustrated in Figure 3. Interestingly, a similar structure has been

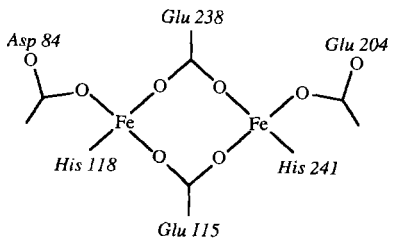

Fig. 3. Structural hypothesis for the diiron center of reduced protein R2. It is highly likely that the coordination of the iron(II) ions is completed by water molecules as found for oxidized R2

found recently by X-ray crystallography for a new form of protein R2 in which the iron centers have been replaced by divalent manganese ions.[22] This observation gives additional support to the above hypothesis.

[12] Proteins R2 and apoR2 were prepared in Tris buffer (0.1 M, pH 7.5, 20% glycerol). The solvent of both solutions was then exchanged for D_2O by successive concentration followed by dilution with D_2O in an Amicon YM-30 centricon. Finally the protein solution was concentrated (1×10^{-3} M, 125 µL) and deaerated on a manifold argon/vacuum line. Reduced R2 was prepared in an anaerobic glove box by adding four equivalents of ammonium iron(II) sulfate to an apoR2 solution in D_2O. That iron was correctly incorporated was shown from the appearance of the tyrosyl radical upon exposure to air. This is observed both by EPR and UV/VIS spectroscopy. Moreover, no free iron(III) could be detected in the reoxidized sample by EPR spectroscopy (signal with $g = 4.3$).

[17] a) Also note that the single-ion ZFS tensors are assumed to be colinear. This simplification places very little restriction on a frozen solution when the J value is small, as found. The average molar magnetization $m_{av}(H)$ along the direction of the magnetic field H is calculated numerically from the partial derivative of the free energy [17 b]. The six parameters J, D, E, g_x, g_y, and g_z of the Hamiltonian are obtained through a least-squares fit to the experimental values of the product $m_{av}(H)\ T$ for all the magnetic fields and temperatures; b) N. W. Ashcroft, N. D. Mermin, *Solid State Physics*, Saunders, Philadelphia, **1976**, p. 643.
[18] The average value for g is 1.992, too low for an iron(II) derivative. We believe that the uncertainty in protein quantitation is responsible for this result, as outlined by Day et al. [11]. The other parameters (J, D, E) are unaffected.

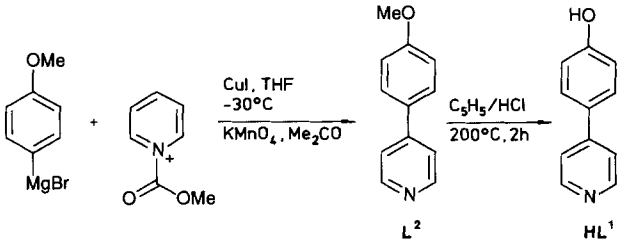
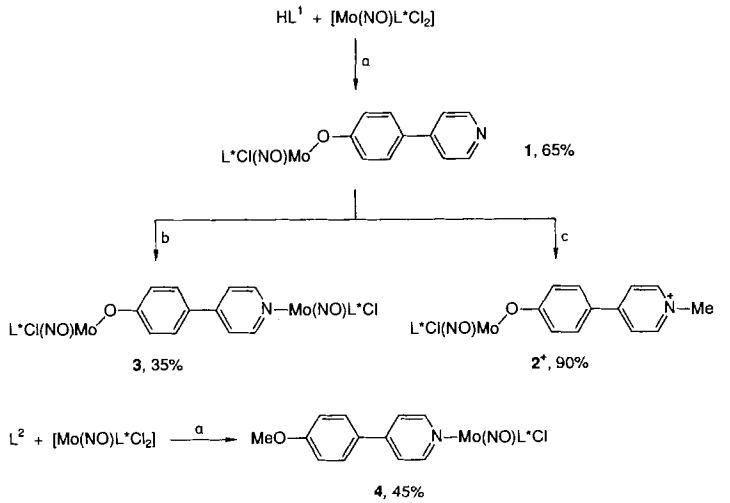
intramolecular electron transfer in mixed-valence systems[1] and the study of magnetic interactions between paramagnetic centers. The most extensively studied such complex is the Creutz–Taube ion;[2] more recently 4,4′-bipyridine-bridged binuclear complexes have received much attention.[3, 4] The synthesis of the symmetrical binuclear complex $[\{Mo(NO)L^*Cl\}_2(\mu\text{-bpy})]$ [L* = tris(3,5-dimethylpyrazolyl)-hydridoborate, bpy = 4,4′-bipyridine] was recently reported,[4] in which a strong electronic coupling between the [Mo(NO)L*Cl] centers caused a difference of 765 mV between the reductions of the first and the second metal centers; EPR spectroscopy showed rapid site exchange of the two unpaired electrons at room temperature. We now report the syntheses, and electrochemical and EPR spectroscopic properties of asymmetric, mixed-valent (17e–16e) and homovalent (17e–17e) (e = valence electrons) binuclear molybdenum complexes containing a 4-(4-hydroxyphenyl)pyridine bridge, and present evidence that metal–metal interactions are assisted by a nearly planar conformation of the bridging ligand.

The precursor L^2 was prepared by extensions of known procedures,[5–7] and demethylated with pyridinium chloride[8] to give HL^1 (Scheme 1). Syntheses of the complexes



Scheme 1. Syntheses of the ligands L^2 [6] and HL^1.

are outlined in Scheme 2.[7] Reaction of $[MoL^*(NO)Cl_2]$ with HL^1 afforded **1**, in which the phenoxide terminus of L^1 is attached to the 16-electron Mo center and the pyridyl group is pendant. This reaction is apparently controlled by the difference in reaction rate between the anionic phenolate and the neutral pyridine with the electron-deficient



Scheme 2. Syntheses of the complexes **1**–**4** under an N_2 atmosphere. a) Toluene, Et_3N, 4 h under reflux; b) $[Mo(NO)L^*Cl_2]$, toluene, Et_3N, 6 h under reflux; c) MeI, CH_2Cl_2, 18 h under reflux.

$[Mo(NO)L^*Cl_2]$. Attachment of the pyridyl terminus to molybdenum could only be achieved if the phenol group was protected, as in L^2; thus, reaction of $[Mo(NO)L^*Cl_2]$ with L^2 produced **4** which has a pendant methoxyphenyl group. This complex has 17 valence electrons; attachment of the pyridyl ligand is accompanied by a one-electron reduction of the molybdenum center, probably by the Et_3N, which is known to act as a hydridic reducing agent.[9]

Methylation of the pendant pyridyl group in **1** gave $\mathbf{2}^+$, isolated as its PF_6^- salt. The electrochemical data (Table 1) show that the metal-centered reduction is anodically shifted

Table 1. Electrochemical and EPR data for the new complexes.

	Electrochemical processes [a]		EPR parameters	
	$E_{1/2}$	$E_{1/2}$	g [b]	Hyperfine splitting [mT]
1	−0.70 (75) [c]	–	–	–

[a] Potentials quoted in V vs. the ferrocene/ferrocenium couple, with peak–peak separations [mV] in parentheses. Electrochemical measurements were made with Pt-bead working and auxiliary electrodes and a saturated calomel electrode as reference electrode in a 0.1 M solution of $(Bu_4N)PF_6$ in CH_2Cl_2. In all cases ferrocene was used as an internal reference. [b] Average value of the g factor. [c] Potentials for the 16e–17e reduction of the [Mo(NO)L*Cl-(phenolate)] moiety. [d] 17e complex produced by in situ reduction of the parent 16e complex with cobaltocene. [e] Potentials for the reduction of the methylpyridinium moiety. [f] Potentials for the 17e–16e oxidation of the [Mo(NO)L*Cl(pyridyl)] moiety. [g] Potentials for the 17e–18e reduction of the [Mo(NO)L*Cl(pyridyl)] moiety.

by 120 mV on *N*-methylation of the pendant pyridyl group. This is in marked contrast to the behavior of polypyridine–ruthenium(II) complexes containing 4,4′-bipyridyl groups, where *N*-methylation of the pendant pyridyl groups results in an anodic shift of the Ru^{II}/Ru^{III} redox couples by just 20 mV per methylpyridinium group.[10] The large interaction in $\mathbf{2}^+$ is due to charge recombination in the deprotonated, methylated ligand resulting in a quinonoidal structure (Fig. 1). This constrains the ligand to be planar, prevents free rotation about the central C–C bond normally associated with biphenyls, and causes a decrease of electron density at the metal center by removal of the phenolate negative charge, thereby facilitating the 16e–17e reduction.

Reaction of **1** with further $[Mo(NO)L^*Cl_2]$ produced the mixed-valence complex **3**,[11] in which the N-coordinated

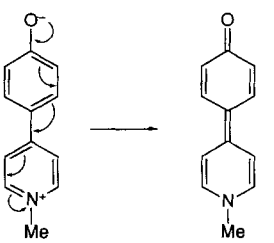

Fig. 1. Resonance structures of the deprotonated, *N*-methylated ligand HL^1.

molybdenum atom has 17 valence electrons, whereas the O-coordinated molybdenum atom has only 16. Thus, here also the addition of the pyridyl ligand is accompanied by a reduction of the molybdenum center. Electrochemical measurements (Table 1) confirm the presence of an electronic interaction between the two metal centers; whereas the difference between the reductions at the metal centers in **1** and **4** is 1.17 V, the presence of a direct link between them in **3** results in a $\Delta(E_{1/2})$ value of 1.35 V, that is, an increase of 180 mV. Again, this may be accounted for by a quinonoidal contribution to the structure of the bridging ligand which results in decreased electron density at the O-terminus and increased electron density at the N-terminus. This contribution will be more significant in **3** than in **1**, due to stabilization of the electron-rich pyridyl N atom by attachment to a 17-electron Mo center; the pyridyl group thus functions as a π donor rather than as a π acceptor, which is its more common role.

The EPR spectra of **4** and the reduced complexes $\mathbf{1}^-$ and **2** (produced by in situ reduction of the 16-electron species **1** and $\mathbf{2}^+$ with cobaltocene) all show hyperfine coupling constants of about 5.0 mT due to coupling to a single molybdenum center (Table 1). The coupling constant is similar for **3**; this indicates that the unpaired electron is trapped at the pyridyl-coordinated molybdenum center, which is to be expected considering the difference in the 16e–17e redox potentials for the two molybdenum sites. The localization of the unpaired electron in **3** is confirmed by virtually identical values of g for **3** (1.979) and **4** (1.978).

One-electron reduction of **3** with cobaltocene affords the 17e–17e species $\mathbf{3}^-$, a biradical where the two electrons are in redox levels 0.77 V apart. Despite this energy gap, the EPR spectrum (Fig. 2) indicates a change from localized to delocalized electrons on the EPR timescale. A single signal is observed at $g = 1.973$, midway between the values for the mononuclear components $\mathbf{1}^-$ and **4** ($g = 1.969$ and 1.978, respectively); this places a lower limit of 4×10^7 Hz on the electron-exchange frequency,[12] a reasonable value since studies of electron transfer across saturated hydrocarbon bridges have shown transfer rates in the region 10^6 to $10^9\ s^{-1}$.[13] Also the hyperfine splitting is halved to 2.6 mT. This confirms that, as with $[\{Mo(NO)L^*Cl\}_2(\mu\text{-bpy})]$,[4] there is fast electron exchange between the two metal centers with $|J| \gg A_0$ ($|J|$ is the exchange integral, A_0 is the hyperfine interaction);[14] in such cases the hyperfine splitting is predicted to be 0.5 ($A_0/g\beta$), that is, half the value found in the spectra of the mononuclear components. No half-field resonance was observed either at room temperature or 77 K, which may be ascribed to the intermetallic separation.[4] Although the complex is asymmetric, there is no barrier to electron exchange arising from reorganization of the metals' coordination spheres, since both metal centers possess 17 valence electrons before and after any exchange. To our knowledge this is the first example of fast exchange in an asymmetric biradical, bimetallic system.

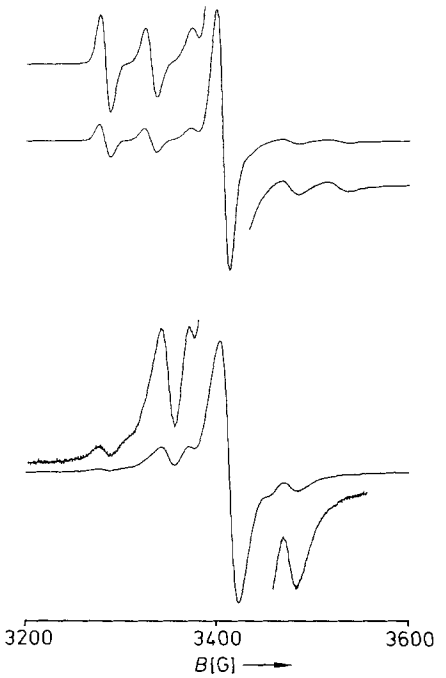

Fig. 2. Room-temperature EPR spectra of **3** and $\mathbf{3}^-$.

The crystal structure of **4** is shown in Figure 3.[15] The coordination geometry is approximately octahedral. The most interesting feature is the nearly coplanar aromatic rings of L^2 (dihedral angle of 5°). By contrast, in the isoelectronic complex $[Mo(NO)L^*(ppy)_2]^+$ (ppy = 4-phenylpyridine, an analogue of L^2 without the electron-donating methoxy group), the torsion angles between the rings are 30 and 41°.[18] This is consistent with our view that planarity of L^2 in **4**, and of L^1 in the other complexes, is due to partial quinonoidal character, although the central C–C bond length in **4** [1.476(9) Å] is close to the average value for biphenyl-type structures[19] and not significantly different from the corresponding distances in $[Mo(NO)L^*(ppy)_2]^+$ [1.430(15) and 1.497(13) Å]. Although near-planarity in the crystal structures of biphenyl-type species may often be ascribed to favorable stacking interactions between the aromatic rings,[19] this does not appear to apply in **4**; the aromatic rings are not especially close to any other groups, so it is less likely that the ligand is being forced into planarity by crystal packing effects.

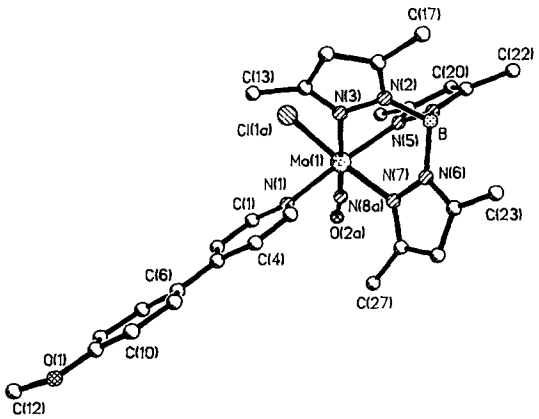

Fig. 3. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: Mo(1)-Cl(1a) 2.432(6), Mo(1)-N(8a) 1.85(2), Mo(1)-N(1) 2.204(5), Mo(1)-N(3) 2.246(5), Mo(1)-N(5) 2.163(5), Mo(1)-N(7) 2.196(5); N(1)-Mo(1)-N(7) 87.4(2), N(1)-Mo(1)-N(3) 86.9(2), N(8a)-Mo(1)-N(1) 92.0(6), Cl(1a)-Mo(1)-N(1) 93.6(2), Cl(1a)-Mo(1)-N(8a) 91.2(6), Cl(1a)-Mo(1)-N(3) 89.7(2), Cl(1a)-Mo(1)-N(5) 95.4(2), N(8a)-Mo(1)-N(5) 96.5(6), N(8a)-Mo(1)-N(7) 94.4(6).

[6] Preparation of L^2: To an ice-cold, stirred suspension of anhydrous CuI (0.1 g, 0.53 mmol) and dry pyridine (1.19 g, 15 mmol) in dry THF (25 cm^3) under N_2 was added methyl chloroformate (0.95 g, 10 mmol); a white precipitate appeared. The mixture was cooled to $-30\,^\circ C$, and a solution of the Grignard reagent prepared from 4-bromoanisole (2.06 g, 11 mmol) and Mg turnings (0.34 g, 14 mmol) in THF (20 cm^3) was added dropwise over 15 min. The mixture was stirred for 15 min at $-30\,^\circ C$ and then at room temperature for 1 h. After hydrolysis with aqueous NH_4Cl, the intermediate dihydropyridine was extracted with ether, concentrated, and rearomatized with $KMnO_4$ in acetone at $0\,^\circ C$. The product L^2 was obtained as a white solid in 65% yield after chromatography on alumina with CH_2Cl_2.
[7] All new compounds gave satisfactory elemental analyses. Data for HL^1: M.p. 250–252 °C. ^1H NMR (270 MHz, CD_3OD, TMS): $\delta = 6.91$ (d, $J = 8.6$ Hz, 2H; phenyl-H^2, -H^6), 7.63 (d, $J = 8.6$ Hz, 2H; phenyl-H^3, -H^5), 7.65 (d, $J = 5.6$ Hz, 2H; pyridyl-H^3, -H^5), 8.49 (d, $J = 5.6$ Hz, 2H; pyridyl-H^2, -H^6); MS: m/z 185 (M^+, 100%). Data for L^2: M.p. 95–96 °C. ^1H NMR (270 MHz, CD_3OD, TMS): $\delta = 3.84$ (s, 3H; OMe); 7.06 (d, $J = 8.6$ Hz, 2H; phenyl-H^2, -H^6), 7.69 (d, $J = 8.6$ Hz, 2H; phenyl-H^3, -H^5), 7.71 (d, $J = 5.6$ Hz, 2H; pyridyl-H^3, -H^5), 8.50 (d, $J = 5.6$ Hz, 2H; pyridyl-H^2, -H^6); MS: m/z 171 (M^+, 100%). FAB mass spectra of complexes **1**–**4** show molecular ion peaks at m/z 630, 644, 1088, and 644, respectively (based on the masses of the most abundant isotopes).

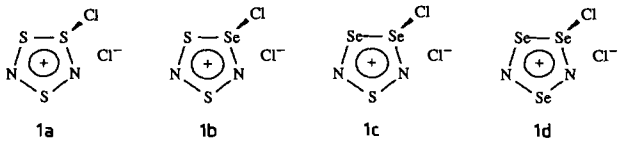
$Se_3N_2Cl_2$, a Novel Selenium–Nitrogen Chloride: Reinvestigation of "Se_4N_2"**

By *Jari Siivari*, *Tristram Chivers*,* and *Risto Laitinen*

The development of selenium–nitrogen (Se–N) chemistry has been impeded by the lack of readily available Se–N reagents.[1] For example, the selenium analogue of the useful synthon $S_3N_2Cl_2$[2] (**1a**) is unknown, although the mixed sulfur–selenium halides $S_2SeN_2Cl_2$ (**1b**)[3] and $SSe_2N_2Cl_2$ (**1c**)[4] have been structurally characterized recently.



In 1991 Dehnicke reported the preparation of tetraselenium dinitride obtained as a black powder [Eq. (a)].[5, 6] The

$$2\,Se_2Cl_2 + 4\,Me_3SiN_3 \xrightarrow{CH_2Cl_2} Se_4N_2 + 5\,N_2 + 4\,Me_3SiCl \qquad (a)$$

identification of Se_4N_2 relied solely on a comparison of the IR spectrum with that of the structurally characterized sulfur analogue *cyclo*-1,3-S_4N_2, which is a six-membered ring in the half-chair conformation,[7, 8] and with the calculated (3-21G*) vibrational frequencies.[5] The formation of 2:1 and 1:1 adducts of Se_4N_2 with $SnCl_4$ and $TiCl_4$, respectively, has also been reported.[9] These adducts were characterized by IR spectroscopy and by chemical analyses.

The reported stability of Se_4N_2 up to 80 °C[5] appeared to us to be incompatible with the facile thermal decomposition of diiminoselanes RN=Se=NR (R = *t*Bu,[10] $SiMe_3$[11]) above 0 °C. These observations, and our interest in heterocycles of the type $Se_xS_{4-x}N_2$ ($x = 1-4$),[12] prompted us to reinvestigate reaction (a). We report here that the compound formulated by Dehnicke et al. as Se_4N_2 is, in fact, $Se_3N_2Cl_2$ (**1d**) and describe an alternative route to this novel selenium–nitrogen halide.

The reaction of trimethylsilyl azide with diselenium dichloride was carried out according to the literature proce-

dure to give an insoluble black powder with an IR spectrum in good agreement with that reported by Dehnicke et al.[5] The insolubility of this black powder in organic solvents and in liquid SO_2 and the possibility of explosions[13] combine to make its characterization by spectroscopic methods (e.g. NMR) difficult. However, complete elemental analyses are consistent with the formula $Se_3N_2Cl_2$ rather than Se_4N_2.[14, 15] Furthermore, when the reaction is carried out with the stoichiometry indicated in Equation (a), the ^{1}H NMR spectrum of the filtrate reveals the presence of unchanged Me_3SiN_3 ($\delta = 0.26$). When the stoichiometry is adjusted to that shown in Equation (b), Me_3SiN_3 is com-

$$3\,Se_2Cl_2 + 2\,Me_3SiN_3 \longrightarrow \underset{\mathbf{1d}}{2\,Se_3N_2Cl_2} + 2\,Me_3SiCl + N_2 \qquad (b)$$

pletely consumed, and the ^{1}H NMR spectrum shows only Me_3SiCl ($\delta = 0.41$). The yield of $Se_3N_2Cl_2$ (found: Cl, 19.75; Se, 70.00) is approximately 70% after 16 h.

Compound **1d** may also be prepared in high yield by the reaction of bis[bis(trimethylsilyl)amino]selane[17] with a mixture of selenium halides designed to mimic "$SeCl_3$" in dichloromethane [Eq. (c)]. The ^{1}H NMR spectrum of the

$$3\,[(Me_3Si)_2N]_2Se + 4\,SeCl_4 + Se_2Cl_2 \longrightarrow \underset{\mathbf{1d}}{3\,Se_3N_2Cl_2} + 12\,Me_3SiCl \qquad (c)$$

filtrate revealed that Me_3SiCl ($\delta = 0.39$) is the exclusive proton-containing product of this reaction, which proceeds according to Equation (c) to give analytically pure samples of $Se_3N_2Cl_2$ (**1d**). The infrared spectra of the products obtained from the reactions (a), (b), and (c) are identical.

The synthesis of $Se_3N_2Cl_2$ completes the series **1a**–**1d** in which one of the sulfur atoms of **1a** is successively replaced by selenium. Although **1b** and **1c** are represented as ionic, we note that covalent forms of both derivatives have been structurally characterized.[3, 4] Thus **1d** may also exist in both covalent and ionic forms. The thermal instability of **1d** relative to the other members of the series is probably due to the presence of the labile NSeN group in **1d** and, as mentioned earlier,[15] samples should be stored at low temperatures to avoid loss of chlorine.

Finally, we note that attempts to convert $Se_3N_2Cl_2$ to the known compound $[Se_3N_2](AsF_6)_2$[18] by reaction with $AgAsF_6$ in liquid SO_2, or to prepare $Se_3N_2Cl^+$ salts by the treatment of $Se_3N_2Cl_2$ with chloride ion acceptors in dichloromethane or liquid SO_2, were unsuccessful, probably due to the insolubility of $Se_3N_2Cl_2$ in these solvents.

Experimental Procedure

A solution of $[(Me_3Si)_2N_2]Se$ [17] (0.200 g, 0.5 mmol) in CH_2Cl_2 (5 mL) was added to a mixture of Se_2Cl_2 (0.0345 g, 0.15 mmol) and $SeCl_4$ (0.143 g, 0.65 mmol) in CH_2Cl_2 (20 mL) at $-78\,^\circ C$ under a dry nitrogen atmosphere. The dark red solution was allowed to warm to room temperature (20 h) and gave a black precipitate, which was washed with CH_2Cl_2 (3 × 5 mL), to give $Se_3N_2Cl_2$ (0.16 g, 0.48 mmol, 95% yield). Analyses: calcd. Cl, 21.12; N, 8.34; Se, 70.54%; found: Cl, 20.73; N, 9.02; Se, 70.44%. IR (Nujol) $\tilde{\nu}$ [cm^{-1}] = 829(s), 584(s), 571(sh), 555(vs), 424(w).

[13] **Caution**: It is reported that this product "can be handled with ease at room temperature" [5]. We find, however, that the *dry* powder is extremely hazardous. For example, it explodes violently on contact with a metal spatula. We recommend, therefore, that it is stored under a hydrocarbon solvent.
[14] No analytical data were reported in ref. [5].
[15] To minimize the risk of explosions in handling the black powder, a weighed sample was mixed with Nujol prior to each analysis. Chloride was determined gravimetrically on sample sizes in the range 100–280 mg, and selenium was determined as red selenium on 100–300 mg samples by using a published procedure. [16] Anal. calcd. for $Cl_2N_2Se_3$: Cl, 21.12; N, 8.34; Se, 70.54. Found: Cl, 20.09; N, 7.45; Se, 72.68. These are average values for two (Se and Cl) and three (N) analyses. It is essential to use freshly prepared samples in order to obtain satisfactory analyses. Samples which have aged for a week give low values for Cl, for example, 13.4 and 15.8%, for two different week-old samples.

The New Subnitride $NaBa_3N$; an Extension of Alkali Metal Suboxide Chemistry**

By *Paul E. Rauch* and *Arndt Simon**

The heavy alkali metals rubidium and cesium form a series of suboxides with unusual structures which display a special separation of metallic and ionic bonds.[1] We were interested in extending this chemistry of alkali metal suboxides to alkaline earth metal subnitrides. Addison et al.[2] showed that barium dissolved in liquid sodium is quite reactive with nitrogen gas, and Ba_2N eventually precipitates. Before the precipitation of Ba_2N begins, however, there appears to be for-

mation of metal-rich clusters that remain in solution. Here we report the synthesis and structure of the new compound $NaBa_3N$.

$NaBa_3N$ was synthesized by slowly cooling a solution of barium and nitrogen in liquid sodium. Hard black needles were obtained.[3] The hexagonal structure consists of a close packing of Na and Ba atoms, that is, a packing of $NaBa_3$ layers, with the trigonal-antiprismatic voids formed by the Ba atoms filled with N atoms. The Ba and N atoms form rods composed of face-sharing Ba_6N octahedra, with single Na atoms arranged between these close-packed rods (Fig. 1). This structure corresponds to the hexagonal perovskite structure known for compounds such as $CsNiCl_3$.[4]

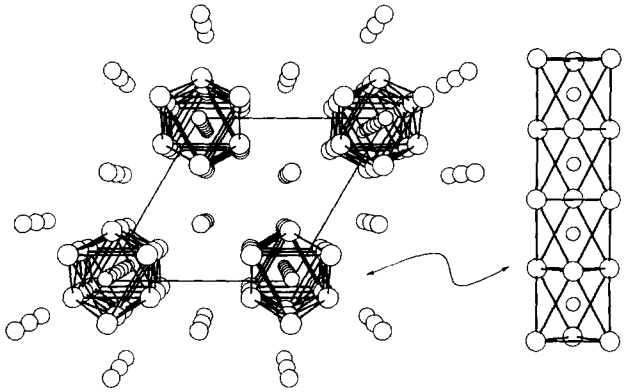

Fig. 1. Central projection of the structure of $NaBa_3N$ along [001] and a Ba_3N column along [210]. The Ba_3N columns are designated by interconnections between the Ba atoms. Distances [Å]: Ba-N 2.734(1), Ba-Ba 3.645(2) (within triangles), 4.076(1) (between triangles), and 4.796(2) (between chains), Ba-Na 4.234(1) and 4.456(1).

The Ba–N and Ba–Ba distances in $NaBa_3N$ (see legend to Fig. 1) compare favorably with the corresponding distances in the structure of the other known barium subnitride Ba_2N (2.760(5) and 3.788(5), 4.016(1), and 4.476(5) Å, respectively).[5] The Ba–Ba distance in Ba metal is 4.341 Å.[6] The shorter of the observed Ba–Na distances (4.234(1) Å) corresponds closely to the sum of the radii (4.154 Å)[7] for Ba and Na in the metals.

A simple model of the chemical bonding in $NaBa_3N$ is based on the much greater electronegativity of nitrogen versus barium and sodium. Tubes of Ba atoms with central N atoms, $\{[Ba^{2+}]_3N^{3-}\}$ $3e^-$, exhibit ionic bonding on the inside and metallic bonding on the "skin" of the tubes and between the tubes and Na atoms, leading to an overall metallic character. This model is verified by the results of a band-structure calculation, which show a low-lying, narrow, filled N2p band; the Fermi level is in a wide band of barium and sodium character.

As we hoped, the metallic and heteropolar bonding are segregated into separate regions in a way that has been seen previously in alkali metal suboxides.[1] Indeed, there is a close structural and bonding relationship between $NaBa_3N$ and the alkali metal suboxides. For example, in Rb_9O_2[8] and Rb_6O,[9] Rb_9O_2 units occur, which represent the first step towards the condensation of M_6X units by face sharing. This finally results in infinite chains as found in $NaBa_3N$.[10] Also in Rb_6O, alkali metal atoms are inserted between the clusters, as reflected in the formula $Rb_3Rb_9O_2$. In another alkali metal suboxide, $Rb_7Cs_{11}O_3$,[14] we see the same preference of different metal atoms for one or the other kind of bond type, as in $NaBa_3N$; the Cs atoms form clusters with oxygen, and the Rb atoms insert between the clusters. The structure of $NaBa_3N$ extends the chemistry of the alkali metal suboxides from discrete clusters to low-dimensional frameworks and on to the layered structure of Ba_2N.[5, 15]

The structure of $NaBa_3N$ helps complete a unified picture of metal cluster compounds.[16] Metal clusters can be grouped into electron-rich species, electron-poor species, and species with an intermediate number of electrons for metal–metal bonding. Within each of these groups we find discrete clusters, quasi-two-dimensional structures (sheets), and quasi-one-dimensional structures (chains).

In the electron-rich case there are enough electrons to form bonds with electronegative elements (Cl, S, etc.) outside the cluster and enough electrons to hold the clusters together by M–M bonding. Examples from this group include Mo_6Cl_{12},[17] Nb_6Cl_{14}[18] (discrete clusters), $ZrCl$[19] (sheets), and $TlMo_3Se_3$[20] (chains). In the intermediate case there are again enough electrons to form bonds with electronegative elements outside the cluster, but interstitial atoms in the cluster are now necessary to stabilize the assembly. Examples from this group include $Nb_6I_{11}H$[21] and $Zr_6Cl_{14}C$[22] (discrete clusters), $GdClH_x$[23] (sheets), and Gd_4I_5C[24] and Ta_4SiTe_4[25] (chains). Finally, in the electron-poor case there are not enough electrons to form bonds with electronegative elements outside the cluster, and an interstitial atom is required. Previously in this category, only discrete clusters such as Rb_9O_2 and $Cs_{11}O_3$, and sheets such as Ba_2N,[5, 14] were known. Now $NaBa_3N$ completes this set with a quasi-one-dimensional chain compound.

Experimental Procedure

The barium metal was purified by distillation, and the sodium metal by filtration of the liquid, prior to use.

$NaBa_3N$: Barium (0.4731 g, 3.445 mmol) and sodium (0.0696 g, 3.02 mmol) were heated to 410 °C in a tantalum crucible under argon (0.0347 MPa), and 27.52 mL of nitrogen (99.99%, 0.0253 MPa at 26.5 °C; ca. 0.28 mmol N_2) was added to this system. The total pressure (argon and nitrogen) was initially 0.0080 MPa. After 1 h this value stopped decreasing to give a final pressure of 0.0047 MPa. Next, enough argon was added to bring the pressure up to 0.0399 MPa, and the reaction mixture was heated at 400 °C for 3.5 h, and then cooled to 100 °C over the next 15 h. Many large (> 1 mm), hard, needle-shaped, black crystals formed, which could be easily separated from the soft solidified "flux" of Ba and Na. Quantitative removal of the crystals from the flux was not possible, hence a yield could not be determined, although $NaBa_3N$ appeared to be the main product.

[10] The Ba_3N chains correspond to those reported in Cs_3O [11], but there is some doubt about the correctness of the reported structure [12]. Crystals of Cs_3O exhibit strong diffuse superstructure reflections not taken into account in the reported structure [13]. The diffraction pattern of $NaBa_3N$ is free of any such diffuse reflections.

Enantioselective Complexation of Chiral Dicarboxylic Acids in Clefts of Functionalized 9,9′-Spirobifluorenes**

By *Victoria Alcazar* and *François Diederich**

The results of several studies on the enantioselective recognition of chiral substrates by optically active receptors have led to the conclusion that large differences in stability between diastereomeric complexes are preferentially obtained when the receptors are *conformationally homogenous*[1, 2] and when differential *oriented bonding interactions*, for example hydrogen bonding, are effective in the complexes.[3–6] Following these guidelines, we recently prepared the receptors **1** and **2** which incorporate a cleft formed by a rigid 9,9′-spirobifluorene unit functionalized with hydrogen-bonding residues. The 9,9′-spirobifluorene unit had previously been introduced by Prelog et al.[7] as spacer in chiral crown ethers. Binding studies with the racemic hosts showed that **1**, but not **2**, was capable of forming 1:1 complexes with aliphatic and aromatic dicarboxylic acids in chloroform (association constants $K_a \approx 10^3$ to 10^5 L mol^{-1} at 293 K). These complexes are mainly stabilized by hydrogen bonds between the two COOH groups of the guests and the two aminopyridine residues in **1** (Scheme 1a).[8, 9] On the other hand, monocarboxylic acids form much weaker complexes ($K_a \approx 100$ to 400 L mol^{-1}). In this report, we describe first investigations of the *enantioselective* complexation of chiral dicarboxylic acids by the enantiopure receptors (*R*)- and (*S*)-**1** and compare their chiral recognition potential to that of similarly functionalized but more flexible 1,1′-binaphthyl hosts.

[**] This work was supported in part by the U.S. National Institutes of Health and by the Fulbright Foundation (fellowship for V.A.).

For the preparation of (*R*)- and (*S*)-**1**, the racemic dicarboxylic acid **3** was prepared according to Prelog et al. and optically resolved via the diastereomeric amides obtained by reaction of the corresponding acyl halide with (−)-dehydroabietylamine.[7b] The conversion of the acyl halides, prepared from (*R*)-(+)- and (*S*)-(−)-**3**,[10] with 2-amino-6-methylpyridine afforded the enantiopure receptors (*R*)-**1** ($[\alpha]_D^{22}$ +177.5 (c = 0.435 in $CHCl_3$) and (*S*)-**1** ($[\alpha]_D^{22}$ −180.0 (c = 0.570 in $CHCl_3$)). The optically active amino acid derivatives needed as substrates for the binding studies were either commercially available or were prepared according to routine procedures.[10] The optically active 2,2′,7,7′-tetrasubstituted spirobifluorene (*S*)-**4** ($[\alpha]_{589}^{22}$ +3.1 (c = 0.450 in acetone)) was obtained by acylation of (*S*)-**3** ($C_7H_{15}COCl$, $AlCl_3$, CS_2, 67% yield).

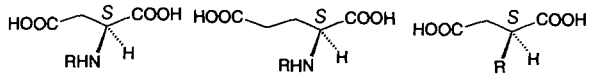
3 R = H
4 R = $CH_3(CH_2)_6CO$

Table 1 shows the results of ^{1}H NMR binding titrations executed under fast-exchange conditions and in significant concentration ranges.[11] The following findings are of particular interest:

1) The *N*-protected derivatives **5**–**8** of the acidic amino acids L-aspartic acid (L-Asp) and L-glutamic acid (L-Glu) are selectively recognized by the enantiomeric receptors. Differences in stability as high as $\Delta(\Delta G^\circ) = 0.9$ kcal mol^{-1} are measured for the diastereomeric complexes of the *N*-carbobenzyloxy (Cbz) protected substrates. Interestingly, L-Asp and L-Glu prefer binding to different host enantiomers. The Asp derivatives **5** and **6** form the most stable complexes with (*S*)-**1**, whereas the Glu derivatives **7** and **8** bind strongest to (*R*)-**1**. As a consequence of the different chain length, which is even-numbered in **5**/**6** and odd-numbered in **7**/**8**, the terminal carboxyl residues adopt very different orientations in the complexes, which ultimately leads to an inversion of the favored host configuration. This explanation is currently being tested in computer modeling studies.[12]

Binding constants of similar magnitude are measured for the complexes of the Cbz derivatives and the *n*-butylcarba-



5 R = $C_6H_5CH_2OCO$ **7** R = $C_6H_5CH_2OCO$ **9** R = C_6H_5S
6 R = *n*BuOCO **8** R = *n*BuOCO **10** R = C_6H_5Se

Table 1. Association constants K_a and binding free energies $-\Delta G°$ (uncertainty 0.1 kcal mol^{-1}) of the diastereomeric complexes formed by the enantiopure receptors **1** and **12** in $CDCl_3$ at 293 K. The value of $\Delta(\Delta G°)$ indicates the difference in stability between diastereomeric complexes.

Host	Guest	K_a [L mol^{-1}]	$-\Delta G°$ [kcal mol^{-1}]	$\Delta(\Delta G°)$ [kcal mol^{-1}]
(*R*)-**1**	**5**	820	3.9	
(*S*)-**1**	**5**	4200	4.8	0.9
(*R*)-**1**	**6**	1400	4.2

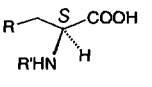
(*R*)-**1**	**7**	14000	5.6	0.8
(*S*)-**1**	**7**	3900	4.8	
(*R*)-**1**	**8**	23000	5.8	0.4
(*S*)-**1**	**8**	10000	5.4	
(*R*)-**1**	**9**	680	3.8	
(*S*)-**1**	**9**	3400	4.7	0.9
(*R*)-**1**	**10**	800	3.9	
(*S*)-**1**	**10**	2200	4.5	0.6
(*R*)-**1**	**11b**	420	3.5	
(*S*)-**1**	**11b**	680	3.8	0.3
(*R*)-**1**	(*S*)-**4**	490	3.6	
(*S*)-**1**	(*S*)-**4**	11300	5.4	1.8
(*R*)-**12**	**7**	20800	5.8	0.1
(*S*)-**12**	**7**	19400	5.7	
(*R*)-**12**	(*R*)-**13**	8500	5.3	0.1
(*S*)-**12**	(*R*)-**13**	7200	5.2	

mates. This indicates that the phenyl residues of the Cbz groups do not have specific stabilizing aromatic interactions with the spirobifluorene unit. This assumption is further supported by the absence of specific, complexation-induced changes in the ^{1}H NMR chemical shifts as well as by the absence of significant intermolecular Nuclear Overhauser effects in the complexes. For stable complexation *and* efficient chiral recognition, the presence of two carboxyl residues in the guest is essential. This is clearly shown in a series of control experiments: Compounds **11a–e** formed weaker complexes ($K_a \approx 10-700$ L mol^{-1}) with binding strengths similar to those exhibited by complexes with monocarboxylic acids, and chiral recognition was less effective (Table 1). On the other hand, considerable enantioselectivity was observed in the complexation of the two chiral succinic acid derivatives **9** and **10**.



11	R	R'
a	HO	Cbz
b	C_6H_5	Cbz
c	C_6H_5	C_6H_5NHCO
d	H_2NCOCH_2	Cbz
e	C_6H_5NHCOO	Cbz

2) Whereas complexation has a pronounced effect on the equilibrium between the *cis* and *trans* conformations of the NH–CO carbamate bond of **5**, no such effect is seen with **7**.[13] The integration of the NH and C(α)H proton NMR resonances, which appear at higher field in the *trans* and at lower field in the *cis* conformation,[14] shows that the *cis*/*trans* ratio of 3:1 in the free substrate **5** changes to 8:1 in the two diastereomeric complexes formed with (*R*)- and (*S*)-**1**. In contrast, the same *cis*/*trans* ratio of 8:1 is measured for both free and complexed carbamate **7**.

3) A very high enantioselectivity, $\Delta(\Delta G°) = 1.8 \pm 0.1$ kcal mol^{-1}, was measured for the complexation of the (*S*)-spirobifluorene-2,2′-dicarboxylic acid **4** by (*R*)- and (*S*)-**1**. The origin of this large difference in stability becomes apparent in examinations of CPK molecular models (Scheme 1b). Only in the complex of similarly configurated host and guest are the two spirobifluorene units capable of assembling in a way to lead to the formation of four hydrogen bonds. In the other diastereomeric complex, the interactions of two COOH groups with the H-bonding functionality of the host are impossible for geometrical reasons. Therefore, the association constant of the latter complex is small and of a magnitude characteristic for 1:1 complexes of monocarboxylic acids and amidopyridines. This result suggests that enantiopure host **1** could be prepared by resolving its direct precursor, the racemic spirobifluorenedicarboxylic acid **3**, through complexation with previously formed optically pure (*R*)- and (*S*)-**1** followed by crystallization, extraction, or chromatography.

4) The findings with the spirobifluorene receptors (*R*)- and (*S*)-**1** are in sharp contrast to the results obtained with the analogous 1,1′-binaphthyl cleft molecules (*R*)-**12** ($[\alpha]_D^{22}$ −19.40 (c = 1.01 in $CHCl_3$)) and (*S*)-**12** ($[\alpha]_D^{22}$ +19.28 (c = 1.12 in $CHCl_3$)).[2b, 8b] Although substrates **5–8** and the dicarboxylic acid (*R*)-**13** ($[\alpha]_D^{22}$ +14.74 (c = 0.231 in $CHCl_3$)) form stable complexes with the binaphthyl receptors, no significant degree of chiral recognition was observed (Table 1).[15] In contrast to the rigid spirobifluorene frame, the binaphthyl unit is conformationally flexible and capable of adopting geometries which fit both substrate enantiomers. As a consequence, diastereomeric complexes of similar ener-

gy are formed. However, through careful control of the 1,1'-binaphthyl geometry, for example by an additional binding site in the 2,2'-positions,[16] it should be possible to rigidify the cleft molecule and enhance its efficiency in chiral recognition. Experiments in this direction are now under way.

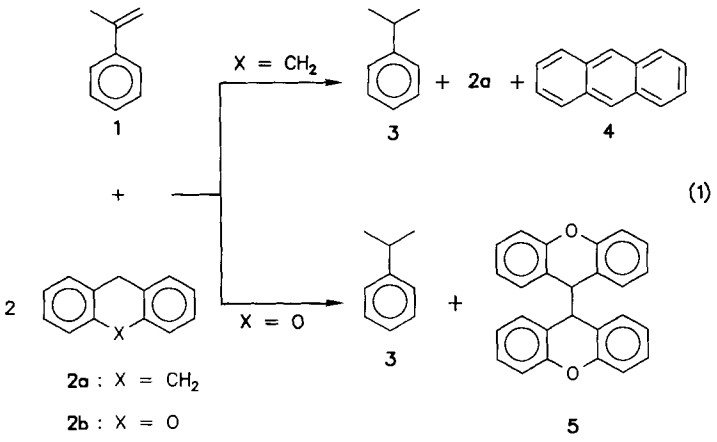
The Uncatalyzed Transfer Hydrogenation of α-Methylstyrene by Dihydroanthracene or Xanthene—a Radical Reaction**

By *Christoph Rüchardt,** *Matthias Gerst,* and *Margot Nölke*

During an investigation of the thermolysis of 3-(1-methyl-1-phenylethyl)pentane-2,4-dione at 290 °C with dihydroanthracene DHA **2a** as a radical trap, we observed that α-methylstyrene (**1**) formed initially was hydrogenated to cumene and that anthracene was an additional product. In independent experiments it was demonstrated that α-methylstyrene (**1**) is hydrogenated by DHA **2a** almost quantitatively at 280–310 °C in an uncatalyzed H-transfer reaction.

Hydrogen-transfer reactions between H donors and H acceptors catalyzed by transition metals are well known,[1] and examples catalyzed by Lewis acids have also been described.[2] Yet the literature contains few examples of uncatalyzed H-transfer reactions between organic or organometallic H donors and unsaturated hydrocarbons. The mechanisms of these reactions were either not examined more closely,[3] or they were described as pericyclic synchronous transfers.[4] For DHA **2a** and xanthene (**2b**) a pericyclic reaction is not possible, since it either cannot be formulated or it is symmetry forbidden as a thermal reaction (e.g. the reaction of **1** with **2a** of the type $[_\sigma 2_s + _\pi 2_s + _\sigma 2_s + _\pi 4_s]$[4c]). Recently, multistep mechanisms have been formulated in which bimolecular radical formation proceeds by H transfer;[5-7] most of the examples concern the assumed initiation steps of radical chains as in the uncatalyzed polymerization of styrene,[5a] the thermal chain addition of alkanes to alkenes,[5b] and the thermal decomposition of dihydronaphthalenes[6] and isotoluene.[7] These reactions are not suitable for an exact mechanistic study. The stoichiometric disproportionantion of DHA **2a** and 2-ethylanthracene[8a] which proceeds by H transfer, and the gas-phase reaction of ethylene and cyclopentene which occurs at 400–500 °C[8b] are exceptions.



(1)

We report here on experiments that prove that the hydrogenation of α-methylstyrene (**1**) by DHA **2a** is one of the few examples of a *stoichiometric*, solution-phase, uncatalyzed transfer hydrogenation of an alkene initiated by the bimolecular formation of a radical by H transfer from a C–H bond. Thus this reaction is a suitable subject for a mechanistic study of the type of "molecule-induced"[9] radical formation discussed as the initiation step in the uncatalyzed polymerization of styrene.

Kinetic measurements (Table 1) show that the rate of the H-transfer reaction [Eq. (1)] is first order in DHA **2a** and in α-methylstyrene (**1**) up to high conversions. Both the decrease in the concentration of **1** (k_2) and the increase of the concentration of **3** (k'_2) were followed by gas chromatography and provided the same results.

The rate constant of the bimolecular reaction is almost independent of the concentration of the H donor, invariant to oxygen, and also unchanged upon addition of the initiator

[a] k_2 in s^{-1}M^{-1}, σ in %. k: decrease in **1** was followed, k': increase in **3** was followed. [b] Deuterated **2a** (95% deuterium incorporation in the methylene position). [c] Addition of 5 mol% of 9,9′-bifluorene [10] relative to **1**, $\tau_{1/2} = 1$ h at 270 °C. [d] Addition of 10 mol% of 9,9′-bifluorene relative to **1**. [e] In kcal mol^{-1}. [f] In e.u. (cal K^{-1}mol^{-1}). [g] The activation data were calculated from the Eyring plot of all values of k_2 from **2a** and **2b** (exception: k_2 at 300 °C with deuterated **2a**).

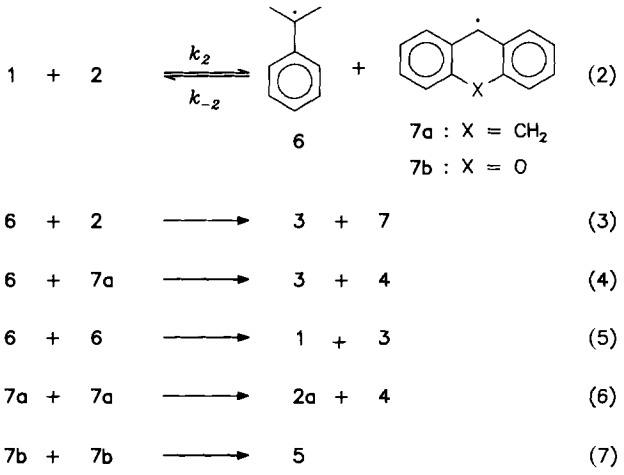
9,9′-bifluorene[10] ($\tau_{1/2} = 1$ h at 270 °C). Radical chain reactions can thus be ruled out.

We assume a bimolecular radical formation[5, 6] [Eq.(2)] followed by H transfer from DHA **2a** to the cumyl radical **6** [Eq.(3)] and subsequent disproportionation of **7a** [Eq.(6)].

Isotopic labeling of **2a** (95% deuterium incorporation at the methylene position) showed that an H atom is transferred from **2a** to **1** in the rate-determining step. The kinetic isotope effect $k_2(H)/k_2(D)$ at 300 °C was 2.1;[11] it has the same order of magnitude as known values.[5b, 8a]

According to isotope analyses by mass spectrometry, the back reaction with $v_{-2} = k_{-2}$[**6**][**7a**] does not take place, since deuterium is not incorporated into α-methylstyrene (**1**) and only dideuteriocumene is formed. Thus the rate of disappearance of **1** is governed solely by $v_2 = k_2$[**1**][**2a**]. Apparently, the reaction with $v_3 = k_3$[**2**][**6**] proceeds much faster than the back reaction with v_{-2} under the reaction conditions and thus certainly faster than the alternative disproportionation according to Equation (4). The reaction enthalpy of the H-transfer reaction [Eq.(2)] calculated from thermodynamic data,[12] ΔH°(25 °C,g) = 31.5 ± 2.0 − 34.2 ± 2.3 kcal mol^{-1}, is only somewhat less than the activation enthalpy $\Delta H^{\neq} = 35.9 \pm 1.4$ kcal mol^{-1} (Table 1); this supports the proposed mechanism. The back reaction should be a disproportionation without activation enthalpy. A metathesis reaction of **7a** and **1**[5b] combined with Equation (3) leads formally to a radical chain reaction. According to the kinetic results of the reaction of **1** with **2a** upon addition of bifluorene, this chain reaction does not seem to occur (Table 1); the radicals **7a** react faster following Equation (6).

The uniform reaction sequence is remarkable when one considers the possible competing side reactions of the radicals involved. The rate constants of the potential reactions of



radicals **6** and **7a** discussed were estimated, and the change in the experimental concentrations of **1** and **3** over time were calculated with the simulation program KISS.[13] The rate of the H transfer from the H donor **2a** to **6** [Eq.(3)] was found to be 10^3 times faster than formation of **3** by the disproportionation reactions in Equations (4) or (5). The fact that $v_3 = k_3$[**2a**][**6**] is favored over $v_4 = k_4$[**6**][**7a**] and $v_5 = k_5$[**6**][**6**] is explained by the low concentration of the radicals. According to work of Fischer et al.,[14] Equation (5) should be neglible relative to Equation (4), since when short-lived radicals **6** and long-lived radicals **7** are formed in equimolar amounts the cross termination reaction [Eq.(4)] dominates.

Moreover, it should be considered that mobile dimerization equilibria exist for the radical recombination of **6** and **7a**; nevertheless, the radicals are converted irreversibly into the reaction products.[15–17] In addition, the polymerization of **1** is outweighed by the corresponding depolymerization.[18]

Because of the fast disproportionation reaction [Eq.(6)], the steady-state concentration of radicals **7a** was too low for proof of their existence by ESR spectroscopy. Thus, we employed xanthene (**2b**) as the H-transfer agent, as xanthyl radicals **7b** cannot disproportionate following Equation (6). The reaction of **2b** proceeded analogously to that of **2a** (Table 1). The difference in the activation enthalpy $\Delta\Delta H^{\neq} = 4.5$ kcal mol^{-1} is related to the difference in the bond dissociation energy in **2a** and **2b** (Δ(C–H bond dissociation energy) = 0.8–3.8 kcal mol^{-1}).[12d, e]

Intense, well-resolved ESR spectra typical of **7b**[16] could be observed during the reaction (280 °C). 9,9′-Bixanthene[16] (**5**) was formed according to Equation (7) in yields of > 90%, thereby reconfirming the two-stage H-transfer hydrogenation with initial bimolecular radical formation. The activation parameters of both reactions (Table 1) are in line with the expectations for bimolecular processes and are similar to the values reported by Stein et al.[8] for the related disproportionation of 2-ethylanthracene and DHA **2a** ($\Delta G^{\neq}_{300\,°C} = 45.7 \pm 1.3$ kcal mol^{-1}, $\Delta H^{\neq} = 36.3 \pm 1.3$ kcal mol^{-1}, $\Delta S^{\neq} = -16.5 \pm 2.2$ e.u.). The effect of the polarity of the solvent on the transfer hydrogenation from **2b** to **1** between 280 and 310 °C in *tert*-butylbenzene (E_T value = 33.7),[19] diphenyl ether (E_T value = 35.3), *ortho*-dichlorobenzene (E_T value = 38.1), and benzonitrile (E_T value = 42) was minimal for k_2 (factor < 5). It is therefore very unlikely that ions or zwitterions are involved.

Initial studies showed that *para*-methylstyrene is also hydrogenated under the same conditions ($k_2^{309\,°C} = 21.6 \times 10^{-5}$ kcal mol^{-1} ± 1.4%), but cyclohexene, acrylonitrile,

and methyl methacrylate are not. Further experiments will show if these substrates will react under more forcing conditions or with more effective H-transfer reagents. Phenalene, known to be an especially reactive H donor, was used successfully.[20]

This uncatalyzed H-transfer reaction with its unequivocal, undisturbed reaction sequence is a good subject for further investigation of additional mechanistic details of the bimolecular radical formation by hydrogen transfer. The structure–reactivity relationships may then be better understood.

[11] This value was not corrected for incomplete deuterium incorporation. This small isotope effect supports the assumption that the hydrogen transfer is almost complete in the transition state. The same holds for Reaction (2), the back reaction of which (disproportionation) should proceed without activation enthalpy. Halpern et al. reported similar results in transfer hydrogenations with pentacarbonylhydridomangenese [5d].

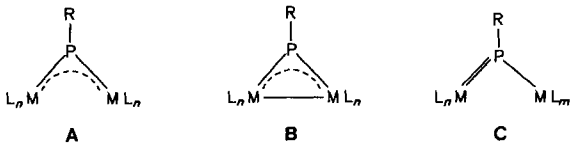
Novel Binuclear Phosphinidene Compounds by Dimerization of the P–H-Functional Phosphenium Complexes $[C_5R_5(CO)_2W{=}PH(Mes)]$ (R = H, Me)**

By *Wolfgang Malisch,* Ulrich-Andreas Hirth, Theresa A. Bright, Harald Käb, Teja Sebastian Ertel, Sabine Hückmann,* and *Helmut Bertagnolli*

Diverse terminal coordination possibilities (η^1, linear, or bent),[1] but above all the bridging μ^2 – μ^4 forms,[2] substantiate the coordination capability of phosphinidenes PR. Most of the known μ^2-phosphinidene complexes have the open structure **A**, in which the sp^2-hybridized phosphorus atom symmetrically bridges two 16-electron metal complex fragments ($ML_n = M(CO)_5$ for M = Cr, Mo, W; $Mn(CO)_2Cp$).[2a] More exceptional are the compounds of type **B** containing 15-electron metal complex fragments (ML_n = $Co(CO)_3$; $M(CO)_2Cp$ for M = Mo, W), in which a metal–metal bond is an additional structural feature.[2b]

In attempts to synthesize PH-functional phosphenium complexes $[L_nM{=}PH(R)]$, we have now obtained the novel structural type **C**. It shows the coordination of a phosphinidene to electronically nonequivalent metal units—a 15-



and a 17-electron fragment—which implies the formation of one M–P single and one M–P double bond. Form **C** may thus be described as a metalliophosphenium complex.[3]

As starting materials for the synthesis of the H(R)P=M systems we used the phosphane complexes *cis*-**1a,b**, accessible by thermal reactions from $[C_5R_5(CO)_3WCl]$ (R = H, Me) and $MesPH_2$ (Mes = mesityl (2,4,6-trimethylphenyl)). Treatment with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in dichloromethane yielded spontaneously and almost quantitatively the phosphinidene complexes **3a,b**. The mesitylphosphenium complexes **2a,b** initially expected on dehydrochlorination of **1a,b** cannot be detected even at −78 °C by NMR spectroscopy, but their presence is proven by trapping reactions with Me_3P that furnish the metallophosphanes **4a,b** (Scheme 1). Phosphinidene complexes **3a,b** are thus the product of the dimerization of the mesitylphosphenium complexes **2a,b**. The addition of a P–H function to the W–P double bond in this dimerization involves a hitherto unknown type of M–P bond formation occurring under unusually mild conditions.

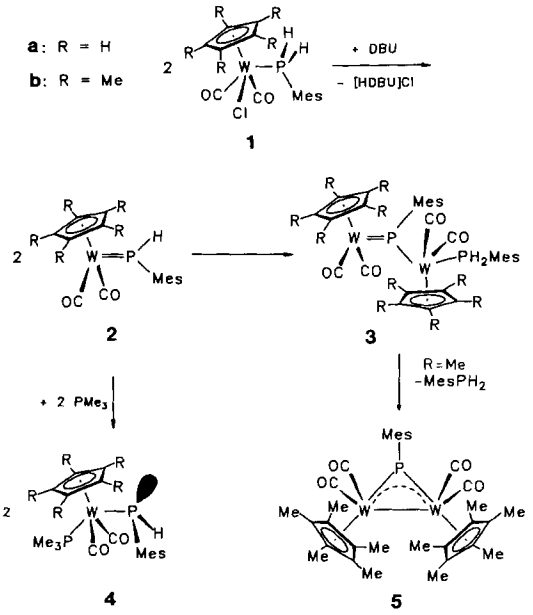
[**] Phosphenium Complexes, Part 18. This work was supported by the Deutsche Forschungsgemeinschaft within project SFB 347 ("Selektive Reaktionen Metall-aktivierter Moleküle") and the Fonds der Chemischen Industrie. T. S. E. thanks the Fonds der Chemischen Industrie for a study grant. Part 17: A. Fried, W. Malisch, M. Schmeusser, U. Weis, *Phosphorus, Sulfur, Silicon Relat. Elem.* **1992**, *64*, 441. The internationally accepted terms phosphinidene and phosphenium complexes have been used instead of the little used IUPAC expressions λ^3- and λ^4-phosphandiyl complexes.



Scheme 1.

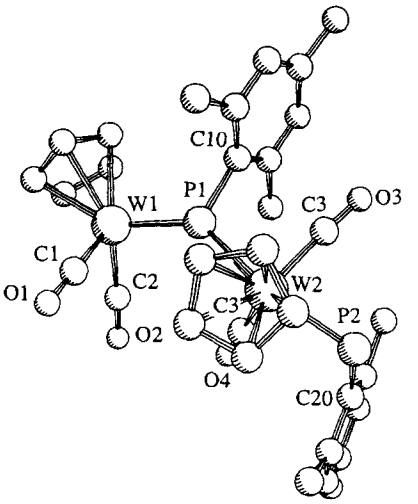


Fig. 1. Molecular structure of **3a** in the solid state. The hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–P1 2.281(3), W2–P1 2.550(3), W2–P2 2.440(3), P1–C10 1.845(4), W1-P1-C10 113.2(3), W2-P1-C10 110.1(3), W1-P1-W2 136.65(8).

Although **3a** is thermally extremely stable and remains unchanged even on heating to 100 °C in toluene, the C_5Me_5 analogue **3b** is only stable at low temperatures. Above −40 °C it reacts to form a "closed" phosphinidene complex **5** (type **B**) by elimination of $MesPH_2$. Therefore, form **C** has to be attributed a role as intermediate in the formation of **B**.

The constitution of **3a,b** is deduced from spectroscopic data as well as X-ray structural analysis and an EXAFS study (EXAFS = *E*xtended *X*-ray *A*bsorption *F*ine *S*tructure). In the ^{31}P NMR spectrum the signal for the bridging phosphorus atom is in the low-field region typical for phosphenium complexes (**3a**: δ = 313.9, **3b**: 397.4), and the widely differing $J(^{183}W^{31}P)$ coupling constants (**3a**: 485.3, 113.1; **3b**: 436.2, 135.6 Hz) are characteristic for a double and a single W–P bond (Table 1).

Table 1. Spectroscopic data of complexes **1a,b**, **3a,b**, **4a,b**, and **5**.

1a/1b: ^{31}P NMR (36 MHz, C_6D_6, 25 °C): δ = −78.9/−67.9 (s, ^1J(P,W) = 269.4/271.1 Hz). IR (benzene): ν(CO) = 1964 (vs), 1877 (s)/1945 (vs), 1863 (vs); ν(PH) = 2350 (w)/2318 (w) cm^{-1}.

3a/3b: ^{31}P NMR (36 MHz, C_6D_6, 25 °C): δ = 313.9/397.4 (d, ^1J(P,W) = 485.3/436.2, ^1J(P,W) = 113.1/135.6, ^2J(P,W,P) = 11.9/36.7 Hz; W=P), −82.8/−60.8 (d, ^1J(P,W) = 225.0 Hz/273.1 Hz; H_2PMes). IR (benzene)/(dichloromethane): ν(CO) = 1954 (m), 1931 (m), 1898 (vs), 1882 (s), 1805 (m)/1943 (s), 1928 (s), 1864 (vs), 1845 (vs), 1807 (m); ν(PH) = 2319 (w)/2320 (w) cm^{-1}.

4a/4b: ^{31}P NMR (36 MHz, C_6D_6/$CDCl_3$, 25 °C): δ = −157.6/−42.9 (d, ^1J(P,W) = 68.4/75.5, ^2J(P,W,P) = 39.1/42.1 Hz; PH(Mes)), −13.5/−21.7 (d, ^1J(P,W) = 249.0/262.3, ^2J(P,W,P) = 39.1/42.1 Hz; PMe_3). IR (benzene): ν(CO) = 1913 (m), 1837 (vs)/1902 (m), 1824 cm^{-1}.

5: ^{31}P NMR (36 MHz, CD_2Cl_2, 25 °C): δ = 589.4 (s, ^1J(P,W) = 335.7 Hz). IR (pentane): ν(CO) = 1927 (m), 1867 (vs) cm^{-1}.

The X-ray structural analysis of **3a** (Fig. 1) shows a trigonal-planar coordination at the P1 atom (angle sum 360°). The largest angle is that between the two metal fragments (W1-P1-W2 = 137°),[4] and the short W1–P1 bond length of 2.28 Å corresponds to that of $[Cp(CO)_2W{=}P(tBu)_2]$.[3] The W2–P1 distance of 2.55 Å represents the first example of a P(sp^2)–W single bond. The interatomic distance between W2 and the phosphorus atom of the $MesPH_2$ ligand (2.44 Å) lies in the anticipated range. For steric reasons the plane defined by W2-P1-C10 is twisted from the orthogonal orientation to the Cp ligand on W1 that would be optimal for metal-d-π–phosphorus-p-π interaction (Cp_z-W1-P1-C10 = −7.77°, Cp_z-W1-P1-W2 = −170.08°). The mesityl group is almost perpendicular to this plane (W1-P1-C10-C11 = 87.7°).

The EXAFS study in solution (Fig. 2) is in excellent agreement with the single-crystal structural data.[5] In benzene three types of W–P distances are detected, and their values of 2.33, 2.48, and 2.67 Å correspond to those for the W1–P1, W2–P2, and W2–P1 bonds, respectively, in the crystal. In addition, the distances between the ligands and the tungsten center could be identified (carbonyl unit: W–C 1.91 and W–(carbonyl)O 3.17 Å (1.90–1.97 and 3.08–3.11 Å, respectively, in the crystal); Cp unit: 2.37 Å (2.28–2.34 Å, in the crystal)). This study shows that the ability of EXAFS spectroscopy to distinguish between different interatomic distances of the same absorber–scatterer pairs[6] can be used for the structural characterization of complexes with different M–P distances that exist only in solution.

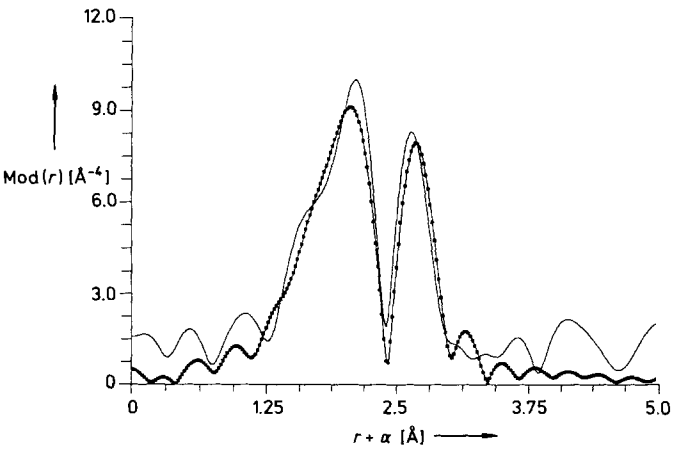

Fig. 2. Fourier transformed $k^3X(k)$ function of **3a** (solid line) and the Fourier transformed result of curve fitting (•).

The M=P unit of the phosphinidene complexes described here represents a reactive center, which we are now investigating with respect to its suitability for the construction of metallacycles and cluster compounds by cycloaddition.

Experimental Procedure

All manipulations were performed in the absence of air and moisture.

1a/b: A suspension of $[Cp(CO)_3WCl]$ (857 mg, 2.33 mmol)/$[C_5Me_5(CO)_3WCl]$ (1.735 g, 3.96 mmol) in methylcyclohexane (20 mL) was treated with $MesPH_2$ (355 mg, 2.33 mmol)/(603 mg, 3.96 mmol) and stirred for 3 h/5 h at 110 °C. After the mixture was cooled to room temperature, the desired product was separated off, washed with pentane, and dried in vacuum. Yield: 964 mg (84%)/1.905 g (85%), orange crystalline powder, m.p. 111 °C (decomp)/127 °C (decomp).

3a: A solution of **1a** (222 mg, 0.45 mmol) in dichloromethane (20 mL) was treated with DBU (69 mg, 0.45 mmol) at room temperature. After removal of the solvent in vacuum, the residue was taken up in toluene (5 mL), insoluble material separated, and the filtrate worked up by column chromatography (15 × 2 cm column; Al_2O_3, activity grade III, neutral; toluene). The first dark green fraction yielded **3a** after the solvent had been removed in vacuum. Yield: 177 mg (86%), green crystalline powder, m.p. 145 °C.

3b: A solution of **1b** (135 mg, 0.24 mmol) in dichloromethane (20 mL) was treated with DBU (36 mg, 0.24 mmol) at −78 °C. Above −40 °C the transformation to $MesPH_2$ and **5** starts, and is quantitative within 30 min at room temperature.

4a/b: A solution of **1a** (254 mg, 0.52 mmol)/**1b** (254 mg, 0.45 mmol) and trimethylphosphane (40 mg, 0.52 mmol/35 mg, 0.45 mmol) in toluene (10 mL) was treated with DBU (79 mg, 0.52 mmol/68 mg, 0.45 mmol) at room temperature. After insoluble material had been removed, the filtrate was concentrated to 2 mL and worked up by column chromatography (10 × 2 cm column; Al_2O_3, activity grade III, neutral; **4a**: toluene; **4b**: toluene/ether). The bright yellow fraction yielded the desired product after removal of the solvent in vacuum. Yield: 235 mg (85%)/196 mg (72%), bright yellow/lemon-yellow crystalline powder, m.p. 128 °C/126 °C).

[5] The EXAFS experiment was performed at a RÖMO II work station (HASYLAB at DESY Hamburg) in transmission at the W-LIII-edge on a 0.08 M solution of **3a** in an inert atmosphere with a liquid path length of 115 μm; Si-311 crystal monochromator, energy calibration with 4 μm thick tungsten foil. The experimental data of the reference material were folded with Gauss functions of different half-widths and determined from the intersection of the curves obtained thus. On the front edge a Victoreen function was fitted in the range 10000.0 to 10175.0 eV. The background $\mu_0(E)$ was determined with a Smoothing Spline routine that was applied to a spectrum folded with a Gauss function of half-width 24.0 eV and the Fourier transform performed on the k^3-weighted structure function $k^3X(k)$ obtained thus, in the range 2.8–12.8 Å^{-1}. [6] Back transformation of the ranges 1.26–2.40 Å, 2.40–3.20 Å, and 1.26–3.20 Å in the impulse space and fitting of the theoretical EXAFS equation to the experiment with theoretical amplitude and phase functions yields the contributions of the individual back scatterers; these are the distance r[Å], the coordination number N, and the Debye–Waller factor σ[Å] (A. G. McKale, *J. Am. Chem. Soc.* **1988**, *110*, 3763): W1-P1: $r = 2.33$, $N = 0.49$, $\sigma = 0.508$; W2-P2: $r = 2.48$, $N = 1.56$, $\sigma = 0.0551$; W2-P1: $r = 2.67$, $N = 0.39$, $\sigma = 0.0708$; W1-C1,2 and W2-C3,4: $r = 1.91$, $N = 1.06$, $\sigma = 0.0545$; W1-C5-9 and W2-C30-34: $r = 2.37$, $N = 2.27$, $\sigma = 0.1497$; W1-O1,2 and W2-O3,4: $r = 3.17$, $N = 2.78$, $\sigma = 0.0390$; W1-C18: $r = 3.44$, $N = 1.87$, $\sigma = 0.1099$.

A Paramagnetic, Mononuclear Organometallic Iridium(II) Complex: $[Ir(C_6Cl_5)_2(cod)]$**

By *María P. García,* M. Victoria Jiménez, Luis A. Oro, Fernando J. Lahoz*, and *Pablo J. Alonso*

Iridium and rhodium complexes with a d^7 electronic configuration are very uncommon, especially as monomeric species.[1] Very recently some paramagnetic, mononuclear rhodium(II) complexes have been described,[2] but in the chemistry of iridium(II) there are only a limited number of reports concerning either species generated by electrolysis that were not isolated[3] or isolated complexes that were examined only with regards to their magnetic properties.[4] To the best of our knowledge, only two paramagnetic, mononuclear Ir^{II} coordination compounds have been structurally characterized, the square-planar complexes *trans*-$[Ir(t\mathrm{Bu}_2PC_6H_3XO)_2]$, X = H, CH_3.[5]

One of our current research interests is the chemistry of pentafluorophenyl derivatives of rhodium, and we reported[6] the preparation of the anion $[Rh(C_6F_5)_5]^{2-}$. Using this complex anion as a starting material, we prepared neutral[7] and anionic[8] mono- and dinuclear rhodium(III) complexes. This research is now extended to complexes with the pentachlorophenyl ligand; we expected that in the same way that this ligand stabilizes the unusual +III oxidation state of platinum,[9] it could allow the preparation of rhodium(II) and iridium(II) complexes. We now report the first fully characterized organometallic Ir^{II} complex, an Ir^{II} compound whose ligands are bound exclusively at C atoms.

The remarkably stable iridium(I) complex **1** (cod = 1,5-cyclooctadiene), prepared according to Equation (a), reacted

$$[\{Ir(\mu\text{-}Cl)(cod)\}_2] + 4\,LiC_6Cl_5 \xrightarrow{-2\,LiCl} 2\,Li[Ir(C_6Cl_5)_2(cod)] \xrightarrow[-2\,LiBr]{+2\,NBu_4Br} 2\,[NBu_4][Ir(C_6Cl_5)_2(cod)] \quad \mathbf{1} \qquad \text{(a)}$$

with iodine in dichloromethane (ratio 1:1) at room temperature, or with silver perchlorate (1:1) at $-10\,^{\circ}C$ to yield a brown solid (almost insoluble in CH_2Cl_2 and acetone) identified as the mononuclear iridium(II) complex **2**. The reaction of **1** with $[Ph_3PAgOClO_3]$ (1:1) in tetrahydrofuran gave rise to the pentacoordinated complex **3**. This complex is very unstable: in solution it decomposes to give the iridium(I) compound **4** identified by its spectroscopic data (IR, NMR), mass spectrometry, and elemental analysis.

$[Ir(C_6Cl_5)_2(cod)]$ **2**

$[Ir(C_6Cl_5)_2(cod)(PPh_3)]$ **3**

$[Ir(C_6Cl_5)(cod)(PPh_3)]$ **4**

The oxidation of complex **1** to yield **2** can also be achieved electrochemically. When an increasing voltage (-1 to $+1$ V with sweep rate of 0.1 Vs^{-1}) is applied to an orange solution of **1** in CH_2Cl_2 (0.5 mM), an oxidation wave is observed at 0.054 V (Fig. 1). The reduction peak is at -0.021 V. The value of $E_p^{ox}-E_p^{red}$ (0.07 V) and the ratio i_c/i_a (1/1) show the process to be reversible and diffusion controlled. We also used cyclic voltammetry to study the reduction of complex **2** and the subsequent reoxidation. Unfortunately the low solubility of this compound prevents the preparation of 0.50 mM solutions; however, with the same scanning conditions, the reduction and oxidation peaks were localized at values identical to those observed for complex **1**, although the peak intensities were smaller.

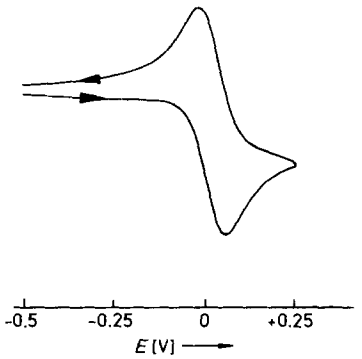

Fig. 1. Cyclic voltammogram of a solution of 0.50 mM of **2** in CH_2Cl_2/0.1 M $[NBu_4][PF_6]$ at room temperature; sweep rate = 0.1 Vs^{-1}, Pt electrode.

The molecular structure of **2** was determined by a single-crystal X-ray diffraction study.[10] Figure 2 shows the structure of the complex. The iridium atom, situated on a site of C_2 symmetry, exhibits a roughly square-planar coordination geometry (maximum deviation from the least-squares plane 0.217(5) Å for C(1)), and is bonded to two carbon atoms of the two symmetry-related pentachlorophenyl groups and to the olefinic bonds of a cyclooctadiene molecule. The perhalogenated aryl ligand is disposed almost perpendicular to the metal coordination plane (dihedral angle 93.0(1)°), and slightly twisted [Ir-C(1)-C(4) 8.9(2)°] so that the *ortho* chlorine atoms (Cl(6) and Cl(6′)) above and below the coordination plane can interact with the iridium center (Ir···Cl(6) 3.077(1) Å). This weak interaction could be partially responsible for the stability of this compound, as it could make oxidation sterically more difficult.

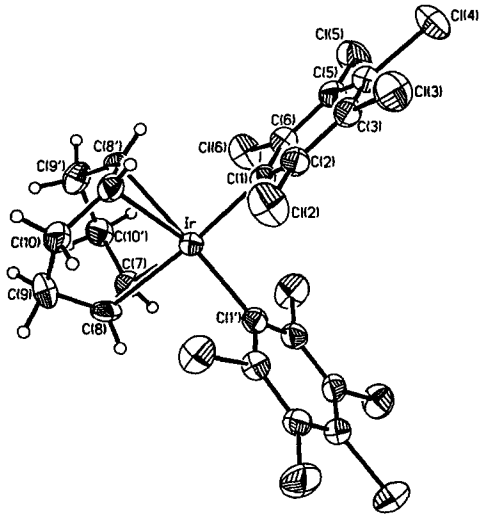

Fig. 2. Crystal structure of **2**. Selected distances [Å] and angles [°]: Ir-C(1) 2.073(5), Ir-C(7) 2.210(5), Ir-C(8) 2.274(5), C(7)-C(8) 1.372(8); C(1)-Ir-C(1′) 93.9(2), C(1)-Ir-M(1) 169.2(2), M(1)-Ir-M(1′) 84.4(1). (M(1) represents the midpoint of C(7)-C(8) olefinic bond; C(1′) and M(1′) are related to C(1) and M(1) by the symmetry relation $1-x, y, 1+(1/2-z)$).

The EPR spectra[11] of polycrystalline samples of **2** and **3** are shown in Figure 3 (solid lines). The spectra are very similar with only minor differences. In spite of iridium having two isotopes with $I = 3/2$ and very close nuclear g-factors, no hyperfine structure was observed. These spectra can be interpreted with an standard electronic Zeeman term with $S = 1/2$ and principal g-factors: $g_x = 3.00 \pm 0.02$, $g_y = 2.79 \pm 0.02$ and $g_z = 1.85 \pm 0.02$. The dotted lines in Figure 3 represent the spectra calculated using a Lorentzian lineshape with peak-to-peak distances in the first derivative of the signal of 25 and 20 mT for **2** and **3**, respectively. This interpretation of the EPR data is in agreement with an iridium(II) ion with an unpaired electron.

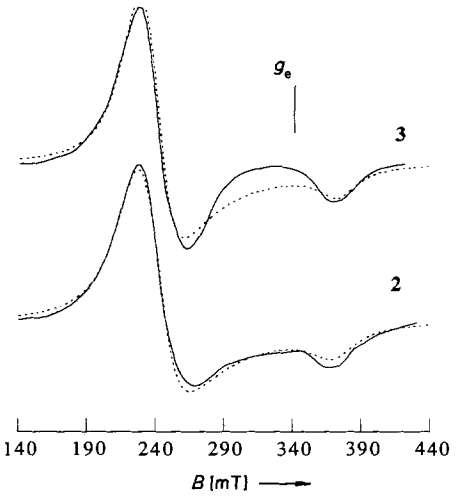

Fig. 3. EPR spectra of powdered samples of complexes **2** and **3** measured at room temperature. The solid lines represent the experimental spectra and the dotted lines the calculated spectra.

Experimental Procedure

1: To a solution of LiC_6Cl_5 (1.5 mmol) in diethyl ether (40 mL) (prepared by slow addition of a solution of *n*BuLi (1.5 mmol) in diethyl ether (10 mL) to a suspension of C_6Cl_6 (0.427 g, 1.5 mmol) in the same solvent (30 mL)) at $-50\,^{\circ}C$ was added solid $[\{Ir(\mu\text{-}Cl)(cod)\}_2]$ (0.200 g, 0.30 mmol). The solid was dissolved in approximately 30 min, and the solution turned orange-brown. As the reaction mixture was allowed to warm to room temperature (over ca. 4 h), an orange oily solid was formed together with a brown solution. The solution was removed and the solid washed twice with 10 mL of aqueous diethyl ether. The residue was treated with a solution of NBu_4Br (0.192 g, 0.60 mmol) in methanol (10 mL) yielding complex **1** (orange crystalline solid; 0.450 g, 70% yield). Correct C,H,N analysis. ^1H NMR ($CDCl_3$): $\delta = 2.1$ (br. m, 8H, CH_2(cod)), 3.4 (br. m, 4H, =CH(cod)), 2.7, 1.4, 1.1, 0.9 (m, 8:8:8:12, NBu_4^+).

2: This complex was prepared by two methods: a) To a solution of **1** (0.100 g, 0.096 mmol) in dichloromethane (4 mL) was added a solution of iodine (0.024 g, 0.096 mmol) in the same solvent (2 mL). The yellow solution changed to red, and a brown solid formed. The reaction mixture was stirred for 30 min, the volume of the solution reduced to 2 mL, and a brown, crystalline solid precipitated upon addition of 4 mL of acetone (0.053 g, 69% yield). Correct elemental analysis. b) Brown crystals of **2** were obtained by slow diffusion at $-10\,^{\circ}C$ of a solution of $AgClO_4$ (0.02 g, 0.096 mmol) in acetone (5 mL) into a solution of $[NBu_4][Ir(C_6Cl_5)_2(cod)]$ (0.100 g, 0.096 mmol) in dichloromethane (3 mL) under a nitrogen atmosphere and with exclusion of light. Crystals could be separated from the metallic silver formed because of the density difference between the crystals and the silver powder. The crystals were washed with acetone and dried under vacuum (0.040 g, 52% yield).

3: To a solution of **1** (0.100 g, 0.096 mmol) in tetrahydrofuran (10 mL) was added solid $[Ph_3PAgOClO_3]$ (0.045 g, 0.096 mmol). The solution was stirred for 1 h under a nitrogen atmosphere and with exclusion of light to yield a black solid (metallic silver) which was removed by filtration through Kieselguhr. Concentration of the resulting solution under reduced pressure to a volume of 1 mL and addition of methanol (5 mL) afforded **3** as a reddish solid which was filtered off, washed with methanol, dried under vacuum (0.053 g, 52% yield). Correct elemental analysis.

4: Concentrated solutions of **3** in dichloromethane or chloroform yielded pink crystals of **4** which were filtered off, washed with diethyl ether, and dried under vacuum. Correct elemental analysis. ^1H NMR ($CDCl_3$): $\delta = 4.57$, 3.19, 2.28, 2.15, 1.89, 1.76 (m, 2H each, cod); 7.23–7.56 (m, 15H, PPh_3). $^{31}P\{^1H\}$: $\delta = 17.45$ (s). IR (Nujol suspension between polyethylene sheets): $\tilde{\nu}(C_6Cl_5)$ [cm^{-1}]: 1335 s, 1320 s, 1285 s, 865 m, 615 s. MS(FAB): *m/z* 812 (M^+, 90%).

[11] Electron paramagnetic resonance spectra were recorded at room temperature with a Varian E-112 spectrometer working in the X-band. The magnetic field was measured with a NMR gaussmeter Bruker ER035M and the diphenylpicrylhydrazyl (DPPH) resonance signal ($g = 2.0037 \pm 0.0002$) was used for determining the microwave frequencies.

Formate-Driven, Non-Enzymatic NAD(P)H Regeneration for the Alcohol Dehydrogenase Catalyzed Stereoselective Reduction of 4-Phenyl-2-butanone**

Von *Dorothée Westerhausen, Sabine Herrmann, Werner Hummel*, and *Eberhard Steckhan**

Biotransformations of organic substrates with enzymes or microorganisms have found widespread application because of their capability to perform stereoselective reactions. The use of redox enzymes for synthetic purposes, however, has been limited because of the necessary cofactor regeneration. For reductions with NAD(P)H-dependent enzymes, enzyme-coupled regeneration systems have been developed. These systems employ either a regeneration enzyme such as formate dehydrogenase (FDH)[1] for NADH-dependent production enzymes, or the production enzyme itself, as in the case of NADPH-dependent alcohol dehydrogenase (ADH) of *Thermoanaerobium brockii* (TBADH).[2]

We developed a non-enzymatic regeneration system for NADH and NADPH with $[(C_5Me_5)Rh^{III}(bpy)(H_2O)]Cl_2$ and similar complexes as the homogeneous redox catalysts and either the electrode[3, 5, 6] or formate[4, 5] as the donor. The reaction mechanism for the formate-driven NAD(P)H regeneration is described by Equations (a)–(c). The important step is the hydride transfer from the intermediate hydridorhodium complex to $NAD(P)^+$ [Eq. (c)] which has been

$$[(C_5Me_5)Rh^{III}(bpy)L]^{2+} + HCOO^- \xrightarrow{K} [(C_5Me_5)Rh^{III}(bpy)(HCO_2)]^+ + L \quad (a)$$

$$[(C_5Me_5)Rh^{III}(bpy)(HCO_2)]^+ \xrightarrow{rds} [(C_5Me_5)Rh^{III}H(bpy)]^+ + CO_2 \quad (b)$$

$$[(C_5Me_5)Rh^{III}H(bpy)]^+ + L + NAD(P)^+ \xrightarrow{fast} [(C_5Me_5)Rh^{III}(bpy)L]^{2+} + NAD(P)H \quad (c)$$

found to take place at a very high rate leading selectively to enzymatically active NAD(P)H.[3–6] Here we describe the formate-driven, non-enzymatic NAD(P)H regeneration for the ADH-catalyzed stereoselective reduction of carbonyl compounds.

In a first model system, the horse liver ADH (HLADH) catalyzed reduction of hexanal with formate-driven, in-situ NADH regeneration catalyzed by $[(C_5Me_5)Rh(bpy\text{-}5\text{-}OAc)(H_2O)]Cl_2$ was examined (Table 1). With a 1:1 ratio of substrate (0.1 M) to formate (0.1 M), 21 U HLADH (acetaldehyde/ethanol), 1 mol% of NAD^+, and 0.5 mol% of redox catalyst, 50% turnover was achieved after about 6 hours. After 30 hours, all of the substrate had been reduced. A comparable result was obtained with butanal as the substrate.

Table 1. Results of the enzymatic reduction of hexanal with formate-driven, in-situ regeneration of NADH [a].

c (Hexanal) [mM]	t [h]	c (Hexanol) [mM]	Turnover number redox cat.	NAD
100.0	0	0	0	0
92.8	1	7.2	14	7
84.6	3	15.4	31	15
57.2	5	42.8	86	43
1.0	24	99.0	198	99
0	30	100.0	200	100

[a] Concentrations: HCOONa = 0.1 M; aldehyde = 0.1 M; NAD^+ = 1 mM; $[(C_5Me_5)Rh(bpy\text{-}5\text{-}OAc)(H_2O)]Cl_2$ = 0.5 mM; HLADH = 21 units (acetaldehyde/ethanol); in 50 mL 0.1 M sodium phosphate buffer, pH 7.5; T = 25 °C; argon atmosphere; GLC analysis.

We then applied this method to the reduction of the interesting prochiral ketone 4-phenyl-2-butanone (Fig. 1). Four different enzymes were compared with respect to the turnover and stereoselectivity in this reaction. Two commercially available alcohol dehydrogenases, HLADH and TBADH, together with two recently isolated secondary alcohol dehydrogenases from *Lactobacillus kefir*[7] (PhEDH = phenylethanol-DH) and from *Rhodococcus* sp.[8] (S-ADH) were investigated. Yeast ADH was not included in the study, as it proved to be very slow in the reduction of 4-phenyl-2-butanone. HLADH and S-ADH are NADH-dependent enzymes while the others are NADPH-dependent.

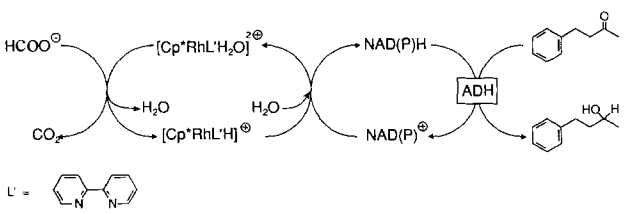

Fig. 1. Enzymatic reduction of 4-phenyl-2-butanone with in-situ cofactor regeneration using $[(C_5Me_5)Rh(bpy)(H_2O)]Cl_2$ as a redox catalyst and formate as a donor.

As standard conditions, 10 mL of KP_i buffer (0.1 M, pH 7) containing the oxidized cofactor (1 mM), $[(C_5Me_5)Rh(bpy)(H_2O)]Cl_2$ (0.5 mM), sodium formate (0.066 M), and 4-phenyl-2-butanone (0.033 M) were used. Because of the low solubility of the ketone in the aqueous buffer system an emulsion was formed. The progress of the reaction was followed by GLC with an HP-1 glass capillary column; the enantiomeric excess was also determined by GLC with a β-cyclodextrin modified capillary column (50 m, FS-Cyclodex beta-I/P, CS-Chromatographie Service GmbH) after esterification of the alcohol with acetic anhydride.

From the study of the reaction progress (Fig. 2), it is obvious that PhEDH, S-ADH, and especially HLADH all lead to a turnover of between 76 and 90% at 30 °C under batch conditions. Although TBADH reaches a turnover of only 24% at 30 °C after 24 h, it reacts much faster and more efficiently at 60 °C giving a turnover of 75% already after 5 h. Initial studies showed that the TBADH preparation used here contains a side-activity leading to NADPH inactivation. This seems to be more an important factor at lower temperatures and leads to the low turnover at 30 °C.

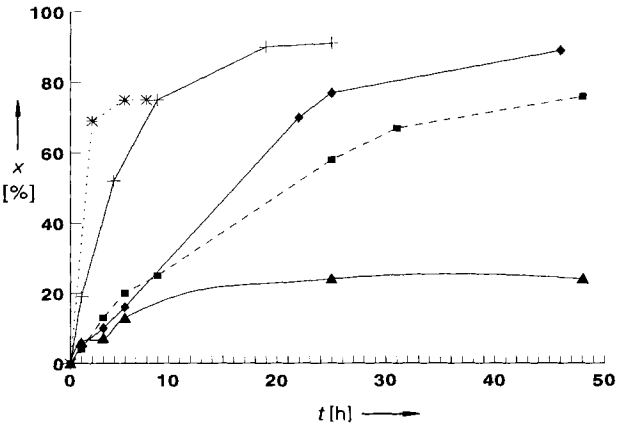

Fig. 2. Dependence of the turnover x on time t for the enzymatic reduction of 4-phenyl-2-butanone with in-situ, formate-driven cofactor regeneration with HLADH at 30 °C (+), TBADH at 30 °C (▲), TBADH at 60 °C (*), PhEDH at 30 °C (■), and S-ADH at 30 °C (◆). [Conditions: 4-phenyl-2-butanone: 33 mM; HCOONa: 66 mM; $NAD(P)^+$: 1 mM; $[(C_5Me_5)Rh(bpy)(H_2O)]Cl_2$: 0.5 mM; in 10 mL 0.1 M KP_i buffer of pH 7; at 30 °C and 60 °C (TBADH only); HLADH: 9 U (4-phenyl-2-butanone); TBADH: 5 U (4-phenyl-2-butanone); PhEDH: 20 U (4-phenyl-2-butanone); S-ADH: 20 U (4-phenyl-2-butanone)].

Comparison of the values for the enantiomeric excess *ee* and the turnover x for the four different enzymes at 30, 38, and 60 °C (Table 2) show that the *ee* values are the same as with other cofactor regeneration systems. TBADH and S-ADH reach values of more than 99% *ee* for the (*S*)-alcohol, while HLADH gives values of about 96% *ee* for the same enantiomer. Interestingly, PhEDH favors the formation of the (*R*)-alcohol (96% *ee*). The high values for the enantiomeric excess prove convincingly that the reaction proceeds selectively by means of the enzyme and not by a direct hydride transfer from the intermediate rhodium hydride to the substrate. This is not only true for a 2:1 formate to substrate ratio, but also even for a ratio of 15:1. A slightly lower enantiomeric excess was observed only in the case of

Table 2. Turnover x and enantiomeric excess *ee* in the enzymatic reduction of 4-phenyl-2-butanone with in-situ, formate-driven redox-catalytic cofactor regeneration [a].

Enzyme activity [U] [b]	Cofactor conc. [mM]	T [°C]	t [h] [c]	x [%]	ee [%]
HLADH [9]	NAD^+ [1]	30	24	90	96 (*S*)
HLADH [9]	NAD^+ [1]	38	24	75	96 (*S*)
TBADH [5]	$NADP^+$ [1]	30	24	24	>99 (*S*)
TBADH [5]	$NADP^+$ [1]	38	24	45	>99 (*S*)
TBADH [5]	$NADP^+$ [1]	60	5	75	>99 (*S*)
PhEDH [20]	$NADP^+$ [1]	30	45	76	96 (*R*)
PhEDH [20]	$NADP^+$ [1]	38	24	81	96 (*R*)
S-ADH [20]	NAD^+ [1]	30	43	89	>99 (*S*)

[a] Conditions identical to those in Fig. 2. [b] Units always with respect to 4-phenyl-2-butanone. [c] Time at which the change in turnover became insignificant.

HLADH for a 15:1 ratio of formate to substrate. The direct hydride transfer from the hydrido complex to the ketone in the absence of cofactor and enzyme leads only to a very low turnover of 7% after 52 hours at 25 °C and 13% after 45 hours at 30 °C. Even at 60 °C, the direct hydride transfer cannot compete with the enzymatic reaction leading to 99% *ee* (see TBADH at 60 °C). For all enzymes studied, the maximum turnover rate of the substrate was already reached with a formate to substrate ratio of 2:1, while with equimolar concentrations the turnover was about 30% lower after the identical reaction time. Possible enzymatic inhibition by the rhodium complex was excluded after intensive studies: After preincubation of the four enzymes with the rhodium complex (0.5 mM) at 30 °C for 5 min, 1 h, 8 h, and 24 h the initial reaction rate was determined and compared with the values obtained in the absence of the rhodium complex. No influence was observed. The turnover rates for the applied enzymes with our new non-enzymatic cofactor regeneration system were usually higher than with the coupled substrate approach (under otherwise identical conditions) using ethanol (HLADH) or isopropanol (TBADH, PhEDH) as cosubstrates. For example, with HLADH in the presence of ethanol as cosubstrate a turnover of 33% was obtained at 25 °C after 24 hours.

The temperature dependence of the reactions with the four enzymes is different. While for HLADH and S-ADH the optimum turnover is reached at 30 °C, the temperature optimum for PhEDH is observed at 35 °C, and for TBADH the turnover increases considerably up to a temperature of 60 °C.

In the case of HLADH, we studied the influence of dioxane as a cosolvent. While with the addition of dioxane to up to 5% by volume the turnover was diminished only to a very small extent and the enantiomeric excess was unchanged, at higher dioxane concentrations the turnover decreased considerably.

We will now apply this system in an enzyme membrane reactor with our water-soluble high-molecular weight rhodium complexes as redox catalysts.[5, 6, 9] Thus, a continuous enzymatic reduction should be possible.

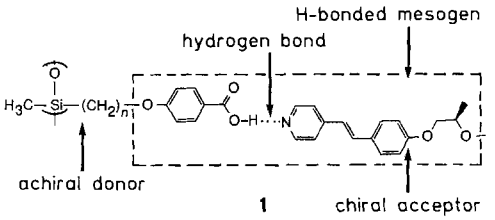
Induction of Ferroelectricity in Polymeric Systems through Hydrogen Bonding**

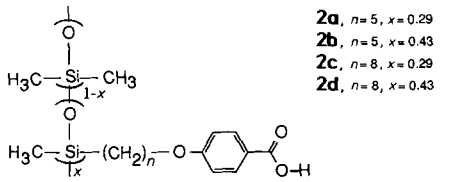
By *Uday Kumar, Jean M. J. Fréchet,* Takashi Kato, Seiji Ujiie,* and *Kazuyoshi Timura*

Ferroelectric liquid crystals have attracted much attention since the discovery of surface-stabilized ferroelectric liquid crystal devices capable of switching on the nanosecond timescale.[1] Recently, ferroelectricity was induced in polymeric liquid crystals by covalently attaching a chiral mesogen of low molar mass onto a polymer backbone by means of a flexible polymethylene spacer.[2a–e] We report here a novel approach to the preparation of ferroelectric liquid crystals through the thermodynamically favorable self-assembly[3] of a suitable hydrogen-bond donor with a hydrogen-bond acceptor.

The concept of inducing ferroelectricity through hydrogen bonding was realized with assemblies such as **1**, which consists of polysiloxanes **2a–2d** with pendant *p*-alkoxybenzoic acid groups complexed with an optically active (*S*)-(−)-*trans*-4-(2-methoxypropyloxy)-4′-stilbazole (**3**).



1



The complexes are designed to form chiral smectic (S_{C^*}) phases over an extended temperature range as a result of the formation of linear structures such as **1** with a large length to breadth ratio. As in liquid crystals of low molar mass, the presence of a strong terminal lateral dipole (methoxy group) and a polarizable core in **1** should aid in the formation of tilted smectic phases.[4] Furthermore the proximity of the chiral center to the linear stilbazole frame restricts its independent motion and should facilitate the spontaneous polarization of the H-bonded structures such as **1**.[5]

Mesogenic polysiloxanes **2a–2d** containing *p*-alkoxybenzoic acid groups in their side chains were prepared as described previously.[6] The weight average molecular weights

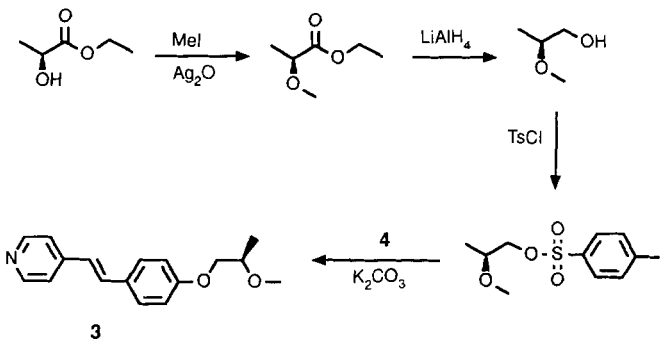
of polymers **2a**–**2d** determined by gel permeation chromatography with a viscometric detector with universal calibration were in the range $\bar{M}_r = 7000-12000$. Stilbazole **3** was made from (*S*)-(−)-ethyl lactate (Scheme 1).[7]



Scheme 1. Synthesis of *trans*-4-(2-methoxypropyloxy)-4′-stilbazole **3** from (*S*)-(−)-ethyl lactate. TsCl: *p*-toluenesulfonyl chloride; **4**: *trans*-4-hydroxy-4′-stilbazole.

The thermal properties of equimolar blends of polymer **2a**–**2d** and stilbazole **3** are given in Table 1. Unless otherwise stated all transition temperatures were measured by differential scanning calorimetry (DSC) on annealed samples, while assignment of the various liquid crystalline phases was done on the basis of DSC, hot stage microscopy, and X-ray experiments. The transition temperatures are dependent on the thermal history. In the following discussion equimolar complexes are represented by [**a**/**b**] where **a** and **b** represent polysiloxane and stilbazole, respectively. The temperatures at which the liquid crystalline complexes [**2a**/**3**], [**2b**/**3**], [**2c**/**3**], and [**2d**/**3**] become isotropic (isotropization temperatures) are higher than either the clearing temperature of the corresponding uncomplexed polymers **2a**–**2d** or the melting point of **3**. This is a consequence of the formation of extended H-bonded assemblies such as **1**, which stabilize the smectic phase. The clearing temperature of [**2c**/**3**] is lower than that of [**2d**/**3**] because of the lower concentration of H-bonded mesogenic structures in the former complex. None of the complexes show a glass transition temperature. The relatively high enthalpy of isotropization is in keeping with the requirement that strong H-bonds be broken during the conversion from the smectic to the isotropic state. The DSC thermogram of an annealed sample of [**2b**/**3**] is shown in Figure 1. Two overlapping endothermic processes at 80 and 90 °C corresponding to solid → solid and crystalline → smectic (K → S) transitions followed by a smectic → isotropic (S → I) transition at 162 °C are observed during heating (Fig. 1a). An isotropic to smectic (I → S) transition at 145 °C followed by two overlapping peaks at 75 and 63 °C are observed during the cooling run (Fig. 1b).

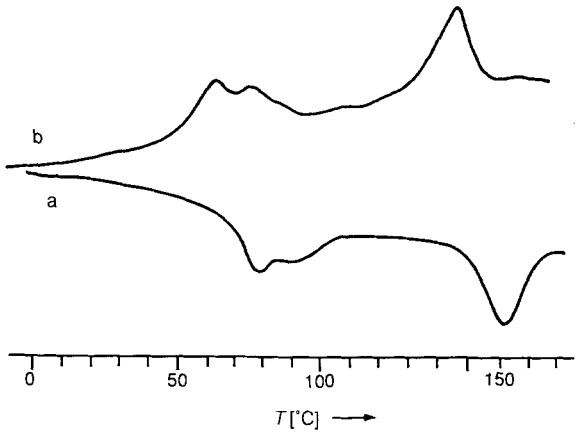


Fig. 1. DSC thermogram of the annealed equimolar complex [**2b**/**3**]. Rate 15 K min^{-1}. [a] Heating run. [b] Cooling run. Endothermic processes are reflected by negative slopes.

The IR spectrum of polymer **2b** shows a strong broad band and two medium-intensity absorptions due to the OH group at 2960, 2675, and 2560 cm^{-1}. In the case of complexes such as [**2b**/**3**], the presence of two intense absorptions at 1930 and 2500 cm^{-1} confirm the existence of a strong hydrogen bond between the COOH group of polysiloxane **2b** and the pyridyl N atom of stilbazole **3**.[3, 8] The non-ionic character of the complexes is further supported by NMR measurements.[6]

The spontaneous polarization was measured by the Sawyer–Tower method[9] from the hysteresis loops (Fig. 2). Ferroelectricity measurements were possible, as the complexes are non-ionic. Plots of the spontaneous polarization P_s of [**2d**/**3**] and [**2b**/**3**] as a function of temperature are given in Figures 3a and 3b, respectively. The decrease of P_s with increasing temperature as is seen for [**2d**/**3**] is normally found in most chiral smectics.[2b, d, 10] This is a result of the decrease

in dipolar ordering that occurs with increasing temperature as a consequence of increased rotations about the molecular axis. The increase of P_s with increasing temperature observed for complex [**2b**/**3**] is rather unusual, though a similar phenomenon has recently been reported for a polyacrylate.[12e]

Table 2. X-ray diffraction studies [a] of equimolar blends of polysiloxanes **2a**–**2d** and optically active stilbazole **3**.

Complex	T [°C]	Layer spacing d [Å]
[**2a**/**3**]	110	45.5 (s) 7.2 (d)
	140	44.1 (s) 7.6 (d)
	145	42.8 (s) 8.0 (d)
[**2b**/**3**]	110	40.1 (s) 7.5 (d)
	140	38.4 (s) 7.6 (d)
[**2c**/**3**]	120	45.0 (s) 21.9 (w) 7.6 (d)
	130	46.4 (s) 7.6 (d)
	140	49.6 (s) 7.6 (d)
[**2d**/**3**]	110	43.7 (s) 21.8 (w) 7.7 (d)
	115	44.1 (s) 22.1 (w) 7.9 (d)
	135	43.2 (s) 21.7 (w) 7.9 (d)
	140	42.8 (s) 21.3 (w) 7.7 (d)
	150	42.1 (s) 21.4 (w) 8.0 (d)
	155	41.6 (s) 21.2 (w) 8.0 (d)

[a] Complexes are crystalline below their crystalline → smectic transition temperatures; the diffuse ring at around 4.5 Å is present in all samples; (s) sharp; (w) weak; (d) diffuse.

The large difference in the magnitude of P_s between [**2d**/**3**] and [**2b**/**3**] is probably related to the more hindered rotation of the H-bonded mesogen about its molecular axis in the latter complex because of the proximity to the polymer backbone.

X-ray diffraction data of the annealed unoriented samples are given in Table 2. An intense ring (sometimes accompanied by its second-order reflection) together with the spontaneous polarization, point to a smectic C phase comprising two overlapping H-bonded moieties such as **1**. Although DSC traces do not indicate a $S_C \rightarrow S_A$ transition, investigations with optical microscopy suggest the possibility of a higher temperature S_A phase.

Our approach, the self-assembly of a complex from two complementary compounds, provides excellent opportunities for the preparation of materials with defined mesophase stability, polarization, dielectric anisotropy, viscosity, and refractive index. New developments may thus be anticipated in the study of liquid crystals.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Chemical Evolution. Origin of the Elements, Molecules and Living Systems. By *S. F. Mason*. Clarendon Press, Oxford, 1991. IX, 317 pp., hardcover £ 19.50.—ISBN 0-19-855272-6

Stephen F. Mason, the author of this book, has made contributions towards answering many unsolved problems of chemical evolution, in particular by studies of stereochemistry, optical activity, and chirality. He has also become well known for his historical studies, and for his book on the history of science. It is becoming increasingly recognized that not only biology, but also chemistry, has an important historical aspect. It is from this standpoint that the book

reviewed here has been written by a chemist who is well versed in the history of the subject, and who thinks of it historically, reflecting all the many different aspects of chemistry. The particular strength of this account is that it unites chemistry, the history of chemistry, and the history of the chemical elements. The early stages of these are described best and in greatest detail, whereas the treatment of prebiotic chemistry and related research is rather brief. Thus one finds an excellent analysis of the early stages of chemical evolution and the contributions of chemists such as Bunsen, Kirchhoff, Fisher, and van't Hoff, whereas the origins of the chemical basis of life and the corresponding work of Oparin, Haldane, Bernal, Urey, Miller, Calvin, etc. are not discussed so thoroughly. To that extent the book does not entirely fulfill the claim of accurately reflecting the state of knowledge at the end of the 1980s, but despite this it can be strongly recommended.

The author gives an excellent description of the formation of the lighter chemical elements in the "big bang", then leads the reader on through the formation of the heavier elements in the stars, and describes the origin of the solar system and of geological minerals. He treats with equal thoroughness the interstellar medium, interstellar dust, meteorites, and comets. The account of the chemical basis of life is divided into the separate aspects of bioenergetics, replication, and polymerization. The last chapter deals with the question of chirality, where the author bases the discussion on his previous work, starting from the concept of the amplification of weak electrical asymmetry.

Subject to the reservations mentioned above, the book can be recommended for study by chemists, physicists, biologists, geologists, and astrophysicists who are interested in chemical evolution. It should also be of considerable interest to scientific historians.

Werner Ebeling

der Humboldt-Universität Berlin (FRG)

Microscopy. 2nd edition. (Series: Physical Methods of Chemistry, Vol. 4.) Edited by *B. W. Rossiter* and *J. F. Hamilton*. Wiley, Chichester, 1991. XI, 539 pp., hardcover £ 109.00.—ISBN 0-471-08026-8

This book describes methods of microscopy by which images can be obtained through different "illumination methods". The volume encompasses ten contributions, each fitting well with the others, from internationally recognized specialists. The contents are best indicated by the chapter titles, given here in order of the contributing authors: 1. Introduction: Principles and Practice of Electron Microscopy, 3. Electron Microscopy of Defects in Crystals (Medium Resolution), and 7. Special Electron Microscopy Techniques, by John M. Cowley; 2. Electron Microscopy of Biological (and Organic) Materials, and 4. High-Resolution Imaging of Crystalline and Amorphous Materials, by David J. Smith; 5. Electron Diffraction and Microdiffraction, by John C. H. Spence; 6. Microanalysis by Electron Energy Loss Spectroscopy and Energy Dispersive X-Ray Analysis, by Peter Rez; 8. Scanning Electron Microscopy, by Ludwig Reimer; 9. Light Microscopy, by Walter C. McCrone; 10. Determination of Particle Size, by George L. Beyer.

Two-thirds of the book is devoted to electron microscopy, which indicates the importance of and the increasing interest in this method. Modern developments are also to be found in light microscopy, and the contribution about light microscopy makes it clear that this field should in no way be forgotten. The contribution on particle size determination provides a practical example of, among other things, the application of light and electron microscopy (also for automated measurement methods).

With the development of electron microscopy to higher resolution it is increasingly the differences and not the analogies between light and electron microscopy that emerge. Electron microscopy has therefore been considered in this book as consistently as possible from the standpoint of the theory of coherent images, whereas light microscopy was usually described using the concept of incoherent images. The wave properties of electrons and the corresponding diffraction effects are set in the foreground. This volume does not attempt to describe the field completely with results, but sufficient reference is made to the literature for examples of applications and further methods. The emphasis on methods contributes to clarity because the fundamental principles are not concealed by detail. This book shows both where the value and the limits of each method lie and gives an impression of the necessary expenditure of time and effort. All important ideas are explained in an easily comprehensible form. The good general index makes the keywords, otherwise to be found scattered in specialized publications, easily accessible. The individual contributions are so fluently written that one will not only consult them but read further with interest.

The fact that transmission electron microscopy constitutes the book's main theme shows that, in this area alone, unusually *fast* and significant advances have been made in the last few years. All types of equipment and imaging techniques now available are introduced, for example, diffraction in a convergent beam, possibilities for imaging and analysis with scanning transmission microscopy, image processing, and simulation procedures. Even the very promising method of holography with electrons is mentioned. Some of these working methods have only become available for normal use by outfitting apparatus with digital technology and by employing computers. All the modern methods of contrast generation, scanning microscopy, and image processing are described in the section on light microscopy. Every chapter is well provided with diagrams, schemes, and illustrations.

This volume, which presents a sound, up-to-date survey, can be highly recommended to all scientists who want to be informed about these methods, their theoretical basis, and the necessary equipment.

Reductions by the Alumino- and Borohydrides in Organic Synthesis. By *J. Seyden-Penne*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim/Lavoisier TEC & DOC, Paris, 1991. XIII, 193 pp., hardcover DM 108.00.—ISBN 1-56081-099-8/3-527-28247-5.

Alumino- and borohydrides can be used to achieve selective reductions in high yields, requiring only a simple protocol, and they have therefore rapidly become an indispensable aid to organic synthesis. Because of the wide variety of special reagents now available, and the large number of efficient reductions that have been described in the primary literature, there was a pressing need for an up-to-date review. This report on the latest situation by J. Seyden-Penne does not claim to be complete, but by reviewing 605 publications,

most of which have appeared during the last decade (35 during 1990), it offers an extensive reference source with particular emphasis on the chemo-, regio-, and stereoselectivity of the reactions.

The book is divided into three parts. The first part, consisting of 13 pages, briefly describes the relevant properties (solubility, stability, reactivity) of the most commonly used alumino- and borohydrides, and of a few boranes. The second part (126 pp.) deals with reductions of the most important functional groups. This main part of the book covers the reductive scission of CX, CO, CN, and CP single bonds, and the reactions of the title reagents with CC, CO, and CN double bonds, and with CC and CN triple bonds, and ends with a chapter on the reduction of other substrates (N-, Hg-, Pd-, S-, P-, Si-, and B-containing compounds). The third part (12 pp.) gives a tabular survey of reductive preparations for the most important functional groups, listing the products, educts, reagents, and relevant sections in the book. These synoptic tables arranged according to the structure of the product, together with the list of contents subdivided according to the structure of the substrate and an additional 11-page index organized according to reaction types, enable the reader to readily locate particular transformations of interest.

The examples chosen to illustrate the selectivities include numerous synthetically relevant polyfunctional substrates, making up a very useful compilation. The main strength of the book undoubtedly lies in the detailed discussion of the differential reactivities of various functional groups towards alumino- and borohydrides, and the clear information that is given regarding suitable chemoselective reagents for each case. An appropriate amount of space is also devoted to substrate- and reagent-induced stereoselective transformations, but the pleasure in reading these sections is marred for the reasons explained below. Nowhere is there any mention of yields; however, a few random checks in the original papers that are cited indicate that the reactions described give high yields.

Unfortunately, the book contains many errors that could easily have been avoided by conscientious proofreading. These include simple slips (for example, p. 39: "most hindered double bond" instead of "least substituted ...", p. 99: "trapping of the aluminum enolates obtained from alkyl halides" instead of "... with alkyl halides", p. 143: "to treat the sulfones" instead of "... the sulfoxides"), wrongly or incompletely drawn structures (for example, p. 26: sultone instead of sulfate, p. 32: free alcohol instead of TMS-ether, pp. 36 and 148: primary ozonide instead of secondary ozonide and, accordingly, wrong products shown, p. 94: missing imide nitrogen atom and missing CH_2 group in the chiral auxiliary, p. 52: stereochemistry of the ring junction in the decalones omitted, p. 97: relative configurations of the 3,5-dimethylcyclohexanones not shown), inappropriate descriptions (e.g. p. 29: "the reaction proceeds with configuration inversion" and p. 37: "the reaction can be regioselective", as comments on reactions that do not show the selectivities referred to, or p. 71: "the reduction follows the Felin–Anh rule", as an explanation of the stereoselective reduction of ketones that do not have a stereogenic center at the α carbon atom), and misleading representations, which are frequent (of all places) in the important chapters on the stereoselective reduction of ketones (for example, pp. 49, 50, 54: confusion between the major and minor products in the reduction of C-22 ketones of the steroids series—here also the methyl group on C-20 is sometimes missing, pp. 62–63: interchanging of the major and minor products in the reduction of 2-acyl-1,3-oxathiones and the wrong enantiomers shown, p. 68: the irrelevant statement that "the two conformations C_1 and C_2 are equally populated", where one is dealing with different reactivities). Readers interested in the stereoselective synthesis of steroid side chains or in applying Eliel's method for the enantioselective preparation of α-hydroxyaldehydes must definitely consult the original publications.

To summarize, therefore, this book leaves one with a mixed impression; a thorough revision would be necessary before this reviewer could agree unreservedly with the recommendation by H. C. Brown in the preface that "this book should be in the personal library of every chemist engaged in organic synthesis".

der Universität Münster (FRG)

The World of Peptides. A Brief History of Peptide Chemistry. By *T. Wieland* and *M. Bodanszky*. Springer, Berlin, 1991. XII, 298 pp., hardcover DM 198.00.—ISBN 3-540-52830-X

When, in 1901 in Berlin, Emil Fischer prepared glycylglycine, the first free "peptide", no one guessed that this compound marked the beginning of the history of a fascinating class of substances. Peptides constitute the link between amino-acids and proteins. The great variety of peptide structures includes compounds with remarkable biological activities. Many important hormones, antibiotics, toxins, sleep regulators, pain regulators, immunostimulants, immunosuppressants, antitumor and anti-AIDS agents, and a variety of other active substances, are peptides.

This "world of peptides" is described in the book by Theodor Wieland and Miklos Bodanszky. The ten chapters (298 pp.) are as follows: 1. Introduction. Aminoacids and a Few Early Paradigmatic Peptides; 2. Synthesis of Peptides. The First Epoch; 3. The Era After Emil Fischer. The Carbobenzoxy Group, Max Bergmann and his Scientific Circle; 4. A Second Breakthrough: New Methods for the Formation of the Peptide Bond; 5. A New Technology: Solid Phase Peptide Synthesis; 6. Structure Elucidation; 7. Peptide Hormones; 8. Biologically Active Fragments of Proteins; 9. Biologically Active Peptides from Microorganisms and Fungi; 10. Peptide Research Around the World.

Reading this highly interesting account one is aware on every page that the authors are thoroughly at home in this world. Indeed, in their scientific careers they have had a part in shaping the history of these developments, through their fundamental contributions to experimentation and to the literature. The first few chapters describe in detail the work of the founders of peptide chemistry (Fischer, Curtius, Abderhalden, Leuchs, Bergmann, and others) and of the pioneers of the post-war period (Du Vigneaud, Rudinger, Merrifield, etc.). One learns more about the difficult relationship between Fischer and Curtius, and about the temporary shift of the center of gravity of peptide research from Germany to the USA. Pioneering advances are related to the subsequent developments in an admirable fashion; for example, the discovery of the Leuchs anhydrides is linked to an excellent review of later work on the chemistry of NCA and polyamino-acids, and that of the benzyloxycarbonyl residue by Bergmann and Zervas is linked to an account of work on protecting groups during the years that followed. The rapid development of peptide chemistry after the Second World War led to numerous innovations in methods of synthesis

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1992 0570-0833/92/1111-1535 $ 3.50+.25/0

and analysis, to the discovery of many new naturally occurring peptide structures, and to the elucidation of a variety of structure–activity relationships. The careful choice of subject matter covers all the important facts and highlights. However, it seems to this reviewer that the application of genetic engineering methods to peptide synthesis has not been treated in adequate detail. One can hardly accept that a few more pages here would have exceeded the planned length of the book.

In Chapter 10 one learns that research in peptide chemistry is now being carried out in 27 countries throughout the world (the names of about 800 peptide chemists are listed, and the appendix contains photographs and short biographical notes on about 60 of the field's "élite").

A comprehensive bibliography at the end of each chapter facilitates quick access to the original publications. Other useful information (not only for the expert) is given in a chronological list of international symposia on peptides (Ch. 3, Ref. 42), and in references to the standard works on the subject.

The "Brief History of Peptide Chemistry" announced in the book's subtitle turns out in practice to be a valuable monograph on the topic. This considerably broadens the potential readership. Scientists with an interest in the history of the subject, especially chemists, biochemists, medical scientists, pharmaceutical chemists, and students of all these disciplines, will find here a wealth of information that could otherwise only be gathered with a great deal of effort. Altogether this is a book that belongs in every specialist library, and that everyone concerned will need to have read.

Hans Jeschkeit
Institut für Organische Chemie
der Universität Halle (FRG)

Molecular Electronics. Edited by *G. J. Ashwell.* Research Studies Press, Taunton (UK)/Wiley, Chichester, 1992. X, 362 pp., hardcover £44.50.—ISBN 0-86380-125-0/0-471-93386-4

Molecular electronics is an intriguing term, which can be understood to include several quite different fields of research. Essentially, however, two major areas can be distinguished. Firstly there is the search for molecular materials that can be used in electronics or microelectronics to make components with improved functions. Secondly one can understand it to cover various investigations, some of which involve highly speculative ideas, with the aim of developing a form of electronics based on individual molecules. The hope here is that an element performing an electronic function can be incorporated within a single molecule or a small number of molecules. It is this latter possibility in particular that has seized the imagination of researchers. The book reviewed here deals only with the first of these problem areas, and even here it does not claim to cover the whole topic. A more appropriate title would therefore have been something like "Molecular Materials for Electronics—Selected Topics".

The six chapters are essentially independent of each other, and cover several aspects that are important in relation to potential applications of molecular materials in electronics. The first chapter, "Molecular Electronic Materials", by G. J. Ashwell, I. Sage, and C. Trundle, begins with a 27-page survey of such interesting topics as photochromism, electrochromism, organic conductors, superconductors, and nonlinear materials. The most important areas of application are in optical data storage, molecular rectifiers, and frequency doubling. A review as short as this is inevitably far from complete, and many important publications do not appear in the bibliography. This is followed by a 30-page review of the physical and chemical properties of liquid crystals, which has no obvious relevance to the theme of the book. The second chapter, on "Conjugated Polymers", by M. F. Rubner, explains conductivity in polymers by introducing the concept of solitons and polarons, then discusses aspects such as stability and processing behavior, and describes applications of conducting polymers as active layers in electronic components, in Schottky junctions, and in field-effect transistors. In Chapter 3 on "Langmuir–Blodgett Films", I. R. Peterson first gives a detailed description (60 pp.) of the preparation and characterization of these films, which allow the development of a "molecular architecture" and make it possible to arrange molecules in well-defined structures. This is followed by 15 pages devoted to potential applications (thin insulating films, dielectrics in capacitors, in lithography, and in nonlinear photonics), the general impression being rather pessimistic. In Chapter 4 on "Nonlinear Optics", S. Allen gives a good overview of the prospects for measuring nonlinear optical properties of organic materials and influencing these chemically, and also of incorporating such molecules into a suitable matrix. However, no practical applications in electronics are cited, which probably reflects the true situation. In Chapter 5, "Piezoelectricity, Pyroelectricity and Ferroelectricity", J. Sworakowski gives an introduction to this group of topics, with particular emphasis on molecular solids. Although there are potential applications in molecular electronics, for sensors, storage devices, and similar purposes, the author's view is that, with the exception of polar monomers, these are unlikely to be realized in the near future. The final chapter by K. Firth on "Holography" gives a short and superficial account of the main features of holography, without really relating this to molecular electronics. Recent developments such as holography based on bacteriorhodopsin are not mentioned.

It is not clear for whom this book is intended. The six chapters contain little that will be new to specialists, although they do provide something of an overview of this broadly interdisciplinary field of research. The interested non-specialist, although not finding as much in the book as its title appears to offer, can nevertheless learn something about several interesting aspects of materials research.

Hans Christoph Wolf
Physikalisches Institut
der Universität Stuttgart (FRG)

The Science of Crystallization. Microscopic Interfacial Phenomena. By *W. A. Tiller.* Cambridge University Press, Cambridge (UK), 1991. XXX, 391 pp., hardcover £40.00.—ISBN 0-521-38138-9/paperback £15.00.—ISBN 0-521-38827-9

The two monographs "The Science of Crystallization. Macroscopic Phenomena and Defect Generation" and "The Science of Crystallization. Microscopic Interfacial Phenomena" together form a complete set from this publisher. As the author indicates in his preface, they are suitable as textbooks for students at postgraduate or advanced undergraduate levels in materials science, chemistry, or related subjects. These compact and straightforwardly presented volumes are themselves a *crystallization* of Tiller's long experience in teaching and research, during a period of far-reaching developments

that laid the basis of modern knowledge of crystal growth phenomena and techniques. Here the chemist, in the narrower sense of the word, may learn how complex spatial, temporal, and energetic factors influence the formation or breakdown of crystalline morphological forms, and how these effects can be understood in terms of the chemical thermodynamics and kinetics of multiphase systems. The volume reviewed here consists of three parts. The first treats general and specific aspects of interfacial phenomena, with examples drawn from the semiconductors field; the second presents "background science" relevant to both volumes (introductory discussions of phase systems, nucleation phenomena, etc.); and the third contains example problems (although solutions are not given).

The general discussion begins by considering research on crystallization phenomena from the standpoint of a "response" theory, from which one arrives at a realistic estimate of the necessary research effort (in man-years) using different approaches. This shows that if one adopts a "black-box" approach (with the emphasis on crystal growth and experimental procedures), then the $(j + k)$-dimensional space of variables (where j is the number of different materials and k the number of experimental parameters) leads in practice to an "art-based technology" (in which crystal-growing becomes an art and a collection of recipes). On the other hand, a "system" approach based on a "clustering" that imposes a predetermined structure leads to a "science-based technology" (with a strategically planned procedure and a minimum of experimentation). The consequences of this viewpoint are then systematically developed. Lastly, Tiller considers an *intelligent* approach in which one chooses "scientific trajectory segments" (p. 34) and aims to minimize the experimental work required. The theoretical procedure is illustrated by examples of experiences with semiconductor materials especially (Si, GaAs); these mainly involve crystallization from the melt, and the wealth of available experimental data allows a quantitative study of the crystallization process. Although Tiller discusses the theory using examples drawn mainly from the semiconductors field, many of the results remain valid for the crystallization of other substances, and under different conditions (solutions or the gas phase).

Although the chemist who frequently encounters difficult crystallization problems is likely to find this knowledge interesting in principle, it will probably not be of great help from a practical standpoint. For those working in the area of crystallization, these two volumes will make interesting, and perhaps essential, reading. On the other hand, the chemist seeking help in this area can certainly learn from this book about modern ideas on interfacial phenomena of crystal growth, but should also refer to other works such as that by K.-T. Wilke and J. Bohm (*Kristallzüchtung*, H. Deutsch, **1988**). For newly synthesized materials that need to be crystallized in order to determine their solid state properties, thermodynamic formulas are only of limited use in general, since one does not usually have sufficient data on the thermodynamic parameters. Thus, success is likely to come more quickly from an approach based on the intuition of the crystal-grower, or on computer-aided empirical strategies (P. van der Sluis et al., *J. Cryst. Growth* **1991**, *112*, 719; G. L. Gilliland, *ibid.* **1988**, *90*, 51).

If there is something to be said against this excellent book, it is that a discussion of the energetic and kinetic aspects of interfacial phenomena should have included recent studies, by methods such as light scattering measurements and in-situ synchrotron radiation experiments, that have shown the existence of a labile transitional region between the growing (or dissolving) crystal and the mobile phase, and have led to a better understanding of its structure (e.g., R. Steiniger et al., *J. Cryst. Growth* **1991**, *112*, 203; D. Cunningham et al., *ibid.* **1990**, *99*, 1065). Also, it would be worthwhile to publish a supplementary volume giving solutions to the exercise problems, which are generally of a very high standard; these examples drawn from practical calculations would serve to elucidate the theoretical methods even better.

Transition Metal Hydrides. Edited by *A. Dedieu*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. X, 399 pp., hardcover DM 182.00—ISBN 0-89573-781-7/3-527-27985-7

Since Hieber's synthesis of tetracarbonyldihydrido-iron $Fe(CO)_4H_2$, in 1931, hydrido-transition metal complexes have occupied a central position in coordination chemistry. Complexes containing a metal–hydrogen bond are usually regarded as belonging to organometallic chemistry, due mainly to the enormous importance of such compounds in homogeneous catalysis. For example, the role of $Co(CO)_4H$ as the catalytically active species in the Roelen oxo-synthesis was recognized at a very early stage, and the insertion of small molecules into the metal–hydrogen bond has long been one of the key reactions of homogeneous catalysis. More recently, transition metal complexes with molecular hydrogen as a ligand came onto the scene, following the discovery by Kubas in 1984 of the prototype compound $[W(P\{iPr\}_3)_2(CO)_3(\eta^2\text{-}H_2)]$.

This superbly produced book "Transition Metal Hydrides" consists of ten review articles devoted *exclusively* to theoretical and physicochemical aspects of hydrido-transition metal complexes. All the articles have been written by internationally recognized experts, who present the current state of knowledge on hydrido-transition metal complexes in a thoroughly competent way from their own particular viewpoints.

In the first chapter Armentrout and Sunderlin describe the results of studies on hydride species in the gas phase, and report experimental data on the bond energies of apparently simple binary species of the type MH. The experimental techniques used are also described by way of introduction. In the following chapter Sweany reviews matrix isolation studies on hydrido complexes. Particular attention is devoted to the elementary reaction of molecular hydrogen with "naked" metal atoms, and spectroscopic methods for investigating metal–hydrogen interactions are critically reviewed.

The middle five chapters of the book discuss, from the standpoint of theoretical chemistry, practically all the areas of the chemistry of hydrido-transition metal complexes that are currently of interest. Bauschlicher and Langhoff summarize the results of theoretical calculations on bonding in binary species of the type MH, and compare these with spectroscopic data. In Chapter 4 Hay reports on ab-initio and semiempirical calculations on oxidative addition and reductive elimination reactions of molecular hydrogen and of saturated hydrocarbons, while Burdett, Eisenstein, and Jackson discuss the nature of the bonding in complexes having molecular hydrogen as a ligand ("non-classical" hydrido complexes). They also discuss polyhydrido complexes, which are still a subject of much structural and spectroscopic investigation. Koga and Morokuma, in a very comprehensive chapter, deal with hydrogen transfer reactions, including both intramolec-

ular (insertion) and intermolecular reactions. These Japanese authors describe how, thanks to the enormous computing capacities that have become available in the last few years, ab-initio methods can now be applied not only to calculations of molecular geometry, but also in many cases to reaction profiles of catalytic cycles. To complete this group of topics, in Chapter 7 Daniel and Veillard discuss theoretical aspects of the photochemistry of hydrido complexes.

The last three chapters are devoted to some properties of hydrido complexes in solution. Bullock gives a detailed account of results on isotope effects in hydrido complexes, and an excellent review of isotope exchange methods as an important tool for mechanistic studies. In the following chapter Kristjánsdóttir and Norton describe results from the extensive studies carried out in Norton's group on the determination of the acidity of hydrido-transition metal complexes. The tables of pK_a values given here will certainly be very useful for comparison purposes. Lastly, Labinger discusses the very interesting question of exactly what is meant by hydride character, and considers which factors influence the nucleophilic properties of hydrido-metal complexes.

The editor Dedieu then rounds off the book with some general comments on the topics treated. The differences in layout and presentation that are often unavoidable in multi-author works, but are nevertheless a continual source of irritation, have been successfully minimized here, and the book is virtually free of printing errors. With its over 1000 literature references and detailed subject index, it offers readers with an interest in this field an up-to-date overview of theoretical and physicochemical aspects of hydrido-transition metal complexes.

Metal–Surface Reaction Energetics. Theory and Applications to Heterogeneous Catalysis, Chemisorption, and Surface Diffusion. Edited by *E. Shustorovich*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1991. XII, 232 pp., hardcover DM 144.00.—ISBN 0-89573-776-0/3-527-27938-5

The interaction of gases with surfaces is an area of chemistry that has been studied intensively for many years. This book offers, in five chapters, a review of theoretical methods for describing the energetics of interactions between gases and metal surfaces, including surface diffusion, dissociative and non-dissociative chemisorption, and catalytic processes. The individual chapters are rounded off by comparing theoretical results with experimental data.

The first chapter (approx. 50 pp.) is concerned with the study of adsorption energies and dissociative reaction pathways using quantum-chemical cluster calculations. After introducing the theoretical concept of cluster calculations, P. E. Siegbahn and U. Wahlgren discuss its capabilities and practical limitations with the help of a number of examples. This chapter impresses by its straightforward presentation of the basic features of this complex topic, and it should be understandable even by non-specialists.

In the following chapter, also of about 50 pages, J. B. Benzinger describes thermodynamic methods for treating the energetics of adsorption and reactions at surfaces. The main emphasis is on applications of the bond order conservation (BOC) method to the estimation of adsorption and reaction energies, which can then be used to determine kinetic parameters. Owing to the complexity of this field and the scarcity of relevant thermodynamic data, the methods described here are, of course, heavily reliant on approximations and empirical procedures.

The next chapter (R. C. Baetzold, approx. 30 pp.) deals with the diffusion of atomic and molecular adsorbates on surfaces. This area of study, which is important in relation to the dynamics of surface processes such as nucleation, crystal growth, and surface reactions, again involves the application of the BOC model.

In the fourth chapter (approx. 40 pp.) D. Halstead and S. Holloway describe simulation calculations on dissociative and non-dissociative adsorption using the split operator method (example: H_2 on metal surfaces). In this method the development with time of the wave function of a molecule is treated by taking into account the translational, rotational, and vibrational degrees of freedom when scattering occurs at a surface potential. After introducing the method of calculation, the authors present results obtained by applying it to model potentials with different reaction barriers.

In the final chapter (approx. 30 pp.) A. T. Bell discusses approaches based on the BOC method for treating mechanisms and kinetics of heterogeneously catalyzed reactions. The chapter begins with an explanation of the underlying concept, then discusses several examples and simulation calculations aimed at determining reaction energetics and pathways.

The book is intended for scientists working in the fields of surface chemistry or heterogeneous catalysis. Although the individual chapters are essentially of a theoretical nature, the material is presented in such a way that it can also be understood by non-theoretical readers. The book can therefore be recommended also for final year students. As it contains many tables listing experimental and calculated energy data for different adsorbates and a wide variety of metallic substrates, it also has some value as a work of reference. Aspects that may be criticized are the overlapping in subject matter between some of the chapters, and the fact that some of them concentrate too heavily on the BOC formalism. In the preface the editor expresses the view that a mutual understanding between theoreticians and experimentalists will be of crucial importance for future progress. This book is a very welcome contribution towards that aim.

Intermolecular Forces. An Introduction to Modern Methods and Results. Edited by *P. L. Huyskens, W. A. P. Luck*, and *T. Zeegers-Huyskens*. Springer, Berlin, 1991. X, 490 pp., hardcover DM 198.00.—ISBN 3-540-53410-5

The properties of chemical substances are greatly dependent on intermolecular interactions. In particular, the occurrence of hydrogen bonding in a substance fundamentally affects its physical and chemical properties. Despite this, according to the editors of this book the subject receives too little attention in undergraduate teaching. Their book, which is based on the contributions presented at a 1989 "Erasmus" course, is thus seen by the editors as, not least, a stimulus for university teachers to give the subject a greater emphasis.

A glance at the contents list of this book of 21 chapters quickly reveals that the main emphasis is on describing recent results on hydrogen bonding. Although this is not in keeping with the book's title, which suggests a more general

concern with intermolecular forces, it undoubtedly takes into account the extreme importance of hydrogen bonding in chemistry and biochemistry. Consequently, the two articles concerned with studies on clusters and with experiments on molecular collisions in the gas phase seem almost out of place in the otherwise uniformly orientated subject matter.

The book consists of three parts. The first part contains a general introduction to intermolecular interactions. T. Zeegers-Huyskens and P. L. Huyskens report on cohesion forces and on specific intermolecular forces. The first of these two sections deals briefly with van der Waals forces, but regrettably does not relate this topic to recent research in the field of cluster physics. The second section discusses hydrogen bonding and related interactions and describes examples. For this introduction it would perhaps have been better to start with van der Waals interactions, and then to proceed via charge-transfer interactions to hydrogen bonding. However, this is put right in the second chapter by L. G. Vanquickenborne, who is concerned solely with the quantum chemical aspects of hydrogen bonding, and gives a detailed description of the Morokuma model for explaining the nature of hydrogen bonding. The first part of the book concludes with chapters on "How to Understand Liquids", by W. A. P. Luck, and "Dynamic Aspects of Intermolecular Interactions", by L. C. M. De Maeyer.

The second part consists of eight chapters describing spectroscopic studies of intermolecular interactions. Six of these are concerned with hydrogen bonding, mainly in the liquid phase. A. Ceulemans gives an introduction to the theoretical treatment of vibrational spectra of hydrogen-bonded systems. T. Zeegers-Huyskens then links this to IR spectroscopic investigations of intermolecular stretching vibrations. W. A. P. Luck discusses the application of IR overtone vibrational spectroscopy to studies of hydrogen-bonded liquids. The same author, in a further chapter entitled "Water—The Most Anomalous Liquid", describes the unique macroscopic properties of water and attempts to explain their causes. K. Rademann gives a short introduction to the various forms of spectroscopy for studying clusters in molecular beams, and shows how these new techniques can be used to investigate intermolecular forces. This part on spectroscopic methods concludes with chapters by H. Kleeberg on "Cooperative Effects Involved in H-Bond Formation", by H. H. Limbach on "NMR Studies of Elementary Steps of Multiple Proton and Deuteron Transfers in Liquids, Crystals and Organic Glasses", and by G. Maes on "Matrix Spectroscopy of Hydrogen-Bonded Complexes".

The third part consists of nine chapters describing non-spectroscopic methods of investigation. For example, U. Buck deals with the determination of intermolecular potentials by scattering experiments with crossed molecular beams. P. Bopp shows what can be achieved by applying "Molecular Dynamics (MD) Computer Simulations of Hydrogen-Bonded Liquids" to the interpretation of experimental results. P. L. Huyskens and G. G. Siegel, in their article on "Hydrogen Bonding and Entropy", attempt a quantitative description of hydrophobic effects.

The appearance of the book gives a good impression, and the quality of the figures and formulas is excellent. A detailed keyword index makes it easy to find one's way around the many chapters. Further help in quickly locating information is provided by the short summary given at the beginning of each chapter, and by the contents lists for the individual chapters. A brief examination of the ample lists of references appended to the chapters shows that the most recent results have been cited.

The book can be recommended for everyone seeking a review of the current state of research in the area of molecular interactions, especially hydrogen bonding. Unfortunately however, recent studies using molecular beams receive only marginal coverage. Also, the wealth of methods and results in the rapidly growing field of research on clusters cannot be adequately covered in only a single chapter. Nevertheless, this is more a criticism of the choice of title for the book, which is too general, than of the otherwise comprehensive and well-balanced contents.

Stereochemistry of Organic Compounds. Principles and Applications. By *D. Nasipuri.* Wiley, Chichester, 1991. XX, 527 pp., hardcover £33.95.—ISBN 0-470-21639-5

A new 500-page book on stereochemistry? One's reaction might be: well, at last!—this raises high expectations—but to write such a book must be a very difficult task, in view of the continuing rapid development of modern methods.

Nasipuri has divided his book into three main subject areas. Following an introductory chapter on the different types of chemical bonding and molecular geometry, he goes on to consider increasingly complex questions of stereochemistry. The basic principles, methods of classification, and definitions are explained with the help of good illustrations and examples of reactions. This first part, consisting of eight chapters, is followed by a second part giving a detailed description of molecular conformations of cyclic and acyclic systems. The discussion includes physicochemical methods of conformational analysis, and conformational behavior of polycyclic and heterocyclic compounds, considering both individual examples and general characteristics. The third part is concerned with dynamic stereochemistry, and consists of three chapters dealing in turn with relationships between conformation and reactivity, stereoselective transformations, and pericyclic reactions. Each chapter of the book begins with a brief introduction outlining the main aspects of the topics to be discussed. Occasional excursions into the historical background serve to stimulate the reader's interest. Each of the fifteen chapters is subdivided into numerous sections, and ends with a brief summary and a bibliography.

The book is intended mainly for advanced undergraduate and post-graduate students. Its greatest strength lies in the first part, which deals with the basic concepts of organic stereochemistry. In many places the text strikes one as material designed to accompany a course of lectures, and often the reader will wish that the author could act as a "course tutor" to explain difficult points. The preface indicates that the literature references cover publications up to 1990; in fact, most of the citations refer to older monographs, review articles, and original papers, which describe results of fundamental importance. It is annoying to find that a lengthy search is often needed to locate a citation in the bibliography. The citations are identified in the text by the author's name and the year, but instead of being listed at the end of the chapter in alphabetical order as one would expect, they are just given in the order of appearance in the text. The frequency of errors is noticeably high, especially in names (e.g., "J. N. Lehn", p. 42; "Nögradi", p. 404; "Gröb fragmentation, Gröb 1969", p. 365; "Yamamotoa", p. 444; "Stereochemie der Kohlenstoffverdunger", p. 105; and

many more). There are also some very unusual abbreviations for journal names, and different ones appear at different places. In a student textbook it would surely have been appropriate to use the standard citation methods of the *Chemical Abstracts Source Index*. Also it is very annoying when a citation given in the text does not appear in the bibliography (e.g., Phillips 1954, p. 236).

The very detailed description of the conformations of organic compounds in the middle part of the book is followed by a compilation of stereoselective transformations and asymmetric synthesis methods. In contrast to the careful and patient explanations of complex matters in the earlier chapters, the style of this part seems hurried and very condensed. The author describes individual examples, but neglects important theoretical explanations, giving repeated references (rather old ones in many cases) for further reading; this is justified by the statement that "...space does not permit any further discussion on this topic" (p. 475). Here it was evidently felt that there was a need to update the book by including in the bibliography some additional citations that are not mentioned in the text (Chapter 13). However, the choice of these seems very haphazard. Some newer areas of research, such as stereoselective free radical reactions and the application of force field calculations to conformational analysis, are completely absent, or are only mentioned incidentally in the text.

Nasipuri's textbook can be thoroughly recommended for its good and detailed introduction to the basic concepts of organic stereochemistry. However, in its treatment of dynamic stereochemistry, and especially of asymmetric synthesis, it still leaves one with the need for a comprehensive textbook dealing effectively with these topics. The relatively low price makes this an attractive new textbook, but does not excuse the poor quality of the typography and binding.

Emil Fischer's Proof of the Configuration of Sugars: A Centennial Tribute**

By Frieder W. Lichtenthaler*

Today's textbooks convey the deceptive impression that chemistry developed in a rational and orderly process with discoveries following one upon another in a vertical progression—an impression that tends to classify Fischer's achievement as a matter-of-fact historical development. This misconception does not consider the instances of serendipity invariably involved, and entirely fails to appreciate the human endeavor, the intellectual struggle of the dedicated researcher, and the forging force of his personality that eventually led to this key insight. The hundredth anniversary of Fischer's classical piece of work provides a welcome opportunity not only to highlight its paramount importance for the development of carbohydrate chemistry, and of organic chemistry in general, but to trace the creative processes underlying this fundamental discovery, the thought patterns at a conceptual level, and the constructive reasoning that eventually led to it. Their understanding and appreciation is essential for emulating Fischer's achievement in a modern context.

Die Geschichte einer Wissenschaft
ist diese Wissenschaft selbst
J. W. von Goethe[***]

The rapid pace and volume of scientific discoveries tend to eclipse not only those of past decades, but those of the past century in particular. This leads to a gross underestimation of the basic contributions of the pioneers of our science who laid the very foundations of current research. Pertinent examples of this are the foundation of organic structural chemistry and the proposal of the benzene formula by Kekulé in 1865[1] and, ten years later, the postulation of tetrahedral geometry for carbon by Le Bel and van't Hoff,[2, 3] which provided an explanation for the occurrence of numerous isomers inexplicable on the basis of the then current structural formulas. Another case in point, substantially undervalued in its impact on the development on organic chemistry, is the establishment of the relative configurations of the sugars by Emil Fischer in 1891,[4, 5] a most remarkable piece of research which not only put carbohydrate chemistry on a rational basis but—more importantly for that time—provided unequivocal proof for the validity of the Le Bel–van't Hoff theory of stereoisomerism.

The essence of what was to become the sugar family tree, and what inaugurated a new mode of writing stereoformulas is contained in two publications by Fischer (Fig. 1) in the *Berichte der Deutschen Chemischen Gesellschaft*, the first appearing in the September issue of 1891[4] (Fig. 2) and the second only two months later.[5] Both papers carried the

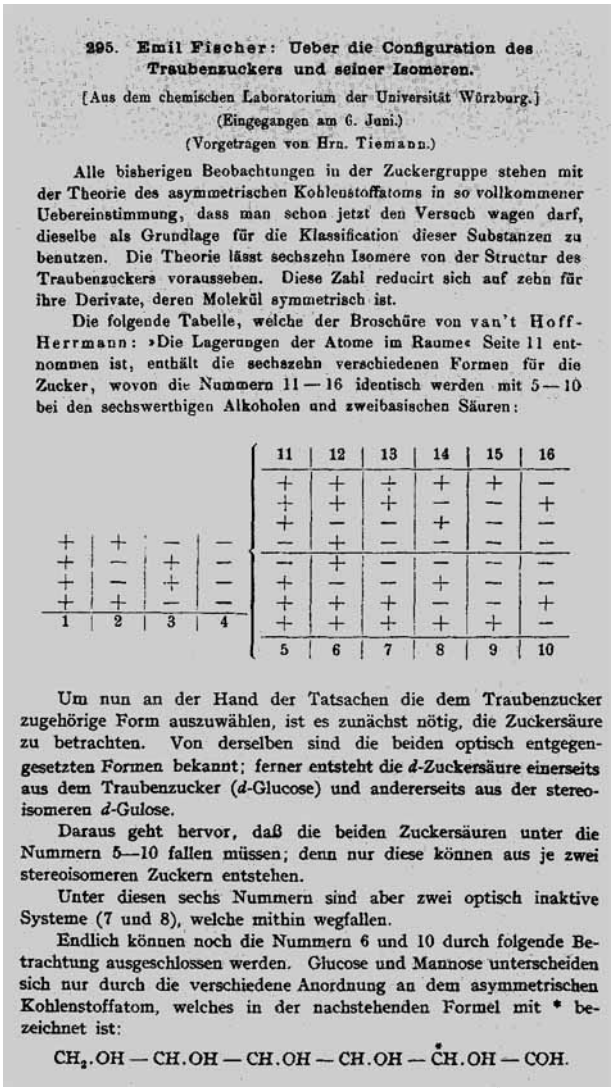
Fig. 1. Emil Fischer (1852–1919) in 1889 [6].

modes title "Über die Configuration des Traubenzuckers und seiner Isomeren" (On the Configuration of Grape Sugar and its Isomers), yet the introductory sentence of the first of these (see Fig. 2) gives a clear indication of the fundamental question to be addressed, and the solution that was achieved:

> "All previous observations in the sugar group are in such complete agreement with the theory of the asymmetric carbon atom, that, by now, one may dare to use this theory as a basis for the classification of those substances."

This not only announced the advent of a rational sugar chemistry but, de facto, that of applied organic stereochemistry as well; the discovery was to shape the development of organic chemistry to an extent that can be compared only with the impact that Kekulé's benzene formula[6] had made 25 years earlier.

Modern textbooks give the deceptive impression that chemistry developed in a rational and orderly way in which discoveries follow one after another in a vertical progression—an impression that tends to classify Fischer's achievement as purely an historical development, accomplished by some remote, legendary historical figure. This misconception does not consider the instances of serendipity invariably involved, and entirely fails to appreciate the human endeavor, the intellectual struggle of the dedicated researcher, and the forging force of his personality that eventually led to this key insight. The hundredth anniversary of this classical piece of work provides a unique opportunity not only to highlight and appraise its paramount importance for the development



295. **Emil Fischer: Ueber die Configuration des Traubenzuckers und seiner Isomeren.**

[Aus dem chemischen Laboratorium der Universität Würzburg.]

(Eingegangen am 6. Juni.)

(Vorgetragen von Hrn. Tiemann.)

Alle bisherigen Beobachtungen in der Zuckergruppe stehen mit der Theorie des asymmetrischen Kohlenstoffatoms in so vollkommener Uebereinstimmung, dass man schon jetzt den Versuch wagen darf, dieselbe als Grundlage für die Klassification dieser Substanzen zu benutzen. Die Theorie lässt sechszehn Isomere von der Structur des Traubenzuckers voraussehen. Diese Zahl reducirt sich auf zehn für ihre Derivate, deren Molekül symmetrisch ist.

Die folgende Tabelle, welche der Broschüre von van't Hoff-Herrmann: »Die Lagerungen der Atome im Raume« Seite 11 entnommen ist, enthält die sechszehn verschiedenen Formen für die Zucker, wovon die Nummern 11—16 identisch werden mit 5—10 bei den sechswerthigen Alkoholen und zweibasischen Säuren:

1	2	3	4	11	12	13	14	15	16
+	+	−	−	+	+	+	+	+	−
+	−	+	−	+	+	+	−	−	+
+	−	+	−	+	−	−	+	−	−
+	+	−	−	−	+	−	−	−	−
+	−	+	−	−	+	−	−	−	−
+	−	+	−	+	−	−	+	−	−
+	+	−	−	+	+	+	−	−	+
+	+	−	−	+	+	+	+	+	−
1	2	3	4	5	6	7	8	9	10

Um nun an der Hand der Tatsachen die dem Traubenzucker zugehörige Form auszuwählen, ist es zunächst nötig, die Zuckersäure zu betrachten. Von derselben sind die beiden optisch entgegengesetzten Formen bekannt; ferner entsteht die *d*-Zuckersäure einerseits aus dem Traubenzucker (*d*-Glucose) und andererseits aus der stereoisomeren *d*-Gulose.

Daraus geht hervor, daß die beiden Zuckersäuren unter die Nummern 5—10 fallen müssen; denn nur diese können aus je zwei stereoisomeren Zuckern entstehen.

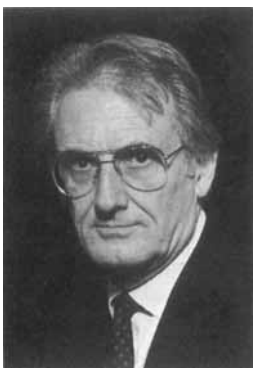
Unter diesen sechs Nummern sind aber zwei optisch inaktive Systeme (7 und 8), welche mithin wegfallen.

Endlich können noch die Nummern 6 und 10 durch folgende Betrachtung ausgeschlossen werden. Glucose und Mannose unterscheiden sich nur durch die verschiedene Anordnung an dem asymmetrischen Kohlenstoffatom, welches in der nachstehenden Formel mit * bezeichnet ist:

$$CH_2.OH - CH.OH - CH.OH - CH.OH - \overset{*}{C}H.OH - COH.$$

Fig. 2. Title page of the first [4] of Fischer's two landmark papers in 1891 on the configuration of sugars.

of organic stereochemistry in general, and carbohydrate chemistry in particular—this has been done, over the years, in many specialized accounts[7–14]—or for keeping pivotal facts from oblivion. During the past hundred years there has been almost unbelievable material and conceptual progress; what has not changed, however, are the creative processes underlying a fundamental discovery and the constructive reasoning that eventually led to it. Their understanding and



Frieder W. Lichtenthaler, born 1932 in Heidelberg, studied chemistry at the University of Heidelberg from 1952–1956 and received his doctorate there in 1959 under F. Cramer for research on enol phosphates. The following three years he spent as a postdoctoral fellow at the University of California, Berkeley, with Hermann O. L. Fischer—the only of Emil Fischer's three sons who survived the first World War.[10d] He subsequently worked as an assistant at the Technische Hochschule Darmstadt, where he acquired his "Habilitation" in 1963, was appointed associate professor in 1968, and was promoted to full professor in 1972. His research activities center on the generation of enantiopure building blocks from sugars, their utilization in the synthesis of oligosaccharides and complex non-carbohydrate natural products, the computer simulation of chemical and biological properties of sugars, and studies towards the utilization of carbohydrates as organic raw materials.

appreciation is required to emulate Fischer's achievement in a modern context.

The attempt to trace these processes starts with the analytical reagent which Fischer was the first to use in carbohydrate chemistry in 1884, and with which he established the relative configurations of the sugars only seven years later: *phenylhydrazine*, a base, which he accidentally discovered in 1875 at the age of 23, while working as an assistant in Baeyer's Strassburg laboratory. The resulting publication[15] (Fig. 3) is unusual in several respects. First, Baeyer, in whose institute the work was done, allowed him to publish it on his own; that there isn't even an acknowledgement to his teacher attests to the seemingly high esteem and encouraging attitude Baeyer had for his gifted pupil; second, the paper is formulated in a concise, clear style undoubtedly adopted from his teacher, and written in the first person. For example, in the paper reproduced in Figure 3, he writes,

> "I have again taken up experiments on the reduction of diazo compounds. ... I arrived at a class of well-characterized bases, for which I propose the name hydrazine compounds".

A rather self-confident statement for a young chemist who had just received his doctorate, and the more so as the parent compound, hydrazine, was discovered only twelve years later, in 1887, by Curtius.[16] Reading Fischer's paper of 1875 today engenders the sensation of contemplating the modest source of what was to become a mighty river within the next 15 years.

The research school of Adolf Baeyer (1835–1917[17]), from which Fischer emerged—first in Strassburg, and then for 40 years after 1875 at the University of Munich—was a major "forge" of talent. A group photograph[18] of 1878 attests to that almost literally: the unusually wide hood in the background is certainly more reminiscent of a forge than of a laboratory. In the center Adolf Baeyer, wearing a prominent hat; since several others also wear headgear, we may deduce that in the winter of 1878 the heating was deficient in that laboratory. To the right of Baeyer the 25-year-old Emil Fischer, in a peaked cap and strikingly self-confident three years after his Ph.D.; to the left Jacob Volhard (1834–1910), who was in charge of the analytical division in Baeyer's institute, and whose successor Fischer was to become in Munich a year later (1879), and at the University of Erlangen in 1882. Far to the left Fischer's cousin Otto Fischer, with whom he did extensive work on rosaniline dyes.[20] Between Baeyer and Volhard stands Wilhelm Koenigs (1851–1906[21]) who in 1900, together with his co-worker Eduard Knorr, discovered the Ag_2CO_3-induced glycosidation of acetobromoglucose,[22] known today as the Koenigs–Knorr reaction.

A survey of the early papers of Emil Fischer indicates the curious fact that although the ability of phenylhydrazine to react with aldehydes was quickly observed by him—the phenylhydrazones of acetaldehyde, benzaldehyde, and furfural were unequivocally characterized and structurally secured[23]—Fischer does not appear to have recognized the tremendous values of the compound for the characterization and identification of carbonyl compounds until nearly 10 years later, in 1884,[24] when he finally applied it to the sugars. This 'induction period' had several reasons:

Over a number of years (1876–1880) he did extensive investigations on rosaniline dyes with his cousin Otto Fischer.[20]

He pursued his habilitation and completed it in the spring of 1878.

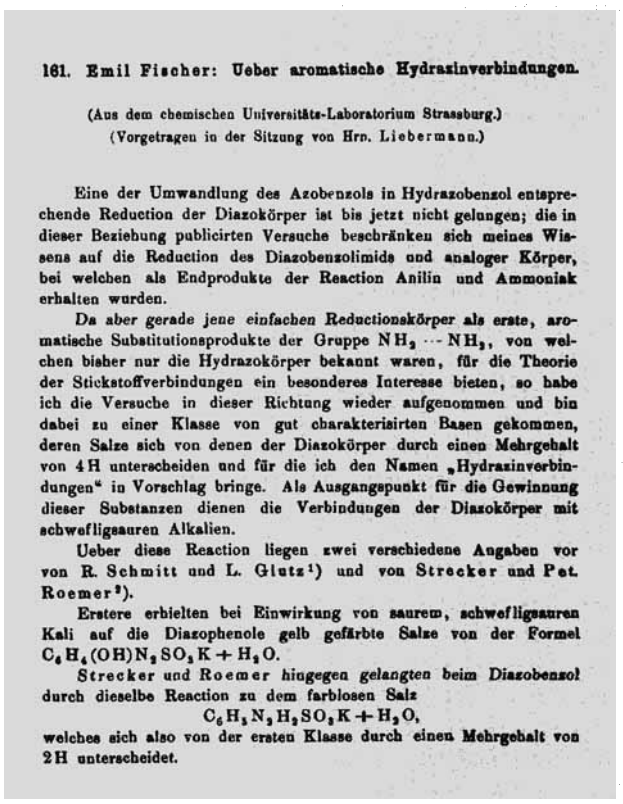
In the fall of 1878, he took charge of the analytical division of Baeyer's institute, as the successor to J. Volhard.

In 1881 he started work on purines, investigating the structure caffeine. Although he initially devised an erroneous formula,[25] the research eventually led to his classification of purines.

In 1882 at the age of 30, he moved from Munich to Erlangen, accepting the chair of chemistry at that university, and there he was intensely occupied with the conversion of phenylhydrazine into N-heterocycles,[26] which led to the Fischer indole synthesis.[27]

Another reason for not applying phenylhydrazine to sugars earlier, although their "aldehyde nature" was known, may have been the desolate state in which the chemistry of sugars was at that time. Because of the nature of these substances, their study was fraught with great difficulty, especially since impure sugars tend to form syrups, which in the second half of last century could not be analyzed reliably. A compound had to be crystalline, and be recrystallizable to a constant melting point and optical rotation to be considered pure. Thus, it is not surprising that early progress in the field of carbohydrates could not be achieved, whereas, for example, the chemistry of the aromatic compounds was well-developed.

Around 1870, chemists recognized two aldohexoses, glucose and galactose, and one ketose (levulose, later named



161. Emil Fischer: Ueber aromatische Hydrazinverbindungen.

(Aus dem chemischen Universitäts-Laboratorium Strassburg.)
(Vorgetragen in der Sitzung von Hrn. Liebermann.)

Eine der Umwandlung des Azobenzols in Hydrazobenzol entsprechende Reduction der Diazokörper ist bis jetzt nicht gelungen; die in dieser Beziehung publicirten Versuche beschränken sich meines Wissens auf die Reduction des Diazobenzolimids und analoger Körper, bei welchen als Endprodukte der Reaction Anilin und Ammoniak erhalten wurden.

Da aber gerade jene einfachen Reductionskörper als erste, aromatische Substitutionsprodukte der Gruppe $NH_2 \cdots NH_2$, von welchen bisher nur die Hydrazokörper bekannt waren, für die Theorie der Stickstoffverbindungen ein besonderes Interesse bieten, so habe ich die Versuche in dieser Richtung wieder aufgenommen und bin dabei zu einer Klasse von gut charakterisirten Basen gekommen, deren Salze sich von denen der Diazokörper durch einen Mehrgehalt von 4H unterscheiden und für die ich den Namen „Hydrazinverbindungen" in Vorschlag bringe. Als Ausgangspunkt für die Gewinnung dieser Substanzen dienen die Verbindungen der Diazokörper mit schwefligsauren Alkalien.

Ueber diese Reaction liegen zwei verschiedene Angaben vor von R. Schmitt und L. Glutz[1]) und von Strecker und Pet. Roemer[2]).

Erstere erhielten bei Einwirkung von saurem, schwefligsauren Kali auf die Diazophenole gelb gefärbte Salze von der Formel $C_6H_4(OH)N_2SO_3K + H_2O$.

Strecker und Roemer hingegen gelangten beim Diazobenzol durch dieselbe Reaction zu dem farblosen Salz

$$C_6H_5N_2H_2SO_3K + H_2O,$$

welches sich also von der ersten Klasse durch einen Mehrgehalt von 2H unterscheidet.

Fig. 3. Title page of Fischer's 1875 paper on the discovery of phenylhydrazine [15].

Fig. 4. Photograph of the Baeyer group in 1878 at the laboratory of the University of Munich (room for combustion analysis), with inscriptions from Fischer's hand [18].

fructose by Fischer). Three disaccarides, sucrose, lactose, and maltose were also characterized as distinct compounds. The experimental evidence for their structures was very scarce, yet it had gradually led to the assumption that they may be straight-chain pentahydroxyaldehydes. Thus, A. Baeyer in an 1870 Berichte paper[28] expressed the opinion:

> "On the basis of all known experience the constitution of grape sugar must correspond to one of the two formulas [shown in Fig. 5 (top left)], or at least be very closely related thereto."

Hugo Schiff, in the same year, formulated "grape sugar as the first aldehyde of mannitol" (Fig. 5 top right).[29] The most elaborate formulations (Fig. 5 bottom) stem from Rudolph Fittig (1835–1910) in 1871:[30]

> "Grape sugar is the aldehyde of mannitol, and mannitol is the saturated sixfold acidic alcohol of hexane. On gentle oxidation of grape sugar, like with all other aldehydes, the CHO group is converted into carboxyl COOH, and a unibasic acid of six atoms $C^6H^{12}O^7$, gluconic acid, is formed. Since gluconic acid contains a second oxidizable CH^2OH group, further oxidation must result in a dibasic acid. This acid is sugar acid, which contains four hydroxyl atoms apart from the two carboxyl groups."

Fittig's formulas (Fig. 5 bottom) did not show any stereochemical relationships of the various hydroxyl groups, and thus many reactions of the sugars were far from being understood.

This explains why, in the course of the 15 years following, very little progress was made either experimentally or conceptually. The interrelationships of the sugars remained something of a black box, except maybe for the fact that in 1883 Tollens (Fig. 6)[31] intuitively anticipated the cyclic hemiacetal forms of sugars, without, of course, fully realizing their significance (see Fig. 7): glucose ("Dextrose") forms a seven or five-membered ring, fructose ("Laevulose") was thought to adopt the furanoid form, which happens to be the one realized in sucrose ("Rohrzucker").

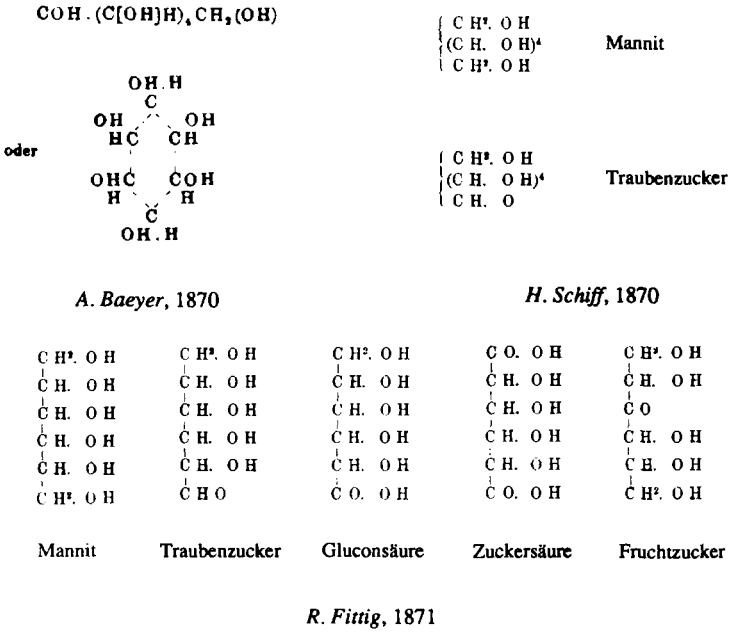


Fig. 5. Structural concepts on sugars around 1870 by Adolf Baeyer [28], Hugo Schiff [29], and Rudolph Fittig [30].

A year after Tollens's intuitive foresight, that is, in 1884, Emil Fischer began his studies with sugars and phenylhydrazine. He found that when heated with this base, glucose and fructose yielded the same, beautifully crystalline compound, which, unlike the free sugars, was readily characterizable; it was designated "phenylglucosazone". Fischer noted that the course of the reaction with these sugars was decisively different from that of standard aldehydes, but understandably, the individual steps of the osazone formation were not clear initially.[24] He formulated only the stoichiometric equation (Fig. 8 top) with the commentary "I cannot say anything definite yet on the fate of the two hydrogen atoms".

In an ensuing paper from 1887,[32] Fischer discovered the intermediate phenylhydrazone by performing the reaction in the cold. Thus, he was able to supply the necessary information for deducing the correct constitutional formula (Fig. 8 bottom).[32]

These hydrazones and osazones have not only rendered invaluable service for the identification and isolation of the

Fig. 6. Bernhard Tollens (1841–1918) in 1890 [6].

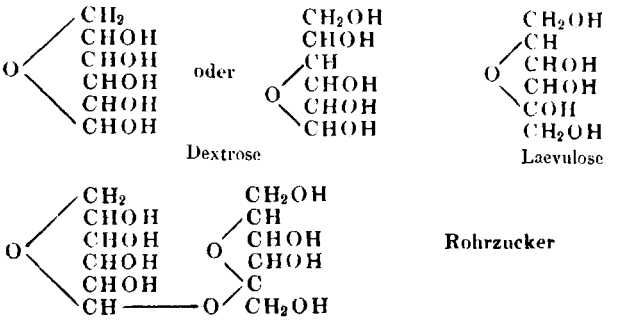

Fig. 7. Tollens' 1883 conception of cyclic hemiacetal formulas for glucose ("Dextrose"), fructose ("Laevulose"), and sucrose ("Rohrzucker") [31].

then existing sugars, but also have been instrumental in the preparation of new ones. At this early stage of his studies, in 1887, Fischer discovered a new hexose in this way: gentle oxidation of mannitol with nitric acid and exposure of the resulting mixture to phenylhydrazine led to a phenylhydrazone, isomeric with the one generated from glucose. By the acid hydrolysis of this product he obtained an as yet unknown hexose, which he named mannose.[33] This study soon led to an important conceptual result: glucose and

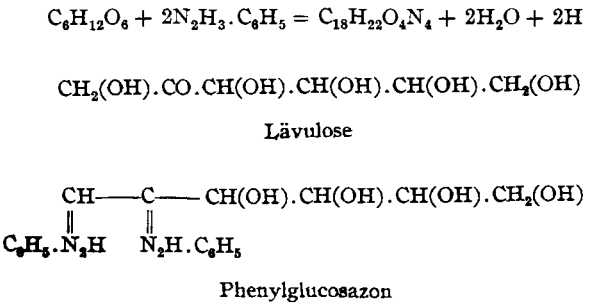

Fig. 8. Formation of osazones from glucose and fructose ("Lävulose") [24, 32].

mannose yield different hydrazones but the same osazone (Fig. 9), hence they must be 2-epimeric aldoses. For the rationalization of these data Fischer, in a 1889 paper with Hirschberger,[34] made use of the Le Bel–van't Hoff theory for the first time:

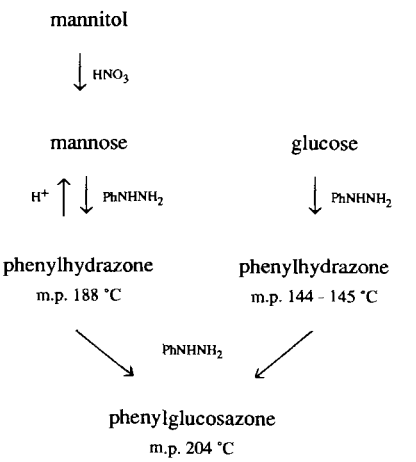

Fig. 9. Glucose and mannose yield the same osazone.

"In the sugar group, dextrose and mannose are the first examples of two isomers, which have the same structure and can be converted into each other. For the explanation of this form of isomerism, we draw entirely on the principles of the Le Bel–van't Hoff theory.
The formula contains four asymmetric carbon atoms, which we find appropriate to differentiate by the designations as_1, as_2, as_3, and as_4:

$$\underset{as_1}{CHO.CHOH}.\underset{as_2}{CHOH}.\underset{as_3}{CHOH}.\underset{as_4}{CHOH}.CH_2OH$$

Each of these carbon atoms causes the existence of two geometric isomers, yielding no less than 16 isomers predicted by theory. From the experimental material at hand it can now be easily proved that the isomerism of dextrose and mannose is determined by carbon atom as_1. The phenylhydrazones of the two sugars are distinctly different, yet with particular ease they give the same osazone with the structural formula

$$HC(N_2HC_6H_5).C(N_2HC_6H_5).\underset{as_2}{CHOH}.\underset{as_3}{CHOH}.\underset{as_4}{CHOH}.CH_2OH$$

in which carbon as_1 has lost its asymmetry. Since it is highly improbable that the carbon atoms as_2, as_3, and as_4 change their steric arrangements during the smooth and particularly easy osazone formation, one must assume that the difference between mannose and dextrose rests on the asymmetry of carbon atom as_1."[34]

The accessibility of mannose was soon greatly improved by its discovery in nature, first in salep mucilage[35] and then in the seeds of the tagua palm,[36] also known as ivory nut, at the time a commercial product used to make buttons. Ivory nut turned out to be a mannose polysaccharide, which yielded a sugar on acid hydrolysis that was identical with the product obtained by gentle oxidation of mannitol (Fig. 10). By further oxidation with bromine water the corresponding aldonic acid was prepared, whilst more rigorous oxidative conditions (HNO_3) led to the aldaric acid, which on the basis of their derivation were named mannonic and mannaric acid, respectively:[37]

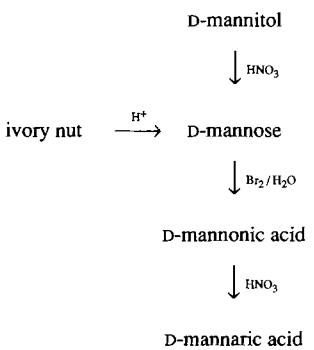

Fig. 10. Elaboration of the ensuing chemistry of mannose after it became available on a large scale by the acid hydrolysis of ivory nut shavings [37, 38].

The experimental difficulties encountered in this type of work because of the techniques available around 1890 were formidable, which made great demands on the experimental skill and patience of Fischer's Ph.D. students who carried out the work. The following excerpt from a letter of Fischer's to his mentor and friend A. Baeyer, dated January 12, 1889, gives ample proof thereof:[39]

"The investigations on sugars are proceeding very gradually. It will perhaps interest you that mannose is the geometrical isomer of grape sugar. Unfortunately, the experimental difficulties in this group are so great, that a single experiment takes more time in weeks than other classes of compounds take in hours, so only very rarely a student is found who can be used for this work. Thus, nowadays, I often face difficulties in trying to find themes for the doctoral theses."

The research of Heinrich Kiliani (1855–1945[40]) proceeded parallel to these studies. His application of the cyanohydrin reaction for the reduction of sugars in 1885[41] was to have a major bearing on unraveling the sugar configurations. The polyhydroxy acids resulting from the hydrolysis of the hydrocyanic acid adducts contained one more carbon atom than the parent sugar, and on reduction with hydrogen iodide/red phosphorus afforded the corresponding "dehydroxylated" carboxylic acids. In this way, Kiliani established that the natural arabinose is a straight-chain aldopentose (1887)[42] and convincingly proved that glucose and galactose are aldohexoses,[43, 44] and that fructose must be a 2-ketohexose since it forms a 2-methyl-branched hexanoic acid (Fig. 11).[41]

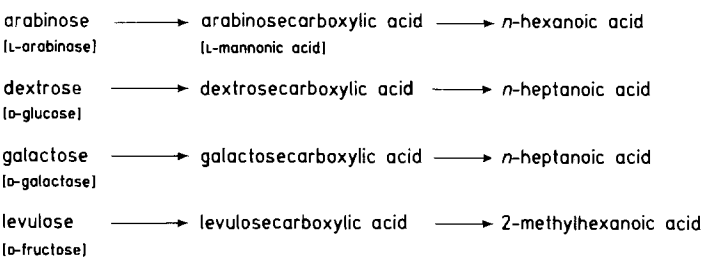

Fig. 11. Kiliani's results, 1885–1889, on the cyanohydrin extension of the sugars, and his proof of their straight-chain nature by reductive "dehydroxylation" with hydrogen iodide/red phosphorus to the corresponding alkanoic acids [41–44].

At this stage of the gradually unfolding interrelationships between the sugars in that still very "black box", an observation was made by Fischer that was to lead to a key insight: the mannonic acid obtained from mannose derived from ivory nut on gentle oxidation proved to be identical—in the form of its nicely crystalline lactone—with that obtained by Kiliani from natural arabinose by cyanohydrin extension, except for the sign of rotation[45] (Fig. 12). Consequently, the two products had to be mirror images, that is, enantiomers—a conclusion Fischer corroborated by comparing the corresponding 1,6-dicarboxylic acids, the sugars themselves, and the sugar alcohols,[44] thus providing an entire set of enantiomeric products. In an 1890 lecture Fischer attests to the conceptual importance of these results:[46]

"The observation that the mannonic acid obtained by oxidation of natural mannose is the optical isomer of ara-

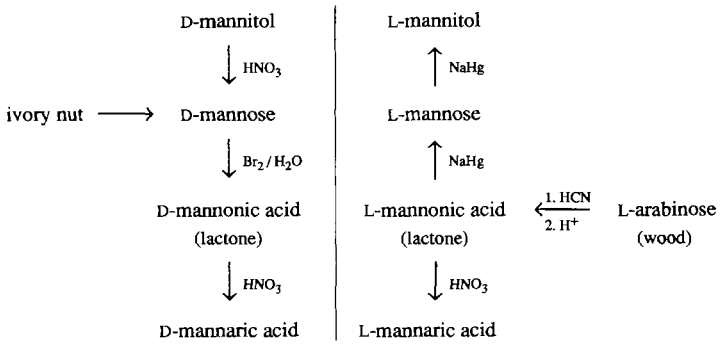

Fig. 12. Elaboration of the first complete set of enantiomers in the sugar group by Fischer [45].

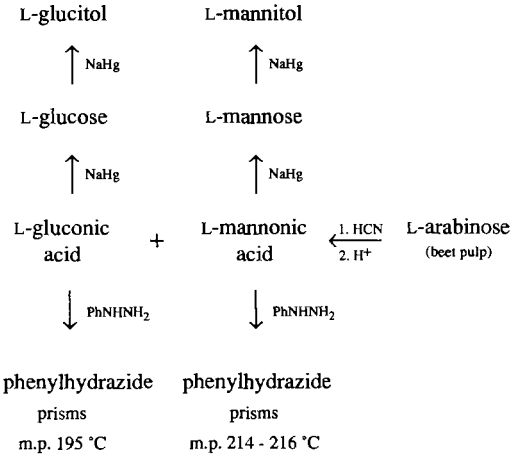

Fig. 13. The first example of an asymmetric synthesis recorded in the literature: not only L-mannonic acid is formed by cyanohydrin synthesis from L-arabinose, but also the 2-epimeric L-gluconic acid, as evidenced by its crystalline phenylhydrazide [51]

binosecarboxylic acid provided the key to determining the interrelationships in the mannitol group."

Fischer had discovered in 1889 that the lactones of sugar acids could be reduced by sodium amalgam to yield the corresponding aldoses.[47] The combination of this reduction with Kiliani's cyanohydrin procedure, which entered the literature as the Kiliani–Fischer synthesis, did not only become a standard method for the chain extension of sugars, (Fischer applied it extensively for the preparation of heptoses,[48] octoses, and nonoses[48, 49]), but more important for the time around 1890, it enabled the intercorrelation of the relative configurations of the individual sugars.

A 100 years ago the purification and unequivocal identification of a compound was a formidable task, requiring crystallinity of the compound as well as a preferably sharp melting point and a constant optical rotation. Hexonic acids certainly formed crystalline lactones, but only under special conditions, and since these lactones exhibited mutarotation, their rotational values were not very useful for comparisons. Here for a second time, phenylhydrazine—and as serendipitously as for the formation of the osazones—proved to be a most useful reagent: when heated with an aldonic acid in aqueous acetic acid, the phenylhydrazides of these acids are formed, which crystallize exceedingly well, exhibit sharp melting points and constant rotational values, and thus, were ideal derivatives for the purification and identification of such sugar acids.[50]

Accordingly, when Fischer repeated Kiliani's work on the C_1 extension of the arabinose derived from sugar beet, and—for identification purposes—heated the reaction mixture (allegedly containing only L-mannonic acid) with phenylhydrazine, he obtained not one, but two phenylhydrazides. Both crystallized in the form of prisms, but their melting points were 20 °C apart.[50] After a lengthy purification procedure he succeeded in isolating the one with the lower melting point in pure form (Fig. 13), which, upon hydrolysis, proved to be the enantiomer of the acid derived from natural glucose by gentle oxidation. In this way a second complete set of enantiomers, namely D- and L-glucose, became available.[51]

As it turned out, this is the first example of an asymmetric synthesis recorded in the literature, on which Fischer commented in the following way:[52]

"The simultaneous formation of the two stereoisomeric products on the addition of hydrogen cyanide to aldehydes, which was observed here for the first time, is quite remarkable in theory as well as in practice."

This first example of an asymmetric synthesis was soon to be followed by a second case, since sodium amalgam reduction of fructose gave rise to two stereoisomeric products, namely, mannitol and sorbitol.[53] Fischer clearly realized the basic importance of this result:

"The reduction of fructose is the second reaction in the sugar group, which generates two stereoisomeric products due to the formation of an asymmetric carbon atom. The same phenomenon will undoubtedly be observed much more frequently in the future, and most probably will be generally found with all compounds that are asymmetric a priori."[53]

Another milestone in the quest for the configurations of sugars proved to be the ensuing chemistry of xylose.[54] The discovery of this sugar in cherry gum in 1886[55] and the establishment of its pentose structure by Tollens et al. two years later[56] came at a most opportune time for Fischer's work. In 1890 he undertook a study of xylose by applying the cyanohydrin synthesis, which led to a hexonic acid different from any yet encountered.[57, 58] It could be reduced to a new sugar and oxidized to a 1,6-dicarboxylic acid, which proved to be the enantiomer of the one obtained from natural glucose. This new sugar was named gulose by Fischer "by exchanging the letter l and u in glucose and eliminating the c".[58] Figure 14 summarizes these interrelationships, refraining from the use of chemical formulas—as Fischer did at the time—yet providing the D- and L-assignments later adopted[38a, b] for clarity.

The correlation between D-glucose and D-gulose revealed by this set of reactions, and particularly the fact that they become identical—as mirror images—at the stage of their dicarboxylic acids, must have given Fischer the strong indication that the two sugars are head-to-tail enantiomers, that is, that gulose has its aldehyde group where glucose has the hydroxymethyl function, and vice versa. This rationalization was soon confirmed by another set of reactions starting from D-glucose-derived 1,6-dicarboxylic acid (D-glucaric acid), in

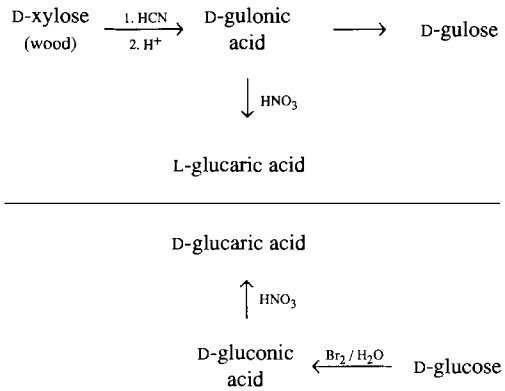

Fig. 14. Experiments which show that D-glucose and D-gulose—on the basis of their 1,6-dicarboxylic acids—are head-to-tail enantiomers. [58, 59].

the form of its 1,4-lactone:[59] sodium amalgam reduction first led to D-glucuronic acid, which was identical with the compound isolated from urine 12 years before by Schmiedeberg and Meyer.[60] Further reduction generated L-gulonic acid,[59, 61] the optical antipode to the hexonic acid obtained from D-xylose by cyanohydrin synthesis.[62] In turn, the 1,4-lactone of L-gulonic acid gave L-gulose on treatment with sodium amalgam.[59]

The level of comprehension reached by these sets of intercorrelating reactions is clearly evident from a passage of the relevant paper published with Piloty:[59]

"A simple consideration shows that gluconic and gulonic acid have the same structure and a very similar configuration. They differ only in the position of the carboxyl group as illustrated by the two formulas,

$$COOH.CHOH.CHOH.CHOH.CHOH.CH_2OH$$

$$CH_2OH.CHOH.CHOH.CHOH.CHOH.COOH$$

which are to be viewed stereometrically. Thus, gluconic and gulonic acid are the first examples of stereoisomeric substances which give identical products if the molecule is symmetrical after the conversion of the terminal alcohol groups into carboxyl functions. This observation appears to be an important confirmation of the theory of the asymmetric carbon atom, which predicts 16 isomers for a compound having the structure of gluconic acid; in the case of dibasic acids, their number is reduced to 10. This indicates that one will soon be in a position to determine the configurations of the sugars in terms of the Le Bel–van't Hoff theory from the factual observations made."

Although the structural formulas given in the citation were to be viewed "stereometrically", half a year prior to his two 1891 landmark papers[4, 5] Fischer still avoided the use of configurational representations—an attitude that dramatically changed after unraveling them.

Now, before discussing the actual proof contained in these two publications, a final piece of evidence has to be mentioned which was to have major bearing on uncovering the configurational relationships, namely, the rotational values of the pentose-derived sugar alcohols and 1,5-dicarboxylic acids. The two pentoses known at the time, xylose and arabinose, gave the respective pentitols on reduction, neither of which showed any rotation.[58, 63] This meant that both are *meso* compounds (Fig. 15). For Fischer, however, this conclusion was too important to be based on the optical inactivity of one compound only, especially since it was known that the alditols encountered so far had comparatively small rotational values.

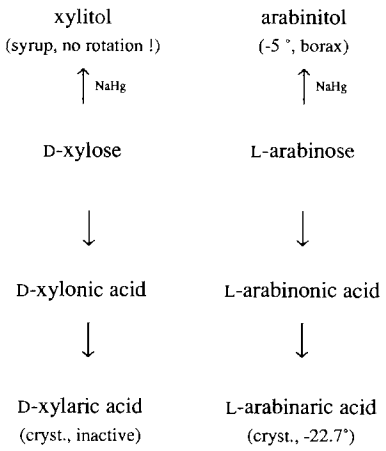

Fig. 15. Correlation between configuration and optical activity of the pentitols and their trihydroxyglutaric acids.

To substantiate this conclusion, Fischer prepared the respective 1,5-dicarboxylic acids by nitric acid oxidation, which each gave crystalline products (Fig. 15). The trihydroxyglutaric acid derived from xylose was indeed optically inactive,[64] yet the arabinaric acid showed a distinct negative rotation. Therefore, Fischer again inspected the rotation of the arabinitol; only on addition of borax, that is, with arabinitol in the form of its boric acid complex, was a small negative rotation finally observed,[58] thus completing the scheme (Fig. 15).

In this context, we are in the fortunate position to add some personal details to these sober experimental facts. In Fischer's autobiography "Aus meinem Leben"[19] there is a delightful passage, which refers to the trihydroxyglutaric acids, and I would like to quote the relevant section:[65]

"The Easter Holidays of 1891 I spent at Bordighera on the Italian Riviera in the company of Baeyer. Needless to say, on our extensive walks, and during the meals we took together, we had intense discussions; there was no important problem of chemistry which we would not have covered. I particularly remember one stereochemical question. In the preceeding winter of 1890/91 I was occupied with the task of clarifying the configuration of the sugars without completely achieving my goal. In Bordighera the idea occurred to me to make the decision concerning the configuration of the pentoses from their relationships to the trioxyglutaric acids. Unfortunately, due to the lack of models I could not determine how many of such acids were theoretically possible, and thus, I put this question to Baeyer. He took up such questions with great warmth and immediately started to construct carbon atom models from toothpicks and little balls of bread. However, after many attempts he finally gave up, allegedly because it

Fig. 16. Jacobus Henrikus van't Hoff (1852–1911) around 1889 [6].

became too difficult for him. Later only back in Würzburg, I succeeded in finding the final solution by extensive study of good models."

The solution Fischer succeeded in finding was based on the theory of Le Bel and van't Hoff.[2, 3] On the basis of purely theoretical considerations, van't Hoff (Fig. 16) had predicted in 1874 that for the case with four chiral carbon centers 16 isomers can be expected. These 16 isomers of the general formula

$$C(R^1R^2R^3)\,C(R^4R^5)\,C(R^4R^5)\,C(R^1R^2R^3)$$

were formulated by van't Hoff as depicted in Figure 17, in which the + and − signs allude to the sign of rotation of the individual chiral centers.

5	6	7	8	9	10

Fig. 17. Van't Hoff's prediction of configurational isomers for compounds with four chiral carbon centers, in his + and − notation [3].

Accordingly, the isomers 1 and 4 are enantiomers, as are the isomers 2 and 3; the other twelve possibilities are listed in such a way as to illustrate the head-to-tail mirror-image symmetry: isomer 5 is the enantiomer of 11, this relationship is also valid for 6 and 12, 7 and 13 etc. In the case where both ends have identical substitutents, as in the hexitols and 1,6-dicarboxylic acids, the isomers 5–10 become identical with 11–16, so the total number of isomers then would be reduced to 10.

The task with which Fischer had been occupied in the years preceeding 1891 was a formidable one: to select the configuration from the sixteen possibilities that represent grape sugar, on the basis of the experimental evidence that had been accumulated. This required models. Those van't Hoff used for his theoretical deductions are shown in Figure 18. Fischer must have used these too, since van't Hoff[3] gave detailed instructions on how to prepare them from cardboard in an appendix to his brochure.

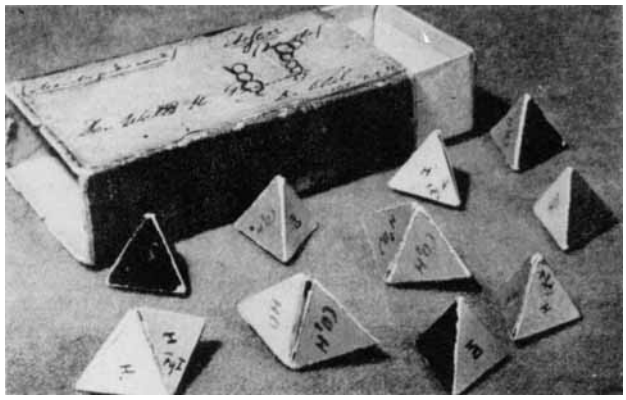

Fig. 18. "Match box" models of van't Hoff (preserved in the chemistry museum of the Maison de la Chimie of the French Chemical Society, Paris).

In his second landmark paper of 1891,[5] however, Fischer also referred to the use of "Friedländer rubber models", the essentials of which were described by V. Meyer:[66]

"They consist of four short pieces of rubber tubing, whose inner diameter is approximately the thickness of a match, and which are soldered together in the middle, so that they extend into space in a tetrahedral arrangement."

These models appear to be very close to the ball and stick models, or those of the Fieser or Dreiding type in use today. Evidently as a result of his extensive use of models, and his intense intellectual involvement in correlating the experimental data available with the 16 sugar configurations available, Fischer arrived at the solution laid down in his first 1891 paper: grape sugar, the natural glucose, has the −+++ configuration (Fig. 19), D-mannose has the ++++ configuration, and D-fructose with only three asymmetric centers, correspondingly, +++.[4]

Now, rather than presenting the Fischer proof of the sugar configuration in the terms of the van't Hoff notation, it is more appropriate and expedient to proceed here as Fischer did: within two months of proposing the sugar configurations in the +/− terminology, he discarded this system altogether, and replaced it by his own. There was ample reason for that. The + and − signs used by van't Hoff for designating the configurations at asymmetric carbon atoms are very confusing, because they are derived by observing the individual tetrahedra—as arrayed in a model (Fig. 20)—from a point within the model, namely, its center. This refers to the center of the whole molecule and not that of an individual tetrahedron. For tartaric acid, the center of the molecule is clear: its the apex where the two tetrahedra are joined (marked by an asterisk in Figure 20); on looking up from that point of reference, the sequence of OH → H is perceived to be counterclockwise, so the asymmetric carbon atom receives a − sign, whereas looking down from the apex results

in a clockwise order of OH towards H, and it is given a + sign. The signs compensate each other, as would do the individual rotational contributions of the two carbon atoms, hence they denote the *meso* form of tartaric acid.

The situation becomes more difficult in cases with three chiral centers, since the "center" of the molecule has to be defined. For pentoses this was placed at the apex between the first and second asymmetric carbon (see position of the asterisk in Fig. 20, center), which results in a + + + sequence of signs for D-arabinose. In hexoses, the point of reference is again the center of the molecule, (Fig. 20 right) which results in the − + + + sequence for D-glucose.

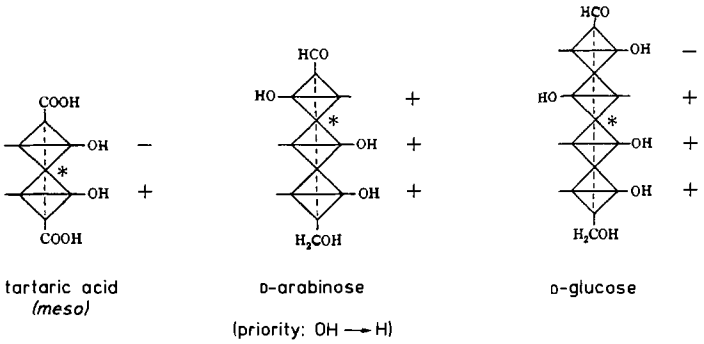

Fig. 20. Derivation of van't Hoff's + and − signs from the "center" (marked by *) of the respective molecules.

Fischer soon realized[5] that "the designation of spacial relationships by + and −, which were introduced by van't Hoff and which were retained by me in unchanged form, can easily lead to an erroneous view in the case of such complicated molecules. To prevent this, I consider a more detailed interpretation of the formula an urgent necessity."

Thus, within two months after the submission of the first 1891 paper (received at Berichte on June 6[4]) Fischer dispatched a second one (received: August 8[5] (Fig. 21) in which he replaced the + and − system of van't Hoff by his

48. Emil Fischer: Über die Konfiguration des Traubenzuckers und seiner Isomeren. II.

[Aus dem chemischen Laboratorium der Universität Würzburg.]

(Eingegangen am 8. August.)

In der ersten Abhandlung[1]) habe ich für den Traubenzucker die Formel

$CH_2(OH).CH(OH).CH(OH).CH(OH).CH(OH).COH$
$\quad + \quad + \quad + \quad -$

entwickelt. Die Bezeichnung der räumlichen Anordnung durch + und −, welche von van't Hoff eingeführt und von mir in unveränderter Form beibehalten wurde, kann aber bei solchen komplizierten Molekülen leicht eine irrtümliche Auffassung zur Folge haben. Um dies zu verhüten, halte ich eine ausführlichere Interpretation der Formeln für nötig.

COOH	COOH
H — C — OH	HO — C — H
HO — C — H	H — C — OH
H — C — OH	HO — C — H
H — *C — OH	HO — C — H
COOH	COOH

Ich wähle wieder willkürlich für die *d*-Zuckersäure die Form I, wobei es natürlich unentschieden bleibt, ob bei dem mit * bezeichneten Kohlenstoffatom die Reihenfolge von Hydroxyl und Wasserstoff im Sinne des Uhrzeigers oder umgekehrt statthat. Dann ergeben sich für Traubenzucker und seine Isomeren folgende Formen:

COH	COH	COH	COH

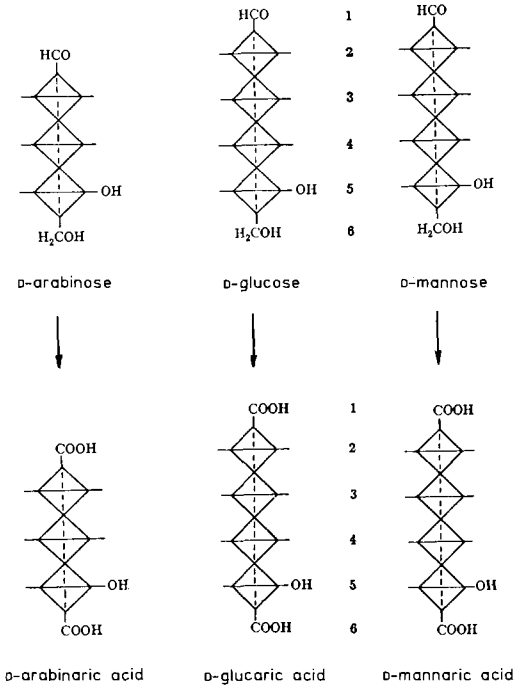
Fig. 21. The second of Fischer's 1891 landmark papers on the configurations of the sugars, with which he introduced the Fischer mode of writing stereoformulas [5].

own: representation of tetrahedral space relationships by their projection into a plane. The resulting formulas were simple to write and easy to visualize, yet required the setting up of conventions; the ones he chose seem as few in number and as simple in character as possible: The carbon chain of a sugar is oriented vertically and to the rear with the aldehyde group at the top; the hydrogen atoms and hydroxyl groups at the asymmetric carbon atoms stand out in front. The resulting three-dimensional model is then imagined to be flattened and the groups are laid on the plane of the paper. If the lowermost asymmetric center (i.e., C-5 in glucose) has the OH group to the right, it is considered to have the D-configuration. Fischer's decision to place the OH group of natural glucose to the right, hence D-glucose, was purely arbitrary, yet proved to be a fortunate one, since much later in 1951, it was proved by special X-ray structural techniques[6,7] that he had made the right choice.

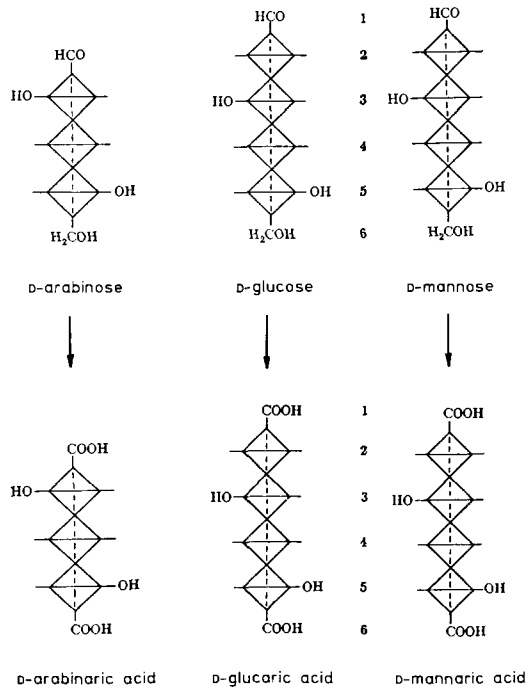
The change of the + and − notation to the projection mode of writing stereoformulas is strikingly evident in the second 1891 paper,[5] (Fig. 21) and this was soon universally adopted. In this presentational mode, by using Fischer's convention that the asymmetric carbon atoms (tetrahedra) have the lower edge in the plane of the paper whilst the corners carrying the H and OH groups lie above this plane can now be delineated.[6,8]

1. Since glucose was selected by definition as having the OH group at the lowermost asymmetric carbon atom at the

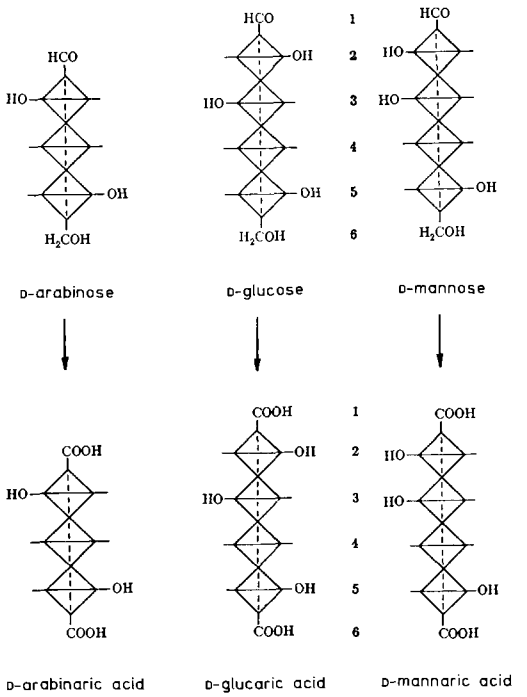
right, all chemically interrelated compounds are of D-configuration:



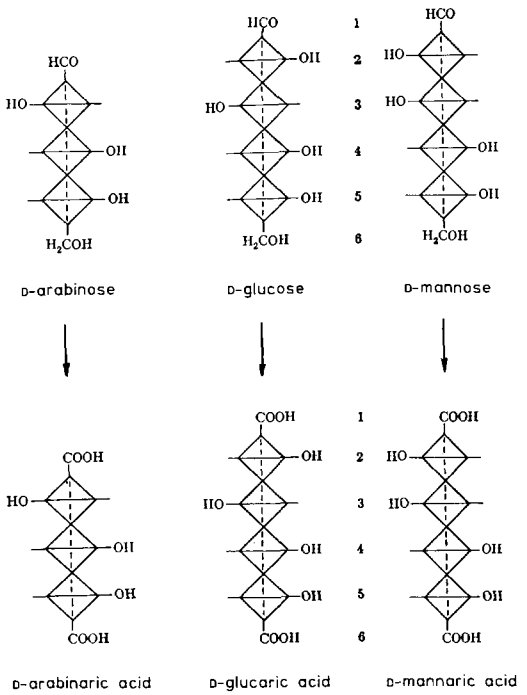
2. The D-arabonic acid showed a distinct optical rotation, thus cannot be a *meso* compound. This means that the OH group at C-2 of D-arabinaric acid must be to the left and thus determines the relative configuration at C-3 of the two hexoses. Therefore, in the entire set of compounds depicted here the OH group is to be placed to the left:



3. D-Glucose and D-mannose are C-2 epimers; hence their 2-hydroxyl groups are oriented in opposite directions. Either one may be selected as having the OH on the right; in the following Figure D-glucose is—for now—arbitrarily considered to have the C-2 OH group to the right, and consequently this group is oriented to the left in D-mannose:

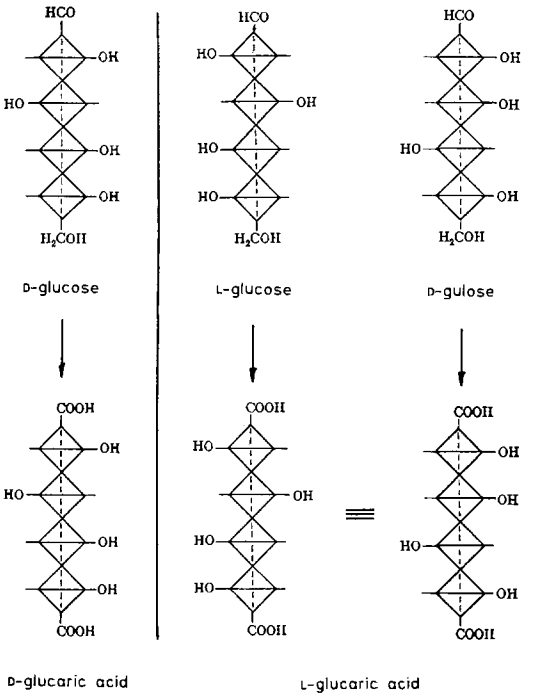


4. Since both D-glucaric and D-mannaric acids are optically active, the configuration of neither of them can possess end-to-end symmetry; hence the OH group on C-4 must be on the right (if it were on the left, the glucaric acid would have end-to-end symmetry and, hence be optically inactive). At this stage the configuration of D-arabinose and its dicarboxylic acid have been established:

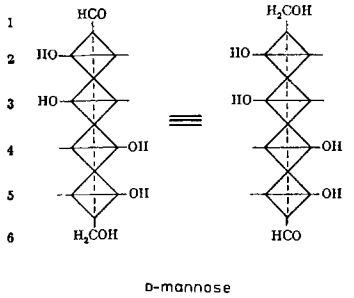


5. D-Glucose and D-mannose have been limited to two configurations but final specification remains to be established. This was done on the basis of the following reason-

ing: D-glucaric acid is obtained from the oxidation of D-glucose, the enantiomeric L-glucaric acid analogously from L-glucose, but also from D-gulose. This is only possible, if D-gulose is the head-to-tail configurational isomer to L-glucose:



D-Gulose, upon exchange of its aldehyde group with CH_2OH and vice versa, yields a different aldose, namely, L-glucose. Applying the same operation to D-mannose, the product is again D-mannose, thus providing a further substantiation of conclusions 1–5:



Thus, the deduction is now in itself conclusive. This proof not only became the basis for the sugar family tree (Fig. 22) as it is—100 years later—in our textbooks today; it also provided a major impulse for the development of organic stereochemistry, which thereafter made rapid and sweeping progress. Up to 1891 relative configurational assignments are not found in the literature. As it turned out, the sugars became the point of reference on which all other configurations—those of hydroxy acids and amino acids in particular—were based by chemical correlation. So, we are con-

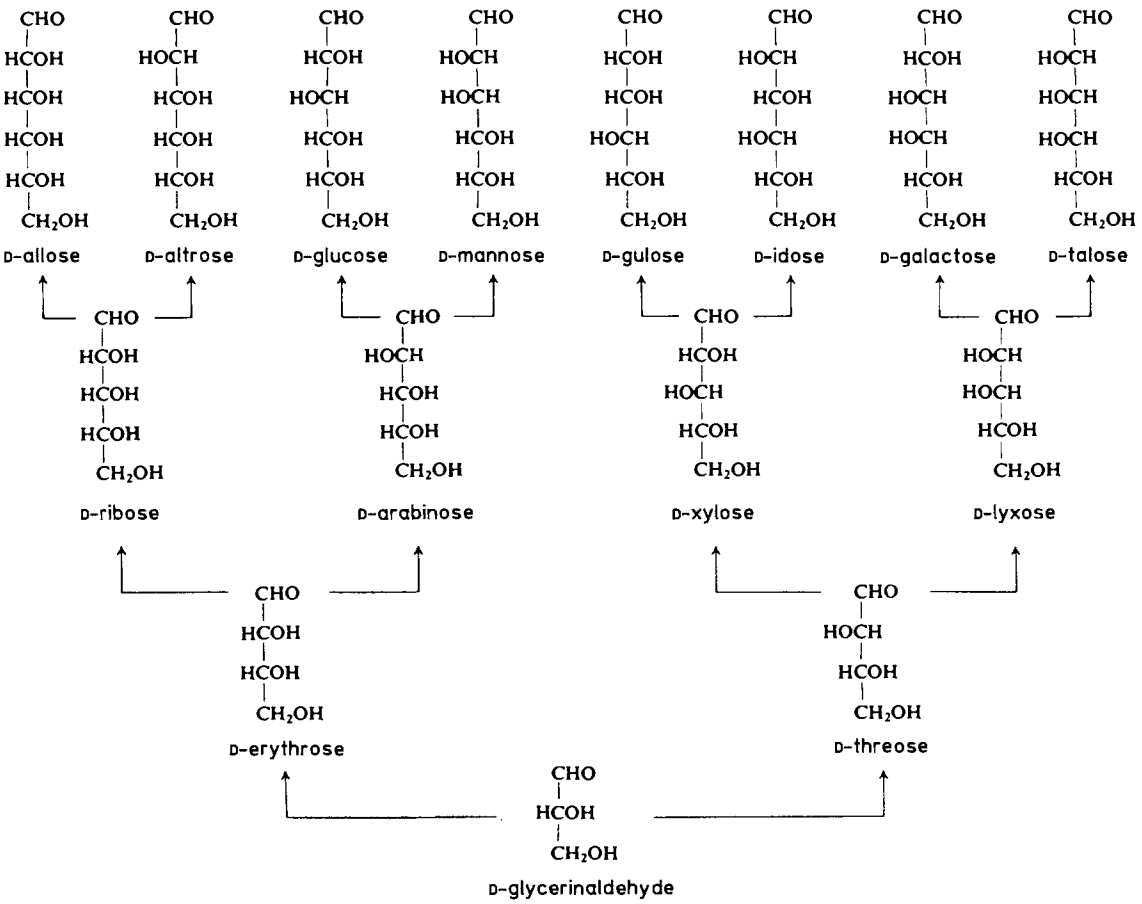


Fig. 22. The sugar family tree of D-aldoses.

fronted with the paradox that at this stage the development of chemistry did not proceed from the understanding of simple cases to the gradual comprehension of more complex ones, but vice versa.

In this context, a number of contemporaries had all the knowledge at hand to unravel the sugar configurations—Kiliani,[69] for example, and Tollens, who later was to write the first comprehensive treatise on carbohydrate chemistry[70]—but it was Emil Fischer who, endowed with a brilliant mind and the necessary self-confidence and perseverance, attacked the problem systematically and after only seven years of involvement with the chemistry of the sugars found the solution.

This classical piece of work was not to remain the only great service Fischer rendered to chemistry, since later he returned to the work he had started in 1882 in Munich on purines. This led to the classification of this class of substances[71] and subsequently to the synthesis of the first nucleosides.[72] Around the turn of the century Fischer began his third great series of investigations on amino acids, polypeptides, and proteins and laid the chemical and biochemical foundations for this field.[13] Finally in 1908 he began work on a further class of natural products, the tannins.[74] The brilliant synthetic work in the sugar series, however, and the manner in which he applied and developed the van't Hoff–Le Bel theory for elucidating their stereochemistry stands out—in my opinion—as the pinnacle of his scientific career.

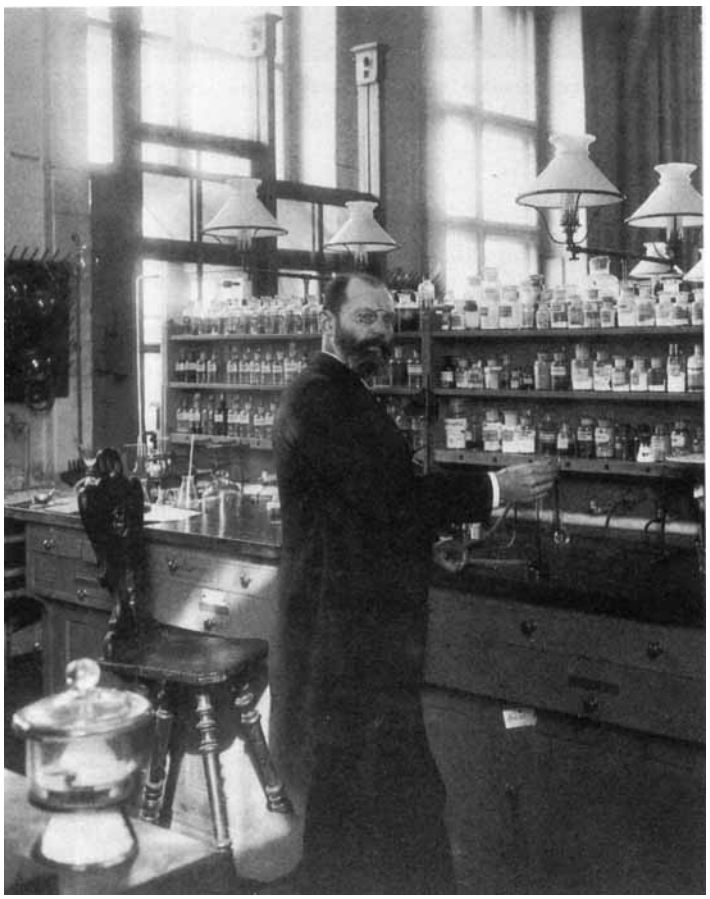

Fig. 23. Emil Fischer around the turn of the century in his laboratory at the University of Berlin [18].

Not only we today, a century later, marvel at this classic example of exact mathematical reasoning in an experimental science, and at the man who accomplished it; his contemporaries also recognized his genius by bestowing many honors on Fischer of which two are mentioned here: in 1892 at the age of 40, mostly on the basis of his work on the sugars, Fischer was offered the most coveted chair of chemistry at the time, at the University of Berlin (Fig. 23), to become successor to A. W. von Hofmann (1818–1892), and in 1902 he was awarded the Nobel Prize in chemistry, the second one ever to be awarded; notably, the recipient of the first in 1901 was van't Hoff. The president of the Royal Swedish Academy of Sciences put his appreciation into the following words:[75]

> "The specific type of research which has characterized organic chemistry during the final decades of the nineteenth century, attained its zenith of development and its finest form in Fischer's studies of sugars and purines. From the experimental point of view they are unsurpassed."

In concluding this centennial tribute to one of the really great figures of our science, a passage from his 1890 lecture at the Universiy of Berlin, in which he outlined the strategy he followed in the pursuit of the sugar configurations, may give a final glimpse of the spirit of the man in his quest for knowledge:[76]

> "I would like to compare chemical investigations of this sort which become more difficult with every step, with the construction of a tunnel. If a mountain ridge is not too wide, one succeeds in driving the tunnel through in one direction. Otherwise, the engineer is forced to start work from the opposite site. However, he is in the fortunate position of being able to predetermine the site of the attack by exact measurements and, thus, is assured of joining the tracks inside.
>
> Our science, unfortunately, is as yet not deductive enough to allow such calculations. The chemist may consider himself fortunate if he drives his tunnels through matter from opposite sites and finds the connection inside, albeit after several zigzag moves. Such a piece of good luck led me to the target."

This should remind us that hard experimental work, clear evaluation of results, mathematical reasoning, and a superb strategy is not all. A piece of serendipity is also involved in the solution of the fundamental problems of science.

[10] K. Hoesch, "Emil Fischer, sein Leben und sein Werk", *Ber. Dtsch. Chem. Ges.* (special issue) **1921**, *54*; also issued as a book with the same title, Verlag Chemie, Berlin/Leipzig (**1922**). This biography, written in an overly pathetic, pompous style appears to been well perceived by many of Fischer's contemporaries, as evidenced by enthusiastic letters of approval from C. Duisberg, A. Gabriel, C. Neuberg and H. Pringsheim [10a]. However, it also met strong criticism; C. Harries who over years had been the assistant in the experimental lecture courses given by A. W. von Hofmann and from 1892 on by E. Fischer, happened to be president of the Deutsche Chemische Gesellschaft, which had commissioned the biography. He strongly disapproved of the fact that he was deprived of seeing the manuscript before publication, and added [10b]: "It is a poetic achievement, a well-accomplished dithyramb on the adored teacher. Unfortunately, however, the author has got carried away by his temperament and made statements that transgress the poetically allowed, which for historical reasons cannot remain uncontradicted. What primarily has to be objected is the comparison of A. W. von Hofmann, Adolf von Baeyer, and Viktor Meyer with Emil Fischer. It is certainly permitted to make comparative evaluations of illustrious personalities, however, a protest must be made about the form, in which this was done here. Quite bluntly the intended portrayal of Emil Fischer unconditionally as the greatest is obvious. A. W. von Hofmann and Viktor Meyer come off quite badly. Instead, we should be delighted that we had such a series of great men, and hence should not attempt to exalt one to be the most important, since each of them more or less stood on th shoulders of the others." R. Willstätter [10c] also criticizes Hoeschs's presentation for lack of depth, insufficient inside knowledge, and its "pathetic style", in sharp contrast with Fischer's refreshing informality. H. O. L. Fischer (1888–1960 [10d]), Emil Fischer's son, initially (1922) approved of the biography: "I am delighted that you have solved your task in a literarily splendid, comprehensive, and sympathetic, warmhearted form" [10a]; in later years (1959), however, he had arrived at a distinctly different opinion: "The Hoesch biography of my father is essentially unreadable, even by an educated German" [10e]. a) The relevant letters to K. Hoesch, dating from 1922 and 1923, are in the Emil Fischer Collection in the Bancroft Library, University of California, Berkeley, the citations given with their kind permission. b) Presentation at a meeting of the Deutsche Chemische Gesellschaft in Berlin on July 3, 1923; the manuscript is in possession of the Bancroft Library. c) R. [18] The original and numerous other photographs are contained in the Collection of Emil Fischer Papers, housed in the Bancroft Library at the University of California, Berkeley. This scientific bequest consists of 34 boxes of material: lab notes, manuscripts, drafts of his autobiography "Aus meinem Leben", which differ from the published version [19], and about 5000 letters, mostly handwritten that reached Fischer during his 40-year scientific career; for example, 157 letters during 1889–1915 from his teacher A. von Baeyer, others from F. Beilstein (11), A. Hantsch (56), F. Haber (35), J. H. van't Hoff (31), A. W. Hofmann (5), A. von Kekulé (6), H. Kiliani (16), V. Meyer (46), W. Nernst (67), B. Tollens (20), P. Walden (13), O. Wallach (46), and R. Willstätter (33); Fischers intense interaction with industry is documented by 181 letters from C. Duisberg (from 1895–1919), from Bayer (271), BASF (54), Boehringer Mannheim (116), Hoechst (50) and Merck (33). Surprisingly, the collection contains also two letters from Konrad Adenauer, written in 1918 as Lord Mayor of Cologne, concerning the establishment of a Kaiser-Wilhelm Institute for Physiology. The papers eventually reached Berkeley through Fischer's son, Hermann Otto Laurens Fischer, [10d] who carried this collection along with him through all the stations of his unusually cosmopolitan career: Privatdozent in Berlin, Professor of Pharmaceutical Chemistry in Basel, Director of the Banting Institute, Toronto, and Professor of Biochemistry at the University of California, Berkeley. The papers were donated to the Bancroft Library by Mrs. H. O. L. Fischer in November 1970.

[38] In Figures 10–15 the gradually evolving affiliation of the individual sugars and their derivatives to the D- or L-series has already been made. It should be noted though, that Fischer only introduced the symbols *d* and *l* as late as 1890 [38a], deriving their meaning from the sign of rotation: "Since sugar derivations change their sign of rotation from right to left and vice versa, I propose to designate all compounds of a series according to the sign of rotation of the aldehyde with the letters *d* (dextro) or *l* (levo), just like the letters *o*, *m* and *p* are used in the case of benzene derivatives". [38] Only later did Fischer take this a step further, so that the signs *d* and *l* were not uniformly derived from the sign of rotation of the parent sugar, but they were also used to express similar or identical steric arrangements between related compounds. "Thus, I desginated natural fructose, which features the same configuration as *d*-glucose, the *d*-designation despite its levorotation [38b]." Rosanoff in 1906 [38c], and Wohl and Freudenberg in 1923 [38d] brought the use of the *d* and *l* symbols on a logical, genetic basis by selecting the enantiomeric glyceraldehydes as points of reference, such that any sugar belongs to the *d*-series, if it can be derived from *d*-glyceraldehyde by successive Kiliani–Fischer syntheses. For sugars defined in this way Rosanoff originally proposed to use δ- and λ-symbols, which did not gain general acceptance. The present use of the D- and L-notation [38e] started around 1940 [38f]. a) E. Fischer, *Ber. Dtsch. Chem. Ges.* **1890**, *23*, 370; b) *ibid.* **1907**, *40*, 102; c) M. A. Rosanoff, *J. Am. Chem. [54] a) The naturally occurring levorotatory xylose, that is, D-xylose in todays nomenclature, was originally designated as *l*-xylose by Fischer [58]. Correspondingly, the products resulting from cyanohydrin synthesis, hydrolysis, and reduction were denoted *l*-gulonic acid and *l*-gulose [58]; in the scheme of Figure 14, the D-notation has been applied to these alleged *l*-compounds, as they are all derived from D-glyceraldehyde. This has to be taken into consideration when studying the older literature [54b, 58]. b) E. Fischer, I. W. Fay, *Ber. Dtsch. Chem. Ges.* **1895**, *28*, 1975; E. Fischer, O. [61] H. Thierfelder, *Z. Physiol. Chem.* **1891**, *15*, 71.
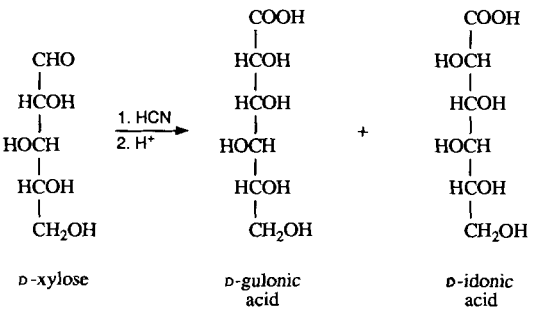
[62] "Encumbered" with the present-day knowledge on the reactions outlined in Figure 14, one can't refrain from marveling at the series of fortuitous circumstances which led Fischer to these rather sparse experimental results. For example, the fact that cyanohydrin synthesis of D-xylose, on subsequent hydrolysis, yields a mixture of D-gulonic acid and its C-2 epimer D-idonic acid (E. Fischer, I. W. Fay, *Ber. Dtsch. Chem. Ges.* **1895**, *28*, 1975), from which the former could only be isolated because its 1,4-lactone crystallizes outstandingly well: "The gulonic acid lactone belongs to the most beautiful compounds of the sugar group. By slow evaporation of its aqueous solution one easily obtains magnificently formed crystals of 1 cm in diameter" [58].



On the other hand, D-glucaric acid forms two monolactones, and only the lactonized carboxyl function is reduced by sodium amalgam to the aldehyde and subsequently to the primary alcohol. Undoubtedly a case of

serendipity, that "the sugar acid liberated from its cadmium salt by hydrogen sulfide, on concentration to a syrup and subsequent heating on a water bath for 5–6 hours" [59], mainly contained the 1,4-lactone of D-glucaric acid, which gave L-gluconic acid on reduction, isolated as its superbly crystalline 1,4-lactone in 10% yield [59]. If Fischer and Piloty had made efforts to purify the sirupy "Zuckerlactonsäure" as obtained above, they would have acquired the crystalline 3,6-lactone, (H. Kiliani, *Ber. Dtsch. Chem. Ges.* **1925**, *58*, 2344). On reduction this would have yielded D-gluonic acid; of no value in unraveling the interrelationships of the sugars. The formulas are presented as Fischer projections, since present day graphic presentations are not necessarily more appropriate for such configurational comparisons.

[68] The individual progressive steps of the proof given here try to trace and follow Fischer's chain of reasoning that undoubtedly developed from the van't Hoff thought patterns. For that reason the projection formulas used are provided with the corresponding tetrahedra, from which they are thought to emerge. A similar presentational mode was used by C. S. Hudson in 1941 [11]. It is rare that one finds a textbook of today, which follows the steps of the original proof. A notable exception is *Organic Chemistry* by R. T. Morrison and R. N. Boyd (2nd ed, Allyn and Bacon, Boston, **1970**, p. 993–997) which gives a detailed, impressively clear derivation of the sugar configurations in slightly modernized form.
[69] In his obituary for H. Kiliani, W. Hückel comments on this as follows: [40] "Here Kiliani passed the gate, through which, only little later, Emil Fischer arrived at the stereochemistry of the sugars. Kiliani, with his experiments, turned the key twice and, thereby closed it again; he would have had to turn only once to open it."

Synchrotron X-ray and Neutron Diffraction Studies in Solid-State Chemistry

By Anthony Kevin Cheetham* and Angus Paul Wilkinson

Neutron diffraction studies, especially with powders, play an important role in structural solid-state chemistry, making possible the precise determination of the location of light atoms, particularly hydrogen, and enabling a distinction to be made between certain neighboring elements in the periodic table that are difficult to distinguish in experiments with X-rays. Neutron diffraction investigations also make a unique contribution in the area of magnetic structure determination. The availability of intense synchrotron X-rays sources, however, is opening up new opportunities to the structural chemist, many of them complementary to the "traditional" strengths of neutron methods. The key features of synchrotron radiation in relation to structural studies are the wavelength tunability, which facilitates the use of resonant diffraction methods, and the high brightness and excellent vertical collimation of the source, which make possible the construction of diffractometers with unparalleled angular and spatial resolution. The following types of experiments are now possible with synchrotron X-ray diffraction: 1) The ab initio determination of structures from powder diffraction data. 2) The differentiation between different oxidation states of an element (valence contrast experiments) based upon the sensitivity of an absorption edge to the valence of the element in question. 3) The differentiation of elements adjacent to each other in the periodic table, which is now feasible with synchrotron X-rays for all elements beyond chromium. 4) Site-selective X-ray absorption spectroscopy. 5) The study of cation occupancies in materials where more than one element occupies a site that is, or may be, partially occupied. (Such problems are important in zeolite chemistry and high-temperature superconductors.) 6) The determination of crystal structures from microcrystals. 7) In situ and rapid, time-resolved diffraction studies. This review examines the roles played by X-ray and neutron diffraction studies in modern solid-state chemistry, and describes some recent examples in which the use of neutron radiation or synchrotron X-rays has been advantageous.

1. Introduction

Our current knowledge of the chemistry of inorganic materials relies heavily upon information obtained from X-ray diffraction studies. For example, the X-ray powder pattern of a compound provides a convenient and characteristic fingerprint which can be used in qualitative analysis; precise values of the d spacings (which are properties of the material itself, independent of the X-ray wavelength) and of estimated line intensities can be compared with those listed in the JCPDS Powder Diffraction File,[1] which contains entries for approximately 40000 inorganic compounds. Powder diffraction studies are also used for the precise determination of lattice parameters and in the elucidation of phase diagrams as a function of composition and temperature. As in other areas of chemistry, single-crystal studies also play a central role, providing the detailed structures of crystalline compounds that form the pillar of our understanding of the solid state. The Inorganic Crystal Structure Database (ICSD),[2] for example, details the structures of approximately 32000 materials. The vast majority of crystal structure determinations are performed using laboratory X-ray sources, but there are circumstances in which the use of the intense beams available from a synchrotron X-ray source may be advantageous. For other experiments, an alternative radiation, commonly neutron radiation, may be appropriate. The essential features of diffraction methods with neutrons and synchrotron X-rays are discussed below.

1.1. Neutron Diffraction

The wave nature of neutrons leads in principle to the possibility of doing diffraction experiments, and this was first demonstrated in 1936 with a radium–beryllium source.[3] At the present time the most common source of neutrons for diffraction experiments is the nuclear reactor, but in recent years there has been a growth in the number of facilities producing neutrons by spallation from metal targets bombarded with high-energy (approximately 500 MeV) protons.[4]

Unlike X-rays, which are scattered by the electrons of atoms, neutrons are scattered by the nucleus. Consequently, the interference effects that cause X-ray scattering to diminish with $(\sin\theta)/\lambda$ are absent with neutrons, and the scattering intensity shows no angular dependence. Because scattering power is a nuclear property, it shows only a weak dependence upon atomic number and, unlike X-ray scattering amplitude, it may vary dramatically from one element to the next (Fig. 1).[5] The neutron also has a magnetic moment, and magnetic scattering is observed from paramagnetic ions, in addition to nuclear scattering. These properties lead to the principal applications of neutron diffraction to solid-state chemistry, namely the location of light atoms, especially hydrogen atoms, in the presence of heavy elements, the differ-

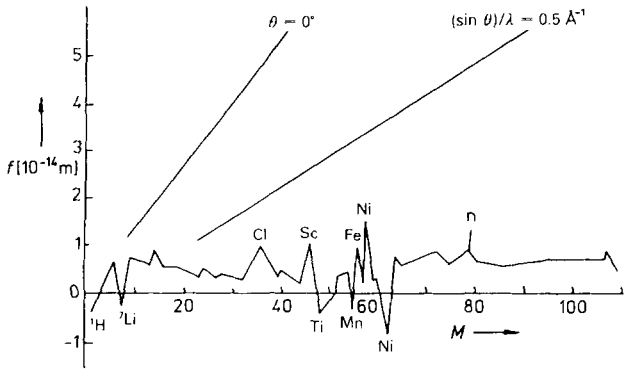

Fig. 1. The variation of neutron scattering power f with atomic weight M. The X-ray scattering amplitudes of the elements shown for comparison increase linearly with atomic number and diminish with increasing scattering angle (or more correctly with increasing $(\sin\theta)/\lambda$).

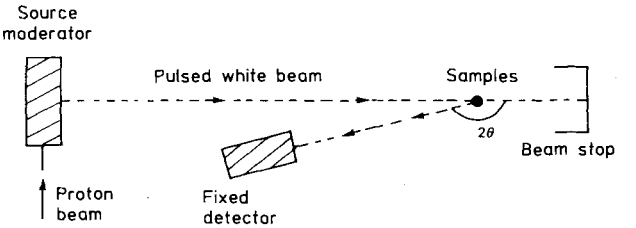

Fig. 2. A schematic diagram of a time-of-flight (TOF) powder neutron diffractometer. A high-energy, pulsed proton beam (energy ca. 500 MeV) is directed onto a metal target, producing pulses of "white" neutrons by spallation. In the simplest diffractometer arrangement, the diffraction pattern of a powder can be collected at a single, fixed detector by measuring the transmitted intensity within each pulse as a function of the time-of-flight (see text). Long-wavelength (low-energy) neutrons within each pulse will arrive after the short-wavelength (high-energy) neutrons. Data from successive pulses (typically 10^6) are summed to give adequate statistics.

entiation between adjacent elements in the periodic table, and the determination of the spin arrangements in magnetically ordered materials (e.g. antiferromagnets).

We noted earlier that the latest generation of intense neutron sources is based upon accelerators rather than nuclear reactors. The pulsed neutron beams that are emitted by such a source can conveniently be used to collect diffraction patterns by time-of-flight (TOF) methods. In a simple case, the neutron detector is placed at a fixed scattering angle, and the different scattering planes, which give rise to the peaks in the diffraction patterns, can be sampled by measuring the times that neutrons with different wavelengths (and therefore different speeds) take to reach the counter (Fig. 2); the neutron velocity is sufficiently slow to permit this. This experiment can be described by the Bragg equation [Eq. (a)]. In a conventional experiment, λ is fixed and θ is varied.

$$\lambda = 2d_{hkl}\sin\theta \qquad \text{(a)}$$

One of the features of the TOF method is that it can readily provide powder diffraction patterns with exceptionally high resolution. As a consequence, data collected on the high-resolution powder diffractometer at ISIS (Rutherford Appleton Laboratory) were used in the first demonstration of solving an unknown crystal structure by powder neutron diffraction.[6] Data collected on the same instrument at low temperature have been used to refine the structure of buckminsterfullerene with good precision.[7]

1.2. Synchrotron X-ray Diffraction

Synchrotron X-rays are produced when electrons (or positrons) with relativistic velocities are held in a circular orbit by magnetic fields.[8] The principal features that distinguish synchrotron X-rays from conventional X-rays, insofar as their applications to inorganic materials are concerned, are the high intensity, the excellent vertical collimation, and the white (continuous) spectral distribution.[9] The excellent instrumental resolution that can be achieved as a consequence of the first two factors is comparable to that obtainable with the best TOF neutron diffractometer (see Section 1.1). Several types of study are greatly facilitated by

Anthony Cheetham is the Director of the Materials Research Laboratory at the University of California, Santa Barbara, and Professor in both the Materials and Chemistry Departments. He has also held the Chair in Solid State Chemistry at the Royal Institution of Great Britain since 1986. His research interests lie in the area of inorganic materials, and embrace the synthesis, characterization, and properties of such materials. Prior to moving to UCSB in 1991, he was the Reader in Inorganic Materials at the University of Oxford. He was awarded the Corday Morgan Medal and Prize by the Royal Society of Chemistry in 1982, and the Medal for Solid State Chemistry in 1988.

Angus Wilkinson (not pictured) gained his doctorate at the University of Oxford in 1991 and is currently a postdoctoral researcher in the Materials Department at the University of California, Santa Barbara. He also holds a Junior Research Fellowship at Christ Church, Oxford. His research interests are in the use of synchrotron X-ray and neutron diffraction methods for the structural characterization of inorganic solids.

such high resolution. An important example is the routine determination of crystal structures from powder data, which will be illustrated later with some recent work on inorganic solids. In another application, high-resolution measurements are uniquely sensitive to the subtle phase transitions that are found in various types of materials, including ferroelectrics.

The continuous spectral distribution of the radiation offers the possibility of performing energy dispersive diffraction (EDXD) experiments (Section 3.4) and allows the radiation to be tuned for monochromatic experiments. The latter point leads to the possibility of 1) determining oxidation-state distributions in mixed-valent compounds, 2) differentiating between neighboring elements in the periodic table, and 3) locating exchangeable cations in ion-exchanged zeolites and other complex materials. These experiments rely on the use of anomalous scattering (Section 3.2) and have been conducted primarily on powders to date. In studies of single-crystals two developments are of great interest: the study of micron-size crystals and the use of imaging plates as detectors for the rapid collection of high-quality diffraction data.

Some of the characteristic features of synchrotron X-ray and neutron diffraction methods are apparent in Figure 3, in which the patterns of rutile (TiO_2) collected by the two techniques are compared. The angular dependence of the X-ray

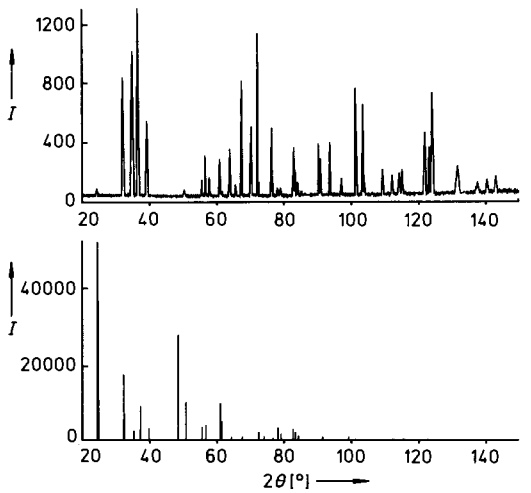

Fig. 3. A comparison of powder diffraction patterns for rutile (TiO_2) from neutron (top) and synchrotron X-ray radiation (bottom). The X-ray data were collected at Daresbury Laboratory (UK) with a mean wavelength of 1.37725 Å; the neutron data were collected at Lucas Heights (Australia) with a mean wavelength of 1.377 Å. The angular dependence of the X-ray scattering amplitudes, described in Figure 1, is clearly seen in the bottom pattern.

scattering intensity leads to poorer signal-to-noise ratios at large angles, and the different scattering factors for neutrons and X-rays are seen in the different relative intensities in the two patterns. The resolution comparison, on the other hand, is somewhat exaggerated, since the neutron data were collected on a medium-resolution instrument.

To a considerable extent, information that can be obtained by synchrotron X-ray diffraction and neutron diffraction is complementary. This point will be illustrated in Sections 2 and 3 by selected examples. On the other hand, there are several areas in which synchrotron X-ray diffraction studies can provide information traditionally extracted from neutron diffraction; this aspect will be examined in the context of locating light atoms and differentiating between neighboring elements in the periodic table. We shall also describe some of the ways in which the combined strengths of the two methods can be harnessed together to provide answers to problems in the solid state.

2. Applications of Neutron Diffraction

2.1. Location of Light Atoms

Many important applications of neutron diffraction are based on the dependence of neutron scattering powers (or scattering lengths, as they are known) upon atomic number (see Fig. 1). The average scattering power shows a rather slow increase with atomic number, with the consequence that light elements, which scatter X-rays weakly, make a more substantial contribution to a neutron diffraction pattern. This leads to better precision in the location of light atoms by neutron diffraction, an advantage that is especially useful in the study of hydrogen-containing materials. As a result, a number of studies of metal hydrides, systems with hydrogen bonds, and biological macromolecules have been conducted. Figure 4[10] shows the neutron diffraction pattern obtained from a powder sample of cerium hydride, or rather cerium deuteride. (Deuterium has superior scattering

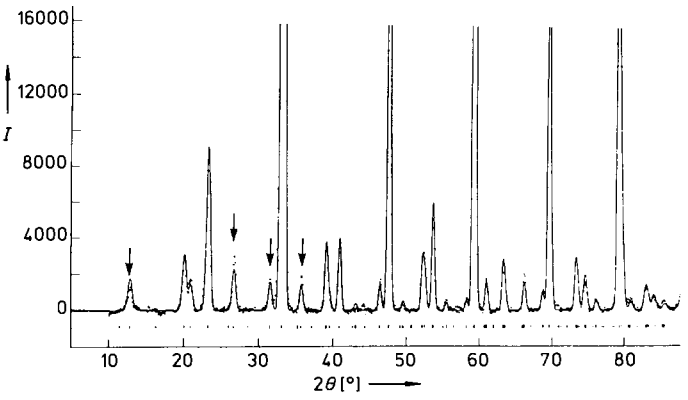

Fig. 4. The powder neutron diffraction pattern of $CeD_{2.5}$. Arrows indicate some of the reflections that arise from the long-range ordering of interstitial deuterium atoms. The corresponding X-ray pattern shows only the strong substructure reflections from the face-centered cubic arrangement of cerium atoms; it contains no information about the distribution of the deuterium atoms.

properties for diffraction experiments.) The key point here is that the diffraction pattern contains specific information about the disposition of the hydrogen (deuterium) atoms. The corresponding X-ray diffraction pattern would contain virtually no such information. In a subtle variation on this experiment Somenkov et al. used the difference in the scattering power of hydrogen and deuterium to show that in CeD_2H hydrogen preferentially occupies the octahedral sites and deuterium the tetrahedral sites.[11] Only with neutron diffraction can such isotopic ordering be detected.

In another example that illustrates the location of light atoms by neutron diffraction, a pyridine molecule was de-

tected inside a zeolite catalyst (Fig. 5).[12] The sorbate forms a Lewis acid–base complex with the K^+ ion, whilst enjoying a short-range, nonbonding interaction with the aluminosilicate framework of the zeolite. This study and other more

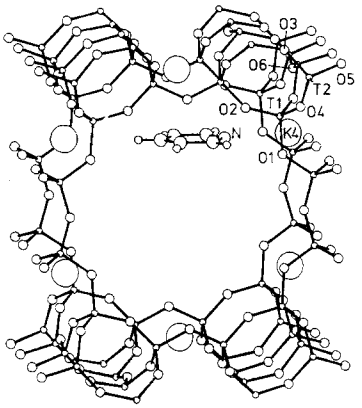

Fig. 5. The location of pyridine in the catalyst potassium zeolite-L determined by neutron diffraction. The nitrogen atom of the pyridine molecule forms a Lewis acid–base complex with the potassium ion, whilst the aromatic ring enjoys short-range interactions with the aluminosilicate framework.

recent examples[13–15] demonstrate unequivocally that adsorbed molecules are preferentially situated in positions close to the inner surfaces of the zeolite; this is a valuable insight into the behavior of organic species in these important catalysts.

2.2. Differentiation between Elements

A second important type of neutron diffraction experiment relies upon the variations in scattering that are sometimes found between elements adjacent to each other in the periodic table. Figure 1 reveals that the elements of the first transition series, for example manganese, iron, and cobalt, have quite different scattering powers; neutron diffraction is therefore able to differentiate between these elements. Their X-ray scattering powers, on the other hand, are almost identical because they have similar numbers of electrons; it is therefore difficult to distinguish them by X-ray methods. The significance of this advantage of using neutron diffraction can be seen in the extensive work that has been done on ferrite magnets. These compounds crystallize in the same structure as the mineral spinel ($MgAl_2O_4$), and their magnetic properties depend crucially upon the distribution of the different transition metal ions in the available cation sites. Until very recently, this information could be obtained only by neutron diffraction. A typical example is provided by a study of the spinel $NiCo_2O_4$[16] which, rather surprisingly, revealed 92% occupancy of the tetrahedral site by cobalt, corresponding to a spinel structure with almost complete inversion.

2.3. Magnetic Structure Determination

A third important class of experiments also relates to magnetic materials, but relies upon the magnetic scattering of neutrons. When the magnetic moments or spins in a material become aligned in a regular manner, for example in what a layman would call a magnet, the neutron diffraction pattern will exhibit additional peaks that contain information about the spin arrangement. Figure 6 shows the patterns of nonstoichiometric ferrous oxide $Fe_{1-x}O$[17] both above and below the temperature at which the spins become antiferromagnetically ordered (200 K). Note the appearance of peaks

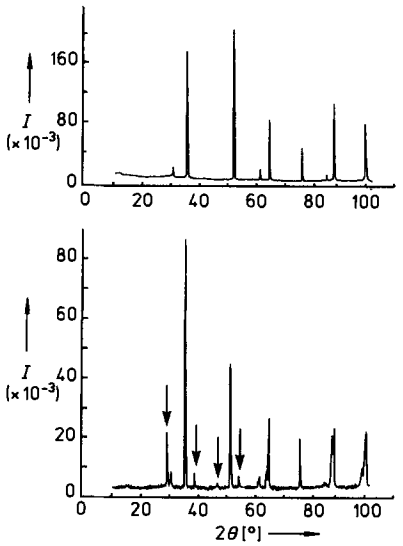

Fig. 6. Powder neutron diffraction patterns of $Fe_{0.943}O$; top: above (293 K) and bottom: below (4.2 K) the magnetic ordering transition at 200 K. Note the appearance of reflections in the low-temperature pattern resulting from magnetic ordering (marked with arrows), and the peak splittings at high scattering angles due to a lowering of symmetry from cubic to rhombohedral at the magnetic ordering temperature.

due to magnetic scattering in the low-temperature pattern. In this and many other magnetic compounds, neutron diffraction provides an unrivaled insight into their behavior at the atomic level.

The sensitivity of magnetic scattering experiments can be dramatically enhanced by utilizing a neutron beam containing neutrons of only one spin and measuring the polarization of the diffracted neutrons.[5] In the case of $Fe_{1-x}O$, such measurements have revealed that the magnetic spins of the iron atoms lie in the (111) plane in the bulk of the crystal, but are perpendicular to that plane in the vicinity of defects comprising octahedral iron vacancies and tetrahedral interstitial Fe^{3+} ions.[18]

Magnetic scattering studies can also be used to form the basis for establishing the charge distribution in mixed-valent compounds. In $Fe^{II}Fe^{III}PO_5$, for example, in which there are two crystallographically distinct iron sites in the crystal structure, magnetic neutron diffraction measurements yielded magnetic moments of $M1 = 3.89(3)\,\mu_B$ and $M2 = 4.22(3)\,\mu_B$, consistent with Fe^{2+} and Fe^{3+} at the positions Fe1 and Fe2, respectively[19] (see Section 3.2.1).

2.4. Rietveld Profile Analysis

Since the flux of a neutron beam is relatively low compared with that of an X-ray source, rather large samples (at

least 1 mm^3) are required for single-crystal neutron diffraction experiments. Such crystals are certainly difficult to prepare; thus powder neutron diffraction techniques have been developed to a point where they can now be used to refine complex, low-symmetry structures. A conventional refinement with structure factors from single, integrated powder intensities is quite feasible for high-symmetry structures, but is clearly impracticable for low-symmetry materials because of overlap between adjacent Bragg reflections (Fig. 7).

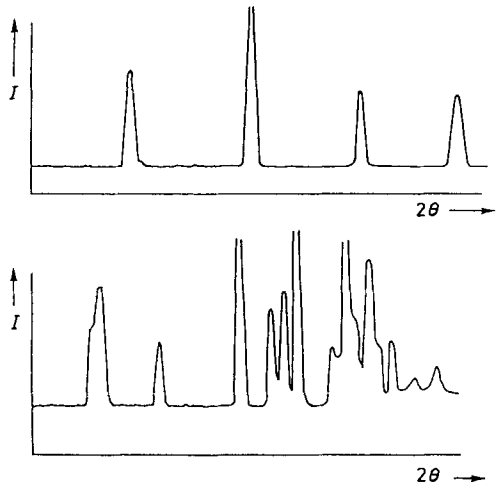

Fig. 7. Schematic representations of powder diffraction patterns of samples with high symmetry (top) and low symmetry (bottom). In the latter case, the intensities of individual Bragg reflections may be difficult or impossible to determine due to peak overlap.

Rietveld[20] has devised a method for analyzing the more complex patterns by means of a curve-fitting procedure in which the least-squares refinement minimizes the difference between the observed and calculated profiles, rather than individual reflections. In order to do this with neutron diffraction patterns, it can normally be assumed that the reflections have a Gaussian distribution, and the calculated intensity at each point (say, 0.05° in 2θ steps) on the profile is obtained by summing the contributions from the Gaussian functions that overlap at that point. Besides the conventional parameters in the least-squares refinement (atomic coordinates and temperature factors of the individual atoms), additional parameters are required: the lattice parameters which determine the positions of the reflections, a correction factor for setting the zero point of the detector, and three parameters that describe the variation of the half-width of the Gaussian distribution (full width at half-maximum intensity) with scattering angle. The Rietveld method was initially developed for the analysis of neutron diffraction data because of the relative simplicity of the peak-shape function, and it has been used in the examination of a wide range of problems in solid-state chemistry.[21–23] A typical example is shown in Figure 8.[24]

Profile analysis procedures have also been developed for the analysis of TOF powder data. The procedure is essentially the same as that used in constant-wavelength experiments except that the peak-shape function is more complex and wavelength-dependent terms must be taken into account.[25] One advantage of TOF powder methods is that the whole

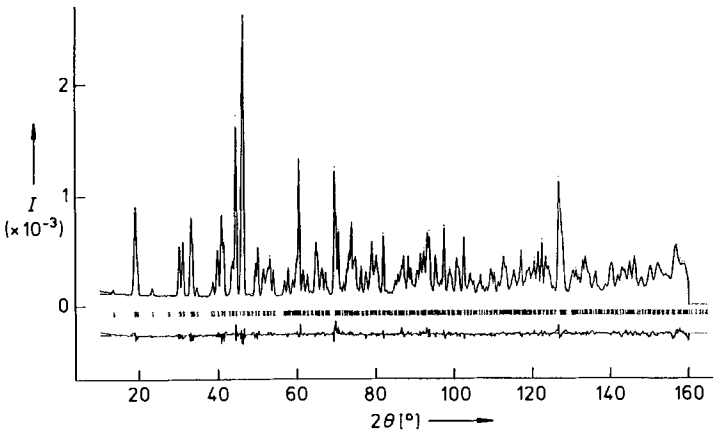

Fig. 8. The observed, calculated, and difference (lower curve) profiles resulting from the Rietveld analysis of powder neutron diffraction data collected on Sr_3CuPtO_6. The ticks mark the calculated positions of the possible reflections. $\lambda = 1.5940$ Å.

diffraction pattern is collected simultaneously (since the detector remains stationary). Thus, it is an attractive way of following structural changes with time, temperature, or pressure. In addition, since the incident and scattered beams can pass through small apertures, such measurements can easily be conducted on materials in special environments, for example in a high-pressure cell[26] (see Section 2.5).

Profile analysis is limited by the same drawback that applies to powder methods in general: the loss of information arising from the compression of the three-dimensional diffraction pattern into a single dimension. The inability to assign intensities to individual reflections, except in the simplest cases, normally leads to difficulties in solving crystal structures from powder data. For example, Patterson techniques may not yield the information necessary to locate heavy atoms and solve the phase problem, and direct methods are also difficult to apply. This serves to underline the fact that profile analysis, though an excellent technique for *refining* structures, requires a good starting model and is *not* a suitable method for *structure determination*. However, this problem should be overcome gradually as instrumental resolution and computational methods improve, giving larger numbers of individual reflections (see Section 3.1).

2.5. In Situ Powder Diffraction Studies

Currently, the majority of powder neutron diffractometers that are used for collecting data for structure refinements require data collection over several hours for a single diffraction pattern. However, it is possible to collect complete diffraction patterns in just a few minutes if a high incident neutron flux is available, efficient detection systems are employed, and a high degree of pattern resolution is not required. This opens up the possibilities of examining the progress of chemical reactions as they occur, or collecting data as a function of some external variable such as temperature or pressure. Neutron diffraction is in many ways well suited to these types of experiments: 1) Most materials do not significantly absorb neutrons; this markedly simplifies the construction of the sample environment (reaction vessel,

electrochemical cell, furnace, pressure cell, etc.). 2) Processes involving light atoms, such as dehydration, can be followed. 3) A fixed-angle detector can be used with TOF techniques (Fig. 2), again considerably simplifying the construction of certain types of sample environment, for example high-pressure cells. However, even the most advanced neutron sources offer considerably lower fluxes than those available with modern X-ray sources, particularly synchrotron storage rings. Consequently, synchrotron X-ray diffractometers are potentially able to follow dynamic processes on a much shorter timescale (see Section 3.4).

2.5.1. *Real-Time Neutron Diffraction*

Some of the applications of real-time neutron powder diffraction have been reviewed.[27-29] Dehydration/hydration reactions such as the industrially important dehydration of gypsum ($CaSO_4 \cdot 2H_2O$) in the manufacture of plaster of Paris have been studied.[30] In this case, the background incoherent scattering in the diffraction pattern provides a sensitive probe of the residual water (proton) content of the material, while the diffraction pattern itself identifies the crystalline phases that are present.

The reaction of gases and solids, for example the absorption of deuterium by the alloys $LaNi_{2.18}$ and $CeNi_{2.16}$, have also been examined.[31] The observed shifts in peak positions and changes in relative peak intensities were interpreted as suggesting that deuterium atoms are initially incorporated into a crystalline phase. As the reaction proceeded, a smooth increase in pattern background intensity combined with a decrease in intensity of the Bragg peaks was observed; this was ascribed to the formation of an amorphous hydride phase.

The processes occurring in electrochemical cells, for instance the study of the reversibility of hydrogen-absorbing TiNi electrodes, have been investigated.[32] The recorded powder patterns demonstrated that when the test cell was charged, the initial TiNi alloy electrode was converted to a new crystalline phase, $TiNiD_x$, but when the cell was discharged the crystalline alloy did not reform and only a small amount of the electrochemically inserted deuterium could be removed from the deuteride.

Intercalation processes, such as the absorption of THF by CsC_{24} have also been studied with real-time neutron diffraction.[33] The time-resolved diffraction patterns clearly showed the formation of $Cs(THF)_{1.74}C_{24}$ via an intermediate compound. The presence of "liquid rings" (diffuse scattering) in the diffraction pattern of the product, but not the intermediate, were interpreted as suggesting that the intercalated solvent is highly disordered (liquidlike) in the former material and ordered in the latter compound.

2.5.2. *High-Pressure Neutron Diffraction*

Neutron diffraction has been used for many years to study the influence of pressure on crystal structure,[34, 35] for example the occurrence of phase transitions and for the measurement of compressibility. The penetrating power and constant scattering power with respect to $(\sin\theta)/\lambda$ make the technique suitable for the acquisition of diffraction data of sufficient quality for quantitative analysis by Rietveld refinement or other methods. This has found application in several areas, including the examination of the influence of pressure on crystal structure in high-temperature superconductors and the correlation of these data with those obtained from T_c measurements.[36] In high-pressure X-ray studies of powder samples, it is often not possible to use the data in crystal structure analysis due to powder averaging problems (i.e. insufficient number of crystallites).

Unfortunately, the low flux of neutrons available from current sources requires that large sample volumes be employed; this is a severe limitation on the design of high-pressure neutron diffraction experiments as there is generally an inverse correlation between the maximum pressure achievable and the sample volume. As a consequence of this restriction, the majority of neutron experiments have been performed at less than 50 kbar in piston/cylinder cells. By contrast, the much higher flux available from synchrotron X-ray sources allows the performance of experiments at very high pressures (in excess of 1 Mbar) on small samples in diamond anvil cells (DACs).

3. Applications of Synchrotron X-ray Diffraction

3.1. Determination of Crystal Structures from Powder Data

A great deal of the development work in the field of structure determination from powder data has relied on conventional, laboratory X-ray sources, and there have been a number of important successes in the area.[37, 38] However, synchrotron X-rays have profound advantages over conventional X-rays for structure determination. In particular, the combination of the high brightness and excellent vertical collimation can be harnessed for the construction of diffractometers with unparalleled resolution. Cox's instrument at the National Synchrotron Light Source (NSLS), Brookhaven National Laboratory,[39] for example, has a resolution at the focusing position of $<0.02°$ in 2θ. This is achieved in part by constructing the instrument in the vertical plane, since the vertical divergence θ_v is only about $0.01°$ at 2.5 GeV. With high-resolution data, the solution of structures from powder data is greatly facilitated, and several successful structure solutions and refinements have recently been performed (Table 1).[40] On the other hand, very few structures have been solved from powder neutron diffraction data. This is partly a consequence of the lower resolution of most neutron diffractometers, but it is mainly due to the near equivalence of the neutron scattering powers for most elements (as a result of which, the phase problem cannot be solved on the basis of locating a small subset of dominant scatterers).

With single-crystal X-ray data that has been collected on an automatic diffractometer, the determination of a crystal structure is normally routine. The unit cell can be identified from an automatic peak search, the space group determined from systematic absences, and the phase problem solved by Patterson or direct methods. Patterson methods are normally used if there are one or more dominant scatterers present, as in many organometallic and coordination compounds,

$Ga_2(HPO_3)_3 \cdot 4H_2O$	$P2_1$	29	[57]

[a] Number of atoms in the asymmetric unit.

and direct methods are particularly suitable for organic compounds, minerals, and other regular solids. The structure can then be refined with a combination of least-squares and difference Fourier techniques. With powders, however, there are serious difficulties, most of which arise because the three-dimensional intensity data is compressed into a single dimension in the powder experiment. This results in peak overlap, which introduces complications at each stage of the structure determination.

The first hurdle to be overcome, that is, indexing of the reflections and determination of the unit cell, is nontrivial, although in our recent experience few determinations now falter at this stage. Several excellent autoindexing programs are available.[58–61] They require very accurate *d*-spacing data, but these can normally be obtained by peak-fitting of individual reflections provided that all systematic errors can be eliminated. Clearly, the autoindexing procedure is greatly facilitated if high-resolution data are available.

Following the determination of the unit cell it may be possible to identify the structure by comparison with a related material, for example, by searching in an appropriate database. In the many cases in which this is not possible, however, the solution of the crystal structure may present formidable obstacles. In particular, the solution of the phase problem is likely to be difficult, largely because the overlapping of adjacent reflections introduces ambiguity into the assignment of intensities to particular *hkl* values. This problem arises with both low-symmetry structures, where the density of reflections may become very high, and high-symmetry structures, where there may be unavoidable overlap of nonequivalent reflections. Ideally, unambiguous intensity data are needed for both Patterson and direct methods calculations.

The extraction of the maximum amount of integrated intensity data I_{hkl} from the powder diffraction pattern is perhaps the most difficult stage in the determination. Both Pawley[62] and Le Bail[63] have developed profile fitting methods by which the observed powder pattern can be decomposed into integrated intensities. It should be stressed that no structural model is required for any of these methods and that this crucial step can be performed more effectively with high-resolution data, underlining again the advantages of using synchrotron X-rays.

From this stage onwards, the analysis mirrors that of a single-crystal study. The possible space groups can be assigned from the systematic absences, although in cases of uncertainty it may be useful to carry out pattern decomposition in a number of possible space groups, or to obtain a series of electron diffraction patterns. The phase problem can be solved by conventional crystallographic methods. The principal difficulties are that the data set will be considerably smaller than that obtained from a single crystal and that some of the data will be unreliable for the reasons discussed above. It is a tribute to the robustness of modern structure-solving techniques that it is still possible to determine structures under these circumstances.

In the first structure solved from synchrotron X-ray powder data carried out in 1986 by Attfield et al.,[41] the orthorhombic structure of α-$CrPO_4$ with eight atoms in the asymmetric unit was solved by Patterson methods using a vector search procedure; 68 well-resolved peaks were utilized. A relatively poor R_{pr} factor (19.3%) was obtained for the final Rietveld refinement with the synchrotron data, no doubt due to problems with preferred orientation and *hkl*-dependent line-broadening effects. But a subsequent medium-resolution neutron study (on the D1a instrument at ILL Grenoble) gave an excellent fit ($R_{pr} = 8.3\%$), confirming the correctness of the model obtained with synchrotron X-ray diffraction. A comparison[64] of the atomic coordinates obtained from these investigations and a subsequent single-crystal study[65] nicely illustrate the relative strengths of the different methods (Table 2). We note that with neutron diffraction the parameters for almost all atoms are more precise in spite of the modest resolution of the data. The level of

[a] For the refinement of the powder X-ray data the overall isotropic temperature factor was $B_{iso} = 0.24(7)$ Å^2.

agreement between the results of powder and single-crystal measurements suggests an underestimate of the estimated standard deviations with the Rietveld method, a feature that is apparent in other comparisons of this type.[66]

3.2. Resonant Diffraction

The tunability of synchrotron radiation allows us to modify the scattering factor f for a particular element by selecting an X-ray wavelength that is in close proximity to an absorption edge. This leads to resonance effects that require modifications to the scattering factor according to Equation (b), where f' is the real part of the correction and f'' is the imaginary part; these corrections have essentially no dependence on $\sin(\theta/\lambda)$. Both f' and f'' can have quite large values. For example, at the iron K-edge f' and f'' reach minima and maxima of -8 and $+4$ electrons, respectively,[67] compared to $f^0 = 26$ at $(\sin\theta)/\lambda = 0$. Such resonant (anomalous) scattering effects can have a marked influence on X-ray patterns and are opening up some exciting opportunities in the study of condensed matter, as will be discussed below. Unfortunately, powder diffraction patterns show poor sensitivity to changes in f''.[68] As a consequence, most experiments involving such materials rely upon the influence of f'.

$$f = f^0 + f' + if'' \qquad \text{(b)}$$

The two components of the anomalous scattering correction, f' and f'', are related to each other by the so-called Kramers–Kronig integral; where ω_i is the angular frequency of the radiation [Eq. (c)]. The term f'' is related to the X-ray

$$f'(\omega_i) = (2/\pi)\int_0^\infty \omega f''(\omega)/(\omega^2 - \omega_i^2)\,\mathrm{d}\omega \qquad \text{(c)}$$

absorption cross section $\sigma(\omega)$ by the optical theorem [Eq. (d)], where r_e is the classical radius of an electron. This close relationship between anomalous scattering and X-ray

$$f''(\omega) = (\omega/4\pi r_e c)\sigma(\omega) \qquad \text{(d)}$$

absorption has implications for several types of experiment. Since the energy of the absorption edge increases by a few eV for each unit increase in oxidation state, it is possible to differentiate between the oxidation states of an element by selectively tuning the wavelength (valence contrast experiments). Additionally, the local coordination environment of an atom affects the anomalous scattering corrections in the vicinity of the absorption edge as a consequence of its influence on the absorption spectrum of the atom (application in XANES and EXAFS experiments).

3.2.1. Valence and Neighboring Element Contrast Experiments

There have already been several illustrations of the opportunities that synchrotron radiation presents for the study of oxidation states and neighboring element contrast (Table 3).

Table 3. Some examples of valence (V) and neighboring element (NE) contrast experiments from synchrotron X-ray studies.

Compound	Exp.	Ref.	Compound	Exp.	Ref.
Y-doped ZrO_2	NE	[69]	Eu_3O_4	V	[76]
$YBa_2Cu_3O_7$	V	[70, 71]	$FeNi_2BO_5$	NE	[77]
$La_{0.9Gd}0.9Sr_{0.2}CuO_4$	NE	[72]	$GaCl_2$	V	[78]
$Fe_{0.5}Co_{0.48}V_{0.02}$	NE	[73]	$FeCo_2(PO_4)_2$	NE	[79]
$Cr_{0.48}Fe_{0.52}$	NE	[74]	α-Fe_2PO_5	V	[19]
$Fe_{0.52}Cr_{0.31}Ni_{0.08}Mo_{0.07}Mn_{0.02}$	NE	[75]	$PbBi_2S_4$	NE	[80]
$EuSm_2O_4$	NE, V	[76]			

The recent study[19] of α-Fe_2PO_5 affords an interesting example, since the same system was also investigated by magnetic neutron diffraction (see Section 2.3). The essence of such a valence contrast experiment is illustrated schematically in Figure 9 for a gallium compound. In the case of the

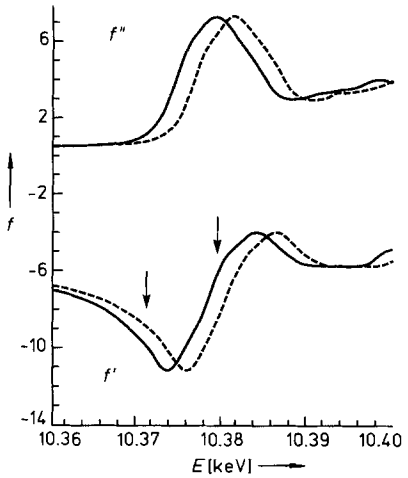

Fig. 9. A schematic diagram illustrating the principles involved in valence contrast experiments. The variations in f' and f'' [electrons] are shown for lower (solid line) and higher (broken line) oxidation states in the vicinity of an absorption edge. In experiments of the type described in the text, datasets are collected well below the edge and at two energies close to the absorption edge (the latter are indicated by arrows).

α-Fe_2PO_5, X-ray data were collected at three wavelengths: one well below the Fe K absorption edge, the second close to the Fe^{2+} edge (as determined by X-ray absorption measurements), and the third close to the Fe^{3+} edge. Since the absorption edge shifts to higher energies with increasing oxidation state, the real part of the anomalous scattering correction should be more negative for the Fe^{2+} site in the second experiment, and for the Fe^{3+} site in the third (see Fig. 9); for the first data set (well below the K absorption edge), the corrections for both iron positions M1 and M2 are expected to be approximately the same. The results, which are presented in Table 4, show that f' is more negative at site M1 in the second experiment and more negative at M2 in the third, consistent with the presence of Fe^{2+} at M1 and Fe^{3+} at M2, and in agreement with the findings from neutron diffraction studies given in Section 2.3. Paradoxically, these sophisticated studies do not afford such a clear-cut answer as simple valence bond calculations,[81] which yield $\sum\sigma_{M1} = 2.077(3)$ and $\sum\sigma_{M2} = 2.997(7)$ based upon the room-temperature crystal structure.

Table 4. Refined values of f' obtained for the M1 and M2 sites in α-Fe_2PO_5 (data collected on diffractometers at SRS, Daresbury Laboratory) [19].

Beamline	8.3	8.3	9.1
Wavelength [Å]	1.78316(4)	1.74179(1)	1.74018(6)
Energy [eV]	6953.1(1)	7118.3(1)	7124.8(3)
ΔE from Fe^{2+} K edge [eV]	−165.2(5)	−2.6(5)	3.9(5)
Estimated bandpass [eV]	3.0(2)	3.0(2)	1.6(2)
f' (M1) [electrons]	−3.57(4)	−9.74(5)	−6.75(11)
f' (M2) [electrons]	−3.56(5)	−8.04(7)	−10.01(17)
f'' (M1) [electrons]	0.472	1.8	4.0
f'' (M2) [electrons]	0.472	1.7	3.2

The ability to distinguish between neighboring elements in the periodic table, which has previously been possible only with neutrons, and even then only when the neutron scattering strengths are reasonably disparate, is now possible for many elements by resonant powder diffraction. For example, Warner et al.[79] have recently shown that the distribution of Fe and Co in $[Fe_2Co(PO_4)_2]$ can be determined with a precision that is comparable to that obtained by neutron diffraction (Table 5). Both experiments confirm that

Table 5. Occupancy of sites M1 and M2 by Fe atoms in $[FeCo_2(PO_4)_2]$ as determined by neutron diffraction and resonant X-ray diffraction experiments [79].

Site	M1	M2
Multiplicity	4	2
Coordination number	5	6
Random distribution	1/3	1/3
Occupancy from neutron data	0.246(5)	0.508(9)
Occupancy from X-ray data	0.243(5)	0.514(10)

iron preferentially occupies the site with octahedral coordination, M2. The differentiation between iron and cobalt is one of the classical applications of neutron diffraction (see Section 2.2), since the relative neutron scattering lengths are $+0.95 \times 10^{-14}$ and $+0.25 \times 10^{-14}$ m for Fe and Co atoms, respectively.[5] However, the X-ray contrast between Fe and Co atoms can be increased from approximately 1 to over 6 electrons by matching the wavelength to the Fe K absorption edge. Since the anomalous scattering corrections are approximately independent of scattering angle, a change of −6 electrons can have a profound influence on the intensities of reflections at large angles. It is already clear that this technique will enable us to tackle many structural problems that have previously been impenetrable with either conventional X-ray or neutron diffraction; the anomalous X-ray scattering approach is feasible for all elements that have an absorption edge in an energy range that is suitable for diffraction studies (i.e. the wavelength required is not too short or too long). With the next generation of synchrotron sources giving high fluxes of short-wavelength X-rays, such experiments will be practicable for all adjacent elements in the periodic table starting at approximately titanium.

3.2.2. *The Effect of Coordination Geometry on Anomalous Scattering*

As a consequence of the close relationship between the anomalous scattering corrections and X-ray absorption, anything that affects the absorption spectrum will also influence the anomalous scattering corrections f' and f''. This implies that anomalous scattering corrections are sensitive to coordination geometry, since the latter influences both the EXAFS (Extended X-ray Absorption Fine Structure) and the XANES (X-ray Absorption Near-Edge Structure) observed in absorption spectra. In practice, the impact of EXAFS on the anomalous scattering corrections is small and can probably be neglected, but in many cases the XANES does have a significant effect. This was recently demonstrated by a series of resonant diffraction experiments on the garnet $Y_3Ga_3^1Ga_2^2O_{12}$ (Ga^1 = tetrahedral, Ga^2 = octahedral coordination geometry).[82] The Ga^{3+} ions in this material with tetrahedral and octahedral coordination environments show distinct X-ray scattering behavior at energies in the near-edge region; the difference between f' for the two sites varies over a range of about four electrons.

This effect is large enough to be of importance in experiments for which a knowledge of the anomalous scattering correction is necessary for the accurate analysis of diffraction data, for example in neighboring element contrast and valence contrast experiments, and for structure solutions. Additionally, it could also provide the basis for a new type of experiment: the examination of the coordination geometry of a given atom through crystallographic determinations of f' or f'' (site-selective XANES). The latter approach could provide information on an atom's coordination environment in an elemental and site-specific fashion. This is something that is not possible with either conventional crystallography or X-ray absorption. Unfortunately, a large amount of resonant diffraction data must be obtained and analyzed in order to obtain any useful information, and this is likely to severely restrict the application of this method.

3.2.3. *Problems Due to Multiple Occupancy in Disordered Materials*

In many crystalline materials of interest to solid-state chemists more than two distinct species are located on a single crystallographic site. The superconductor $La_{0.9}Gd_{0.9}Sr_{0.2}CuO_{0.4}$ which has potentially three types of cations located on the same site is one such compound; it is not possible to determine uniquely the distribution of the cations on the site from a single diffraction data set.[72] In order to solve a problem of this type unambiguously, one diffraction pattern is required for every unknown occupancy, and each of these diffraction patterns has to be measured in such a way that the form factors for the disordered elements vary between them. This can be achieved by collecting both X-ray and neutron diffraction data, using isotope substitution in combination with neutron diffraction, or by using anomalous scattering to alter the X-ray scattering power of an element.

In the case of the superconductor just mentioned, a minimum of two diffraction data sets are required, as there are three cations and each crystallographic site is fully occupied. However, in partially zinc-exchanged sodium zeolite-Y ($Na_{0.07}Zn_{0.11}Al_{0.28}Si_{0.72}O_2$), in which there are potentially only two cations (Zn and Na) on each of the extra-framework sites, two diffraction data sets are still required as these

sites are not necessarily fully occupied. It was possible to resolve the latter problem by collecting two X-ray data sets, one near the Zn K absorption edge (1.284 Å) and the other at much shorter wavelength (0.8 Å).[82] The difference in scattering powers for Zn at these wavelengths is sufficient to allow the determination of the distribution of cations in the extra-framework sites.

3.2.4. Structure Solution Using Anomalous Scattering

Anomalous scattering plays a very important role in the solution of the phase problem for macromolecules,[83] but it has found little use in the solution of inorganic crystal structures from single-crystal or powder diffraction data. In the case of single-crystal data, it is nearly always possible to solve the crystal structure without recourse to such an expensive technique if the crystal is of reasonable quality, and the few examples of its use tend to be illustrating points of technique rather than solving new structures.[84, 85] While there have been no examples of the application of anomalous scattering data in solving structures from powder diffraction, there has been some discussion as to how this may be achieved.[40, 86] There may be some advantage here in using multiwavelength anomalous scattering data for structure solution rather than a single powder pattern. The extra information provided by the anomalous scattering may be able to partially compensate for that lost due to the overlap of reflections in the pattern.

3.3. Rietveld Analysis with Synchrotron X-ray Data

The extension of Rietveld profile analysis to laboratory X-ray diffraction data is now widely practiced, although, in general, the method does not appear to be as precise as its neutron counterpart. One disadvantage of using X-rays is that the falloff in intensity with increasing $(\sin\theta)/\lambda$ reduces the amount of useful data that can be measured, a serious drawback for a method that is intrinsically short of data compared with single-crystal experiments. In extending the technique to synchrotron data, the higher quality of the data leads to improved precision in the final structure, although Rietveld analysis can be more difficult at high resolution if sample effects such as anisotropic strain or particle-size broadening give rise to complex peak shapes. Nevertheless, Cox et al.[87] and other authors have shown that profile analysis can be applied routinely to synchrotron data; an example is shown in Figure 10.[88]

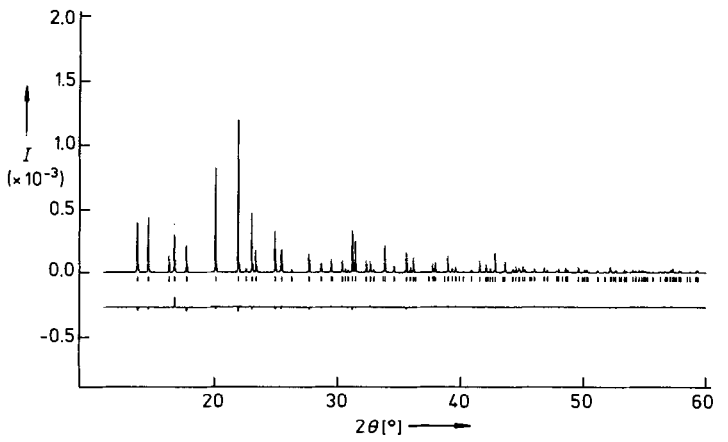

Fig. 10. The observed, calculated, and difference patterns (lower curve) resulting from the Rietveld analysis of the synchrotron X-ray powder pattern of $LiNbO_3$. The ticks mark the calculated positions of the possible reflections. The data were collected on beamline X7A at the NSLS, Broookhaven National Laboratory. $\lambda = 0.6543$ Å.

3.4. Synchrotron X-ray Diffraction In Situ

The use of synchrotron X-ray diffraction for time-resolved studies offers one major advantage over neutron diffraction: the radiation from synchrotron X-ray sources is typically many orders of magnitude more intense than that from neutron sources. This suggests that faster processes can be studied and that samples with smaller volumes can be examined. The latter point is of great importance when the design of the sample cell places severe restrictions on the amount of material that can be used, as for example in high-pressure experiments with diamond anvil cells (DACs).

There are several possible approaches to time-resolved X-ray experiments. 1) A conventional angle-scanning diffractometer can be used to perform short scans. However, while this approach has been used for some laboratory studies such as the formation of synthesis gas from methane over $Eu_2Ir_2O_7$,[89] it is only suitable for the examination of processes over extended times due to the time difference between the recording of the beginning and end of the diffraction pattern.

2) A position-sensitive detector can be used to simultaneously record either the entire monochromatic diffraction pattern or a substantial section of it. This method often, but not necessarily, gives diffraction patterns which are of lower angular resolution than those recorded in the angle-scanning mode. The timescale on which processes can be studied, usually a few seconds, is to some extent limited by the counting electronics typically employed with such detectors, although it could be improved considerably. The technique has found use in the study of electrode surfaces in situ[90] and has been employed in combination with time-resolved X-ray absorption spectroscopy to study the decomposition of carbonate precursors to oxide catalysts and the reduction of oxide mixtures.[91]

3) In energy-dispersive X-ray diffraction (EDXD) techniques, data are collected using "white" synchrotron radiation in an experiment similar to the TOF neutron diffraction experiment. The detector is again placed at a fixed 2θ value, but the different wavelengths are resolved, not by time-of-flight, but with an energy-dispersive X-ray detector (for example a Li-drifted silicon detector). As in the neutron diffraction experiment, this has the advantage that the whole diffraction pattern is accumulated simultaneously. The technique generally gives low pattern resolution due to the poor energy resolution of the detector, but it does offer some advantages over angle-dispersive techniques. EDXD enables the experimenter to employ a large fraction of the hard X-ray photons produced by the source and consequently allows the rapid collection of data. Once again, the timescale on which data can be collected is sometimes limited by the counting

electronics, but this problem can be overcome partly by examining selected areas of the diffraction pattern.[92] It has been demonstrated that data can be acquired on a 20 ms timescale.[93] Since EDXD is a fixed-angle experiment, it is an attractive technique for the study of samples in highly restricted environments, as in DACs. This, in combination with the high intensity of synchrotron radiation, has led to the extensive use of the technique for the investigation of phase relationships at very high pressures and the kinetics of phase transitions.[93,94] Examples include the transformation of CsI from an orthorhombic to an hexagonal structure type at approximately 2 Mbar[95] and the conversion of the olivine form of Mg_2GeO_4 to a spinel.[96] In addition, the technique has been applied in the study of the crystallization of metallic glasses,[97,98] the hydration of cements,[97] and the formation of crystalline zirconium(IV) oxide from hydroxide gels.[98] A recent application to the formation of a catalyst from a pyrochlore precursor as shown in Figure 11.[99]

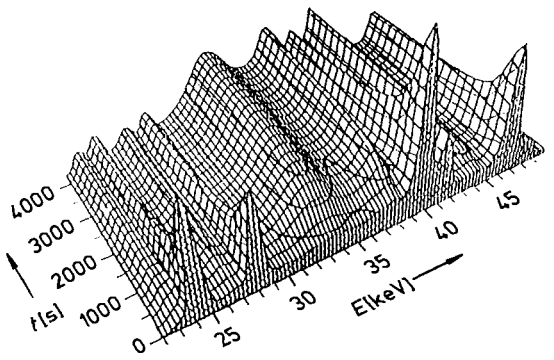

Fig. 11. The time-dependent evolution of the EDXD pattern of $Eu_2Ir_2O_7$ as the compound decomposes to Ir and Eu_2O_3 under a stream of CH_4/CO_2 at 888 K. The formation of small particles of iridium metal (diameter ca. 40 Å) is evident by the appearance of the broad peak at 35 KeV. Data were collected at Daresbury Laboratory.

3.5. Single-Crystal Studies

3.5.1. Microcrystal Experiments

The use of intense synchrotron X-ray sources to collect diffraction data on very small crystals promises to bring advances in three main areas: 1) the structural study of compounds which cannot be obtained as single crystals large enough for conventional diffractometry, 2) the collection of extinction-free data (at short wavelengths) for use in high-accuracy crystal structure analysis, and 3) the examination of materials in special environments, particularly under high pressures where the samples should be small in volume in order to simplify the construction of the cell and minimize any pressure gradients across the sample.

There have been several articles in which microcrystal diffraction experiments are discussed.[100-103] The published studies focused on test specimens such as CaF_2 (minimum size 2.2 μm^3),[104-106] the zeolite cancrinite (800 μm^3),[107] molybdenum (0.3 μm^3),[108] and bismuth (0.4 μm^3),[109] as well as a small number of materials whose crystal structures were not well determined previously, for instance piperazine silicate (25 200 μm^3)[110] and zeolite theta-1 (4000 μm^3).[111]

The majority of the early studies in this area were performed with conventional detectors and angle-scanning diffractometers.[104-107] Although this approach is capable of providing high-quality data, it suffers from the disadvantage that the time required for data acquisition may be long, since the crystal must be oriented for each Bragg reflection and then scanned. Two other techniques have been employed in an attempt to reduce the time required for data collection. Area detectors such as the CCD (Charged Coupled Device) camera[110,111] or imaging plates have been used with monochromatic radiation, and Laue diffraction studies have been conducted with either film,[112] imaging plates,[109] or in one case a solid-state detector.[108] The Laue technique is undoubtedly the quickest way of obtaining data, but unfortunately it is perhaps the most demanding in terms of crystal quality; crystals with large mosaic spreads produce data that are hard to analyze.

While the number of crystal structures that have been solved and refined from data collected on microcrystals is small, it appears likely that this technique will rapidly find widespread application. Many compounds that are currently regarded as only being available in powder form are potentially characterizable as microcrystals; this approach would considerably simplify the solution of their crystal structures.

3.5.2. Data Collection with Imaging Plates

Imaging plates (IPs) were originally developed for medical radiography as an alternative to film.[113] They offer the advantages of reduced radiation exposure to the patient and less expenditure on consumable materials. Each plate consists of a plastic sheet coated with a thin layer of an organic binder containing a phosphor (e.g. Eu-doped BaFBr). X-ray exposure produces color centers in the phosphor which can subsequently be "read out" by irradiation with laser light and monitoring of the resultant photostimulated luminescence (PSL). In addition, imaging plates have also found use as area detectors in the recording of X-ray diffraction patterns, both in the laboratory and at synchrotron X-ray sources.[114-117]

The use of IPs for the recording of X-ray diffraction patterns has largely been motivated by the need to reduce the radiation exposure required to obtain a given signal-to-noise ratio in the resulting diffraction pattern. However, there are several other advantages associated with their use as area detectors: 1) IPs have a large dynamic range, which permits the recording of the strong and weak data together on a single plate; X-ray film often requires multisheet packs of film. 2) There is effectively no limitation on count rate with imaging plate detectors, unlike pulse-counting devices such as multiwire proportional chambers. 3) The image recorded on an IP is essentially free of distortion, which is a significant improvement over video detectors. 4) IPs offer good spatial resolution. Together, these characteristics lead to a detection system that allows the rapid collection of high-quality diffraction data over a large area of reciprocal space. While this is particularly important in the case of protein samples that are often easily damaged by radiation exposure,[118-121] it is

also of use in time-resolved[122, 123] and diffuse-scattering studies, and the examination of small sample volumes. Furthermore, results obtained by using an imaging plate with short-wavelength radiation have demonstrated a dramatic enhancement in the sensitivity to hydrogen atoms, for example in organic clathrates.[124]

For inorganic compounds, which are not usually sensitive to radiation exposure, the reduction in the time required for the acquisition of a dataset is clearly advantageous, particularly in the case of time-resolved studies such as the examination of the diffuse scattering during a phase transformation in a single crystal of AgZn.[125] It appears likely, however, that the main application will be to high-pressure studies. To date there have been several studies of materials in diamond anvil cells, for example Ag, Mn, Cs, BN, Br, I,[126] InSb, and La_2CuO_4.[127] In such cases the two-dimensional nature of the imaging plate detector combined with suitable integration around the Debye–Scherrer rings recorded on the plate facilitate the collection of data with a reasonable signal-to-noise ratio and a significant improvement in powder averaging. The latter point is important if quantitative analysis of the intensity data is envisaged.

4. Conclusions and Future Prospects

The preceding sections underline the substantial and wide-ranging contributions that the use of neutron and synchrotron X-ray diffraction have already made to our understanding of solid-state chemistry, and the future is certain to bring new and exciting applications of these powerful tools. Furthermore, as a result of recent advances in software, there will be a growing awareness of the scope for combined X-ray and neutron refinements. For example, the simultaneous Rietveld analysis of X-ray and neutron powder data is now possible with the GSAS[128] suite of programs. In a recent study, the structure of $K_{0.5}Na_{0.5}TiOPO_4$ (a material with nonlinear optical properties) was analyzed by this method.[129] The neutron diffraction data gave better precision for the oxygen atoms than was possible with X-ray diffraction data, but the distribution of K^+ and Na^+ ions over the two available cation sites could not be determined, since the neutron scattering powers of potassium and sodium are almost identical.[5] When the X-ray data were included in the refinement, it became clear that sodium occupies one cation site and potassium occupies the other.

Another area in which X-ray and neutron diffraction data have traditionally been combined is in the determination of deformation densities; X–N maps, for example, show how the electron density is redistributed when atoms come together to form molecules.[130] In such experiments the neutron diffraction data is used to determine the nuclear positions and the X-ray diffraction data reveals the electron density distribution. In some cases this may lead to small differences in atomic coordinates between the two types of crystal structure analysis, especially for light elements. While we are unaware of any cases in which X–N maps have been calculated using synchrotron X-ray data, such data has been employed in the calculation of so-called X–X maps.[131] Here the X-ray diffraction data collected at high scattering angles is used to define the nuclear positions and that at low scattering angles provides information on the redistribution of charge density due to bonding. Synchrotron X-ray diffraction potentially offers significant advantages over conventional X-ray diffraction for such studies, in particular a reduction in the effects of extinction and absorption as a consequence of using small crystals at short wavelengths. However, there are several technical difficulties in performing such experiments[131] and further effort is needed in the area.

The examples described in Sections 2 and 3 illustrate many of the strengths and weaknesses of neutron and synchrotron X-ray diffraction for structural studies in the solid state. Whilst neutron diffraction is a mature area that has benefitted from the evolution of high-flux beam reactors and pulsed sources during the last three decades, it continues to play a vital role in key areas such as high-temperature superconductivity and zeolite catalysis. By contrast, synchrotron X-ray methods are less well developed because most facilities have only become available during the 1980s. The construction of advanced synchrotron sources, which operate at higher ring energies and give access to shorter X-ray wavelengths, is well under way in both Europe (the European Synchrotron Radiation Facility, ESRF) and the USA (the Advanced Photon Source, APS). These will certainly open up new possibilities, beyond the ideas discussed in this review. In some areas, particularly light-atom detection and neighboring element contrast, the unique role of neutron diffraction is already under some pressure from experiments with synchrotron radiation, and future developments will certainly lead to further inroads. Nevertheless, there are many experimental applications for which the use of neutron diffraction will continue to be mandatory. These include the study of magnetic materials (notwithstanding the recent advances in the magnetic scattering of X-rays, in particular, resonant enhancement[132, 133]), neighboring element contrast for light elements, and the use of neutron diffraction to give superior precision for most atoms in Rietveld analysis.[68] X-rays and neutron diffraction will always have their protagonists in the crystallographic community, but there will clearly continue to be a role for both methods in solid-state chemistry.

APW would like to acknowledge Christ Church, Oxford (UK) for giving him leave from a Junior Research Fellowship. We are also grateful to Shell for financial support and Dr. R. J. Cernik and Dr. C. J. Howard for providing the data in Figure 3.

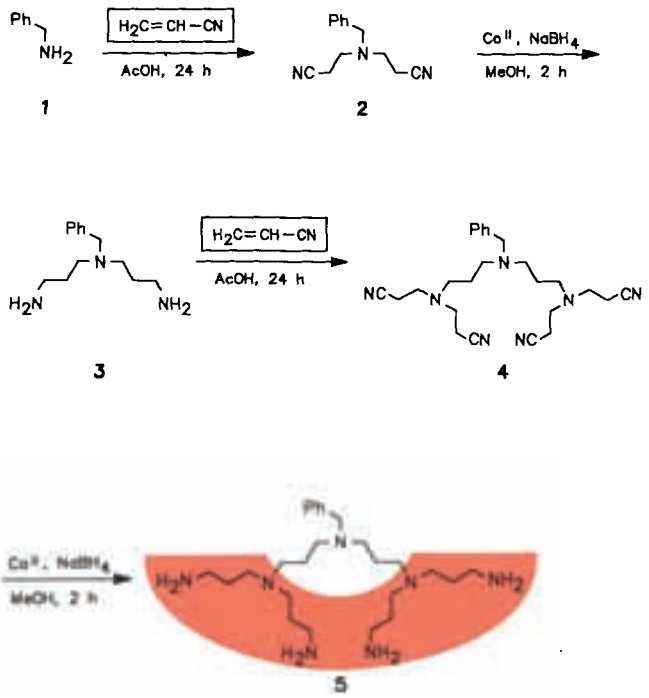
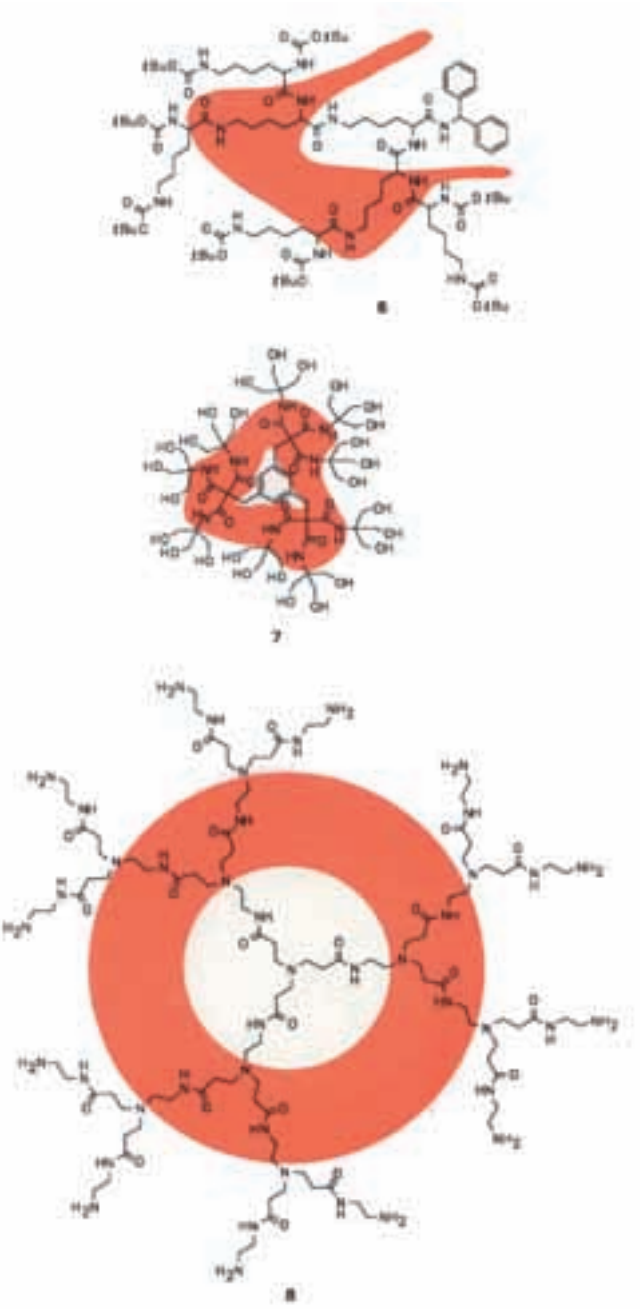
Dendrimers, Arborols, and Cascade Molecules: Breakthrough into Generations of New Materials

By *Hans-Bernhard Mekelburger, Wilfried Jaworek,* and *Fritz Vögtle**

Over a decade ago dendritic (Greek: branched) molecules began to attract ever increasing attention in organic, supramolecular, and polymer chemistry, and recently also in coordination chemistry. The initial impetus can be traced to our cascadelike synthesis of noncyclic, branched polyamines in 1978 (Scheme 1).[1] Thereafter the research groups of



Denkewalter, Newkome, Tomalia, and others expanded this theme considerably (Scheme 2).[2] The extremely branched molecules are mainly synthesized from identical building blocks that contain branching sites, and often have a variety of functional groups on the periphery. These dendrimers[3] are constructed in stages in repeatable synthesis steps (repetitive synthesis strategy[1]). Each reaction cycle creates a new "generation". In the schemes we have highlighted the first, third, and fifth generation in red; the "core" (K) that is usually in the center of the molecule and the even generations are not highlighted (see in particular **27** in Scheme 6). The divergent synthesis method (construction, as it were, from the center outwards) is distinguished from the convergent method in which larger fragments are built up first and then coupled to the core; both methods have their strengths and their weaknesses.[4]



Scheme 2. Three examples of dendrimers [2]: polylysine **6** (Denkewalter et al.), arborol **7** (Newkome et al.), and polyamidoamine **8** (Tomalia et al.).

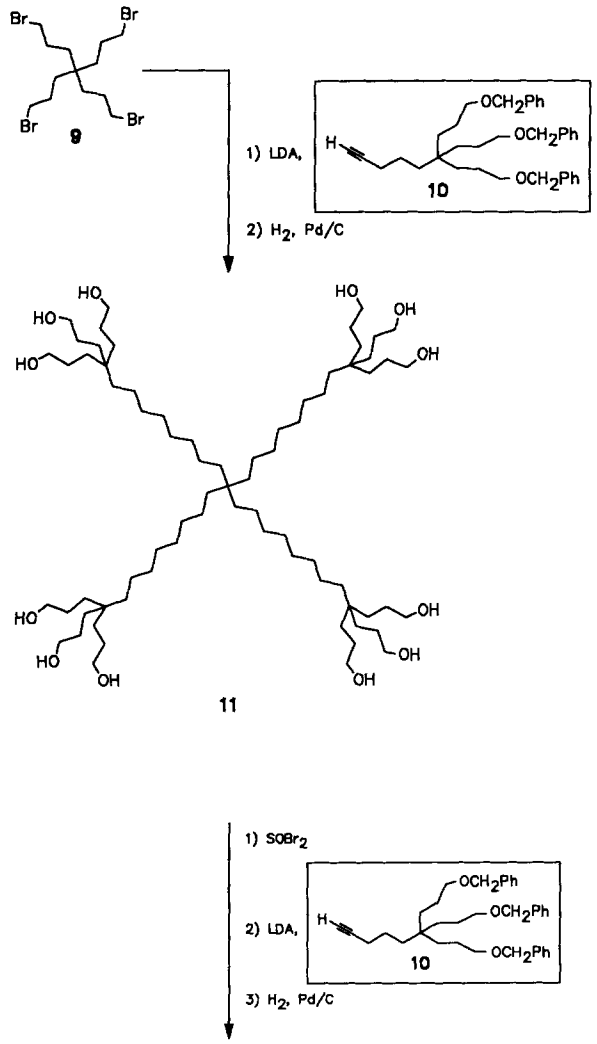
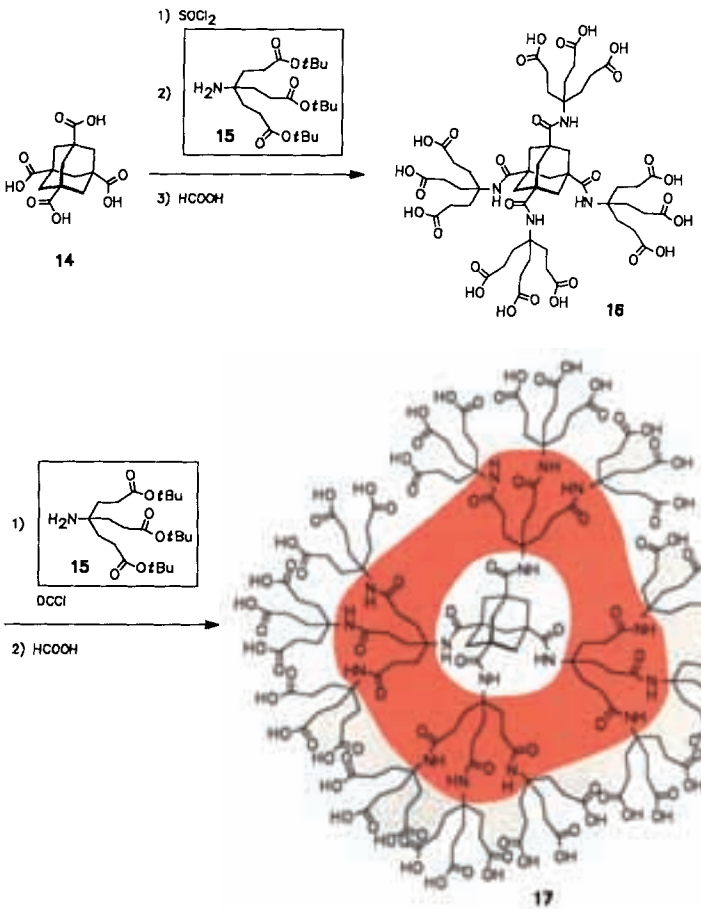
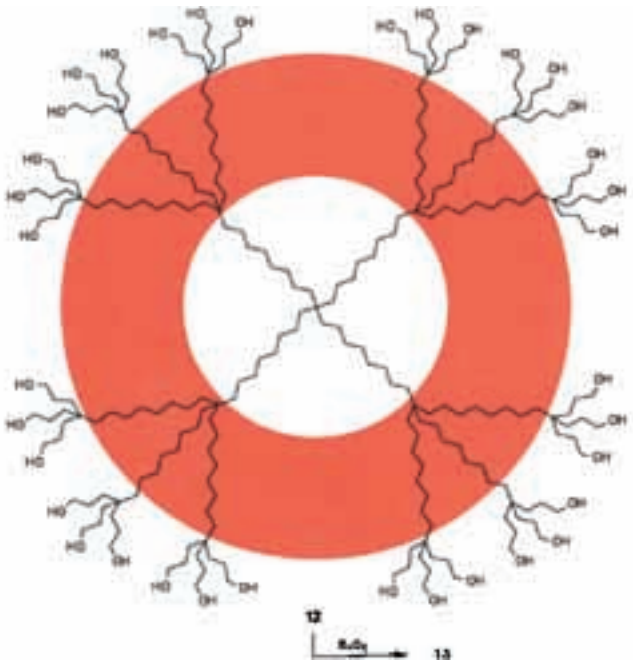




Scheme 4. Preparation of the dendrimer **17** containing 36 carboxy groups.



Scheme 3. Divergent synthesis of arborols with an exclusively hydrocarbon skeleton [7].

The pronounced branching provides the higher generations with an increasingly three-dimensional structure that is characterized by a growing number of cavities within the molecule. One aim in the design of new dendrimers is therefore the formation of niches tailormade for specific guests in order to generate host/guest relationships and aggregates. The dendrimers became even more attractive after it was shown that their surfaces displayed fractal (self-imaging) features. This contribution explores the most important developments in this field.

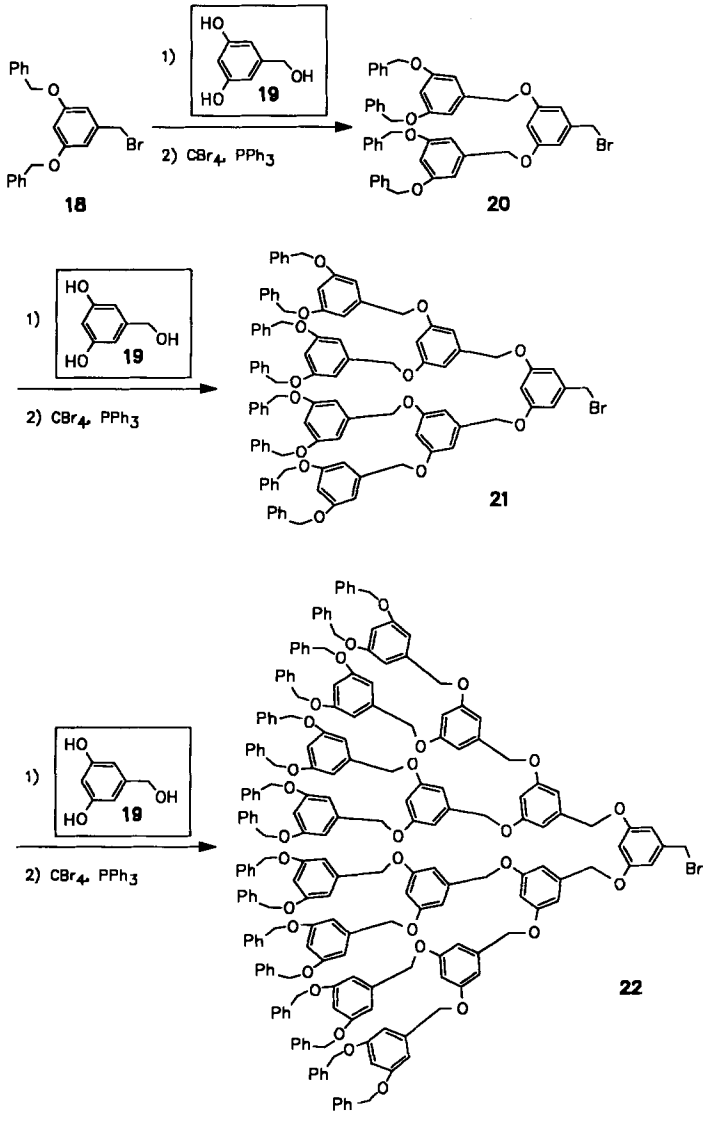
Newkome et al. reported the synthesis of arborols[6] with saturated hydrocarbon skeletons. They have the characteristics of globular micelles (Scheme 3).[7] Treatment of the core unit **9** with the anion of the alkyne **10** yielded the dodecahydroxy compound **11** after cleavage of the protecting groups and hydrogenation of the triple bond. After bromination with thionyl bromide the reaction sequence was repeated. Like its lower analogue **11**, the 36-fold alcohol **12** is very soluble in alcohol, but only slightly soluble in chloroform or water. Finally this second generation polyalcohol was oxidized with ruthenium tetroxide to form hexatriacontacarboxylic acid **13**, from which the water-soluble ammonium and tetramethylammonium derivatives were made. Both these dendrimers accept nonpolar molecules (for example, diphenylhexatriene, chlorotetracycline, or pinacyanol chloride) as guests in the niches within their lipophilic framework. They do not aggregate and can therefore be considered "unimolecular micelles".[8]

Newkome also approached the preparation of micellar dendrimers with a hydrophilic surface and a compact lipophilic interior from the core building block adamantanetetracarboxylic acid (**14**, Scheme 4), lengthening the chains through the amide bonds.[9] Each amine molecule **15** has three *tert*-butyl ester groups. Their hydrolysis yielded the dodecacarboxylic acid **16**, which was again treated with the amine **15**. Another hydrolysis afforded the water-soluble second generation dendrimer **17** containing 36 carboxyl groups at its periphery.

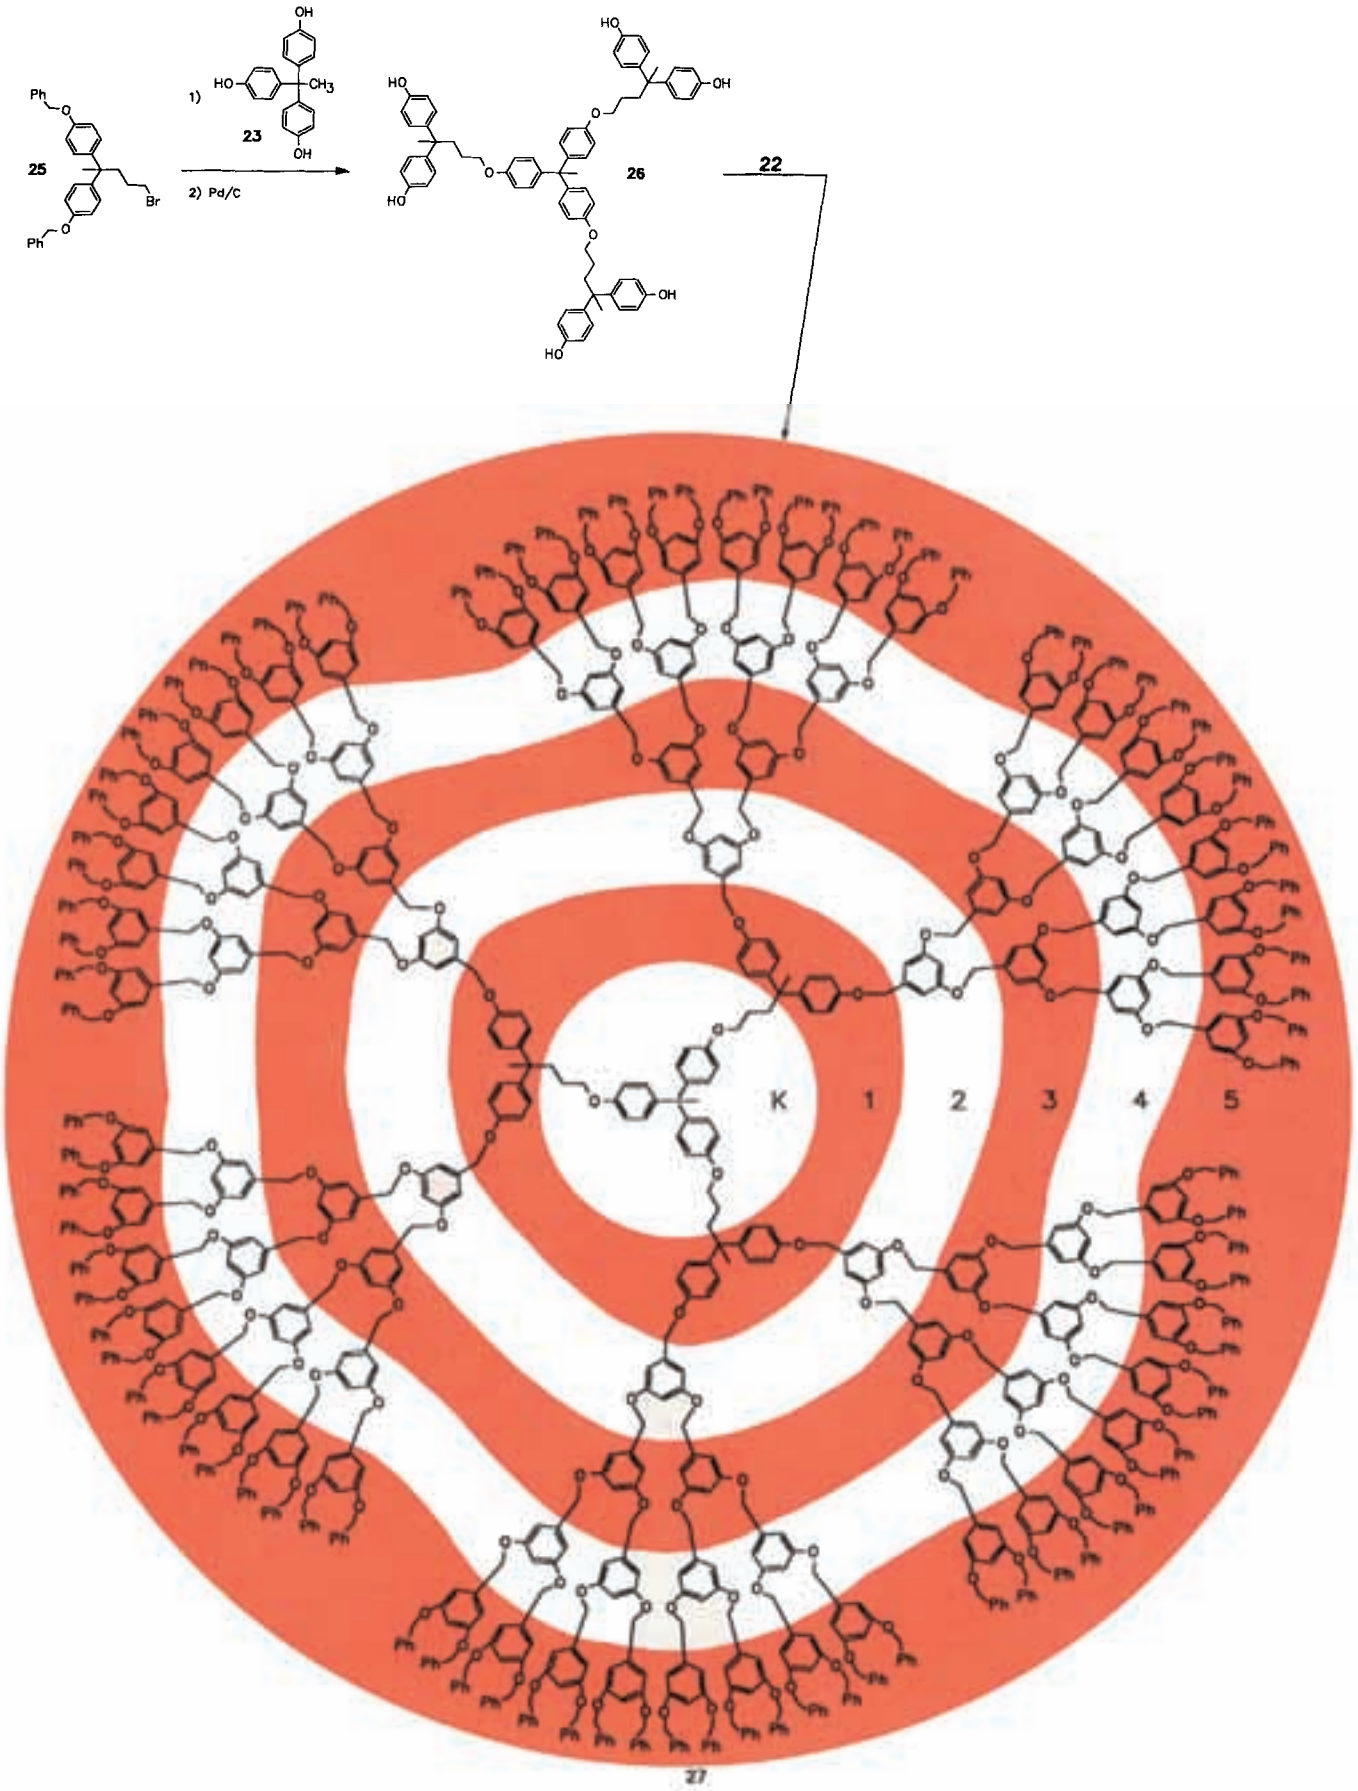
Recently the same author reported on poly(amidoalcohol)s with two spherical head groups joined to a central C–C triple bond through alkyl chains.[10] These dumbbell-shaped arborols form rodlike structures constructed by helical or scissorlike stacking, which can in turn cluster together to form aggregates of higher order. This property is reflected in the macroscopic tendency to form thermally reversible aqueous gels.

Fréchet et al.[4] employed the convergent method to synthesize dendritic polyethers up to the sixth generation. Bromide **18**, which is at the periphery of the dendrimer and contains two benzyl ether units, was treated with 3,5-dihydroxybenzyl alcohol **19**, a monomeric building block (Scheme 5). On reaction with tetrabromomethane and triphenylphosphane in excess, another bromide (**20**) was formed that could be extended with the monomeric building block **19** to give the second generation. At the end of the synthesis the reaction of the wedge-shaped bromides (e.g. **20**, **21**, **22**) with the trifunctional core unit afforded spherical polyethers such as **24**. In a variation of this synthesis, even unsymmetrically substituted polyethers could be obtained.[11] The attraction of the convergent method is the small number of molecules that are involved in the reaction steps to give each successive generation. The large excesses of reagents can be avoided, which results in good yields. However, for higher generations the yields decrease because of increasing steric hindrance at the reacting functional groups. The use of more flexible monomers (e.g. **25**) should therefore provide better yields. After convergent synthesis and cleavage of the benzylic protecting groups, Fréchet et al. obtained the sixfold phenol **26** (Scheme 6) that was used as extended core for a divergent procedure in a reaction with the bromide of the third generation (**22**) to give the spherical dendrimer (**27**).[12]

Miller, Neenan et al.[13] also used the convergent method to prepare aromatic hydrocarbon dendrimers. Aryl boronic



Scheme 5. Convergent synthesis of polyether dendrimers [4].



Scheme 6. Convergent–divergent synthesis of larger polyethers through incorporation of more flexible building blocks [12].

acids were coupled to the building block 3,5-dibromo-1-trimethylsilylbenzene in a Suzuki reaction, and the aryltrimethylsilane was subsequently transformed into an aryl boronic acid again. This procedure yielded poly(1,3,5-phenylene)s after the final coupling with the core molecule 1,3,5-tribromobenzene. The hydrocarbon of the third generation, containing 46 benzene rings, was obtained in a combined convergent–divergent synthesis. These dendrimers, with the exception of the sparingly soluble first generation, dissolve in THF, toluene, and chloroform and are thermally stable.

Only a short while ago Moore et al. [14] succeeded in preparing particularly stiff dendrimers constructed from phenylacetylene building blocks. Using the palladium-catalyzed Heck reaction in a convergent synthesis, they obtained the largest pure hydrocarbon yet isolated (molecular mass over 14 kDa). The incorporation of numerous *tert*-butyl groups on the periphery of the molecule ensured an excellent solubility in organic solvents.

Masumune et al.[15] reported the synthesis of silicon dendrimers[16] up to the third generation. The repetitive sequence consists of two steps: the terminal Si–H groups are first transformed catalytically into Si–OH groups, and then the new generation is produced in a reaction with chlorosilane building blocks. The surface of these dendrimers is therefore covered with many Si–H groups. Their facile transformations make other functional groups readily accessible, which enables the modulation of the physical properties of these dendrimers.

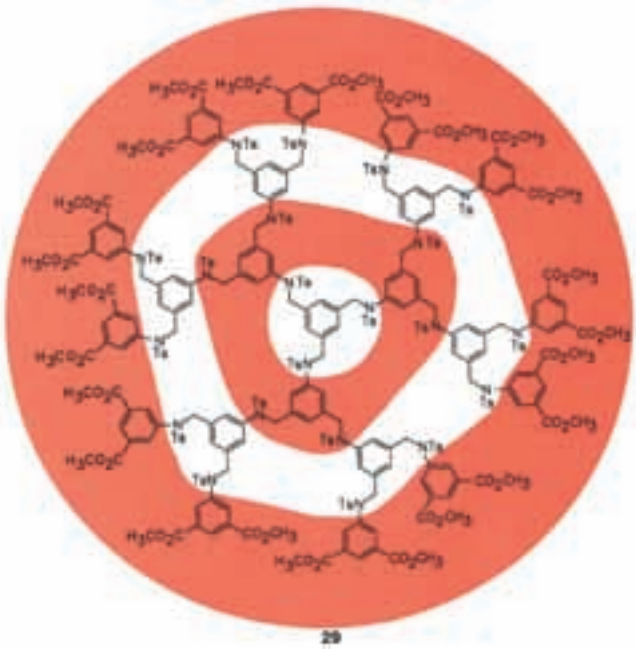
Dendrimers having charges within the cascade structure were described by Engel et al. These polyphosphonium[17] and polyammonium salts[18] contain tris(*p*-methoxymethylphenyl)phosphane and triethanolamine as monomeric building blocks, respectively. Whereas the ammonium dendrimers are soluble in alcohols and particularly in water, the phosphonium dendrimers display somewhat different behaviour. To the second generation they are soluble in organic solvents and slightly soluble in water; however, from the third generation the solubility is very limited.

Recently Shinkai et al.[19] reported the first arborols incorporating crown ethers. After the divergent method failed to achieve the desired goal, a dendrimer of the second generation was synthesized stepwise in a convergent process through amide bonds. Apart from aromatic building blocks it contains nine diaza[18]crown-6 units. The oily substance should be able to bind alkali metal ions selectively, but this has not yet been demonstrated.

Polynuclear transition metal complexes of a dendritic nature were first described by Balzani et al.;[20] their building blocks are not linked exclusively by covalent bonds but also by metal–ligand bonds (Scheme 7). In a divergent synthesis strategy ruthenium(II) ions form complexes with ligands of the 2,3-bis(2-pyridyl)pyrazine type and are therefore deliberately placed a definite distance apart. The complex **28** containing 22 metal centers can be oxidized and shows luminescence effects.

We prepared dendrimers with large monomeric units in a divergent synthesis (Scheme 8).[21] Readily soluble dendrimers were formed up to the third generation (**29**). This general synthesis can be extended to other core units and to higher generations. Further synthetic goals are "functional dendrimers" with properties characteristic, for example, of dyes, complexing agents for metals, or liquid crystals. For instance, a dendrimer containing six azobenzene groups undergoes reversible switching processes on irradiation with light of a suitable wavelength.[22]

Scheme 7. Dendritic metal complex **28** containing 22 ruthenium ions [20].



Scheme 8. Aromatic–aliphatic dendrimer **29** containing 24 carboxy groups [21].

All these examples from the past two years show that dendrimers (or cascade molecules) are a topical field of research[23] because their hierarchical architecture promises interesting properties and applications (the micelles are only one example). Nevertheless, the properties of strongly branched molecules are largely unknown and await discovery. In this connection the chemical reactions between multifunctional dendrimers, for example, may be mentioned, as well as dendrimers with many chiral elements, which might display chiroselective recognition.

Above all, the synthesis of large, branched molecules bordering on polymers challenges synthetic and analytical chemists alike. A large number of reaction centers or considerable steric congestion hinders the synthesis of monodisperse molecules. The classical methods of analysis in organic chemistry are sometimes pushed to their limits. NMR spectra and elemental analyses are becoming increasingly less informative, and mass spectrometry of very heavy molecules also is not without problems. Likewise the nomenclature of cascade molecules according to the common rules has its difficulties. The names become extremely long and the fundamental structure of the molecule is not immediately clear from them. And then the effort of naming a dendrimer of the second generation is out of all proportion. Newkome et al.[24] therefore recently proposed a new system that reflects the structure in the sense that it names the molecule from the core towards the periphery.[25] Furthermore, the class of compound becomes clear, since the names begin with "Z-Cascade", where Z is the number of functional groups on the periphery.

In conclusion, these dendritic compounds cross the boundaries of classical organic chemistry and as new materials will penetrate deeper into the topical fields of "nanostructures", supermolecules, and polymers in the future. Even now the dendrimers form a bridge to "soft materials", as de Gennes called polymers, tensides, liquid crystals, and colloids in his Nobel lecture.[26]

The Structure of Water—A Mixture of Cubes and Planar Four-Membered Rings?

By *Helmut Bertagnolli**

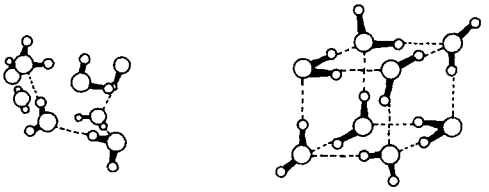
The structure of water—a theme without end? One may have been under the impression that the structure had been explained. Many X-ray, neutron, and electron diffraction measurements have been carried out and modern spectroscopic techniques utilized to determine the microscopic structure of water.[1] Statistical-mechanical calculations and computer simulations have used these results and concluded the correctness of the applied model. However, all this has been put into question, since Benson and Siebert[2] proposed a completely different model for the structure of liquid water.

The starting point of all previous calculations had been the intermolecular interaction potential, which was determined with the help of extensive quantum-mechanical procedures. From this potential, statistical-mechanical methods[3] were used to calculate thermodynamic quantities and provide information about the microscopic structure from the calculation of pair distribution functions $g_{\alpha\beta}(r)$, which give the probability of finding an atom of type β at a distance r from an atom of type α. These functions contain, however, one-dimensional information only, and the inference of a three-dimensional structure cannot be clearly drawn.

The computer simulations[4] also start with the intermolecular potential. If the positions and velocities of all particles are known at a certain time, the forces acting on the particles can be calculated from the potential, and the positions of the particles can be determined at a later time. In this way the microscopic structure and its development with time can be simulated. This procedure is known as molecular dynamic simulation. The Monte–Carlo method dispenses with the strictly deterministic solution of the motion equations; here the particles are shifted at random, and the change of the total energy is used as the criterion for whether this shift can be accepted or not. Thus, both methods generate a set of configurations, which should be representative for the microscopic structure. By averaging all the configurations, both microscopic and also macroscopic physical-chemical quantites can be calculated.

In order to test the results of the computer simulations, preferably those quantites are used that provide information about the short-range order, for example, the pair distribution functions $g_{\alpha\beta}(r)$, which can be determined from diffraction experiments. In contrast, the energy of the system and its derivation with respect to the volume or temperature, which by definition leads to the pressure and the heat capacity, respectively, at constant volume is seldom used. The latter two quantities in particular are not entirely suitable for a comparison, since they are defined as ensemble average values, and the size of the systems, despite powerful computers is limited to edge lengths of approximately 100 Å. According to these calculations, the structure of liquid water resembles a disordered network with partly formed hydrogen bonds. Thus, the structure of water appeared to have been explained, and research consequently turned to the simulation of more complex systems, for example, the treatment of phase boundary surfaces.

However, is this picture correct? S. W. Benson and E. D. Siebert[2] do not think so. They dispense with extensive computer simulations and attempt to derive the structure of water based on thermodynamic quantities. The starting point is the energy of sublimation of ice. The authors assume that this energy is used mainly for breaking of hydrogen bonds and from this estimate the energy of one hydrogen bond. With this value and the assumption that for the melting of ice only hydrogen bonds are broken, the number of the hydrogen bonds still intact in liquid water per H_2O molecule is determined to be approximately 1.75 from the enthalpy of melting. In the opinion of the authors—and this is a decisive assumption—discrete units must occur in liquid water, which can move independently of each other. However, which structures might these units have that contain 1.75 hydrogen bonds per H_2O molecule, but possess no ring strain? The simplest ring structure is a cyclic tetramer consisting of four H_2O molecules. If two tetramers dimerize, a cube is formed with eight H_2O molecules and 1.5 hydrogen bonds per water molecule, thus a number, which is already closer to the value of 1.75. Furthermore, if the octamers are linked through hydrogen bonds, the missing 0.25 hydrogen bonds per H_2O can be easily explained. Thus, the structure of water is a mixture of tetramers and octamers! Scheme 1 shows (left) the classical perception of the microscopic structure of water and (right) the structure of the octamer.



Scheme 1.

This formulation could be easily dismissed as unproven if Benson and Siebert had not used it to explain the heat capacity of water. They assume an ideal mixture of n_o mol H_2O, bound in the octamers, and n_t mol H_2O, bound in the tetramers, with $n_o + n_t = 1$, whose mixture enthalpy is given by (a).

$$H_{mix} = n_o H_o + n_t H_t = H_o + n_t(H_t - H_o) \quad (a)$$

The heat capacity C_p of the mixture is defined as the derivative of H_{mix} with respect to the temperature [Eq. (b)],

$$\left(\frac{dH_{mix}}{dT}\right)_p = C_p = C_{p,0} + n_t \Delta C_p \quad (b)$$

with $\Delta C_p = d(H_t - H_o)/dT$. This formulation would be correct if an equilibrium between tetramers and octamers did

[*] Prof. Dr. H. Bertagnolli
Institut für Physikalische Chemie der Universität
Pfaffenwaldring 55 D-W-7000 Stuttgart (FRG)

not occur and thus n_t is temperature dependent. Formula (b) is thus to be replaced by Equation (c).

$$C_p = C_{p,o} + n_t \Delta C_p + (H_t - H_o)\left(\frac{dn_t}{dT}\right) \quad (c)$$

This term is new. It completely changes the calculation of C_p. The isomerization equilibrium contributes to the heat capacity. To calculate the heat capacity Benson and Siebert estimate the reaction entropy $\Delta S°$, the reaction enthalpy $\Delta H°$, and from this, the free reaction enthalpy $\Delta G° = \Delta H° - T\Delta S°$ on the basis of known data. The equilibrium constant K can then be calculated from $\Delta G°$ according to $-\Delta G° = RT \ln K$ and once the equilibrium constant is known, from that n_t can be calculated. The calculation of the change of n_t with temperature is then also no longer difficult. Since $\Delta H°$ is known, the temperature dependence of the equilibrium constant can be calculated according to van't Hoff's equation $d(\ln K)/dT = \Delta H°/(RT^2)$, and from this also that of n_t, that is, dn_t/dT can be determined. There still remains the estimation of the quanities $C_{p,o}$ and ΔCp. This is achieved by the calculation of the librational and torsional degrees of freedom of the octamer and the tetramer according to the classical formula: per vibrational degree of freedom the contribution is given by the value of the gas constant R. The remaining internal motions of one molecule relative to another within the cluster have been assumed to be icelike.

Thus, all that is needed is the application of classic physical-chemical formulas! And what is the result? The temperature dependence of the heat capacity between 0 and 100°C is reproduced with an accuracy of ±2%. An astounding result! The introduction of an equilibrium between two forms of water clusters which additionally contributes to the heat capacity is the decisive factor. This is certainly an aspect, which so far has not received enough attention and which will lead to a re-examination of the calculation of heat capacities, particularly for systems with hydrogen bonds such as formic or benzoic acid. In comparison, the kind of isomers is of minor significance. The numerical values suggest an equilibrium between tetramers and octamers, however, as the authors admit, it could also be one between pentamers and decamers. Perhaps completely different forms of water clusters are also possible. The postulated structures of tetramers and octamers are contrary to the results of the diffraction experiments, which one might say deliver the spatial average from a snapshot of the liquid structure. For an assumed O–O distance of 2.89 Å, distances of 4.09 Å and 5.01 Å should be found preferably for the existence of square tetramers and cubic octamers, respectively. However, the second maximum in the pair distribution function lies at 4.5 Å,[1] which is more indicative of a tetrahedral structure. This indication, however, does not detract from the fundamental significance of this work.

A Milestone in Genome Sequencing: The Complete DNA Sequence of the Yeast Chromosome III**

By *Ernst-L. Winnacker**

Baker's or brewer's yeast is one of the most useful organisms in the immediate environment of our own species *Homo sapiens*. Though we make great use of it for our nourishment and for our pleasure with equal enthusiasm, there is more to yeast than just these aspects. For decades, it has been one of the favorite and most important tools of biochemistry and molecular biology. It is cheap and easy to manipulate, but it is nonetheless not simply a bacterium. Yeast is a eucaryotic microorganism with (almost) all the attributes of higher cells, including a cell nucleus, cellular organelles such as mitochondria and lysosomes, and even such a typical characteristic of higher organisms as sexuality. The great biochemists of this century, from Eduard Buchner to Hans Krebs and Feodor Lynen, to name but a few, made just as much use of yeast in their experiments as do today's geneticists and molecular biologists. Without these studies on baker's yeast, what would we know today about the structure of the cell membrane, about the cell cycle, mechanisms of signal transfer, and intracellular protein transport?

In spite of this background it may come as a surprise that it is only eight years ago that the exact number of chromosomes in yeast, namely 16, was first determined. This result, which at a first glance is anything but exciting, nonetheless created a furor in the field when it first appeared. It was not simply the result of a glance through a microscope—yeast chromosomes are far too small for that—but the outcome of applying a novel electrophoresis technique, pulsed field gel electrophoresis. In this method, developed by Cantor and Schwartz,[1] a sophisticated arrangement of electrodes is used and pulses of current are applied in alternating patterns, making possible the separation of very large biological macromolecules, even as large as entire chromosomes. These

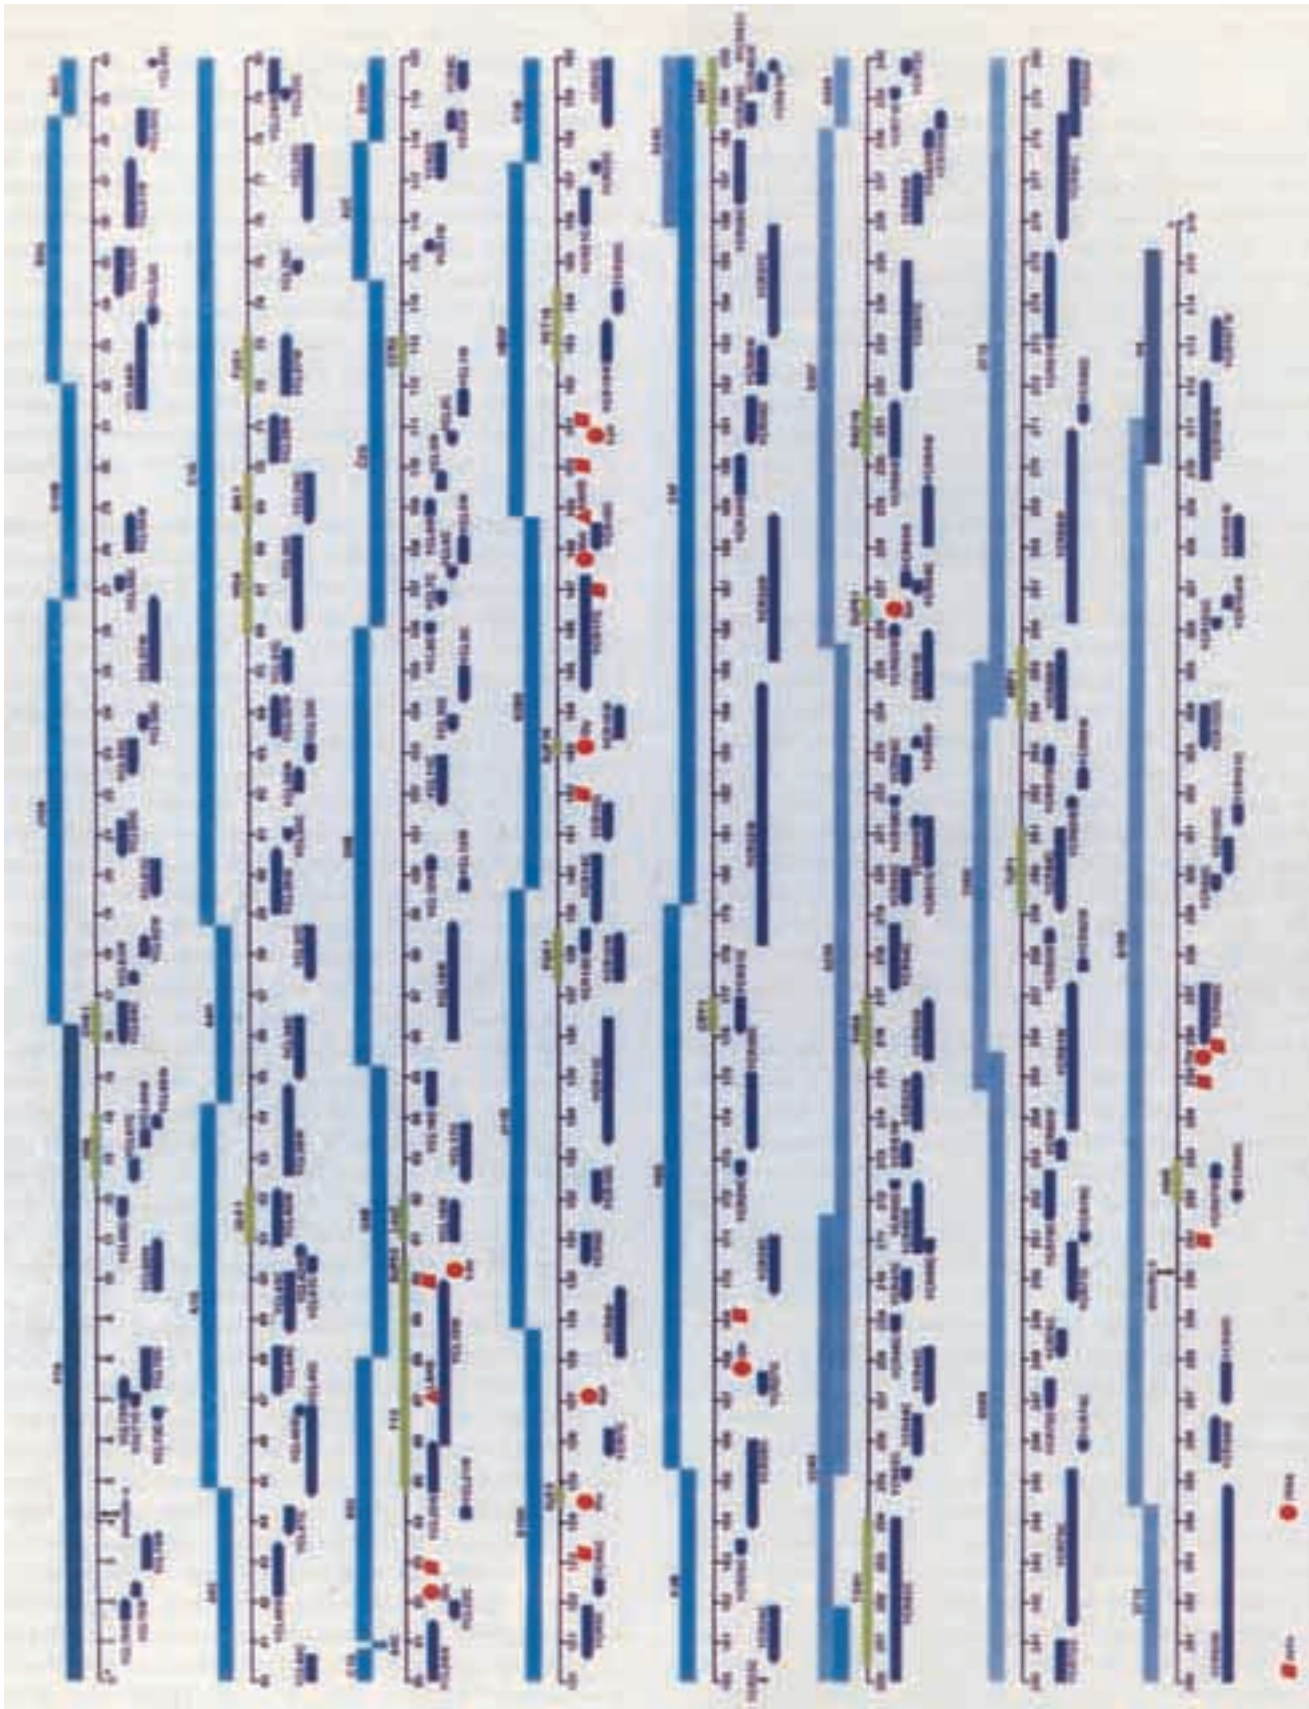

Fig. 1. Positions of the open reading frames and the known genetic markers on chromosome III of yeast.

can hence not only be counted, but can actually be isolated. This method has therefore become one of the decisive prerequisites for the elucidation of the structure of individual chromosomes of living organisms, including those of baker's yeast.

A few weeks ago the first result of these endeavors was revealed with the publication, by a consortium of 35 European laboratories, of the total DNA sequence of chromosome III from the yeast *Saccharomyces cerevisiae*, with its 315357 base pairs (Fig. 1).[2] The project, which began three years ago and for which the European Commission paid the 147 participating scientists 5 ECU per base pair (1 ECU = ca. 2 DM or $ 1.35), was initiated and coordinated by the Belgian biochemist André Goffeau. He was assisted by Stephen G. Oliver of the Manchester Biotechnology Centre UMIST in England, who as co-coordinator was responsible for the distribution of the DNA samples, and by a group at the Martinsried Institute for Protein Sequences (MIPS) at the Max Planck Institute for Biochemistry, who carried out the evaluation of the sequence data.

Whether this news is worth a "Highlight" in *Angewandte Chemie* is indeed a good question. The technique used for DNA sequencing is in fact by no means new; the authors themselves point out that only 25000 base pairs, that is, approximately 7%, were sequenced by new, automated sequencing procedures, while the rest were assigned conventionally and by hand, based on the work of Sanger in 1977. In addition, chromosome III of yeast is the third smallest of the yeast chromosomes and represents only about 2% of the entire yeast genome. It is therefore only a drop in the ocean on the way to sequencing the whole genome, with its 14 million base pairs (14 megabasepairs (MBp)); this "drop" would nonetheless fill some fifty pages of *Angewandte Chemie*.

And yet the importance of this result cannot be overestimated. It represents the largest continuous DNA sequence that has ever been determined, a record held until now by the genome of the cytomegalovirus with its 230000 base pairs. It is the first sequence of a complete, intact chromosome, and is therefore a milestone on the way to the characterization of human chromosomes, the eventual goal of these endeavors. The logistics required for the project should not be underestimated either. Thirty-five European laboratories were successfully harnessed together over a period of two and a half years to one scientific target. It is such an achievement which makes this project a model and example for the even larger, global arrangements which will be required to sequence the human genome. Finally, however, this result is fascinating mainly because of its wealth of scientific data and surprises. The sequence contains 182 open reading frames coding for proteins longer than 100 amino acids. On the classical genetic map, only 34 genes were marked on chromosome III of yeast. Thus, even in such a well-studied organism as baker's yeast, classical genetic and biochemical methods had only been able to localize 20% of the actual number of genes. If one extrapolates this result to the human genome, which is genetically much less studied than that of yeast, then the estimate of the number of our genes must be revised dramatically upwards, to 500000 or more. This is also a result arising from this study.

However, the most interesting aspect of a DNA sequence is not so much the mere sequence of its base pairs, but how it is converted into biological function. DNA is essentially nothing more than a carrier of information, though this information exists at multiple levels, and includes many kinds of signals for a multitude of functions, not least those for its own replication. The best known of these functions is, however, translation into proteins, which is why first priority in analyzing a DNA sequence is always given to the search for open reading frames. This was the case here, too. Since yeast genes only rarely come in pieces, the problem was not too difficult to solve. The decisive question which remained, however, was that of assigning biological functions to the open reading frames that had been found. To answer this question, at least two options are open to the biochemist or molecular biologist: sequence comparisons with known sequences, and the so-called Knock-Out (KO) technology.

Computer-assisted sequence comparisons are a routine procedure today, and because of their great usefulness, they are even carried out in our beginners' practical courses.[3] The programs used must always be able to fulfill two requirements: they must be able to find similarities between two sequences, and measure the significance of these similarities. In other words, they must be able to determine whether the similarity found is a purely chance one, or whether it represents real relatedness. The extreme case, complete identity, is, of course, simple to analyze. If two protein or DNA sequences are identical over long stretches, this cannot be due to chance. The situation becomes more difficult, however, if the two sequences contain gaps, if conservative amino acid exchanges occur, or if proteins are pieced together from sections or domains of various other proteins. These are of course the situations which are most interesting to the biochemist, since biological function may be conserved despite considerable amino acid exchanges. It requires great experience to carry out such "low-stringency" searches in a manner which allows identification of functionally related proteins on the basis of only slight similarities. The number of sequences known is growing rapidly—at the end of June 1992 there were approximately 90 million base pairs in almost 60000 reading frames—and with today's programs the assignment of unknown reading frames to particular protein families is becoming more and more reliable.

In the specific case of chromosome III of yeast such assignments were possible for 54 of the 145 unknown reading frames. They showed homologies to, for example, protein kinases, ion channels, methyltransferases, peptidyl-prolyl-*cis*,*trans*-isomerases, and G-proteins. Remarkably, homologies were found not only to the corresponding proteins from yeast, but also to organisms as diverse as the fruit fly *Drosophila*, the frog *Xenopus*, tobacco, and even *Homo sapiens*. This result leads to a new definition of the gene. If it is really true that genes from organisms representing the whole spectrum of life on earth are not only closely related to those of yeast, but can even replace them functionally, then the gene can no longer be defined in an organismic sense. Instead of speaking of a yeast gene, a fly gene, or a human gene, we must regard the gene as a continuum of biological information: Nature has conserved its function for as long as it has proved serviceable over millions of years.

In the present case, the most unusual of the relationships found was a high homology to the gene *nif*S from the nitrogenase operon of nitrogen-fixing bacteria (Fig. 2). Yeast can-

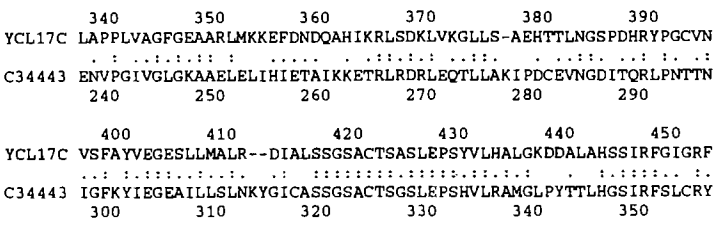

Fig. 2. Sequence comparison between a segment of reading frame YCL17C of yeast chromosome III and the *nif*S gene product from *Anabaena*. Identical bases are marked by two dots, exchanges between functionally related amino acids (e.g. between valine and isoleucine) by one dot. Gaps in the sequence are bridged with hyphens. The homology in this segment is 43.6% over a total length of 383 amino acids.

not fix nitrogen, but this gene is nonetheless essential for its existence. It must therefore code for a gene product which in the relevant bacteria is concerned with the formation of the nitrogenase operon proteins, but can, and must, also carry out its role in the biosynthesis of other proteins. It is assumed to fulfill a "modulating" function, that is, a function of general nature which may perhaps play a part in the formation of tRNA from its precursors, or in protein folding.

Once the search for protein families has been exhausted, it can be extended to a search for protein domains. One of the most important advances of recent years has been the recognition that proteins with different function may carry domains with related sequences, each with a particular partial functionality. Membrane proteins of any category are characterized by trans-membrane domains which anchor them in the membrane; DNA-binding proteins reveal so-called zinc-finger or helix-loop-helix motifs, which help them to recognize specific DNA sequences; short sequences of basic amino acids predestine the protein for the cell nucleus, while nucleotide-binding domains, at which ATP is bound and hydrolyzed, are found in specific types of transport proteins. The search for these and other domains was also successful here, so that in the end it was possible to assign particular functions to about 42% of the unknown reading frames using the sequence comparison procedure. Biochemistry will have to check each of these predictions individually, but this "computer biochemistry" makes the task significantly easier.

The second way in which the function of the unknown reading frames may be investigated is by so-called gene inactivation. This process, also called "knock-out", is based on the principle of general genetic recombination.[4] It involves the exchange of DNA between two identical (homologous) DNA double strands, and is normally responsible for the genetic diversity in the offspring of sexual reproduction. If the maternal and paternal chromosomes come to be aligned with each other after fertilization, an actual, physical exchange of DNA takes place between the two strands, between identical sequences on the chromosomes, leading to chromosomal chimeras. In general this process takes place statistically, that is, at random along the chromosomes. It is therefore impossible to predict which sequences derive from the paternal and which from the maternal chromosome. An effect on the phenotype is of course only seen if the two differ at a particular position. Even within one and the same species such differences are not rare, which explains the variations in phenotypes observed between parents and their offspring.

Under certain circumstances, the process of recombination can also take place in a directed manner. If a plasmid bearing only a short DNA sequence is introduced into a living cell, such as a yeast cell, then recombination events between this sequence and its partner on the yeast chromosome will lead, at a certain frequency, to the substitution of the endogenous gene by the exogenous one. If the reading frame in the exogenous gene has previously been destroyed by mutation, then this mutation is transferred into the chromosome by the recombination process, and the endogenous gene is thereby inactivated. This process is not particularly efficient, so an additional gene is usually added to the inactivated reading frame, often an antibiotic resistance gene. In this way inactivation of a particular gene is coupled to a selection marker so that in the presence of the antibiotic only the inactivated cells can grow, and they can thus be separated easily from those in which the exchange has not occurred. The selected cells can then be studied to determine what effect inactivation of the gene in question has on each cell.

For 55 of the unknown reading frames on chromosome III, this has already been carried out. For three of the genes, their deletion was lethal for the cell; for 24 of the others, a series of phenotypic changes were observed, ranging from heat- or cold-sensitivity, to sterility or to morphological changes. Although the deletions were compatible with life, they nonetheless led to recognizable changes. The biochemical defects responsible for these changes can now be analyzed in detail. For about half of the reading frames, however, their loss had no perceivable effects on the phenotype. This was extremely surprising, because it cannot seriously be suggested that half of the genes in yeast are dispensable for its existence. Even if these genes simply represented redundant systems, which Nature has built in to ensure survival of the species, they must, in the end, have provided a selective advantage of some sort. In the course of the millennia, yeast would surely have lost any gene sequences for which it had no use.

The knock-out experiments therefore show that molecular biology is far ahead of biochemistry in this field. They also prove how little we really know, even about an organism such as baker's yeast, which seemed to have been exhaustively studied. In many ways, then, the sequence determination of yeast chromosome III opens up undreamed of perspectives for a new biology and biochemistry of yeast. Not only is the number of genes vastly greater than previously thought, but the analysis of the function of their products afforded associations with known biochemical functions for only half of the genes. What is concealed behind the other half will now have to be shown by future studies.

Presumably, similar veins of gold can be expected to be unearthed by the genome projects of many other organisms which have been initiated, ranging from the nematode *C. elegans*, to the mouse-ear cress (Arabidopsis) *A. thaliana*, to *Homo sapiens*. Even the most enthusiastic supporters of these projects could not have expected such interesting scien-

tific perspectives to emerge. The discussion of the sense and nonsense of the projected mapping and sequencing of the human genome has thus died down to a large extent. Its direction has been set worldwide for some time now. A detailed description of the human genome project is beyond the scope of such a highlight, but it is clear that its dimensions are orders of magnitude greater than those of the yeast project. The human genome is approximately 300 times larger than that of yeast. In the past year, on average, one human gene was identified and sequenced every day around the world. For 500000 genes, then, our present technology would require several hundred years to complete this project. To predict with optimism that it will be finished in 15 to 20 years therefore requires not simply an improvement of current technologies, but the development of fundamentally new methods for mapping and sequencing. These may be in sight. Given the results that can be expected, it is to be hoped that Germany, including the pharmaceutical industry, will also take an intensive part in this project. Industry as well as biomedical research will be able to make rapid use of the possibilities described.

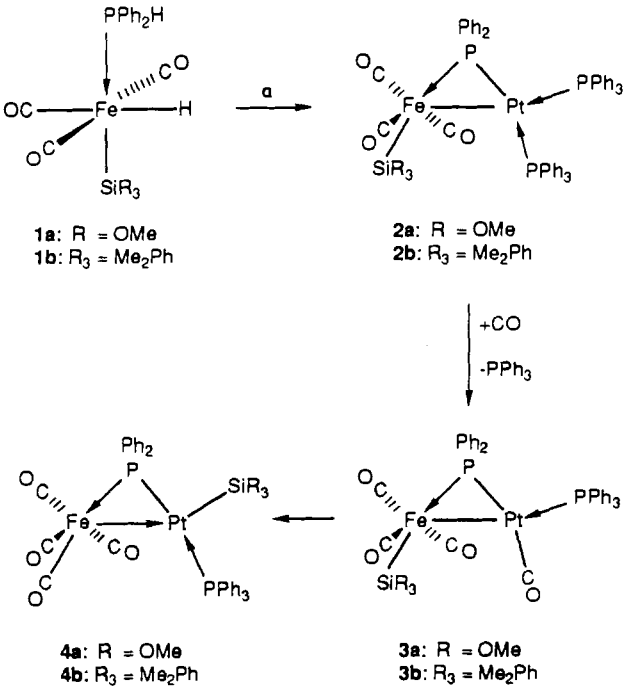
The First Metal–Metal Silyl Migration in a Heterobimetallic Complex, and the Structure of the Rearrangement Product $[(OC)_4Fe(\mu\text{-}PPh_2)Pt\{Si(OMe)_3\}(PPh_3)]$ (*Fe–Pt*)**

By *Pierre Braunstein,* Michael Knorr, Brigitte Hirle, Georg Reinhard,* and *Ulrich Schubert*

Dedicated to the memory of Ernest Colomer

Metal–silicon single or multiple bonds are key functionalities in a number of important catalytic transformations, such as the hydrosilylation of alkenes and alkynes and the coupling of organosilanes by dehydrogenation.[1] This largely accounts for the considerable research endeavor devoted to the organometallic chemistry of silicon. Whereas migration of a metal-bound silyl group to a ligand has been observed in mononuclear[2] and cluster compounds,[3] we report here on the first examples in molecular chemistry of the migration of a silyl group from one metal center to another. In this process, which requires very mild reaction conditions, the silyl group is transferred from the iron to the platinum center in Fe–Pt bimetallic complexes.

Oxidative addition of $[Fe(H)\{Si(OMe)_3\}(CO)_3(PPh_2H)]$ (**1a**)[4b] to $[Pt(C_2H_4)(PPh_3)_2]$ across the P–H and Fe–H bonds (Scheme 1) afforded the Fe–Pt complex **2a** with a phosphido bridge.[4a, 6] Despite the lability of the PPh_3 ligand (see reaction to give **3a**), the ^1H NMR spectrum of **2a** shows a singlet at $\delta=3.68$ for the nine equivalent methoxy protons, which rules out a dative MeO → Pt interaction and thus the occurrence of the unusual η^2-μ_2-SiO coordination recently discovered in some Fe–Pd, Fe–Pt, and Fe–Rh complexes.[4] When CO was bubbled through a CH_2Cl_2 solution of **2a**, substitution of PPh_3 occurred, which led to the rapid and quantitative formation of **3a** ($^{31}P\{^1H\}$ NMR monitoring $\delta PPh_2=159\cdot5$, $^1J(Pt,P) = 2657$ Hz). The *cis* arrangement of the P atoms [$^2J(P,P) = 13$ Hz] is consistent with previous observations on $[M(\mu\text{-}PR_2)Pt(CO)(PR_3)]$(*M–Pt*) systems, which revealed the preference of the Pt-bound CO ligand to occupy the position *trans* to the phosphido bridge.[7] The IR spectrum of **3a** contains CO bands for the Fe-bound ligands at 1989 (m) and 1928 (s, br) cm^{-1} and for the Pt-bound CO ligand at 2061 (m) cm^{-1}.



Scheme 1. Synthesis of the complexes **2**–**4**. a) $[Pt(H_2C{=}CH_2)(PPh_3)_2]$, in toluene, 298 K; loss of $H_2C{=}CH_2$ and H_2.

Unexpectedly, complex **3a** quantitatively rearranges in solution within approximately 1 h to its isomer **4a**, in which the Si atom is now bound to Pt, whereas the Pt-bound CO ligand has migrated to the Fe center, as established by an X-ray structure analysis (Fig. 1).[8]

The $^{31}P\{^1H\}$ NMR signal of the phosphido bridge of **4a** now appears at $\delta = 116.9$ and shows a strong *trans* coupling to the PPh_3 ligand [$^2J(P,P) = 308$ Hz]. Interestingly, the po-

sition of the CO bands in the IR spectrum of **4a** is almost identical with that in the spectrum of $[Fe(CO)_4(PPh_3)]$ in CH_2Cl_2 [2049 (vs), 1974 (m), and 1938 (vs) cm^{-1}].[9] Only a splitting of the *E* vibration mode is observed, presumably due to steric factors, which induce a slight distorsion of the Fe moiety of **4a** away from the C_{3v} symmetry found for $[Fe(CO)_4(PPh_3)]$. This also supports the assumption that **4a** is a $Fe(d^8) \rightarrow Pt(d^8)$ system with a dative bond between a Fe^0 and a Pt^{II} center.

Without the introduction of CO, pure **2a** in CH_2Cl_2 or toluene is transformed only slowly (4–5 days at room temperature) into **4a** (the slow decomposition of **2a** liberates CO), that is, the introduction of CO significantly accelerates the reaction **2a** → **4a**.[10]

In order to evaluate the influence of the ligands R attached to Si on this SiR_3 transfer reaction, **3b** was prepared quantitatively from **2b**. In contrast to **3a**, which rearranges too rapidly, **3b** can be isolated in a pure form as a yellow, air-stable solid. In CH_2Cl_2, however, it rearranges quantitatively at room temperature within approximately 5 h to the isomer **4b** (IR and $^{31}P\{^1H\}$ NMR monitoring). The IR spectrum of **4b** is similar to that of **4a** in the CO stretching frequency region; the bands are slightly shifted to lower wavenumbers owing to the stronger electron-donating properties of the $SiMe_2Ph$ group.

Migration of the silyl group from Fe to Pt is prevented by stronger σ-donor/ π-acceptor ligands on Pt, for example, *t*BuNC in **5**, or $Ph_2PCH_2PPh_2$ (dppm) in **6**. That the silyl-

$[(OC)_3(Ph_3Si)Fe(\mu\text{-}PPh_2)Pt(PPh_3)(CO)]$ **3c**

$[(OC)_3\{(MeO)_3Si\}Fe(\mu\text{-}PPh_2)Pt(PPh_3)(CN\,tBu)]$ **5**

$[(OC)_3\{(MeO)_3Si\}Fe(\mu\text{-}PPh_2)Pt(dppm)]$ **6**

group transfer reported here is strongly influenced by subtle changes in the molecule is further illustrated by the fact that neither the $SiPh_3$ derivative **3c**, nor the complexes analogous to **2a** and **3a**, which contain a μ-PHPh or a μ-PHCy (Cy = *cyclo*-C_6H_{11}) bridge, isomerize under similar conditions. A possible explanation invokes the Thorpe–Ingold effect,[11] whereby bulky geminal substituents on the μ-P atom would promote the formation of transition-state or intermediate structures containing additional bridging ligands and thus facilitate their transfer from one metal to another. This effect has also been put forward to account for the suppression of intramolecular, intermetal transfer of CO in heteronuclear complexes $[M(\mu\text{-}PR_2)Pt]$ on going from $\mu\text{-}PR_2$ to μ-PRH systems.[12] Whereas silatropic shifts are well known in organic chemistry,[13] and intramolecular metal to ligand migrations of silyl substituents have been reported,[2, 3] this CO-promoted transfer of a silyl-group from *one metal to another* is unprecedented. It may open up the possibility of "switching on" a catalyst system by converting a M–Si into a M′–Si bond under very mild conditions. It is particularly notable that a Pt–Si bond results from this migration, since platinum is known to be an important metal for catalysts in the chemistry of silicon compounds.[1]

Experimental Procedure

2a: **1a** (0.448 g, 1 mmol) [4b] was treated with $[Pt(C_2H_4)(PPh_3)_2]$ (0.749 g, 1 mmol) in toluene (15 mL). The solution was stirred for 1 h at 25 °C and concentrated. The product was precipitated by addition of hexane and obtained in 78% yield as an air-stable, yellow powder. IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2006s, 1942sh, 1932vs (ν(CO)); ^1H NMR (200 MHz, C_6D_6, 303 K, TMS): δ = 3.68 (s, 9H, OCH_3), 6.95–7.51 (m, 40H, C_6H_5). $^{31}P\{^1H\}$ NMR (81.02 MHz, [D_6]benzene/CH_2Cl_2, external reference H_3PO_4, for all compounds): δ = 27.8 (d, PPh_3(Pt), ^2J(P,P) = 9, ^1J(Pt,P) = 3482 Hz), 35.8 (d, PPh_3(Pt), ^2J(P,P) = 232, ^1J(Pt,P) = 3209 Hz), 181.9 (dd, μ-PPh_2, $^2J(P,P_{trans})$ = 232, $^2J(P,P_{cis})$ = 9, ^1J(Pt,P) = 2636 Hz).

2b was prepared in a manner similar to **2a** starting from **1b**. [5] $^{31}P\{^1H\}$ NMR: δ = 27.5 (d, PPh_3(Pt), ^2J(P,P) = 12, ^1J(Pt,P) = 3469 Hz), 36.2 (d, PPh_3(Pt), ^2J(P,P) = 228, ^1J(Pt,P) = 3239 Hz), 183.7 (dd, μ-PPh_2, $^2J(P,P_{trans})$ = 228, $^2J(P,P_{cis})$ = 12, ^1J(Pt,P) = 2643 Hz).

3b was prepared by purging a solution of **2b** (0.945 g, 1 mmol) in CH_2Cl_2 (30 mL) at 25 °C with a stream of CO. The reaction is quantitative (ca. 10 min, IR monitoring of the CO bands). The solution was concentrated to approximately 6 mL and slow addition of hexane (20 mL) induced precipitation of yellow **3b**. IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2055m, 1974m, 1910sh, 1902vs (ν(CO)); $^{31}P\{^1H\}$ NMR: δ = 26.9 (d, PPh_3(Pt), ^2J(P,P) = 16, ^1J(Pt,P) = 3436 Hz), 163.6 (d, μ-PPh_2, ^2J(P,P) = 16, ^1J(Pt,P) = 2589 Hz).

4a: A solution of **2a** (0.583 g, 0.5 mmol) in CH_2Cl_2 (15 mL) was purged at 25 °C with a stream of CO. After rearrangement was complete (ca. 1 h, IR-monitoring of the disappearence of the CO bands due to **3a**), the yellow-brown solution was concentrated to approximately 5 mL and hexane (20 mL) was slowly added, inducing precipitation of 0.429 g (92%) yellow **4a**. IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2040vs, 1975m, 1949s, 1927s (ν(CO)); ^1H NMR (200 MHz, C_6D_6, 303 K): δ = 3.12 (s, 9H, OCH_3), 7.06–8.12 (m, 25H, C_6H_5); $^{31}P\{^1H\}$ NMR: δ = 36.0 (d, PPh_3(Pt), ^2J(P,P) = 308, ^1J(Pt,P) = 3027 Hz), 116.9 (d, μ-PPh_2, ^2J(P,P) = 308, ^1J(Pt,P) = 2152 Hz).

4b: IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2034vs, 1972s, 1945s, 1920s (ν(CO)); $^{31}P\{^1H\}$ NMR: δ = 31.4 (d, PPh_3(Pt), ^2J(P,P) = 315, ^1J(Pt,P) = 3168 Hz), 118.5 (d, μ-PPh_2, ^2J(P,P) = 315, ^1J(Pt,P) = 2324 Hz).

5: IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2180s (ν(CN)), 1969s, 1900vs, br. (ν(CO)); ^1H NMR ($CDCl_3$, 303 K): δ = 1.26 (s, 9H, *t*Bu), 3.72 (s, 9H, OCH_3), 7.07–7.35 (m, 25H, C_6H_5); $^{31}P\{^1H\}$ NMR: δ = 27.4 (d, PPh_3(Pt), ^2J(P,P) = 7, ^1J(Pt,P) = 3618 Hz), 153.0 (d, μ-PPh_2, ^2J(P,P) = 7, ^1J(Pt,P) = 2709 Hz).

6: IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 1964s, 1892vs, br. (ν(CO)); ^1H NMR ($CDCl_3$, 303 K): δ = 3.53 (s, 9H, OCH_3), 4.76 (t, 2H, CH_2, ^2J(P,H) = 9.5, ^3J(Pt,H) = 40.4 Hz), 7.24–7.83 (m, 30H, C_6H_5).

All new compounds gave satisfactory elemental analyses.

Detection of the Tungsten–Carbene–Olefin Intermediates in Catalytic Metathesis Systems Containing High-Valent Metal Centers

By *Jacky Kress** and *John A. Osborn*

Metal–carbene–olefin complexes have been postulated as key intermediates in catalytic olefin metathesis reactions and in cycloolefin ring-opening metathesis polymerization (ROMP) reactions.[1] Although several such complexes have been reported,[2] these do not lead to metathesis,[3] probably because the transition metal is in low or medium oxidation states. Adducts between olefins and high-valent, d^0[4] metal–alkylidene complexes, which would be intermediates or at least models for the most active catalyst systems,[1] are still unknown, although their formation has been predicted by several theoretical studies[6] and on the basis of indirect experimental arguments.[7] We now report the first characterization of such alkylidene–olefin complexes with a d^0 metal center which are also intermediates in catalytic ROMP reactions of cycloalkenes.

Cycloheptene (**2**) was shown by low-temperature ^{13}C NMR (Fig. 1) to interact with the tungsten–cyclopentylidene complex **1**[8] following Scheme 1. The equilibrium is displaced toward the π olefin adduct **3** at low temperature, and toward the two reactants at high temperature. No polycycloheptene[9] is detected after 30 min at (or below) 245 K. The carbene–olefin nature of **3** is clearly established by the presence at 200 K of a signal at $\delta = 355.3$ (^1J(W,C) = 142 Hz), which is assigned to the α C atom of the cyclopentylidene

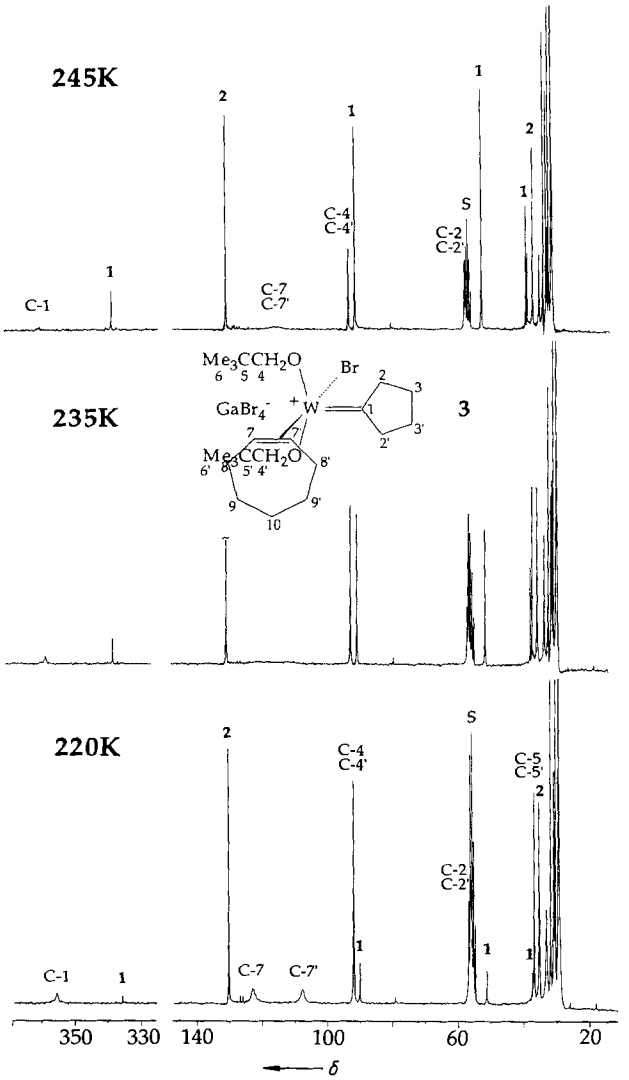

Fig. 1. ^{13}C NMR spectra (50 MHz) of the reaction mixture obtained after addition of 1.8 equiv of cycloheptene (**2**) to **1** (0.28 M in CD_2Cl_2 (S)) at 177 K.

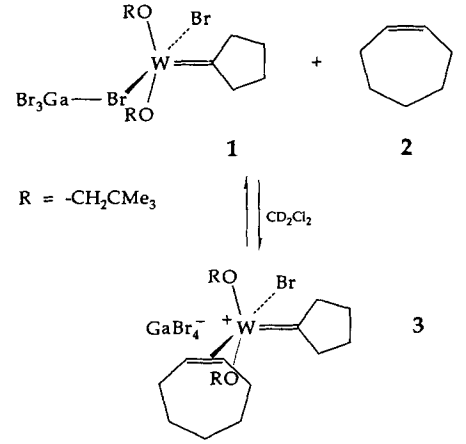
unit, and of two signals at $\delta = 124.4$ and 107.8 (^1J(C,H) = 165 Hz) corresponding to two nonequivalent olefinic carbon atoms.[10] The assumption that $GaBr_4^-$ has left the coordination sphere of tungsten to yield a cationic complex is based on the large low-field shift of the alkylidene carbon atom and on the substantial decrease of the coupling constant ^1J(W,C),



Scheme 1. Formation of the tungsten–carbene–olefin adduct **3**.

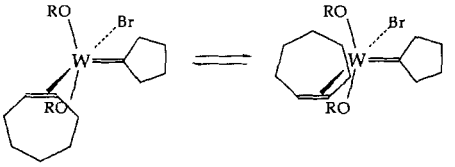
which suggest that the tungsten center is significantly more electron deficient in **3** than in **1** ($\delta = 335.6$ and $^1J(W,C) = 169$ Hz[8c]).[11] The limiting spectrum observed at 200 K[10] is fully consistent with a trigonal-bipyramidal coordination geometry (Fig. 1) with an equatorial "parallel" position for the cyclopentylidene ligand.[12] The arrangement of the two neopentoxo ligands with respect to the cyclopentylidene group is similar to that found for **1**.[8c] The olefin occupies an apical site with its C=C axis aligned with the W=C axis and with its "plane" parallel to that of the cyclopentylidene ligand.[14] Notably, this particular conformation is the only one suitable for subsequent conversion into a metallacyclobutane,[15] one of the fundamental steps of the metathesis mechanism.[1]

The ^{1}H NMR spectra[16] confirm these observations, showing moreover that the two hydrogen atoms of each β-methylene group of the cyclopentylidene ligand, as well as those of the neopentoxo methylene groups, are also nonequivalent, in agreement with the structure proposed for **3**. The two signals for the olefinic hydrogen atoms, on the other hand, are not distinguishable, giving rise to a single multiplet at $\delta = 5.64$. The position of this signal is shifted remarkably little from the corresponding signal of free cycloheptene ($\delta = 5.76$). The corresponding ^{13}C resonance signal ($\delta = 132.4$, $^1J(C,H) = 154$ Hz for free **2**), on the other hand, is shifted to an average position of $\delta = 116.1$.[10] Such small changes, compared to classical non-alkylidene d^2 olefin complexes,[17] tend to show that the alkylidene complex **3** should be viewed as a d^0 metal complex in which the olefin is bound mainly through donation of its π electrons into an empty d orbital of tungsten. A weak additional interaction of the π^* orbital with the π electrons of the W=C bond may, however, be at the origin of the parallel configuration and of the substantial barrier to rotation (see below).

Measuring the equilibrium constants at various temperatures, from the integrals of ^{1}H and ^{13}C NMR signals ($K = [\mathbf{3}]\,[\mathbf{1}]^{-1}\,[\mathbf{2}]^{-1} = 4.5 \pm 1\ \text{M}^{-1}$ at 235 K, for instance) allowed us to draw a linear Van't Hoff plot from which the thermodynamic values, $\Delta H^0 = -13.6 \pm 0.5$ kcal mol^{-1} and $\Delta S^0 = -55 \pm 3$ cal K^{-1}mol^{-1}, could be obtained for the formation of **3**.

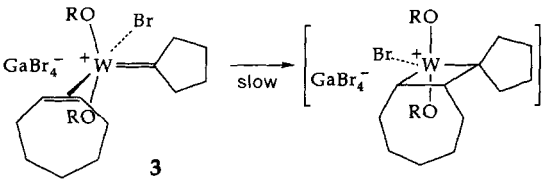
Raising the temperature leads to the reversible coalescence of several of the ^{13}C and ^{1}H NMR signals of **3**. Most notable is the coalescence at 240 K of the two ^{13}C NMR signals of the olefinic C atoms C-7/C-7′ (Fig. 1). Other pairs such as C-3/C-3′, C-5/C-5′,[10] and $H_c/H_{c'}$[16] also coalesce to singlets at 215, 210, and 220 K respectively, whereas the two AB (2H) patterns due to CH_aH_b and $CH_{a'}H_{b'}$[16] simplify into a single AB (4H) pattern above 225 K; the same applies for the two AB patterns due to the two -OCH_2- groups. Using the Eyring equation,[18] equal and concentration-independent values for the free energy of activation are obtained for all these coalescences ($\Delta G^{\neq} = 10.6 \pm 0.1$ kcal mol^{-1}), showing that they result from a single intramolecular dynamic process. In this process, equilibration of the two neopentoxo ligands and of the two sides of both cycloheptene and cyclopentylidene ligands occurs, leaving their CH_2 protons nonequivalent. This can only be reconciled with the occurrence in **3** of olefin ligand rotation about the tungsten–olefin bond axis (Scheme 2). Such rotational barriers are relevant to the stereoselectivity in olefin metathesis and ROMP reactions.[1]

If the temperature is raised above 255 K, the catalytic ROMP reaction of cycloheptene[9, 19] begins in the reaction mixture, indicating that **3** can be considered as a true initiating intermediate in this catalytic system. No further intermediate, initiating or propagating, can however be detected,



Scheme 2. Olefin ligand rotation about the tungsten–olefin bond axis.

and **1** is almost not consumed in this reaction, showing that the conversion of **3** into the metallacyclobutane derivative (Scheme 3) is slower than the following steps of this process.



Scheme 3. Conversion of **3** into the corresponding metallacyclobutane derivative.

Furthermore, we found that: 1. Replacing bromides by chlorides[20a] cyclopentylidene by cyclohexylidene,[20b] or cycloheptene by cyclooctene[20c] leads to similar observations. In particular, the small low-field shift of the $^1H_{ol}$ NMR signal of cyclooctene on complexation to **1**[20c] confirms our description of the metal–olefin bonding in **3**. 2. When one bromo ligand is replaced by a neopentoxo group, or cyclopentylidene by neopentylidene, no intermediate can be detected, and polymerization of cycloheptene occurs at temperatures as low as 240 K. This suggests that the difference in energy between the initial carbene–olefin intermediate and the metallacyclobutane derivative as well as the reactants is smaller in these systems, and shows that the stability of **3** actually limits the rate of polymerization of **2** in the presence of **1**. 3. No interaction can be found between **1** and cyclohexene, indicating that ring-strain relief is involved in the formation of the cycloolefin adducts.[21] This may significantly contribute to the negative values found for ΔH^0. As expected, cyclohexene does not undergo polymerization by ring opening in the presence of **1**. 4. Replacing the cyclopentylidene ligand by *n*-pentylidene leads instead to a metallacyclobutane species as the main observable intermediate,[22] and the ROMP reaction of **2** starts at even lower temperatures (220 K). This behavior is similar to that found for the more strained norbornenes[23] and arises probably from further ring-strain relief on conversion of the carbene–olefin complexes into the metallacyclobutanes. The cycloalkylidene–monocycloolefin complexes described here are thus more stable than their metallacyclobutane derivatives (Scheme 3), probably because the tricyclic structure of the latter is more strained.

These results show that subtle changes in the nature of the metal–alkylidene catalyst or of the olefin substrate can lead to important modifications in the relative stability of the three types of intermediates involved in catalytic olefin metathesis reactions.

[10] ^{13}C NMR of **3** (50 MHz, CD_2Cl_2, 200 K): δ = 355.3 (C-1), 124.4, 107.8 (C-7, C-7'), 91.7 (C-4, C-4'), ≈54.4 (C-2, C-2'), 33.8, 33.5 (C-5, C-5'); 31.9 (C-10), 30.0, 29.4 (C-3, C-3'), 27.3 (C-9, C-9'), 25.8 (C-6, C-6'), ≈25.2, 24.8 (C-8, C-8'). The assignments are based on chemical shifts, signal intensities, gate-decoupled and DEPT NMR experiments; numbering of the nuclei is given in Figure 1.

[11] Similar variations in the NMR spectra were found for related complexes after conversion of $GaBr_3$ adducts into cationic species [8a], coordination of Lewis acids to a bromo ligand [8a,b], or replacement of neopentoxo ligands by less π electron donating bromo ligands [8b]. The neutral pentacoordinate alkylidene complexes were moreover shown to be only weak Lewis acids [8b], and their interaction with olefins to produce hexacoordinate π olefin adducts is unlikely. However, addition of excess $GaBr_4^-$ (1 equiv/**1**) in the form of its tetrabutylammonium salt has only little effect on the equilibrium position, according to the ^1H MR spectra [16], indicating that **3** is better viewed as non-separate ion pairs.

[12] This was shown to be the most favorable configuration for such complexes, both theoretically [6b, 13] and experimentally [8c].

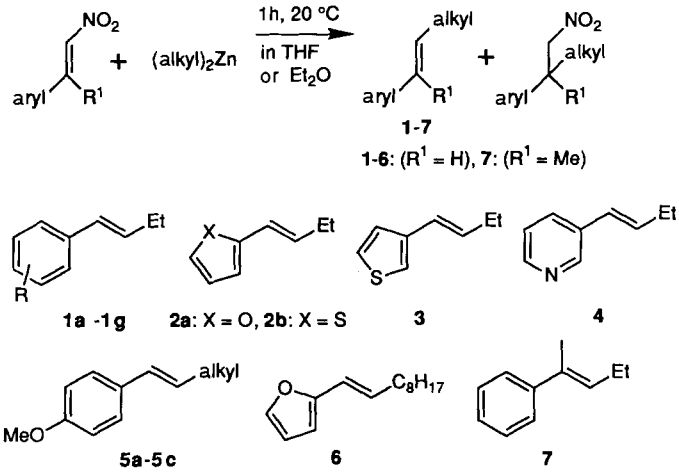
C–C Coupling with NO_2/Alkyl Substitution at the Vinylic Carbon by Reaction of 2-Aryl-1-nitro-1-alkenes with Dialkylzinc Compounds—A Novel Reaction**

By *Dieter Seebach,* Harald Schäfer, Beat Schmidt,* and *Martin Schreiber*

In the course of our work on enantioselective Michael additions of diethylzinc to ω-nitrostyrene in the presence of chiral titanates[1] we were surprised to find not only the expected 1-nitro-2-phenylbutane but also 1-phenyl-1-butene,[2a] the product of the substitution of the vinylic nitro group by an ethyl group.[2b]

We soon found that substitution is preferred in the absence of a Lewis acid[2c] and in ethereal solvents. Under the optimized conditions shown in Scheme 1, 2-aryl- and 2-heteroarylnitroethenes reacted with both primary and secondary dialkylzinc compounds, affording the substitution products **1**–**6** in 30 to 40% yield[2d] (Scheme 1, Table 1). Due to their low polarity, these products[3] are readily purified by filtration through silica gel. According to their IR and NMR spectra all products **1**–**6** have (*E*) configuration, even if the starting material has (*Z*) configuration.[4] The nitroolefins used are readily available,[5] Et_2Zn (Schering) and $(octyl)_2Zn$[6] were used in pure form and dissolved in the required ethereal solvent, while $(iPr)_2Zn$ and $(tBu)_2Zn$ were prepared in situ and salt free, according to a recently published experimental procedure.[1b]



Scheme 1. Olefins **1**–**6** and **7** prepared by substitution of the NO_2 group of 1-aryl-2-nitroethenes and 1-nitro-2-phenylpropene, respectively, upon reaction with dialkylzinc compounds (for the specification of R and alkyl see Table 1).

The reaction is sensitive to steric hindrance in the starting materials (see for example **1c**, **5c**, **7**);[7] the substitution reaction was not successful with diallyl-, dibenzyl-, and diphenylzinc, nor with 3,3-dimethyl-1-nitrobutene (led to Michael adducts).

[a] Flash chromatography performed with additional 15% EtOAc in the eluent. [b] Sample ca. 90%, pure could not be further purified by distillation or chromatography. [c] Flash chromatography, eluent C_5H_{12}/CH_2Cl_2 (8:1), column 20 × 3 cm. [d] The reaction time was longer (ca. 20 h) than that given in Scheme 1.

The substitution reaction described herein is remarkable for the following two reasons: a) Normally, the nitro group acts as a leaving group only in special cases[8] and probably is the best "activator" for Michael additions.[9] b) Vinylic C–C coupling is usually carried out with halides and organometallic coumpounds, and normally requires a Pd or Ni catalyst (e.g. the Heck reaction).[2e, 10]

Since the starting materials leading to the products **1**–**7** are more accessible (aldehyde or ketone + CH_3NO_2)[5] than the corresponding vinyl halides or metal derivatives, the reaction described here could be applied preparatively[11] in some cases, despite the low yields achieved to date.[12]

Experimental Procedure

Typical synthetic procedure: A solution of 1.00 g (5.58 mmol) of 1-(4-methoxyphenyl)-2-nitroethene in 25 mL THF, under argon at room temperature was treated with 1.4 equiv of a 2 M Et_2Zn solution in THF. After 1 h, the reaction was quenched at 0 °C with 20 mL of saturated NH_4Cl solution and stirred for half an hour at room temperature. The mixture was filtered through celite and the solids washed with Et_2O (alternatively the precipitated zinc salts can be dissolved by addition of 2 M HCl). The organic layer was washed with 50 mL brine, dried over $MgSO_4$, and the solvent evaporated in vacuo. The oil obtained was filtered through silica gel (14 × 3 cm, ca. 70 mL dry material, ca. 400 mL C_5H_{12}/CH_2Cl_2 (5:1)), and 1-(4-methoxyphenyl)-1-butene **1e** was eluted as the least polar product. After removal of most of the solvent, the residue was further dried at ca. 0.1 Torr for 10 min[13] to give pure **1e** in 38% yield. Spectroscopic data [14] for **1e**: ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 6.30$ (d, $J = 16$ Hz, 1 H; C1-H), 6.08 (dt, $J = 15.8$ Hz, $J = 6.3$ Hz, 1 H; C2-H); IR ($CHCl_3$): $\tilde{\nu}$[cm^{-1}] = 966.

German version: *Angew. Chem.* **1992**, *104*, 1680

[1] a) B. Schmidt, D. Seebach, *Angew. Chem.* **1991**, *103*, 1383–1385; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1321–1323; b) J. L. von dem Bussche-Hünnefeld, D. Seebach, *Tetrahedron* **1992**, *48*, 5719–5730.

[2] a) The Michael adduct was essentially racemic; b) The "wrong" nucleophilic addition of $(alkyl)_2Zn$ to the nitroolefin is disfavored by many powers of ten [$pK_a(ArCH_2alkyl) > 35$, $pK_a(alkylCH_2NO_2)$ ca. 10]; c) Other Lewis acids, i.e. 2.8 equiv of $MgBr_2/MgCl_2$ in Et_2O (suspension), led selectively to the Michael adduct [e.g. 94% yield of 2-(4-methoxyphenyl)-1-nitrobutane starting from 1-(4-methoxyphenyl)-2-nitroethene and Et_2Zn in Et_2O at 20 °C]; d) Addition of 6 equiv of 1,3-dimethyl-2-oxo-hexahydropyrimidine (DMPU) (T. Mukhopadhyay, D. Seebach, *Helv. Chim. Acta* **1982**, *65*, 385–391) caused the yield of **1e** to increase to 44%; e) In the presence of $[Pd\{P(C_6H_5)_3\}_4]$, **1e** was obtained in 22% yield. We believe that the observed substitution is not caused by some metal impurity in the dialkylzinc compounds, because not only were they generated from different sources but were also purified by different methods.

[3] In addition to the Michael adduct (ca. 40%), a product aryl-CH(alkyl)-CH(alkyl)-NO_2 (ca. 5%) arising from a second addition was isolated.

[4] Tested with (*Z*)-1-nitro-2-phenylethene (D. B. Miller, P. W. Flanagan, H. Shechter, *J. Org. Chem.* **1976**, *41*, 2112–2120; D. Seebach, A. K. Beck, J. Golinsky, J. N. Hay, T. Laube, *Helv. Chim. Acta* **1985**, *68*, 162–172).

[11] It is difficult to compete successfully with the Wittig–Horner reaction, McMurry coupling, and other olefination reactions, as well as with the partial hydrogenation of acetylenes.

[12] Experiments investigating the mechanism of the reaction are in progress (see also ref. [2]), and may lead to an improvement of the yield.

[13] Particular care was taken with the furyl and phenyl derivatives, which were kept in vacuo for a shorter time because of their higher volatility.

[14] In the ^{1}H NMR spectra of the compounds **1**, **2b**, **3**, and **5a** the vinylic protons have chemical shifts $\delta = 6.3$ to 6.5 (C1-H) and 6.0 to 6.2 (C2-H) and coupling constants $J = 15$–16 Hz. For protons C2-H and C3-H_2 the coupling constant is ca. 6.2 Hz. The IR spectra of the compounds **1** to **6** contain strong bands between 953 and 972 cm^{-1}, typical of 1,2-disubstituted (*E*) olefins.

A Homologous Series of Stable Polyenes: Synthesis, Structure, and Redox Behavior**

By *Alfried Kiehl, Anke Eberhardt, Martin Adam, Volker Enkelmann,* and *Klaus Müllen**

Dedicated to Professor Klaus Hafner on the occasion of his 65 th birthday

Linear polyenes serve on one hand as textbook examples for the description of "the electron in a one-dimensional box" in molecular orbital theory[1] and on the other as defect-free model compounds for electrically conducting materials such as polyacetylene.[2] We describe here a facile way to a homologous series of monodisperse polyenes, based on the palladium-catalyzed coupling of organotin compounds with electrophiles, developed by Stille. Furthermore, we followed the electron-transfer behavior of the polyenes by cyclic voltammetry and proved the unusual layered structure of dodecahexaene (all-(*E*)-**10**) by X-ray crystallography.

Recently Schrock and Knoll[4] described a synthesis of polyenes that was based on the metathetical ring opening of cyclobutene derivatives and yielded polydisperse mixtures; chromatographic separation is required to provide defined homologues. We have developed a "warehouse" of olefin precursors that allow stable and soluble polyenes of defined

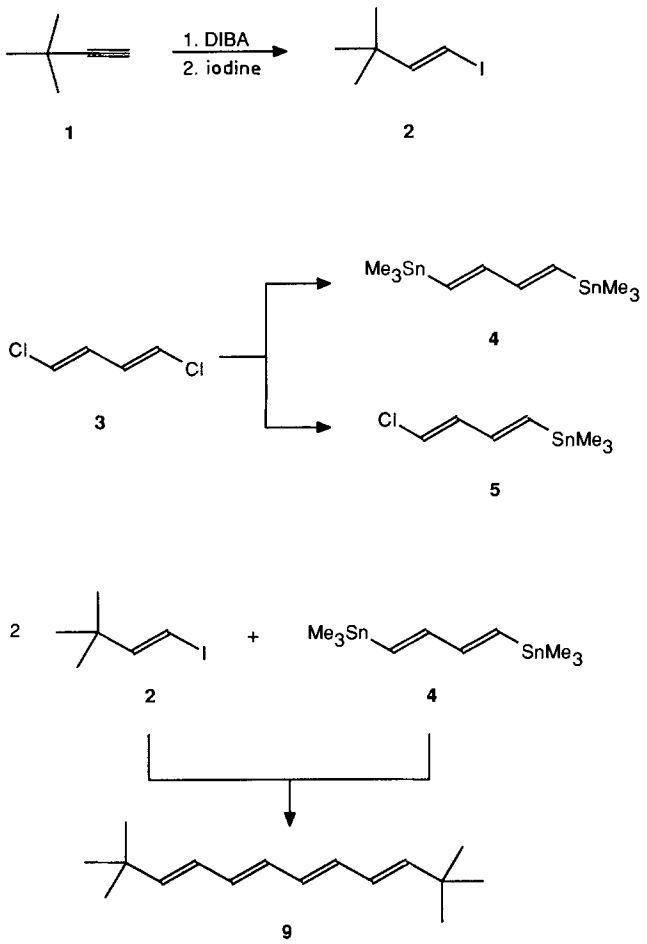
chain length to be obtained in good yields. A further advantage of our procedure is the significantly smaller amount of catalyst required (2–5%), which simplifies the recovery of very pure samples.[5] The *tert*-butyl terminal groups in the title compounds provide the steric protection for the chain ends and ensure good solubility. In contrast to the carotenoids, the main chain of the polyenes should remain unsubstitued to prevent a twisting of the π-electron system.[6]

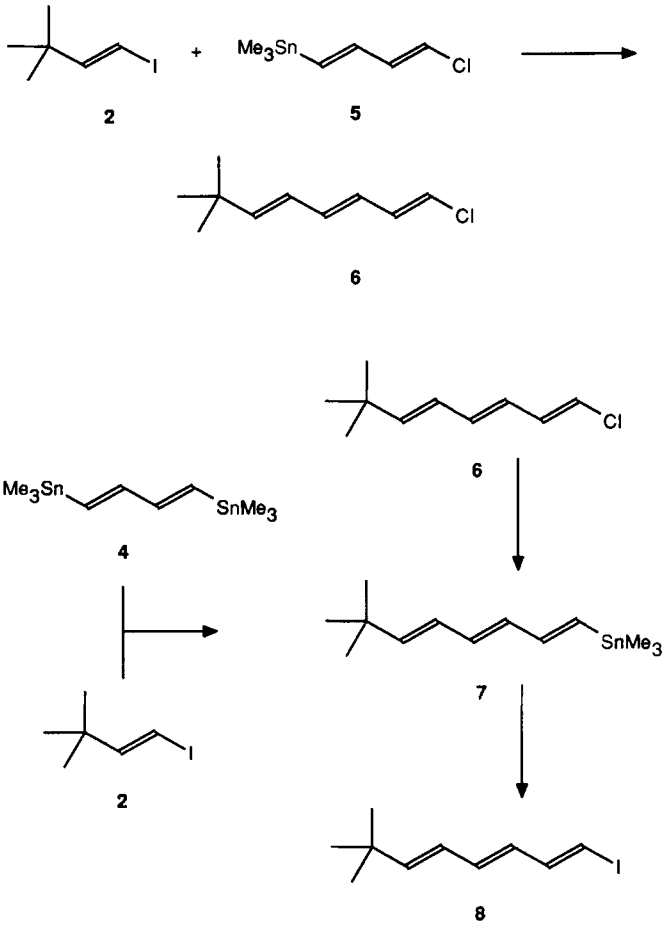
By hydroalumination of *tert*-butylacetylene with diisobutylaluminum hydride (DIBA) and subsequent cleavage by iodine, one obtains the iodide **2** as pure (*E*) isomer in 67% yield.[7] The butadiene **4** can be prepared from (*E*,*E*)-dichlorobutadiene **3**[8] and two equivalents of trimethylstannyllithium.[9] This procedure yields a distillable mixture of 65% (*E*,*E*), 31% (*E*,*Z*), and 4% (*Z*,*Z*) isomers.[10]



The best catalyst systems for the coupling of the vinyl iodide **2** with the bifunctional organyltin compound **4** proved to be $[PdCl_2(CH_3CN)_2]$/DMF and $[Pd(tfp)_2]$/DMF (tfp = trifurylphosphane, DMF = dimethyl formamide).[11] With these the tetraene **9** could be isolated after about 1 h in gram quantities and satisfactory yields (42%). The coupling of **9** also affords about 20% of **10** and small amounts of still higher oligomers with even numbers of double bonds in the chain. This finding can be explained by an exchange of iodine and trimethyltin in the catalyst, which leads, for example, to the formation of **8**.

All coupling reactions proceed with complete retention of the olefin configuration; that is, there is no isomerization of the starting materials **2** and **4** in the product **9**. Pure all-(*E*)-tetraene **9** is obtained by a simple recrystallization from ethyl acetate.

The dichloride **3** can be transformed into 1-chloro-4-trimethylstannyl-1,3-butadiene **5**, a bifunctional building block, with less than the stoichiometric amount of trimethylstannyllithium. The chlorohexatriene **6** is formed in 64% yield through a coupling reaction between **5** and the iodide **2** in which the chloro substituent, which is significantly more inert than iodine, remains unchanged. A further stannylation of **6** affords the hexatriene **7**. This product can also be obtained through a direct coupling of the iodide **2** with the stannane **4**, but small amounts of **4** are always present as impurity (5–10%). The iodine hexatriene **8** arises on cleavage of the stannyl group from **7** by iodine. Thus the way to the higher polyenes is open: the coupling reaction of the hexatrienes **7** and **8** furnishes di-*tert*-butyldodecahexaene **10** in 82% yield. This higher yield relative to tetraene **9** results from the already described exchange reaction. Since the transformation of **7** and **8** always yields **10** as final coupling product, higher oligomers are not formed. Finally reaction of the iodide **8** with the distannylbutadiene **4** gives rise to the hexadecaoctaene **11** in 39% yield. As in the coupling to form tetraene **9**, UV spectroscopy and mass spectrometry detect higher enes as side products, in particular di-*tert*-butylicosadecaene **12**. The physical properties of the compounds **5**–**8** are summarized in Table 1.



Compared with other polyenes, the di-*tert*-butyl polyenes thus accessible under mild reaction conditions (see ref. [5] and *Experimental Procedure*) display a remarkable thermal

Table 1. Selected physical data of the compounds **5**–**8** [a].

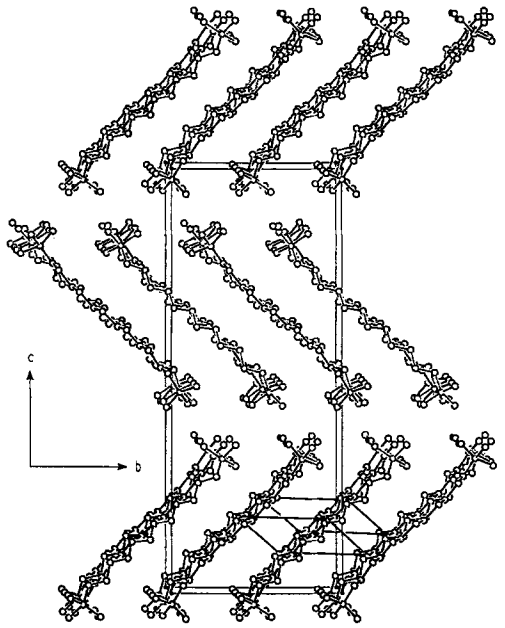
stability and inertness.[12] Low temperature crystallization from *n*-pentane yields square crystals of the dodecahexaene **10**. The crystal structure of **10**[13] is depicted in Figure 1 in two projections. In the layered structure the molecules are tilted both relative to the plane of the layer and to the plane of projection shown to provide an angle of about 90° between the oligoene chains in adjacent layers. Remarkably, this packing accommodates the bulky *tert*-butyl groups in the spaces between the layers in such a way that each polyene chain is surrounded by six neighbors, and an arrangement with a subcell structure very similar to that of *trans*-polyacetylene[14] results. Therefore, analogously to other polyenes, **10** can be regarded as a model for the packing in *trans*-polyacetylene. The subcell is indicated at the top of Figure 1, and as projection in the direction of the chain at the bottom.



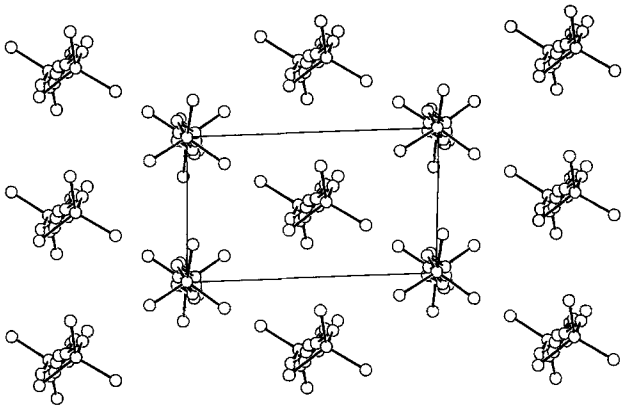


Fig. 1. Top: Unit cell of **10** (hydrogen atoms omitted). In addition the subcell of *trans*-polyacetylene is indicated. Bottom: view in the direction of the molecular axis of **10**.

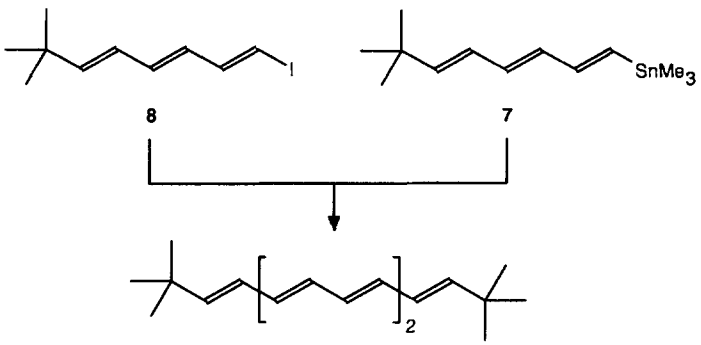

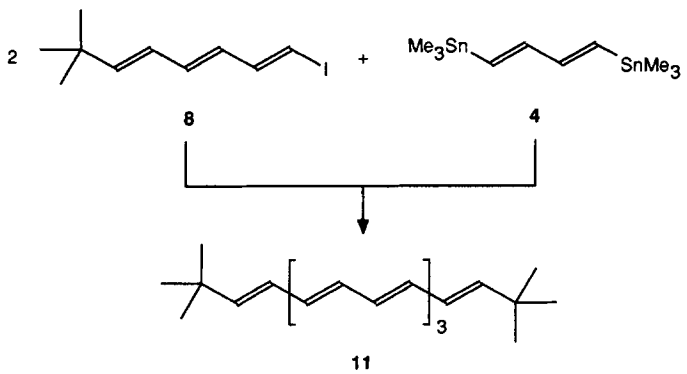

As in *trans*-polyacetylene,[16] the lengths of the double and single bonds in **10** are not completely equivalent. Instead it shows an alternating structure. The average length of the double bonds is 1.34 Å and that of the single bonds, 1.44 Å. A contraction of the bond lengths toward the center of the molecule[15] is not observed; the lengths of both double and single bonds are subject only to statistical variations.

The dodecahexaene **10** and its higher homologues can also serve as models for doped polyacetylene, because polyenes containing six to ten double bonds are comparable with those regions of the polyacetylene chain that become charged on oxidation or reduction.[17] If the layered structure can be maintained on reduction, intercalation com-

pounds should arise in which the charged oligoene layers are separated by layers of counterions.

As in polyacetylene,[18, 19] the oligomers described here have a high redox activity. The cyclic voltammogram of even the tetramer **9** (see Table 2) reveals two oxidation and two reduction peaks. The HOMO-LUMO energy difference ΔE can be estimated at 3.5 eV from the first reduction and oxidation potentials. The hexamer **10** does not show a more extended redox sequence, but the energy gap ΔE decreases to about 2.9 eV. Finally, in hexadecaoctaene **11** seven successive charge-transfer steps from tetraanion to trication can be detected, and ΔE is decreased even further to 2.6 eV. The band gap of polyacetylene can be calculated by plotting ΔE against $1/n$ (n = the number of double bonds) and extrapolating.[20] The resulting value of 1.7 eV agrees well with the band gap (1.4–1.8 eV) determined experimentally and theoretically for polyacetylene itself.[18]

Our investigations have shown that the structurally well-defined polyenes **9**–**11** make a valuable contribution to the understanding of the properties and the structure of polyacetylene. In addition the syntheses presented here open a versatile alternative to conventional methods of preparation for polyenes such as the Wittig reaction.[7, 21] In a later publication we shall describe how homologues with an uneven number of double bonds and, in particular, homologues with even longer chains are accessible.

Experimental Procedure

Palladium-catalyzed coupling reactions (general procedure): Into a "deactivated" Schlenk tube under an argon atomsphere was placed 2–5 mol% of catalyst. About 10 mL of DMF per mmol of stannyl equivalent was distilled into the tube. When $[Pd^0_2(dba)_3]$ (dba = dibenzylidene acetone) was used, two equivalents of trifurylphosphane were also added. Then the iodide and the stannane were injected into the solution. The course of the reaction could be followed clearly by thin-layer chromatography. At room temperature the reaction time varied between 30 and 90 minutes, depending on the subtrate. As workup the solution was taken up in ether, the organic phase washed three times with degassed water and subsequently dried over $MgSO_4$. The ether was then distilled off, and the final workup of the products was either by chromatography on degassed silica gel or by distillation.

Further workup of the polyenes **9**, **10**, and **11**: Low temperature chromatography ($-30\,^{\circ}C$) with n-pentane/$CHCl_3$ mixtures. The isolation of isomerically pure all-(*E*)-polyenes is achieved by irradiation with light of suitable wavelength [$\lambda > 300$ nm for **9** (in the presence of iodine) and **10**, $\lambda > 345$ nm for **11**] and subsequent recrystallization.

All analytical data agree with those of Schrock et. al (see ref. [4]).

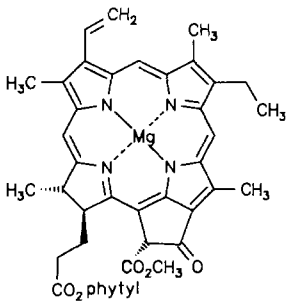
Chlorins Designed for Photodynamic Tumor Therapy and as Model Systems for Photosynthesis**

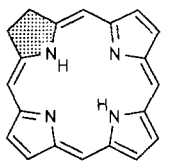
By *Franz-Peter Montforts,* Axel Meier, Gerhard Scheurich, Gerold Haake,* and *Jan. W. Bats*

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

Chlorophyll a (**1**), the green photosynthesis pigment, is the prototype of the chlorin class of natural products,[1] which has recently been expanded to include a number of compounds[2] with differing structures, biological sources, and functions. The common structural unit in this class is the chlorin framework **2** with a partially saturated pyrrole ring, which is derived from the completely unsaturated porphyrin. The photophysical properties of the chlorins resulting from this structural modification predestine them as pigments for photosynthesis[3] and for medical applications, for example in photodynamic tumor therapy (PDT).[4]



1



2

The chlorin *rac*-**3**[5] with geminal dialkyl substitution in the saturated pyrrole ring was easily obtained from the red blood pigment heme and functionalized in the 3 position by degradation of the double bond. Artifical photosynthesis systems may thus be prepared containing "natural" chlorins as the structural units in contrast to the previously synthesized model systems based on porphyrins. The functionalized chlorin *rac*-**8** may be modified to provide sensitizer structures and fluorescence markers[6] for photodynamic tumor therapy and other diagnostic/therapeutic applications.

Chlorin *rac*-**3** was first complexed with zinc(II) ions to protect the chromophore (Scheme 1). The oxidative cleavage of the exocyclic double bond and subsequent decomplexation under acidic conditions led to oxochlorin *rac*-**7**. The amide function in *rac*-**6** was hydrolyzed readily due to the anchimeric participation of the 3-oxo group to give *rac*-**14**. The preparation of the corresponding nickeloxochlorin *rac*-**11** required the hydrolysis of the amide function and cleavage of the double bond by iodolactonization, followed by a retro-aldol-type fragmentation and oxidation with MnO_2.[7] The X-ray structure analysis[8] of the nickeloxochlorin *rac*-**11**, which was conducted in light of the coenzyme function of metal-containing chlorins,[2g, k] proved to be difficult: all of

34 Equiv $LiAlH(OtBu)_3$, THF, room temperature, 30 min; 2. $NaHCO_3$; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (6/1); recrystallization ($CHCl_3$/*n*-hexane); *rac*-**8** 81%. j) 1. 10 Equiv **16**, 0.9 equiv $N(nBu)_4Br$, 50% aq NaOH, CH_2Cl_2 room temperature, evacuated sealed tube, 90 h; 2. pH 4 buffer; 3. 5 M KOH, THF, 50 °C, vacuum, 90 h; 4. pH 4 buffer; flash chromatography, silica gel CH_2Cl_2/methanol (9/1), then methanol/water (1/1); 5. methanol, 10 vol% conc H_2SO_4, room temperature, 18 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (6/1), recrystallization ($CHCl_3$/*n*-hexane); *rac*-**9** 42%. k) 1. 9.5 Equiv **19**, 0.9 equiv $N(nBu)_4Br$, 50% aq NaOH, CH_2Cl_2, room temperature, evacuated sealed tube, 90 h; 2. pH 4 buffer; 3. 5 M KOH, THF, 50 °C, vacuum, 90 h; 4. pH 4 buffer; flash chromatography, silica gel, CH_2Cl_2/methanol (9/1), then methanol/water (1/1); 5. methanol, 10 vol% conc H_2SO_4, room temperature, 18 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (6/1), recrystallization ($CHCl_3$/*n*-hexane); binary mixture of diastereomers **10a** + **10b**, each 24%; analytical HPLC, Polygosil 60-10, CH_2Cl_2/methyl acetate (95/5), 2 mL min^{-1}, t_{R1} = 7.7 min, t_{R2} = 9.2 min, separation of the diastereomers.

the crystals were twinned, two crystallographically independent molecules are found in the unit cell, and these molecules have a certain degree of disorder. Both molecules, which differ primarily in the conformations of the side chains, are saddle-shaped and deviate from planarity (Fig. 1).[9] Some

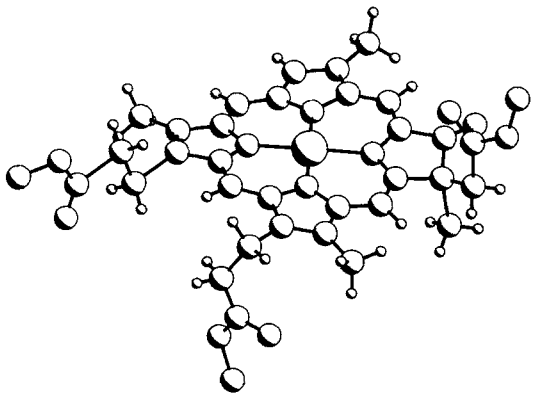

Fig. 1. Crystal structure of one of the two independent molecules of *rac*-**11** with the d_m parameter[9] 0.21 Å. The side view shows the marginal deviation of the ligand system from planarity ("ruffling"). The second molecule differs only in the relative orientation of its side chains.

of the atoms in the molecules have large values for the anisotropic temperature parameter in the direction perpendicular to the ring system. This indicates that each of the two molecules actually has at least two conformations that are less planar than the structures obtained in the X-ray analysis. The Ni–N distances range from 191(1) to 199(1) pm; as expected the Ni–N bond to the saturated pyrrole ring is the longest. We are currently investigating the effect the saddle-shaped deformation has on the redox behavior of chlorin, as this could be of importance in the biological function of metallochlorins.

The Wittig and Wittig–Horner reactions were used to attach functionalized residues to the keto group of the nickelchlorin *rac*-**11** to yield *rac*-**12** and *rac*-**13**; the metal-free oxochlorin *rac*-**14** did not react. The keto function of *rac*-**14** was reduced stereoselectively with excess $LiAl(OtBu)_3H$ under the directing influence of the acetic acid side chain to give the α-hydroxychorin *rac*-**8**. The trace amounts of the β-alcohol reacted with the acetic acid side chain also positioned β to form a lactone which could be removed easily by chromatography.

The hydroxyl group in *rac*-**8** was etherified with various alkyl groups under phase-transfer catalysis. With a view to photosynthesis models we treated the hydroquinone bromide **16**, available from **15** in five steps (Scheme 2), with *rac*-**8** to provide the chlorinhydroquinone ether *rac*-**9**.

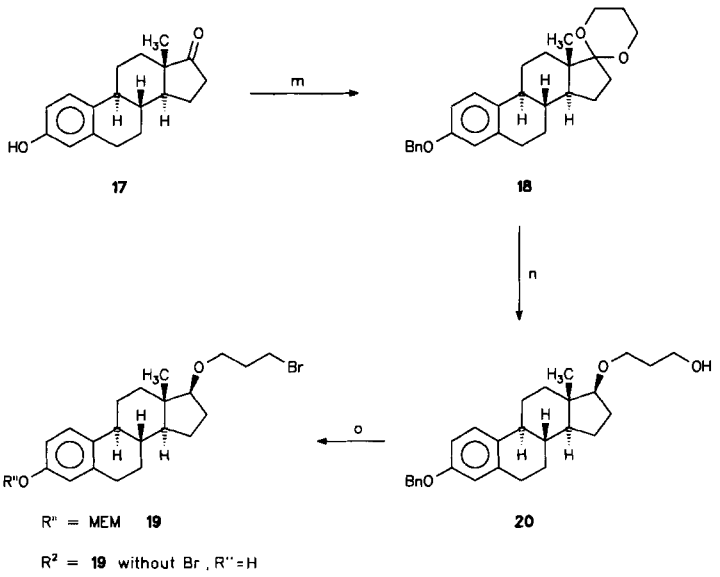
Scheme 2. l) 1. 3 Equiv methoxyethoxymethyl chloride (MEMCl), 3 equiv *N*,*N*-diisopropylethylamine, 0.01 equiv 4-dimethylaminopyridine (DMAP), CH_2Cl_2, 0 °C to room temperature, 20 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (9/1), ether/petroleum ether (2/1); 73%; 2. $(H_3CO)_2P(O)CH_2CO_2CH_3$, *n*BuLi, THF, −10 °C, 15 min; addition of the lithium phosphonate, 0 °C to room temperature, 6 h; flash chromatography, silica gel, ether/petroleum ether (2/1); 93%; 3. H_2 (1 atm), Pd/C (10%), methyl acetate, room temperature, 20 h; flash chromatography, silica gel, ether/petroleum ether (2/1); 85%; 4. 2.9 equiv $LiBH_4$, diglyme, 110 °C, 5.5 h; flash chromatography, silica gel, ether/petroleum ether (2/1); 70%; 5. 1.4 equiv methanesulfonyl chloride, 1.5 equiv triethylamine, CH_2Cl_2, −10 °C, 2 h; 3.2 equiv KBr, 2.7 equiv [18]crown-6, acetone, room temperature, 18 h, flash chromatography, silica gel, ether/petroleum ether (2/1); **16** 91% (37% based on **15**).



R^2 = **19** without Br, R"=H

Scheme 3. m) 1. 1.1 Equiv benzyl chloride, 1.1 equiv K_2CO_3, ethanol, reflux, 6 h; 0.5 M NaOH; 94%; 2. 2.2 equiv propane-1,3-diol, 0.03 equiv *p*-toluenesulfonic acid monohydrate, Na_2SO_4, 3 Å molecular sieves, toluene, reflux, 22 h; flash chromatography, silica gel, CH_2Cl_2/petroleum ether (5/1); **18** 67% (63% based on **17**). n) 1. 1.25 Equiv $H_3B{\cdot}S(CH_3)_2$, 1.26 $F_3CSO_3Si(CH_3)_3$, CH_2Cl_2, −78 °C, 1.5 h [10]; 2. saturated aq $NaHCO_3$ solution; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (19/1), recrystallization (methanol); **20** 92%. o) 1. 1.6 Equiv benzoyl chloride, 0.09 equiv DMAP, pyridine, 0 °C to rooom temperature, 3.5 h; kugelrohr distillation; flash chromatography, silica gel, CH_2Cl_2/petroleum ether (4/1), recrystallization (acetone); 91%; 2. H_2 (1 atm), Pd/C (10%), ethyl acetate, room temperature, 16 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (19/1); 94%; 3. 1.2 equiv *n*BuLi, THF, −10 °C, 30 min; addition of 1.3 equiv MEMCl, −10 °C, 2 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (19/1); 92%; 4. NaOMe/NaOH, methanol/water (3/1), room temperature, 20 h; flash chromatography, silica gel, CH_2Cl_2/methyl acetate (9/1); 96%; 5. 1.3 equiv methanesulfonyl chloride, 1.5 equiv triethylamine, CH_2Cl_2 −15 °C, 2 h; 7 equiv KBr, 5 equiv [18]crown-6, acetone, room temperature, 18 h; flash chromatography, silica gel, CH_2Cl_2/petroleum ether (9/1); **19** 75% (57% based on **20**).

Chorin *rac*-**8** was attached to estradiol derivative **19**, which was prepared in a few steps (Scheme 3), in order to optimize the biological properties of photodynamically active sensitizers and to bind chlorins to the estrogen receptors as fluorescence markers.[6a] In estrogens the structural region with the phenolic hydroxyl group is crucial for receptor binding;[6b] thus the chlorin was attached with a diether spacer of appropriate length to the 17-hydroxyl function of the estradiol.

The homochiral diastereomeric estrogen chlorin ethers **10a** and **10b** obtained by the introduction of the enantiomerically pure estrogen unit were separated by analytical HPLC; this should also be possible for the preparative-scale resolution of chlorin *rac*-**8**. Spectroscopic data for selected compounds are provided in Table 1.

Table 1. Selected spectroscopic data for *rac*-**8**, *rac*-**9**, *rac*-**10a,b**, *rac*-**11**, and *rac*-**14**.

$KCeSe_4$: A New Solid-State Lanthanide Polychalcogenide**

By *Anthony C. Sutorik* and *Mercouri G. Kanatzidis**

Although interest in both solid-state and soluble metal polychalcogenide compounds has increased over the last few years, the extension of this work to the lanthanides and actinides has yet to be fully realized. At present only a handful of these compounds have been confirmed to possess polychalcogenido ligands, although several others are suspected to by analogy.[1] Rare earth metals are highly oxophilic, which precludes the use of oxygen-containing solvents commonly employed for solution reactions. A preparative

method which satisfies the requirements of being both oxygen-free and enables the use of large quantities of polychalcogenides is the molten salt technique. The use of molten alkali metal polychalcogide fluxes as both reactant and media has been shown to give a wide variety of new alkali metal/transition metal polychalcogenide compounds, especially when the reaction temperature is maintained within the range of 250–400 °C, which favors polychalcogenide formation.[2, 3] We have studied the reactivity of lanthanides and actinides in various alkali metal polychalcogenide fluxes, and we now report on the synthesis of $KCeSe_4$, a new solid-state lanthanide polychalcogenide compound with a novel, but remarkably simple, structure, containing exclusively Se_2^{2-} units.

In the $KCeSe_4$ structure,[4] Ce and Se form anionic layers with K^+ ions in the cavity between the layers. The anionic layers themselves are further partitioned into two layers of Se_2^{2-} units, which sandwich a layer of Ce^{3+} ions. The Ce^{3+} ions are in a square antiprismatic environment, coordinated to the ends of eight diselenide ions, four above the Ce plane and four below (see Fig. 1). The Se_2^{2-} units point in one direction within one layer and this direction is reversed in the layer below. The net effect is such that when projected onto the (001) plane, a pattern of two crosses with a common center as inversion center is seen. Each Se_2^{2-} unit bridges four Ce^{3+} ions, whereby each Se atom acts as a μ_2 bridge; the expanded anionic layer is shown in Figure 2. The K^+ ions are not shown but are, in fact, colinear with the Ce^{3+} ions and are displaced from these by only half the length of the c axis. Hence, except for their distances from the Se_2^{2-} layers, Ce^{3+} and K^+ have the same coordination environment. A further feature of this structure is the formation of channels parallel to (110), which are bound on both sides by Ce^{3+} and above and below by Se_2^{2-} (Fig. 3). Their dimensions are 4.16 Å (Ce–Ce) by 3.61 Å (Se–Se), and hence, they are too small for intercalation of most species, although Li intercalation may be possibile by the reduction of Se_2^{2-} to $2Se^{2-}$.

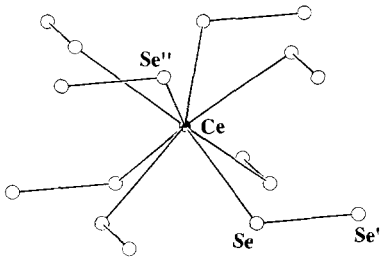

Fig. 1. Immediate coordination environment of Ce^{3+} in $KCeSe_4$. The Ce^{3+} ion is coordinated to one end of eight separate Se_2^{2-} units in a square-antiprismatic arrangement. The Ce^{3+} ion has the point symmetry of 422 and the Se atom resides on a mirror plane; hence, all Se atoms are crystallographically equivalent. Selected bond lengths [Å] and angles [°]: Ce-Se 3.075(1); Se-Se' 2.385(3); Se-Ce-Se'' 69.92(3); Ce-Se-Se' 110.20(3).

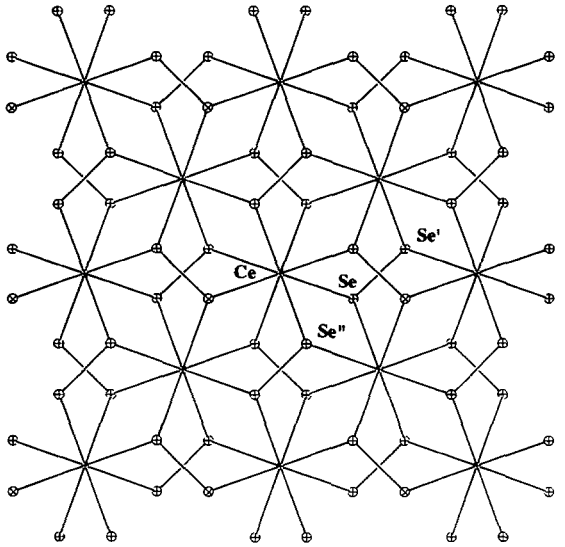

Fig. 2. View along the c axis of the anionic layers in $KCeSe_4$. The Ce^{3+} ions are represented by the eight-coordinate, shaded ellipses, and the Se atoms by the nonshaded ellipses.

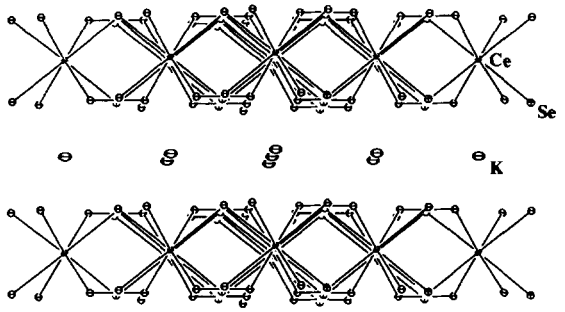

Fig. 3. View of $KCeSe_4$ showing intralayer channels parallel to the (110) planes. K^+ ions are included between the layers. The dimensions of the intralayer channels are 4.16 Å (Ce–Ce) by 3.61 Å (Se–Se).

The repeating unit shown in Figure 1 is the same unit which is found in two closely related three-dimensional structure types: $CuAl_2$ and $NbTe_4$. The former is found in several compounds of the formula TX_2 (T = transition metal, X = Sb, Ge, Sn, or Pb).[5] It is simply the result of fusing the anionic layers of $KCeSe_4$, through face-sharing at the square antiprisms, into a three-dimensional structure. Indeed, since K and Ce share coordination spheres, $KCeSe_4$ can be considered as a derivative of $CuAl_2$, in which the two cations alternate in the Cu positions along the c axis. The $NbTe_4$ structure[6] is also closely related to $CuAl_2$; the Nb cations reside in half of the Cu positions and are ordered such that every second plane of metal positions is vacant, forming a porous structure. $NbTe_4$ has Te_2^{2-} units, analogous to the Se_2^{2-} units in $KCeSe_4$.

Previously, only two structure types had been known for alkali metal(A) lanthanide(Ln) chalcogenide(Q) systems. Both have the stoichiometry $ALnQ_2$.[7] The first type is simply a NaCl structure with the A^+ and Ln^{3+} ions randomly distributed in the lattice. The second is the α-$NaFeO_2$ structure type, itself derived from the NaCl structure, in which the two cations are partitioned into alternating layers throughout the lattice. Thus, $KCeSe_4$ represents a new structural motif for a potential new family of alkali metal lanthanide polychalcogenides.[8]

A solid-state far-IR spectrum of $KCeSe_4$ shows only a broad absorption band beginning at 250 cm^{-1}. A conductivity measurement on a pressed pellet using four probes was performed at 300 K. A value of 5.1×10^{-6} $S cm^{-1}$ was found, indicating a semiconducting material. The diffuse reflectance spectrum of a microcrystalline sample of $KCeSe_4$ measured in the range of 2500 to 190 nm shows an abrupt absorption edge at approximately 780 nm, which suggests a band gap in the neighborhood of 1.59 eV.

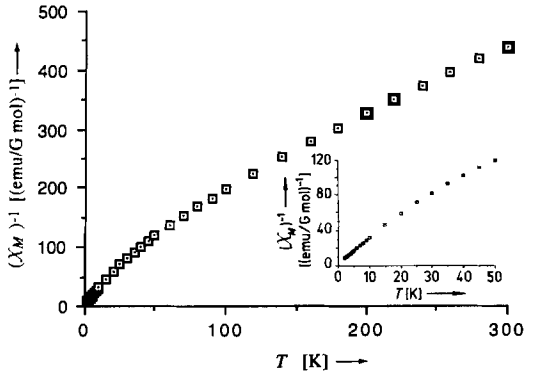

Fig. 4. Plot of $1/\chi_m$ vs. T; data taken at 500 G for $KCeSe_4$. The inset graph shows an expanded plot of the region between 2–50 K.

The magnetic susceptibility of $KCeSe_4$ was measured from 2 to 300 K at 500 G; a plot of $1/\chi$ vs. T is shown in Figure 4. $KCeSe_4$ appears to be paramagnetic, although several anomalies in the data are present. At temperatures below 100 K, the curve deviates negatively from a straight line extrapolated from the higher temperature data. Similar deviations have been reported for several Ce^{3+} compounds and have been attributed to crystal-field splitting of the cation's $^2F_{5/2}$ ground state.[9] At temperatures above 100 K, the Curie–Weiss law is not strictly adhered to, and a slight curvature remains in the data. In this temperature range an average μ_{eff} value of 2.29 μ_B has been calculated. This value is in accordance with the usual range for Ce^{III} compounds (2.3–2.5 μ_B) and is close to that of the free ion (2.54 μ_B) due to the shielding effect the outer electron cloud has on the embedded f orbitals.[10] We found that the measurements must be done on freshly prepared samples of $KCeSe_4$; older samples tend to give artificially high values for μ_{eff}, implying a phase change. This phase change probably occurs to a small extent on the sample surface because the bulk of the sample remains intact as shown by X-ray powder diffraction.

With the synthesis of $KCeSe_4$, we have demonstrated that alkali metal polychalcogenide fluxes can be employed to synthesize new lanthanide polychalcogenide materials. This, along with the recently discovered molecular complex $[U(Se_2)_4]^{4-}$,[11] also synthesized from a molten salt flux, opens the entire f block to further investigation. Given the potential these metals have for eightfold coordination and the known structural diversity of polychalcogenido ligands, the possibilities for synthesizing new and novel structure types become intriguingly vast.[8]

Experimental Procedure

$KCeSe_4$ was synthesized from a reaction of K_2Se (0.078 g, 0.5 mmol), Ce (0.035 g, 0.25 mmol), and Se (0.158 g, 2 mmol). These starting materials were thoroughly mixed in a glove box under a nitrogen atmosphere and loaded into pyrex tubes, which were subsequently evacuated to approximately 2×10^{-3} mbar and flame-sealed. The mixture was heated at 300 °C for 6 days and cooled at a rate of 2 °C h^{-1} to 100 °C then cooled to 50 °C in 1 h. The product was isolated by dissolving away the residual polyselenide flux with several portions of degassed dimethylformamide (DMF) under a nitrogen atmosphere until the solvent remained clear, indicating complete removal of the polyselenide. The remaining material consisted of deep blue to black chunks of $KCeSe_4$. The product was insoluble in DMF and was inert in both air and water for extended periods, although some surface degradation was evidence in the magnetic susceptibility studies. Homogeneity was confirmed by a comparison of the product's powder X-ray diffraction against one calculated with X-ray single-crystal data. A yield of 61%, based on Ce, was typical.

Mutual Catalysis of Neutral and Anionic Cobalt Carbonyls in Their CO Scrambling Reactions**

By *Giuseppe Fachinetti** and *Tiziana Funaioli*

Carbonyl substitution is thought to be an important step in many syntheses and catalytic processes involving metal carbonyls, and there is a considerable interest in methods of assisting thermal substitution of CO ligands.[1] It was thought that $[Co(CO)_4]^-$, like a number of mononuclear 18-electron carbonylmetalates, for example $[V(CO)_6]^-$, $[Mn(CO)_5]^-$, $[Re(CO)_5]^-$, does not react with either labeled CO or phosphanes.[2] However, it was recently shown that alkali metal counterions accelerate the substitution reactions

[**] This work was supported by Ministero dell' Università e della Ricerca Scientifica e Tecnologica (MURST). We thank Dr. G. Fochi for helpful discussions.

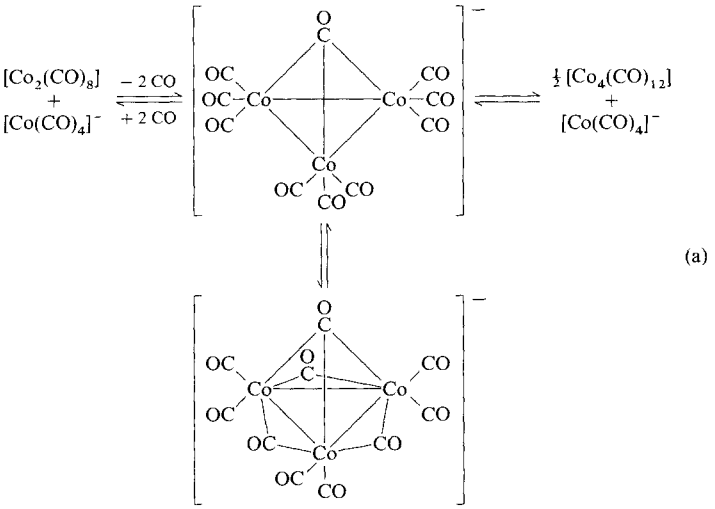
of CO groups in $[Co(CO)_4]^-$ in tetrahydrofuran (THF) solution:[3] the important role of ion-pairing phenomena was recognized, and the involvement of the 16-electron species $[Co(CO)_3]^-$ suggested.

Fig. 1. IR spectrum of a solution of $[NaCo(CO)_4]$ (0.02 M) in THF equilibrated under a ^{13}CO atmosphere (ratio $CO/^{13}CO = 1/1$).

Our own investigations of the factors affecting lability of CO ligands in $[Co(CO)_4]^-$, however, show that ion pairing with alkali metal counterions does not promote thermal CO dissociation from the carbonylmetalate at room temperature. Such a dissociation would require ^{13}CO exchange with $Na[Co(CO)_4]$ to occur in THF, in which ion pairs are evident.[4] However, this is not the case if the solution is pretreated with a reducing agent in order to destroy adventitious oxidants. The addition of the homogeneous reducing agent $[CoCp_2]$ (Cp = η^5-cyclopentadienyl) to a 0.02 M solution of $Na[Co(CO)_4]$ (1:10 molar ratio) completely inhibits the scrambling reaction between $[Co(CO)_4]^-$ and gaseous ^{13}CO. On the other hand, CO exchange is initiated by oxidizing the solution with sufficient oxygen to destroy the added $[CoCp_2]$: the IR spectrum shown in Figure 1 is obtained within 30 to 90 min at room temperature, when the CO ligands of $Na[Co(CO)_4]$ are equilibrated with an equimolar amount of ^{13}CO in THF. It seems possible, therefore, that the previously reported facile substitution reactions of $[Co(CO)_4]^-$ with acidic counterions in THF[3a] had arisen from a mechanism induced by traces of oxygen. Thus, the ion-pairing phenomena may merely increase the air sensitivity of $[Co(CO)_4]^-$ due to perturbation by the polarizing cation.[4b] Accordingly, the symmetrical $[Co(CO)_4]^-$ with a PPN^+ (PPN^+ = bis(triphenylphosphoranylidene)ammonium) counterion reacts only slowly with air, and was found to be inert towards substitution reactions.

These findings indicate that CO scrambling reactions of $[Co(CO)_4]^-$ follow a chemical oxidation and are therefore an example of electron-transfer catalysis (ETC).[5] A radical-chain mechanism would account for this ETC: trace amounts of oxygen react with $[Co(CO)_4]^-$, when the latter is activated by ion pairing; the intermediate $[Co(CO)_4]^\bullet$ could thus be generated. Like other 17-electron metal carbonyl radicals $[Co(CO)_4]^\bullet$ is expected to be prone to substitution:[6] electronic stabilization of the 19-electron hypervalent transition state, resulting from the association between the 17-electron radical and the incoming ligand, supplies the low-energy pathway for the substitution process.

An alternative mechanism for the CO scrambling of $[Co(CO)_4]^-$ catalyzed by electron transfer suggested itself when we found the anionic cluster $[Co_3(CO)_{10}]^-$ as a product of the reaction between the ion-pair activated $[Co(CO)_4]^-$ and traces of oxygen. After the short exposure of a 0.015 M diethyl ether solution of $Na[Co(CO)_4]$ to air, the formation of $[Co_3(CO)_{10}]^-$ was revealed by the appearance of an intense red color (λ_{max} = 530 nm); moreover analysis of the solution by IR spectroscopy revealed an absorption at 2006 cm^{-1}, characteristic for $[Co_3(CO)_{10}]^-$.[7] On the other hand, it has been stated that $[Co_3(CO)_{10}]^-$ participates in the fast equilibrium reaction (a),[7, 8] and it has also been observed that CO groups of this anionic cluster interchange rapidly with each other through a fast equilibrium between terminal and edge-bridging CO groups [see Eq. (a)].[9]



(a)

Therefore, we propose that $[Co_3(Co)_{10}]^-$ is the intermediate which causes the observed lability of the CO ligands of both neutral and anionic cobalt carbonyls in a solution where $[Co(CO)_4]^-$ and $[Co_2(CO)_8]$ or $[Co_4(CO)_{12}]$ exist simultaneously. This hypothesis requires that even the CO ligands of the reportedly inert $PPN[Co(CO)_4]$[3a] are activated by catalytic amounts of either $[Co_2(CO)_8]$ or $[Co_4(CO)_{12}]$ and that, reciprocally, catalytic amounts of $[Co(CO)_4]^-$ salts make the CO ligands of neutral cobalt carbonyls labile. We found that under a CO atmosphere, catalytic amounts of $[Co_2(CO)_8]$ promote CO scrambling in $PPN[Co(CO)_4]$ (case a), under an inert atmosphere, catalytic amounts of $[Co_4(CO)_{12}]$ promote the CO scrambling between $PPN[Co(CO)_4]$ and $PPN[Co(^{13}CO)_4]$ (case b), and that reciprocally, catalytic amounts of $Na[Co(CO)_4]$ accelerate the CO scrambling between $[Co_2(CO)_8]$ and gaseous ^{13}CO (case c) and promote the scrambling between $[Co_4(CO)_{12}]$ and $[Co_4(^{13}CO)_{12}]$ under an inert atmosphere (case d).

Case a: While $PPN[Co(CO)_4]$ is known not to incorporate ^{13}CO at room temperature,[3a] upon addition of $[Co_2(CO)_8]$ to a 0.016 M THF solution of the PPN^+ salt ($[Co_2(CO)_8]/PPN[Co(CO)_4]$, 0.05 molar ratio), a fast CO scrambling occurs. The IR spectrum shown in Figure 2 is obtained within 15 min when CO ligands bonded to cobalt are allowed to equilibrate with equimolar amounts of gaseous ^{13}CO.

Case b: Under an argon atmosphere, no CO scrambling is observed in a solution of $PPN[Co(CO)_4]$ and $PPN[Co(^{13}CO)_4]$ (each 0.08 M) in THF: the CO stretching region of the IR spectrum (Fig. 2 dashed line) remains unchanged for hours and shows two strong bands at 1887 and 1842 cm^{-1} due to unperturbed $[Co(CO)_4]^-$ and $[Co(^{13}CO)_4]^-$, respectively. A weak absorption at 1808 cm^{-1} accompanies the

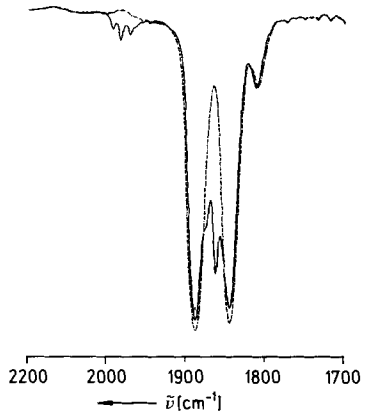


Fig. 2. IR spectrum of a solution of PPN[Co(CO)$_4$] and PPN[Co(^{13}CO)$_4$] in THF (both 0.08 M) (dashed line) and after the addition of a catalytic amount of [Co$_4$(CO)$_{12}$] (solid line).

band at 1842 cm^{-1} and is probably due to traces of ^{13}C^{18}O. However, if [Co$_4$(CO)$_{12}$] is added to the solution of PPN[Co(CO)$_4$] and PPN[Co(^{13}CO)$_4$] ([Co$_4$(CO)$_{12}$]/tetracarbonylcobaltates, 0-01 molar ratio), the IR spectrum in Figure 2 (solid line) shows that complete CO scrambling occurs immediately after mixing.

Case c: In agreement with Brown et al.,[10] we found that the [Co$_2$(CO)$_8$]/^{13}CO scrambling reaction proceeds even in the absence of [Co(CO)$_4$]$^-$; however, the addition of Na[Co(CO)$_4$] accelerates this reaction in Et$_2$O at 0 °C. As monitored by IR spectroscopy (Fig. 3), equilibration of a 0.013 M solution of [Co$_2$(CO)$_8$] in Et$_2$O with ^{13}CO at atmospheric pressure requires 50 min, whereas following the addition of Na[Co(CO)$_4$] to this solution (0.1 molar ratio) complete scrambling is attained within 10 min.

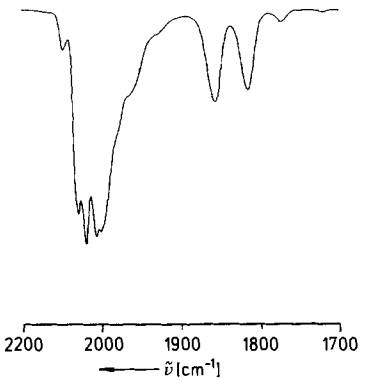

Fig. 3. IR spectrum of solution of [Co$_2$(CO)$_8$] (0.013 M) in Et$_2$O equilibrated under a ^{13}CO atmosphere (ratio CO/^{13}CO = 1/1).

Case d: Under an argon atmosphere, no CO scrambling is observed in a solution of [Co$_4$(CO)$_{12}$] and [Co$_4$(^{13}CO)$_{12}$] (each 0.008 M) in Et$_2$O on the timescale of the subsequent experiment for the catalysis with Na[Co(CO)$_4$]. After one hour at room temperature, the CO stretching region of the IR spectrum of this solution is still the sum of the spectra of isotopically pure [Co$_4$(CO)$_{12}$] and [Co$_4$(^{13}CO)$_{12}$] (Fig. 4a). However, the IR spectrum recorded immediately after the addition of Na[Co(CO)$_4$] (molar ratio 1:20) (Fig. 4b) shows that the [Co(CO)$_4$]$^-$ catalyzed CO scrambling occurs extremely rapidly.

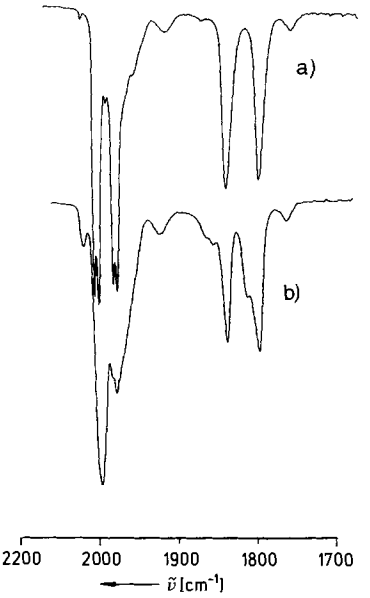

Fig. 4. IR spectra of a solution of [Co$_4$(CO)$_{12}$] and [Co$_4$(^{13}CO)$_{12}$] in Et$_2$O (both 0.008 M) a) before, and b) after the addition of a catalytic amount of Na[Co(CO)$_4$].

Our findings indicate that CO scrambling reactions of [Co(CO)$_4$]$^-$ are electron transfer catalyzed processes that can be initiated by traces of oxygen. While a radical-chain mechanism was documented for other oxidatively induced CO substitutions in metal carbonyls,[5] in the present case a redox condensation mechanism is proposed. In fact a redox condensation between [Co(CO)$_4$]$^-$ and the neutral cobalt carbonyls formed by the oxidation of [Co(CO)$_4$]$^-$ has been observed[7] [Eq. (a)]; this accounts for the mutual catalysis of their respective CO scrambling. Furthermore, a radical-chain mechanism based on [Co(CO)$_4$]$^\bullet$ cannot justify the extremely rapid CO scrambling observed under an inert atmosphere (cases b and d), when compared to the relatively moderate catalytic effect under a CO atmosphere (cases a and c). On the contrary, the fact that the free, incoming CO ligand slows the mutually catalyzed CO scrambling of both neutral and anionic cobalt carbonyls can be rationalized by assuming [Co$_3$(CO)$_{10}$]$^-$ as an intermediate. Its steady-state concentration in a [Co$_2$(CO)$_8$]/[Co(CO)$_4$]$^-$ solution is indeed controlled by CO partial pressure.[7] Apart from the mechanism which needs further support, this work demonstrates that the fundamental property of both neutral and anionic cobalt carbonyls, that is, CO ligand lability, is influenced dramatically by the presence of complexes belonging to the other class.

These observations are of general interest, first because the [Co(CO)$_4$]$^-$ ions formed in disproportionation reactions always accompany neutral cobalt carbonyls, unless in hydrocarbon solvents and under strictly controlled conditions, and second neutral cobalt carbonyls can be formed by oxidation of [Co(CO)$_4$]$^-$.

Experimental Procedure

Solid Na[Co(CO)$_4$] (78 mg, 0.40 mmol) was added under argon to a pale red solution of [CoCp$_2$] (0.002 M) in THF (20 mL) in a 150 mL closed vessel. Through a rubber septum, ^{13}CO (99% isotopical purity, MSD Isotopes) (38 mL, 1.6 mmol) was added to the atmosphere above the solution with a syringe. After the solution had been stirred for 24 h, a sample was withdrawn for IR analysis. 3 mL of air were then added, and additional samples were withdrawn after 15, 30, 60, and 90 min. The CO scrambling in PPN[Co(CO)$_4$],

$[Co_2(CO)_8]$, and $[Co_4(CO)_{12}]$ was studied by similar techniques. $Na[Co(^{13}CO)_4]$ was synthesized by Hieber's cyanide method [11]. The product was isolated as an analytically pure solid on saturation of the water solution with NaCl followed by continuous extraction with Et_2O. The extract was dried with Na_2SO_4 and finally evaporated to dryness. Typical yields were 60% based on the ^{13}CO introduced. $PPN[Co(^{13}CO)_4]$ was prepared by a metathesis reaction between PPNCl and $Na[Co(^{13}CO)_4]$ in CH_3OH/H_2O.

$[Co_4(^{13}CO)_{12}]$: To a suspension of $Na[Co(^{13}CO)_4]$ (480 mg, 2.42 mmol) in *n*-hexane (100 mL) was added HCl (60 mL, 2.50 mmol) through a rubber septum. The suspension was stirred for 24 h at 50 °C and then refluxed for 3 h. Solid impurities were removed by filtration, and black crystals of $[Co_4(^{13}CO)_{12}]$ were obtained (210 mg; 60% yield) by cooling the mother liquor to −20 °C.

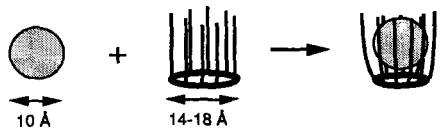
C_{60} and C_{70} in a Basket? – Investigations of Mono- and Multilayers from Azacrown Compounds and Fullerenes

By *Francois Diederich, Jochem Effing, Ulrich Jonas, Ludovic Jullien, Thomas Plesnivy, Helmut Ringsdorf,* Carlo Thilgen,* and *David Weinstein*

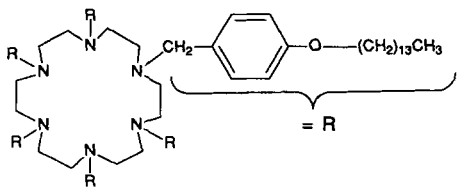
The spreading behavior of fullerenes at the air–water interface and the formation of Langmuir–Blodgett (LB) films on solid substrates has already been described in several publications. [1–4] The results are in part contradictory. The behavior of pure fullerenes C_{60} and C_{70} at the air–water interface indicates a collapsed film rather than a homogeneous monolayer. Even mixed films of C_{60} and fatty acids or long-chain alcohols in a 1:1 ratio[2–4] do not give the expected areas, but also point to C_{60}-aggregates; we have confirmed these results.[5] We report here on mono- and multilayers of 1:1 mixtures of the C_{60} and C_{70} fullerenes (represented by **1**) and amphiphilic molecules **2** containing a lipophilic cavity (the "basket") (Scheme 1).



1 **2**

Scheme 1.

Although hydrophobic cyclodextrins,[6, 7] calixarenes,[7] and alkylated and acylated azacrown derivatives of different ring sizes were used as component **2** of Scheme 1, only the results with the alkylated hexaazacrown compound **3** and the acylated octaazacrown compound **4** will be reported here.



3

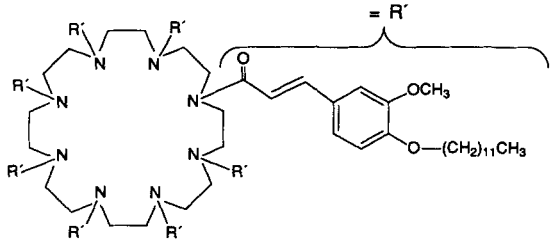


Figure 1 shows the surface pressure–area behavior of pure hexaazacrown **3** and that of 1:1 mixtures of **3** with C_{60} or C_{70}. The surface density, that is, the number of spread molecules **3** per air–water surface area, was the same in all experiments.[8] All curves are reproducible, and repeated compression–expansion experiments (hysteresis curves) give identical plots.

The fact that for all three systems similar collapse areas were found is a first indication that the fullerenes may at least partially be situated inside the cavities of the crown molecules. This is supported by the comparison of the width of the "transition regions" of the different mixing ratios (C_{60}/**3**). The less C_{60} is incorporated into the crowns, the narrower is the width of the plateau. Further indications pointing to such a complexation are the slight shifts in the UV/VIS spectra of the multilayers (see below).

The incorporation of the fullerenes into the monolayers of the azacrown compounds has a stabilizing effect on the film as clearly shown in Figure 2 for the octaazacrown **4** with C_{60} and C_{70}.

Although **4** has a larger diameter than **3**, the collapse area of **4** increases slightly in the presence of the fullerenes (average of three experiments); this is not the case for **3**. The

collapse area, the collapse pressure, and the area at pressure 0 mN m^{-1} of the azacrown/fullerene monolayers are given in Table 1.

Table 1. Data for monolayers of the hexa- and octaazacrown compounds **3** and **4**, respectively, with and without C_{60} or C_{70} [a].

Film	A_c [Å^2 mol^{-1}]	p_c [mN m^{-1}]	A_0 [Å^2 mol^{-1}]
3	148 ± 3	47 ± 3	170 ± 6
3/C_{60}	141 ± 6	52 ± 3	225 ± 5
3/C_{70}	137 ± 6	54 ± 3	205 ± 15
4	229 ± 3	40 ± 1	275 ± 2
4/C_{60}	263 ± 12	48 ± 1	325 ± 15
4/C_{70}	269 ± 8	46 ± 3	325 ± 9

[a] A_c: collapse area, p: collapse pressure, A_0: area at 0 mN m^{-1} pressure. A [Å^2 mol^{-1}] = area per crown molecule or fullerene/crown molecule pair. The numbers are average values of three or four experiments.

In addition, apparently well-defined multilayers can be built from all monolayers of azacrown/fullerene mixtures by the LB technique. However, all attempts to transfer pure hexaazacrown **3** to a hydrophilic substrate (quartz, glass, mica) or to hydrophobic supports (teflon, hydrophobized quartz) were unsuccessful. Likewise, it was not possible to transfer a defined monolayer of pure C_{60}, as already shown by other researchers.[2–4] Multilayers from mixtures of C_{60} with classical amphiphiles like icosanoic acid[3] or octadecanol,[4] which themselves can form stable multilayers, were described. Both **3** and the fullerene are unable to form LB films alone. In contrast, the 1:1 mixtures of **3** with C_{60} and C_{70} form homogeneous LB multilayers (Y-type, both on hydrophilic and on hydrophobic substrate) with an average bilayer thickness of approximately 47 Å (SAXS[9]). The incorporation of **3** and of the fullerenes into the multilayers was confirmed by UV/VIS spectroscopy. Figure 3 shows the absorption spectrum of the C_{60}/**3** LB film and a calculated spectrum (addition of the spectra of the components). Similar results were obtained for the multilayers of C_{70}/**3**. The microscopic environment of the fullerene molecules in the azacrown films (layer composition) seems to remain unchanged if more layers are added, as shown by the linear relationship between the number of layers and the absorption maxima of the peaks in the UV/VIS spectra.

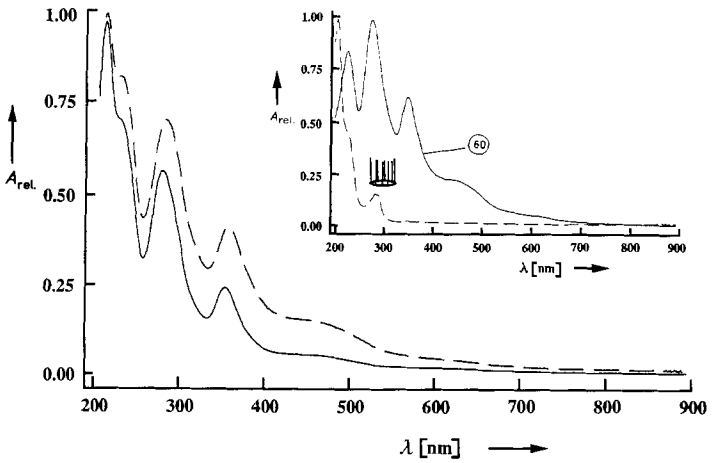

Fig. 3. Experimental and theoretical UV/VIS spectra of an LB multilayer consisting of LB films of a 1:1 mixture of C_{60} and **3** (2 × 17.5 bilayers). Solid line: recorded spectrum. Broken line: the spectrum obtained by addition of the spectra of films of pure **3** and C_{60}. The absorption values are relative ($A_{rel.}$); the highest peak is arbitrarily set to 1. The inset shows the UV/VIS spectra of the films of pure **3** and C_{60}.

The UV/VIS spectrum of the C_{60}/**4** film (Fig. 4) shows, in addition to the typical absorptions of the two pure compounds, a new peak at 256 nm, possibly arising from interactions between the C_{60} π-electron system and the cinnamic amide π electrons. Another interesting feature of the multilayer spectra is the fact that the broad band of the absorption of pure C_{60} (at 400–480 nm), arising from the interaction between different fullerene molecules (microcrystallites),[10] is diminished. This could indicate that the C_{60}-aggregation existing in the solid is in this case somewhat reduced.

As observed with the films of **3**, the regularity of the formation of the multilayers of **4** with and without the fullerenes was also confirmed by SAXS measurements (see Fig. 5). For all three multilayers Kiesig fringes were found. The bilayer thickness of the pure azacrown derivative **4** is about 40 Å, and thus only slightly greater than that for the 1:1 mixtures:

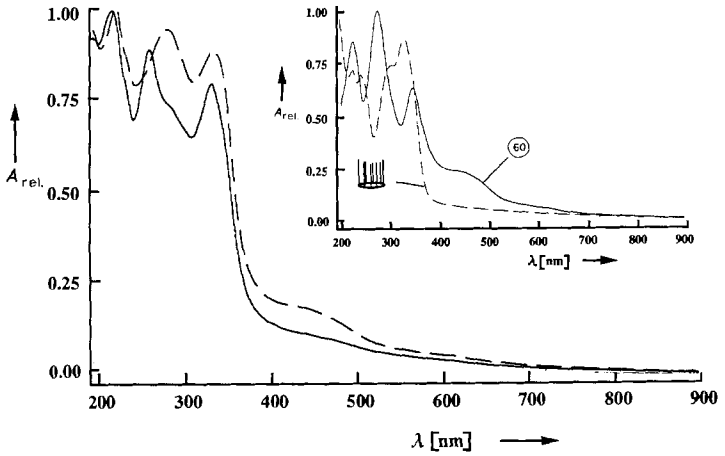

Fig. 4. Experimental and theoretical UV/VIS spectra of a LB multilayer consisting of LB films of a 1:1 mixture of C_{60} and **4** (2 × 12.5 bilayers). Solid line: recorded spectrum. Broken line: the spectrum obtained by addition of the spectra of films of pure **4** and C_{60}. The absorption values are relative ($A_{rel.}$), the highest peak is arbitrarily set to 1. The absorption at 256 nm is not present in the spectra of the pure compounds shown in the inset.

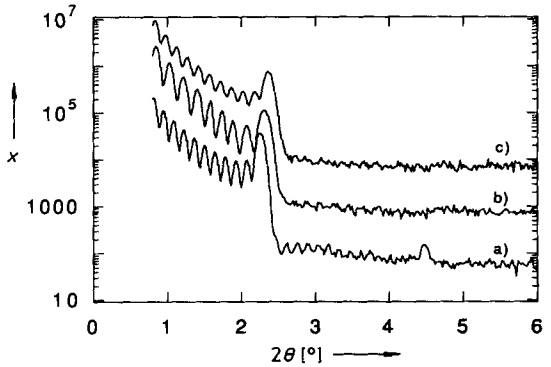

Fig. 5. Small-angle X-ray scattering plots of a) the LB film of pure **4** (15.5 bilayers), b) the C_{60}/**4** film (12.5 bilayers), and c) the C_{70}/**4** film (15.5 bilayers), all on quartz. The upper two curves are shifted in intensity by a factor of 12 for b) and by a factor of 120 for c). x = counts per 5s.

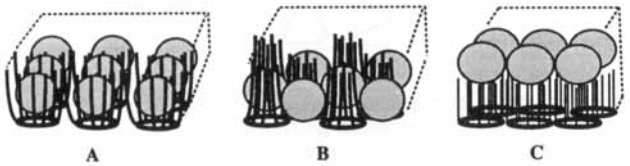
approximately 37 Å for the C_{60}/**4** LB film and approximately 38 Å for the C_{70}/**4** film.

On the basis of the present data one can only speculate on the real packing of the multilayers. Since the measured bilayer thicknesses of the pure **4** film and the 1:1 mixture films differ by just 2–3 Å, the possibility of finding the fullerenes in ordered layers on top of the films of **4** (**C** in Scheme 2) seems unlikely. Two hypothetical structures for regular films are depicted in Scheme 2 as **A** and **B**. In **B** the fullerenes would sit between the deformed crown compounds. However, this structure cannot explain the slight increase in area of the fullerene/crown complexes at the air–water interface (see Table 1). We prefer the hypothetical structure **A**, in which each fullerene molecule is located inside a crown molecule: C_{60} in the basket.



Scheme 2.

We obtained some support for the structure **A** from atomic force microscopy (AFM) measurements. Monolayers of pure **4** have homogeneous, flat surfaces. However, when the **4**/C_{60} mixture is transferred at 25 mN m^{-1}, irregular aggregates (ca. 1000 × 200 Å) appear, indicating C_{60} microcrystallites. These aggregates are also observed in the system **3**/C_{60} (Fig. 6b); here they are transferred at the same pressure (above the "transition region" in Fig. 1). If the mixed monolayer is transferred below the "transition region" at 5 mN m^{-1}, the surface is flat, and no aggregates are visible in the AFM image (Fig. 6a). This can indicate a well-mixed monolayer at low pressure in which C_{60} molecules are possibly situated inside the crown molecules. At pressures of 15–20 mN m^{-1} a demixing might occur, resulting in crystallization of the fullerenes.[11, 12]

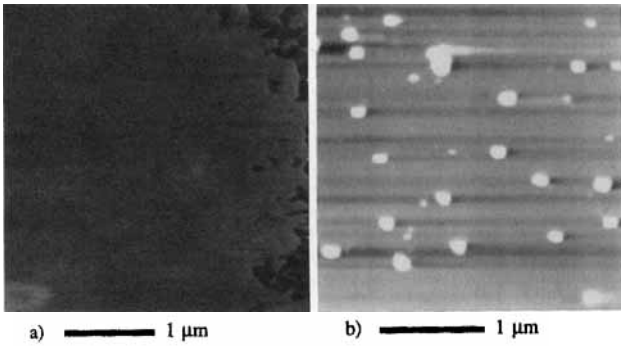


Fig. 6. Atomic force micrographs of monolayers of C_{60}/**3** (1:1 mixture) a) transferred at 5 mN m^{-1} and showing a flat film on mica (film edge visible on the right); b) transferred at 25 mN m^{-1} and revealing crystallites on the film.

In addition, AFM measurements on monolayers of calixarenes and hydrophobized cyclodextrins acting as "baskets" are under way [7]. Their mono- and multilayer behavior agree very well with the results described here for the aza-crown/fullerene mixtures.

[4] J. Milliken, D. D. Dominguez, H. H. Nelson, W. R. Barger, *Chem. Mater.* **1992**, *4*, 252–254.
[5] Area–pressure measurements were performed on a self-built, computer-controlled teflon trough with a surface of approximately 180 cm^2 and a Langmuir pressure pickup system. The measured area for the fullerenes is dependent on the spreaded amount and varied from ca. 70 Å^2 molecule^{-1} (spreading volume: 0.14 μL cm^{-2} of a 0.1 mM concentrated solution) to ca. 25 Å^2 molecule^{-1} (1.7 μL cm^{-2}; 0.1 mM) in the case of C_{60}. Areas from ca. 50 Å^2 molecule^{-1} (0.14 μL cm^{-2}; 0.1 mM) to ca. 25 Å^2 molecule^{-1} (1.7 μL cm^{-2}; 0.1 mM) were obtained for C_{70}. This behavior varies with the trough dimensions, and is most probably due to crystallization and collapse of the film at the water–teflon rim.
[6] A γ-cyclodextrin/C_{60} complex was previously described by T. Anderson, K. Nilsson, M. Sundahl, G. Westman, O. Wennerström (*J. Chem. Soc. Chem. Commun.* **1992**, 604–606).
[7] V. Böhmer, F. Diederich, J. Effing, U. Jonas, L. Jullien, T. Plesnivy, H. Ringsdorf, W. Vogt, unpublished.

[8] The alkylated hexaazacrown **3** and the acylated octaazacrown **4** were spread from a 0.1 mM solution of the pure crown compound in benzene at 20 °C on a water subphase (distilled, millipore filtered, 18 MΩcm). The same trough as in [5] was used, on which 50 or 100 μL were spread in different runs. The 1:1 mixtures were prepared by combining equal volumes of the fullerene and the crown solution (both 0.1 mM in benzene). To obtain the same surface density of the crown compounds, 100 and 200 μL of these 1:1 mixtures were spread. As a result of the hypothesis that fullerenes are accommodated inside the crown molecule, all area calculations are based on the concentration of the crown molecules.

[9] Small-angle X-ray scattering (SAXS) measurements were performed on LB films consisting of about 17 bilayers on quartz slices with a θ-2θ goniometer from Siemens.

[10] The long wavelength absorption between 400 and 480 nm due to C_{60} aggregation is relatively intense and must not be mistaken for the very weak bands between 500 and 650 nm for homogeneous solutions of C_{60} (violet!). Arguments that this relatively strong absorption at 400–480 nm is caused by C_{60} aggregation result from the comparison of the spectrum of a hexane solution (H. Ajie, M. M. Alvarez, S. J. Anz, R. D. Beck, F. Diederich, K. Fostiropoulos, D. R. Huffman, W. Krätschmer, Y. Rubin, K. E. Schriver, D. Sensharma, R. L. Whetten, *J. Phys. Chem.* **1990**, *94*, 8630) with a solid C_{60} film (W. Krätschmer, L. D. Lamb, K. Fostiropoulos, D. R. Huffman, *Nature* **1990**, *347*, 354–358). Furthermore, the spectrum of a $C_{60}/CHCl_3$ solution with C_{60} precipitate, which shows the normal absorptions of the dissolved fullerene, changes upon sonication to the spectrum of solid C_{60} (suspension of C_{60} aggregates, brown color).

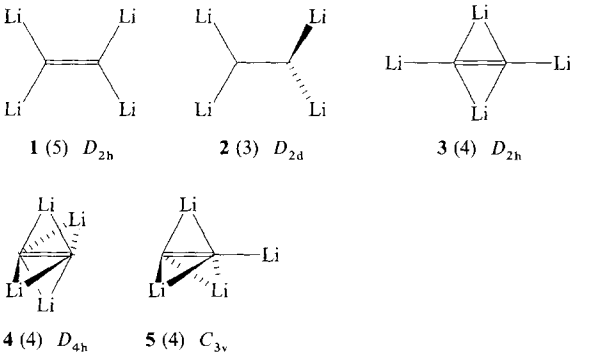
The Isomers of the Acetylene Derivatives C_2Li_4: Transferable Structural Units in Hyperlithiated Compounds**

By *Andrea E. Dorigo, Nicolaas J. R. van Eikema Hommes, Karsten Krogh-Jespersen*, and *Paul von Ragué Schleyer**

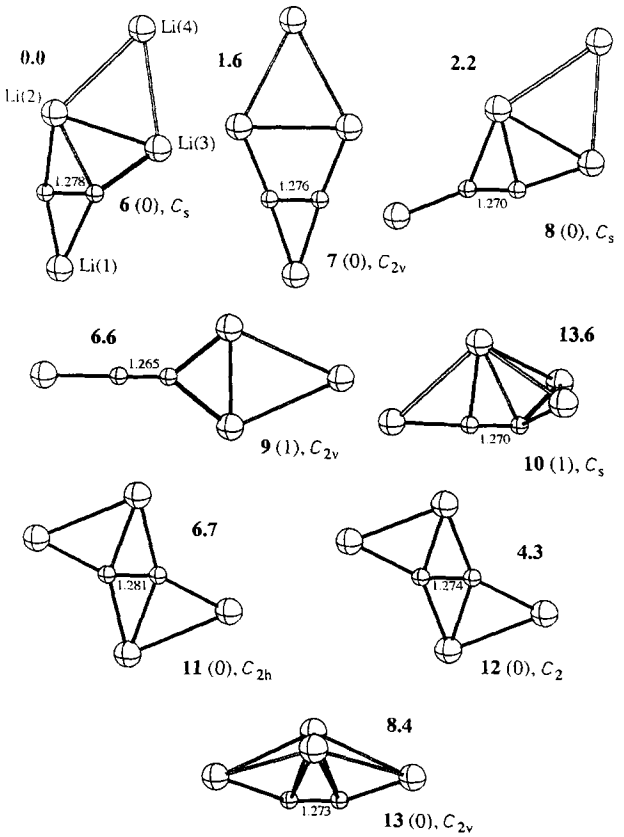
Hyperlithiated molecules[1a] such as CLi_6,[1,2] OLi_4,[3] PLi_5,[4] and OLi_6,[1a,4] which formally violate the octet rule, cannot be defined in terms of classical Lewis structures. Instead they involve bonding between the metal ligands[5] and between the metal ligands and the central atom. We now describe C_2Li_4 isomers which are not ethylene-like but which also exhibit hypermetallic bonding. Several stable Li_n structural units common to hyperlithiated molecules are discernable in the optimized structures.

The experimental evidence for C_2Li_4 is modest: Lagow et al. observed C_2D_4 among the deuterolysis products of lithiated substrates.[6] Although we have computed various structures of C_2Li_4 for over more than a decade, no thorough comprehensive study has been undertaken before. Only a few calculations of several possible C_2Li_4 structural candidates, performed at the SINDO1, HF/STO-3G, and HF/3-21G levels, have been mentioned in the literature.[7,8] However, the highly symmetrical structures **1**–**5** (Scheme 1)



Scheme 1. Schematic structures of isomers **1**–**5**. The numbers in parentheses indicate the number of imaginary frequencies at the HF/3-21G level. None of these isomers corresponds to a minimum on the potential energy surface and all are much higher in energy than **6**–**13**.

have now proven to be high in energy and to have several imaginary frequencies; we will not refine them further at higher levels here. Note in particular that at the HF/3-21G level the ethylene-like D_{2h} structure **1** has five imaginary frequencies and is 41.0 kcal mol^{-1} higher in energy than structure **6**. Structures **6**–**13** (Scheme 2) are energetically much more favorable. All geometries were optimized[9] at the electron-correlated MP2/6-31G* level, and single-point calculations were carried out at the MP4(SDTQ)(FC)/6-31+G* level [MP4(SDTQ)(FC)/6-31+G*//MP2(FU)/6-31G*].[10] Structures **6**–**13** all have short carbon–carbon bonds (1.265–1.281 Å), and while the average length ex-



Scheme 2. MP2/6-31G* optimized structures and relative energies of the C_2Li_4 isomers **6**–**13**. The number of imaginary frequencies (0 = minimum, 1 = transition state) at the MP2/6-31G* level is given in parenthesis after the compound number. Relative energies (bold, in kcal mol^{-1}) were calculated at the MP4(SDTQ)/6-31+G*//MP2/6-31G* level.

ceeds that in acetylene (1.21 Å), both linear and doubly bridged C_2Li_2 forms have similar C–C bond lengths.[11] Hence, all C_2Li_4 isomers we have studied are acetylene rather than ethylene derivatives! The C_2^{2-} ion is bound to different Li_n structural units in **6**–**13**. Thus, the global minimum at the MP4(SDTQ)/6-31+G* level (**6**) can be characterized as $Li^+C_2^{2-}Li_3^+$: an acetylide triple ion "salt" with Li^+ and Li_3^+ counterions. In the cyclic Li_3^+ moiety,[12] the two lithium atoms closest to the C_2^{2-} unit (Li(2) and Li(3) in Scheme 2) have large fractional positive charges, while the third, more remote Li(4) is calculated to have a negative charge.[13, 14] The $Li^+C_2^{2-}Li_3^+$ description is also valid for **7** (C_{2v}) and **8** (C_s), which also are energy minima, as well as for **9** (C_{2v}), which is a transition structure for the interconversion of two equivalent forms of **8**. Since no interaction between the lithium atoms and the π_{C-C} bond takes place, the energy of **9** is 6.6 kcal mol^{-1} higher than that of **6**.

Lithium atoms in bridging positions are known to be favorable, for example in LiCN.[15] In C_2Li_2[11] the isomer with two bridging lithium atoms is the global minimum. A bridging lithium atom is also present in **10**. However, even though all three atoms of the Li_3^+ unit interact with the C_2 fragment, **10** is a transition structure lying 13.6 kcal mol^{-1} higher in energy than **6**, in which only two Li–C_2 interactions are present. The preference for the edge interaction in **6** over the face interaction in **10** is due to the polarization of the Li_3^+ unit in **6**. This leads to an alternating quadrupole-like distribution of charges.[13] In polylithium compounds with cyclic Li_3^+ moieties, edge coordination is generally preferred to face coordination, for example, in OLi_4 with C_{2v} symmetry ($Li^+O^{2-}Li_3^+$).[3]

Structures **11** and **12** both contain another such lithium cluster "fragment", namely the $Li_2^{\bullet+}$ radical cation, which has been identified in OLi_5 (i.e. $Li_2^{\bullet+}O^{2-}Li_3^+$).[1a] Two such $Li_2^{\bullet+}$ units in a molecule may give rise either to singlet or triplet electronic states. The singlet species **11** (+6.7 kcal mol^{-1} above **6**) can be viewed as a complex of C_2^{2-} and two $Li_2^{\bullet+}$ radical cations. Structure **12** is a triplet molecule which lies 4.3 kcal mol^{-1} above **6**. Still higher levels of theory may be necessary to refine the singlet–triplet energy difference, but the structural features we describe are not expected to change.

Finally, **13** (C_{2v}) contains another intriguing Li_n structural unit—a four-center, two-electron Li_4^{2+} ion.[16] This description is supported both by the natural charges and the roughly tetrahedral arrangement of the lithium atoms; the distortion of the Li_4 unit is due to the C_2^{2-} unit which opens up one edge of the tetrahedron. For the free Li_4^{2+} ion the T_d structure is the global minimum on the potential energy surface,[16] and it is also preferred by OLi_4,[3] in which the O^{2-} ion fits into the center of the Li_4^{2+} tetrahedron. The alternative $Li_3^+O^{2-}Li^+$ isomer, analogous to **6**, is a higher energy minimum.[1a, 3] In C_2Li_4 the C_2^{2-} unit is too bulky to fit into the tetrahedral cage without considerable distortion, and therefore **13** is less stable than **6**.

C_2Li_4 illustrates the richness of structural possibilities available even to small polylithium compounds. The identification of similar discernable Li_n structural fragments recurring in other molecules will be the subject of future reports.

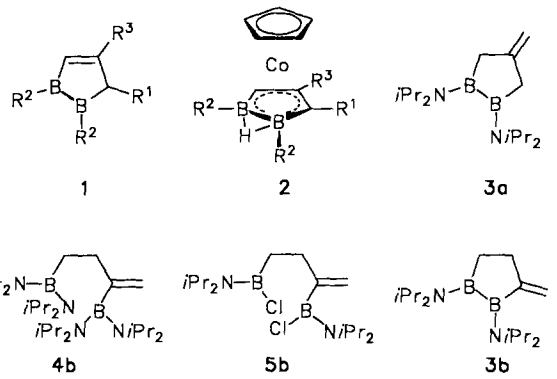
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247), the Fonds der Chemischen Industrie, and BASF AG.

mation of a B-H-B bridge is to be expected by the migration of one H atom,[3] so that the heterocycle can now act as a 4e donor as in **2**. The preparation of a derivative of **1** (R^1 = H, R^2 = N*i*Pr$_2$, R^3 = Me) was achieved starting from 4-methylene-1,2-diborolane **3a**.[4] We report herein about the synthesis and structure of the 3-methylene-1,2-diborolane **3b** as well as the reactions of **3a,b** with $[(C_5H_5)Co(C_2H_4)_2]$ to give mononuclear complexes.



Analogous to the formation of 1,2-diborolane **3a**[4] the diboryl compound **4b** is formed by the reaction of 2,4-dilithio-1-butene[5] with ClB(N*i*Pr$_2$)$_2$; the subsequent substitution of one diisopropylamino group at each boron by chlorine leads to **5b**, and its reductive ring closure with Na/K alloy affords **3b**.[6] The constitution of **3b** was deduced from the spectroscopic data and confirmed by a crystal structure analysis.[7] The heterocycle is strongly folded along the line C3–B1 (angle between the planes C3-B2-B1/C3-C4-C5-B1 = 46.4°), and the bond lengths lie within the expected range (Fig. 1).

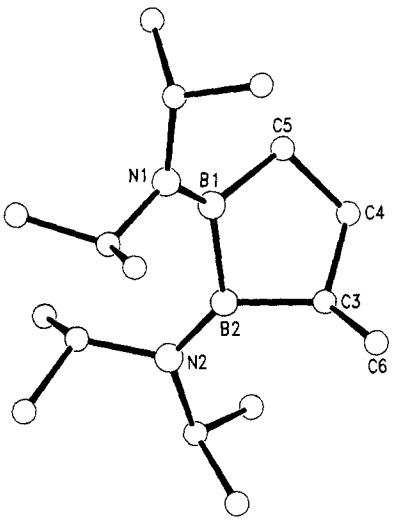


Fig. 1. Molecular structure of **3b**. Selected bond lengths [Å] and angles [°]: B1-B2 1.709(4), B1-C5 1.601(4), B2-C3 1.583(4), C3-C4 1.532(4), C4-C5 1.540(5), C3-C6 1.319(5), B1-N1 1.400(3), B2-N2 1.398(3); C5-B1-B2 101.1(2), C3-B2-B1 96.4(2), C4-C3-B2 104.1(2), C6-C3-B2 128.1(3), C6-C3-C4 120.5(3), C3-C4-C5 107.3(3), C4-C5-B1 106.5(3).

The two 1,2-diborolanes **3a** and **b** react with $[(C_5H_5)Co(C_2H_4)_2]$ in hexane, with the liberation of ethene, to give red solutions, from which red crystals (**A**) and a red oil (**B**), respectively, can be isolated by chromatographic workup in 73% and 42% yields, respectively. Both complexes show the required signals for the molecular ions of **2a,b** in the mass spectrum. Surprisingly, however, they show differing ^{11}B NMR signals: Substance **A** shows a broad singlet at δ = 35, and **B** two signals in a ratio of 1:1 at δ = 46 and 24, which are not in agreement with **2b** but with **6b**. We assign the low-field signal to the noncomplexed boron atom in the opened heterocycle. Both the ^{11}B NMR and the ^{1}H NMR spectrum of **A** are in accordance with **2a** and with a fluctuating molecule **6a**: the two CH groups of the ligand result in one signal, but that a doublet, as a result of the coupling with the BHB hydrogen. Temperature-dependent ^{1}H NMR spectra (to 180 K) show only a freezing of the free rotation (at 293 K) of the diisopropylamino groups about the B–N bond at 195 K. The protons of the CH groups are still magnetically equivalent at this temperature; that is, in the molecule the mirror plane through the Co atom and the substituent R^3 = Me is retained within the NMR time scale.

The crystal structure analysis[8] of **A** shows that by the metal-induced migration of a hydrogen atom to each of the atoms B5 and C6, the heterocycle **3a** is opened to give the complexed 4-boryl-1-borabutadiene in **6a** (Fig. 2). The ligand is only coordinated to the Co atom by the atoms B1, C2, C3, and C4. Since the B1–C2 bond length (1.493 Å), like the one in (B=C)π complexes,[9] corresponds to a very short BC single bond, and because C2–C3 as well as C3–C4 have identical interatomic distances (1.404 Å) this ligand can be described as a heterobutadiene. However, the likewise short

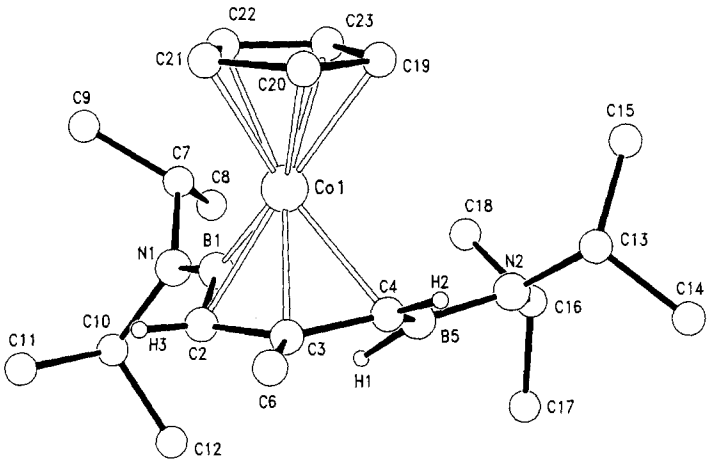

Fig. 2. Molecular structure of **6a**. Selected bond lengths [Å] and angles [°]: Co1-C2 2.022(3), Co1-C3 1.992(3), Co1-C4 2.072(2), Co1-B1 1.987(3), Co1-B5 2.714(3), B1-C2 1.493(4), B1-B5 2.758(5), B5-C4 1.522(4), C2-C3 1.404(4); C3-C4 1.404(4), B1-H1 2.31(4), B5-H1 1.15(3), B1-N1 1.390(3), B5-N2 1.409(3); N1-B1-C2 139.3(4), B1-C2-C3 119.9(2), C2-C3-C4 119.3(2), C3-C4-B5 125.9(2), C4-B5-N2 124.9(2), H1-B5-N2 118(1), H1-B5-C4 117(1), N1-B1-Co1 146.6(2).

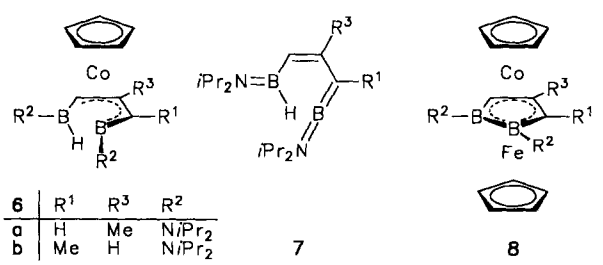

B5–C4 bond (1.524 Å) indicates a partial extension of the π electrons of the heterobutadiene onto B5, which obviously makes the above-mentioned fluctuation of the molecule **6a** easier.

The Co1–B1 distance (1.957 Å) is, in contrast to many metal complexes with B–C=C bonding, shorter than the Co1–C2 bond (2.022 Å). This can be explained by a strong back bond from the cobalt to the boron (population of the (B=C)π* MOs).[9] Furthermore, the geometry of the N1-B1-C2 group is very similar with that of the first (B=C)π ligand 9-fluorenylidene(2,2,6,6-tetramethylpiperidino)borane in the $(C_5H_5)Co(CO)$ and in the $Fe(CO)_4$ complex,[9a] whose electronic structure of has been described in detail.[9c] Therefore, for the previously unknown free diisopropylamino-substituted 4-boryl-1-borabutadiene **7** we also expect a N=B=C structure analogous to the 9-fluorenylidene(2,2,6,6-tetramethylpiperidino)borane.[9] In the solid state no interaction between Co1 and B5 (2.714 Å) occurs, the hydrogen H1 is only bound to B5 (B5–H1 1.15, B1–H1 2.31 Å). By a small rotation of the boryl groups about C3–C4 and C2–C3, respectively, a rapid exchange of the positions of H1 and B1 occurs, which can be observed in solution. This is not observed in **6b** because of the different position of the methyl group at the ring. We assume that the opening of the heterocycle in **2** is caused by the electronic saturation of the amino-substituted boron atoms. When R^2 is an alkyl group, the thus stabilized **2** should also enable the formation of the triple-decker sandwich complex **8**.[2]

The (*Z*)-4-boryl-1-borabutadiene **7** in the complexes **6a,b** is, with regard to its bonding situation, comparable with the H-bridged 1,3-diboraallyl R^1-C(R^2-B)$_2$(μ-H),[10] from which it is formally derived by the inclusion of a H-C=C unit.

Experimental Procedure

4b: Crystallization from hexane, yield: 48%; m.p. 68 °C; ^{1}H NMR (300 MHz, C_6D_6): Signals of the CH_2-C protons overlapped by the methyl of *i*Pr; $\delta = 6.68$ (s, 1H), 5.30 (s, 1H), 3.64 (sept, 4H), 3.56 (sept, 4H), 2.45 (m, 2H), 1.27 (d, 24H), 1.22 (d, 24H); ^{13}C NMR (75 MHz, C_6D_6): $\delta = 160$ (br.), 116.5, 48.0, 46.9, 33.1, 25.4, 24.8, 18 (br.); ^{11}B NMR (29 MHz, C_6D_6): $\delta = 38$; EI MS: *m/z* 476 (M^+, 28%), 461 ($M^+ - Me$, 26), 433 ($M^+ - i$Pr, 100).

5b: Filtration, distillation 92 °C/5×10^{-3} Torr; yield: 82%; ^{1}H NMR (200 MHz, $CDCl_3$): Signals of the CH_2-C protons overlapped by the methyl of *i*Pr; $\delta = 5.18$ (s, 1H), 4.94 (s, 1H), 4.08 (sept, 1H), 4.01 (sept, 1H), 3.62 (sept, 1H), 3.42 (sept, 1H), 2.30 (m, 2H), 1.38 (d, 6H), 1.19 (d, 12H), 1.11 (d, 6H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 154$ (br.), 116.2, 51.5, 47.9, 47.5, 45.7, 32.4, 23.3, 23.1, 22.2, 19.3, 19 (br.); ^{11}B NMR (29 MHz, $CDCl_3$): $\delta = 37.5$; EI-MS: *m/z* 346 (M^+, 7%), 331 ($M^+ - Me$, 28), 303 ($M^+ - i$Pr, 2).

3b: **5b** (7.5 g, 21.4 mmol) was added dropwise to a suspension of $NaK_{2.8}$ (2.03 g, 42.6 mmol) in pentane at 20 °C. Filtration and distillation (35 °C/5×10^{-3} Torr) afforded **3b** in 38% yield. ^{1}H NMR (300 MHz, $CDCl_3$): Signals of the C4 protons overlapped; $\delta = 4.97$ (m, 1H), 4.82 (m, 1H), 3.71 (sept, 1H), 3.62 (sept, 1H), 3.46 (sept, 1H), 3.28 (sept, 1H), 2.59 (m, 2H), 1.25 (d, 6H), 1.18 (d, 6H), 1.12 (d, 6H), 1.09 (d, 6H); ^{13}C NMR (75 MHz, $CDCl_3$): a C atom attached to a boron was not observed; $\delta = 163$ (br.), 110.6, 57.0, 55.7, 46.6, 45.1, 35.0, 25.6, 24.7, 22.6, 22.5; ^{11}B NMR (29 MHz, $CDCl_3$): $\delta = 53$; EI MS: *m/z* 276 (M^+, 56%), 261 ($M^+ - Me$, 100), 232 ($M^+ - i$Pr, 7).

6a: **3a** (1.10 g, 3.99 mmol) was added to a solution of $[(C_5H_5)Co(C_2H_4)_2]$ (0.69 g, 3.69 mmol) in hexane at −10 °C. After chromatography (at −40 °C, Al_2O_3, deactivated with 5% H_2O) **6a** remained in 72% yield, m.p. 97 °C; ^{1}H NMR (200 MHz, C_7D_8, 293 K): $\delta = 4.63$ (s, 5H), 3.62 (sept, 4H), 3.12 (C2-H and C4-H, d, 2H; $^3J_{CH-BH} = 2.8$ Hz), 2.32 (s, 3H), 1.2 (BH, t, br., 1H), 1.18 (d, 12H), 1.12 (d, 12H); ^{1}H NMR (200 MHz, C_7D_8, 180 K): $\delta = 4.51$ (s, br., 5H), 4.10 (sept, br., 2H), 3.05 (s, br., 2H), 2.72 (sept, br., 2H), 2.35 (s, 3H), 1.10 (br., 24H); ^{13}C NMR (50 MHz, C_7D_8, 293 K): $\delta = 115.2$, 81.0, 51.0, 47.6, 27.3, 24.8, 23.6; ^{13}C NMR (50 MHz, C_7D_8, 180 K): $\delta = 115.3$, 80.0, 49.7, 44.0, 27.1, 25.1, 23.0; ^{11}B NMR (29 MHz, C_7D_8): $\delta = 35$; EI MS: *m/z* 400 (M^+, 35%), 357 ($M^+ - i$Pr, 100).

6b: **3b** (290 mg, 1.10 mmol) was added to a solution of $[(C_5H_5)Co(C_2H_4)_2]$ (189 mg, 1.11 mmol) in hexane at −10 °C. After chromatography at −78 °C (Al_2O_3, deactivated with 5% H_2O) **6b** remained as an air-sensitive oil in 42% yield. ^{1}H NMR (200 MHz, C_6D_6): BH not found; $\delta = 5.86$ (d, 1H), 4.68 (s, 5H), 3.93 (sept, 2H), 3.32 (sept, 2H), 2.98 (dd, 1H), 1.51 (s, 3H), 1.23 (d, 6H), 1.18 (d, 6H), 1.06 (d, 12H); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 102.1$, 80.3, 50.4, 46.7, 25.2, 24.2, 23.9, 23.2, 22.9; ^{11}B NMR (64 MHz, C_6D_6): $\delta = 46$, 24; EI MS: *m/z* 400 (M^+, 38%), 357 ($M^+ - i$Pr, 100).

$[(\pi\text{-}Me_5C_5)_2SiH]^+$—A Novel Silyl Cation

By *Peter Jutzi** and *Ernst-August Bunte*

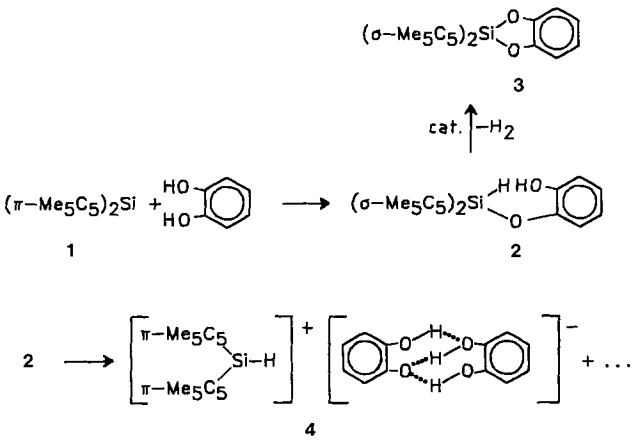
Dedicated to Professor Ulrich Wannagat on the occasion of his 70th birthday

Despite intensive investigations, the possible existence of triorganosilyl cations R_3Si^+ in solution or in the solid state is still debated. In contrast, the existence of related alkyl cations in which carbon is the cationic center has been proven unequivocally.[1] According to the extensive studies of Lambert et al., triorganosilyl cations can be detected in very dilute solution in the presence of perchlorate anions.[2] Olah et al. maintained that the effects Lambert observed arose from impurities and contested the dissociation of triorganosilylium perchlorates.[3] Eaborn also questioned the

[*] Prof. Dr. P. Jutzi, Dr. E.-A. Bunte
Fakultät für Chemie der Universität
Universitätsstrasse, D-W-4800 Bielefeld (FRG)

existence of R_3Si^+ ions.[4] The current state of the controversy was recently summarized by Lickiss.[5] Here we report on the first example of a new type of R_3Si^+ cation in which π ligands contribute to the stabilization of the cationic center.

The reaction of the π complex decamethylsilicocene Cp^*_2Si (**1**) ($Cp^* = Me_5C_5$) and catechol in toluene first gave rise to aryloxysilane **2** by means of an oxidative addition to the divalent silicon atom (Scheme 1). Compound **2** is not stable



Scheme 1.

for very long, but its structure is supported by conclusive NMR data. The structure of the analogous addition product from the reaction of **1** with 4-methylcatechol was proven by an X-ray structure analysis conducted at $-100\,^\circ C$.[7, 8] The transition from **1** to **2** is associated with an η^5–η^1 slippage of the Cp* ligand.

Compound **2** can react further by two paths: With catalysis[8] and loss of H_2 **2** was converted to heterocycle **3**, whose structure was determined by X-ray structure analysis.[8, 10] Compound **2** decomposes in toluene solution after a few hours to give **4** as the unexpected main product containing the cation $[(\pi\text{-}Me_5C_5)_2SiH]^+$. When the reaction of **1** with catechol in toluene was conducted at 60 °C, **4** was obtained directly (see Experimental Procedure).

Compound **4** was obtained as a colorless, extremely air- and moisture-sensitive, amorphous[11] solid. It is soluble in toluene, tetrahydrofuran, and nitrobenzene; in acetonitrile and nitromethane the compound decomposes instantaneously.[12] Even in toluene, tetrahydrofuran, and nitrobenzene **4** decomposes slowly. Compound **4** is stable for longer periods at $-40\,^\circ C$ dissolved in toluene as well as in the solid state. Freshly prepared solutions of **4** were used in the investigations described here.[13]

The molecular mass, determined with a 0.025 M solution of **4** in nitrobenzene, is 300; this is roughly half of the expected value (518) and supports a dissociation of **4**. The results of conductance measurements in nitrobenzene can be explained by the presence of a 1:1 electrolyte. The products of the hydrolysis or decomposition of **4** can be ruled out as sources of the measured conductance.[14]

In the ^1H and ^{13}C NMR spectra of **4**,[15] the cation has signals for only one type of methyl group and one type of ring C atom, which are independent of concentration and temperature.[16] This finding is in agreement with the existence of π-bound Cp* ligands;[17] σ-bound Cp* ligands in related compounds (e.g. **2** or $Cp^*_2SiH_2$[18]) give rise to broad signals at room temperature and resolved signals at lower temperatures as a result of sigmatropic rearrangements that are slow on the NMR timescale. The signal for the Si–H proton in **4** at $\delta = 3.23$ is in the expected range.[20]

In the coupled ^{29}Si NMR spectrum of **4** a doublet is observed at $\delta = -12.1$ (J(Si,H) = 302 Hz). The δ value corresponds to a downfield shift of $\Delta\delta = 386$ upon conversion of **1** to $[(\pi\text{-}Me_5C_5)_2SiH]^+$. According to calculations, a ^{29}Si resonance at $\delta = 350$ would be expected for bonding situations with σ-bound ligands, as in Me_3Si^+.[21] The effectiveness of the π-bound Cp* ligands in reducing the electron deficiency at the silicon atom relative to that in Me_3Si^+ is reflected in the position of the ^{29}Si NMR signal.

The comparison of the J(Si,H) coupling constants in **4** (302 Hz), **2** (217 Hz), and $Cp^*_2SiH_2$ (194 Hz) is also diagnostic.[19] The tremendous increase of the coupling constants upon going from $Cp^*_2SiH_2$ and **2** to $[(\pi\text{-}Me_5C_5)_2SiH]^+$ is in agreement with the increased amount of s character in the Si–H bond of $[(\pi\text{-}Me_5C_5)_2SiH]^+$, as expected for sp^2-hybridized silicon.[22, 23]

The IR spectrum of a 0.2 M solution of **4** in THF shows a Si–H stretch at $\tilde{\nu} = 2200\ cm^{-1}$; this value is best explained by a positively polarized hydrogen atom[24] and correlates well with the value for the J(Si,H) coupling constant according to a known relationship.[25]

The anion in **4**, $H_4C_6O_2H_3O_2C_6H_4^-$, has been described as the Bu_4N^+ salt.[26] The ^1H and ^{13}C NMR spectra of the anions in **4** and in the ammonium salt are identical; the two types of aromatic H atoms and three types of C atoms support the symmetric structure with exchanging OH protons.[27] One of the possible static bonding situations for the anion in **4** is represented in Scheme 1.

According to Austin Model 1 (AM1) calculations,[28] the phenyl groups in the anion in **4** are oriented perpendicular to each other. The resulting tetrahedral arrangement of the oxygen atoms in the O_4H_3 unit allows an effective shielding of the negative charge. To our knowledge anions of this type have not been used previously to stabilize especially electrophilic cations, but apparently they are not very nucleophilic.

The deuterated cation $[(\pi\text{-}Me_5C_5)_2SiD]^+$ was prepared by the reaction of **1** with deuterated catechol $C_6H_4(OD)_2$; the ^2D NMR signal at $\delta = 3.18$, the ^{29}Si NMR signal at $\delta = -12.3$ (triplet), and the J(Si,D) coupling constant of 46.0 Hz have the expected values.[29]

Exactly how **4** arises from **2** is not yet understood. The addition of one equivalent of catechol to **2** surprisingly did not lead to **4**, but to complete decomposition and ill-defined products. Compound **2** was not even formed at a 1:2 stoichiometry of **1** and catechol. Compounds analogous to **4** were prepared with the catechol derivatives 4-methyl, 4-*tert*-butyl- and 4,6-di-*tert*-butylcatechol. The cation in **4** may most likely also be generated by the reaction of **1** with two equivalents of trifluoromethanesulfonic acid.[30] Up to this point it has not been possible to generate this cation by halide abstraction from precursors of the type $(\sigma\text{-}Me_5C_5)_2SiHHal$.

Cations that are significantly stabilized by π-bound cyclopentadienyl ligands are not unknown in the chemistry of the p-block elements as shown by the following examples: $[(\pi\text{-}Me_5C_5)BX]^+$, X = Cl, Br, I,[31] $[(\pi\text{-}Me_5C_5)Ge]^+$,[32] $[(\pi\text{-}Me_5C_5)Sn]^+$,[32, 33] $[(\pi\text{-}Me_5C_5)PNHtC_4H_9]^+$,[34] $[(\pi\text{-}Me_5C_5)_2As]^+$,[35] and $[(\pi\text{-}Me_5C_5)_2Sb]^+$.[35] We propose that the cation $[(\pi\text{-}Me_5C_5)_2SiH]^+$ has a structure with η^2/η^3-bound Cp* ligands, whereby the π ligands undergo rapid haptotropic rearrangements. A similar situation is found for the iso(valence)electronic cation $[(\pi\text{-}Me_5C_5)_2As]^+$. In $[(\pi\text{-}Me_5C_5)_2SiH]^+$, however, one finds a covalent bond to a hydrogen atom instead of a lone pair on the central atom.

Experimental Procedure

4: A solution of **1** (960 mg, 3.22 mmol) and catechol (354 mg, 3.22 mmol) in toluene (20 mL) was stirred at 60 °C for 16 h. The volatile components were removed under vacuum, and the residue was washed repeatedly with pentane. Compound **4** was isolated as a colorless solid; yield 560 mg (34% based on **1**). ^{1}H NMR (C_6D_6): $\delta = 1.77$ (s, 30 H, C_5Me_5), 3.22 (s, 1 H, Si-H), 6.68–6.71 (m, 4 H) and 7.00–7.03 (m, 4 H, AA'BB' spectrum for phenyl-H); ^{13}C NMR (C_6D_6): $\delta = 10.8$ (s, C_5Me_5), 113.5 (s, phenyl-C), 120.4 (s, C_5Me_5), 121.0 (s, phenyl-C), 149.3 (s, phenyl-C-O). MS (70eV): m/z 299 ($[\pi\text{-}C_5Me_5)_2SiH]^+$, 32%), 137 ($Cp^*H_2^+$, 100), 135 ($Cp^{*+}$, 74). Correct C,H analysis.

Distortional Isomerism in Oxomolybdenum Systems; the Evidence Re-evaluated**

By *Alan P. Bashall, S. W. Annie Bligh, Andrew J. Edwards, Vernon C. Gibson,* Mary McPartlin,** and *Oliver B. Robinson*

In recent years, there has been an upsurge of widespread interest in the phenomenon of distortional or bond stretch isomerism.[1–4] The term distortional isomerism was proposed in 1971 by Chatt, Manojlovic-Muir, and Muir[5] to describe two forms of $[Mo(O)Cl_2(PMe_2Ph)_3]$, one blue with $\tilde{\nu}$(Mo=O) at 954 cm^{-1} and the other green with $\tilde{\nu}$(Mo=O) at 943 cm^{-1}. These are members of a range of analogous blue and green oxomolybdenum compounds with high or low (Mo=O) vibrational frequencies, respectively, reported earlier by Butcher and Chatt and thought at first to be *cis* and *trans* isomers.[6] X-ray structure determinations showed that blue $[Mo(O)Cl_2(PMe_2Ph)_3]$ and the green diethylphenylphosphane derivative [$\tilde{\nu}$(Mo=O) = 940 cm^{-1}] in fact possessed similar *cis–mer* configurations, but with strikingly different organophosphane orientations and markedly different Mo=O bond lengths.

Based on these observations Chatt and co-workers proposed a new form of isomerism involving "two equilibrium arrangements of ligands which differ in the distortions of the highly strained coordination polyhedron of the metal". They suggested that the blue and green forms of *cis–mer*-$[Mo(O)Cl_2(PMe_2Ph)_3]$, which they concluded had different organophosphane orientations (resulting in C_s symmetry in the blue complex and C_1 in the green), exhibited this type of "distortional isomerism".

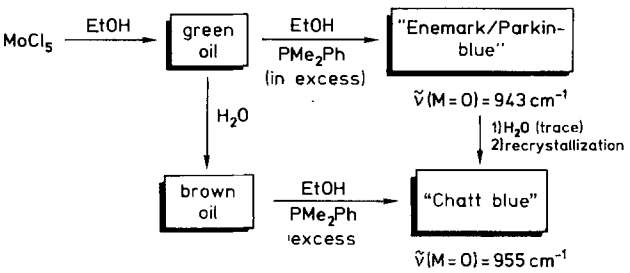
The award of the Frankland Fellowship by the Royal Society of Chemistry is gratefully acknowledged (V.C.G.).

The marked differences in Mo=O bond length between these two isomers[7, 8] led Hoffmann to include them within the description of bond stretch isomerism,[9] a term that had originally been coined to describe hypothetical isomers "whose *only* structural difference is a relatively small increment in the length of one or several bonds" but not in any rotation or topological change.[10] Thus, recently the terms distortional isomerism and bond stretch isomerism have both been used somewhat arbitrarily to describe either phenomenon. Here we present results arising from a reinvestigation of the oxomolybdenum system which show that two blue forms of $[Mo(O)Cl_2(PMe_2Ph)_3]$ exist; they may reasonably be described as distortional isomers, but not bond stretch isomers.

The groups of Parkin and Enemark have recently subjected the Chatt system to detailed scrutiny. Extensive X-ray[11] studies by Parkin and coworkers, and independent spectroscopic[12] work by the Enemark group show that green $[Mo(O)Cl_2(PMe_2Ph)_3]$ [$\tilde{\nu}$(Mo=O) = 943 cm^{-1}] arises from cocrystallization of blue $[Mo(O)Cl_2(PMe_2Ph)_3]$ [$\tilde{\nu}$(Mo=O) = 943 cm^{-1}] with a yellow contaminant, $[MoCl_3(PMe_2Ph)_3]$, and they therefore concluded there was no need to invoke the existence of a second oxomolybdenum species in this system. Central to this argument is the absence of a second Mo=O stretch in the infrared spectra, although Butcher and Chatt had clearly recorded two Mo=O stretches, at 943 and 954 cm^{-1}, for the green and blue forms respectively. Following a thorough spectroscopic reinvestigation of the system, Enemark and coworkers concluded that the 954 cm^{-1} assignment was incorrect, since they had never been able to observe this band in any of their samples. Thus, the simple and persuasive contaminant theory gained widespread acceptance as providing an explanation for all the spectroscopic and crystallographic observations surrounding this distortional isomer system.[1, 3]

We, however, remained puzzled by the discrepancies between the infrared data recorded by Chatt on blue $[Mo(O)Cl_2(PMe_2Ph)_3]$ and subsequently by Enemark, not only in the Mo=O region but also in the Mo–Cl stretching region of the spectrum. One clue to a possible explanation for these was the fact that the Mo–Cl bond lengths reported by Parkin[11] for blue $[Mo(O)Cl_2(PMe_2Ph)_3]$ are significantly different from those reported in the original determination by Manojlovic-Muir.[7] It thus seemed possible that two blue oxo forms with differing bond lengths exist, thus providing an explanation for the discrepancies in the spectroscopic data.[2] In the hope of isolating the elusive Chatt blue isomer with $\tilde{\nu}$(Mo=O) at 954 cm^{-1}, we have explored methods as close as possible to those used in the earlier work and have been successful in isolating two blue forms of $[Mo(O)Cl_2(PMe_2Ph)_3]$ (**1a** and **1b**) and their bromo analogues (**2a** and **2b**) (see Scheme 1).



Scheme 1. The synthesis of the high (**1a**) and low (**1b**) frequency isomers of $[MoOCl_2(PMe_2Ph)_3]$.

In the original report Butcher and Chatt[6] described the reaction of molybdenum pentachloride with ethanol (added dropwise) to give a "brown" oil. This was subsequently treated with excess PMe_2Ph and refluxed for 5 min in ethanol to give a good yield of the blue isomer displaying $\tilde{\nu}$(Mo=O) at 954 cm^{-1}. During our attempts to reproduce this synthesis, we invariably obtained a green oil (reported earlier by Wardlaw and Webb to be molybdenyl chloride $[Mo(O)Cl_3]$[13]); upon subsequent treatment with PMe_2Ph followed by recrystallization from ethanol, this green oil afforded blue crystals that correspond to the compound described by Parkin and Enemark and displaying $\tilde{\nu}$(Mo=O) at 943 cm^{-1} (Scheme 1). However, when water was added dropwise to the green oil it turned brown. This led, on identical workup, to the Chatt blue isomer with $\tilde{\nu}$(Mo=O) at 955 cm^{-1}.

Solution IR spectra of the two blue forms at room temperature are identical and show an intermediate $\tilde{\nu}$(Mo=O) of 947 cm^{-1}. It therefore seems likely that the form that crystallizes depends upon the nature of the nucleation sites, possibly influenced by trace amounts of water. Indeed a solution of the "Enemark/Parkin blue", upon reflux in ethanol in the presence of a small amount of added water, gives the "Chatt blue" isomer on crystallization.

The bromide analogues $[Mo(O)Br_2(PMe_2Ph)_3]$, namely **2a** [$\tilde{\nu}$(Mo=O) 956 cm^{-1}] reported by Butcher and Chatt and the previously unknown form **2b** [$\tilde{\nu}$(Mo=O) 943 cm^{-1}], have been synthesized by treatment of the chloro isomers with LiBr, followed by recrystallization from ethanol.

X-ray structure analyses[14] show highly symmetrical dimethylphenylphosphane orientations in molecules of almost exact C_s symmetry for **1a** and **2a** (Fig. 1a) similar to that established[7] for the original Chatt blue $[Mo(O)Cl_2(PMe_2Ph)_3]$, while the molecules of the two low frequency compounds, **1a** and **2b**, have virtually identical asymmetric conformations of the dimethylphenylphosphanes resulting in only C_1 symmetry (Fig. 1b). The low frequency form (**1b**) of C_1 symmetry proves to be identical to the blue component of "green $[Mo(O)Cl_2(PMe_2Ph)_3]$" for which full structural details are now available[15] and is clearly a different blue form to that of C_s symmetry reported by Chatt.

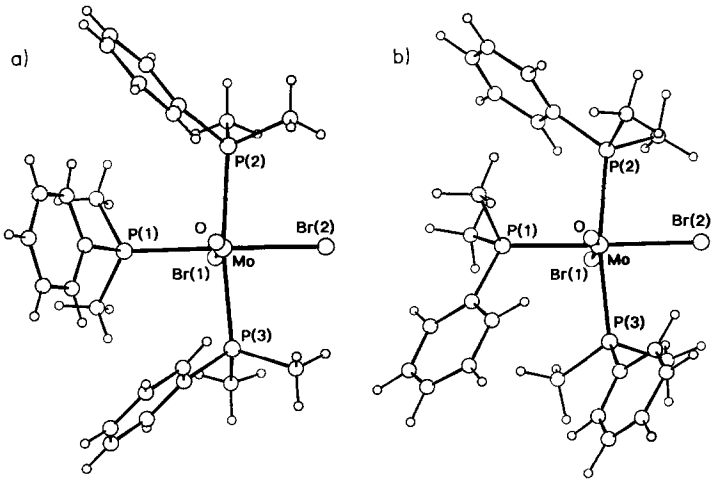


Fig. 1. The structures of the two forms of $[Mo(O)X_2(PMe_2Ph)_3]$ (X = Cl or Br), illustrated for X = Br. a) The structure of C_s symmetry for the high frequency form **1a**, **2a**. For selected bond lengths and angles see Table 1. b) The structure of C_1 symmetry for the low frequency form **1b**, **2b**. For selected bond lengths and angles, see Table 1.

The parameters of the two isomers differ most dramatically in large variations between equivalent angles at the metal atom (for example the angle Cl2-Mo-P1 has the nearly linear value of 177.8(1)° in **1b** but is reduced to 162.4(1)° in **1a**), and these distortions are reflected in significant differences in many of the metal–ligand bond lengths. The Mo=O length of 1.663(2) Å observed in the high frequency from **1a** is significantly shorter than 1.675(3) Å, the length in **1b**,[15] in line with the 12 cm^{-1} difference in their (Mo=O) stretching frequency. This difference in Mo=O length together with the differences in other bonds to the metal are undoubtedly related to the distortions of the coordination polyhedron and Chatt's original description of distortional isomers would still seem quite appropriate.[16] The phenomenon is not simple polymorphism because it has been clearly established that the differences are not merely a result of two different crystal packings; the two blue forms contain different molecules readily distinguished by their characteristic (Mo=O) stretching frequencies and symmetry.[17] Confirmation that the (Mo=O) stretching frequencies are molecular properties of the two isomers, not the result of a particular crystalline arrangement, is provided by the stretching frequency $\tilde{\nu}$(Mo=O) at 943 cm^{-1} exhibited by the low symmetry isomer in both the pure orthorhombic crystalline modification and in the contaminated monoclinic polymorph studied by Enemark[12] and Parkin.[15]

Table 1. Selected bond lengths [Å] and angles [°] of **1** (X = Cl) and **2** (X = Br).

[a] Values for "Chatt blue" in parentheses [7]. [b] Values for "Enemark/Parkin blue" in parentheses [15].

This study demonstrates the importance of distinguishing between the phenomena of distortional isomerism and bond stretch isomerism. It should be noted that different ligand conformations cannot explain the differences in IR spectra reported for systems where the two "bond stretch isomers" are isostructural and give isomorphous crystals.[18]

[16] Different orientations of bulky organophosphane ligands in metal complexes were shown previously to cause significant differences in bond lengths and angles but such a distinct and marked effect on the IR spectrum has not been noted before. For example *cis*-$[PtCl_2(PMePh_2)_2]$ crystallizes in two forms, differing markedly in phosphane orientation [Ho K.-C., G. M. McLaughlin, M. McPartlin, G. B. Robertson, *Acta Cryst. B38*, **1982**, 421–425]. Very accurate X-ray structure analyses showed small but significant differences in the Pt–Cl lengths related to marked differences in the angles at the Pt atom.
[17] The concepts involved in this type of isomerism in some ways parallel those invoked for isomerism in the tetrahedral cluster systems $[(Ph_3P)_2N][H_3M_4(CO)_{12}]$ (M = Ru and Os). Tautomeric anions of C_{3v} or C_2 symmetry equilibrate rapidly in solution and can only be separated in the solid state [J. W. Koepke, J. R. Johnson, S. A. R. Knox, H. D. Kaesz, *J. Am. Soc.* **1975**, *97*, 3947; B. F. G. Johnson, J. Lewis, P. R. Raithby, G. M. Sheldrick, K. Wong, M. McPartlin, *J. Chem. Soc. Dalton Trans.* **1978**, 673]. The two ruthenium isomers have been structurally characterized in the solid state, but in the case of osmium, the two different crystalline forms proved to be polymorphs each containing the same monoanion isomer of C_2 symmetry [M. McPartlin, W. H. Nelson, *J. Chem. Soc. Dalton Trans.* **1986**, 1557].

Determination of the H^N–H^α Coupling Constant in Large Isotopically Enriched Proteins**

By *Stephan Seip, Jochen Balbach*, and *Horst Kessler**

New multidimensional pulse techniques in NMR spectroscopy in combination with isotopic enrichment of the important heteronuclei ^{15}N and ^{13}C allow the structure determination of larger proteins up to a molecular weight of >30 kDa.[1–3] The information obtained from the coupling constants becomes more and more important in conformational analysis and molecular dynamics calculations.[4, 5] The H^N–H^α coupling constant plays an important role in the

Flükiger for the preparation of the sample of the uniformly labelled P13 domain. Stephan Seip thanks the Fonds der Chemischen Industrie for a grant.

determination of the backbone conformation, because it restricts the range of values of the angle Φ[6] (Fig. 1). It can be obtained from the splitting of the H^N or H^α signal in the one-dimensional spectra of small peptides. For larger peptides (up to medium-sized proteins), methods are available that allow the determination of the desired coupling from antiphase crosspeaks in COSY spectra.[7, 8] This requires sufficient magnetization transfer by homonuclear J-coupling. No homonuclear transfer is possible, however, for larger proteins (>30 kDa). Therefore, a method must be chosen that combines high sensitivity and large spectral dispersion of the heteronuclear couplings to reduce overlap of resonances. In addition, it is desirable to determine the coupling constant independent of the width of the signal.

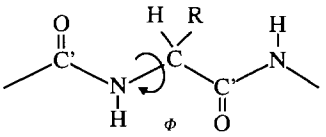

Fig. 1. Part of the polypeptide chain with definition of the angle Φ. The range of Φ can be restricted with the aid of the H^N-H^α coupling constant.

A number of pulse sequences were previously described that allow for the measurement of the H^N–H^α coupling constant in $^{15}N/^{13}C$ enriched proteins.[9–11] They all exploit the "E. COSY" pattern in the $F1/F3$ planes of a 3D spectrum for extraction of the coupling constant: The large coupling of the directly bound proton ($^1J_{C,H}$) is used to separate the two multiplet components of the C^α signal (H^α in α and in β state) in $F1$, where C^α is allowed to evolve (that means no proton decoupling is used in that dimension). This separation prevents mutual interference between the two components, which may lead to a wrong coupling constant. The $^3J_{H^N,H^\alpha}$ coupling leads to a displacement of the two multiplet components in the directly detected dimension and is therefore extracted in $F3$ (the dimension with the best digital resolution).

We propose two pulse sequences that utilize the same principle, but are optimized for sensitivity. The determination of the $^3J_{H^N,H^\alpha}$ coupling constant with high sensitivity, even for proteins that are larger than 30 kDa, can be achieved with these sequences. The pulse sequences correlate C^α, N, and H^N through large one-bond couplings ($^1J_{N,H}$ (ca. 90 Hz) and $^1J_{C,N}$ (ca. 11 Hz)).

The pulse sequences shown in Figure 2 excite the C^α nucleus (via the NH proton and nitrogen), which evolves in $F1$ as antiphase magnetization with respect to ^{15}N during t_1 without proton decoupling. After the constant-time evolution of ^{15}N in t_2, the magnetization is then transferred back to protons and detected during t_3. The "E.COSY" pattern of the $C^\alpha(F1)$–$H^N(F3)$ crosspeaks is achieved by selective excitation of the protons bound to nitrogen, thereby avoiding the mixing of the H^α spin states.[12] In practice, this is achieved by a "jump–return" sequence at the end of the pulse train, which acts as a selective 90° pulse for H^N.[13]

The application to larger proteins requires careful optimization of all pulsewidths and delays. In particular, the delays must be optimized under consideration of the relaxation behavior of the different nuclei. Equation (a) is found for 2τ, Equation (b) for $\tau_1 + \tau_2 + \delta$; the latter should be

$$A(\tau') = \sin(\pi\,{}^1J_{N,C}2\tau')\cos(\pi\,{}^2J_{N,C}2\tau')\exp(2\tau'/T_{2,N(SQ)}) \quad (a)$$

$$A(\tau_1,\tau_2,\delta) = \sin(\pi\,{}^1J_{N,C}(\tau_1+\tau_2+\delta)) \cdot\cos(\pi\,{}^2J_{N,C}(\tau_1+\tau_2+\delta))\exp((\tau_1+\tau_2+\delta)/T_{2,NH}) \quad (b)$$

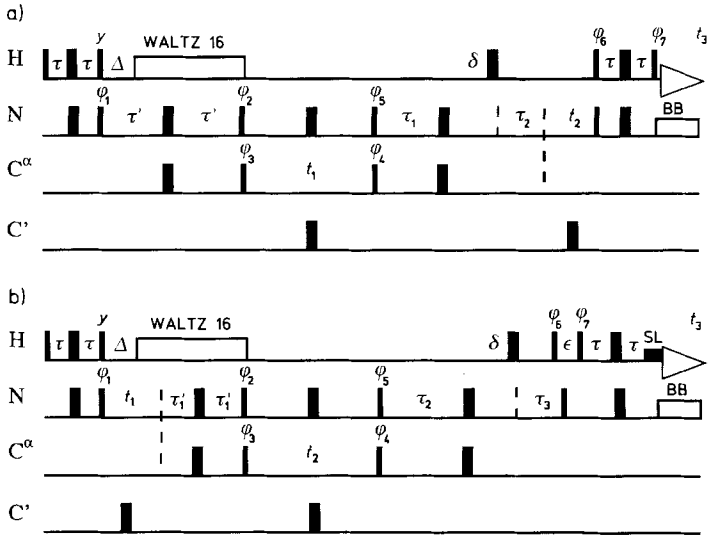

Fig. 2. Pulse sequences for the determination of the H^N–H^α coupling constants in large proteins. Both sequences correlate ^{15}N with $^{13}C^\alpha$ and H^N. The rf field strength from the X channel is reduced to 4 kHz for the selective excitation of the C^α carbon nuclei without affecting the C′ nuclei, by using the first zero crossing of the excitation function. Phase-modulated pulses [2,3] are used for selective inversion of the C′ spins, without switching of the transmitter frequency. a) Coupled HNCA (correlates H, N, and α-C) with "constant-time" evolution of nitrogen chemical shifts and jump–return pulse for selective excitation of the H^N resonances. $\tau = 2.25$, $\Delta = 4.5$, $\tau' = 13$, $\tau_1 = 10$, $\delta = 7.75$, $\tau_2 = 2.25$ ms. τ_1 is decremented with increasing t_2. The WALTZ decoupling is performed with an 8 kHz field. The water resonance is irradiated during the relaxation delay. b) Coupled HNCA with "constant-time" evolution of the nitrogen chemical shifts. The proton frequency is set on the water resonance. The jump–return pulse leads to a sinusoidal offset-dependent excitation. In this way excitation of the H^α protons is avoided (prerequisite for the "E. COSY" pattern) and the water resonance is suppressed. Sequence b) is superior to sequence a) when presaturation of the water resonance may lead to saturation transfer of H^N protons. Parameters are the same as in a) except for: $\tau_2 = 10$, $\tau_3 = 2.25$ ms, $\varepsilon = 60$ µsec (at 600 MHz). τ_1' is decremented with increasing t_1. Phase cycling for both experiments is $\phi_1 = x, x, -x, -x$, $\phi_2 = x, x, -x, -x$, $\phi_3 = x, \phi_4 = 8(x), 8(-x)$, $\phi_5 = 16(x), 16(-x)$, $\phi_6 = x, -x, \phi_7 = -x, x$, receiver $= x, -x, -x, x, -x, x, x, -x, 2(-x, x, x, -x, x, -x, -x, x), x, -x, -x, x, -x, x, x, -x$. All other pulses are applied from the x axis.

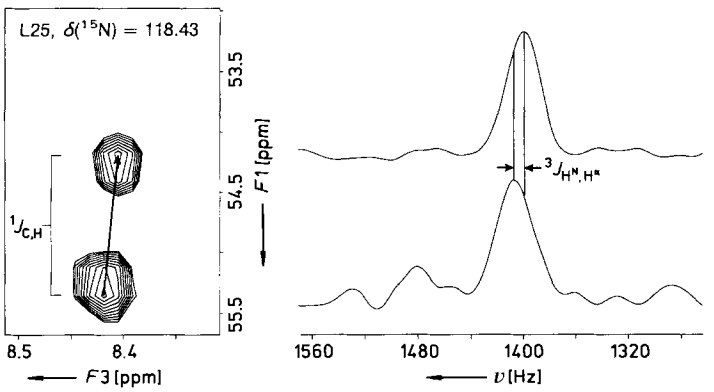

Fig. 3. Application of the pulse sequence shown in Figure 2a on a 1 mM solution of uniformly ^{15}N, ^{13}C labeled P13 domain of mannose permease of *E. coli*. The experiment was performed on a Bruker AMX 600 spectrometer equipped with a multichannel interface and a triple-resonance probe. 128 × 54 × 512 real points were taken with 32 scans each. Total measuring time was 74 hours. Multiplication with a 70° shifted $\sin^2$ function was applied in all dimensions to avoid truncation artifacts. The final spectrum consisted of 128 × 64 × 512 real points. Left: Section of the 2D plane with the crosspeak of Leu^{25} at a ^{15}N resonance frequency of $\delta = 118.43$. The "E.COSY" pattern is evident. For the determination of the coupling constants two rows which crossed the maxima of the two peaks along the $F3$ dimension were extracted from the spectrum. The displacement of the two maxima was measured after inverse Fourier transformation, zero-filling to 8192 points, and retransformation. The coupling constant is 8.0 Hz (the error is estimated at ±1 Hz).

shorter than $2t'$, because of the strong dipolar relaxation of the proton, $N_{x,y}H_z$ antiphase magnetization decays faster than ^{15}N in-phase magnetization which is present during $2\tau'$.[14] The T_2 times can be extracted from Heteronuclear Single Quantum Correlation (HSQC) and refocused HSQC spectra.[15]

The evaluation of the 3D spectrum is shown for the C^{α}–H^{N} crosspeak of Leu^{25} in the fully $^{15}N/^{13}C$ labeled P13 domain of mannose permease (31 kDa)[16] (Fig. 3). Because of the low digitization in the 3D spectrum, the coupling constant is best determined from selected rows, in analogy to the DISCO procedure.[17] The pulse sequence from Figure 2b yields an identical spectrum. Evaluation is performed in the $F2/F3$ planes.

The experiments described here allow for the determination of the homonuclear $^{3}J_{H^{N},H^{\alpha}}$ coupling constant even in very large (by NMR standards) proteins, which do not show any correlations in COSY or TOCSY spectra. Coupling constants provide structural information, which, together with distances determined from NOESY spectra, significantly enhance the quality of protein structures obtained by NMR spectroscopy.

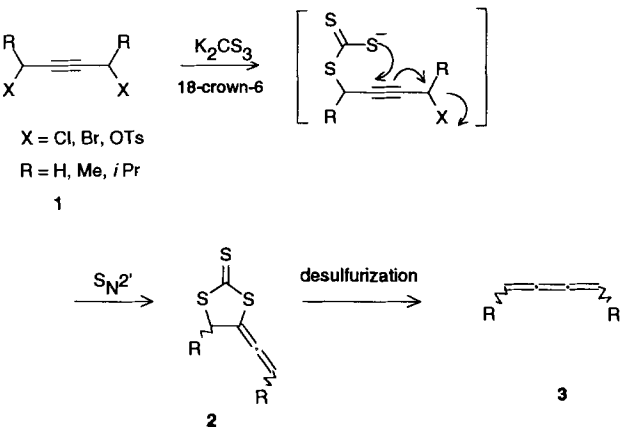
Butatrienes by Desulfurization of Cyclic Trithiocarbonates**

By *Rainer Herges** and *Christoph Hoock*

Most of the numerous butatriene syntheses[1, 2] are based on dehalogenation of 1,4-dichloro-2-butynes.[3, 4] Recently we reported a novel method for the synthesis of the parent butatriene **3** (R = H) starting from 1,4-dihalo- or 1,4-bistosyl-2-butyne **1** via 4-vinylidene-1,3-dithiolane-2-thione **2**.[5] The subsequent Corey–Winter desulfurization to butatriene **3** (R = H) was accomplished with the phosphorous base 1,3-dimethyl-2-phenyl-1,3,2-diazaphospholidine at 0 °C with yields exceeding 90%.



The net reaction is homologous to a fragmentation reaction that we discovered recently using computer-aided reaction design,[6] namely the reaction of 1,4-dichloro-2-butene with potassium trithiocarbonate and subsequent desulfurization to 1,3-butatriene. Compared with the conventional method of Schubert et al.[3] and Brandsma et al.[4] for the synthesis of butatriene, our method gives higher yields and a very pure product. For the extension to alkyl-substituted butatrienes, one could use the easily accessible bistosylates **1** (X = OTs) instead of the 1,4-dihalogen-2-butynes **1** (X = Br, Cl, R = alkyl), which are difficult to prepare. Unfortunately, the reaction is restricted to the parent butatriene when the conventional phosphorous bases for Corey–Winter reactions are used. All attempts to desulfurize alkyl-substituted dithiolanes **2** with the phosphorous bases trimethyl phosphite, triphenyl phosphite, tris(dimethylamino)phosphane, and diazaphospholidine to the corresponding cumulenes failed. After testing a number of transition metals and transition metal complexes[7] we found Raney nickel[8] (deactivated with ketones) to be an excellent desulfurization agent.

Alkylated 1,4-butynediols **1** (X = OH) were easily prepared from acetylene and aldehydes or ketones.[9] The corresponding bistosylates **1** (X = OTs) were then synthesized in almost quantitative yields according to a slightly modified method of Brandsma[10] with tosyl chloride. Reaction with anhydrous potassium trithiocarbonate was accomplished in dichloromethane with 10 mol% crown ether and using ultrasound to give excellent yields of the dithiolanes **2** (Table 1).[5] Dithiolanes **2** are yellow, light- and air-sensitive oils that can be stored in solution under nitrogen at −30 °C for several weeks. Characteristic spectroscopic features of **2** are the low-field NMR shift of the trithiocarbonate carbon atom (δ = 223–224),[11] the large C–H coupling constant of the terminal allene carbon atom (165–171 Hz), the strong IR stretching vibration of the C=S bond at 1070–1060 cm^{-1},[12] and the strong UV absorption at 330–338 nm (ε_{max} = 4000–15000 $L\,mol^{-1}\,cm^{-1}$).[13] According to the ^{13}C and ^{1}H NMR spectra, the two stereoisomeres *syn*- and *anti*-**2** (R = Me, *i*Pr) are formed in a 1:1 ratio (Fig. 1).

For subsequent desulfurization the crude product can be used without purification. A proper choice of the solvent was crucial for the desulfurization. Dimethylformamide and other higher boiling formamides are most suitable. The sensitive

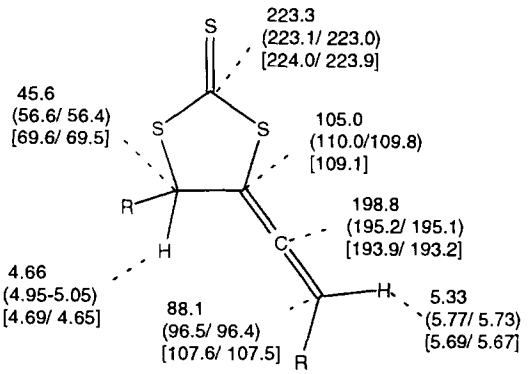

Fig. 1. The most important ^1H and ^{13}C NMR data (δ, $CDCl_3$) of dithiolanes **2** (data for R = H, R = Me (in parentheses), and R = *i*Pr (in brackets)). The spectra of the *syn* and *anti* isomers of the substituted dithiolanes formed in a 1:1 ratio are distinguishable and the chemical shifts are given separately.

butatrienes were removed from the reaction mixture under reduced pressure as they formed and were condensed in cold traps. Deactivation of the Raney nickel with ketones (acetone, acetophenone, or benzophenone) is recommended in order to avoid formation of alkanes (which are formed under not rigorously anhydrous conditions). The yields of butatrienes **3** range from 20 (R = H) to 95% (R = *i*Pr) (Table 1). The products are unequivocally characterized as butatrienes not only by comparison to the reported ^1H and ^{13}C NMR, and IR spectra, but also by the extraordinary large C–H coupling constants of the terminal cumulene carbon atoms (166.6–171.1 Hz).[14]

Table 1. Yields [%] for the preparation of dithiolanes **2** from bistosylates **1** and for the desulfurization of **2** to provide **3**.

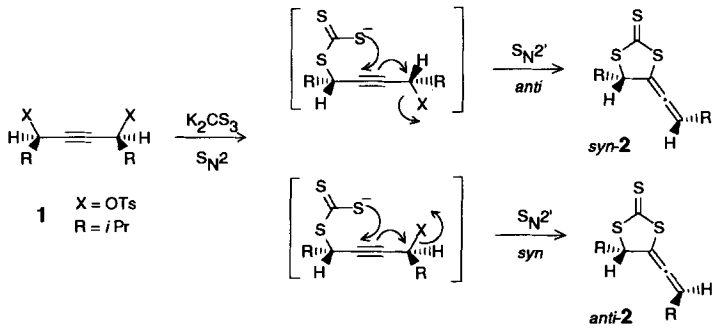
Me	72	70	[17]
*i*Pr	82	95	[18]

[a] Yields after chromatographic purification. [b] Yields determined by ^1H NMR spectroscopy in $CDCl_3$ at −40 °C, after condensation and addition of a standard. [c] References giving the spectroscopic data of the butatrienes.

In order to investigate the stereochemistry of the S_N2' addition and the desulfurization to the butatrienes **3**, we synthesized the *meso* isomer of 2,7-dimethyl-3,6-ditosyl-4-octyne **1** (X = OTs, R = *i*Pr)[15] and treated it with potassium trithiocarbonate. Two stereoisomeric dithiolanes **2** were formed in a 2:1 ratio (Scheme 1).

NOE experiments suggest that the main product is the *syn* compound which arises by an internal *anti* S_N2' reaction.[16]



Scheme 1. Stereochemistry of the S_N2' reaction.

Since the two isomers could not be separated in preparative scale, the mixture was used for desulfurization with Raney nickel and a 1:1 mixture of *E*- and *Z*-substituted butatriene **3** (R = *i*Pr) was obtained. In contrast to the Corey–Winter reaction, the fragmentation is apparently not stereoselective or the cumulenes isomerize immediately after formation by coordination to nickel.

Experimental Procedure

1 (X = OTs, R = H, Me, *i*Pr): To a 10% solution of 19.1 g (0.1 mol) tosyl chloride in diethyl ether was added a concentrated solution of 0.04 mol diol **1** (X = OH) in ether or THF, and the reaction mixture was cooled to −15 °C. Thereafter 20 g (0.36 mol) finely powdered potassium hydroxide was added in small portions (1 g per min) to the vigorously stirred solution; the temperature was kept below −5 °C. To complete the reaction, the solution was stirred for another 1–2 h at 0–5 °C and then poured into ice water. The aqueous phase was extracted several times with ether or dichloromethane. After the collected organic extracts were dried over magnesium sulfate, the solvent was removed in vacuo and the crude product recrystallized. Yields were 80–90% after crystallization. The colorless crystals can be stored at −30 °C for several months without decomposition.

2: (R = H, Me, *i*Pr): To a suspension of 2.0 g (11 mmol) anhydrous potassium trithiocarbonate in 100 mL anhydrous dichloromethane were added 10 mmol bistosylate **1** (X = OTs) and 10 mg (0.04 mmol) 18-crown-6 under a nitrogen atmosphere. After treatment of the suspension with ultrasound at 20 °C for 12 h most of the red suspended potassium trithiocarbonate had reacted. The light-yellow precipitate was removed by filtration, the filtrate reduced in vacuo to 20 mL, and the yellow solution chromatographed over silica gel eluting with tetrachloromethane (to remove small amounts of polymers and crown ether). The yellow oily products were pure according to thin-layer chromatography (TLC), and ^1H and ^{13}C NMR spectroscopy; however, they polymerized rapidly when exposed to oxygen, moisture, or light. Solutions of 10% in dichloromethane are stable at −30 °C for several weeks. For desulfurization the crude product can be used without chromatographic purification.

3: (R = H, Me, *i*Pr): 10 g Raney nickel (Fluka, suspended in water) was dried in vacuo at 10^{-2} Torr and deactivated by stirring for 20 min with 30 mL acetophenone (in the case of R = *i*Pr deactivation with a solution of the higher boiling benzophenone in ether is recommended). After filtration from acetophenone under nitrogen, the Raney nickel was suspended in 40 mL anhydrous dimethylformamide (*N*-formylmorpholine, in the case of R = *i*Pr). The solution was heated to 60–70 °C, and a solution of 5 mmol dithiolane **2** in 10 mL dimethylformamide (or *N*-formyl-morpholine) was added dropwise. The product formed was continuously removed from the reaction mixture at 20 Torr (10^{-2} Torr for R = *i*Pr) and condensed in two cold traps at −198 °C. Small amounts of carbon disulfide were removed by condensation in vacuo. The stability of the butatrienes to oxygen and polymerization decreases in the series R = *i*Pr, Me, H. Whereas butatriene polymerizes vigorously even at 0 °C, the diisopropyl substituted triene can be destilled at 10 Torr under nitrogen.

Rate Constants for the Attack of Carbenium Ions at Arenes—A Link between the Chemistry of Aliphatic and Aromatic π Systems**

By *Herbert Mayr,* Jörg Bartl,* and *Gisela Hagen*

Dedicated to Professor Klaus Hafner on the occasion of his 65th birthday

The mechanism of the Friedel–Crafts alkylation is one of the most thoroughly investigated in organic chemistry,[1] and countless investigations have been concerned with the determinations of relative reactivities of differently substituted arenes.[2] Amazingly, absolute rate constants for the attack of carbenium ions at arenes, the key step of these reactions, have hardly been available. Some investigations on the attack of metal-coordinated carbenium ions at highly activated arenes[3] and studies of fluorenyl cations generated by laser flash photolysis published[4a] recently in this journal are, to our knowledge, the only sources of such data.[4b]

We now report that the method, which we used for the determination of the nucleophilicity of aliphatic π systems,[5] can also be applied to arenes. As described previously, diarylhalomethanes **1** are quantitatively ionized by Lewis acids to give colored solutions of diarylcarbenium ions **2**; addition of nucleophiles causes bleaching, which can be monitored photometrically (Scheme 1). The methoxy-substituted arenes are so reactive that the kinetics of their reactions with donor-substituted benzhydryl cations **2** (X = OCH_3, Y = H, OCH_3) can be studied without difficulty. Since alkoxy-substituted arenes form complexes with those Lewis acids (BCl_3, $TiCl_4$, or $GaCl_3$) usually employed for the ionization **1** → **2**, we used trimethylsilyl triflate (Me_3SiOTf) for the ionization of the diarylchloro- and diarylfluoromethanes in these cases. The reactions of the arenes with the benzhydryl cations thus generated follow a second-order rate law (first order with respect to Ar_2CH^+, first order with respect to arene). The reaction rate is independent of the concentration of Me_3SiOTf (excess), and the coordination of Me_3SiOTf with the oxygen of the aryl ether can thus be excluded.

The strong Lewis acid $GaCl_3$ was used for the generation of the highly electrophilic bis(*p*-chlorophenyl)carbenium ion, which was then allowed to react with benzene and its methyl derivatives. Complex rate laws were observed for ion concentrations $\leq 10^{-4}$ mol L^{-1}, which may indicate that the alkylation step is partially reversible. In accord with this hypothesis, we found that addition of benzyltriethylammonium tetrachlorogallate (10^{-3}–10^{-2} mol L^{-1}) accelerates the reaction and gives rise to second-order kinetics, since at high concentrations of $GaCl_4^-$[6] (which acts as a base) the intermediate benzenium ion is rapidly deprotonated. The irreversibility of the C–C bond-forming step under these conditions is supported by the absence of a primary kinetic isotope effect for the reaction of $(p\text{-}ClC_6H_4)_2CH^+GaCl_4^-$ with *p*-deuteriotoluene ($k_H/k_D = 1.01$). As shown in several previous investigations,[5, 7] the nature of the counterion does not affect the electrophilicity of the diarylcarbenium ions, and the rate constants given in Table 1 can directly be compared with each other.

From the partial rate constants of the reactions with benzene and toluene, the large value of $\rho = -13$ is derived for the reaction constant, which indicates a transition state with pronounced benzenium character. In accord, the slopes of the correlations between nucleophilic reactivity and basicity of the arenes[8] are 0.94–1.05 (Fig. 1), which are reduced to 0.63–0.80 when one accounts for the different temperatures to which equilibrium and rate constants refer. As the correlation lines are almost parallel, one can now estimate rate

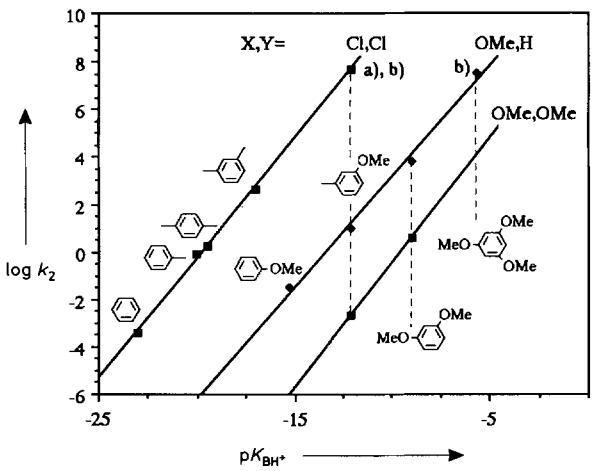

Fig. 1. Relationship between the basicity of arenes and their reactivity to diarylcarbenium ions (CH_2Cl_2, −70 °C). a) Since the value of pK_{BH^+} is not available for this compound the value of the abscissa was set. b) Ref. [14].

Table 1. Rate constants (CH_2Cl_2, $-70\,^{\circ}C$) and activation parameters for the reactions of *para*-substituted benzhydryl salts $[(XC_6H_4)(YC_6H_4)CH^+Z^-]$ with arenes.

Arene	X, Y	Z^-	k_2 ($-70\,^{\circ}C$) [$L\,mol^{-1}s^{-1}$]	$\Delta H^{\neq}$ [$kJ\,mol^{-1}$]	$\Delta S^{\neq}$ [$J\,mol^{-1}K^{-1}$]
	Cl, Cl	$GaCl_4^-$	$\approx 4\times10^{-4}$	≈ 34.7	≈ -136
	Cl, Cl	$GaCl_4^-$	7.8×10^{-1}	24.9	-121
	Cl, Cl	$GaCl_4^-$	1.8		
	Cl, Cl	$GaCl_4^-$	4.2×10^{2}	15.5	-115
	OMe, H	OTf^-	3.1×10^{-2}	31.2	-117
	Cl, Cl	Cl^-	$\approx 5\times10^{7}$ [a]		
	OMe, H	OTf^-	1.0×10^{1}	24.8	-100
	OMe, OMe	OTf^-	2.2×10^{-3}	31.3	-138
	OMe, H	OTf^-	6.4×10^{3}		
	OMe, OMe	OTf^-	3.9	21.9	-123
	OMe, OMe	OTf^-	18 (CH_3CN) [b]	20.5	-117
	OMe, H	Cl^-	3.3×10^{7} [a]		

[a] These values were determined with carbenium ions generated by laser flash photolysis in acetonitrile at 20 °C [14]. In view of the reactivity range that covers many orders of magnitude these rate constants can be compared directly with the others in this column, since the solvent effect in these reactions is generally small (cf. penultimate entry in Table 1 and ref. [5a]). A temperature correction is not necessary because $\Delta H^{\neq} = 0$. [b] Extrapolated from the activation data.

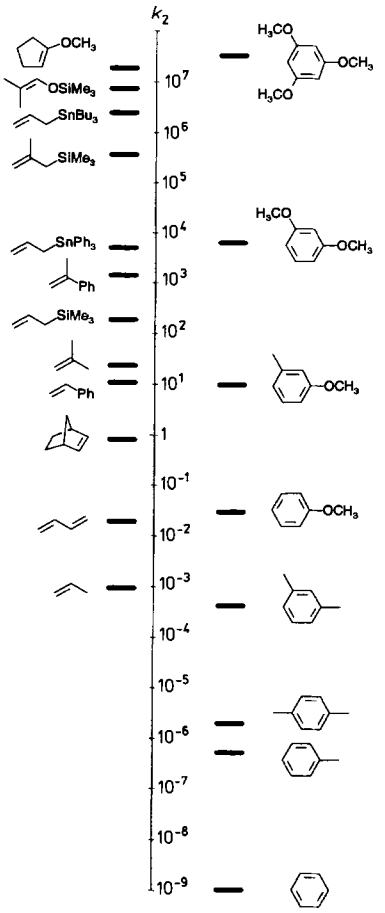

Fig. 2. Comparison of the nucleophilicity of alkenes [7c,d], allyl main group element compounds [7b], and arenes toward the *p*-methoxy substituted diphenylcarbenium ion ($-70\,^{\circ}C$).

constants for the reactions of the *p*-methoxy substituted benzhydryl cation with benzene, toluene, and the two xylenes. Since this carbenium ion has also been employed to characterize the nucleophilicity of numerous aliphatic π systems,[7] one can now directly compare the nucleophilic reactivities of aliphatic and aromatic π systems. Figure 2 shows, for example, that *m*-xylene and propene, *m*-methylanisole and styrene, and 1,3,5-trimethoxybenzene and various enol ethers show similar reactivities toward carbon electrophiles. A competition experiment corroborates the relationship between aliphatic and aromatic reactivity derived from the absolute rate constants: according to the product analysis 1,3-dimethoxybenzene is 16 times more reactive than allyltrimethylsilane towards $(p\text{-}MeOC_6H_4)_2CHCl/Me_3SiOTf$; absolute rate constants yield a rate ratio of 14.

In summary, it is now possible to recognize relation ships between aliphatic and aromatic reactivity and plan new reactions in one of these areas on the basis of known reactions in the other. The experience of the preparative chemist that methylene iminium ions react with α-methylstyrene but not with styrene or dialkylethylenes, and with 1,3,5-trimethoxybenzene and 1,3-dimethoxybenzene but not with anisole,[9] is in accordance with the nucleophilicity order given in Figure 2. Interestingly, Figure 2 can also be used to rationalize reactions with other types of electrophiles. From the chemistry of arenes it is known, for example, that anisole reacts with the 2,4-dinitrobenzenediazonium ion but not with the 4-nitrobenzenediazonium ion.[10] Accordingly, reactions of the 2,4-dinitrobenzenediazonium ion with various 1,1-dialkylethylenes,[11] styrene,[11] and allylsilanes[12] have been described, while we have not been able to achieve reactions with monoalkylated ethylenes.

For the reactions of carbenium ions with aliphatic π systems we had observed that in several cases the relative nucleophilicities of the π systems depend somewhat on the nature of the reference electrophile.[7a, 13] We intend to account for this fact by introducing an additional parameter in order to increase the predictive power of the nucleophilicity scale of Figure 2.

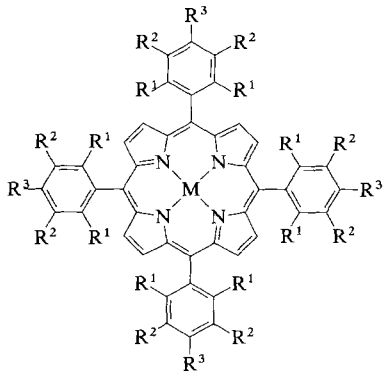
Spectroscopic Characterization of Two Types of Tetraarylporphyrin Cation Radicals**

By *Zeev Gross** and *Claudia Barzilay*

Characterization of metalloporphyrins with metal ions in high oxidation states remains an intriguing challenge in the context of understanding and mimicking the chemistry of heme-dependent enzymes.[1, 2] These include catalases (CAT), peroxidases [especially horseradish (HRP) and cytochrome c (CCP) peroxidase], chloroperoxidases, and cytochrome P-450 enzymes, for which the intermediates obtained from two- and one-electron oxidations (starting from Fe^{III}) are referred to as compounds I and II, respectively. A considerable number of spectroscopic methods, including UV/VIS, ESR, NMR, and resonance Raman (RR) spectroscopy,[3] was utilized in the characterization of the intermediate isolated from the two-electron oxidation of (TMP)FeCl (**2**, M = Fe instead of Zn; TMP = tetramesitylporphyrin).[4] As a result of these and related studies it is presently accepted that upon oxidation of (TMP)FeCl only one electron is removed from the metal ion, forming an oxoiron(IV) center, while the second electron is removed from the porphyrin ligand, which is thus oxidized to the cation radical. The diverse types of interactions between the porphyrin radical and the metallic center are emphasized by close inspection of supposedly similar compounds. Whereas in the oxidation product of (TMP)FeCl the two paramagnetic centers strongly interact ferromagnetically,[4, 5] in the corresponding products of (TDCPP)FeCl (**3**, M = Fe instead of Zn; TDCPP = tetrakis(2,6-dichlorophenyl)porphyrin) and HRP the interaction is very weak and antiferromagnetic;[5, 6] for CCP an amino acid and not the porphyrin is oxidized;[7] in chloroperoxidase the interaction is antiferromagnetic and moderately strong,[8] and finally in cytochrome P-450, compound I remains elusive. Another point of concern is that in porphyrin cation radicals the unpaired electron can reside in one of two neighboring orbitals, A_{2u} and A_{1u} (in D_{4h} symmetry). As the spin distributions in these orbitals differ considerably, the interaction of the porphyrin radical with the metal center will vary according to symmetry considerations.[9] An early example emphasizing the importance of these possibilities and the relationship between oxidized enzymes and their synthetic analogues is the similarity of the electronic spectra of the cation radicals of zinc and magnesium complexes of tetraphenylporphyrin (TPP) and octaethylporphyrin (OEP) to those of compounds I of HRP and CAT, respectively, and their relation to the two different possible magnetic orbitals, A_{2u} and A_{1u}, respectively.[10]



1, M = Zn, $R^1 = R^2 = R^3 = H$
2, M = Zn, $R^1 = R^3 = CH_3$, $R^2 = H$
3, M = Zn, $R^1 = Cl$, $R^2 = R^3 = H$
4, M = Mg, $R^1 = R^2 = R^3 = F$
5, $[1]^{\cdot+}$ $SbCl_6^-$
6, $[2]^{\cdot+}$ $SbCl_6^-$
7, $[3]^{\cdot+}$ $SbCl_6^-$
8, $[4]^{\cdot+}$ $SbCl_6^-$

Since OEP and TPP have very different structures, great efforts were expended in trying to obtain the two types of radicals from each of the porphyrin classes. For OEP this was accomplished by several groups,[10, 11] but to our knowledge in all tetraarylporphyrin radicals studied to date the unpaired electron was considered to be located in an A_{2u} orbital. We present here evidence, which indicates that in oxidized phenyl-substituted tetraphenylporphyrins, the magnetic orbital can be an A_{2u} as well as an A_{1u} orbital, depending on the properties of the substituents.

The cation radicals **5**–**8** were quantitatively prepared by oxidation of ZnTPP **1**, ZnTMP **2**, ZnTDCPP **3**, and MgTpFPP **4** with [PH(SbCl$_6$)] (PH = phenoxathiin radical cation) and isolated as black solids.[12] In the solid state the compounds were found to be stable for days, and no fast decomposition was observed in degassed $CHCl_3$ or CH_2Cl_2

solutions; where they appeared green as expected for porphyrin cation radicals. Addition of nBu$_4$NI regenerated the unoxidized precursors, thus eliminating the possibility of irreversible oxidation to isoporphyrins. All spectroscopic data of our ZnTPP oxidation product **5** was identical to that of ZnTPP$^{\cdot+}$ClO$_4^-$ reported previously.[13]

The four complexes **5**–**8** were characterized by ESR, UV/VIS, and IR spectroscopy.[10, 14, 15, 16] The ESR spectra (Fig. 1) clearly separate the four compounds into two groups; the spectra of ZnTPP$^{\cdot+}$ **5** and ZnTMP$^{\cdot+}$ **6** are almost identical, but very different from those of ZnTDCPP$^{\cdot+}$ **7** and MgTpFPP$^{\cdot+}$ **8**, whose spectra also resemble each other. In particular, for A_{2u} cation radicals an ESR spectrum with nine lines is expected due to high unpaired spin densities at the four equivalent nitrogen atoms and at the *meso* carbon atoms. These lines may be broad because of the interactions of the

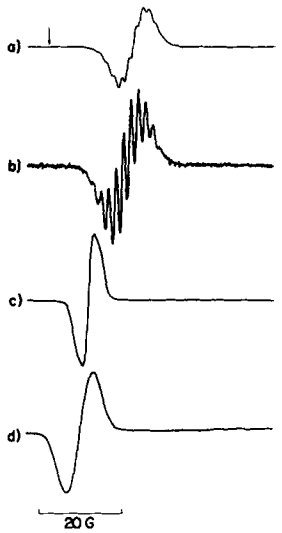

Fig. 1. ESR spectra at room temperature for a) **5**, b) **6**, c) **7**, d) **8**. Arrow indicates the position of $g = 2.0015$ (Mn^{2+} in MgO). The g values of **5**, **6**, **7**, and **8** are 2.0050, 2.0068, 2.0117, and 2.0126, respectively.

C spin centers with the phenyl protons. As shown in traces a and b of Figure 1, compounds **5** and **6** satisfy this expectation and thus provide definite evidence for the identity of the magnetic orbital as A_{2u} (the spectral narrowing of **6** relative to **5** is qualitatively similar to that observed in the spectra recorded for *ortho*- and *para*-deuterated ZnTPP$^{\cdot+}$ClO$_4^-$).[17] The broad and quite characterless VIS spectrum of **6** (solid line in Fig. 2) is also in accord with previous reports of A_{2u} cation radicals.[10]

On the other hand, the intense red shifts in the VIS spectra of **7** (broken line in Fig. 2) and **8** (not shown but very similar to that of **7**) were previously observed only for OEP$^{\cdot+}$ and similar compounds with an A_{1u} magnetic orbital.[15] Since for such radicals, theory and experiment suggest unpaired spin densities only at the α (mostly) and β carbon atoms of the pyrrole units[18] and not at the nitrogen atoms or at the *meso* carbon atoms, the ESR spectra of **7** and **8** (c and d in Fig. 1) should be very different from those of **5** and **6**. The spectra of **7** and **8** do not necessarily have to resemble that of OEP$^{\cdot+}$ because of the absence of *meso* protons in the former and the absence of pyrrole protons in the latter. Rather, the broad singlets observed in the ESR spectra of **7** and **8** indicate that most of the spin density is located at the α carbon atoms of the pyrrole units with some unresolved splitting from the β hydrogen atoms of the pyrrole units contributing to the linewidths. Furthermore, the remarkable similarity

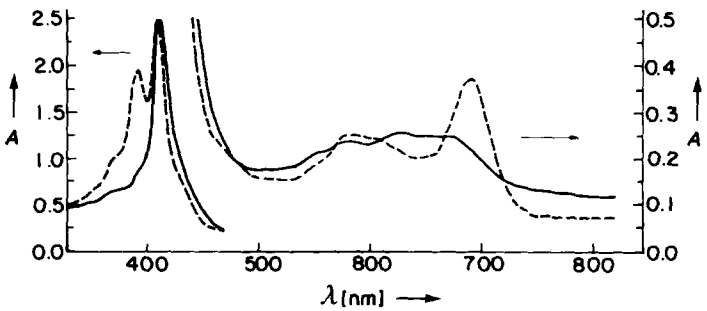

Fig. 2. Electronic absorption spectra of **6** (solid line) and **7** (broken line). The spectra of **5** and **8** are very similar to that of **6** and **7**, respectively. A = absorbance.

between the spectra of **7** and **8** is very strong evidence for essentially zero, unpaired spin density at the *meso* positions, since otherwise the fluorine substituents in **8** would be expected to cause very large splitting and thus affect the spectrum dramatically.

The examination of the IR spectra of porphyrin cation radicals showed that new bands at 1270–1290 cm^{-1} are diagnostic for TPP A_{2u} cation radicals, whereas for OEP A_{1u} cation radicals these bands appear at 1520–1570 cm^{-1}.[15] Attempts to identify these absorptions for compounds **6** and **8** were hampered by the strong bands of their unoxidized precursors **2** and **4** in that spectral region, thus only the spectra of **7** and its precursor **3** are shown in Figure 3. As can be judged by comparison of the spectra of **3** and **7**, the main new band appears at 1283 cm^{-1} together with two very weak bands at 1467 and 1580 cm^{-1}. These features are thus remarkably similar to those in the spectrum of **5** and not to those of OEP$^{\cdot+}$ despite the assignment of **7** as a A_{1u} cation radical. Thus, we might conclude that the position of the IR bands of porphyrin cation radicals is not sensitive to electronic configuration but rather to structural parameters. A similar conclusion was reached previously based on the IR spectra of the two types of cobalt OEP cation radicals.[15]

In summary, we have shown that cation radicals of tetraarylporphyrins with an A_{1u} magnetic orbital can be produced, which is understandable if the high spin density at *meso* carbons for A_{2u} radicals is considered. This should be disfavored by the electron-withdrawing substituents in **7** and **8**.[19] These results provide further insight into the factors affecting the inherent structural and electronic variations in the "compound I" of heme-dependent enzymes and their synthetic analogues; for any given axial ligand or geometry (e.g., displacement of the metal center from the porphyrin plane or deviation of the porphyrin from planarity, *the interaction of a paramagnetic metal center with a porphyrin cation*

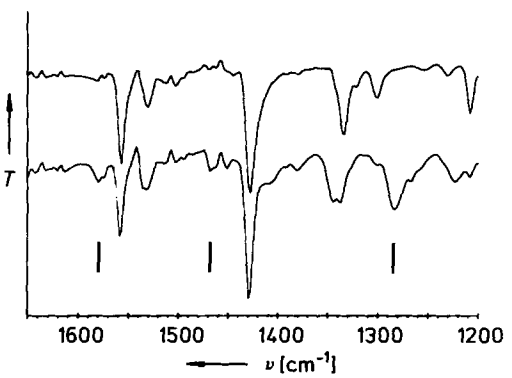

Fig. 3. FTIR spectra of **7** (bottom) and its neutral precursor **3** (top). The vertical lines indicate new bands which appear in **7**. T = transmittance.

radical is much smaller for an A_{1u} than for an A_{2u} orbital, because of the negligible spin density at the nitrogen atoms in the former. In order to test the generality of this phenomena, we are currently investigating the oxidized iron and manganese complexes of the porphyrins described here.

DNA Recognition by Hybrid Oligoether–Oligodeoxynucleotide Macrocycles**

By *Squire Rumney IV* and *Eric T. Kool**

The sequence-specific binding of RNA and DNA by synthetic oligonucleotides and analogues is important as a diagnostic tool in the study of naturally ocurring polynucleotides and is the subject of intense research as a potential therapeutic strategy as well.[1–3] Two limitations of natural DNA oligomers in these applications are their low binding affinity[2] and also their limited stability, due to cleavage by exo- and endonucleases which occur in natural systems.[4, 5] We report here the construction of circular hybrid molecules which contain two oligonucleotide domains bridged by two oligoethylene glycol chains. These molecules bind with high affinity to complementary strands of RNA and DNA and display exceptional resistance to degradation by nucleases.

Oligoethylene glycol chains have been successfully used as simple linking groups which replace nucleotide units in linear oligonucleotide chains[6] and in hairpin-shaped oligonucleotides in duplexes and triplexes as well.[7] We wished to determine whether such spacers could be incorporated into circular structures and what the effect on their recognition properties and stability would be. We have previously shown that circular oligonucleotides can display very strong binding affinity[8] and high sequence selectivity[9] for single-stranded DNA and RNA by forming bimolecular triple helices. These macrocycles bind by forming bonds on two sides of a linear target strand, and their unusual recognition characteristics arise from the preorganized circular structure.[10]

Examination of models[11] and published data on DNA triple helices[12] revealed that a group 19–21 Å long would be ideal for bridging the outer pyrimidine strands, and that five-base nucleotide loops might be replaced with penta- or hexaethylene glycol chains. In addition to confirming our model for the binding, such a replacement might lead to favorable properties, such as lower cost and higher synthesis yield (by decreasing the number of nucleotide units), longer lifetimes in biological media, and possibly, improved membrane permeability (by decreasing total negative charge).

The linear precursors to the compounds investigated in this study **1**–**3** were constructed by automated DNA syn-

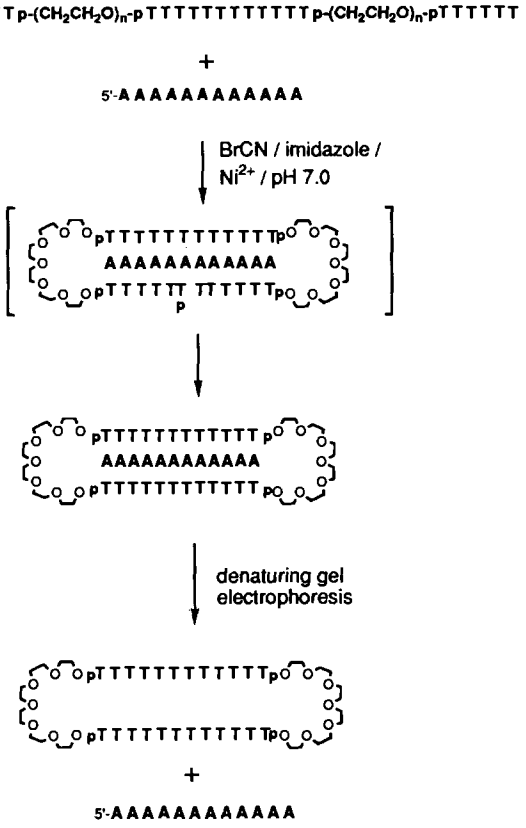
thesis methods[13] (*Experimental Procedure*) with the introduction of the synthetic dimethoxytrityl hexa- or pentaethylene glycol (HEG or PEG) phosphoramidites[7] at two positions. The oligomers $d(A)_{12}$ (for **1**) and dAAGAAAAGAAAG (for **2** and **3**) were used as templates in cyclization to align the reactive phosphate and hydroxyl ends in an intramolecular esterification reaction in the presence of BrCN, imidazole, and $NiCl_2$, as reported previously.[10]



Thermal denaturation studies were carried out to investigate the binding properties of the macrocycles with their complementary 12-base oligonucleotides (Table 1) at a concentration of 3 μM in a buffer approximating physiological conditions (pH 7.0, 100 mM NaCl, 10 mM $MgCl_2$). The dissociation curves reveal sharp, two-state transitions, and similar hyperchromicities for both complexes, with an average value of 28% at 260 nm. Mixing curves of absorbance (at 260 nm) vs. mole ratio for both complexes confirm a 1 : 1 stoichiometry of binding, consistent with a bimolecular triple-helical structure. The complex of compound **1** and $d(A)_{12}$ has a melting transition (T_m) of 51 °C, which is 14 °C higher than the corresponding Watson–Crick duplex, $d(A)_{12} \cdot d(T)_{12}$[8] (Table 1). Curve-fitting analysis[14] gives an estimated free energy (37 °C) of -15 kcal mol^{-1} for the complex of **1** and $d(A)_{12}$, which is 7 kcal mol^{-1} more favorable than the duplex. Similarly, compound **2** binds its complementary oligonucleotide to give a complex with a T_m of 58 °C ($\Delta G^\circ_{37} = -17$ kcal mol^{-1}), compared to 42 °C (-10 kcal mol^{-1}) for the analogous duplex.

Thus, in both cases the binding by the macrocycles is much stronger than that achieved by simple Watson–Crick binding of the same sequences, giving equilibrium binding constants (K_{assoc}) which are approximately five orders of magnitude greater than those of the duplexes at 37 °C. Comparison with

Table 1. Melting temperatures (T_m) and free energies of complexation ($-\Delta G^\circ_{37}$) for linear duplexes and complexes of oligonucleotides and circular ether–DNA hybrids.

Complex [a]	T_m [°C] [b,c]	$-\Delta G^\circ_{37}$ [kcal mol^{-1}]
TTTTTTTTTTTT AAAAAAAAAAAA	37	8
HEG pTTTTTTTTTTTTp HEG pTTTTTTTTTTTTp	51	15
TTCTTTTCTTTC AAGAAAAGAAAG	42	10
PEG pTTCTTTTCTTTCp PEG pTTCTTTTCTTTCp	53	15
HEG pTTCTTTTCTTTCp HEG pTTCTTTTCTTTCp	58	17

[a] Hexa- and pentaethylene glycol are abbreviated as HEG and PEG, respectively. [b] The data are for pH 7.0, 100 mM NaCl, 10 mM $MgCl_2$, and oligomer concentrations of 3 μM in each strand. [c] Precision in T_m values is ± 1 °C, and in free energies, ± 10%.

the all-DNA analogues containing nucleotide loops reveals that these synthetic hybrid macrocycles bind only slightly less strongly. For example, the analogue of **1** containing five-base loops (sequence -CACAC-) forms a complex with a T_m of 57 °C ($\Delta G^\circ_{37} = -16$ kcal mol^{-1}) under identical conditions.[8] The small decrease of this value upon introduction of the HEG chain may be due to the increased flexibility relative to a more rotationally restricted nucleotide chain. The fact that the effect is small also helps to confirm the model for "circle binding",[10] which requires loops mainly for bridging and not for other more specific interactions.

Model studies[11] and fiber diffraction data[12] indicate that a bridge between the outer pyrimidine strands at a given base triad in a DNA triple helix must span a distance of approximately 20 Å. Molecular modeling studies indicate that in its extended conformation, HEG-monophosphate has a length of 23 Å, while penta- (PEG) and tetraethylene glycol (TEG) monophosphates have lengths of 19 and 16 Å, respectively. To test this length requirement, we also attempted construction of versions of **2** with these shorter spacers. Melting studies of the complex of the PEG-bridged macrocycle **3** with its template complement show that this complex is somewhat less stable than the analogous HEG complex (T_m = 53 °C, 5 °C less than the T_m of the adduct of **2**). Attempts at constructing the TEG circle failed; apparently, this bridge is too short to span the distance required for full complexation of the 12-base template in the cyclization reaction. Thus, it appears that of these three cases the hexaethylene glycol spacer is the best suited for optimum complexation, and the spacer length of 23 Å is consistent with published models for triple-helix structure.[11]

The primary cause of degradation of standard DNA oligomers in biological applications is a 3′-exonuclease activity found in cells.[4, 5] Although present in lower activity, endonucleases are also found, which degrade DNA oligomers at internal phosphodiester bonds.[2] Attempts at cleavage of **1** and **2** by exonucleases confirm that they are completely resistant, due to their circular structures. Interestingly, we find that exonucleases cleave the linear precursors of **1** and **2** only through the first six bases from the end, leaving

the oligoether units, which are apparently not recognized by the enzymes.

In order to test susceptibility of such macrocyclic DNA compounds to degradation in a biological medium, we incubated compound **2** and its all-DNA analogue (see Table 2) in fresh human serum at 37 °C and removed aliquots periodically, analyzing the structural integrity by gel electrophoresis (data not shown here). A linear version of this sequence was found to have a half-life for cleavage of 20–30 min, while both circular compounds showed no sign of cleavage after two days. Thus, circular oligomers are highly resistant in this medium, and exonucleases appear to be the dominant cleaving enzymes in serum, consistent with published findings.

To examine specifically the sensitivity to an endonuclease, we studied the cleavage of compound **2** by Nuclease S1, a single-strand-specific DNA-cleaving enzyme. We compared the results to those for the 34-base all-DNA analogue (Table 2). The sensitivity to degradation was tested with oligomers both alone and in the presence of a complementary oligonucleotide, since the resulting secondary structures (such as triple helices) may not be recognized by enzymes and thus confer added resistance.

Table 2. Susceptibility of synthetic circular DNA and DNA–ether compounds to degradation by staphylococcal endonuclease (S1) in the absence and presence of the complementary oligonucleotide sequence.

Oligomer(s) [a]	Nuclease cleavage $t_{1/2}$ [min]
	1
	20

	>24 h

[a] Hexaethylene glycol loops are abbreviated as HEG.

The experiments show that both types of macrocycles are susceptible to single-strand endonuclease cleavage (Table 2). Both linear and circular sequences showed the same rates of cleavage (data not shown here). Interestingly, we find that both circular oligomers are considerably more resistant to cleavage when bound to their complement. This is evidently due to the fact that they are held in a tight triple-helical secondary structure in the complex. More significant is the finding that whereas the all-DNA compound is still cleaved, albeit at a slower rate, when bound, we find no evidence for any cleavage of the DNA–oligoether macrocycle **2** after 24 hours of incubation. This difference is likely due to the variance in loop structure for the two complexes: the all-DNA compound still presents single-stranded cleavable nucleotides in the complex, while in **2** there is no single-stranded region of DNA exposed to solvent. In the presence of a binding structure, compounds such as **1**–**3** are unlikely to be substrates for any exo- or endonuclease enzyme, and would likely be stable during diffusion through serum as well. The combination of this stability and the high binding affinity makes such compounds good candidates for use in biological systems.

Experimental Procedure

1 was prepared from the linear precursor 5′-pTTTTTTpO-$(CH_2CH_2O)_6$-pTTTTTTTTTTTTpO-$(CH_2CH_2O)_6$-pTTTTTT; **2** from 5′-pTTTCTTpO-$(CH_2CH_2O)_6$-pTTCTTTTCTTTCpO-$(CH_2CH_2O)_6$-pCTTTCT; and **3** from 5′-pTTTCTTpO-$(CH_2CH_2O)_5$-pTTTCTTTTCTTTCpO-$(CH_2CH_2O)_5$-pCTTTCT. Reaction conditions were as described previously [10]. The conversion to macrocyclic product was 85–95% (by gel analysis) in both cases, and the circular products were isolated by preparative gel electrophoresis, giving 43% (**1**), 48% (**2**), and 24% (**3**) isolated yields. The circular structure was confirmed by complete resistance to T4 polymerase exonuclease cleavage under conditions under which the linear precursors are fully cleaved up to the ether linkage. Dimethoxytrityl-HEG- and -PEG-phosphoramidites were synthesized by the method of Thuong et al. [7]. Coupling yields for these linkers were > 90%. Intact incorporation of HEG and PEG spacers after final deprotection was also confirmed by ^{1}H NMR and FAB-MS studies on short oligomers having the sequence dTpO-$(CH_2CH_2O)_n$-pT.

Thermal denaturation studies and curve fitting were carried out as described [10]. Mixing studies were carried out at a total concentration of 6 μM in a buffer containing 100 mM NaCl, 10 mM $MgCl_2$, and 10 mM Tris · HCl at pH 7.0. Exonuclease cleavage was carried out at 37 °C with 20 μM DNA, 6 mM $MgCl_2$, 4 mM potassium phosphate (pH 7.5), and 55 units mL^{-1} of enzyme with T4 Polymerase from New England Biolabs. Nuclease S1 was purchased from Pharmacia, and cleavage reactions were carried out at a DNA concentration of 100 μM, 100 U mL^{-1} enzyme, using published buffer conditions [15]. Human serum was prepared by the published procedure [4], and cleavage studies were carried out at a DNA strand concentration of 50 μM at 37 °C and analyzed by gel electrophoresis.

One-Step Synthesis of a Fourfold Functionalized Catenane**

By *Fritz Vögtle,** *Stephan Meier*, and *Ralf Hoss*

Catenanes and other molecules with similar construction have become "Highlights" in supramolecular chemistry[1] thanks to the outstanding work of Sauvage[2] and Stod-

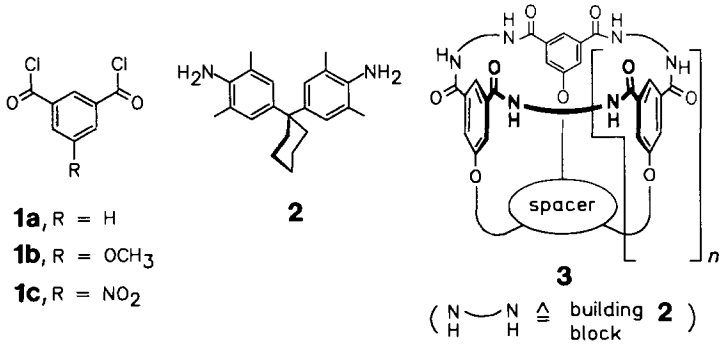
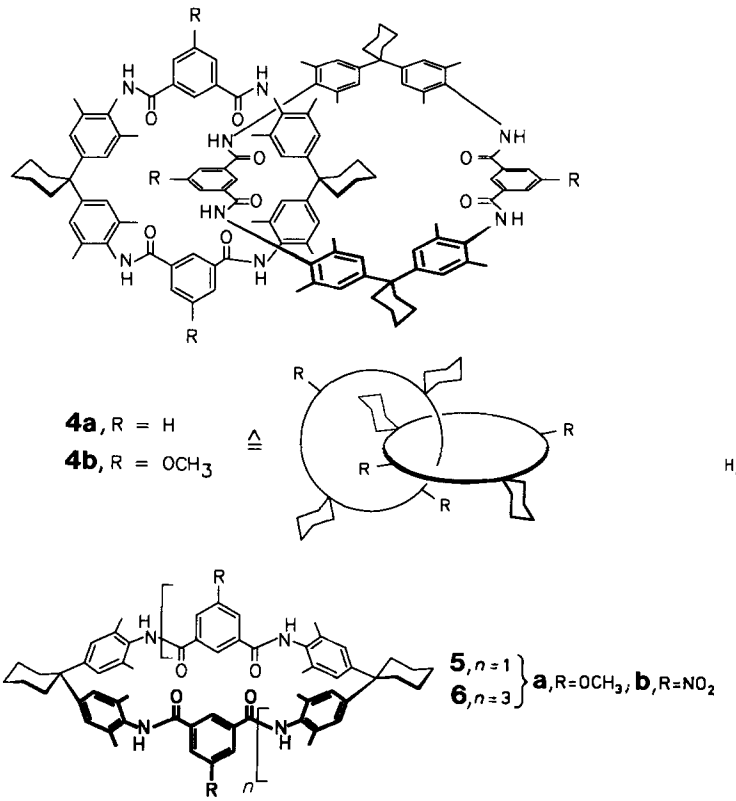
[**] This research was supported by the Deutsche Forschungsgemeinschaft (project no. 145/38-1). We thank Dr. K. Rissanen, University of Jyväskylä, Finland, for the crystallization, preliminary measurements, and the transfer of a single crystal to the University of Joensu, Finland, for further studies.

dart.[3] In our work on the syntheses of basket-shaped host molecules[4] we unexpectedly found an amazingly simple catenane synthesis in 1991.

In order to increase the solubility of macropolycyclic lactams of type **3** we employed the cyclohexylidene-substituted diamine **2**[5] instead of unsubstituted diphenylmethane, *p*-phenylene, or naphthalene units.[6] The OCH_3 substituents introduced by use of **1b** were intended as "handles" to be used for further bridging and in particular for attaching the bottom of the basket (spacer in **3**).[6] These studies surprisingly led to the one-step synthesis of catenane **4b** (for properties and analytical data see Experimental Procedure) from the simple components **1b** and **2** [Eq. (a)].



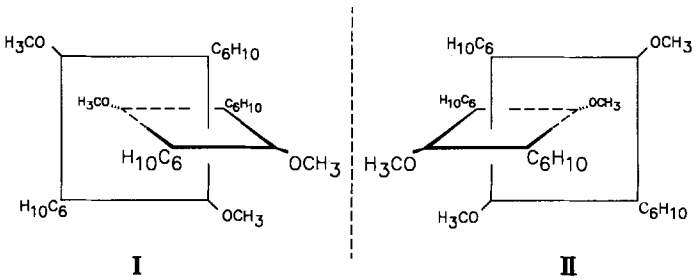
1b + **2** $\xrightarrow[\text{benzene}]{\text{chloro-}}$ **4b** + **5a** + **6a** (a)



Methoxyisophthaloyl dichloride **1b** was allowed to react with diamine **2** in chlorobenzene with a catalytic amount of 4-(*N*,*N*-dimethylamino)pyridine (DMAP) at 50–60 °C under dilution conditions. The sparingly soluble dimethoxy-substituted macromonocycle **5a** (12.4% yield; m.p. >300 °C (decomp)) was isolated along with the 72-membered "tetramer" **6a** (10% yield; m.p. 285–290 °C), which has the lowest R_f value of all macrocycles isolated. An isomer, **4b** (m.p. >300 °C, $R_f = 0.64$), a catenane (Fig. 1) according to FAB-MS, and ^1H and ^{13}C NMR spectroscopic data, was obtained in 8.4% yield. The spectroscopic properties of **4b** are in full accord with those of the unsubstituted catenane **4a** reported by Hunter et al.,[7] even down to the details: The mass spectrum shows the characteristic fragmentation due to the loss of one of the catenane rings. The NMR spectra of **4b** are more complicated than those of its isomer **6a**; H,H-COSY and NOE spectra also support the catenane structure. Attempts (since October 1991) to obtain an X-ray crystal structure have not yet been successful, though small single-crystals could be prepared, for which a unit cell of 17172 Å^3 was measured.[8]

Fig. 1. CPK model of [2]catenane **4b** (isomer **II**); for clarity the 16 methyl groups are not shown.

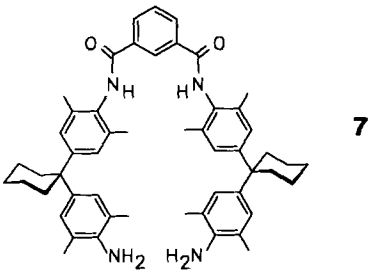
In the ^1H NMR spectrum of **4b** the four methoxy groups give rise to two singlets. One explanation is that neither the cyclohexylidene units nor the methoxybenzene groups pass easily through the second macrocycle, if at all. Thus, **4b** has a relatively fixed conformation which has two inner and two outer methoxy groups. As a consequence **4b** should have two enantiomeric forms **I** and **II**, which are expected to be more stable than the enantiomers of **4a**.



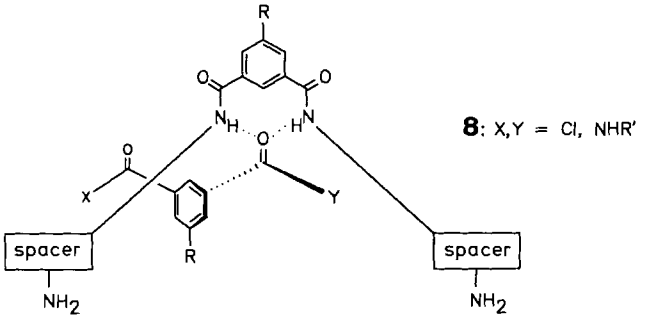
The latter were recently prepared with remarkable yield (34%) by Hunter et al.[7] in a two-step synthesis starting from the isolated intermediate **7** and isophthaloyl dichloride **1a**.

The template assistance in the reaction, which appears to be necessary for the smooth formation of the catenane, may be due to hydrogen-bonding interactions between the car-

bonyl group of the isophthaloyl unit and the NH group of the amide (cf. **8**), as well as π–π interactions between the benzene rings of the spacer units. The readily soluble, bulky diamine **2**, which shows a preference for forming large rings, seems to favor the catenane formation.



7



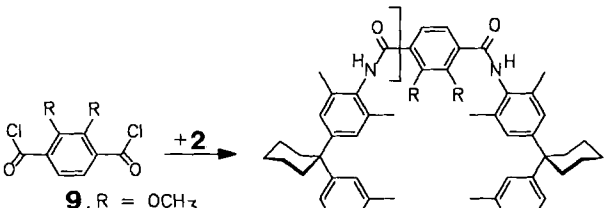
8: X,Y = Cl, NHR'

The analogous cyclization of the nitro-substituted **1c** with **2** [Eq. (b)], however, yielded the dimer **5b** (11% yield) as the main product and a tetramer (7% yield); the FAB-MS spec-

$$\mathbf{1c} + 2 \xrightarrow[\text{benzene}]{\text{chloro-}} \mathbf{5b} + \mathbf{6b} \qquad \text{(b)}$$

trum of the latter hints at the macromonocycle **6b**, and the isomeric catenane has not been detected so far. In the templating interaction here the NO_2 groups may possibly compete with the carbonyl groups in forming hydrogen bonds with the NH groups.

The compounds with extraannular methoxy substituents have the advantage that they can be converted into the hydroxy compounds according to known procedures.[9] Hydroxy-substituted catenanes should be suitable for further cyclizations and for linkage to oligomeric catenanes. By affixing large extra- and intraannular groups the conformational mobility of the catenane rings can be manipulated.



9, R = OCH_3

10: $n = 1$

11: $n = 3$

When other carbonyl compounds, for example the substituted terephthalic dichloride **9**, were employed, catenanes were not formed, but rather the 34- and 68-membered macromonocycles **10** (<1%) and **11** (34% yield), respectively. In this case the arrangement of the amino groups is apparently not complementary to the carbonyl groups, so that templated catenane formation is not possible.

As shown in the last two examples, a directed catenane synthesis requires exact planning of the self-associating intermediates (cf. **8**). The macromonocycles **10** and **11** can also be integrated in such synthetic strategies.

Experimental Procedure

Synthesis of **4b**, **5a**, and **6a**: A solution of **1b** (0.59 g, 2.5 mmol) in anhydrous chlorobenzene (250 mL) and a solution of **2** (1.60 g, 5 mmol) in anhydrous chlorobenzene (250 mL) were added synchronously over 24 h to chlorobenzene (1 L, 50–60 °C) containing a catalytic amount of DMAP. The reaction mixture was concentrated to dryness and the residue dissolved in dichloromethane/water. The organic phase was washed with water, dried over $MgSO_4$, filtered, and concentrated. Column chromatography on silica gel (60–100 μm) eluting with dichloromethane/ethyl acetate 8/1 (v/v) afforded three fractions, A, B, and C.

Fraction A (catenane **4b**): yield 100 mg (8.4%); m.p. >300 °C (decomp); thin-layer chromatography (TLC, SiO_2) $R_f = 0.64$ (dichloromethane/ethyl acetate 8/1), ^{1}H NMR (250 MHz, $CDCl_3/CD_3OD$): $\delta = 0.5$–2.5 (br., 88H; aliph. H, $ArCH_3$), 3.85, 3.90 (2s, 12H; OCH_3), 6.28, 6.31 (2s, 4H; arom. H), 6.75 (br., 4H; arom. H), 6.9 (s, 2H; arom. H), 7.0 (s, 2H; arom. H), 7.1 (s, 2H; arom. H), 7.3 (br., 4H; arom. H), 7.6 (s, 4H; arom. H), 7.7 (s, 2H; arom. H), 7.85 (s, 2H; arom. H), 8.5 (s, 2H; arom. H), 8.65 (s, 2H; arom. H), 9.15 (s, 2H; CO-NH), 9.3 (s, 1H; CO-NH), 9.45 (s, 1H; CO-NH); ^{13}C NMR (62.9 MHz, $CDCl_3/CD_3OD$): $\delta = 17.12$, 18.54, 18.75, 18.89 (Ar-CH_3), 23.37, 26.68, 34.92, 35.13 (CH_2), 36.55, 36.84, 45.18, 45.65 (C_q), 55.93, 56.31 (OCH_3), 111.98, 117.57, 117.81, 117.92, 118.05, 123.23, 123.89, 125.58, 128.03, 128.51 (CH), 130.85, 131.46, 131.50, 131.56, 133.83, 134.42, 134.71, 134.77, 135.34, 135.44, 136.26, 136.47, 137.62, 146.63, 146.90, 149.08, 150.00, 160.57, 160.74, 163.74, 164.59, 169.19 (C_q); FAB-MS: m/z 1930.8 [$(M + H)^+$].

Fraction B (dimer **5a**): yield 150 mg (12.4%); m.p. >300 °C (decomp); $R_f = 0.18$; IR (KBr, −78 °C); $\tilde{\nu}$[cm^{-1}] = 752 (m), 776 (m), 870 (w), 1051 (w), 1125 (w), 1163 (w), 1248 (w), 1309 (m), 1333 (m), 1373 (m), 1451 (s), 1496 (vs), 1592 (s), 1664 (vs), 2854 (m), 2931 (s), 3294 (m); FAB-MS: m/z 965.6 [$(M + H)^+$].

Fraction C (tetramer **6a**): It was the last fraction and was eluted with methanol/dichloromethane (20/1 (v/v)): 120 mg (10% yield; m.p. >300 °C (decomp); ^{1}H NMR (250 MHz, $CDCl_3/CD_3OD$): $\delta = 1.3$–1.6 (br., 24H; aliph. CH_2), 2.0–2.3 (br., 64H; $ArCH_3$, aliph. CH_2), 3.85 (s, 12H; OCH_3), 6.85 (s, 16H; arom. H), 7.55 (s, 8H; arom. H), 7.95 (s, 4H; arom. H), 8.7 (s, 4H; NH); ^{13}C NMR (62.9 MHz, $CDCl_3/CD_3OD$): $\delta = 18.33$ (CH_3), 22.56, 26.05, 36.68 (CH_2), 44.90 (C_q), 55.53 (OCH_3), 116.06, 117.66 (C_q), 126.62, 130.81, 134.79 (CH), 135.94, 147.22, 159.74, 165.67 (C_q); FAB-MS m/z 1930.9 [$(M + H)^+$].

Synthesis of **10** and **11**: A solution of terephthaloyl dichloride **9** (0.18 g, 0.7 mmol) in chlorobenzene (25 mL) and a solution of diamine **2** (0.45 g, 1.4 mmol) in chlorobenzene (25 mL) were added synchronously with a perfusor (peristaltic pump) over 12 h to chlorobenzene (1.2 L; 60 °C) containing a catalytic amount of DMAP. The solution was filtered through celite, the solvent evaporated to dryness, and the residue dissolved in dichloromethane. This solution was washed with water, dried over $MgSO_4$, filtered, and concentrated. Column chromatography on silica gel (60–100 μm) eluting with dichloromethane/methanol (20/1) afforded:

Fraction A (**10**): <1% yield; m.p. >250 °C (decomp); $R_f = 0.2$ (dichloromethane/methanol 20/1) FAB-MS: m/z 1025.6 [$(M + H)^+$]).

Fraction B (tetramer **11**): 240 mg (34%) yield; $R_f = 0.2$; m.p. >250 C (decomp); ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 1.64$ (br., 24H; aliph. H), 2.25 (br., 64H; aliph. H, CH_3), 4.06 (s, 24H; OCH_3), 7.15 (s, 16H; arom. H), 8.01 (s, 8H; arom. H), 9.17 (s, 8H; NH); ^{13}C NMR (62.9 MHz, $CDCl_3$) [DEPT135, the δ values of the corresponding protons are in superscript]: $\delta = 19.1$ ($C^{2.25}H_3$), 23.3, 26.1 (CH_2), 36.1 (CH_2), 45.2 (aliph. C_q), 62.1 ($C^{4.06}H_3$), 126.5 ($C^{7.15}H$), 126.8 ($C^{8.01}H$), 130.2, 132.1, 135.7, 147.9, 152.4 (C_q) 162.6 (C=O); FAB-MS: m/z = 2051 [$(M + H)^+$].

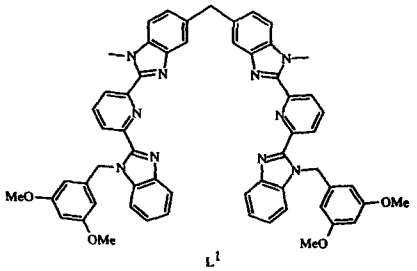
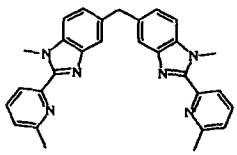
The First Self-Assembled Dinuclear Triple-Helical Lanthanide Complex: Synthesis and Structure**

By *Gérald Bernardinelli, Claude Piguet,** and *Alan F. Williams*

There is currently considerable interest in the use of self-assembly processes for the selective formation of organized supramolecular units.[1] Double-helical[2] and triple-helical[3] structures have been generated by the complexation of "oligopolydentate" ligands around two or more metal ions, which lie on the helical axis; Dietrich-Buchecker and Sauvage[4] have used a double-helical Cu_2^I complex for the synthesis of the first molecular knot. Previous work has concentrated on the use of 3d and 4d metals to control the self-assembly, but in principle any metal ion with known preference for a particular coordination geometry may direct a self-assembly reaction. To illustrate this, and in connection with our interest in the photophysics of lanthanide complexes,[5] we report the synthesis and the X-ray crystal structure of the first dinuclear, triple-helical lanthanide complex. In a previous study,[3] we showed how a bis(bidentate) ligand forms a triple-helical structure with metal ions, which prefer octahedral coordination; for the lanthanide ions in which higher coordination numbers are observed, a bis(terdentate) ligand, for example, bis[1-methyl-2-{6′-[1″-(3,5-dimethoxybenzyl)benzimidazol-2″-yl]pyrid-2′-yl}benzimidazol-5-yl]-methane (L^1), offers the possibility of forming a triple-helical complex with two 4f metal cations, in which each cation has a coordination number of nine, as observed in the pseudo-D_3 symmetry of the mononuclear complex $[Eu(terpy)_3]^{3+}$ (terpy = terpyridyl).[6] The ligand L^1 is a logical development of our previous ligand L^2,[3, 7] and carries two terdentate units separated by a spacer; Constable et al.[8] have recently reported the formation of a mononuclear monohelical complex of Eu^{III} with the hexadentate ligand sexipyridyl (sexipy). It is not clear whether the mononuclear structure is a result of the lack of a spacer between the two terpy units or due to the additional complexation of nitrate anions.



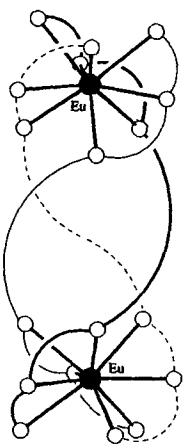
L^1



L^2

The lipophilic 3,5-dimethoxybenzyl groups bound to the terminal benzimidazole rings in L^1 were introduced to increase the solubility of the ligand and to enable the investigation of the structure in solution by ^1H NMR spectroscopy by using the intramolecular diastereotopic effect.[9] Reaction of L^1 with hydrated Eu^{III} perchlorate in acetonitrile gives a yellow solution from which yellow prisms of $[Eu_2L_3^1](ClO_4)_6$ (yield 80%) separate after slow vapor diffusion of diethyl ether. The FAB mass spectrum (FAB = *F*ast *A*tom *B*ombardment) of this complex exhibits two peaks centered at *m/z* 3690.0 and 3590.9, whose isotopic distributions correspond to the species $[Eu_2L_3^1](ClO_4)_5^+$ and $[Eu_2L_3^1](ClO_4)_4^+$, respectively.

The X-ray crystal structure determination of $[Eu_2L_3^1](ClO_4)_6 \cdot 9CH_3CN$ confirms the existence of a triple-helical cation $[Eu_2L_3^1]^{6+}$ formed by the three L^1 ligands wrapped around the helical axis defined by the two Eu^{III} atoms. This leads to an approximate D_3 symmetry (Scheme 1). The helicity of each strand is defined by a total



Scheme 1. Schematic representation of the triple-helical complex formed from L^1 and Eu^{3+} ions. The coordinating N atoms of the ligands are shown as white spheres.

length of approximately 14–15 Å (between the terminal benzimidazole groups) for slightly more than one turn, which leads to a pitch of approximately 12 Å comparable to that found by Lehn for double-helical complexes with Cu^{I}.[2] Figure 1 shows a stereoview (ORTEP[10]) of the cation per-

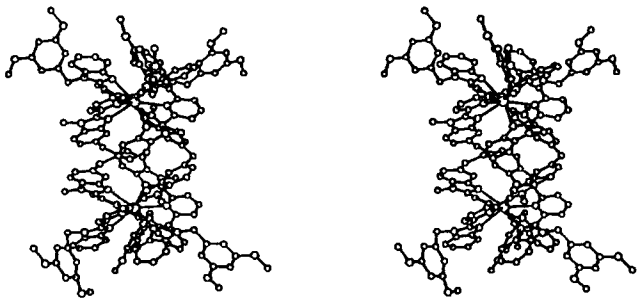

Fig. 1. Stereoview (ORTEP) of the cation $[Eu_2L^1_3]^{6+}$ perpendicular to the helical axis.

pendicular to the helical axis; Figure 2 shows a projection down the Eu–Eu axis (right), and a computer-generated representation (left)[11] of the structure in which the different strands are shown in different colors.

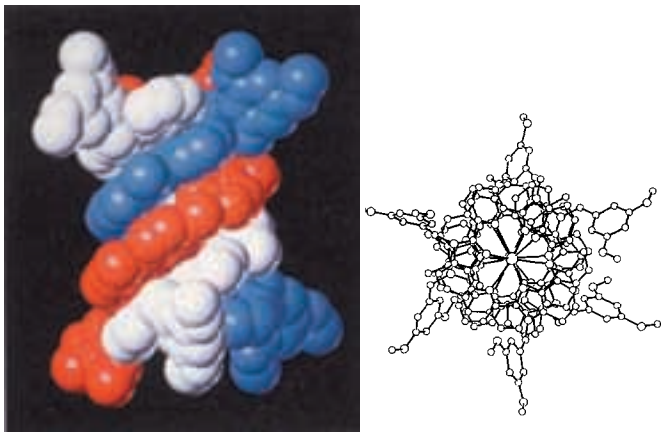

Fig. 2. Left: Computer-generated representation (MOLCAD [11]) of the non-hydrogen atoms of $[Eu_2L^1_3]^{6+}$ represented with van der Waals radii. The three strands of the helical complex are shown with different colors. Right: View along the Eu–Eu axis showing the approximate C_3 symmetry.

The coordination geometries of the two Eu atoms are very similar and may be described as slightly distorted, tricapped trigonal prisms, in which the six N atoms of the benzimidazole (bzim) units occupy the vertices of the prism and three N atoms of the pyridine (py) units occupy the capping positions, forming an intermediate plane containing the Eu^{3+} ion (maximum deviation of Eu^{3+} from the plane 0.019(6) Å). Table 1 gives the structural parameters obtained by averaging the distances of the Eu atoms to the N atoms in the vertices of the prisms and capping groups. The Eu–N distances are very similar for all the coordinated N atoms and are close to the reported values in $[Eu(sexipy)(NO_3)_2](PF_6)$[8] (2.57 Å) and $[Eu(terpy)_3](ClO_4)_3$[6] (2.60 Å). The N(bzim)–Eu–N(py) "bite" angles within one terdentate unit are typical for the meridional coordination of terpyridine derivatives to metal ions.[12]

Table 1. Structural parameters for the coordination sphere of the Eu^{3+} ion.

	Average [a]	Minimum	Maximum
Eu-N(bzim)	2.59(6)	2.54	2.67
Eu-N(py)	2.60(6)	2.58	2.64
ligand "bite angle"	63(2)	61.5	65.1
py-Eu-py	120(3)	116	124.2

[a] Bond lengths [Å] and angles [°] are average values of the distances to the vertices and the capping units. The estimated standard deviations (esd's) given in parentheses were obtained from the values used to obtain the average. The experimental esd's are smaller.

The aromatic rings of the ligands are planar within experimental error, and the helical twisting of the L^1 ligand is achieved by twisting about the interannular C–C bonds. Table 2 gives selected angles between the planes of the aromatic rings. The average angle between adjacent pyridine and benzimidazole aromatic planes within a chelate terdentate unit is 23.3°, close to the value observed for $[Co_2L^2_3]^{4+}$ (22.7°).[3] The main torsion responsible for the helical twist is found between the two terdentate units of each ligand, where the average angle between the benzimidazole rings connected by the CH_2 bridge is 67.1°, appreciably smaller than the 80.0° observed for $[Co_2L^2_3]^{4+}$. In contrast to the structure of $[Co_2L^2_3]^{4+}$, in which no significant π stacking interactions were found,[3] we observe aromatic stacking interactions between the strands as shown in Figure 2 (left). This is supported by the nearly parallel head-to-tail arrangement of the central benzimidazole aromatic planes belonging to different strands (angles 14.8–21°; distance between stacked planes 3.7–4.6 Å). However, these interactions remain rather weak and the self-assembly of the triple-helical $[Eu_2L^1_3]^{6+}$ ion is probably controlled by the coordinating possibilities of the bis(terdentate) ligand and the preference of lanthanide ions for high coordination numbers rather than by the interactions between the ligands.

Table 2. Selected angles [°] between the planes of the aromatic rings.

Ring 1 [a]	Ring 2	Angle	Ring 1	Ring 2	Angle	Ring 1	Ring 2	Angle
tbA1	pA1	31.3	tbB1	pB1	20.8	tbC1	pC1	26.7
pA1	bA1	21.1	pB1	bB1	25.9	pC1	bC1	14.4
bA1	bA2	63.2	bB1	bB2	64.8	bC1	bC2	73.3
bA2	pA2	29.5	bB2	pB2	28.4	bC2	pC2	18.0
pA2	tbA2	16.5	pB2	tbB2	22.2	pC2	tbC2	24.3
bA1	bC2	17.7	bB1	bA2	14.8	bC1	bB2	21.0

[a] The rings are denoted as pyridine p, benzimidazole b, or terminal benzimidazole tb, belonging to ligand strand A, B, or C and bound to Eu1 or Eu2. Thus tbC1 is the terminal benzimidazole ring of strand C that is bound to Eu1. The error in the angles is typically 1°.

^1H NMR measurements show that the high symmetry (D_3) of the complex $[Eu_2L^1_3]^{6+}$ is maintained in acetonitrile solution. The chiral nature of the triple-helical structure is confirmed by the intramolecular diastereotopic effect observed for the methylene protons of the 3,5-dimethoxybenzyl groups.[7, 9] Spectroscopic titrations[7] indicate that $[Eu_2L^1_3]^{6+}$ is the only species formed in acetonitrile solution ($\lg\beta = 20.7(7)$), which strongly suggests the existence of a cooperative, strict self-assembly[13] leading to the triple-helical complex. We are currently investigating the photophysical properties of these compounds, together with more detailed studies of the influence of ionic radius on the structure and the stability of the system. Preliminary luminescence

studies reflect the highly symmetrical environment of the Eu atoms and show the possibility of energy transfer between the lanthanide ions in doped compounds.

Experimental Procedure

The ligand L^1 was obtained by a modified Phillips condensation [14] of 3,3'-diamino-4,4'-bis(*N*-methylamino)diphenylmethane [7] with 2-(2-benzimidazol)-6-carboxypyridine (prepared by the oxidation of 2-(2-benzimidazol)-6-methylpyridine [15]) followed by a double alkylation with 3,5-dimethoxybenzylbromide [9]. Crystals of $[Eu_2L_3^1](ClO_4)_6 \cdot 9\,CH_3CN$ were grown by vapor diffusion of diethyl ether into a concentrated acetonitrile solution of the complex. A yellow crystal ($0.26 \times 0.26 \times 0.26$ mm^3) was sealed in a capillary tube with some of the supernatant liquid. $M_r = 4159$, triclinic, $P\bar{1}$, $a = 17.634(3)$, $b = 21.408(4)$, $c = 29.437(7)$ Å, $\alpha = 82.13(1)$, $\beta = 85.76(1)$, $\gamma = 89.79(1)°$ based on 28 reflections ($10° < 2\theta < 20°$), $V = 10978(4)$ Å^3, $Z = 2$. Intensity data were collected at room temperature on a Philips PW 1100 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $6° < 2\theta < 38°$, 17573 unique reflections measured. Structure solved by direct methods [16], other calculations made with XTAL [17]. The six uncoordinated ClO_4^- ions and the six phenyl rings of the 3,5-dimethoxybenzyl substituents were refined as rigid groups; of the nine acetonitrile molecules, three were observed with three atomic sites, five with two atomic sites, and one with only one atomic site attributed to a nitrogen atom. Blocked-matrix refinement was performed with four blocks (ligand A and Eu, ligand B, ligand C, ClO_4^- and solvent molecules; maximum of variables = 1117). The Eu and the N atoms were refined with anisotropic thermal displacement parameters (32 atoms) and all the other atoms (239) with isotropic thermal displacement parameters. Final *R* factor $R = R_w = 0.127$ for 8322 observed reflections ($|F_o| > 4\sigma|F_o|$). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

Mössbauer Spectroscopy and Electronic Structure Calculations of the Nitridoferrates(III): $Li_3[FeN_2]$ and $Ba_3[FeN_3]$**

By *Nils Jansen, Hartmut Spiering, Philipp Gütlich,* Dagmar Stahl, Rüdiger Kniep, Volker Eyert, Jürgen Kübler,* and *Peter C. Schmidt**

Dedicated to Professor Horst Elias on the occasion of his 60th birthday

Nitridoferrates show a multitude of structural elements unknown for other iron compounds, most of which are characterized by a low coordination number for the iron atom. In order to obtain a greater insight into the nature of Fe^{III}–N bonds, we have examined the nitridoferrates(III) $Li_3[FeN_2]$ and $Ba_3[FeN_3]$ with ^{57}Fe Mössbauer spectroscopy. Quantitative analyses of the isomer shifts and the quadrupole splittings in the Mössbauer spectra were performed with the help of band structure calculations.

Nitridoferrates have not been known very long. In their crystal structures, complex anions are found which are formally isosteric to systems with main group elements.[1] The crystal structure of $Li_3[FeN_2]$[2] can be described as a fluorite superstructure in which the nitrogen atoms build a slightly distorted cubic close-packing arrangement and the Fe^{III} ions occupy neighboring tetrahedral holes along [001] forming $^1_\infty[FeN^{3-}_{4/2}]$ chains of edge-sharing tetrahedra (formally isosteric to SiS_2, see Fig. 1 left). The Fe^{III}–N bond length (195.7(2) pm) is consistent with a single bond. An especially short Fe^{III}–N bond exists in the trigonal-planar $[FeN_3]^{6-}$ anion analogous to CO_3^{2-} ($Ba_3[FeN_3]$[3] see Fig. 1 right) whereby a Fe–N bond order greater than one must be considered. Correspondingly, the IR spectrum of $Ba_3[FeN_3]$ shows a high-frequency $n_3(E')$ vibration mode at 618 cm^{-1} for a structural group with D_{3h} symmetry.[4] In the crystal structure of $Ba_3[FeN_3]$ all the atoms fall on (001) planes at

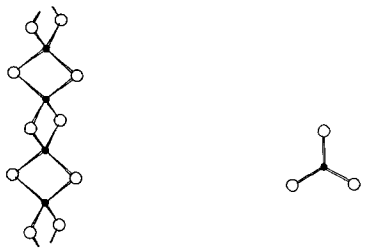

Fig. 1. Fe in $Li_3[FeN_2]$ is present in $^1_\infty[FeN^{3-}_{4/2}]$ chains consisting of edge-sharing tetrahedra, whereas in $Ba_3[FeN_3]$ Fe is found in trigonal-planar anions $[FeN_3]^{6-}$ analogous to CO_3^{2-}.

heights of $z = 1/4$ and $z = 3/4$; the barium atoms are surrounded by nitrogen atoms of $[FeN_3]^{6-}$ groups as distorted trigonal planes. By stacking the layers along [001] in the sequence ..ABAB.., the coordination spheres about the nitrogen atoms are completed to form distorted octahedra and about the barium atoms to give trigonal bipyramids.

Electronic structures were obtained through band structure calculations based on the "local spin density functional approach",[5] whereby Bloch states were determined by the ab initio ASW method (Augmented Spherical Wave).[6] The band structure calculations for $Li_3[FeN_2]$ and $Ba_3[FeN_3]$ indicate a charge transfer from Li/Ba to the complex nitridoferrate ions and the presence of strong covalent d_{Fe}–p_N bonds. Figure 2 shows a simplified d-orbital level diagram of the wave function around the central iron atom in $Ba_3[FeN_3]$. The lower E' and E'' levels as well as their

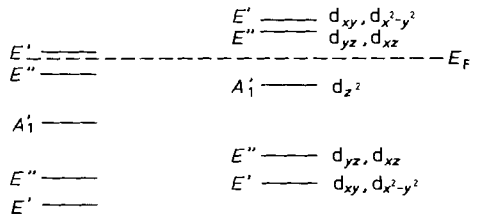

Fig 2. A simplified level diagram for both spin directions (α and β in the antiferromagnetic state) based on the partial density of the d-orbital states for Fe in $Ba_3[FeN_3]$. The positions of the levels correspond to the center of the maxima in the density of states. E_F = Fermi energy.

respective partially occupied antibonding levels are utilized for the covalent bonding to nitrogen. The A levels correspond to the nonbonding iron states.

For the Mössbauer measurements, the compounds were prepared according to reported procedures[2, 3] and checked for phase purity by X-ray diffraction and chemical analyses. At higher temperatures the Mössbauer spectra[7] of $Li_3[FeN_2]$ and $Ba_3[FeN_3]$ contain doublets due to quadrupole interactions. The isomer shift $\delta_{\alpha-Fe}$ (i.e., relative to α-iron) for $Li_3[FeN_2]$, $\delta_{\alpha-Fe}(263\,K) = 0.06(2)\,mm\,s^{-1}$, falls in the region common for low-spin iron(III) compounds. In contrast, in the case of $Ba_3[FeN_3]$ the $\delta_{\alpha-Fe}(263\,K)$ value of $-0.55(2)\,mm\,s^{-1}$ is unusually negative for low-spin Fe^{III}. This strong negative isomer shift can be explained by both d_π–p_π backbonding between the nitrido ligands and the central atom (the s-electron density on the Fe nucleus is increased because of the reduced shielding by the d-electrons, see also Table 1), and a predominate σ-donating effect of the electron-rich nitrido ligands. In essence, the 4s orbital is filled, whereby the short Fe–N bond (173.0(12) pm) together with the low coordination number (3) allow for strong overlapping, and the charge-accepting 4s orbital of the central atom is represented by a relatively large contribution to the corresponding molecular orbital. Further increase of s-electron density at the Fe nucleus could be brought about by $4s3d_{z^2}$ hybridization, which has been calculated by Yee and Hughbanks[8] with extended-Hückel and ab initio methods.

For a quantitative theoretical analysis of the isomer shifts, the charge density ρ on the Fe nucleus in $Li_3[FeN_2]$, $Ba_3[FeN_3]$, and a series of other iron compounds was computed by the ASW method.[6] The results are summarized in Figure 3; a remarkably good linear correlation appears between the measured isomer shifts and the calculated charge densities. The slope of the fitted line, $\alpha = -0.35\,a_0^3\,mm\,s^{-1}$,

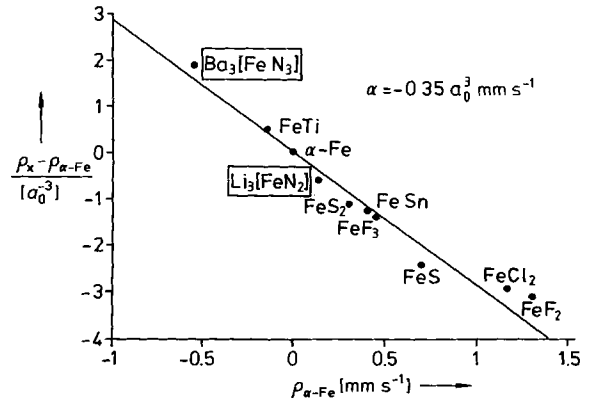

Fig 3. A plot of the charge density ($\rho_x - \rho_{\alpha-Fe}$) on the Fe nucleus was computed with the ASW technique as function of the measured isomer shift $\delta_{\alpha\,Fe}$ reported in ref. [11–15] for a series of compounds; structural data in ref. [16]. α is the slope of the fitted line, $\delta_{\alpha-Fe} = \alpha(\rho_x - \rho_{\alpha-Fe})$ [17].

is in accord with the results of other nonrelativistic Hartree–Fock calculations [9].

The individual contributions of the 3s and 4s charge densities to the isomer shift δ, ($\rho_x(3s) - \rho_{\alpha-Fe}(3s)$ and $\rho_x(4s) - \rho_{\alpha-Fe}(4s)$), as well as the data concerning the charges are given in Table 1. The charge Q of the valence electrons within

Table 1. The contributions of the 3s and 4s charge densities to the isomer shift δ and the partial charge Q on Fe in FeTi, $Li_3[FeN_2]$, and $Ba_3[FeN_3]$ (in multiples of $-e$). The last terms are the s, p, and d portions of the valence electron charge within a sphere having a radius $r = 119$ pm about the Fe nucleus.

	$Li_3[FeN_2]$	FeTi	$Ba_3[FeN_3]$
Q_{4s}	0.35	0.38	0.44
Q_{4p}	0.44	0.33	0.58

$Q = Q_{4s} + Q_{4p} + Q_{3d}$	6.98	6.90	6.85
Q_{4s}/Q [%]	5.00	5.50	6.30
$\rho_x(3s) - \rho_{\alpha-Fe}(3s)$ [a_0^{-3}]	−0.14	0.06	1.21
$\rho_x(4s) - \rho_{\alpha-Fe}(4s)$ [a_0^{-3}]	−0.16	0.41	1.02

a sphere around the Fe nucleus was calculated for $Li_3[FeN_2]$, $Ba_3[FeN_3]$, and FeTi. In order to analyze for trends in the values of charges for the three compounds, spheres of equal radii, 119 pm, were utilized; this radius corresponds to the Wigner–Seitz radius for $Li_3[FeN_2]$. The values for Q in Table 1 show that the valence electron charge within the sphere decreases from $Li_3[FeN_2]$ with $Q = -6.98e$ to $Ba_3[FeN_3]$ with $Q = -6.85e$.

In accordance with the basis functions used in the ASW method, the charge Q is distributed according to angular momentum. For $Ba_3[FeN_3]$, the 4s-like portion of Q and therefore the magnitude of the direct 4s contribution to δ is greatest (6.30%, see Table 1), and because of the lowest Q the nucleus-shielding through the 3s shell valence electrons is weakest. This explains the unusually strong negative isomer shift $\delta_{\alpha-Fe}$ observed for $Ba_3[FeN_3]$.

The quadrupole splitting ΔE_Q is $0.86(2)\,mm\,s^{-1}$ for $Li_3[FeN_2]$ and $0.65(2)\,mm\,s^{-1}$ for $Ba_3[FeN_3]$. By measuring the Mössbauer spectra in an external magnetic field, the sign of the V_{ZZ} component of the electric field gradient (EFG) tensor for $Ba_3[FeN_3]$ was determined to be negative. Thus it can be assumed that the distribution of the negative charge can be visualized as cigar-shaped. The partial charge or the "occupation number" of the levels shown in Figure 2 pro-

vides a qualitative explanation for the sign of the EFG, whereby the angular part of the EFG for the levels A_1' and E'' are negative and for E' positive.[10] We find a clear predominance for the partial charging of the A_1' and E'' levels over E'.

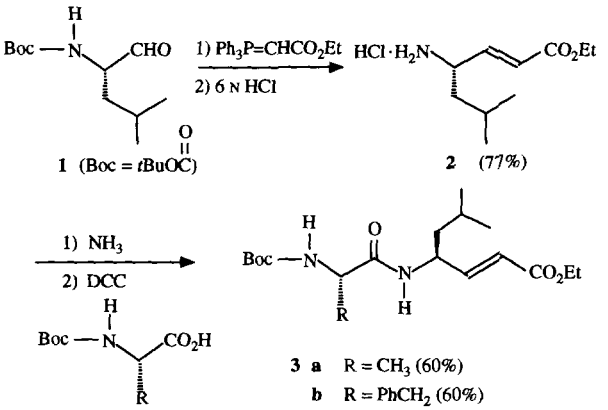
Stereoselective Nucleophilic Addition Reactions of Reactive Pseudopeptides**

By *Manfred T. Reetz,* Jürgen Kanand, Nils Griebenow,* and *Klaus Harms*

Dedicated to Professor Ulrich Schöllkopf on the occasion of his 65th birthday

Little is known concerning natural or synthetic peptides with functional groups such as aldehyde or α,β-unsaturated ester moieties at the terminal positions in addition to the usual structural characteristics.[1] Nevertheless, their potential biological and pharmaceutical activity deserves attention.[1, 2] We are interested in whether stereoselective Grignard and cuprate additions can be conducted with these reactive peptides. Although the influence of the directly neighboring stereocenter would be expected to dominate within the context of 1,2-asymmetric induction, the more distant asymmetric centers could also influence product formation (1,*n*-asymmetric induction).

To begin with, the L,L pseudopeptides **3** with C-terminal α,β-unsaturated ester groups were prepared as outlined in Scheme 1. The Boc-protected leucinal **1**[3] was converted



Scheme 1. Synthesis of pseudopeptides **3**.

without racemization into the vinylogous γ-amino acid ester **2** by Wittig olefination and subsequent deprotection with anhydrous HCl in dioxane. After the corresponding amine was obtained from **2** by treatment with ammonia, the peptide coupling was carried out with dicyclohexylcarbodiimide (DCC).

Whereas the reactions of $(CH_3)_2CuLi$ with pseudopeptides **3** were not diastereoselective,[4] the analogous addition of the bulky cuprate reagent $(tBu)_2CuLi$ in the presence of chlorotrimethylsilane[5] led to mixtures of the diastereomers **4** and **5** (80:20) with almost quantitative conversions (isolated yields **4a**/**5a**: 95% (R = CH_3) and **4b**/**5b**: 77% (R = $PhCH_2$). The products could be separated easily by chromatography.[6] As no other diastereomers were formed, the C–C bond forming reaction apparently proceeds without epimerization.

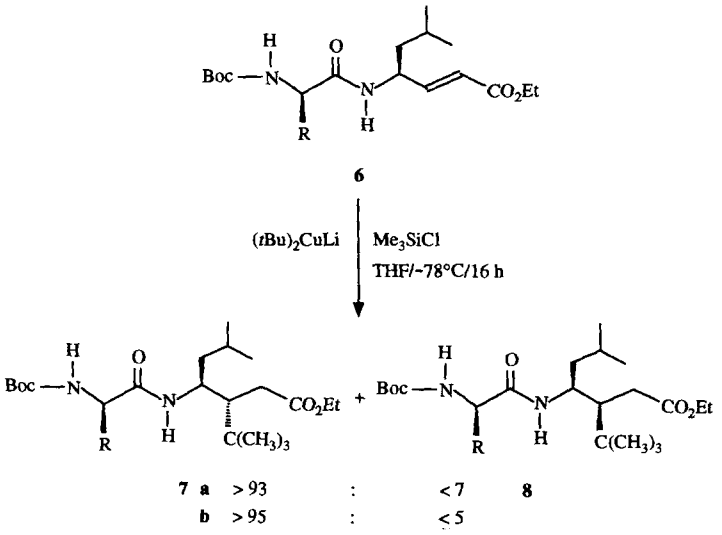
[**] This research was supported by the Deutsche Forschungsgemeinschaft (Leibniz Programm) and the Fonds der Chemischen Industrie.

In order to test whether the adjacent stereocenter in peptides **3** solely determines the direction and degree of diastereoselectivity, the D,L pseudopeptides **6** were prepared analogously to **3**. Here the addition of the cuprate $(t\mathrm{Bu})_2\mathrm{CuLi}$ proceeded with high diastereoselectivity and with almost exclusive formation of peptides **7** (isolated yields: **7a** ($R = CH_3$) 94%, **7b** ($R = PhCH_2$) 79%). The structure of the products **4**/**5** and **7**/**8** was assigned by X-ray structure analysis and NMR spectroscopy.[6] For example, ester **7a**, an oil, was hydrolyzed to give the corresponding crystalline carboxylic acid **9**; the results of the X-ray structure analysis (Fig. 1)[7] prove the relative and absolute configuration. The molecule is found to fold itself in an interesting fashion: the lipophilic and polar portions form separate "regions".



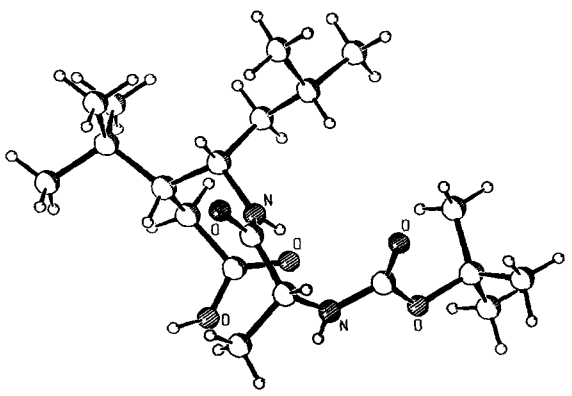


Fig. 1. Crystal structure of **9**.

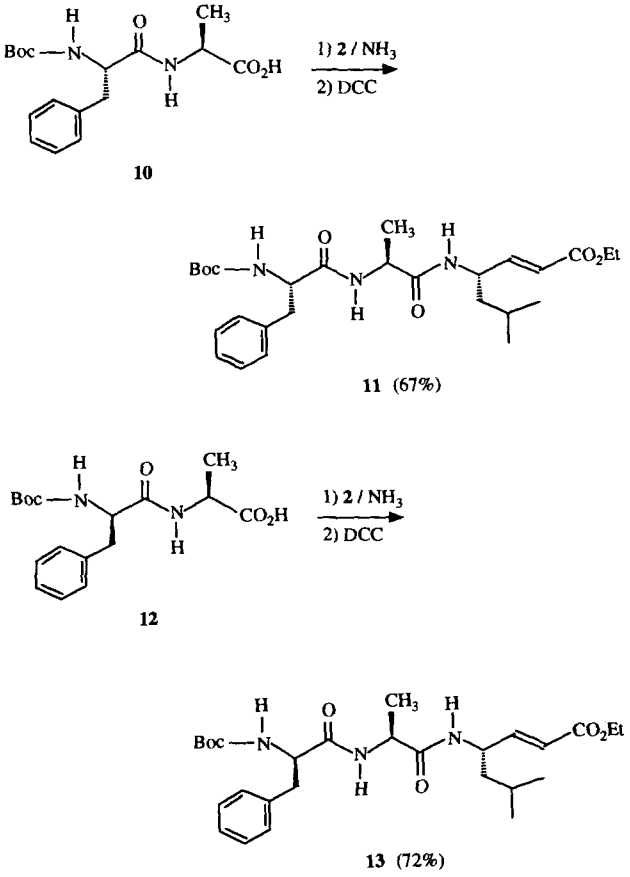
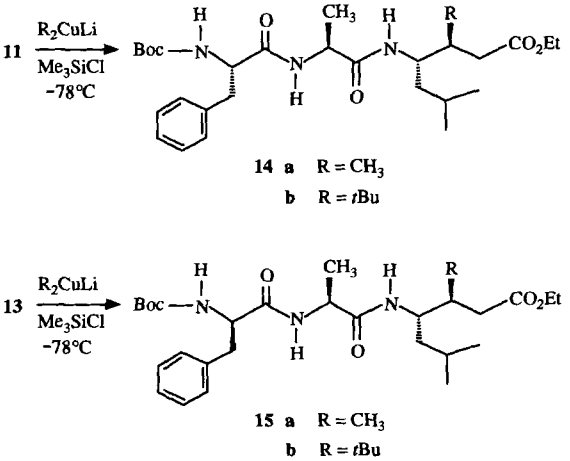
These results show that in our examples the D,L pseudopeptides **6** always react more stereoselectively than the L,L analogues **3**. Thus, the influence of the directly adjacent stereocenter dominates, although 1,5-asymmetric induction is also evident.

In view of possible 1,8-asymmetric induction, the L,L,L and D,L,L pseudopeptides were prepared (Scheme 2). Dipeptides **10** and **12**, accessible by conventional methods, underwent DCC-mediated peptide coupling to give the respective diastereomeric L,L,L (**11**) and D,L,L (**13**) pseudopeptides without epimerization.[6]

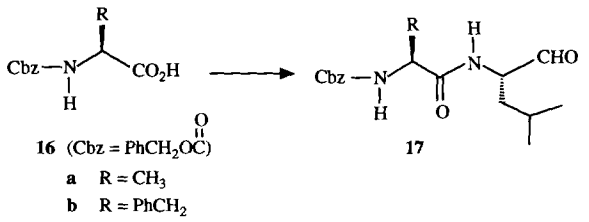


Scheme 2. Synthesis of pseudopeptides **11** and **13**.

The reactions of the L,L,L peptide **11** with $(CH_3)_2\mathrm{CuLi}$ and $(t\mathrm{Bu})_2\mathrm{CuLi}$ proceeded with diastereoselectivities of 82:18 and 88:12, respectively (95% yield of **14a** and **14b**). The same reactions conducted with the D,L,L peptide **13** had diastereoselectivities of only 67:33 and 79:21 with yields of 89% (**15a**) and 97% (**15b**). Although the final assignment of the relative configuration has not been made, it is most plausible that the direction of diastereoselectivity here is the same as in the reactions of the dipeptides (cf. **4**, **7**, **14**, and **15**). As in the case of the pseudopeptides **3**/**6**, 1,2-asymmetric induction dominates, but here again, the effect of the most distant stereocenter is apparent (1,8-asymmetric induction).

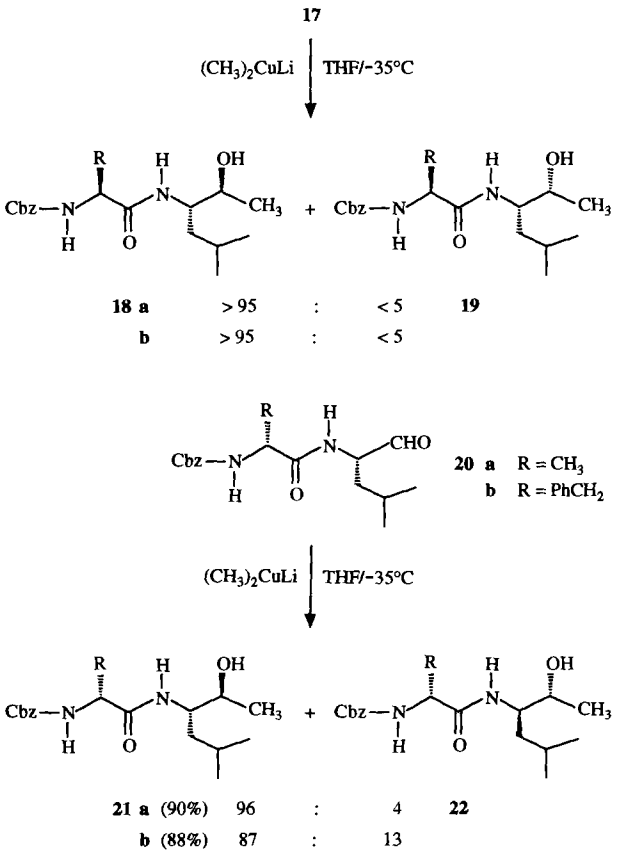


In order to investigate Grignard-type C–C bond forming reactions with peptide aldehydes,[3] we synthesized the L,L derivatives **17**; the reactions in Scheme 3 proceeded in high yield and without epimerization.[8] Following quantitative Swern oxidation and aqueous workup, the aldehydes were used in subsequent reactions without further purification.

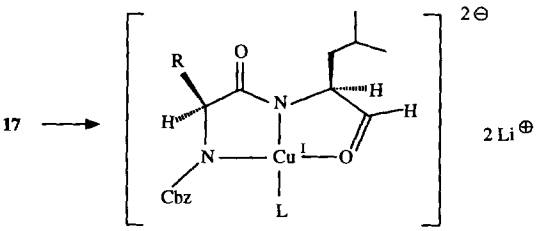


Scheme 3. Synthesis of peptide aldehydes **17**. 1) *N*-hydroxysuccinimide/DCC: 92–93%. 2) Leucinol: 86–90%. 3) DMSO/$(COCl)_2$: > 95%.

Whereas the peptide aldehydes **17** reacted with methylmagnesium iodide to give mixtures of four diastereomers due to undesired epimerization and nonstereoselective C–C bond formation, the reactions with $(CH_3)_2CuLi$ gave a single product in each case (**18a** and **18b** in yields of 92 and 85%, respectively). These Grignard-type reactions proceed under strict chelation control without epimerization.[3, 9] The diastereomeric peptide aldehydes **20**,[8] available in high yields, react similarly; besides the major products **21** only a small amount of a second diastereomer **22** was observed, the product of the chelation-controlled addition to the α-epimerized aldehydes.[10] Interestingly, control experiments showed that the L,L dipeptides **17** are configuratively much more stable than the D,L analogues **20**.[11]



Concerning the mechanisms of the 1,2- and 1,4-additions to the aldehydes and α,β-unsaturated esters, respectively, metalation at the NH-acidic functions along the corresponding peptide chains is likely.[12, 13] A more detailed discussion of the reactions of α,β-unsaturated esters is problematic at this point, but plausible mechanisms can be formulated for the reactions of the peptide aldehydes. After deprotonation or metalation of the NH-acidic positions, a chelate complex of type **23** is formed in which the Cu^I center is tetracoordinated. Attack from the less shielded side then leads to the observed products. The "double" chelation in intermediate **23** could certainly be important, since the same reactions involving the Boc-protected α-amino aldehydes (cf. **1**) are less selective.



Further studies relating to classical Michael additions and cycloadditions are underway. The biological properties[2] of the peptides and their addition products also provide the basis of future investigations.

A New Type of Mn–O Cluster with a Mn_4 Chain Unit—Relevance to the Photosynthetic Oxygen Evolving Center

By *Christian Philouze, Geneviève Blondin, Stéphane Ménage, Nathalie Auger, Jean-Jacques Girerd,* Daniel Vigner, Monique Lance*, and *Martine Nierlich*

The Oxygen Evolving Center (OEC) in photosystem II in plants is the subject of considerable research efforts.[1] Based on ESR studies Dismukes et al. and Brudvig et al. proposed that this reaction center contains a Mn_4 cluster.[2] More recently our group in collaboration with Zimmermann reinvestigated the S_2 step of the enzymatic cycle by ESR spectroscopy and confirmed the presence of a Mn_4 unit in the active site in this particular step.[3] Extensive EXAFS studies point out the presence of di-μ-oxo-dimanganese units with a Mn–Mn distance of 2.7 Å.[4] In the S_2 state, the average number of Mn atoms that are 2.7 Å away from another Mn atom was found to be 1.2 ± 0.5.[4c] Klein et al.[5] interpreted their EXAFS results by a model of the OEC in which four Mn ions are linked in a chainlike fashion. The first and the last links are di-μ-oxo bridges 2.7 Å in length, the middle one is an oxo-di-μ-carboxylato bridge 3.3 Å in length. The assignment of the 3.3 Å distance is much debated,[1c] as it could also be attributed to a Mn–Ca bond.

Since the most information on the naturally occurring cluster is obtained by ESR spectroscopy,[1–3] this research is also linked to work on the magnetic properties of metal clusters.[6] Several research groups have synthesized new tetranuclear manganese complexes[7] which are potential models of the OEC. But none of these contain two di-μ-oxo-dimanganese chains as in the model proposed by Klein et al.[5] We report here the synthesis, preliminary structural characterization, and magnetic study of a new type of Mn_4 cluster with a linear $[Mn_4O_6]^{4+}$ core which has a chain structure.

The cluster was synthesized by condensation of $[Mn(bpy)Cl_3(H_2O)]$[8] (0.2 g, 0.59 mmol) in 15 mL of H_2O/HNO_3 (pH = 2). During the addition (with stirring) the pH was maintained at a value of 2 by addition of small amounts of a sodium hydroxide solution. Then the reaction mixture was centrifuged and filtered, and the filtrate collected. Sodium perchlorate (0.146 g, 1.19 mmol) was added to the filtrate with stirring. After a few days dark-brown crystals of **1** were obtained (30% yield based on Mn). Elemental analysis (C, H, O, Cl, Mn, N) provided the stoichiometry of **1**.

$[Mn^{IV}_4O_6(bpy)_6](ClO_4)_4 \cdot 2H_2O$ **1**

A preliminary X-ray study[9] of **1** indicates that each cationic unit is made up of two di-μ-oxo-dimanganese units linked by a di-μ-oxo bridge (Fig. 1). The cation in **1** has close

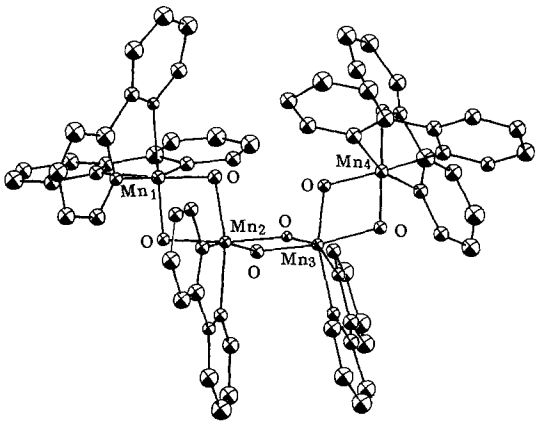

Fig. 1. Structural model for the $[Mn^{IV}_2O_6(bpy)_6]^{4+}$ ion in **1**. Data from a preliminary X-ray structure analysis.

to C_2 symmetry. The average number of Mn atoms that are 2.7 Å away from another Mn atom is 1.5, which is within the error range for the value found in the OEC.[4c] The linkage of the two $Mn_2(\mu\text{-}O)_2$ subunits is the main difference between cluster **1** and the proposed structure for the OEC based on EXAFS studies. But as pointed out above, the assignment of the peak in the EXAFS spectrum to a unit with a 3.3 Å bridge in the natural reaction center is uncertain. Thus our molecule could be a good structural model of the OEC. An EXAFS study of **1** is under way for comparison with the EXAFS spectrum of the OEC.

Compound **1** and other complexes illustrate the richness of the chemistry of $Mn^{III}Mn^{IV}$ in water. The condensation of $[Mn(bpy)Cl_3(H_2O)]$ in aqueous solution led to the dinuclear mixed-valent cluster $[Mn^{III}Mn^{IV}O_2(bpy)_4]^{3+}$ (pH = 4.5)[10] and the trinuclear cluster $[Mn^{IV}_3O_4(bpy)_4(H_2O)_2]^{4+}$ (pH = 0.4)[11]. The trinuclear cluster was also obtained by acidification of $[Mn^{III}Mn^{IV}O_2(bpy)_4]^{3+}$ in water.[12] The analogous phenanthroline complex forms the dinuclear monovalent cluster $[Mn^{IV}_2O_2(phen)_4]^{4+}$ in strongly acidic so-

lutions.[13] With other ligands the chemistry of Mn^{III}, Mn^{IV} compounds in water is equally interesting.[14] The mechanism of these reactions is not yet known, although it is likely that the first step involves formation of Mn^{III}–O–Mn^{III} complexes followed by disproportionation to give $Mn^{III}Mn^{IV}$ complexes by the proton-dependent process proposed by Wieghardt.[14b]

The magnetic coupling in a Mn_4 unit can be studied with cluster **1**. The molar magnetic susceptibility χ_M of **1** as a function of the temperature T is given in Figure 2. The

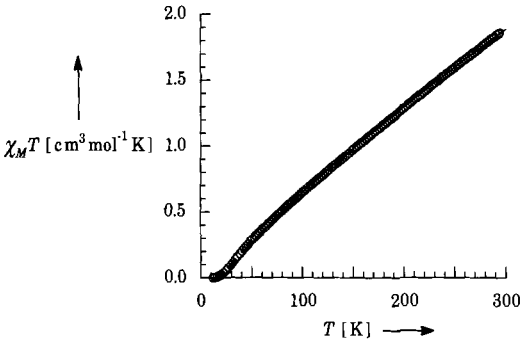

Fig. 2. Magnetic susceptibility ($\chi_M T$) of **1** as a function of temperature T (o experimental data, —— theoretical fit).

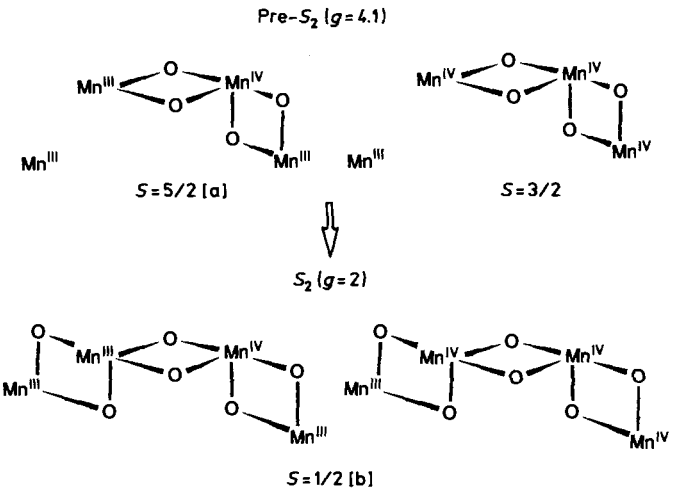
product $\chi_M T$ per mole of **1** is 1.85 cm^3mol^{-1} K at 293 K and decreases to 0 at 12 K. This behavior is characteristic of antiferromagnetic coupling between the electronic spins of the Mn^{IV} ions, which produces a ground state with $S = 0$. The structural information available for **1** allowed us to analyze the data with the Heisenberg–Hamiltonian operator as defined in Equation (a), where $S_i = 3/2$ is the value of the spin of the Mn_i^{IV} in Figure 1.

$$H_S = -J_{12}(S_1S_2 + S_3S_4) - J_{23}(S_2S_3) \quad \text{(a)}$$

Despite its simplicity, the topology of this cluster is such that there is no analytical solution for the eigenvalues since no subspin is a good quantum number. The only good quantum number is the total spin. The eigenvalues of H_S were calculated by diagonalizing the full 4^4 spin problem using the matrices constructed from six J coefficients and following the irreducible tensor theory. The magnetic susceptibility was calculated using Van Vleck's formula, and the fitting procedure with J_{12} and J_{23} as free parameters was linked to the diagonalization procedure. The best fit was obtained for antiferromagnetic couplings, $J_{12} = -176\ cm^{-1}$ and $J_{23} = -268\ cm^{-1}$; g was assigned a value of 2.00 (see Fig. 2). With these values the first excited state is calculated to be a spin triplet at $E(S=1) = 76\ cm^{-1}$.

The ground state has $S = 0$ since the spins can be organized in an antiparallel way to minimize interactions with each nearest neighbor (Scheme 1). Comparison of the structure proposed by Klein et al., a chainlike Mn_4 arrangement in the OEC,[5] with the structure of **1** points out the viability of the latter as a model for the OEC. As $(\mu\text{-O})_2Mn^{III}Mn^{III}$ and $-Mn^{III}Mn^{IV}$ units[7e, 12, 14a] are also strongly antiferromagnetic, a compound with a structure analogous to **1** would have an $S = 1/2$ ground state if the Mn_4 chains had the combination of oxidation states $Mn_3^{III}Mn^{IV}$ or $Mn^{III}Mn_3^{IV}$. The four spins could not negate each other regardless of the position of the odd spin along the chain. This would correspond to the S_2 state (Scheme 2). The synthesis of such a linear cluster would be very valuable.



Scheme 2. Hypothetical model for the pre-S_2 and S_2 states of the OEC based on the structure of **1** and its magnetic properties. [a] If Mn^{IV} is terminal a value of $S = 3/2$ is obtained. [b] The position of the odd spin is undetermined.

One attractive feature of the proposal that the reaction center of the OEC has a cubane structure[1a] is that a small change in the coupling parameters could induce a change in the spin state of the ground state. This could explain why the spin of the ground state is $S = 3/2$ or 5/2 in the pre-S_2 state of the enzyme.[15] In a model with a Mn_4 chain the $S = 1/2$ ground state is less sensitive to a change in J. These spin values for the pre-S_2 state can be reconciled with the chain topology if the active site is composed of a linear trinuclear system plus a mononuclear unit, for instance Mn^{III}–Mn^{IV}–Mn^{III} ($S = 5/2$ or 3/2, depending on the position of the odd spin) + Mn^{III} or Mn^{IV}–Mn^{IV}–Mn^{IV} ($S = 3/2$) + Mn^{III} (Scheme 2). This arrangement corresponds to the proposals in refs. [4b, 16]. Such bent linear Mn_3 units were considered by Klein et al. and agree with their data.[17] We are currently trying to synthesize such compounds to compare their ESR spectroscopic properties with those of the enzyme in the pre-S_2 state.[18]

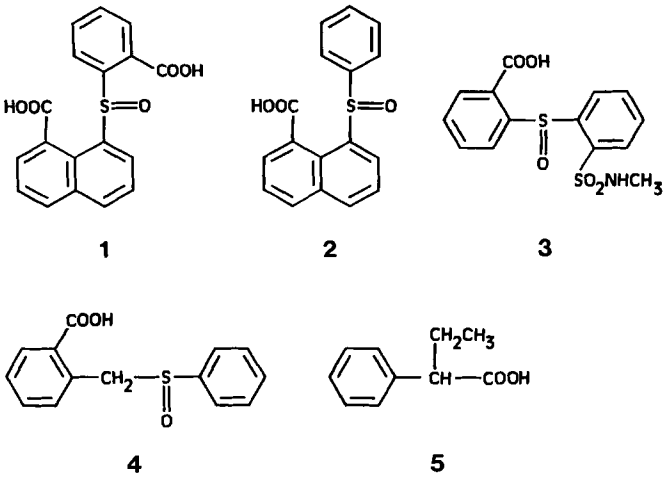
Salting Out Selective Extraction—A Novel Method for the Optical Resolution of Chiral Sulfinylcarboxylic Acids and Its Application for the Convenient Determination of Optical Purity**

By *József Rábai**

Although the production of optically pure chiral compounds has attracted much interest, new and economical methods are slow to emerge.[1] In the synthesis of chiral compounds the enantiomers are often resolved by the preparation of diastereomeric salts.[2] The separation of the p- and n-salts formed is generally carried out by fractional crystallization.[3] We now report a novel optimized method of resolution, Salting Out Selective Extraction (SOSE), for the separation of noncrystallizable mixtures of diastereomeric salts. This method is demonstrated here with the racemic carboxylic acids **1**–**5**.[4]



Our approach combines the advantages of the methods of Fogassy,[5] and of Pope and Peachey[6] as well as those of the selective extraction technique devised by Newton and Shapiro.[7] The treatment of two equivalents of racemic acid (±)-HA with one equivalent of the enantiopure chiral base (−)-B and one equivalent of NaOH leads to the formation of two diastereomeric salts, (−,−)-BHA (p-salt) and (−,+)-BHA (n-salt), besides the sodium salts of the enantiomeric anions of the carboxylic acid, (−)-NaA and (+)-NaA. The salts are partitioned between water and a water-immiscible solvent. The partition equilibrium of the p- and n-salts is determined by the separation constant β.[8] Thus the thermodynamic chiral recognition[2d] $\Delta\Delta G = -RT\ln\beta$ describes the molar free energy differences of the two diastereomeric salts in their formation and transfer equilibria. Only when $\beta \neq 1$ is separation of the diastereomeric salts expected. For example, in the optical resolution of racemic sulfinylcarboxylic acids **1**–**4** and 2-phenylbutyric acid (**5**) with (−)-quinine using a chloroform/water system, the respective optical yields[10] were 46, 31, 8, 11, and 1% after one extraction. Of course, successive extractions lead to a very high enantiomeric excess; when **1** was extracted three times 95% *ee* was achieved.

The compositions of the organic phase y and the aqueous phase z at equilibrium are described (in terms of enantiomeric excess) by the special resolution equations (a) and (b),

$$y = [a - \{(x + a)^2 - bx\}^{1/2}]/x \quad \text{(a)}$$

$$z = [l - d + a - \{(x + a)^2 - bx\}^{1/2}]/(1 - x) \quad \text{(b)}$$

$$a = (\beta d + l)/(\beta - 1);\ b = 4\beta d/(\beta - 1)$$

where β is the separation constant for the (+)-enantiomer, d and l denote the mole fractions of the (+)- and (−)-enantiomers before the extraction, and x represents the corresponding mole fractions of the chiral base. Equations (a) and (b) allow the calculation of the equilibrium composition y and z for any d, l, and x values at a given value of β. For example, if the concentration ratio of the racemate in solution is infinitely high (or only a catalytic amount of the resolving base is used, i.e. $d/x \rightarrow \infty$) then the enantiomeric

[**] The author thanks Dr. I. Kövesdi for NMR measurements, and Prof. E. Fogassy (Technical University, Budapest) and Dr. I. T. Horváth (Exxon Corporate Research, Annandale) for valuable discussions. This research was supported by the Hungarian Academy of Sciences (OTKA 1234).

excess of the organic phase is described by $y = (\beta - 1)/(\beta + 1)$, the optical yield by $OY = yx/d$, and the optimal amount of the chiral base by $x_{optimal} = (\beta d - l)/(\beta - 1)$, provided that the relationship) $1/(\beta + 1) < d < \beta/(\beta + 1)$ holds. For a racemate with $d = l = 0.5$, $x_{optimal}$ has a value of 0.5.[2a, 6]

The maximum salt separation[11] that can be obtained by SOSE in one step is dependent on the selectivity for the preferred salt (or enantiomer) β^p which is related to the formation constants (k^p and k^n), the molar volumes and the polarities (δ^p and δ^n) of the diastereomeric salts, the polarity of the solvent pair (δ^w and δ^*), and the temperature by the general resolution equation (c).[12]

$$\ln \beta^p = \ln(k^p/k^n) + 2V(\delta^n - \delta^p)(\delta^w - \delta^*)/RT \qquad (c)$$

Since the molar volumes of the two salts are very similar, they are considered equal (V). While the Hildebrand polarity values (δ) are well documented for solvents,[13] the polarity differences between the two diastereomeric salts can be set high by the proper choice of the resolving agent. (Table 1, empirical). The solvent effect on the resolution of **1** with quinine appears to follow the general resolution equation (c) (method A, Fig. 1).

Table 1. Effectiveness of a number of chiral bases in resolving sulfinylcarboxylic acids **1** and **2** (method A). The sign of the separation constant β refers to the preferred enantiomer in the organic phase.

Base	β_1	OY [%]	β_2	OY [%]
(−)-brucine	1.20	5	1.0	0
(−)-quinine	7.38	46	3.57	31
(+)-quinidine	−4.55	36	−2.44	22
(+)-cinchonine	−2.04	18	−1.52	10
(−)-cinchonidine	2.63	24	1.73	14
(−)-3-pinanmethylamine	1.0	0	1.0	0

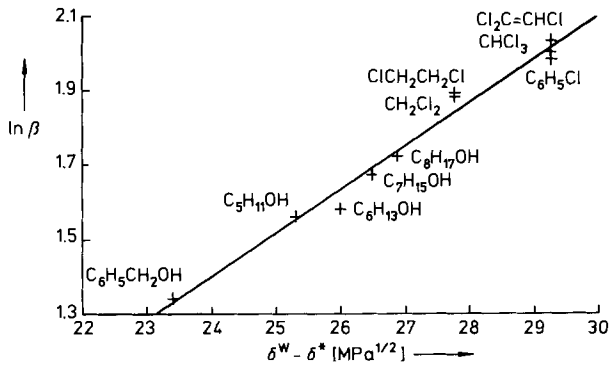

Fig. 1. Solvent dependence of the separation constant β for [(quinine)$_2$ · (+)-**1**]. The solid line was calculated with the equation $\ln\beta = -1.39 + 0.116(\delta^w - \delta^*)$, which was determined by least-squares fitting ($r = 0.99$) of the experimental data.

A new method to determine optical purity was also devised based on SOSE. Considering that β is constant and a function of [α] and [α^*],[8] one can derive Equation (d) for the calculation of the value of the absolute rotation. Here [α_1], [α_1^*], and [α_2], [α_2^*] are the specific rotations of the samples recovered from the aqueous (α) and organic (α^*) phases in two independent experiments designated by 1 and 2. For sulfinylcarboxylic acid **1** (method B) the following values were obtained: $\beta = 5.85$; $[\alpha_1]_D = -213$, $[\alpha_1^*]_D = +198$, $[\alpha_2]_D = -418$, $[\alpha_2^*]_D = -168$ ($c = 0.5$, DMF, 25 °C). Thus the calculated value of $[\alpha_{max}]_D$ is 495, and after total resolution $[\alpha]_D = 496 \pm 6$.[14] The corresponding dimethyl esters were prepared from partially resolved and racemic **1**. According to the ^{1}H NMR spectra of these mixtures recorded with Eu(tfc)$_3$ (tfc = 3-(trifluoromethylhydroxymethylene)-D-comphorato) in $CDCl_3$/TMS $[\alpha]_D$ has a value of 495 (100% *ee*). A sample of the carboxylic acid **1** with $[\alpha]_D = 330 \pm 4$ was treated with CH_2N_2. The enantiomeric excess of the resulting dimethyl ester was found to be 67% by ^{1}H NMR measurements.

$$\{[\alpha]_{max}\}^2 = \{[\alpha_1^*][\alpha_2^*]([\alpha_1] - [\alpha_2]) - [\alpha_1][\alpha_2]([\alpha_1^*] - [\alpha_2^*])\}/\{([\alpha_1] - [\alpha_2]) - ([\alpha_1^*] - [\alpha_2^*])\} \qquad (d)$$

Experimental Procedure

Solutions of the carboxylic acids **1**–**5** (5 equiv) in 0.2 N NaOH (25 mL) [method A] or in 0.50 N $KHCO_3$ (25 mL) [method B] were treated with crystalline quinine sulfate dihydrate (0.985 g, 1.25 mmol, 2.5 equiv) and then shaken with $CHCl_3$ (50 mL) at 20 °C until all the solid material dissolved and then 1 h longer. The two phases were separated, and the aqueous phase was acidified with 0.2 N H_2SO_4 (pH = 1) at 0 to 5 °C. The precipitate formed was filtered, washed with water, and dried over P_2O_5. The organic phase was extracted with 0.2 N NaOH (3 × 10 mL) then acidified, and the precipitate formed was isolated as described above. For the isolation of **5** the acidified aqueous phases were extracted with $CHCl_3$. Starting from (±)-**1** (0.895 g, 2.5 mmol, 5 equiv, method B) the aqueous phase gave 0.392 g (1.09 mmol) acid with $[\alpha_1]_D = -208$, while the organic phase gave 0.364 g (1.02 mmol) acid with $[\alpha_1^*]_D = +198$. Starting from **1** (5 equiv) with $[\alpha]_D = -342$ and quinine sulfate dihydrate (0.492 g, 0.625 mmol) as described above, the aqueous phase yielded 0.606 g acid with $[\alpha_2]_D = -418$ and the organic phase 0.228 g acid with $[\alpha_2^*]_D = -168$ ($c = 0.5$, DMF, 25 °C).

[8] When SOSE is established [4a], the isolations occur with no optical fractionation, and the Horeau effect [9] is excluded (optical purity = *ee*); β can be calculated as: $\beta = \{(c_d^{org}/c_d^w)\ (c_l^w/c_l^{org})\}$ $k_d/k_l = ([\alpha_{max}^+] + [\alpha^*])/([\alpha_{max}^-] + [\alpha])([\alpha_{max}^+] - [\alpha^*])([\alpha_{max}^-] - [\alpha])$, where k_d and k_l are the formation constants for the appropriate diastereomeric salts in the aqueous phase. $[\alpha]_{max}$ is the absolute rotation; [α] and [α^*] are the specific rotations of the recovered samples from the aqueous and organic phases, respectively. For a reaction of (−)-B + (+)-HA ⇌ (−,+)-BHA the formation constant is $k_d = [(-,+)\text{-BHA}]/[(-)\text{-B}]\,[(+)\text{-HA}]$.

[11] When starting with racemates, $OY_{max} = (\beta^{1/2} - 1)/(\beta^{1/2} + 1)$, while for a sample of composition (d, l) $OY_{max} = \{(\beta d + l) - 2(\beta d l)^{1/2}\}/d(\beta - 1)$. The optical yield can be related to the thermodynamic chiral recognition. $\Delta\Delta G = -RT \ln \beta$, as $\beta = [(1 + OY)/(1 - OY)]^2$ when $d = l = x = 0.5$ $(0 \leq OY \leq 1)$.

[12] This expression was obtained from $\beta = (K_D^p/K_D^n)$ (k^p/k^n) by applying the distribution constant (K_D)-Hildebrand solubility (= polarity) parameter (δ) relationship [12a,b] to both diastereomeric salts. a) H. [14] The total resolution of carboxylic acid **1** was effected by selective solubilization with dioxane. The enantiomeric excess of the sample is soluble in this solvent, while the racemic part forms a stable and insoluble solvate [(±)-**1** · dioxane] [4b].

Gas-Phase Reactions of M^+ and $[CpM]^+$ (M = Fe, Co, Ni) with 1,3,5-Trisilacyclohexane: First Evidence for the Formation of 1,3,5-Trisilabenzene**

By *Asgeir Bjarnason** and *Ingvar Arnason*

The chemistry of carbosilanes has recently been reviewed,[1] and a number of silicon-substituted cyclohexane derivatives have been reported including $C_5H_{12}Si$ **1**,[2] $C_3H_{12}Si_2$ **2a**,[3] and Si_6H_{12} **3**.[4] Metal-catalyzed triple dehydrogenation of the all-carbon analogue to form cyclohexatriene (benzene) is well known, and its mono- and disila analogues, C_5H_6Si **4** and $C_4H_6Si_2$ **5**, have been isolated and characterized at low temperature in an argon matrix.[5] To our knowledge, however, neither $C_3H_6Si_3$ **6** nor Si_6H_6 have yet been observed. We report here on $C_3H_6Si_3$, $C_3H_8Si_3$, and $C_3H_{10}Si_3$ as ligands produced in the reactions of Fe^+, Co^+, Ni^+, $[CpFe]^+$, $[CpCo]^+$, and $[CpNi]^+$ with **2a**. The formulas

for the ligands were unambiguously determined, but the structures, especially that of $C_3H_6Si_3$, can only be speculated on; nevertheless, these appear to be the first observations of the trisilabenzene **6**.

Reactions of metal ions with organic molecules in the gas phase have been extensively studied in recent years by several research groups.[6] Dehydrogenation of cyclohexane by Fe^+,[7–9] Co^+,[8–10] Ni^+,[8, 9] $[CpCo]^+$,[11] and $[CpNi]^+$[12] have been reported, and in all cases, save Ni^+, elimination of up to three hydrogen molecules was observed to form the benzene ligand. Reactions of metal ions with silicon compounds in the gas phase have not been studied extensively. Of particular interest for us was the study of Beauchamp et al. on methylsilanes,[13] in which elimination of molecular hydrogen from a single silicon atom was observed and a product with a metal–silicon double bond proposed. The formation of the coordinated benzene from cyclohexane in the reactions with metal ions and ionic metal complex fragments prompted us to investigate reactions of such ions with **2a** in the gas phase, since efforts to produce **6** have been unsuccessful so far.

The product distribution in the dehydrogenation reactions of M^+ and $[CpM]^+$ with **2a** is shown in Table 1. Interesting-

Table 1. Product distribution [%] in dehydrogenation reactions of 1,3,5-trisilacyclohexane with M^+ and $[CpM]^+$.

Reactant ion	Elimination of		
	H_2	$2H_2$	$3H_2$
Fe^+	86	13	1
Co^+	16	81	3
Ni^+	66	33	1
$[CpFe]^+$	25	63	12
$[CpCo]^+$	7	71	22
$[CpNi]^+$	10	37	53

ly, $[CpM]^+$ ions are more reactive than the bare metal ions and cleave more than one H_2 molecule from **2a**. $[CpNi]^+$ is the most efficient, which is somewhat surprising: if the structure and bonding in $[CpMC_3H_6Si_3]^+$ were analogous to that in $[CpMC_6H_6]^+$, then in the case of M = Ni it would be a 20-electron, in the case of M = Co a 19-electron, and in the case of M = Fe an 18-electron species. From this point of view one would have expected the Fe complex to be formed more favorably than the Ni complex.

To test if H_2 is cleaved only from the carbosilane and whether the Cp ligand participates in that process, isotopically labeled $[[D_5]CpFe]^+$ was allowed to react with **2a**. Although minor products (< 5%) from loss of deuterium were observed, the main elimination reactions left the Cp ligand intact.

Another question that arises in light of the results of Beauchamp et al.[13] is whether hydrogen is eliminated only from Si, and if the metal than possibly forms a double bond to Si. The dissociation energies of the Si–H and C–H bonds are 314 and 414 kJ mol^{-1}, respectively.[1] As less energy is required to break the Si–H bond and in addition, backbonding may exist in the bond between the metal ion and Si, it was essential to establish which hydrogen atoms are eliminated in the reactions.

For this purpose, a sample of **2b** was prepared and allowed to react with M^+ and $[CpM]^+$. The results indicate that Ni^+ eliminates only D_2 (1 and 2 equiv). Fe^+ eliminates H_2, HD, and D_2 in the ratio 0.2:0.6:1.0, but only a minor amount of double dehydrogenation is observed (see

Table 1); in the case of Co^+, the cleavage of one equivalent of molecular hydrogen from **2a** is a minor reaction, but in the reaction with **2b** two equivalents of molecular hydrogen are formed as H_2, HD, or $H_2 + D_2$, $HD + D_2$, and D_2 in the ratio 0.05:0.1:0.8:1.0. These results suggest that Ni^+ eliminates hydrogen only from Si and, thus, may form bonds only to silicon atoms in the ring. Fe^+ and Co^+ show less preference for elimination from the silicon atoms, and elimination of HD points to the formation of a double bond between C and Si. Triple dehydrogenation in the reactions of $[CpM]^+$ with **2b** was shown to involve mostly elimination of 3 HD and to a lesser extent $2\,HD + D_2$. Only traces of the product of the elimination of 3 equivalents of D_2 was observed, which supports the hypothesis that the main product in the triple dehydrogenation reaction requires the formation of three carbon–silicon double bonds and that the 1,3,5-trisilabenzene **6** ligand is produced.

Collision-induced dissociation (CID) experiments can give valuable information about the structure of ions trapped in the cell of an FT mass spectrometer; Jacobson and Freiser successfully employed this technique to study products from the reactions of $[CpCo]^+$ with cyclohexane.[11] They found, for example, that $[Co(Cp)(benzene)]^+$ lost benzene upon CID, consistent with a stronger bond between Co–Cp than between Co–benzene. CID studies on $[CpNiC_3H_6Si_3]^+$ (accelerated to 90 eV) were performed with Ar as the collision gas. Aside from losses of one, two, and three molecules of hydrogen, three other fragment ions were observed at m/z 123 (45%), 58 (35%), and 93 (20%), corresponding to $[CpNi]^+$, Ni^+, and $C_5H_5Si^+$, respectively. The last ion is probably formed by rearrangements, since under multiple-collision conditions (higher pressure of Ar) it was the dominant fragment ion, but at conditions approaching the single-collision regime this ion became less intense with respect to the signal corresponding to $[CpNi]^+$, which became the dominant fragment ion. These observations are in accord with the proposed structure of $[CpNiC_3H_6Si_3]^+$.

The results from the CID experiments and the deuterium labeling studies lead us to the conclusion that the trisilabenzene **6** was formed as a ligand in these experiments. Further studies of reactions of metal ions and ionic metal complex fragments with other silicon-containing compounds are in progress in light of these promising results.

Experimental Procedure

The experimental method has been described in detail elsewhere [14], but it is summarized briefly here: The experiments were conducted with an EXTREL FTMS-2000 Fourier-transform mass spectrometer with dual-cell configuration [15]. Fe^+ and $[CpFe]^+$ were generated from $[CpFe(CO)_2I]$, which was introduced into the mass spectrometer in a sample vial on the direct insertion probe. The ions were produced by electron impact in the source side of the dual cell and transfered to the analyzer side. The ion of interest was isolated with double-resonance techniques [16] and allowed to react with **2a** or **2b**, which was introduced to the analyzer side through two pulsed valves from the batch inlet system. Co^+ and $[CpCo]^+$ were produced in the same manner from $[Cp_2Co]$, and Ni^+ and $[CpNi]^+$ from $[CpNiCO]_2$. It should be noted, that only $[CpNi]^+$ containing the ^{58}Ni isotope was isolated and allowed to react with the carbosilane. The course of the reaction could be monitored by collecting mass spectra after a variable delay time and/or by varying the pressure of the sample in the expansion volume of the batch inlet system. For CID studies a second set of pulsed valves was used to introduce the Ar collision gas on the analyzer side after isolation of the ion of interest. This ion was then excited to kinetic energies sufficient for its dissociation upon collision with the Ar atoms.

2a was prepared from **2c** according to a published procedure [3]. **2b** was prepared in an analogous manner using $LiAlD_4$ instead of $LiAlH_4$ and characterized by NMR spectroscopy.

A 1:1 Adduct of 2-Aminobenzothiazole and a Urea Derivative, and Its Spatial Arrangement**

By *David R. Armstrong, Matthew G. Davidson, Avelino Martín, Paul R. Raithby, Ronald Snaith,* and Dietmar Stalke*

We reported recently the fortuitous isolation and structural characterization of the unique 1:1 adduct of 2-aminobenzothiazole $OxNH_2$ (**1**) and hexamethylphosphoramide (HMPA **2**), which is stable even in boiling water.[11] In view of the similarity between **1** and certain of the natural bases found in DNA (A, G, and C have *exo*-NH_2 groups as well as N atoms and/or NH units in their ring systems; T has ring NH units), this adduct (**1** · **2**) was suggested as a model to help explain the carcinogenicity of **2**. The carcinogenicity

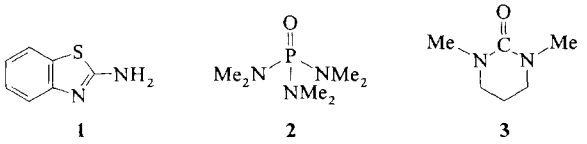
of **2** has prompted recommendations that dimethylpropyleneurea (DMPU, **3**), a proven non-carcinogen, should be



1 **2** **3**

used as an alternative to or replacement for **2**, both as a dipolar solvent and as a Lewis base in organometallic complexes.[2] Reasoning that the respective carcinogenic and non-carcinogenic properties of **2** and **3** have an essentially structural basis, we have now prepared and characterized the 1:1 adduct of **1** and **3**. There are indeed (at least in the solid state) striking structural differences between **1** · **3** and **1** · **2** in terms of the arrangement within the dimeric adducts and also the arrangement in space. Such findings are relevant also to the design of hydrogen-bonded supramolecular systems within the field of molecular recognition.[3, 4]

The adduct **1** · **3** can be obtained as a crystalline material simply by stirring a 1:1 mixture of the two components in toluene and then cooling the resulting solution (see Experimental Procedure). The crystal structure of **1** · **3**,[5] the first reported for a complex of **3** and another organic molecule, differs significantly from that of **1** · **2**, although at first glance the structures appear to be similar. The adduct **1** · **2** is dimeric; two molecules of **1** form a base pair through HN–H ··· N(ring) hydrogen bonds (N ··· N distances 3.014(5) Å); the other hydrogen atom of each NH_2 group of **1** forms a hydrogen bond with the oxygen atom of **2** (O ··· N 2.783(5) Å).[1] Adduct **1** · **3** is also dimeric (Fig. 1) and has analogous HN–H ··· N(ring) hydrogen bonds linking the $(\mathbf{1})_2$ base pair (N ··· N 2.988(7) Å) and terminal HN–H ··· O hydrogen bonds (O ··· N 2.748(7) Å). One difference between the two

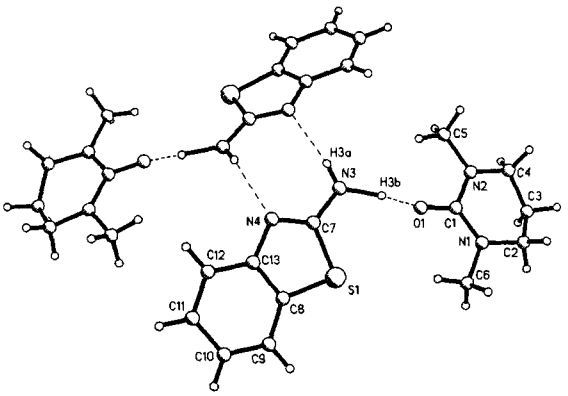


Fig. 1. Molecular structure of $(\mathbf{1} \cdot \mathbf{3})_2$.

structures is that in $(\mathbf{1} \cdot \mathbf{2})_2$ the base pair is essentially coplanar, whilst in $(\mathbf{1} \cdot \mathbf{3})_2$ the base pair is almost hemispherical. However, the N ··· N and O ··· N distances imply that not only the base-pair linkages in the two adducts but also the base–acceptor interactions (acceptor = **2** and **3**) are of similar strength. Ab initio MO calculations on a model system of the **1** · **2** adduct (e.g., HC=CHSC(=N)NH_2 for **1**, O=PH_3 for **2**) implied that the base-pair linkage is relatively weak (ca. 5.4 kcal mol^{-1}) compared to the interaction between the NH_2 group of **1** and the O atom of **2** (ca. 10.2 kcal mol^{-1}, the formation energy for a monomeric adduct).[1] Preliminary MO calculations on HC=CHSC(=N)NH_2, on **3**, and on their monomeric adduct indicate a slightly lower base–acceptor interaction energy of approximately 8.9 kcal mol^{-1}.[6] This may imply that the base-pair linkage in **1** · **3** is stronger.

The interesting structural differences between the two adducts are found in the spatial arrangement of the dimers. The dimers of **1** · **2** are aggregated further by (**2**)O ··· HC(aromatic) interactions,[1] whereas dimers of **1** · **3** are discrete and not linked together in any way. This does not seem to be a consequence of any substantial electronic differences between **2** and **3**. Ab initio calculations[6] indicate that the polarities of the C=O and P=O bonds, and the partial charges on the oxygen centers in these compounds, are similar: in $(H_2N)_3P{=}O$, a model for **2**, the partial charge on the phosphorus atom is +1.32 and that on the oxygen atom −0.60; in **3** the partial charge on the carbonyl carbon atom is +1.12 and that on the oxygen atom −0.67. It seems, then, that the aggregation of dimers of **1** · **2** and the discrete nature of dimers of **1** · **3** has a steric cause. The oxygen atom in **3** is clearly far less open and thus less available than the oxygen atom in **2** for interdimer hydrogen bonding for two reasons. Firstly, the C=O bond is shorter (1.220(7) Å in the crystal structure of $(\mathbf{1} \cdot \mathbf{3})_2$; 1.241 Å in the optimized structure of **3**) than the P=O bond (1.471(3) Å in the crystal structure of $(\mathbf{1} \cdot \mathbf{2})_2$;[1] 1.470 Å in the optimized structure of $(H_2N)_3P{=}O$). Secondly, the oxygen atom in **3** is blocked by the two NMe groups, which are in fixed positions by virtue of being part of a ring system; in contrast, the NMe_2 groups of **2** are pinned back from the P=O bond and quite flexible in the positions they adopt.

The spatial arrangements of adducts **1** · **2** and **1** · **3** are shown in Figure 2. Figure 2a shows the unit cell of the **1** · **2** adduct (view along the *c* axis); the higher aggregation of the adduct dimers is apparent. Figure 2b reveals the spatial arrangement of the **1** · **3** adduct; here the dimers are discrete.

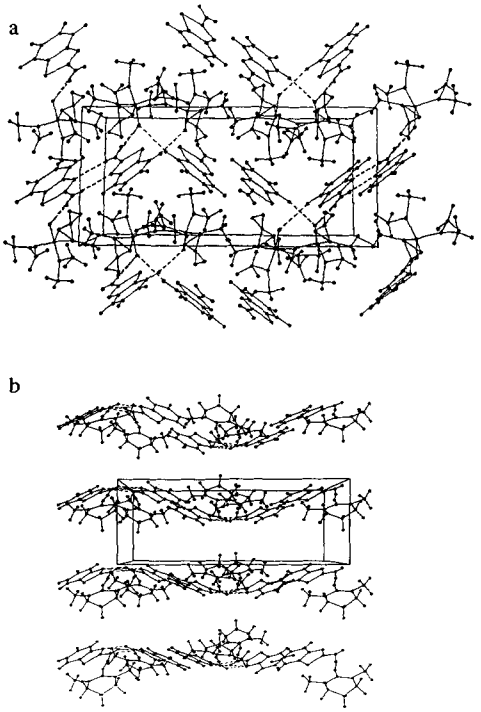

Fig. 2. a) View along the *c* axis of the unit cell of $(\mathbf{1} \cdot \mathbf{2})_2$ showing the crystal packing and the interactions between the dimers. b) View along the *c* axis of the unit cell of $(\mathbf{1} \cdot \mathbf{3})_2$.

This is more evident if one looks down the *b* axis of the unit cell of **1** · **3** (in effect, the space between pairs of dimers); then the beautiful packing shown in Figure 3 emerges; the central

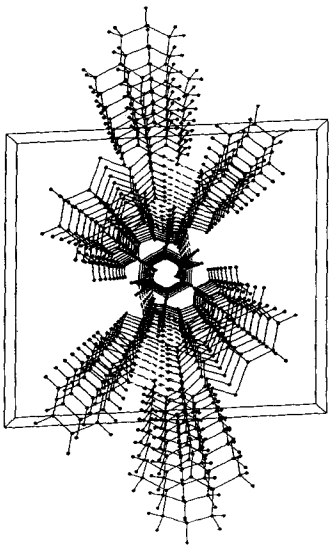

Fig. 3. View down the *b* axis of $(\mathbf{1}\cdot\mathbf{3})_2$ illustrating the highly symmetrical, tunnel-like stacking.

"tunnel" is formed by oxygen atoms of **3**. Interestingly, a hot toluene solution of the adduct $(\mathbf{1}\cdot\mathbf{3})_2$ dissolves solid LiBr, further heating of the resulting solution then causes precipitation of a white solid. The adduct also absorbs appreciable quantities of Br_2 gas to afford a mustard-colored powder. The identities of both products are being investigated.

We are also investigating supramolecular systems with similar components to those described here. To explore further the reasons for the carcinogenicity of **2** and the relative innocuousness of **3**, we are also examining their adducts with individual DNA bases and with natural base pairs.

Experimental Procedure

(**1** · **3**): 2-aminobenzothiazole (**1**) (3.00 g, 20 mmol) was dissolved at room temperature in a solution of **3** (2.56 g, 20 mmol) in toluene (20 mL). This solution was cooled at 0 °C for 1 d to afford white crystals of the adduct (first batch yield 5.05 g, 91%; m.p. 101–102 °C; correct elemental analysis; ^{1}H NMR ($CDCl_3$, 250 MHz, 25 °C): δ = 7.53–7.44 (m, 2H; **1**), 7.23 (t, 1H; **1**), 7.04 (t, 1H; **1**), 6.33 (br.s, NH_2; **1**), 3.18 (t, 4H; **3**), 2.88 (s, $2CH_3$; **3**), 1.95–1.86 (quin, 2H; **3**). Crystals suitable for X-ray analysis were grown slowly from a more dilute solution (5 mmol of each component in 10 mL toluene).

Corannulene Tetraanion: A Novel Species with Concentric Anionic Rings**

By *Ari Ayalon, Mordecai Rabinovitz,* Pei-Chao Cheng,* and *Lawrence T. Scott**

Dedicated to Professor Emanuel Vogel and Professor Klaus Hafner on the occasion of their 65th birthdays

Tetraanions of polycyclic aromatic hydrocarbons have only rarely been observed.[1] The possibility that corannulene (**1**) might be easily reduced and even "supercharged" with four electrons to make a stable, closed-shell tetraanion, however, was suggested by the prediction[2] that the lowest unoccupied molecular orbital (LUMO) of this unique bowl-shaped molecule should be doubly degenerate and lie below the antibonding energy level (E_{LUMO} = − 0.922 eV by MNDO calculations). The prospect that the tetraanion of corannulene might enjoy special stability as an aromatic cyclopentadienyl anion (6e/5C) suspended by five radial bonds within the hole of an aromatic 18e/15C annulenyl trianion as in **2** provided additional impetus to examine this system, since such a species might fulfill the long quest for a π-electron system having concentric aromatic rings, which began with the heroic synthesis of kekuléne.[3] Herein we report the preparation, ^{1}H and ^{13}C NMR spectra, and proton quenching experiments of the corannulene tetraanion.

2

Reduction of corannulene (**1**)[4] at −78 °C with excess lithium metal in [D_8]THF over a period of several days leads to a series of three color changes, first to green, then to purple, and finally to brownish-red. Only for the last stage could an NMR spectrum be recorded, presumably owing to the presence of paramagnetic species at the intermediate stages of reduction.[5] Quenching this solution with water affords tetrahydrocorannulene (GC/MS, *m/z* 254) as the major product accompanied by lesser amounts of dihydrocorannulene and corannulene (ratio ≈ 4:2:1). The formation of tetrahydrocorannulene upon protonation constitutes one piece of evidence for the presence of a quadruply charged system.

Further evidence that the final reduction product is indeed a tetraanion comes from its ^{13}C NMR spectrum: ([D_8]THF) $\delta = 86.8$ (d, $^1J_{CH} = 151$ Hz, rim CH), 95.1 (tt ≈ heptet, $^3J_{CH} = 7.0$ Hz, $^2J_{CH} = 3.6$ Hz, rim quaternary C),[6] 112.4 (m, $^3J_{CH}$ and two different $^4J_{CH}$, hub C). All three ^{13}C NMR bands of the reduction product are dramatically shifted to high field compared to those of the neutral hydrocarbon (cf. **1**: $\delta = 127.9$, 132.3, 136.9, respectively, in [D_8]THF); the weighted center of the ^{13}C NMR bands shifts by $\Delta\delta = -36.1$. Charge/chemical shift correlations first proposed by Fraenkel et al.[7a] predict a total ^{13}C NMR signal shift of $\Delta\delta \approx 160$ per negative charge. A subsequent modification of this correlation introduced by Eliasson, Edlund, and Müllen,[7b] which takes into account the anisotropy of π-electron systems, predicts a shift of $\Delta\delta \approx 150$ per unit of charge. The actual value we observe is $\sum\Delta\delta = 722$ (!) or $\Delta\delta = 180.5$ per unit of charge. These correlations provide convincing evidence that the species observed is a quadruply charged system.

The ^1H NMR spectrum of the corannulene tetraanion in [D_8]THF consists of a single line at $\delta = 6.95$ (cf. **1**: $\delta = 7.93$ in [D_8]THF). This low-field chemical shift is surprising in view of the high electron density on the rim methine carbon atoms (see ^{13}C NMR data and charge density calculations). Ordinarily, protons attached to anionic hydrocarbon C atoms are strongly shielded and resonate at exceptionally high field, for example, in the pentadienyl anion $\delta_{avg} = 4.0$.[8] Apparently, the π system of the corannulene tetraanion supports an induced diamagnetic ring current (or two) that is strong enough to counterbalance the shielding effect of four negative charges.

Whether or not the "annulene-within-an-annulene" structure **2** is the best description of this tetraanion remains to be established. MNDO calculations, with the lithium ions included,[2] yield a global minimum in which all four lithium ions lie on the convex face of a bowl-shaped tetraanion, each located over the face of a different benzene ring. This structure has 1.1 units of negative charge on the five hub carbon atoms, 2.2 units of negative charge on the ten rim methine carbon atoms, and 0.7 units of negative charge on the five rim quaternary carbon atoms. The five radial bonds of the tetraanion are calculated to be 0.01–0.06 Å longer than the five C–C bonds within the inner ring, as one would expect for **2**. High-level theoretical calculations on all the reduced (and oxidized) states of corannulene would be most desirable;[9] however, it is already clear from the initial results reported herein first that corannulene can be easily reduced to a stable tetraanion, and second that this tetraanion carries substantial negative charge on both the hub and the rim carbon atoms, thereby classifying it as a species with concentric anionic rings.

Towards Artificial Ion Channels: Transport of Alkali Metal Ions across Liposomal Membranes by "Bouquet" Molecules**

By *Marko J. Pregel, Ludovic Jullien*, and *Jean-Marie Lehn**

Transmembrane ion transport is essential to living systems and is involved in vital processes such as energy metabolism and the excitability of nerve and muscle.[1] Transport may take place by mechanisms involving either diffusive carrier (shuttle) or membrane-spanning channel (pore) species.[2] In the field of supramolecular chemistry, free carrier processes have been actively investigated for many years.[3] More recently the design, synthesis, and study of molecular assemblies capable of transporting ions across membranes by the channel mechanism has been a subject of increasing inter-

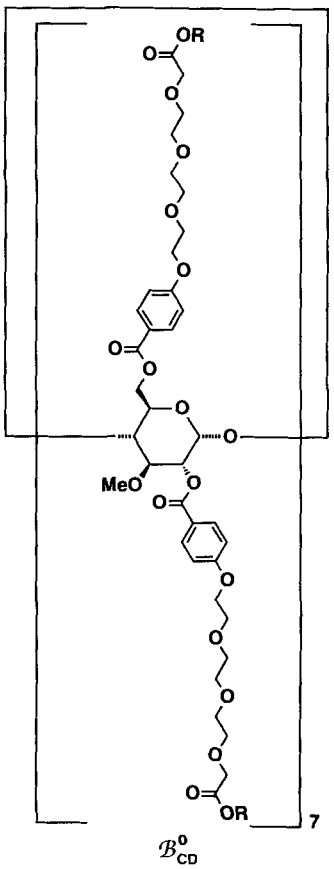
$\mathcal{B}^0_M$



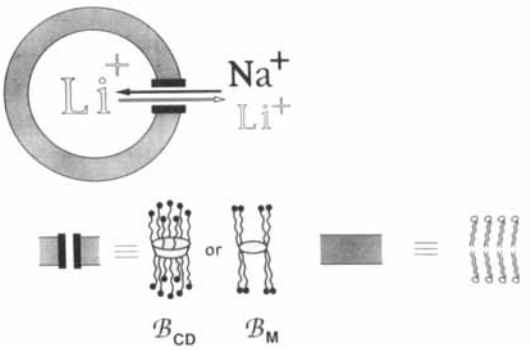
$\mathcal{B}^0_{CD}$

Scheme 1. Structures of bouquet molecules having a macrocyclic crown ether annulus (top: $\mathcal{B}^o_M$, R = Na) and a cyclodextrin annulus (bottom: $\mathcal{B}^o_{CD}$, R = H) with poly(oxyethylene) side chains. Analogous compounds with polymethylene side chains ($\mathcal{B}^c_M$ and $\mathcal{B}^c_{CD}$) were also prepared and studied.

est.[4] In general, two approaches may be noted: 1) formation of a pore by aggregation of monomeric transmembrane species, mimicking the naturally occurring channel protein alamethicin,[5] and 2) application of molecules with channel structures with defined tunnel geometry, such as in the gramicidin channel. The "bouquet" approach to artificial ion channels described here falls into the second category and involves grafting poly(oxyethylene) or polymethylene chains bearing charged endgroups onto a macrocyclic core. Previous reports have outlined the design and synthesis of two series of bouquet molecules,[6] one based on a macrocyclic polyether core ($\mathcal{B}_M$), the other having a β-cyclodextrin nucleus ($\mathcal{B}_{CD}$) (Scheme 1). We now report preliminary studies showing that the bouquet molecules function as ion transporters in bilayer membranes.

Natural and artificial ion transporters have been studied in liposome systems by a wide variety of methods including atomic absorption analysis,[4b] conductimetry in planar bilayers,[4d, f] fluorescence and UV/VIS spectroscopy,[4a, c, e, h] and pH-stat techniques.[4e] Alkali metal ion NMR spectroscopy has also been used to follow ion transport across the phospholipid bilayer of liposomes.[4g, 7, 8] Alkali metal ions in the aqueous solution outside the liposomes may be distinguished from those inside by adding a shift reagent.[9] Thus, two resonance signals are seen which correspond to internal (unshifted signal) and external (shifted signal) metal ions. In this context, we have chosen to follow the collapse of opposing gradients of Na^+ and Li^+ ion concentrations across the membrane by ^{23}Na and ^7Li NMR spectroscopy.[7]

Liposomes were prepared in an aqueous LiCl solution. After addition of a shift reagent solution (based on $DyCl_3$, see Experimental Procedure), opposing gradients of Na^+ and Li^+ ion concentrations were created by the addition of an iso-osmolar NaCl solution. Initially, Na^+ ions were found only in the exterior volume. The entry of Na^+ ions into the liposomes was then followed as a function of time by integration of the signal corresponding to "internal" Na^+ ions (see Scheme 2). This approach has a number of advantages: first, both alkali metal ions (Na^+, Li^+) capable of being transported may be observed directly and almost simultaneously; second, liposome breakage during the experiment, which would release Na^+ and Li^+ ions, cannot be confused with transmembrane transport because one observes the entry of Na^+ ions; and third, the gradient experiment allows the determination of a wide range of transport



Scheme 2. Schematic representation of the transport experiment in which aqueous NaCl solution is added to a preparation of liposomes containing bouquet molecules in the membrane in aqueous LiCl solution, creating opposing gradients in Na^+ and Li^+ ion concentrations. The entry of Na^+ ions, initially found only in the external volume, into liposomes is followed by ^{23}Na NMR spectroscopy; the exit of Li^+ may also be followed by ^7Li NMR spectroscopy.

rates: the timescale of the experiment can range from 10^2 to 10^4 min.

Results for the transport of Na^+ ions across liposomal membranes containing bouquet molecules are shown in Figure 1. Comparison of these results with those of a control

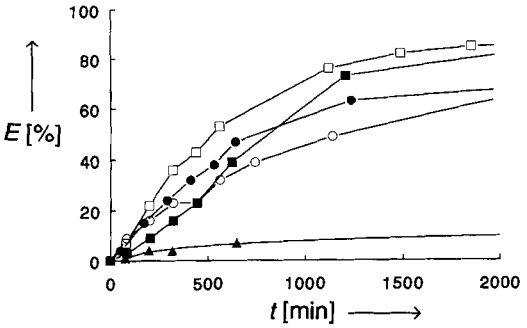


Fig. 1. Extent of entry of Na^+ ions into liposomes (E) as a function of time in the presence of bouquet molecules $\mathscr{B}^o_M$ (●), $\mathscr{B}^c_M$ (○), $\mathscr{B}^o_{CD}$ (■), and $\mathscr{B}^c_{CD}$ (□), and in the absence of bouquet molecules (▲). The extent of entry is a normalized parameter: maximum entry is taken as an extent of entry of 100% for each experiment. Concentrations of bouquet molecules were 62 μM ($\mathscr{B}^o_M$), 27 μM ($\mathscr{B}^c_M$), 56 μM ($\mathscr{B}^o_{CD}$), and 51 μM ($\mathscr{B}^c_{CD}$); lipid concentrations ranged from 8.4 to 11.2 mg mL^{-1}.

experiment without bouquet molecules reveals that both the rate and extent of transport are significantly greater in the presence of bouquet molecules than in their absence. Therefore, these molecules increase the permeability of phospholipid membranes to alkali metal ions. Interestingly (and unexpectedly), bouquet molecules with polymethylene chains transport about as efficiently as bouquet molecules with poly(oxyethylene) chains in both series ($\mathscr{B}_M$ and $\mathscr{B}_{CD}$). Furthermore, corresponding compounds in the two series transport at only slightly different rates. Finally, it should be noted that under these conditions the rates of transport by the bouquet molecules are relatively low (apparent first-order rate constants of the order of 10^{-3} min^{-1}) in comparison with those reported for other artificial ion-channel compounds. However, strict comparisons are not really justified since different experimental conditions apply.

Transport of alkali metal ions may proceed by a number of mechanisms including cation–cation antiport, cation–proton antiport, and cation–anion symport.[10] In the present system, influx of Na^+ ions into liposomes was followed by ^{23}Na NMR spectroscopy. In some experiments, efflux of Li^+ ions was monitored simultaneously by ^7Li NMR spectroscopy. It was therefore possible to compare the amount of Na^+ which had entered to the amount of Li^+ which had exited the liposomes at various times (Fig. 2). Within experimental error, the two values are identical at any given time, leading to the conclusion that Na^+ and Li^+ ion transport by the bouquet molecules occurs by a one-for-one exchange of sodium ion for lithium ion (cation–cation antiport). The more slowly transfered ion (probably Li^+) determines the overall rate of transport.

These results do not allow a precise description of the mechanism by which the bouquet molecules mediate transmembrane cation flow. However, it has been found that bouquet molecules $\mathscr{B}^c_M$ and $\mathscr{B}^o_{CD}$ allow cation passage through membranes of dipalmitoyl phosphatidylcholine (DPPC) in the *gel* state with rates similar to those observed in egg phosphatidylcholine (EPC) membranes which are in the *fluid* state. In contrast, the rate of transport by

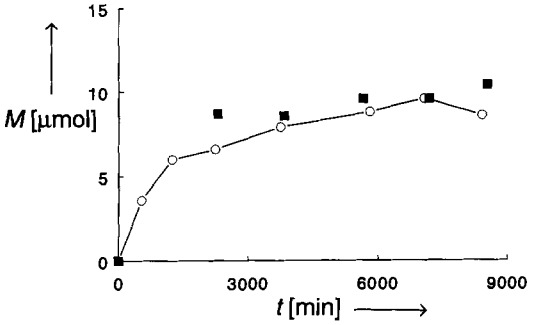

Fig. 2. Comparison of the amount M of Na^+ having entered liposomes (○) with the amount of Li^+ having exited (■) as a function of time for liposomes with $\mathscr{B}^o_M$. Other bouquet molecules gave similar results.

monensin A, an ionophore antibiotic which operates by the carrier (shuttle) mechanism, is sharply reduced in DPPC membranes in the gel state, as compared to fluid EPC membranes. Therefore, for the bouquet molecules $\mathscr{B}^c_M$ and $\mathscr{B}^o_{CD}$ at least, a shuttle mechanism can be excluded. While a perturbation of membrane structure by the bouquet molecules causing an overall change in membrane permeability cannot be excluded, our results are consistent with a channel mechanism of ion transport.

In conclusion, we have shown that bouquet molecules may be incorporated into the phospholipid membrane of liposomes. These compounds increase the permeability of the membrane to Na^+ and Li^+ ions, and ion transfer proceeds by a cation–cation antiport mechanism. Variations in the bouquet molecule including changing from poly(oxyethylene) to polymethylene chains and changing from a crown ether annulus to a cyclodextrin annulus did not have drastic effects on ion-transport activities. A carrier mechanism can be excluded for two of the compounds studied since ion-transport activity is undiminished in membranes in the gel state. Further studies are underway to investigate the mechanism of transport and the effects of parameters such as membrane composition, alkali metal ions, and concentration of bouquet molecules on the transport rate in order to better describe the mode of action of these compounds.

Experimental Procedure

Large unilammelar vesicles (liposomes) were prepared from egg phosphatidylcholine by the dialytic detergent-removal technique [11]. Bouquet molecules were incorporated into the membrane during liposome formation: stock solutions of bouquet molecules, lipid, and detergent were mixed, evaporated to dryness, hydrated with aqueous 100 mM LiCl solution, and dialyzed against aqueous 100 mM LiCl solution. The lipid content of the liposome preparation was measured by analysis of the phosphate content after digestion [12]; the concentration of bouquet molecules present was measured by using the absorption of bouquet molecules at 250 or 255 nm. In a typical transport experiment, iso-osmolar shift reagent solution (30 mM, $(Me_4N)_5P_3O_{10}$, 10 mM $DyCl_3$; 0.3 mL) and 100 mM NaCl solution (0.8 mL) were added to the liposome preparation (1.0 mL), creating transmenbrane gradients in Na^+ and Li^+ ion concentrations. The entry of Na^+ ions into liposomes was followed by ^{23}Na NMR spectroscopy by integration of the signal corresponding to "internal" Na^+ ions. Exit of Li^+ ions was followed by ^7Li NMR spectroscopy in an analogous manner. The temperature was maintained at 25 ± 1 °C during the experiment.

Optimization of the Production and Separation of Fullerenes**

By *Andreas Mittelbach, Wolfgang Hönle, Hans Georg von Schnering,* Jürgen Carlsen, Rolf Janiak,* and *Helmut Quast**

The observed superconductivity of alkali metal compounds like $K_3(C_{60})$[1] prompted our investigations of fullerenes. Not only had we looked for a new direction in our search for superconducting materials,[2] we also thought that $K_3(C_{60})$ may be described as an analogue of Zintl phases like Li_3B_{14}, Li_2B_6, and Li_6B_{19} (electron transfer with structural consequences).[3]

Fullerenes[4] can be produced by laser vaporization,[5] vaporization of graphite in an arc,[6] by plasma discharge,[7] or in a high-frequency furnace[8] under reduced pressure of an inert gas. These methods provide soot containing up to 44% fullerenes.[7, 9] The mixture usually consists of C_{60} and C_{70} in a ratio of 85:15 and a small amount of higher fullerenes. Isolation and separation of the fullerenes is achieved by extraction of the soot with toluene followed by chromatography or directly by chromatography of the soot.[10]

[**] We thank Dr. H. Schmidt (University of Halle) for preliminary work and Dr. T. P. Martin (Max-Planck-Institut, Stuttgart) for the measurement of the TOF mass spectrum.

Previous procedures[11–13] succeeded in separating fullerenes only in small amounts (for example, separation of 400 mg extract[14, 15] in 4–6 hours to give 32 mg C_{60}[11] after 11 hours or 170 mg C_{60} after 25 hours[13]) incompletely or only in limited amounts on special column materials. Only Gügel et al.[16] described a procedure for the separation of reasonable amounts of a fullerene mixture (5 g in 24 hours); however, a baseline separation was not achieved, and large mixed fractions were obtained.

In our investigations we used a DC furnace[17] for the preparation of fullerene-containing soot. This has the advantage that the cathodes hardly burn down when electrodes of equal diameter are used (Fig. 1). We observed a strong

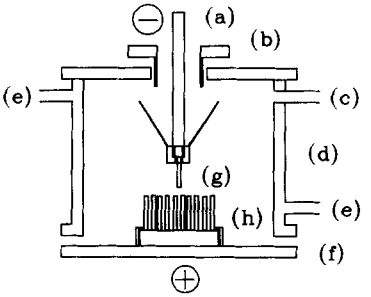

Fig. 1. Drawing of the arc furnace (not to scale): a) water-cooled cathode connection, b) insulation, c) inert gas–vacuum vent, d) water-cooled stainless-steel container, e) cooling-water supply, f) water-cooled copper plate, g) cathode $\varnothing = 6.15$ mm, h) close arrangement of anodes $\varnothing = 6.15$ mm.

change in the ratio of C_{60}/C_{70} (hitherto 85:15) in favor of C_{70} when we used a higher current. With 400 A DC (hitherto about 100–200 A, AC or DC) we obtained fullerene mixtures containing up to 50% C_{70} (Fig. 2). Subsequent extrac-

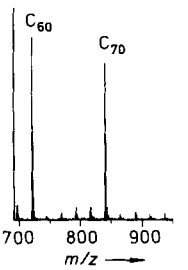

Fig. 2. Time-of-flight mass spectrum [18] of the soot. The ordinate corresponds to the ion/time channel.

tion with toluene provided C_{60}/C_{70} mixtures greatly enriched in C_{70}. Unfortunately, details of the events in the plasma are not known. All hypotheses about the formation of fullerenes in the arc are based on the premise of the existence of single carbon atoms as basic units.[20] We presume that the use of high current produces larger regions of higher temperature. The temperature gradient is much steeper than that formed at lower current, which favors the formation of C_{70}.

The C_{60}/C_{70} mixture could be separated by medium-pressure chromatography according to two procedures (A, B), both of which start with material dried under vacuum at 200 °C until constant weight was achieved. In procedure A the fullerene mixture was extracted with hexane (vapor extractor, or extraction, from a precolumn under constant pressure, which was filled with a mixture of silica gel and fullerenes). This saturated or oversaturated solution was injected directly onto the separation column and eluted with

hexane. For the separation we used a glass column with a high number of plates ($N = 14000$) and a good symmetry index (SI ≤ 1.05).[20] It is possible to run this procedure continuously. For example, injections can be made every 5–10 min (Fig. 3), so that six to three 50 mL portions of

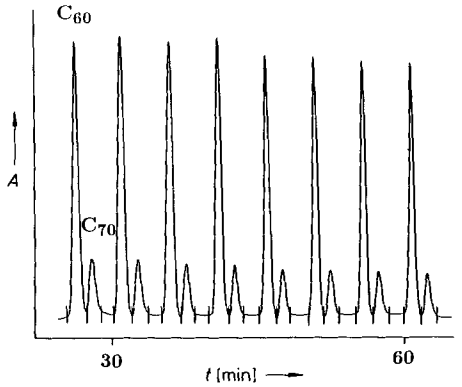

Fig. 3. Typical chromatogram (detection wavelength 300 nm) for the preparative separation on silica gel with hexane. The lines indicate the cut-off points for the fractions. A = absorption.

extract can be separated simultaneously. Depending on the concentration of the extract, up to 400 mg of fullerenes may be separated per hour (Fig. 4).

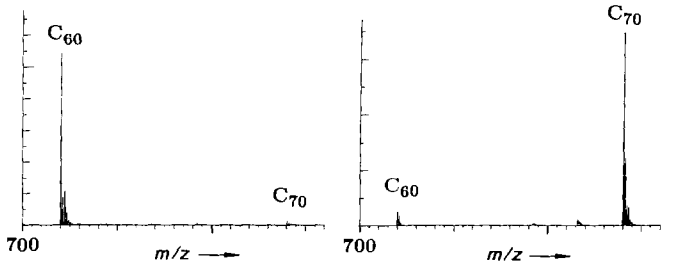

Fig. 4. Time-of-flight mass spectrum [18] after the preparative separation on silica gel with hexane with only *two* fractions (Fig. 3). The ordinate corresponds to the ion/time channel.

In procedure B the chromatography was carried out with toluene/acetonitrile[21] (75:25) as the eluent and a glass column packed with C18 reversed-phase silica gel. The fullerenes were injected by extraction under pressure with

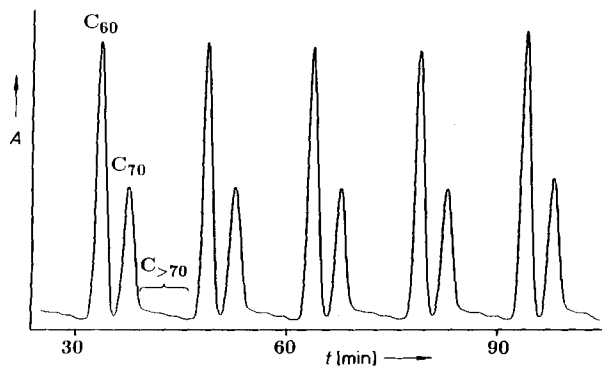

Fig. 5. Typical chromatogram (detection wavelength 300 nm) for the preparative separation on C18 reversed-phase silica gel with toluene/acetonitrile (75:25). A = absorption.

toluene/acetonitrile (75:25) from a shunt column which was filled with a mixture of reversed-phase silica gel and fullerenes (12:1). Injections lasting 45 s were made every 15–20 min. In this way we separated up to 300 mg of fullerenes per hour (Fig. 5). In the chromatogram from procedure B higher fullerenes like C_{76}, C_{78}, etc. are apparent. They can be separated after enrichment.

Experimental Procedure

C_{70} enrichment of the fullerene mixture: The arc furnace [17] was furnished with graphite electrodes [22] and was evacuated (2 Pa) and refilled with helium gas (purity grade 4.6) several times. Then the furnace was filled with helium to a pressure of 8×10^3 Pa. After ignition of the arc at lower current the electrodes were brought into contact. The intensity of current was raised to 400 A at 58 V (maximum 18 kW). During the vaporization the pressure was as high as 2×10^4 Pa. From previous experiments with tungsten electrodes, we know that the temperature at 400 A and 58 V is higher than 3000 K. We estimate that the temperature here is roughly 5000 K at the electrode and about 15000 K in the plasma. With this method 7–10 g of graphite per hour could be evaporated. Afterwards the soot was collected and extracted with toluene for 24 h. Without further extraction (for example, as described in ref. [5, 7]) the total yield of fullerenes after removal of the solvent in vacuum was 7–10%.

Procedure A: Chromatography with hexane on silica gel [23]. A glass column 70 × 6 cm) was packed with silica gel (LiChroprep Si60 15–25 μm, Merck) as described in ref. [20]. Solvent hexane, flow 100 mL min^{-1} at 1.6×10^6 Pa. The fullerene mixture was extracted for 45 min with 200 mL of hexane in a vapor extractor to remove impurities. This extract was discarded. With another portion of 400 mL hexane the fullerene mixture was extracted in the same way for 4–6 h. This extract was injected in portions of 50 mL every 5–10 min onto the separation column. The pure fullerenes were then eluted with hexane.

Procedure B: Chromatography with toluene/acetonitrile on C18 reversed-phase silica gel [23]. A glass column (70 × 6 cm) was packed with C18 reversed-phase silica gel (Europrep 60–30 C18 20–45 μm, Knauer). In an adaptation of ref. [20], the column was packed by using methanol/water in a ratio of 95:5; $N = 5000$, SI ≤ 1.25. Solvent toluene/acetonitrile (75:25), flow 72 mL min^{-1} at 1.8×10^6 Pa. The crude fullerene mixture was loosely mixed with reversed-phase silica gel in a ratio of 1:12 and stored in a 25 × 4 cm glass column which acted as shunt column and was filled with solvent and kept under pressure. When the solvent flowed through this precolumn for 45 s the extract was injected on the separation column. The pure fullerenes were then eluted with toluene/acetonitrile (75:25) [24].

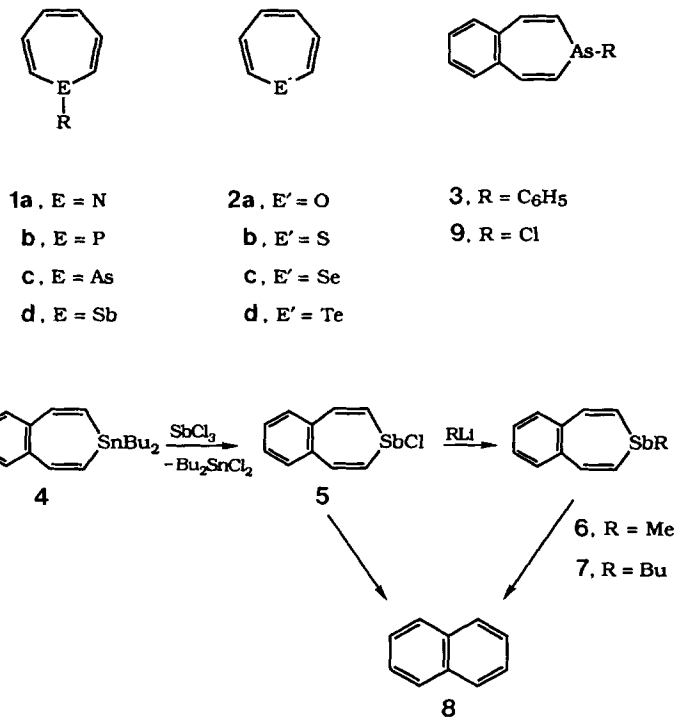
The First Stibepine: Synthesis and Structure of *Sb*-Chlorobenzo[*d*]stibepine**

By *Arthur J. Ashe III,* Lukas Goossen, Jeff W. Kampf,* and *Hisatoshi Konishi*

Dedicated to Professor Kenneth B. Wiberg on the occasion of his 65th birthday

Fully unsaturated seven-membered ring heterocycles containing Group 15 and 16 elements are of substantial interest. The well-studied azepines **1a** and oxepines **2a**[1] are relatively stable compounds in contrast to their heavier homologues, phosphepines **1b**[2] and thiepines **2b**,[3] for which most derivatives are thermally labile towards heteroatom extrusion. Derivatives of selenepine **2c**[4] and tellurepine **2d**[5] have been reported recently, while the labile *As*-phenylbenzo[*d*]arsepine (**3**) has been detected at low temperature by spectroscopy.[2a] We report here on the first synthesis of benzo[*d*]stibepines and the structural characterization of *Sb*-chlorobenzo[*d*]stibepine (**5**).[6]



The reaction of dibutylbenzo[*d*]stannepine (**4**)[7] with one equivalent of $SbCl_3$ in $CHCl_3$ at 0 °C affords **5** and dibutyltin dichloride, which may be removed by extraction with pentane. Recrystallization from diethyl ether/CH_2Cl_2 affords **5** as well-formed yellow crystals. Compound **5** may be converted to the alkyl derivatives **6** and **7** by treatment with MeLi and BuLi, respectively. All the above operations must be performed at low temperature since benzo[*d*]stibepines are thermally labile, forming naphthalene **8** and unidentified antimony-containing products. The conversion of **6** and **7** to **8** in $CDCl_3$ at 25 °C was monitored by ^{1}H NMR spectroscopy and showed first-order kinetics with $t_{1/2}$ = 370 and 660 min, respectively.

For comparison we have also examined benzo[*d*]arsepines. The reaction of **4** with $AsCl_3$ in $CHCl_3$ gave **9** and Bu_2SnCl_2. It was not possible to separate these products, but the identity of **9** was established by the similarity of its NMR spectra of those of **5**. In $CDCl_3$ **9** decomposes to form **8** with $t_{1/2}$ = 50 min at 25 °C. Thus, surprisingly, the arsepine is more labile than the stibepine.

Since prior structural data on the heavier heteroepines was available only for derivatives of thiepine,[3] it was of interest to determine the crystal structure of a benzostibepine. The structure of **5**[8] illustrated in Figure 1 shows a boatlike stibepine ring. This boat conformation has angles of 41.7

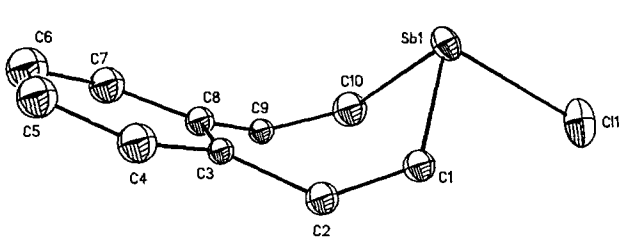


Fig. 1. Solid-state structure of **5** (ORTEP). Important distances [Å] and angles [°]: Sb1–Cl1 2.403(1); Sb1–C1 2.116(4); Sb1–C10 2.116(4); C1–C2 1.325(5), C2–C3 1.476(5); C8–C9 1.470(5), C9–C10 1.320(6); Cl1–Sb–C1 92.6(1), Cl1–Sb–C10 93.6(1), C1–Sb1–C10 89.9(1).

and 34.0° between the base plane (C1-C2-C9-C10) and the bow (C1-Sb1-C10) and stern (C2-C3-C8-C9), respectively. The bond angles about Sb are close to 90° as has been found in other antimony heterocycles.[9] These structural features and the marked alternation between single and double C–C bond lengths of the stibepine moiety are consistent with little conjugation. Overall the structure is remarkably similar to those of the thiepines.

Experimental Procedure

5: A solution of **4** (1.87 g, 5.2 mmol) in $CHCl_3$ (5 mL) was added in one portion with vigorous stirring to $SbCl_3$ (1.18 g, 5.2 mmol) in $CHCl_3$ (20 mL) at 0 °C. After 10 min the solvent was removed in vacuo leaving a gray residue which was washed with pentane (3 × 5 mL) at −50 °C. The residue was dissolved in diethyl ether/CH_2Cl_2 (50 mL), and the solution was filtered through $MgSO_4$. Cooling to −20 °C gave 750 mg of **5** as yellow crystals, decomp >30 °C. ^{1}H NMR ($CDCl_3$): δ = 7.68 (d, J = 12.3 Hz, 2H), 7.28 (A_2B_2 pattern, 4H), 6.84 (d, J = 12.4 Hz, 4H). ^{13}C NMR ($CDCl_3$): δ = 141.0, 139.6, 132.1, 126.8, (signal of the quaternary C not observed). High-resolution CI-MS(NH_3/CH_4): m/z ($M^+ + 1$) calcd for $C_{10}H_8{}^{121}Sb^{35}ClH$: 284.9431, found 284.9417.

6: To a solution of **5** (50 mg, 0.18 mmol) in diethyl ether (50 mL) at −10 °C was added 0.1 N MeLi (2 mL) until the solution became red. The excess MeLi was then destroyed with a drop of 1,2-dibromoethane, and the mixture was filtered through $MgSO_4$. Removal of the solvent left 50 mg of a yellow residue, which was recrystallized from diethylether at −78 °C affording **6**, m.p. 35 °C. ^{1}H NMR ($CDCl_3$): δ = 7.46 (d, J = 12.0 Hz, 2H), 7.22 (A_2B_2 pattern, 4H), 6.50 (d, J = 12.0 Hz, 2H), 0.95 (s, 3H). ^{13}C NMR ($CDCl_3$): δ = 141.2, 138.4, 132.9, 131.5, 125.9, 28.0. High-resolution CI-MS (CH_4): m/z ($M^+ + 1$) calcd. for $C_{11}H_{11}{}^{121}SbH$: 264.9770, found 264.9958.

8: In the same manner, the reaction of BuLi with **5** gave **8**, m.p. −10 °C. ^{1}H NMR ($CDCl_3$): δ = 7.49 (d, J = 12.4 Hz, 2H), 7.23 (A_2B_2 pattern, 4H), 6.49 (d, J = 12.4 Hz, 2H), 1.5–0.7 (bu, 9H). ^{13}C NMR ($CDCl_3$): δ = 141.4, 138.4, 131.9, 131.5, 125.8, 29.8, 26.2, 14.7, 13.6. High-resolution CI-MS ($Cl(C_4H_{10})$: m/z ($M^+ + 1$) calcd for $C_{14}H_{17}{}^{121}SbH$: 307.0447, found 307.0451.

9: Prepared in the same manner as **5**: ^{1}H NMR ($CDCl_3$): δ = 7.25 (A_2B_2 pattern, 4H), 7.17 (d, J = 12.4 Hz, 2H), 6.49 (d, J = 12.4 Hz, 2H). ^{13}C NMR ($CDCl_3$): δ = 137.3, 135.8, 135.5, 132.0, 127.0.

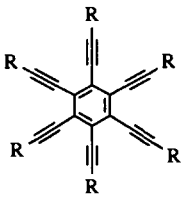
The First Hexabutadiynylbenzenes: Synthesis and Structures**

By *Roland Boese,* James R. Green, Joachim Mittendorf, Debra L. Mohler*, and *K. Peter C. Vollhardt**

Our disclosure of the Pd-catalyzed hexaethynylation of hexabromobenzene to give **1**[1] has prompted considerable synthetic activity. The method has been used to prepare polyalkynyl aromatics, particularly with the aim of generating novel discotic liquid crystals[2] or precursors to new organic solids with unusual properties (hardness, thermal and electric conductivity, lubrication).[3] We are interested in these compounds because of their more fundamental physical organic properties and synthetic potential. They are new, very electron-rich, reactive hydrocarbons with high C/H ratios.[1] In synthesis they are precursors to allotropes of carbon, such as C_{60},[4a] or substrates in CpCo-catalyzed cocyclizations with monoalkynes on route to multiphenylenes,[4b,c] and also function as multidentate ligands to transition-metal clusters.[4d]



1a, R = Si(CH$_3$)$_3$
1b, R = H
1c, R = C(CH$_3$)$_2$OH

Along these lines, hexabutadiynylbenzene **2d** was deemed a highly attractive target, because a) it is the first $C_{30}H_6$ hydrocarbon; b) it contains 54(!) conjugated π-electrons, which might give rise to unusual spectral properties indicative of σ-delocalization;[5] c) it could function as a substrate in the regioselective, CpCo-catalyzed, triple cocyclization with ethyne to assemble the fascinating circular [6]phenylene, antikekulene,[5] [the scheme requires the (not unprecedented) ring opening of the initial 1,4,5,8,9,12-hexaethynyltrisbenzocyclobutadienobenzene to the corresponding hexadehydro[12]annulene[4c] and subsequent renewed (intramolecular) triple [2+2+2] cycloaddition of the nine alkyne units (in analogy to the preparation of angular [3]phenylene[6])]; and d) X-ray analysis of protected derivatives would not be complicated by steric effects (as in the case of **1a**).[1] We report here the syntheses of **2a–c** and some of their structural (**2a**, **2c**), physical, and preliminary chemical characteristics.

The substituted butadiynes **3** required for the reaction with hexabromobenzene were made by published (**3a,c**)[7, 8] or adapted (**3b**) literature procedures. The Pd-catalyzed coupling step (with toluene: **2a**, 18%; **2b**, 11%; without toluene: **2c**, 36%)[9] proceeded with a facility and efficiency

3a, R = $Si[CH(CH_3)_2]_3$
3b, R = $(CH_3)_2Si[C(CH_3)_2CH(CH_3)_2]$
3c, R = $C(CH_3)_3$

2a, R = $Si[CH(CH_3)_2]_3$
2b, R = $(CH_3)_2Si[C(CH_3)_2CH(CH_3)_2]$
2c, R = $C(CH_3)_3$
2d, R = H

that is remarkable in the light of the reactivity of the species involved. Indeed, this reactivity appears responsible for the failure to form derivatives of **2** in which R = Ph or $Si(CH_3)_3$.

Some physical data of **2a–c** are given in Table 1. The compounds were obtained as yellow crystals, stable to air, but losing X-ray diffraction capability in the absence of the solvent of crystallization. Their NMR and IR absorptions are found at the expected positions and compare well to those of **1** and related models.[1, 4c] The clearest manifestation of the change in electronic structure on going from **1** to **2** is provided by UV measurements (of **1a** and **2a**; Fig. 1), a pronounced shift of all the spectral bands to higher wavelengths ($\Delta\lambda_{max} \approx 50$ nm), a generally dramatic increase of the associated molar absorptivities, and the detection of a new set of higher energy transitions is observed.[10] The quite striking hexagonal symmetry of **2** was confirmed by an X-ray structural determination of **2c** (Fig. 2).[11] The compound crystal-

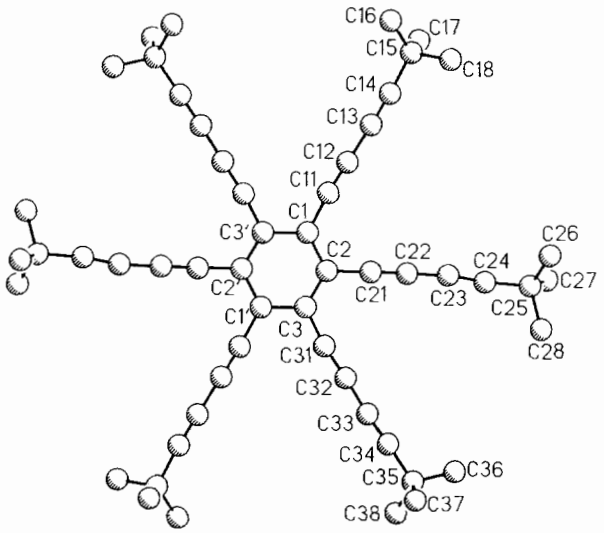

Fig. 2. Molecular structure of **2c** [11]. Mean distances [Å]: C_{arom}–C_{arom} 1.39(2), C_{arom}–C≡1.42(2), C≡ 1.19(1), ≡C–C≡ 1.38(2), ≡C–$C(CH_3)_3$ 1.48(2).

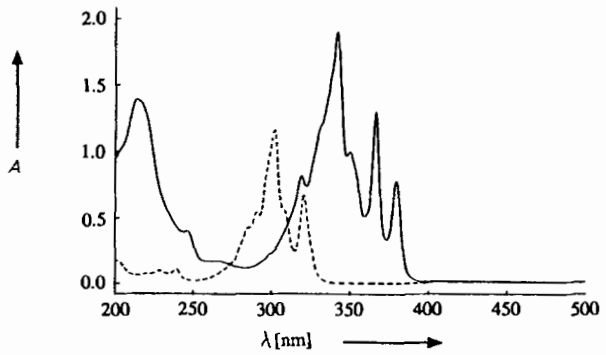

Fig. 1. Electronic spectra of **1a** (– – –) and **2a** (——) in hexane (7.64×10^{-6} M). A = absorption.

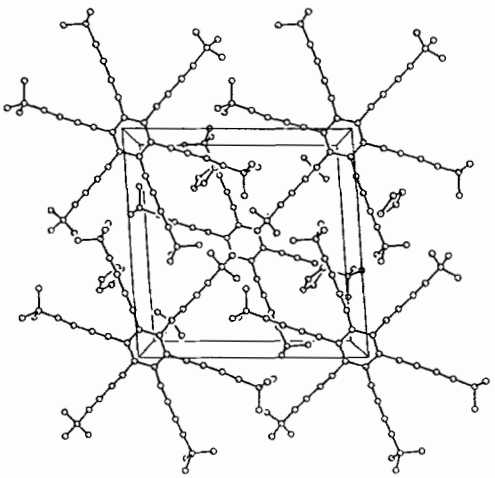

Fig. 3. The unit cell of the crystal structure of **2c** [11].

lized from THF with two solvent molecules in intermolecular spaces (Fig. 3) and had to be kept in the mother liquor to enable acceptable diffraction measurements. An additional complication is presented by the mobility of the diyne substituents, evidenced by the increase in the value of the atomic displacement parameters with increasing distance from the ring. As a consequence, the degree of accuracy of the structural details is diminished.

A few qualitative experiments probing the reactivity of **2** have been moderately encouraging. Surprisingly, **2a–c** show remarkable resilience to irradiation (at 254, 300, 350 nm) in solution and as solids. However, **2a** and **2c** react in the presence of $[CpCo(CO)_2]$ and $[L_3Cr(CO)_3]$ (L = CH_3CN) to form new complexes, they appear to undergo charge-transfer complexation, and they reveal promising electrochemistry. Stepwise protodesilylation of **2a** can be monitored by spectral techniques, but the parent system **2d** could not yet be obtainable pure.

Experimental Procedure

1a: To a solution of 2-methyl-6-triisopropylsilyl-3,5-hexadiyn-2-ol [4b] (19.68 g, 74.4 mmol) and phenothiazine (50 mg, 0.25 mmol) in toluene (450 mL) was added KOH (5.5 g, 98 mmol). The mixture was kept at 70 °C for 2 h under a nitrogen atmosphere. After the reaction had been quenched with an aqueous solution of NH_4Cl, the mixture was extracted repeatedly with pentane. The combined organic layers were dried over $MgSO_4$, filtered, and concentrated to 25 mL under reduced pressure. The resulting oil was divided into three portions and dissolved at 12 h intervals in a boiling solution of hexabromobenzene (1.422 g, 2.58 mmol), $PdCl_2(PPh_3)_2$ (0.268 g, 0.41 mmol), and CuI (0.163 g, 0.86 mmol) in triethylamine (80 mL). Subsequently the mixture was maintained at reflux for an additional 12 h. The solution was filtered through Celite, the residue rinsed with petroleum ether, and the solvents removed from the combined filtrates under reduced pressure. Flash chromatography on silica with pentane and subsequent crystallization from ethyl acetate yielded **1a** (0.611 g, 18%) as yellow crystals.

New Layered Iron-Lanthanum-Oxide-Sulfide and -Selenide Phases: $Fe_2La_2O_3E_2$(E = S,Se)**

By *James M. Mayer,* Lynn F. Schneemeyer,* Theo Siegrist, Joseph V. Waszczak,* and *Bruce Van Dover*

Metal oxides, sulfides, and selenides are amongst the most studied classes of solid-state compounds, yet there are surprisingly few examples of mixed oxide-sulfides or oxide-selenides.[1] The only ternary transition metal oxide-chalcogenides are ZrOS and HfOS,[2] although a variety of rare earth derivatives are known, the most common having the stoichiometry M_2O_2E (M = rare earth metal, E = S, Se, Te), $M_2O_2(S_2)$, and $M_4O_4Se(Se_2)$.[3] These compounds are typically layered materials, in which the oxide, sulfide, or selenide ions are in separate sheets. We are particularly interested in the preparation of new phases that contain transition metals, because layered phases may display interesting electronic and/or magnetic behavior in one or two dimensions. A number of quaternary phases containing rare earth and main group elements are known, and they often do adopt two-dimensional structures.[4] The analogous compounds with transition metals have been less studied. The silver and copper derivatives AgLaOS and CuLaOS have layered structures,[4] while $CrMOS_2$, $CrLaOSe_2$,[5] $V_3La_5O_7S_6$,[6] $La_2Ta_3O_8S_2$, and $M_2Ta_3O_8Se_2$[7] have three-dimensional structures. We report here on the synthesis and initial characterization of $Fe_2La_2O_3S_2$ (**1**) and $Fe_2La_2O_3Se_2$, (**2**), members in a new class of layered compounds exhibiting novel structural features and interesting magnetic behavior.

Compounds **1** and **2** are formed on sintering mixtures of La_2O_3 + 2Fe + 2S or 2Se (stoichiometric with respect to **1** and **2**, respectively) in sealed quartz tubes to temperatures above 1000 °C. Single crystals were obtained from samples heated to higher temperatures. Coating the inside of the tube with carbon minimized attack on the quartz. Compounds **1** and **2** are stable to 1175 and 1250 °C, respectively; above

these temperatures melting apparently occurs with decomposition. Single-crystal and powder X-ray structural studies show that **1** and **2** form isomorphous compounds, which crystallize in the tetragonal space group *I4/mmm*. The unit cell parameters (Table 1) bear a strong resemblance to those of $La_4Ga_{1.33}O_4S_4$, but **1** and **2** have a different stoichiometry and structure type, and contain divalent iron.

Table 1. The unit cell parameters for $Fe_2La_2O_3S_2$ (**1**) and $Fe_2La_2O_3Se_2$ (**2**) as well as positional parameters of **2**.

a [Å]		4.0408(1)	4.0788(2)		4.12
c [Å]		17.8985(6)	18.648(2)		18.54
Positional parameters		*x*	*y*	*z*	B_{iso}
La	(4e)	1/2	1/2	0.18445(5)	0.54(3)
Fe	(4c)	1/2	0	0	1.55(12)
Se	(4e)	0	0	0.09669(9)	0.84(5)
O(1)	(4d)	1/2	0	1/4	0.8(3)
O(2)	(2b)	1/2	1/2	0	1.0(6)

Compounds **1** and **2** are isostructural and thus, for brevity in the remaining text and in Figure 1 only **2** is refered to. The structure of **2** (Fig. 1) consists of layers, stacked along the *c* axis in the order Fe_2O/Se/La/O/La/Se/Fe_2O. The packing in

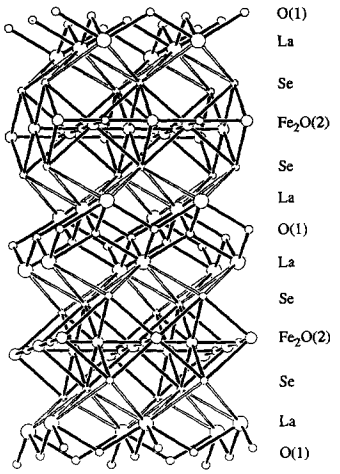

Fig. 1. View of the packing in **2**.

the Fe_2O layer is a novel square network of face-sharing octahedrons and these layers are connected by double layers of Se_4O_4 square antiprisms (La in the middle of the antiprisms). The coordination about iron is a strongly distorted octahedron made up of two *trans* oxide ions and four selenide ions. (Fe–O(2) = 2.0394(2), Fe–Se = 2.722(1) Å). The Fe-O(2)-Fe units are linear and the coordination at the O (2) atom is square planar. Four of the eight Se_2O faces of each iron octahedron are shared with another iron atom. We know of no other compound with a fourfold network of face-sharing octahedrons—fourfold octahedral networks are commonly edge-sharing or vertex-sharing.[8] The packing in **1** and **2** is possible only because of the very different Fe–O and Fe–Se distances, which produce a highly distorted octahedral unit.

The lanthanum coordination in **2** is a square antiprism with four selenide ions on one side and four oxide ions on the other side (La–O(1) = 2.378(1), La–Se = 3.316(1) Å). The coordination geometry about O(1) is a flattened tetrahedron with La-O(1)-La angles of 118.1(1) and 105.3(1)°. The double layer of square antiprisms (Se/La/O(1)/La/Se) is similar to that found in the lanthanum oxide halides LaOX and is a characteristic of the BiOCl (or PbFCl) structure type.[1] This structure is seen in compounds containing large cations with anions of two different sizes. In **2**, $La_4Ga_{1.33}O_4S_4$, and several other oxide-sulfides, the metal ions and the chalcogenide ions are inserted between the sheets of double lanthanum antiprisms.[4]

The formally divalent iron atoms in **2** form a two-dimensional network. Because the Fe octahedrons are face sharing, the shortest Fe–Fe distances are 2.8842(3) Å. The double Se/La/O layers between neighboring Fe layers lead to a large separation (8.95 Å in **1** and 9.32 Å in **2**). Measurements of the temperature dependence of the resistivity for **1** and **2** show activated behavior typical of semiconductors. At room temperature **1** and **2** have resistivities of 200 and 10^3 Ω cm, respectively. The magnetic susceptibility data of **1** and **2** show a peak at about 100 K (Fig. 2), indicating a magnetic ordering. Furthermore, a large temperature-independent paramagnetic susceptibility can be observed, and because the compounds are semiconductors, this is probably Van Vleck paramagnetism.[9] In contrast, the observed maximum is

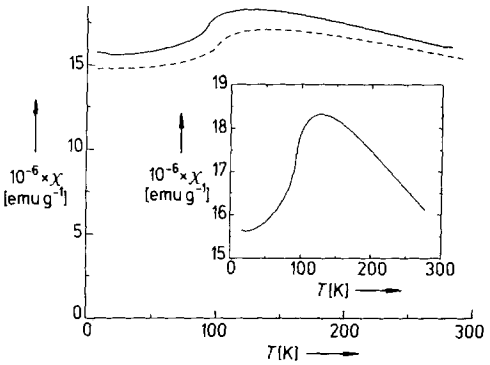

Fig. 2. Temperature dependence of the magnetic susceptibility χ of **1** (---) and **2** (—). In the inset the peak for **2** is enlarged.

probably a consequence of antiferromagnetic exchange in the two-dimensional Fe^{2+} lattice; in a three-dimensional system, a cusp would be observed.[10] Detailed studies of the interesting magnetic behavior of **1** and **2** and extensions to other rare earth elements are underway.

Experimental Procedure

A mixture of La_2O_3, 2 Fe, and 2 S or 2 Se, (stoichiometric with respect to **1** and **2**, respectively) was ground together, pressed into a pellet, loaded into a carbonized quartz tube, and sealed in vacuo. The mixture was heated at 650 °C for 12 h and 1085 °C for 9 days to yield essentially single-phase materials. Black crystals were mounted on quartz fibers, and X-ray data were obtained on a CAD4 diffractometer at 23 °C with $Mo_{K\alpha}$ radiation. **2**: 1197 measured reflections were averaged to give 169 unique reflections, 152 or which had $I > 2\sigma(I)$; 15 variables were refined to $R = 0.028$, $R_w = 0.029$ GOF = 5.78 [11]. **1** is isomorphous with **2**, with a very similar unit cell and atom positional parameters; a full discussion of the structure will be published separately. The resistivity (direct current) of a single crystal was measured by using an electrometer with a van der Pauw arrangement of four silver epoxide contacts. Magnetic susceptibilities were measured on polycrystalline samples from 4.2 to 300 K by the Faraday technique[12].

A Phenoxy-Bridged Homodinuclear Zn Complex with an Unusual Coordination Sphere; Model Compound for the Active Site of Phospholipase C**

By *Stefan Uhlenbrock* and *Bernt Krebs**

A considerable flexibility of coordination numbers and coordination polyhedra is possible in the chemistry of zinc complexes. The d^{10} electron configuration rules out ligand field stabilizing effects for Zn complexes and often leads to strongly distorted coordination polyhedra. This "entatic state"[1, 2] is also observed in many zinc enzymes, in which the metal center frequently acts as a strong Lewis acid and participates in solvolysis and substitution reactions. Particularly important for this is the ability of the metal center to permit acid catalysis also at pH values at which a protonation cannot occur without participation of Zn^{2+} ions.[3, 4]

Apart from numerous zinc enzymes with one metal bonding site, such as carbonic anhydrase and carboxypeptidase A, enzymes which contain two or more zinc ions at the active site are currently of particular interest. One of these is the important enzyme phospholipase C (PLC), which cleaves phospholipids by hydrolysis.[5] X-ray structural analysis confirmed the presence of three zinc atoms in the active site of PLC obtained from *bacillus cereus*.[6] Two of these atoms are connected to each other through one OH^- group or one H_2O molecule as well as through the carboxylate function of an asparagate unit (Fig. 1). The Zn–Zn distance is 3.3 Å. The third zinc atom, which lies somewhat removed from this dinuclear center, shows, like the other two zinc atoms, a distorted trigonal bipyramidal coordination.

Very little is known about dinuclear zinc complexes that can function as models for zinc systems.[7] Herein we report

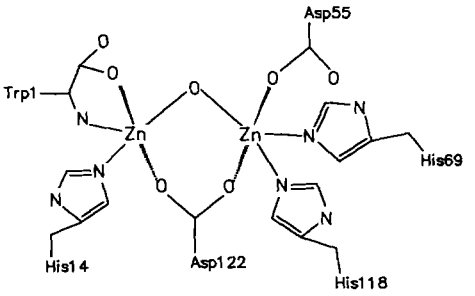

Fig. 1. Structure of the dinuclear unit in the active site of PLC [6].

for the first time on a phenoxy-bridged homodinuclear zinc complex with an entirely biomimetic N_2O ligand sphere, in which the two metal centers are unsymmetrically coordinated. This complex models the dinuclear unit in the active site of PLC. 2,6-Bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenol (Hbbap) was used as the ligand, since it has proved to be suitable for the stabilization of dinuclear metal complexes.[8] The reaction of two equivalents of $Zn(ClO_4)_2 \cdot 6H_2O$ with one equivalent of Hbbap and sodium benzoate (NaOBz) in an ethanol/methanol mixture led to colorless crystals of **1**.

$[Zn_2(bbap)H_2O(\mu\text{-}OBz)](ClO_4)_2 \cdot 4MeOH$ **1**

The cation of **1** is shown in Figure 2.[9] The two zinc ions are bridged by the phenoxy unit of $bbap^-$ and by the carboxylate function of the benzoato ligand. In contrast to a

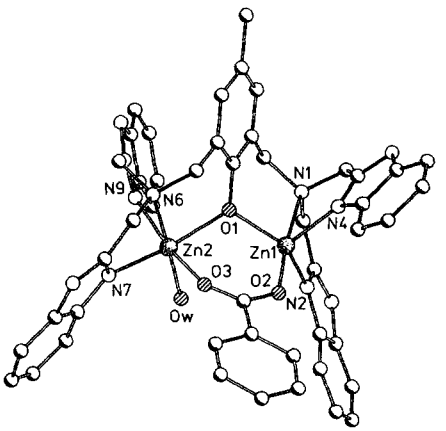

Fig. 2. Structure of the cation $[Zn_2(bbap)H_2O(\mu\text{-}OBz)]^{2+}$ in **1**. Important distances [Å] and angles [°]: Zn1-Zn2 3.443(3), Zn1-O1 1.947(6), Zn1-O2 2.010(6), Zn1-N1 2.480(7), Zn1-N2 2.009(7), Zn1-N4 2.012(7), Zn2-O1 2.099(5), Zn2-O3 2.095(6), Zn2-Ow 2.068(6), Zn2-N6 2.276(7), Zn2-N7 2.141(7), Zn2-N9 2.090(7); Zn1-O1-Zn2 116.6(2).

series of complexes with Hbbap and similar heptadentate chelate ligands, which form dinuclear complexes with fivefold coordinated zinc atoms,[10] the coordination numbers of the two metal centers in **1** are different from each other. Whereas Zn1 is fivefold coordinated (trigonal bipyramid), Zn2 is octahedrally surrounded by four donor atoms of the bbap ligand, one O atom of the benzoato bridge, and one additional bonded H_2O molecule. A coordinated water molecule, which is polarized and can, thus, nucleophilically attack the substrate, is significant for the catalytic procedure

[*] Prof. Dr. B. Krebs, Dipl.-Chem. S. Uhlenbrock

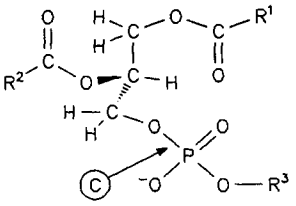
Wilhelm-Klemm-Strasse 8, D-W-4400 Münster (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

and is assumed to be the transition state in a series of zinc enzymes.[3] The analogy between the enzyme PLC and the model complex **1** is also supported by the Zn–Zn distance in **1** (3.443(3) Å), which is comparable with the value determined for the emzyme. As a result of its unusual coordination geometry complex **1** can be regarded as a structural model for the transition state of the catalytic process of the enzyme PLC.

The unsymmetrical coordination (a polarized coordinated H_2O at Zn2, coordination gap at Zn1) offers—irrespective of whether the bond of the phospholipid substrate (Scheme 1) is, as expected, one-sided terminal or bridges both Zn atoms—favorable conditions for a catalytic acid–base reaction in accordance with a concerted zinc hydroxide and/or zinc phosphoryl mechanism.[3]



Scheme 1. Phospholipid substrate. The P–O bond of the substrate marked by the arrow is cleaved by the enzyme PLC. In biochemistry this bond is denoted as bond C (symbolized by ©).

The IR spectrum of **1** shows, apart from the vibrations of the $bbap^-$ ligand and the perchlorate anion, also the vibrations of the carboxylate group of the benzoate unit. The symmetric and antisymmetric stretching vibrations of this unit are 1440 and 1590 cm^{-1}, respectively. The difference of 150 cm^{-1} confirms the bidentate bridging coordination of the carboxylate group.

The objective of future work is the development of functional models for the cleavage of phospholipids based on complex **1**. As the first attempts at the catalytic cleavage of different phosphoric acid esters as substrates have shown, the prospects are promising. The systematic improvement of the specificity of **1** by ligand variation is a possible starting point for the modeling of a functional biomimetic dimetal center in a similar way as was recently reported[7a, 11] in the first successful approaches for mononuclear metal centers in carbonic anhydrase.

Experimental Procedure

$Zn(ClO_4)_2 \cdot 6H_2O$ (0.54 g, 1.4 mmol) was dissolved in methanol (10 mL) and added to a solution of Hbbap (0.5 g, 0.7 mmol) in ethanol (15 mL). After the addition of sodium benzoate (0.1 g, 0.7 mmol) in methanol (10 mL), colorless crystals of **1** were formed.

Tetraalkynylmethanes: Synthesis of Diethynyldipropargyl- and Tetrapropargylmethane**

By *Uwe Bunz*,* *K. Peter C. Vollhardt*, and *Jennifer S. Ho*

We report here on the synthesis of the compounds diethynyldipropargylmethane **5** and tetrapropargylmethane **6**.[1] These molecules may serve as a new type of monomer for highly crosslinked and electroactive hydrocarbon polymers,[2] as initiator nuclei and building blocks for dendrimers,[3] as tetrafunctional complex ligands (possibly for use in the construction of organometallic networks and clusters), and as starting materials for the synthesis of new types of tetrakis(polyalkyne)s. As a result of their topology and functionality **5** and **6** could be suitable precursors to building blocks for molecular electronic devices;[4] an investigation of the interaction between the four C–C triple bonds should be instructive.[5] In addition, **5** and **6** are suitable substrates for

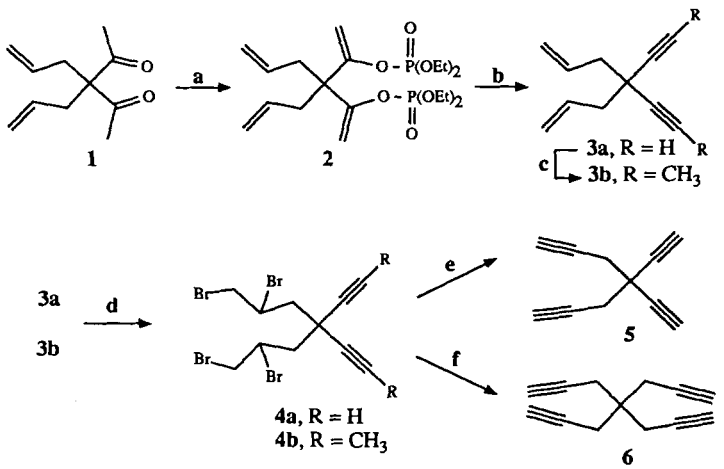
[**] This work was supported by the Director of the Office of Energy Research, Office of Basic Energy Sciences, Chemical Science Division of the U.S. Department of Energy (DE-AC03-76SF00098). U.B. thanks the Deutsche Forschungsgemeinschaft for a postdoctoral fellowship. The X-ray crystal structure analysis of 6 was carried out by Dr. F. J. Hollander, the departmental crystallographer. According to the IUPAC rules, the title compounds are designated 4,4-diethynyl-1,6-heptadiyne and 4,4-di(2-propynyl)-1,6-heptadiyne. The semisystematic names diethynyldipropargylmethane and tetrapropargylmethane, however, are easier to remember and equally unequivocal.

the construction of new spirocyclic systems[6] using cobalt-mediated [2 + 2 + 2] cycloaddition. Because of their high level of symmetry these molecules are also aesthetically attractive.

A general route to **5** and **6** is provided by the preparation of the diyne **3a**. Negishi[7] developed an efficient method for the conversion of methyl ketones into terminal alkynes, which we have been able to modify into a one-pot synthesis of **3a**. Compound **1**[8] was treated with 2.1 equivalents of lithium diisopropylamide (LDA) and the resulting bisenolate converted with diethylchlorophosphate into bis(enolphosphate) **2** (Scheme 1). Treatment of **2**, which was not isolated,



Scheme 1. a) 2.1 equiv LDA, −78 °C → 20 °C, 1 h, then 2.2 equiv ClP = O(OEt)$_2$, 3 h; b) 4.3 equiv LDA, −78 °C → 20 °C, 2 h, then 5 N HCl (**3a**: 59%); c) 2 equiv *n*BuLi, then CH_3I (**3b**: 82%); d) 2 equiv Br_2, CH_2Cl_2, −78 °C (**4a**: 82%, **4b**: 41%); e) **4a**, 11 equiv $NaNH_2$ in liq. NH_3, then 5 N HCl (**5**: 67%); f) **4b**, 45 equiv KNH_2 in liq. NH_3, 8 h, then 5 N HCl (**6**: 18%).

in a further step with an excess of LDA afforded **3a** in 61% yield. In spite of the presence of the ethynyl groups[9] the double bonds in **3a** can be selectively brominated at low temperature; thus, the crystalline tetrabromide **4a**[10] was formed in high yield as a pair of diastereomers (ratio (*d,l*:*meso*) 1:1), as shown by integration of the signals of the alkyne protons in the ^{1}H NMR spectrum. Dehydrohalogenation of **4a** with sodium amide in liquid ammonia gave **5** in 66% yield. The tetraalkyne **5**, stable in air, separates out as a colorless oil; crystallization takes place on standing at approximately 5 °C. Compound **5** is not miscible with pentane and hexane at every concentration but is completely miscible with chloroform or dichloromethane.

Attempts to obtain **6** by exhaustive alkynylation of tetra(bromomethyl)methane were unsuccessful.[4] *n*-Butyllithium effected double deprotonation of the diyne **3a**; subsequent reaction with CH_3I gave **3b**,[11] which was converted to the crystalline tetrabromide **4b**[10] by reaction with bromine. Compound **4b**, analogous to **4a**, was also obtained as a mixture of two diastereomers in a ratio of about 1:1. Potassium amide (in a tenfold excess per alkyne group) in liquid ammonia effected both complete dehydrohalogenation and isomerization to the all-terminal potassium salt of **6**. Finally, tetrapropargylmethane **6** was obtained in 18% yield after aqueous acidic workup.[12] This compound is only slightly sensitive to oxygen and hardly soluble in pentane and hexane, but very soluble in chloroform and dichloromethane.

The ^{13}C NMR spectrum of **5** shows six signals, of which four can be assigned to the two pairs of nonequivalent acetylene groups; in addition, the nondecoupled ^{13}C NMR spectrum shows that the signal of the terminal acetylene carbon atom, which is shifted to lower field, must be assigned to the heptadiyne unit as a result of the fine splitting expected for the propargyl group. Four signals are observed in the broadband-decoupled ^{13}C NMR spectrum of **6**. The alkyne resonances in the proton-coupled ^{13}C NMR spectrum display coupling constants of the expected magnitude[13] (Table 1). The IR spectrum shows few signals, with characteristic bands at 3304, 2915, and 2121 cm^{-1}; no signals were recorded in the range 2100 to 1450 cm^{-1}.

Table 1. Physical data for **3a**, **5**, and **6** [a].

3a: B.p. 38–39 °C (2.2 Torr); IR (KBr): ν[cm^{-1}] = 3298, 3078, 3011, 2984, 2915, 1643, 1565, 1549, 1512, 993; ^{1}H NMR ($CDCl_3$): δ = 2.22 (s, 2H; alkyne H), 2.35 (d, ^3J(H,H) = 7.1 Hz, 4H; CH_2-CH=CH_2), 5.09–5.21 (m, 4H; CH_2-CH=CH_2), 5.84–6.00 (m, 2H; CH_2-CH=CH_2); ^{13}C NMR ($CDCl_3$): δ = 34.19 (C-4), 44.62 (CH_2-CH=CH_2), 70.44 (C≡*C*-H), 84.05 (*C*≡C-H), 118.55 (CH_2-CH=*C*H_2), 132.70 (CH_2-*C*H=CH_2); MS (70 eV): *m/z* 128 ($M^{\oplus}$ − CH_4, 70%), 115 (31), 102 ($M^{\oplus}$ − C_3H_6, 33), 77 (100); high-resolution MS: *m/z* 143.0857 (calculated for $M^{\oplus}$ − H, $C_{11}H_{11}$: *m/z* 143.0861).

5: B.p. 31 °C (0.05 Torr); IR (KBr): ν[cm^{-1}] = 3307, 3294, 2947, 2921, 2123, 1428, 1294, 1102; ^{1}H-NMR ($CDCl_3$): δ = 2.13 (t, ^4J(H,H) = 2.6 Hz, 2H; 1-, 7-H), 2.39 (s, 2H; C≡C-H), 2.72 (d, ^4J(H,H) = 2.6 Hz, 4H; 3-, 5-H$_2$); ^{13}C NMR ($CDCl_3$): δ = 30.48 (t, ^1J(C,H) = 136.2 Hz; C-3, -5), 33.61 (s; C-4, central C atom), 71.26 (d, ^1J(C,H) = 251.7 Hz; C≡*C*-H), 72.01 (dt, ^1J(C,H) = 249.2 Hz; C-1, -7), 78.39 (dt, ^2J(C,H) = 49.9 Hz; C-2, -6), 82.35 (d quint d, ^2J(C,H) = 49.9 Hz; *C*≡C-H); MS (70 eV): *m/z* 140 ($M^{\oplus}$, 18%), 139 ($M^{\oplus}$ − H, 100), 114 ($M^{\oplus}$ − C_2H_2, 19), 101 ($M^{\oplus}$ − C_3H_3, 29); high-resolution MS: *m/z* 139.0544 (calculated for $M^{\oplus}$ − H, $C_{11}H_7$: *m/z* 139.0547).

6: M.p. 126 °C; IR (KBr): ν[cm^{-1}] = 3304, 2934, 2915, 2120, 1434, 1327; ^{1}H NMR ($CDCl_3$): δ = 2.04 (t, ^4J(H,H) = 2.6 Hz, 4H; CH_2-C≡C-*H*), 2.47 (d, ^4J(H,H) = 2.6 Hz, 8H; CH_2-C≡C-H); ^{13}C NMR ($CDCl_3$); δ = 25.51 (t oct, ^1J(C,H) = 132.5 Hz; CH_2-C≡C-H), 39.29 (s; C-4, central C atom), 71.18 (dt, ^1J(C,H) = 247.2 Hz; CH_2-C≡*C*-H), 80.02 (dt, ^2J(C,H) = 49.9 Hz; CH_2-*C*≡C-H); MS (70 eV): *m/z* 165 (12%), 152 ($M^{\oplus}$ − CH_4, 22), 141 (9), 128 ($M^{\oplus}$ − C_3H_4, 100), 115 (12), 102 (28).

[a] ^{1}H and ^{13}C NMR spectra were recorded at 400 and 100 MHz, respectively.

The differences in the mass spectra of **5** and **6** are remarkable. In the case of **5** the (M^+−H) signal (*m/z* 139) appears as the base peak and the molecular ion (*m/z* 140) can be observed, whereas for **6** the cleavage of a C_3H_4 fragment (*m/z* 40) is immediate: the signal at *m/z* 128 forms the base peak, and that of the molecular ion is not visible. The interpretation of this observation becomes clear when the results from pyrolysis of 1,5-hexadiyne (**7**) and 1,6-heptadiyne (**8**) are taken into consideration. Compound **7** rearranges, according to Huntsman and Wristers,[14a] with an activation energy of 34 kcal mol^{-1}, whereas **8**, after overcoming an energy barrier of about 50 kcal mol^{-1}, loses allene by way of a retro-ene reaction with formation of vinylacetylene. The same behavior is observed in the mass spectrometric investigations of these compounds;[15] accordingly, **6** behaves in analogous fashion to **8**. It would appear, however, that the retro-ene reaction of **5** does not take place because of the much higher activation energy; the hexadiyne rearrangement is thus preferred. The appearance of the (M^+−C_2H_2) ion with *m/z* 114 supports this argument, as the parent system **7**[14b] also undergoes elimination of acetylene in the mass spectrometer to give an (M^+−C_2H_2) ion (*m/z* 52). The latter is presumably formed by the [2 + 2] retrocyclization, as described by Huntsman and Wristers for the rearrangement of bis(*exo*-methylene)cyclobutene. Nevertheless, the signal for the molecular ion of **7**, in contrast to that of **5**, is

markedly more intense than the signal for the (M^+–H) fragment.

Initial attempts to effect rearrangement of **5** with KO*t*Bu in dimethylsulfoxide (DMSO)[16] appear to be successful. GC-MS analysis shows that, in addition to approximately 30% starting material, five new isomers are present: we have indications that one of these isomers is a dimethyl-substituted tetraethynylmethane.[17] Preliminary investigations also show that tetraalkyne **5** readily forms complexes with transition metals.

Because of the novelty of these compounds a crystal structure analysis[18] of **6** was conducted (Fig. 1). The deviation

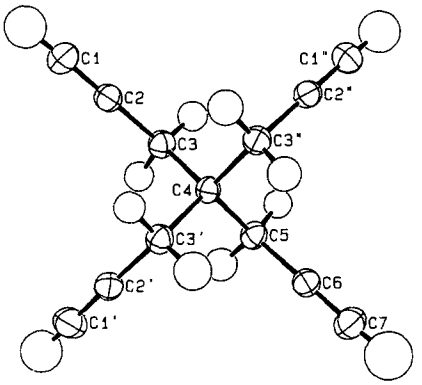


Fig. 1. Crystal structure of **6**[18]. Important bond lengths [Å] and angles [°]: C1-C2 1.183(2), C2-C3 1.462(2), C3-C4 1.545(2); C1-C2-C3 179.5(2), C2-C3-C4 114.6(1), C3-C4-C5 106.0(1), C3-C4-C3' 111.1(1).

from molecular D_{2d} symmetry is minimal; the bond angles at the symmetrically substituted C-4 are not 109.4° (ideal tetrahedral angle), rather two pairs of 106.0(1)° and 111.2(1)°. Both molecular mirror planes are at an angle of 93° to each other; nevertheless, it cannot be ruled out that this is an artefact. The lengths of the acetylenic [1.183(2) Å] and the propargylic [1.463(2) Å] C–C bonds are in excellent agreement with known values.[19]

The packing of **6** in the crystal (Fig. 2) leads to layers parallel to the *bc* plane, within which the shortest intermolecular C–C distance (between C-1 and C-1″) amounts to 3.366(2) Å. The alkyne groups with this short contact are not aligned parallel. The alkyne groups of two neighboring molecules lying parallel to each other are more than 3.5 Å apart.

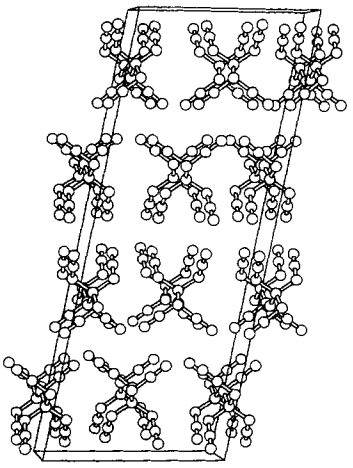

Fig. 2. Packing of **6** in the crystal [18]. The viewing direction is along the crystallographic b axis

Experimental Procedure

3a: To a solution of LDA, prepared from diisopropylamine (12.0 g, 119 mmol) in THF (100 mL) and *n*BuLi (53 mL, 116 mmol, 2.2 M solution in hexane), was added **1** (10.0 g, 55.5 mmol) at −78 °C; after warming to room temperature the mixture was stirred for 1 h, then treated with diethylchlorophosphate (21.1 g, 122 mmol) at −78 °C. The resulting mixture was allowed to warm to room temperature and stirred for 3 h. This solution was cooled to −78 °C and then added to a solution of LDA, prepared from diisopropylamine (24.1 g, 238 mmol) and *n*BuLi (96 mL, 212 mmol, 2.2 M solution in hexane), in THF (200 mL) at the same temperature. After 2 h reaction at room temperature the reaction mixture was hydrolyzed with 5 N aqueous HCl. Workup by distillation gave **3a** (4.67 g, 59%) as a colorless oil.

5: A suspension of $NaNH_2$ (from 2.75 g (120 mmol) Na) in liquid ammonia was prepared according to [20]. A solution of **4a** (4.94 g, 10.7 mmol) in 10 mL ether was then added. The reaction mixtrue was held at reflux (−33 °C) for 5 h. Aqueous acidic workup and distillation gave **5** (989 mg, 67%) as a colorless oil.

6: A solution of potassium amide was prepared from potassium (4.30 g, 110 mmol) in liquid ammonia (ca. 200 mL)[20]. To this solution was added **4b** [10] (1.20 g, 2.44 mmol) in ether (10 mL). The mixture was stirred for 8 h at −33 °C. Workup as for **5** followed by sublimation at a bath temperature of ca. 30–70 °C (0.05 Torr) afforded **6** (74.0 mg, 18%).

[7] E. Negishi, A. O. King, J. M. Tour, *Organic Syntheses, Coll. Vol. 7*, Wiley, New York, **1990**, p. 63; this method was used for the synthesis of diethynylcubane: P. Eaton, D. Stoessel, *J. Org. Chem.* **1991**, *56*, 5138.
[8] R. B. Davis, P. Hurd, *J. Am. Chem. Soc.* **1955**, *77*, 3284.
[9] It is known that triple bonds are inert toward bromine at −78 °C; lithium acetylide can be converted under these conditions to bromoacetylene without difficulty: L. Brandsma, *Preparative Acetylic Chemistry*, 2nd ed., Elsevier, Amsterdam, **1988**, p.143, and references therein.
[10] The bromination of **3a** and **3b** was carried out at −78 °C in CH_2Cl_2; the solution of bromine in CH_2Cl_2 was also cooled beforehand to this temperature: **4a** (m.p. 72–74 °C, from CH_2Cl_2/hexane) 82%; **4b** (m.p. 120–130 °C from CH_2Cl_2/hexane) 41%; both compounds exist as mixtures of diastereoisomers and have been fully characterized by their spectroscopic data and combustion analysis.
[11] The methylation resulted from double deprotonation of **3a** with *n*BuLi in THF at −30 °C; 3 equiv CH_3I were added and the reaction mixture stirred 12 h at 20 °C. Hydrolysis and distillation afforded **3b** in 82% yield; the latter was characterized by its spectroscopic data and high-resolution mass spectrum.
[12] The relatively low yield of 18% can be explained on the grounds that there are ten reaction steps before the hydrolysis; the average yield of any given step is 84%.

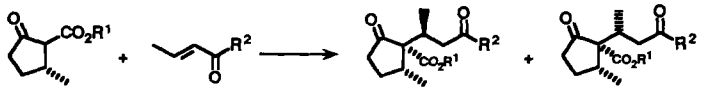
Diastereoselective Three-Center Michael Addition of β-Ketoesters to Prostereogenic α,β-Unsaturated Carbonyl Compounds Catalyzed by K_2CO_3 or Cs_2CO_3**

By *Nicole Ouvrard, Jean Rodriguez,* and Maurice Santelli*

In our investigations[1] on the synthesis of the Prelog–Djerassi lactone[2] it appeared that another attractive and direct way for the preparation of the key intermediate would be the Michael addition[3] of a β-ketoester to an α,β-unsaturated carbonyl compound. The (2*S*,3*R*)-β-ketoesters **1**[4] serve as a model compounds for our study (Scheme 1). The correct (2*R*,3*S*) enantiomer can be formed from readily available (*S*)-(−)-pulegone.[1]



1a, R^1 = Me **2a**, R^2 = Me
1b, R^1 = *t*Bu **2b**, R^2 = H
1c, R^1 = Bz

3

4
a, $R^1 = R^2$ = Me
b, R^1 = *t*Bu, R^2 = H
c, R^1 = Bz, R^2 = H
d, R^1 = *t*Bu, R^2 = Me

Scheme 1. Michael addition of β-ketoesters to α,β-unsaturated compounds.

The diastereoselective Michael addition has been studied extensively in recent years and constitutes one of the most useful methods for carbon–carbon bond formation.[5] We wish to report here on the highly diastereoselective, three-center Michael addition[6] of simple chiral β-ketoesters with a prostereogenic α,β-unsaturated carbonyl compound; this provides a stereocontrolled route to compounds with three contiguous stereogenic centers.[7]

The K_2CO_3 or Cs_2CO_3 catalyzed reaction of **1** with Michael acceptors **2** in acetone provides **3**,[8] one of the four possible diastereomers, with high selectivity (entries 1–7, Table 1).[9] Compounds **3** arise in a reaction with *lk* relative topicity[10] via a cyclic synclinal transition state **I**[5b] (Scheme 2).

Table 1. Michael addition of **1** to **2** in the presence of 0.5 equivalent of K_2CO_3 or Cs_2CO_3.

Entry	1	2	R^1	R^2	Conditions [a]	Isolated yields [%]	3:4 [c]
1	a	a	Me	Me	K_2CO_3, 40 °C, 6 h	[b]	70:30

I **3**

II, Z = CO_2R^1 **4**

Scheme 2. Possible cyclic transition states **I** and **II**.

Examination of molecular models shows that in transition state **II** there is substantial nonbonding interaction between the alkoxycarbonyl group of the Michael donor and the carbonyl part of the α,β-unsaturated function (Scheme 2). This finding is supported by the observed effect of R^1 and R^2 on the diastereoselectivity of the reaction at room temperature or below. The ratio **3**:**4** is only 85:15 for R^1 = Me, R^2 = H (entry 3), while **3** is obtained almost exclusively when R^1 = *t*Bu or Bz, R^2 = H (entries 4, 6, and 7).

In all cases, the diastereofacial control is total; this is probably a consequence of the almost planar structure of the enolate derived from **1**. By analogy with related systems, one can expect that this endocyclic enolate will be attacked exclusively from the face opposite to the methyl substituent.[11] The highest diastereoselectivity is obtained with K_2CO_3 at room temperature (entries 4 and 6) or at −30 °C when Cs_2CO_3 is used as catalyst (entry 7). It is of interest to note that poor or no stereoselectivity was reported previously for the addition of simple cyclic or acyclic β-ketoesters to methyl ethylidenemalonate with K_2CO_3 as base.[7a] To our knowledge, our results constitute the first example of three-center

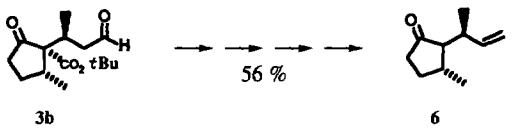
diastereoselectivity for five-membered carbocyclic ring systems.[5b, 6]

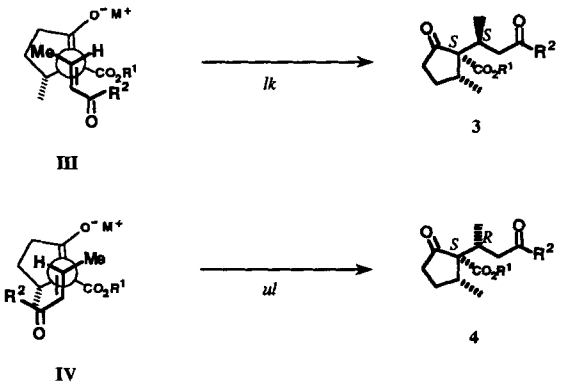
The configurations of **3** and **4** were confirmed by chemical correlation with the known γ,δ-unsaturated ketone **6**.[12] Preparation of **6** from **3b** was straightforward (Scheme 3): selective reduction of the aldehyde functionality ($NaBH_4$, *i*PrOH, room temperature, 57%[12b]) was followed by decarboxylation and selenoxide elimination (*o*-nitrophenylselenocyanate, Bu_3P, CH_2Cl_2; 15% *p*TsOH, C_6H_6, reflux, then H_2O_2, THF, 72% overall[12c]). The spectroscopic and analytical data of **6** prepared in this way were identical to those of a sample synthesized previously by a different route.[12]



3b **6**

Scheme 3. Preparation of ketone **6**.

A slight increase in temperature affects the diastereoselectivity; the reaction then most likely proceeds to a certain extent via transition state **II**. The other explanation, equilibration of the products, can be ruled out. A mixture of **3a** and **4a** in the ratio 60:40 did not equilibrate when treated with K_2CO_3 in acetone for seven days (compare entries 1 and 2, 4 and 5). A specific complexing agent has a greater effect on the diastereoselectivity. Indeed, the complexation of the metal ion by either a crown ether (entries 8 and 9) or by Kryptofix 222 (entries 10–12) results in a reverse diastereoselectivity; **4**, arising from the *ul* relative topicity, is obtained with high selectivity. Under these conditions lower temperature is required because of the enhanced basicity and potential side reactions. The ratio **3**:**4** is independent of the reaction time, indicating that the Michael addition remains under kinetic control. These results[13] provide evidence for the participation of the metal ion in the stabilization of the cyclic transition state **I** (Scheme 2). The results can be best explained by assuming that in the presence of a complexing agent, the bulky complex formed by the specific cryptand and the cation (M^+ in Scheme 4) favors the ion pair dissociation[14] and suppresses the coordination between the enolate and the α,β-unsaturated compound. These two facts are in agreement with an open antiperiplanar transition state[15] **IV** rather than **III** in which the nonbonding interaction between the ester group of the Michael donor and the carbonyl part of the α,β-unsaturated function is present (Scheme 4).



III **3**

IV **4**

Scheme 4. Possible acyclic transition states **III** and **IV**.

The diastereoselectivity increases significantly when R^2 = Me instead of R^2 = H (cf. entries 10 and 12).

The results presented here are in accord with a cyclic transition state characterized by a chelate complex between the enolate and the carbonyl functions; this is an important requisite for stereocontrol under kinetic conditions. This proposition is supported by the observed effect of a specific complexing agent which causes the reaction to proceed through a nonchelated antiperiplanar transition state giving rise to a reverse diastereoselectivity. The base-catalyzed Michael addition of the β-ketoesters **1** to a prostereogenic α,β-unsaturated carbonyl compound **2** has high diastereoselectivity and offers a synthetically attractive approach to the optically active Prelog–Djerassi lactone and related compounds.

meta-Phenylene Units as Conjugation Barriers in Phenylenevinylene Chains

By *Heike Gregorius, Martin Baumgarten, Ronald Reuter, Nikolai Tyutyulkov*, and *Klaus Müllen**

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

The incorporation of *meta*-phenylene units into conjugated oligomers and polymers has wide-reaching effects on their properties. Alongside the commonly observed increase in solubility[1] is the formation of "non-Kekulé" structures, which hinder the spin pairing in potential high-spin systems such as **1**.[2] In compounds with singlet states, *meta* systems such as **2** and **3** are expected at first glance to display extended π conjugation just like the "*para*" analogues (for example, **4**). We can, however, now show that for the neutral and ionic (doped) derivatives of **2** and **3** the *meta*-phenylene unit interrupts the conjugative interaction and induces charge localization. As a result, intervalence bands appear in the absorption spectra of the charged species at extremely high wavelengths in the near-IR region.

The *meta*-distyrylbenzene **3a** (= **2b**) and the homologous oligo(*meta*-phenylenevinylene)s **3b–3d** were each synthesized by Wittig olefination. In this process the use of 3,5-di-*tert*-butylphenyl terminal groups to increase the solubility (as in the preparation of the *para* analogues **4**) was invaluable.[3] A Wittig reaction with **5**[4] and 3-methylbenzaldehyde yields the one styryl unit longer 3,5-di-*tert*-butyl-3′-methylstilbene, which on bromination with *N*-bromosuccinimide affords both the phosphonium salt **6** and the corresponding aldehyde **8** formed in a Sommelet reaction. Oligomers with even *n* (**3b** and **3d**) arise in the reaction of stilbene-3,3′-bis(methyltriphosphonium bromide)[5] with the aldehydes **7**[6] and **8**, respectively, whereas those with uneven *n* (**3a** and **3c**) are formed from isoterephthaldialdehyde and the phosphonium salts **5** and **6**, respectively. Subsequent isomerization with iodine yields the corresponding all-*trans* compounds **3a–d**.[7]

The new hydrocarbons were electrochemically and chemically (with alkali metals) reduced. The electron-transfer products were characterized by cyclic voltammetry, electron absorption spectroscopy (Table 1, Fig. 1), and ESR and NMR spectroscopy.

Table 1. Absorption maxima λ_{max} [nm] of neutral and charged oligo(*meta*-phenylenevinylene)s.

Compound	λ_{max} (neutral) ($CHCl_3$, T = 300 K)		λ_{max} (monoanion) (THF/K^+, T = 300 K)		
stilbene	309		496	699	
3a	240	306	476	636	1810
3b	239	306	493	653	1864
3c	240	312	487	667	1984
3d	242	312	484	685	1983

The *meta*-distyrylbenzene **3a** has a distinctly higher redox activity than *para*-distyrylbenzene **4a**: whereas **4a** is reduced by alkali metals only to the dianion,[8] **3a** yields the tetraanion, which can be detected chemically by trapping it with dimethylsulfate;[9] in a well-resolved ^1H NMR spectrum the signals of the olefinic protons appear at very high field (δ = 2.5–3.5).

The cyclic voltammetry shows that the first reduction potential of **3a–3d** is almost independent of the number of repeating units (**3a**: −2.41, **3b**: −2.29, **3c**: −2.29, **3d**: −2.34 V). These values are similar to those for stilbene,

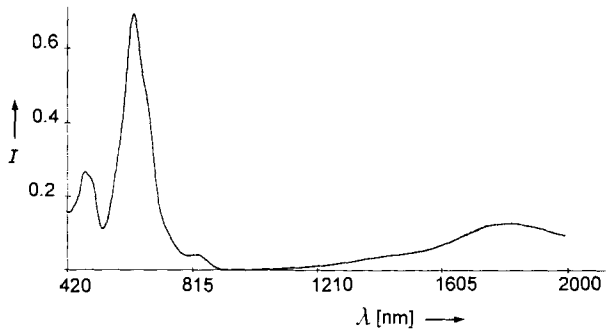

Fig. 1. Absorption spectrum of $3a^{\bullet -}$ (THF/K, $T = 300$ K). I = relative intensity in arbitrary units.

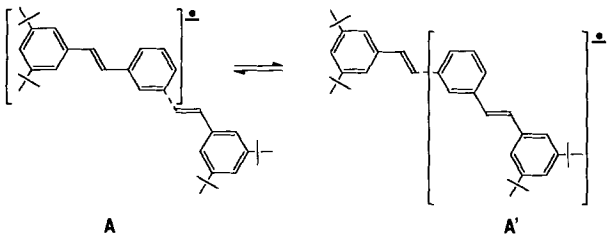
whose first reduction potential is at -2.45 V (for comparison see **4**[3]).[10]

Even more drastic differences between *meta* and *para* systems are observed in the absorption spectra of the reduction products: Whereas the radical anion $4a^{\bullet -}/K^+$ has its longest wavelength band at $\lambda_{max} = 1085$ nm, $3a^{\bullet -}/K^+$ absorbs at $\lambda_{max} = 1810$ nm(!). Moreover, whereas in the homologous series of the radical anions of the *para* compounds **4** an increasing bathochromic shift is observed with extension of the chain,[11] the position of the bands in the *meta* series **3** is largely independent of the chain length.[12] Apart from the longest wavelength band, the spectra of the monoanions of the *meta* species agree with the spectrum of the stilbene monoanion in each case ($\lambda_{max} = 496$, 699 nm).

These results are readily explained by a localization of the charge on a stilbene unit in the *meta*-phenylenevinylenes. The ion $3a^{\bullet -}$ can be described by structure **A**, which contains a charged and an uncharged unit. The longest wavelength absorption of $3a^{\bullet -}$ at 1810 nm is thus attributable to an intervalence or charge-transfer band. Both the extreme broadening of this band and its bathochromic shift of about 140 nm on lowering the temperature (200 K) are in accord with this assignment.

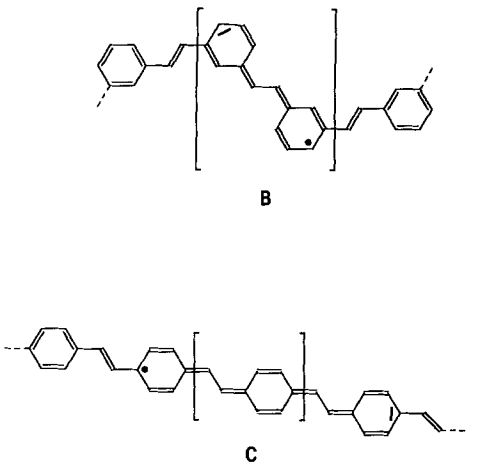
A calculation of the absorption spectrum of the paramagnetic species $3a^{\bullet -}$ with an open-shell PPP SCF/CI procedure[13] does not reproduce the extremely long wavelength band and the two characteristic VIS transitions at approximately 500 and 700 nm. If, however, a localized structure **A** (Scheme 1) is assumed and a decoupling (e.g., a significant twisting about the formal single bond) of the uncharged styryl group is taken into account, the calculation yields a band at $\lambda = 1740$ nm as charge-transfer transition between the charged stilbene subunit and the uncharged styryl group.



Scheme 1. Charge delocalization in $3a^{\bullet -}$.

The type of charge and spin-density distribution in $3^{\bullet -}$ can also be determined by ESR/ENDOR spectroscopy. Identical ESR/ENDOR spectra each with only three hyperfine couplings [0.540 (2H), 0.267 (4H), 0.137 mT (4H)] were recorded for the oligomers $3b^{\bullet -}$, $3c^{\bullet -}$, and $3d^{\bullet -}$. The hyperfine coupling constants and their multiplicity leave no doubt that the spin density is localized in a central stilbene unit. Only for the *meta*-distyrylbenzene radical anion $3a^{\bullet -}$ (K^+, 2-methyltetrahydrofuran, $-78\,^{\circ}C$) can an electron delocalization be detected. The contradiction between the results from ESR and VIS/near-IR spectroscopy for $3a^{\bullet -}$ is resolved if the different timescales of the two experiments are considered (10^{-7} and $10^{-11}\,s^{-1}$).[14] A rapid charge fluctuation between **A** and **A'** gives rise to the ESR findings (Scheme 1).

The characterization of the neutral and anionic *meta*-phenylenevinylenes **3** is in accord with a conjugation barrier caused by topological features: the resonance structures cannot be formulated over the whole chain, but only over each stilbene unit. This resonance form represents a polaron in a poly(*meta*-phenylenevinylene) chain (**B** in Scheme 2). In contrast, in poly(*para*-phenylenevinylene) chains polaron structures can be formulated which contain different numbers of quinoid arene rings (**C**).



Scheme 2. Structures of polarons of poly(*meta*-phenylenevinylene)s and poly(*para*-phenylenevinylene)s.

The special situation of conjugated systems with *meta*-phenylene units documented here suggests corollaries: The type of charge distribution in doped polymers often serves as a criterium for the description of charge defects such as polarons and bipolarons,[15] which are considered the charge carriers when conductivity is present. Furthermore, it has been postulated that on doping *meta*-phenylene systems such as **2**, ferromagnetism can arise if the two side chains are sufficiently long for bipolaron formation.[16] We shall therefore soon report on the behavior of high molecular weight compounds of series **2** and **3**.

Structure of the Lowest Temperature Phase of the Solid Benzene–Hexafluorobenzene Adduct**

By *Jeffrey Huw Williams,* Jeremy Karl Cockcroft,* and *Andrew Nicholas Fitch*

We report the results of complementary high-resolution powder diffraction studies by neutron and synchrotron radiation of the solid phases of C_6H_6:C_6F_6 including the ab-initio structure determination of the lowest temperature phase IV. Although in the last few years powder diffraction has been used to solve the structures of inorganic materials or compounds containing second-row or heavier elements,[1, 2] we believe that this work represents a significant achievement by demonstrating that moderately complicated structures of organic compounds can be solved directly by powder methods for those cases where single-crystal techniques are not applicable.

[**] We thank the ILL Grenoble and the SERC Daresbury Laboratory for the provision of neutron and synchrotron-radiation beam time, respectively, and the European Community for financial support.

The charge distributions of the simple aromatic molecules benzene and hexafluorobenzene are of considerable interest; their symmetry implies that all odd electric moments vanish and that there is just one independent quadrupole moment. The large magnitudes and the difference in the polarity of the quadrupole moments of benzene and hexafluorobenzene[3] imply that the electrostatic interaction between these two molecules is particularly strong. Indeed, mixing equimolar quantities of C_6H_6 and C_6F_6 yields a crystalline solid with a melting point of 24 °C.[4]

From calorimetric and NMR experiments performed on the deuterated analogue,[5] three thermodynamic anomalies are observed at 199, 247.5, and 272 K. To understand the origin of these phase transitions, one of us has investigated the proton dynamics of the benzene partner in a series of quasi-elastic and inelastic neutron scattering experiments.[6, 7] A neutron and X-ray scattering study of molten C_6H_6:C_6F_6 indicated the existence of dimers in the liquid state.[8] Structural studies of the solid are limited to a single-crystal X-ray investigation of the disordered highest temperature phase I, which is made up of columns of alternating benzene and hexafluorobenzene molecules arranged perpendicular to the threefold axis in a rhombohedral lattice.[9] Single crystals of phase I do not survive cooling below the phase transition temperature of 272 K; thus the low-temperature structures have remained unsolved.

Initial neutron diffraction studies ($\lambda = 2.99$ Å) of a deuterated sample were only partially successful; because of the lower resolution and the similar scattering lengths of D and

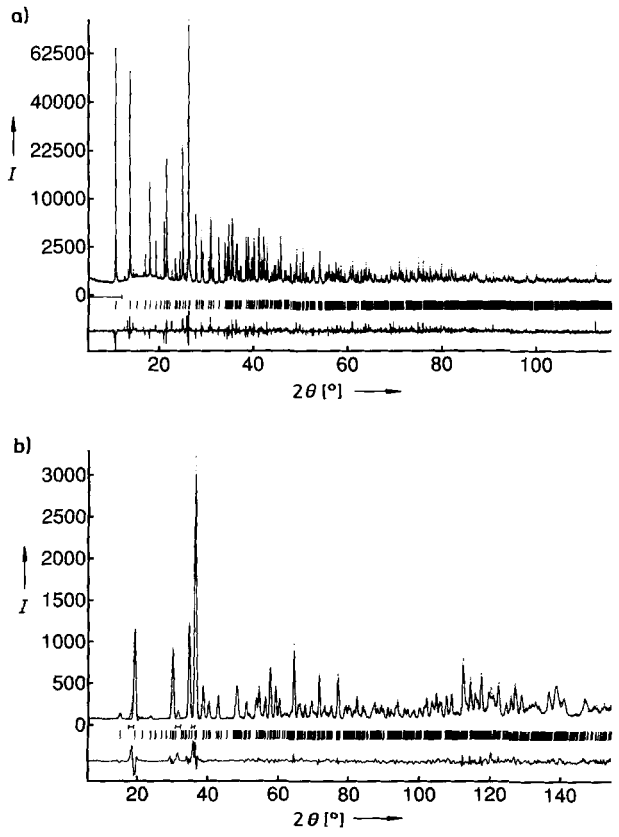

Fig. 1. Study of phase IV of C_6H_6:C_6F_6 a) with synchrotron radiation at 30 K, b) with neutron radiation at 1.5 K. The vertical ticks between the observed and calculated diffraction profiles (top dotted and solid lines, respectively) and the difference profile (bottom) indicate the reflection positions (956 and 567 for a) and b), respectively). A square-root scale has been used for the intensity of a) to show the quality of the weaker high-angle data. The residual phase III is clearly visible in the difference plot.

Table 1. Results of the indexing of the diffraction profiles obtained with synchrotron radiation with the program FZON [10] for the benzene–hexafluorobenzene phases II–IV [a].

Phase	T [K]	a [Å]	b [Å]	c [Å]	α [°]	β [°]	γ [°]	V [Å^3]	Z	Lines indexed	M_{20}	Space group
IV [b]	30	9.516	7.429	7.537	90	95.596	90	530	2	14	225	$P2_1/a$
III	215	6.380	12.338	7.295	93.994	96.732	91.849	568	2	20	246	$P\bar{1}$
II	260	6.631	12.330	7.302	90	99.666	90	589	2	20	230	$I2/m$
I [9]	279	11.952	11.952	7.238	90	90	120	897	3	-	-	$R\bar{3}m$

[a] The program FZON requires the positions of twenty low-angle reflections. The figure of merit, M_{20}, is particularly impressive, leaving no doubt as to the correct indexing of the patterns, and demonstrating the very high quality of the data from the 2.3 diffractometer [11]. With this instrument the peak positions are insensitive to the effects of specimen transparency and diffractometer misalignment, and can therefore be obtained very accurately. [b] For phase IV, indexing was successful despite the inclusion of six peaks from residual phase III whose presence in the sample was unsuspected until the output of FZON was analyzed and subsequent measurements on phase III were carried out.

F, the unit cells of phases II and IV obtained from standard indexing programs were only subcells, and no solution was found for phase III. Complementary synchrotron-radiation measurements were therefore made. These high-quality diffraction patterns were easily indexed yielding definitive unit cells for all phases (Table 1), despite peaks from residual phase III remaining in the diffraction pattern of phase IV.

Assuming phase IV to be the most ordered, we attempted the determination of the structure of this phase first. The intensity profile of the synchrotron radiation was decomposed into individual F^2_{hkl} by the method of Le Bail et al.[16] These were used as input in the direct methods program SIR88.[17] The nine most intense peaks found in the electron density map corresponded to all the C and F atoms required to define the crystal structure, which is composed of the two types of rings, each centered on a point of inversion. No additional refinement or difference procedures were required.

Separate refinements of the structure of phase IV were made with the synchrotron-radiation data (30 K) and the neutron data (1.5 K) (Fig. 1). The fit to the neutron data, which contains very little residual phase III, is better (Table 2). Figure 2 shows the structure, which is based on columns of equispaced, alternating C_6H_6 and C_6F_6 molecules running parallel with the c axis. The columnar nature

[a] Temperature factor = $\exp(-B \sin^2\theta/\lambda^2)$

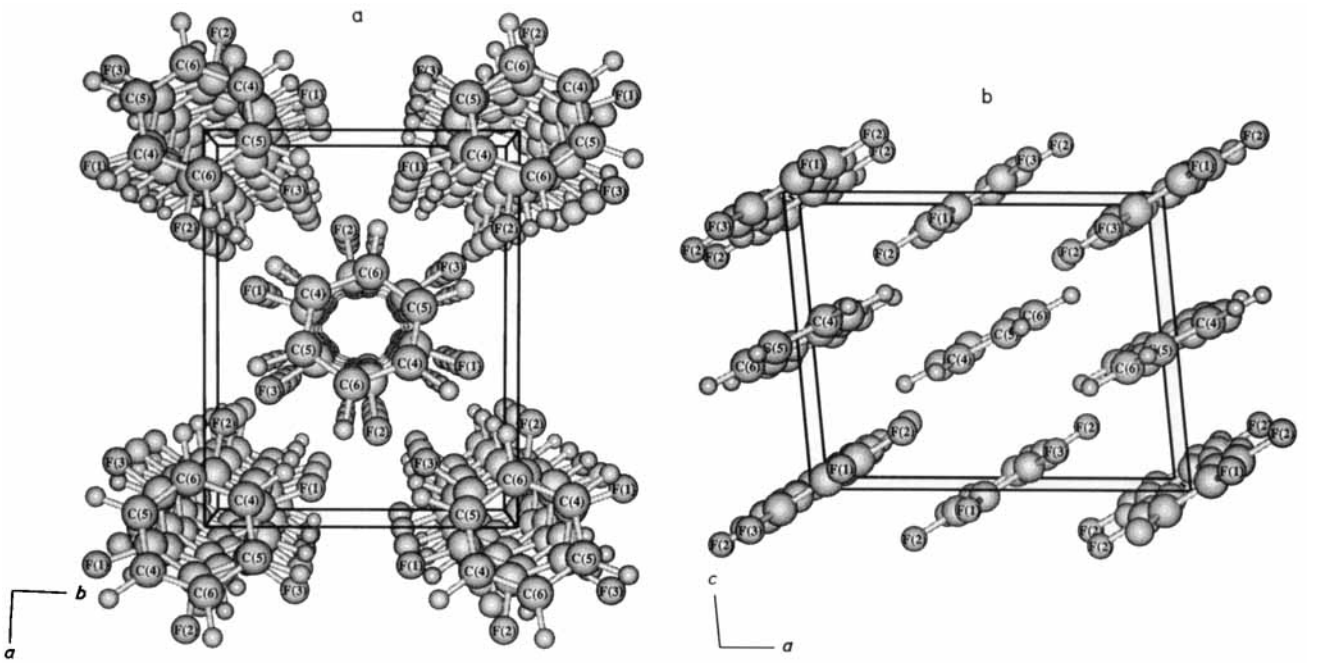

Fig. 2. The structure of phase IV. a) View down the c axis. The alternating sequence of equispaced benzene and hexafluorobenzene molecules along the c axis is clearly seen. The relative orientation of successive molecules in the alternating sequence is neither fully staggered nor eclipsed. b) View along the b axis. Alternate planes at $z = 0$ and $z = 1/2$ contain only C_6F_6 and C_6H_6 molecules, respectively. The planes of the molecules are tilted away from the c axis by approximately 23° for benzene and 27° for hexafluorobenzene.

of the structure is a result of the strong attraction between the quadrupole moments of opposite phase of the benzene and hexafluorobenzene molecules. The quadrupole moment characterizes the overall charge distribution within the molecule. Shorter range interactions involving electrostatic forces between atomic centers and between bond dipole moments may be expected to play a significant local role, particularly in defining the interactions between the columns, the orientation of the molecules within the columns, and hence the nature of the phase transitions. As can be seen in Figure 2a, the alternating molecules in the columns adopt neither a fully staggered nor fully eclipsed configuration. The shortest intermolecular contacts are between molecules in neighboring columns with distances summarized in Table 3.

Table 3. Interatomic contacts of less than 3.0 Å between molecules in adjacent columns.

F(1)-D(6)	2.536(7)	F(1)-F(3)	2.826(5)
F(2)-D(5)	2.522(7)	F(2)-F(3)	2.882(8)
F(2)-D(4)	2.703(6)	D(4)-D(5)	2.897(6)
F(3)-D(4)	2.612(7)	D(4)-D(6)	2.752(7)
F(3)-D(6)	2.665(6)	D(5)-D(6)	2.913(6)

Preliminary analysis of the triclinic phase III shows that on passing from phase III to phase IV, where there is a marked change in the dynamics of the molecules,[5-7] half of the columns are displaced by half a unit cell parallel to the column axis. This leads to the large hysteresis observed and the residual presence of phase III down to 1.5 K. Full details on all phases will be published elsewhere.[19]

From these studies, one may surmise the sequence of molecular reorganization during the phase transitions in C_6H_6:C_6F_6 and the increase in dimensionality of the system with decreasing temperature. In phase I the molecules are rotating about the column axis,[7] and the system behaves like parallel cylindrical rods. On lowering the temperature the molecules first tilt with respect to the column axis, leading to a monoclinic phase, followed by a distortion to a triclinic phase due to freezing out of the rotations of the heavier C_6F_6 molecules. At this stage the unfavorable interaction between columns is compensated by the rotational freedom of the C_6H_6 molecules. Reduction of their rotational energy leads to a realignment of the columns and the unusual transition from a triclinic to a monoclinic phase with decreasing temperature.

The change of dimensionality in solid C_6H_6:C_6F_6 with temperature is analogous with the hierarchy of phase transitions seen in liquid crystals, for example, sodium dodecyl sulfate-water.[20, 21] Here, the sequence of structures is determined by minimum periodic surfaces, which minimize the boundary interactions present in the system. In C_6H_6:C_6F_6 the phase transitions seen on increasing temperature may be viewed in terms of an increase in the rotational energy of the molecules which reduces the interaction between parallel columns.

Experimental

The diffraction data were measured at 30 K with synchroton radiation on the powder diffractometer 2.3 [11] at Daresbury, by using $\theta/2\theta$ geometry with $\lambda = 1.40302(1)$ Å (from Si standard) over the 2θ range 5 to 125° in steps of 0.01° with a counting time of 2s per point. The sample was rotated in a circular specimen holder (diameter 25 mm, depth 2 mm, covered by a Kapton foil) in a continuous-flow liquid-helium cryostat with Mylar windows. The structure was refined by the Rietveld method [12] with the program PROFIL [13] and a pseudo-Voigt peak-shape function. The symmetry of each molecule was restrained to D_{6h} symmetry, and the C–C distances were based on the known values [14, 15]. The lattice parameters refined to $a = 9.5159(1)$, $b = 7.4290(1)$, $c = 7.5378(1)$ Å, $\beta = 95.5913(7)°$. Thirty-six positional parameters were refined for the 12 crystallographically unique atoms with separate isotropic temperature factors for C(1)–C(3), F(1)–F(3), C(4)–C(6), and H(4)–H(6). The small amount (about 5%) of phase III persisting to low temperature is clearly seen in the difference profile in Figure 1a. $R_{wp} = 0.190$, $R_{exp} = 0.043$, $R_I = 0.096$.

Neutron diffraction data were measured at 1.5 K on the powder diffractometer D1A at ILL Grenoble, with a nominal wavelength of 1.9087 Å over the 2θ range 6 to 156° in steps of 0.05° in 12 h. The sample, ground at 8 °C, was contained in a cylindrical (diameter 16 mm) sample can made from vanadium mounted in a helium-cooled "orange" cryostat. The structure was refined with similar symmetry restraints as applied to the synchrotron-radiation refinement, with the neutron scattering lengths $b_C = 6.6484$, $b_F = 5.654$, $b_D = 6.674$ fm [18]. $R_{wp} = 0.111$, $R_{exp} = 0.033$, $R_I = 0.072$.

Ziegler, T. 1358 [1369]
Ziessel, R. 775 [796]
Ziller, J. W. 1081 [1114]
Zimmermann, N. 886 [928]
Zubieta, J. 1197 [1236]
Zuhse, R. 870 [914]
Zwahlen, C. 1248 [1233]
Zybill, C. 173 [180]

INDEX OF AUTHORS AND REVIEWERS OF BOOKS

This index lists separately the names of Authors/Editors and Reviewers, respectively, of books reviewed in *Angew. Chem. Int. Ed. Engl.* **1992**, *31*.

Bookauthors

Abruna, H. D. 238
Alcock, N. W. 663
Almond, M. J. 362
Altman, S. L. 1097
Ashwell, G. J. 1536
Atkins, P. W. 1095
Austin, J. 802
Baizer, M. M. 656
Balzani, V. 104
Belen'kii, I. A. 238
Boche, G. 241
Bodanszky, M. 1535
Bonačić-Koutecký, V. 242
Bouas-Laurent, H. 804
Bowman, M. K. 243
Brandsma, L. 485
Braun, A. M. 360
Brereton, R. G. 663
Brown, T. A. 1099
Büchel, K. H. 799
Buck, B. 928
Burger, K. 803
Butcher, S. S. 799
Callaghan, P. T. 1394
Carlson, R. 1393
Carruthers, W. 240
Cheetham, A. K. 1396
Ciferri, A. 358
Collins, D. J. 107
Colquhoun, H. M. 662
Connors, K. A. 239
Cornell, R. M. 658
Crichton, R. R. 930
Culvenor, C. C. J. 107
Damani, L. A. 107
Davies, M. B. 802
Day, P. 1396
Dedieu, A. 1537
Dequasie, A. 1096
Dorfner, K. 802
Dürr, H. 363, 804
Eckstein, F. 1398
Falbe, J. 799
Fan, L. T. 659
Flanigen, E. M. 661
Fried, B. 360
Fringuelli, F. 364
Fruton, J. S. 103
Fuchs, E. 108
Fujita, H. 240
Glasby, J. S. 1396
Gray, P. 109
Greene, T. W. 658
Hagemann, H. 799
Hallenga, K. 484
Hamilton, J. F. 1534
Hanack, M. 799
Hansen, J. C. 661
Hardie, D. G. 657
Harrington, P. J. 365
Hassall, K. A. 242
Hon, D. N. S. 801
Huyskens, P. L. 1538
Jacob, J. 364
Janoschek, R. 800
Johnson, J. A. 803
Jones, J. 798
Jordan, R. B. 1397
Kevan, L. 243
Klamann, D. 237, 799
Kosower, E. M. 659
Kreher, R. 799
Kropf, H. 799
Krygowski, T. M. 359
Lamberton, J. A. 107
Lichtenthaler, F. W. 361
Loder, J. W. 107
Luck, W. A. P. 1538
Lukevics, E. 1098
Lund, H. 656
Luque de Castro, M. D. 484
Macaulay, V. A. 928
Mason, S. F. 1533
Maurette, M.-T. 360
Mayo, D. W. 799
Merian, E. 102
Meyer, G. 105
Michl, J. 242
Moore, G. R. 1098
Morss, L. R. 105
Nakanishi, K. 245
Nasipuri, D. 1539
Neogi, D. 659
Nicholson, J. W. 486
Olah, G. A. 660
Oliveros, E. 360
Oppholzer, H. 108
Parish, R. V. 108
Partridge, D. A. 802
Patai, S. 1395
Pettigrew, G. W. 1098
Pike, R. M. 799
Popov, A. I. 484
Prelog, V. 1395
Price, J. R. 107
Rappoport, Z. 105, 1395
Regitz, M. 799
Rehme, H. 108
Robinson, J. W. 236
Rossiter, B. W. 1534
Ruelle, D. 798
Scandola, F. 104
Schaumann, E. 799
Scheffold, R. 1393
Schneider, H.-J. 363
Schügerl, K. 1397
Schwertmann, U. 658
Scott, S. K. 109
Servos, J. W. 797
Seyden-Penne, J. 1534
Shepherd, M. K. 1264
Sherma, J. 360
Shiraishi, N. 801
Shorter, J. 359
Shustorovich, E. 1538
Sokolov, V. I. 1096
Taticchi, A. 364
Thompson, D. J. 662
Tiller, W. A. 1536
Trumper, P. K. 799
Tschesche, H. 245
Twigg, M. V. 662
Ulman, A. 929
Valcárel, M. 484
van Bekkum, H. 661
Wade, K. 660
Walborsky, H. M. 241
Webster, B. 661
Wieland, T. 1535
Williams, R. E. 660
Wuts, P. G. M. 658
Yashima, M. 659
Zablocka, A. 1098
Zalewski, R. I. 359
Zeegers-Huyskens, T. 1538

Reviewers

Adam, G. 1396
Alper, H. 662
Baumgarten, M. 486
Becker, H. 107
Beck-Sickinger, A. 245
Berger, S. 245

Zentel, R. 358
Zumofen, G. 659

Ab initio calculations
- Ab Initio Investigations of Structure and Stability of $[R_3SiAl]_4$, R = H, Me, *t*Bu (C) 353
- 1,2,4-Cyclohexatriene, an Isobenzene, and its [2 + 2] Cycloaddition with Styrene: A Theoretical Study (C) 476
- Effect of Torsional Strain and Electrostatic Interactions on the Stereochemistry of Nucleophilic Additions to Cyclohexanone and Related Systems (C) 1019
- $[Ga(C_5H_5)]$: Synthesis, Identification, and Ab Initio Investigations (C) 1362
- "Kinetically Enhanced Metalation"—How Substituents Direct *ortho* Lithiation (C) 755
- Large Hyperconjugative and Inductive Effects on C-C-X Bond Angles (X = Main-Group Element): The Crystal Structure of Triethylborane and Ab Initio Investigations (C) 314
- Origin of the Stabilization of Vinyldiazonium Ions by β-Substitution; First Crystal Structure of an Aliphatic Diazonium Ion: β,β-Diethoxyethenediazonium Hexachloroantimonate (C) 740
- Structures, Structures, and Structures (H) 290
- Synthesis and Structure of $[Ni(PtBu_6)]$ and $[Ni_5(PtBu)_6(CO)_5]$ and Calculations on the Electronic Structure of $[Ni(PtBu)_6]$ and $(PR)_6$, R = *t*Bu, Me (C) 323
- The Electronic Structure of $[(\eta^5\text{-}C_5H_5)_2Co_2]$: Comment on the Existence of a Complex with an Unsupported Co–Co Double Bond (C) 471
- The Isomers of the Acetylene Derivatives C_2Li_4: Transferable Structural Units in Hyperlithiated Compounds (C) 1602
- The Structure of Pentamethyltantalum (C) 1462
- The Structures of Pentamethyltantalum and -Antimony: One Square Pyramid and One Trigonal Bipyramid (C) 1464
- The Structures of Thiosulfuric Acid $H_2S_2O_3$ and Its Monoanion $HS_2O_3^-$ (C) 58
- Transition Structures of Hydrocarbon Pericyclic Reactions (R) 682

Acceleration of reactions
- En Route to Synthetic Phosphodiesterases: Supramolecular Phosphoryl-Transfer Mediated by Amidinium–Phosphate Contact Ion-Pairs (C) 207

Actinoid compounds
- Synthesis of Lanthanide and Actinide Compounds (B) 105

Adenosine monophosphates
- A Synthetic Receptor for Cyclic Adenosine Monophosphate (C) 61

Aldol reactions
- One-Pot Synthesis of Tagatose 1,6-Bisphosphate by Diastereoselective Enzymatic Aldol Addition (C) 56

Alkali metal compounds
- [2,3] Wittig Rearrangements of Nonconjugated Secondary α-Lithioethers: Proof of Stereospecificity and Inversion of the Configuration of the Carbanion C Atom (C) 647
- A Novel Six-Center Deprotonation–Lithiation Reaction Mechanism Supported by the X-Ray Structure Analysis of a Lithium Carbazolide (C) 1209
- A One-Pot Synthesis of Ketones and Aldehydes from Carbon Dioxide and Organolithium Compounds (C) 1035
- A Remarkable Change in Framework Cation Positions upon Lithium Exchange: the Crystal Structure of $LiMnPO_4(OH)$ (C) 1090
- A Supramolecular Assembly of Two Torands, Two Lithium Ions, and Three Water Molecules (C) 348
- A Water-Complexed Organolithium Compound: $[LiCH(CN)_2 \cdot H_2O \cdot TMEDA]_\infty$ (C) 77
- Conformational Preference of the Torand Ligand in Its Complexes with Potassium and Rubidium Picrate (C) 345
- Control of the Reaction of *n*-Butyllithium with Benzo[*b*]tellurophene by the Solvent—Either Metalation or Tellurium–Lithium Exchange To Give an Interesting Lithiostyryllithium (C) 1339
- Crystal and Solution Structures of the Novel Complex of Sodium Ketimide with Two Ketimine Ligands $[(tBu_2C{=}NNa)_4(HN{=}CtBu_2)_2]$: Stacking of Complexed and Uncomplexed $(NNa)_2$ Rings to give a Highly Distorted $(NNa)_4$ Cubane (C) 93
- Diastereoselective Three-Center Michael Addition of β-Ketoesters to Prostereogenic α,β-Unsaturated Carbonyl Compounds Catalyzed by K_2CO_3 or Cs_2CO_3 (C) 1651
- "Kinetically Enhanced Metalation"—How Substituents Direct *ortho* Lithiation (C) 755
- Lithiodiphenylmethylisocyanide-(−)-sparteine bis(tetrahydrofuran): Crystal Structure of a Lithiated Isocyanide (C) 79
- *N*-Lithiomethyl-*N*,*N*′,*N*″,*N*″′-tetramethyldiethylenetriamine: The First Alkyllithium Compound which is Monomeric in Hydrocarbons (C) 633
- [Lithium Piperidide–Piperidine]$_4$: Crystal Structure of an Oligomeric 1:1 Lithium Amide–Amine Mixed Complex, an Intermediate in the *N*-Lithiation of Amines (C) 1205
- Perlithiated and Hyperlithiated Methane (H) 584
- Preparative Polar Organometallic Chemistry 2 (B) 485
- Structures of Two Highly Reactive Intermediates upon $LiAlH_4$ Reduction in the Solid State and in Solution: $[(Me_3Si)_2NAlH_3Li \cdot 2Et_2O]_2$ and $[(Me_3Si)_2N]_2AlH_2Li \cdot 2Et_2O$ (C) 854
- The Isomers of the Acetylene Derivatives C_2Li_4: Transferable Structural Units in Hyperlithiated Compounds (C) 1602
- The New Subnitride $NaBa_3N$; an Extension of Alkali Metal Suboxide Chemistry (C) 1519

Alkaloids
- A Short Diastereoselective Entry to Indole Alkaloids of the Corynanthe Type by the Intramolecular Ene Reaction (C) 1079
- The Enchanting Alkaloids of Yuzuriha (R) 665

Alkene complexes
- New Route to α-[(1*E*,3*E*)-dienyl]allenes via Butadiene-tricarbonyliron Complexes (C) 224
- Preparation, Ligand Exchange Reactions, and Structure of a Diene(aqua)-ruthenium Complex $[(cod)Ru(H_2O)_4](OTs)_2$ (C) 440

Alkyl transition-metal compounds
- On the Influence of Heteroatoms in α- and β-Functionalized Alkyl Transition-Metal Compounds (R) 401

Alkyne complexes
- Inhibition of the [2+2+2] Cyclization by the Formation of Chelates: Alkyne and Vinylidene Complexes with Cyclopentadienylcobalt(I) (C) 1066

Alkynes
- Cycloalkadiynes—From Bent Triple Bonds to Strained Cage Compounds (R) 27
- Intermolecular Additions and Cycloisomerizations by a Pd-Catalyzed Sequence of an Intramolecular Redox Reaction and an Addition (C) 1335
- Synthetic Approaches toward Molecular and Polymeric Carbon Allotropes (R) 1101
- Tetraalkynylmethanes: Synthesis of Diethynyldipropargyl- and Tetrapropargylmethane (C) 1648
- The First Hexabutadiynylbenzenes: Synthesis and Structures (C) 1643

Allenes
- 1,2,4-Cyclohexatriene, an Isobenzene, and Bicyclo[4.4.0]deca-1,3,5,7,8-pentaene, an Isonaphthalene: Generation and Trapping Reactions (C) 473
- 1,2,4-Cyclohexatriene, an Isobenzene, and its [2 + 2] Cycloaddition with Styrene: A Theoretical Study (C) 476
- New Route to α-[(1*E*,3*E*)-dienyl]allenes via Butadiene-tricarbonyliron Complexes (C) 224
- Synthesis and Reactions of Isothiocyanate-Substituted Allenes and 1,3-Butadienes (C) 90
- Synthesis of Isocyanate-Substituted Allenes and 1,3-Butadienes by [3,3] Sigmatropic Rearrangements (C) 866

Allylations
- Allylation of Quinones with Allylsilane in the Presence of Lithium Perchlorate in Ether (C) 313
- Catalysis of the Addition of Allyltrimethylsilane to Aldehydes by Silylating Agents. $Me_3SiB(OTf)_4$, a New, 'Supersilylating' Reagent (C) 470

Aluminophosphates
- Solid-State NMR Spectroscopic and X-Ray Diffraction Studies of the Low-Temperature Structural Transformation of Hydrated Porous Aluminophosphate VPI-5 (C) 610
- Solving the Structure of a Metal-Substituted Aluminum Phosphate Catalyst by Electron Microscopy, Computer Simulation, and X-ray Powder Diffraction (C) 1472

Aluminum compounds
- Ab Initio Investigations of Structure and Stability of $[R_3SiAl]_4$, R = H, Me, *t*Bu (C) 353

- Structures of Two Highly Reactive Intermediates upon $LiAlH_4$ Reduction in the Solid State and in Solution: $[(Me_3Si)_2NAlH_3Li \cdot 2Et_2O]_2$ and $[(Me_3Si)_2N]_2AlH_2Li \cdot 2Et_2O$ (C) 854
- Synthesis and Structure of $Al(OAr^*)_3$ ($Ar^* = 2,6\text{-}tBu_2\text{-}4\text{-}MeC_6H_2$): The First Three-Coordinate Homoleptic Aluminum Aryloxide (C) 921

Amidines
- The Chemistry of Amidines and Imidates. Vol. 2 (B) 1395

Amines
- Molecular Recognition of Primary Amines by Three-Point Binding with Boron-Containing Host Molecules (C) 1017
- Perfluorotriethylamine: An Amine with Unusual Structure and Reactivity (C) 1467

Amino acids
- Enzymatic Preparation of Enantiomerically Pure *N*-alkyl Amino Acids (C) 195

D-amino acids
- Proteins from the D-Chiral World (H) 1457

Amino acids
- The Photochemistry of *N*-Phthaloyl α-Amino Acid Esters: A New Approach to β,γ-Unsaturated α-Amino acids and Dihydrobenzazepinediones (C) 73
- The ^{31}P-NMR Spectroscopic Determination of the Enantiomeric Excess of Unprotected Amino Acids (C) 1092

Amino alcohols
- Stereoselective Generation of 1-Acyloxy-2-amino Carbanions by Deprotonation; Synthesis of Enantiomerically and Diastereomerically Pure β-Amino Alcohols (C) 1505

Amino sugars
- Configuratively Stable Dipeptide Aldehydes from D-Glucosamine Hydrochloride (C) 1391

Ammonium compounds
- Interactions Between Acyclic and Cyclic Peralkylammonium Compounds and DNA (C) 1207

Analytical methods
- Atomic Spectroscopy (B) 236
- Detection of Subpicomole Levels of Compounds Containing Hydroxyl and Amino Groups with the Fluorogenic Reagent, 2-Naphthoylimidazole (C) 890
- Microscopy (B) 1534
- Non-Chromatographic Continuous Separation Techniques (B) 484
- Particle Beam Microanalysis. Fundamentals, Methods and Applications (B) 108
- Salting Out Selective Extraction—A Novel Method for the Optical Resolution of Chiral Sulfinylcarboxylic Acids and Its Application for the Convenient Determination of Optical Purity (C) 1631
- Synchrotron X-ray and Neutron Diffraction Studies in Solid-State Chemistry (R) 1557
- The Chemistry of GALLEX—Measurement of Solar Neutrinos with a Radiochemical Gallium Detector (R) 1283
- The ^{31}P-NMR Spectroscopic Determination of the Enantiomeric Excess of Unprotected Amino Acids (C) 1092

Annelations
- Alkyne(carbene) Complexes: Stabilization of an Intermediate of Carbene Annelation (C) 1236

Annulenes
- Corannulene Tetraanion: A Novel Species with Concentric Anionic Rings (C) 1636

Antibiotics
- Enzymatic Preparation of Enantiomerically Pure *N*-alkyl Amino Acids (C) 195

Antibodies
- Activation Parameters and Stereochemistry of an Antibody-Catalyzed Claisen Rearrangement (C) 182
- ^{99m}Tc Labeled Biotin Conjugate in a Tumor "Pretargeting" Approach with Monoclonal Antibodies (C) 1507

Antidepressants
- Enantioselective Synthesis of the Antidepressant Rolipram by Michael Addition to a Nitroolefin (C) 870

Antimony compounds
- $[SbCl([15]Crown\text{-}5)](SbCl_6)_2$ and $[BiCl([18]Crown\text{-}6)(CH_3CN)_2](SbCl_6)_2$: Salts with Antimony(III) and Bismuth(III) Dications (C) 334
- The First Stibepine: Synthesis and Structure of *Sb*-Chlorobenzo[*d*]stibepine (C) 1642
- The Structures of Pentamethyltantalum and -Antimony: One Square Pyramid and One Trigonal Bipyramid (C) 1464

Antisense RNA
- Inhibition of Fruit Ripening by Antisense-RNA Technology (H) 175

Antitumor agents
- 1-*O*-(2-Acetoxyhexadec-1-enyl)choline Iodide, a New Anticancer Agent (C) 64
- Chlorins Designed for Photodynamic Tumor Therapy and as Model Systems for Photosynthesis (C) 1592
- Crosslinking of Adjacent Guanine Residues in an Oligonucleotide by *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$: Kinetic Analysis of the Two-Step Reaction (C) 1483
- Synthesis and Biological Activity of D-3-Deoxy-3-Fluorophosphatidylinositol—A New Direction in the Design of non-DNA Targeted Anticancer Agents (C) 1379

Aqua complexes
- Preparation, Ligand Exchange Reactions, and Structure of a Diene(aqua)-ruthenium Complex $[(cod)Ru(H_2O)_4](OTs)_2$ (C) 440

Arene complexes
- A New Approach to Bis(arene)titanium(0) and -titanium(−1) Complexes; Structure of Bis(arene)titanates(1−) (C) 1495
- Benzene and Its Derivatives as Bridging Ligands in Transition-Metal Complexes (R) 247
- Ether-Soluble Ti^0 and Bis(η^6-arene)-titanium(0) Complexes from the Reduction of $TiCl_4$ with Triethylhydroborate (C) 1490
- One-Pot Syntheses of Novel Arene Tricarbonyl Chromium Macrocycles and Macrobicycle: Structure of a Pentanuclear Trichromium(0)-Dicopper(I) Cryptate (C) 775

Arenes
- Cyclobutarenes. The Chemistry of Benzocyclobutene, Biphenylene, and Related Compounds (B) 1264
- Oligo(9,10-anthrylenes), Organic Compounds with Stable High-Spin States (C) 448
- One-Pot Multifunctionalization of Polymethyl Hydrocarbon π Ligands. Maximum Space Occupancy by Double Branching and Formation of Arboroles (C) 458
- Rate Constants for the Attack of Carbenium Ions at Arenes—A Link between the Chemistry of Aliphatic and Aromatic π Systems (C) 1613
- Structure of the Lowest Temperature Phase of the Solid Benzene–Hexafluorobenzene Adduct (C) 1655
- The Benzene Ring as Dienophile in an Intramolecular [4+2] Cycloaddition: Degenerate Rearrangement of 7,8-Benzobicyclo[4.2.2]deca-2,4,7,9-tetraene (C) 872
- The First Hexabutadiynylbenzenes: Synthesis and Structures (C) 1643

Aromaticity
- Aromatic Boron Heterocycles: The Generation of 1H-Borepin and the Structure of Tricarbonyl(1-phenylborepin)molybdenum (C) 1255
- Corannulene Tetraanion: A Novel Species with Concentric Anionic Rings (C) 1636
- Equilibria between Nonclassical and Classical Boron Compounds, Competition between Aromaticity in Two and Three Dimensions (C) 607
- The First Stibepine: Synthesis and Structure of *Sb*-Chlorobenzo[*d*]stibepine (C) 1642

Arsenic compounds
- An Arsanylidensilane ("Arsasilene") and its Derivatization with Tellurium and Benzophenone (C) 316
- $(H_2Si)_2E_2$ and $(Mes(tBu)Si)_2E_2$ (E = As, P): Incommensurable Systems of Different Stability with Unusually Long E–E Bonds (C) 460
- (Organoarsonato)polyoxovanadium Clusters: Properties and Structures of the V^V Cluster $[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{4-}$ and the V^{IV}/V^V Cluster $[H_2\{V_6O_{10}(O_3AsC_6H_5)_6\}]^{2-}$ (C) 1197
- The Reaction of Tetramesityldisilene with As_4: Synthesis and Structure of a Novel Arsenic–Silicon Tricyclic Ring System (C) 1217

Arylethenes
- C–C Coupling with NO_2/Alkyl Substitution at the Vinylic Carbon by Reaction of 2-Aryl-1-nitro-1-alkenes with Dialkylzinc Compounds—A Novel Reaction (C) 1587

Arynes
- 2,4-Didehydrophenol—First Proof of a *meta*-Aryne by IR Spectroscopy (C) 1230

Asymmetric syntheses
- A Short Diastereoselective Entry to Indole Alkaloids of the Corynanthe Type by the Intramolecular Ene Reaction (C) 1079
- "Artificial Metabolisms" for the Asymmetric One-Pot Synthesis of Branched-Chain Saccharides (C) 614
- Asymmetric Deprotonation as an Efficient Enantioselective Preparation of Functionalized Secondary Alcohols (H) 1459
- Asymmetric Ligands for Transition-Metal-Catalyzed Reactions: 2-Diphenylphosphinobenzoyl Derivatives of C_2-Symmetric Diols and Diamines (C) 228
- *trans*-2-*tert*-Butylcyclohexanol, a Simple Selectively Optimized Cyclohexanol Auxiliary (C) 1190
- Diacetoneglucose as Auxiliary Group for the Asymmetric Hetero-Diels–Alder Reaction with Nitrosoalkenes (C) 1033
- Diastereoselective Addition of Allylsilanes to Aldehydes: Synthesis of Enantiomerically Pure Homoallylic Alcohols (C) 1372
- Diastereoselective Complexation of Temporarily Chirally Modified Ligands: Enantioselective Preparation and Configurational Assignment of Synthet-

ically Valuable η^6-Tricarbonylchromium-1-tetralone Derivatives (C) 631
- Diastereoselective Synthesis of Substituted Cyclohexadienes from Enantiomerically Pure Tricarbonyl(2-phenyl-4,5-dihydrooxazole)chromium Complexes (C) 1071
- Diastereoselective Three-Center Michael Addition of β-Ketoesters to Prostereogenic α,β-Unsaturated Carbonyl Compounds Catalyzed by K_2CO_3 or Cs_2CO_3 (C) 1651
- Enantiomerically Pure Tertiary Alcohols by TADDOL-Assisted Additions to Ketones—or How to Make a Grignard Reagent Enantioselective (C) 84
- Enantioselective Rhodium(II) Catalysts (H) 1183
- Enantioselective Syntheses of Cyclopentanoid Compounds from Isoprene and *trans*-1,3-Pentadiene (C) 305
- Enantioselective Synthesis of 3-Substituted 2-Ketoesters (C) 618
- Enantioselective Synthesis of the Antidepressant Rolipram by Michael Addition to a Nitroolefin (C) 870
- *meso* Epoxides in Asymmetric Synthesis: Enantioselective Opening by Nucleophiles in the Presence of Chiral Lewis Acids (H) 1179
- First Atropo-Enantioselective Ring Opening of Achiral Biaryls Containing Lactone Bridges with Chiral Hydride-Transfer Reagents Derived from Borane (C) 761
- Formate-Driven, Non-Enzymatic NAD(P)H Regeneration for the Alcohol Dehydrogenase Catalyzed Stereoselective Reduction of 4-Phenyl-2-butanone (C) 1529
- Ligand Effects in Grignard Additions (C) 342
- New Chiral α-Benzyloxyacryliron(II) Complex for Asymmetric Synthesis of α,α-Dialkyl-α-hydroxycarbonyl Compounds (C) 193
- One-Pot Synthesis of Tagatose 1,6-Bisphosphate by Diastereoselective Enzymatic Aldol Addition (C) 56
- Oxazaborolidines and Dioxaborolidines in Enantioselective Catalysis (H) 729
- Stereocontrolled Construction of 6 · 5 · 6 and 5 · 5 · 6 Ring Systems by Radical Tandem Cyclization (C) 910
- Stereoselective Generation of 1-Acyloxy-2-amino Carbanions by Deprotonation; Synthesis of Enantiomerically and Diastereomerically Pure β-Amino Alcohols (C) 1505
- Stereoselective Nucleophilic Addition Reactions of Reactive Pseudopeptides (C) 1626
- Sugars as Chiral Auxiliaries for the Synthesis of Enantiomerically Pure Compounds (H) 288
- The Hydroxyl-Directed Hydrogenation of Vinylstannanes and Silanes: A Highly Diastereoselective Route to β-Stannyl and β-Silyl Alcohols (C) 232
- The Tandem Sakurai–Carbonyl–Ene Reaction: A New and Highly Stereoselective Sequential Transformation and Its Use for the Synthesis of Steroid Derivatives (C) 1221

Atomic force microscopy
- Photodimerization of Anthracenes in the Solid State: New Results from Atomic Force Microscopy (C) 595
- Photodimerization of Cinnamic Acid in the Solid State: New Insights on Application of Atomic Force Microscopy (C) 592
- Scanning Tunneling Microscopy and Atomic Force Microscopy in Organic Chemistry (R) 1298

Atropo-enantioselectivity
- First Atropo-Enantioselective Ring Opening of Achiral Biaryls Containing Lactone Bridges with Chiral Hydride-Transfer Reagents Derived from Borane (C) 761

Aza crown ethers
- Designing Synthetic Cationic Molecular Receptors for Alcohols (C) 478

Azaallenium ion
- Tetraferrioazaallenium—Product of a Novel Reaction of Coordinated CN^- (C) 590

Azaboranes
- Opening of an Aza-*closo*-dodecaborane to an Aza-*nido*-dodecaborate (C) 1227

Azacyclopentadiene
- 2,2',5,5'-Tetra-*tert*-butyl-1,1'-diazaplumbocene—a Stable Azacyclopentadienyl Compound of Lead (C) 778

Azines
- An Organometallic Analogue of the "Criss-Cross" Cycloaddition Reaction (C) 1053

Aziridines
- The Total Synthesis of (±)-Mitomycin K (C) 915

Azobenzenes
- Photoswitchable Association of an Azobenzene-Bipyridinium Diad to Eosin: Photostimulated "On-Off" Guest Binding (C) 1243

Band theory
- Band Theory of Solids. An Introduction from the Point of View of Symmetry (B) 1097

Barium compounds
- Alkoxyalkyl-Substituted β-Diketonate Complexes of Barium and Copper: Evidence for Inter- and Intramolecular Stabilization (C) 735
- The New Subnitride $NaBa_3N$; an Extension of Alkali Metal Suboxide Chemistry (C) 1519

Beilstein test
- The Beilstein Test: An Unintentional Dioxin Source in Analytical and Research Laboratories (C) 443

Belousov–Zhabotinskii reaction
- Chemiluminescence Oscillations Driven by a Flow-through Reactor in the $[Ru(bpy)_3]^{2+}$ Catalyzed Belousov–Zhabotinskii Reaction (C) 355

Benzazepines
- The Photochemistry of *N*-Phthaloyl α-Amino Acid Esters: A New Approach to β,γ-Unsaturated α-Amino acids and Dihydrobenzazepinediones (C) 73

Benzothiazoles
- A 1:1 Adduct of 2-Aminobenzothiazole and a Urea Derivative, and Its Spatial Arrangement (C) 1634

Biaryls
- First Atropo-Enantioselective Ring Opening of Achiral Biaryls Containing Lactone Bridges with Chiral Hydride-Transfer Reagents Derived from Borane (C) 761

Bifluorenes
- Enantioselective Complexation of Chiral Dicarboxylic Acids in Clefts of Functionalized 9,9'-Spirobifluorenes (C) 1521

Binaphthol complexes
- Unprecedented Stereospecific Ligand Exchange at a W≡W Template (C) 66

Biochemical messengers
- Biochemical Messengers. Hormones, Neurotransmitters and Growth Factors (B) 657

Biochemistry
- Biochemical Degradation of Cyanamide and Dicyandiamide (C) 620
- 5'-*P*-Borane-Substituted Thymidine Monophosphate and Triphosphate (C) 1373
- Do Pheromone Receptors that Receive the Same or Similar Signal Molecules Have the Same or Similar Structure? (C) 330
- Elementary Steps in Synaptic Transmission Revealed by Currents through Single Ion Channels (Nobel Lecture) (R) 830

- Natural Products as Probes of Cellular Function: Studies of Immunophilins (R) 384
- Radical Intermediates in the Coenzyme B_{12} Dependent Methylmalonyl-CoA Mutase Reaction Shown by ESR Spectroscopy (C) 215
- Selective Inhibition of Trypanosomal Triosephosphate Isomerase by a Thiopeptide (C) 328
- Synthesis of (2-Arylindol-3-yl)acetamides as Probes of Mitochondrial Steroidogenesis—A New Mechanism for $GABA_A$ Receptor Modulation (C) 1060
- Synthesis of Octameric Phosphodiesters of [3,3-Bis(hydroxymethyl)cyclobutyl]-adenine and -thymine as well as their Hybridization Properties (C) 482
- The Biochemistry and Uses of Pesticides. Structure, Metabolism, Mode of Action and Uses in Crop Protection (B) 242

Bioinorganic chemistry
- Biocoordination Chemistry: Coordination Equilibria in Biologically Active Systems (B) 803
- Synthesis of Cubane-like and Double Cubane-like Tungsten–Copper–Sulfur Clusters from the "Butterfly" Cluster $[Cu_2S_3W(O)(PPh_3)_3]$ (C) 1085
- Synthetic Models for Iron—Oxygen Aggregation and Biomineralization (H) 1010
- Tris(cyclopentanolato)oxovanadium(V): a Model for the Transition State of Enzymatic Phosphoester Cleavage (C) 447

Biomineralization
- Control and Design Principles in Biological Mineralization (R) 153
- Synthetic Models for Iron—Oxygen Aggregation and Biomineralization (H) 1010

Biopolymers
- Photolithographic Immobilization of Biopolymers on Solid Supports (C) 759

Biosensors
- Molecular Mechanism for Sensory Signals (B) 659

Biotechnology
- Biotechnology. A Multi-Volume Comprehensive Treatise. Vol. 4. Measuring, Modelling and Control (B) 1397

Biotin
- ^{99m}Tc Labeled Biotin Conjugate in a Tumor "Pretargeting" Approach with Monoclonal Antibodies (C) 1507

Biradicals
- 2,4-Didehydrophenol—First Proof of a *meta*-Aryne by IR Spectroscopy (C) 1230

Bismuth compounds
- Bismuth Alkoxide Dimer Complexes Containing Planar $Bi_2(\mu\text{-}OR)_2$ Cores: Syntheses and Structures of $[\{Bi[OCH(CF_3)_2]_3(thf)\}_2]$ and $[\{Bi(OC_6F_5)_3(C_7H_8)\}_2] \cdot 2C_7H_8$ (C) 451
- $[SbCl([15]Crown\text{-}5)](SbCl_6)_2$ and $[BiCl_2([18]Crown\text{-}6)(CH_3CN)_2](SbCl_6)_2$: Salts with Antimony(III) and Bismuth(III) Dications (C) 334

Blood substitutes
- Protein Engineering: Modified Hemoglobin as a Blood Substitute (H) 848

Bond-stretch isomerism
- Bond-Stretch Isomers: Fact or Artifact? (H) 286
- Distortional Isomerism in Oxomolybdenum Systems; the Evidence Re-evaluated (C) 1607

Boron compounds
- Aromatic Boron Heterocycles: The Generation of 1H-Borepin and the Structure of Tricarbonyl(1-phenylborepin)molybdenum (C) 1255
- Bis(trisyl)oxadiborirane (C) 1040
- 1-Borabutadiene(cyclopentadienyl)cobalt Complexes (C) 1603
- 5′-*P*-Borane-Substituted Thymidine Monophosphate and Triphosphate (C) 1373
- Boriranes: Structures and Thermal Ring Openings (C) 1384
- Compounds with Three-Membered Rings Containing Boron (H) 1329
- Cyclometallaborazines: Borazines with Metal Atoms as Ring Building Blocks: $PhB(MeN)_3(TiCl_2)_2$ (C) 598
- Electron Deficient Boron and Carbon Clusters (B) 660
- Equilibria between Nonclassical and Classical Boron Compounds, Competition between Aromaticity in Two and Three Dimensions (C) 607
- First Atropo-Enantioselective Ring Opening of Achiral Biaryls Containing Lactone Bridges with Chiral Hydride-Transfer Reagents Derived from Borane (C) 761
- Formation of a 2,5-Diborabicyclo-[2.1.1]hexane Derivative and its Conversion to a Tetracarbahexaborane (C) 606
- Homodiboriranides: The Simplest Negatively Charged Homoaromatic Compounds (C) 1238
- Large Hyperconjugative and Inductive Effects on C-C-X Bond Angles (X = Main-Group Element): The Crystal Structure of Triethylborane and Ab Initio Investigations (C) 314
- Molecular Recognition of Primary Amines by Three-Point Binding with Boron-Containing Host Molecules (C) 1017
- $[Nb\{B(\eta^6\text{-}C_6H_5)_2(C_6H_5)_2\}(\eta^2\text{-}H_3CC_2CH_3)]$: the First Compound with Bent Tetraphenylborate as 12-Electron Donor Ligand (C) 1235
- "Non-Coordinating" Anions: Underestimated Ligands (H) 1181
- Opening of an Aza-*closo*-dodecaborane to an Aza-*nido*-dodecaborate (C) 1227
- Oxazaborolidines and Dioxaborolidines in Enantioselective Catalysis (H) 729
- Reduction of a Boron–Nitrogen 1,3-Butadiene Analogue: Evidence for a Strong B–B π-Bond (C) 1082
- Synthesis and Structure of the First Trinuclear, Half-Sandwich Carboranegadolinium(III) Cluster (C) 432
- The Green Flame: Surviving Government Secrecy (B) 1096
- Zinc Pyrazolylborate Complexes Relevant to the Biological Function of Carbonic Anhydrase (C) 92

Bredt rule
- Anti-Bredt Enol Ethers by Transannular Cyclization of Cycloalkynols (C) 791

Bridging ligands
- A New Structure–Magnetism Relationship for Face-Sharing Transition-Metal Complexes with d^3–d^3 Electronic Configuration (C) 311
- A Structurally Distorted Ligand in an Electron-Deficient Dizirconocene Cation: Unusual 1,2- and 1,1-Dimetallioalkenes (C) 876
- Benzene and Its Derivatives as Bridging Ligands in Transition-Metal Complexes (R) 247
- Double Open-Edged P_{10} Dihydrofulvalene as a 16-Electron Donor Ligand (C) 1027
- $[Et_4N]_2[\{MO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]$ (M = Mo, W)—Doubly Bridged Complexes with S_7^{2-} and Doubly End-On-Bound H_2NNH_2 Bridging Ligands (C) 87
- Molecular Machines: Molecular Structure of $[(p\text{-}Tol_3P)_{10}Au_{13}Ag_{12}Cl_8](PF_6)$—a Cluster with a Biicosahedral Rotorlike Metal Core and an Unusual Arrangement of Bridging Ligands (C) 445
- Pyridine-2-thiolato Complexes of V^{II}, V^{III}, and V^{IV} with Unusual Structural Features (C) 1253
- Stable Intermediates in the Addition and Elimination of $SnBuCl_3$ at Molybdenum Centers by Cleavage or Formation of an Sn–Cl Bond: Crystal Structure of $[Mo(CO)_2(PCy_3)(\mu\text{-}Cl)(\mu\text{-}S_2CPCy_3)(BuSnCl_2)] \cdot CH_2Cl_2$ (C) 76
- The Reaction of $[Cp_2^+Nb_2(B_2H_6)_2]$ ($Cp^+ = \eta\text{-}EtMe_4C_5$) with Sulfur: Stabilization of the Tetrathioborato Ligand in Novel Sulfido Niobium Clusters (C) 1021
- The Trapping of Iron Hydroxide Units by the Ligand "heidi": Two New Hydroxo(oxo)iron Clusters Containing 19 and 17 Iron Atoms (C) 191

Butadienes
- Synthesis and Reactions of Isothiocyanate-Substituted Allenes and 1,3-Butadienes (C) 90
- Synthesis of Isocyanate-Substituted Allenes and 1,3-Butadienes by [3,3] Sigmatropic Rearrangements (C) 866

Butatrienes
- Butatrienes by Desulfurization of Cyclic Trithiocarbonates (C) 1611

Cadmium compounds
- Indirect $^{113}Cd,^{14}N$ Spin-Spin Coupling Constants as a Structural Probe of Solid Cadmium Thiocyanate Complexes (C) 1222

Cage compounds
- A Donor Cage with Two Tetrathiafulvene Units (C) 309
- A New Reaction Type in the Conversion of Enamines with 1,4-Diphenyl-2-butene-1,4-dione to Give Cage Compounds (C) 768
- A Rh^I-Centered Cage Compound with Selective Catalytic Properties (C) 905
- $C_{36}H_{36}$—Tetrahedral Clamping of Four Benzene Rings in a Spherical Hydrocarbon Framework (C) 1069
- Selective Ketone Pyrolysis: New Synthetic Method for Mono- and Polycyclic Hydrocarbons (C) 307

Calicheamicins
- Synthesis of the Calicheamicin Aryltetrasaccharide Domain Bearing a Reducing Terminus: Coupling of Fully Synthetic Aglycone and Carbohydrate Domains by the Schmidt Reaction (C) 338
- Total Synthesis of Calicheamicin–Dynemicin Hybrid Molecules (C) 340

Calixarenes
- Bicyclocalix[4]arenes (C) 96
- Nitrocalix[4]arenes as Molecules for Second-Order Nonlinear Optics (C) 1075

Calorimetry
- Microcalorimetry of the Spin-Transition Systems $[Fe(bts)_2(NCS)_2]$ and $[Fe(2\text{-}pic)_3]Cl_2 \cdot EtOH$ in the Range $15\ K < T < 300\ K$ (C) 178
- The Stability of Buckminsterfullerene (C_{60}): Experimental Determination of the Heat of Formation (C) 63

Carbanions
- Preparative Polar Organometallic Chemistry 2 (B) 485
- Stereoselective Generation of 1-Acyloxy-2-amino Carbanions by Deprotonation; Synthesis of Enantiomerically and Diastereomerically Pure β-Amino Alcohols (C) 1505

Carbene complexes
- Alkyne(carbene) Complexes: Stabilization of an Intermediate of Carbene Annelation (C) 1236
- Carbene Osmium Complexes by Double Metalation of Alkoxylalkyl- and Aminoalkylphosphanes (C) 1025
- Detection of the Tungsten–Carbene–Olefin Intermediates in Catalytic Metathesis Systems Containing High-Valent, Metal Centers (C) 1585

Carbenes
- Enantioselective Rhodium(II) Catalysts (H) 1183

Carbocations
- Cyclohexadienyl-Type Cationic Intermediates in the Friedel–Crafts Alkylation of Benzene Derivatives with the 9-Fluorenyl Cation—Observation by Laser Flash Photolysis (C) 743
- Houben-Weyl. Methoden der Organischen Chemie. Band E19c: Carbokationen, Carbokation-Radikale (B) 799
- Kinetics of Hydride Transfers from CH, SiH, GeH, and SnH Groups to Carbenium Ions (C) 1046

Carbohydrates
- A New Strategy for Solid-Phase Synthesis of *O*-Glycopeptides (C) 857
- "Artificial Metabolisms" for the Asymmetric One-Pot Synthesis of Branched-Chain Saccharides (C) 614
- Carbohydrates as Organic Raw Materials (B) 361
- Detection of Subpicomole Levels of Compounds Containing Hydroxyl and Amino Groups with the Fluorogenic Reagent, 2-Naphthoylimidazole (C) 890
- Emil Fischer's Proof of the Configuration of Sugars: A Centennial Tribute (R) 1541
- One-Pot Synthesis of Tagatose 1,6-Bisphosphate by Diastereoselective Enzymatic Aldol Addition (C) 56
- Reagents with Hypervalent Iodine: Formation of Convenient Chiral Synthetic Intermediates by Fragmentation of Carbohydrate Anomeric Alkoxy Radicals (C) 772
- Selective Binding of Sugar to β-Cyclodextrin: A Prototype for Sugar–Sugar Interactions in Water (C) 745

- Sugars as Chiral Auxiliaries for the Synthesis of Enantiomerically Pure Compounds (H) 288
- Synthesis and Biological Activity of D-3-Deoxy-3-Fluorophosphatidylinositol—A New Direction in the Design of non-DNA Targeted Anticancer Agents (C) 1379
- Synthesis of Esterase-resistant 9-*O*-Acetylated Polysialoside as Inhibitor of Influenza C Virus Hemagglutinin (C) 1478
- Synthesis of *C*-Glycopeptides via Free Radical Addition of Glycosyl Bromides to Dehydroalanine Derivatives (C) 902

Carbon dioxide
- A One-Pot Synthesis of Ketones and Aldehydes from Carbon Dioxide and Organolithium Compounds (C) 1035

Carbon–carbon linkage
- Addition of Benzyl Radicals to Alkenes: The Role of Radical Deformation in the Transition State (C) 635
- Alkyne(carbene) Complexes: Stabilization of an Intermediate of Carbene Annelation (C) 1236
- Allylation of Quinones with Allylsilane in the Presence of Lithium Perchlorate in Ether (C) 313
- Assistance by Electrophiles in Photoinduced Alkylidyne–Carbonyl Coupling (C) 747
- Catalysis of the Addition of Allyltrimethylsilane to Aldehydes by Silylating Agents. $Me_3SiB(OTf)_4$, a New, 'Supersilylating' Reagent (C) 470
- C–C Coupling with NO_2/Alkyl Substitution at the Vinylic Carbon by Reaction of 2-Aryl-1-nitro-1-alkenes with Dialkylzinc Compounds—A Novel Reaction (C) 1587
- Enantiomerically Pure Tertiary Alcohols by TADDOL-Assisted Additions to Ketones—or How to Make a Grignard Reagent Enantioselective (C) 84
- New Route to α-[(1*E*,3*E*)-dienyl]allenes via Butadiene-tricarbonyliron Complexes (C) 224
- Palladium(0)-Catalyzed Three-Component Coupling Reaction of Allyl Benzoates, Carbon Monoxide, and Zincioesters (C) 645
- Reaction of Heterodinuclear μ-Ethynediyl Complexes Containing Palladium and Platinum: Multiple and Successive Insertion of Isocyanides (C) 851

Carbonic anhydrase
- Zinc Pyrazolylborate Complexes Relevant to the Biological Function of Carbonic Anhydrase (C) 92

Carbonylation (B) 662

Carboranes
- Formation of a 2,5-Diborabicyclo-[2.1.1]hexane Derivative and its Conversion to a Tetracarbahexaborane (C) 606
- Multidentate Macrocyclic Lewis Acids: Release of "[12] Mercuracarborand-4" from Its Iodide Complex and the Structure of Its Tetra(tetrahydrofuran) Dihydrate Complex (C) 893
- Synthesis and Structure of the First Trinuclear, Half-Sandwich Carborane-gadolinium(III) Cluster (C) 432

Carbosilanes
- On the Bonding in Carbosilanes (C) 185

Carboxylic acids
- A Simple Method for the Replacement of the OH Group in Free Carboxylic Acids by the Phosphonium Ylide Group (C) 1064
- Enzymatic Oxidation of Methyl Groups on Aromatic Heterocycles: A Versatile Method for the Preparation of Heteroaromatic Carboxylic Acids (C) 774

Carbyne complexes
- New Routes to Alkylidyne-Bridged Ditungsten Compounds Supported by Alkoxide or Siloxide Ligands by the Activation of Ethylene (C) 462

Caro's acid
- Caro's Acid: Molecular Structure and Association in the Solid State at −130 °C (C) 436

Carotenoids
- Dual Fluorescence of Novel Modified Carotenoids (C) 1042

Cascade molecules

- On the Influence of Heteroatoms in α- and β-Functionalized Alkyl Transition-Metal Compounds (R) 401
- Oxazaborolidines and Dioxaborolidines in Enantioselective Catalysis (H) 729
- Proof of the Catalytic Activity of a Naked Metal Cluster in the Gas Phase (C) 636
- Regioselectivity Control in the Palladium-Catalyzed Copolymerization of Propylene with Carbon Monoxide (C) 303
- Selective Oxidation of Methane to CO and H_2 over Ni/MgO at Low Temperatures (C) 1189
- Selectivity Control By Temperature Variation in the Formation of Isotactic vs. Syndiotactic Polypropylene with a Titanocene/Alumoxane Catalyst (C) 199
- Synthesis of Optically Active Macromolecules Using Metallocene Catalysts (H) 47
- 'Bis(oxazolines)' as Ligands for Self-Assembling Chiral Coordination Polymers—Structure of a Copper(I) Catalyst for the Enantioselective Cyclopropanation of Olefins (C) 430

Catenanes
- One-Step Synthesis of a Fourfold Functionalized Catenane (C) 1619

Ceramics
- The Thermal Conversion of Poly[(silylene)diacetylene] Metal Oxide Composites: A New Approach to β-SiC—MC Ceramics (C) 1195

Cesium effect
- Does the Naked Fluoride Ion Exist? (H) 292

C-H activation
- Palladium-Catalyzed C-H Activation of Methoxy Groups: A Facile Synthesis of Substituted 6*H*-Dibenzo[*b*,*d*]pyrans (C) 1023

Chalcogen compounds
- New Layered Iron-Lanthanum-Oxide-Sulfide and -Selenide Phases: $Fe_2La_2O_3E_2$ (E = S,Se) (C) 1645

Charge transfer complexes
- A Donor Cage with Two Tetrathiafulvene Units (C) 309
- Three-Dimensional Structure of an Unsymmetrical Proton–Electron Transfer System Containing a Disulfide Bond: The Bis(4-hydroxyphenyl)disulfide–Benzoquinone Complex (C) 852

Chelate ligands
- Chelate Complexes of Tripodal, Aliphatic Triisocyanide Ligands (C) 1212
- Chelate Stabilization of a Monomeric Lithium Tellurolate (C) 1260
- Transition Metal in a Cube—A Discrete Eight-Coordinate $[Mn^{2+} \subset [2.2.2]\text{cryptand}]$ as a Body-Centered Cube with an N_2O_6 Donor Set (C) 764

Chemiluminescence
- Chemiluminescence Oscillations Driven by a Flow-through Reactor in the $[Ru(bpy)_3]^{2+}$ Catalyzed Belousov–Zhabotinskii Reaction (C) 355

Chemistry of the atmosphere
- Transport and Fate of Organic Compounds in the Global Environment (R) 487

Chemometrics
- Chemometrics. Applications of Mathematics and Statistics to Laboratory Systems (B) 663

Chiral auxiliaries
- Asymmetric Ligands for Transition-Metal-Catalyzed Reactions: 2-Diphenylphosphinobenzoyl Derivatives of C_2-Symmetric Diols and Diamines (C) 228
- *trans*-2-*tert*-Butylcyclohexanol, a Simple Selectively Optimized Cyclohexanol Auxiliary (C) 1190
- Diacetoneglucose as Auxiliary Group for the Asymmetric Hetero-Diels–Alder Reaction with Nitrosoalkenes (C) 1033
- Diastereoselective Complexation of Temporarily Chirally Modified Ligands: Enantioselective Preparation and Configurational Assignment of Synthetically Valuable η^6-Tricarbonylchromium-1-tetralone Derivatives (C) 631
- Sugars as Chiral Auxiliaries for the Synthesis of Enantiomerically Pure Compounds (H) 288

Chirality
- A Diels–Alder Route to [5]- and [6]-Helicenes (C) 1093
- Chirality and Optical Activity in Organometallic Compounds (B) 1096
- Chirality—From Weak Bosons to the α-Helix (B) 800
- Enantioselective Polymerization of 1,2-Diisocyanoarenes—Synthesis of Optically Active, Helical Poly(quinoxaline-2,3-diyl)s (C) 1509
- On Quantifying Chirality (R) 989

- Solid-State Columns Made from Twisted, Self-Complementary Terpyridine Units (C) 1244

Chlorinated hydrocarbons
- Formation of a Toxic Dimerization Product of 3,4-Dichloroaniline by Lignin Peroxidase from *Phanerochaete chrysosporium* (C) 68
- The Beilstein Test: An Unintentional Dioxin Source in Analytical and Research Laboratories (C) 443

Chlorins
- Chlorins Designed for Photodynamic Tumor Therapy and as Model Systems for Photosynthesis (C) 1592

Chlorophins
- First Example of a Chlorophin from an Unexpected Oxidative Ring-Opening of an (Octadehydrocorrinato)nickel(II) Salt (C) 70

Choline derivatives
- 1-*O*-(2-Acetoxyhexadec-1-enyl)choline Iodide, a New Anticancer Agent (C) 64

Chromatography
- Handbook of Thin Layer Chromatography (B) 360

Chromium compounds
- A New Structure–Magnetism Relationship for Face-Sharing Transition-Metal Complexes with d^3–d^3 Electronic Configuration (C) 311
- $[Cp^*Cr(\mu_3\text{-}H)]_4$—a Paramagnetic Chromium Hydride with a Cubane Structure (C) 1077
- Diastereoselective Complexation of Temporarily Chirally Modified Ligands: Enantioselective Preparation and Configurational Assignment of Synthetically Valuable η^6-Tricarbonylchromium-1-tetralone Derivatives (C) 631
- Diastereoselective Synthesis of Substituted Cyclohexadienes from Enantiomerically Pure Tricarbonyl(2-phenyl-4,5-dihydrooxazole)chromium Complexes (C) 1071
- One-Pot Syntheses of Novel Arene Tricarbonyl Chromium Macrocycles and Macrobicycle: Structure of a Pentanuclear Trichromium(0)-Dicopper(I) Cryptate (C) 775
- Stepwise Stacking of Three Paramagnetic Metallocene Units: [CpNiCp-$(SiMe_2)_2$CpCrCp$(SiMe_2)_2$CpNiCp] (C) 1258

Circular dichroism
- Chirality and Optical Activity in Organometallic Compounds (B) 1096

Claisen rearrangements
- Activation Parameters and Stereochemistry of an Antibody-Catalyzed Claisen Rearrangement (C) 182
- New Thermo-Response Dyes: Coloration by the Claisen Rearrangement and Intramolecular Acid–Base Reaction (C) 204

Closest packings
- Are Denser Packings of Spheres than Closest Packings Possible? How Many Closest Packings of Spheres Exist? (H) 727

Clusters
- Dependence of the Reactivity of Ag and Ni Clusters Deposited on Solid Substrates on the Cluster Size (C) 1062
- Electron Deficient Boron and Carbon Clusters (B) 660
- Empty Octahedral Hexazirconium Clusters with Only Ten Electrons, $[Zr_6X_{14}(PR_3)_4]$ (C) 1050
- Idealized Pentagonal-Planar Coordination for Indium in $[(\mu_5\text{-}In)\{Mn(CO)_4\}_5]^{2-}$ (C) 350
- Molecular Machines: Molecular Structure of $[(p\text{-}Tol_3P)_{10}Au_{13}Ag_{12}Cl_8](PF_6)$—a Cluster with a Biicosahedral Rotorlike Metal Core and an Unusual Arrangement of Bridging Ligands (C) 445
- New Directions in Polyvanadate Chemistry: From Cages and Clusters to Baskets, Belts, Bowls, and Barrels (H) 49
- New Intermediate Steps in the Synthesis of Larger Nickel Clusters (C) 321
- $[Ni(PtBu)_6]$—a Strain on the 18 Electron Rule? (H) 424
- Novel Iron Carbonyl Telluride Clusters: Synthesis and Characterization of $[Fe_5Te_4(CO)_{14}]^{2-}$ and $[Fe_8Te_{10}(CO)_{20}]^{2-}$ (C) 913
- Oxoniobates Containing Metal Clusters (R) 1437
- $[(Ph_3PAu)_6Mn(CO)_3]^+$, a Cluster with Pentagonal-Bipyramidal Structure (C) 464
- Si_{60}, an Analogue of C_{60}? (H) 173
- Structure and Reactivity of Silicon Clusters in the Gas Phase (H) 172
- Synthesis and Structure of $[Ni(PtBu_6)]$ and $[Ni_5(PtBu)_6(CO)_5]$ and Calculations on the Electronic Structure of $[Ni(PtBu)_6]$ and $(PR)_6$, R = *t*Bu, Me (C) 323
- Synthesis and Structure of the Cluster $[NaAu_{12}Se_8]^{3-}$: An Inorganic Cryptand Complex (C) 787
- Synthesis, Structure, and Bonding of $[CpCoW_2(OCH_2tBu)_6]$, and Comments on the Combining Properties of CO and CpCo (C) 896
- Synthetic Models for Iron—Oxygen Aggregation and Biomineralization (H) 1010
- The Trapping of Iron Hydroxide Units by the Ligand "heidi": Two New Hydroxo(oxo)iron Clusters Containing 19 and 17 Iron Atoms (C) 191

Cobalt compounds
- 1-Borabutadiene(cyclopentadienyl)cobalt Complexes (C) 1603
- "[Cp*Co=CoCp*]" is a Hydride (C) 1341
- Cyclopentadienyl Cobalt Complexes of Cobaltapentalenes: Products Formed by Reaction of (μ-Cyclopentadienylidene) Cobalt Complexes with Silylalkynes (C) 1058
- Inhibition of the [2+2+2] Cyclization by the Formation of Chelates: Alkyne and Vinylidene Complexes with Cyclopentadienylcobalt(I) (C) 1066
- Mutual Catalysis of Neutral and Anionic Cobalt Carbonyls in their CO Scrambling Reactions (C) 1596
- Novel Metal Thiolates: $[Co_2(SC_3H_7)_5]^-$, the First Complex with Face-Sharing MS_4 Tetrahedra (C) 1368
- On the Reaction of Pentamethylcyclopentadiene with Cobalt Atoms: A Reexamination 1392

Complexes with nitrogen ligands
- Arborols Based on Luminescent and Redox-Active Transition Metal Complexes (C) 1493
- Crystal and Solution Structures of the Novel Complex of Sodium Ketimide with Two Ketimine Ligands $[(tBu_2C{=}NNa)_4(HN{=}CtBu_2)_2]$: Stacking of Complexed and Uncomplexed $(NNa)_2$ Rings to give a Highly Distorted $(NNa)_4$ Cubane (C) 93
- $[Et_4N]_2[\{MO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]$ (M = Mo, W)—Doubly Bridged Complexes with S_7^{2-} and Doubly End-On-Bound H_2NNH_2 Bridging Ligands (C) 87
- Indirect $^{113}Cd,^{14}N$ Spin-Spin Coupling Constants as a Structural Probe of Solid Cadmium Thiocyanate Complexes (C) 1222
- Nitrido Complexes of Transition Metals (R) 955
- Pyridine-2-thiolato Complexes of V^{II}, V^{III}, and V^{IV} with Unusual Structural Features (C) 1253
- Self-Assembly of a Cu_4 Complex with Coplanar Copper(I) Ions: Synthesis, Structure, and Electrochemical Properties (C) 733
- Synthesis and Structure of a Mononuclear η^2-Hydrazine Complex by Protonation of an $[N_2H_2]^{2-}$ Complex (C) 1081
- The First Reaction of S_5N_6; Structure of a Complex Containing an $S_2N_3^-$ Ligand (C) 616
- The Synthesis and Structure of an Unusual Uranium Pentachloride Derivative (C) 72
- Trigonal-Monopyramidal M^{III} Complexes of the Type $[M(N_3N)]$ (M = Ti, V, Cr, Mn, Fe; $N_3N = [(tBuMe_2Si)\ddot{N}CH_2CH_2]_3N$) (C) 1501
- $[\ddot{V}(SNC_9H_6)_3]$ and $[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$, Homoleptic Vanadium(III) Complexes with Sulfur–Nitrogen Donor Ligands, and $[V(SNC_5H_4)_3]^-$, the First Thiolatovanadium(II) Complex (C) 1366

Complexes with oxygen ligands
- A Dramatic Difference in the Reactivities of Alkoxido- and Aryloxidorhenium Complexes in Insertion Reactions (C) 220
- A New Type of Mn–O Cluster with a Mn_4 Chain Unit. Relevance to the Photosynthetic Oxygen Evolving Center (C) 1629
- A Phenoxy-Bridged Homodinuclear Zn Complex with an Unusual Coordination Sphere; Model Compound for the Active Site of Phospholipase C (C) 1647
- Alkoxyalkyl-Substituted β-Diketonate Complexes of Barium and Copper: Evidence for Inter- and Intramolecular Stabilization (C) 735
- Bismuth Alkoxide Dimer Complexes Containing Planar $Bi_2(\mu\text{-}OR)_2$ Cores: Syntheses and Structures of $[\{Bi[OCH(CF_3)_2]_3(thf)\}_2]$ and $[\{Bi(OC_6F_5)_3(C_7H_8)\}_2] \cdot 2C_7H_8$ (C) 451
- Catecholates as σ- and π-Donating Ligands: The Synthesis and Structure of $(Et_4N)_2[W(CO)_4(O_2C_6H_4)]$ and the "Sixteen Electron" Analogue Resulting from CO Dissociation (C) 1503
- Distortional Isomerism in Oxomolybdenum Systems; the Evidence Re-evaluated (C) 1607
- New Routes to Alkylidyne-Bridged Ditungsten Compounds Supported by Alkoxide or Siloxide Ligands by the Activation of Ethylene (C) 462
- Tris(cyclopentanolato)oxovanadium(v): a Model for the Transition State of Enzymatic Phosphoester Cleavage (C) 447

Complexes with phosphorus ligands
- Synthesis and Structure of $[Ni(PtBu_6)]$ and $[Ni_5(PtBu)_6(CO)_5]$ and Calculations on the Electronic Structure of $[Ni(PtBu)_6]$ and $(PR)_6$, R = tBu, Me (C) 323
- The Formation of *cyclo*-P_4 Ligands with Maximum Electron Donor Ability (C) 1377
- The Reaction of Unactivated Cobalt Powder with Iodophosphoranes. The Synthesis of $[Co(PMe_3)_2I_3]$ and the Isolation of the "Frozen Transition-State" Complex $[(nBu_3PI)_2(\mu\text{-}I)][(nBu_3PI)(\mu\text{-}I)CoI_3]$ (C) 919

Complexes with silicon ligands
- The First Metal–Metal Silyl Migration in a Heterobimetallic Complex, and the Structure of the Rearrangement Product $[(OC)_4Fe(\mu\text{-}PPh_2)Pt\{Si(OMe)_3\}(PPh_3)]$ (*Fe–Pt*) (C) 1583

Complexes with sulfur ligands
- $[Et_4N]_2[\{MO(S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}H_2NNH_2)]$ (M = Mo, W)—Doubly Bridged Complexes with S_7^{2-} and Doubly End-On-Bound H_2NNH_2 Bridging Ligands (C) 87
- Indirect $^{113}Cd,^{14}N$ Spin-Spin Coupling Constants as a Structural Probe of Solid Cadmium Thiocyanate Complexes (C) 1222
- Molecular Mechanisms of the Reduction of NO to NH_2OH at Mo–S Centers (C) 205
- $[Ni_4(SC_3H_7)_8Br]$ and $[Ni_4(SC_3H_7)_8I]$: Mixed Valent Nickel Thiolates with Integral and Nonintegral Metal Oxidation States (C) 54
- Novel Metal Thiolates: $[Co_2(SC_3H_7)_5]^-$, the First Complex with Face-Sharing MS_4 Tetrahedra (C) 1368
- Pyridine-2-thiolato Complexes of V^{II}, V^{III}, and V^{IV} with Unusual Structural Features (C) 1253
- Stable Intermediates in the Addition and Elimination of $SnBuCl_3$ at Molybdenum Centers by Cleavage or Formation of an Sn–Cl Bond: Crystal Structure of $[Mo(CO)_2(PCy_3)(\mu\text{-}Cl)(\mu\text{-}S_2CPCy_3)(BuSnCl_2)] \cdot CH_2Cl_2$ (C) 76
- Synthesis of Cubane-like and Double Cubane-like Tungsten–Copper–Sulfur Clusters from the "Butterfly" Cluster $[Cu_2S_3W(O)(PPh_3)_3]$ (C) 1085
- The Reaction of $[Cp^+_2Nb_2(B_2H_6)_2]$ ($Cp^+ = \eta\text{-}EtMe_4C_5$) with Sulfur: Stabilization of the Tetrathioborato Ligand in Novel Sulfido Niobium Clusters (C) 1021
- $[V(SNC_9H_6)_3]$ and $[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$, Homoleptic Vanadium(III) Complexes with Sulfur–Nitrogen Donor Ligands, and $[V(SNC_5H_4)_3]^-$, the First Thiolatovanadium(II) Complex (C) 1366

Concave reagents

Ion pairs
- Penetrated Ion Pairs: a New Form of Ion Pair (H) 731
- The Crystal Structure of $[(\text{Pyrene}^{\cdot-})\{Na^+[(C_2H_5)_2O]\}]$: A Model for Stacked Radical Anion Salts (C) 878

IR spectroscopy
- 2,4-Didehydrophenol—First Proof of a *meta*-Aryne by IR Spectroscopy (C) 1230

Iridium compounds
- A Paramagnetic, Mononuclear Organometallic Iridium(II) Complex: $[Ir(C_6Cl_5)_2(cod)]$ (C) 1527
- Structure of a Product of Double Addition to C_{70}: $[C_{70}\{Ir(CO)Cl(PPhMe_2)_2\}_2] \cdot 3C_6H_6$ (C) 1356

Iron compounds
- Dynamic Motion in $[HFe(CO)_4]^-$ Ions as Observed by Mössbauer Spectroscopy—Evidence for Hydride "Tunneling" (C) 884
- Inorganic Biochemistry of Iron Metabolism (B) 930
- Iron Oxides in the Laboratory. Preparation and Characterization (B) 658
- Microcalorimetry of the Spin-Transition Systems $[Fe(bts)_2(NCS)_2]$ and $[Fe(2\text{-pic})_3]Cl_2 \cdot EtOH$ in the Range $15\ K < T < 300\ K$ (C) 178
- Mössbauer Spectroscopy and Electronic Structure Calculations of the Nitridoferrates(III): $Li_3[FeN_2]$ and $Ba_3[FeN_3]$ (C) 1624
- Multifield Saturation Magnetization Measurements of Oxidized and Reduced Ribonucleotide Reductase from *Escherichia coli* (C) 1513
- New Chiral α-Benzyloxyacryliron(II) Complex for Asymmetric Synthesis of α,α-Dialkyl-α-hydroxycarbonyl Compounds (C) 193
- New Route to α-[(1*E*,3*E*)-dienyl]allenes via Butadiene-tricarbonyliron Complexes (C) 224
- Novel Iron Carbonyl Telluride Clusters: Synthesis and Characterization of $[Fe_5Te_4(CO)_{14}]^{2-}$ and $[Fe_8Te_{10}(CO)_{20}]^{2-}$ (C) 913
- Proof of the Catalytic Activity of a Naked Metal Cluster in the Gas Phase (C) 636
- Synthetic Models for Iron—Oxygen Aggregation and Biomineralization (H) 1010
- Tetraferrioazaallenium—Product of a Novel Reaction of Coordinated CN^- (C) 590
- The Trapping of Iron Hydroxide Units by the Ligand "heidi": Two New Hydroxo(oxo)iron Clusters Containing 19 and 17 Iron Atoms (C) 191

Isoarenes
- 1,2,4-Cyclohexatriene, an Isobenzene, and Bicyclo[4.4.0]deca-1,3,5,7,8-pentaene, an Isonaphthalene: Generation and Trapping Reactions (C) 473
- 1,2,4-Cyclohexatriene, an Isobenzene, and its [2+2] Cycloaddition with Styrene: A Theoretical Study (C) 476

Isocoumarins
- 3,4-Dihydroisocoumarins, a New Class of Ant Trail Pheromones (C) 795

Isocyanates
- An Unusual Interplay Between Macromolecular and Supramolecular Helicity

in Polyisocyanates Dissolved in a Chiral Liquid Crystal (C) 88
- Synthesis of Isocyanate-Substituted Allenes and 1,3-Butadienes by [3,3] Sigmatropic Rearrangements (C) 866
Isocyanide complexes
- (Isocyanide)ruthenate Analogues of Tetracarbonylferrate (C) 83
Isocyanides
- Chelate Complexes of Tripodal, Aliphatic Triisocyanide Ligands (C) 1212
- Enantioselective Polymerization of 1,2-Diisocyanoarenes: Synthesis of Optically Active, Helical Poly(quinoxaline-2,3-diyl)s (C) 1509
- Lithiodiphenylmethylisocyanide-(−)-sparteine bis(tetrahydrofuran): Crystal Structure of a Lithiated Isocyanide (C) 79
- Observation and Properties of a Hydrogen Bond to Carbon in a Short-Lived, Gas-Phase Complex of Methyl Isocyanide and Hydrogen Fluoride (C) 202
- Reaction of Heterodinuclear μ-Ethynediyl Complexes Containing Palladium and Platinum: Multiple and Successive Insertion of Isocyanides (C) 851
Isoinversion principle
- *trans*-2-*tert*-Butylcyclohexanol, a Simple Selectively Optimized Cyclohexanol Auxiliary (C) 1190
Isolobal relationship
- Synthesis, Structure, and Bonding of $[CpCoW_2(OCH_2tBu)_6]$, and Comments on the Combining Properties of CO and CpCo (C) 896
Isomerization
- Intermolecular Additions and Cycloisomerizations by a Pd-Catalyzed Sequence of an Intramolecular Redox Reaction and an Addition (C) 1335
Isothiocyanates
- Synthesis and Reactions of Isothiocyanate-Substituted Allenes and 1,3-Butadienes (C) 90
Isotope effect
- Deuterium-Induced Phase Transition of an Organic Metal—An Unusual Isotope Effect (C) 859

Ketenimines
- Investigations of the Structure and Reactivity of a Stannaketenimine (C) 437
Ketimines
- Crystal and Solution Structures of the Novel Complex of Sodium Ketimide with Two Ketimine Ligands $[(tBu_2C{=}NNa)_4(HN{=}CtBu_2)_2]$: Stacking of Complexed and Uncomplexed $(NNa)_2$ Rings to give a Highly Distorted $(NNa)_4$ Cubane (C) 93
Ketoesters
- Diastereoselective Three-Center Michael Addition of β-Ketoesters to Prostereogenic α,β-Unsaturated Carbonyl Compounds Catalyzed by K_2CO_3 or Cs_2CO_3 (C) 1651
- Enantioselective Synthesis of 3-Substituted 2-Ketoesters (C) 618
Ketone pyrolysis
- Selective Ketone Pyrolysis: New Synthetic Method for Mono- and Polycyclic Hydrocarbons (C) 307
Ketones
A One-Pot Synthesis of Ketones and Aldehydes from Carbon Dioxide and Organolithium Compounds (C) 1035
Kinetics
- Chemical Kinetics (B) 239
- Chemical Oscillations and Instabilities. Nonlinear Chemical Kinetics (B) 109
- Kinetics of Hydride Transfers from CH, SiH, GeH, and SnH Groups to Carbenium Ions (C) 1046
- Rate Constants for the Attack of Carbenium Ions at Arenes—A Link between the Chemistry of Aliphatic and Aromatic π Systems (C) 1613

Laboratory practice
- Essential Molecular Biology. A Practical Approach (B) 1099
- Microscale Techniques for the Organic Laboratory (B) 799
Ladderanes
- Quest for Higher Ladderanes: Oligomerization of a Cyclobutadiene Derivative (C) 1488
Langmuir films
- Two-Dimensional Crystallography of Amphiphilic Molecules at the Air–Water Interface (R) 130
Lanthanide compounds
- One-Dimensional $M^{III}Cu^{II}$ Compounds with an Unprecedented, Tubelike Structural Motif (M = Rare-Earth Metal) (C) 626
- Synthesis and Structure of a Mononuclear η^2-Hydrazine Complex by Protonation of an $[N_2H_2]^{2-}$ Complex (C) 1081
- Synthesis of Lanthanide and Actinide Compounds (B) 105
- The First Self-Assembled Dinuclear Triple-Helical Lanthanide Complex: Synthesis and Structure (C) 1622
Lanthanoid compounds
- $KCeSe_4$: A New Solid-State Lanthanide Polychalcogenide (C) 1594
- New Layered Iron-Lanthanum-Oxide-Sulfide and -Selenide Phases: $Fe_2La_2O_3E_2$ (E = S,Se) (C) 1645
Laser photolysis
- Cyclohexadienyl-Type Cationic Intermediates in the Friedel–Crafts Alkylation of Benzene Derivatives with the 9-Fluorenyl Cation—Observation by Laser Flash Photolysis (C) 743
Laser spectroscopy
- High Resolution Spectroscopy below the Doppler Width (R) 263
Layer structures
- $TaNi_2Te_2$, A Novel Layered Telluride, and $TaCo_2Te_2$, a Structural Variant with Peierls Distortion (C) 217
Lead compounds
- 2,2′,5,5′-Tetra-*tert*-butyl-1,1′-diazaplumbocene—a Stable Azacyclopentadienyl Compound of Lead (C) 778
- The Structure and Stability Trends of Fluoro(methyl)plumbanes (C) 1224
Lignin peroxidase
- Formation of a Toxic Dimerization Product of 3,4-Dichloroaniline by Lignin Peroxidase from *Phanerochaete chrysosporium* (C) 68
Lignins
- Matrix-Assisted Laser Desorption Mass Spectrometry of Lignins (C) 762
Lipids
- High-Yield Synthesis of Lipid Systems with Giant Rings (C) 1492
- Synthetic Bilayer Membranes: Molecular Design, Self-Organization, and Application (R) 709
Lipopeptides
- Ion-Spray Mass Spectrometry of Lipopeptide Vaccines (C) 226
Liposomes
- Towards Artificial Ion Channels: Transport of Alkali Metal Ions across Liposomal Membranes by "Bouquet" Molecules (C) 1637
Liquid crystals
- An Unusual Interplay Between Macromolecular and Supramolecular Helicity in Polyisocyanates Dissolved in a Chiral Liquid Crystal (C) 88
- Induction of Ferroelectricity in Polymeric Systems through Hydrogen Bonding (C) 1531
- Liquid Crystallinity in Polymers. Principles and Fundamental Properties (B) 358
- Paramagnetic Chiral Smectic C Materials: A New Class of Ferroelectric Liquid Crystals (C) 1471
ortho Lithiation
- "Kinetically Enhanced Metalation"—How Substituents Direct *ortho* Lithiation (C) 755
Lithium amides
- A Novel Six-Center Deprotonation—Lithiation Reaction Mechanism Supported by the X-Ray Structure Analysis of a Lithium Carbazolide (C) 1209
- [Lithium Piperidide–Piperidine]$_4$: Crystal Structure of an Oligomeric 1:1 Lithium Amide–Amine Mixed Complex, an Intermediate in the *N*-Lithiation of Amines (C) 1205
Lithium perchlorate
- Allylation of Quinones with Allylsilane in the Presence of Lithium Perchlorate in Ether (C) 313
Low-valent compounds
- A New Approach to Bis(arene)titanium(0) and -titanium(−1) Complexes; Structure of Bis(arene)titanates(1−) (C) 1495
- Ether-Soluble Ti^0 and Bis(η^6-arene)-titanium(0) Complexes from the Reduction of $TiCl_4$ with Triethylhydroborate (C) 1490
- $[Ga(C_5H_5)]$: Synthesis, Identification, and Ab Initio Investigations (C) 1362
- $[Ga_4\{C(SiMe_3)_3\}_4]$ with a Tetrahedral Ga_4 Skeleton (C) 1364
- Stable Cyclic Germanediyls ("Cyclogermylenes"): Synthesis, Structure, Metal Complexes, and Thermolyses (C) 1485

Macrocycles
- A Binary Quinone Receptor (C) 792
- A Nonaromatic Expanded Porphyrin Derived from Anthracene—A Macrocycle which Unexpectedly Binds Anions (C) 452
- A Supramolecular Assembly of Two Torands, Two Lithium Ions, and Three Water Molecules (C) 348
- Conformational Preference of the Torand Ligand in Its Complexes with Potassium and Rubidium Picrate (C) 345
- Decamethylcucurbit[5]uril (C) 1475
- Designing Synthetic Cationic Molecular Receptors for Alcohols (C) 478
- Efficient Synthesis of Nanoscale Macrocyclic Hydrocarbons (C) 922
- High-Yield Synthesis of Lipid Systems with Giant Rings (C) 1492
- Ion-Selective Hydrazone–Azine Tautomerism of a 14-Membered Macrocyclic Ligand (C) 749
- Molecular Recognition of Primary Amines by Three-Point Binding with Boron-Containing Host Molecules (C) 1017
- One-Pot Syntheses of Novel Arene Tricarbonyl Chromium Macrocycles and Macrobicycle: Structure of a Pentanuclear Trichromium(0)-Dicopper(I) Cryptate (C) 775

- One-Step Synthesis of a Fourfold Functionalized Catenane (C) 1619
- Selective Ketone Pyrolysis: New Synthetic Method for Mono- and Polycyclic Hydrocarbons (C) 307
- The Triolide of (*R*)-3-Hydroxybutyric acid – Direct Preparation from Polyhydroxybutyrate and Formation of a Crown Estercarbonyl Complex with Na Ions (C) 434

Magnetic properties
- A Novel Polyoxotungstate Containing a *triangulo* Ni^{II}_3 Cluster with Ferromagnetic Exchange Interactions and an $S=3$ Ground State (C) 649
- Bis(*P,P*-di-*tert*-butylphosphinic-*N*-isopropylamidato-*N,O*)nickel(II), a Paramagnetic Planar Complex (C) 612
- Induction of Ferroelectricity in Polymeric Systems through Hydrogen Bonding (C) 1531
- Multifield Saturation Magnetization Measurements of Oxidized and Reduced Ribonucleotide Reductase from *Escherichia coli* (C) 1513
- One-Dimensional $M^{III}Cu^{II}$ Compounds with an Unprecedented, Tubelike Structural Motif (M = Rare-Earth Metal) (C) 626
- Paramagnetic Chiral Smectic C Materials: A New Class of Ferroelectric Liquid Crystals (C) 1471

Manganese compounds
- A New Type of Mn–O Cluster with a Mn_4 Chain Unit. Relevance to the Photosynthetic Oxygen Evolving Center (C) 1629
- A Remarkable Change in Framework Cation Positions upon Lithium Exchange: the Crystal Structure of $LiMnPO_4(OH)$ (C) 1090
- Idealized Pentagonal-Planar Coordination for Indium in $[(\mu_5\text{-In})\{Mn(CO)_4\}_5]^{2-}$ (C) 350
- $[(Ph_3PAu)_6Mn(CO)_3]^+$, a Cluster with Pentagonal-Bipyramidal Structure (C) 464
- Transition Metal in a Cube – A Discrete Eight-Coordinate $[Mn^{2+} \subset [2.2.2]cryptand]$ as a Body-Centered Cube with an N_2O_6 Donor Set (C) 764

Mass spectrometry
- Ion-Spray Mass Spectrometry of Lipopeptide Vaccines (C) 226
- Matrix-Assisted Laser Desorption Mass Spectrometry of Lignins (C) 762
- O–H Bond Activation in the Gas Phase: The Reactions of Water and Methanol with $[FeCH_3]^+$ (C) 603
- Proof of the Catalytic Activity of a Naked Metal Cluster in the Gas Phase (C) 636
- Structure and Reactivity of Silicon Clusters in the Gas Phase (H) 172
- The Neutralization of HeC_{60}^+ in the Gas Phase: Compelling Evidence for the Existence of an Endohedral Structure for He@C_{60} (C) 183
- The Phosphorus Ylide CH_2PH_3 is Stable in the Gas Phase (C) 86

Materials science
- Spectral Hole Burning at Room Temperature and with a Single Molecule: Two New Perspectives (H) 426
- The Photochemistry of Stilbenoid Compounds and Their Role in Materials Technology (R) 1399

Matrix isolation
- 2,4-Didehydrophenol – First Proof of a *meta*-Aryne by IR Spectroscopy (C) 1230
- Evidence for [PdSiO] from IR Spectroscopy (C) 638
- Matrix Isolation of Diisocyanogen CN-NC (C) 1218

Maximum entropy method
- Maximum Entropy in Action (B) 928

Medium-sized rings
- Ten-Membered Ring Enediynes with Remarkable Chemical and Biological Profiles (C) 1044

Membranes
- Synthetic Bilayer Membranes: Molecular Design, Self-Organization, and Application (R) 709
- Synthetic Chain-Substituted Phospholipids: Ion Transport Across Their Bilayer Membranes (C) 898
- Towards Artificial Ion Channels: Transport of Alkali Metal Ions across Liposomal Membranes by "Bouquet" Molecules (C) 1637

Mercury compounds
- Multidentate Macrocyclic Lewis Acids: Release of "[12] Mercuracarborand-4" from Its Iodide Complex and the Structure of Its Tetra(tetrahydrofuran) Dihydrate Complex (C) 893

Metabolites
- Dictionary of Plants Containing Secondary Metabolites (B) 1396

Metacyclophanes
- Pronounced Conformational Changes in Sixfold Nitrogen-Functionalized Metacyclophanes: Syntheses and Crystal Structures of Two 1,10-Diaza[11]metacyclophanes (C) 882

Metal compounds
- Metals and Their Compounds in the Environment: Occurrence, Analysis and Biological Relevance (B) 102

Metalates
- The $[(\mu_3\text{-}WSe_4)_3(\mu_3\text{-}Se)_2(Cu_3)_2]^{4-}$ Anion, an Inorganic Cluster with a Pinwheel Shape (C) 1477

Metalation
- Chemical Attachment of Organometallics to Proteins in Reverse Micelles (C) 789

Metallacumulenes
- Metallacumulenes: Activation of Diynes and Access to a Novel Bis(Alkenylallenylidene)ruthenium Complex with the Structural Unit $R_2C=C=C=Ru=C=C=CR_2$ (C) 651

Metallacycles
- Cyclometallaborazines: Borazines with Metal Atoms as Ring Building Blocks: $PhB(MeN)_3(TiCl_2)_2$ (C) 598
- Cyclophosphazene Metal Oxides, a New Class of Compounds, and Model Compounds for the Polymerization of Phosphazenes (C) 601
- 1,3-Dimetallabenzene Derivatives of Niobium or Tantalum (C) 1261

Metathesis
- A Cyclometalated Aryloxy(chloro)-neopentylidenetungsten Complex: A Highly Active and Stereoselective Catalyst for the Metathesis of *cis*- and *trans*-2-Pentene, Norbornene, 1-Methylnorbornene, and Ethyl Oleate (C) 628
- Detection of the Tungsten–Carbene–Olefin Intermediates in Catalytic Metathesis Systems Containing High-Valent, Metal Centers (C) 1585

Michael additions
- Diastereoselective Three-Center Michael Addition of β-Ketoesters to Prostereogenic α,β-Unsaturated Carbonyl Compounds Catalyzed by K_2CO_3 or Cs_2CO_3 (C) 1651
- Enantioselective Synthesis of the Antidepressant Rolipram by Michael Addition to a Nitroolefin (C) 870

Microscopy (B) 1534

Mitomycins
- The Total Synthesis of (±)-Mitomycin K (C) 915

Mixed-valent compounds
- Mono- and Binuclear Molybdenum Complexes Incorporating 4-(4-Hydroxyphenyl)pyridine: Metal–Metal Interactions Across an Asymmetric Bridging Ligand (C) 1515
- $[Ni_4(SC_3H_7)_8Br]$ and $[Ni_4(SC_3H_7)_8I]$: Mixed Valent Nickel Thiolates with Integral and Nonintegral Metal Oxidation States (C) 54

Molecular biology
- A Milestone in Genome Sequencing: The Complete DNA Sequence of the Yeast Chromosome III (H) 1578
- Essential Molecular Biology. A Practical Approach (B) 1099

Molecular dynamics
- Calculation of Molecular Dynamics for Peptides in Dimethyl Sulfoxide: Elimination of Vacuum Effects (C) 210
- Cyclodextrin Derivatives as Chiral Selectors—Investigation of the Interaction with (*R,S*)-Methyl-2-chloropropionate by Enantioselective Gas Chromatography, NMR Spectroscopy, and Molecular Dynamics Simulation (C) 319
- Dynamic Forcing, a Method for Evaluating Activity and Selectivity Profiles of RGD (Arg-Gly-Asp) Peptides (C) 326

Molecular electronics
- Molecular Electronics (B) 1536

Molecular modeling
- Molecular Modeling of the Class I Human Histocompatibility Molecule HLA-A2 Presenting an Allele-Specific Nonapeptide from Influenza Matrix Protein (C) 886

Molecular recognition
- A Synthetic Receptor for Cyclic Adenosine Monophosphate (C) 61
- Crosslinking of Adjacent Guanine Residues in an Oligonucleotide by *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$: Kinetic Analysis of the Two-Step Reaction (C) 1483
- DNA Recognition by Hybrid Oligoether–Oligodeoxynucleotide Macrocycles (C) 1617
- Enantioselective Complexation of Chiral Dicarboxylic Acids in Clefts of Functionalized 9,9'-Spirobifluorenes (C) 1521
- In Vitro Selection of Specific Ligand-binding Nucleic Acids (R) 979
- Interactions Between Acyclic and Cyclic Peralkylammonium Compounds and DNA (C) 1207
- Molecular Recognition of Primary Amines by Three-Point Binding with Boron-Containing Host Molecules (C) 1017
- Selective Binding of Sugar to β-Cyclodextrin: A Prototype for Sugar–Sugar Interactions in Water (C) 745

Molybdenum compounds
- Distortional Isomerism in Oxomolybdenum Systems; the Evidence Re-evaluated (C) 1607
- Molecular Mechanisms of the Reduction of NO to NH_2OH at Mo–S Centers (C) 205
- Mono- and Binuclear Molybdenum Complexes Incorporating 4-(4-Hydroxyphenyl)pyridine: Metal–Metal Interactions Across an Asymmetric Bridging Ligand (C) 1515
- Stable Intermediates in the Addition and Elimination of $SnBuCl_3$ at Molybdenum Centers by Cleavage or Formation of an Sn–Cl Bond: Crystal Structure of $[Mo(CO)_2(PCy_3)(\mu\text{-}Cl)(\mu\text{-}S_2CPCy_3)(BuSnCl_2)] \cdot CH_2Cl_2$ (C) 76

Mössbauer spectroscopy
- Dynamic Motion in $[HFe(CO)_4]^-$ Ions as Observed by Mössbauer Spectroscopy—Evidence for Hydride "Tunneling" (C) 884
- Mössbauer Spectroscopy and Electronic Structure Calculations of the Nitridoferrates(III): $Li_3[FeN_2]$ and $Ba_3[FeN_3]$ (C) 1624
- $[SbCl([15]Crown-5)](SbCl_6)_2$ and $[BiCl([18]Crown-6)(CH_3CN)_2](SbCl_6)_2$: Salts with Antimony(III) and Bismuth(III) Dications (C) 334

Multiple bonds
- An Arsanylidensilane ("Arsasilene") and its Derivatization with Tellurium and Benzophenone (C) 316
- Investigations of the Structure and Reactivity of a Stannaketenimine (C) 437
- Novel Strategies for the Synthesis and Crystallization of Electrophilic Dinuclear Cations: Solution and Solid-State Properties of $[Re_2(NCCH_3)_{10}][Mo_6O_{19}]_2$ (C) 1360
- On the Reaction of Pentamethylcyclopentadiene with Cobalt Atoms: A Reexamination 1392
- Reduction of a Boron–Nitrogen 1,3-Butadiene Analogue: Evidence for a Strong B–B π-Bond (C) 1082
- The Electronic Structure of $[(\eta^5\text{-}C_5H_5)_2Co_2]$: Comment on the Existence of a Complex with an Unsupported Co–Co Double Bond (C) 471
- The First Complex with a $\sigma^2\pi^4$ Triple Bond between Vanadium Atoms in a Ligand Framework of Fourfold Symmetry—$[V_2\{(p\text{-}CH_3C_6H_4)NC(H)N(p\text{-}C_6H_4CH_3)\}_4]$ (C) 737

Multiple peptide synthesis
- Multiple Peptide Synthesis Methods and Their Applications (R) 367

NADH
- Formate-Driven, Non-Enzymatic NAD(P)H Regeneration for the Alcohol Dehydrogenase Catalyzed Stereoselective Reduction of 4-Phenyl-2-butanone (C) 1529

Natural products
- Dictionary of Plants Containing Secondary Metabolites (B) 1396

Rotaxanes
- Cyclodextrins, Off-the-Shelf Components for the Construction of Mechanically Interlocked Molecular Systems (H) 846
- Synthesis of a Lipophilic Cyclodextrin-[2]-Rotaxane (C) 783
- Threading Cyclodextrin Rings on Polymer Chains (C) 197

Ruthenium compounds
- Arborols Based on Luminescent and Redox-Active Transition Metal Complexes (C) 1493
- (Isocyanide)ruthenate Analogues of Tetracarbonylferrate (C) 83
- Metallacumulenes: Activation of Diynes and Access to a Novel Bis-(Alkenylallenylidene)ruthenium Complex with the Structural Unit $R_2C=C=C=Ru=C=C=CR_2$ (C) 651
- Preparation, Ligand Exchange Reactions, and Structure of a Diene(aqua)-ruthenium Complex $[(cod)Ru(H_2O)_4]$-$(OTs)_2$ (C) 440
- $[RuO(dppz)(tpy)]^{2+}$: a DNA Cleavage Agent with High DNA Affinity (C) 1048
- Stepwise Synthesis of Binuclear Photoactive Complexes with a Bridging 3,4-Dihydroxyphenylterpyridine Ligand (C) 1028
- The Structure of the [1.1]Ruthenocenophane Dication: Metal–Metal Bond Formation and the Consequences of Proximity (C) 1352

Sandwich complexes
- A New Approach to Bis(arene)titanium(0) and -titanium(−1) Complexes; Structure of Bis(arene)titanates(1−) (C) 1495
- A Structurally Distorted Ligand in an Electron-Deficient Dizirconocene Cation: Unusual 1,2- and 1,1-Dimetallioalkenes (C) 876
- 1-Borabutadiene(cyclopentadienyl)cobalt Complexes (C) 1603
- "[Cp*Co=CoCp*]" is a Hydride (C) 1341
- $[(\eta^5\text{-Cp})_2Sn(\mu\text{-}\eta^5\text{-Cp})Na \cdot PMDETA]$, a Compound with a Trigonal-Planar "Paddle Wheel" Triorganostannate Ion (C) 1226
- Cyclopentadienyl Cobalt Complexes of Cobaltapentalenes: Products Formed by Reaction of (μ-Cyclopentadienylidene) Cobalt Complexes with Silylalkynes (C) 1058
- Ether-Soluble Ti^0 and Bis(η^6-arene)-titanium(0) Complexes from the Reduction of $TiCl_4$ with Triethylhydroborate (C) 1490
- $[(\pi\text{-}Me_5C_5)_2SiH]^+$—A Novel Silyl Cation (C) 1605
- $[Nb\{B(\eta^6\text{-}C_6H_5)_2(C_6H_5)_2\}(\eta^2\text{-}H_3CC_2CH_3)]$: the First Compound with Bent Tetraphenylborate as 12-Electron Donor Ligand (C) 1235
- "Non-Coordinating" Anions: Underestimated Ligands (H) 1181
- On the Reaction of Pentamethylcyclopentadiene with Cobalt Atoms: A Reexamination 1392
- One-Pot Multifunctionalization of Polymethyl Hydrocarbon π Ligands. Maximum Space Occupancy by Double Branching and Formation of Arboroles (C) 458
- Stepwise Stacking of Three Paramagnetic Metallocene Units: $[CpNiCp(SiMe_2)_2CpCrCp(SiMe_2)_2CpNiCp]$ (C) 1258
- Synthesis and Structure of the First Trinuclear, Half-Sandwich Carboranegadolinium(III) Cluster (C) 432
- Synthesis of Optically Active Macromolecules Using Metallocene Catalysts (H) 47
- 2,2',5,5'-Tetra-*tert*-butyl-1,1'-diazaplumbocene—a Stable Azacyclopentadienyl Compound of Lead (C) 778
- The Electronic Structure of $[(\eta^5\text{-}C_5H_5)_2Co_2]$: Comment on the Existence of a Complex with an Unsupported Co–Co Double Bond (C) 471
- The Structure of the [1.1]Ruthenocenophane Dication: Metal–Metal Bond Formation and the Consequences of Proximity (C) 1352

Scanning tunneling microscopy
- Molecular Imaging of Alkanol Monolayers on Graphite (C) 189
- Scanning Tunneling Microscopy and Atomic Force Microscopy in Organic Chemistry (R) 1298

Selenium compounds
- Benzo-1,2,3-triselenolium Trifluoromethanesulfonate—a C_2Se_3 Radical Cationic Salt with Unusual Solid-State Structure (C) 779
- $KCeSe_4$: A New Solid-State Lanthanide Polychalcogenide (C) 1594
- New Intermediate Steps in the Synthesis of Larger Nickel Clusters (C) 321
- Phosphorus(V) Selenides with Phosphorus in a Trigonal-Planar Environment (C) 1350
- Selenonium Hexafluoroantimonate, $H_3Se^+SbF_6^-$ (C) 643
- $Se_3N_2Cl_2$, a Novel Selenium–Nitrogen Chloride: Reinvestigation of "Se_4N_2" (C) 1518
- Se_2NCl_3 and $[Se_2NCl_2]^+[GaCl_4]^-$, Chloride Nitrides of Trivalent Selenium (C) 1251
- Synthesis and Structure of the Cluster $[NaAu_{12}Se_8]^{3-}$: An Inorganic Cryptand Complex (C) 787
- The $[(\mu_3\text{-}WSe_4)_3(\mu_3\text{-}Se)_2(Cu_3)_2]^{4-}$ Anion, an Inorganic Cluster with a Pinwheel Shape (C) 1477

Self-assembly
- Decamethylcucurbit[5]uril (C) 1475
- Induction of Ferroelectricity in Polymeric Systems through Hydrogen Bonding (C) 1531
- Self-Assembly of a Cu_4 Complex with Coplanar Copper(I) Ions: Synthesis, Structure, and Electrochemical Properties (C) 733
- Solid-State Columns Made from Twisted, Self-Complementary Terpyridine Units (C) 1244
- Spontaneous Self-Assembly of a Dinickel(II) Double Helicate Containing a 1,3-Benzenediyl Spacer Group (C) 230
- Supramolecular Self-Assemblies of Two-Directional Cascade Molecules: Automorphogenesis (C) 917
- Synthetic Bilayer Membranes: Molecular Design, Self-Organization, and Application (R) 709
- The First Self-Assembled Dinuclear Triple-Helical Lanthanide Complex: Synthesis and Structure (C) 1622

Self-replication
- Artificial Replication Systems (H) 1013

- Self-Replication by Condensation of 3-Aminobenzamidines and 2-Formylphenoxyacetic Acids (C) 654

Semiempirical calculations
- Product Predictions for Nucleophilic Additions to C_{70} (C) 1468

Sensors
- Field-Effect Transistors as Sensors of Neural Systems (H) 45

Separation techniques
- Non-Chromatographic Continuous Separation Techniques (B) 484

Serovar 21
- Synthesis of the Species-Specific *Mycobacterium avium* Trisaccharide (Serovar 21) for the Preparation of a Neoglycoprotein for Immunological Studies (C) 1358

Sesquichalcogenides
- A Germanium Sesquisulfide, $(t\text{BuGe})_4S_6$, without Adamantane Structure (C) 59

Sialosides
- Synthesis of Esterase-resistant 9-*O*-Acetylated Polysialoside as Inhibitor of Influenza C Virus Hemagglutinin (C) 1478

Siderophores
- Synthesis and Complexation Properties of a Cyclodextrin-Derived Siderophore Analogue (C) 1381
- The First Structural Characterization of a Metal–Enterobactin Complex: $[V(\text{enterobactin})]^{2-}$ (C) 466

Si-H activation
- Triphosphatrisilacyclohexanes as Tridentate Coronands in Cr and Mo Complexes: Activation of Si–H in an Early Stage versus Phosphane Coordination (C) 1510

Silicon compounds
- An Arsanylidensilane ("Arsasilene") and its Derivatization with Tellurium and Benzophenone (C) 316
- $[t\text{BuSiO}(ReO_4)]_4$, a Model Compound for Metal Oxides on Silicate Surfaces—Synthesis from the Stable Triol $t\text{BuSi(OH)}_3$ and Re_2O_7 (C) 599
- Control and Design Principles in Biological Mineralization (R) 153
- Gas-Phase Reactions of M^+ and $[CpM]^+$ (M = Fe, Co, Ni) with 1,3,5-Trisilacyclohexane: First Evidence for the Formation of 1,3,5-Trisilabenzene (C) 1633
- $(H_2Si)_2E_2$ and $(Mes(t\text{Bu})Si)_2E_2$ (E = As, P): Incommensurable Systems of Different Stability with Unusually Long E–E Bonds (C) 460
- $[(\pi\text{-}Me_5C_5)_2SiH]^+$—A Novel Silyl Cation (C) 1605
- Model Compounds for Metal Oxides on SiO_2 Surfaces (H) 586
- Octakis(1,1,2-trimethylpropyl)octasilacubane: Synthesis, Molecular Structure, and Unusual Properties (C) 1354
- On the Bonding in Carbosilanes (C) 185
- Si_{60}, an Analogue of C_{60}? (H) 173
- Structure and Reactivity of Silicon Clusters in the Gas Phase (H) 172
- Synthesis, Structure, and Thermolysis of an Unusual Azaphosphasiliridine (C) 751
- The Reaction of Tetramesityldisilene with As_4: Synthesis and Structure of a Novel Arsenic–Silicon Tricyclic Ring System (C) 1217
- The Thermal Conversion of Poly[(silylene)diacetylene] Metal Oxide Composites: A New Approach to β-SiC—MC Ceramics (C) 1195
- Triphosphatrisilacyclohexanes as Tridentate Coronands in Cr and Mo Complexes: Activation of Si–H in an Early Stage versus Phosphane Coordination (C) 1510

Silicon monoxide
- Evidence for [PdSiO] from IR Spectroscopy (C) 638

Silver compounds
- Ag_5GeO_4, a New Semiconducting Oxide (C) 653
- $[(CO)_3(PPh_3)_2OsAg(O_2CCF_3)]$: A Model for an Intermediate on the Reaction Coordinate in Electron Transfer (C) 770
- Molecular Machines: Molecular Structure of $[(p\text{-}Tol_3P)_{10}Au_{13}Ag_{12}Cl_8](PF_6)$—a Cluster with a Biicosahedral Rotorlike Metal Core and an Unusual Arrangement of Bridging Ligands (C) 445

Similarity modeling
- Similarity Models in Organic Chemistry, Biochemistry and Related Fields (B) 359

Size exclusion chromatography
- Preparative-Scale Separation of C_{60} and C_{70} on Polystyrene Gel (C) 644

Sodalite
- $Zn_7[P_{12}N_{24}]Cl_2$—A Sodalite with a Phosphorus–Nitrogen Framework (C) 213

Solid-phase synthesis
- A New Strategy for Solid-Phase Synthesis of *O*-Glycopeptides (C) 857

Solid-state chemistry

- Cyclometallaborazines: Borazines with Metal Atoms as Ring Building Blocks: $PhB(MeN)_3(TiCl_2)_2$ (C) 598
- Ether-Soluble Ti^0 and Bis(η^6-arene)-titanium(0) Complexes from the Reduction of $TiCl_4$ with Triethylhydroborate (C) 1490
- Template-Controlled Organization of a Fluoride Surface—An Analogue of a Crown Ether in the Reaction of $[\{(\eta^5\text{-}C_5Me_5)TiF_3\}_2]$ with Sodium Fluoride (C) 864

Torands
- A Supramolecular Assembly of Two Torands, Two Lithium Ions, and Three Water Molecules (C) 348
- Conformational Preference of the Torand Ligand in Its Complexes with Potassium and Rubidium Picrate (C) 345

Total syntheses
- Synthesis of the Calicheamicin Aryltetrasaccharide Domain Bearing a Reducing Terminus: Coupling of Fully Synthetic Aglycone and Carbohydrate Domains by the Schmidt Reaction (C) 338
- The Total Synthesis of (±)-Mitomycin K (C) 915
- Total Synthesis of Calicheamicin–Dynemicin Hybrid Molecules (C) 340
- Total Synthesis of the Carbohydrate Fragments of Esperamicin A_1 (C) 855
- Transition Metals in Total Synthesis (B) 365
- [4 + 4]-Cycloaddition Reactions in the Total Synthesis of Naturally Occurring Eight-Membered Ring Compounds (H) 422

Toxicity
- Formation of a Toxic Dimerization Product of 3,4-Dichloroaniline by Lignin Peroxidase from *Phanerochaete chrysosporium* (C) 68

Triolides
- The First Structural Characterization of a Metal–Enterobactin Complex: $[V(enterobactin)]^{2-}$ (C) 466
- The Triolide of (*R*)-3-Hydroxybutyric acid—Direct Preparation from Polyhydroxybutyrate and Formation of a Crown Estercarbonyl Complex with Na Ions (C) 434

Triquinanes
- Stereocontrolled Construction of 6 · 5 · 6 and 5 · 5 · 6 Ring Systems by Radical Tandem Cyclization (C) 910

Tungsten compounds
- A Cyclometalated Aryloxy(chloro)-neopentylidenetungsten Complex: A Highly Active and Stereoselective Catalyst for the Metathesis of *cis*- and *trans*-2-Pentene, Norbornene, 1-Methylnorbornene, and Ethyl Oleate (C) 628
- A Novel Polyoxotungstate Containing a *triangulo* Ni^{II}_3 Cluster with Ferromagnetic Exchange Interactions and an $S=3$ Ground State (C) 649
- Assistance by Electrophiles in Photoinduced Alkylidyne–Carbonyl Coupling (C) 747
- Catecholates as σ- and π-Donating Ligands: The Synthesis and Structure of $(Et_4N)_2[W(CO)_4(O_2C_6H_4)]$ and the "Sixteen Electron" Analogue Resulting from CO Dissociation (C) 1503
- Detection of the Tungsten–Carbene–Olefin Intermediates in Catalytic Metathesis Systems Containing High-Valent, Metal Centers (C) 1585
- Hydride Transfer by Hydrido Transition-Metal Complexes. Ionic Hydrogenation of Aldehydes and Ketones, and Structural Characterization of an Alcohol Complex (C) 1233
- New Routes to Alkylidyne-Bridged Ditungsten Compounds Supported by Alkoxide or Siloxide Ligands by the Activation of Ethylene (C) 462
- Novel Binuclear Phosphinidene Compounds by Dimerization of the P–H-Functional Phosphenium Complexes $[C_5R_5(CO)_2W{=}PH(Mes)]$ (R = H, Me) (C) 1525
- Synthesis of Cubane-like and Double Cubane-like Tungsten–Copper–Sulfur Clusters from the "Butterfly" Cluster $[Cu_2S_3W(O)(PPh_3)_3]$ (C) 1085
- Synthesis, Structure, and Bonding of $[CpCoW_2(OCH_2tBu)_6]$, and Comments on the Combining Properties of CO and CpCo (C) 896

- Unprecedented Stereospecific Ligand Exchange at a W≡W Template (C) 66

Tunichromes
- Structure of the Tunichrome of Tunicates and its Role in Concentrating Vanadium (C) 52

Uranium compounds
- The Synthesis and Structure of an Unusual Uranium Pentachloride Derivative (C) 72

Urea derivatives
- A 1:1 Adduct of 2-Aminobenzothiazole and a Urea Derivative, and Its Spatial Arrangement (C) 1634

Valence isomerization
- How High is the Barrier for the Valence Isomerization of Cyclobutadiene? (C) 738

Vanadium compounds
- A Novel Host/Guest System with a Nanometer Large Cavity for Anions and Cations: $[2NH_4^+, 2Cl^- \subset V_{14}O_{22}(OH)_4(H_2O)_2(C_6H_5PO_3)_8]^{6-}$ (C) 1192
- New Directions in Polyvanadate Chemistry: From Cages and Clusters to Baskets, Belts, Bowls, and Barrels (H) 49
- (Organoarsonato)polyoxovanadium Clusters: Properties and Structures of the V^V Cluster $[V_{10}O_{24}(O_3AsC_6H_4\text{-}4\text{-}NH_2)_3]^{4-}$ and the V^{IV}/V^V Cluster $[H_2\{V_6O_{10}(O_3AsC_6H_5)_6\}]^{2-}$ (C) 1197
- Pyridine-2-thiolato Complexes of V^{II}, V^{III}, and V^{IV} with Unusual Structural Features (C) 1253
- Structure of the Tunichrome of Tunicates and its Role in Concentrating Vanadium (C) 52
- The First Complex with a $\sigma^2\pi^4$ Triple Bond between Vanadium Atoms in a Ligand Framework of Fourfold Symmetry—$[V_2\{(p\text{-}CH_3C_6H_4)NC(H)N(p\text{-}C_6H_4CH_3)\}_4]$ (C) 737
- The First Structural Characterization of a Metal–Enterobactin Complex: $[V(enterobactin)]^{2-}$ (C) 466
- Tris(cyclopentanolato)oxovanadium(v): a Model for the Transition State of Enzymatic Phosphoester Cleavage (C) 447
- $[V(SNC_9H_6)_3]$ and $[V(SNH_2C_6H_4)_2(SNHC_6H_4)]^-$, Homoleptic Vanadium(III) Complexes with Sulfur–Nitrogen Donor Ligands, and $[V(SNC_5H_4)_3]^-$, the First Thiolatovanadium(II) Complex (C) 1366

Vinyldiazonium ions
- Origin of the Stabilization of Vinyldiazonium Ions by β-Substitution; First Crystal Structure of an Aliphatic Diazonium Ion: β,β-Diethoxyethenediazonium Hexachloroantimonate (C) 740

Vitamin B_{12}
- Radical Intermediates in the Coenzyme B_{12} Dependent Methylmalonyl-CoA Mutase Reaction Shown by ESR Spectroscopy (C) 215

Vitamin C
- Vitamin C: Its Chemistry and Biochemistry (B) 802

Water
- The Structure of Water—A Mixture of Cubes and Planar Four-Membered Rings? (H) 1577

Wittig rearrangements
- [2,3] Wittig Rearrangements of Nonconjugated Secondary α-Lithioethers: Proof of Stereospecificity and Inversion of the Configuration of the Carbanion C Atom (C) 647

Wood
- Wood and Cellulosic Chemistry (B) 801

Ylides
- A Simple Method for the Replacement of the OH Group in Free Carboxylic Acids by the Phosphonium Ylide Group (C) 1064
- The Phosphorus Ylide CH_2PH_3 is Stable in the Gas Phase (C) 86
- Three Independent Molecules in the Unit Cell of a Phosphorus Ylide; Changes in the Molecular Geometry on Rotation about the Phosphorus–Carbon Ylide Bond (C) 99

Zeolites
- Introduction to Zeolite Science and Practice (B) 661
- Solid-State NMR Spectroscopic and X-Ray Diffraction Studies of the Low-Temperature Structural Transformation of Hydrated Porous Aluminophosphate VPI-5 (C) 610
- $Zn_7[P_{12}N_{24}]Cl_2$—A Sodalite with a Phosphorus–Nitrogen Framework (C) 213

Zinc compounds
- A Phenoxy-Bridged Homodinuclear Zn Complex with an Unusual Coordination Sphere; Model Compound for the Active Site of Phospholipase C (C) 1647
- C–C Coupling with NO_2/Alkyl Substitution at the Vinylic Carbon by Reaction of 2-Aryl-1-nitro-1-alkenes with Dialkylzinc Compounds—A Novel Reaction (C) 1587
- Palladium(0)-Catalyzed Three-Component Coupling Reaction of Allyl Benzoates, Carbon Monoxide, and Zincioesters (C) 645
- Zinc Pyrazolylborate Complexes Relevant to the Biological Function of Carbonic Anhydrase (C) 92

Zirconium compounds
- A Structurally Distorted Ligand in an Electron-Deficient Dizirconocene Cation: Unusual 1,2- and 1,1-Dimetallioalkenes (C) 876
- Cationic Metallocene Polymerization Catalysts. Synthesis and Properties of the First Base-Free Zirconocene Hydride (C) 1375
- Empty Octahedral Hexazirconium Clusters with Only Ten Electrons, $[Zr_6X_{14}(PR_3)_4]$ (C) 1050
- High Molecular Weight Polypropylene through Specifically Designed Zirconocene Catalysts (C) 1347
